which it is effective,† the activity of the MCM catalyst seems to follow a simpler trend with respect to reflux temperature of the solvent. However, it is clear that more polar solvents are disadvantageous (Fig. 2). While the reasons for this behaviour are still under investigation, it may be the case that the rate of reaction is influenced by the partitioning of the (polar) reactants between the catalyst surface (polar) and the bulk medium (non-polar). The silica-based catalysts have a significantly lower polarity, as measured by the Reichardts dye method[4] (Table 1). This might mean that partitioning away from the catalyst is pronounced even in moderately polar solvents such as toluene, whereas the much more polar MCM catalysts can more effectively compete for the substrate, thus effectively extending the range of useful solvents, leading to reaction rates greater than those achievable with the silica-based materials.

In conclusion, the novel organofunctionalised MCM catalysts described here represent novel catalytic materials, differing significantly in many respects from their post-functionalised silica counterparts. Under optimum conditions they can outperform the silicas, in terms of both activity and catalyst turnover.

† The relative rates of reaction at reflux in various solvents are as follows: octane > heptane > cyclohexane > hexane > toluene > pentane ≫ chlorobenzene, 1,2-dichloroethane. Octane and heptane, however, lead to rapid deactivation of the catalyst. Initial rate studies with the alkane solvents indicate an Arrhenius-type behaviour, showing a simple temperature dependence of rate. More polar solvents such as toluene, PhCl and other chlorinated solvents show rates much reduced from those achieved in a hydrocarbon of similar boiling point.

**The reaction of thulium(II) iodide with 2 equiv. of lithium naphthalenide in dme (dme = 1,2-dimethoxyethane) yields a binuclear thulium(III) complex with one bridging and two terminal dianions of naphthalene [{Tm(dme)}$_2$($\eta^2$-$C_{10}H_8$)$_2$($\eta^2$-$\eta^4$ : $\eta^4$-$C_{10}H_8$)] 1.**

Recently, the first molecular complex of divalent thulium, [$TmI_2$(dme)$_3$][1] was synthesized and characterized crystallographically. To develop the chemistry of divalent thulium further we studied its reaction with lithium naphthalenide. Previously, it had been shown that exchange reactions of the lanthanoid dihalides, [$LnI_2$(thf)$_2$] (Ln = Sm, Eu, Yb), and cyclopentadienyl lanthanoid dihalides, [Ln($\eta^5$-$C_5H_5$)$Cl_2$] (Ln = Y, Gd, Er, Tm, Lu), with alkali-metal naphthalenides in thf or dme resulted in the formation of naphthalene lanthanoid complexes of the type [Ln($C_{10}H_8$)(thf)$_2$][2] or [Ln($\eta^5$-$C_5H_5$)($C_{10}H_8$)(dme)].[3,4] While the latter complexes were fully characterized by structural and spectroscopic analyses, no structural information on the cyclopentadienyl-free complexes was obtained owing to difficulties in the preparation of crystalline samples suitable for X-ray analysis. In the case of lanthanoid triiodides, including [$TmI_3$(dme)$_3$], reactions with $LiC_{10}H_8$ in various molar ratios gave no products that could be identified. The only exception was the structurally characterized complex of lanthanum [{$LaI_2$(thf)$_3$}$_2$($C_{10}H_8$)] isolated from the reaction of equimolar amounts of [$LaI_3$(thf)$_3$], naphthalene and Li in dme.[5]

Here we report that the treatment of a [$TmI_2$(dme)$_3$] solution in dme with $LiC_{10}H_8$ in a 1 : 2 molar ratio leads to the formation of the binuclear naphthalene complex **1** in good yield (Scheme 1).

**Scheme 1**

The black crystals of **1** are sparingly soluble in dme and thf and insoluble in hydrocarbon solvents. They decompose slowly in solution at room temperature. In the solid state decomposition is observed above *ca*. 100 °C. The complex gave satisfactory elemental analysis for thulium (calc. 37.43; found 36.71%). Total elemental analysis could not be performed because of an extreme sensitivity of the complex to moisture and air. Careful oxidation of **1** in air leads to the formation of naphthalene in about 90% yield, in good agreement with the composition of the complex. The magnetic moment of **1** (6.59 $\mu_B$/Tm, 293 K) is somewhat lower than the value typical for thulium(III) derivatives (7.1–7.5 $\mu_B$).[6] That might be explained by the existence of an intramolecular antiferromagnetic Tm–Tm interaction. The observed magnetic moment is significantly different from the $\mu_{eff}$ of [$TmI_2$(dme)$_3$] (4.5 $\mu_B$)[1] confirming the oxidation of thulium during the course of the reaction. One can suggest that the reaction proceeds *via* the formation of [$Tm^{2+}$($C_{10}H_8$)$^{2-}$] a transient intermediate, which then reacts with free naphthalene, contained in the solution of $LiC_{10}H_8$, to give **1**. However, it should be noted, that in spite of the high reduction potential of $Tm^{II}$ (*ca*. −2.3 V),[7] [$TmI_2$(dme)$_3$] does not react with free naphthalene.

The IR spectrum† of **1** contains the absorption bands of the bridging (1500, 1400 $cm^{-1}$) and terminal naphthalene dianions (1250 $cm^{-1}$) which were observed previously in the complexes [{$LaI_2$(thf)$_3$}$_2$(μ-$C_{10}H_8$)][5] and [Lu($\eta^5$-$C_5H_5$)($C_{10}H_8$)(dme)].[3] An X-ray crystal structure analysis confirms this assignment.

Crystals formed directly in the reaction procedure were suitable for X-ray diffraction.‡ An ORTEP representation of the molecular structure of **1** is shown in Fig. 1. The molecule rests on the inversion centre located in between C(11) and C(11′), so only half of the molecule is unique. Both of the naphthalene rings of the bridging ligand are bent along the axis defined by the 1,4 naphthalene positions. The dihedral angle between the planes represented by C(12)C(13)C(14)C(15) and C(11)C(11′)C(15)C(12) is 19.28°. this value is somewhat higher than in the lanthanum(III) complex [{$LaI_2$(thf)$_3$}$_2$(μ-$C_{10}H_8$)] containing a bridging naphthalene dianion (15.2°).[5] The terminal naphthalene ligands display a different geometry: the naphthalene ring C(2)–C(4) remains flat, while the other ring is bent. The dihedral angle between the planes C(5)C(6)C(9)C(10) and C(6)C(7)C(8)C(9) (26.22°) is smaller than in complex [Lu($\eta^5$-$C_5H_5$)($C_{10}H_8$)(dme)] (30°).[3] The thulium–bridging naphthalene bonding mode is the same as that observed in the lanthanum complex mentioned above. Four Tm–C distances lie in a narrow range (2.59–2.62 Å) and are 0.2 Å shorter than in the lanthanum complex. This is in agreement with the difference in ionic radii between Tm and La.[8] The bonding mode of Tm with the terminal naphthalene ligand is quite different. The Tm–C(6) and Tm–C(9) distances are much

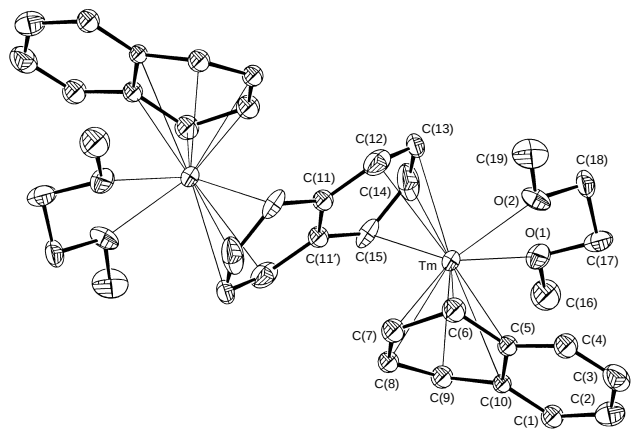

**Fig. 1** ORTEP representation of the molecular structure of **1**

shorter than Tm–C(7) and Tm–C(8) (2.41. 2.43, 2.54, 2.54 Å, respectively). The overall geometry of this fragment is almost identical to that observed in the complex [Lu($\eta^5$-$C_5H_5$)($C_{10}H_8$)(dme)]. The Tm–C(terminal $C_{10}H_8$) bond lengths are also close to Lu–C distances (2.406, 2.397, 2.579, 2.562 Å) owing to the nearly identical ionic radii of Tm and Lu (CN = 8: 0.994 and 0.977 Å, respectively).[8] Redistribution of C–C bond lengths in the naphthalene ligands and their non-planar shape reflect a dianionic nature of the ligands: the distances C(13)–C(14) and C(7)–C(8) become shorter (1.35, 1.31 Å) while all other C–C bonds are elongated compared to free naphthalene.[9] The naphthalene ring which is not coordinated to the Tm atom retains its aromaticity with similar C–C distances. Thus, the negative charge in the bridging naphthalene ligand is delocalized between all carbon atoms, but in the terminal naphthalene it is concentrated mainly on the C(6) and C(9) positions.

Previously we had shown that naphthalene complexes of the lanthanoids are very reactive towards organic and organometallic substances.[2,10,11] To illustrate the reactivity of **1** we carried out its reaction with cyclopentadiene. As might be anticipated the reaction proceeded smoothly at room temp. to give [Tm($\eta$-$C_5H_5$)$_3$] in good yield. We hope to use **1** for the synthesis of previously inaccessible complexes of thulium.

We thank the Russian Foundation for Basic Research (Grant No. 97-03-33112a) and the Volkswagen-Stiftung for financial support.

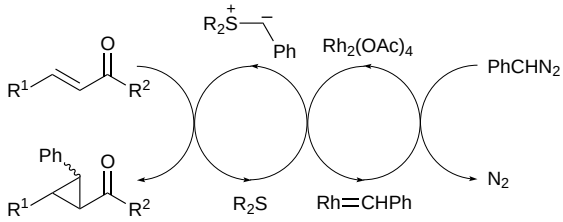
# Catalytic asymmetric cyclopropanation of electron deficient alkenes mediated by chiral sulfides



**Varinder K. Aggarwal,*[a] Helen W. Smith,[a] Ray V. H. Jones[b] and Robin Fieldhouse[b]**

[a] *Department of Chemistry, University of Sheffield, Brook Hill, Sheffield, UK S3 7HF*

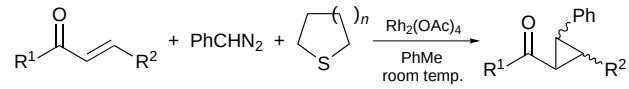
**Catalytic asymmetric cylopropanation of enones has been achieved using diazo compounds, catalytic quantities of a metal catalyst and a camphor-derived thioacetal; this sulfide shows exceptionally high levels of enantioselectivity.**

Cyclopropanes are common functional groups in biologically active molecules, the most notable examples being the pyrethroids which are a highly potent class of insecticides.[1] Much effort has therefore been expended in the synthesis of cyclopropanes in racemic and more recently, in asymmetric form.[2,3] High enantioselectivity has been achieved in the Simmons–Smith[4,5] cyclopropanation of allylic alcohols using chiral promoters.[6,7] High enantioselectivity has also been achieved in metal catalysed reactions of diazocarbonyl compounds with alkenes. The chirality may be linked to the metal in the form of a chiral ligand (*e.g.* bis-oxazolines[8]) or linked to both the metal and the diazo compound to enhance the enantioselectivity.[9,10] However, in all the above cases, the metal carbenoid only reacts efficiently with electron rich alkenes[11] and so methods are required for the cyclopropanation of electron deficient alkenes. Towards this end enantiomerically pure aminosulfoxonium ylides have been successfully employed in asymmetric cyclopropanation of electron deficient alkenes.[12,13] However, such reagents have to be employed in stoichiometric amounts, and cannot be recycled. Sulfur ylides are also known to react with electron deficient alkenes to furnish cyclopropanes, but there are no asymmetric examples and so we embarked on such a study. In addition, we sought to utilise our recently reported catalytic process for asymmetric epoxidation[14,15] and aziridination[16] so that catalytic quantities of sulfides could ultimately be employed (Scheme 1). Here we report our success in achieving these goals.

Reactions were carried out on enones with phenyldiazomethane (Table 1) and we initially used tetrahydrothiophene, in stoichiometric amounts, as a representive sulfide under the conditions previously employed for the epoxidation reaction.[15] However, only low yields of cyclopropanes were obtained (entries 1 and 2). We were surprised at the low yields obtained, as high yields were obtained in the related epoxidation and aziridination reactions. We suspected that the lower reactivity of enones compared to aldehydes† and imines could have been responsible for the lower yields observed, as the ylide will have a longer lifetime in reactions with enones. This in turn would mean that the ylide might have time to undergo competitive rearrangement reactions, such as the Stevens[17,18] or the Sommelet–Hauser rearrangement,[17,18] and indeed the Sommelet–Hauser product was observed.‡ Under standard reaction conditions an excess of the sulfonium salt[22] or the ylide is typically used to cyclopropanate alkenes, perhaps for this reason.



**Scheme 1** Catalytic process for cyclopropanation

To reduce the extent of this rearrangement the six membered analogue, pentamethylene sulfide, was employed and, gratifyingly, high yields of cyclopropanes were obtained (entries 3–6). Even using catalytic amounts of sulfide, cyclopropanes were formed in moderate to good yields (entries 7–10). The least reactive enone (entry 10) gave reduced yields as the rearrangement of the ylide was once again a significant competing side reaction.

We next explored asymmetric cyclopropanation (Table 2) and chose oxathiane **1** as this sulfide had previously given high enantioselectivity in epoxidation of carbonyl compounds[14] and aziridination of imines.[16] Furthermore, sulfide **1** is readily available, in either enantiomeric form, from camphorsulfonyl chloride in two steps.[14] We applied this sulfide to the 4-phenyl substituted enones (as this would give rise to a maximum of two diastereoisomers) and we were delighted to find that exceptionally high levels of enantioselectivity were obtained with both stoichiometric and catalytic amounts of sulfide.§ However, reduced yields were obtained when using catalytic compared to stoichiometric amounts of sulfide. This was also observed in the related epoxidation process[14,15] but the differences in yield are greater in cyclopropanation, presumably because of the lower reactivity of enones compared to aldehydes. The constant enantiomeric excess (no reduction observed) in reactions using catalytic quantities of sulfides indicates that no direct cyclopropanation occurs and that the sulfide reacts with the metal carbenoid (to give a sulfur ylide) at a significantly faster rate than the alkene (to give direct cyclopropanation). The major isomer of the cyclopropane is *tentatively* assigned as the *R,R*

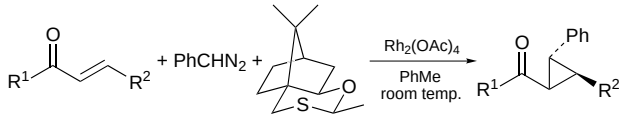


**Table 1** Cyclopropanation of enones using simple sulfides

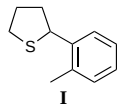
| 4 | Me | Ph | 12 | 0.2 | 14 | 4 : 1 | > 98[g] | − 65 |

[a] Addition of $PhCHN_2$ using syringe pump. [b] Yield of *cis* and *trans* isomers. [c] Ratio determined by NMR spectroscopy. [d] Determined using HPLC (see footnote §). [e] Conditions: $c$ = 1, $CH_2Cl_2$. [f] Retention times: (*R*,*R*) enantiomer, 4.41 min; (*S*,*S*) enantiomer, 4.70 min. [g] Retention times: (*R*,*R*) enantiomer, 6.10 min; (*S*,*S*) enantiomer, 6.68 min.

isomer by analogy with the epoxidation[14] and the aziridination[16] processes. In these latter cases similarly high enantioselectivity was obtained (93–97% ee) for epoxides[14] and aziridines[16] and proof of their absolute stereochemistry (*R*,*R*) was obtained.



In conclusion we have developed a process for the catalytic asymmetric cylopropanation of enones, using a camphor-derived sulfur ylide which shows exceptionally high levels of enantioselectivity. We are currently extending the scope of this reaction.

† Competetive experiments between PhCHO, chalcone and substoichiometric amounts of ylide yielded epoxide only, indicating that aldehydes were much more reactive than enones towards benzylfulfonium ylide.

‡ Sulfide **I** was formed in 20% yield as a result of ylide equilibration and Sommelet–Hauser rearrangement from the reaction. Ylide equilibration and rearrangement has been reported (refs. 19–21).

**I**

§ A typical procedure for asymmetric cyclopropanation reaction: Chalcone (0.5 mmol), oxathiane **1** (0.5 mmol) and $Rh_2(OAc)_4$ (1 mol%) were dissolved in toluene (0.5 ml) under $N_2$. A solution of phenyldiazomethane in toluene (1.5 mmol) was added over 12 h *via* an inverted syringe pump. The crude mixture was purified by column chromatography to furnish the cyclopropane as a white solid (60%). The enantiomeric excess was determined by chiral HPLC on Hichrom column, stationary phase D-phenylglycine, using $Pr^iOH$–light petroleum (0.7 : 99.3) as eluent with a flow rate of 2 ml $min^{-1}$. The *R*,*R* enantiomer eluted at 265 s and the *S*,*S* enantiomer at 282 s.

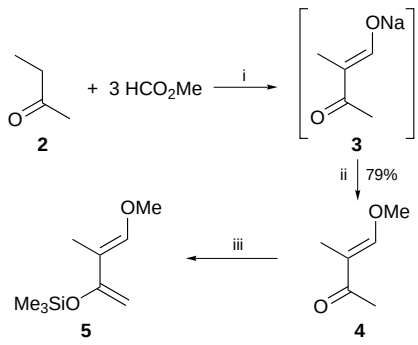
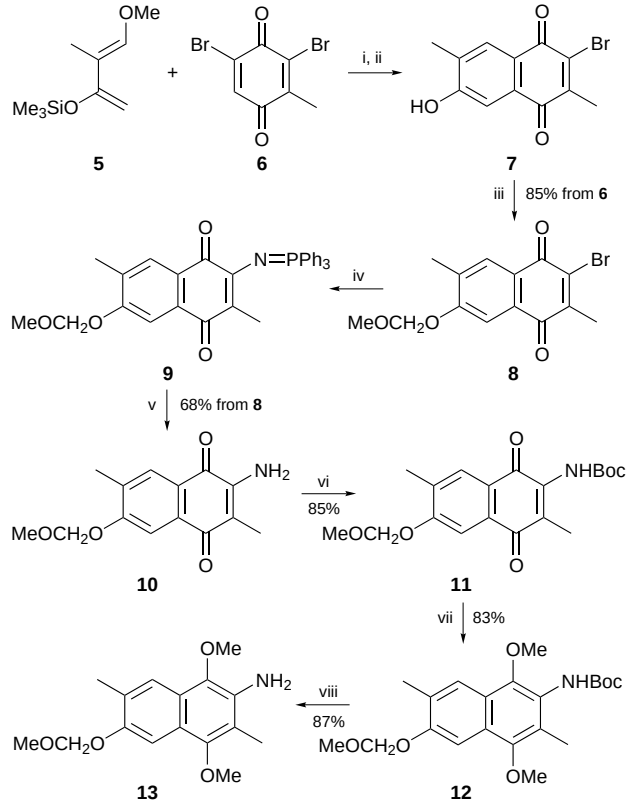
**The efficient and regioselective synthesis of the naphthoquinone core of streptovaricin U 1 *via* the Diels–Alder reaction of 1-methoxy-2-methyl-3-trimethylsilyloxybuta-1,3-diene 5 with the 2,6-dibromo-3-methyl-1,4-benzoquinone 6 is described.**



The streptovaricin family are representative ansamycin antibiotics as well as rifamycins and have been used clinically as an important class of antibiotics.[1] So far more than fifteen congeners have been isolated from *Streptomyces spectabilis* and all consist of a unique naphthoquinone core and a polypropionate ansa chain composed of nine contiguous chiral centres.[1] The unique structures and important biological activity of the streptovaricins have elicited considerable attention from synthetic chemists.[2]

Recently we reported the highly stereoselective synthesis of the ansa chain segment of streptovaricin U **1** and protostreptovaricins including nine contiguous chiral centres[3] by the use of the stereospecific methylation of γ,δ-epoxy acrylates with trimethylaluminium.[4] Streptovaricin U **1** is a unique open-chain ansamycin from the streptovaricin family and shows inhibitory activity against RAUSCHER leukemia virus RNA-dependent DNA polymerase.[5] We now report the highly efficient synthesis of the naphthoquinone core of streptovaricin U **1** *via* the Diels–Alder reaction of the silyloxy diene **5** with the dibromoquinone **6**.



Streptovaricin U **1**

Although 1-methoxy-2-methyl-3-trimethylsilyloxybuta-1,3-diene **5** is a known compound and has often been used in Diels–Alder reactions,[6] we prepared it by the modified procedure shown in Scheme 1 for improved yield and synthetic convenience. Thus butan-2-one **2** was treated with NaH and $HCO_2Me$ in THF at 0 °C to give the sodium enolate **3**, which was treated, after the solvent was replaced from THF to DMF, with dimethyl sulfate to give *trans*-4-methoxy-3-methylbut-3-en-2-one **4**[7] in 79% yield.† The butenone **4** was quantitatively transformed into the silyloxy diene **5** by treatment with LDA in THF followed by addition of $Me_3SiCl$. The crude diene **5** thus obtained was used directly for the Diels–Alder reaction. On the other hand, 2,6-dibromo-3-methyl-1,4-benzoquinone **6**, the dienophile for the Diels–Alder reaction, was synthesized according to the protocol of Trost and Pearson[8] in two steps; (i) bromination of *m*-cresol with $Br_2$ in AcOH; (ii) oxidation of the resulting tribromide with chromium(III) oxide in AcOH (90% yield for the two steps).

**Scheme 1** *Reagents and conditions*: i, NaH (1.5 equiv.), THF, 0 °C, 1 h; ii, $(MeO)_2SO_2$ (2 equiv.), DMF, 0 °C, 1 h, then 1 M aq. $K_2CO_3$, MeOH; iii, LDA, THF, −78 °C, then $Me_3SiCl$, −78 °C to room temp.

The key Diels–Alder reaction was performed by heating a mixture of the diene **5** (4.1 mmol) and the dibromoquinone **6** (3.2 mmol) in benzene (20 ml) at 90 °C for 2 h in a sealed tube (Scheme 2). After cooling, the solvent was evaporated under

**Scheme 2** *Reagents and conditions*: i, $C_6H_6$, sealed tube, 90 °C, 2 h; ii, 2% HCl, DME, 12 h; iii, $MeOCH_2Cl$, $Pr^i_2NEt$, $CH_2Cl_2$, 3.5 h; iv, $NaN_3$, $PPh_3$, DMSO, 3 h; v, aq. HCHO, THF, 2 d; vi, $H_2$, $PtO_2$, $Boc_2O$ (5 equiv.), EtOH, 3 h, then $O_2$, 12 h; vii, $H_2$, $PtO_2$, EtOH, 1 h, then $(MeO)_2SO_2$ (10 equiv.), 1 M NaOH, 2 h; viii, $Ph_2O$, 185 °C, sealed tube, 12 h

reduced pressure and the residue was treated with 2% HCl in DME, giving rise to the adduct **7**. The crude product **7** was subsequently treated with $ClCH_2OMe$ and $Pr^i_2NEt$ in $CH_2Cl_2$ to afford the protected bromoquinone **8** as light yellow crystals (mp 169–172 °C) in 85% overall yield. Subsequent conversion of **8** to the aminonaphthoquinone **10** was accomplished by the reaction of **8** with $NaN_3$ and $PPh_3$ in DMSO followed by treatment of the resulting iminophosphorane **9** with aqueous formaldehyde in THF. Thus the desired aminonaphthoquinone **10** was obtained as red crystals (mp 177–179 °C) in 68% yield. Although compound **10** is itself the naphthoquinone core of streptovaricin U **1**, it is necessary to further transform it into the naphthalene derivative **13** for the coupling reaction with the ansa chain segment, since the amino group on a naphthoquinone ring such as **10** is not sufficiently basic for further transformation. The conversion of **10** into the target molecule **13** was, however, unexpectedly troublesome and required ingenuity. Eventually the desired transformation was overcome by the following reaction sequence. Hydrogenation of **10** over Adams' catalyst in EtOH in the presence of di-*tert*-butyl dicarbonate ($Boc_2O$) followed by treatment with oxygen gave rise to the *N*-Boc-aminonaphthoquinone **11** as light yellow crystals (mp 141–143 °C) in 85% yield. The product **11** was subsequently converted to the naphthalene dimethyl ether **12** (mp 104–106 °C) by hydrogenation over Adams' catalyst in EtOH followed by treatment of the resulting dihydroquinone with dimethyl sulfate and 1 M NaOH in 83% yield. The synthesis of the fully functionalized aromatic core **13** of streptovaricin U **1** was accomplished by removal of the Boc group in **12** by thermolysis in $Ph_2O$ at 185 °C (sealed tube), resulting in formation of **13** in 87% yield.

Thus an efficient and regioselective synthesis of the naphthoquinone core of streptovaricin U **1** has been established. The overall yield of **13** from the dibromoquinone **6** was 35%. The manipulations employed in the conversion of **10** into **13** may be widely applicable to the synthesis of various aminonaphthoquinones. The coupling reaction of the aromatic core **13** with the ansa chain segment toward the total synthesis of **1** is now in progress.

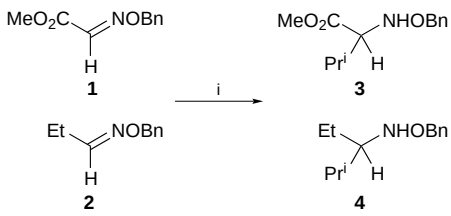
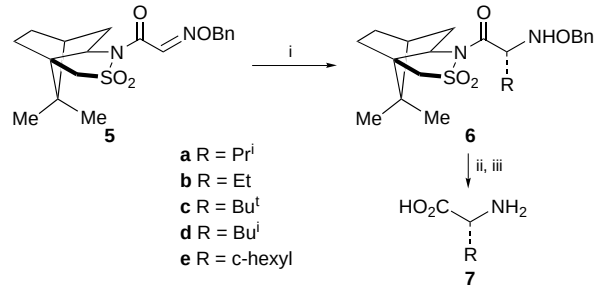
# Highly diastereoselective radical addition to glyoxylic oxime ether: asymmetric synthesis of α-amino acids

**Hideto Miyabe, Chikage Ushiro and Takeaki Naito***



*Kobe Pharmaceutical University, Motoyamakita, Higashinada, Kobe 658, Japan*

**A high degree of stereocontrol in radical addition to the Oppolzer's camphor sultam derivative of glyoxylic oxime ether was achieved, providing a convenient method for preparing a variety of enantiomerically pure α-amino acids.**



Asymmetric induction in free radical-mediated reactions of acyclic systems is a subject of current interest.[1] Oxime ethers are well known to be excellent radical acceptors because of the extra stabilisation of the intermediate aminyl radical provided by the lone pair on the adjacent oxygen atom.[2] We now describe the first example of an efficient and diastereoselective carbon radical addition to acyclic oxime ethers which was successfully applied to the novel asymmetric synthesis of α-amino acids.

Studies on the radical reaction of oxime ethers have concentrated on radical cyclisation,[3] except for a few outstanding examples of intermolecular radical reaction.[4] Therefore, stereocontrol in intermolecular radical addition to oxime ethers is a challenging problem. Prior to exploring diastereoselective radical addition to acyclic oxime ethers, we first investigated competitive reactions using two types of oxime ether in order to survey the intermolecular reactivity of oxime ethers with carbon radicals. Treatment of a 1 : 1 mixture of glyoxylic oxime ether **1** and aldoxime ether **2** with isopropyl radical, generated from $Pr^iI$, $Bu_3SnH$ and $Et_3B$ as a radical initiator, at −78 °C for 30 min gave the isopropylated product **3** in 78% yield with no detection of the other adduct **4** (Scheme 1). As expected, the addition of an isopropyl radical to **2** under the same reaction conditions did not take place and 90% of the starting compound **2** was recovered. These results suggest that the carbon radical does not add to the aldoxime ether **2**, but does add to glyoxylic oxime ether **1** even at −78 °C.

We then extended the carbon radical addition to the Oppolzer's camphor sultam derivative of glyoxylic oxime ether **5**[5] which would allow access to a wide range of enantiomerically pure natural and unnatural α-amino acids (Scheme 2). The reaction of **5** with $Pr^iI$, $Bu_3SnH$ and $Et_3B$ in $CH_2Cl_2$ at 20 °C proceeded smoothly to give a 86 : 14 diastereomeric mixture of the desired isopropylated product **6a** accompanying by a small amount of the ethylated product **6b**, which would be formed by a competitive reaction with ethyl radical generated from $Et_3B$ and $O_2$ (Table 1, entry 1). In the absence of $Pr^iI$, treatment of **5** with $Bu_3SnH$ and $Et_3B$ afforded exclusively the corresponding ethylated product **6b** as the result of a similar stereoselective radical reaction. In order to optimise the reaction conditions, we then investigated the reaction by varying the

**Scheme 1** *Reagents and conditions*: i, $Pr^iI$ (1.1 equiv.), $Bu_3SnH$ (1.1 equiv.), $Et_3B$ (1.1 equiv.), $CH_2Cl_2$, −78 °C, 30 min

**Scheme 2** *Reagents and conditions*: i, RI, $Bu_3SnH$, $Et_3B$, 30 min; ii, $Mo(CO)_6$; iii, LiOH

reaction temperature, solvent and Lewis acid. The stereoselectivity for **6a** was shown to be dependent on the reaction temperature, thus changing the temperature from 20 to −78 °C led to an effective increase in the diastereoselectivity to 94 : 6 (entry 2). The replacement of $CH_2Cl_2$ with $Et_2O$ as solvent led to higher selectivity, comparable to or better than that obtained by the known addition of organometallic reagents to the oxime ethers (entry 4).[5,6] Although the addition of Lewis acids as an additive did not dramatically influence the degree of stereoselectivity, the presence of $BF_3{\cdot}OEt_2$ in $CH_2Cl_2$ was found to be useful for asymmetric induction (entry 5). The absolute configuration at the newly formed stereocentre of the major product was determined to be *R* by converting the adduct **6a** into authentic D-valine **7a**. The reductive cleavage of the nitrogen–oxygen bond of **6a** by treatment with $Mo(CO)_6$[7] and subsequent removal of the sultam auxiliary by standard hydrolysis[8] afforded the enantiomerically pure D-valine **7a** without any loss

**Table 1** Radical addition to the oxime ether **5**[a]

| Entry | RI[b] | Lewis acid[c] | Solvent | Yield[d] (%) | Selectivity[e] |

[a] Reaction was carried out with $Bu_3SnH$ (2.5 equiv.) and $Et_3B$ in hexane (5 equiv.) under $N_2$ at 20 °C (entry 1). Other reactions were carried out at −78 °C (entries 2–16). [b] 5 equiv. of RI was used. [c] 2 equiv. of Lewis acid was used. [d] Isolated yields of major diastereomer **6a**–**f**. [e] Diastereoselectivities were determined by $^1H$ NMR analysis. [f] The ethylated product **6b** was obtained in 3–22% yield.

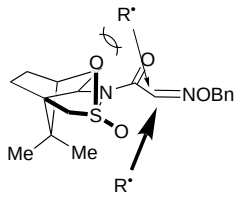

**Figure 1**

of stereochemical purity. High chemical yield and diastereoselectivity were also observed in radical additions using different radical precursors such as ethyl, *tert*-butyl, isobutyl and cyclohexyl iodides (entries 9–16).

The stereochemical features of this reaction can be rationalised in terms of steric control in the conformationally restricted sultam derivative **5**. The s-*cis* conformation of **5** would be preferred due to repulsion between the oxime ether and sulfonyl groups, thus alkyl radical addition takes place predominantly from the less hindered π-face of the oxime derivative **5**, as indicated (Fig. 1).

The traditional addition of anionic carbon nucleophiles to oxime ethers has been widely investigated as a carbon–carbon bond forming reaction with excellent stereoselectivity, although the addition is frequently plagued by the abstraction of α-protons adjacent to the carbon–nitrogen double bond, the lability of the nitrogen–oxygen bond, and the poor electrophilicity of the oxime ether group.[9] We suggest that many of these fundamental problems would be solved by the newly found mild addition of strictly neutral species such as uncharged free radicals.

# Mechanism of photobleaching of Ethyl Violet non-covalently bound to bovine serum albumin

**Mauricio Baptista and Guilherme Indig***

*School of Pharmacy, University of Wisconsin, Madison, WI53706, USA*

**Upon laser excitation of Ethyl Violet non-covalently bound to bovine serum albumin, leuco-Ethyl Violet and 4,4'-bis(diethylamino)benzophenone are formed as reaction photoproducts**

Photodynamic Therapy (PDT)[1] has recently been approved by regulatory agencies of several countries as a new modality of cancer treatment. The current enthusiasm for this general technique has fomented the search for new photosensitizers tailored for specific therapeutical applications.[1b,c] The development of new drugs for PDT requires the comprehension of the mechanisms of action of promising dyes, or families of dyes, under conditions that closely parallel those observed *in vivo*. This report describes a study on the mechanisms of photoreaction of a triarylmethane dye (Ethyl Violet, EV) non-covalently bound to a model biological host (bovine serum albumin, BSA). Triarylmethanes (TAM) are known to efficiently bind to anionic polyelectrolytes in solution,[2] and are among the families of dyes presently under intense evaluation as potential photosensitizers for employment in PDT.

The fluorescence lifetime of triarylmethane dyes in low viscosity environments is typically in the picosecond range as a consequence of fast relaxation processes that occur *via* rotational motions of their aromatic rings.[3] Accordingly, TAM dyes show poor photoreactivity in aqueous solutions. In more viscous media, or in microenvironments that render steric hindrance to rotational relaxation processes, fluorescence and intersystem crossing become more competitive events, and photoreactivity tends to increase.[2c] The effect of BSA on EV fluorescence in 0.01 M phosphate buffer pH 7.3 at 20 °C is shown in Fig. 1. The increase in EV fluorescence as a function of BSA concentration indicates that the BSA binding sites are very effective in preventing 'free rotor' motions in the dye moiety. This reduces the efficiency of radiationless deactivation of EV, a process that involves a low-lying twisted intramolecular charge transfer state (TICT),[3c] and leads to an enhancement in its fluorescence quantum yield from $9.6 \times 10^{-5}$ (free) to $1.7 \times 10^{-2}$ (protein-bound), as measured using corrected fluorescence spectra and quinine sulfate[4] as fluorescence standard. The fluorescence decay of EV bound to BSA (a typical multiple-binding-site carrier[5]) follows double exponential functions. The global analysis of three independent determinations yielded fluorescence lifetimes of 392 ± 42 ps and 2.95 ± 0.19 ns ($\chi^2$ = 1.032). These are remarkably high values if compared with the lifetime of EV free in low viscosity media (5 to 10 ps[3b,d]), and suggest the existence of two dominant ground state conformers of EV in the BSA environment (bound to different types of binding sites[5b,c]). Upon photoexcitation, the population of EV molecules displaying conformation closer to that of the TICT state is the one which relaxes faster.[3b] The Scatchard analysis[5b] of our fluorescence data confirmed the existence of two distinct types of BSA binding sites capable of accommodating EV molecules. The amino acid composition of these macromolecular domains may also affect the fluorescence lifetime of bound EV molecules (see below).

The observed increase in EV fluorescence lifetime and quantum yield suggests that the efficiency of intersystem crossing ($\phi_{ISC}$) might also undergo expressive increase as a consequence of binding. The bleaching of BSA-bound EV upon laser excitation at 532 nm is shown in Fig. 2. Under photolysis conditions essentially all dye molecules are bound to BSA (plateau region of the binding isotherm; large [protein] : [dye] ratio), therefore experiencing loss of rotational degrees of

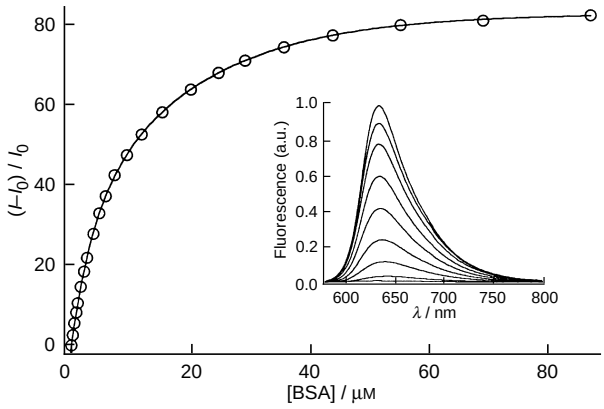

**Fig. 1** Effect of BSA concentration on the integrated fluorescence of EV. Inset: representative spectra employed in the construction of the binding isotherm. For visual clarity only one third of the data set is shown. From the bottom, in order of increasing fluorescence intensity at 634 nm, the BSA concentrations were 0.0, 0.27, 1.06, 2.64, 5.76, 11.8, 24.7, 44.0 and 87.4 μM. Excitation at 520 nm; [EV] = 10 μM; phosphate buffer (0.01 M) pH 7.3; $T$ = 20 °C.

**Scheme 1**

freedom. The quantum efficiency of photobleaching was found to be two fold higher in nitrogen-purged than in air-equilibrated samples. The increased bleaching efficiency in nitrogen-purged as compared to air-equilibrated samples is direct evidence of the involvement of the first excited triplet state of the dye in the bleaching process. The comparison between the photobleaching efficiency of EV free in solution and protein-bound is more prominent. A 13-fold increase is observed as a consequence of binding (air-equilibrated samples). Using Methylene Blue[2c] as a laser flash photolysis standard we have estimated $\phi_{ISC}$ as 0.03 for BSA-bound EV. For the case of the dye free in solution we were unable to detect any transient signal (ns–μs range) following ns laser excitation at 560 nm.

The analysis of reaction products was performed by extraction of photolysed samples with EtOAc and characterization of the extracted compounds by thin-layer chromatography (silica gel; 2 : 1 hexanes–EtOAc). 4,4′-Bis(diethylamino)benzophenone and leuco-EV were identified as photoproducts. The former was more prominent in air-equilibrated samples, the latter in nitrogen-purged samples. The reaction mechanism shown in Scheme 1 accommodates the results observed. The reductive formation of leuco-EV from EV is a two electron process (formally $2e^- + H^+$ or $H + e^-$), initiated in this case by a photoinduced electron or hydrogen atom transfer from the protein to the dye moiety. 78 out of the 583 BSA amino acid residues are readily susceptible of photosensitized oxidation[2a] (2 Trp, 4 Met, 17 His, 20 Tyr and 35 Cys).[6] After initiation the semi-reduced dye radical can either react with dissolved molecular oxygen to produce 4,4′-bis(diethylamino)benzophenone or accommodate a second electron to form leuco- EV (Scheme 1). The intermediate dye radical can also transfer one electron back to the protein or to molecular oxygen to regenerate EV. Because the electronic excitation of the dye moiety occurs within a ground state protein-dye complex, the first excited singlet state of EV is born physically attached to the protein. Therefore, it is conceivable that not only the dye's triplet, but also the relatively short lived excited singlet populations, engage in the initial electron transfer process that leads to the formation of the semi-reduced dye radical (no diffusion needed for the reaction to occur). The competitive reaction pathways demonstrated by the characterization of reaction products in air-equilibrated and nitrogen-purged samples is also made evident through absorption spectroscopy measurements. Fig. 2 [inset (*a*)] shows that upon laser excitation of BSA-bound EV in nitrogen-purged solution the photoproduct that absorbs in the 380 nm region, 4,4′-bis(diethylamino)benzophenone, is not formed in significant amounts, but the differential absorption spectrum in the 250–280 nm region clearly indicates the formation of the dye's reduced (leuco) form as photoproduct [Fig. 2, inset (*b*)]. Under aerobic conditions a parallel route of formation of 4,4-bis(diethylamino)benzophenone is possible. The singlet oxygen generated by triplet–triplet energy transfer from triplet EV to ground state oxygen might, in principle, add to EV to generate an unstable dioxetane intermediate, whose thermal cleavage would produce 4,4′-bis(diethylamino)benzophenone. This last mechanistic path is, however, unlikely to be playing a significant role here.[7]

Another mechanistic possibility of interest, and presently under investigation, is the formation of heteroadducts through the covalent linkage of the semi-reduced dye radical with BSA. Independently of the bleaching path that is dominant under anaerobic conditions (sequential two-electron abstraction from the protein *or* one-electron abstraction followed by covalent-linking), upon laser excitation of protein-bound EV the photoinduced transformation of the host protein occurs *via* a free radical process that does not require molecular oxygen. This peculiar reaction course is well suited for the treatment of hypoxic or poorly perfused tumour areas. Our preliminary investigations have demonstrated that the photobleaching of Malachite Green and Crystal Violet proceed *via* equivalent paths, suggesting that this novel oxygen-independent mechanism may be rather common when considering the photochemistry of cationic photosensitizers non-covalently bound to biopolymers. Based on the relative values of photodecomposition quantum efficiency for a larger series of TAM dyes bound to BSA and other model proteins, and the extent to which the mechanistic details are conserved among the series, a better understanding of the structure–photoreactivity relationship for TAM dyes will be achieved, allowing the development of more effective photosensitizers.

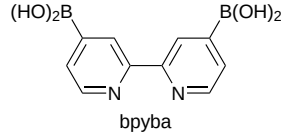
# Chiroselective transcription of the sugar structure to Δ- or Λ-$[Co^{III}(bpy)_3]^{3+}$ using a boronic acid–sugar template interaction



**Toshihisa Mizuno,[a] Masayuki Takeuchi,[a] Itaru Hamachi,[a] Kazuaki Nakashima[b] and Seiji Shinkai*[a]**

[a] *Department of Chemical Science and Technology, Faculty of Engineering, Kyushu University, Fukuoka 812, Japan*

**In order to apply boronic acid–saccharide interactions to the chiroselective synthesis of Δ- and Λ-$[Co^{III}(bpy)_3]^{3+}$ a saccharide-binding ligand, 2,2′-bipyridine-4,4′-diboronic acid (bpyba) is newly synthesized; the enantiomeric excess under the optimum reaction conditions reached 79% ee!**

The recognition of biologically important molecular species by synthetic molecular receptors has gained momentum. Since the chemistry of saccharides plays a significant role in the metabolic pathways of living organisms, the detection of biologically important saccharides is necessary in a variety of medical and industrial contexts. Although hydrogen-bonding interactions play a central role in most reported synthetic receptors,[1] it has recently been shown that boronic acid–saccharide covalent interactions which readily and reversibly form in aqueous media represent an important alternative binding force in the recognition of saccharides and related molecular species.[2–7] Stable boronic acid-based saccharide receptors offer the possibility of designing saccharide sensors which are selective and sensitive for the specific saccharide.[6] Through these studies we have noticed that boronic acid–saccharide interactions create a variety of supramolecular structures which are founded on the absolute configuration of each saccharide.[8–10] This implies that saccharides are very useful as chiral building blocks to create oriented supramolecular assemblies or as chiral auxiliaries for asymmetric syntheses. This viewpoint has escaped attention for a long time, even though nature gifts us with a variety of saccharides with chiral structures. Tris[2,2′-bipyridine(bpy)]–metal complexes have inherent Δ *vs.* Λ chirality. It occurred to us that two pyridine rings may be asymmetrically oriented by a boronic acid–saccharide interaction[11] and the metal complexes thus formed may contain an excess amount of either Δ- or Λ-isomer over the other.[12]

With this object in mind we synthesized 2,2′-bipyridine-4,4′-diboronic acid (bpyba),[13] expecting that the saccharide-induced chiral orientation of this ligand eventually leads to the enantiomeric excess of either Δ- or Λ-isomer in the resultant metal complexes.

bpyba

To test the above working hypothesis we contrived the following reaction scheme. First, bpyba (6.37 mg, $1.69 \times 10^{-5}$ mol) and a saccharide ($3.38 \times 10^{-5}$ mol) were dissolved in a water (pH 7.4 with 50 mM MOPS buffer–methanol (1 : 1 v/v) solution (1.0 ml), and then the solution was mixed with a water–methanol (1 : 1 v/v) solution (1.0 ml) containing $Co(OAc)_2$ (1.00 mg, $5.65 \times 10^{-6}$ mol) at the appropriate temperature. The reaction mixture was stirred at this temperature for 2 days under a nitrogen atmosphere. As $[Co^{II}(bpy)_3]^{2+}$ is known to isomerize between Δ- and Λ-isomer (*i.e.* substitution active),[14] the $[Co^{II}(bpyba)_3]^{4-}$–saccharide complex should reach some Δ *vs.* Λ equilibrium under the influence of added saccharides. Then, the $[Co^{II}(bpyba)_3]^{4-}$–saccharide complex was oxidized to the $[Co^{III}(bpyba)_3]^{3-}$–saccharide complex by bubbling $O_2$ into this solution for 48 h. The completion of this oxidation process was confirmed by the following observations: (*i*) the absorption spectrum of the resultant complex is the same as the authentic $[Co^{III}(bpyba)_3]^{3-}$ complex prepared from $[Co^{III}Cl(NH_3)_5]^{2+}$ and bpyba, (*ii*) the absorption spectrum is unaffected by further oxidation with $H_2O_2$, (*iii*) the complex is EPR silent and (*iv*) the $^1H$ NMR spectrum does not show any indication that the complex is paramagnetic (*e.g.* line-broadening, unusual chemical shift, *etc.*). As $[Co^{III}(bpyba)_3]^{3-}$ is substitution-inactive,[14] the Δ *vs.* Λ ratio has been fixed at this step.

The CD spectrum of the $[Co^{III}(bpyba)_3]^{3-}$–saccharide complex obtained at 4 °C in the presence of D-glucose (sample A) is shown in Fig. 1(*a*). We also prepared a complex (sample B) in which D-glucose was added after $[Co^{II}(bpyba)_3]^{4-}$ is oxidized to $[Co^{III}(bpyba)_3]^{3-}$ [Fig. 1(*b*)]. Although both samples are CD active, one must consider that the CD band arising from Δ *vs.* Λ chirality overlaps with the saccharide-induced ICD band. In fact, a mixture of racemic $[Co^{III}(bpyba)_3]^{3-}$ and D-glucose resulted in a CD spectrum similar to Fig. 1(*b*). To estimate whether the CD spectra truly contain the CD band arising from Δ *vs.* Λ chirality we added an excess amount of optically inactive *cis*-cyclopentane-1,2-diol (*cis*-CPD): this compound shows the high affinity with boronic acids and can competitively substitute D-glucose bound to the boronic acid groups in $[Co^{III}(bpyba)_3]^{3-}$.[3–15] As shown in Fig. 1(*b*), the CD band of sample B decreased with increasing *cis*-CPD concentration and almost disappeared at [*cis*-CPD]/[D-glucose] = 25. In contrast, the CD band of sample A also decreased with increasing *cis*-CPD concentration but remained still CD active with $[\theta]_{460}$ =

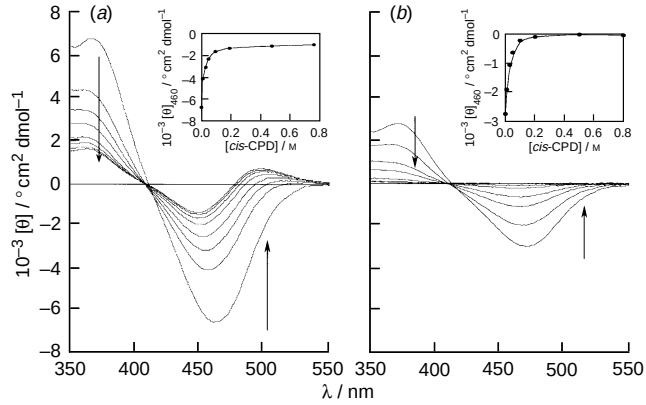

**Fig. 1** CD spectra of $[Co^{III}(bpyba)_3]^{3-}$ ($5.56 \times 10^{-4}$ M) and the influence of added *cis*-CPD at 25 °C: (*a*) sample A, [D-glucose] = 3.38 mM, [*cis*-CPD] = 0, 10, 30, 50, 100, 200, 500, 800 mM (from bottom to top at 460 nm); (*b*) sample B, [D-glucose] = 3.38 mM, [*cis*-CPD] = 0, 10, 30, 50, 100, 200, 500, 800 mM (from bottom to top at 460 nm)

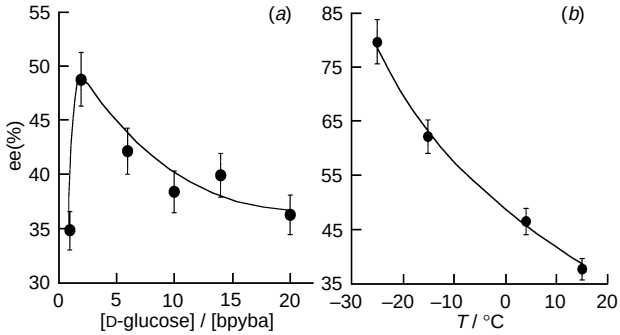

**Fig. 2** Influence of the D-glucose concentration (*a*) and the reaction temperature (*b*) on the ee of $[Co^{III}(bpy)_3]^{3+}$

1100° cm² dmol$^{-1}$ even in the presence of excess *cis*-CPD. The results clearly indicate that sample B consists of a 1 : 1 racemic mixture of Δ- and Λ-isomers whereas in sample A one isomer exists in excess over the other.

To estimate the enantiomeric excess (ee) of the $[Co^{III}(bpyba)_3]^{3-}$–saccharide complexes we applied a HPLC method with chiral-packed columns and a $^1$H NMR spectroscopic method with chiral shift reagents but failed. It is known that a boronic acid group in phenylboronic acid can be eliminated by treatment with $AgNO_3$.[16] We applied this method to the $[Co^{III}(bpyba)_3]^{3-}$–saccharide complexes and tried to determine the ee by comparison with authentic Δ- and Λ-$[Co^{III}(bpy)_3]^{3+}$.[17] Thus, $AgNO_3$ (500 mg, 2.9 mmol) was added to the sample A solution and the mixture was stirred at room temperature. The progress of the reaction was monitored by HPLC [Zorbax ODS, water–methanol (1 : 4 v/v)]. It showed that $[Co^{III}(bpyba)_3]^{3-}$ is quantitatively converted to $[Co^{III}(bpy)_3]^{3+}$ after one day.[18] After membrane filtration (Millipore LCR 13-LH), the filtrate was purified using gel filtration [Toyopearl HW-40, water–methanol (1 : 1 v/v)]. The yield of recovered $[Co^{III}(bpy)_3]^{3+}$ after gel filtration was 80%. The CD spectrum of $[Co^{III}(bpy)_3]^{3+}$ was thus obtained. By comparison with the CD spectrum of optically pure Δ-$[Co^{III}(bpy)_3]^{3+}$[17] the optical purity of this sample could be determined to be 47% ee (Δ excess). We repeated the sample preparation in the presence of various saccharides and obtained the following results: 47% ee (Λ excess) for L-glucose, 2% ee (Δ excess) for D-ribose, 10% ee (Δ excess) for D-mannose, 2% ee (Λ excess) for D-talose, 6% ee (Λ excess) for D-xylose, 12% ee (Δ excess) for D-maltose, and 3% ee (Δ excess) for D-cellobiose. Further examination was carried out with D-glucose which gave the highest ee among saccharides tested herein.

Fig. 2(*a*) shows the influence of the D-glucose concentration (in feed) on the ee of Δ-$[Co^{III}(bpy)_3]^{3+}$. The maximal ee (47%) appeared at [D-glucose] = $5.66 \times 10^{-3}$ M, which corresponds to [D-glucose]/[bpyba] = 2.0. This ratio indicates that the ee of Δ-$[Co^{III}(bpy)_3]^{3+}$ becomes maximal when one boronic acid group binds one D-glucose molecule. Fig. 2(*b*) shows the influence of the reaction temperature on the ee of Δ-$[Co^{III}(bpy)_3]^{3+}$. It is seen from Fig. 2(*b*) that the ee increases with lowering the reaction temperature and at −25 °C it even reaches 79%. Under the similar conditions in the presence of L-glucose we could obtain Λ-$[Co^{III}(bpy)_3]^{3+}$ in 79% ee.

The foregoing results clearly establish that the saccharide-templated synthesis is useful as a new concept for the preparation of chiral tris(2,2′-bipyridine)–metal complexes. Furthermore, the Δ *vs.* Λ equilibrium can be shifted in either direction by the selection of saccharide enantiomers. The chemistry of chiral tris(2,2′-bipyridine)–metal complexes has become a very active area of endeavour in relation to asymmetric synthesis, asymmetric memory transduction, non-linear optics, photoinduced electron or energy transfer, *etc.*[19–21] However, these fields have always been hampered by difficulty in the preparation of the chiral metal complexes. We believe that the present method provides an important breakthrough for these advanced fields of science.

We thank Dr Tony D. James (University of Birmingham) for helpful discussions.

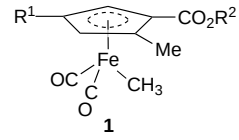
# Induction of metal-centered chirality by planar chirality in [Fe{η-$C_5H_2Me(R^1)(CO_2R^2)$}(COR)(CO)($PR_3$)] complexes

**Yasushi Morimoto, Katsuhiro Ando, Mitsunari Uno and Shigetoshi Takahashi***

*The Institute of Scientific and Industrial Research, Osaka University, 8-1 Mihogaoka, Ibaraki, Osaka 567, Japan*

**The reaction of planar-chiral (alkyl)(cyclopentadienyl)dicarbonyliron complexes with triphenylphosphine gives [Fe{η-$C_5H_2Me(R^1)(CO_2R^2)$}(CO)(COR)($PPh_3$)] with a high diastereoselectivity ( > 90%) for the induction of metal-centered chirality.**

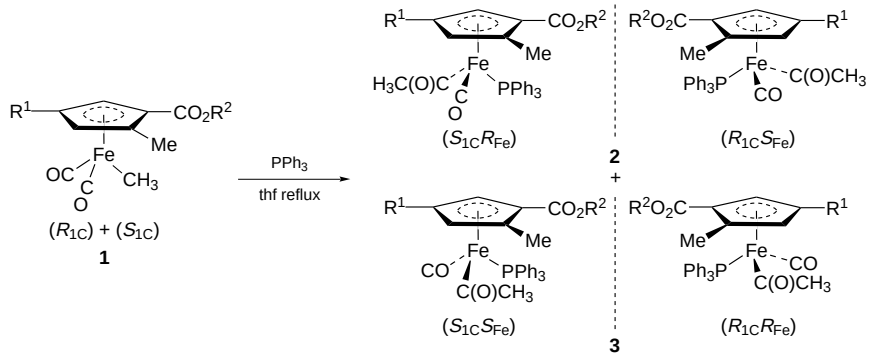


Optically active organometallic complexes have increasingly become useful in application to organic syntheses and mechanistic studies. Among the complexes, optically active cyclopentadienyl–metal complexes such as planar-chiral and chiral-at-metal cyclopentadienyl complexes have received recent interest.[1] Several asymmetric reactions using the latter complexes including [Fe(η-$C_5H_5$)(COR)(CO)($PR_3$)],[2] [Re(η-$C_5H_5$)(NO)($PPh_3$)(ArCHO)][$PF_6$][3] and [Rh(η-$C_9H_6$-1-$(CH_2)_m PR_2$)(COR)I][4] have appeared in the literature, whereas successful examples, in which a stereocontrol reaction occurring at a metal center is effectively governed by a planar chirality, are scarce. Information about the stereochemistry controlled by a certain chirality source is of prime importance in new applications to asymmetric reactions.

We previously showed a new method for the synthesis of planar chiral cyclopentadienyl–cobalt,[5] –rhodium[6] and –ruthenium[7] complexes using a chiral trisubstituted cyclopentadiene and isolated them in an enantiomerically pure form. Here we have applied this method to the preparation of planar chiral (alkyl)(cyclopentadienyl)dicarbonyliron complexes and found that they undergo asymmetric induction of metal-centered chirality controlled by the planar chirality [eqn. (1)].

$$[Fe\{\eta\text{-}C_5H_2Me(R^1)(CO_2R^2)\}(CO)_2R] + L \rightarrow [Fe^*\{\eta\text{-}C_5H_2Me(R^1)(CO_2R^2)\}(COR)(CO)L] \quad (1)$$

It is well known that cyclopentadienyliron–alkyl complexes, [Fe(η-$C_5H_5$)$(CO)_2$R], undergo a migratory insertion of carbon monoxide on treatment with phosphorus compounds such as phosphines and phosphites, and afford three-legged piano-stool iron-acyl complexes, [Fe(η-$C_5H_5$)(CO)($PR_3$)(COR)], which show chirality at the metal center.[8] Several reports have appeared on the induction of iron-centered chirality,[9] however only a modest diastereoselectivity of the asymmetric induction has been attained using chiral cyclopentadienyl ligands.[9b] Here we report the effective induction of metal-centered chirality in the reaction of planar-chiral (alkyl)(trisubstitutedcyclopentadienyl)dicarbonyliron complexes with phosphines.



We synthesized the planar-chiral iron–alkyl complexes **1** by a literature method starting from trisubstituted cyclopentadienes.[10]

**1**

**1a** $R^1 = R^2 = Me$
**b** $R^1 = Ph$; $R^2 = Me$
**c** $R^1 = Me$; $R^2 = Et$
**d** $R^1 = Ph$; $R^2 = Et$

We investigated the influence of the planar chirality on the stereochemistry of a reaction occurring at the iron center in the reaction with phosphines giving acetyl iron complexes. Thus racemic iron–methyl complexes **1** ($R_{1c}$ + $S_{1c}$) were heated with 5 equiv. of triphenylphosphine in thf for 48 h and acetyl complexes were obtained as a stereoisomeric mixture (Scheme 1), which were purified by column chromatography on alumina and identified by $^1$H and $^{31}$P NMR and IR spectroscopy. The resulting acetyl complexes possess two chiral centers, *i.e.* metal-centered chirality and planar chirality, and hence may exist as a mixture of two diastereomerically related pairs of enantiomers **2**(*SR,RS*) and **3**(*SS,RR*). The ratio of **2** to **3** has been determined by $^1$H NMR† and HPLC‡ using a chiral column. The diastereoselectivities found in the above reactions are summarized in Table 1 along with chemical yields. The planar chirality effectively induces iron-centered chirality, and the size of a range of substituents $R^1$ on the cyclopentadienyl ligand strongly affects the diastereoselectivity of the reaction. A methyl group on the cyclopentadienyl ring gives a modest diastereoselectivity of *ca.* 75 : 25 while a larger phenyl group results in an increased diastereoselectivity up to *ca.* 95 : 5. It has already been reported that planar-chiral [Fe(η-$C_5H_3$Me-1-Ph-3)$(CO)_2$Me] did not exhibit any diastereoselectivities upon reaction with triphenylphosphine[9a] and even a diastereomeric analog bearing a chiral (*S*)-binaphthyl group on the cylopentadienyl ring showed only a modest diastereoselectivity of 40%.[9b] The high diastereoselectivity (*ca.* 90% de) observed in the

**Scheme 1**

**Table 1** Asymmetric induction of planar-chiral [Fe{η-$C_5H_2Me(R^1)$-$(CO_2R^2)$}$(CO)_2$Me] complexes on treatment with $PPh_3$

| Product | $R^1$ | $R^2$ | Yield (%) | **2** : **3**[a] |
|---|---|---|---|---|
| **2a**, **3a** | Me | Me | 80 | 74 : 26 |
| **2b**, **3b** | Ph | Me | 58[b] | 96 : 4 |

[a] Determined by HPLC using Chiralcel OD and $^1$H NMR analyses. [b] Some decomposition of **1** was observed during the reaction, but the crude and purified products showed the same ratio of **2** to **3**.

present work may be attributed to an effective asymmetrical environment constructed by three suitable substituents, *i.e.* small, moderate and large groups, on the cyclopentadienyl ring.

A diastereomeric mixture of acetyl complexes was separated into two diastereomerically related pairs of enantiomers, **2** and **3**, by fractional crystallization from hexane–benzene. X-Ray crystallographic analysis has been performed for the major isomer **2c** (Fig. 1) and revealed that the absolute configuration is a pair of (*SR*) and (*RS*) configurational isomers, indicating that planar chirality $S_{1c}$ induces metal-centered chirality $R_{Fe}$ in the reaction of **2** with $PPh_3$.§,¶ In addition, the diastereoselectivity in the present reaction has been found to be thermodynamically controlled since a separate experiment showed that pure diastereomer **2c** was converted to a mixture of **2c** and **3c** with a diastereoisomer ratio of 75 : 25 when heated in thf for 48 h which is the same diastereoisomeric ratio as observed in the reaction of **1c** with triphenylphosphine under the same reaction conditions.

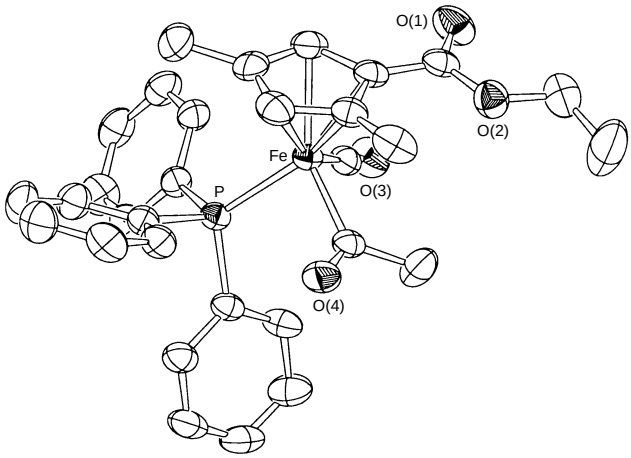

**Fig. 1** Molecular structure of **2c** with hydrogen atoms omitted for clarity

# Reaction of an alkynyllithium reagent with boron trifluoride: the structure of a likely intermediate in alkynyl anion chemistry

**John E. Davies, Paul R. Raithby, Ronald Snaith and Andrew E. H. Wheatley***

*Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW*

**Lithium phenylacetylide reacts with 1 equiv. of $BF_3{\cdot}OEt_2$ in thf–toluene to yield both a thf adduct of tris(phenylacetylido)borane 2, which is probably the true intermediate in RC≡CLi/$BF_3$-promoted alkynyl anion chemistry, and $LiBF_4$, products which are considered to form *via* sequential LiF elimination from previously proposed acetylidoborate intermediates; complex 2 is the first structurally characterised tris(alkynyl)borane and in the solid state it forms an unusual hydrogen-bonded dimer.**

The value of organometallic nucleophilic addition to imines[1] has been limited in the past by the poor reactivity of the latter as acceptors,[2] and by their propensity for enolisation in the presence of, for example, organolithium species.[3] While initial attempts at activating imines towards nucleophilic addition of organometallic reagents involved the use of organocopper–boron trifluoride complexes[4] it was subsequently reported that supposed *in situ* generation of alkynylborane/borate species[5] led to β-aminoacetylenes from aldimines.[6] More recent work has incorporated the use of similar *in situ* boron-containing intermediates in the synthesis of allenes from *N*-aziridinylimines.[7] In each case, however, the existence of the alkynylborane/borate intermediate was assumed, the presumption being that lithium phenylacetylide[8] reacted with 1 equiv. of $BF_3{\cdot}OEt_2$ to yield either the monophenylacetylidoborate, **1a**, or, following the elimination of lithium fluoride, the monophenylacetylidoborane, **1b** (Scheme 1). An unexplained anomaly was that the subsequent nucleophilic addition reactions gave higher yields in the presence of 2 or, better, 3 equiv. of **1a**/**b**.

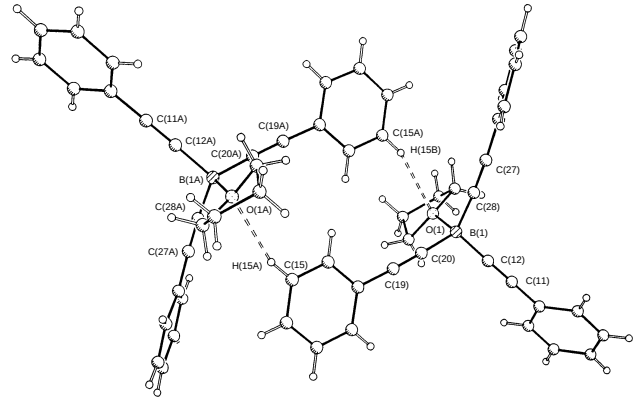
**Scheme 1**

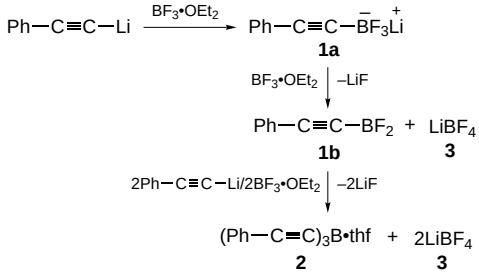
We have investigated and now report on the actual species obtained from reacting a 1 : 1 mixture of a lithium acetylide with $BF_3{\cdot}OEt_2$. They are not the intermediates **1a**/**b** suggested previously (Scheme 1). They do, however, explain the preference for excess intermediate to be present during subsequent reaction with amide,[5] aldimine,[6] or *N*-aziridinylimine.[7] Thus, reaction of *in situ* generated lithium phenylacetylide with just 1 equiv. of $BF_3{\cdot}OEt_2$ in thf–toluene affords, as one of the products, an air-stable mono-thf adduct of tris(phenylacetylido)borane **2**,† the X-ray crystal structure of which has been determined.‡ A search of the Cambridge Crystallographic Database shows that **2** is not only the first structurally characterised tris(acetylido)borane, but that it is also the first acetylidoborane structure to incorporate an O-donor molecule. It exists as a hydrogen-bonded dimer in the solid state (Fig. 1), the boron centres having distorted tetrahedral geometries, with the fourth coordination site being occupied by the oxygen of the thf [mean C–B–C 114.2(2)°, mean O–B–C 104.1(2)°]. Unsurprisingly, at 1.633(3) Å, the observed B–O distance is rather longer than any previously observed in three-coordinate monoacetylidoborane structures containing direct B–O linkages.[11] Both the B–C [mean 1.580(4) Å] and C≡C [mean 1.209(3) Å] distances show close agreement with those in other (*i.e.* mono and bis) acetylidoboranes. Dimerisation *via* hydrogen bonding is seemingly a new feature in the solid state for acetylidoborane structures. The relevant interaction is between the adduct O-centre and the *m*-aromatic proton on a phenylacetylide ligand in an adjacent borane monomer. This results in the formation of a 16-membered ring, incorporating an O···C hydrogen bonding distance[12] of 3.46(1) Å.

Notwithstanding the structure of **2**, obtained from the 1 : 1 reaction of Ph–C≡C–Li and $BF_3{\cdot}OEt_2$ in thf, NMR studies show that the bulk product is a co-crystalline mixture. While $^1$H and $^{13}$C NMR spectra of the product were consistent with the observed structure of **2**, $^{11}$B NMR spectroscopy in $Me_2SO$ yielded only a first-order quintet at $\delta$ −0.75. At 1.1 Hz, coupling was identical to that demonstrated by the quartet observed in the $^{19}$F spectrum at $\delta$ −147.59 and accorded with previously observed $^1J_{^{11}BF}$ coupling for the tetrafluoroborate anion.[13] Confirmation that $LiBF_4$, **3**, was present in the isolated crystals came from the observation of a very sharp singlet at $\delta$ −0.11 in the $^7$Li spectrum in $Me_2SO$, suggesting the presence of $[Li(Me_2SO)_4]^+$.

At room temperature, $^{11}$B NMR spectroscopy of the bulk product in $Me_2SO$ failed to yield any signal attributable to **2**. Studies were therefore undertaken in alternative media. Whereas treatment of the co-crystalline product (**2**/**3**) with $Me_2SO$ yielded a solution, $^{11}$B NMR spectroscopy demonstrated that the necessity to filter the suspension afforded in [$^2H_6$]benzene prior to spectral analysis reflected the complete failure of the tetrafluoroborate component to dissolve. Accordingly, the $^{11}$B NMR spectrum at room temp. now showed no quintet, but rather a broad signal attributable to **2** ($\delta$ *ca.* 0.03, $\Delta\nu_{1/2}$ = 450 Hz). Complete dissolution of **2**/**3** was afforded by [$^2H_8$]thf, yielding both the tetrafluoroborate quintet ($\delta$ −1.18) with a slightly expanded $^1J_{BF}$ coupling (1.8 Hz), and a broad, high-field signal ($\delta$ *ca.* −7.32, $\Delta\nu_{1/2}$ = 340 Hz), the relative integrations suggesting a 1.25 : 1 ratio of **2** to **3**.

Spectroscopic evidence points, therefore, not only to the elimination of LiF from **1a**, yielding **1b** in the first instance, but also to the subsequent addition of LiF to an unreacted boron





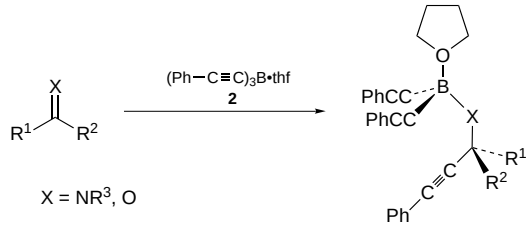


**Fig. 1** Dimeric structure of **2**; hydrogen bonding between thf and a *m*-aromatic proton yields a 16-membered ring

**Scheme 2**

trifluoride molecule, generating **3**. Furthermore, it appears that **1b** is attacked by 2 further equiv. of lithium phenylacetylide, eliminating LiF each time and ultimately giving **2** (Scheme 2). It is also apparent that an explanation of the favourability of utilising 2 or 3 equiv. of the supposed acetylidoborate/borane intermediate (**1a**,**b**) in subsequent nucleophilic addition chemistry is then at hand. Thus, the true alkynyl anion intermediate, **2**, contains not one, but three phenylacetylido-ligands. The implication is that one phenylacetylido-ligand is relatively active with respect to subsequent nucleophilic behaviour while the other two are largely inactive. This can be rationalised in terms of the sterically congested intermediate species resulting from the addition of **2** across just one carbonyl,[5] imine[6] or *N*-aziridinylimine (Scheme 3).[7]

**Scheme 3**

In conclusion, formation of **2**, the first example of a structurally characterised tris(acetylidoborane), is probably *via* the sequential elimination of LiF from acetylidoborate precursors (*e.g.* **1a**). Addition of the eliminated LiF to unreacted boron trifluoride means that formation of **2** is concomitant with that of $LiBF_4$, **3**, as evidenced by multinuclear NMR spectroscopy. Finally, the fact that **2** is the true intermediate in RC≡CLi/$BF_3$-promoted alkynyl anion chemistry, rather than **1a** or **1b**, helps to explain the stoichiometries required for efficient subsequent nucleophilic addition reactions.

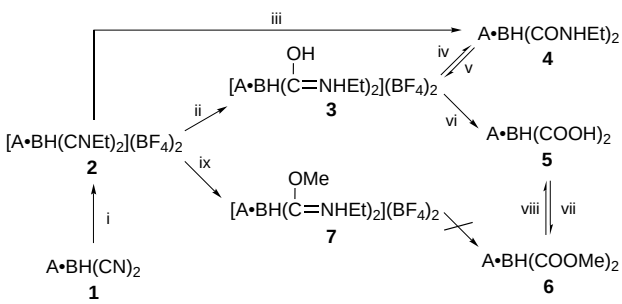
# Synthesis of the first amine–dicarboxyboranes and their derivatives

**Zoltán Berente and Béla Györi***



*Department of Inorganic and Analytical Chemistry, Lajos Kossuth University, Debrecen, H-4010, Pf. 21., Hungary*

**The first amine–dicarboxyboranes and their dimethyl esters are synthesized from amine–dicyanoboranes *via* [amine–bis(ethylnitrilium)hydroboron(2+)] tetrafluoroborates, [amine–bis(*C*-hydroxy-*N*-ethyliminium)hydroboron(2+)] cations and amine–bis(*N*-ethylcarbamoyl)boranes; *C*-methoxy-*N*-ethyliminium groups adjacent to boron undergo unusual hydrolysis.**

Amine–carboxyboranes have been known for two decades,[1] and their biological and pharmaceutical activities have been extensively studied.[2] Amine–carboxyboranes and related compounds have shown anticancer,[3] antiosteoporotic,[4] anti-inflammatory[5] and hypolipidemic[6] properties. Since the preparation of the first representative of amine–carboxyboranes they have been generally considered to be the boron analogues of the protonated amino acids,[7] based on the isoelectronic relation between C–$N^+$ and B–N bonds. On the other hand, amine–carboxyboranes can be regarded as analogues of aliphatic carboxylic acids, since the B–N bond is not only isoelectronic but also isosteric to the C–C bond, according to Langmuir's definition.[8] In contrast to amino acids, amine–carboxyboranes do not form chelates with transition metal ions and their p$K_a$ values are approximately 6 units larger than those of amino acids.[9] These facts, along with many qualitative observations, suggest that the $R_3N$–B group has a marked electron-donating effect towards its substituents.[10]

Here we report the synthesis of the first amine–dicarboxyboranes, the boron analogues of geminal dicarboxylic acids. Our long-term project, directed towards the synthesis of boron-substituted amine–carboxyboranes,[11] was initiated for two reasons. First, the introduction of new functional groups (here a second carboxylic group) offers potential biological activity. Second, the substitution of a hydrogen for an electron-withdrawing substituent on the boron is expected to increase the stability of the B–H bond, and brings the electron distribution of the carboxylic group closer to that in aliphatic carboxylic acids.

The synthetic sequence is outlined in Scheme 1.† The amine–dicyanoboranes **1a**–**d** were readily synthesized by base exchange (Table 1). The reaction between **1a**–**c** and $Et_3OBF_4$ in refluxing $CH_2Cl_2$ afforded the [amine–bis(*N*-ethylnitrilium)hydroboron(2+)] tetrafluoroborates **2a**–**c**. Owing to their low solubility in $CH_2Cl_2$, pure **2a** and **2c** could be isolated from the reaction mixtures in 80–88% yields. However, **2b** could not be separated from the excess $Et_3OBF_4$, but it did not cause the formation of byproducts in the subsequent reactions. **2d** could not be obtained at all, though both mono- and di-ethylated products were formed in the initial stage, but later they decomposed when a significant amount of starting material was still present. NMR monitoring of the ethylation reactions showed significant amounts of **1** and/or **2** besides the intermediate [amine–cyanoethylnitriliumhydroboron(1+)] cations during the whole reaction period even when only 1 mol equiv. of $Et_3OBF_4$ was employed. Consequently, there is only a surprisingly small difference between the rates of the consecutive steps, and preparation of the pure intermediates does not seem feasible.

**Scheme 1** (**a** A = quinuclidine; **b** A = $Me_3N$; **c** A = pyridine; **d** A = DMAP; **e** A = piperidine). *Reagents and conditions:* i, 2.5 mol equiv. $Et_3OBF_4$, $CH_2Cl_2$, reflux, 6–10 h; ii, $H_2O$, room temp. 50–70 min; iii–iv, 1 M NaOH, room temp. immediate; v, $HBF_4$, $H_2O$ room temp., immediate; vi, 1 M HCl, 120 °C, 1.5 atm, 10 min; vii, 7.5 mM HBr–MeOH, room temp., 5–10 min; viii, 0.05 M HCl, 60 °C, 15 min; ix, MeOH, room temp. 5–10 min.

Water readily adds to **2a**–**c** in 50–70 min in water or in 1 M HCl at room temp. affording [amine–bis(*C*-hydroxy-*N*-ethyliminium)hydroboron(2+)] tetrafluoroborates **3a**–**c**. **3a** could be prepared and characterized as a solid,‡ since it precipitated from water. Such stability of protonated aliphatic amides in aqueous medium is quite unusual,[12] and is probably due to the strong electron-releasing effect of the $R_3N$–B group. Water addition also takes place when **2a**–**c** are exposed to moisture.

In 1 M NaOH **2a**–**c** were transformed to the corresponding amine–bis(*N*-ethylcarbamoyl)boranes **4a**–**c** within 5 min, and the pure products were obtained from the $CH_2Cl_2$ extracts of the alkaline solutions. **4d** and **e** were synthesized from **4a** or **b** employing base exchange reactions (Table 1). Protonation of **4** leads to **3**: addition of 50% $HBF_4$ to a concentrated aqueous solution of **4a** resulted in the precipitation of **3a**.

In contrast to amine–*N*-ethylcarbamoylboranes, the acidic hydrolysis of amine–bis(*N*-ethylcarbamoyl)boranes **4**, presumably *via* **3** cations formed *in situ*, required vigorous conditions, probably owing to the much larger steric hindrance of the acyl carbons.[14] **4a** and **e** could be transformed into the amine–dicarboxyboranes **5a**§ and **e**. Best yields (60%) were achieved

**Table 1** Syntheses employing base exchange

[a] Yields are not optimized. [b] For preparation see ref. 13. [c] Q = quinuclidine. [d] The reaction was run in piperidine. [e] The crude product was a mixture of **5** and its salt formed with the corresponding base. Pure **5d**, **e** were obtained from the suspension of the crude products in 0.1 M HCl.

for **5a** in 1 M HCl, at 120 °C. **4b**–**d** completely decomposed at even lower temperatures and/or less acidic solutions to the corresponding amine hydrochlorides. The lower hydrolytic stability of **4b** and **c** may be due to the relatively weak B–N bond in these complexes. On the other hand, the B–N bond in both **4d** and **5d** is presumably stronger than in **4a** and **5a**, since **4d** and **5d** could be prepared *via* a base exchange reaction (Table 1) from **4a** and **5a**. In accordance with our expectations, preliminary observations (salt formation during base exchange, –COOH chemical shifts) suggest that amine–dicarboxyboranes are stronger acids than amine–carboxyboranes. Decomposition during the hydrolysis of **4d** in acidic medium may be the consequence of the strong electron-donating property of DMAP (4-dimethylaminopyridine), which increases the hydridic character of the hydrogen attached to the boron. Such phenomena have been reported in the case of amine–(alkyl)carbamoylboranes.[15]

Similarly to amine–carboxyboranes,[16] all amine–dicarboxyboranes **5a**, **d**, **e** can be conveniently esterified in methanol in the presence of a catalytic amount (3 mol% relative to carboxyl groups) of HBr. Hydrolysis of the resulting amine–bis(methoxycarbonyl)boranes **6a**, **d**, **e** yielded the corresponding amine–dicarboxyboranes in minutes at 50 °C at pH ≈ 1. The latter reaction might offer a different, mild route to amine–dicarboxyboranes, so we attempted to synthesize **5** through the path **2** → **7** → **6** → **5**, since the acidic hydrolysis of alkylimidate salts $[RC(OR')=NR''R''']^+$ typically yields the corresponding esters $RC(O)OR'$.[17] [Amine–bis(*C*-methoxy-*N*-ethyliminium)hydroboron(2+)] tetrafluoroborates **7a**–**c** were readily obtained in minutes after dissolving **2a**–**c** in methanol. Unexpectedly, the hydrolysis of **7a**–**c** does not result in the formation of **6a**–**c** even in 1 M HCl (Scheme 2). Instead, NMR studies of the hydrolysis of **7a**, **b** showed release of methanol, and the resulting [amine–*N*-ethylcarbamoyl-(*C*-methoxy-*N*-ethyliminium)hydroboron-(+1)] tetrafluoroborates **8a**, **b** could be isolated.¶ Further hydrolysis of **8a** leads to a mixture of **4a** and quinuclidine–*N*-ethylcarbamoylmethoxycarbonylborane **9a** in both 1 M HCl and 1 M NaOH, producing more **4a** in alkaline medium. Hydrolysis of **8b** follows a similar pattern, but yields other products as well. **7c** undergoes no reaction in 1 M HCl at 25–80 °C, but it slowly decomposes to give boric acid and pyridinium chloride at 100 °C. Our results for **7c** are in agreement with those observed in the acidic hydrolysis of pyridine–(*C*-methoxy-*N*-ethylimino)borane.[18]

**Scheme 2**

In conclusion, we have investigated three different synthetic methods for the preparation of amine–dicarboxyboranes, boron analogues of geminal dicarboxylic acids. Based upon our findings three amine–dicarboxyboranes and their derivatives have been prepared and several more compounds of this type may be synthesized in the future.

The support of the Hungarian Science Foundation (OTKA T014985/1995) is appreciated.

# Cycles frustrating fractal formation in an $AB_2$ step growth polymerization

**Colin Cameron,[a] Allan H. Fawcett,*[b] Cecil R. Hetherington,[b] Richard A. W. Mee[b] and Frederick V. McBride[c]**

**The step growth of a flexible $AB_2$ monomer, normally considered to produce dendrimers or fractal molecules, as they are themselves self-similar to their branches, is frustrated by the formation of one cycle within each molecule, according to a Monte Carlo lattice study of the evolution of the topological trees that are embedded in three-dimensional space; the number of cycles of $m$ residues is well fitted by the relationship $R_m = K_0 p_a^m m^{-e}$, $p_a$ being the extent of reaction of the A groups; at the end of a polymerization of $N_0$ monomers the total number of cycles, and of molecules, is given by the product of $K_0$ and the Euler–Riemann function $\xi(e)$ so there is a simple relationship between these quantities and the mean number average degree of polymerization at infinite time: $N_0 = K_0 < x >_{n,\infty} \xi(e)$.**

The step growth of an $AB_2$ monomer, the next more elaborate after the AB system, is usually considered to follow the classical branching pattern of polymerization of Flory,[1,2] the molecules evolving in the forms of Cayley trees,[3] each being rooted upon an A group. At each step the A group of one molecule reacts with a B group of another. A and B groups might form, for example, ester links. The growth has a fractal characteristic, for at each step molecules and branches are self-similar.[4] The assumption that intramolecular reactions do not take place, or the neglect of them in the treatment, means that molecules tend towards an infinitely high molecular mass with one A group each.[1] This common[5] assumption is inherently unrealistic, unless some special stiffness factor applies, such as the presence of *p*-substituted aromatic rings.[6] We envisage intramolecular reactions in molecules that have several flexible bonds between the functional groups, each bond being subject to simple rotational isomeric state considerations,[7] as when developing step-growth chemistry of difunctional monomers did Carothers, who recognised the formation of small rings as competing with linear growth.[8] To tackle such issues in a manner that allows the proper competition in three-dimensional space between fractal growth to yield trees and their cyclisation to yield graphs[3,9] we have embedded them upon a lattice of a type that we have devised to minimise any effect from its particular structure,[10] and explore it with the Monte Carlo method to establish the involved and elusive pattern of behaviour.[11,12] Our three-dimensional lattice model for step growth[10] resembles the two-dimensional fluctuating bond model used for other purposes:[13] components of the structures are linked through bonds that lie on the lattice spacings, $l$, on the in-plane diagonals, $\sqrt{2}l$, and on the through-space diagonals, $\sqrt{3}l$. (One such bond corresponds to several covalent bonds in a real molecule.[10,13]) Here we represent the monomer on four lattice sites as $A–N(B)_2$, the A group and the two B groups attached directly to the node *N*. This allows the explicit representation as a three-membered ring of the loop, the pendent structure that forms from an A group and a B group on the same node. 10% of the lattice sites were left vacant to represent free volume to facilitate movement throughout the polymerization.

We show a single monomer and a dimer placed upon the lattice in two dimensions in Fig. 1(*a*) in the form of Cayley trees. In Fig. 1(*b*) is the structure obtained by a B group movement, and the product after that dimer reacts to form a loop. In Fig. 1(*c*) is a hexamer with two possible internal reactions of the A group, and one is performed. Though this is rather confined, it does show that, as the lattice-represented molecule grows in size, the A group may become surrounded by an increasing number of B groups within the same molecule, and the chance of an intramolecular reaction may well increase. A group reactions will take place quite readily for there is always an excess of B groups. A simple consideration will recognise that eventually all the free A groups, located throughout at the root of a tree,[3] if not used in a step growth to enhance the degree of polymerization, will be so consumed, and then growth within the system will cease. This may have happened with a tetrafunctional siloxane alkene system,[14] for it was reported that the molecular mass was not increased by extra time or catalyst.

Initially the molecules were placed in random orientations within layers, and then were moved to randomise their configurations and positions. A,B pairs adjacent upon the lattice were randomly joined by a new bond, and simultaneously units moved upon the lattice by exchanging bead sites within the constraints of the molecular framework to randomise configurations.[15,16] We have tested that movements cause no bond or unit to pass through another: topological requirements are respected.[15] Five attempts at movement were performed each time a reaction was with success rates ( > 70%) higher than for a single chain on a simple cubic lattice.[17] The competing processes of chain branching and cycle formation thus take place in a manner that faithfully reflects the considerations of space, topology and configurations, as the A groups react with the excess of B groups present. (This competition is also present in gel formation.[18,19]) For the system of $60^3$ lattice sites, we used 5M CHOICE[11] or time cycles, when only 0.003% of the A groups remained.

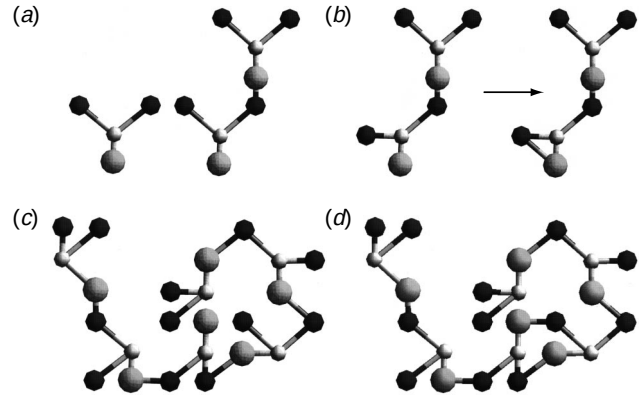

**Fig. 1** (*a*) $AB_2$ monomer and dimer displayed as trees, (*b*) dimer after a B group movement that facilitates the reaction whose product is shown, (*c*) a representative hexamer: note how the A end group is adjacent to two B groups on the same molecule, (*d*) the structure formed by an intramolecular reaction: a two-residue ($m$ = 2) cycle with two two-residue tails. The products in (*b*) and (*d*) lack A groups. These illustrations are drawn in two dimensions; the simulations were performed in three dimensions.

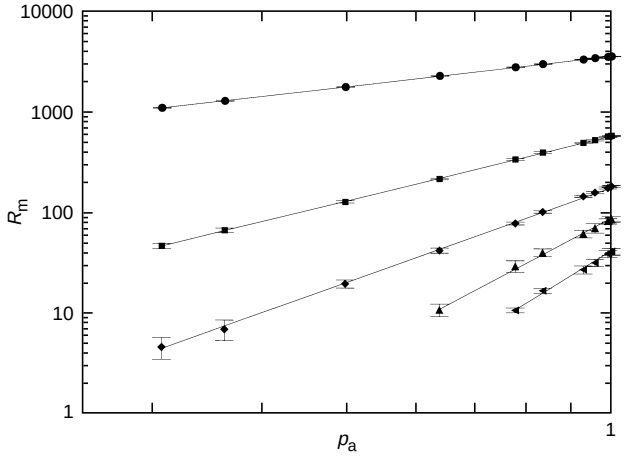

**Fig. 2** Logarithmic plots of $R_m$, the number of rings of size $m$ found in the system, against the extent of reaction, $p_a$. The lines fall in the order $m$ = 1,2, . . 5, and have integer slopes.

We obtained from the records $R_m$, the number of cycles involving $m$ residues, at several values of $p_a$. From nine simulations we plot the mean data for loops ($m$ = 1) and cycles up to $m$ = 5 on the log $R_m$–log $p_a$ plots of Fig. 2, where it may be seen that the points fall onto good straight lines: the slopes of these lines are well given by the integers, $m$, within a standard error or so [*e.g.* for the cycles with $m$ = 5 the exponent obtained by non-linear least-squares fitting[20] is 5.13 (±0.14)]. Thus $R_m = C_m p_a^m$. It is not difficult to envisage such integer power relationships as a limiting behaviour at low $p_a$ and when $m$ is small, for example the formation of a loop ($m$ = 1) will have a finite probability at the very start, and once a dimer has formed with a chance proportional to $p_a$ its cyclization will have the same proportionality to $p_a$. But this clearly persists to the end of the reaction and at higher $m$, where it expresses the structural results of a complex set of serial and parallel chemical reactions within a variety of configurations and structural isomers of an increasingly large range of oligomers.

If we examine the data as a function of $m$, we find that at each value of $p_a$ they are well fitted by $R_m = A_p m^\gamma$, the values of $\gamma$ falling linearly with $p_a$ as usual during the reaction.[10] It appears that $\gamma$ at the end of the polymerization is 2.714 (±0.0005), which is not significantly different from e. These two power relationships may be combined to yield:

$$R_m = K_0 p_a^m m^{-e} \quad (1)$$

the incidence of rings of size $m$ within the system at any $p_a$, when growth is kinetically controlled ($K_0 = A_1 = C_1$).

When $p_a$ = 1, the total number of rings is the product of $K_0$ and the Euler–Riemann $\xi$ function,[21] $K_0\,\xi(e) = K_0\,(1 + 2^{-e} + 3^{-e} + \ldots)$, a finite number as e > 1. Since the number of rings and the number of molecules is then identical, for each molecule contains one cycle, we have the relationship between the initial number of molecules, $N_0$ the number average degree of polymerization finally achieved, $\langle x \rangle_{n,\infty}$:

$$N_0 = K_0 \langle x \rangle_{n,\infty}\, \xi(e) \quad (2)$$

Taking our value of $C_1 = 3564 \pm 3 = K_0$, we find $\langle x \rangle_{n,\infty}$ to be 10.75 ± 0.01 model residues, a number which compares well with the ratio of the number of molecules present at the start to that at the end, 10.78 ± 0.07. A real $AB_2$ molecule may have a different propensity to form loops from the 78.2% predicted in this calculation, depending upon the configurations it might adopt and the possibilities of ring strain,[7] so cycle numbers may deviate from eqn. (1). (There might be too few bonds to allow a reaction between the A and B functional groups to form loops: then rings of size $m$ = 2 might assume the main role for limiting the formation of high molecular mass material.[16]) We note a second study using a different lattice representation of the flexible $AB_2$ monomer found essentially the same behaviour:[22] the forms of eqns. (1) and (2) are not dependent upon the monomer representation. As well as first utilising e,[23] Euler also introduced the $\xi$-function with real arguments when developing number theory.[21] Here e appears unusually as an exponent of the integers $m$ in this account of the formation of single cycle graphs from Cayley trees when both are embedded and growing from $AB_2$ monomers within three-dimensional space.

This $AB_2$ step growth follows a complicated pattern of two competing processes, the development of highly branched structures resplendent with functional groups and simultaneous cyclizations to give a range of ring sizes. Though cyclization consumes only a small proportion of the A functional groups, the proportion being 1 in $\langle x \rangle_{n,\infty}$, it does eventually terminate the polymerization. Fractal formation by a flexible $AB_2$ monomer is frustrated by the formation of cycles.

C. R. H. thanks DENI for a CAST Studentship, supported by Courtaulds Coatings and R. A. W. M. thanks the EPSRC for a Fellowship.

# Unique silane modified perfluorosulfonic acids as versatile reagents for new solid acid catalysts

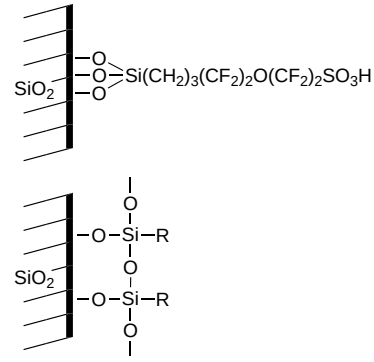
**Mark A. Harmer,* Qun Sun, Michael J. Michalczyk and Zhenyu Yang**

*Central Research and Development, The DuPont Company, Wilmington, Delaware 19880-0356, USA*

**A new versatile reagent, a perfluorosulfonate/trisilanol [$(OH)_3Si(CH_2)_3(CF_2)_2O(CF_2)_2SO_3^-M^+$], is synthesized and a series of surface bound strong solid acid catalysts developed which are active for catalyzing a range of reactions, for example alkene isomerization, alkylations and acylations.**

Over recent years there has been considerable interest in the development of solid acid catalysts[1–6] as environmentally benign replacements for their homogeneous counterparts such as HF. The importance of this area of research has been highlighted by a number of reviews where the use of strong solid acids such as sulfated zirconia,[1] heteropolyacids,[2] zeolites,[3] aluminosilicates,[4] perfluorinated resinsulfonic acids[5] and the weaker polystyrene-based sulfonic acid resins with low thermal stability[6] has been described. In the case of perfluorinated sulfonic acid resins, access to the acid sites can be restricted giving rise to low activity for reactions in non-polar solvents or in the gas phase. The high acid strength and chemical and thermal stability of perfluorosulfonic acids is well known[5] and the ability to heterogenize these functional groups, at the same time maintaining ready accessibility, would be a major step forward.

In this paper we describe the synthesis of $[(OEt)_3Si(CH_2)_3(CF_2)_2O(CF_2)_2SO_2F]$ **1** *via* the direct hydrosilylation of $CH_2{=}CHCH_2(CF_2)_2O(CF_2)_2SO_2F$ with $HSi(OEt)_3$ using a platinum catalyst which produces exclusively **1** in 85% yield.† This can be hydrolyzed to $[(OH)_3Si(CH_2)_3(CF_2)_2O(CF_2)_2SO_3^-M^+]$ **2**. This new reagent can be surface attached to yield a new type of strong solid acid catalyst.



The triethoxysilyl perfluorosulfonyl fluoride, **1**, can be hydrolyzed by the reaction of **1** in a mixture of distilled water, dimethyl sulfoxide and potassium hydroxide (58% water–30% $Me_2SO$–12% KOH). Typically compound **1** is left to react at 90 °C for 18 h in water and basic $Me_2SO$ solution, after which time the sulfonyl fluoride is completely hydrolyzed giving a stable, clear solution. The loss of the sulfonyl fluoride peak at 47 ppm can be monitored using $^{19}F$ NMR spectroscopy. After hydrolysis only signals at −77.2 ($–OCF^*_2CF_2SO_2F$), −83 ($–CH_2CF_2CF^*_2O–$), −112 ($–CH_2CF^*_2CF_2–$) and −112.3 ($–CF_2CF^*_2SO_2F$) ppm are observed in the $^{19}F$ NMR spectrum. The $^{29}Si$ NMR spectrum with a peak at −46.3 ppm, shows the silicon alkoxides are hydrolyzed to $–Si(OH)_3$ (or ion-dissociated forms), having less than 10% forming –SiOSi– bonds. The new compound, which can be described as $[(OH)_3Si(CH_2)_3(CF_2)_2O(CF_2)_2SO_3^-M^+]$ **2**, has been used to synthesize a series of surface-bound strong solid acid catalysts.

Solid acid catalysts formed from **2** can be made by surface modification and attachment to an existing support or, alternatively, materials can be synthesized using an *in situ* sol–gel technique. Using both of these approaches a covalently bonded perfluorosulfonic acid is attached to the surface (see Scheme 1, the two structures denote low to high loadings). We have found the acid functionality to be readily accessible, stable on the surface and very active for a range of catalytic reactions.

Using an *in situ* sol–gel approach, tetralkoxysilanes are hydrolyzed and co-condensed in the presence of **2** to yield very high surface area materials with pendent sulfonic acid groups. The formation of silica networks and organically modified silica networks[8,9] has been described in detail previously. A typical procedure for these new materials is outlined below. Compound **2** (from heating **1**, 2.6 g in 40 ml of the water–$Me_2SO$–KOH mixture, overnight at 90 °C), was cooled and the pH was adjusted to 6 (4 M HCl). A solution of hydrolyzed tetramethoxysilane was then added (68 g TMOS, 10.9 g water and 1 g of 0.04 M HCl, stirred for 30 min). Gellation occurs in *ca*. 30 s. The dried modified silica network is then re-acidified by washing with 4 M nitric acid. The final materials (*ca*. 0.5–2 mm in size) are hard, glass-like, with high surface areas. The surface area (determined by BET), pore volume, and pore diameter are found to be 550 $m^2\ g^{-1}$, 0.75 $cm^3\ g^{-1}$ and 55 Å respectively. Successful incorporation of **2** is shown using solid-state $^{19}F$ NMR spectroscopy, chemical analysis, thermogravimetry (TG) coupled with measurements of the acid equivalents. The number of acid equivalents (for a material which contains 6 mass% organics from TG in the range 300–500 °C) is 0.18 mequiv. $g^{-1}$ (determined *via* titration), with F and S contents of 2.77 and 0.69 mass% respectively from pendent $–(CH_2)_3(CF_2)_2O(CF_2)_2SO_3H$ functionalities. The solid-state $^{19}F$ NMR spectrum has strong peaks at −84.5 and −122.5 ppm (close to the parent **2**). We estimate *ca*. 90% incorporation of **2** within the silica network. Higher loadings (up to 25 mass% of **2**) have also been developed.

Compound **2** has also been attached to a range of pre-formed supports. The chemistry strongly parallels that of silane coupling chemistry to surfaces (using trialkoxysilanes) which is well documented.[10] A solution of **2** was added to a high surface area silica support (CS-1020E, PQ corporation; *ca*. 400 $m^2\ g^{-1}$) and the support and surface modifier were treated with acid to neutrality. The material was then dried and re-acidified. The materials are very stable to leaching; for example, when left overnight in 4 M nitric acid at 90 °C no significant leaching occurred.

These materials are catalytically active for a number of acid catalyzed reactions. In some cases the activity of these materials (based upon acid equivalents) compared to Amberlyst resins are orders of magnitude higher reflecting the increased acid strength due to the perfluorosulfonic acid group. In Table 1, we

Surface attached perfluorosulfonic acid

[a] Reaction conditions: 1 g catalyst, 21.5 g benzene, 10 g of dodec-1-ene, reacted at 80 °C for 1 h. Dodec-1-ene conversion measured using GC. [b] 1 g catalyst, 8.4 g heptene, 15.6 g of toluene, reacted at 100 °C for 2 h, conversion is based on hept-1-ene. [c] Conversion of but-1-ene to *cis–trans* isomers of but-2-ene over 5 g catalyst under ambient pressure with flow rates of He = but-1-ene = 38 ml $min^{-1}$, MHSV of but-1-ene = 1 $h^{-1}$ at 50 °C. [d] 1 g catalyst, 14 g benzoyl chloride and 21.2 g *m*-xylene reacted at 140 °C for 6 h, conversion is based on benzoyl chloride, the reaction rates are 76 and 300 mM (mequiv $H^+)^{-1}$ $h^{-1}$ for NR50 and the surface modified catalyst, respectively. [e] Reaction temperature too high for Amberlyst-15 catalyst.

show the catalytic activity of this material for three types of reactions, electrophilic aromatic alkylations, alkene isomerizations and Friedel–Crafts acylation. For comparison we also show the activity of a perfluorinated resinsulfonic acid (Nafion resin NR50) which in non-swelling solvents is known to have limited access to all the acid sites,[11] and that of Amberlyst-15. Both the surface modified materials and the *in situ* formed materials show the same kind of activity. The results demonstrate the utility of these new materials as solid acid catalysts. Notice that the acid capacities of Amberlyst-15 and NR50 are significantly higher than that of the surface modified catalyst. The differences of reaction rates based on the same amount of acids in the catalysts are much more pronounced than the conversions. Linear alkylbenzenes (LAB) which are made in large quantities (using HF) are widely used in the manufacture of detergents. The new catalyst was found to be very effective as the alkylation catalyst. Conversion of > 99% was obtained with 2 g of catalyst and after 6 h. Similar activity patterns (the optimum being the surface attached fluorosulfonic acid) were observed for the isomerization of longer chain α-alkenes (> $C_{12}$) which are important for use as lubricants. The higher activity of these materials, compared to the polymer Nafion NR50 resin, indicates that most of the acid sites, which are exclusively on the surface, are readily accessible in contrast to the gel type NR50 where most of the acids are buried inside the polymer particles. Data in Table 1 indicated that the surface modified catalyst and NR50 are very effective heterogeneous catalysts for Friedel–Crafts acylation. This is routinely carried out using Lewis acids such as $AlCl_3$, which produces large amounts of waste streams, for use in the fine chemical and other industries. NR50 is more efficient for this reaction mainly due to the higher temperature and polar reagent employed that swells the framework of Nafion resin which enhances the acid sites accessibilities.

A quantitative kinetic study of the dimerization of α-methylstyrene (AMS) catalyzed by sulfonic acid resins was also investigated. A detailed kinetic study has been reported previously.[6,12] The first order rate constants for the surface attached **2**, Nafion NR 50 and Amberlyst-15 (AMS, 6 g in 54 g of cumene as solvent, using 1 g of catalyst, at 50 °C) was found to be 1000, 0.1 and 0.6 [(mequiv. $H^+)^{-1}$ $h^{-1}$], respectively. Supported Nafion also shows low activity. The higher activity, > 1000-fold, is striking.

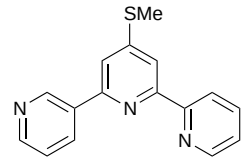
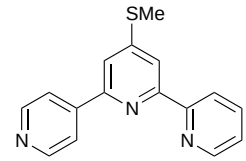
# Controlled aggregation of supramolecular boxes



**Michael J. Hannon,* Claire L. Painting and William Errington**

*Department of Chemistry, University of Warwick, Gibbet Hill Road, Coventry, UK CV4 7AL*



**Supramolecular boxes are prepared and their aggregation controlled by self-assembly; the crystal structure of a polymeric assembly of silver(I) cage units of 4-thiomethyl-6-(4-pyridyl)-2,2′-bipyridine is reported.**

The controlled design of complex molecular architectures represents a considerable synthetic challenge. The supramolecular synthetic approach has been used to assemble large molecular aggregates[1–3] and extension to polymeric systems has impacted on the field of crystal engineering.[4,5] Sophisticated macromolecular targets will require the ability to assemble small supramolecular units which may be further aggregated in a controlled fashion. To achieve this we are targeting metallosupramolecular species which contain binding sites on their exterior. Recently, we reported the construction of metallosupramolecular cage species by interacting metal ions with simple dinucleating ligands.[2] These cyclophane analogues were prepared in a single-step assembly process without the need for ancillary ligands which block coordination sites on the metal centre. The metal centres incorporated into the box framework did not use all of their coordination sites in the construction process and we reasoned that these unused coordination sites (which are filled with solvent molecules) might be used to aggregate the box structures. To achieve our sophisticated assemblies, an additional ligating site must be incorporated within the system in such a way that it does not interfere with the box assembly process. Our cage design utilises dinucleating ligands which contain bipyridyl and pyridyl binding sites. Thiomethyl substituents may readily be introduced onto the outside of such ligands.[6] Although thiomethyl groups on the back of oligopyridyl units have not previously been observed to coordinate to metal ions, the chemistry of thioether ligands is well established.[7] Indeed Reid and coworkers recently reported a polymeric 3D coordination array generated by ligating silver(I) to a ligand containing two monodentate thioether sites.[8] The thiomethyl unit is a less effective donor than the pyridine groups and therefore should not compete with or disrupt the box formation while the hard/soft principle might allow the problem of controlled and selective aggregation to be addressed.

The ligand 4-thiomethyl-6-(3″-pyridyl)-2,2′-bipyridine (bpy-3-py) forms discrete box structures with copper(I) and cadmium(II) and thioether coordination is not observed with these metals.[2] Switching to the softer silver(I) ion might allow access to this bonding mode. Reaction of the ligand with silver(I) salts gives colourless solutions from which salts of formula $\{Ag(bpy\text{-}3\text{-}py)X\}_n$ may be isolated (X = counter-ion). Unfortunately we have so far been unable to obtain material suitable for X-ray structural characteristation from this reaction.

bpy-3-py

bpy-4-py

Modelling indicated that the related ligand 4-thiomethyl-6-(4″-pyridyl)-2,2′-bipyridine (bpy-4-py) should give analogous box structures and so we have examined the ligation of silver(I) to this ligand. The ligand was prepared in good yield (72%) in a one-pot Potts[6] reaction of 3,3-bis(methylthio)-1-(2′-pyridinyl)prop-2-en-1-one with the potassium enolate of 4-acetylpyridine, followed by ring closure with ammonium acetate.

Warming methanolic solutions of the ligand with 1 equiv. of silver(I) salts leads to the rapid formation of colourless solutions from which white salts of formula $[Ag_2(bpy\text{-}4\text{-}py)_2][PF_6]_2$ were isolated on the addition of methanolic ammonium hexafluorophosphate. Mass spectrometric analysis (FAB) showed the presence of dinuclear $M_2L_2$ and $M_2L_2X$ peaks consistent with this formulation. Recrystallisation of the salt from acetonitrile solution by the slow diffusion of diethyl ether afforded colourless crystals, the structure of which has been determined† and which is shown in Fig. 1.

As anticipated the bpy-4-py ligand bridges between metal centres. Each silver(I) centre is bound to a bipyridyl unit from one ligand and a pyridyl from the other, resulting in the formation of a dimeric $M_2L_2$ box species. The metal–ligand bond lengths and angles are unremarkable and the intermetallic Ag···Ag distance is 6.686(2) Å. The pyridyl and bipyridyl binding domains are twisted with respect to each other [dihedral

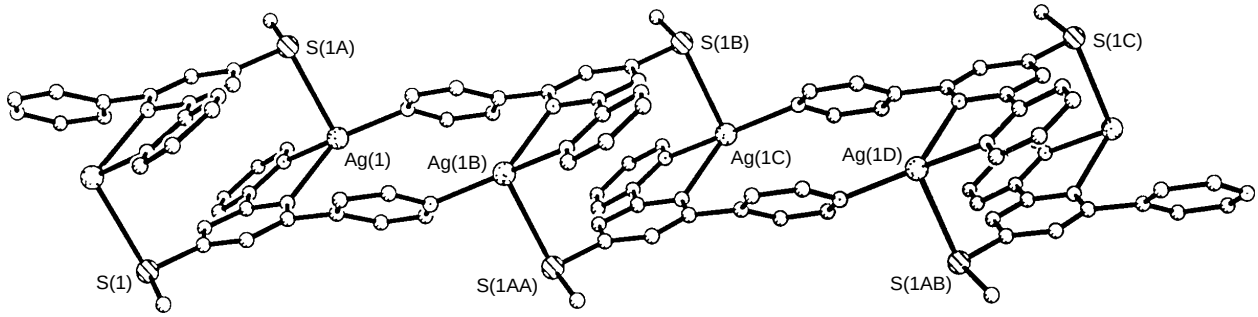


**Fig. 1** Crystal and molecular structure of the cation $[Ag_2(bpy\text{-}4\text{-}py)_2]_n^{2n+}$

angle 47.4(4)°] and a cavity between the pyridyl units of the two ligands results. This twisting is anticipated and is similar to that observed in the box complexes of bpy-3-py. The twisting results in the aromatic rings defining an aryl-lined cavity. The centroid–centroid distance between the two monodentate pyridyl rings, which define the cavity, is 4.00 Å. The box structure is, as would be anticipated from the ligand connectivity, slightly flatter than those formed with bpy-3-py.[2]

Each silver(I) ion is four coordinate and its coordination sphere is completed by coordination to a thioether unit from an adjacent box. This interaction links the boxes together into a polymeric array. The elongated Ag–S bonds [2.940(3) and 2.961(3) Å] are approximately 0.3 Å longer than those observed in other thioether silver(I) complexes.[8] The coordination of the thioether groups brings the aryl rings of adjacent boxes into close contact. The central pyridyl rings, bearing the thiomethyl substituents, are coplanar and offset, with a centroid–centroid distance of 3.86 Å. This may represent a weak π-stacking contribution to the aggregation process.

This form of supramolecular architecture may be contrasted with the elegant solid-state cavity-containing arrays of Robson and coworkers and Fujita *et al*.[5] In their approach they allow the repeat cavity unit to propagate through the stucture with each cavity sharing a corner and/or side with the adjacent units. Our structure is somewhat different. The repeat cavity unit is assembled independently and the units are then linked *via* sulfur bridges. The cavities share neither edges nor corners with their adjacent neighbours.

While the crystallographic study confirms the aggregation in the solid state this is not the case in solution. The $^1$H NMR spectra of $CD_3CN$ solutions of the salts showed the expected eight resonances in the aromatic region and the presence of a single thiomethyl resonance. The thiomethyl resonance appears at a similar chemical shift in both the complex ($\delta$ 2.69) and the free ligand ($\delta$ 2.66), indicating that the aggregation process is not occurring in acetonitrile solution. This is unsurprising as the donor solvent is expected to compete effectively with the weakly coordinating thiomethyl group.

We are grateful to the EPSRC for a studentship (C. L. P.) and the EPSRC and Siemens for grants enabling the purchase of the diffractometer.

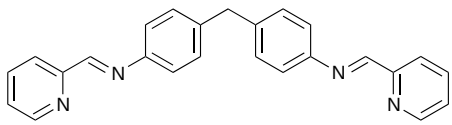
# An inexpensive approach to supramolecular architecture

**Michael J. Hannon,* Claire L. Painting, Alexander Jackson, Jacqueline Hamblin and William Errington**

*Department of Chemistry, University of Warwick, Gibbet Hill Road, Coventry, UK CV4 7AL*



**A new approach to generating supramolecular architectures, based on inexpensive and easy-to-prepare imine ligands, is described together with its application to the self-assembly of supramolecular triple-helicates.**

There is considerable current interest in the supramolecular synthetic approach and its application to the quest to control molecular architecture.[1] The application of metal–ligand interactions has proved particularly fruitful and complex molecular architectures such as helicates,[2–4] knots,[5] grids,[3] catenanes,[5] cylinders[3] and boxes[6] have all been assembled. Indeed in a recent report, Lehn and co-workers have described a supramolecular system in which a number of different structural motifs are possible.[7]

A disadvantage to this metallo-supramolecular approach has been the almost exclusive use of ligand systems constructed from polypyridyl,[2,3] benzimidazole[4] and catechol binding sites.[4] These systems require time-consuming multi-step syntheses from relatively expensive starting materials. If supramolecular chemistry is to achieve its full potential then it is highly desirable that new, inexpensive and easy-to-prepare systems be developed. Not only should the development of an inexpensive system enable wider access to and application of this field, but creating systems which are easy to prepare and readily modified should enhance the rate at which novel molecular architectures are developed. For these reasons we are targeting inexpensive approaches to supramolecular architecture and communicate here both our approach and the preliminary results of our studies.

As an alternative donor set we have selected imine-based ligands. Imines are formed in high yield by simply mixing aldehydes and amines, a large number of which are available commercially at very competitive prices. Moreover multinucleating imine ligands may be prepared by simple iterative reactions.[8] The stability of the imine bond towards hydrolysis is greatly enhanced by conjugation with an aryl ring and the coordination chemistry of such donor units is well established. One of us has recently used copper(I) pyridylimine compounds to control atom transfer radical polymerisation processes.[9] An earlier report of an imine based double helix has appeared and recent work has identified double-helical twists in imine based macrocyclic complexes.[10]

To date, helices represent the best developed and most investigated supramolecular architectures.[1–4] To establish our approach we chose to address the challenge of creating the triple-helical architecture[4] using an inexpensive system. To achieve this we have prepared the ligand L. Our ligand design

L

incorporates two pyridylimine binding sites separated by a spacer. The chosen spacer incorporates phenylene groups that sterically prevent the two metal binding sites from coordinating to a single metal centre. The central methylene unit introduces enhanced flexibility into the ligand backbone. This enhanced flexibility permits the ligand to support triple-helical ligand arrays. Importantly, the ligand is not sufficiently flexible to give the bridging non-helical arrangement observed by others.[11] Thus, octahedral metal ions, which require three didentate pyridylimine units to satisfy their coordination requirements, should induce the formation of the triple-helical architecture.

The ligand is prepared by simply mixing ethanolic solutions of pyridine-2-carbaldehyde and 4,4′-methylenedianiline. On stirring at room temperature, the ligand precipitates from the reaction mixture in high yield (80% after 8 h) and may be isolated by filtration. The ease of synthesis and the high yield in a single-step reaction from commercial, inexpensive reagents makes this an extremely attractive ligand system.

Warming methanol solutions containing 3 equiv. of ligand and 2 equiv. of nickel(II) salts at reflux for 4 h leads to the formation of red solutions from which salts of formulation $[Ni_2L_3][X]_4$ are isolated in high ( > 80%) yield on addition of methanolic $[NH_4][X]$ (X = $PF_6$ or $BF_4$). Mass spectrometric analysis (ESI) shows the presence of peaks corresponding to $\{M_2L_3X_3\}^+$, $\{M_2L_3X_2\}^{2+}$, $\{M_2L_3X\}^{3+}$ and $\{M_2L_3\}^{4+}$ consistent with this formulation. Modelling indicates that this formulation is consistent only with a triple-helical structure. Recrystallisation of the tetrafluoroborate complex salt from methanol afforded crystals suitable for X-ray analysis.† The structure of one of the two enantiomers of the cation is shown in Fig. 1 and confirms the formation of the triple-helical structure. Each nickel(II) centre is bound to three pyridylimine binding units to attain a pseudo-octahedral coordination geometry. Coordination to the metal centre forces interannular twisting between the phenylene ring and the pyridylimine unit and the logical consequence is the formation of a triple-helical array. The bond lengths and angles are unremarkable and the two nickel(II) centres are separated by 11.576(1) Å. The ligand twists through a half-turn around the metal–metal axis leading to a helical pitch of about 27 Å. This compares with pitches of around 18 Å for Williams' cobalt triple helicates[4] and 41 Å for Lehn's nickel triple helix.[3] The twisting of the phenylene units results in a chiral aryl-lined cavity at the centre of the helix with the shortest carbon–centroid distance *ca.* 2.8 Å, giving a 'hole' with the potential to trap small molecules. No face–face π-stacking interactions are observed.

Reaction of methanol solutions of 3 equiv. of the ligand with 2 equiv. of iron(II) salts leads to the instantaneous formation of

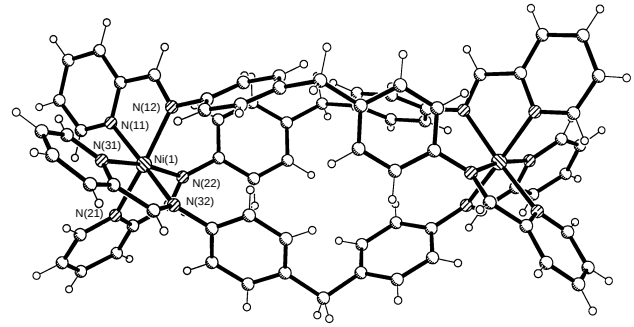


**Fig. 1** Crystal and molecular structure of the cation $[Ni_2L_3]^{4+}$

purple solutions. Heating at reflux for 3 h followed by treatment with $[NH_4][X]$ gives similar $[Fe_2L_3][X]_4$ salts. The purple colour ($\lambda_{max}$ = 572 nm, $\varepsilon$ = 15 000 dm$^3$ mol$^{-1}$ cm$^{-1}$) is characteristic of iron(II) trispyridylimine compounds. Mass spectrometric analysis (ESI) is consistent with this formulation and a preliminary crystallographic study has confirmed the triple-helical nature of the cation. The 250 MHz $^1$H NMR spectrum of this diamagnetic compound in $CD_3CN$ reveals, as anticipated, the presence of one aliphatic and seven aromatic proton resonances. The phenylene rings in the spacer rotate freely at room temperature and the four protons give rise to two resonances. As the temperature is decreased to 243 K, the rate of rotation decreases and the peaks split to give four resonances.

Reacting the ligand with tetrahedral metal ions such as copper(I) and silver(I) gives rise to dimeric $[M_2L_2]^{2+}$ cations. Whilst modelling indicates a unique triple-helical structure when the ligand complexes to octahedral metal ions, the flexibility of the ligand is such that for the dimeric $[M_2L_2]^{2+}$ species two conformations are possible: a double-helical structure or a non-helical bridging cage-like structure. At low temperature, the $^1$H NMR spectra of $CD_3CN$ solutions of the salts show the presence of two species, one of which is present only in small amounts. Similar behaviour in potentially double-helical systems has been reported by Harding and Sauvage.[12] This is the subject of further investigation.

We have established a novel ligand system which is prepared simply by mixing inexpensive commercial reagents and which allows us to generate a complex triple-helical molecular architecture. This inexpensive system makes the triple-helical architecture readily accessible for the first time. We are currently investigating the possibililty of binding small molecules in the chiral helical cavity and we are also developing our approach further to create related ligands with which we will address a variety of alternative architectures.

We are grateful to the Nuffield Foundation for an Award to Newly Appointed Science Lecturers (M. J. H.) and an Undergraduate Research Bursary (NUF-URB96; A. J.), the EPSRC for a studentship (C. L. P.) and the Swansea National Mass Spectrometry Centre for recording the mass spectra.

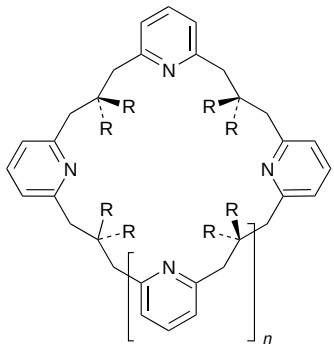
# A cage ligand with three convergent pyridine donors†



**Fritz Vögtle,*[a] Stefan Ibach,[a] Martin Nieger,[b] Christine Chartroux,[c] Torsten Krüger,[c] Holger Stephan[c] and Karsten Gloe[c]**

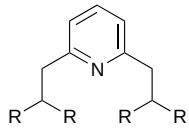
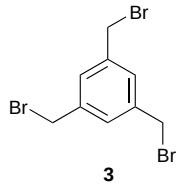
**A macrocyclic malonic ester condensation with pyridine building blocks leads to the new bicyclic host molecule 1 with defined cavity size, the X-ray structure analysis of which reveals three convergent nitrogen donor centres; in radiotracer phase-transfer measurements 1 turns out to be remarkably selective for $Ag^{I}$ cations while discriminating against $Cu^{I}$ and $Cu^{II}$ cations.**

Owing to their interesting complexation behaviour, pyridine subunits play an important role as donor sites for selective complexation of cations.[1,2] In this context Newkome's Cryptanal,[3] the bipyridine cryptands[4] synthesised by Lehn and coworkers, aza-bridged cage ligands[5] and homocalixpyridines[6] are characteristic examples.



A few years ago we reported about macromonocyclic ligands containing pyridine subunits of the metacyclophane type **I**,



**I** R = $CO_2Et$

**1** R = $CO_2Et$

**2** R = $CO_2Et$

**3**

which could be obtained with different ring sizes by a malonic ester condensation-like pathway.[7] Now we are able to extend this method into the third dimension and to obtain the macrobicyclic tris(pyridine) cage ligand **1**. Because of the convergent (*endo*) orientation of the pyridine nitrogens in **1**, a cooperative binding of guest ions and incorporation in the cavity should be possible. In addition, the overall 12 peripheral ethyl ester groups guarantee good solubility in organic solvents like $CHCl_3$, $CH_2Cl_2$, THF and acetone.

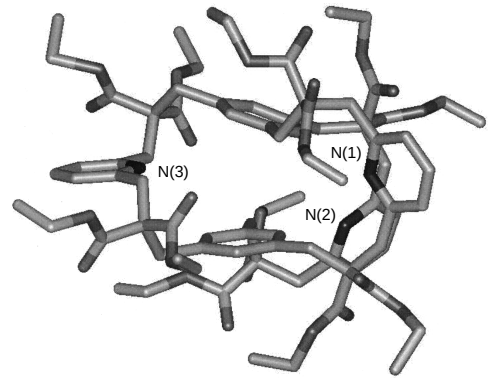
The synthesis of **1** was achieved as follows: the tetraethyl ester[7] **2** and 1,3,5-tris(bromomethyl)benzene[8] **3** were added dropwise and simultaneously under dilution conditions to a stirred suspension of NaH in refluxing 1,4-dioxane, and stirred for 48 h. The reaction mixture was then concentrated *in vacuo*, and the oily residue recovered was dissolved in $CH_2Cl_2$, washed with diluted HCl and water and dried over $Na_2SO_4$ to give a brown oil upon removal of the solvent. After chromatographic separation of the crude product, **1**‡ was isolated as colourless crystals (mp 203 °C, EtOH–$CHCl_3$) in 4% yield.§ The rather poor yield is due to the fact that five components must approach each other to close six σ-bonds and is in accordance with the literature.[1a,9] The optimisation of the yield by stepwise synthesis[1b] or metal ion template strategy (*e.g.* caesium or silver) is currently being investigated.

Indeed, the X-ray structure of **1** shows an *endo* orientation of the pyridine units with a distance of 475 pm between two pyridine nitrogen atoms [N(1), N(2)], while the third pyridine nitrogen N(3) has distances of 771 and 749 pm, respectively, from these two atoms [Fig. 1]. The two benzene rings are not exactly parallel to each other, and the distance between their centres is 454 pm. The deviation from the parallel orientation amounts to 36°. Thus, the cavity of the free ligand is slightly contracted.¶

Molecular modeling calculations revealed almost the same conformation [*cf.* Fig. 1]. The calculated minimum energy conformation of the ligand (PM3) is in very good accordance with the X-ray results (RMS deviation 0.13 Å).

The ligand **1** therefore seems to be suitable for the complex formation with metal ions preferring a linear coordination ($Cu^{I}$, $Ag^{I}$) between the two adjacent pyridine donor atoms. Starting from the minimum energy conformation, a silver complex of **1** was calculated (ZINDO/1). The conformation of the complexed ligand is only a little changed compared to the free ligand. The silver ion is arranged in the middle of N(1) and N(2), both Ag–N bonds being 251 pm long. Additional interaction with N(3) or with benzene rings seems unlikely considering the steric situation.

The complexation behaviour of **1** has been studied experimentally by liquid–liquid extraction[10]‖ measurements: as designed, the pyridine-containing cage ligand **1** shows evidence for $Ag^{I}$ selectivity in extraction. Under experimentally chosen conditions 19.5% of the silver were transferred into the organic phase. In contrast to this, the other metal ions investigated ($Na^{I}$, $Tl^{I}$, $Cu^{I}$, $Ca^{II}$, $Cu^{II}$, $Zn^{II}$, $Hg^{II}$) remained in the aqueous phase (> 99.9%). The high selectivity for $Ag^{I}$ over $Cu^{I}$, $Cu^{II}$ and $Hg^{II}$



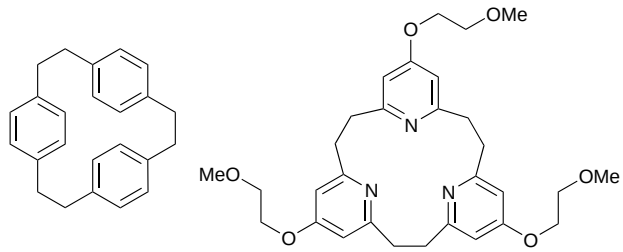


**Fig. 1** X-Ray structure of **1** (side view)

is particularly remarkable. Measuring the distribution ratio $D_{Ag}$ as a function of the ligand concentration in the organic phase, the data obtained with a slope of 1 from the Log $D_{Ag}$ *vs.* Log $c_L$ diagram indicate that 1 : 1 complexes are formed both in picrate (Log $K_{Ex,1}$ = 4.35) and nitrate (Log $K$ = 1.33) containing solution.

Compound **1** turns out to be a more efficient silver extracting reagent than silver-selective concave hydrocarbons[11] and the hydrocarbon [2.2.2]paracyclophane (**4**, picrate system, Log

**4** **5**

$K$ = 3.62) while remaining very selective [Fig. 2]. The interaction of the pyridine nitrogen with the silver ion is apparently stronger than that of π-donors. When a third pyridine nitrogen donor atom is introduced into a ligand molecule (at a suitable distance), the silver affinity is further raised. This is the case for the *all*-homocalix[3](2,6) pyridine (**5**, nitrate system, Log $K_{Ex,1}$ = 5.00)[12,6] with a much more coplanar orientation of the pyridine rings compared to **1**. However, it is at the expense of the separation selectivity; in the case of **5**, mercury(II) and copper(II) ions are extracted as well [Fig. 2].

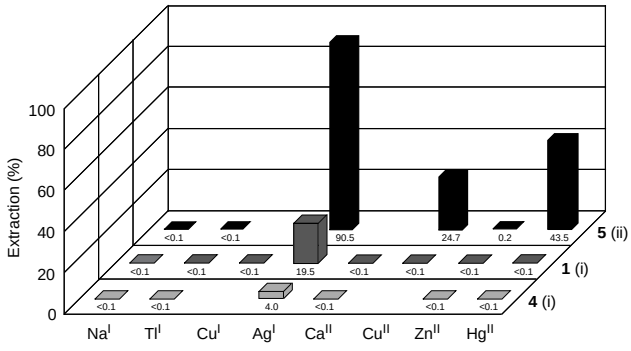

**Fig. 2** Extraction of different metal ions using compounds **1**, **4** and **5**. *Experimental conditions*: (i) [$AgNO_3$] = 1 × $10^{-4}$ M, [picric acid] = 1 × $10^{-2}$ M, [ligand] = 5 × $10^{-4}$ to 5 × $10^{-2}$ M, $CHCl_3$; (ii) [$AgNO_3$] = 1 × $10^{-4}$ M, [$KNO_3$] = 1 × $10^{-1}$ M, pH 6.3 (MES–NaOH buffer, 5 × $10^{-2}$ M), [ligand] = 5 × $10^{-4}$ to 4 × $10^{-3}$ M, $CHCl_3$.

The MALDI-TOF mass spectrum of ligand **1** revealed the molecule peak $[M]^+$ and the species $[Na\cdot\mathbf{1}]^+$ (*m/z* 1519.8) and $[K\cdot\mathbf{1}]^+$ (*m/z* 1535.7). The addition of $CF_3SO_3Ag$ to the sample solution totally suppresses $[Na\cdot\mathbf{1}]^+$ and $[K\cdot\mathbf{1}]^+$ and is accompanied by the formation of $[Ag\cdot\mathbf{1}]^+$ (*m/z* 1607.4).

Because of its ability to form stable complexes due to its novel molecular architecture and its well balanced lipophilicity, **1** is a highly selective phase-transfer host for silver ions. Replacing the ethyl ester groups by long chain aliphatic ones will lead to (ion selective) membrane insertable $Ag^I$ ligands.[13] Similar novel host molecules with larger cavities having more pyridine donor sites should be accessible for the selective complexation of biological relevant guests such as carbohydrates, amino acids, purine and pyrimidine bases.[1b]

We thank the Deutsche Forschungsgemeinschaft for partial support of this work (Vo 145/46-1, GI 183/3-1), and Professor Dr G. R. Newkome, University of South Florida, for providing unpublished results regarding Cryptanal.

**Screened anionic copolymerisation of methyl methacrylate with the perfluoroalkyl methacrylates 2 affords well-defined AB block copolymers 4–6, which serve as effective surfactants in the dispersion polymerisation of methyl methacrylate in supercritical carbon dioxide.**

Fluorinated polymers possess interesting properties such as low surface energy, toughness, good chemical resistance and high temperature stability.[1–3] It is consequently expected that AB block copolymers consisting of a flexible poly(methyl methacrylate) (PMMA) block and a more rigid poly(perfluoroalkyl methacrylate) (PFMA) block will also exhibit interesting properties, and that they may have potential uses in specialist applications. The 'screened' anionic polymerisation (SAP) method has been developed to obtain well-defined block copolymers of methyl methacrylate (MMA) derivatives with narrow molecular weight distribution.[4] The key advantage of this methodology is the ability to operate at temperatures close to 0 °C while maintaining a controlled polymerisation, which results from the 'shielding' of the propagating terminus from unwanted side reactions by a bulky lithium–aluminium alkyl complex at the enolate chain-end. We report the use of a modified SAP methodology for the synthesis of AB block copolymers, consisting of a PMMA block and a PFMA block, as well as their application as novel surfactants in the dispersion polymerisation of methyl methacrylate in supercritical carbon dioxide ($scCO_2$).[5]

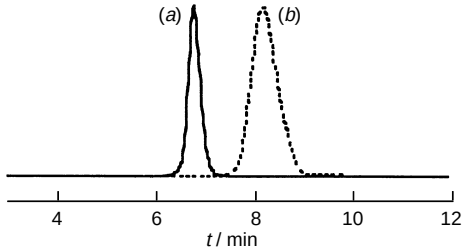
The syntheses of three AB block copolymers **4**, **5** and **6** with different lengths of perfluoroalkyl side chains in the PFMA block are shown in Scheme 1. The fluorinated monomers **2** were synthesised by esterification of methacryloyl chloride **1** with the corresponding fluorinated alcohols in the presence of triethylamine. Table 1 summarises the polymerisation results. The SAP initiator was prepared by mixing *tert*-butyllithium with (2,6-di-*tert*-butyl-4-methylphenoxy)diisobutylaluminium [Al(BHT)-$Bu^i_2$] **3** in toluene at 0 °C. A toluene solution of methyl methacrylate (MMA) was added dropwise to the initiator and polymerisation took place within minutes. Directly afterwards, a toluene solution of fluorinated monomer **2** was added to the reaction mixture. This resulted in ill-defined block copolymers for some examples (*e.g.* entry 3) where the proportion of **2b** incorporated into the PFMA block was less than expected, as indicated by the yield and $^1$H NMR analysis. Gel permeation chromatography (GPC) against polystyrene standards revealed that the sample contained a copolymer with broad molecular weight distribution, whereas a sample of the PMMA block obtained before addition of **2b** revealed a polymer composition of low polydispersity ($Mw/Mn \leqslant 1.3$). This indicated that loss of control occurred after addition of **2b**, which is probably a result

**Scheme 1** *Reagents and conditions*: i, ROH, $Et_3N$, THF, 69–79%; ii, $Bu^tLi$, PhMe, 0 °C; iii, MMA, PhMe; iv, **2**, PhMe, 1,3-bis(trifluoromethyl)benzene, −10 °C

**Table 1** Synthesis of AB block copolymers **4**, **5** and **6**[a]

| Entry | **2** (mmol) | Solvent[b] | Polymer | PMMA : PFMA[c] | Yield[d] (%) | $M_n$[e]/$10^{-3}$ | $M_w/M_n$[e] |
|---|---|---|---|---|---|---|---|
| 1 | **2a** (5.9) | 1 : 0 | **4′** | 1.0 : 2.1 | 76 | 20.0 | 1.2 |
| 2 | **2a** (5.8) | 3 : 1 | **4″** | 1.0 : 2.3 | 83 | 19.0 | 1.2 |
| 3 | **2b** (1.9) | 1 : 0 | **5′** | 1.0 : 0.3 | 45 | *f* | *f* |
| 4 | **2b** (1.9) | 4 : 3 | **5″** | 1.0 : 0.6 | 86 | 217 | 1.1 |
| 5 | **2c** (2.5) | 1 : 3 | **6′** | 1.0 : 1.1 | 81 | 17 | 1.5 |
| 6 | **2c** (3.5) | 1 : 15 | **6″** | 1.0 : 1.3 | 72 | 197 | 1.3 |

[a] To initiate the polymerisation a mixture of *tert*-butyllithium (0.17 mmol) and Al(BHT)$Bu^i_2$ (0.7 mmol) was used. In each experiment 2.8 mmol of MMA were used except entry 5 (2.5 mmol). [b] Ratio (v/v) toluene : 1,3-bis(trifluoromethyl)benzene. [c] Determined from $^1$H NMR spectroscopy. [d] Yields quoted after two reprecipitations in hexane. [e] From GPC analysis ($CHCl_3$, polystyrene standards). [f] GPC assay revealed two peaks: (i) $M_n$ 16 400 $M_w/M_n$ 1.3, (ii) $M_n$ 245 000 $M_w/M_n$ 2.0.



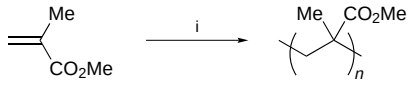


**Fig. 1** GPC trace (polystyrene standards, $CHCl_3$) of a sample of (*a*) **5″** ($M_n$ 218 000, $M_w/M_n$ 1.1) and (*b*) the PMMA block before addition of **2b** ($M_n$ 9300, $M_w/M_n$ 1.3)

of the insolubility of the propagating fluorinated block. In the case of the copolymer **4′** with a shorter perfluoroalkyl side chain, this solubility problem was less apparent. Good yields of **4′** were obtained, and the polydispersity was relatively narrow, even for samples with a high proportion of PFMA in relation to the PMMA block (entry 1). The solubility problem could be overcome by the use 1,3-bis(trifluoromethyl)benzene as a co-solvent with toluene, which enabled the preparation of block copolymer **5″** with a high proportion of PFMA block (entry 4). The GPC chromatogram of copolymer **5″** is shown in Fig. 1. The chromatogram of a sample of PMMA obtained before addition of **2b** is also shown. Both unimodal traces with narrow polydispersity reveal that a controlled polymerisation is maintained throughout the reaction.†

Block copolymers can exhibit micelle-like aggregation if they are dissolved in a solvent which is more selective towards one of the blocks.[6] Fluorinated homopolymers have been known to be very soluble in both liquid $CO_2$ and $scCO_2$.[7] In the case of the AB block copolymers described above, the PFMA block will have a much higher solubility in $scCO_2$ compared with the PMMA block, and may thus be employed as a stabiliser or surfactant in a dispersion polymerisation.[7] In preliminary studies we have polymerised MMA under free radical conditions in $scCO_2$ using copolymers **4** and **6** as surfactants (Scheme 2).[8] These results demonstrate that these surfactants play an important rôle in stabilising a dispersion of the growing PMMA chain in $scCO_2$. In the presence of **4″** (Table 2, entry 2), both the yield and molecular weight ($M_n$) of the polymer are significantly higher than observed in the control experiment without surfactant (Table 2, entry 1). However, elongation of the fluorinated side-chain improved these results even more (Table 2, entry 3). The effect of the molecular weight of the surfactant, where there is an increase of the length of the different blocks, is illustrated by comparing the surfactant **6′** with **6″**. In the latter case (Table 2, entry 4) we were able to obtain PMMA as a free flowing powder together with further increase in molar mass.

In summary, we have developed a highly controlled synthesis of fluorinated AB block copolymers. The ability to vary the side chain as well as to 'tune' the length of the different blocks in these block copolymers, according to specific requirements, is an advantage of the synthetic route described. Moreover, the improved stabilising efficiency of block copolymer **6″**, compared with block copolymer **4″**, in the dispersion polymerisation of MMA in $scCO_2$ demonstrates the applicability of this synthetic methodology. We shall describe the power of the tunability of the surfactant in a forthcoming publication.

**Scheme 2** *Reagents and conditions*: i, AIBN, $scCO_2$, 285 bar, 70 °C, 5 h, **4** or **6**

**Table 2** Radical polymerisation of MMA (1.2 M) with AIBN (2 wt%) as initiator in $scCO_2$ with and without block copolymers as surfactant

| Entry | Surfactant (1 wt%) | Yield[a] (%) | $M_n$[b]/$10^{-3}$ | $M_w/M_n$[b] |
|---|---|---|---|---|
| 1 | — | 22 | 12.0 | 2.0 |
| 2 | **4″** | 56 | 38.0 | 2.2 |
| 3 | **6′** | 69 | 77.4 | 3.0 |
| 4 | **6″** | 72[c] | 81.9 | 2.3 |

[a] Yields quoted after two reprecipitations in hexane. [b] GPC analysis ($CHCl_3$, polystyrene standards) confirmed by multiple angle light scattering analysis in THF. [c] Yield quoted without reprecipitation; free-flowing powder obtained.

We thank EPSRC for support of this work and provision of the Swansea Mass Spectroscopy Service, ICI for a Strategic Research Fund award (T. M. Y.), the UK Committee of Vice-Chancellors and Principals for an ORS award, the Cambridge Commonwealth Trust for a bursary, Clare College for a Research Fellowship (T. M. Y.) and Zeneca Agrochemicals for a CASE award (W. P. H.). We acknowledge with gratitude the extensive advice received from Professor M. Poliakoff and Dr S. Howdle (Nottingham).

## Footnotes and References

# Novel dimanganese(II) complexes with ($\mu$-$H_2O$)($\mu$-OAc)$_2$ bridges. Models for dimanganese enzymes

**Bao-Hui Ye, Toby Mak, Ian D. Williams and Xiao-yuan Li***

*Department of Chemistry, The Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong*

**We describe the syntheses and characterization of two new complexes, $Mn_2(\mu\text{-}H_2O)(\mu\text{-}OAc)_2(L)_4(OAc)_2$ 1 (L = imidazole) and 2 (L = benzimidazole), which display some novel structural features, and may have implications for the hydrolytic activity of arginase.**

The cooperative action of closely coupled dinuclear or multinuclear centers is required for several manganese enzymes to carry out their biological functions.[1,2] In arginase[3] and the ribonuclease H domain of HIV-1 reverse transcriptase,[4] the coupled di-$Mn^{II}$ center is required for the hydrolysis of substrate through activation of a water molecule. In redox-type Mn enzymes such as Mn catalase,[2,5] bacterial ribonucleotide reductase[6] and photosynthetic water oxidase,[2,7] Mn ions were also found or estimated to be assembled in very close proximity by the protein's coordinating side chains such as carboxylate groups from glutamates and/or aspartates.[1] Therefore, carboxylate bridged di- or poly-manganese centers have been attracting growing interest in both synthetic modelling and physical characterization.[8,9] Three di-$Mn^{II}$† model complexes with $[Mn_2(\mu\text{-}H_2O)(\mu\text{-}O_2CR)_2]^{2+}$ cores have been reported to date.[9] One of them is based on all-oxygen coordination spheres,[9a] while the other two are based on $N_2O_4$ coordination spheres around each Mn ion but with synthetic bidentate N-donor ligands.[9b] Our goal has been to synthesize aqua and carboxylate bridged dimetallic complexes employing monodentate N-donor ligands such as imidazole (Im) and benzimidazole (Bzim) which are truly good mimics of the histidine side chain. We chose Im and Bzim as the N-donor ligands not only to avoid the steric strains in most of the bidentate or multidentate ligands but also for utilization of the non-coordinating NH groups which can form hydrogen bonds with neighbouring molecules. Such hydrogen bonding is believed to play a very crucial role in the structural assembly and/or the function of many biological systems.[10] Here we report the syntheses, crystal structures and magnetic properties of two new di-$Mn^{II}$ complexes with a ($\mu$-aqua)bis($\mu$-carboxylate) unit, $[Mn_2(\mu\text{-}H_2O)(\mu\text{-}OAc)_2(L)_4(OAc)_2]$ (L = Im **1**, Bzim **2**), which are very good structural models for the active sites of di-$Mn^{II}$ enzymes such as arginase and manganese catalase. Certain novel structural features in **1** and **2** provide some insight into the possible mode of enzyme action for arginase.[3a]

Complexes **1** and **2** were synthesized by mixing Im or Bzim with $Mn(OAc)_2{\cdot}4H_2O$ in 2.4 : 1 ratio, in absolute ethanol under nitrogen at room temperature. Prism-shaped, pale tan single crystals of **1** and **2** were grown from mixed solvents of absolute ethanol and diethyl ether. Their molecular structures were determined by single-crystal X-ray diffraction.‡ Both complexes are of similar structure and contain a di-$Mn^{II}$ core bridged by an aqua and two bidentate acetates. Each of the $Mn^{II}$ ions is further coordinated by one additional monodentate carboxylate and two N-donor ligands, forming two equivalent but slightly distorted $MnN_2O_4$ octahedra joined at their shared vertex by the oxygen atom of the bridging aqua ligand in a face-to-face fashion (see Fig. 1). The molecules lie on a crystallographically imposed twofold axis passing through the bridging aqua oxygen O(1). The hydrogen atoms of the bridging aqua were revealed as the highest residual electron density peak after all other atoms were included in X-ray structure elucidation. The bridging aquas were identified on the basis of the Mn–O(1) distances in **1** [2.246(2) Å] and in **2** [2.227(2) Å] which are significantly longer than those in $\mu$-O–$Mn^{III}_2$ complexes (1.78–1.81 Å)[8] and those in $\mu$-OH–$Mn^{II}_2$ complexes (2.05–2.09 Å).[8] The Mn···Mn distances in **1** [3.777(1) Å] and **2** [3.756(1) Å] are longer than those in **4** [3.5950(9) Å][9b] and **5** [3.621(2) Å],[9b] but very similar to that in **3** [3.739(2) Å].[9a] This is attributable to the opening up of the Mn–O($H_2$)–Mn angles from *ca*. 110° in **4** and **5** to *ca*. 114° in **1**, **2** and **3**, and the elongation of Mn–O(aqua) distances from 2.182(3) Å in **4** and 2.215(5) Å in **5** to 2.228(7) Å in **3**, 2.227(2) Å in **2** and 2.246(2) Å in **1**. The N–Mn–N angles in **1** (92.6°) and **2** (92.9°) are significantly

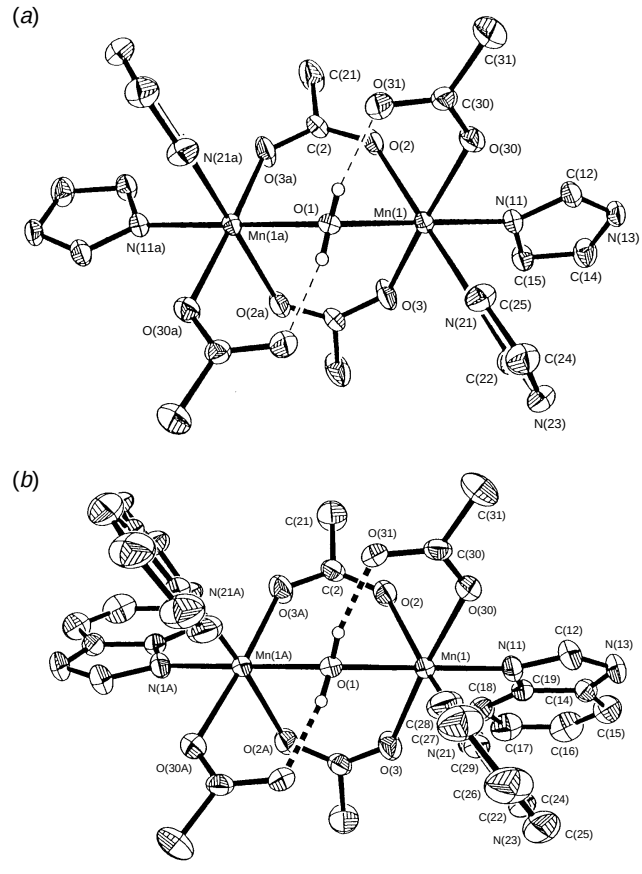

**Fig. 1** Structures of **1** (*a*) and **2** (*b*), showing 40% probability thermal ellipsoids and the atom-labelling scheme. Important interatomic distances (Å) and angles (°) of **1** and **2** [in brackets] are as follows: Mn(1)···Mn(1a) 3.777(1) [3.756(1)], O(1)···O(31) 2.631(5) [2.621(3)], N(23)···O(31b) 2.741(6) [2.737(4)], N(13)···O(2c) 2.775(6) [2.808(4)], Mn(1)–O(1) 2.246(2) [2.227(2)], Mn(1)–O(2) 2.212(3) [2.206(2)], Mn(1)–O(3) 2.109(3) [2.138(2)], Mn(1)–O(30) 2.171(3) [2.183(2)], Mn(1)–N(11) 2.212(3) [2.248(2)], Mn(1)–N(21) 2.249(3) [2.269(3)], Mn(1a)–O(1) 2.246(2) [2.227(2)], C(2)–O(2) 1.252(4) [1.254(4)], C(2)–O(3a) 1.247(4) [1.242(4)], C(30)–O(30) 1.242(4) [1.252(4)], C(30)–O(31) 1.258(4) [1.262(4)]; Mn(1)-O(1)–Mn(1a) 114.4(2) [114.97(14)], O(1)–H(1)–O(31) 164.9(5) [160.6(6)].

larger than those in **4** (72°) and **5** (78°), resulting apparently from the replacement of the bidentate N-donor ligands in the latter by the two monodentate N-donor ligands. The Mn···Mn distances observed in $[Mn^{II}_2(\mu\text{-}H_2O)(\mu\text{-}O_2CR)_2]^{2+}$ cores (3.595–3.777 Å ) are between those observed in the $[Mn^{II}_2(\mu\text{-}OAc)_3]^+$ core [4.034(2) Å][8] and the $[Mn^{II}_2(\mu\text{-}OH)(\mu\text{-}OAc)_2]^+$ core [3.351(3)Å].[8]

Several quite interesting structural features are noticeable in **1** and **2**. First and most important, the terminal monodentate acetate groups display an unexpected geometry. The distances of C–O(free) in **1**, 1.258(4) Å and **2**, 1.262(4) Å, are actually longer than those of their respective C–O(binding) in **1**, 1.242(4) Å and in **2**, 1.252(4) Å. Although this is only just of statistical significance based on the bond length standard deviation, this observation is contrary to the classical geometry of the terminal monodentate binding mode of a carboxylate group. Examination of over 40 related transition-metal carboxylates in the Cambridge Structural Database§ showed that the distance of C–O(free) is typically 0.03Å shorter than that of C–O(binding).[11] The reversal of C–O bond lengths is rare but has been seen, for example, in $M(CO)_5(O_2CCF_3)$ anions (M = Mo, Cr).[12] A careful examination of the structures led us to believe that the elongated C–O(free) distance may be a consequence of two hydrogen bonds, an intramolecular one with the bridging aqua ligand [O(free)···O(1) distance in **1**, 2.631(5) Å and in **2**, 2.621(3) Å] and an intermolecular one with the non-coordinating NH group from an adjacent molecule [O(free)···N in**1**, 2.741(6) Å and in **2**, 2.737(4) Å], giving rise to what may be regarded as a 'pseudo-bridging' arrangement in the terminal acetate groups.[13] The second interesting observation is that the bidentate acetate bridges are markedly asymmetric which can be attributed in part to an additional intermolecular H-bond formed between one oxygen atom of the acetate bridge and the NH group from an adjacent molecule [O(2)···N(13c) distances in**1**, 2.775(6) Å and in **2**, 2.808(4) Å], and in part to the structural *trans* effect. The significance of the observed framework of H-bonds in the formation and stabilization of **1** and **2** can therefore be envisioned. The aqua molecule bridging between two metals is stabilized by intramolecular H-bonds formed with the terminal carboxylates. This typical H-bond plays a crucial role in fixing and activating the bridging aqua or hydroxide in the process of arginine hydrolysis by arginase.[3a] Indeed, search of the CSD§ revealed *ca*. 25 other μ-aqua transition-metal complexes and in almost all cases the μ-aqua ligand was stabilized by H-bonds.

Magnetic susceptibility data for a powder sample of **1** were collected in the temperature range 5–285 K. The molar paramagnetic susceptibility increases with decreasing temperature and reaches a maximum at *ca.* 9 K with $\chi_m T = 2.129$ cm$^3$ mol$^{-1}$ K, below which the susceptibility starts to decrease, indicative of antiferromagnetic coupling between the two $Mn^{II}$ ions. A least-squares fit of the molar susceptibility by the general isotropic exchange Hamiltonian, $H = -2JS_1S_2$, $S_1 = S_2 = 5/2$, produced the best fit with $J = -1.26$ cm$^{-1}$ and $g = 1.97$. The very small negative exchange coupling constant $J$ in **1** is consistent with the relatively large Mn···Mn separation and the weak superexchange provided by the aqua bridge.[9a] The $J$ value found for **1** is comparable with that deduced from EPR measurements for arginase from rat liver ($J = -2.0 \pm 0.5$ cm$^{-1}$),[3b] and that of **4** ($J = -2.73$ cm$^{-1}$) and **5** ($J = -2.952$ cm$^{-1}$).[9b] We also made variable temperature EPR mesurements on **1** and found the same $J$ value as obtained from variable temperature magnetic measurements.

In summary, we have reported the syntheses, the structures and the magnetic properties of two new di-$Mn^{II}$ complexes with (μ-aqua)bis(μ-carboxylate) bridging cores and with monodentate N-donor Im or Bzim ligands in each of the two joint $MnN_2O_4$ coordination spheres. This is the first symmetric di-$Mn^{II}$ complex built up entirely with true mimics of amino acid side chains. The terminal monodentate carboxylates bind to Mn with a distinctive geometry in **1** and **2**, suggesting the possible existence of tautomeric forms of carboxylate in its coordination chemistry. Finally, we believe that the formation of strong H-bonds between the bridging aqua and the ancillary carboxylate groups in **1** and **2** provides a good mimic for arginase in which the terminal carboxylate Asp128 stabilizes and activates the bridging aqua or hydroxide, generating the basic $Mn^{II}_2(\mu\text{-}OH)^{3+}$ or superbasic $Mn^{II}_2(\mu\text{-}O)^{2+}$ by H-bond-guided proton transfer.[3a] The study of the reactivity of the title compounds and related synthetic models are currently in progress.

FEATURE ARTICLE

# Solid-state chemistry of lithium power sources†

**Peter G. Bruce***

*School of Chemistry, University of St. Andrews, St. Andrews, Fife, UK KY16 9ST*

**This article describes the solid-state chemistry of intercalation compounds that underpins a revolutionary new rechargeable lithium battery which has recently achieved phenomenal commercial success. The battery can store more than twice the energy compared with conventional alternatives of the same size and mass and holds the key to the future improvement of consumer electronic products (*e.g.* mobile telephones), electric vehicles and implantable medical devices (*e.g.* the artificial heart). Attention is focused on those lithium intercalation compounds that are useful as positive electrodes in rechargeable lithium batteries. The basic operation of the cell is summarised briefly and the structure/property relationships are developed that are important for the solid-state chemist when attempting to design and synthesise new lithium intercalation compounds capable of operating as positive electrodes. Finally, the structure, electronic structure and intercalation chemistry of several important positive intercalation electrodes are discussed including some which show considerable promise for applications in future generations of rechargeable lithium batteries.**

## Introduction

Why should chemists be interested in rechargeable lithium batteries? For better or worse, chemical research must now find expression in its benefit to industrial competitiveness or the quality of life. This is not necessarily in conflict with its more timeless *raison d'être, i.e.* the advancement of knowledge. In many areas of chemistry it is possible, although often hard, to be interesting and useful at the same time. Some of the most exciting fundamental scientific developments in solid-state chemistry within the last decade, *e.g.* zeolites for catalysis, have occurred against a background of attempting to advance technology and reduce energy costs.

The overwhelming need for lightweight and compact sources of portable electricity has resulted in a massive international effort into the development of radically new rechargeable batteries. This has led recently to the first successful commercialisation of a rechargeable lithium battery.[1,2] The device is a triumph of solid-state chemistry and electrochemistry; the relevance of electrochemistry to lithium batteries is obvious, however if it were not for crucial advances in the solid-state chemistry of intercalation solids, rechargeable lithium batteries would not have achieved the success that they have. In this article I aim to highlight the key challenge presented to the solid-state chemist, namely, the development of new intercalation compounds as positive electrodes for rechargeable lithium batteries.

## Rechargeable lithium batteries

The considerable technological impetus in this area comes from three main sources, consumer electronics (*e.g.* mobile telephones), electric vehicles and implantable medical devices (*e.g.* the artificial heart).

The introduction by Sony in 1990 of the world's first commercially successful rechargeable lithium battery represented a revolution in the power source industry.[1–3] It has been likened by some to the semiconductor revolution which saw the replacement of the valve by the transistor in the 1940s and 50s. The new cell can store more than twice the energy compared with conventional rechargeable batteries of the same size and mass, an achievement which is remarkable in an industry that traditionally measures improvements in a few percentage points. The Sony cell represents but a first step on the road to greatly improved sources of portable electrical power, there is much scope and indeed need for further development.[2]

The essential elements of the Sony cell are shown schematically in Fig. 1(*a*). The cell is constructed in the discharged state and consists of a positive electrode composed of a thin layer of powdered $LiCoO_2$ mounted on aluminium foil, a negative electrode formed from a thin layer of powdered graphite, or certain other carbons, mounted on a copper foil. The two electrodes are separated by a porous plastic film soaked typically in $LiPF_6$ dissolved in a mixture of dimethyl carbonate and ethylene carbonate. Charging the cell involves diffusion of lithium ions within the $LiCoO_2$ particles towards their interface with the electrolyte, the lithium ions then cross the electrolyte and are intercalated between the carbon layers in the graphite electrode. Charge balance requires that the equivalent number of electrons must pass around the external circuit. Discharge reverses the process moving lithium out of the graphite and reforming $LiCoO_2$. This cell may be contrasted with earlier designs which employed lithium metal rather than graphite as the negative electrode, Fig. 1(*b*). The reactivity of lithium metal and the difficulty of plating and stripping it with high efficiency, have resulted in concerns over safety and the performance of this design. The Sony cell, which is known variously as a rocking-chair, swing or LION cell, to distinguish it from the lithium metal design, is a true expression of solid-state intercalation chemistry involving, as it does, the flow of lithium

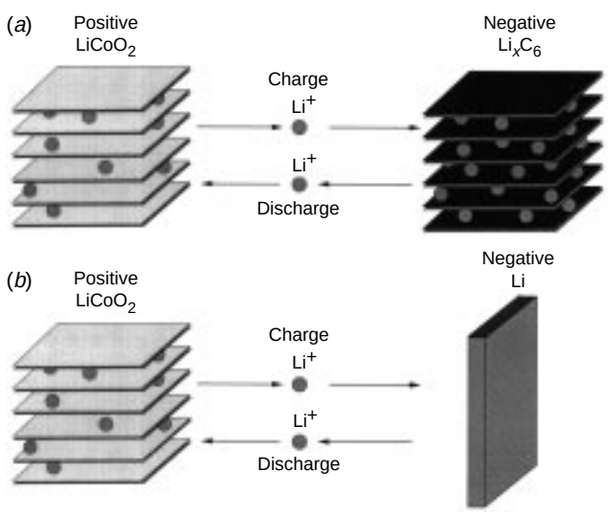

**Fig. 1** Schematic representation of (*a*) the Sony rocking-chair cell and (*b*) a rechargeable lithium cell with a lithium metal negative electrode. The maximum lithium content in ordered graphite is $LiC_6$.

ions between two intercalation hosts. The performance advantage over more conventional rechargeable batteries such as nickel–cadmium lies largely in the voltage. The Sony cell has an average potential of 3.6 V which is almost three times that of nickel–cadmium so that three conventional cells can be replaced by only one lithium cell![1,3]

A number of reviews have appeared which deal with rechargeable lithium batteries including graphite and other carbon-based negative electrodes.[4–7] Although the Sony cell currently uses a liquid electrolyte, the future will see replacement of this by a solid polymer leading to all-solid-state rechargeable lithium batteries.[8]

## Relating solid-state chemistry to positive intercalation electrodes

For our purposes, intercalation or insertion solids may be defined as hosts into which atoms (or more commonly ions + electrons) may be inserted or removed without a major disruption of the structure.[9–12] Molecular intercalation has been reviewed by O'Hare.[13]

In order to use our knowledge of solid-state chemistry to design and synthesise new intercalation compounds that will exhibit improved performance as positive electrodes for new generations of rechargeable lithium batteries, we must first understand what properties the intercalation solid should possess and how this relates to the structure and composition of the solid. The key structure/property relationships are listed in Table 1. As can be seen, a single compound must possess fourteen, often quite distinct, attributes and this serves to illustrate how challenging it is to develop solids which will be technologically competitive! Let us consider some of these attributes and their relationship to the solid-state chemistry in more detail.

Firstly, positive electrodes must be intercalation compounds; only such compounds avoid the large kinetic barriers of defect diffusion and nucleation and growth associated with the majority of solid-state reactions. Also, as prepared, they should contain lithium, *i.e.* be in the fully discharged state since rocking chair cells are assembled in this state.

The voltage of the cell is a crucial parameter and this should be large. If we consider a rocking-chair cell, such as graphite/$LiCoO_2$, then the voltage between the two electrodes is related to the work the cell can deliver on transferring electrons around an external circuit and to the free energy change on transferring lithium from one intercalation electrode to the other. The free energy change associated with the transfer of one mole of lithium between the two intercalation electrodes is equivalent to the difference in the chemical potential of lithium in the two electrodes [eqn. (1)],[14,15]

$$V = -\frac{(\mu_{Li}^{int} - \mu_{Li}^{graph})}{nF} \quad (1)$$

where $V$ is the open circuit voltage of the cell, $\mu_{Li}^{int}$ and $\mu_{Li}^{graph}$ the chemical potentials of lithium in the positive intercalation and graphite electrodes respectively, $n = 1$ (since one $e^-$ is transferred for each lithium) and $F$ is Faraday's constant. On discharge, lithium is transferred from a state of high $\mu_{Li}^{graph}$ (high energy) in the negative graphite electrode to one of low $\mu_{Li}^{int}$ (low energy) in the positive intercalation electrode; as a result work can be done by the cell. According to eqn. (1), in order to ensure a large cell voltage we must select positive intercalation electrodes which possess a low $\mu_{Li}^{int}$. On discharging a rocking-chair cell the lithium content and hence chemical potential and voltage, will change in each electrode ($\mu_{Li} = \mu_{Li}^{o} + RT\ln a$, where $a$ is the activity of lithium). It is convenient and normal practice therefore to measure the potential of a positive intercalation electrode against lithium metal (which has an invariant $\mu_{Li}$) and to use the latter's chemical potential as the standard state for lithium in the positive electrode. Lithium is rarely in the form of Li atoms in the intercalation compounds of interest here but instead exists as $Li^+$ ions along with their charge-compensating electrons, the latter located in the d levels of the transition-metal ion. As a result, it is helpful when considering structure–property relationships to separate $\mu_{Li}^{int}$ according to eqn. (2)

$$\mu_{Li}^{int} = \mu_{Li^+}^{int} + \mu_{e^-}^{int} \quad (2)$$

where $\mu_{Li^+}^{int}$ and $\mu_{e^-}^{nt}$ represent respectively the chemical potentials of $Li^+$ ions and electrons.‡ The ion and electron chemical potentials include both energy and entropy terms. In developing the gross structure–property relationships the entropy terms may be neglected since over most of the composition range they are small, vary little and make a similar contribution to each intercalation compound. The entropy of electrons in a band is negligible.

This torrid trip through some simple thermodynamics has brought us to the conclusion, important for the solid-state chemist, that the potential of a positive intercalation electrode, and hence the voltage of the cell, will depend on the energy of the electrons and the $Li^+$ ions in the host. On inserting electrons into an intercalation host they will enter at the Fermi level, $E_F$ and this is the electron energy of importance [eqn. (3)].§¶

$$E_F = \mu_e \quad (3)$$

The site energy for $Li^+$ is the major factor determining the ion contribution to the overall energy. Mutual repulsion between the $Li^+$ ions is usually of secondary importance. Hence maximising the positive electrode potential reduces to designing intercalation compounds with a low Fermi level and a high stability (low energy) for $Li^+$ in its sites. It is important to note that the electrode potential of graphite or other carbon electrodes is some +10 to +800 mV *vs*. lithium, therefore for rocking chair cells we must select intercalation electrodes with somewhat larger positive potentials (*i.e.* lower Li chemical potentials) than is necessary for cells with lithium metal electrodes.

Let us consider further the problem of engineering a low Fermi level. The lowest Fermi level which can be achieved for an intercalation compound is determined by the energy corresponding to the top of the valence band. In oxides the valence band is largely of oxygen 2p parentage and lies significantly below the top of the 3p valence band in the corresponding sulphides. As a result, Fermi levels in oxides can be more than 2 eV lower, resulting in potentials of between 4 and 5 V *vs*. the $Li^+$/Li couple. Therefore, the focus is on oxides rather than chalcogenides. For any given transition-metal oxide the Fermi level is set by the position of the cation d levels. The lowest d levels are associated with those ions from the centre or right of the first transition series, *i.e.* Cr, Fe, Mn, Co, Ni; these all exhibit +4 oxidation states corresponding to d levels which lie close to (usually just above) the top of the oxygen valence

**Table 1** Criteria for intercalation compounds as positive electrodes

| | |
|---|---|
| 1 | Must be an intercalation host for lithium |
| 2 | Low Fermi level and $Li^+$ site energy → high open-circuit voltage |
| 3 | Electrode potential varies little with lithium content → cell voltage varies little with state of charge |
| 4 | Capable of accommodating large quantities of lithium per formula unit → high capacity |
| 5 | Low formula mass → high gravimetric energy density |
| 6 | Low molar volume → high volumetric energy density |
| 7 | Sustain high rates of lithium intercalation and deintercalation → high cell discharge/charge rates |
| 8 | Highly reversible lithium intercalation → many charge–discharge cycles |
| 9 | Avoid co-intercalation of solvent |
| 10 | Stable in contact with candidate electrolytes |
| 11 | Adequate electronic conductivity |
| 12 | Low cost |
| 13 | Easily fabricated into electrode |
| 14 | Evironmentally friendly |

band. $Li_{1-x}Cr_2O_4$, for example, when combined with a lithium negative electrode gives an open circuit potential of 5 V associated with the $Cr^{4+/3+}$ mixed-valence state.[17]

As lithium is inserted into the intercalation host forming a continuous range of solid solutions, the electrons fill up the band while the mutual repulsions between the $Li^+$ ions rises. The net effect is that the potential will decrease somewhat with increasing Li content; whereas in many systems it turns out that this can be rationalised entirely by considering only the ion repulsions,[14] in some cases both ion and electron interactions are important.[18] If, on the other hand, intercalation induces the formation of a new phase and both phases have fixed composition then insertion is simply accompanied by the conversion of one phase to the other. This in turn is associated with a constant change of chemical potential and therefore a constant voltage as a function of the degree of intercalation (state-of-charge).

Before leaving the topic of electrode potentials it is worth noting that the relationship between the cell voltage and the lithium chemical potentials in the electrodes can be derived in another way which serves to highlight a frequently misunderstood fact. It is often stated that the voltage of a cell is determined by the difference between the Fermi levels of the two electrodes, this is incorrect. The voltage is equal to the difference in the Fermi levels between the electrodes only when they are in a cell *i.e.* in mutual contact with an electrolyte. Such Fermi levels are not those of the isolated electrodes. Selecting a lithium intercalation electrode based on its Fermi level will not yield the desired cell voltage.‖

One of the most important factors governing the performance of a cell is the energy which can be stored per unit weight and volume, *i.e.* the gravimetric and volumetric energy density. For electric vehicles, batteries are required which provide a high gravimetric energy density whereas for implantable medical devices volumetric energy is more important. Since energy is stored in the form of lithium in the intercalation electrodes the gravimetric and volumetric energy density of the positive electrode is of great importance and is given by eqn. (4),

$$E = V_e Q \quad (4)$$

where $E$ is the volumetric or gravimetric energy density, $V_e$ is the electrode potential and $Q$ is the charge stored per unit mass or volume of the intercalation compound. Energy densities are conventionally expressed in terms of W h $kg^{-1}$ or W h $l^{-1}$ whereas $Q$ is expressed in terms of mA h $g^{-1}$ or A h $l^{-1}$. The energy density depends therefore on two separate factors, the electrode potential and the charge. Potential has been dealt with above. The charge stored is equivalent to the amount of lithium that can be accommodated within the intercalation host. It is important for the solid-state chemist to design intercalation hosts which can reversibly insert a large amount of lithium per formula unit. If the capacity to store lithium is high, then a high gravimetric energy density will be assured provided the molar mass of the intercalation host is small. A high volumetric energy density will be obtained provided the molar volume is small. We see again that oxides will be preferable to chalcogenides in order to achieve a high gravimetric energy density and that we wish to choose intercalation hosts that contain the active redox couple and little else. Considering both $V_e$ and $Q$, a metal oxide of the formula $LiMO_2$ from which all the lithium may be reversibly deintercalated and in which M is a light element, in a high oxidation state ($M^{4+/3+}$ couple) and with a close-packed structure would seem to be optimal. It is no coincidence that the positive electrode in the Sony cell is $LiCoO_2$.

The rate at which a cell can be discharged or charged is an important parameter and is limited by the rate of lithium intercalation or deintercalation. Electroneutrality demands that the magnitude of the flux of $Li^+$ ions and their charge compensating electrons into and out from the host must be the same. It is the coupled diffusion of $Li^+$ and electrons down a concentration gradient that is important, rather than the individual diffusivities (mobilities) of the ions and electrons alone. A coupled diffusion coefficient may be defined, it is generally known as the chemical diffusion coefficient, $\tilde{D}_{Li}$, and is a measure of the intrinsic rate capability of the electrode.

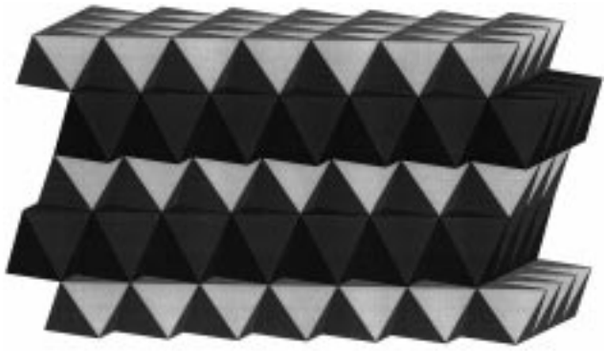

**Fig. 2** The crystal structure of $LiCoO_2$ or $LiNiO_2$. Dark and light octahedra represent respectively the sites for the transition-metal and lithium ions.

Several other factors are also of crucial importance. The chosen electrode must be stable in contact with the electrolyte of the cell. The surfaces of transition-metal oxides provide an ideal environment for catalytic decomposition of many electrolytes and this can present problems. Indeed metal oxide electrodes are frequently used for electrocatalysis in other applications! The starting materials used to prepare the intercalation electrode should be of low cost as should the preparation method. However, above all, the intercalation electrode must be environmentally benign.

## Intercalation electrodes

Many intercalation compounds have been studied as possible positive electrodes for rechargeable lithium batteries. Limitations of space demands that attention is concentrated on the three compounds of main interest. The author apologises to those whose work could not be included.

### *$LiCoO_2$ and $LiNiO_2$*[19–21]

The structures of $LiCoO_2$ and $LiNiO_2$ are identical and shown in Fig. 2. The oxide ions adopt a cubic close-packed arrangement with $Co^{3+}$ or $Ni^{3+}$ ions occupying octahedral sites between adjacent oxide ion layers. Only alternate sheets of octahedral sites are occupied by the transition metal ions with the remaining sheets being occupied by $Li^+$. The structure is slightly distorted giving rise to rhombohedral symmetry, space group $R\bar{3}m$.

The electronic structure of intercalation electrodes is an important factor which as we have seen has a strong influence on the voltage and can also induce structured distortions. Too little attention has been paid to the rôle of electronic structure in the past. The electronic structure of $LiCoO_2$ may be derived as follows. $Co^{3+}$ ($3d^6$) adopts a low-spin configuration ($t_{2g}{}^6e_g{}^0$) in an octahedral oxygen environment. The $t_{2g}$ orbitals are energetically close to the oxygen 2p orbitals and those 2p orbitals of $\pi$ symmetry will overlap strongly with the Co $t_{2g}$ orbitals. As a result there is considerable covalent mixing and consequently a high degree of delocalisation over the $CoO_6$ octahedra. The Co–O–Co angle is close to 90° and hence neighbouring cobalt ions overlap with mutually orthogonal 2p orbitals on the bridging oxygens. This inhibits long-range Co–O–Co interactions, thus attenuating band formation due to metal–oxygen interactions. Spectroscopic data suggests that the electronic structure of $LiCoO_2$ more closely approximates to a localised Co($3d^6$) electronic configuration than to a band. Full occupancy of the $t_{2g}$ $\pi^*$ orbitals which are separated energetically from the $e_g$ $\sigma^*$ orbitals ensures semiconductor behaviour for $LiCoO_2$. The extraction of lithium from between the oxide ion layers is facile and a chemical diffusion coefficient for the

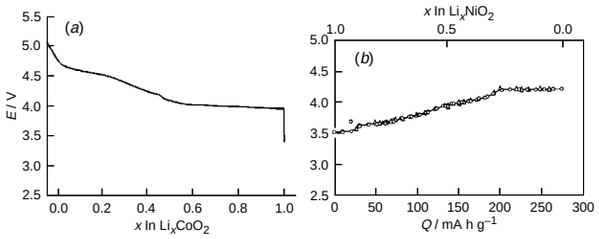

**Fig. 3** Open-circuit voltage *vs*. $Li^+/Li$ couple as a function of lithium content in (*a*) $Li_xCoO_2$, reproduced from ref. 28 and (*b*) $Li_xNiO_2$, based on a figure presented in ref. 29. With the permission of The Electrochemical Society.

coupled ($Li^+ + e^-$) diffusion of $5 \times 10^{-8}$ $cm^2$ $s^{-1}$ at $Li_{0.65}CoO_2$ has been measured.[22] Such extraction is accompanied by oxidation of $Co^{3+}$ to $Co^{4+}$ (low-spin $d^5$). The associated contraction of the *a* axis of the unit cell (which lies in the oxide layers) signals a shorter Co···Co distance, reduced from 2.83 Å in the case of $LiCoO_2$ to 2.81 Å for $Li_{0.9}CoO_2$. The strongly covalent Co–O interactions, will, due to the nephaluxetic effect, produce expanded antibonding d orbitals. Together the orbital expansion and shorter Co···Co distance conspire to make possible direct overlap of cobalt $t_{2g}$ orbitals across a shared octahedral edge resulting in a narrow d band and hole conduction in the mixed valence $Co^{4+/3+}$ system. The critical Co···Co distance for direct $t_{2g}$–$t_{2g}$ interactions is 2.82 Å, consistent with the switch from insulator to metallic behaviour on extracting a relatively small amount (10%) of lithium from $LiCoO_2$. Experimental evidence verifies that extraction of small quantities of lithium from $LiCoO_2$ does indeed induce metallic behaviour.[23] Of course we cannot rule out the possibility of $Co^{4+}$ d levels being located just below the top of the oxygen 2p band and introducing holes in it which would also lead to metallic behaviour; further studies are required to resolve this. In any case the low lying $Co^{4+/3+}$ couple gives rise to a high potential of $>4$ V *vs*. the $Li^+/Li$ couple, Fig. 3.

$LiNiO_2$ adopts a low-spin $d^7$ configuration with fully occupied $t_{2g}$ levels and one electron in the $e_g$ orbitals. Full occupancy of the $t_{2g}$ levels implies that we must focus our attention on the single electron in the $e_g$ orbitals to understand the conduction process. The $e_g$ orbitals will overlap with oxygen 2p orbitals of σ symmetry giving rise to strong interactions but again neighbouring nickel ions form a 90° Ni–O–Ni geometry and therefore overlap is with mutually orthogonal 2p orbitals on the bridging oxygen. This inhibits delocalisation extending beyond the $NiO_6$ octahedron and again attenuates band formation. As a result the $e_g$ electron remains in a localised atomic orbital on nickel although these are strongly antibonding associated with significant Ni–O covalency. A localised low-spin $d^7$ configuration is Jahn–Teller active. There is some evidence for a dynamic Jahn–Teller distortion from EXAFS studies but no cooperative, static, distortion of the structure has been detected.[24] Deintercalation is again facile with the chemical diffusion coefficient for Li reaching a maximum of $2 \times 10^{-7}$ $cm^2$ $s^{-1}$, amongst the highest observed in such materials.[25] Extraction of lithium is associated with oxidation of $Ni^{3+}$ to $Ni^{4+}$. Since the $e_g$ orbitals point towards the coordinating oxygens there is little opportunity for direct nickel–nickel interaction in contrast to the situation with the $t_{2g}$ orbitals in the cobalt compound. As a result, measurements of electronic transport on $Li_xNiO_2$ exhibit a small but definable activation energy for electronic transport associated with small polaron hopping in the mixed-valence $Ni^{4+/3+}$ state.[26] The location of the Fermi level in the higher energy $e_g$ orbitals, compared with the lower energy $t_{2g}$ orbitals in the analagous cobalt compound, results in an average voltage several hundred mV lower for $Li_xNiO_2$, Fig. 3(*b*).[19,27,28]

Considering now the structural changes that accompany lithium deintercalation from $LiCoO_2$ in more detail; this process does not correspond to a simple continuous solid solution as was first believed, instead several minor structural transformations occur.[28] Within the composition range $0.9 < x < 1$ in $Li_xCoO_2$, a single hexagonal phase exists, whereas within the range $0.78 < x < 0.9$, two hexagonal phases coexist giving way to a region, $0.51 < x < 0.78$, within which the second hexagonal phase exists alone. On further removal of lithium a monoclinic distortion of this second phase is observed for compositions in the narrow range $0.46 < x < 0.51$. Extraction of lithium from $x = 1$ to $x = 0.5$ is accompanied by an expansion in the *c* lattice parameter from approximately 14.1 to 14.5 Å. The loss of lithium from between the otherwise weakly van der Waals' bonded oxide layers is the origin of this expansion. Decrease in the *a* lattice parameter associated with oxidation of $Co^{3+}$ to the smaller $Co^{4+}$ has been highlighted above. Further deintercalation below $x = 0.46$ results in reversion to a hexagonal phase until the composition $Li_{0.22}CoO_2$ is reached whereupon a second monoclinic phase appears coexisting with the hexagonal phase until the composition $Li_{0.18}CoO_2$ is obtained, at which point the monoclinic phase exists alone. Below $x = 0.15$ another hexagonal phase appears corresponding to the fully delithiated $CoO_2$.[28] The monoclinic distortion at around $x = 0.5$ has been ascribed to lithium ordering,[27] however a complete rationale for the structural phase changes which occur on deintercalation has not yet been presented; nevertheless, there is no doubting the complexity of the structural chemistry. Until the recent studies by Amatucci, Tarascon and Klein,[28] it had been generally believed that the weak van der Waals' bonding exhibited by adjacent oxide ion layers would result in instability for a layered $CoO_2$ compound. These authors have shown this to be incorrect and have demonstrated that the structure of $CoO_2$ is not based on cubic close-packing but hexagonal close-packing ($CdI_2$ structure). This is the same structure commonly adopted by the layered chalogenides, *e.g.* $TiS_2$.[28] Two factors may play a rôle in stabilising $CoO_2$ with adjacent oxide layers. First, the low-lying $d^5$ configuration of $Co^{4+}$ ensures very significant covalent mixing with the neighbouring oxygen 2p orbitals resulting in a high degree of delocalisation. It is not therefore realistic to view the compound as possessing adjacent $O^{2-}$ layers. Second, as proposed before, a cooperative displacement of the $Co^{4+}$ ions results in a ferroelectric distortion establishing dipoles which will oppose the repulsive interactions between the oxide ion layers thus assisting stabilisation of the structure.[22]

The structural chemistry of $Li_xNiO_2$ is also complex.[27,29,30] Solid solutions with rhombohedral symmetry exist within the composition ranges $0.85 < x < 1$ and $0.32 < x < 0.43$. Between $x = 0.50$ and 0.75 a single monoclinic phase is observed. Over the range $x = 0$–$0.32$ a mixture of two rhombohedral phases is evident, one of these being $NiO_2$. Two-phase mixtures are also observed between each of the other single-phase ranges. The monoclinic distortion is believed to be associated with a superlattice arising from the ordering of lithium ions.[24,27,29] Arguments similar to those used for $CoO_2$ may be employed to explain the stability of $NiO_2$ particularly the high degree of Ni–O covalency. It is interesting to note that $NiO_2$ retains the cubic close packed structure of $LiNiO_2$ (*i.e.* the $CdCl_2$ structure type).[29]

In contrast to $LiCoO_2$, $LiNiO_2$ has proved impossible to prepare as a stoichiometric material. Instead compounds with the formula $Li_{1-\delta}Ni_{1+\delta}O_2$ are obtained. The closest approach to stoichiometry that has been possible so far corresponds to a δ of approximately 0.02 and may be prepared by reacting $Li_2O_2$ with NiO in oxygen at 700 °C.[31] Non-stoichiometry is associated with lithium deficiency and the presence of $Ni^{2+}$ ions in the lithium layers. These nickel ions serve to pin the oxide layers together reducing the mobility of the lithium ions, however compounds approaching the stoichiometric composition do exhibit a similar *c* lattice expansion on deintercalation to that observed for $LiCoO_2$. There is evidence that at high degrees of deintercalation further nickel ions may migrate from the Ni to the Li layers. Work by Delmas *et al.* has shown that the quantity

of lithium extracted on first charging lithium nickel oxide cannot be reinserted.[24] In fact these authors claim that the capacity loss on the first cycle is a more significant factor than any loss of capacity due to continuous disordering of nickel on extended cycling. Even for relatively stoichiometric materials, reintercalation up to the composition $Li_{0.85}NiO_2$ is easy but beyond this limit proves very difficult. The mechanism they propose to explain this capacity loss is based on oxidation of the nickel ions in the lithium layers at high degrees of deintercalation, subsequent structural collapse around the $Ni^{3+}$ ions and the relatively high charge of these ions mitigates against $Li^+$ ions reoccupying the sites around nickel. The best electrochemical performance is obtained from materials that are as close as possible to the stoichiometric composition.

Comparing the properties of the $LiCoO_2$ and $LiNiO_2$ compounds as positive electrodes for rechargeable lithium batteries, both exhibit high voltages and facile lithium diffusion rates despite the complex structural changes. The fact that these structural changes are small and in some cases, at least, only associated with lithum ordering, explains the preservation of fast cycling kinetics. Complete removal of lithium from $LiNiO_2$ corresponds to a charge storage capacity of 275 mA h $g^{-1}$. In practical cells based on liquid electrolytes cycling can occur over the approximate composition range $0.3 < x < 0.9$ corresponding to 150–160 mA h $g^{-1}$ depending on the rate of charge/discharge. In the case of $LiCoO_2$, deintercalation to $Li_{0.5}CoO_2$ is possible with almost complete reinsertion of lithium, corresponding to a more modest 130 mA h $g^{-1}$ but at a slightly higher potential than the nickel electrode. As we now know the limits of deintercalation for this compound are not imposed by structural collapse *per se* but by the instability of the highly charged, and therefore high voltage, oxide in contact with the liquid electrolytes used in the commercial cells.[21] It is the somewhat more modest voltage of $LiNiO_2$ which gives rise to the greater capacity. $LiNiO_2$ is also attractive because it is cheaper than the cobalt alternative. However, $LiCoO_2$ has the significant advantage that it is easier to synthesise as a highly stoichiometric material and its structure is robust with respect to cycling, at least over the limited composition range stated above, with no evidence for cobalt disordering into the lithium layers. It is this that led to its selection by Sony for the first generation rechargeable lithium batteries.

### *Li(NiAl)$O_2$ and Li(NiCo)$O_2$*

In an attempt to improve on the properties of $LiNiO_2$ and take advantage of the lower cost of this material, partial substitution of nickel by other ions has been investigated. The work of Ohzuku *et al*. has shown that $LiAl_{0.25}Ni_{0.75}O_2$ can deliver a capacity of *ca*. 150 mA h $g^{-1}$ and with excellent capacity retention on cycling.[32] A complete range of solid solutions $Li(Ni_{1-y}Co_y)O_2$ may be prepared. It has been shown that partial replacement of Ni by Co yields a material which is cheaper than $LiCoO_2$ but with many of its advantages.[33] This solid solution will be used in future commercial rocking chair cells.

### *$LiMn_2O_4$ and related spinels*

Manganese is approximately 1% of the cost of cobalt and significantly more environmentally benign than either cobalt or nickel. These are major advantages and explain the intense interest in developing manganese oxide based positive electrodes. The use of $LiMn_2O_4$ spinels as positive electrode materials was first reported in 1983.[34–36] The attractive features of $LiMn_2O_4$ led in 1996 to the announcement by Nippon Moli, Japan of the first commercial rechargeable lithium battery in which $LiCoO_2$ is replaced by the lithium manganese oxide spinel.[37]

$LiMn_2O_4$ is quite distinct from the layered oxides mentioned above in that it is a three-dimensional host. The spinel structure (space group $Fd\bar{3}m$) consists of cubic close-packed oxide ions

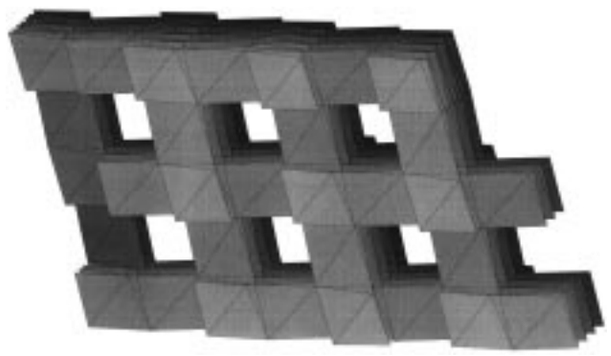

**Fig. 4** The $Mn_2O_4$ framework of the $LiMn_2O_4$ spinel consisting of a three-dimensional network of $MnO_6$ octahedra

with Mn ions in one half of the octahedral sites and $Li^+$ in one eighth of the tetrahedral sights within the cubic close-packed oxide array.[34,36] The $Mn_2O_4$ framework of the spinel structure is highly stable, Fig. 4, and defines a series of tunnels formed by the face-sharing of tetrahedral lithium (8a) and empty octahedral (16c) sites. These tunnels intersect in three dimensions and support rapid lithium diffusion, but unlike the layered compounds the spinels, because of their greater structural rigidity, are selective for lithium ions over solvent molecules or other larger cations (*i.e.* deleterious effects of solvent co-intercalation are avoided). Half of the octahedrally coordinated manganese ions are $Mn^{3+}$ (high-spin $3d^4$, $t_{2g}^3e_g^1$) and half $Mn^{4+}$ ($3d^3$, $t_{2g}^3$). Neighbouring Mn ions form 90° Mn–O–Mn interactions ensuring that the $t_{2g}$ and $e_g$ orbitals on adjacent Mn ions interact with mutually orthogonal oxygen 2p orbitals on the bridging oxygens, inhibiting band formation. The $t_{2g}$ orbitals are too contracted to overlap directly across a shared octahedral edge. As a result the d electrons are localised. Half the Mn sites are occupied by the Jahn–Teller active $Mn^{3+}$ ions and this is insufficient to promote a cooperative Jahn–Teller distortion until just below room temperature, the crystal structure at and above room temperature remains cubic. Electronic transport will occur by thermally activated small polaron hopping of the $e_g$ electron between neighbouring $Mn^{3+}/Mn^{4+}$ ions, the polaron is magnified by a dynamic Jahn–Teller distortion which must follow the electron. $LiMn_2O_4$ is a remarkable material. Li may be extracted yielding, when fully deintercalated, a polymorph of $MnO_2$($MnO_2$-λ) which cannot be prepared by other means. This is an excellent example of the rational synthesis of a target compound by *chimie douce* (soft chemistry).[38] Such deintercalation is associated with a potential of 4 V *vs*. $Li^+$/Li, Fig. 5. Lithium may also be intercalated into $LiMn_2O_4$ up to a maximum composition $Li_2Mn_2O_4$.[34,36] This is associated with the insertion of lithium into the octahedral (16c) sites and a potential of 3 V *vs*. $Li^+$/Li. The origin of this large voltage difference between lithium removal and insertion is believed to be related to the difference in the site energy of $Li^+$ in the tetrahedral (8a) and octahedral (16c) positions and its influence on the $\mu_{Li^+}^{int}$ and hence the potential [eqns. (1) and (2)]. In both cases the redox couple is $Mn^{4+/3+}$.

Let us consider the important intercalation chemistry of $LiMn_2O_4$ in more detail beginning with $Li_xMn_2O_4$ where $1 < x < 2$. Although this is a 3 V process and of limited interest in the context of rocking-chair cells it is of considerable importance for cells employing lithium metal negative electrodes. The gravimetric energy density of lithium is 3860 mA h $g^{-1}$, more than ten times that of graphite (372 mA h $g^{-1}$). For this reason, particularly in the context of developing batteries for electric vehicles, lithium metal systems continue to be intensively studied, although key problems connected with lithium cycling and safety remain to be solved. On inserting lithium into the octahedral (16c) sites of $Li_xMn_2O_4$ ($x = 1$), the $Mn^{4+}$ ions are reduced to $Mn^{3+}$ and a continuous solid solution is obtained up

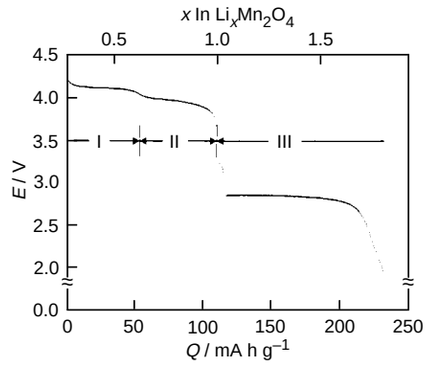

**Fig. 5** Open-circuit voltage *vs*. $Li^+/Li$ couple as a function of lithium content in $Li_xMn_2O_4$. Reproduced with permission from Ohzuku, Kitagowa and Hiral, *J. Electrochem. Soc.*, 1990, **17**, 769.

to $x = 1.1$. At this composition the Jahn–Teller active $Mn^{3+}$ ions are present in sufficient concentration to promote a cooperative distortion of the octahedral sites to tetragonal symmetry. Associated with this the cubic crystal symmetry of $LiMn_2O_4$ is lowered to tetragonal.[34,36] For $1.1 < x < 2$ a mixture of the cubic and tetragonal spinels coexist and intercalation involves the continuous conversion, within each particle, of the former phase to the latter. As a result the voltage does not vary with the lithium content in this composition range. Although the phase change is displacive and appears to be quite facile as judged by the rate of lithium insertion and removal, the abrupt change in unit-cell volume (6.5%) which accompanies the cubic-to-tetragonal phase transition in the spinel has a deleterious effect on the cyclability. Only tetragonal $Li_2Mn_2O_4$ should be present at the end of each discharge; however we have shown by X-ray diffraction carried out as a function of cycling that cubic $LiMn_2O_4$ accumulates at the end of discharge and that this is the primary cause of the significant loss of capacity to store lithium observed on cycling the spinel electrodes, Fig. 6.[39,40] The capacity loss arises because the particles contract on deintercalation resulting in a loss of mutual contact. Some particles may become isolated from the rest of the electrode and hence unable to act as host for lithium insertion on subsequent discharge. The $LiMn_2O_4$ compounds used in early studies were prepared by the solid-state reaction between lithium carbonate and $Mn_2O_3$ at 850 °C in air. Alternative synthesis routes to the spinel have been reported which possess the common factor that they employ low firing temperatures and this significantly improves the capacity retention on cycling.[41–43] Our solution-based synthesis may be carried out in air and involves the reaction between $Li_2CO_3$ and $Mn(MeCO_2)_2$ in aqueous solution followed by firing at the exceptionally low temperature of 200 °C.[40,42,43] This route gives a marked improvement in the cycling performance compared with the original spinel materials. X-Ray data have shown a significant reduction in the amount of cubic (unintercalated) $LiMn_2O_4$ phase present at the end of discharge on extended cycling.[39] We have also found that by adding < 1 mass% of carbon black to the aqueous solution before firing, a dramatic improvement in the capacity retention of up to 50% after 300 cycles and at high cycling rates (currents of 1 mA $cm^{-2}$ of the electrode area), can be obtained.[42,43] Powder X-ray diffraction has demonstrated that there is a further marked drop in the accumulation of cubic material at the end of discharge when synthesised with carbon.[40] The low-temperature routes yield material of lower crystallinity as is evident from the broad peaks in the powder X-ray diffraction patterns but the particle size remains in the micron range. It may be that there is an extensive mosaic structure of small coherent crystalline regions within each particle that is better able to accommodate the volume change. Alternatively the carbon black may act as a flexible electronic contact between particles facilitating the cubic to tetragonal conversion. As well as

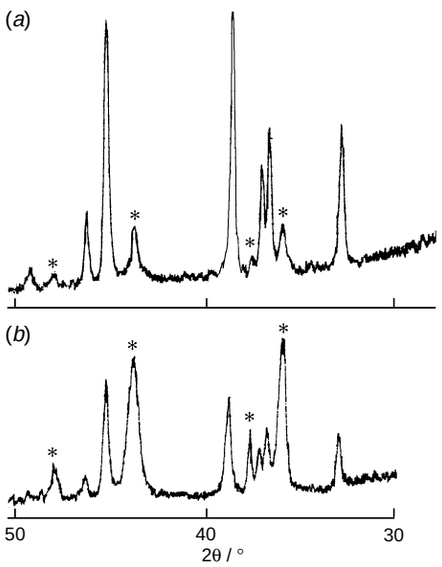

**Fig. 6** Powder X-ray diffraction patterns of electrodes constructed from $LiMn_2O_4$ prepared by solid-state reaction at 850 °C, (*a*) at the end of discharge after two cycles, (*b*) at the end of discharge after 50 cycles. In both cases peaks from residual cubic phase (denoted by *) are present and this phase accumulates with cycling. Cells were cycled at 0.5 mA $cm^{-2}$ between 3.7 and 2.0 V *vs*. $Li^+/Li$.

improving capacity retention on cycling, the low-temperature synthesis yields material which depart from the stoichiometric $LiMn_2O_4$ composition, for example our low-temperature solution route yields, after firing at 200 °C, a composition $LiMn_2O_{4.1}$. These compounds are in fact cation deficient with two possible extreme cation distributions, $Li_{0.98}[Mn_{1.95}\square_{0.05}]_{oct}O_4$ (where □ represents a vacant cation site) or $Li_{0.93}[Mn_{1.95}Li_{0.05}]_{oct}O_4$. $LiMn_2O_{4.1}$ contains 60% $Mn^{4+}$ and this implies an increase in the theoretical capacity to accept lithium from 148 to 178 mA h $g^{-1}$, *i.e.* 20% more than the stoichiometric spinel. To accommodate this, lithium ions must simultaneously occupy face-sharing octahedral (16c) and tetrahedral (8a) sites. The fact that improved overall capacity, in addition to the improved capacity retention on cycling, can be obtained from these low-temperature materials transformed the lithium manganese oxide spinels from materials with little practical interest, despite their other attributes, to compounds that are competitive for applications, Fig. 7.

Turning now to the performance of the spinel in the 4 V regime within which lithium is extracted from the 8a sites, this appears to occur over a continuous range of solid solutions for $0.5 < x < 1$.[35,44] At *x ca.* 0.5 it has been suggested that lithium ion ordering occurs involving occupancy of one half of the tetrahedral 8a sites and that deintercalation below this composition is an event in which two cubic spinel phases of approximate composition $x = 0$ and 0.5 coexist (note that the precise composition range over which the two phases are observed is still controversial). A small step of around 100 mV between two essentially flat voltage profiles is observed at *x ca.* 0.5. Again, the original materials prepared by high-temperature solid-state reaction at 850 °C gave disappointing cycling performance, although significantly better than that in the 3 V region. Several reasons have been advanced for this.

(*i*) The two-phase nature of the process in the range $0 < x < 0.5$ leading to a cell volume change and loss of particle contact.[45] (*ii*) Dissolution of $Mn^{2+}$ in the electrolyte as a result of the disproportionation reaction $2Mn^{3+} \rightarrow Mn^{2+} + Mn^{4+}$.[46,47] (*iii*) Electrolyte decomposition at a high degree of deintercalation *i.e.* high voltage.[48]

Probably all these factors play a role in the capacity fade of the spinel material. It has however been shown that by careful control of the composition a dramatic improvement in the

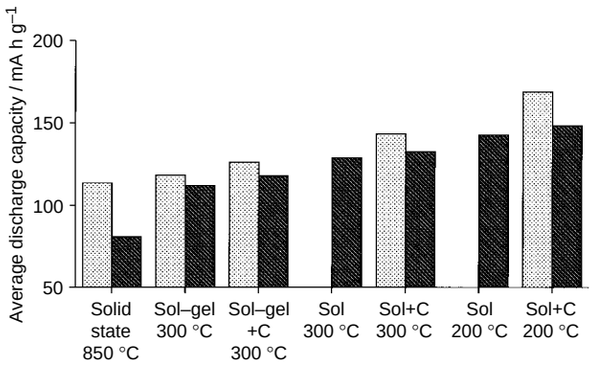

**Fig. 7** Histogram plot comparing the performance of several 3 V electrodes containing lithium manganese oxide spinels prepared under different conditions. The electrodes and cycling conditions are identical in all cases, the only difference being the active material. The discharge capacities on the *y*-axis are an average taken over the first four cycles. The cycling current densities are 0.5 mA cm$^{-2}$ (left) and 1 mA cm$^{-2}$ (right). The temperatures used to fire the spinels are shown. C refers to the addition of 1 mass% carbon black during the synthesis, 'sol–gel' refers to the use of the synthesis method described in ref. 41 and 'sol' indicates use of our own synthesis described in the text. The material prepared from the solid-state reaction was obtained by firing $Li_2CO_3$ and $Mn_2O_3$ in air.

cycling performance may be achieved.[46,49,50] Excellent cyclability can be obtained by replacing a small amount of the manganese on the 16d octahedral sites by lithium, $Li_{1+\delta}Mn_{2-\delta}O_4$ ($\delta$ = 0.1).[30,47,51] Other divalent ions *e.g.* Zn, Mg, *etc*. have also been used,[47] however lithium is attractive since it introduces no new cations into the system and a small amount of this monovalent ion corresponds to a significant increase in the average manganese valence above $Mn^{3.5+}$. This seems to be the key factor responsible for improved capacity retention on cycling. It should be noted however that such solid solutions will reduce the capacity associated with the 4 V plateau, since there is less $Mn^{3+}$ available for oxidation. It has also been shown that such solid solutions reduce dissolution of Mn and promote a single phase composition over the range $0 < x < 1$.[45] The synthesis of a spinel modified to yield an oxidation state slightly greater than $Mn^{3.5+}$ may be easily carried out by firing an aqueous mixture of $Li_2CO_3$ and $Mn(MeCO_2)_2$, first at 200 °C (*i.e.* the same conditions used to prepare a spinel for use at 3 V) and then heating at 650 °C, thus forming the non-stoichiometric spinel $LiMn_2O_{4.02}$ which is marginally cation deficient.[43,52,53] Our compound shows excellent capacity retention on cycling even at high current rates, Fig. 8. Many other solid solutions have been formed based on replacing Mn by, for example, Co, Ni, Cu, Be, Ga, Cr, *etc.*[54,55] and some of these also demonstrate improved performance. It is evident that the performance of the spinels, in contrast to $LiCoO_2$, is very sensitive to the preparative conditions.

## Future prospects

### *Layered $LiMnO_2$*[40,56]

Despite strenuous effects by a number of groups over the past few years the synthesis of $LiMnO_2$ with the $LiCoO_2$ structure had proved elusive until recently. Layered $LiMnO_2$ is potentially attractive since it combines the proven performance of the $LiCoO_2$ structure with the low cost and low toxicity of manganese. Furthermore, $MnO_2$ is more stable than $CoO_2$ in liquid solvents offering the possibility of obtaining the full capacity to deliver lithium compared with only half a lithium in the case of $LiCoO_2$. The difficulty is that Li–Mn–O compositions do not readily form layered structures. Very recently we have succeeded in synthesising layered $LiMnO_2$ with the structure of $LiCoO_2$ using an ion-exchange route.[40,56] Neutron powder diffraction has confirmed the layered structure. All of the lithium may be removed chemically or electrochemically

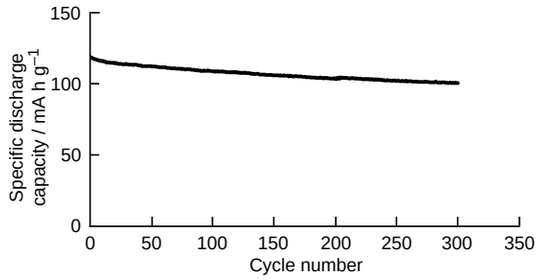

**Fig. 8** Capacity to store charge in the spinel at 4 V *vs*. number of charge–discharge cycles. Cycling was carried out between 4.3 and 3.6 V at 30 °C and at charge and discharge currents of 0.5 mA cm$^{-2}$. The electrolyte was a 1 molar solution of $LiPF_6$ dissolved in a 1 : 1 mixture of dimethyl carbonate and ethylene carbonate.

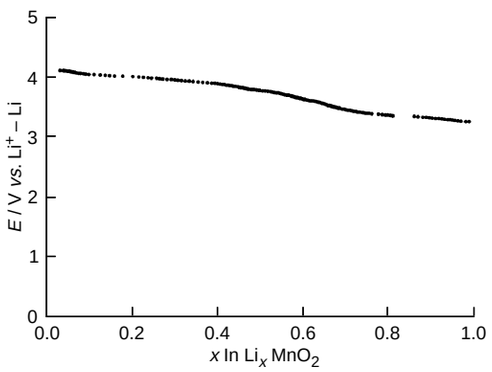

**Fig. 9** Variation of the voltage with lithium content in layered $Li_xMnO_2$ on charging at a low current (10 μA cm$^{-2}$)

yielding a total capacity of 270 mA h g$^{-1}$, Fig. 9.[40,56] Despite the high capacity, the cycling performance of these early materials is not satisfactory.[56,57] It is important to recall that the early $LiMn_2O_4$ spinels, although attractive in many ways, did not demonstrate sufficient capacity retention on cycling, however minor modification of their composition has resulted in their commercial success. The importance of layered $LiMnO_2$ may be that it opens a new avenue of exploration that will lead to optimised materials.

### *Iron Oxides*

An interesting recent development is the use of iron(III) sulfates as hosts for lithium intercalation.[58] Up to two lithiums may be reversibly inserted into $Fe_2(SO_4)_3$ accompanied by the reduction of $Fe^{3+}$ to $Fe^{2+}$. The host consists of $FeO_6$ octahedra linked by corner-sharing through $SO_4$ tetrahedra. Lithium intercalation is associated with a potential of 3.6 V *vs*. $Li^+/Li$ which is much higher than the potential associated with the same $Fe^{3+/2+}$ couple in a simple oxide. Replacement of $O^{2-}$ by $SO_4$ groups polarises the oxygens reducing the covalency of the Fe–O interactions and lowering the energy of the antibonding d levels. As a result the voltage is higher. The fact that more modest oxidation states of the first-row transition-metal ions can achieve higher voltages in these more complex framework compounds is something which deserves further exploration and may lead to a range of possibilities for the synthesis of new intercalation hosts as positive electrodes in rechargeable lithium batteries in the future.

There can be no doubt that significant advances in the performance of rechargeable lithium batteries will be achieved over the next 10 years. As was the case with the success of the first-generation systems, future development will rely heavily on the ability of solid-state chemists to rise to the challenge of designing new intercalation compounds for lithium which optimise the many different properties that are important for a positive electrode in a rechargeable lithium battery.

‡ It should be recalled that this separation does not imply independence of these terms since ion–electron interactions must be present, only $\mu_{Li}^{int}$ has a rigorous thermodynamic meaning.

§ Strictly $E_F$ equates to the electrochemical potential of the electron which can include a, usually small, contribution from electric fields due to dipoles on the surface of the solid, even for an otherwise uncharged solid.[16] We shall neglect this perturbation.

¶ Note that the ion–electron interactions (including those between the $Li^+$ ions and the electrons) together with the electron–electron interactions and the one-electron energy of the $e^-$ all contribute to the Fermi energy of the electron.

‖ A derivation which demonstrates that the cell voltage depends on the Fermi level difference between the two electrodes but only when they are in the cell, can be found in the enhanced version of this article on the WWW.

# Positive and negative ionochromism and UV sensor properties of oxygen-containing polysilanes

**Chien-Hua Yuan and Robert West***

*Department of Chemistry, University of Wisconsin, Madison, WI 53706-1396, USA*

**Addition of lithium trifluoromethanesulfonate (LiOTf) to poly[(4-ethoxyethoxybutyl)octylsilylene] (PEBOS) prevents the normal thermochromic transition to longer wavelength (negative ionochromism), whereas addition LiOTf to poly-[bis(5-ethoxyethoxypentyl)silylene] (PEEPS) induces a thermochromic transition (positive ionochromism); the latter effect is reversed in the presence of water or THF vapour, so that LiOTf-doped PEEPS serves as a UV sensor for $H_2O$ or THF.**

Recently, polythiophenes having oligoether ($OCH_2CH_2O$) sidechains have been shown to undergo chromotropic changes in the presence of alkali metal cations.[1] The cations are presumed to bind to the oligoether oxygens and alter the chain conformation, resulting in a strong blue shift of the absorption bands; this type of change we will term 'negative ionochromism.'†

Polysilane polymers generally display strong electronic absorption bands in the near ultraviolet region, assigned to $\sigma \rightarrow \sigma^*$ transitions.[3] The energy of this transition depends on the conformation of the polymer chain.[4] Many polysilanes show chromotropic behavior, associated with changes in the backbone conformation which after the σ-conjugation. Thermochromism is especially common, but in selected polysilanes electrochromism,[5] piezochromism[6] and solvatochromism[7] have also been reported.

We have now synthesized several polysilanes containing oxygen atoms in the organic side chains,[8] and examined the effect of added cations.‡ The UV spectrum of a thin film of PEBOS as a function of temperature is shown in Fig. 1(*a*). As the polymer is cooled, the absorption band at 320 nm disappears and is replaced by one at 354 nm; the midpoint of the transition is at *ca.* −32 °C. This sort of thermochromic transition, reflecting a change from a coiled to an all-*trans* conformation, is found for many polysilanes.[3,4]

The effect of adding lithium trifluoromethanesulfonate to PEBOS is shown in Fig. 1(*b*)–1(*d*). With 12.5 and 25.0 mol% LiOTf, the thermochromic transition is progressively inhibited. At 50 mol% LiOTf, no change in the UV spectrum is observed upon cooling, even at −70 °C [Fig. 1(*d*)]. The lithium-complexed PEBOS thus exhibits negative ionochromism, perhaps because the lithium ions freeze the polymer into a coiled conformation.

The UV spectrum for PEEPS is shown in Fig. 2(*a*). Like PEBOS, this polymer also undergoes a thermochromic transition from 320 to 352 nm, with a midpoint at *ca.* −38 °C. The effect of added lithium triflate is, however, entirely different. As shown in Fig. 2(*b*), with 0.75 mol% LiOTf, PEEPS exhibits a thermochromic transition centred at *ca.* 35 °C. Thus in this polymer, lithium complexing causes the bathochromic shift, providing an example of positive ionochromism; the lithium cations apparently serve to lock the polymer into an extended conformation.

For both polymers, these changes in optical absorption upon LiOTf complexing were reflected in the thermal properties. In

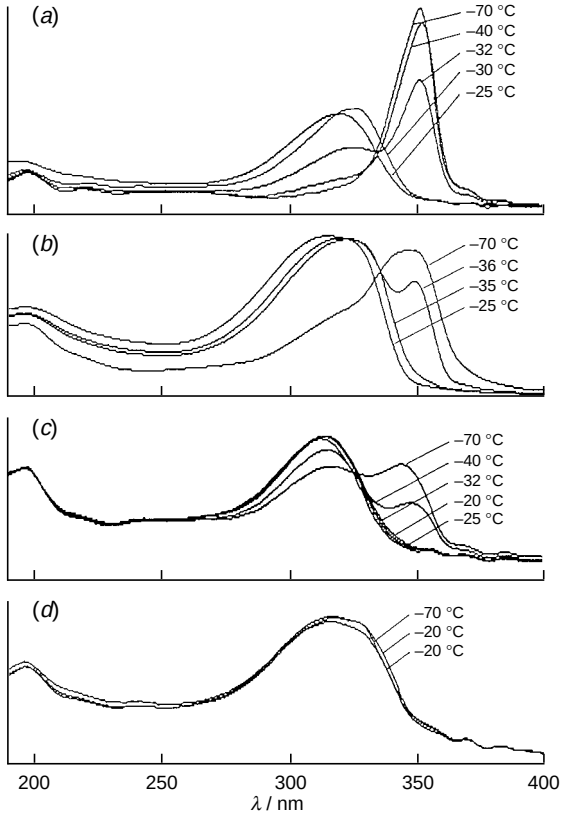

**Fig. 1** Thermochromism of PEBOS complexes with LiOTf: Li/Si = (*a*) 0, (*b*) 12.5, (*c*) 25 and (*d*) 50 mol%

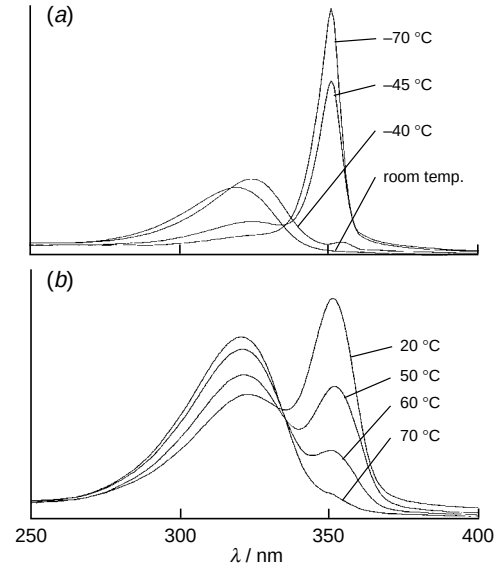

**Fig. 2** Thermochromism of (*a*) a thin film of PEEPS compared to (*b*) a thin film of PEEPS–$LiSO_3CF_3$ complex (Li/Si = 75 mol%)

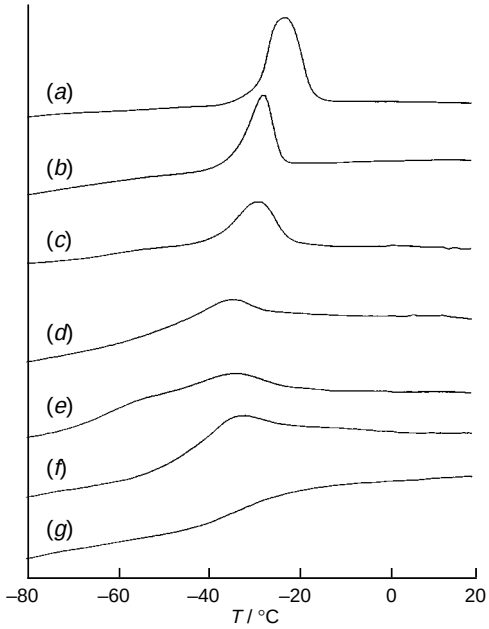

**Fig. 3** DSC thermogram of PEBOS–$LiSO_3CF_3$ complexes. Li/Si = (*a*) 0, (*b*) 12.5, (*c*) 25, (*d*) 40, (*e*) 50, (*f*) 60 and (*g*) 80 mol.

the differential scanning calorimetry (DSC) thermogram for PEBOS, shown in Fig. 3(*a*) a first order transition is found at a temperature near that of the thermochromic change.§ As LiOTf is added, the thermal transition weakens and moves to lower temperature [Fig. 3(*b*)–(*d*)]; with 50 mol% LiOTf, only a second-order transition is seen. For PEEPS, a thermal transition is found at −35 °C (Fig. 4). As LiOTf is added this transition weakens and a new thermal transition appears above 0 °C. With 75 mol% LiOTf, the thermogram is dominated by a transition at 35 °C, corresponding to the UV thermochromic transition.

PEEPS exhibits yet another unexpected phenomenon involving a new type of chromotropic behavior. The spectra in Fig. 2 were determined in a cryostat, out of contact with the atmosphere. If the cryostat is opened to admit moist air (at 25 °C) the long wavelength band at 352 nm disapears and is replaced by the higher energy, 320 nm absorption. This change is reversible; pumping on the sample to remove moisture regenerates the long wavelength band. Exposure to THF vapour likewise reversibly shifts the absorption band from 352 to 320 nm. Thus PEEPS behaves as an ultraviolet sensor for small basic molecules. We theorize that water and THF compete with the oxygen atoms in the PEEPS sidechains for the lithium cations,[10] allowing the polymer to relax into the coiled form which it normally adopts at room temperature. The effect is quite structure-specific, since diethyl ether vapour does not induce the hypsochromic shift.

Similar, but much weaker, effects were observed when salts of $Na^+$ or $K^+$ were added to PEBOS and PEEPS. The reason for the striking difference in behaviour between these two polymers is not clear; we are now synthesizing other ($OCH_2CH_2O$)-containing polysilanes to explore the effect of structural variability on these novel chromotropic effects.

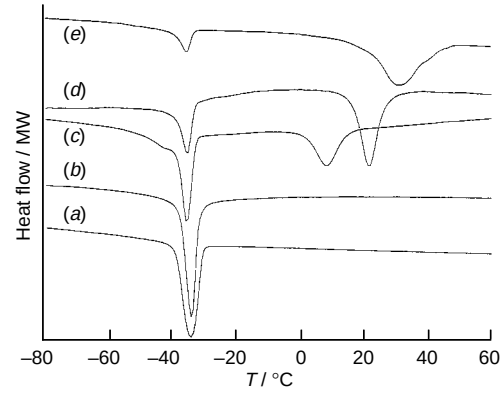

**Fig. 4** DSC curve of PEEPS–$LiSO_3CF_3$ complexes. Li/Si = (*a*) 0, (*b*) 25, (*c*) 50, (*d*) 75 and (*e*) 100 mol%.

This work was supported by a grant from the U.S. Office of Naval Research.

## Footnotes and References

† Positive ionochromism has been observed for polythiophenes having calixarene substituents with $Na^+$ ion (ref. 2).

‡ The prepartion of PEBOS and PEEPS was carried out by sodium condensation of diorganodichlorosilanes, as described in an earlier paper (ref. 9). PEBOS was precipitated from PhMe solution with MeOH, and PEEPS was precipitated from PhMe with MeCN–$H_2O$ (1 : 2). The structures of the polymers were confirmed by $^1H$, $^{13}C$ and $^{29}Si$ NMR spectroscopy. Gel permeation chromatography indicated a bimodal *M*w distribution for PEBOS (*M*w $1.4 \times 10^6$ and $2 \times 10^4$ *vs.* polystyrene standard) and a monomodal distribution for PEEPS (*M*w $1.6 \times 10^6$).

§ Differential scanning calorimetry thermograms were determined at a heating and cooling rate of 10 °C $min^{-1}$ under a dry helium atmosphere over the temperature range from 100 to −100 °C.

# Synthesis of 1,3-dioxolan-4-one from trioxane and carbon monoxide on HZSM-5 zeolite

**Tsuneji Sano,*[a] Takashi Sekine,[a] Zhengbao Wang,[a] Kazuo Soga,[a] Ikuo Takahashi[b] and Takashi Masuda[c]**

[a] *School of Materials Science, Japan Advanced Institute of Science and Technology, Tatsunokuchi, Ishikawa 923-12, Japan*

[c] *National Institute of Materials and Chemical Research, Tsukuba, Ibaraki 305, Japan*

**Cabonylation of formaldehyde with carbon monoxide has been carried out on HZSM-5 zeolite; from spectroscopic analysis of the products obtained, the formation of 1,3-dioxolan-4-one on the Brønsted acid sites of HZSM-5 zeolite has been demonstrated.**

Carbonylation with carbon monoxide (CO) is one of the most important reactions for fundamental and industrial applications, and various kinds of homogeneous and heterogeneous catalysts are used.[1,2] Recently, carbonylation on zeolite catalysts has received considerable attention. It has been shown that CO and $H_2O$ can react with small alkenes on HZSM-5 zeolite to form carboxylic acids[3,4] and that, under anhydrous conditions, ethene, isobutene and oct-1-ene react to form ketones instead of carboxylic acids.[5] The formation of benzoic acid on HY zeolite from the carbonylation of benzene with CO has also been reported.[6] However, no report is available of the synthesis of lactones. Here we report the formation of 1,3-dioxolan-4-one (1,3-DOX-4) *via* carbonylation of formaldehyde with CO on HZSM-5.

HZSM-5 zeolites and silicalite were prepared following the previously described procedure.[7] The $SiO_2/Al_2O_3$ ratios (53, 101, 191 and 3300) were determined by X-ray fluorescence. Prior to the experiments, the zeolite was activated by heating at 400 °C for 8 h. Trioxane was used as the source of formaldehyde, and was purified by crystallization from $CH_2Cl_2$ and dried *in vacuo* at room temperature for 1 h. $CH_2Cl_2$ (research grade) was used as solvent. When the residual moisture in the $CH_2Cl_2$ was greater than 1000 ppm, the carbonylation of formaldehyde with CO did not occur and paraformaldehyde was mainly obtained. Therefore, dehydration of the $CH_2Cl_2$ was required using 4 Å molecular sieves, the residual moisture, measured by the Karl Fischer method, was less than 30 ppm.

The carbonylation of formaldehyde with CO was carried out using a 100 ml autoclave as follows. Trioxane (10 g), $CH_2Cl_2$ (40 ml) and zeolite (1 g) were placed in the autoclave under a nitrogen atmosphere, and CO ( > 99.95%) was introduced. The initial CO pressure at room temperature was varied in the range of 15 to 75 MPa. The reaction temperature (40–180 °C) was reached within 1 h. After 2–50 h of reaction, the zeolite and the solid product were filtered off. The filtrate was distilled under reduced pressure several times. The product (a colourless liquid) obtained by distillation at 85 °C and 60 mmHg was analysed by GC–MS, as well as IR and $^1$H and $^{13}$C NMR spectroscopy. The yield of 1,3-DOX-4 obtained was calculated by GC using sulfolane as an internal standard. GC analyses were carried out on a Shimadzu GC-15A gas chromatograph (FID) equipped with a 25 m × 0.22 mm ID HiCap-CBP1 Shimadzu capillary column. $^1$H and $^{13}$C NMR spectra were recorded on a Varian Gemini 300 spectrometer (300 MHz for $^1$H, 75.4 MHz for $^{13}$C).

In the $^1$H NMR spectrum of the product obtained by distillation, two intense signals were observed at $\delta$ 5.5 and 4.2. These signals were assigned to the $OCH_2O$ and $OC(=)CH_2O$ methylene groups, respectively. In the $^{13}$C NMR spectrum, three signals were observed at $\delta$ 171.3, 96.1 and 62.4. These signals were assigned to the $CO_2$ carboxyl carbon and the methylene carbons of the $OCH_2O$ and $OC(=O)CH_2O$ groups, respectively. Characteristic bands were also observed in the IR spectrum. The 1798 $cm^{-1}$ band is characteristic of the stretching vibration of C=O ester groups and the band at about 1210 $cm^{-1}$ is characteristic of stretching of C–O ester groups. These results strongly indicate the selective formation of 1,3-DOX-4 on the HZSM-5 zeolite catalyst. The formation of 1,3-DOX-4 (*m/z* 88, 87 and 44) was also confirmed by GC–MS. Although it has already been reported that glycolic acid[8] and the polymer polyglycolide[9,10] can be synthesized from formaldehyde and CO using various acid catalysts, the preferential formation of 1,3-DOX-4 has never been reported.

To obtain more information related to carbonylation on HZSM-5 zeolite, the catalytic performance of HZSM-5 zeolite was examined under various reaction conditions. At first, to clarify the active site of the formation of 1,3-DOX-4, the carbonylation was conducted on various HZSM-5 zeolites with different $SiO_2/Al_2O_3$ ratios. As shown in Table 1, the yield of 1,3-DOX-4 decreased with an increase in the $SiO_2/Al_2O_3$ ratio (entries 1–4). In the case of silicalite, which has almost no Brønsted acid sites, 1,3-DOX-4 was not obtained. This indicates that the carbonylation is promoted on the acid sites of HZSM-5 zeolite. Next, the influence of the reaction temperature and CO pressure on the 1,3-DOX-4 yield was studied. 1,3-DOX-4 was obtained in very low yields at 40 and 80 °C (entries 5 and 6). At reaction temperatures higher than 80 °C, the yield increased with the reaction temperature and then decreased after reaching a maximum yield at 160 °C (entries 7–9). The yield of 1,3-DOX-4 was dependent on the initial CO pressure (entries 8, 10–12). The yield increased with the initial CO pressure and a

**Table 1** Synthesis of 1,3-DOX-4 from trioxane and CO on zeolite catalysts[a]

[a] Reaction conditions: trioxane (10 g, 111 mmol), $CH_2Cl_2$ (40 ml), zeolite (1 g). [b] Initial CO pressure at room temperature.

maximum yield of 114 mmol was obtained at a CO pressure of 55 MPa. As the maximum yield of 1,3-DOX-4 calculated from the amount of trioxane (111 mmol) used is 166.5 mmol, this indicates the preferential formation of 1,3-DOX-4. The time dependence of the 1,3-DOX-4 yield was also studied. The yield increased with the reaction time, and then decreased markedly after the maximum yield was reached at a reaction time of *ca*. 5 h (entries 8, 13–15). Taking into account the fact that the yield of solid product increased with an increase in the reaction time, this seems to indicate that 1,3-DOX-4 is the initial product and that the decrease in the yield is attributable to the later ring opening polymerization of 1,3-DOX-4 to form polyglycolide, probably inside the zeolite crystals.[9,10]

From the above results, it has been shown that 1,3-DOX-4 is selectively synthesized from trioxane and CO, although the CO pressure needed for the synthesis is higher than 15 MPa. Although the detailed reaction mechanism has not been clarified at the present time due to limited data, the preferential formation of 1,3-DOX-4 appears to be due to the supression of formation of polymers because the active sites (Brønsted acid sites) are in zeolitic pores.

# Conjugate addition of allylic and prop-2-ynylic alcohols to 3-halogeno-1-phenylsulfonylprop-1-enes; synthesis and radical induced cyclization of 2-alkenyloxy-3-halogenopropylphenyl sulfones

**Riccardo Giovannini and Marino Petrini***

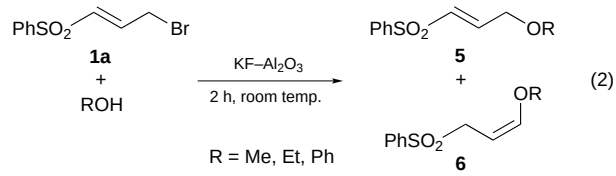
*Dipartimento di Scienze Chimiche, Università di Camerino, via S. Agostino, 1 I-62032 Camerino, Italy*

**Allylic and prop-2-ynylic alcohols add in a conjugate fashion to 3-halogeno-1-phenylsulfonylprop-1-enes in the presence of KF–basic alumina and the resulting halogenoallyl sulfones can be efficiently cyclized using tributyltin hydride under various conditions.**

The ability of vinyl sulfones to act as two carbon acceptors in Michael additions is the basis of their widespread use in synthesis.[1] In this context, 3-halogeno-1-alkenyl sulfones **1**

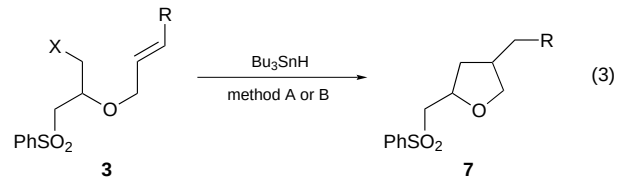
**1a** X = Br, $R^1$ = $R^2$ = H
**b** X = Cl, $R^1$ = $R^2$ = H
**c** X = Br, $R^1$ = H, $R^2$ = Me
**d** X = Br, $R^1$ = $R^2$ = Me

possess two electrophilic adjacent carbon atoms in their structure and therefore conjugate additions would compete with direct $S_N2$ displacements of the halogen atom. Allylic and aryl Grignard reagents are able to attack the double bond of **1a** and ultimately lead to substituted cyclopropanes *via* a subsequent nucleophilic displacement of the bromide anion.[2] On the contrary, sodium enolates afford direct substitution products when reacted with **1a**.[3]



The behaviour of these systems towards different nucleophiles has been studied in great detail by Bordwell and coworkers.[4] They showed that weakly basic nucleophiles react with primary halogeno derivatives **1a**,**b** giving exclusively direct substitution products arising from an $S_N2$ process. Michael adducts are obtained only when tertiary halogeno derivative **1d**, which is almost unreactive towards $S_N2$ substitutions, reacts with sodium methoxide in MeOH.[4b]

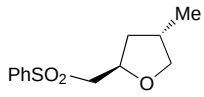
We report here that allylic, prop-2-ynylic and benzylic alcohols efficiently add to the double bond of vinyl sulfones **1a**,**b** in the presence of KF–basic alumina [eqn. (1)].[5] The

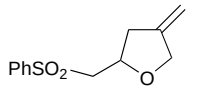


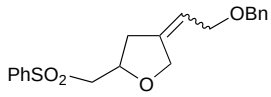
reaction is carried out under heterogeneous conditions by simply mixing the vinyl sulfone **1** with the appropriate alcohol and adding the solid base at room temperature.† The corresponding adducts are usually obtained in satisfactory yields upon extraction with $CH_2Cl_2$ and purification by column chromatography (Table 1).‡ The yields of these adducts obtained starting from bromide **1a** are generally comparable with those attained using chloride **1b**, especially when simple allylic and prop-2-ynylic alcohols are used (Table 1, entries 1–4). Chloride **1b** displays enhanced reactivity towards substituted allylic alcohols (Table 1, entries 8–11) which react poorly with the bromide derivative **1a**. No solvent is required for this procedure, and the presence of solvents as THF, $CH_2Cl_2$ and $Et_2O$ gives rise to complex product mixtures and prolonged reaction times. Steric crowding around the reaction centre also has a deleterious effect on reactivity. Every attempt to obtain addition products from vinyl sulfone **1c** results in a fast, base-assisted dehydrobromination that produces (*E*)-1-phenylsulfonylbuta-1,3-diene **4** in 40% yield.

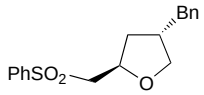
A completely different result is observed when short chain alcohol such as methanol, ethanol or phenol are used. In this instance an ordinary direct nucleophilic displacement of the halogen atom occurs, followed by a partial regioisomerisation of the double bond with consequent formation of products **5** and **6** [eqn. (2)].[6]

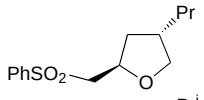
The allylic ethers **3** prepared by this procedure were recognized immediately as ideal candidates for the synthesis of a tetrahydrofuran moiety *via* a radical cyclization route [eqn. (3)].[7] Ring closure of compound **3** under standard conditions

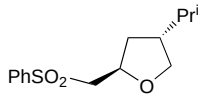












($Bu_3SnH$, AIBN catalytic, benzene at reflux)§ gives the corresponding 2,4-disubstituted tetrahydrofuran derivatives **7**

[a] Method A: $Bu_3SnH$, AIBN, benzene at reflux. Method B: $Bu_3SnH$, $Et_3B$, $O_2$, −78 °C. [b] Cyclization is conducted on the iodide obtained by refluxing the corresponding halide with sodium iodide in acetone. [c] This ratio refers to the *E*/*Z* stereoisomers. [d] Reaction conducted at room temperature.

as a diastereoisomeric mixture, usually in good yields (Table 2, method A).‡ These diastereoisomers are inseparable by standard chromatographic techniques, but a survey of available literature data on similar compounds allowed us to assign the *trans* configuration to the major component of the mixture.[8] It is known that radical cyclizations of monohalogeno derivatives of type **7** proceed following a chair-like transition state in which the phenylsulfonylmethyl group and the alkene prefer an equatorial orientation **8** (Scheme 1) that produces the *trans* isomer.[9] The diastereoselectivity obtainable in refluxing benzene is, however, rather poor as witnessed for the cyclization of compound **3a** (Table 2, entry 1, method A, *trans*:*cis* 68:32). Better results are achieved using $BEt_3$ initiator ($Bu_3SnH$, $BEt_3$, $O_2$, $CH_2Cl_2$, method B),§ which permits rapid cyclization even at very low temperatures (−78 °C).[10] In this way the diastereoisomeric ratio can be substantially improved for ring closure of **3a** (Table 2, entry 1, method B, *trans*:*cis* 86:14), although in other entries (Table 2, entries 4–6) this gain in diastereoselectivity is rather small, as the isomeric ratio is already quite satisfactory even with method A. The cyclization of alkyne derivative **3e** proceeds with a low degree of stereoselectivity (Table 2, entry 3). This is not surprising since the stereochemistry of compound **7e** is governed by the topicity of the hydrogen abstraction, in which the intermediate alkenyl radical is involved.[11]

In conclusion, a chemoselective conjugate addition of unsaturated alcohols to 3-halogenovinyl sulfones has been accomplished using KF–basic alumina as the basic medium. The resulting adducts can be stereoselectively cyclized by a radical process, affording functionalized 2,4-disubstituted tetrahydrofurans that are suitable for further transformations.

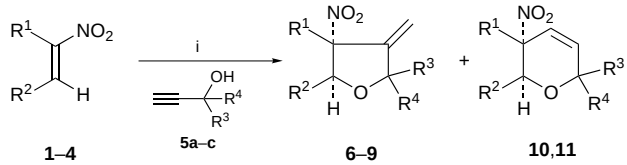
# Studies towards a new one-pot heterocyclization: Bu$^t$OK-promoted oxa- and aza-Michael addition–intramolecular carbocyclization of prop-2-ynyl alcohols and amines with α,β-disubstituted nitroalkenes

**Estelle Dumez, Jean Rodriguez and Jean-Pierre Dulcère**



*RéSo, Réactivité en Synthèse organique, Faculté des Sciences et Techniques Centre de St Jérôme, UMR 6516, av. Esc. Normandie-Niemen, Boîte D 12, F-13397 Marseille Cedex 20, France*

**Bu$^t$OK-promoted reaction of prop-2-ynyl alcohols 5 or *N*-methylprop-2-ynylamine 12 with nitroalkenes 1–4 affords 3-methylenetetrahydrofurans 6–9 and 3,4-dihydropyrans 10 and 11 or 3-methylenepyrrolidines 13–16, respectively, in moderate to good yields, with total allylic 1,3-strain-controlled diastereoselectivity.**

Five-membered heterocycles are among the most common structures in bioactive compounds.[1] Moreover, the presence of an unsaturated bond available for further elaboration, particularly in α-methylene γ-butyrolactones,[2] has for many years stimulated interest in synthetic routes to 3-methylenetetrahydrofurans.[2,3] Finally, the pyrrolidine ring is an extensively studied heterocyclic system,[4] as a consequence of the interesting biological activity exhibited by several polysubstituted pyrrolidines.[5] This paper describes a new one-pot access to these heterocyclic compounds from readily available α,β-disubstituted nitroalkenes **1**–**4**.

While the oxa-Michael addition of prop-2-ynyl alcohols to β-monosubstituted α-nitroalkenes in the presence of sodium or potassium hydride led to β-nitroprop-2-ynyl ethers,[6] to the best of our knowledge, only few recent preparation of five- or six-membered heterocycles involve intramolecular addition of carbon nucleophiles to alkynes;[7]† among them, Bu$^t$OK-promoted double Michael addition of 4-hydroxybut-2-ynoates[8] and tandem oxa-Michael $S_N2'$ substitution of 4-chlorobut-2-yn-1-ol[9] with α,β-disubstituted nitroalkenes generate a nitro-stabilized carbon nucleophile, which adds to the activated alkyne moiety to provide unsaturated tetrahydrofurans or pyrans.‡ Also of interest is the two-step synthesis of α-methylene γ-lactams from 1-nitrocyclohexene, involving the formation of β-nitroamides, which then undergo a Triton B-promoted carbanion addition to an unactivated terminal alkyne.[10] These results enhance the crucial effect of both the nitroalkene substitution pattern and the nature of the base on the reaction process.

Therefore, we investigated the base-promoted Michael addition of prop-2-ynyl alcohols **5a**–**c** to α,β-disubstituted

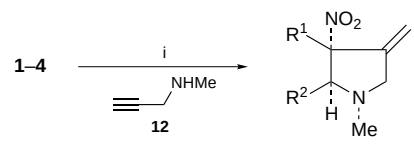
| **4** | **c** | 58 | **9c**[b] | |



[a] Isolated total yields of chromatographically homogeneous, spectroscopically pure products are reported. [b] 6-*endo* adducts were not detected by $^1$H NMR in the crude reaction mixture.

α-nitroalkenes **1**–**4**, since this route should afford 3-methylenetetrahydrofurans, provided a nucleophilic addition of the resulting nitronate on the triple bond occurs.

Best results were obtained when nitroalkenes **1**–**4** were added slowly to a solution of prop-2-ynyl alcohols **5** in THF containing Bu$^t$OK (Scheme 1). Other bases such as BuLi, KH, or $K_2CO_3$ were ineffective; for instance, the reaction of **1** with **5a** in the presence of BuLi produced a complex reaction mixture,§ while changing the base for KH delivered β-nitroprop-2-ynyl ethers.[6]

Although the reaction proceeded with total diastereoselectivity due to allylic 1,3-strain,[9,11] unexpected regioselectivity was observed (Table 1). Indeed, 5-*exo* adducts **6**–**9** were isolated, along with **10** and **11**¶‖ resulting from 6-*endo* cyclization mode when the reaction was performed on nitroalkenes **1** and **3** (ratio 5-*exo*/6-*endo* 1.7–20 : 1). Heterocycles **6b**–**9b** and **10b** and **11b** provided by reaction with secondary alcohol **5b** were obtained as a 0.7–0.9/1 mixture of diastereomers.

Interestingly, aza-Michael addition of *N*-methylprop-2-ynylamine **12** on nitroalkenes **1**–**4** also proceeded with intramolecular nucleophilic addition to provide, regio- and diastereo-selectively, 3-methylenepyrrolidines **13**–**16**¶‖ (Scheme 2).

**Scheme 2**

Factors that govern the regioselectivity of this new one-pot heterocyclisation are currently under investigation.

## Footnotes and References

# The synthesis and structure of the symmetrical isomer of $C_5H^-$

**Stephen J. Blanksby, Suresh Dua, John H. Bowie* and John C. Sheldon**

*Department of Chemistry, The University of Adelaide, Adelaide, South Australia 5005, Australia*

**The ion $(C_2CHC_2)^-$ is formed in the gas phase by the process $^-C{\equiv}C–CH(OCOR)–C{\equiv}CD \rightarrow (C_2CHC_2)^- + (\text{'}RDCO_2\text{'})$ [R = H, Me or Et]; the ground state structure is a singlet, with $C_{2v}$ symmetry.**

Unusual organic molecules have been detected in circumstellar gas and dust envelopes which surround red giant stars.[1] These include $C_3$, $C_5$ and the hydrocarbons $C_nH$ ($n$ = 2–6), which have been identified around the bright carbon-rich star IRC + 10216.[1–3] The high electron affinities of these neutrals suggest the possibility that the corresponding anions may co-occur with the neutrals in circumstellar envelopes,[4,5] and it is of interest in this context that negative ions are present in the coma of comet Halley.[6] We have reported the syntheses of $C_3H^-$,[7] $C_5^{-\cdot}$,[8] and linear $C_5H^{-\cdot}$[8] (and their conversion through the appropriate neutral to decomposing positive ions) in the ion source of a VG ZAB 2HF mass spectrometer. *Ab initio* calculations [at CISD/6-311G (d,p) level] indicate that linear $C_5H^-$ has both singlet and triplet states, with triplet **1** being the ground state, and that the corresponding neutral has an electron affinity of 2.4 eV.[8]

**1** **2**

*Ab initio* calculations [GAUSSIAN 94[9] at CISD/6-311G (d,p) level] indicate further that (i) there is a stable symmetrical isomer $C_2CHC_2^-$, and that this isomer (like linear $C_5H^-$) also has stable singlet and triplet forms, and (ii) there is no energy and stable species $C_3CHC^-$. *Ab initio* data for $C_2CHC_2^-$ are summarised in Tables 1 and 2. In this case the singlet is significantly more stable than the triplet. The geometry of the central carbon of the ground-state singlet approximates to trigonal planar (the $C_2$–$C_3$–$C_4$ angle is close to 130°), and the $C_1$–$C_2$ and $C_2$–$C_3$ bonds have significant triple and double bond character respectively (see Table 2). The structure is depicted (in valence bond form) as **2**. Isomer **2** is less stable than isomer **1** by 170 kJ mol$^{-1}$ at the level of theory indicated. The electron affinity of the neutral corresponding to **2** is calculated to be 4.2 eV.

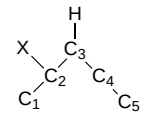
**Table 1** *Ab initio* calculations for $C_2CHC_2^-$ [a]

| State | Singlet | Triplet |
|---|---|---|
| Symmetry | $C_{2v}$ | $C_{2v}$ |
| HF/6-311G (d,p) | −189.74150 | −189.67132 |
| Zero point vibrational energy | 0.03188 | 0.02767 |
| Total thermal energy | 0.03685 | 0.03282 |
| CISD/6-311G (d,p) | −190.286804 | −190.20186 |

[a] *Ab initio* optimization used the Berny procedure (ref. 12) at HF/6-311G (d,p), GAUSSIAN 94 (ref. 9). The correctness of the geometries was confirmed by the lack of negative analytical computed harmonic vibration frequencies. The post Hartree–Fock energies (CISD) were calculated at the Hartree–Fock geometries. All energies are recorded in hartrees.

We initially attempted to form the elusive **2** in the ion source of the VG 2HF mass spectrometer by a number of methods related to that shown in eqn. (1):

$$^-(C{\equiv}C)–CH(OMe)–C{\equiv}CD \rightarrow [(:C{=}C{=}CH–C{\equiv}CD)\ ^-OMe] \rightarrow C_5D^- + MeOH \quad (1)$$



$$^-(C{\equiv}C)–CH(OCOR)–C{\equiv}CD \rightarrow (C_2CHC_2)^- + [RCDO_2] \quad (2)$$

$$^-(C{\equiv}C)–CD(OCOR)–C{\equiv}CH \rightarrow (C_2CDC_2)^- + [RCHO_2] \quad (3)$$

unfortunately, the base deprotonates exclusively at the central position to yield linear $C_5D^-$ (*cf.* **1**) rather than remove $D^+$ to form $C_2CHC_2^-$. However the energised precursor anions shown in eqns (2) and (3) (R = H, Me, Et) [formed by the reaction of $HO^-$ with DC≡C–CH(OCOR)–C≡CD and HC≡C–CD(OCOR)–C≡CH] decompose to yield $(C_2CHC_2)^-$ and $(C_2CDC_2)^-$ respectively and exclusively. We are not sure whether this process involves incipient $R^-$ deprotonating at the terminal position (to yield $CO_2$ and RH as neutral products) or whether the acetylenic H transfers to oxygen to yield $RCO_2H$ as the neutral products.

When source formed $(C_2CHC_2)^-$ ions are fired through a collision cell containing Ar (at $2 \times 10^{-7}$ Torr; 1 Torr = *ca.* 133 Pa) the resultant tandem negative ion mass spectrum exhibits only loss of H$^\cdot$ to form $C_5^{-\cdot}$ (*cf.* ref. 8). Under the same experimental conditions, charge stripping of $(C_2CHC_2)^-$ ions yields energised parent cations $C_5H^+$, whose resultant spectrum [the charge reversal spectrum[10,11] of $(C_2CHC_2)^-$] is *m/z* (composition relative abundance) 61 ($C_5H^+$, 35), 60 ($C_5^{+\cdot}$, 100), 49 ($C_4H^+$, 77), 48 ($C_4^{+\cdot}$, 62), 37 ($C_3H^+$, 81), 36 ($C_3^{+\cdot}$, 69), 25 ($C_2H^+$, 4), 24 ($C_2^{+\cdot}$, 21), 12 ($C^{+\cdot}$, 0.2). Although this spectrum shows the same peaks as those observed in the corresponding spectrum of isomer **1** (*cf.* ref. 8), the peak abundances in the two spectra are significantly and reproducibly different. In particular, the abundances of *m/z* 61 ($C_5H^+$) and 60 ($C_5^{+\cdot}$) are 35 and 100 for **2**, and 100 and 76 for **1**. Since the two charge reversal spectra are different, we conclude that isomers **1** and **2** are stable. However, the data cannot exclude the possibility of

**Table 2** Bond lengths and angles for $C_2CHC_2^-$ taken from *ab initio* calculations

| | Singlet | Triplet |
|---|---|---|
| *Bond length*/Å | | |
| $C_1$–$C_2$ | 1.2425 | 1.2746 |
| $C_2$–$C_3$ | 1.3679 | 1.3636 |
| $C_3$–H | 1.0843 | 1.1048 |
| *Bond angle* (°) | | |
| $C_1$–$C_2$–X | 85.3 | 80.0 |
| X–$C_2$–$C_3$ | 90.0 | 90.0 |
| $C_2$–$C_3$–H | 115.3 | 107.2 |

minor interconversion of **2** to **1** under the experimental conditions.

The neutral analogue of **1** has already been detected in the interstellar environment:[1–3] it would be of interest to search for anions **1**, **2** and the neutral corresponding to **2**.

We thank the Australian Research Council for the financial support of this project.

# A highly efficient catalyst precursor for ethanoic acid production: $[RhCl(CO)(PEt_3)_2]$; X-ray crystal and molecular structure of carbonyldiiodo(methyl)bis(triethylphosphine)rhodium(III)

**Joanne Rankin,[a] Andrew D. Poole,[b] Attila C. Benyei[a]† and David J. Cole-Hamilton*[a]**

[a] *School of Chemistry, University of St Andrews, Fife, Scotland, UK KY16 9ST*
[b] *B.P. Chemicals Ltd, Hull Research and Technology Centre, Saltend, Hull, UK HU12 8DS*

**Under mild conditions, $[RhI(CO)(PEt_3)_2]$, is more active for the carbonylation of methanol to ethanoic acid than $[Rh(CO)_2I_2]^-$, which is widely used industrially; intermediates in the catalytic cycle have been identified and characterised.**

The $[Rh(CO)_2I_2]^-$ catalysed carbonylation of methanol is the most widely used commercial route to ethanoic acid.[1] The rate determining step for the catalytic cycle[2] is oxidative addition of iodomethane to $[Rh(CO)_2I_2]^-$, so that increasing the electron density on the metal centre should increase the rate of oxidative addition and hence the overall rate of production of ethanoic acid. There have been attempts to modify $[Rh(CO)_2I_2]^-$ by using electron donating ligands.[3–6] For instance, Baker *et al.*[3] used $[RhI(CO)(Ph_2PCH_2P(S)Ph_2)]$ to enhance the rate of carbonylation at 185 °C. Cavell and coworkers[4] prepared complexes of the form, $[RhCl(CO)(PPh_2CH_2PPh_2NR)]$, where R is a substituted phenyl group. Wegman *et al.*[5] compared the methanol carbonylation rate at 80 °C using $[Rh(CO)_2I_2]^-$ and $[RhCl(CO)_2(Ph_2P(CH_2)_2P(O)Ph_2)]$ and noted an 80-fold increase with the latter. Dilworth *et al.*[6] used rhodium(I) carbonyl complexes containing phosphinothiolate and thioether ligands to promote the rate of carbonylation of methanol under the relatively forcing conditions of 70 bar and 185 °C. To our knowledge, the use of trialkylphosphines as promoters for rhodium based carbonylation catalysts has not been investigated, despite the fact that they are strongly electron donating. We now report the results of such a study.

Complexes of the form $[RhX(CO)(PEt_3)_2]$ (X = Cl, Br or I) have $\nu_{CO}$ at *ca.* 1960 $cm^{-1}$ compared with 1988 and 2059 $cm^{-1}$ for $[Rh(CO)_2I_2]^-$, suggesting that the rhodium centre is more electron rich in the triethylphosphine complexes. We have shown that these complexes are active for the double carbonylation of $CH_2I_2$[7] and of allylic halides[8] and so have attempted to increase the rate of carbonylation of methanol by using these complexes and have found that $[RhCl(CO)(PEt_3)_2]$ is an extremely active catalyst precursor for ethanoic acid production. We report the first direct comparison of $[Rh(CO)_2I_2]^-$ with a rhodium phosphine complex under the conditions of 120–150 °C and 27 bar carbon monoxide pressure. The initial carbonylation rates using $[RhCl(CO)(PEt_3)_2]$ and $[Rh(CO)_2Cl]_2$ as sources of rhodium at 120 and 150 °C in the presence of differing water concentrations are shown in Table 1.

The results of Table 1 show that, in the presence of 17.1% m/m $H_2O$ under the mild conditions of 120 or 150 °C and 27 bar pressure (runs 1–4), $[RhI(CO)(PEt_3)_2]$ catalyses the carbonylation of methanol at a rate nearly double that of $[Rh(CO)_2I_2]^-$. Water acts to maintain the catalyst in its active form[9] *i.e.* as a rhodium(I) complex and decreases the formation of inactive rhodium(III) complexes such as $[Rh(CO)_2I_4]^-$ or $[RhI_3(CO)(PEt_3)_2]$. Thus, as shown in Table 1, the rate of carbonylation is dramatically enhanced in the presence of a significant concentration of water. Under lower water conditions (runs 5 and 6), no appreciable benefit is obtained by using $[RhCl(CO)(PEt_3)_2]$ over $[Rh(CO)_2Cl]_2$ as catalyst precursors.

The mechanistic cycle has been studied using high pressure and variable temperature NMR and high pressure IR spectroscopies[10] as well as stoichiometric reactions. Thus, addition of methyl iodide to $[RhI(CO)(PEt_3)_2]$ in $CH_2Cl_2$ leads smoothly to the formation of $[RhMeI_2(CO)(PEt_3)_2]$, which has been fully characterised spectroscopically‡ and by single crystal X-ray diffraction§ (Fig. 1). The methyl group is *cis* to the carbon monoxide, as required for migratory insertion. There have been no previously published crystallographic analyses of complexes of the type $[RhX_2Me(CO)(PR_3)_2]$. However, there are examples of crystal structures of other six-coordinate rhodium phosphine complexes where methyl iodide has been oxidatively added.[11–13] Most have iodide and methyl ligands in mutually *trans* positions.

The isolation of the methyl complex for a catalytically active system is rather unusual since, generally, the insertion of carbon monoxide into the Rh–C bond is extremely rapid. For $[Rh(CO)_2I_2]^-$, the methyl complex has a very short lifetime and has only been detected as a transient by IR spectroscopy in neat methyl iodide,[14] whilst for the related $[RhCl(CO)(PPh_3)_2]$, oxidative addition of methyl iodide gives the six-coordinate $[RhMeClI(CO)(PPh_3)_2]$, but this is in equilibrium with the five-coordinate insertion product, $[RhClI(MeCO)(PPh_3)_2]$.[15] Presumably the high electron density on the metal in $[RhMeI_2(CO)(PEt_3)_2]$ is responsible for the less facile methyl migration in this case. Despite the stability of the methylrhodium(III) complex, preliminary kinetic studies suggest that oxidative addition of MeI is still rate determining. The catalytic reaction

**Table 1** Results of carbonylation experiments[a]

| Run | *T*/°C | Rhodium source | Initial water (% m/m) | Initial rate/ mol $dm^{-3}$ $h^{-1}$ |
|---|---|---|---|---|

[a] Experiments were carried out in a 300 $cm^3$ Hastelloy B2 autoclave equipped with a ballast vessel, Magnedrive stirrer, liquid injection facility and cooling coils. For reactions requiring 17.1% $H_2O$ m/m, a solution of MeCOOH (987 mmol), MeOAc (474 mmol), $H_2O$ (1.82 mol) and MeI (396 mmol) was charged to the vessel. Similarly for reactions requiring 3.2% $H_2O$ m/m, a solution of MeCOOH (1.75 mol), MeOAc (286 mmol), $H_2O$ (354 mmol) and MeI (396 mmol) was charged to the vessel. The reaction vessel was heated to the required temperature whilst stirring under *ca.* 5 bar CO pressure. Once the desired temperature had been reached, the rhodium source, dissolved in MeOAc (13.5 mmol) and $MeCO_2H$ (117 mmol), was injected into the autoclave to initiate the reaction. The autoclave was pressurised to 27 bar and stirred at 600 rpm. The rate of carbonylation was monitored by recording the rate of carbon monoxide uptake from a ballast vessel every 2 s. [b] Assumed to form $[RhI(CO)(PEt_3)_2]$ rapidly under the reaction conditions. [c] Forms $[Rh(CO)_2I_2]^-$ under the reaction conditions.

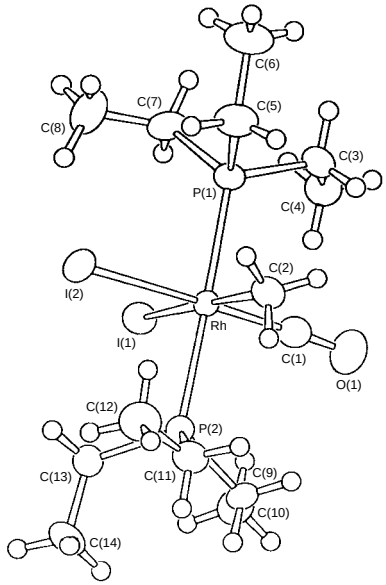

**Fig. 1** X-Ray crystal structure and numbering scheme for [$RhMeI_2$-$(CO)(PEt_3)_2$]

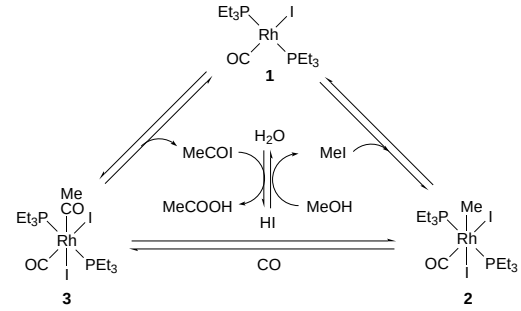
is zero order in $p_{CO}$ and first order in [MeI]. However, we have found that at 298 K the rate of oxidative addition of MeI for $[RhI(CO)(PEt_3)_2]$ ($1.37 \times 10^{-3}$ dm$^3$ mol$^{-1}$ s$^{-1}$) is 57 times faster than that for $[Rh(CO)_2I_2]^-$ ($2.39 \times 10^{-5}$ dm$^3$ mol$^{-1}$ s$^{-1}$); this compares with 120 times faster[16] for $[Ir(CO)_2I_2]^-$ relative to $[Rh(CO)_2I_2]^-$.

Migratory insertion of carbon monoxide occurs under CO pressure (27 bar) to form $[RhI_2(MeCO)(CO)(PEt_3)_2]$ which has been fully spectroscopically characterised.‡ The rate of the insertion reaction at room temperature and 27 bar is 38 times slower than for $[RhMe(CO)_2I_3]^-$,¶ but this slowing is not sufficient to make the migratory insertion step rate determining at 150 °C (shifts to 1740 cm$^{-1}$, MeOAc, on addition of MeOH). In contrast, for $[Ir(CO)_2I_2]^-$, the insertion reaction is slowed by $10^5$–$10^6$ times[16] compared to $[Rh(CO)_2I_2]^-$ and becomes rate determining.



Heating a solution of $[RhI_2(MeCO)(CO)(PEt_3)_2]$ to 75 °C in the presence of excess methyl iodide and 40 bar carbon monoxide produces a product with a large absorption at 1799 cm$^{-1}$ arising from ethanoyl iodide.[17] This reductive elimination step completes the catalytic cycle. It has been shown that the usual mechanism for the formation of ethanoic acid or methyl ethanoate involves reductive elimination of ethanoyl iodide followed by reaction with water or methanol;[2,18] however, it is unusual to observe ethanoyl iodide. The high electron density on the rhodium centre caused by the electron donating system would be expected to favour the $Rh^{III}$ complex, $[RhI_2(MeCO)(CO)PEt_3)_2]$, over $[RhI(CO)(PEt_3)_2]$ and MeCOI. However, the way in which the reaction is performed allows the catalytic production of MeCOI because the $Rh^{I}$ complex can be trapped by addition of methyl iodide when this is in excess. The overall catalytic cycle for the carbonylation of methanol in the presence of $[RhI(CO)(PEt_3)_2]$, for which each complex has been characterised, is shown in Scheme 1.

At 150 °C the catalyst loses activity over *ca*. 10 min with the formation of $Et_3PO$ and $[Rh(CO)_2I_2]^-$. Current studies are aimed at stabilising the catalyst towards phosphine loss.

We thank Dr Anthony Haynes for useful discussions. We thank B.P. Chemicals Ltd and the EPSRC for a studentship (J. R.) and the European Commission for support under a TEMPUS programme (A. C. B.).

# Mono- and bis-silylated tellurium reagents in silver–telluride cluster synthesis: characterisation of $Ag_{30}Te_{21}$ and $Ag_{46}Te_{29}$ complexes

**John F. Corrigan and Dieter Fenske***

*Institut für Anorganische Chemie der Universität, Engesserstrasse, Geb. Nr. 30.45, D-76128 Karlsruhe, Germany*

**AgCl, dissolved in ether solvents with tertiary phosphine ligands, reacts with a combination of the silylated reagents $Te(SiMe_3)_2$ and $Te(R')SiMe_3$ (R′ = Ph, mes) to yield the cluster complexes $[Ag_{30}(TePh)_{12}Te_9(PEt_2R)_{12}]$ (R = Et 1a, Ph 1b) and $[Ag_{46}\{Te(mes)\}_{12}Te_{17}(PEt_3)_{16}]$ 2 in good yields; the molecular structures of 1a and 2 are described.**

The synthesis of mono-disperse, high-nuclearity metal–chalcogenide nanocluster particles represents a formidable challenge. Recent efforts in this area have lead to the isolation and structural characterisation of zinc– and cadmium–sulfide complexes whose molecular structures may be viewed as fragments of the bulk semi-conducting solid materials.[1] Reports detailing the synthesis of high-nuclearity metal–chalcogenide clusters of the heavier congeners Se and Te are, however, still relatively rare.[2] Our efforts in this area have focussed on low-temperature reactions using the bis-silylated reagents $E(SiMe_3)_2$ (E = S, Se, Te) with copper(I) salts in the presence of solubilising and (kinetically) stabilising phosphine ligands.[3] Controlled reaction conditions are essential in ensuring crystalline cluster formation *vs.* the precipitation of amorphous, bulk phase solids and it has thus been possible to isolate and characterise a variety of copper–chalcogenide clusters. Efforts to extend this chemistry to related silver–chalcogenides using a similar synthetic strategy have however proven unsuccessful to date as the phosphine ligands are unable to sufficiently stabilise the Ag–E molecular cores. We,[4a,b] and others,[4c,d] have however shown that silver–chalcogenolate $[Ag_x(ER)_x$, R = alkyl, aryl] polynuclear complexes are accessible. Using sterically demanding or functionalised chalcogenolato ligands, it has been possible to isolate homoleptic polynuclear complexes.[4c,d] We set out to exploit the utility of both phosphine ligands and tellurium bonded alkyl/aryl chains in order to stabilise various AgTe cores. The synthesis of these complexes offers a rich and varied structural chemistry by modification of the $PR_3$ and TeR centres.[4a,b] We reasoned that the incorporation of additional Te sites within the cluster cores should be possible with the reagent $Te(SiMe_3)_2$ leading to even larger molecular frameworks. Herein we present the initial results of our findings, detailing the synthesis and molecular structures of $[Ag_{30}(\mu_3\text{-}TePh)_{10}(\mu_4\text{-}TePh)_2Te_9(PREt_2)_{12}]$ **1** (R = Et **1a**, Ph **1b**) and $[Ag_{46}\{\mu_3\text{-}Te(mes)\}_{12}Te_{17}(PEt_3)_{16}]$ **2** (mes = $C_6H_2Me_3$).

The preparations of **1** and **2**† are summarised in Scheme 1. Thus when a AgCl–$PR_3$ (1 : 2) solution is treated with 0.5 equiv. of $Te(Ph)SiMe_3$ and 0.25 equiv. $Te(SiMe_3)_2$ at −40 °C, a dark red, homogeneous solution is produced from which crystals of **1** form within a few days at −30 °C (yield: **1a** = 20%; **1b** = 95%). The molecular structures of both **1a** and **1b** are essentially identical, and, owing to the better quality of the X-ray data set of the former, only it will be used in discussing the structural parameters.‡ The cluster core is comprised of 12 tellurolate [$Te(Ph)^-$, Te(1)–Te(12)] and 9 telluride [$Te^{2-}$, Te(13)–Te(21)] ligands in addition to the 30 silver atoms (Fig. 1).[5] The order of addition of the silylated reagents does not affect the yield of product produced. The tellurolate ligands in **1a** adopt both $\mu_3$ [Te(1)–Te(9), Te(11)] and $\mu_4$ [Te(10)–Te(12)] bonding modes. The former exhibit an unsymmetrical pattern of one 'shorter' [2.717(3)–2.826(3) Å], one longer [2.842(3)–2.981(3) Å] and one intermediate Ag–Te bonding distances with Te(9) and Te(11) showing the least deviation [Ag–Te 2.817(3)–2.853(3), 2.790(3)–2.842(3) Å, respectively]. On average, the difference in length between the longest and shortest Ag–Te contacts is 0.14 Å. The $\mu_4$-Te(Ph)–Ag bond lengths in **1** are noticeably longer [2.933(8) Å av.] than their $\mu_3$ counterparts. The nine $Te^{2-}$ ligands [Te(13)–Te(21)] are each six coordinate [Ag–Te 2.703(3)–3.185(3) Å] and atoms Te(14) and Te(16) also exhibit a longer contact to a seventh metal site [3.260(3), 3.229(3) Å, respectively]. A +1 oxidation state can be assigned to the silver atoms and the Ag···Ag contacts [2.849(3)–3.351(3) Å] preclude any strong bonding interactions between them. Of the twelve phosphine bonded silver sites, all exhibit tetrahedral coordination with the exception of Ag(1) and Ag(2) which are trigonal planar. Of the phosphine free silver atoms, Ag(18) and Ag(19) form but two bonds each [Te–Ag–Te 153.1(1) and 153.22(9)°, respectively], whereas atoms Ag(3), Ag(6), Ag(11), Ag(12), Ag(17), Ag(20), Ag(25) and Ag(26) are three coordinate and Ag(9), Ag(10), Ag(13), Ag(14), and Ag(21)–Ag(24) display tetrahedral coordination geometries. This varied coordination about silver contrasts with the solid state structure of the mineral

**Scheme 1**

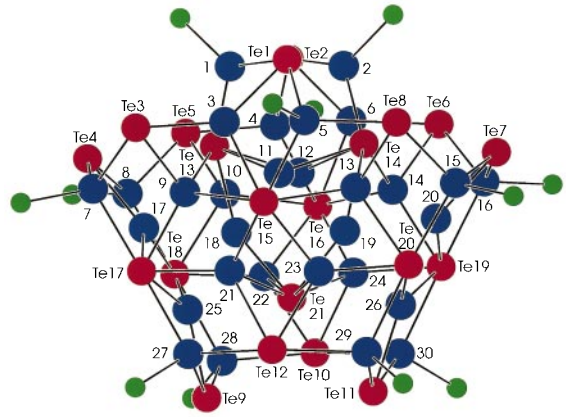

**Fig. 1** Molecular structure of $[Ag_{30}(TePh)_{12}Te_9(PEt_3)_{12}]$ **1a** (carbon atoms omitted; red: Te; blue: Ag; green: P). Silver atoms are labelled with numbers only for clarity. Tellurium atoms labelled Te(1)–Te(12) are the tellurolate ligands. Selected bond lengths (Å): Te–C: 2.13(1)–2.18(2), $\mu_3$-Te(Ph)–Ag 2.717(3)–2.981(3); $\mu_4$-Te(Ph)–Ag 2.878(3)–3.013(3); $\mu_{6/7}$-Te–Ag 2.703(3)–3.229(2), Ag···Ag 2.849(3)–3.351(3).

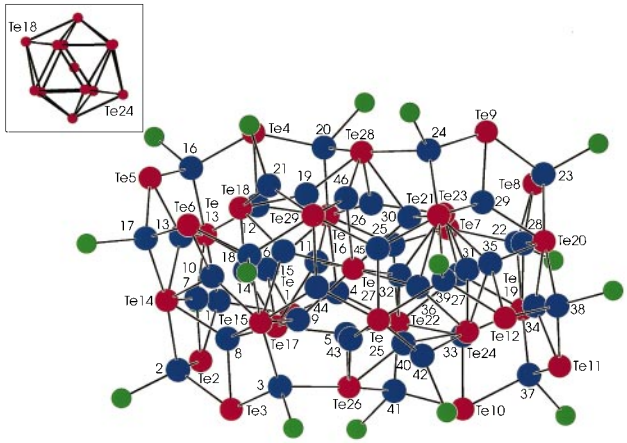

**Fig. 2** The molecular structure of $[Ag_{46}\{Te(mes)\}_{12}Te_{17}(PEt_3)_{16}]$ **2** (carbon atoms omitted; red: Te; blue: Ag; green: P). Tellurium atoms Te(1)–Te(12) are the tellurolate ligands. Selected bond lengths (Å): Te–C 2.139(13)–2.179(11), $\mu_3$-Te(mes)–Ag 2.732(2)–2.947(2), $\mu_6$-Te–Ag 2.688(2)–3.338(2), $\mu_7$-Te–Ag 2.676(2)–3.304(2), $\mu_8$-Te–Ag 2.785(2)–3.294(2), Ag···Ag 2.748(9)–3.377(4).

hessite ($Ag_2Te$) in which all Ag atoms are in tetrahedral sites.[6]

The Ag–Te framework in **1** is less spherical in nature than those observed in related CuTe systems.[7] The latter crystallise with parallel $Cu_nTe_m$ layers yielding a rather close packed arrangement. In **1**, the AgTe planes defined by Te(4)Te(18)-Te(9)Te(17)/Ag(7)Ag(8)Ag(27)Ag(28) and Te(7)Te(19)-Te(11)Te(20)/Ag(15)Ag(16)Ag(29)Ag(30) lie at an angle of 56° to one another.

An analogous reaction as for **1** with the bulkier reagent $Te(mes)SiMe_3$ (Scheme 1) leads to the exclusive formation of $[Ag_{46}Te_{17}(Temes)_{12}(PEt_3)_{16}]$ **2** as dark red–black crystals (yield 85%, Fig. 2). As in **1**, cluster **2** contains a mixture of telluride and tellurolate ligands. There is a pseudo, non-crystallographic twofold rotation axis which bisects the central $Te^{2-}$ [Te(27)] approximately perpendicular to the plane defined by the page (the projection is slightly rotated for clarity). About the central telluride can be found an additional 12 $Te^{2-}$ [Te(15)–Te(18), Te(21)–Te(26), Te(28), Te(29)] arranged to form a slightly distorted [non-bonded, Te···Te 4.523(2)–5.288(2) Å] centered icosahedron (Fig. 2, insert). Eight silver metal atoms are bonded to Te(27) [2.814(2)–3.198(2) Å] and are found within the icosahedral frame with six additional Ag atoms [Ag(4), Ag(5), Ag(25), Ag(26), Ag(44), Ag(45)] lying within its deltahedral faces. Twenty of the thirty $Te_2$ edges of the icosahedron are spanned by Ag atoms. This central $Ag_{36}Te_{13}$ unit is surrounded by 16 tellurium [12 × $Te(mes)^-$, 4 × $Te^{2-}$] and 12 Ag centres. As observed in **1**, the coordination number about the silver centres varies from two to four.

As in **1**, the metal core is stabilised with $PR_3$ ligands and aromatic groups bonded to the outer tellurium atoms. Indeed, there is a close structural relationship between the outer fragments found in **1** and **2**. The relative arrangement in **1** of atoms Te(3)–Te(5), Te(9), Te(10), Te(12) and Te(13) and the silver atoms bonded to them is also repeated in cluster **2**. Two such fragments share a common 'edge' in **1** whereas in **2** they are separated by the larger inner core. This perhaps reflects the better shielding ability of the bulkier mesityl groups and the additional coordinated $PR_3$ ligands.

The synthetic strategy outlined herein opens the doorway to accessing a variety of silver–chalcogenide clusters. We are currently actively pursuing the generation and characterisation of new and even larger molecular species.

We are grateful to the Deutsche Forschungsgemeinschaft (SFB 195), to the Fonds der Chemischen Industrie and the EU through the HCM program for support of this work. J. F. C. thanks the Natural Sciences and Engineering Research Council (Canada) for a postdoctoral fellowship.

† *Preparation of* **1**: a 0.16 g (1.12 mmol) sample of AgCl was dissolved in 36 ml of dried ether–thf (3 : 1) with 2.2 mmol of $PEt_2R$ (R = Et **1a**, Ph, **1b**) and the clear, colourless solution cooled to −40 °C. 0.13 ml $Te(Ph)SiMe_3$ (0.6 mmol) was added followed by 0.06 ml $Te(SiMe_3)_2$ resulting in a homogeneous yellow reaction solution. The solution was stirred for 1 h while warming to −30 °C gradually darkening in colour to deep red. Crystals of **1** grew within several days at this temperature. Yield: **1a**, 20%; **1b**, 95%. A similar procedure using $PEt_3$ and $Te(mes)(SiMe_3)$ in ether yielded red–black crystals of **2** in 85% yield.

‡ *Crystal data*: for **1a**: $C_{144}H_{240}Ag_{30}P_{12}Te_{21}{\cdot}OC_4H_{10}$, red plate fragment, 0.15 × 0.19 × 0.23 mm, $M$ = 8332.8, monoclinic, space group $P2_1/n$, $a$ = 28.614(6), $b$ = 28.163(6), $c$ = 29.296(6) Å, $\beta$ = 93.56(3)°, $U$ = 23580(8) Å$^3$, at 200 K, $Z$ = 4, $D_c$ = 2.347 g cm$^{-3}$, $\mu$ = 5.089 mm$^{-1}$, $2\theta_{max}$ = 52.2°, 40888 independent reflections measured ($R_{int}$ = 0.1266) on a STOE IPDS diffractometer. The structure was solved by direct methods and refined on $F^2$ using SHELXTL software. All P, Ag and Te atoms were refined anisotropically, all C atoms isotropically to yield $R$ = 0.0900, $wR_2$ = 0.2345, GOF = 1.073 for 18883 data [$F_o > 4\sigma F_o$]. Phenyl rings were refined as rigid groups, the bond distances of the solvent molecule and the P–C distances about P(1) and P(2) were each refined with common values.

**1b**: $C_{192}H_{240}Ag_{30}P_{12}Te_{21}$, red plate fragment, 0.06×0.15×0.20 mm, $M$ = 835.2, monoclinic, space group $P2_1/n$, $a$ = 24.052(5), $b$ = 31.045(6), $c$ = 37.611(8) Å, $\beta$ = 103.33(3)°, $U$ = 27327(9) Å$^3$, at 180 K, $Z$ = 4, $D_c$ = 2.147 g cm$^{-3}$, $\mu$ = 4.398 mm$^{-1}$, $2\theta_{max}$ = 44.5°, 18826 independent reflections measured ($R_{int}$ = 0.1544) on a STOE IPDS diffractometer. The structure was solved by direct methods and refined as for **1a** to yield $R$ = 0.1392, $wR_2$ = 0.3698, GOF = 1.050 for 12081 data [$F_o > 4\sigma F_o$]. Phenyl rings were refined as rigid groups and not all C atoms could be located in the difference Fourier map.

**2**: $C_{204}H_{372}Ag_{46}P_{16}Te_{29}{\cdot}3OC_4H_{10}$, dark red block, 0.7 × 0.7 × 0.7 mm, $M$ = 12205.3, triclinic, space group $P\bar{1}$, $a$ = 19.894(4), $b$ = 25.672(3), $c$ = 37.771(3) Å, $\alpha$ = 72.94(1), $\beta$ = 81.17(2), $\gamma$ = 68.37(2)°, $U$ = 17121(4) Å$^3$, at 180 K, $Z$ = 2, $D_c$ = 2.368 g cm$^{-3}$, $\mu$ = 5.093 mm$^{-1}$, $2\theta_{max}$ = 44.5°, 42728 independent reflections measured ($R_{int}$ = 0.0905) on a STOE IPDS diffractometer. The structure was solved by direct methods and refined as for **1** to yield $R$ = 0.0663, $wR_2$ = 0.1771, GOF = 1.057 for 33664 data [$F_o > 4\sigma F_o$]. Atoms Ag(21) and Ag(42) were disordered over two sites and each refined satisfactorally with 70 : 30 and 65 : 35 relative occupancies, respectively. CCDC 182/558.

# Solution volume studies of a deep cavity inclusion complex of $C_{60}$: [*p*-benzylcalix[5]arene ⊂ $C_{60}$]

**Neil S. Isaacs,*[a] Peter J. Nichols,[b] Colin L. Raston,*[b] Christian A. Sandova[b] and David J. Young*[c]**

[a] *Department of Chemistry, University of Reading, PO Box 224, Reading, UK RG6 2AD*

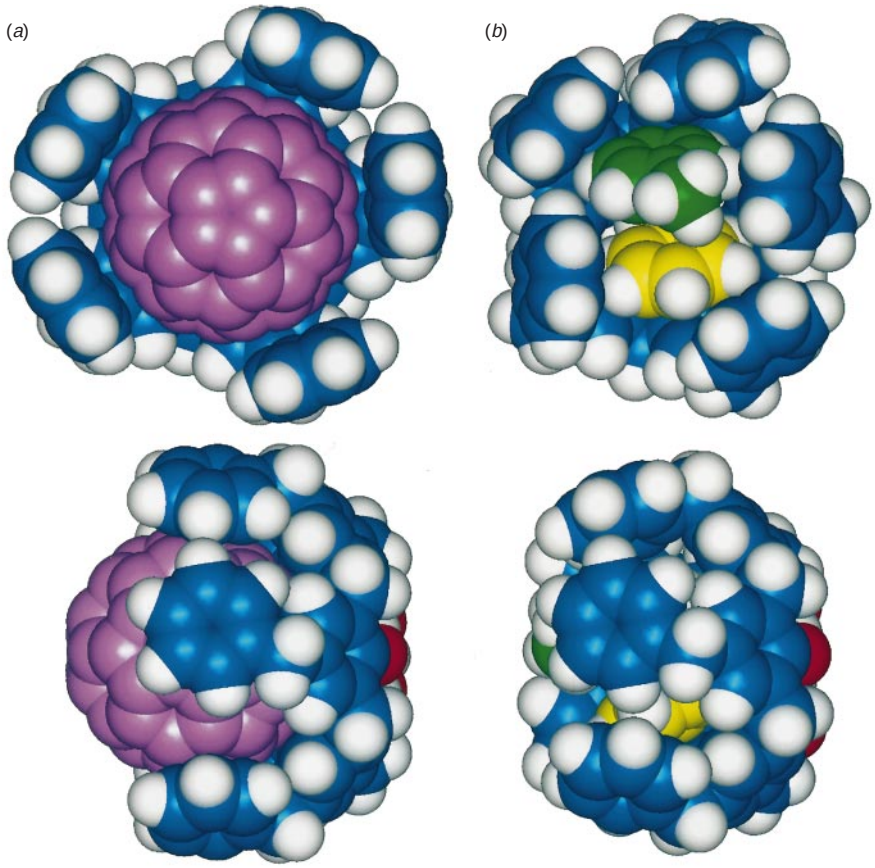
[c] *Faculty of Science and Technology, Griffith University, Nathan, Brisbane, Queensland 4111, Australia*

**Molecular complexation of $C_{60}$ with *p*-benzylcalix[5]arene in toluene is associated with a partial molar volume change of +195 cm$^3$ mol$^{-1}$ which is consistent with the displacement of two toluene molecules from the cavity of the calixarene.**

Inclusion of fullerenes in container molecules is of interest in the direct purifying of fullerenes from fullerite, and the opportunities that such host–guest complexes have as nanometer size components in building up novel supramolecular arrays.[1–17] Further developments require gaining control over inherently weak host–guest interactions which are in competition with fullerene–fullerene, solvent–host and guest–solvent interactions, and is compounded by the essentially spherical, non-polarised nature of $C_{60}$.[10,15] Container molecules which form discrete complexes with $C_{60}$ and/or $C_{70}$ include calix[6,8]arenes,[5–13] cyclotriveratrylene (CTV),[14,15] γ-cyclodextrin,[16] and azacrown ethers.[17] Only three of these complexes have been structurally authenticated, a bis-mixed *p*-methyl/iodo-substituted calix[5]arene complex with $C_{60}$,[13] and two complexes of CTV with $C_{60}$ of composition $(C_{60})_n$(CTV), ($n$ = 1, 1.5). The latter structures are based on 'ball-and-socket' local host–guest supermolecules with the gross structures dominated by fullerene–fullerene interactions. The solid-state structure of another complex, the 1:1 complex of *p*-Bu$^t$-calix[8]arene with $C_{60}$ has been predicted as containing a micelle-like triangular aggregate of three fullerenes shrouded by three host molecules, each in a double cone conformation.[10] Similar micelle-like species are formed in the confines of a mesoporous silica with mean pores size diameter of 5.4 nm.[12]

In solution there is some evidence for the formation of solvated host–guest supermolecules[13,15] which can lead to micelle-like species.[15] We now further explore host–guest chemistry in solution for $C_{60}$ in the presence of *p*-benzylcalix[5]arene **1** using high-precision densitometry to measure the change in partial molar volume ($\Delta\bar{V}$) on complexation. This technique has been recently employed to measure the partial molar volume of $C_{60}$ in different organic solvents[18] but has not been used previously for studying supramolecular assemblies in



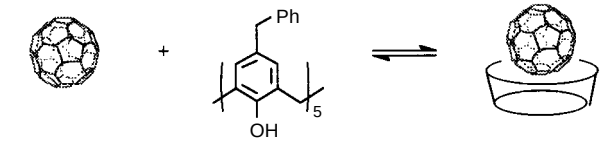


**Fig. 1** Space filling molecular mechanics structures of (*a*) [*p*-benzylcalix[5]arene ⊂ $C_{60}$] and (*b*) [*p*-benzylcalix[5]arene ⊂ $(toluene)_2$] [Insight II/Discover with standard CVFF forcefields; structure minimised using the conjugate gradients algorithm with a convergence criterion of the average derivative being < 0.001 kcal mol$^{-1}$ (1 cal = 4.184 J]

$C_{60}$ **1** **2**

**Scheme 1**

solution. Choice of calixarene **1** was based on the availability of a deep cavity with a large internal surface area offering π-cloud overlap with the electron deficient fullerene. Furthermore, this overlap is optimised by the matching of the $C_5$ symmetry of the calixarene cavity with a $C_5$ symmetry axis of the fullerene.

*p*-Benzylcalix[5]arene, **1**, was prepared by a variation of a published procedure.[19] On heating a toluene solution of **1** with $C_{60}$ (1 : 1) the characteristic magenta colour of $C_{60}$ in solution changed to red and crystals slowly precipitated on cooling, albeit as the 2 : 1 calixarene to $C_{60}$ complex.† However, titration of $C_{60}$ with **1** in toluene revealed the appearance of a shoulder in the visible spectrum around 450 nm which was unchanged for concentrations of **1** in excess of 1.0 equiv., indicating 1 : 1 stoichiometry of the complex in solution. This is consistent with a recent finding that a *p*-methyl/iodo-substituted calixarene forms a 1 : 1 complex in solution,[13] while a 2 : 1 complex precipitates from solution. $^1$H and $^{13}$C NMR analysis of solutions of **1** and $C_{60}$ (1 : 1) revealed little change on complexation other than a small downfield shift (0.2 ppm) in the $^1$H resonance for the phenolic protons which is consistent with proximity of the O centres to the electron deficient $C_{60}$ and a commensurate upfield shift (0.3 ppm) in the $^{13}$C resonance for $C_{60}$.[13]

Molecular modelling of the 1 : 1 complex (Fig. 1) shows that while much of the fullerene is in the cavity of the calixarene an area is exposed for intimate contact with a fullerene of another supermolecule. In solution, the absence of an interfullerene resonant band at 460 nm[15] rules this out and the spectrum is similar to that obtained on mixing $C_{60}$ in toluene with a toluene solution of an allyl substituted CTV where there is formation of solvated host–guest species.[15] Interestingly, this CTV is like *p*-benzylcalix[5]arene in having extended arms. When a toluene solution of **1** is added to a mesoporous silica containing pre-mobilised $C_{60}$, a broad band at 460 nm appears which is assigned as an interfullerene resonant transition.[12] Thus in the confines of the mesopores there is some association of the supermolecules *via* fullerene–fullerene interactions, but not so in solution, and also in the solid state where the fullerene is most likely completely shrouded by two calixarenes.

The partial molar volumes of $C_{60}$, calixarene **1** and the 1 : 1 complex **2** in toluene at infinite dilution (Scheme 1) were determined using a Parr high-precision, vibrating-tube density meter at 25.35 ± 0.05 °C. At least three density measurements were made at three–six concentrations over the range 6.5 × 10$^{-4}$ –2.0 × 10$^{-3}$ M and extrapolated to $c$ = 0. The partial molar volume measured for $C_{60}$ in toluene was in good agreement with the range given by Ruelle *et al.* (358.3–364.4 cm$^3$ mol$^{-1}$).[18] The partial molar volume of **2** was calculated assuming a negligible dissociation to $C_{60}$ and calixarene as indicated by the UV spectrum. The uncertainties in the volume measurements for $C_{60}$ and **2** are perhaps somewhat larger than usual (5% for $C_{60}$, 4% for **2**) owing to the sparing solubility of these compounds in toluene which precludes density measurements over a wider concentration range.

The reaction volume ($\Delta\bar{V}_{c\rightarrow 0}$) on complex formation is, therefore, +195 cm$^3$ mol$^{-1}$ which is equivalent to the partial molar volume of *ca*. 1.8 toluene molecules.[18] This value can be interpreted in terms of the displacement of two toluene molecules from the cavity of the calixarene by $C_{60}$. This interpretation is supported by molecular mechanics using BIOSYM software.[20] Several minimised conformations for toluene molecules within the *p*-benzylcalix[5]arene cone were found. In particular, the toluene molecules with the same orientation (either both methyl groups orientated towards or away from the O rim) or reverse orientations (as shown in Fig. 1) gave rise to similar system energies. The minimised complex [*p*-benzylcalix[5]arene ⊂ $C_{60}$] and two free toluene molecules is favoured energetically by approximately 28 kcal mol$^{-1}$ over the minimised complex comprising [{*p*-benzylcalix[5]arene} ⊂ (toluene)$_2$] and free $C_{60}$.

One practical implication of this positive reaction volume is that elevated pressures would, perhaps unexpectedly, disfavour complex formation.

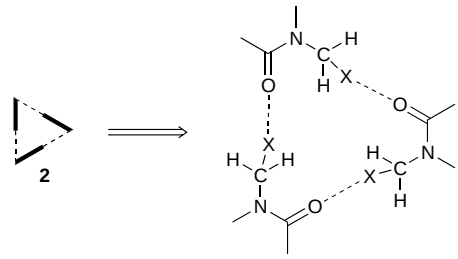
**The title compound has a C–H··O hydrogen bond-mediated trigonal network structure that leads to octupolar NLO behaviour in the solid state.**

Crystal engineering,[1] or solid state supramolecular synthesis,[2] is increasingly turning towards the design of functionalised materials.[3] Non-linear optical (NLO) properties, with such applications as second harmonic generation (SHG) or electrooptic (EO) modulation have attracted interest.[4] Traditional crystal engineering strategies towards SHG-active materials have been based on preventing the crystallisation of molecules with large dipole moments in an antiparallel and therefore centrosymmetric arrangement. These dipolar molecules suffer from other disadvantages.[1,5] Recently, a new class of SHG-active substances, octupolar molecules, have been proposed and been shown to display significant NLO behaviour at the molecular level.[6] The engineering problem at the crystalline or supramolecular level amounts to steering the structure of an appropriately substituted trigonal molecule **1** towards the trigonal, non-centrosymmetric network structure **2** characterised by specific interactions between unlike groups in the molecular skeleton, rather than towards the hexagonal, centrosymmetric network **3** characterised by close approaches between like groups.[7] Of course, the majority of trigonal molecules **1** adopt neither structure **2** nor **3** and instead adopt a trivial close-packed structure, and this renders the engineering problem more challenging.



**2** **1** **3**

Some of us have reported the crystal structure of the 1 : 1 complex of trimethyl isocyanurate **4** and 1,3,5-trinitrobenzene wherein the respective components are in distinct layers, each possessing the trigonal symmetry of **2**.[8] Specifically, the molecules of **4** are linked *via* C–H··O mediated supramolecular synthon **5** that may be readily identified in network **2**.[2b] In general, single component crystals are preferred to molecular complexes for NLO applications because of issues connected with material purification, crystal growth and optical characterisation in both solution and the solid state. Therefore we turned our attention to the symmetrical isocyanurates, all of which have alternating C–H··O donors and acceptors in the molecular structure. Such an alternation is a prerequisite for the formation of network **2**. In pure **4**, the structure consists of a complicated three-dimensional networking of C–H··O hydrogen bonds.[9,10] In triethyl isocyanurate **6**, however, the trigonal network **2** is not

**4** R = Me
**6** R = Et
**7** R = Bn

**2**

**5** X = H
**8** X =

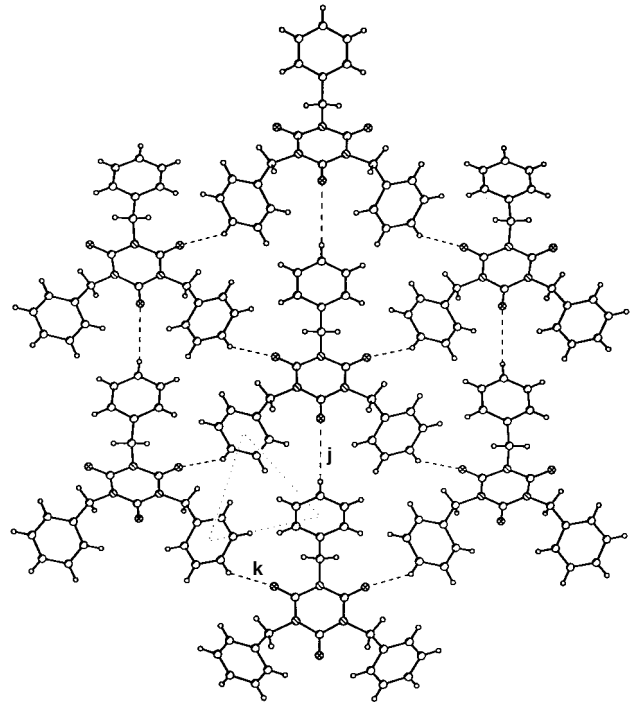


**Fig. 1** A view of the crystal structure of tribenzyl isocyanurate **7** down [010] to show the trigonal network structure. C–H··O hydrogen bonds are indicated as **j** and **k**, while herringbone interactions are indicated as dotted lines. Notice the occurrence of supramolecular synthon **8** and the overall non-centrosymemtry of the network.

found;[10] the very low acidity of the C–H groups probably leads to non-adoption of the desired structure, based as it is on C–H··O hydrogen bonds.

Keeping such carbon acidity considerations in mind,[11] tribenzyl isocyanurate **7** was examined. The crystal structure (Fig. 1) shows that the desired non-centrosymmetric trigonal network has been obtained.‡ The structure is characterised by synthon **8**, which is the tris-phenylogous extension of synthon **5**. Fig. 2 shows that **7** is far from planar. With respect to the central heterocyclic ring, two benzyl groups point in one direction whilst the third points in the other, leading to an overall 'chair'-shape. The layer structure in **7** is corrugated as shown in Fig. 3, with two distinct intralayer C–H··O hydrogen bonds. Molecules translated along [001] are connected by the interaction designated **j** in Fig. 1 (*D*, 3.91 Å; *d*, 2.97 Å; $\theta$, 145°) to form chains. Adjacent chains are *n*-glide related and connected by interaction **k** (*D*, 3.43 Å; *d*, 2.51 Å; $\theta$, 142°). The chains are additionally interconnected by herringbone interactions (dotted lines in Fig. 1). The corrugated layers are stacked along [010] and weak C–H··π interactions (*D*, 3.51, 3.63 Å; *d*, 2.73, 3.32 Å; $\theta$, 139, 150°) complete the structure.

The non-centrosymmetric nature of crystalline **7** was confirmed by a visible SHG powder signal at 1.064 μm of the order of 0.1 × urea. The nonlinear characterisation of **7** at the molecular level was performed by harmonic light scattering (HLS) measurements in solution.[5,12,13] The nonlinear $\beta = \sqrt{\langle\beta^2\rangle}$ HLS coefficient measured at 1.064 μm in $CHCl_3$ is (10 ± 2) × $10^{-30}$ esu, which is comparable to that of the classical dipolar PNA molecule under the same measurement conditions. We note that **7** is completely transparent in the visible region. The weak second harmonic signal of **7** can be ascribed to poor charge transfer, the methylene groups preventing conjugation between the peripheral and central rings. The octupolar structure of **7** was confirmed by a HLS depolarisation measurement and the depolarisation ratio[14] $D = 0.65$ is close to the theoretical value of 2/3 for purely octupolar molecular structures.[14] In the context of planar octupolar structures, the orientational isotropic averaging relation[5] $\langle\beta\rangle = 8/21\beta_{\gamma\gamma\gamma}$ leads to a predominant molecular nonlinear coefficient $\beta_{\gamma\gamma\gamma} = 16.2 \times 10^{-30}$ esu. The theoretical crystalline nonlinear coefficient was inferred from the molecular hyperpolarisability using the oriented gas model. From the geometry of the unit cell, the overall norm of the macroscopic coefficient is 96 × $10^{-9}$ esu.

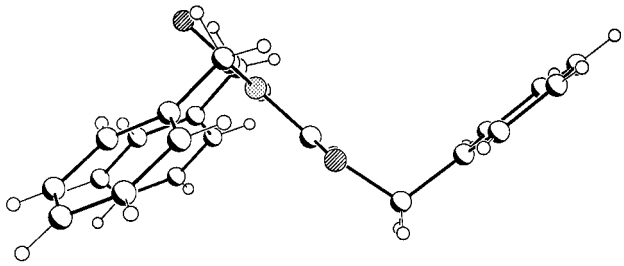

**Fig. 2** View of an individual molecule of **7** to show its non-planar character. Nitrogen and oxygen atoms are shown as dotted and hatched circles.

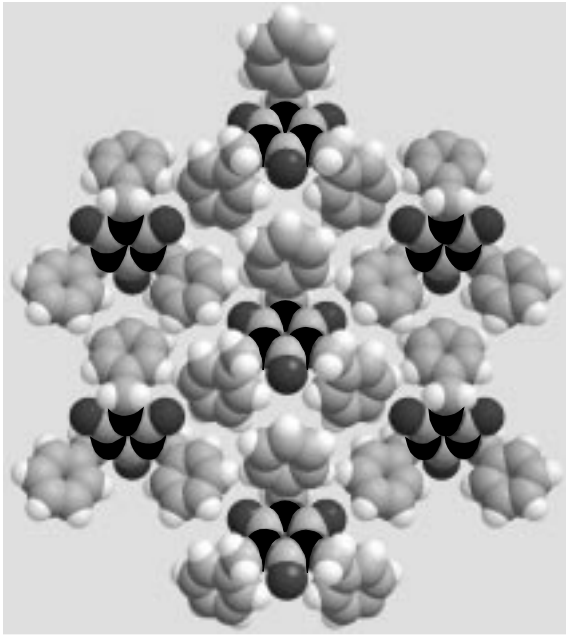

**Fig. 3** Space-filling view of the network structure shown in Fig. 1. Notice the corrugation in the layer structure.

This work describes a successful application of the supramolecular retrosynthetic strategy for the design of an octupolar nonlinear crystal and shows that network structures can be developed with the supposedly weak C–H··O interactions. Further molecular engineering that seeks to optimise the electronic charge transfer is necessary, but such manipulations must keep the favourable crystal packing intact and this is not a trivial exercise, involving as it does a carry-over of molecular symmetry into crystal symmetry or pseudosymmetry.

# Synthesis of direct templated aligned mesoporous silica coatings within capillaries

**Maria E. Raimondi,[a] Thomas Maschmeyer,[b] Richard H. Templer[a] and John M. Seddon*[a]**

[a] *Department of Chemistry, Imperial College, London, UK SW7 2AY*

**Mesoporous liquid-crystal templated silica forms intact coatings with channels adopting a curious alignment, when synthesised within thin capillaries.**

The design of tailor-made mesoporous structures, templated by assemblies of surfactant molecules, has attracted a great deal of interest from materials scientists and chemists alike. The synthesis and structural characterisation of one particular family of silica-based mesoporous materials, denoted M41S, is now well documented.[1,2] These materials are templated under alkaline conditions, at elevated temperatures, in the presence of cationic quaternary ammonium surfactants. Several other synthetic procedures employing different surfactant templates, silica precursors and/or reaction conditions to prepare similar mesoporous products, have been described in the literature.[3–6] Most of the synthetic procedures use low surfactant concentration regimes, and rely on a co-precipitation process whereby the surfactant micelles are trapped within the silica, providing a structure-directing environment for the mesostructured solid.

By contrast, in our work gels containing relatively high concentrations of a non-ionic polyoxyethylene surfactant are used as a 'direct' templating medium for the formation of hexagonal mesoporous silica. The synthetic method was first described by Attard *et al.*,[7] and is termed true liquid crystal templating (TLCT). Their calcined products, templated using octaethylene glycol monododecyl ether ($C_{12}EO_8$) consisted of hexagonal arrays of 28 Å diameter channels, as seen by transmission electron microscopy, with a *d*-spacing of 34 Å (seen by powder X-ray diffraction). The arrays of pores in the TLCT materials strongly resembled those seen for MCM-41, the hexagonal M41S analogue. $N_2$ BET adsorption measurements showed that the calcined mesoporous silica had a specific surface area of 1400 $m^2\ g^{-1}$. Our synthetic mixtures were closely analogous to those used by Attard *et al.*,[7] consisting of an *n*-alkyl, octaoxyethylene surfactant template in an acidic TLCT system with tetramethylorthosilicate (TMOS) as the silica precursor. Two different surfactants were used as templates: octaethylene glycol monododecyl ether ($C_{12}EO_8$) and octaethylene glycol monodecyl ether ($C_{10}EO_8$). The weight ratio of the components in both synthetic mixtures was 1 $C_nEO_8$ : 1 $H_2O$ (pH 2) : 2.11 TMOS ($n$ = 10 or 12), and the hydrolysis/polymerization reaction was carried out overnight under vacuum at room temperature. The mesoporous product obtained from these mixtures was transparent, with the same characteristic optical texture under the polarising microscope as previously observed by Attard *et al.*[7]

The synthesis of a single, monolithic mesoporous structure, containing aligned pores, is a particularly exciting goal. A material of this kind would have potential applications in nanoscale engineering, separation technology, microelectronics, biomaterials engineering and catalysis. In biological systems, control of hierarchical ordering in biomineralization processes is achieved by the use of organic templates and confinement by surfaces such as membranes. Various attempts at aligning MCM-41 type materials with a view to producing monoliths (monodomain samples) have been described in the literature; such work could lead to an extension of the applications of the powder-like products usually obtained.[8–11] The alignment of these mesoporous films relied on heterogeneous nucleation of the surfactant/inorganic precursor onto the aligning surface being favoured over precipitation (homogeneous nucleation) within the bulk solution.

To produce alignment of the TLCT material, we inserted the synthesis gel into a 0.5 mm (internal diameter) glass or quartz capillary by capillary action. The capillary was left with one end dipping into the synthesis gel and the assembly was placed under vacuum overnight, coating the inside walls of the capillary with birefringent mesoporous material which was stable to removal of the template by calcination at 500 °C. Polarising microscopy on the calcined quartz capillary gave similar optical textures to the as-synthesized material, with enhanced colours. A void in the centre of the capillary was clearly visible and the coating was continuous. No discernible difference between coatings on glass and quartz walls was observed, indicating that the precise atomic arrangement of the silica within the capillary walls does not influence the alignment.

Very well aligned six-spot patterns were systematically obtained by X-ray diffraction, employing an image intensified CCD-based X-ray detector of our own design,[12] when the beam was passed at right angles to the capillary axis through the top or bottom edges of the coated capillary before calcination. The orientation of the reciprocal lattice shows that in real space the channels are arranged on a hexagonal lattice, one face of which is parallel to the capillary wall [Fig. 1(*a*)]. After calcination these six-fold spots [corresponding to the (10) reflections] were more intense, and two higher orders [the (11) and the (20) reflections] of the hexagonal diffraction pattern became visible. This implies that calcination results in increased local ordering of the mesoporous product. Both the X-ray diffraction and the polarising microscopy results suggest that the channels of the as-synthesised and calcined products are arranged in rings, or a tight coil, as depicted in Fig. 1(*a*).

When the X-ray beam was passed through the capillary at positions marginally closer to its centre, the diagonal spots in the six-fold pattern spread into arcs, suggesting that the hexagonally packed channels twist and/or bend within their coiled arrangement, *cf.* Fig. 1(*b*). When the beam was passed centrally through the capillary, no diffraction spots were observed. The alignment experiment was found to be reproducible using both $C_{10}$ and $C_{12}$ POE surfactant systems. The *d*-spacings of the materials were 40 and 45 Å before calcination, and 35 and 38 Å after calcination, respectively, for the two chain lengths. The corresponding lattice parameters for the two templated materials were respectively 46 and 52 Å before calcination, and 40.5 and 44 Å after calcination.

For both as-synthesised and calcined products, a slight distortion away from hexagonal symmetry, presumably induced by the surface alignment interactions, was observed. A similar distortion has recently been observed for films of mesoporous silica aligned on mica and graphite surfaces.[9] The fact that the coating remained intact after calcination suggests that the channels in the coating must have outlets through which the organic phase can escape, without disturbing the structure. We

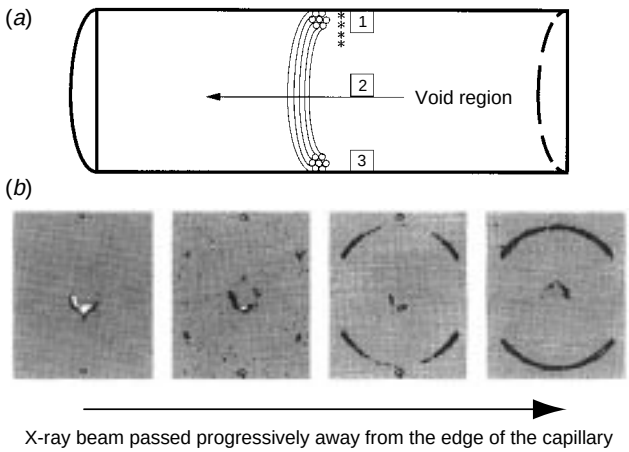

**Fig. 1** (*a*) Schematic longitudinal section of a coated capillary showing hexagonally packed channels of mesoporous $SiO_2/C_nEO_8$ product lining the capillary walls ($n$ = 10 or 12). Six-spot patterns were obtained when the X-ray beam was passed perpendicularly through the capillary at positions (1) and (3); no diffraction pattern was obtained when the X-ray beam was passed through the centre of the capillary (2). (*b*) Sequence of X-ray diffraction patterns obtained for the aligned $SiO_2/C_{10}EO_8$ composite coating when the X-ray beam crossed the capillary at positions shown by asterisks in (*a*). (*c*) Pattern obtained for the calcined sample when the X-ray beam was passed through the edge of the capillary.

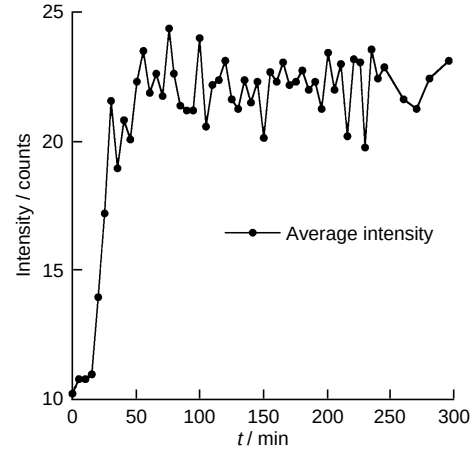

**Fig. 2** Plot of average diffraction spot intensity *versus* time for an *in situ* X-ray diffraction experiment to probe the kinetics of the alignment process

propose that the channels are in fact spiralling in tight coils from one end of the coating to the other, with an outlet at either end, rather than consisting of individual closed rings.

When the alignment experiment was carried out using capillaries treated with phenyltrimethoxysilane (to render the surfaces hydrophobic), both polarising microscopy and X-ray diffraction suggest that the alignment of the product was severely disturbed. The nature of the supporting surface is therefore important for successful alignment. However, it should be noted that the alignment effect is not observed when the synthesis mixtures were spread in a thin layer on a flat piece of glass or quartz and allowed to react under vacuum, under identical conditions to those used for the capillary alignment experiments. This indicates that the alignment is predominantly due to confinement within the capillaries.

The kinetics of self-assembly were followed using *in situ* X-ray diffraction. The intensity of the X-ray diffraction *versus* time is plotted in Fig. 2 for one of the six spots of the aligned pattern (obtained when passing the beam through the edge of the capillary). An exposure was taken every five minutes over a period of 3 h, and a 'box integration' was made on the same area of each pattern (containing the diffraction spot) to obtain the intensity data. The data show that the self-assembly occurs over a period of about 15 min. Interestingly, there were no patterns other than the aligned six-fold spot pattern observable throughout the experiment, indicating the observed alignment to be both the kinetically and thermodynamically favoured arrangement.

In this work, TLCT has been found to be a suitable method for producing aligned mesoporous siliceous materials. The results obtained show that macroscopically aligned coatings can be made from TLCT systems, simply by confining the synthesis mixtures in a capillary. The coatings, which are systematically and reproducibly obtained, contain coils of aligned mesopores, lining the walls of the capillary. The aligned coatings of composite product are stable to calcination (removal of the organic template) at 500 °C. The kinetic investigations of the system show that there are no detectable intermediate structures between gel hydrolysis and the final aligned coating.

M. E. R. thanks the EPSRC for a studentship and T. M. thanks the EU for a TMR Fellowship. Helpful discussions with Professor C. R. A. Catlow are gratefully acknowledged.

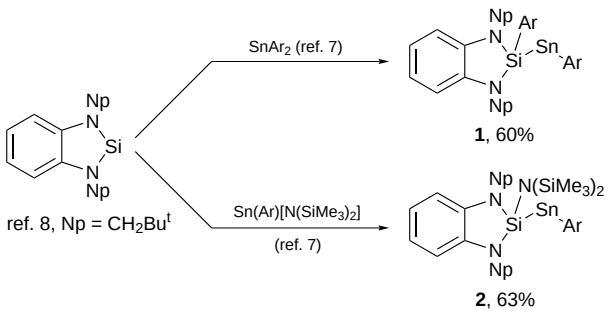
# Synthesis and characterisation of the first stable, heteroleptic silylstannylenes†

**Christian Drost, Barbara Gehrhus, Peter B. Hitchcock and Michael F. Lappert***



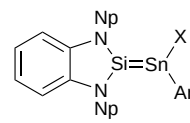
*The Chemistry Laboratory, University of Sussex, Brighton, UK BN1 9QJ*

**Treatment of the silylene Si[$C_6H_4$($NCH_2Bu^t$)$_2$-1,2] with $SnAr_2$ or SnAr[$N(SiMe_3)_2$] yields the thermally stable (silyl)stannylene SnAr[Si{$C_6H_4$($NCH_2Bu^t$)$_2$-1,2}X] [X = Ar 1 or $N(SiMe_3)_2$ 2], having $\delta$ [$^{119}$Sn{$^1$H}] 412 [$^1J$($^{29}$Si–$^{117/119}$Sn) 715/749 Hz] (1) and $\delta$ 621 (2); crystalline 1 has a V-shaped Si–Sn–C skeleton, $l$(Sn–Si) = 2.636(2) Å and two remote Sn···N contacts, av. 2.75 Å (to one $NMe_2$ group of each of the aryl groups).**

Homoleptic heavier group 14 metal(II) (M = Ge, Sn or Pb) compounds in which M is bound to a more electropositive element than carbon (*e.g.*, Si, Ge or a metal) are rare. Two types of group 6 metal complexes are known, [Pb{Mo($\eta^5$-$C_5Me_5$)-$(CO)_3$}$_2$(thf)][1a] [and $\eta^5$-$C_5H_5$ or $\eta^5$-$C_5H_3(SiMe_3)_2$-1,3 analogues] and [Ge{$C_6H_3$($C_6H_2Me_3$-2′,4′,6′)$_2$-2,6}{Mo($\eta^5$-$C_5H_5$)$(CO)_2$}],[1b] as well as some tin(II) phosphides[2a,b] and arsenides,[2b,c] but especially relevant to the present work are three silyl derivatives: [Sn{$Si(SiMe_3)_3$}$_2$]$_2$,[3] [Sn{$Si(SiMe_3)_3$}$_2$($\mu$-Cl)Li(thf)$_3$][4] and Pb[$Si(SiMe_3)_3$]$_2$[3] (thf = $OC_4H_8$). Each of these five X-ray characterised compounds was prepared by a metathetical exchange reaction, using an alkali metal salt of the appropriate ligand and M′$Cl_2$ (M′ = Ge or Pb) or[3] M′[$N(SiMe_3)_2$]$_2$ (M′ = Sn or Pb). Two transient heterobinuclear complexes have been identified spectroscopically or by trapping experiments, Ge($C_6H_2Me_3$-2,4,6)$_2$M′$X_2$ [M′$X_2$ = Si($C_6H_2Me_3$-2,4,6)$_2$[5] or Sn($C_6H_2Pr^i_3$-2,4,6)$_2$],[6] each obtained from tetravalent precursors.

Thermally stable mononuclear heavier group 14 metal(II) compounds $MX_2$ (M = Ge, Sn or Pb and $X^-$ is a mono- or bidentate ligand) are highly reactive, but insertion reactions into M–X bonds leading to new $M^{II}$ complexes MX′$_2$ or M(X)X′ have not previously been reported. The latter (heteroleptic) type is in any event rare.[7]

We now describe the synthesis (Scheme 1) and characterisation of the first heteroleptic (silyl)stannylenes, the crystalline, yellow–orange, diamagnetic SnAr[Si{$C_6H_4$($NCH_2Bu^t$)$_2$-1,2}Ar] **1** and the red–brown SnAr[Si{$C_6H_4$($NCH_2Bu^t$)$_2$-1,2}{$N(SiMe_3)_2$}] **2** [Ar = $C_6H_3(NMe_2)_2$-2,6]. They were obtained by treatment of the yellow silylene Si[$C_6H_4$($NCH_2Bu^t$)$_2$-1,2][8] with for **1** the yellow $SnAr_2$[7] in *n*-hexane at ambient temperature in a slow reaction, or for **2** with the yellow SnAr[$N(SiMe_3)_2$][7] under the same conditions but in a faster reaction.



**Scheme 1** Synthesis of the silylstannylenes **1** and **2** [Ar = $C_6H_3(NMe_2)_2$-2,6]; yields refer to crystalline products (from $Et_2O$ for **1** or *n*-$C_6H_{14}$ for **2**)

The crystalline aryl(silyl)stannylenes **1** and **2** were thermally robust, decomposing before melting only at *ca.* 120 °C. The orange (**1**) and orange–red (**2**) hexane solutions were more labile (**1** > **2**), the former slowly (days) depositing tin at ambient temperature. Their stability may, in part, be due to close contacts between tin and one or more *o*-nitrogen atoms of the $Ar^-$ ligand(s), *cf.* ref. 7. Each of **1** and **2** gave satisfactory microanalytical results, as well as multinuclear NMR spectra.‡ The EI (70 eV) mass spectra showed the parent molecular ion in 2% intensity for **1** and 9% for **2**, as the highest *m/z* peak; the most intense fragment ion was [Si{$C_6H_4$($NCH_2Bu^t$)$_2$-1,2}Ar]$^+$ for **1** and [Si{$C_6H_4$($NCH_2Bu^t$)$_2$-1,2}{$N(SiMe_3)_2$}]$^+$ for **2**. Single crystal X-ray diffraction data established the molecular structure of **1**.§

The $^1$H NMR spectrum of **1** in $C_6D_6$ at 298 K showed separate signals for each of the two $CH_2C\mathit{Me}_3$ groups and several for the eight NMe groups of the two Ar moieties.‡ The corresponding spectrum of **2** in [$^2H_8$]toluene at 298 K revealed two signals for the $SiMe_3$ groups but only one for the two $CH_2C\mathit{Me}_3$ groups and a broad feature for the $NMe_2$ protons. The latter split into two separate signals at 238 K. This indicates that at the higher temperature there is a rapid N → Sn exchange process involving the Sn···NMe-2⇌Sn···NMe-6 fragments, while at the lower temperature only one of the two $NMe_2$ groups is bound to tin, as also found in the solid state for **1**, *vide infra*. This interpretation is consistent (at least for **1**) with the values found for the $^{119}$Sn{$^1$H} NMR spectral chemical shifts: $\delta$ 412 (**1**) and $\delta$ 621 (**2**) in PhMe–$C_6D_6$ at 298 K, which may be compared with $\delta$ 442 for $SnAr_2$ and 422 for SnAr[$N(SiMe_3)_2$] having four- and three-coordinate tin, respectively.[7] A comparison of these results with the two existing (silyl)tin(II) compounds is not possible; since attempts to detect $^{119}$Sn or $^{29}$Si NMR spectral signals in the range −60 to +30 °C for [Sn{$Si(SiMe_3)_3$}$_2$]$_2$ were unsuccessful,[3] while for [Sn{$Si(SiMe_3)_3$}$_2$($\mu$-Cl)Li(thf)$_3$] only the $^{29}$Si chemical shifts were recorded, $\delta$ −6.23 for *Si*($SiMe_3$)$_3$ and $\delta$ −22.14 for Si(*Si*$Me_3$)$_3$.[4] The SiSn $^{29}$Si{$^1$H} NMR spectral chemical shifts in PhMe–$C_6D_6$ at 298 K were found at $\delta$ 48.8 for **1** and $\delta$ −27.8 for **2**. The former signal, unlike the latter, showed readily discernible coupling to tin: $^1J$($^{29}$Si–$^{117}$Sn) 715 Hz and $^1J$($^{29}$Si–$^{119}$Sn) 749 Hz; these values may be compared with $^1J$($^{29}$Si–$^{119}$Sn) of 580 Hz for Sn($SiMe_3$)$Me_3$[9] and 515 Hz for $(SnPh_3)_2SiPh_2$.[10] The $^{29}$Si–Sn coupling in **2** may have been obscured by coupling to the $^{14}$N nucleus of the $N(SiMe_3)_2$ group.

The pathway leading to **1** or **2** may have implicated an initial transient heterodinuclear tin–silicon 'double-bonded' complex **3**, which was rapidly isomerised by a 1,2-shift of X [X = Ar or $N(SiMe_3)_2$] from tin to silicon. Evidence for **3** rests on the

**3a** X = Ar
**3b** X = $N(SiMe_3)_2$

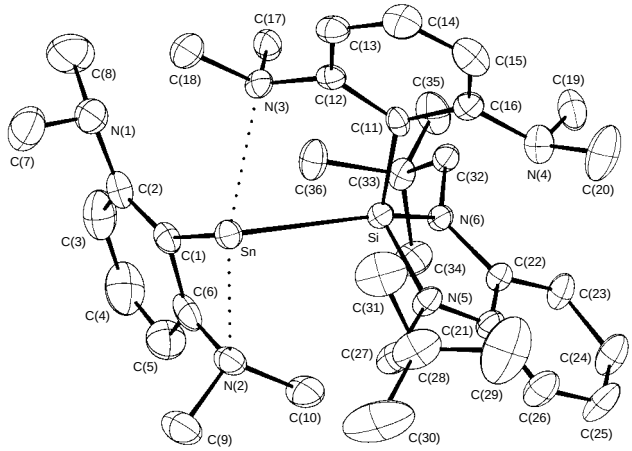


**Fig. 1** CAMERON[16] representation (50% thermal vibration ellipsoids) of the molecular structure of SnAr[Si{$C_6H_4$($NCH_2Bu^t$)$_2$-1,2}Ar] **1** [Ar = $C_6H_3(NMe_2)_2$-2,6]. Selected bond lengths (Å) and angles (°): Sn–C(1) 2.210(8), Sn–Si 2.636(2), Sn···N(3) 2.569(6), Sn···N(2) 2.580(6), Si–C(11) 1.904(8); C(1)–Sn–Si 107.0(2), N(5)–Si–N(6) 91.0(3), C(6)–C(1)–Sn 102.5(6), C(2)–C(1)–Sn 140.0(6).

existence of related kinetically inert homonuclear complexes such as [Sn{$CH(SiMe_3)_2$}$_2$]$_2$,[11] [Sn{$Si(SiMe_3)_3$}$_2$]$_2$[3] and X″$_2$SnSnCl$_2$ [X″ = $CH(SiMe_3)C_9H_6$N-8][12] and the labile heterodinuclear analogue X′$_2$SiGeX′$_2$ (X′ = $C_6H_2Me_3$-2,4,6) **4**.[5] Precedents for a 1,2-aryl shift in group 14 element chemistry include Wagner–Meerwein rearrangements, the photolytic scrambling between $Si_2X'_4$ and $Si_2X'''_4$ (X‴ = $C_6H_3Me_2$-2,6),[13] and the trapping of **4** with Si(H)$Et_3$ generating GeH($SiEt_3$)-($SiX'_3$)X′ with GeX′($SiX'_3$) as the presumed intermediate.[5]

The molecular structure of the crystalline aryl(arylsilyl)-stannylene **1**, illustrated in Fig. 1, shows it to be mononuclear with a V-shaped Si–Sn–C(1) skeleton but with Sn having further remote contacts to N(2) and N(3) (from an $NMe_2$ of each aryl group). The tin bonding environment may thus be regarded as approximating to a distorted trigonal bipyramid, N(2) and N(3) being axial and Si, C(1) and the lone pair in equatorial sites. The Si–Sn–C(1) angle of 107.0(2)° is similar to the 105.6(2)° in $SnAr_2$,[7] and the Sn–C(1) distance of 2.108(2) Å in **1** is likewise close to the av. of 2.214 Å in $SnAr_2$.[7] The Sn–Si bond length of 2.636(2) Å is comparable to the av. 2.672 Å in [Sn{$Si(SiMe_3)_3$}$_2$]$_2$[3] and the 2.681(2) Å in [Sn{Si-($SiMe_3$)$_3$}$_2$(μ-Cl)Li(thf)$_3$].[4] The Sn···N(2) and Sn···N(3) contacts in **1**, av. 2.75 Å, are slightly more remote than in $SnAr_2$ (av. 2.64 Å)[7] or Sn[$C_6H_3$($CH_2NMe_2$)($CH_2NMe_2$)-2,6]Cl (2.56 Å).[14] The aromatic ring containing C(1) is strongly tilted about the Sn–C(1) vector so as to allow N(2) to approach Sn, as evident from the significant deviations from the sp$^2$ values of the C(6)–C(1)–Sn [102.5(6)°] and C(2)–C(1)–Sn [140.0(6)°] angles; these are close to those found in $SnAr_2$, 104.0 and 138.2°.[7] The Sn···N(3) contact from the SiAr group does not involve strain, as shown by the more typical sp$^2$ values for the C(12)–C(11)–Si [118.3(6)°] and C(16)–C(11)–Si [123.5(6)°] angles.

The reactions shown in Scheme 1 provide the first examples of insertion of (i) an unsaturated reagent into an M–Z bond of a carbene or a heavier group 14 element analogue $MZ_2$ generating a new metallene and (ii) a silylene into a metal–aryl or metal–amide bond. As to (ii), the reaction leading to **2** demonstrates that the migratory aptitude of N($SiMe_3$)$_2$ is greater than that of Ar, as also evident from the faster rate of formation of **2** than **1**. Such reactions are likely to be antecedents of a wider series; for example involving the silylene and M[N($SiMe_3$)$_2$]$_2$ (M = Ge, Sn or Pb).[15]

We thank the European Comission for providing fellowships for C. D. and B. G. (category 30), Drs A. G. Avent (NMR) and A. Abdul-Sada (MS) for data and the EPSRC for other support.

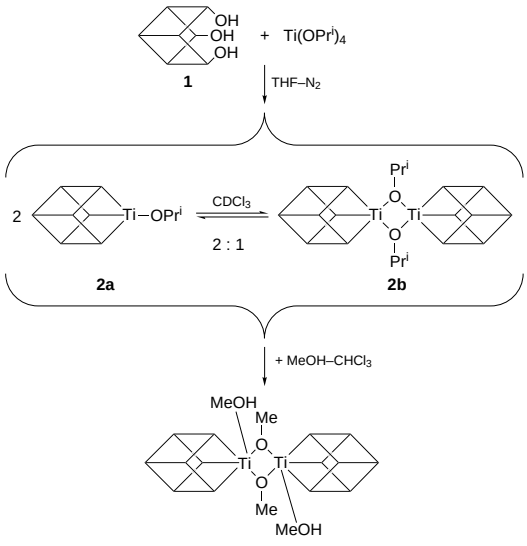
**By synthesising and structurally characterising new soluble titanosilsesquioxanes, and by following the dynamics of epoxidation of cyclohexene in their presence, the tripodally anchored $Ti^{IV}$ active sites in Ti–$SiO_2$ heterogeneous catalysts are modelled structurally and catalytically.**



There is a growing family of titanosilicates (*e.g.* titano-zeolite β,[1] TS-1,[2] TS-2,[3] ETS-10,[4] JDF-L1[5] and Ti-MCM41[6–8]) which are particularly good catalysts for the selective oxidation of organic molecules. Of these, Ti ↑ MCM41 (in which isolated, accessible $Ti^{IV}$ ions are grafted to the inner surface of the mesoporous silica MCM41 using titanocene dichloride as precursor) exhibits high performance in the epoxidation of alkenes under mild conditions.[9,10]

As direct studies of the active site in heterogeneous systems are difficult, modelling studies, by either chemical or computational methods,[11] are essential in any attempts to elucidate the full characteristics of the active site(s). It is therefore desirable to prepare soluble molecular titanosilicates, especially since previously a similar strategy has proved helpful in the elucidation of the nature of the active site in Os- and Cr-containing silicas.[12]

We extend earlier modelling studies[13,14] by going beyond the simulation of just the first step of anchoring titanocene dichloride to the silica surface; the coordination environment after removal of the cyclopentadienyl ligand is modelled by reacting the well characterised cubic trisilanols [(c-pentyl)$_7$-$Si_7O_9(OH)_3$], **1a**, and [(c-hexyl)$_7Si_7O_9(OH)_3$], **1b**, with titanium tetra(isopropoxide) in tetrahydrofuran (THF) (Scheme 1).†

Three of the four titanium isopropoxide ligands of the trisilanols were substituted yielding titanosilsesquioxane **2** of formula [(c-pentyl)$_7Si_7O_9Ti(OPr^i)]_n$·THF with loosely coordinated THF molecules. On extraction in hexane and recrystallisation from chloroform it is possible to displace the THF molecules and obtain pure **2**.‡ Studies of the $^{13}C$ NMR spectrum of this compound in $CDCl_3$ show an equilibrium between the four-coordinate monomer **2a** and five-coordinate dimer **2b**. A related dimeric $Ti^{III}$ silsesquioxane without additional alkoxide ligands has been observed previously.[15] These monomeric and dimeric forms are easily identified on the basis of their cycloalkyl *ipso*-carbon resonances.[16] In addition, bridging[17] and terminal[18] isopropoxide ligands have been identified, by both $^1H$ and $^{13}C$ NMR spectroscopy, the relative ratios of which indicate a monomer–dimer ratio of *ca.* 2 : 1 in $CDCl_3$ at room temp.[17]

Addition of methanol to a solution of **2** in $CDCl_3$ leads to fast ligand exchange and the almost exclusive formation of the six-coordinate dimer, titanosilsesquioxane **3**. Interestingly, no monomeric species could be observed in solution by NMR spectroscopy.[17] By switching from trisilanol **1a** to **1b** it has been possible to isolate a single crystal of **3** suitable for X-ray diffractive analysis and to establish its molecular structure (Fig. 1).§

**Scheme 1**

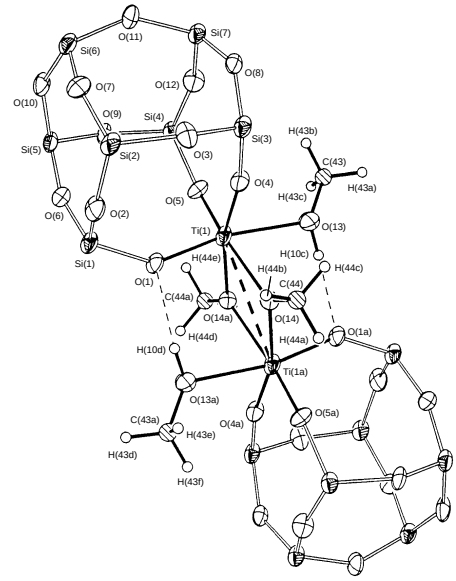


**Fig. 1** Molecular structure of **3**, showing the atomic labelling scheme and H-bonding interactions in the dimer. Principal bond distances (Å) and angles (°): Ti(1)–O(1) 1.837(7), Ti(1)–O(13) 2.210(7), Ti(1)–O(14) 2.004(7), Ti(1)–O(14a) 2.022(7), Ti(1)···Ti(1a) 3.253(4), mean Si–O 1.619(8); O(1)–Ti(1)–O(4) 98.4(3), O(1)–Ti(1)–O(5) 100.6(3), O(1)–Ti(1)–O(13) 168.8(3); H(10d)–O(1) 1.985 Å shows directionality w.r.t the O(1) lone pair, O(13a)-H(10d)-O(1) 147.6, $C_6H_{11}$ groups are omitted for clarity. Symmetry operation: $-x, -y, -z$.

The molecule is composed of two quasi-cubic silsesquioxanes related by a centre of inversion which lies between the two titanium atoms. These in turn are linked by two bridging methoxy groups with a mean Ti–O bond distance of 2.014(7) Å. The sixth position in the coordination sphere around the titanium is occupied by a datively bonded methanol group. The mean Ti–O silsesquioxane bond distance of 1.826(7) Å corresponds closely to that of grafted Ti ↑ MCM41 determined by EXAFS spectroscopy and calculational studies (1.81 Å and 1.82 Å, respectively).[9,11] The Ti–O distance of the datively coordinated methanol group [2.213(7) Å] corresponds closely to that observed for the Ti–substrate interaction (2.25 Å), observed for Ti ↑ MCM41 in its reactive state. This suggests a similar dative bonding of the substrate (most likely the peroxide, *cf*. Ti–O bonding distance of 2.26 Å in a *tert*-butylperoxotitanium complex[19]) to the titanium centre of the heterogeneous catalyst.

Dimer **2b** provides one free coordination site per titanium centre and the monomer **2a** two, allowing interactions with substrate molecules. Reactions with various peroxides showed that yellow peroxide complexes were readily formed, $\lambda_{max}$ = 320 nm, indicative of $\eta^2$-coordinated peroxide.[20]

Monomer **2a**, with its readily available second free coordination site on the same titanium centre, makes this a close model for the postulated tripodally surface-anchored titanium monohydroxide proposed for grafted Ti ↑ MCM41.

Model compound **2** displays catalytic activity which compares well with earlier studies† in that after 1 h at 50 °C, 48% conversion was achieved for the epoxidation of cyclohexene with tetrabutylperoxyhydroxide (TBPH) in $CDCl_3$ using a catalyst–substrate ratio of 1 : 70 : 70 with 98% selectivity towards the epoxide. When comparing its turnover frequency (TOF) with that of the actual grafted Ti ↑ MCM41 catalyst (3 mmol cyclohexene g $cat^{-1}$ $min^{-1}$) under identical conditions,¶ a TOF of 0.7 mmol g $cat^{-1}$ $min^{-1}$ was observed, resulting in 13% conversion after 1 h. Interestingly, the titanosilsesquioxane **3** exhibited a much higher TOF (4.8 mmol cyclohexene g $cat^{-1}$ $min^{-1}$) resulting in 93% conversion after 1 h. Importantly, the catalytic conversion of cyclohexene to the epoxide is highly selective (98%) for both catalysts.

The lower performance of titanosilsesquioxane **2** relative to **3** runs counter to simple expectation as **3** is coordinatively saturated and the dimer–monomer equilibrium established for **2** shows it has free coordination sites. This result might be taken to imply a synergistic effect of the two titanium centres being in close proximity. However, such an effect has not been claimed for the Sharpless catalyst $[Ti(tartrate)(OR)_2]_2$ which is structurally related to **3**,[21] nor is there any evidence for it in heterogeneous catalysts, where it is well established that the TOF per titanium centre increases with their increased dispersion and isolation

Therefore, we have also prepared a series of titanosilsesquioxanes, encompassing methoxy, butoxy and isopropoxy groups at the fourth coordination site and find that the reactivity of these catalysts is indeed dependent upon the nature of the alkoxy group (in the order of decreasing activity : MeO > $OBu^t$ ≫ $OPr^i$). The longer, but linear, butoxy group allows better access to the titanium centre than the shorter, but non-linear, isopropoxy group, further suggesting that accessibility to the tetrahedral $Ti^{IV}$ centre is the main parameter controlling reactivity.

We are grateful for the support of the EPSRC, the EU and ICI.

# Co-ZSM-5 and Mn-ZSM-5 synthesised directly from aqueous fluoride gels

**Catherine I. Round, Craig D. Williams* and Catherine V. A. Duke**

*University of Wolverhampton, School of Applied Sciences, Wulfruna Street, Wolverhampton, UK WV1 1SB*

**Isomorphously substituted zeolite ZSM-5 is synthesised using an aqueous, slightly acidic, fluoride medium incorporating tetrahalometallate compounds of cobalt and manganese; final products were characterised using XRD, SEM, XRF, FTIR, TG–DTA, and evidence of metal incorporation into the zeolite framework is given.**

Zeolite ZSM-5 is a catalyst of great industrial importance owing to its reactant, product and transition-state selectivity.[1] Modification to acid site strengths and density by isomorphic substitution of transition-metal elements can enhance catalytic activity, stability and selectivity. For example methane is generally regarded as a non-selective reducing agent, yet a cobalt or manganese exchanged HZSM-5 has proved to be an effective catalysts for the selective catalytic reduction of $NO_x$ by methane, with excess oxygen.[2–4]

Zeolite gels are normally prepared from solutions of silicates and aluminates at high pH. The as-synthesised material is then calcined and ion-exchanged with acid or ammonium salts to produce the Brønsted- and Lewis-acid sites necessary for catalytic activity. Metals are exchanged into the zeolite matrix by such complex secondary synthesis methods as cation exchange using metal nitrate solutions[5] and impregnation by metal carbonyl vapour.[6] The metal either inserts into lattice defect sites, or it acts as a charge balancing species which can then migrate and agglomerate at the external surface.[7,8]

This work reports the synthesis of Co-ZSM-5 and Mn-ZSM-5 by primary synthesis methods, employing a non-alkaline aqueous fluoride medium. Synthesis in a fluoride medium, replacing $OH^-$ with $F^-$ as a mineralising agent has been extensively studied in recent years.[9,10] It allows controlled nucleation and slower growth rates resulting in larger crystals with fewer lattice defects.[10]

Pure silica ZSM-5 was synthesised from a gel with molar composition $0.25HF : 0.75NaF : 0.25NaCl : 1.25TPABr : 10SiO_2 : 330H_2O$.[11] CAB-O-SIL M5 fumed silica (BDH 98%) was dispersed in deionised water, NaF (Fluka Chemika 99%) and HF (Fluka Chemika, puriss 40%) were added to the silica slurry, NaCl (General purpose reagent) and TPABr (Aldrich 98+%) added last and stirred by hand to homogeneity. Gels were heated to 170 °C in Teflon-lined reaction vessels. Samples were removed at regular intervals, quenched, filtered and dried at 40 °C. X-Ray powder diffraction (XRD) analysis confirmed highly crystalline ZSM-5 had been synthesised (Fig. 1). Scanning electron microscopy (SEM) analysis showed elongated prismatic crystals, typical of ZSM-5[12] 490–570 μm long.

$[NEt_4]_2[CoCl_4]$ and $[NPr_4]_2[MnBr_4]$ were crystallised as salts of large organic cations.[13] These tetrahedral tetrahalometallates have been used successfully in the synthesis of a number of highly substituted aluminophosphate zeotypes[14] but are unstable in basic conditions. The reaction gels for the metal substituted zeolites had a molar composition of $0.25HF : 0.75NaF : 0.25NaCl : 1.25\ (1 - x)$ TPABr : $x[NR_4]_2[MX_4] : 10SiO_2 : 330H_2O$ where $x$ is in the range 0–0.5, and $[NR_4]_2[MX_4]$ represents $[NEt_4]_2[CoCl_4]$ or $[NPr_4]_2$-$[MnBr_4]$. Molar compositions of the various reaction gels, and the products formed are listed in Table 1.

XRD analysis showed the products to be crystalline with the orthorhombic space group *Pnma* (Fig. 1). The volume of the unit cell, given in Table 2, increases with the levels of gel substitution.

SEMs of the substituted systems showed a change in crystal morphology. The 0.1 mole fraction cobalt system produced smaller crystals *ca*. 80–100 μm in length with irregular facets. This system showed a decreasing level of crystallinity inversely proportional to the level of substitution, which could be attributed to the increasing mole fraction of the associated $TEA^+$. The manganese system at 0.1 mole fraction showed an average crystal length of *ca.* 165 μm with the appearance of raised faces along the crystallographic *c* axis. The 0.2 Mn

[a] X-Ray fluorescence. [b] Loss on ignition determined by TG. [c] Unit-cell volume. [d] Pure Si form. [e] Lit. value for ZSM-5 = 5332 Å.[16] [f] Not obtained, poorly crystalline. [g] Not obtained.

system had smaller crystals, *ca.* 60 μm and there was crystal twinning along both *b* and *c* crystallographic axes with raised faces still evident (see graphical abstract). The reduction in crystal sizes is similar to that observed by Dwyer *et al.*,[15] and the raised faces indicates that crystallisation has occurred in a less supersaturated medium.[10]

TG losses on ignition (LOI) for the most crystalline samples compare well with the literature value[11] of 12%. The manganese substituted series has one type of templating species, $TPA^+$, and shows a two stage mass loss above 300 °C. The DTA trace shows a regular increase in the second stage mass loss, at the higher temperature, with increasing levels of substitution. The small mass losses, below 300 °C, in both the cobalt and the manganese systems are attributed to the water content, or to the two types of template cations either on the crystal surface or associated to anionic surface species ($F^-$ or $CoO_2^{2-}$).

The DTA trace in the cobalt system, also shows a two-stage mass loss above 300 °C. This system contains two types of templating species, $TPA^+$ and $TEA^+$ as the levels of substitution are increased. However, according to Szostak,[16] a two-stage mass loss is due to two types of $TPA^+$ species. The first type is occluded in the zeolite channels, it is less strongly bound and is lost at a lower temperature. The second type is a more strongly bound counter ion species and is lost at a higher temperature. The counter ions could be associated with an occluded fluoride anion or to a negatively charged $MO_4^{2-}$ coordinated into the silica framework. The fluoride in the gel has remained constant at 1 mole fraction, the increase in the template loss therefore could be due to those cations associated with the increased mole fraction of heteroatoms.

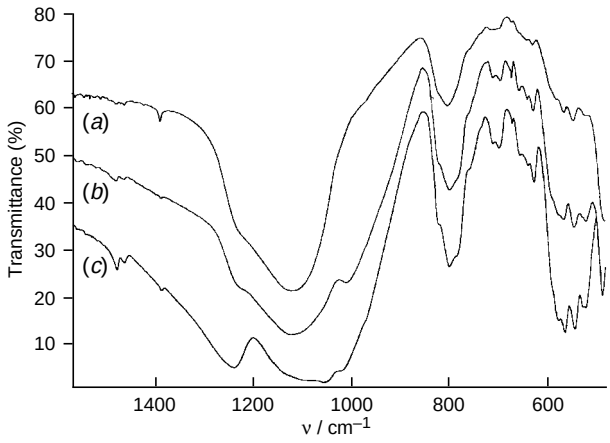

**Fig. 2** FTIR transmission spectra of (*a*) pure silica ZSM-5, (*b*) cobalt 1.5 mole fraction and (*c*) manganese 1.5 mole fraction

FTIR transmission spectra of the pure silica ZSM-5 closely matched literature spectra.[17] Substitution of cobalt and manganese into ZSM-5 resulted in a broadening in the T–O–T asymmetric stretching region, ranging from 1230 to 1085 $cm^{-1}$ (Fig. 2), which indicates heteroatom substitution.

It is clear from the analytical data that there are changes in the substituted materials compared with the pure silica form. This work represents levels of substitution comparable to levels currently reported but with the advantage of using a simple primary synthesis procedure. The materials produced in a fluoride medium do not require complex ion-exchange procedures to obtain the protonated form necessary for catalytic activity.

# Synthesis and characterization of new electron donors containing 1,2,5-thiadiazole and 1,1′-dihydro-4,4′-bi(pyridylidene) units

**Yoshiro Yamashita,* Katsuhiko Ono, Masaaki Tomura and Kenichi Imaeda**

*Institute for Molecular Science, Myodaiji, Okazaki 444, Japan*

**Novel electron donors composed of the title heterocycles are highly polarized and afford cation radical salts and charge transfer complexes with interesting crystal structures.**

Molecules containing 1,2,5-thiadiazole rings have been used as components of organic conductors.[1] Introduction of this electron-withdrawing heterocycle to strong electron-donating skeletons leads to novel highly-polarized electron donors.[2–4] In some cases, interesting molecular networks are formed by intermolecular interactions between the heteroatoms of the thiadiazoles. For example, 4,7-dimethyl-4,7-dihydro-

[1,2,5]thiadiazolo[3,4-*b*]pyrazine **1** is a highly-polarized strong electron donor which forms a sheet-like network in the crystal.[2] On the other hand, viologens **2** are widely used as electron-transfer reagents since they are easily prepared and show well-defined redox processes.[5] Although viologens are stable in air, their cation radical and neutral states are unstable toward oxygen due to their very low oxidation potentials. We have now fused 1,2,5-thiadiazole rings to the dihydrobipyridine skeleton in order to enhance the stability of the neutral state of viologens. The compounds **3** are expected to be highly polarized and form a tape-like network with short S···N contacts, as are found in the related bis[1,2,5]thiadiazole derivatives.[6] We report here the preparation and properties of **3** and its cation radical salts and charge-transfer complexes.

Thiadiazolopyridone derivative **4a** was obtained from chloropyridine derivative **5**.[4] The ethyl derivative **4b** was prepared by ethylation of **4c**, which was obtained by hydrolysis of **5** with hydrochloric acid. Reaction of **4a**,**b** with trifluoromethanesulfonic anhydride afforded pyridinium compounds **6a**,**b**. The bi(pyridothiadiazolylidene)s **3a**,**b** were obtained by reduction of **6a**,**b** with zinc in acetone. The yields of **3** from **4** were 20–40% over two steps. The donors **3a**,**b** are stable in air, in contrast to the unstable neutral viologens. They have absorption maxima in the long wavelength region (**3a**: 623, **3b**: 627 nm in $CH_2Cl_2$), which are regarded as the intramolecular charge-transfer bands. Their cyclic voltammograms showed reversible two-stage one-electron oxidation waves (**3a**: 0.27, 0.57 V, **3b**: 0.26, 0.56 V).† Their oxidation potentials are higher than those of methylviologen (−0.40, −0.81 V),[5] leading to the stability of **3**. This is attributed to the electron-withdrawing properties of the thiadiazole ring. However, the values are lower than those of tetrathiafulvalene (TTF) (0.46, 0.87 V) measured under the same conditions, indicating that they are stronger electron donors than TTF. The difference between the first and second oxidation potential in **3** (0.30 V) is smaller than that in TTF (0.41 V), methylviologen (0.41 V) and **1** (0.80 V),[2] indicating that the on-site Coulomb repulsion in **3** is decreased due to extended π-conjugation.

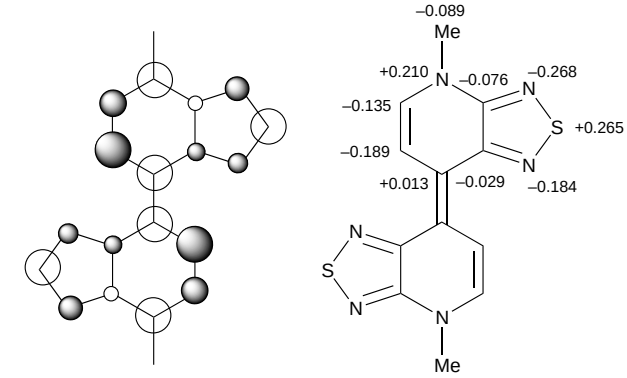

**Fig. 1** HOMO and net atomic charges of **3a** calculated by the PM3 method

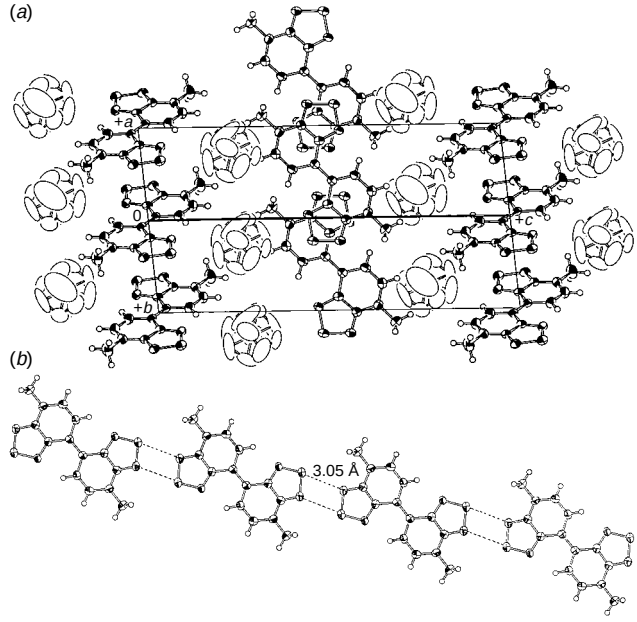

**Fig. 2** (*a*) Crystal structure of **3a**–$PF_6$; (*b*) tape-like network

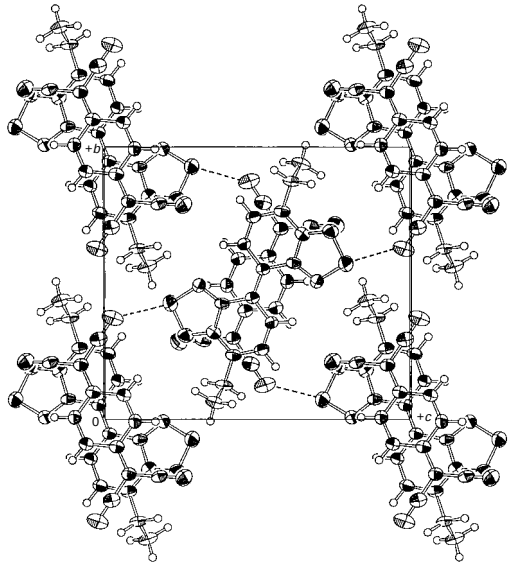

**Fig. 3** Crystal structure of **3b**–TCNQ

The HOMO and net atomic charges of **3a** calculated by the PM3 method[7] are shown in Fig. 1. The charge distribution indicates that the sulfur atom is positively charged and the nitrogen atoms of the thiadiazoles are negatively charged. For this polarized structure, short S···N contacts between the thiadiazole rings are expected to give a molecular network. There may be an electronic interaction through the S···N contacts in the cation radical state since these atoms have fairly large coefficients in the HOMO.

The donor **3a** gave $PF_6$ and $AsF_6$ salts of the cation radical upon electrochemical oxidation in $CH_2Cl_2$. They are 1 : 1 salts and show low conductivities (**3a**–$PF_6$: $8 \times 10^{-5}$ S cm$^{-1}$ as a compressed pellet, **3a**–$AsF_6$: $5 \times 10^{-4}$ S cm$^{-1}$ as a single crystal). The temperature dependence of the conductivity of the $AsF_6$ salt showed semiconductive behaviour, with an activation energy of 0.27 eV. The structures of the salts are isomorphous.‡ The crystal structure of the $PF_6$ salt is shown in Fig. 2. The planar donor molecules are stacked in an interesting mode where one donor molecule bridges two other molecules. Another interesting feature is that a tape-like network of the donor molecules is formed by short S···N contacts (3.05 Å) as expected. The counter anions exist between the molecular tapes which are arranged in two difference directions.

The donors **3a**,**b** afforded 1 : 1 charge-transfer complexes with tetracyanoquinodimethane (TCNQ). They showed moderate conductivities (**3a**–TCNQ: $1.6 \times 10^{-2}$ S cm$^{-1}$, **3b**–TCNQ: $4.9 \times 10^{-3}$ S cm$^{-1}$ as compressed pellets). We succeeded in preparing a single crystal of **3b**–TCNQ and carried out an X-ray crystal analysis.‡ The structure is shown in Fig. 3. The donor and TCNQ molecules form a mixed stack. The C–C bond length of the dicyanomethylene of the TCNQ molecule (1.416 Å) is comparable to that of TCNQ anion,[8] indicating that almost complete charge transfer occurs in the complex. An interesting feature is that short S···N contacts (3.15 Å) exist between the sulfur of the thiadiazole ring and the nitrogen of the cyano group, forming a two-dimensional network. This finding suggests that the inter-heteroatom interactions can be used for controlling the structures of charge transfer complexes.

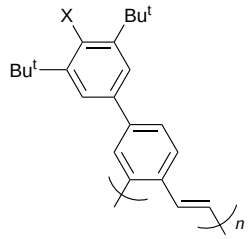
# Optical nonlinearity of an open-shell and degenerate π-conjugated polymer: poly(4-oxyphenyl-1,2-phenylenevinylene) radical



**Masahiro Takahashi,[a] Shinji Yamada,[b] Hiro Matsuda,*[b] Hachiro Nakanishi,[c] Eishun Tsuchida[a] and Hiroyuki Nishide*[a]**

[a] *Department of Polymer Chemistry, Waseda University, Tokyo 169, Japan*
[b] *National Institute of Materials and Chemical Research, Tsukuba 305, Japan*
[c] *Institute for Chemical Reaction Science, Tohoku University, Sendai 980-77, Japan*

**Third-order nonlinear optical susceptibility is enhanced by three orders of magnitude for the degenerate and high-spin ground state conjugated polymer, poly(4-oxyphenyl-1,2-phenylenevinylene), as compared with a precursor conjugated polymer with a closed-shell configuration, in a z-scan measurement.**

A great deal of research has been done on π-conjugated backbone polymers in regards to achieving sufficient third-order nonlinearity to produce optical devices.[1] Typical examples exhibiting this type of third-order nonlinear optical susceptibility ($\chi^{(3)}$) are poly(diacetylene)s[2] and poly(phenylenevinylene)s.[3] The authors at the National Institute in Tsukuba studied the optical nonlinearity of poly(diacetylene) derivatives that have π-conjugated side-chain groups,[4] and also recently measured $\chi^{(3)}$ values of their polymers with the z-scan method using a picosecond laser.[5]

On the other hand, much effort has been expended in synthesizing purely organic π-conjugated polyradicals which are in a high-spin or multiplet ground state and display molecular-based magnetism.[6] Some of the π-conjugated and alternant but non-Kekulé-type polymers that were substituted with polyradical groups satisfied the formulation based on MO or VB theory and yielded a stable radical or open-shell configuration and a degenerate high-spin ground state. Recently, the authors at Waseda University have for the first time succeeded in realizing this type of high-spin polymer, by synthesizing poly(1,2-phenylenevinylene) that is 4-substituted with a 3,5-di-*tert*-butyl-4-oxyphenyl group (**1a**).[7] The π-conjugated polyradical is characterized by the degenerate and delocalized single occupied molecular orbitals (SOMOs) on the poly(phenylenevinylene) backbone which overlap each other. The effective overlap integral of the SOMOs provides a spin-exchanging interaction sufficient to realize the high-spin ground state. This characteristic of the open-shell π-conjugated linear polymer bearing side-chain radical groups is in contrast to the electron configuration of open-shell but cross-conjugated polyradicals or radicals formed on the main chain,[8] where the SOMOs are localized in their diradial repeating unit.

**1a** X = O•
**b** X = OH

There has been only one research paper about the optical nonlinearity of a π-conjugated open-shell radical dye molecule. Zyss[9] studied 2-(4-nitrophenyl)-4,4,5,5-tetramethyl-4,5-dihydro-1*H*-imidazolyl-1-oxy 3-oxide which exhibits ferromagnetic behaviour below 0.9 K,[10] by the electric-field-induced second-harmonic generation method, but they could not find any differences in the nonlinear optical responses of the radical dye molecule. This is probably because the spin interaction in the radical molecules is caused by a through-space or intermolecular interaction between the radical, low-molecular-weight molecule and does not involve any overlapping of SOMOs.

π-Conjugated polymers with extensively delocalized electrons have highly nonlinear optical responses and numerous conjugated polymers with high third-order nonlinearities have been reported to try and understand their structure–property relationship and to provide a strategy for the synthesis of materials with large optical nonlinearities.[1,11] Here we have examined the possibility of a high-spin organic radical (open-shell) polymer, which possesses delocalized and degenerate SOMOs in its π-conjugated structure, as a nonlinear optical material.

The polyradical, poly[4-(3,5-di-*tert*-butyl-4-oxyphenyl-1,2-phenylenevinylene)] **1a**, was prepared *via* the oxidation of our precursor polymer **1b**.[7] The resulting brown–green powder with a molecular weight of 5100 and a spin (radical) concentration of 0.6 spin unit$^{-1}$ was soluble in common solvents such as $CHCl_3$, benzene and THF. The half-life of the polyradical in $CHCl_3$ solution was 3.4 days at room temperature. The UV–VIS absorption spectrum of the porlyradical **1a** (Fig. 1) involves π—π* absorption at $\lambda_{max}$ = 420 nm and broad absorption at *ca.* 680 nm. The former, which is based on the poly(1,2-phenylenevinylene) backbone, shifted bathochromically in comparison with that of **1b** ($\lambda_{max}$ = 350 nm), which can be ascribed to the development of π-conjugation or a

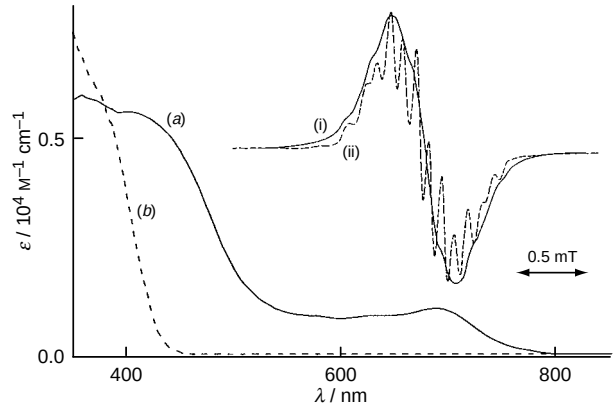


**Fig. 1** UV–VIS spectra of (*a*) polyradical 1a and (*b*) precursor polymer **1b**. Inset: solution EPR spectra of the radicals: (i) the polyradical **1a** at a low spin concentration, and (ii) 1-(3,5-di-tert-butyl-4-oxyphenyl)-3,4-di-styrylbenzene.

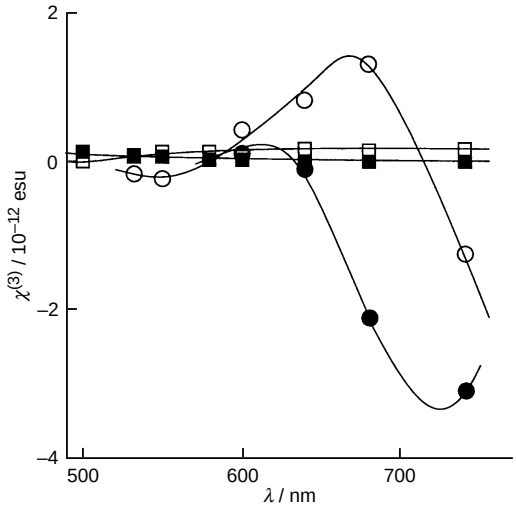

**Fig. 2** Wavelength dependency of Re$\chi^{(3)}$ and Im$\chi^{(3)}$ for a 0.091 wt% $CHCl_3$ solution of the polyradical **1a** [(○) Re$\chi^{(3)}$ and (●) Im$\chi^{(3)}$] and a 1.8 wt% $CHCl_3$ solution of the precursor **1b** [(□) Re$\chi^{(3)}$ and (■) Im$\chi^{(3)}$

narrowing of the band gap that was caused by radical SOMO generation between the HOMO and LUMO. The latter absorption is a n–π* forbidden transition which is similar to that of 2,4,6-tri-*tert*-butylphenoxyl.

The formation of the polyradical was recognized by a strong EPR signal (inset in Fig. 1). The EPR spectrum of **1a** at low spin concentration gave a broadened hyperfine structure at $g$ = 2.0043 due to an unresolved coupling of 5–7 protons of the phenyl ring and the phenylenevinylene backbone. The spin density distribution over the whole π-conjugation of **1a** was supported by the clear hyperfine structure (the dashed line in the inset in Fig. 1) of the repeating unit analogue, 1-(3,5-di-*tert*-butyl-4-oxyphenyl)-3,4-di-styrylbenzene,† which was ascribed to the coupling of 7–9 protons of the phenyl ring and two vinylenes. Static magnetic susceptibility and magnetization of **1a** were mesured with a SQUID magnetometer.‡ The former gave a spin concentration of 0.6, and the latter indicated quintet spin multiplicity at ground state.

The $\chi^{(3)}$ of the polyradical was measured with a z-scan laser setup.[5]§ The z-scan method has the following two advantages: (i) it can estimate both real and imaginary parts of $\chi^{(3)}$, Re$\chi^{(3)}$ and Im$\chi^{(3)}$, respectively, including positive or negative signs, and (iii) can elongate the interaction time with the sample. The nonlinear refractive index and the nonlinear absorption coefficient were calculated from the z-scan signals using a procedure that was developed by Sheik-Bahae *et al.*,[12] which gave the Re$\chi^{(3)}$ and Im$\chi^{(3)}$ values in Fig. 2, respectively.¶ There was no damage to the sample, as was confirmed by a scan from the opposite direction on the z-axis which gave an identical result. Sample damage or degradation of the polyradical was also ruled out by UV–VIS and NMR spectroscopy after the laser-irradiated measurements.

Both Re$\chi^{(3)}$ and Im$\chi^{(3)}$ for a 1.8 wt% $CHCl_3$ solution of the precursor **1b** were quite small ($10^{-13}$ esu) at over 500 nm in the nonresonant region, and could not be distinguished from the nonlinearity of the $CHCl_3$ solvent. On the other hand, the wavelength dependence of the nonlinearity for the polyradical **1a** was clearly observed in the region between 500 and 740 nm. The maximum values of Re$\chi^{(3)}$ and Im$\chi^{(3)}$ for a 0.091 wt% $CHCl_3$ solution of the polyradical **1a**, obtained at 740 nm, were $-2.4 \times 10^{-12}$ esu and $-3.1 \times 10^{-12}$ esu, respectively. Converting these results with respect to the polymer concentration, gave a third-order optical nonlinearity for the polyradical **1a** of *ca.* $10^{-9}$ esu, an enhancement of more than three orders of magnitude.‖ Re$\chi^{(3)}$ and Im$\chi^{(3)}$ swiched from positive to a negative at *ca.* 700 and 650 nm, respectively, which corresponds to a band gap narrowing due to SOMO generation and/or a resonant effect *via* the degenerate SOMOs.

This work was partially supported by a Grant-in-Aid for Scientific Research (Nos. 267/08236231 and 09305060) from the Ministry of Education, Science and Culture, Japan, and the Shorai Foundation for Science and Technology.

## Footnotes and References

† 1-(3,5-Di-*tert*-butyl-4-hydroxyphenyl)-3,4-distyrylbenzene was synthesized *via* sequential Heck coupling reactions of 4-(3,5-di-*tert*-butyl-4-acetoxyphenyl)-2-bromostyrene with iodobenzene and styrene, and the deprotection of the acetyl group. $\delta_H$ ($CDCl_3$, 500 MHz) 1.51 (s, 18 H, $C(CH_3)_3$], 5.28 (s, 1 H, OH), 7.01–7.76 (m, 19 H, phenyl); *m/s* 486 ($M^+$), calc. for M, 486.

‡ Magnetization and static magnetic susceptibility were mesured with a Quantum Design MPMS-7 SQUID magnetometer from 2 to 300 K in a field from 0.5 to 7 T.

§ An LBO-based OPG/OPA output (420–1800 nm), which was pumped by a third-harmonic from Nd:YAG laser, was used as a light sourse. The pulse width was *ca.* 20 ps and the repetition rate was 10 Hz. The Gaussian beam was extracted by a spatial filter using a diamond pin-hole (100 μm) in an evacuated chamber. Transmittance of the samples with and without a finite aperature in the far field was measered as the sample was scanned through the focal plane along the propagation direction z. At each z position, 15 laser shots were averaged in order to remove noise.

¶ For the calculation, the refractive index of $CHCl_3$ ($n_D$ = 1.446) was used for sample solutions in which there is no wavelength dispersion in the measuring region.

‖ For the conversion from $\chi^{(3)}$ of the solution to that of the neat sample, the density of the polymers was assumed to be unitiy. This enhancement of Re$\chi^{(3)}$ was, however, accompanied with increase in the linear absorption. As the sign of Im$\chi^{(3)}$ was negative, the strong absorption saturation should be effective for applications for optical devices without loss of light intensity.

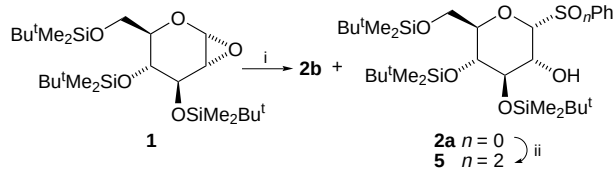
# Reaction of thiophenol with glucal epoxides: X-ray structure of 3,4,6-tri-*O*-*tert*-butyldimethylsilyl-1-*S*-phenyl-1-thio-α-D-glucopyranoside

**Caroline Walford, Richard F. W. Jackson,* Nicholas H. Rees, William Clegg and Sarah L. Heath**



*Department of Chemistry, Bedson Building, The University of Newcastle, Newcastle upon Tyne, UK NE1 7RU*

**The reaction of the *tert*-butyldimethylsilyl protected glucal epoxide 1 with thiophenol under a variety of conditions gives three distinct adducts, including the α-phenylthioglycoside 2a, which exists both in solution and in the solid state in a $^1C_4$ conformation in which the C-2, C-3, C-4 and C-5 substituents are all axial.**

1-Phenylthioglucosides have been widely used in glycosylation reactions. In the context of a project to develop nucleophilic glycosyl donors, we were interested in the development of effective routes to protected α- and β-phenylthioglucosides **2a** and **2b**. Our planned approach involved the reaction of the epoxide **1** (prepared by oxidation of the readily available glucal with dimethyldioxirane)[1] with phenylthiolate, a reaction which had been previously reported on the corresponding tribenzyl protected derivative by Spilling (using NaSPh)[2] and Danishefsky (using $Bu_4NSPh$).[3] Spilling obtained a low yield, and Danishefsky obtained a mixture of both α- and β-phenylthioglucosides. When the epoxide **1** was treated with lithium phenylthiolate (Scheme 1), the adduct **3** was cleanly obtained (72%), in which the initial product of ring-opening had undergone a silyl shift. However, treatment of the epoxide **1** with thiophenol in the presence of triethylamine did give the expected sulfide **2b** (85%). The structures of the two products were assigned on the basis of extensive two-dimensional NMR studies, including the preparation of acetylated derivatives. While conversion of the sulfide **2b** into the *tetra*-silylated derivative **4** (*tert*-butyldimethylsilyl trifluoromethanesulfonate, 2,6-lutidine, −78 °C to room temp., 16 h) proceeded reasonably efficiently (58%), the analogous reaction on **3** was very slow, and gave **4** in very poor yield (12%), testifying to the hindered nature of the C-3 hydroxy group.[4] We believe that the best explanation for these results is that the presence of two bulky protecting groups at C-3 and C-4 is unfavourable, and it is the relief of steric hindrance which is the driving force in the silyl migration.[5] In the ring-opening reaction in the presence of triethylamine, the triethylammonium cation presumably acts as a proton source, thus neutralising the C-2 alkoxide and thereby preventing silyl migration.

**Scheme 1** *Reagents and conditions*: i, PhSLi (from PhSH and BuLi), 0 °C to room temp., THF, 16 h; ii, PhSH, $NEt_3$, 0 °C to room temp., 16 h, THF; iii, $Bu^tMe_2SiOSO_2CF_3$, 2,6-lutidine, $CH_2Cl_2$, −78 °C to room temp., 16 h

**Scheme 2** *Reagents and conditions*: i, PhSH, 0 °C to room temp., THF, 16 h; ii, MCPBA, $NaHCO_3$, $CH_2Cl_2$, 0 °C, 1.5 h

In order to explore this reaction further, we also examined the reaction of the epoxide **1** with thiophenol itself (Scheme 2). The major product from this reaction was the α-phenylthioglycoside **2a** (36%), together with a minor amount of the β-phenylthioglycoside **2b** (28%), already identified. Although the yields are not very high, the process has not been optimised, especially with respect to solvent. In this case, the reaction probably proceeds through the intermediacy of an oxonium ion, formed by ring opening of the epoxide, which is then selectively trapped from the α-face.

The adduct **2a** was crystalline, and we were able to confirm its structure by X-ray diffraction, as indicated in Fig. 1.† We were surprised to discover a $^1C_4$ conformation in the crystalline state, in which the four substituents at C-2, C-3, C-4 and C-5 are in axial positions, with the phenylthio group equatorial. The other notable feature is that there is a hydrogen bond between the C-2 hydroxy proton and O-1, which may help to stabilise the $^1C_4$ conformation. The $^1C_4$ conformation does appear to be very rare, although it has been observed in the case of a bis(*tert*-butyldiphenylsilyl) α-aryl *C*-olivoside, in which three substituents, rather than four, are in an axial position.[6] Analysis of the $^1H$ NMR spectrum of **2a** suggested that, in $CDCl_3$ at least, the solution conformation was very similar to that in the solid

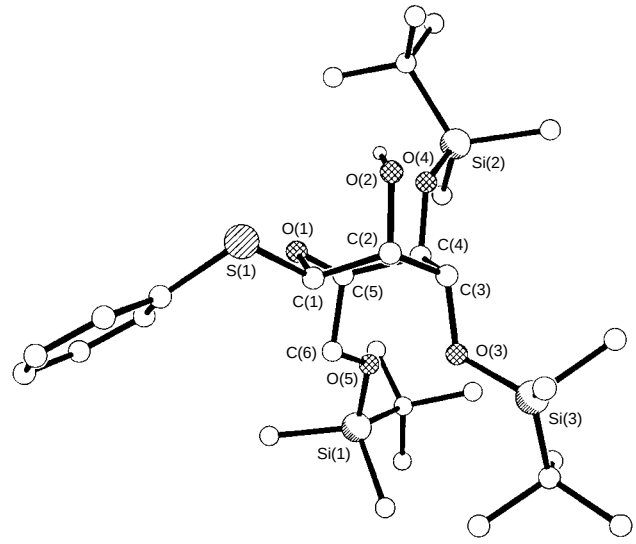


**Fig. 1** The conformation of **2a** in the crystal structure. Hydrogen atoms, other than the hydroxy proton, and minor disorder components are omitted for clarity.

state, with very small vicinal coupling constants around the ring, and significant long-range (*W*) coupling between H-2 and H-4, and between H-3 and H-5 (indicating that each of these protons was in an equatorial position). The corresponding sulfone **5**, prepared by oxidation of the sulfide **2a**, exhibited almost identical coupling constants and is therefore probably also in the same conformation in solution.

The '*A* value' of the phenylthio group (4.60–5.19 kJ $mol^{-1}$)[7] is not sufficiently large to force the other substituents axial, so the most obvious explanation is that the adjacent *tert*-butyldimethylsilyloxy groups at C-3 and C-4 are more sterically encumbered when they are diequatorial than when they are diaxial.‡ Eliel's important report on the '*A* values' of silyloxy groups, which clearly showed (rather counter-intuitively) that a *tert*-butyldimethylsilyloxy group had a *smaller* '*A* value' than a trimethylsilyloxy group,[8] provides strong support for this idea. The ease with which the *tert*-butyldimethylsilyl group at C-3 of **2b** migrates to C-2 is probably another manifestation of this same phenomenon.

It is clear that the pronounced conformational effects of *tert*-butyldimethylsilyl ethers may have useful consequences in control of reaction stereoselectivity.

We thank the EPSRC for a CASE award (C. L. W.) and for equipment grants, Rhône-Poulenc Rorer for support and Drs B. Porter, A. J. Ratcliffe and M. Podmore (RPR) for helpful discussions. R. F. W. J. also thanks the Nuffield Foundation for a One Year Science Research Fellowship.

† *Crystal data* for **2a**: $C_{30}H_{58}O_5SSi_3$, $M_r$ = 615.1, orthorhombic, $P2_12_12_1$, $a$ = 27.1719(17), $b$ = 10.9754(7), $c$ = 12.3479(8) Å, $V$ = 3682.4(4) Å$^3$, $Z$ = 4, $D_c$ = 1.109 g cm $^{-3}$, $\mu$ = 0.22 mm$^{-1}$ (Mo-K$\alpha$, $\lambda$ = 0.71073 Å), $T$ = 160 K. Measurements were made on a Siemens SMART CCD area detector diffractometer. Data were collected by narrow-frame $\omega$ rotation. 19 575 reflections, $2\theta \leqslant 50°$, 6467 unique reflections, $R_{int}$ = 0.091, semi-empirical absorption correction, transmission 0.84–0.97. Structure solution was by direct methods, refinement on $F^2$ for all data, with anisotropic displacement parameters, riding H atoms (with rotational freedom for methyl and hydroxy hydrogen atoms), and two-fold disorder for one silyl group. $R_w = [\Sigma w(F_o^2 - F_c^2)/\Sigma w(F_o^2)^2]^{\frac{1}{2}} = 0.223$ for all data, conventional $R = 0.101$ for $F$ values of 5551 reflections with $F_o^2 > 2\sigma(F_o^2)$, goodness of fit 1.129, absolute configuration indicated by refinement of enantiopole parameter (ref. 9) to −0.3(2), residual electron density within ± 0.61 e Å$^{-3}$. The indicated absolute configuration was consistent with the known absolute configuration of the starting material. The quality of data collection and structure refinement are limited by the deformed nature of the crystals (apparently slightly bent, giving distorted reflections) and the structural disorder. Programs were standard Siemens control and integration software, Siemens SHELXTL, and local programs. CCDC 182/580.

‡ This suggestion was first made by Suzuki (ref. 6). This type of behaviour has been noted before in the case of glycals (ref. 10), and in β-lactams derived from glycals by cycloaddition (ref. 11). It has also been suggested as an influence on reactivity, but without direct evidence (ref. 4.).

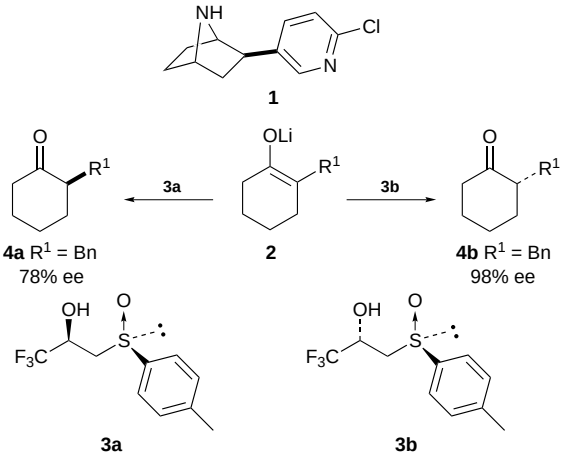
# A study of asymmetric protonation with chiral β-hydroxy sulfoxides. Asymmetric synthesis of (−)-epibatidine

**Hiroshi Kosugi,* Makito Abe, Ryota Hatsuda, Hisashi Uda and Michiharu Kato**

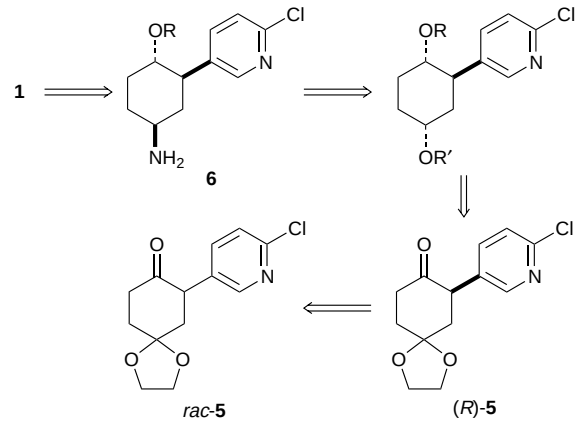
*Institute for Chemical Reaction Science, Tohoku University, Katahira, Aoba-ku, Sendai 980-77, Japan*

**The asymmetric synthesis of (−)-epibatidine 1, employing as the key step the asymmetric protonation of the achiral lithum enolate of cyclohexanone derivative 5 with chiral β-hydroxy sulfoxide 3b, is described.**



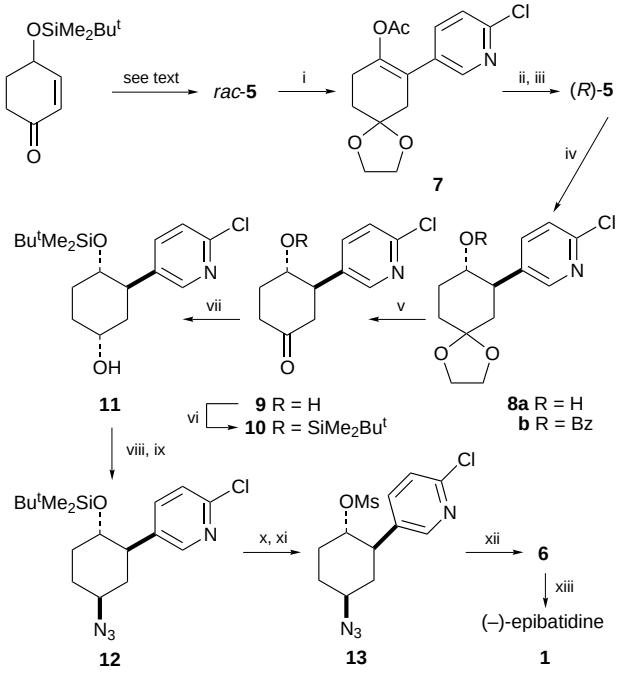
Epibatidine **1** was isolated from the poisonous Ecuadoran frog *Epipedobates tricolor*, and was found to be a novel potent antinociceptive agent that acts through nicotinic receptors.[1] Because of the scarcity of **1** in nature, the determination of its absolute stereochemistry was extremely difficult. In 1994, Fletcher *et al*. reported the absolute stereochemistry of **1** to be 1*R*,2*R*,4*S* by the HPLC comparison of synthetic specimens with natural **1**.[2f] Owing to interest in this novel biological activity and its intriguing chemical structure, many synthetic routes to **1** have been reported.[2] The synthetic approaches to optically active **1** are somewhat limited and involve an optical resolution of either a product at some stage of the synthesis or the final product **1**. [2g,3] Here we report the asymmetric synthesis of (−)-**1** based on the asymmetric protonation of achiral lithium enolates derived from cyclohexanone derivatives with chiral β-hydroxy sulfoxides.

We have recently developed, using enantiomerically pure β-hydroxy sulfoxides **3a** or **3b** as protonating reagents, the effective asymmetric protonation of achiral lithium enolates of 2-substituted cyclohexanones **2** to give enantiomers **4a** and **4b**, respectively, with high enantiopurity (Scheme 1).[4] Extension of the methodology to other substituted cyclohexanones, especially 4,4-ethylenedioxycyclohexanone derivatives, would be useful for procurement of chiral synthetic intermediates for natural product synthesis. For example, as shown in Scheme 2, when the asymmetric protonation is applied to the cyclohexanone acetal bearing a 4-chloropyridinyl moiety at the C(2) position, the compound (*R*)-**5** obtained might be readily converted to **6**, which has been employed as the common synthetic intermediate for the construction of the 7-azabicyclo-[2.2.1]heptane system of epibatidine, in the synthesis originally developed by Broka.[2a]



The starting cyclohexanone derivative *rac*-**5** was synthesized from 4-*tert*-butyldimethylsilyloxycyclohex-2-en-1-one[5] by a sequence of conventional reactions: (i) conjugate addition of 4-lithio-2-chloropyridine in the presence of lithium thienylcyanocuprate according to a reported procedure,[2i] and (ii) acetalisation and deprotection of the silyloxy group, followed by Swern oxidation to give *rac*-**5** (Scheme 3).

Regioselective enol acetate formation was accomplished by treatment of *rac*-**5** with Bu$^t$OK, followed by addition of $Ac_2O$ to give enol acetate **7** in 99% yield. The asymmetric protonation was performed as follows. The lithium enolate generated from **7** by treatment with MeLi (2 equiv.) in $Et_2O$ was protonated by adding **3b**[6] (2.5 equiv.) in $CH_2Cl_2$ at −90 °C for 1.5 h, during which time the reaction temperature rose to −60 °C. The product (*R*)-**5** [63% yield, $[\alpha]_D^{25}$ + 18.3 (*c* 0.316, $CHCl_3$)] obtained was found to have an enantiomeric excess of 82% by HPLC (Daicel AD chiralcel column). The chiral **5** was reduced with $NaBH_4$ in MeOH to the *trans*-alcohol **8** (77%) accompanied by some of the *cis*-alcohol (18%). It is worthwhile to mention that, at this stage, optical purification to obtain the enantiomerically pure **8a** was achieved using achiral silica gel chromatography.† The absolute stereochemistry was determined to be 3*R*,4*S* by applying the exciton coupled circular dichroic (CD) method[6] to the benzoate **8b** [UV (MeOH) $\lambda_{max}$ 218 nm ($\varepsilon$ 16 700); CD (MeOH) $\lambda_{ext}$ 227.4 nm ($\Delta\varepsilon$ +12.9), 215.4 (−1.04)] derived from **8a**. Consequently, the absolute structure of (+)-**5** is suggested to be 3*R*, as depicted in Scheme 3. It should be noted that the sense of the enantiofacial recognition of cyclohexanone derivatives bearing an acetal moiety at the C(4) position is the reverse of that of simple 2-substituted cyclohexanones in the asymmetric protonation with **3b**.[4]



Conversion of the enantiomerically pure alcohol **8a** to epibatidine **1** was straightforward, employing the slightly modified procedure of Broka.[2a] Deprotection of the carbonyl group, followed by protection of the hydroxy group as the Bu$^t$Me$_2$Si ether afforded **10** in 81% overall yield from **8**. The carbonyl reduction of **10** with LiBBu$^s_3$H (L-selectride) in THF

**Scheme 1**

**Scheme 2**

**Scheme 3** *Reagents and conditions*: i, Bu$^t$OK, $Ac_2O$, THF; ii, MeLi (2 equiv.), $Et_2O$, 0 °C, 15 min; iii, **3b**, $CH_2Cl_2$, (2.5 equiv.), −90 to −60 °C; iv, $NaBH_4$, MeOH; v, 80% aq. AcOH; vi, Bu$^t$Me$_2$SiCl, Pr$^i_2$NEt, DMF; vii, LiBBu$^s_3$H, THF; viii, MsCl, $Et_3N$, $CH_2Cl_2$; ix, $NaN_3$, DMF; x, $Bu_4NF$, THF; xi, MsCl, $Et_3N$, $CH_2Cl_2$; xii, $SnCl_2·2H_2O$, MeOH–THF; xiii, $CHCl_3$, reflux

afforded the axial alcohol **11** (63%). Conversion of the hydroxy group to azide was performed *via* a two-step procedure to give **12** in 76% yield from **11**. Deprotection of the silyl ether, followed by mesylation ($MeSO_2Cl$, $Et_3N$, $CH_2Cl_2$) gave the mesylate **13** in 95% yield. Finally, the mild reduction of the azide function with $SnCl_2$ and ring closure of the resulting amine **6** in refluxing $CHCl_3$ for 3 d gave enantiomerically pure (−)-**1** {$[\alpha]^{25}_D$ −6.99 (*c* 0.229, $CHCl_3$): mp 62–62.5 °C, 69% yield from **13**} which was identical in all respects with the reported physical data.[2f]

In conclusion, the synthetic utility of asymmetric protonation of prochiral lithium enolates with chiral β-hydroxy sulfoxides has been demonstrated by the asymmetric synthesis of enantiomerically pure (−)-epibatidine. Further studies on the scope and limitations of the present asymmetric protonation are in progress.

We are grateful to Professor Nobuyuki Harada of this Institute for a helpful discussion of the CD spectroscopic analysis. This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, and Culture of Japan.

† There have been a few examples of the chromatographic separation of partially enantio-enriched compounds under achiral conditions (ref. 8). When a sample of the hydroxy acetal **8a** (80% ee) was loaded on a silica gel column [MPLC: Kusano pre-packed silica gel column Si-10; eluted with 3 : 1 hexane–EtOAc; UV (254 nm) and RI detectors], enantiomerically pure **8a** was first eluted, followed by *rac*-**8a** as a shoulder. We have examined the separation of some partially enantio-enriched (23–80% ee) homologues such as *trans*-3-substituted 4-hydroxycyclohex-1-enone ethylene ketals {*e.g.* 3-benzyl and 3-[(*E*)-3-phenylprop-2-enyl] derivatives} as well as their *cis*-isomers by achiral silica gel column chromatography, and found that the chromatographic behaviour is quite general. The results will be reported elsewhere.

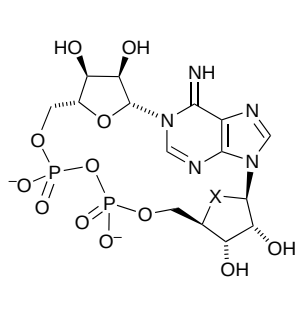
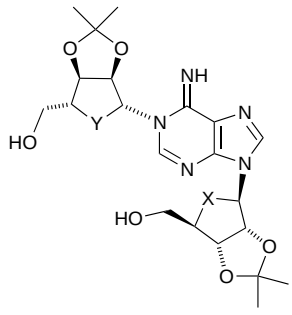
# Stereospecific synthesis of 1,9-bis(β-D-glycosyl)adenines: a chemical route to stable analogues of cyclic-ADP ribose (cADPR)

**Edward J. Hutchinson, Brian F. Taylor and G. Michael Blackburn***



*Krebs Institute for Biomolecular Science, Department of Chemistry, University of Sheffield, Sheffield, UK S3 7HF*

**Stereospecific syntheses of two hydrolysis-resistant analogues of the 1,9-bis(β-D-ribosyl)adenine moiety of cyclic-ADP ribose are described.**

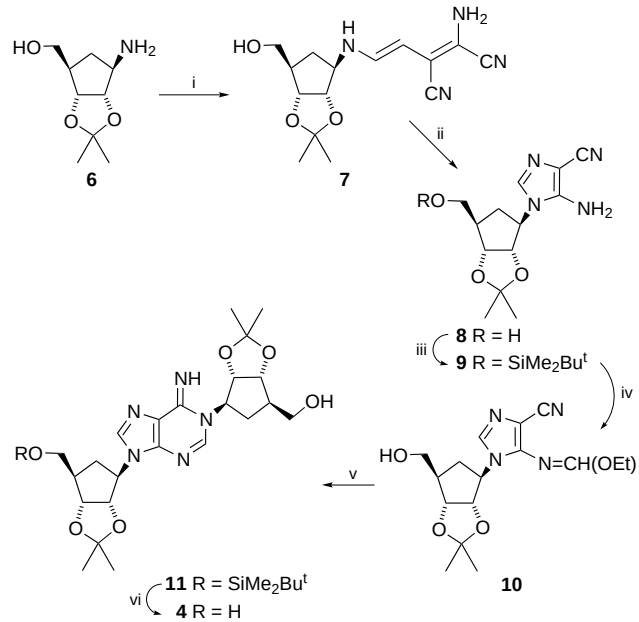


Cyclic-ADP Ribose, cADPR **1**, is a naturally occurring metabolite of $NAD^+$ and is deemed to be a secondary messenger involved in intracellular calcium mobilisation.[1] The precise role of this compound and the mechanism by which it acts at receptor sites other than those activated by inositol-1,4,5-triphosphate[2] remain unclear. cADPR is formed through the action of ADP-ribosyl cyclase, an enzyme found in many mammalian and invertebrate tissues, which brings about displacement of the nicotinamide group of $NAD^+$ by $N^1$ of its own adenine residue with overall retention of configuration.[3] The labile $C^{1''}$–$N^1$ glycosylic bond formed in this process is easily hydrolysed to give adenosine diphosphate ribose, ADPR **2**, by either enzymatic or spontaneous hydrolysis, thus accounting for the extremely low concentrations (sub-micromolar) of cADPR observed in cells.

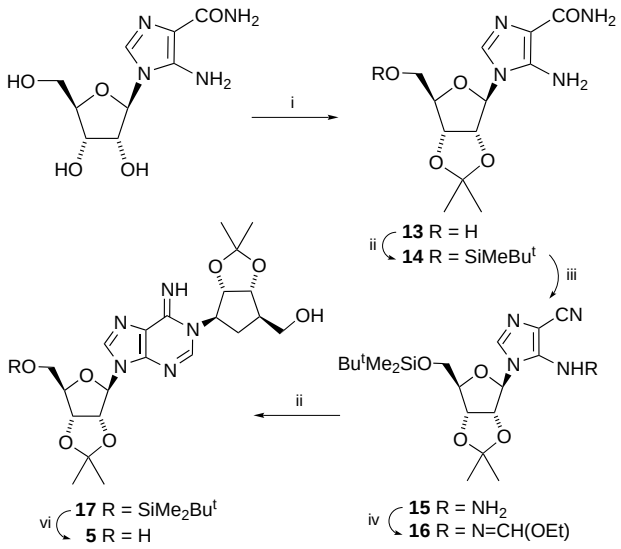
As part of an ongoing investigation of the detailed function of cADPR, we are seeking to make novel analogues of cADPR for use in competitive enzyme inhibition studies as well as in investigations of agonist/antagonist action at the ryanodine receptor.[4] In a recent report,[5] we described the synthesis of a carbocyclic $NAD^+$ analogue containing a stable methylenebisphosphonate linkage which is designed to inhibit the formation of cADPR and thus can be employed in structural studies in a binary complex with the enzyme.

Hitherto, analogues of cADPR have generally been formed by enzymatic cyclisation[6] of an analogue of $NAD^+$, though Sekine has described a chemical procedure which gave the α-configuration at $N^1$ for a cADPR derivative.[7] Both Lee[8] and Potter[9] have described antagonist activity from 8-substituted cADPR derivatives whilst Sih[10] has used a part enzyme, part chemical synthesis to generate cADPR species with changes in the pyrophosphate linkage. Potter[11] has employed aristeromycin to prepare a longer-acting cADPR analogue **3** with a carbaribose moiety at $N^9$ though necessarily retaining a ribofuranose moiety at $N^1$.

**1** X = O, cADPR
**3** X = $CH_2$



**4** X = $CH_2$, Y = $CH_2$
**5** X = O, Y = $CH_2$



No group has as yet sought directly to address the inherent instability of the labile (O)$C^{1''}$–$N^1$ glycosylic bond. Carbocyclic sugars have been employed in many nucleoside analogues to achieve stability of the glycosylic linkage,[12] and the incorporation of a carbaribose at $N^1$ in cADPR seemed a logical target for this application. Because we predicted† that a nicotinamide carbocyclic riboside $NAD^+$ derivative would have insufficient reactivity at the glycosylic position to be a substrate for enzymatic cyclisation, the choice of a chemical route to carbaribose analogues of cADPR became unavoidable.

We here report the stereospecific synthesis of the nucleoside framework of two analogues of cADPR, both having a carbocyclic sugar moiety at the $N^{1'}$ position, namely the derivative **4** and the 1-β-D-carbaribosyl-9-β-D-ribofuranosyladenine derivative **5**. This route can also be employed to prepare the parent 1,9-bis(β-D-ribofuranosyl)adenine. We are currently developing both of these carbocyclic species *via* 5′,5″-bisphosphorylation and 5′,5″-methylenebisphosphorylation to generate novel, hydrolytically-stable analogues of cADPR.

The synthetic scheme is built around the repeated use of the cyclopentylamine **6** of defined β-configuration at $C^1$ (Scheme 1). Amine **6** is obtained in five high-yielding steps from commercially available (−)-2-azabicyclo[2.2.1]hept-5-en-3-one as outlined in a previous report.[5] Imidazole **9** was prepared *via* amidine **7** using diaminomaleonitrile as described by Booth,[13] which proved much superior to alternative reagents explored. Intermediate **7** was purified by silica gel chromatography, although prolonged exposure to air and light resulted in extensive darkening and decomposition. The required amino

**Scheme 1** *Reagents and conditions*: i, diaminomaleonitrile, $PhNH_3^+Cl^-$ (cat), EtOAc, room temp., dark, 18 h, 65%; ii, DBU (2 equiv.), $H_2O$, room temp., 2 h, 100%; iii, $Bu^tMe_2SiCl$, imidazole, DMF, room temp., 18 h, 92%; iv, $HC(OEt)_3$, heat, 4 h, 94%; v, **6**, EtOH, $EtO^-$ (cat), 50 °C, 40%; vi, $Bu_4NF$, THF, room temp., 18 h, 96%

**Scheme 2** *Reagents and conditions*: i, acetone, HC(OEt)$_3$, TsOH, room temp., 2 h, 78%; ii, Bu$^t$Me$_2$SiCl, imidazole, DMF, room temp., 18 h, 84%; iii, TsCl, pyridine, room temp., 3 h, 83%; iv, HC(OEt)$_3$, heat, 4 h, 100%; v, **6**, EtOH, EtO$^-$ (cat), 50 °C, 40%; vi, Bu$_4$NF, THF, room temp., 18 h, 94%

imidazole **8** was duly formed by base-induced cyclisation with excess DBU and followed by silyl protection with Bu$^t$Me$_2$SiCl to give imidazole **9**. Reaction of **9** with neat triethyl orthoformate resulted in near quantitative conversion into imidate **10**, the key precursor for cyclisation. Addition of amine **6** to an ethanolic solution of imidate **10** in the presence of catalytic sodium ethoxide for 48 h at 50 °C provided 1,9-bis(carbaribosyl)adenine **11** in 40% yield. Deprotection of the 5′-hydroxy group with Bu$_4$NF gave the required diol **4** in an overall yield of 14% after twelve synthetic steps.

Attempts to prepare the corresponding imidazole **15** using this procedure with commercially available 2,3-*O*-isopropylidene-1-β-D-ribofuranosylamine were unsuccessful. It appeared that the intermediate amidine is considerably more labile than its carbocyclic counterpart **7** and only degradation fragments were obtained. In an alternative synthesis (Scheme 2), commercially available AICAR **12** was protected as its 2′,3′-*O*-isopropylidene derivative using acetone–triethyl orthoformate–TsOH to give **13** in 78% yield. Following silylation of the 5′-hydroxy group, dehydration of the amide to nitrile **15** was achieved using TsCl in pyridine in 84% yield. Refluxing **15** in triethyl orthoformate produced imidate **16** which was condensed with carbocyclic amine **6** and cyclised as before. Removal of the 5′-*O*-SiMe$_2$Bu$^t$ protecting group with Bu$_4$NF gave the required 1-β-D-carbaribosyl-9-β-D-ribofuranosyladenine derivative **5** in 21% overall yield.

The 1,9-dialkyladenine structure for the analogues rests not only on synthesis but is confirmed by their p$K_a$ and spectroscopic characteristic. The p$K_a$ values of 8.36 for the 1,9-bis(β-D-carbaribosyl)adenine derivative **4** and 7.93 for the 1-β-D-carbaribosyl-9-β-D-ribosyladenine derivative **5** are close to p$K_a$ 8.30 for cADPR[3] and differ greatly from the p$K_a$s for 6,9-dialkyladenines,[3,16] which lie in the range 3.5–4. The UV absorption spectra for analogues **4** and **5** exhibit the strong shoulder at 300 nm characteristic of both cADPR and of 1,9-dialkyl adenines and absent in 6,9-dialkyl adenines.[15] Compounds **4** and **5** and the related intermediates described have been fully characterised by UV,‡ NMR and mass spectral analysis.§ In both analogues, the N$^1$–C$^{1''}$ bond appears to have the desired level of stability to hydrolysis, with no cleavage of the N$^1$–C$^{1'}$ bond over a week in aqueous solution under ambient conditions. In fact, the slow transformations of **4** and **5** observed at higher pH appear to result from isomerisation by a Dimroth rearrangement to give *N*$^6$,*N*$^9$-disubstituted adenines, as characterised by markedly changed UV spectral properties.[15] Such rearrangements have been shown[16] to be accelerated by a β-D-ribofuranosyl group at the 9-position. This process appears to be very slow in the case of analogues **4** and **5** (half life ⩾1 day at pH 9) and is the subject of further investigations.

We thank the EPSRC for financial support (GR/J39120).

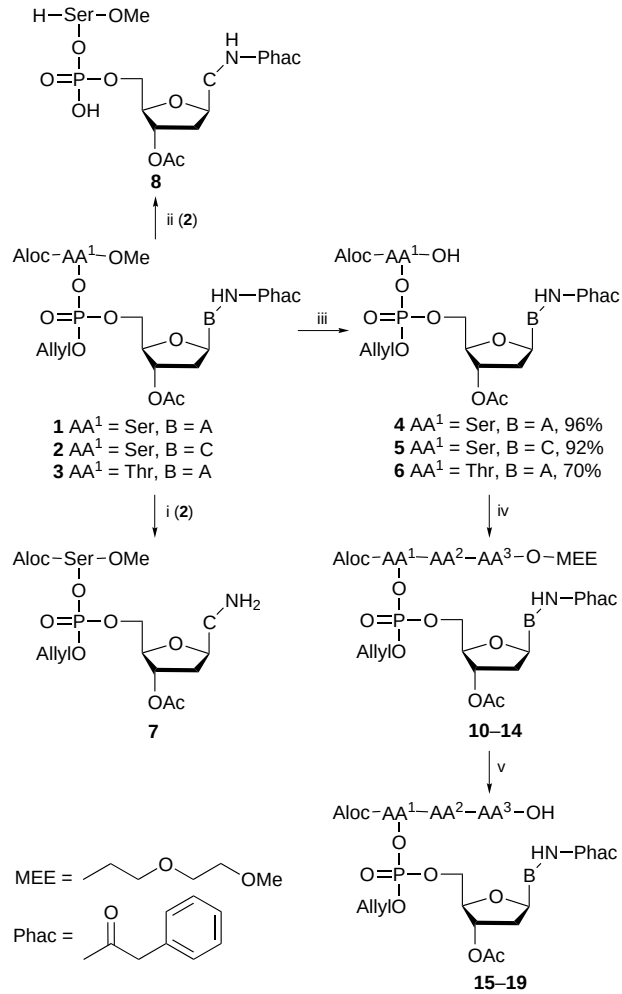
# Chemoenzymatic synthesis of nucleopeptides

**Herbert Waldmann* and Stefanie Gabold**

*Universität Karlsruhe, Institut für Organische Chemie, Richard-Willstätter-Allee 2, D-76128 Karlsruhe, Germany*

**Acid- and base-labile multifunctional nucleopeptides have been selectively constructed under mild conditions by means of enzymatic protecting group techniques.**

Nucleoproteins are naturally occuring biopolymers in which the hydroxy group of a serine, a threonine or a tyrosine is linked *via* a phosphodiester group to the 3′- or 5′-end of DNA or RNA.[1] These protein conjugates play decisive roles in important biological processes; in particular, they may hold a central position in the process of viral replication *via* nucleoprotein-primed elongation of the oligonucleotide strand.[2] For the study of the biological phenomena in which nucleoproteins are involved, nucleopeptides embodying the characteristic linkage between the peptide chain and the oligonucleotide of their parent nucleoproteins may serve as powerful tools. In particular, the possibility of delineating the details of the above-mentioned mechanism of viral replication and developing a new class of antiviral agents based thereupon calls for the development of efficient methods for the construction of these peptide conjugates. However, their synthesis poses two major challenges: (i) the multifunctionality of the peptide-nucleotide conjugates makes the application of a variety of orthogonally stable amino, carboxy-, phosphate- and hydroxy-blocking groups necessary, and (ii) fully protected serine/threonine nucleopeptides are acid-labile (under acidic conditions the purine nucleotides may be depurinated[3]) and base-labile (under basic conditions, *i.e.* pH ⩾ 8, the entire oligonucleotide part may be split off *via* β-elimination[4]).



Consequently, in nucleopeptide chemistry not only is a variety of orthogonally stable blocking functions needed, they all must be removable selectively under mild, preferably neutral conditions. In the light of these seemingly contradictory demands it is not surprising that only a few reports on the successful construction of nucleopeptides have appeared.[4,5]

We have now found that enzymatic protecting group techniques[6] are efficient methods for the selective deprotection of the carboxylic acids and nucleobases of nucleopeptides.

In order to develop an enzymatic protecting group strategy for nucleopeptide synthesis, the protected nucleoamino acids **1**–**3** were constructed by means of established methods of oligonucleotide chemistry.† In these compounds, the nucleobases were masked with enzyme-labile phenylacetamide groups[7] and the carboxy groups of the amino acids were protected as methyl esters.

From the nucleoamino acid esters **1**–**3** the C-terminal protecting groups could be selectively removed by saponifying the methyl esters with the protease papain from *Carica papaya* at pH 6.6 and 37 °C (Scheme 1).[8] The conditions of the enzymatic transformations were so mild that the selectively unmasked nucleoamino acids **4**–**6** were obtained in high yield and without any undesired side reactions, *i.e.* the acid labile purine nucleosides remained intact and a β-elimination of the nucleotide, which readily takes place under weakly basic conditions (*vide supra*), was not observed. The protease did not attack the *O*-acetates. On the other hand, the nucleobase of *e.g.* **2** could be selectively N-deprotected by means of penicillin acylase-catalysed removal of the phenylacetamido base protecting group[7] at pH 7 and room temp. in 77% isolated yield (Scheme 1). In addition, the allyl-type blocking groups present in **2** were cleaved off without undesired side reaction by $Pd^0$-mediated allyl transfer to $PhSiH_3$ as accepting nucleophile[9] at room temp. in 89% isolated yield (Scheme 1).

Whereas the protease papain could advantageously be used to unmask the amino acid esters **1**–**3** its application to the deprotection of nucleopeptides might result in an undesired attack of the enzyme on the formed peptide bonds.[10] Therefore, for the selective C-terminal deprotection of nucleopeptides the lipase-mediated cleavage of the 2-(2-methoxyethoxy)ethyl (MEE) esters[11] was investigated, since lipases do not display any protease activity. To this end, the selectively deprotected nucleoamino acids **4**–**6** were coupled with different amino acid or dipeptide MEE esters **9** to give the fully masked nucleopeptides **10**–**14** in high yields (Scheme 1, Table 1). Upon treatment of the nucleopeptide acid MEE esters **10**–**14** with lipase from

**Scheme 1** *Reagents and conditions*: i, Penicillin acylae, phosphate buffer pH 7)–MeOH, 80 : 20; ii, $Pd(PPh_3)_4$, $PhSiH_3$; iii, papain from *Carica papaya*, cysteine buffer, pH 6.6; iv, H–$AA^2$–$AA^3$–OMEE **9**, 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride, 1-hydroxybenzotriazole; v, lipase from *Aspergillus niger*, phosphate buffer (pH 7)–acetone, 90 : 10

**Table 1** Synthesis of the nucleopeptide esters **8**–**12** and their selective deprotection with lipase from *Aspergillus niger* (AA = amino acid, B = nucleobase)

| | | | | | Coupling | | Deprotection | |
|---|---|---|---|---|---|---|---|---|
| Entry | AA[1] | AA[2] | AA[3] | B | Yield (%) | | Yield (%) | |
| 1 | Ser | Gly | Asp (All) | C | **10** | 61 | **15** | 70 |
| 2 | Ser | Glu (All) | — | C | **11** | 62 | **16** | 58 |
| 3 | Ser | Phe | — | C | **12** | 75 | **17** | 70 |
| 4 | Ser | Val | Phe | C | **13** | 69 | **18** | 59 |
| 5 | Thr | Phe | — | A | **14** | 71 | **19** | 63 |

*Aspergillus niger* at pH 7 and 37 °C the C-terminal carboxylic acid was smoothly deprotected (Scheme 1, Table 1). In the case of these multifunctional, complex peptide conjugates, too, the enzymatic transformations occured without any undesired side reaction, *i.e.* neither the acetate, N-terminal urethane, allyl phosphate, phenylacetamide and peptide bonds, nor the acid-labile purine nucleoside and the extremely base-labile serine phosphates were attacked. The biocatalyst again tolerated the presence of purine and pyrimidine bases and different amino acids and amino acid sequences in the nucleopeptides. Its substrate specificity guaranteed that the allyl esters which were employed for masking of the amino acid side chain functions in **10** and **11** were not removed either. By means of this enzymatic protecting group technique the desired selectively unmasked nucleopeptides **15**–**19** were obtained in high yield. Nucleopeptide **15** represents the characteristic linkage region of the nucleoprotein of adenovirus 2,[12] and **16** is derived from the nucleoprotein of bacteriophage Ø 29.[13]

Overall, the enzymatic protecting group strategy and the set of orthogonally stable blocking groups described here open a route to the construction of complex and sensitive nucleopeptides by means of a flexible building block strategy. The ready accessibility of these multifunctional peptide conjugates may serve to develop new tools for research at the interface between chemistry and biology.

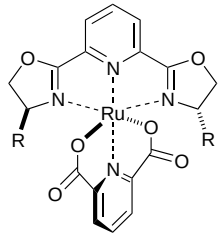
# Novel ruthenium–pyridinedicarboxylate complexes of terpyridine and chiral bis(oxazolinyl)pyridine: a new catalytic system for alkene epoxidation with [bis(acetoxy)iodo]benzene as an oxygen donor

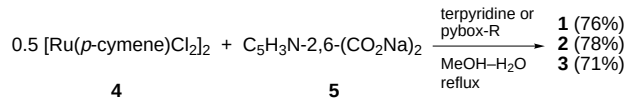
**Hisao Nishiyama,* Tomoo Shimada, Hirofumi Itoh, Hirotaka Sugiyama and Yukihiro Motoyama**



*School of Materials Science, Toyohashi University of Technology, Tempaku-cho, Toyohashi 441, Japan*

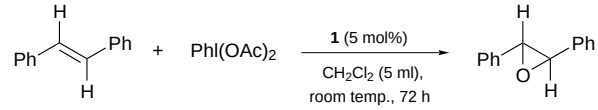
**Ruthenium–pyridine-2,6-dicarboxylate (pydic) complexes 1–3 of terpyridine and chiral bis(oxazolinyl)pyridines (pybox-*ip* and pybox-*ph*), which can be synthesized from [Ru(*p*-cymene)$Cl_2$]$_2$ and the corresponding ligands, exhibit catalytic activity for epoxidation of *trans*-stilbene in combination with [bis(acetoxy)iodo]benzene: asymmetric induction with 2 was observed in 74% ee for *trans*-stilbene.**

Ruthenium complexes with nitrogen-based ligands have been intensively investigated in order to develop catalysts for organic oxidation processes and to simulate the mechanism of bio-organic oxidation. This is because ruthenium complexes act as oxidation catalysts, often *via* ruthenium-oxo species, oxidizing alcohols or alkanes and epoxidizing alkenes.[1,2] We are especially interested in Balavoine's alkene epoxidation using $RuCl_3$–bipyridine–$NaIO_4$, in which addition of bipyridine can efficiently minimize cleavage of the alkene, even in the presence of $NaIO_4$.[3] In connection of our studies of transition-metal catalysis with terdentate bis(oxazolinyl)pyridine (Pybox) ligands,[4] we have been studying an applicaton of Ru–bisoxazoline catalysts for catalytic epoxidation of alkenes accompanied by asymmetric induction.[5] In this respect, Waegell reported an asymmetric alkene epoxidation with Ru–oxazoline catalysts with low asymmetric induction,[6] and Che described an asymmetric and stoichiometric oxygen transfer from a chiral ruthenium complex to styrene; 56% ee for 4-chlorostyrene.[7] As a new catalyst design, we adopted the introduction of dual closed meridional stereotopes around an active metal and consequently chose pyridine-2,6-dicarboxylate (pydic) as the counterpart. Here we disclose a synthesis of Ru(pydic)(terpy) (terpy = 2,2′:6′,2″-terpyridine) **1** as a non-



**1**

**2** R = Pr$^i$
**3** R = Ph



chiral catalyst and Ru(pydic)(pybox-R) **2** (R = Pr$^i$) and **3** (R = Ph) as chiral catalysts, and their catalytic activity for alkene epoxidation is also demonstrated.

A mixture of [Ru(*p*-cymene)$Cl_2$]$_2$ **4**, disodium pyridine-2,6-dicarboxylate **5**, and 2,2′:6′,2″-terpyridine was treated in MeOH–$H_2O$ at reflux for 1 h under argon atmosphere. After cooling the reaction mixture, Ru(pydic)(terpy) **1** was obtained in 78% yield as a dark violet precipitate by filtration (Scheme 1).† Complex **1**, which is stable in air, is slightly soluble in MeOH (*ca*. 10 mg in 25 ml), but almost insoluble in $CH_2Cl_2$ and $CHCl_3$ (*ca*. < 10 mg in 200 ml). Chiral complexes **2** and **3** were also prepared by the same procedure as shown in Scheme 1.‡

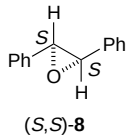
**Scheme 1**

We first examined epoxidation of *trans*-stilbene **6** (0.5 mmol) with iodosobenzene (PhIO) (1.5 mmol) in $CH_2Cl_2$ (5 ml) in the presence of **1** (5 mol%) (Scheme 2) (Table 1, run 1) *trans*-Stilbene oxide **8** was obtained in good to excellent yield (67%) with a small amount of benzaldehyde (8%), and some **6** (5%) was recovered. After screening of several oxidants, we found that [bis(acetoxy)iodo]benzene **7** [PhI(OAc)$_2$]§ served as an efficient oxygen donor assisted by complex **1**; PhI(OAc)$_2$ has better solubility in $CH_2Cl_2$. When **7** (1.0 mmol) was added to a suspension of complex **1** (14 mg, 5 mol%) in a $CH_2Cl_2$ (5 ml) solution of **6** (0.5 mmol), complex **1** spontaneously reacted, dissolved and gave a dark brown solution. The catalytic epoxidation proceeded slowly at room temperature for 72 h to give *trans*-stilbene oxide in excellent yield (92%) (run 3). However, use of $NaIO_4$ resulted in exclusive cleavage of the alkene (run 5). Epoxidation under aerobic epoxidation with Bu$^t$CHO/$O_2$ (1 atm). (run 6) and use of Bu$^t$OOH (run 7) resulted in yields of 86 and 81%, respectively.

**Scheme 2**

We then examined asymmetric epoxidation of *trans*-stilbene **6** with Ru(pydic)(pybox-*ip*) **2** (5 mol%), which also exhibited catalytic activity with PhIO (3 equiv.) and PhI(OAc)$_2$ (3 equiv.)

**Table 1** Catalytic epoxidation of *trans*-stilbene with Ru(pydic)(terpy) **1**[a]



| Run | Oxidant | Oxidant : *trans*-stilbene/mmol | *t*/h | Yield (%) | Recovered alkene (%) |
|---|---|---|---|---|---|
| 1 | PhIO | 1.5 : 0.5 | 72 | 67 | 5 |
| 2 | PhI(OAc)$_2$ | 0.5 : 0.5 | 96 | 49 | 39 |
| 3 | PhI(OAc)$_2$ | 1.0 : 0.5 | 72 | 92 | 0 |
| 4 | PhI(OAc)$_2$[b] | 1.0 : 0.5 | 96 | 90 | 5 |

[a] Catalyst **2** (0.025 mmol, 5 mol% of *trans*-stilbene), solvent (10 ml). The yields are based on 0.5 mmol of *trans*-stilbene. Benzaldehyde was obtained in the range 2–14%. The ees were determined by chiral LC (Daicel Chiralcel OD). All epoxides had (1*S*,2*S*) configuration. [b] $NaIO_4$ (3.5 mmol), $H_2O$ (2.5 ml). [c] Bu$^t$CHO (2.5 mmol), $O_2$ (1 atm).

(*S*,*S*)-**8**

**9**

to give 67 and 80% yields of (1*S*,2*S*)-*trans* stilbene oxide (*S*,*S*)-**8** (24 and 63% ee), respectively (Table 2, runs 1 and 2). The best result for this catalytic system was obtained at 0 °C (74% ee, run 3). When performed in toluene rather than $CH_2Cl_2$ or $C_6H_6$, epoxidation using complex **2** (5 mol%) and $PhI(OAc)_2$ (3 equiv.) gave higher yields (runs 2, 4 and 5). Aerobic oxidation and oxidation with Bu$^t$OOH proceeded but gave relatively low yields and enantiomeric excesses (runs 7 and 8).

The Ru(pydic)(pybox-*ph*) complex **3** gave slightly lower enantioselectivities than **2**; oxidation of *trans*-stilbene under the same conditions as in run 2 of Table 2 gave the epoxide in 84% yield (58% ee).

In comparison, *trans*-$(AcO)_2$Ru(pybox-*ip*)(pyridine) **9**, prepared by reaction of $[Ru(p\text{-cymene})(OAc)_2]_2$,[8] pybox-*ip* and pyridine, was examined as an oxidation catalyst with $PhI(OAc)_2$. The complex **9** (5 mol%) similarly catalysed the epoxidation of **6** under the same conditions as in run 2 of Table 2 to give racemic *trans*-stilbene oxide in 49% yield; 15% of the alkene was recovered. This finding implies that the meridional tridentate connected structure of pydic on **2** and **3** must be rigid enough during the catalysis to help pybox maintain the chiral environment, inducing the enantioselection.

Thus, we have found a new alkene epoxidation methodology utilizing ruthenium(II) complexes having the dual meridional system of pydic with terpyridine and pybox, in combination with $PhI(OAc)_2$ as the oxygen donor. Our studies are now focused on the scope and limitations of this alkene epoxidation and its mechanism.

# Solvent effects on thermodynamic parameters for porphyrin–quinone interaction through multiple hydrogen bonding

**Takashi Hayashi,*† Takashi Miyahara, Norihiro Koide and Hisanobu Ogoshi*‡**

*Department of Synthetic Chemistry and Biological Chemistry, Graduate School of Engineering, Kyoto University, Sakyo-ku, Kyoto 606-01, Japan*

**The enthalpy–entropy compensation plots for noncovalently linked porphyrin–quinone complexation exhibit a non-linear hook-shaped relationship between $\Delta H°$ and $T\Delta S°$ at various polarities in a toluene–ethanol binary solvent.**

In general, water disrupts the formation of host–guest complexes linked by hydrogen bonding and complicates the binding mode in biological systems.[1,2] Thus, a simple host–guest model system would be very useful for evaluation of the effect of water on the thermodynamic parameters of the binding process. Recently, we have examined hydrogen-bonded porphyrin–quinone complexation,[3] in which ethanol was used as a co-solvent to simulate the behaviour of traces of water in a hydrophobic binding pocket in an enzyme. Here we report the solvent effects on the enthalpy and entropy changes upon binding between *meso*-α,α,α,α-tetrakis(2-hydroxy-1-naphthyl)porphyrin **1** and 2,3,5,6-tetramethoxy-*p*-benzoquinone **2** in a toluene–ethanol or toluene–butan-2-one binary solvent system (Fig. 1).[4,5]

Upon addition of ethanol or butan-2-one to the toluene solution, the affinity of **2** for **1** decreased with the increasing polarity of solvent.[6]§ Thermodynamic parameters ($\Delta H°$ and $\Delta S°$) for **1·2** complexation at various polarities were determined from van't Hoff plots obtained by UV–VIS titrimetric measurement. The van't Hoff plots show linearity in pure toluene and at > 5.2 mol% of ethanol in toluene, whereas the plots at 0.36–3.5 mol% of ethanol in toluene gave a curved line, suggesting that $\Delta H°$ is a temperature-dependent parameter with non-zero heat capacity changes.¶ In contrast, a linear relationship was observed for the toluene–butan-2-one binary solvent system.

It is known that enthalpy–entropy diagrams for host–guest complexation generally display a linear relationship in a solvent system of varying polarity.[7] However, in this work, the $\Delta H°$ *vs.* $T\Delta S°$ compensation plots for **1·2** complexation in a toluene–ethanol binary system exhibit a unique hook-shaped line as shown in Fig. 2(*a*), with a turning point at approximately 3.5 mol% ethanol in toluene. One plausible interpretation is given in Fig. 3. In the presence of a polar solvent such as ethanol, we observe only the overall complexation comprised of solvent free complex **1·2** and various states of solvated complex **1·2**. Assuming that the affinity of ethanol molecules for complex free **1** and **2** is larger than that for complex **1·2**, $-\Delta H°$ drastically decreases upon addition of ethanol, since the functional sites of complex free **1** and **2** are saturated and stabilized by ethanol co-solvent even at low concentrations of ethanol ($|\Delta H°_a| > |\Delta H°_b|$ in Fig. 3). In contrast, the solvation of complex **1·2** gradually increases with the increasing number of ethanol molecules, and $\Delta H°$ becomes more negative in the presence of sufficient interactive ethanol to complex **1·2** ($|\Delta H°_b| < |\Delta H°_c|$ in Fig. 3). On the other hand, the entropy changes seem to depend on the behaviour of the ethanol molecules. At lower concentrations of ethanol, the desolvation of functional groups in **1** and **2** upon complexation contributes to entropy gain, whereas at higher concentrations of ethanol, the ethanol solvation of complex **1·2** and the formation of aggregated cluster of excess ethanol itself in apolar toluene

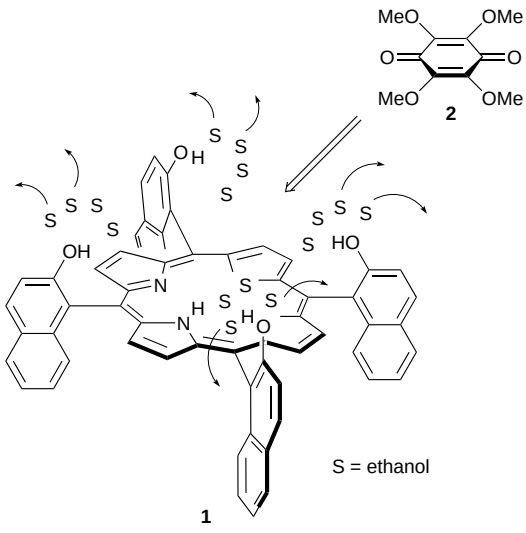

**Fig. 1**

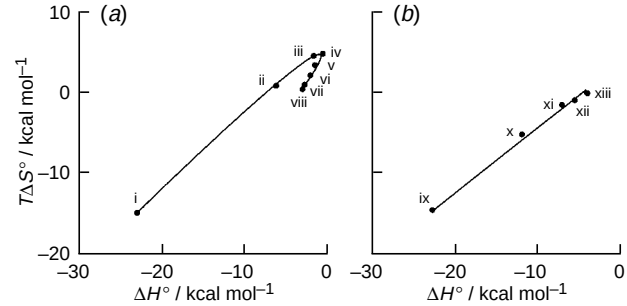

**Fig. 2** Plots of the apparent $\Delta H°$ *vs.* $T\Delta S°$ for the binding of quinone **2** to porphyrin **1** at 298 K in (*a*) toluene–ethanol and (*b*) toluene–butan-2-one mixtures: (i) 0, (ii) 0.9, (iii) 1.8, (iv) 3.5, (v) 5.2, (vi) 8.3, (vii) 13 and (viii) 15 mol% EtOH in toluene, and (ix) 0, (x) 3.4, (xi) 11, (xii) 19 and (xiii) 28 mol% butan-2-one in toluene

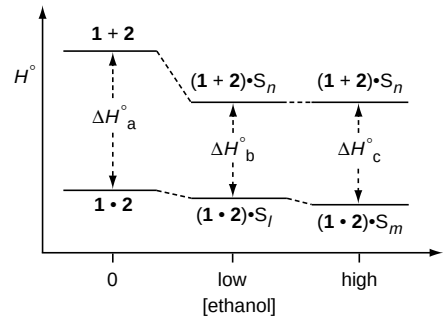

**Fig. 3** Variation of $H°$ with concentration of EtOH; (**1** + **2**)·S = solvated **1** and **2**, (**1·2**)·S = solvated complex of **1·2**, S = ethanol molecule(s), *l*, *m* and *n* represent the number of ethanol molecules

gives rise to entropy loss.[8] In contrast, the same compensation plots in the toluene–butan-2-one binary solvent system show a linear relationship [Fig. 2(*b*)], suggesting that the solvation of functional groups in **1** and **2** in toluene–butan-2-one is weaker than that in the toluene–ethanol binary solvent system.

To the best of our knowledge, this is the first example of a hook-shaped $\Delta H°$ *vs.* $\Delta S°$ relationship in host–guest complexation *via* hydrogen-bonding interaction. Eftink has reported the simulation of the hook-shaped enthalpy–entropy relationship due to the protonation of a protein–ligand complex in a variety of pH conditions.[9,10]‖ Thus, our present results derived from the solvation of recognition sites at a variety of polarities is consistent with previous results from the literature that focused on the protonation of each component in protein–ligand binding.

In conclusion, this work indicates that the enthalpy and entropy changes for binding processes *via* hydrogen-bonding recognition are strongly influenced by solvation in a compensating manner.

§ In the $^1$H NMR spectrum of **1**, the OH proton at δ 4.97 in pure toluene was shifted downfield with increasing concentration of ethanol or butan-2-one. The downfield shift in toluene–ethanol is approximately twice that in toluene–butan-2-one.

¶ The discussion of heat capacity changes has been previously reported [ref. 3(*c*)]. We calculated the thermodynamic parameters from non-linear van't Hoff plots by use of following equation:

$$R\ln K(T) = -[\Delta H°(T)/T] + \Delta S°(T)$$
$$= -[\Delta H°(T_0) + (T - T_0)\Delta C_p°]/T + \Delta C_p°\ln(T/T_o) + \Delta S°(T_0)$$

where $K(T)$, $\Delta H°(T)$ and $\Delta S°(T)$ are temperature-dependent parameters and $\Delta H°(T_0)$ and $\Delta S°(T_0)$ are constants with $T = T_0$.

‖ It has been suggested that hook-shaped $\Delta H°$ *vs.* $\Delta S°$ compensation plots in ligand binding could be caused by a change in pH, ionic strength, solvent composition or macromolecule concentration (ref. 10).

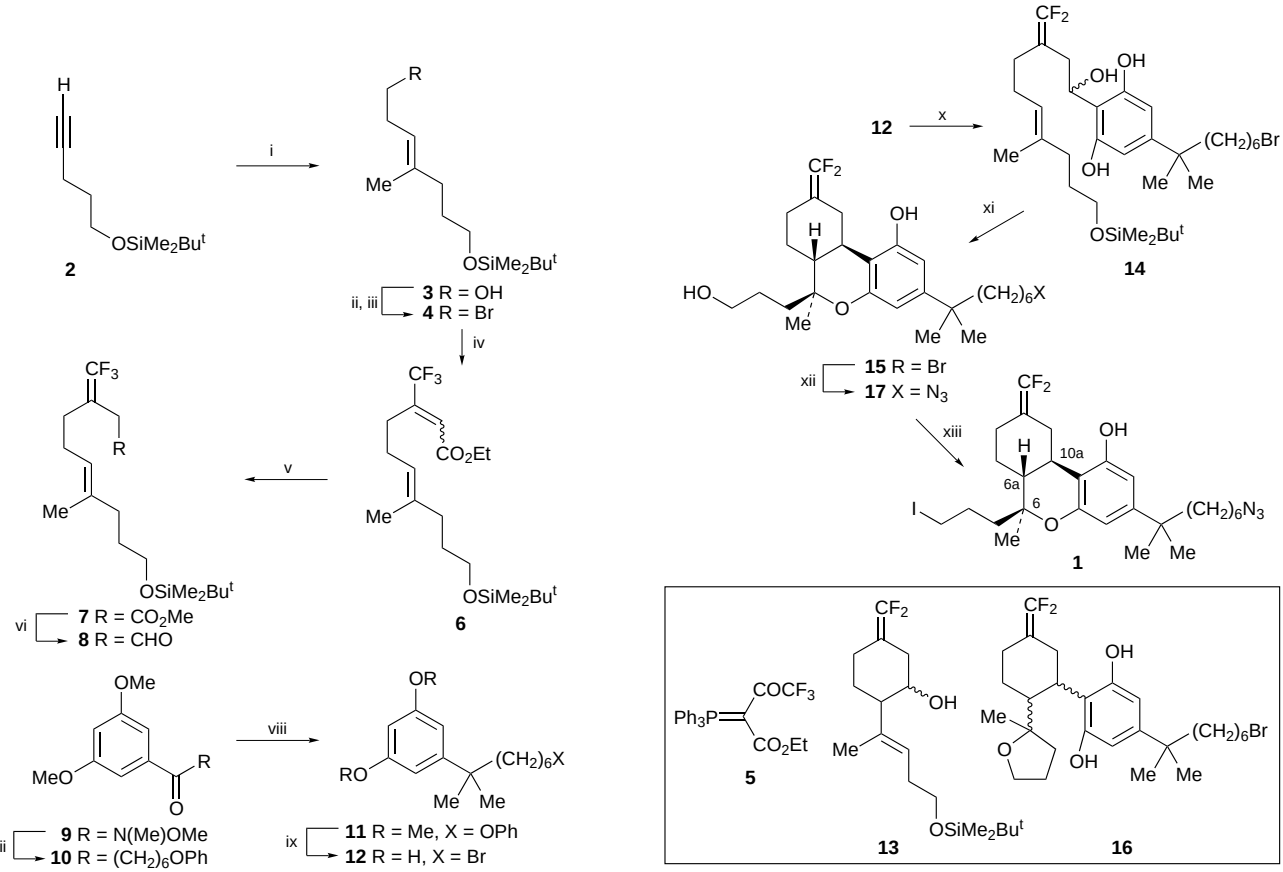
# Synthesis of a bifunctional cannabinoid ligand

**Marcus A. Tius,* Jakob Busch-Petersen and Andrew R. Marris**

*Department of Chemistry, University of Hawaii, 2545 The Mall, Honolulu, Hawaii 96822, USA*



**A novel bifunctional classical-nonclassical hybrid cannabinoid has been prepared expeditiously through the Diels–Alder reaction of an *ortho*-quinomethane.**

The identification of two distinct cannabinoid receptors[1] has led to a resurgence of interest in this area. Rational design of new materials for pharmaceutical development requires a detailed understanding of receptor–ligand interactions at the molecular level. The availability of cloned cannabinoid CB1 receptor and our identification of a class of high-affinity ligands suggested an experiment in which irreversible covalent binding[2] of the ligand to the receptor at two sites would take place. Partial digestion of the receptor–ligand covalent complex, followed by analysis of the fragments, would serve to locate the ligand within the active site.

A convergent synthesis of the racemate of classical-nonclassical cannabinoid **1** (Scheme 1) is described. The C7′ azido group in **1** can be activated photochemically, whereas the iodo group is expected to react with proximal nucleophilic residues within the active site. In earlier work we have shown that the β-3-iodopropyl group at C6 confers improved binding properties of ligands to the CB1 receptor.[3]

The aliphatic portion of **1** was prepared from the *tert*-butyldimethylsilyl ether of pent-4-yn-1-ol **2** *via* a carboalumination–alkylation process (Scheme 1).[4] Published procedures call for evaporation of the halogenated solvent and its replacement by $Et_2O$ prior to the formation of the alanate. This works well, but is inconvenient on a large scale. We have determined that solvent replacement is unnecessary. Slow addition of a precooled solution of *n*-butyllithium in hexane to the intermediate alane derived from **2** in either $ClCH_2CH_2Cl$ or $CH_2Cl_2$ at −78 °C produced the alanate.[5] Quenching with ethylene oxide gave alcohol **3** in 88% yield. This represents a significant improvement for the process.

Bromide **4** was obtained from **3** *via* the toluene-*p*-sulfonate following treatment with LiBr. Metal–halogen exchange, addition of the lithio species to phosphorane **5**[6] and treatment with acetic acid gave α,β-unsaturated ester **6**. Exposure of **6** to

**Scheme 1** *Reagents and conditions*: i, $Cp_2ZrCl_2$, $AlMe_3$, $CH_2Cl_2$, 0 °C, 16 h; $Bu^nLi$, −45 °C, 0.5 h; ethylene oxide, −30 to 0 °C, 4 h, 88%; ii, TsCl, pyridine, 0 °C; iii, LiBr, acetone, room temp., 82% from **2**; iv, $Bu^tLi$, $Et_2O$, −78 °C; **5**, THF, −78 to −14 °C, 16 h; AcOH, 0 °C, 0.5 h, 74%; v, Mg, MeOH, room temp., 16 h; vi, DIBAL-H, $Et_2O$, −78 °C, 3 h; EtOH, −78 °C, 91% from **6**; vii, $Li(CH_2)_6OPh$, THF, −78 °C, 62%; viii, $TiCl_4$, $ZnMe_2$, $CH_2Cl_2$, −30 °C to room temp., 4 h; ix, $BBr_3$, $CH_2Cl_2$, −78 °C to room temp., 84% from **10**; x, MeMgBr, $Et_2O$, 0 °C, 1 h; $MgBr_2$, **8**, $CH_2Cl_2$, −78 °C to room temp.; xi, $Tf_2NH$, $ZnCl_2$, toluene, reflux, 4 h; $Tf_2NH$, $ZnCl_2$, MeOH, reflux, 4 h, 38% from **8**; xii, $TMGN_3$, $MeNO_2$, 50 °C, 3 h; xiii, $I_2$, $PPh_3$, imidazole, PhH, 35 °C, 0.75 h, 69% from **15**

Mg in MeOH led to difluoromethylene compound **7**, the desired product of fluoride elimination from a β-anionic intermediate. Small amounts (5–7%) of the saturated, β-trifluoromethyl ester were also obtained. Reduction of **7** with DIBAL-H led to aldehyde **8**.

The aromatic portion of **1** was prepared from the Weinreb amide **9** of 3,5-dimethoxybenzoic acid. Reaction of **9** with 6-phenoxyhexyllithium gave phenone **10**. Treatment of **10** with $TiCl_4$ and $ZnMe_2$ introduced the benzylic *gem*-dimethyl grouping in nearly quantitative yield.[7] Subsequent exposure of **11** to $BBr_3$ in $CH_2Cl_2$ cleaved all three ether groups and introduced the C7′ bromide of **12**. The overall yield of **12** from **10** was 84%. This protocol represents a significant improvement in terms of total number of steps and convenience over the established synthesis of the 5-(1′,1′-dimethylheptyl)resorcinol moiety.[8,9]

The coupling of **12** to **8** was challenging. Attempts to effect the reaction under Lewis acid catalysis led primarily to **13**, from the intramolecular ene reaction of **8**. Success was realized when resorcinol **12** was first converted to the monobromomagnesium salt, and then treated with a deficiency of aldehyde **8** in the presence of catalytic $MgBr_2$ to produce the coupled material **14** in 53% yield.[10] Unreacted **12** was recycled. Exposure of **14** to toluene-sulfonic acid (TsOH) in MeOH at reflux[11] gave a modest yield of dihydrobenzopyran **15** accompanied by larger amounts of tetrahydrofuran **16**.† The tetrahydrofuran probably results from a stepwise, ionic process.

The cyclization to **15** took place upon treatment of **14** with bis(trifluoromethylsulfonyl)amine[12] and $ZnCl_2$, first in toluene and then in MeOH. The relative stereochemistry at C6, C6a and C10a was determined by NOE experiments in conjunction with HMQC and HMBC experiments. The observed stereochemistry could not have been predicted with confidence from the outset. Cyclization to form the C9 methyl cannabinoid skeleton is known from precedent[11] to produce the C6a–C10a *trans* stereoisomer. Our own work[13] has shown that cyclization to form the $\Delta^9$ unsaturated series produces the unnatural C6a–C10a *cis* stereoisomer as the exclusive product, therefore the stereochemical outcome of the cyclization is easily perturbed by minor structural changes in the *seco* precursor (*cf.* **14**).

The conversion of **14** to **15** is also noteworthy because it provides the strongest support to date for the mechanism, which is postulated to involve formation of a transient *ortho*-quinomethane which undergoes intramolecular hetero-Diels–Alder cycloaddition. Product **15** provides the first example of a Diels–Alder cyclization to a cannabinoid with a stereogenic C6 carbon atom. The fact that only the β-3-hydroxypropyl isomer was formed is consistent with a concerted cycloaddition proceeding through an *exo* transition state. A stepwise ionic process would have led to diastereoisomers at C6.[14] All earlier examples of this reaction led to cannabinoids with a *gem*-dimethyl group at C6.

The conversion of **15** to C7′ azido derivative **17** was effected with tetramethylguanidinium azide ($TMGN_3$).[15] Treatment of the crude reaction product with $PPh_3$–$I_2$ complex in the presence of imidazole[16] gave **1** in 69% overall yield from **15**.‡ It is critical that an excess (*ca.* 20 mol%) of $I_2$ over $PPh_3$ be used so as to suppress the Staudinger reaction of the phosphine with the azide. It is significant that no protecting groups were used during the execution of these steps. The enantiomers of **1** were easily separated by chiral HPLC.

The methodology which has been outlined in Scheme 1 is currently being applied to the synthesis of a series of cannabinoid ligands. Full experimental details of this work, as well as the receptor binding properties of the products, will be reported in due course.

Acknowledgement is made to NIDA (DA 09158 and DA 07215) for their generous support of this work.

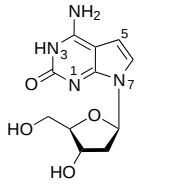
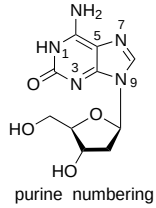
# 7-Deazaisoguanine quartets: self-assembled oligonucleotides lacking the Hoogsteen motif



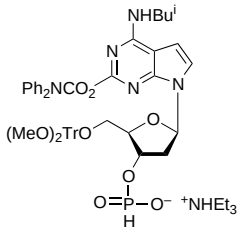
**Frank Seela* and Changfu Wei**

*Laboratorium für Organische und Bioorganische Chemie, Institut für Chemie, Universität Osnabrück, Barbarastr. 7, D-49069 Osnabrück, Germany*

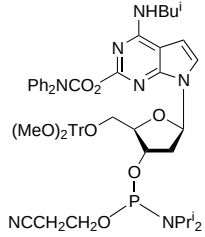


**Oligonucleotides containing consecutive 7-deazaisoguanine residues form self-assembled quartets, indicating that the purine nitrogen-7 of isoguanine is not participating in the hydrogen bonding pattern.**

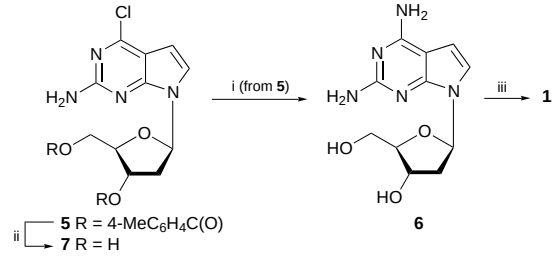
Oligodeoxyribonucleotides with consecutive isoguanine residues, *e.g.* d($T_4$isoG$_4T_4$),† form self-assembled structures.[1,2] Such aggregates have also been observed in the case of the homopolyribonucleotide poly(isoguanylic acid)[3] and the monomeric ribonucleoside isoguanosine.[4] Like the G-quartet the aggregate of isoguanine has properties of an ionophore.[5] The stability of the metal complexes depend on the size of the particular ion.[6] Ion-exchange HPLC experiments showed that the aggregate of d($T_4$isoG$_4T_4$) has the same number of negative phosphate charges as that of d($T_4G_4T_4$). Due to this observation a tetrameric structure was also proposed for d($T_4$isoG$_4T_4$).[2] The stoichiometry of this complex was established using isoguanine-containing oligonucleotides with different dT-tails at the 3′- and 5′-termini.[7] So far, the isoguanine-quartet shows behaviour similar to that of guanine. Although the tetrameric assembly of isoguanine has been verified, several structural motifs have been proposed for the quartet structure.[2–4]



Base-modified nucleosides are useful tools to probe the structure of such high-molecular assemblies, in particular those which are held together by hydrogen bonds. Regarding this it has already been shown that the base pairing pattern can be restricted to the Watson–Crick motif when 7-deazaguanine is replacing guanine.[8] As a result, Hoogsteen quartets cannot be formed and the oligonucleotides are unable to form aggregates.[9] Based on this principle, 7-deaza-2′-deoxyisoguanosine **1** ($c^7iG_d$) has been employed to probe the oligonucleotide quartet structure formed by 2′-deoxyisoguanosine **2** (isoG$_d$). New oligonucleotide quartets should be accessible when the purine nitrogen-7 does not participate in the hydrogen bonding pattern. For this purpose the oligonucleotide building blocks **3** and **4** were synthesised. Oligonucleotides with consecutive 7-deaza-isoguanine residues were prepared and their ability to form self-assembled aggregates was studied.



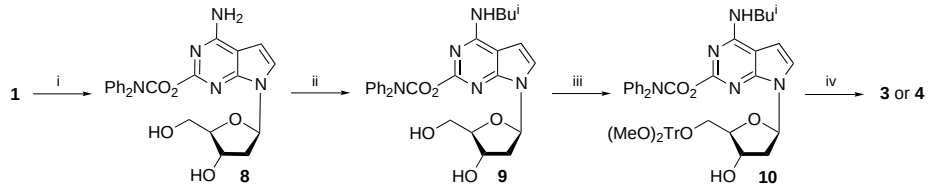
**1**



**2**

**3**

**4**



**Scheme 1** *Reagents and conditions*: i, 25% $NH_3$–dioxane (1:1 v/v), 120 °C, 3 d, 88%; ii, 25% $NH_3$–dioxane (1:1 v/v), 60 °C, 3 d, 80%; iii, $NaNO_2$, 20% aq. AcOH, 67%

7-Deaza-2′-deoxyisoguanosine **1** has already been prepared (i) by convergent nucleoside synthesis[10] or (ii) by photosubstitution on 2-chloro-7-deaza-2′-deoxyadenosine.[11] Now, a more efficient route has been employed using glycosylation of the 2-amino-4-chloro-7*H*-pyrrolo[2,3-*d*]pyrimidine anion[12] with 2-deoxy-3,5-di-*O*-(4-methylbenzoyl)-α-D-*erythro*-pentofuranosyl chloride. The resulting nucleoside **5** was treated with conc. $NH_3$–dioxane (autoclave, 120 °C, 3 d) to give 2-amino-7-deaza-2′-deoxyadenosine **6**.[13] The deprotected compound **7** was also obtained (60 °C, conc. $NH_3$–dioxane, 3 d). Selective deamination of **6** ($NaNO_2$ in aq. AcOH) furnished the nucleoside **1** (Scheme 1). It is stable in acidic solution whereas 2′-deoxyisoguanosine **2** is an extremely labile nucleoside.[1]

For the preparation of **3** and **4**, compound **1** was blocked on the 2-oxo function with a $Ph_2NC(O)$ group ($Ph_2NCOCl$, $Pr^i_2NEt$–pyridine, room temp.) to give derivative **8**. The isobutyryl residue was then introduced to protect the amino group, yielding compound **9**. Standard conditions were employed to block the 5′-hydroxy group with a DMT residue† (**9** → **10**).‡ The phosphonate **3** as well as the phosphoramidite **4** were prepared from **10** according to known procedures (Scheme 2).

As discussed above, DNA quartets have been constructed from oligonucleotides containing short runs of isoguanine, *e.g.* d($T_4$isoG$_4T_4$).[1,2] These self-assembled structures were identified by HPLC ion exchange chromatography [Fig. 1(*a*)].[2] Their chromatographic behaviour was almost identical to that observed for d($T_4G_4T_4$). The chromatogram shows two peaks, a fast migrating peak for the monomeric oligonucleotide and a slow migrating peak for the tetramer (Fig. 1). The same experiment was then performed with oligonucleotides containing consecutive 7-deazaisoguanine residues.§ For this purpose, the oligomers 5′-d($T_4c^7iG_4T_4$) **11** and 5′-d($T_2c^7iG_6T_4$) **12** were prepared by solid-phase synthesis.

The oligomer 5′-d($T_4c^7iG_4T_4$) **11** gives only one peak when chromatographed on an ion exchange HPLC column under the conditions described for d($T_4$isoG$_4T_4$) [Fig. 1(*b*)].[2] This fast migrating peak contains only the single-stranded oligomer. However, when the number of consecutive $c^7iG_d$-residues is increased from four to six by replacing another two dT-residues as in the oligomer d($T_2c^7iG_6T_4$) **12**, a slow migrating zone

**Scheme 2** *Reagents and conditions*: i, $Ph_2NCOCl$, 80%; ii, $Me_3SiCl$, $Bu^iCl$, 80%; iii, DMTCl, 51%; iv (for **3**) $PCl_3$, *N*-methylmorpholine, 1*H*-1,2,4-triazole, 93%; (for **4**) $(NCCH_2CH_2O)(Pr^i_2N)PCl$, $EtNPr^i_2$, 85%

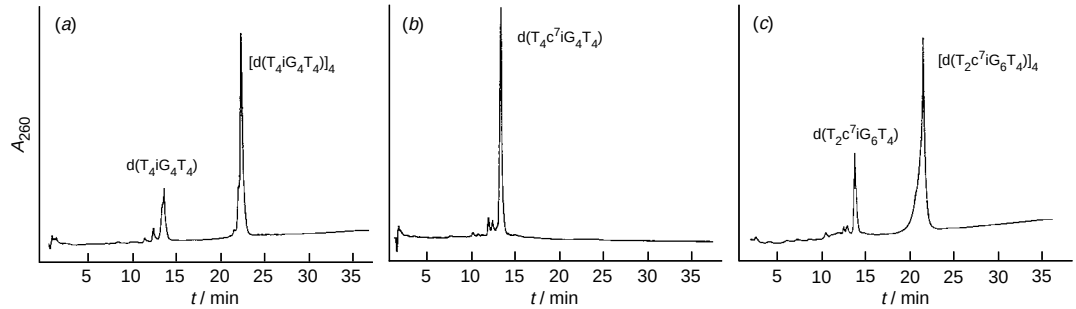


**Fig. 1** Ion exchange HPLC profiles of (*a*) 5′-d($T_4$iso$G_4T_4$), (*b*) 5′-d($T_4c^7iG_4T_4$) and (*c*) 5′-d($T_2c^7iG_6T_4$) at 25 °C. Solvent systems: A = 25 mM Tris-HCl (containing 1 mM EDTA buffer, pH 8.0)–MeCN, 90 : 10; B = A containing 1.0 M NaCl. Gradient: $t$ = 0–30 min, 20 → 80% B in A; $t$ = 30–35 min, 80% B in A.

($t_R$ = 22 min) appeared along with the fast migrating peak ($t_R$ = 14 min) [Fig. 1(*c*)]. The latter contains the single-stranded oligomer, while the slow migrating peak represents the aggregate. Consequently, the aggregate of d($T_2c^7iG_6T_4$) **12** reflects a self-assembled structure. The almost identical mobilities of compounds d($T_4$iso$G_4T_4$) and d($T_2c^7iG_6T_4$) on ion-exchange HPLC indicate that both aggregates are formed by assembly of four strands. This is the result of an identical number of negative phosphate charges, which are responsible for the chromatographic mobility.

From model building it is obvious that the structure of the isoguanine quartet has to be different from that of guanine. The structure of the two bases differs with regard to the position of the purine substituents, thereby changing their donor–acceptor pattern. Various aggregate motifs have been suggested for the polyribonucleotide poly(isoG),[3] for the monomeric isoguanosine,[4] and also for oligodeoxyribonucleotides.[2,14] Some structures do not use the purine nitrogen-7 to form the supramolecular assembly. Among them the most probable structure for the quartet of **12** is **A** (Fig. 2). It follows a motif which has been proposed for a monomeric isoguanosine derivative.[4]

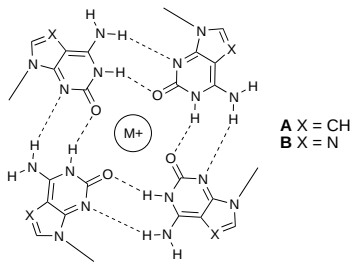

**Fig. 2**

The experiments described suggest that oligonucleotides containing either 7-deazaisoguanine or isoguanine form similar supramolecular structures with an identical hydrogen bonding pattern (**A** or **B**). Nevertheless, due to the structural changes of the heterocyclic base—a purine system is replaced by a pyrrolo[2,3-*d*]pyrimidine heterocycle—the strength of the hydrogen bonding array results in somewhat lower stability for the 7-deazaisoguanine quartet **A** compared to that formed by isoguanine (**B**). Unlike 2′-deoxyisoguanosine, which is very sensitive to acidic conditions (glycosylic bond hydrolysis), 7-deaza-2′-deoxyisoguanosine is very stable. This makes it a good candidate to form ionophors with good chemical stability.

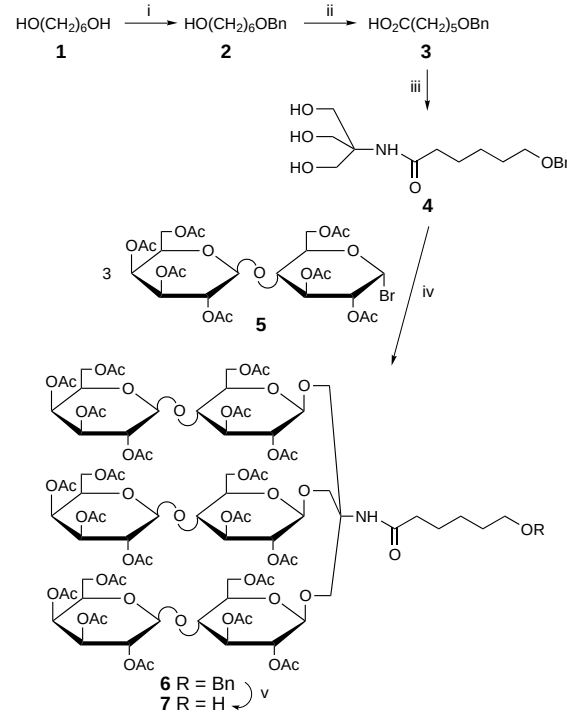
# Synthesis of a D-lactosyl cluster–nucleoside conjugate†

**Andrew R. Vaino,[a] William T. Depew[b] and Walter A. Szarek*[a]**

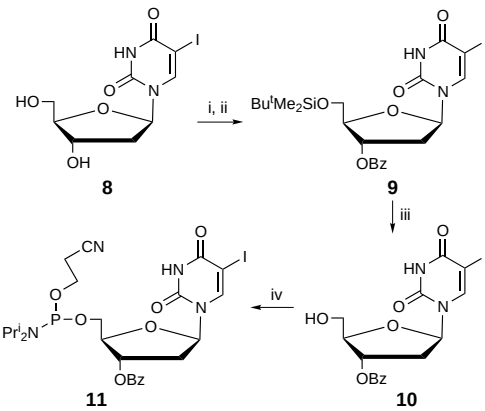
[a] *Department of Chemistry, Queen's University, Kingston, Ontario, Canada K7L 3N6*
[b] *Department of Medicine, Queen's University, Kingston, Ontario Canada K7L 3N6*

**The synthesis of a nucleoside–oligolactoside conjugate, expected to provide site-specific drug delivery to the human liver, is described.**



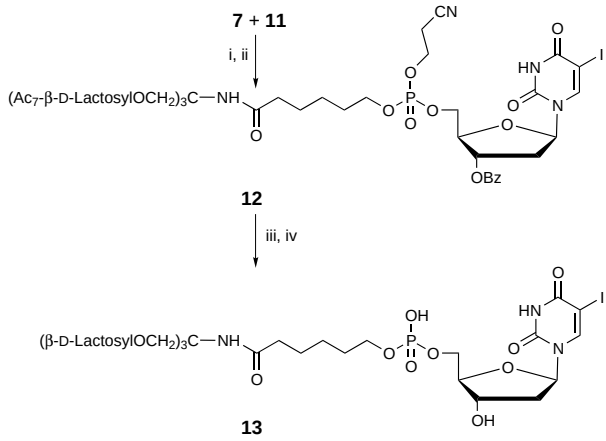
The hepatitis B virus (HBV) represents a major health concern, afflicting 350 million people worldwide.[1] While the virus itself is debilitating, it is not always fatal. However, liver cancer, which often arises from HBV infection, is responsible for upwards of 1 million deaths annually.[2] The mode of action of the HBV is thought to be similar to that of the HIV virus, in that it involves reverse transcription in the cytoplasm.[3] Thus, many nucleosides known to inhibit HBV reverse transcriptase, with their unwanted side-effects, have been examined as a means of controlling this deadly affliction.

The mammalian hepatocyte plasma membrane expresses the asialoglycoprotein receptor (ASGP-R),[4] a unique integral membrane receptor exhibiting specificity for terminal, nonreducing, β-D-galactopyranosyl or 2-acetamido-2-deoxy-β-D-galactopyranosyl residues. This specific binding to liver cells has been examined with a variety of oligogalactosides[5] and oligolactosides.[6] The biological evaluation of the binding of a host of molecules containing various numbers of terminal D-galactopyranosyl residues has demonstrated that, as the number of these residues increased, so did binding.[5b,6] Previous studies in this laboratory have involved adding one, two or three D-lactose units to a glycerol backbone.[7] Thus, attempts were made to extend this type of molecule, with its *hepatophilicity*, by the addition of an extra functional group, through which a hepatotoxic nucleoside could be appended. Ideally, by directing such a nucleoside directly to the liver, the devastating side-effects of HBV treatment would be obviated.



Previous work with D-galactose has utilized the well-known buffer tris(hydroxymethyl)methylamine (TRIS) as a backbone.[5] In the present work TRIS was modified such that, after addition of three D-lactose units, a cytotoxic nucleoside could be readily introduced. The nucleoside chosen was 2′-deoxy-5-iodouridine (dIU), known to inhibit HBV.[8]

To synthesize the acetylated *delivery vehicle* **7** (Scheme 1), a suitably modified backbone was required. Beginning with hexane-1,6-diol, a single benzyl group was introduced, followed by oxidation of the remaining hydroxy group to the corresponding carboxylic acid. Addition to the amino group of TRIS was performed using the well-known peptide-coupling agent 2-ethoxy-1-ethoxycarbonyl-1,2-dihydroquinoline (EEDQ).[9] Glycosylation of the three primary hydroxy groups of **7** with 2,3,6,2′,3′,4′,6′-hepta-*O*-acetyl-α-D-lactosyl bromide, prepared by the method of Kartha and Jennings,[10] was achieved in 69% yield using the Helferich modification[11] of the Königs–Knorr reaction. Removal of the benzyl group was readily accomplished in 85% yield by catalytic hydrogenolysis. The confirmation of the structure of this oligolactoside was accomplished using Fourier-transform, proton chemical-shift correlation spectroscopy (COSY)[12] and heteronuclear correlation spectroscopy (HETCOR).[13] The β-D configuration for the glycosidic linkage between the lactose units and the backbone was revealed by the observation of a characteristic coupling constant[14] ($J_{1,2}$ 7.9 Hz). It should be noted, however, that identification of trace amounts of material having α-D linkages would have been precluded by the detection limit of the NMR experiment.



The nucleoside selected, namely dIU, required protection of the hydroxy group at C-3′ prior to attachment to the delivery moiety. Thus, the selectivity of the $Bu^tMe_2Si$ group for primary hydroxy groups[15] allowed for an efficient two-step, one-pot procedure to form **9** (Scheme 2) in a high yield. The $Bu^tMe_3Si$

**Scheme 1** *Reagents*: i, BnBr (0.7 equiv.), NaH, THF; ii, Jones reagent; iii, $(HOCH_2)_3CNH_2$, EEDQ, EtOH; iv, **5** (3 equiv.), $Hg(CN)_2$, 1 : 1 $MeNO_2$–$C_6H_6$; v, $H_2$, 10% Pd/C, $HCO_2H$, MeOH

**Scheme 2** *Reagents and conditions*: $Bu^tMe_2SiCl$, pyridine, room temp.; ii, BzCl, 0 °C, pyridine; iii, 1% $I_2$ in MeOH; iv, β-CDCP, $Pr^i_2NEt$, MeCN, 0 °C

**Scheme 3** *Reagents*: i, 1*H*-tetrazole, MeCN; ii, $I_2$, THF, $H_2O$, pyridine; iii, LiOH, MeOH; iv, Amberlite IR-120 ($H^+$)

group was readily removed by treatment with a solution of $I_2$ in MeOH at reflux temperature[16] to afford **10**, ready for coupling.

Many possibilities exist for the joining of the nucleoside and the carrier molecule, however, most of these were quickly discounted on the basis of possible reactivity *in vivo*; the use of a phosphoric monoester was selected. A well-established modification of the standard phosphite assembly method[17] was employed, with the reagent β-cyanoethyl *N*,*N*-diisopropylchlorophosphoramidite (β-CDCP)[18] as the coupling agent. Compound **10** afforded an unstable intermediate, presumably **11**, which, on coupling to the carrier molecule **7** in the presence of 1*H*-tetrazole followed by oxidation of the product with iodine, afforded **12** (Scheme 3) in 12% yield.‡ Simultaneous cleavage of the acetic and benzoic esters, along with elimination of the β-cyanoethyl group, afforded the desired conjugate **13**.§

To conclude, we have demonstrated the synthesis of an easily prepared vehicle for the targeting of drugs directly to the mammalian liver. The advantages of site-specific, drug delivery are clear. Thus, the potential for conjugates such as **13**, in which a vehicle known to have a high specificity for hepatocytes is coupled to a hepatotoxic nucleoside, is tremendous. Full experimental details of this and related compounds, along with biological evaluation of the binding of these compounds to the ASGP-R and inhibition studies with HBV, will be reported in due course.

The authors thank the Natural Sciences and Engineering Research Council Canada for financial support of this research.

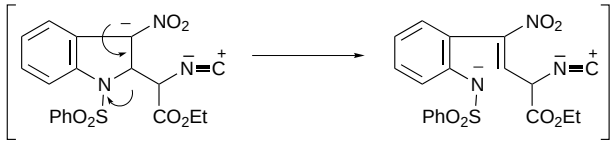
# One-step syntheses of the pyrrolo[3,4-*b*]indole and pyrrolo[2,3-*b*]indole ring systems from 3-nitroindoles

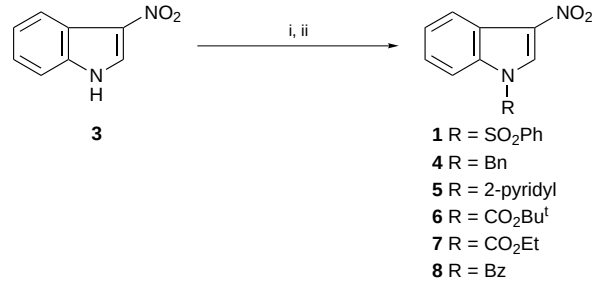
**Erin T. Pelkey and Gordon W. Gribble***

*Department of Chemistry, Dartmouth College, Hanover, NH 03755, USA*

**The reaction of 1-ethoxycarbonyl-3-nitroindole with ethyl isocyanoacetate in the presence of DBU gives ethyl 4-ethoxycarbonyl-2,4-dihydropyrrolo[3,4-*b*]indole-3-carboxylate, averting a novel rearrangement that we previously reported with 3-nitro-1-phenylsulfonylindole that yielded ethyl 8-phenylsulfonyl-1,8-dihydropyrrolo[2,3-*b*]indole-2-carboxylate.**



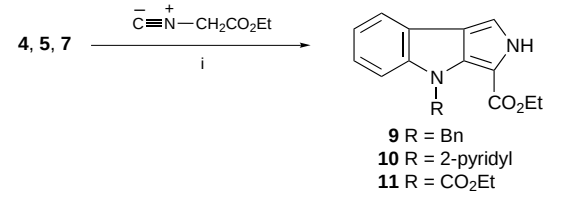
We recently reported a remarkable rearrangement which led to an expeditious synthesis of the pyrrolo[2,3-*b*]indole ring system.[1] Thus, treatment of 3-nitro-1-phenylsulfonylindole **1** with ethyl isocyanoacetate[2] and DBU gave pyrrolo[2,3-*b*]indole **2** in 85% yield (Scheme 1).[1] We anticipated that this application of the Barton–Zard pyrrole synthesis[3] would give a pyrrolo[3,4-*b*]indole[4–7] which could be utilized as a fused stable analogue of indole-2,3-quinodimethane,[8] in continuation of our interest in a related fused ring system, the furo[3,4-*b*]indoles.[9]



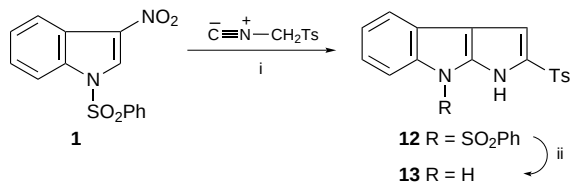
**Scheme 1** *Reagents and conditions*: i, DBU, THF, room temp., 20 h, 85%

To explain the outcome of this abnormal Barton–Zard reaction leading to the rearranged product **2**, we proposed a mechanism which involved a fragmentation of the indole ring system (Scheme 2),[1] which can be rationalized by the presence of a good leaving group, the aryl sulfonamide anion [*N*-(phenylsulfonyl)benzenesulfonamide has a p$K_a$ of 11.8[10]].

To circumvent this fragmentation and subsequent rearrangement in order to develop a succinct route to the pyrrolo[3,4-*b*]indole ring system, which was our original goal, we have investigated this reaction with 3-nitroindole substrates containing *N*-protecting groups that are less electron-withdrawing than *N*-phenylsulfonyl but which will still activate the indole double bond to the initial C-2 Michael addition. The requisite protected 3-nitroindoles were synthesized from 3-nitroindole **3**[11] utilizing sodium hydride as the base in DMF. For example, treatment of **3** with sodium hydride in DMF followed by benzenesulfonyl chloride gave **1**[12] in 86% yield. Likewise, 3-nitroindoles **4**–**8** were synthesized in variable yields utilizing benzyl bromide (79% yield), 2-fluoropyridine (19% yield),[13] *tert*-butyl phenyl carbonate (40% yield),[14] ethyl chloroformate (50% yield)[15] and benzoyl chloride (31% yield),[15] respectively (Scheme 3).



**Scheme 2**

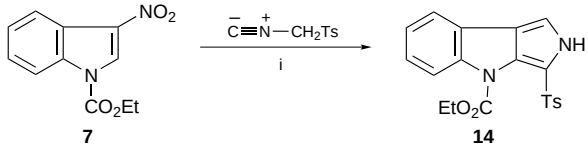


**Scheme 3** *Reagents and conditions*: i, NaH, DMF, 0 °C, 0.5–2 h; ii, (for **1**) $PhSO_2Cl$, 86%; (for **4**) $PhCH_2Br$ (79%); (for **5**) 2-fluoropyridine, 100 °C, 10 h, 19%; (for **6**) $PhOCO_2Bu^t$, 40%; (for **7**) $ClCO_2Et$, 50%; (for **8**) BzCl, 31%

The abatement of the rearrangement was first observed when *N*-benzylindole **4** was subjected to the Barton–Zard pyrrole synthesis conditions (Scheme 4). In the event, treatment of **4** with ethyl isocyanoacetate and DBU in THF at room temperature resulted in no reaction, but after being heated at reflux for 9 h, pyrrolo[3,4-*b*]indole **9**† was obtained in 30% yield. The low yield is most likely due to the decreased degree of electrophilicity associated with **4** as compared to **1**. To confirm the structure of this product, we synthesized the corresponding known isomer, ethyl 8-benzyl-1,8-dihydropyrrolo[2,3-*b*]indole-2-carboxylate,[16] which was clearly different from **9** in all respects (IR, TLC, UV, and $^1$H NMR). An increase in yield utilizing milder reaction conditions was observed with the more electrophilic *N*-(2-pyridyl)indole **5**, which, upon treatment with ethyl isocyanoacetate and DBU in THF at room temperature, gave pyrrolo[3,4-*b*]indole **10** in 72% yield. A simple and reliable method for determining the regiochemistry of these Barton–Zard reactions is to determine the pyrrole ring C-1 proton–NH coupling constant. For the pyrrolo[2,3-*b*]indole systems, the resulting four bond coupling is usually 1.5 Hz, while for pyrrolo[3,4-*b*]indole systems the resulting three bond coupling is usually 3.0 Hz. Indeed, the coupling constant observed for the pyrrole ring proton of **10** is 3.3 Hz.

Although the synthesis of **10** in good yield accomplished the initial goal of precluding the rearrangement, a more practical protecting group was sought which could provide a similar result. Treatment of *N*-benzoylindole **8** under the usual conditions resulted in deprotection, and similar treatment of *N*-butoxycarbonylindole **6** resulted in no reaction even after prolonged reflux. Finally, to our delight, treatment of

**Scheme 4** *Reagents and conditions*: i, (for **9**) DBU, THF, reflux, 9 h, 30%; (for **10**) DBU, THF, room temp., 12 h, 72%; (for **11**) DBU, THF, room temp., 18 h, 91%



**Scheme 5** *Reagents and conditions*: i, DBU, THF, room temp., 22 h, 63%; ii, 6% Na/Hg, THF, MeOH, −40 °C, 73%

*N*-ethoxycarbonylindole **7** with ethyl isocyanoacetate in DBU at room temperature gave the desired pyrrolo[3,4-*b*]indole **11**† in 91% yield.

We have also found that the fragmentation–rearrangement pathway occurs with tosylmethyl isocyanide (TsMIC).[17] Treatment of **1** with TsMIC and DBU in THF gave pyrrolo[2,3-*b*]indole **12**† in 63% yield, which was subsequently deprotected with sodium amalgam[18] to afford pyrrolo[2,3-*b*]indole **13** in 73% yield (Scheme 5). In accord with the structural assignment, the coupling constants for the pyrrole ring protons of **12** and **13** are 1.8 and 1.5 Hz, respectively.

In contrast, treatment of **7** under the same conditions gave the corresponding pyrrolo[3,4-*b*]indole **14**† in 41% yield (Scheme 6). Support for the structural assignment of **14** can again be found with the observed pyrrole ring proton coupling constant of 3.3 Hz.

**Scheme 6** *Reagents and conditions*: i, DBU, THF, room temp., 20 h, 41%

In conclusion, we have shown that both pyrrolo[2,3-*b*]indoles and pyrrolo[3,4-*b*]indoles can be synthesized from 3-nitroindole substrates depending on the *N*-indole protecting group in one step *via* the Barton–Zard pyrrole synthesis.

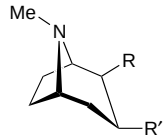
# An enantioselective synthesis of 2-alkyl-3-phenyltropanes by an asymmetric 1,3-dipolar cycloaddition reaction



**Gian Luca Araldi,[a] K. R. C. Prakash,[a] Clifford George[b] and Alan P. Kozikowski*[a]**

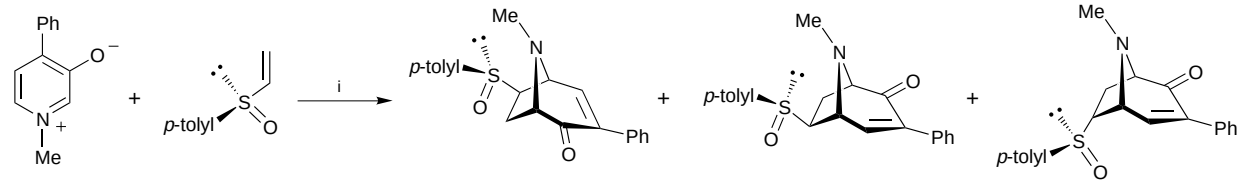
[a] *Drug Discovery Laboratory, Georgetown University Medical Center, Institute for Cognitive and Computational Sciences, 3970 Reservoir Road NW, Washington, DC 20007-2197, USA*

[b] *Laboratory for the Structure of Matter, Code 6030, Naval Research Laboratory, 4555 Overlook Avenue SW, Washington, DC 20375-5000, USA*

**A method for gaining access to 2-alkyl-3-phenyl-substituted tropanes using the chiral dipolarophile (*R*)-*p*-tolyl vinyl sulfoxide in the asymmetric 1,3-dipolar cycloaddition reaction with the oxidopyridinium betaine 4 is described.**

(*R*)-Cocaine[1] **1** is a plant alkaloid purified from the leaves of *Erythroxylum coca*; its abuse is one of the greatest concerns of the American public today, and it is clear that immediate therapies are needed for the treatment of individuals who have become addicted to this powerful reinforcing drug.[2] In order to discover agents for use in the treatment of cocaine abuse, we believe that it will be valuable to identify molecules that can act as cocaine antagonists or partial agonists. Previously, we have shown that cocaine's C-2 ester group can be replaced by alkyl and alkenyl groups as in **3** with no loss in activity,[3] while other workers have shown that replacement of the C-3 benzoate by phenyl leads to compounds **2** of higher potency (these phenyl-bearing structures are often referred to as the WIN series compounds).[4] In order to more quickly identify those structural changes that may lead to altered functional activity, we required a chemical approach to diversely substituted 2-alkyl-3-phenyltropanes. We recently reported[5] a pyridinium betaine-based dipolar cycloaddition route to racemic tropane derivatives **3**.

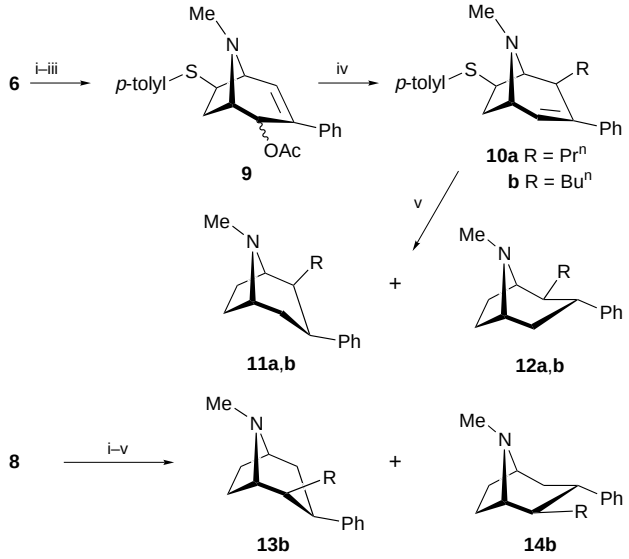
**1** R = $CO_2$Me, R′ = OBz
**2** R = $CO_2$Me, R′ = Ph
**3** R = alkyl or alkenyl, R′ = Ph



Asymmetric 1,3-dipolar cycloaddition reactions using chiral dipolarophiles are well documented.[6] Herein we report the cycloaddition reaction of the sulfoxide **5**[6a] and the oxidopyridinium betaine **4**[5] to afford the tropenone intermediates **6**–**8** with good diastereoselectivity and complete regioselectivity (Scheme 1). The reaction was performed in dioxane at reflux for 20 h to give a mixture of both *exo* and *endo* cycloadducts (70 : 30). Silica gel flash column chromatography of the crude mixture led to the separation of the *exo* products (4 : 1 mixture of the diastereomers **6** and **7**; 55% overall yield) from the *endo* product **8** (22% yield). The major *exo* diastereomer **6** was obtained by crystallization from EtOAc of the above 4 : 1 mixture and had $[\alpha]_D^{25}$ −51 (*c* 0.5, acetone), $R_f$ 0.6 (EtOAc), and mp 166 °C. The *endo* product **8** had $[\alpha]_D^{25}$ +73 (*c* 0.5, acetone), $R_f$ 0.3 (EtOAc), and mp 98–104 °C. The absolute configurations of **6** and **8** were determined by X-ray diffraction studies.†

The major *exo* product **6** was converted to the 2β-alkyl-3β-phenyltropane derivatives **11a** and **11b** as shown in Scheme 2. Thus, ketone **6** underwent exclusive 1,2-reduction using the Luche protocol[7] to provide the allylic alcohol intermediate as a mixture of the α- and β-stereoisomers. These alcohols were converted to their acetates followed by reduction of the sulfoxide with $PCl_3$ in DMF at 0 °C.[6b] The resulting sulfide **9** (3 : 1 mixture of the α- and β-acetates) underwent a CuCN-catalysed cross coupling reaction using RMgBr (R = $Pr^n$ or $Bu^n$) as the nucleophile[8] to afford the alkene intermediates **10a** and **10b**. As previously reported,[5] this reaction is completely regioselective (only γ-alkylation products are observed), and the final stereochemistry of the alkyl-bearing centre is independent of that of the acetate intermediate (*i.e.* only β-diastereoisomers are observed).

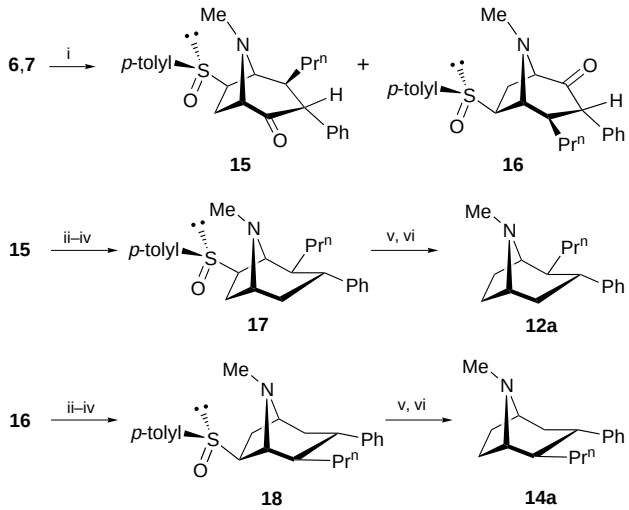
The alkenes **10a** and **10b** were subjected in turn to a one-step desulfurization and hydrogenation reaction using Raney-nickel (W2) in EtOH to yield the 2β,3β-isomers **11a** and **11b** (12–13%) together with the 2β,3α-isomers **12a** and **12b** (40–43%) derived from β-face hydrogenation. These mixtures were separated by preparative TLC (hexane–EtOAc–$Et_3N$ 9 : 0.8 : 0.2) on silica gel. The 2β-*n*-propyl-3β-phenyltropane **11a** had $[\alpha]_D^{25}$ −49 (*c* 0.25, $CH_2Cl_2$); the corresponding 2β,3α-isomer **12a** had $[\alpha]_D^{25}$ −50 (*c* 1.0, $CH_2Cl_2$). The *n*-butyl derivatives **11b** and **12b** had $[\alpha]_D^{25}$ −64 (*c* 0.2, $CH_2Cl_2$) and −43 (*c* 0.5, $CH_2Cl_2$), respectively.



Compound **8** was subjected to the same sequence of reactions as presented in Scheme 2 for the intermediate **6** using $Bu^n$MgBr as Grignard reagent. Two products were obtained after complete reduction of the intermediate alkene: 2β-*n*-butyl-3β-phenyltropane **13b** with $[\alpha]_D^{25}$ +62 (*c* 0.2, $CH_2Cl_2$) and the corresponding 2β,3α isomer **14b** with $[\alpha]_D^{25}$ +41 (*c* 0.5, $CH_2Cl_2$).

The structures and stereochemical assignments for these compounds were determined using $^1$H NMR, $^{13}$C NMR,

**4** **5** (1*S*, 5*S*, 6*R*, $R_S$)-**6** (44%) (1*R*, 5*R*, 6*S*, $R_S$)-**7** (11%) (1*R*, 5*R*, 6*R*, $R_S$)-**8** (22%)



**Scheme 1** *Reagents and conditions*: i, 1,4-dioxane, reflux, 24 h

**Scheme 2** *Reagents and conditions*: i, $NaBH_4$, $CeCl_3$, MeOH, room temp.; ii, $Ac_2O$, pyridine, room temp.; iii, $PCl_3$, DMF, 0 °C, 88%; iv, RMgBr, CuCN, $Et_2O$, room temp., 77%; v, Raney-Ni (W2), EtOH, reflux

HETCOR and 2D COSY experiments. Because the stereochemical assignment of the final compounds **11** and **12** is problematic due to the complexity of their $^1$H NMR spectra, we synthesized the chair-like compounds **11a**,**b** from natural (−)-cocaine by the procedure previously reported.[3] Our synthetic samples proved to be identical in all respects with the samples obtained from natural (−)-cocaine.

Additionally using the mixture of diastereoisomers **6** and **7**, we developed another route that would unequivocally afford only the 2β,3α-tropane derivatives **12a** and **14a** (Scheme 3). This mixture readily underwent the copper(I)-catalysed conjugate addition reaction of $Pr^nMgBr$ in the presence of $Me_3SiCl$ and HMPA[9] to afford the two alkylated derivatives **15** and **16**, which were separated by flash chromatography on silica gel. The relative stereochemistry of the C-3 and C-4 substituents in these two derivatives was assigned by the observation of $J_{3,4}$ = 8.1 and 7.5 Hz for compounds **15** and **16**, respectively. These coupling constants are comparable with those reported

**Scheme 3** *Reagents and conditions*: i, $Pr^nMgBr$, CuBr.$Me_2S$, HMPA, $Me_3SiCl$, THF, −78 °C; ii, $LiAlH_4$, THF, room temp.; iii, LDA, ClC(S)OPh, THF, −78 °C; iv, $Bu_3SnH$, AlBN, toluene, 90 °C; v, $PCl_3$, DMF, 0 °C; vi, Raney-Ni, EtOH, reflux

earlier in the literature[5] wherein the stereochemistry of these compounds was confirmed by X-ray analysis.

The ketone **15** was reduced with $LiAlH_4$ to afford the 2α-alcohol in 56% yield as a single isomer. Next, this alcohol was treated with LDA followed by *O*-phenyl chlorothioformate in THF to provide the thiocarbonate intermediate, which was deoxygenated with $Bu^n_3SnH$ and AIBN[10] to give the tropane **17** in an overall yield of 34%. Reduction of the sulfoxide with $PCl_3$ followed by desulfurization with Raney-nickel in EtOH at reflux yielded the tropane **12a**. The $^1$H NMR spectrum and optical rotation of this sample were identical to those of the sample obtained by the methods of Scheme 2; this result accordingly further supports the assignment of the stereochemistry of compounds **11** and **12**.

Using the same methodology of Scheme 3, **16** was converted to the *trans* derivative **14a** that had $[\alpha]_D^{25}$ +53 (*c* 1.0, $CH_2Cl_2$).

In conclusion, the use of (*R*)-*p*-tolyl vinyl sulfoxide in the 1,3-dipolar cycloaddition reaction affords access to the non-racemic alkyltropanes **11** and **12**. This synthetic approach is particularly useful for the asymmetric synthesis of compounds of the general formula **3** bearing a substituent in position 6 of the tropane ring. The versatility of this method may be further enhanced through chemical modification of the *p*-tolyl sulfoxide moiety other than by reduction. Furthermore, using the method described in Scheme 3, we are able to selectively synthesize either enantiomer of the 2β,3α-tropane derivatives in optically pure form. These analogues are important since they are more selective for the dopamine transporter relative to the 5-HT transporter than the 2β,3β-isomers.[11]

We are indebted to NIH/NIDA (grant No. DA 10458) for support of this work.

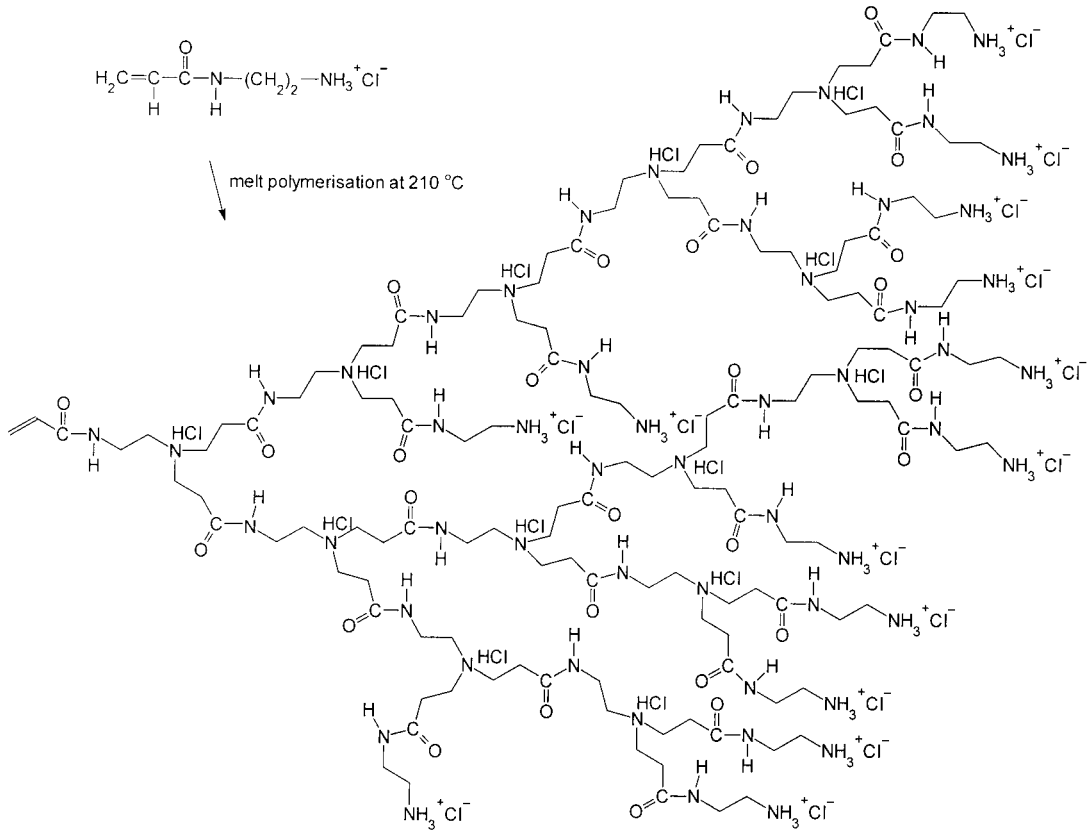
# A simple 'one pot' route to the hyperbranched analogues of Tomalia's poly(amidoamine) dendrimers

**Lois J.Hobson, Alan M. Kenwright and W. James Feast***



*I.R.C. in Polymer Science and Technology, University of Durham, Durham, UK DH1 3LE*

**Melt polymerisation of *N*-acryloyl-1,2-diaminoethane hydrochloride gives the hyperbranched hydrochloride salt analogues of Tomalia's poly(amidoamine) dendrimers, for which spectroscopic analysis establishes a branching ratio close to one.**

Scientific and technological interest in dendrimers grew rapidly following Tomalia's stimulating review,[1] but bulk applications remain inhibited by the labour intensive syntheses involved. A characterising feature of dendritic polymers is that, past a critical point, their intrinsic viscosity decreases with increasing molecular weight.[2] This contrasts with linear and lightly branched polymers and has potential technological implications. It would be attractive to mimic this unusual molecular weight–viscosity behaviour in more readily accessible materials.

As part of a programme of research into the synthesis and properties of $AB_n$ hyperbranched polymers we have studied the melt polymerisation of *N*-acryloyl-α,ω-diaminoalkane hydrochlorides, $H_2C{=}CHCONH(CH_2)_nNH_3^+Cl^-$, ($n$ = 2–7). The monomers, produced by a straightforward protection/deprotection strategy,[3] polymerised, *via* a Michael addition process, on heating at 210 °C under nitrogen. The products, water soluble polyelectrolytes, had the same elemental analysis as the monomers. Variation of the polymethylene spacer length ($n$ = 2–7) had a marked effect on both monomer reactivity (*e.g.* $n$ = 2 reacts much faster than $n$ = 6) and the structure and properties of the polymer. The process is summarised in Scheme 1 for the case where $n$ = 2.

$^1$H and $^{13}$C NMR spectroscopy unambiguously demonstrated the loss of the acrylamide vinyl unit and generation of new methylene units during polymerisation, and allowed an estimation of the number average molecular weight ($M$n) based on end group counting, The $M$n values obtained would be overestimates if significant cyclisation through the focal acrylate group had occurred. Aqueous gel permeation chromatography of these polyelectrolytes was uninformative, but MALDI-TOF mass spectrometry (2,5-dihydroxybenzoic acid matrix, Kratos Kompact MALDI IV in linear detection mode) showed a series of ions corresponding to degrees of polymerisation (dp) in the range 2 to 38. In the spectrum reproduced in Fig. 1, recorded for the polymer derived from *N*-acryloyl-1,6-diaminohexane hydrochloride ($n$ = 6), the major ion sequence corresponds to the simple multiple addition products detected as mono-protonated oligomers of the free base. The minor series, 55 mass units behind the parent ions, corresponds to loss of the focal

**Scheme 1**

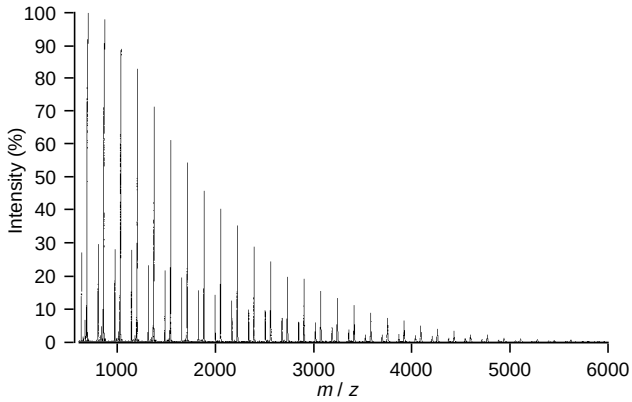


**Fig. 1** MALDI-TOF mass spectrum of the polymer prepared from *N*-acryloyl-1,6-diaminohexane hydrochloride ($n$ = 6) recorded using MALDI 4 with pulsed extraction

$CH_2$=CHCO unit or to one part of a process of random amide link fragmentation. The comparative intensity of this minor series increases with increasing laser power. However, the absence of the other fragment expected from a random cleavage at amide links leads us to favour the first postulate. In further support of this view we observe that under conditions which favour fragmentation, both of the expected series of ions from random fragmentation at amide bonds can be seen.

Analysis of this spectrum using the Kompact software gave a value of 1500 for *M*n of the free base, which compared well with the value of 1570 calculated from the $^1$H NMR spectrum. The intensity distribution of peaks in Fig. 1 qualitatively resembles the distribution predicted by Flory,[4] but careful quantitative analysis shows that in these cases the MALDI-TOF technique fails to provide a representative picture of the whole sample, this is particularly evident when considering materials of broader polydispersity and produced at higher degrees of conversion.[5]

Michael addition polymerisation of these monomers can, in principle, yield secondary or tertiary amines corresponding to linear or branched sub-units. Thus amide and primary (terminal, T), secondary (linear, L) and tertiary (branched, B) amine nitrogen environments are possible. The frequency of the branched and terminal groups is connected, T = B + 1. $^{15}$N NMR spectroscopy, recorded quantitatively in natural abundance, revealed three signals; the amide and primary amine nitrogens are readily identified on the basis of chemical shift (relative to liquid ammonia) and literature assignments of related compounds,[6] but the signals for amine nitrogens in linear and branched units overlap; however, integration allows an assignment of the extent of branching.

Thus, for polymers derived from *N*-acryloyl-α,ω-diaminoalkane hydrochlorides, each repeat unit contributes one amide and one amine nitrogen species. Three signals are observed in the spectra, which we assigned as one amide and two amine salt signals. Where $n$ = 2, (Fig. 2) the two amine salt signals are of approximately equal intensity and must represent terminal and branched units since, if the polymer was composed entirely of linear units, the terminal contributions would be negligible (only one signal per chain) and the linear salt signal would be equal in intensity to the amide signal.

In fact the sum of the relative intensities of the terminal and branched signals equals that of the amide signal within the limits of experimental error, an observation consistent with

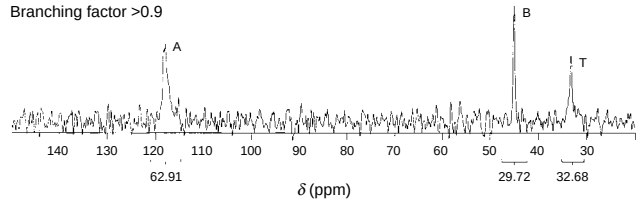

**Fig. 2** Quantitative $^{15}$N NMR spectrum ($D_2O$) of the polymer prepared from *N*-acryloyl-1,2-diaminoethane hydrochloride (pH 1)

virtually complete branching. For this system the relationship between the degree of branching[7] and the terminal (T), branched (B) and amide (A) contributions can be expressed as: branching factor = (B + T)/A. It can therefore be concluded that the polymer is highly branched with few or no linear units, and within the limits of the experiment a degree of branching greater than 0.9 can be assigned. Only monomers with $n$ = 2 give rise to such highly branched polymers. Increasing the internal $CH_2$ chain length of the monomer decreases the degree of branching; for example, the polymers where $n$ = 4, display a branching factor of *ca*. 0.7, much closer to the statistical value proposed by Flory.[4]

These poly(amidoamine) hydrochlorides exhibit classic polyelectrolyte viscosity–concentration behaviour, which can be suppressed by the addition of 1% lithium chloride to allow an experimental value for intrinsic viscosity to be obtained. For these polymers we observe a trend of decreasing intrinsic viscosity with increasing molecular weight, a property more associated with dendritic than with linear structure.

As their hydrochloride salts these $AB_2$ poly(amidoamine) hyperbranched wedges are readily soluble in both water and MeOH, but are insoluble in all common organic solvents as their free bases. However, further work has revealed that core terminated systems, prepared through $AB_2/B_n$ copolymerisations using the $AB_2$ monomer *N*-acryloyl-1,2-diaminoethane hydrochloride, retain their solubility as free bases. Consequently this work provides a simple route to hyperbranched polymers with a degree of branching approaching one and some of the structural features and properties of materials with perfect dendritic architecture.

We thank Kratos Analytical for recording the spectrum reproduced as Fig. 1.

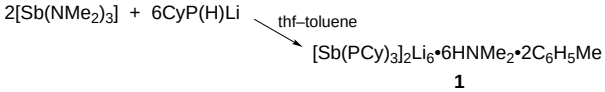
# Stoichiometric assembly of $[Sb(PCy)_3]_2Li_6{\cdot}6HNMe_2{\cdot}2C_6H_5Me$; a highly fluxional antimony(III) phosphinidine complex containing $Me_2NH$ ligation of lithium†



**Michael A. Beswick,* Jonathan M. Goodman, Christopher N. Harmer, Alexander D. Hopkins, Michael A. Paver, Paul R. Raithby, Andrew E. H. Wheatley and Dominic S. Wright***

*Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW*

**All of the $Me_2NH$ produced by the reaction of $[Sb(NMe_2)_3]$ with CyP(H)Li (Cy = $C_6H_{11}$) coordinates the $Li^+$ cations of the product $[Sb(PCy)_3]_2Li_6{\cdot}6HNMe_2{\cdot}2C_6H_5Me$ 1; the complex contains the first example of a group 15 metal phosphinidine anion $\{[Sb(PR)_3]^{3-}\}$.**

Although group 13 metal imido ($RN^{2-}$) and phosphinidine ($RP^{2-}$) compounds are now comparatively common,[1] far fewer imido complexes are known for the heaviest (most metallic) group 14 (Sn, Pb) and 15 (Sb, Bi) elements. We have recently investigated the use of the stepwise metallation of primary amines with organolithiums and $[Sb(NMe_2)_3]$ as a general strategy to a range of polyimido antimony anions, *e.g.* the $[Sb(NR)_3]^{3-}$ trianion of the cage complex $[\{Sb(NCH_2CH_2Ph)_3\}_2Li_6{\cdot}2thf]$.[2,3] These species have an extensive coordination chemistry towards alkali, transition and p-block metals, where they act as surprisingly robust multidentate ligands.[4] A related methodology, involving the transmetallation reactions of lithiated primary amines and phosphines with imido tin(II) cubanes,[5] provides an approach to the metallacyclic phosphinidine complex $[Sn(\mu\text{-}PCy)_2(\mu\text{-}PCy)]_2(Li{\cdot}thf)_4$.[6]

We report here the stoichiometric assembly of the complex $[Sb(PCy)_3]_2Li_6{\cdot}6HNMe_2{\cdot}2C_6H_5Me$ **1** from the reaction of $[Sb(NMe_2)_3]$ with CyP(H)Li (Scheme 1).‡ The cage arrangement of **1** is similar to that occurring in the imido antimony(III) complex $[\{Sb(NCH_2CH_2Ph)_3\}_2Li_6{\cdot}2thf]$[3] and in a few unsolvated group 14 cages of $Si^{IV}$ and $Ge^{IV}$.[7] However, this complex contains the first phosphinidine anion of a group 15 element (As–Bi). Although solvation of alkali-metal cations by $NH_3$ has been well documented for solutions of the metals in liquid ammonia,[8] the incorporation of a small protic ligand such as $Me_2NH$ (a gas above 7 °C) in a reaction involving conventional organic solvents is a surprising structural feature of **1**.

**Scheme 1**

A low-temperature X-ray crystallographic study of **1**§ shows it to be a mixed-metal cage complex, $[Sb(PCy)_3]_2Li_6{\cdot}6HNMe_2{\cdot}2C_6H_5Me$, consisting of a 14-membered $\{Sb_2P_6Li_6\}$ core (Fig. 1). In addition there are two lattice-bound toluene molecules per molecule of **1**. The structure, which arises from the association of two $[Sb(PCy)_3]^{3-}$ trianions by six $Li^+$ cations, can be described as a hexameric phosphido-lithium 'stack' capped at the open $Li_3P_3$ faces by two Sb atoms. However, direct evidence of the integrity of the $[Sb(PCy)_3]^{3-}$ trianions of **1**, and the fact that these units dominate the bonding pattern of the core,[9] is given in the $^7Li$ NMR spectrum in which a binomial septet ($^1J_{^{31}P^{7}Li}$ 14 Hz) occurs as a result of the coupling of all the $Li^+$ cations to the P atoms of two intact trianions (203–298 K) (Fig. 2). Preliminary semi-empirical PM3 calculations¶ indicate that interchange of the six $Li^+$ cations occurs by a

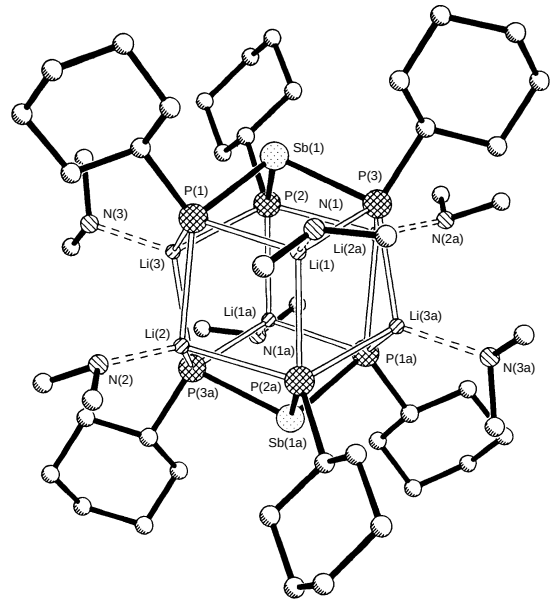


**Fig. 1** The molecular structure of $[Sb(PCy)_3]_2Li_6{\cdot}6HNMe_2{\cdot}2C_6H_5Me$ **1** showing the atom numbering scheme. The $C_6H_5Me_3$ lattice solvation and hydrogen atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): Sb(1)–P(1) 2.519(6), Sb(1)–P(2) 2.517(5), Sb(1)–P(3) 2.516(5), Li(1)–P(3) 2.59(3), P(1)–Li(3) 2.56(3), Li(1)–P(1) 2.55(3), Li(3)–P(2) 2.62(3), P(1)–Li(2) 2.62(3), N(3)–Li(3) 2.08(3), N(2)–Li(2) 1.96(4), N(1)–Li(1) 2.10(4); P(3)–Sb(1)–P(2) 101.3(2), P(2)–Sb(1)–P(1) 103.4(2), P(3)–Sb(1)–P(1) 100.3(2).

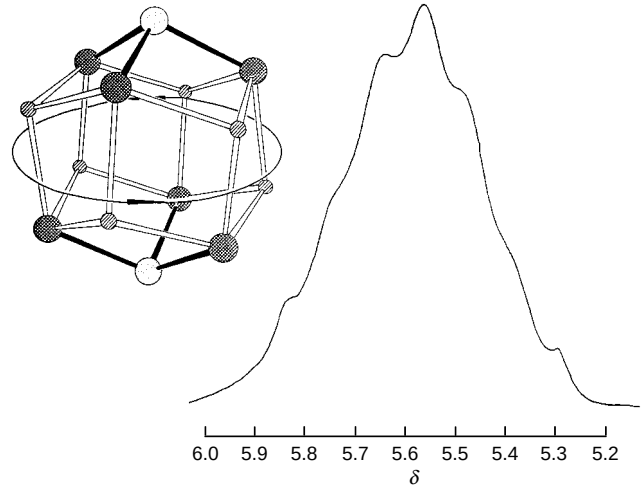

**Fig. 2** Dynamic 'carousel' process and the $^7Li$ NMR spectrum of **1**

dynamic ('carousel') process, analogous to that observed for $[Me_2Si(NSiMe_3)_2]_2InLi$ in solution,[10] in which the $Sb^{III}$ centres are not involved. The $^{31}P$ NMR chemical shift ($\delta$ −263.5) is vastly different to that observed for $[(2,4,6\text{-}Bu^t_3C_6H_2)P{=}Sb\{CH(SiMe_3)_2\}]$ ($\delta$ 600),[11] reflecting the development of negative charge on the P centres of **1**.

In the polymeric ladder structure of the monolithiated cyclohexyl phosphine precursor to **1** $(CyPHLi\cdot thf)_\infty$,[12] the P–Li bonds (av. 2.61 Å) are similar to those found in **1** [range 2.55(3)–2.66(3) Å]. The Sb–P bonds in **1** (av. 2.52 Å) are close to those observed in $[SbP(2,4,6\text{-}Bu^t_3C_6H_2)]_2$ [range 2.561(2)–2.583(1) Å] (the only other Sb or Bi phosphinidine complex to be structurally characterised).[13] An interesting structural feature of complex **1** is that the P–Sb–P angles (av. 101.6°) are significantly larger than the N–Sb–N angles (av. 94.5°) found in the related imido complex $[\{Sb(NCH_2CH_2Ph)_3\}_2Li_6\cdot 2thf]$.[3] Although the flattening of the $[Sb(PCy)_3]^{3-}$ trianion may partially reflect the differences in the extents of Lewis-base solvation of the cores {two thf in $[\{Sb(NCH_2CH_2Ph)_3\}_2Li_6\cdot 2thf]$ and six $Me_2NH$ in **1**}, it is likely that the major reason for this is the lower electronegativity difference between Sb and P (*ca*. 0.2 on the Pauling scale; *cf*. 1.1 between Sb and N).

A particularly novel structural feature of **1** is the complexation of the six $Li^+$ cations of the core by $Me_2NH$. This is a gas above 7 °C and its formation can be envisaged as normally providing the thermodynamic driving force in the reactions of $[Sb(NMe_2)_3]$ with organic acids. However, the stoichiometric inclusion into **1** of all the $Me_2NH$ formed in this reaction is surprising since it not only competes for $Li^+$ coordination with thf but exists as a gas under normal conditions. $^1H$ NMR spectroscopic studies and elemental analysis of **1** illustrate that, although the $Me_2NH$ ligation is almost completely removed by placing the complex under vacuum (0.1 atm, 15 min), this solvation is comparatively robust and is largely retained in fresh samples not subjected to reduced pressure. Recent *ab initio* calculations[14] on the deprotonation of organic acids (RH) with lithium amides ($R'_2NLi$)[15] suggest that complexation of the amine produced ($R'_2NH$) to the $Li^+$ cation {in $[(R'_2NH)LiR]$} may contribute significantly to the thermodynamics of these reactions. The formation of **1** provides the first direct evidence in favour of this proposition and that even for gaseous amines $Li^+$ ligation is likely to play a role.

The incorporation of a phosphorus donor functionality in the $[Sb(PCy)_3]^{3-}$ trianion creates a softer ligand set and a greater ligand bite than the imido congeners and may allow the stabilisation of low oxidation state transition-metal centres.

‡ *Synthesis of* **1**: to a stirred and chilled suspension of $[LiP(H)Cy]_n$ (7.53 mmol of monomer) in toluene (5 ml) was added a solution of $[Sb(NMe_2)_3]$ (2.51 mmol, 1.36 $cm^3$, 1.84 mol $dm^{-3}$ in toluene). The suspension was stirred and gradually allowed to warm towards 0 °C at which stage a yellow precipitate was observed. This was dissolved by the addition of chilled toluene (8 $cm^3$) and thf (1 $cm^3$). The red solution produced was stored at −35 °C for 48 h over which period crystals suitable for X-ray diffraction studies grew. The complex loses $Me_2NH$ of solvation gradually at 25 °C and this is almost completely removed by placing **1** under vacuum (15 min, 0.1 atm). However, if isolated without exposure to vacuum the $Me_2NH$ is largely retained. The following data refer to this material: yield 1.02 g (57%); decomp. 170 °C; IR (Nujol), major bands at 1257m, 1178s, 1051s, 992.5m, 897s, 846s, 730m, 694w $cm^{-1}$; $^1H$ NMR (400.16 MHz, +25 °C, $C_6D_5CD_3$), $\delta$ 7.0 (5 H, m, aryl C–H, $C_6H_5CH_3$), 3.94 (13 H, s, Me, $Me_2NH$), 2.5–1.2 [33 H, overlapping m, Cy and $C_6H_5CH_3$ (2.10)]; $^7Li$ NMR (1.55.513 MHz, +25 °C, $C_6D_5CD_3$), $\delta$ 5.57 (binomial spt, $^1J_{31P^7Li}$ 14 Hz) (rel. to LiCl–$D_2O$) ($\delta$ 7.14 rel. to PhLi–$C_6D_5CD_3$); $^{31}P$ NMR (162.000 MHz, +25 °C, $C_6D_5CD_3$), $\delta$ −263.5 [rel. to neat $(MeO)_3P$; br s, width at half-height 1130 Hz]; Analysis Calc. C, 52.3; H, 8.7; N, 5.6. Found: C, 52.0; H, 8.4; N, 4.4 (no N remains after 15 min at 0.1 atm).

§ *Crystal data* for **1**; $C_{31}H_{62}Li_3N_3P_3Sb$, $M$ = 712.32, monoclinic, space group $P2_1/c$, $a$ = 13.460(3), $b$ = 18.123(3), $c$ = 16.589(4) Å, $\beta$ = 99.83(2)°, $U$ = 3987(2) Å$^3$, $Z$ = 4, $D_c$ = 1.187 Mg m$^{-3}$, $T$ = 150(2) K, $\mu$(Mo-K$\alpha$) = 0.834 mm$^{-1}$, $F$(000) = 1496. Yellow cubes, crystal dimensions 0.30 × 0.25 × 0.20 mm. 3717 reflections ($2\theta$ < 45.0°) were collected on a Siemens R3mV diffractometer using Mo-K$\alpha$ radiation ($\lambda$ = 0.710 73 Å), graphite monochromator and $\omega$–$2\theta$ scans ($2.57 \leqslant \theta \leqslant 19.99°$). 3717 independent reflections ($R_{int}$ = 0.021) after a semiempirical absorption correction was applied. The structure was solved using direct methods and refined by full-matrix least squares based on $F^2$ (SHELXL93),[16] with all non-hydrogen atoms assigned anisotropic displacement parameters; cyclohexyl, toluene and amine H atoms were fixed in idealised positions and allowed to ride on the relevant C or N atoms. The refinement converged to $R_1$ = 0.0748 for data $I > 2\sigma(I)$ and $wR_2$ = 0.2722 for all data, goodness of fit = 1.013, and weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.0597P)^2 + 18.32P]$, where $P = (F_o^2 + 2F_c^2)/3$. Largest peak and hole in the final difference map; 0.913, −0.689 e Å$^{-3}$. Crystals of **1** were weakly diffracting. Restraints were applied for the lattice-bound toluene which is disordered over two (50 : 50) sites about a twofold axis. CCDC 182/564.

¶ Calculations were carried out using VAMP 5.6 (Oxford Molecular) (J. J. P. Stewart, *J. Comput. Chem.*, 1989, **10**, 209) on a Silicon Graphics R4400 workstation.

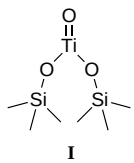
# On the formation of titanyl (Ti=O) groups in mesoporous and microporous titanosilicate catalysts: a computational study



**Phillip E. Sinclair* and C. Richard A. Catlow***

*The Davy Faraday Research Laboratory, The Royal Institution of Great Britain, 21 Albemarle Street, London, UK W1X 4BS*

**Density functional theory calculations are reported which suggests that titanyl groups, $Ti^{IV}$=O, can form by relatively low energy pathways in titanium(IV) silicate catalysts, thereby providing a possible route to the active oxygen donating site responsible for partial oxidation reactions in these materials.**

Knowledge of the structure and chemical properties of the active site in any catalytic reaction is critical to the understanding of the detailed reaction mechanisms. Industrially important examples are provided by the partial oxidation processes over titanium(IV) framework silicates[1] exemplified by TS-1, TS-2[2] and Ti-MCM-41.[3–5] These reactions occur essentially in the liquid phase involving reactant, solvent, sacrificial oxidant such as $H_2O_2$ or $Bu^tOOH$, and the titanium(IV) substituted heterogeneous catalyst. Use of $Ti^{IV}$ embedded in some manner into a silicate framework produces a catalyst with the desirable qualities of guest molecule shape selectivity and one in which oxidation is effected with very high turnover rates and selectivities with respect to both the reactant and the sacrificial oxidant.[5–9] Although it is becoming increasingly evident[5,8] that $Ti^{IV}OH$ centres tripodally attached by O to Si are the major sites for catalytic activity in these systems, a number of questions concerning intermediate titanates still remain. This work reports first principles quantum chemical calculations in order to derive possible models for titanium containing species that could occur on the reaction coordinate to formation of the active oxygen donating species in these systems.

One of the earliest suggestions for the nature of these titanium containing species (originally with respect to $Ti^{IV}$ incorporated into amorphous silicates) was that of a titanyl group stabilised by the silicate host (species **I**, Fig. 1).[10,11] It has been suggested that this titanyl species is responsible for the very high oxidation capacity of titanium(IV) silicates. Titanyl groups have not, however, been observed in TS-1 or similar catalysts unlike its unambiguous characterisation (albeit in a state of five coordination) in the mineral fresnoite[12] and the synthetic layered titanosilicate JDFL-1.[13] Indeed, the lack of UV–VIS absorption corresponding to species **I**[14] has been taken by many to indicate that this species is not present in these materials. Species **I** can, however, account for a number of experimental observations such as the catalyst's IR and NMR responses and its behaviour in $^{18}O$ labelling experiments.[15] Many workers, however, favour the model of $Ti^{IV}$ in four-coordinate sites within the framework, (Fig. 2, species **II**), or grafted onto the surface of a silicate material, (Fig. 2, species **III** and **IV**).[5,7,16,17] Species **III** and species **IV** illustrate the hydroxide forms of the $Ti^{IV}$ sites.

**I**

**Fig. 1** Schematic representation of a titanyl (Ti=O) group, a species suggested as a possible titanium(IV) oxygenate in titanium(IV) silicate catalysts

Organic derivatives have also been prepared[18] and it is noted that these catalysts may behave differently. It is also noted that Fig. 2 represents the state of the $Ti^{IV}$ centres in a dehydrated system. Expansion of the $Ti^{IV}$ coordination shell on addition of coordinating solvents such as water has now been well characterised both experimentally[1,16] and computationally.[19] The partial hydrolysis of the Ti–OSi bonds in the absence of coordinated water can also be described in terms of species **II**, **III** and **IV** (see the reaction at the bottom of Fig. 2).[17]

Recently, we have reported first principles, density functional theory cluster calculations of the processes shown in Fig. 2,[19] *i.e.* over the hydroxide forms of the catalyst. Using a $H_3SiOH$ fragment to model the silanol species produced during the hydrolysis and calculating the energy differences at infinite separation of the silanol and the hydrolysed $Ti^{IV}$ fragment, the internal energies, $\Delta E_1$ and $\Delta E_2$, were calculated to be 20 and 22 kJ $mol^{-1}$, respectively. However, given that in an actual silicate system the hydrolysed titanium(IV) hydroxide complex and the resulting silanols would be in hydrogen-bonding distance, and that typical hydrogen-bond energies are of the order of 20 kJ $mol^{-1}$, it is expected that a mixture of species **II**, **III** and **IV** would be present in systems where $Ti^{IV}$ is isomorphously substituted into the silicate framework, *e.g.* TS-1;[17] and a mixture of species **III** and **IV** would be present in systems where $Ti^{IV}$ is grafted onto a silicate surface, *e.g.* the titanium(IV) hydroxide form of surface grafted Ti-MCM-41.[5] We also showed that within the cluster approximation and in the absence of any adsorbates the formation of species **I** from **III** was energetically unfavourable (requiring 110 kJ $mol^{-1}$). We now report on new computational evidence suggesting that species **I** is energetically accessible from the hydroxide form of titanium(IV) silicates, species **III** and **IV**, in the presence of water and/or other protic solvents.

Fig. 3 shows the calculated reaction profile for formation of species **I** from **III**, unsolvated and in the presence of one molecule of water. The geometries and energies were optimised using the Becke–Perdew'86 gradient corrected density functional included self-consistently in all stages of the calculation as implemented in the Cray Research code DGauss 3.0[20] (a 'fine' integration grid was also employed). A valence double-zeta basis set with polarisation functions on non-hydrogen atoms (DZVP) was used throughout. This method has now been used for a number of problems in the field of silicate chemistry and is known to give reliable geometries and binding ener-

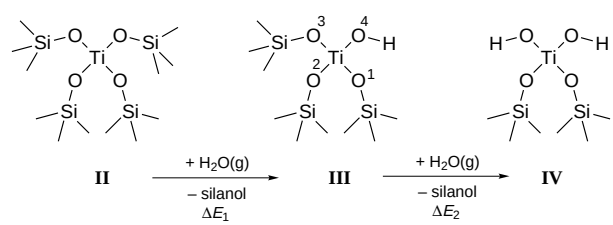


**Fig. 2** Schematic representation of possible four-coordinate titanium(IV) oxygenates in titanium(IV) silicate catalysts. The process shown at the bottom of the figure illustrates the hydrolysis of these species in the presence of a single molecule of water.

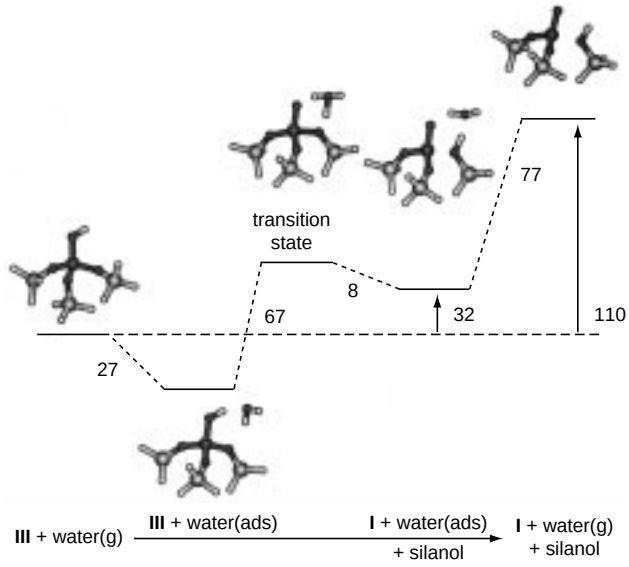

**Fig. 3** DFT optimised reaction path for the formation of a titanyl group (species **I**), modelled by $(H_3SiO)_2Ti{=}O{\cdot}HOSiH_3$, from a silicate embedded titanium hydroxide (species **III**), modelled by $(H_3SiO)_3TiOH$, in the presence of a single molecule of water. Energies are in kJ mol$^{-1}$.

gies.[21,19,22] Activation barriers are more problematic and are generally accepted to be underestimates.[23] The cluster model for the hydroxide species **III**, $(H_3SiO)_3TiOH$, was fully optimised with respect to all atomic degrees of freedom. All other clusters models were then optimised under the constraint that the Si coordinates were fixed at the values obtained from the cluster model of species **III**. These constraints were enforced to prevent unrealistic relaxation of the cluster. This does however introduce an unknown error into the calculated energy changes for the hydrolysis reaction due to structural strain. The strain is difficult to estimate without resorting to computationally prohibitive clusters, for example, 'closed' cubic silasesquioxanes. The error will however be system- and site-dependent although it is likely that the constraints imposed in the current calculations will lead to the energy changes being upper bounds; the silanols formed during the reaction being unable to relax (under the constraints imposed by the silicate host).

Clearly the process shown in Fig. 3 is essentially one of proton transfer from $O^4$ to one on the other oxygens $O^1$ to $O^3$ (Fig. 2) and is thus dependent on one of the hydroxide forms of $Ti^{IV}$ being present. It is also clear that, as described above, unsolvated species **III** is much more stable than species **I**. In the presence of a single molecule of water however, titanyl species **I** can be formed with a true activation barrier of 67 kJ mol$^{-1}$ or an effective barrier of 40 kJ mol$^{-1}$ with respect to the original reactants. Furthermore, in the presence of a single water molecule, species **I** is only 32 kJ mol$^{-1}$ less stable than the separated titanium(IV) hydroxide (species **III**) and water, a change of 77 kJ mol$^{-1}$ with respect to the unsolvated case. Despite the hydrophobic nature of TS-1 and similar silicates, small amounts of water and/or other protic solvents (generated, for example, during oxidation reactions) will be present enhancing the probability of forming titanyl species **I** from any accessible titanium(IV) hydroxide groups.

At present, no account of the environment of the $Ti^{IV}$ site has been included within the calculations. However, if we examine the calculated change in the dipole moment ($\mu$) of the complexes leading to the transition state for formation of titanyl species **I**, we note that activation results in an increase in $\mu$ [3.23–4.21 D (1 D $\approx 3.336 \times 10^{-30}$ C m)]. We expect therefore that the environment provided by a partial ionic silicate framework would stabilise the transition state more than the solvated titanium(IV) hydroxide (species **III**) and that the calculated activation barrier shown in Fig. 3 would therefore be an overestimate. It is also expected that the real barrier would be strongly correlated with the topological position of the titanium(IV) complex within the host framework as well as with the chemical composition of that framework.

In conclusion, we have employed density functional theory methods to show that titanyl groups, *i.e.* species **I**, can be formed with relative ease from the hydroxide forms of four-coordinate titanium(IV) silicates in the presence of even small amounts (in this case one molecule) of water and probably other protic solvents. Their formation is likely to be correlated with the precise nature of the $Ti^{IV}$ environment. However, given that the limiting case of aqueous $TiO^{2+}$ is known to be a very labile species (oxygen exchange rate estimated at 16 000 ± 5000 s$^{-1}$ at 298 K)[24] and that no Ti=O UV–VIS absorption has been measured in silicates, titanyl species are probably very short-lived species in dynamic equilibrium with the hydroxide species **III** and/or species **IV**. We suggest however, on the basis of the current calculations, that they could be present in sufficient concentration to provide a route to the active oxygen-donating species for partial oxidation catalysis in hydroxide forms of titanium(IV) silicates.

The authors would like to thank Professor Sir J. M. Thomas, Dr Sankar and Dr Oldroyd both of the Royal Institution of Great Britain for useful discussions and collaboration. P. E. S. would also like to thank EPSRC for financial support and computer resources.

**Thermolysis of $Fe_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}\eta^1,\eta^2\text{-}C_2Ph)$ affords the rectangular cluster $Fe_4(CO)_8(\mu\text{-}PPh_2)_2(\mu_4\text{-}\eta^1,\eta^1,\eta^2,\eta^2\text{-}C_2Ph)_2$ with two face-capping acetylides linked through the $Fe_4$ face by a short carbon–carbon contact: reaction with CO leads to $Fe_3(CO)_8\{\mu\text{-}Ph_2PC(CPh)\text{=}C(CPh)PPh_2\}$ as a result of C–C and C–P bond-forming processes.**

The acetylide group (–C≡CR) is an extremely versatile ligand capable of binding to one or more metal centres in a variety of coordination modes, donating up to 5 electrons to a cluster centre.[1] In fact, metal acetylides and polyacetylides have recently emerged as promising molecules and precursors for advanced materials and there is now intense interest in both carbon-rich polyacetylide complexes and multimetallic systems where the π-electrons of the polyunsaturated fragment are used for additional coordination. One strategy for the synthesis of polymetallic arrays is to effect the coupling of multi-site bound acetylides and we have recently described the generation of a series of new tetraruthenium clusters from bimetallic precursors.[2] Herein we describe the high yield synthesis of the symmetrical rectangular tetrairon cluster $Fe_4(CO)_8(\mu\text{-}PPh_2)_2(\mu_4\text{-}\eta^1,\eta^1,\eta^2,\eta^2\text{-}C_2Ph)_2$ **2** *via* dimerisation and CO loss on thermolysis of $Fe_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}\eta^1,\eta^2\text{-}C_2Ph)$ **1**. The molecule **2** has two face-capping acetylides with a short 'through-the-cluster' $C_\alpha$–$C_\alpha$ distance such that the two acetylides resemble a $PhC_4Ph$ diyne. Complex **2** undergoes a further facile conversion to $Fe_3(CO)_8\{\mu\text{-}\eta^2,\eta^4,\eta^2\text{-}Ph_2PC(CPh)C(CPh)PPh_2\}$ *via* acetylide–phosphido coupling.

Heating a toluene solution of $Fe_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}\eta^1,\eta^2\text{-}C_2Ph)$[3] **1** at 140 °C for 2 h results in a darkening of the solution and the appearance of new ν(CO) bands at 2004 and 1976 $cm^{-1}$ in the IR spectrum. After removal of solvent and washing with hexane, $Fe_4(CO)_8(\mu\text{-}PPh_2)_2(\mu_4\text{-}\eta^1,\eta^1,\eta^2,\eta^2\text{-}C_2Ph)_2$ **2** was isolated as a dark red solid in 90% yield.† The simplicity of the IR spectrum and the presence of a single resonance in the $^{31}P\{^1H\}$ NMR spectrum at δ 252.2 were suggestive of high symmetry. The precise nature of **2** was established by a crystallographic study (Fig. 1).‡

The molecule is centrosymmetric and consists of a rectangle of iron atoms characterised by Fe–Fe distances of 2.5282(4) [Fe(1)–Fe(2)] and 2.8652(5) Å [Fe(1a)–Fe(2)], short edges being bridged symmetrically by phosphido ligands [Fe(1)–P(1) 2.1996(7); Fe(2)–P(1) 2.2010(7) Å]. Each face of the rectangle is capped by an acetylide ligand which is σ-bonded to two metal atoms [Fe(1)–C(5a) 1.992(2); Fe(2)–C(5a) 2.002(2) Å] and π-bonded to the other two [Fe(1)–C(5) 2.143(2); Fe(2)–C(5) 2.141(2); Fe(1)–C(6) 2.030(2); Fe(2)–C(6) 2.001(2) Å]. Although several clusters with $\mu_4$-acetylides on $M_4$ faces are known,[4] we are unaware of any examples where two such moieties are bound on opposite faces of an $M_4$ rectangle. Within each acetylide ligand the $C_\alpha$–$C_\beta$ distance [C(5)–C(6) 1.383(3) Å] is similar to that found in $Ru_5(CO)_{13}(\mu\text{-}PPh_2)(\mu_4\text{-}\eta^1,\eta^1,\eta^2,\eta^2\text{-}C_2Ph)$ [1.342(11) Å] where the acetylide is also coordinated on an $M_4$ face.[5] The most noteworthy feature of **2** is the C(5)–C(5a) distance of 1.596(4) Å, indicative of a direct through-space interaction between the two $C_\alpha$ carbon atoms. Indeed this distance could be interpreted as indicative of a C–C single bond elongated somewhat *via* interactions of C(5) and C(5a) with the iron atoms. The metallic valence electron count (MVEC) of **2** is 62 or 64 electrons depending on whether the hydrocarbyl ligands $(C_2Ph)_2$ are acting as one 8-electron donor diyne or as two 5-electron donor acetylides. Extended Hückel computations show that the LUMO for **2** lies 1.99 eV above the HOMO, ensuring the stability of **2** for an MVEC of 64 electrons. This model for the electronic structure of **2**, with the acetylides contributing 10 electrons to the MVEC, does not require any through-space C···C bonding. Nevertheless, a strongly positive $C_\alpha$-$C_\alpha$ overlap population (+0.66) is computed, reflecting a significant attractive interaction between the $C_\alpha$ atoms capping the metallic core. Both size and electronic factors contribute to the short C···C contact in**2**. A smaller P···P overlap population of 0.226, indicative of a P···P interaction across the cluster face in $Fe_4(CO)_{12}(\mu_4\text{-}PH)_2$ has been calculated by Halet and coworkers.[6] The EHMO calculations on **2** also revealed that the negative charge on $C_\beta$ was significantly higher than that on $C_\alpha$ (−0.21 *vs.* + 0.20). Consistent with this, in the $^{13}C\{^1H\}$ NMR spectrum of **2**, $C_\alpha$ [$\delta$ 143.23(d); $J_{P-C}$ 23.0 Hz] is much more deshielded than $C_\beta$ [$\delta$ 95.21(s)].

In light of the interaction between $C_\alpha$ atoms in **2** we investigated whether formal coupling of the two acetylides to a diyne could be induced. While **2** is stable to prolonged reflux at 160 °C, bubbling CO through a toluene solution at 100 °C leads

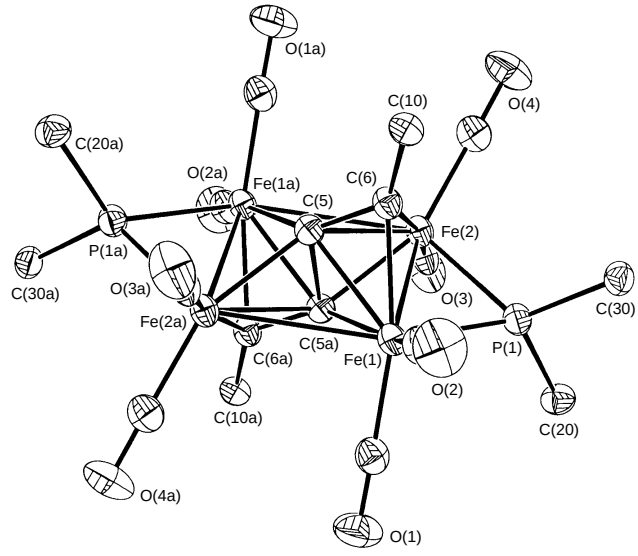

**Fig. 1** Molecular structure of **2** with selected bond lengths (Å) and angles (°): Fe(1)–Fe(2) 2.5282(4), Fe(1)–Fe(2a) 2.8652(5), Fe(1)–P(1) 2.1996(7), Fe(2)–P(1) 2.2010(7), Fe(1)–C(5a) 1.9916(22), Fe(2)–C(5a) 2.0018(23), Fe(1)–C(5) 2.1429(22), Fe(2)–C(5) 2.1407(22), Fe(1)–C(6) 2.0296(22), Fe(2)–C(6) 2.0008(23), C(5)–C(6) 1.383(3), C(5)–C(5a) 1.596(4); Fe(1)–P(1)–Fe(2) 70.130(22), C(5)–C(6)–C(10) 130.77(21)

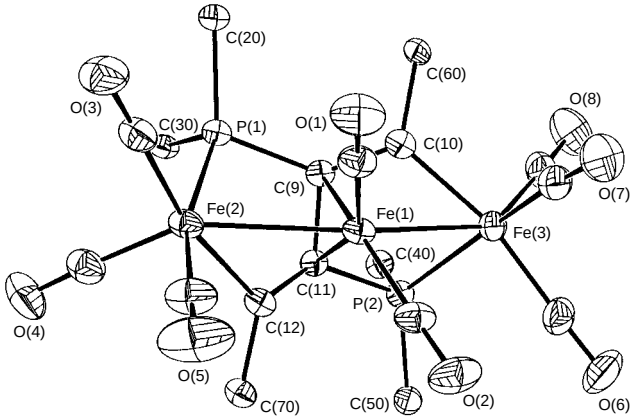

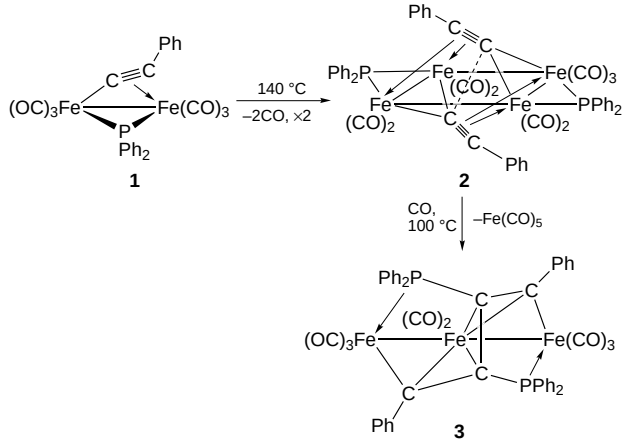

**Fig. 2** Molecular structure of **3** with selected bond lengths (Å) and angles (°): Fe(1)–Fe(2) 2.6327(15), Fe(1)–Fe(3) 2.6506(15), Fe(2)–P(1) 2.247(2), Fe(3)–P(2) 2.258(2), Fe(1)–C(9) 2.037(6), Fe(1)–C(10) 2.104(7), Fe(1)–C(11) 2.038(6), Fe(3)–C(10) 2.004(7), Fe(1)–C(12) 2.108(6), Fe(2)–C(12) 2.029(6), C(9)–C(10) 1.422(9), C(11)–C(12) 1.418(9), C(9)–C(11) 1.485(9), P(1)–C(9) 1.821(6), P(2)– C(11) 1.821(6); Fe(2)–Fe(1)–Fe(3) 153.37(5)

to the rapid appearance of new IR bands and the isolation after workup of $Fe_3(CO)_8\{\mu\text{-}Ph_2PC(CPh)=C(CPh)PPh_2\}$ **3** in 65% yield as a cherry-red solid.§ The $^{31}P$ NMR spectrum showed only a single resonance ($\delta$ 67.1) well upfield of **2**, suggesting that P–C coupling had occurred. An X-ray analysis revealed the molecular structure shown in Fig. 2.‡

The molecule consists of a near linear triiron backbone [Fe(2)–Fe(1)–Fe(3), 153.37(5)°] with the two outer atoms carrying three carbonyls and the central iron atom carrying two. This metal core [Fe(1)–Fe(2) 2.6327(15), Fe(1)–Fe(3) 2.6506(15) Å] is spanned by an unusual bis-2,3-diphenylphosphinodiyne which has resulted from the coupling of both of the phosphido bridges and the two acetylide ligands. To our knowledge, this diphosphine has not previously been synthesised. The coupling of the acetylides is through the two α-carbon atoms as might be expected from their close proximity in **2**. The phosphido groups also couple to the α-carbons and each is coordinated to a single outer iron centre. This new bridging ligand acts as 10-electron donor to the cluster, which then has the expected 50-electron count for a linear trimetallic complex. A closer look at the bond lengths within the diphosphine ligand reveals that the C(9)–C(11) distance of 1.485(9) Å is only 0.11 Å shorter than the corresponding $C_\alpha$-$C_\alpha$ distance found in **2**, while the C(9)–C(10) and C(11)–C(12) lengths of 1.422(9) and 1.418(9) Å are somewhat longer than those in the precursor. It is interesting to note that binuclear **1**[3] results from the reaction of $Fe_3(CO)_{12}$ with the phosphinoalkyne, $Ph_2PC_2Ph$, and thus the overall transformation of this ligand *via* **1** and **2** to give **3** (Scheme 1) represents the metal-mediated $C_\alpha$–$C_\alpha$ coupling of two phosphinoalkynes.

**Scheme 1**

We are currently exploring both the mechanism of formation of **2** and the broader implication of acetylide coupling at polynuclear centres for the synthesis of new polyyne clusters.

We are grateful to the Natural Sciences and Engineering Research Council of Canada and the National Research Council for financial support of this work.

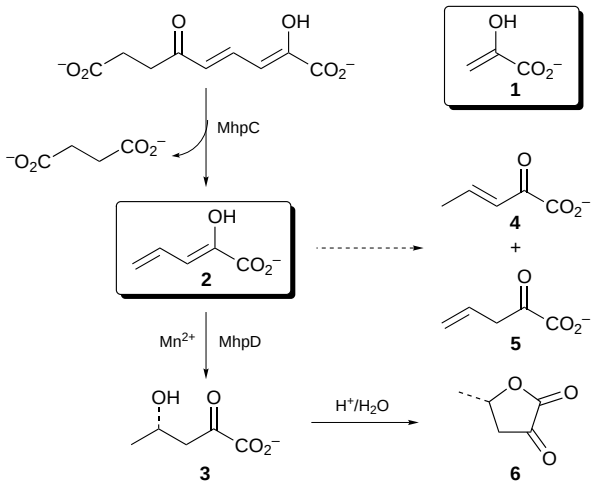
# Chemical and biochemical properties of 2-hydroxypentadienoic acid, a homologue of enolpyruvic acid



**John R. Pollard,† Ian M. J. Henderson and Timothy D. H. Bugg***

*Department of Chemistry, University of Southampton, Highfield, Southampton, UK SO17 1BJ*

**2-Hydroxypentadienoic acid is shown to be a biochemical intermediate on the phenylpropionate catabolic pathway of *Escherichia coli*; its stability and ketonisation behaviour are compared with those of its homologue, enolpyruvate.**

The enol tautomer of pyruvic acid, enolpyruvate **1**, has been implicated as an intermediate in several enzymatic reactions.[1,2] The buffer- and enzyme-catalysed ketonisation of **1** have been studied in detail.[1–4] Its extended homologue 2-hydroxypentadienoic acid **2** has been proposed as an intermediate in a number of bacterial *meta*-cleavage pathways,[5–8] however very little is known about its chemical and biochemical properties. We have previously verified using $^1$H NMR spectroscopy that **2** is the product of the reaction catalysed by C–C hydrolase MhpC, on the phenylpropionate catabolic pathway in *Escherichia coli* (see Scheme 1).[6] However, there is uncertainty over whether the dienol tautomer of **2** or one of two possible keto tautomers **4** or **5** is the substrate for the subsequent enzymatic hydration reaction to give 4-hydroxy-2-oxopentanoic acid **3**.[8–10] Here we analyse some chemical properties of 2-hydroxypentadienoic acid **2**, compare them with those of its homologue enolpyruvate, and confirm the biochemical intermediacy of **2**.

2-Hydroxypentadienoic acid **2** was generated by the reaction of C–C hydrolase MhpC, as previously described.[6] The appearance of **2** was monitored by UV spectroscopy ($\lambda_{max}$ 270 nm) and organic acids HPLC.‡ Production of **2** was followed by a first-order decay in $A_{270}$ over a 1–10 min time period (see Fig. 1), correlating with the disappearance of the HPLC peak, thus corresponding to the decomposition of **2**. The appearance and disappearance of **2** could be fitted accurately to a double exponential curve, allowing determination of the rate constants for production and decomposition of **2**. By extrapolation of the first-order decay of **2** to zero time, starting from a known concentration of the MhpC substrate ($\varepsilon_{394}$ 15 600 M$^{-1}$ cm$^{-1}$), the extinction coefficient for **2** was determined as $\varepsilon_{270}$ = 19 200 M$^{-1}$ cm$^{-1}$ at pH 5.0 in 50 mM NaOAc. This value was found to remain fairly constant over the pH range 5–10, and is somewhat higher than the value of 9600 M$^{-1}$ cm$^{-1}$ reported for enolpyruvate,[2] as expected for a more conjugated system.

**Scheme 1** The substrate for MhpC is the extradiol ring fission product of 2,3-dihydroxyphenylpropionic acid, whose structure has been verified previously (ref. 6).

The observed decomposition of **2** was thought to correspond to the ketonisation of its dienol functional group, which could take place either at C-3 (α-protonation) or C-5 (γ-protonation). A sample of **2** generated by MhpC was allowed to decompose, and after lyophilisation was analysed by $^1$H NMR spectroscopy. The product contained 90% 2-oxopent-3-enoic acid **4**, 10% 2-oxopent-4-enoic acid **5** and a small amount (< 5%) of dienol **2**,§ verifying that decomposition was due to ketonisation, and indicating a 9 : 1 ratio of γ-protonation to α-protonation.

By carrying out the MhpC conversion in various buffers, it was possible to determine the rate of ketonisation ($k_{obs}$) *versus* pH and buffer type. Compound **2** was found to be more than five-fold more stable in phosphate or acetate buffers than in citrate, Mes or Tris buffers. $k_{obs}$ was found to increase with pH [see Figs. 1 and 2(*a*)], as observed for enolpyruvate,[4] implying that the ketonisation of **2** is base-catalysed. In 50 mM NaOAc pH 5.0 a $k_{obs}$ value of 0.026 min$^{-1}$ was measured, corresponding to a half-life of 27 min. The half-life of enolpyruvate in $H_2O$ at pH 5.0 is approximately 30 s,[3] thus **2** is more than 50-fold more stable than enolpyruvate in aqueous solution. Generation of **2** in 50 mM NaOAc (pH 5.0) in the presence of 5 mM $MnCl_2$ gave a 2.4-fold increased $k_{obs}$, indicating that the ketonisation of **2** is catalysed by divalent metal ions, as found for enolpyruvate.[3]

It was also found that $k_{obs}$ increased when larger amounts of MhpC were used for its generation [see Fig. 2(*b*)], thus the ketonisation of **2** is also catalysed by MhpC. At normal assay concentrations of MhpC (0.05–0.1 u ml$^{-1}$), < 20% of the observed decomposition is enzyme-catalysed, but at concentrations of 1 u ml$^{-1}$ approximately 75% of $k_{obs}$ is due to enzyme-catalysed ketonisation. This behaviour can be rationalised mechanistically, since the first step of the MhpC-catalysed reaction is thought to be the ketonisation of a structurally similar dienol precursor at C-5.[6] From the gradient

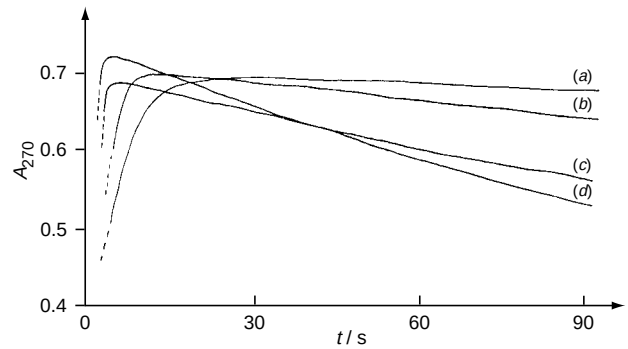


**Fig. 1** Production of **2** by the reaction catalysed by hydrolase MhpC, and the subsequent decomposition of **2** at (*a*) pH 5, (*b*) pH 6, (*c*) pH 7 and (*d*) pH 8, as observed by UV spectroscopy. Assays contained 40 μM ring fission product, 0.1 u ml$^{-1}$ MhpC and 50 mM buffer (NaOAc at pH 5, $KH_2PO_4$ at pH 6, 7 and 8), and were carried out at 20 °C.

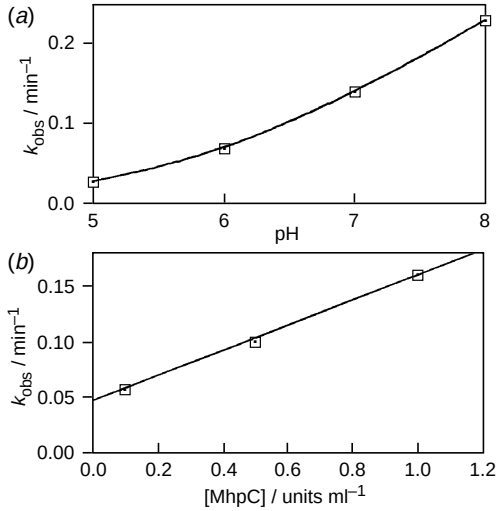

**Fig. 2** Deduced first-order rate constants ($k_{obs}$) for ketonisation of **2**. (*a*) Variation of $k_{obs}$ *versus* pH. Assays contained either 50 mM sodium acetate (pH 5) or 50 mM potassium phosphate (pH 6, 7 and 8). (*b*) Variation of $k_{obs}$ *versus* concentration of the producing enzyme MhpC (measured in units MhpC per ml assay mixture). Specific activity of MhpC is 75 u mg$^{-1}$, $M_r$ 29 kDa, substrate concentration, 58 μM.

of the plot in Fig. 2(*b*) the rate of MhpC-catalysed ketonisation of **2** can be calculated at 18 min$^{-1}$, 1.5% of $k_{cat}$ for the MhpC-catalysed production of **2**. The ketonisation of enolpyruvate is also catalysed by an enzyme, pyruvate kinase (see Table 1).[2]

Is the dienol tautomer of **2** the substrate for the ensuing hydratase enzyme MhpD? Addition of *E. coli* extract containing MhpD enzyme activity to a solution of freshly-generated **2** gave rise to a rapid decrease in $A_{270}$. The rate of the enzyme-dependent decomposition of **2** was proportional to enzyme concentration, and samples of protein containing no MhpD showed no effect on **2**. This assay has been used to purify hydratase enzyme MhpD, as described elsewhere, and the pure enzyme shows the same effect by UV spectroscopy.[11] The conversion of **2** to 4-hydroxy-2-oxopentanoic acid **3** by MhpD has been confirmed by the lactonisation of **3** under acidic conditions, to give a sample of 2-oxo-4-methyl-γ-butyrolactone **6** which shows identical analytical data to synthetic samples of **6**.[12] Enzymatic processing of dienol **2** at rates considerably in excess of $k_{obs}$ for ketonisation of **2** implies that the dienol tautomer is used as a substrate for MhpD-catalysed hydration. Studies to elucidate the mechanism of the MhpD-catalysed hydration are discussed elsewhere.[11] The $Mn^{2+}$- and MhpC-catalysed decomposition of **2** lead to low yields for large scale substrate conversions of **2** by hydratase MhpD, which requires $Mn^{2+}$ for activity.[11]

**Table 1** Comparison of the properties of **2** with its homologue enolpyruvate **1**

| | Enolpyruvate **1** | 2-Hydroxypentadienoic acid **2** |
|---|---|---|
| $\lambda_{max}$/nm | 225 | 270 |
| $\varepsilon_{max}$/M$^{-1}$ cm$^{-1}$ | 9600[a] | 19 200 |
| $k_{obs}$ (pH 5)/min$^{-1}$ | 1.32[b] | 0.026 |
| $t_{1/2}$ (pH 5)/min | 0.5 | 27 |
| Non-enzymatic catalysis | $OH^-$, $M^{2+}$ [b] | $OH^-$, $M^{2+}$ |
| Enzymatic catalysis ($k_{cat}$/min$^{-1}$) | pyruvate kinase (50)[a] | MhpC (18) |

[a] Data from ref. 2. [b] Data from ref. 3. Measured in 20mM NaOAc (pH 5), 0.2 mM $MnCl_2$.

On the catechol *meta*-cleavage pathway of *Pseudomonas putida*, **2** is generated by a decarboxylase enzyme which forms a 1 : 1 complex with the ensuing hydratase enzyme.[10] It has been proposed that the formation of such a complex favours the processing of the unstable intermediate **2**.[10] We have no evidence of any association between hydrolase MhpC and hydratase MhpD, however it is noteworthy that the catalytic efficiency of purified MhpD is very high ($k_{cat}/K_m$ = 1.1 × 10$^7$ M$^{-1}$ s$^{-1}$).[11] In conclusion, 2-hydroxypentadienoic acid shows similar chemical properties but enhanced kinetic stability with respect to its homologue enolpyruvate, and represents a further example of a biologically important enol.

This work was supported by an Earmarked studentship (J. R. P.) and a research grant (B04835) from the BBSRC. We thank Sarah Fleming for assistance with NMR spectroscopy, and Dr Jonathan Percy (University of Birmingham) for helpful comments.

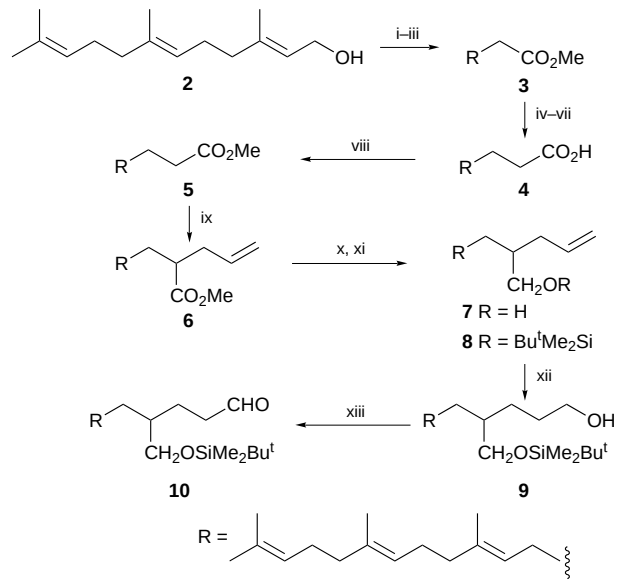
# Synthesis of norsesterterpene *rac*- and *ent*-rhopaloic acid A

**Ryukichi Takagi, Asami Sasaoka, Satoshi Kojima and Katsuo Ohkata***

*Department of Chemistry, Faculty of Science, Hiroshima University, 1-3-1 Kagamiyama, Higashi-Hiroshima 739, Japan*

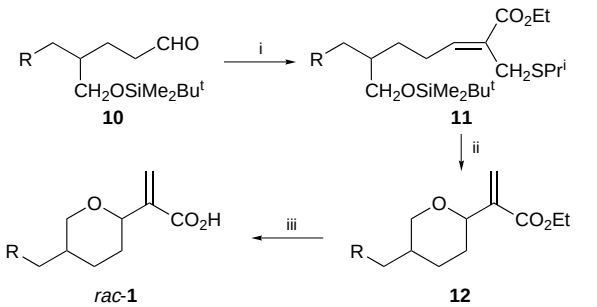
**The stereoselective synthesis of *rac*- and *ent*-rhopaloic acid A 1 has been accomplished, *via* successive homologation of (2*E*,6*E*)-farnesol 2 and cyclization to form a tetrahydropyran ring, together with final introduction of an α-methylene group; the asymmetric synthesis was achieved *via* an Evans' asymmetric alkylation using (*S*)-4-benzyloxazolidin-2-one as a chiral auxiliary; the synthetic rhopaloic acid A, with a predicted absolute configuration of (2*S*,5*R*), had a specific rotation of opposite sign to that of the natural product, and therefore the configuration of natural rhopaloic acid A should be assigned as (2*R*,5*S*).**

(+)-Rhopaloic acid A (+)-**1**, a potent cytotoxic agent, was isolated from the marine sponge *Rhopaloeides* sp.[1] The interesting biological activity of the compound may be attributed to the structurally unique feature of having a hydrophilic pyranylacrylic acid moiety connected to a hydrophobic isoprenoid part.[2] The acrylic acid moiety is also found in compounds such as conconadine[3a] and gerin,[3b] and the related 2-methylene-γ-lactone group is found in many bioactive natural products. The potential of (+)-**1** and its analogues as biological probes provided the incentive for this synthetic undertaking. Here the total syntheis of racemic rhopaloic acid A *rac*-**1** and the nonnatural enantiomer *ent*-rhopaloic acid A (−)-*ent*-**1** is described.



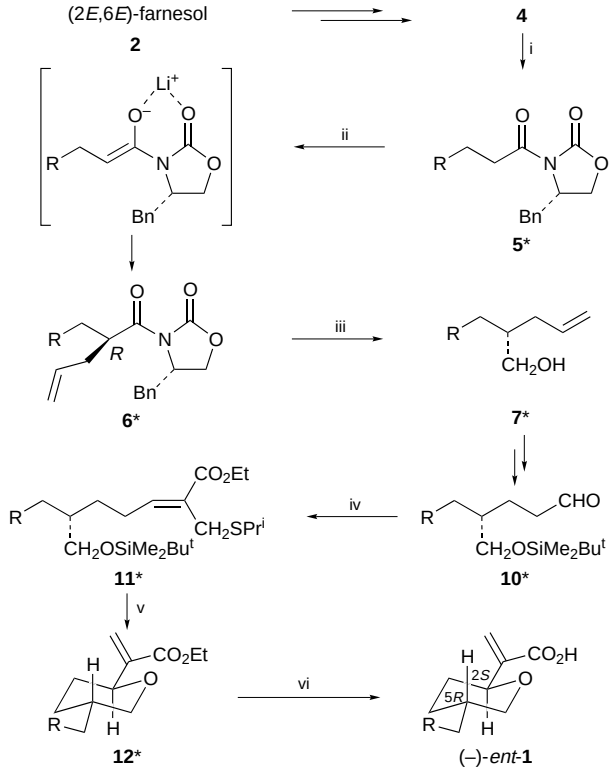
(+)-**1**

Our synthetic strategy consists of successive homologations of (2*E*,6*E*)-farnesol **2** and cyclization to form a tetrahydropyran ring, together with the final introduction of an α-methylene group.



The two-carbon homologation exploited malonic esterification starting from (2*E*,6*E*)-farnesol **2** (Scheme 1). Treatment of farnesol with $PPh_3$–$CBr_4$ at 0 °C afforded farnesyl bromide.[4] The bromide contained less than 5% of the (2*Z*,6*E*)-isomer and was used for the following reaction without further purification. Treatment of the bromide with dimethyl malonate (5 equiv.) in the presence of NaH (1 equiv.) gave the dimethyl ester in 80% yield.[5] Demethoxycarbonylation of the dimethyl ester under neutral conditions (NaCl in moist DMF) afforded monomethyl ester **3** in 87% yield. Reduction of **3** with $LiAlH_4$ afforded the alcohol in quantitative yield. Treatment of the alcohol with $Ph_3P$–$CBr_4$ gave the bromide in 86% yield. Cyanation of the bromide with NaCN in DMF afforded the nitrile in quantitative yield. Hydrolysis of the nitrile under basic conditions afforded carboxylic acid **4** and esterification of **4** with MeI–$K_2CO_3$[6] gave methyl ester **5** in 76% yield over two steps.

Treatment of **5** with LDA followed by allyl bromide gave allylated methyl ester **6** in 83% yield. Reduction of **6** with $LiAlH_4$ afforded alcohol **7** in 88% yield. Protection of **7** with *tert*-butyldimethylsilyl chloride followed by hydroboration–oxidation with 9-BBN–$H_2O_2$ gave primary alcohol **9** (79%). Swern oxidation of **9** afforded aldehyde **10** (80%).



The modified Wittig–Horner–Emmons reaction of **10** with $(EtO)_2P(O)C(=CH_2)CO_2Et$ in the presence of $NaSCHMe_2$ furnished **11** with only *Z* geometry in 57% yield as a single isomer (Scheme 2).[8]† Exposure of **11** to methylation reagent MeI–$AgBF_4$ followed by desilylation with $Bu_4NF$ afforded ethyl pyranylacrylate derivative **12** in 32% yield as the *trans* isomer.[9]‡ The ester **12** contained less than 10% of the *cis* isomer. Hydrolysis of **12** with aq. KOH afforded *rac*-**1** with

**Scheme 1** *Reagents and conditions*: i, $PPh_3$ (1.2 equiv.), $CBr_4$ (1.3 equiv.), $CH_2Cl_2$, 0 °C, 3 h; ii, NaH (1 equiv.), $CH_2(CO_2Me)_2$ (5 equiv.), DMF, 0–25 °C, overnight, 80% over two steps; iii, NaCl (2 equiv.), $H_2O$ (2 equiv.), DMF, reflux, 20 h, 87%; iv, $LiAlH_4$ (1.3 equiv.), THF, 0 °C, 1 h, 96%; v, $Ph_3P$ (1.2 equiv.), $CBr_4$ (1.5 equiv.), $CH_2Cl_2$, 0 °C, 1 h, 86%; vi, NaCN (2.5 equiv.), DMF, 25 °C, 1 h, 99%; vii, KOH (10 equiv.), $H_2O$, EtOH, reflux, 30 h, 78%; viii, MeI (2 equiv.), $K_2CO_3$ (2 equiv.), 25 °C, 3 h, 98%; ix, LDA (1.1 equiv.), THF, −78 °C, 30 min, then allyl bromide (4 equiv.), −78 to 25 °C, overnight, 83%; x, $LiAlH_4$ (1.5 equiv.), THF, 0 °C, 3 h, 88%; xi, $Bu^tMe_2SiCl$ (1.1 equiv.), imidazole (2 equiv.), DMF, 3 h, 87%; xii, 9-BBN (1.5 equiv.), THF, 0 to 25 °C, overnight, then aq. NaOH (4 equiv.), 30% aq. $H_2O_2$ (4 equiv.), overnight, 79%; xiii, DMSO (2 equiv.), $(COCl)_2$ (1.1 equiv.), $Et_3N$ (5 equiv.), $CH_2Cl_2$, −60 °C, 5 h, 80%

**Scheme 2** *Reagents and conditions*: i, NaH (1 equiv.), $Me_2CHSH$ (1 equiv.), $(EtO)_2P(O)C(=CH_2)CO_2Et$ (1 equiv.), THF, 0 °C, 10 min, then **10**, 25 °C, overnight, 57% (*Z* isomer only); ii, MeI (3 equiv.), $AgBF_4$ (1 equiv.), $CH_2Cl_2$, 2 h, then $Bu_4NF$ (3 equiv.), THF, 16 h, 32%; iii, aq. KOH (excess), reflux, 14 h, 34%

**Scheme 3** *Reagents and conditions*: i, $Et_3N$ (1.2 equiv.), pivaloyl chloride (1.2 equiv.), THF, then *N*-lithiooxazolidin-2-one, THF, −78 °C, 15 h, 66%; ii, LDA (1.1 equiv.), THF, −78 °C, 30 min, then allyl bromide (4 equiv.), −20 to −10 °C, 6 h, 44%; iii, $LiAlH_4$ (3 equiv.), THF, 0 °C, 15 h, 92% iv, NaH (1 equiv.), $Me_2CHSH$ (1 equiv.), $(EtO)_2P(O)(=CH_2)CO_2Et$, THF, 0 °C, 10 min, then **10***, 25 °C, 28 h, 46% (*Z* isomer only); v, MeI (3 equiv.), $AgBF_4$ (1 equiv.), $CH_2Cl_2$, 5 h then $Bu_4NF$ (3 equiv.), THF, 25 °C, 13 h, 35%; vi, aq. KOH (excess), reflux, 18 h, 56%

retained stereochemistry in 34% yield.§ The $^1H$ and $^{13}C$ NMR and mass spectra of the carboxylic acid *rac*-**1** and the ethyl ester **12** were identical with those recorded for authentic samples of (+)-rhopaloic acid A (+)-**1** and its ethyl ester derivative, respectively.

Asymmetric synthesis of *ent*-rhopaloic acid A was carried out by way of the Evans' asymmetric alkylation as shown in Scheme 3. The auxiliary moiety, (*S*)-4-benzyloxazolidin-2-one, was introduced into **4** (66%) to give **5***. The lithium enolate of **5*** was treated with allyl bromide at −20 to −10 °C to give **6*** as the pure diastereoisomer (44% yield, 99% de).[7,10]¶ Consideration of the chelation model of the enolate intermediate predicted the stereochemistry at the C2 position of **6*** to be 2*R*.[10] Following removal of the chiral auxiliary by $LiAlH_4$ reduction (92%) and protection (79%) of the alcohol **7*** with a *tert*-butyldimethylsilyl group, silyl ether **8*** was subjected to regioselective hydroboration with 9-BBN followed by oxidation with $H_2O_2$ to give **9*** (68%). Swern oxidation of **9*** gave **10*** in 80% yield. The modified Wittig–Horner–Emmons reaction of **10*** afforded α,β-unsaturated ester **11*** (46%), which was cyclized into **12*** (35%). Hydrolysis of **12*** gave the optically pure (2*S*,5*R*)-*ent*-**1**‖ in 9% overall yield from **10***. The specific rotation of *ent*-**1** was $[\alpha]_D^{25}$ −37.6 (*c* 0.315, $CHCl_3$), which was of opposite sign to that of the natural product (+)-**1**. Therefore, it is presumed that the configuration of natural rhopaloic acid A {$[\alpha]_D^{25}$ + 40 (*c* 0.47, $CHCl_3$)}[1] is 2*R*,5*S*.

In order to investigate the structure–bioactivity relationship of **1** and other biomechanistic problems, an alternative synthesis of **1** and related compounds is now progress.[11]

Spectra of an authentic sample were kindly provided by Dr S. Ohta (Hiroshima University). The authors thank Shiono Koryo Kaisha, Ltd. and Kurare Co. for the gift of farnesol. NMR and mass spectra and optical rotations were measured at the Instrument Center for Chemical Analysis, Hiroshima University.

† The product ratio changed with the reaction conditions. Only the *Z* isomer, the thermodynamically stable product, was obtained when the reaction mixture was stirred overnight at 25 °C. A ratio of *Z*:*E* = 2.4:1.0 was obtained when the reaction mixture was stirred at 0 °C for 3 h. The relative configuration of the product was determined with difference NOE experiments: when 3-H of the *E* isomer was irradiated, the intensity of the 2-$CH_2$S signal was enhanced by 8.2%.

‡ For **12**, the assigned relative stereochemistry was confirmed by intensity enhancement of 2-H by 10.9% upon irradiation of 6-$H_{ax}$. The assignment of 6-$H_{ax}$ was determined by measurement of coupling constants: $J_{5,6\text{-ax}}$ = 11.2 Hz, $J_{5,6\text{-eq}}$ = 3.9 Hz.

§ The relative stereochemistry of *rac*-**1** was assigned using the same considerations as for **12** ($J_{5,6\text{-ax}}$ = 11.2 Hz, $J_{5,6\text{-eq}}$ = 3.9 Hz); when 6-$H_{ax}$ was irradiated, an intensity enhancement of 2-H by 6.9% was observed.

¶ The diastereoselectivity of the allylation was evaluated by conversion of the optical active alcohol **7*** into its benzoate ester, followed by analysis with a DAICEL CHIRALCEL-OD column (hexane–AcOEt 400:1).

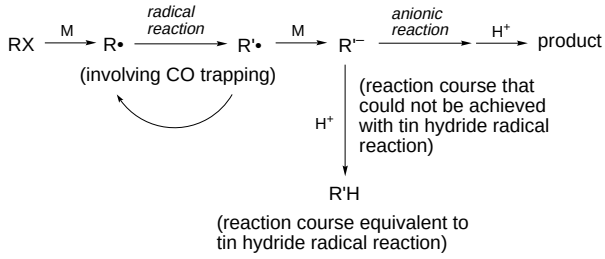
# Tandem annulations: a one operation construction of bicyclo[3.3.0]octan-1-ol and bicyclo[3.2.1]octan-1-ol skeletons by a three-component coupling reaction of alk-4-enyl iodides with CO and alkenes in the presence of zinc



**Shinji Tsunoi,[a] Ilhyong Ryu,*[b]† Sumiaki Yamasaki,[b] Minoru Tanaka,[a] Noboru Sonoda*[b]‡ and Mitsuo Komatsu[b]**

**Under a one-electron reduction system composed of zinc and an aprotic solvent, alk-4-enyl iodides react with CO and alkenes to give bicyclo[3.3.0]octan-1-ols and bicyclo[3.2.1]octan-1-ols *via* radical/anionic dual annulations.**

Tin radical mediated C1 chemistry has the potential to play an increasingly important role in the synthesis of a variety of carbonyl compounds.[1] In a previous paper, we have shown that a one-electron reduction system composed of zinc and a protic solvent can replace some of the useful transformations developed for tin hydride mediated radical carbonylation reactions.[2] An attractive feature of metal mediated one-electron reduction chemistry is its applicability to the design of unique tandem reaction systems, in which two different species, radicals and anions, can be subtly combined in synthetically useful reactions (Scheme 1).[3] Recent reports provide a useful reminder of the effectiveness and importance of this concept.[4] Here we report a three-component coupling reaction of alk-4-enyl iodides, CO and alkenes in the presence of zinc that delivers bicyclo-[3.3.0]octanols[5] and bicyclo[3.2.1]octanols, providing the first demonstration that radical carbonylation can be successfully sequenced by consecutive radical/anionic reactions.

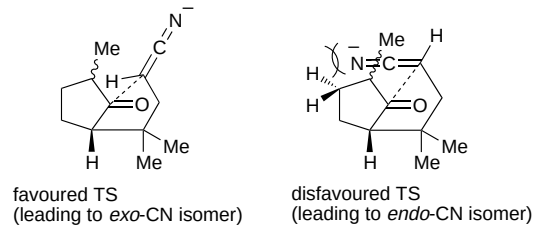
In radical carbonylation using a reductive metal/protic solvent system, after an acyl radical cyclization and addition to a C–C double bond, the newly formed radical is reduced to an anion, which is subsequently protonated.[2] In aprotic solvents, however, the anionic species could conceivably undergo nucleophilic addition to the newly formed internal carbonyl group rather than undergoing protonation.[6] To test this hypothesis, we conducted the reaction of 6-iodo-2-methylhept-2-ene **1** with zinc under CO pressures in aprotic solvents to determine if a bicyclic compound is produced *via* a pathway outlined in Scheme 2. After several experiments, we found that when the usual zinc powder[7] was used in THF or MeCN solvent, the desired reaction took place. In a stainless steel autoclave, a THF solution of **1** (476 mg, 2 mmol, 0.1 M), acrylonitrile (53 mg, 1 mmol) and zinc (197 mg, 3 mmol) was sitrred under CO pressure (60 atm) at 60 °C. After 10 h, the anticipated 2-cyano-4,4,8-trimethylbicyclo[3.3.0]octan-1-ol **2** (137 mg, 71% yield, 60 : 40) was obtained after isolation by flash chromatography on silica gel (Table 1, entry 1). Only two of the four possible diastereoisomers were produced, as judged by both $^1$H and $^{13}$C NMR spectroscopy. A separation of the diastereoisomers was performed by careful chromatography on silica gel, and the absolute structures were confirmed to be *exo* at the CN group and either *endo* or *exo* at the Me group by NOE experiments.§ The major isomer was identified as 8-*exo*-Me, and the minor as 8-*endo*-Me. The consecutive radical/anionic reactions shown in Scheme 2 account for the formation of **2**: (i) an alkyl radical, formed by a one-electron reduction of the starting iodide, adds to CO; (ii) the resulting acyl radical cyclizes in the 5-*exo* mode to give a tertiary alkyl radical; (iii) this radical adds to acrylonitrile; (iv) the resulting α-cyano radical is reduced to an α-cyano anion **3**; (v) anion **3** adds to an internal carbonyl group, (vi) protonation during the work-up leads to bicyclo[3.3.0]octan-1-ol **2**. The observed diastereoselectivities with respect to the *exo*-orientation of the CN group may be rationalized on the basis of steric effects in the anionic cyclization step: the transition state giving the *endo*-CN product is disfavoured, due to steric repulsion between the CN group and the cyclopentanone ring (Fig. 1).[8]

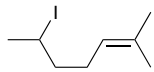
**Scheme 1**

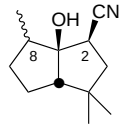
**Scheme 2**

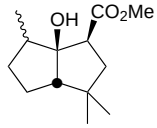
Similarly, carbonylation of **1** in the presence of methyl acrylate and zinc gave the corresponding bicyclo[3.3.0]octanol **4** in 50% yield (entry 2). Again, only two of the four possible diastereoisomers were produced. With diethyl fumarate, a mixture of four isomers of bicyclo[3.3.0]octanol **5** was obtained in 52% yield (entry 3).

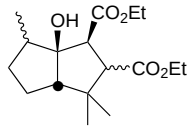
We demonstrated cases where the initial acyl radical cyclization takes place in the 5-*exo* mode. An extension of the present strategy, which uses a system that favours 6-*endo*

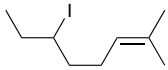


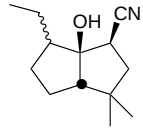


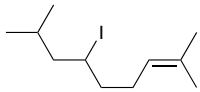


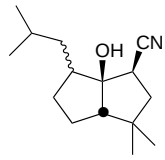


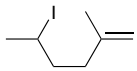


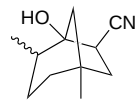












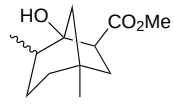


**Fig. 1**

**Table 1** Synthesis of bicyclic octanols[a]

| Entry | Alk-4-enyl iodide | Alkene | Product (% yield,[b] *exo*/*endo* ratio[c]) |
|---|---|---|---|
| 1 |  **1** |  |  **2** (71, 60:40) |
| 2 | **1** |  |  **4** (50, 52:48) |
| 3 | **1** |  |  **5** (52, 32:31:20:17)[d] |
| 4 |  **6** |  |  **7** (63, 61:39) |
| 5 |  **8** |  |  **9** (64, 59:41) |
| 6 |  **10** |  |  **11** (51, 57:43) |
| 7 | **10** |  |  **12** (43, 50:50) |

[a] Conditions: alk-4-enyl iodide (2 mmol), alkene (1 mmol), Zn (3 mmol), CO (60 atm), THF (10–20 ml), 60 °C, 10–22 h. [b] Isolated yields (based on the alkene used) by column chromatography for the *endo*/*exo* mixture. [c] Determined by $^1$H NMR spectroscopy (except for entry 3: GC). [d] Stereochemistry was not determined.

cyclization[9] rather than 5-*exo* cyclization to the construction of bicyclo[3.2.1]octanol skeletons was also successful. Thus, we examined 5-iodo-2-methylhex-1-ene **10**, a substrate having a methyl group at an internal position on the alkene. As expected, the reaction of **10** with CO and acrylonitrile in the presence of zinc led to bicyclo[3.2.1]octanol **11** in 51% isolated yield (entry 6). Similarly, reaction with methyl acrylate yielded the corresponding bicyclo[3.2.1]octanol **12** in 43% yield (entry 7).

This study demonstrates that radical carbonylation can be successfully combined with a sequential radical/anionic reaction system,[10] which is of great synthetic potential. The reaction reported here provides a convenient route to bicyclo[3.3.0]octanols and bicyclo[3.2.1]octanols from easily accessible starting compounds, such as alk-4-enyl iodides, CO and electron deficient alkenes. It is also noteworthy that the former reactions involve [4 + 1](radical)/[3 + 2](anionic) dual annulations, and the latter reactions involve [5 + 1](radical)/[3 + 2](anionic) dual annulations. We believe that the concepts outlined in this study have wide applicability for numerous synthetically useful processes.

This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture, Japan. We are grateful to Professor Kazuhiko Takai for stimulating discussions.

# Switching 'on' the luminescence of one metal ion with another: selectivity characteristics with respect to the emitting and triggering metal

**A. Prasanna de Silva, H. Q. Nimal Gunaratne, Terence E. Rice and Siobhan Stewart**

*School of Chemistry, Queen's University, Belfast, UK BT9 5AG*

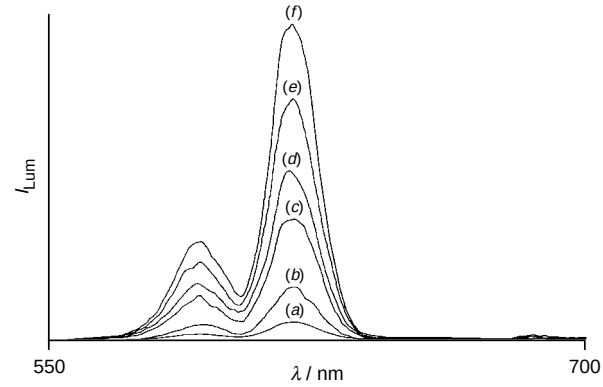
**Complexes 1a·Eu$^{III}$ and 1b·Eu$^{III}$, but not 1a·Tb$^{III}$ and 1b·Tb$^{III}$, display strong 'off–on' switching of delayed luminescence with alkali cations; the switching efficiency of 1b·Eu$^{III}$ is stronger with K$^+$ rather than Na$^+$.**

Light emission of many organic molecules[1] and supermolecules[2] can be triggered by metal ions. This forms the basis of fluorescent sensors for metal ions.[3] Conversely, metal-centred emission can be induced by non-metal guests in a few carefully designed instances.[4] The third combination, that of organic molecular emission arising from the complexation of organic species, is also being developed in several laboratories.[5] The final combination of this quartet, that of metal ion-triggered metal-centred emission, is currently unavailable according to the best of our knowledge.[6] Metal-containing, but not metal-centred, emissive systems have been switched 'on' or 'off' by various species including metal ions.[7] We now fill this gap with examples of europium(III) complexes whose luminescence is switched 'on' with alkali metal ions.[8] We also note an interesting selectivity aspect in that the corresponding terbium(III) complexes are relatively immune to alkali cation-induced switching. Following this proof of principle, it will be possible to design delayed luminescent[9] sensors for metal ions of medical and environmental interest which operate in aqueous solution. Many suitable metal ion receptors[10] and lanthanide lumophores[11] are available[6] for incorporation into this design.

The following systems are designed as delayed luminescent versions of fluorescent PET (photoinduced electron transfer) sensors[2b,3a] for alkali cations.[12] Ligands **1a**,**b** were synthesized from the known compound 4,4″-bis(*p*-tolyl)-6,6″-bis-(methoxycarbonyl)-2,2′:6′,2″-terpyridine[13] **1c** by bromination with *N*-bromosuccinimide and amination with the appropriate monoazacrown ether.† The binding of **1a**,**b** with Tb$^{III}$ or Eu$^{III}$, when monitored by UV absorption spectroscopy, fits a 1:1 binding isotherm.[14] The conformational locking of the terpyridyl diester by the lanthanide ion leads to the growth of long-wavelength bands upto 340 nm. Monitoring of the complexation process in **1c** by $^1$H NMR spectroscopy shows Eu$^{III}$-induced upfield displacement of the methoxycarbonyl signal by 0.6 ppm as well as displacements of the other signals by upto 1.0 ppm. Much higher lanthanide ion concentrations than those employed here are needed before they bind to the azacrown moieties of **1a**,**b**.[10b] Binding of alkali cations to the azacrown units of **1a**·Eu$^{III}$ and analogues leads to small but measurable hypsochromic shifts in their UV absorption spectra. These allow determination of the binding constants $\beta_{Na}$ and $\beta_K$, which are in close agreement with literature values for the binding of alkali cations to unsubstituted monoazacrown ethers.[10b]

Most importantly, the delayed luminescence of **1a**·Eu$^{III}$ and **b**·Eu$^{III}$ is enhanced by over an order of magnitude when the azacrown units are bound by alkali cations (Fig. 1). Luminescence quantum yields reach values as high as 0.47 (for **1a**·Eu$^{III}$–K$^+$ in MeOH). Such switching 'on' of luminescence arises from the alkali cation-induced suppression of PET from the azacrown nitrogen to the lumophore.[12] Eu$^{III}$ complexes are known to participate in PET processes.[15] It is notable that K$^+$ produces the larger luminescence enhancement (LE) with **1b**·Eu$^{III}$ in spite of its lower charge density than Na$^+$. This is probably because the loosely fitting Na$^+$ moves away from the soft nitrogen towards the harder oxygens, thus lessening the PET suppression. Analysis of these luminescence intensity ($I_{Lum}$) – $(M)_{total}$ profiles (M = Na or K) gives $\beta_{Na}$ and $\beta_K$ values which are gratifyingly close to the values determined absorptiometrically. The average number of lanthanide-bound MeOH molecules[16] ($q$), determined by comparison of luminescence lifetimes ($\tau$) in MeOH and MeOD, is two. This suggests that the usual minimum coordination number of nine[17] is made up by two counterions, which is reasonable given the substantial ion-pairing in the moderately dielectric medium and the tripositive nature of **1a**·Eu$^{III}$ and analogues.

The immeasurably weak delayed luminescence of complexes **1a**·Tb$^{III}$ and **b**·Tb$^{III}$ is not noticeably enhanced by Na$^+$ or K$^+$ ions. However protons, the strongest PET suppressants of all,



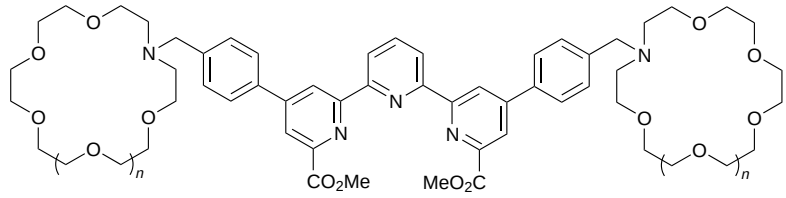


**Fig. 1** Delayed luminescence emission spectra of **1b**·Eu$^{III}$ upon addition of K$^+$. The spectra are uncorrected for the wavelength response of the detector which degrades rapidly at wavelengths longer than 650 nm. p$K_{total}$ = (*a*) ∞, (*b*) 5.0, (*c*) 4.4, (*d*) 4.2, (*e*) 4.0 and (*f*) 3.4.

[a] **1a** or **1b** $10^{-6}$ M in MeOH with $TbCl_3^{III}$ or $EuCl_3^{III}$ ($3 \times 10^{-5}$ M) and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) ($10^{-4}$ M) as proton scavenger, except when $\phi_{Lum\cdot H}$ ($LE_H$) values are being determined. $Na^+$ and $K^+$ added as acetates. $H^+$ added as trifluoroacetate. The $\lambda_{Abs}$ (log $\varepsilon$) values for **1a** and **1b** are 240 (5.05), 276sh (4.86) and 324sh (4.07), and 240 (5.14), 276sh (5.03) and 324sh (4.32) nm, respectively. Lanthanide luminescence emission spectra were obtained by excitation at the isosbestic wavelength of 340 nm, with a delay time of 0.1 ms and a gate time of 1.5 ms for all four lanthanide complexes. [b] Extinction coefficient $\varepsilon$ in units of $M^{-1}\,cm^{-1}$. [c] The binding constant for the **1**–lanthanide (Ln) interaction was obtained by analysing absorbance ($A$) − (Ln) profiles according to: $\log[(A - A_{min})/(A_{max} - A)] = \log[(Ln)_{total} - (\mathbf{1})_{total}(A - A_{min})/(A_{min})/(A_{max} - A)] + \log\beta$ (ref. 14). Log $\beta_{Na\ or\ K}$ values for the **1**·Ln–Na or **1**·Ln–K interaction were similarly determined by analysing absorbance − $(M)_{total}$ profiles according to: $\log[(A - A_{min})/(A_{max} - A)] = \log[(M)_{total} - (\mathbf{1}\cdot Ln)_{total}(A - A_{min})/(A_{max} - A)] + \log\beta_{Na\ or\ K}$. M = $Na^+$ or $K^+$. Luminescence intensity can be used instead of absorbance as the dependent variable for determining log $\beta_{Na\ or\ K}$. [d] Luminescence quantum yields obtained by comparison with the $Eu^{III}$ complex of the carboxylate form of **1c** (ref. 13) and the $Tb^{III}$ complex with EDTA and sulfosalicyclic acid (ref. 19). [e] Luminescence measurements. [f] Absorbance measurements. [g] Spectroscopic change is too small to permit measurement. [h] Ion ($Na^+$, $K^+$ or $H^+$) induced luminescence enhancement factor, *e.g.* $LE_{Na} = \phi_{Lum\cdot Na}/\phi_{Lum}$. [i] Determined by the first-order decay expression for luminescence intensity. $\tau$ values are given as an average (±0.01 ms) in the presence of $Na^+$, $K^+$ or $H^+$ for $Eu^{III}$ complexes. Only the value in the presence of $H^+$ is accessible for $Tb^{III}$ complexes. [j] $q$ values are given as an average (±0.1) in the presence of $Na^+$, $K^+$ or $H^+$ for $Eu^{III}$ complexes. Only the value in the presence of $H^+$ is accessible for $Tb^{III}$ complexes.

produce measurable, but still small, luminescent quantum yields of 0.016 and 0.014, respectively. The weakness of this emission is probably due to an additional deactivation channel of the $Tb^{III}$ $^5D_4$ emissive state. The triplet level of the complexed ligand, as measured from the 77 K phosphorescence maximum of **1c**·$Gd^{III}$, lies only 4.1 kcal $mol^{-1}$ (1 kcal = 1 kJ) above the $Tb^{III}$ $^5D_4$ state, which means that rapid back energy transfer occurs under ambient conditions.[18] This leads to the complexed ligand triplet and subsequent de-excitation *via* the ligand state manifold. Such back energy transfer is absent in **1a**·$Eu^{III}$ and **1b**·$Eu^{III}$ owing to the much larger triplet $Eu^{III}$ $^5D_0$ state energy gap of 13.2 kcal $mol^{-1}$.

In conclusion, metal-triggered metal-centred emission has been demonstrated. The selectivity determinants are (i) the ability of the triggering metal to block PET from an azacrown nitrogen and (ii) the energy separation of the ligand triplet and the metal emitting state.

We thank the SERC/EPSRC and DENI for support.

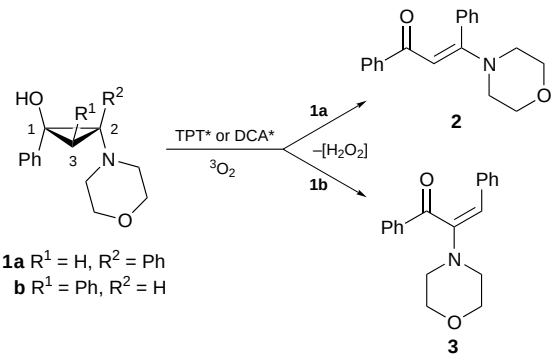
# A novel synthesis of α- and β-morpholino enones by electron transfer sensitized photooxidation of 2-morpholinocyclopropanols

**Wilfried Weigel* and Hans-Georg Henning**



*Department of Chemistry, Humboldt-University of Berlin, Hessische Str. 1-2, D-10115 Berlin, Germany*

**An electron transfer mechanism is proposed to account for the photooxidation of 2-morpholinocyclopropanols 1 to the amino enone derivatives 2 and 3 in the presence of 9,10-dicyanoanthracene or triphenylpyrylium tetrafluoroborate and triplet oxygen.**

Photoinduced electron transfer (ET) *cis–trans* isomerization and oxidative ring opening of cyclopropanes have been the subject of numerous investigations.[1,2] Dioxolane derivatives and, in some cases, hydroperoxides and chalcones are formed by electron transfer photooxidation of aryl substituted cyclopropanes. Several mechanisms involving the superoxide anion radical, a chain reaction with triplet oxygen, or reaction of triplet oxygen with a 1,3-biradical formed by back electron transfer to the cyclopropane cation radical have been discussed.[3–5] Recently we reported that the irradiation of β-(*N*,*N*-dialkylamino)propiophenones gives 2-aminocyclopropanols that undergo oxidative ring opening to β-amino enones.[6a] Due to the electron donor properties of amino groups, 2-morpholino-1,2-diphenylcyclopropanol **1a** and 2-morpholino-1,3-diphenylcyclopropanol **1b** appeared to be excellent candidates for electron transfer studies. They were synthesized by photocyclization[6] and used as model compounds to investigate the possibility of oxidative ring opening in presence of the photoexcited electron acceptors 9,10-dicyanoanthracene (DCA) or triphenylpyrylium tetrafluoroborate (TPT).

Irradiation ($\lambda_{irr}$ > 395 nm) of aerated solutions of **1a** ($2 \times 10^{-4}$ M) in the presence of catalytic amounts (0.1 equiv.) of DCA in MeCN or TPT in $CH_2Cl_2$ gave the β-morpholino-β-phenylvinyl phenyl ketone **2** in 36 ($t_{irr}$ = 0.5 min) and 41% ($t_{irr}$ = 5.2 min) yield, respectively. Photolysis of a mixture of **1b** and DCA or TPT under the same conditions gave the α-morpholino chalcone **3** in 28 and 26% yield, respectively (Scheme 1). Continuous irradiation leads to the decomposition of **2** and **3**. The reported yields are the maximum values observed during the photolysis.† The formation of **2** and **3** was confirmed by HPLC analysis with authentic reference compounds.‡

The oxidation potentials $E(D/D^+)$ of **1a** and **1b** together with the $\Delta G$ values for photoinduced ET are given in Table 1. The free energy changes ($\Delta G$) for the one-electron transfer process

**1a** $R^1$ = H, $R^2$ = Ph
**b** $R^1$ = Ph, $R^2$ = H

**Scheme 1**

**Table 1** Oxidation potentials and calculated $\Delta G$ values for ET from **1** to $^{1/3}$TPT* and $^1$DCA*

| | | $\Delta G$/kcal mol$^{-1}$ | | |
|---|---|---|---|---|
| Compound | $E(D/D^+)/V^{a,b}$ | $^1$TPT*[c] | $^3$TPT*[c] | $^1$DCA*[d] |
| **1a** | 1.44 | −25.11 | −13.11 | −12.27 |
| **1b** | 1.37 | −26.72 | −14.72 | −13.88 |

[a] Pt electrode/SCE, 0.1 M $Et_4NClO_4$ in MeCN. [b] **2**: $E(D/D^+)$ = 1.53 V. [c] $E(A^-/A)$ = −0.29 V, $E(^1A^*)$ = 65 kcal mol$^{-1}$, $E(^3A^*)$ = 53 kcal mol$^{-1}$ (ref. 13). [d] $E(A^-/A)$ = −0.89 V, $E(^1A^*)$ = 66 kcal mol$^{-1}$ (ref. 13).

from the cyclopropane derivatives to photoexcited $^1$TPT* or $^1$DCA* were estimated by application of the Rehm–Weller equation [eqn. (1)].[8] The Coulombic term ($e^2/\varepsilon a$) was neglected

$$\Delta G = E(D/D^+) - E(A^-/A) - E(A^*) - e^2/\varepsilon a \qquad (1)$$

due to the lack of charge separation in case of TPT and the small estimated value of 0.06 eV[9] in MeCN for DCA as photosensitizer. Involvement of $^3$TPT* in photoinduced ET processes, especially at low donor concentrations (*ca.* $10^{-4}$ M), has been reported and cannot be ruled out in the case of **1**.[10,11]

Fluorescence quenching experiments of $^1$TPT* by **1a** and **1b** ($0.4 \times 10^{-3}$–6 x $10^{-3}$ M) were performed in aerated $CH_2Cl_2$ solutions.§ The fluorescence was quenched at almost diffusion controlled rates (**1a**: $k_q = 2.1 \times 10^{10}$ M$^{-1}$ s$^{-1}$; **1b**: $k_q = 2.0 \times 10^{10}$ M$^{-1}$ s$^{-1}$), calculated from the slopes of the Stern–Volmer plots (**1a**: $k_q\tau$ = 61 M$^{-1}$; **1b**: $k_q\tau$ = 58 M$^{-1}$) and a singlet lifetime of TPT of 2.9 ns.[12] As expected, the formation of **2** in the DCA-sensitized photolysis of **1a** was completely quenched by the addition of an equimolar amount of triethylamine, whose oxidation potential [$E(D/D^+)$ = 0.76 V, SCE, MeCN][13] is lower than that of **1a**. The DCA anion radical was detected by EPR measurements in the DCA-sensitized photoreaction of **1a** and **1b** in oxygen free MeCN.¶ No signals could be detected for the cation radical of **1**. The formation of the DCA anion radical was also observed by DCA-sensitized photolysis of the β-amino enone **2**.

The values of the oxidation potentials of **1** (Table 1) are lower than those of the *trans* and *cis* isomers of 1,2-diphenylcyclopropane, [$E(D/D^+)$ = 1.51 and 1.75 V].‖ Even though the measured oxidation potentials of **1a,b** are unexpectedly high compared to those for tertiary amines [*N*-methylmorpholine: $E(D/D^+)$ = 1.1 V, Ag/AgCl, MeCN][9] for reasons that are not clear, they reflect the good electron donor ability of **1**. The negative $\Delta G$ values for single electron transfer from **1a** and **1b** to $^{1/3}$TPT* and $^1$DCA*, the fluorescence quenching of $^1$TPT* at a diffusion controlled rate and the detection of $DCA^{-\cdot}$ by EPR spectroscopy strongly suggest that the formation of the radical cation of **1** by photoinduced ET is the primary process in the photooxidation of **1**. The cation radical of **1** could undergo reaction with triplet oxygen to give **1**–$O_2^{+\cdot}$. Back ET gives **1**–$O_2$ or the ground state reactants. Hydroperoxides formed from **1**–$O_2$ by internal hydrogen transfer are assumed to be intermediates which form **2** or **3** by elimination of hydrogen peroxide. In contrast to TPT, the DCA-sensitized photooxida-

$$\mathbf{1} + TP^{+*} / DCA^{*} \rightarrow \mathbf{1}^{+\bullet} + TP^{\bullet} / DCA^{-\bullet}$$

$$\mathbf{1}^{+\bullet} + {}^3O_2 \rightarrow \mathbf{1}\text{–}O_2^{+\bullet}$$

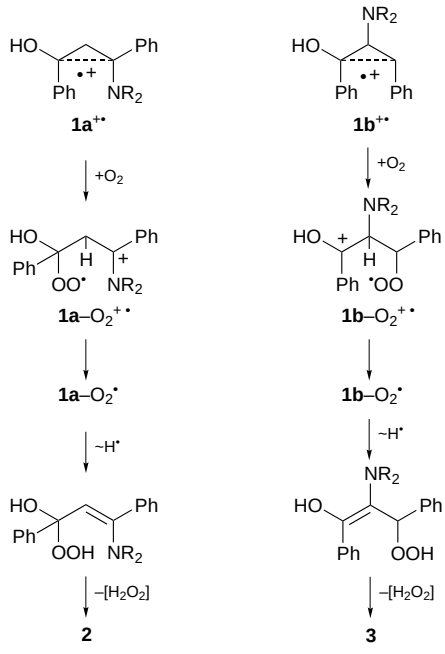
$$\mathbf{1}\text{–}O_2^{+\bullet} + TP^{\bullet} / DCA^{-\bullet} \rightarrow \mathbf{1}\text{–}O_2 + TP^{+} / DCA$$

$$DCA^{-\bullet} + {}^3O_2 \rightarrow DCA + {}^3O_2^{-\bullet}$$

$$\mathbf{1}^{+\bullet} + {}^3O_2^{-\bullet} \rightarrow \mathbf{1}\text{–}O_2$$

$$\mathbf{1}\text{–}O_2 \rightarrow \mathbf{2} \text{ or } \mathbf{3} + H_2O_2$$

**Scheme 2**



tion could lead to the formation of a superoxide anion radical by reaction of triplet oxygen with $DCA^{-\bullet}$ and would provide a second pathway to generate **1**–$O_2$.[10] A simplified mechanism for photoinduced ET oxidation of **1** is summarized in Scheme 2.

Possible pathways for the formation of **2** and **3** by reaction of the cation radicals of **1a** and **1b** with oxygen are given in Scheme 3. Obviously, the regioselectivity of ring opening is determined by the position of the phenyl groups. C(1)–C(3) ring cleavage of **1b** excludes resonance stabilization of the radical cation by the electron releasing morpholino group. However, the almost bisected conformation of the C(3)-phenyl group and the cyclopropane ring of **1b** should allow a strong interaction between their orbitals, in contrast to the morpholino group, which is the better electron donor but is arranged in a perpendicular fashion.[6a]**

High quantum yields for consumption of **1a** in the presence of TPT* ($8 \times 10^{-5}$ M) in $CH_2Cl_2$ were found.†† The values show considerable dependence on the concentration of the donor **1a** and amount to 11 ([**1a**] = $4.1 \times 10^{-4}$ M), 20 ([**1a**] = $6.0 \times 10^{-4}$ M) and 27 ([**1a**] = $1.6 \times 10^{-3}$ M). The high values indicate that a chain reaction occurs with generation of $\mathbf{1a}^{+\bullet}$ by hole transfer from **1a**–$O_2^{+\bullet}$ to **1a**. Quantum yields > 1 were reported for ET sensitized oxygenations and ring opening of several cyclopropanol derivatives and small strained ring systems.[3,16] An alternative pathway for the photooxidation could involve singlet oxygen generated by energy transfer from photoexcited TPT and DCA. However, the cyclopropanol **1a** was completely recovered after photolysis ($\lambda_{irr}$ > 395 nm) in MeCN in the presence of Methylene Blue as photosensitizer for singlet oxygen.

In summary, the novel synthesis of α- and β-morpholinoenones by DCA- or TPT-sensitized photooxidation of 2-morpholinocyclopropanols described herein increases the synthetic utility of the photochemical reactivity of cyclopropane derivatives.

We thank Professor Dr H. Kurreck at the Free University of Berlin for use of his EPR spectrometer. Helpful discussions with Professor Dr W. Abraham at the Humboldt University of Berlin are gratefully acknowledged.

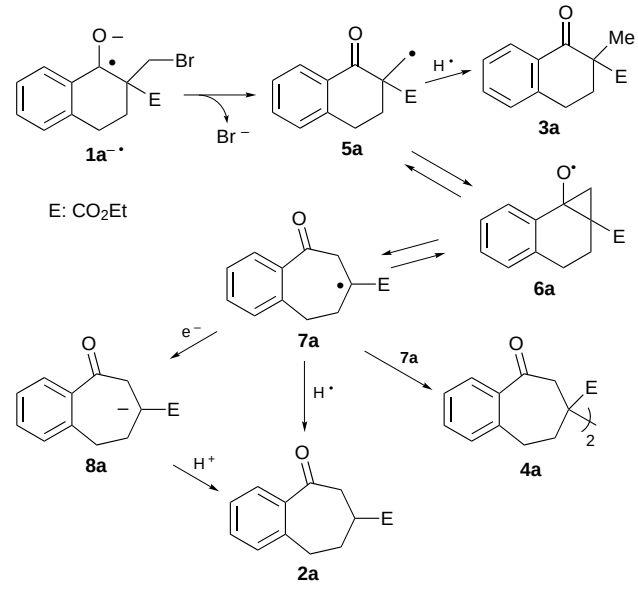
**Photoreaction of ethyl 2-bromomethyl-1-oxo-1,2,3,4-tetrahydronaphthalene-2-carboxylate 1a or other related compounds 1b–d with $Me_3SiCH_2NEt_2$ in aqueous MeCN afforded ethyl 5-oxo-6,7,8,9-tetrahydrobenzocycloheptene-7-carboxylate 2a or corresponding ring expansion products 2a–d respectively.**

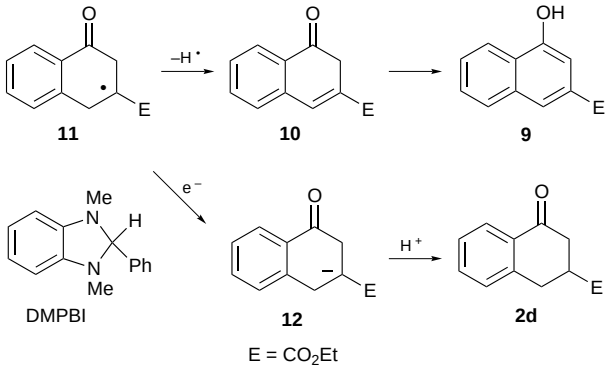
Irradiation of carbonyl compounds in the presence of electron donors such as amines produces carbonyl anion radicals and donor cation radicals.[1] Apparently proton transfer from donor cation radicals to carbonyl anion radicals is a feasible process. On the other hand, it is also reasonable to expect that carbonyl anion radicals must act as single electron donors. Therefore, generation of carbonyl anion radicals would irreversibly reduce distant carbon–halogen bonds in the same molecules through intramolecular electron transfer.[2] Although photoreactions of a few carbonyl compounds categorized in this group have been explored in the presence of electron donors, the substrates studied were limited to enones and dienones.[3] In this context, photoinduced electron transfer (PET) reaction of haloalkylated benzocycloalkanones such as **1** must be interesting since reductive carbon–halogen bond cleavage should generate carbon radicals followed by radical cyclization and ring expansion pathways.[4] Moreover, the literature observation that the yields of ring expansion products from **1** (X = Br) were relatively low under ordinary free radical conditions[5] also prompted us to explore photoreaction of **1** with electron donors. We report here the first example of PET promoted radical cyclization and ring expansion reactions of ethyl 2-bromomethyl-1-oxo-1,2,3,4-tetrahydronaphthalene-2-carboxylate **1a** and other related compounds **1b–d** (Scheme 1).

When a $N_2$ pre-purged MeCN solution (10 ml) of **1a** ($\lambda$ = 295 nm, $\varepsilon$820; 0.64 mmol) and $Me_3SiCH_2NEt_2$ (5 equiv.)[6] was irradiated for 1 h with a 500 W Xe-Hg lamp through Pyrex, 50% of the desired benzocycloheptanone **2a**, 10% of the reduced product **3a** and 21% of unexpected dimeric compound **4a** (as a mixture of two diastereomers $\mathbf{4a_1}:\mathbf{4a_2}$ = 55 : 45) was isolated together with 35% of unreacted **1a** after chromatographic separation (the product yields are reported on the basis of the conversion of **1a**).† Stirring of a similar solution for 2 h in the dark resulted in quantitative recovery of **1a**. Upon irradiation of **1a** for 2 h in the absence of $Me_3SiCH_2NEt_2$, 92% of **1a** was recovered without formation of **2a**. These control experiments clearly suggest that **2a** is produced through the interaction between the photoexcited **1a** and $Me_3SiCH_2NEt_2$.



**1a** X = Br, *n* = 1
**b** X = I, *n* = 1
**c** X = Br, *n* = 2
**d** X = Br, *n* = 0

**2a** *n* = 1
**c** *n* = 2
**d** *n* = 0



**Scheme 1**

It was also found that water significantly affects the product ratio when the reactions were conducted for 1 h in MeCN containing various amounts of water: 61% of **2a**, 10% of **3a**, 20% of **4a** and 24% of **1a** in 5% aq. MeCN; 68, 7, 16 and 25% in 10% aq. MeCN; 75, 6, 10 and 25% in 30% aq. MeCN. While addition of water increased the yield of **2a** and decreased the yields of **3a** and **4a**, the total yield of the products remained almost constant at about 90%. This would suggest that the observed products are formed through common intermediates. In order to obtain information on the nature of the intermediates, a deuterium labeling experiment was performed. Thus, when irradiation of **1a** for 2 h were conducted in 5% $D_2O$ as well as 5% $H_2O$ containing MeCN solutions, similar conversions (90 and 90%) as well as product yields (**2a**: 60 and 59%; **3a**: 7 and 7%) were observed, respectively. NMR analyses of the isolated products revealed that *ca.* 82% of hydrogen at $C_3$ in **2a** was substituted by deuterium and no deuterium was incorporated in **3a**. Therefore, **2a** is mainly formed through an ionic route in which its precursor is protonated. On the other hand, **3a** is formed through hydrogen abstraction by the radical intermediate.

On the basis of the above results, the reaction mechanism in Scheme 2 is proposed. Single electron transfer to the photoexcited state of **1a** from $Me_3SiCH_2NEt_2$ produces the anion radical of **1a** and the cation radical of $Me_3SiCH_2NEt_2$.‡ The resulting anion radical of **1a** rapidly reacts,§ undergoing carbon–bromine bond cleavage through intramolecular electron transfer to give the carbon radical **5a**. The radical **5a** abstracts hydrogen to produce **3a**, which is consistent with the deuterium labeling experiment. On the other hand, **5a** cyclizes to give the oxy radical **6a** followed by the ring opening to the ethoxy

**Scheme 2**

**Scheme 3**

carbonyl substituted carbon radical **7a**. Apparently, **7a** has a long enough lifetime to dimerize, giving **4a**. Cyclization of the carbon radical on the carbonyl group and ring opening would be a reversible process (**5a** → **6a** → **7a**).[7] If **7a** abstracts hydrogen, **2a** should be formed. However, the deuterium labeling experiment suggests that this is a minor route, even though it exists. Instead, **7a** is reduced to its anion **8a** followed by protonation to give the formation of **2a**.

In the proposed reaction mechanism, the most plausible candidate for the reducing agent of **7a** must be the α-amino radical formed through desilylation of the cation radical of $Me_3SiCH_2NEt_2$. Thus, effective formation of the α-amino radical is required for the formation of **2a**. Indeed, when **1a** was irradiated with 1,4-diazabicyclo[2.2.2]octane (DABCO) for 5 h in MeCN, no formation of **2a** was observed. Although DABCO is a strong enough electron donor,‡ its cation radical is known to be stable, so that the efficient formation of the α-amino radical by deprotonation cannot be expected.[8] In the reaction system of **1a** and $Me_3SiCH_2NEt_2$, water would act as a silophile to generate the α-amino radical by desilylation of the cation radical of $Me_3SiCH_2NEt_2$.[9] On the other hand, water would not be a strong enough base for α-deprotonation of an amine cation radical.[10] This was confirmed by the observation that photoreactions of **1a** with triethylamine‡ in dry as well as wet MeCN reveal no significant water effect on the product ratio. Another notable observation was made when the reactions were conducted for 1 h with addition of various quantities of $Me_3SiCH_2NEt_2$ in 10% aq. MeCN: 56% of **2a**, 7% of **3a**, 24% of **4a** and 39% of **1a** with 1.5 equiv. of $Me_3SiCH_2NEt_2$; 68, 7, 16 and 25 with 5 equiv.; 73, 10, 12 and 27 with 10 equiv. Increasing the quantity of $Me_3SiCH_2NEt_2$ increased the yield of **2a** as well as **3a** and decreased that of **4a**, which would suggest that excess $Me_3SiCH_2NEt_2$ donates a hydrogen to the radical intermediates, leading to the formation of **2a** and **3a**, and eventually decreasing the yield of **4a**.

In order to determine the generality of this PET reaction, photoreactions of other halo ketones **1b**–**d** were briefly conducted (product yields were not optimized). Irradiation of the iodide **1b** with $Me_3SiCH_2NEt_2$ produced 46% of **2a**. The moderate yield of **2c** (41%) from **1c** is still encouraging since thermal reaction of **1c** with tributyltin hydride produced **2c** only as a minor product.[5] More interestingly, it turned out that the major product from **1d** was ethyl 1-hydroxynaphthalene-3-carboxylate **9** (52%) instead of **2d**, which was isolated in 14% yield in the photoreaction of **1d** with $Me_3SiCH_2NEt_2$. As shown in Scheme 3, naphthol **9** is considered to be an enol form of ketone **10**, which is probably formed *via* hydrogen abstraction from the ethoxy carbonyl substituted carbon radical **11**. If so, the relative yield of **2d** *vs.* **9** should increase under the conditions in which **11** is efficiently reduced to its anion **12**. This was actually the case when $Me_3SiCH_2NEt_2$ was replaced by 1,3-dimethyl-2-phenylbenzimidazoline (DMPBI),[11] which gave 47% of **2d** and 11% of **9**.¶ Since the α-amino radical derived from the cation radical of DMPBI is readily oxidized to a stable imidazolium ion, it would act as a stronger reductant than that from the cation radical of $Me_3SiCH_2NEt_2$.

As described above, we have discovered that a PET process can promote the conversion of certain halomethyl substituted benzocyclic ketones to ring expanded ketones. Further studies focused on designing substrates as well as electron donors are now in progress, with the aim of providing a thorough mechanistic understanding and an expansion of the synthetic versatility of this unique PET reaction.

This work was partly supported by a Grant-in-Aid for Scientific Research (No. 08640676) from the Ministry of Education, Science, Sports and Culture of Japan. We thank Professors Yasutake Takahashi and Tsutomu Miyashi (Tohoku University) for performing the pulsed laser photolyses and their useful comments. We thank Professor Masaki Kamata (Faculty of Education) for his assistance in measuring redox potentials. We thank Professors Yoshiki Okamoto and Takaaki Horaguchi (Faculty of Science) for their generous support.

† Ring expansion products **2a**,**c** and the reduced product **3a** are known compounds (ref. 5). The structure of unknown **2d** was determined by direct comparison of its spectral data with that of the compound independently prepared by reaction of **1d** with tributyltin hydride. Compounds **4a** and **9** were satisfactorily characterized by their NMR and IR spectroscopic data.

‡ Free energy changes ($\Delta G$) for single electron transfer between the triplet excited state of **1a** and amines were estimated (D. Rehm and A. Weller, *Isr. J. Chem.*, 1970, **8**, 259) from the triplet energy of 1,2,3,4-tetrahydronaphthalen-1-one (72.7 kcal $mol^{-1}$: S. L. Murov, *Handbook of Photochemistry*, Marcel Dekker, New York, 1973) and the redox potentials of **1a** (−1.85 V *vs.* SCE) and amines[3] (−19 kcal $mol^{-1}$ for $Me_3SiCH_2NEt_2$, −15 kcal $mol^{-1}$ for DABCO, −11 kcal $mol^{-1}$ for $NEt_3$).

§ Pulsed laser photolysis (355 nm) of **1a** in nitrogen-saturated MeCN resulted in a transient absorption around 370 nm which was assigned as the T–T absorption. In the presence of $Me_3SiCH_2NEt_2$, the T–T absorption was replaced by a new shoulder absorption ranging from 400 to 500 nm, which decayed with a rate constant of *ca.* $3 \times 10^6$ $s^{-1}$. A plausible explanation for these observations is that the triplet excited state of **1a** is quenched by $Me_3SiCH_2NEt_2$ to generate the anion radical of **1a**, which decays rapidly owing to its high intramolecular reactivity. The cyclic voltammetric behaviour of **1a** is also consistent with the above explanation: the redox process of **1a** is totally irreversible (100 mV $s^{-1}$ in MeCN).

¶ An alternative explanation for this phenomenon would be the occurrence of direct hydrogen transfer from the cation radical of DMPBI or its neutral form to the radical **11** to give **2d** (Note added in proof).

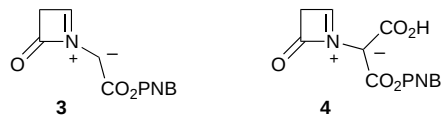
# The azomethine ylide strategy for β-lactam synthesis: the structure of the key 1,3-dipolar intermediate

**Sarah R. Martel,[a] Denis Planchenault,[a] Richard Wisedale,[a] Timothy Gallagher*[a]† and Neil J. Hales*[b]**

[a] *School of Chemistry, University of Bristol, Bristol, UK BS8 1TS*
[b] *Zeneca Pharmaceuticals, Mereside, Alderley Park, Macclesfield, UK SK10 4TG*

**The thermolysis of the β-lactam-based oxazolidinone 1 leads to the formation of cycloadducts 2 and evidence is presented for the participation of the carboxylated azomethine ylide 4, rather than 3 (the more conventional product of oxazolidinone fragmentation), as the key 1,3-dipolar intermediate in this process.**



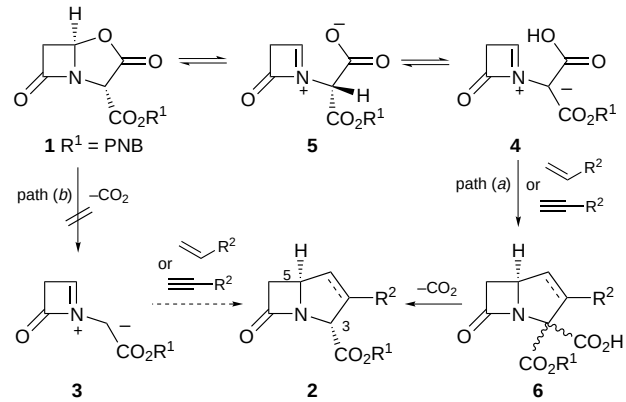
Recently, we disclosed a new and highly convergent cycloaddition strategy for the synthesis of bicyclic β-lactams **2**, encompassing carbapenems and $\Delta^1$-carbapenems (Scheme 1),[1] as well as the sulfur-based penams and penems.[2] A critical step in this sequence involves the fragmentation of a β-lactam-based oxazolidinone **1** to release a reactive 1,3-dipole (a stabilised azomethine ylide); evidence for the structure of this key reaction intermediate is presented here.

**1** **2**

**Scheme 1** *Reagents and conditions*: i, $RCH{=}CH_2$ or $RC{\equiv}CH$, MeCN, 80 or 100 °C

Simpler oxazolidinones are known[3] to undergo a concerted and irreversible decarboxylation to produce azomethine ylides and this reaction has contributed significantly to the utility of 1,3-dipolar cycloaddition reactions within heterocyclic chemistry.[4,5] Extrapolating this established mechanism to the process shown in Scheme 1 points, in the first instance, towards participation of the ester-stabilised azomethine ylide **3** formed *via* direct decarboxylation of **1**. While production of cycloadducts **2** (which is usually the major regioisomer observed with monosubstituted alkenes/alkynes) can obviously be formulated in terms of the simple azomethine ylide **3**, we can now provide evidence that, under our usual reaction conditions, fragmentation of the β-lactam-based oxazolidinone **1** leads to the carboxylated azomethine ylide **4** as the key intermediate involved in the conversion of **1** to cycloadducts **2**.

**3** **4**



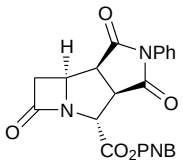
Thermolysis of the enantiomerically-pure oxazolidinone **1**[6] in the presence of an alkene or an alkyne provides the racemic carbapenams and $\Delta^1$-carbapenems respectively. The rate of formation of cycloadducts **2** shows a significant dependence on the reactivity of the dipolarophile and, although this observation in of itself is not inconsistent with the 'concerted decarboxylation' pathway,[7] this would require participation of a relatively stable dipolar intermediate which has never been detected.‡ The more general fate of oxazolidinone **1** cannot, however, be reconciled with the established ('concerted decarboxylation') mechanism.[3] When oxazolidinone **1** was heated (as a 0.033 M solution in MeCN at 80 °C for 17 h) in the *absence* of a dipolarophile, decomposition (decarboxylation) of **1** was *not observed*. Moreover, the starting oxazolidinone **1**, which was recovered cleanly after this period of time, had undergone *complete racemisation* under these conditions, which correspond to those employed in the cycloaddition process shown in Scheme 1.§

A mechanistic rationale for the formation of cycloadducts **2**, which is consistent with our experimental observations and does not require involvement of the azomethine ylide **3**, is presented in Scheme 2.

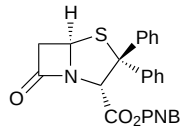
We suggest that oxazolidinone **1** undergoes an initial fragmentation to generate the iminium intermediate **5** and this step is then followed by tautomerisation of the now highly activated malonyl proton to provide azomethine ylide **4**, a carboxylated variant of **3**. Azomethine ylide **4** is then the reactive species involved in the subsequent cycloaddition step but in the absence of a trap, collapse of **4** back to oxazolidinone **1** is facile and this provides an explanation for the observed thermal racemisation of **1**. The equilibrating steps linking **1** and **4** can, however, be intercepted by a dipolarophile (alkene or alkyne, or thiocarbonyl), displacing the equilibrium and leading, in what is likely to be the rate determining event, to cycloadduct **6** [path (*a*)]. Finally, decarboxylation of **6** serves to set the thermodynamically more stable relative *cis* configuration[9] between C(3) and C(5) of the bicyclic β-lactam product **2**.

The principal difference between path (*a*) (Scheme 2) and that normally associated[3] with the generation of azomethine ylides from oxazolidinones [path (*b*) *via* **3**] is that the decarboxylation step *follows, rather than precedes*, the cycloaddition event, although studies are still needed to establish all the details of this mechanism.

While no details are available for the positions of the two pre-cycloaddition equilibria shown in Scheme 2, displacing either of these to the right should increase the concentration of azomethine ylide **4** and accelerate the overall cycloaddition process. This acceleration has been achieved using LiBr as a



**1** $R^1$ = PNB **5** **4**



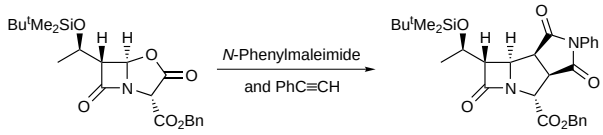
**3** **2** **6**

**Scheme 2**

mild Lewis acid¶ and thermolysis of **1** in the presence of *N*-phenylmaleimide (NPM) (0.040 M of **1**, 1.1 equiv. of NPM and 1.1 equiv. of LiBr in MeCN at 80 °C) led to complete consumption of **1** in 4 h and cycloadduct **7**[1] was isolated in 42% yield. This compares to a reaction time of 25 h (and 49% yield of **7**) when the same reaction was carried out in the absence of LiBr. Using thiobenzophenone as the dipolarophile, reaction time was cut (from 80 h to 1.5 h) using 1.1 equiv. of LiBr, although the yield of cycloadduct **8**[2] did decrease (30 *vs.* 51% without LiBr). The role played by the Lewis acid is not yet clear but it would be premature to exclude the intermediacy of an alternative dipolar component, for example **3**, under these modified conditions.

**7**

**8**



The mechanism shown in Scheme 2 does not require any reassessment of the 1,3-dipolar cycloreversion mechanism which characterises the concerted fragmentation of simpler oxazolidinones.[3] When compared to the more usually encountered oxazolidinones, β-lactam derivatives such as **1** are different in a number of important respects that may favour the formation of azomethine ylide **4**: **1** is an *N*-acyl-, rather than an *N*-alkyl-oxazolidinone, which also incorporates a significant degree of strain and contains an unusual malonate moiety.‖ Nevertheless, we have uncovered an alternative pathway for expressing azomethine ylide reactivity from an oxazolidinone precursor and this unexpected pathway provides a method for generating cycloadducts carrying new and varied substitution patterns. These mechanistic concepts are currently being evaluated for a range of bicyclic oxazolidinones other than those based on a β-lactam, both to define the more general applicability and also to establish further details of this alternative 'cycloaddition-decarboxylation' sequence outlined in Scheme 2.

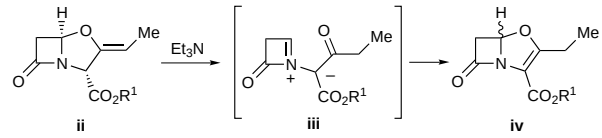
## Footnotes and References



† E-mail: t.gallagher@bristol.ac.uk

‡ Qualitative rate differences have been observed for the reaction of **1** with a variety of dipolarophiles and more detailed kinetic studies are underway. In addition, direct competition experiments have been carried using *N*-phenylmaleimide and PhC≡CH with a limiting quantity of the C(6) substituted β-lactam oxazolidinone **i** and only the maleimide cycloadduct (ref. 1), which is enantiomerically pure, was observed.

**i** only adduct observed

§ The racemisation of **1** was followed by both optical rotation and $^1$H NMR spectroscopy using Eu(hfc)$_3$ and was shown to be a first order process ($t_{\frac{1}{2}}$ = 2.5 h, MeCN at 80 °C). After more prolonged heating (48 h), decomposition of **1** was observed. Workers at Glaxo (ref. 8) have reported that desoxyclavulanic acid **ii** undergoes both C=C bond isomerisation *and* racemisation to give (±)-**iv** when treated with $Et_3N$. The intermediacy of the stabilised azomethine ylide **iii**, which is structurally related to **4**, has been implicated in this study.

**ii** **iii** **iv**

¶ A wide variety of other, more conventional Lewis acids have been evaluated [*e.g.* AgOAc, $AgNO_3$, $ZnBr_2$, $Sc(OTf)_2$, $Ti(OPr^i)_4$] but all led to decomposition of oxazolidinone **1**.

‖ The strain associated with **1** may play an important activating role in the specific case of the β-lactam-based system and, for this reason, a stepwise cycloaddition pathway may intervene. Alkenes (dimethyl maleate and dimethyl fumarate) do undergo stereospecific cycloaddition (ref. 1), but the possibility that, for example, the iminium component of **5** is trapped by a direct nucleophilic addition (as the first step of a cycloaddition process) cannot be excluded, especially when more highly polarisable dipolarophiles, such as thiocarbonyls, are involved. Solvent effects are also apparent and the rate of formation of cycloadducts **2** is faster in MeCN than in toluene at comparable temperatures.

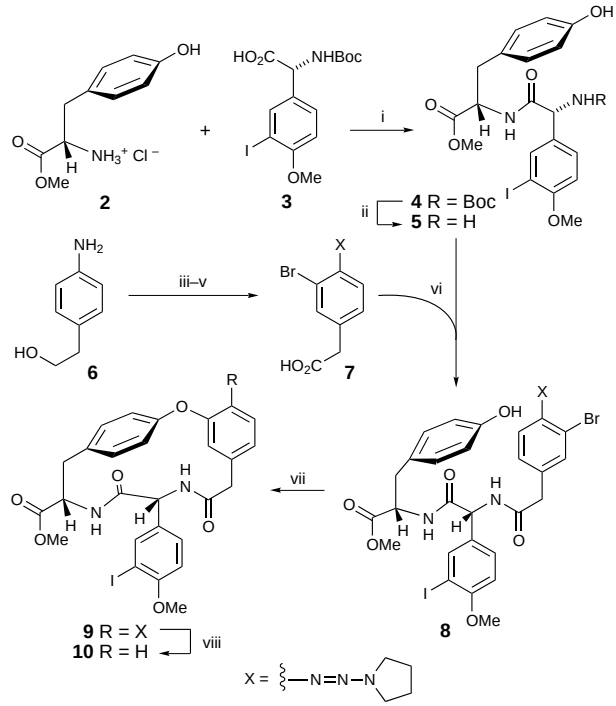
# A Suzuki coupling–macrolactamization approach to the *AB-COD* bicyclic system of vancomycin

**K. C. Nicolaou,* Joshi M. Ramanjulu, Swaminathan Natarajan, Stefan Bräse, Hui Li, Christopher N. C. Boddy and Frank Rübsam**

*Department of Chemistry and The Skaggs Institute for Chemical Biology, The Scripps Research Institute, 10550 North Torrey Pines Road, La Jolla, California 92037, USA* and *Department of Chemistry and Biochemistry, University of California, San Diego, 9500 Gilman Drive, La Jolla, California 92093, USA*

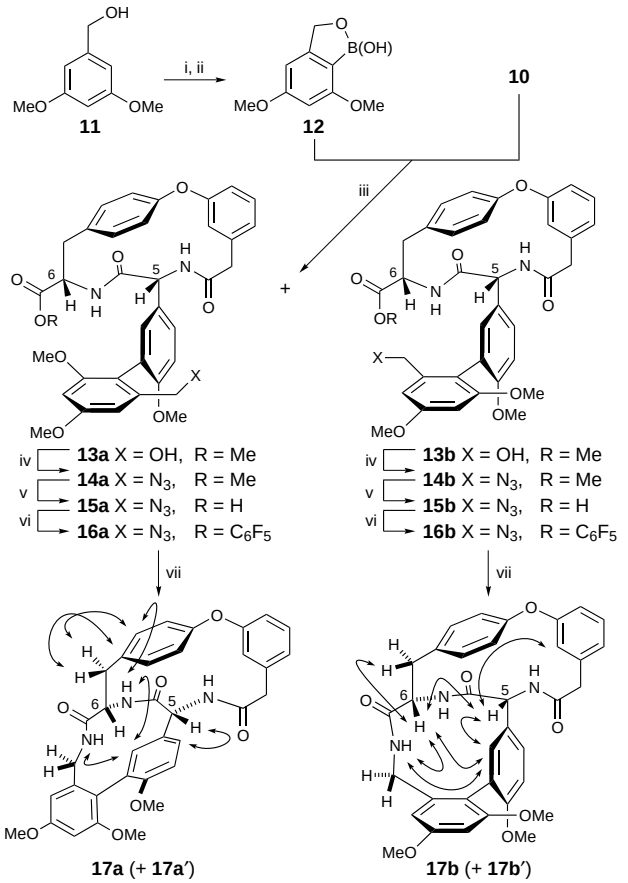
**The effectiveness of the Suzuki coupling reaction in the formation of the *AB* biaryl moiety and the beneficial role of a preexisting *COD* ring system in a lactamization approach to the *AB-COD* ring system of vancomycin is demonstrated.**

Vancomycin **1** is a polycyclic glycopeptide antibiotic effective against drug-resistant bacterial strains.[1] The daunting synthetic challenge posed by its structure[2,3] is largely due to the strained nature of the 12-membered biaryl framework (*AB* ring system) and the two 16-membered biaryl ethers (*COD* and *DOE* ring systems). While several approaches for the construction of the biaryl ether rings have been reported,[4–6] only two methods so far exist for the synthesis of the *AB* biaryl ring system.[7,8] Here we report a macrolactamization strategy to this system that has the potential of contributing to vancomycin's total synthesis.



vancomycin **1**

Since attempts to form the *AB* framework of vancomycin as a single system by a lactamization approach were unsuccessful,[9] we reasoned that an attached *COD* structure might facilitate the process by preorganization, in much the same way as occurred in the elegant synthesis of a similar *AB-COD* framework by the Evans group, who employed a vanadium catalyst.[7] A Suzuki coupling reaction was chosen for the construction of the biaryl system which, of course, is potentially capable of atropisomerism.



Scheme 1 summarizes the construction of the requisite *COD* model system **10**. Thus, (*S*)-tyrosine methyl ester **2** was coupled with (*R*)-4-methoxy-3-iodophenylglycine derivative **3**[8] in the presence of 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) and $Et_3N$ to afford dipeptide **4**† in 80% yield.

Removal of the Boc group from **4** with TFA gave, in quantitative yield, amine **5**, which was coupled with triazene carboxylic acid **7** [prepared from **6** by monobromination (62%), triazene formation (83%) and 2,2,6,6-tetramethyl-1-piperidyloxy (TEMPO) oxidation (86%)] as described above for **2** and **3**, leading to tripeptide **8** (90% yield). Cyclization[5] of **8** in the presence of $K_2CO_3$–CuBr·$SMe_2$ in refluxing MeCN furnished triazene **9** in 67% yield, along with 10% recovered starting material and 6% of the arylglycine epimer of **9**. Chromatographic purification of **9** was followed by reductive removal of the triazene moiety with TFA–$Cu_2O$[10] at reflux to give the desired *COD* intermediate **10** (90% yield).

The elaboration of the *COD* building block **10** to the vancomycin bicyclic systems is shown in Scheme 2. Thus, 2,5-dimethoxybenzyl alcohol **11** was converted to boronic acid **12** by *N*-iodosuccinimide (NIS) iodination followed by reaction with BuLi and $B(OMe)_3$ in 27% overall yield (unoptimized). Suzuki coupling of iodide **10** with **12** was facilitated by $Pd(Ph_3P)_4$ catalyst and $Na_2CO_3$ to afford a 1 : 1 mixture of the two atropisomers **13a** and **13b** in 80% combined yield.[9,11] Suzuki coupling of the parent boronic acid corresponding to **12** (without the methoxy groups) with iodide **10** (Scheme 2) led to

**Scheme 1** *Reagents and conditions*: i, HBTU (1.2 equiv.), $Et_3N$ (3 equiv.), DMF 0 → 25 °C, 3 h, 90%; ii, TFA–$CH_2Cl_2$ (1 : 1), 0 °C, 1 h, 100%; iii, NBS (1.2 equiv.), DMF, 62%; iv, conc. **Scheme 2** *Reagents and conditions*: i, NIS (1.2 equiv.), DMF, 25 °C, 12 h, 89%; ii, BuLi (2.1 equiv.), $B(OMe)_3$ (3 equiv.), THF, −40 → 25 °C, 3 h, dil. HCl, 30%; iii, $Pd(PPh_3)_4$ (10 mol%), $Na_2CO_3$ (1 equiv.), MeOH–toluene–$H_2O$, 90 °C, 2 h, 80%; iv, $HN_3$ (5 equiv.), DEAD (5 equiv.), $PPh_3$ (5 equiv.), THF, 0 → 25 °C, 1 h, 69%; v, LiOH (1.5 equiv.), THF–$H_2O$ (1 : 1), 0 °C, 0.5 h, 100%; vi, $C_6F_5OH$ (2 equiv.), DCC (1.2 equiv.), DMAP (0.2 equiv.), $CH_2Cl_2$, 25 °C, 1 h; vii, 4-pyrrolidinopyrridine (3 equiv.), 10% Pd/C (30 mol%), dioxane–EtOH–cyclohexene (90 : 8 : 2), high dilution, 90 °C, 5 h, 30% from **15a**

a single compound by TLC and $^1$H NMR spectroscopy, supporting the atropisomeric relationship of isomers **13a** and **13b** (no epimerization at C5 and C6). In contrast to the simpler coupling product, isomers **13a** and **13b** did not interconvert, even at 333 K. The two isomers were chromatographically separated and individually elaborated further. Thus, the more polar compound **13a** ($R_f$ = 0.20, silica, 80% EtOAc in hexanes) was treated with $HN_3$–diethyl azodicarboxylate (DEAD)–$PPh_3$[9] (**CAUTION**: hydrazoic acid is toxic and explosive!) to afford azide **14a** (69% yield) which was saponified (LiOH, THF–$H_2O$, 0 °C) and converted to the corresponding pentafluorophenyl ester **16a** *via* carboxylic acid **15a**. Slow addition of a dioxane–cyclohexene solution of crude **16a** to a mixture of 10% Pd/C and pyrrolidinopyridine in dioxane and EtOH at 90 °C led to the formation of two cyclic products, **17a** and **17a′** epimeric at C-6 (*ca.* 1 : 2 ratio) in 30% combined yield overall from acid **15a**. The less polar atropisomer **13b** ($R_f$ = 0.30, silica, 80% EtOAc in hexanes) was subjected to the same sequence of reactions, leading to **17b**‡ and **17b′** in similar yields. The observed epimerization at C-6, which is presumed to occur in the final step of the sequence, may not be an issue when the entire *AB-COD-DOE* framework of vancomycin is in place, particularly if thermodynamics favour the desired stereoisomer.

The stereochemical assignments of the four bicyclic systems **17a**, **17a′**, **17b** and **17b′** were based on $^1$H–$^1$H NOESY experiments, which revealed the NOEs for **17a** and **17b** shown in Scheme 2.

In summary, we have demonstrated the power of the Suzuki coupling reaction in the formation of the fully substituted *AB* biaryl moiety[9,11] and the beneficial effect of a preexisting *COD* ring system in a lactamization approach to the *AB* ring system of vancomycin. The asymmetric version of the Suzuki reaction and its application in an intramolecular sense may offer further opportunities in this area of synthesis.

# Surface plasmon enhanced non-linear optical response of gold nanoparticles at the air/toluene interface

**Rodolphe Antoine,[a] Pierre F. Brevet,[a] Hubert H. Girault,*[a] Donald Bethell[b] and David J. Schiffrin[b]**

**Colloidal gold nanoparticles in toluene solution, synthesised using a two-phase liquid/liquid system, display second harmonic generation, wavelength analysis of which indicates the narrow frequency band of the gold surface plasmon for nanoparticles present at the air/toluene interface.**

There is a great deal of interest in the preparation of simple thiol derivatised gold metal clusters of nanometre dimensions[1–4] and more recently, in the synthesis of a new family of well defined compounds in which clusters of metal atoms are stabilised by groups carrying organic functionalities.[5–7] Two aspects are of current interest, the chemistry of the stabilising groups and the electronic properties of the metal core, the size of which can be altered by the preparation conditions. The control of these properties is essential for the use of these compounds in the preparation of superlattices[8] and other applications where the linking of nanoparticles can lead to complex structures with unusual electronic properties. Potential applications are in many fields such as chemical catalysis, molecular electronics or biosensors.[9] Here, we report the use of surface second harmonic generation (SSHG)[10,11] as a new technique for the characterisation of the noble-metal nanoparticles at air/liquid interfaces where the technique has been shown to be powerful, even in the non-resonant case.[12] This non-linear technique is highly sensitive to resonant plasmon excitation, which is observed for the first time for gold nanoparticles adsorbed at the air/toluene interface.

Colloidal gold nanoparticles were prepared using a two-phase (water/toluene) reduction of $AuCl_4^-$ by sodium tetrahydroborate.[13] The solution was stored in the dark at room temp. and the colloid did not show any signs of precipitation after several months. High-resolution TEM photographs of similar preparations gave an average particle diameter of 6 mm.[13] The UV–VIS absorption spectrum of the Au solution presents a strong absorption band at $\lambda_{max}$ *ca.* 530 nm. This prominent optical feature is attributed to plasmon oscillation modes of conduction electrons in the colloidal nanoparticles which are coupled to the applied electromagnetic field. Both the physical nature of this plasmon mode and its dependence on particle size and shape is well understood.[14,15]

Second harmonic generation experiments were carried out at the air/toluene interface for the gold nanoparticles in toluene. Wavelength analysis of the second harmonic response from the gold particles adsorbed at the interface was performed with a nanosecond $Nd^{3+}$–YAG system pumping an optical parametric oscillator (Spectra-Physics, GCR170-10 pumping a MOPO 710) delivering pulses in the wavelength range 800–1200 nm, at a frequency of 10 Hz and of 5 ns duration. Pulse energy was kept below 1.5 mJ to avoid surface damage. The incident beam was collimated by a telescope and directed onto the air/toluene interface. The reflected SSHG signal generated in the visible range at each exciting wavelength was collected with a lens. It was then passed through IR filters to reject residual fundamental radiation, focused onto a monochromator and detected with a gated photon counter (recording of 50 s duration). The frequency of the exciting laser was changed in steps between 800 and 1200 nm.

Fig. 1 shows the intensity of the second harmonic response as a function of the SSHG wavelength for a solution of gold nanoparticles. Toluene shows no absorbance between 800 and 1200 nm and as expected, negligible SSHG signal was observed from a pure toluene/air interface. In the presence of colloidal gold, the SSHG spectrum displays a strong resonance in the range 450–600 nm of the harmonic wavelength with a maximum of the SSHG resonance at 520 nm. The bandwidth and the maximum of the SSHG response are very similar to those observed in the absorption spectrum and hence, the SSHG spectrum clearly shows the narrow frequency band of the plasmon excitations caused by the Au nanoparticles adsorbed at the air/toluene interface. This enhancement arises from the coupling, through the surface, between the resonant local field of the incident light wave with the conduction electrons of the metal colloid.

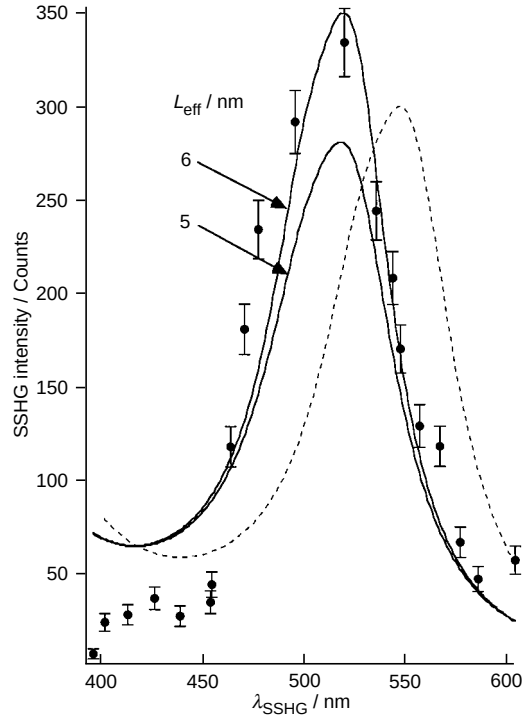

**Fig. 1** SSHG spectrum for the underivatised gold nanoparticles at the air/toluene interface (circles). The adsorption band corresponds to surface plasmon excitations and has a maximum at 520 nm. The solid line represents the calculated SSHG spectrum, using eqn. (1) (term in brackets multiplied by $\omega^2$) for gold nanoparticles in toluene taking size effects into account ($L_{eff}$ = 6 and 5 nm). The solid line is for $\lambda_p$ = 138.5 nm, corresponding to bulk gold; the dotted line is for a material with a free electron concentration 10% lower than that of bulk gold, for $\lambda_p'$ = 146 nm and $v_f'$ = 1.342 × $10^6$ m $s^{-1}$ (and $L_{eff}$ = 6 nm).

The theory of second harmonic signal generation for metal spheres in the Mie approximation has been developed by Agarwal and Jha.[16] At the plasmon resonance frequency, the term attributed to the surface non-linear polarization contribution dominates over the volume contribution, with a net enhancement compared to the non-resonant case. The output second harmonic power for spherical particles in vacuum is given by eqn. (1):[16]

$$S = \frac{3ce^2|E^{(i)}|^4}{m_e^2}\left(\frac{2R}{c}\right)^6 \omega^2 \left\{\left|\frac{1-\varepsilon(2\omega)}{[\varepsilon(\omega)+2][\varepsilon(2\omega)+2]}\right|^2 + \frac{36}{5}\left|\frac{\varepsilon(\omega)-1}{[\varepsilon(\omega)+2]^2[2\varepsilon(2\omega)+3]}\right|^2\right\} \quad (1)$$

where $E^{(i)}$ is the intensity of the electric field at the surface, $\varepsilon$ is the complex dielectric function of the particles, $\omega$ is the frequency of the exciting radiation, $2\omega$ is the second harmonic frequency, $m_e$ is the effective mass of the electron, $R$ is the particle radius, $c$ is the velocity of light and $e$ is the electronic charge. For particles in a medium of relative permittivity $\varepsilon_m$, the dielectric function to be used in eqn. (1) is the permittivity relative to that of the medium, $\varepsilon_{rel} = \varepsilon/\varepsilon_m$.

In order to show qualitatively that the SSHG signal observed does correspond to the presence of colloidal gold at the interface, the dielectric function for particles of radius $R$ was calculated following well established procedures.[17] When the interband contribution is small compared with that due to core and free electrons, the complex dielectric function is given by eqn. (2):[18]

$$\varepsilon = \varepsilon_\infty - \frac{\omega_p^2}{\omega^2 - i\omega\left(\frac{1}{\tau_{bulk}} + \frac{v_f}{L_{eff}}\right)} \quad (2)$$

where $\omega_p$ is the bulk plasma frequency, $\varepsilon_\infty$ is the dielectric contribution due to the atomic core polarizability, $\tau_{bulk}$ is the electron relaxation time in the bulk metal, $v_f$ is the electron velocity at the Fermi level and $L_{eff}$ is the effective electronic mean free path. Values of $\omega_p = 1.36 \times 10^{16}$ s$^{-1}$ ($\lambda_p = 138.5$ mm), $v_f = 1.4 \times 10^6$ m s$^{-1}$ and $\tau_{bulk} = 9.1 \times 10^{-15}$ s were used in the calculations,[18] $\varepsilon_m$ for pure toluene was taken as 2.23. The dielectric function of gold employed was calculated from eqn. (2) taking a value of $\varepsilon_\infty$ of 9.9 based on the data from Innes and Sambles.[18] The data from Johnston and Christy[19] leads to a value of 12.0. However, the differences between these and other values in the literature for the dielectric function of Au are due to the nature of the thin films used in the measurements, since other effects related to film thickness, crystallographic orientation and imperfections come into operation. Different values of $\varepsilon_\infty$ lead to a shift in the position of the maximum in the SSHG signal but do not alter the features of the calculated wavelength dependence. The calculated second harmonic intensity functions, using eqn. (1) (term in brackets multiplied by $\omega^2$), for gold nanoparticles in toluene, with 6 and 5 nm of effective electronic mean free path, are presented in Fig. 1. The agreement between experimental data and calculation for $L_{eff} = 6$ nm is very good. Fig. 1 also shows the effect of a decrease of 10% in the concentration of free electrons, highlighting the sensitivity of the technique to the electronic properties of the nanoparticles. For the calculation, we only consider that the change of the free electron density alters the bulk plasma frequency and the Fermi velocity ($\omega_p' = 1.29 \times 10^{16}$ s$^{-1}$, $v_f' = 1.342 \times 10^6$ m s$^{-1}$).[20] Changing the free electron density may probably affect $\varepsilon_\infty$ and $\tau_{bulk}$, but since there is no straightforward relation with the free electron density, we use the same value already mentioned (*i.e.* $\varepsilon_\infty = 9.9$ and $\tau_{bulk} = 9.1 \times 10^{-15}$ s). Although the sample is not monodisperse, from the point of view of a preliminary analysis of the experimental observations, the results shown in Fig. 1 represent a strong confirmation of the non-linear optical properties of Au nanoparticles present at the air/toluene interface.

To our knowledge, this is the first example of a SSHG resonance observed for solutions of nanosized metal particles. Previous SSHG work on colloidal metal particles was carried out by Efrima and coworkers.[21] In this work silver metal liquid-like films were formed at the interface of immiscible liquids from large individual colloidal silver particles stabilised by detergents and shown to exhibit second harmonic signals. Gold nanoparticles are easily derivatised with functional ligands for the subsequent attachment of chromophores, redox labels or biomolecules.[5,6] The optical SSHG technique described is a powerful method to investigate specific interfacial adsorption, and the electronic properties of chemically functionalised metal nanoclusters. The latter is of importance owing to the rapid advances in synthetic nanoparticles chemistry.[6]

This work is supported by the European Community Training and Mobility of Researchers Programme (TMR) through the Network on Organization, Dynamics and Reactivity at Electrified Liquid–Liquid Interface (ODRELLI), European Community Contract No. FRMX-CT96-0078. Useful comments by Dr Jha, Tata Institute of Fundamental Research, Mumbai, India, on the second harmonic response from small metal particles, are gratefully acknowledged.

**The hydrogen atom locations in $[Re_4(\mu_3\text{-}H)_4(CO)_{12}]$ are accurately determined by joint X-ray single-crystal and time-of-flight neutron powder diffraction analysis; this new methodology does not require large crystals of several mm dimensions but only a sizeable amount of monophasic microcrystalline sample.**

A number of different methodologies are available to solve structural problems, whatever the aggregation state of the sample.[1] Surely single-crystal (SC) X-ray (X) diffraction is the easiest, quickest and most definitive method. However, when (*i*) suitable crystals are unavailable or (*ii*) the relative atomic scattering powers in the sample are too different (hampering, for instance, the location of hydrogens in the presence of heavy atoms) or (*iii*) too similar (inhibiting the distinction of neighbouring elements), the power of XSC weakens and other techniques are better suited. While it has been known for a long time that neutron (N) diffraction on relatively large SCs offers an elegant, although expensive, solution to point (*ii*), only recently powder (P) diffraction has been shown to overcome point (*i*) (at least for moderately complex structures).[2] As large SCs needed for neutron diffraction are often not available, we propose, to tackle point (*ii*) [and (*iii*)], a joint XSC, NP approach which relies, for the burden of the structure determination, on XSC data, while subtle structural details are essentially rescued from NP measurements, the final model being validated by simultaneous refinements on both data sets. A similar approach has been used in studying the cation distribution in doped $KTiOPO_4$[3] and the incommensurately modulated structure of $Bi_2Sr_2CaCu_2O_{8+y}$.[4]

The combined use of different radiations as well as of different spectroscopic and computational methods, under the assumption that 'different' biases may cancel out, likely affords results of higher quality than those obtainable from the individual techniques, allowing to refine more complex structures. This approach has been pioneered, within the crystallographic community, by the combined use of X–N data (from either two SC datasets[5] or two P diffraction experiments[6]), by the introduction of steric energy contributions into protein structure refinements[7] or, more frequently, by the sagacious use of stereochemical knowledge (by imposing geometrical restraints) in complex refinements. Combined EXAFS and powder diffraction analyses have been recently reported.[8] The proposed methodology differs from other more conventional complementary X–N studies, in which juxtaposition of individual results leads to a unitary interpretation; moreover, even if it can be exemplified on a high symmetry crystal phase, it may not necessarily require simple systems (like other powder diffraction methods), since XSC data should grant superior convergence properties to the joint least-squares refinement.

Despite the relevance of transition-metal hydrides in modern inorganic chemistry, the ubiquitous hydrido ligand is still the most poorly structurally characterised. Even if its coordination behaviour and/or classical/non-classical nature can be qualitatively retrieved from a number of experimental techniques (X-ray diffraction, IR, NMR, inelastic neutron scattering), the only definitive technique is neutron diffraction. Compounds containing face-bridging ($\mu_3$) hydrides are much less common than those with edge-bridging ($\mu$) or terminal hydrides, with only five NSC crystal structures reported in the literature, $[FeHCo_3(CO)_9\{P(OMe)_3\}_3]$,[9] $[Ni_4H_3(C_5H_5)_4]$,[10] $[Rh_4H_4(C_5Me_5)_4][BF_4]_2$,[11] $[HCu\{P(p\text{-}C_6H_4Me)_3\}]_6$[12] and $[Cr_4(\mu\text{-}H)_5(\mu_3\text{-}H)_2(C_5R_5)_4]$,[13] none of them regarding third-row transition elements. $[Re_4(\mu_3\text{-}H)_4(CO)_{12}]$ **1** is unusual among metal cluster compounds, being one of the few known 'unsaturated' carbonyl clusters (56 *vs.* 60 CVEs); its XSC structure has been previously reported and the $\mu_3$-H character inferred from local stereochemical considerations and an 'image enhanced' (*i.e.* symmetry averaged) difference Fourier map (estimated average Re–H 1.77 Å).[14] Here we present the complete structural characterisation, from XSC and TOF NP diffraction data,† of the new $\mathbf{1}\cdot 2C_6D_6$ crystal phase which is the major product of the standard synthetic approach to **1**,‡ but has never been recognized before. The availability of sizeable amounts of this phase (but not of large SC) and our experience with XP on coordination and organometallic systems[15] prompted us to attempt the viability of the above mentioned method.

TOF neutron scattering measurements (Fig. 1) easily afford powder patterns with good counting statistics (if compared to the constant wavelength mode); however, their analysis in conjunction with conventional laboratory X-ray diffraction data needs some extra care. Since the very same structural model (coordinates and $U_{ij}$ values) is being refined simultaneously on X and N diffraction data, but there are intrinsic differences in physical interactions, size of the samples and experimental geometries, one must ensure that systematic errors have been properly corrected. In particular, since absorption effects may lead to fake, incongruent thermal parameters, a $\theta$-dependent

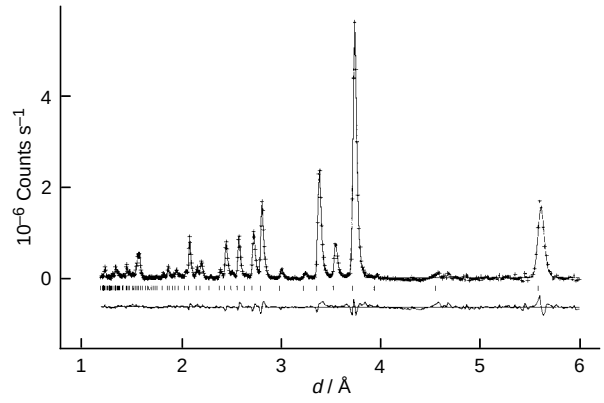

**Fig. 1** Final Rietveld refinement plot for TOF neutron data, in the range 1.2 < $d$ < 6.0 Å. Peak markers and difference plot at the bottom. For sake of clarity, the high $d$-values section (6.0 < $d$ < 9.0 Å, with only two reflections) has been omitted from the plot.

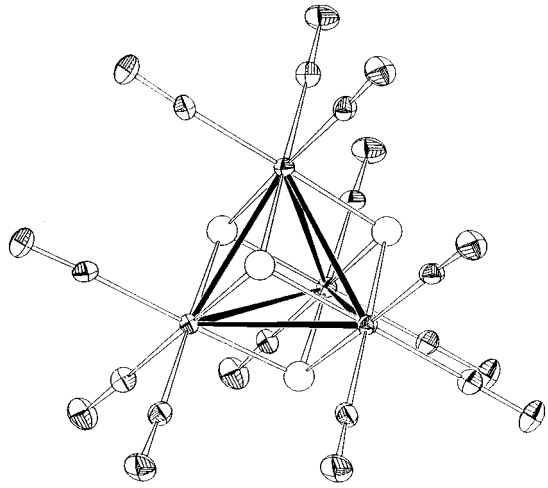

**Fig. 2** An ORTEP drawing of the $[Re_4H_4(CO)_{12}]$ molecule, showing the $H_n$ atom position at 1.99(2) Å from the rhenium atoms. Selected bond distances (Å) and angles (°): Re–Re 2.924(2), Re–C 1.912(8), C–O 1.14(1), Re–$H_x$ 1.88(12), Re–$H_n$ 1.99(2); Re–C–O 178(1), C–Re–C 86.9(4), $H_n$–Re–$H_n$ 85.(1), C–Re–$H_n$ 93.8(6) and 179.0(9), Re–$H_n$–Re 94.(1), Re–Re–C 92.2(3) and 136.5(2).

(spherical—on top of $\psi$-scans, XSC) and a *d*-dependent (NP) corrections have been carefully applied. In addition, in order to deal with the different interactions of X and N beams (with electrons and nuclei, respectively) and the off-centre polarisation of H-valence electron(s) due to the metal–H bond(s), a split-atom H refinement has been performed, defining two pseudoelements [$H_x$ and $H_n$] with null contribution to the N and X structure factors, respectively. This makes, *inter alia*, the $H_n$ location substantially insensitive to the intrinsic 'overweightness' of the X data set (in terms of quality and, perhaps, number of observations).

Our results show that $[Re_4(\mu_3\text{-}H)_4(CO)_{12}]$ in **1**·$2C_6D_6$ has a crystallographically imposed $T_d$ symmetry (see Fig. 2), with a $Re_4(CO)_{12}$ core virtually identical to that found in **1**, and confirm the $\mu_3$-nature of the hydrido ligands as originally proposed by Wilson and Bau;[14] however, significant differences are observed in the H-bonding parameters [Re–$H_x$ 1.88(12) *vs.* 1.77 Å, Re–$H_n$ 1.993(17) Å]. As for the precision of our results, our study shows that the (room temp.) esd values related to the $H_n$ atoms are about three to five times poorer than those from conventional NSC data (mostly collected at temperatures below 90 K), but one order of magnitude smaller than those concerning $H_x$. Unfortunately, in assessing the accuracy of this work we lack the internal consistency check with the C–D distance because the clathrated $C_6D_6$ molecules are rotationally disordered; however, since the observed $\Delta$(Re–$H_x$, Re–$H_n$) value (0.11 Å) is within the range found in most structural comparisons between X- and N-SC results, we think that the actual Re–$H_n$ bond distance should not be affected by severe systematic errors. The observed M–H value might look slightly longer than that in $[Rh_4H_4(C_5Me_5)_4][BF_4]_2$[11] (58 CVEs, av. Rh–H and Rh–Rh 1.86 and 2.76 Å, respectively); however, a much larger apparent metal radius [Re–Re 2.924(2) Å] partially accounts for the observed difference.

† *Crystal data* for **1**·$2C_6H_6$: $C_{24}H_{16}O_{12}Re_4$, $M$ = 1241.2, cubic, *Pn*-3*m*, $a$ = 11.1774(5) Å, $U$ = 1396.4(1) Å$^3$, $Z$ = 2, $D_c$ = 2.951 g cm$^{-3}$. XSC data were collected on a 0.15 × 0.15 × 0.15 mm crystal with Mo-Kα radiation on an Enraf-Nonius CAD4 diffractometer ($6 < 2\theta < 54°$); 316 unique data [230 with $F_o^2 > 3\sigma(F_o^2)$], corrected for Lorentz, polarisation and absorption effects ($\psi$-scan + spherical corrections, $\mu R$ = 2.0, min. max. transmission factors = 0.061, 0.093); NPD data ($1.0 < d < 10$ Å) were collected on the TOF neutron diffractometer ROTAX at the spallation source ISIS at the RAL (UK). 600 mg of finely ground sample, containing 100% perdeuteriated benzene (as checked by $^1$H NMR of dissolved material), were enclosed in a vanadium can with a drop of $C_6D_6$ (to ensure crystal stability) under an $N_2$ atmosphere. Structure solution was performed by Patterson, difference Fourier and least-squares techniques using the XSC dataset. The combined use of X-ray and neutron data and the Fourier routines for powder diffraction data implemented in GSAS[16] allowed unambiguous location of the hydrogen atom of the organometallic cluster and of the deuterium atom bound to the benzene molecules clathrated in the crystal lattice. Fig. 1 shows the final Rietveld refinement plot for TOF data; final agreement factors: (XSC) $R_w(F^2)$ 0.048; $R(F^2)$ 0.042; $R(F)$ 0.023; (NP) $R_{wp}$ 0.040, $R_p$ 0.028. The $C_6D_6$ molecule was found to be disordered in two in-plane orientations [30° off, with refined populations of 0.65(2) : 0.35(2)]; its refinement required the use of geometrical restraints, making any internal accuracy assessment on the C–D distance meaningless. CCDC 182/584.

‡ $[Re_4H_4(CO)_{12}]$ was prepared by hydrogenation of $[Re_2(CO)_{10}]$ (1.214 g) at 165 °C in decalin and isolated as a deep red solid by addition of benzene to the solution, according to a literature method.[17] In the original paper, the presence of solvated decalin was reported, while the solid we have obtained in this way contained benzene (as indicated by $^1$H NMR and X-ray analyses). Four cycles of dissolution in $CH_2Cl_2$ and evaporation to dryness enabled complete elimination of benzene. $[Re_4H_4(CO)_{12}]\cdot 2C_6D_6$ (615 mg) was obtained by slow precipitation with $C_6D_6$ (3 ml) from a $CH_2Cl_2$ solution (150 ml).

# EXAFS analysis of a chiral alkene polymerisation catalyst incorporated in the mesoporous silicate MCM-41

**Stephen O'Brien,[a] Jonathan Tudor,[a] Thomas Maschmeyer[b] and Dermot O'Hare*†**

[a] *Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QR*
[b] *The University Chemical Laboratories, University of Cambridge, Lensfield Road, Cambridge, UK CP2 1EW*

**The chiral metallocene *rac*-ethylenebis(1-indenyl)zirconium dichloride, when immobilised on the surface of methylalumoxane-modified mesoporous silica MCM-41, is an effective catalyst for the production of highly isotactic polypropene with a unique spherulite morphology; Zr K-edge EXAFS studies of the organometallic–inorganic composite reveal not only an intact indenyl ligand framework after the immobilisation, but also the presence of a short Zr–C bond and the absence of the chloride ligands.**

We have recently reported that the modification of the mesoporous silicate MCM-41 with an excess of methylalumoxane (MAO) effectively removes the protic sites on the surface silanol groups, yielding a high surface area material (although the surface area is reduced from on average 900 to 400 $m^2\ g^{-1}$).[1] Subsequent treatment with saturated solutions of (EBI)$ZrCl_2$ [EBI = *rac*-ethylenebis(1-indenyl)zirconium dichloride] in toluene produces a hybrid organometallic–inorganic composite material in which the organometallic moiety has been grafted onto the surface of the MCM-41. This hybrid organometallic–inorganic material is active in the stereoselective polymerisation of propylene to yield highly isotactic polypropylene. The as produced polymer exhibits a higher melting point and has a distinct spherulite morphology atypical of polymers produced from an analogous homogeneous system. We suggest that the heterogeneous catalyst is effective due to the adsorptive capacity of the mesoporous silica support, and whilst not being homogeneous in nature, it allows a great deal of contact between the catalytic centres and propene. We believe that the spherulite polymer morphology is formed as a result of the channels inherent to MCM-41, as it has been observed that a similar catalyst on ordinary amorphous silica does not produce the same morphology. X-Ray powder diffraction indicates that the hexagonal framework of the mesoporous material is retained after reaction with both MAO and the organometallic catalyst precursor, but provides no information regarding the nature of the local atomic environment of the organometallic metal centre. We have recently used EXAFS to verify the status of organometallic molecules successfully grafted onto the walls of MCM-41,[2] and one of us (T. M.) used both XANES (X-ray absorption near edge structure) and EXAFS to determine the local structure around titanium centres incorporated into MCM-41.[3]

In order to study the local coordination around the zirconium catalyst, X-ray absorption spectroscopy was used to measure the Zr K-edge EXAFS. Data was collected on Station 9.2 at the SRS, Daresbury Laboratory, UK.‡ Data analysis of the EXAFS was performed using the XFIT(WIN95) suite of programs[5] employing both single and multiple scattering techniques.

The observed EXAFS data and the corresponding Fourier transform, together with the calculated fits are shown in Fig. 1. The EXAFS structural model parameters resulting from multiple scattering treatments are shown in Table 1. Initially, a broad range of model structures was examined, however, when varying atom types and refining structural parameters using single scattering techniques a clear trend became apparent, pointing towards retention of both indenyl ligands and an absence of the chloride ligands. The single scattering calculations, although providing sensible model parameters, were unable to account for some contributions in the Fourier transform at $R > 2.5$ Å (not phase shift corrected). These might be due to multiple scattering effects. Multiple scattering paths involving the $C_5$ 'cyclopentadienyl' fragment of the indenyl rings correspond to a distance comparable to that of the outer ligand framework, and when this is incorporated into the refinement the second envelope might be modelled more fully. Hence, by using a three-dimensional model based on the simplified crystal structure of the starting material it was possible to obtain very good agreement between theory and experiment.

The first shell of the final model corresponds to radius of 2.12 Å which is a short distance for a Zr–$CH_3$ bond. There are crystal structures for a cationic zirconocene derivative based upon the EBI ligand, in which the Zr–C bond length was found to be 2.18

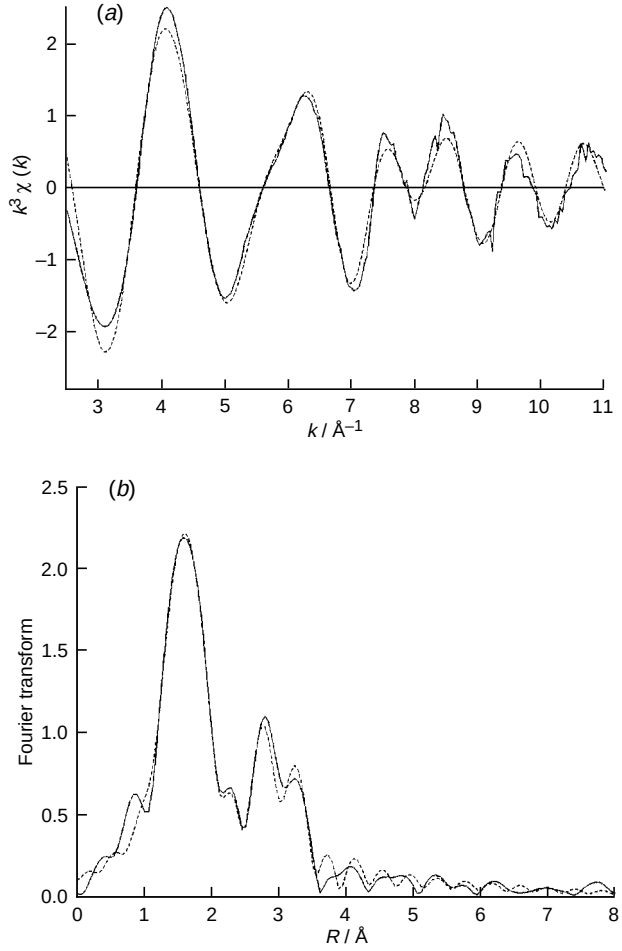

**Fig. 1** (*a*) Zr K-edge $k^3$ weighted EXAFS and (*b*) Fourier transform data for the (EBI)$ZrCl_2$/MAO/MCM-41 material [(—) experimental and (---) theoretical]

**Table 1** Structural parameters of multiple scattering model for Zr K-edge EXAFS of (EBI)$ZrCl_2$/MAO/MCM41[a]

| Shell | Scattering atom | *N* | *r*/Å | $\sigma^2$/Å$^2$ | Assignment |
|---|---|---|---|---|---|
| 1 | C | 1.3 | 2.12 | 0.008 | methyl C |
| 2 | C | 5.1[b] | 2.60 | 0.008 | $C_5$ indenyl C |
| 3 | C | 5.1[b] | 2.78 | 0.007 | $C_5$ indenyl C |
| 4 | C | 1.8 | 3.32 | 0.010 | methylene bridge |
| 5 | C | 3.6 | 3.47 | 0.011 | $C_6$ indenyl C |
| 6 | C | 2.5 | 4.24 | 0.012 | $C_6$ indenyl C |

*N* = coordination number, *r* = interatomic distance, $\sigma^2$ = root mean-square deviation of the interatomic distance about *r*. [b] Restrained to keep rings co-planar and equal number of atoms.

Å.[6] The EXAFS data does not show any evidence for a Zr–Cl bond, or the presence of a Cl scatterer beyond normal bond lengths. The chloride anion need not necessarily reside in close proximity to the central Zr atom; if the Zr species becomes highly polarised or cationic in nature, then the associated chloride anion can be dissipated in the MAO oligomeric cage away from the metal centre. The second and third shells have been assigned to the carbon atoms of the two $C_5$ rings of the bridging indenyl ligand, and correspond to average bond lengths for similar Zr–C bonds in *rac*-(EBI)$ZrCl_2$. It should be noted that the two $C_5$ rings were modelled with two slightly different distances (*i.e.* 2.60 and 2.78 Å), indicating that the rings may be tilted. The fourth shell at 3.32 Å contains contributions from C atoms from both the $C_6$ rings of the indenyl system and the ethylene bridge. The fifth (3.47 Å) and sixth (4.24 Å) shells are due to the remaining C atoms on the $C_6$ rings of the indenyl system.

Our assignments for each shell are based upon the known crystallographic information for *rac*-(EBI)$ZrCl_2$,[7] and are consistent with the previously proposed general mechanism for the interaction of MAO with group 4 metallocene dichlorides, which assumes the metal chloride bonds are first methylated, and a cationic monoalkylated species is formed as the active catalyst.[8,9] The preservation of the ligand framework is also supported in the literature.[10] Based upon this model of a highly electropositive zirconium centre, one could anticipate a shorter Zr–$CH_3$ distance for the species bound to the mesopore.

In conclusion, X-ray absorption spectroscopy has proved to be a powerful technique in the structural characterisation of *rac*-(EBI)$ZrCl_2$ bound to the surface of MAO modified MCM-41. The ability to use three-dimensional models as inputs for the multiple scattering calculations in XFIT(WIN95) has been essential in deriving a good fit between theory and experiment. EXAFS data analysis of the hybrid organometallic–inorganic material indicates that the carbon framework has remained essentially intact around the central Zr. The Fourier transform also reveals a short Zr–C bond, indicative of the increased charge at the metal centre as a result of the interaction between the metal chloride and the MAO-MCM-41 support.

We would like to thank J. F. W. Mosselmans and G. E. Van Dorssen (Daresbury Laboratory) for discussions and advice, and Shell UK for financial support.

† D. O'Hare is the Royal Society of Chemistry Sir Edward Frankland Fellow.
‡ K-edge transmission EXAFS of the Zr compound were performed at room temp. on Station 9.2 at the CLRC Radiation Source, Daresbury, operating in multi-bunch mode, 2 GeV, with typical currents of 180–250 mA. A double crystal monochromator in non-dispersive configuration equipped with flat (220) Si crystals was used. Calibration was done on Zr foil of 50 μm thickness. Samples of *rac*-(EBI)$ZrCl_2$/MAO/MCM-41 were diluted in dry MgO (5 : 1), compressed into a pellet of minimal thickness (*ca.* 1 mm) and then sealed in an inert polyimide wallet under $N_2$.

# Addition of alcohols and pyrroles to *trans*-$[RuCl_2\{(Ph_2P)_2C{=}CH_2\}_2]$. A polypyrrole bearing a covalently bound metal–diphosphine complex†

**Simon J. Higgins,* Heather L. Jones, Mark K. McCart and Thomas J. Pounds**

*Department of Chemistry, University of Liverpool, Chemistry Buildings, Crown Street, Liverpool, UK L69 7ZD*

**Alcohols and pyrroles undergo base-catalysed addition to *trans*-$[RuCl_2\{(Ph_2P)_2C{=}CH_2\}_2]$ to afford *trans*-$[RuCl_2\{(Ph_2P)_2CHCH_2Z\}_2]$ (Z = $-OCH_2Ph$ 2a, $-OCH_2CH_2C_4H_3S$-3 2b, $-NC_4H_4$ 3a, $-NC_4H_3C_6H_{13}$-3 3b); complexes 2b and 3b are suitable for electropolymerization to give heterocyclic conducting polymers, and 3b is copolymerized with *N*-methylpyrrole to afford a polypyrrole incorporating a functionalized metal–diphosphine complex, for the first time.**

There is much interest in electrodes modified with polymers containing redox-active metal complexes, since these have potential applications in sensing, in electrocatalysis and in electrochromic displays.[1,2] The electrochemical polymerization of complexes bearing pendant *N*-pyrroles, by oxidation of the pyrrole moieties, is often employed to prepare such modified electrodes.[3,4] The complexes used have normally been classical redox-active and potentially electrocatalytic species, for example porphyrins[4] or complexes of 2,2′-bipyridine (bpy) derivatives;[1,5] the latter have the advantage that the synthesis of pyrrole-functionalized derivatives is straightforward. In spite of the interest in fixing them to surfaces for catalysis, metal–phosphine complexes (apart from a few examples with bpy derivatives as coligands[5]) have not so far been incorporated into conducting polymers, and have rarely been investigated for electrode modification.[6]

Although the synthesis of chelating phosphine ligands bearing pendant heterocycles, suitable for electropolymerization, might be expected to be problematic, nucleophilic addition to coordinated dppen [dppen = $(Ph_2P)_2C{=}CH_2$] offers a route to functionalized diphosphine complexes in one step and in high yield.[7,8] We have shown that prolonged treatment of *trans*-$[RuCl_2(dppen)_2]$ **1** with a large excess of $RNH_2$ affords functionalized, redox-active diphosphine complexes *trans*-$[RuCl_2\{(Ph_2P)_2CHCH_2NHR\}_2]$, and that one example {R = $-(CH_2)_3Si[OEt]_3$} could be used to modify oxide surfaces with a ruthenium(II)–diphosphine complex monolayer.[6] Amine addition is inappropriate for the preparation of derivatives bearing pendant thiophenes or pyrroles for oxidative electropolymerization; the linkage between the heterocycle and metal centre must be non-basic.[9] Although the reactivity of **1** towards nucleophiles is limited compared with platinum(II) and palladium(II) complexes of dppen,[10] we were gratified to find that treatment of **1** in $CH_2Cl_2$ with a large (≥ 10-fold) excess of a primary alcohol, in the presence of catalytic amounts of $KOBu^t$ and 18-crown-6, generated the hoped-for adducts $[RuCl_2\{(Ph_2P)_2CHCH_2Z\}_2]$ (Z = $-OCH_2Ph$ **2**, $-OCH_2CH_2C_4H_3S$-3 **2b**) in acceptable yield.‡ These were characterized by $^{31}P\{^1H\}$ and $^1H$ NMR spectroscopy, microanalytical data and FAB mass spectrometry.§ Their spectroscopic properties are similar to those of the primary amine adducts described earlier.[6,10] The addition of other primary alcohols (EtOH, $n$-$C_6H_{13}OH$) to **1** also proceeds in solution, as monitored by $^{31}P\{^1H\}$ NMR spectroscopy, but we did not isolate the products. The adduct **2b** has been the subject of an X-ray crystal structure determination; details will be reported later. Complex **2b** is in principle suitable for incorporation, by electropolymerization, into polythiophenes.

Pyrrole NH groups have p$K_a$s similar to alcohol OH groups.[11] Earlier, we found that the very reactive complex $[Pd(OAc)_2(dppen)]$ reacted with pyrrole *via* electrophilic aromatic substitution, to give a mixture of (after metathesis) $[PdI_2\{(Ph_2P)_2CHCH_2C_4H_3NH\text{-}x\}]$ ($x$ = 2, major isomer; $x$ = 3; minor isomer).[8] Interestingly, on treatment with an excess of pyrrole in chlorobenzene in the presence of catalytic amounts of $KOBu^t$ and 18-crown-6, **1** gave, exclusively and in high yield, *trans*-$[RuCl_2\{(Ph_2P)_2CHCH_2NC_4H_4\}_2]$ **3a**, also fully characterized; the pyrrole proton resonances (AA′XX′ spin system) in the $^1H$ NMR spectrum were particularly diagnostic.¶ Complex **3a** was insufficiently soluble for electrochemical study, and we therefore added 3-*n*-hexylpyrrole[12] to **1** to give *trans*-$[RuCl_2\{(Ph_2P)_2CHCH_2NC_4H_3R\}_2]$ (R = *n*-hexyl, **3b**), which was much more soluble in $CH_2Cl_2$.‖

The cyclic voltammogram** of **3b** in $CH_2Cl_2$–0.2 M $NBu_4BF_4$ showed a reversible one-electron oxidation wave at +0.11 V owing to the $Ru^{II}$–$Ru^{III}$ couple, and a further irreversible oxidation wave commencing at *ca.* + 0.87 V owing to the oxidation of the pendant pyrrole units; this high value for a pyrrole is likely a consequence of the fact that it is both N- and 3-substituted, and is in a sterically crowded environment. No polymer film formed, even when we used a 10 mM solution of **3b**. Since N-functionalized pyrroles have significantly higher oxidation potentials than pyrrole itself, we therefore chose to co-polymerize **3b** (10 mM) with *N*-methylpyrrole (20 mM). Once grown, the copolymer-modified electrodes were washed, and transferred to MeCN–0.2 M $NEt_4BF_4$ media for redox-cycling experiments.

Fig. 1 compares the cyclic voltammogram (CV) of a poly(*N*-methylpyrrole) film grown using a 30 mM monomer solution, from 0.2 M $NBu_4BF_4$–$CH_2Cl_2$ (*i.e.* conditions as similar as possible to those used for copolymer formation), and the CV of the copolymer. The poly(*N*-methylpyrrole) CV closely resembles those of films grown using more conventional media (*e.g.* $NEt_4BF_4$–MeCN);[13] use of $CH_2Cl_2$–$NBu^n_4BF_4$ as the electrolyte for film growth does not appear to have a detrimental effect on the voltammetry of the polymer. It can be seen that, at 10 mV $s^{-1}$ scan rate, a $Ru^{II}$–$Ru^{III}$ wave is superimposed upon the broad redox wave due to the poly(*N*-methylpyrrole) backbone for the copolymer film. It occurs at a potential *ca.* 0.05 V more positive than that for **3b** in solution in $CH_2Cl_2$. This

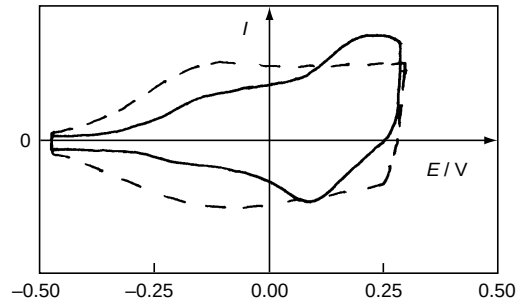

**Fig. 1** Cyclic voltammograms of (dashed line) poly(*N*-methylpyrrole) (30 mV $s^{-1}$) and (full line) a copolymer of *N*-methylpyrrole and **3b** (10 mV $s^{-1}$). Pt disk electrode, 0.30 $cm^2$ area.

is excellent evidence that the copolymerization strategy has worked and we have prepared a polypyrrole bearing a covalently bound metal–diphosphine complex, the first time that this has been demonstrated. Moreover, the electroactivity of the conducting polymer backbone has been preserved. For a surface-localised redox process, there should be no peak separation between anodic and cathodic processes. This is clearly not the case for the $Ru^{II}$–$Ru^{III}$ wave in the copolymer, but there are likely to be kinetic limitations due to the necessity for ion ingress/egress from the polymer film.

In summary, we have used base catalysis to add alcohols and pyrroles, weak nucleophiles, to **1**, and this affords a convenient route to thiophene- and pyrrole-functionalized ruthenium(II)–diphosphine complexes. We have successfully electrocopolymerized the pyrrole derivative **3b**, immobilising a redox-active ruthenium(II)–diphosphine complex in a polypyrrole matrix for the first time. This chemistry offers the opportunity of coating conducting surfaces with a polymer layer containing defined platinum metal–diphosphine complexes, providing that the latter are stable at the positive potentials needed to electropolymerize the heterocycles.

We thank the EPSRC for 'Earmarked' (T. J. P.) and Quota (M. K. M.) studentships, the Royal Society for a grant (ref. 18038), the EPSRC National Mass Spectrometry Service (Swansea) for FAB mass spectra, Dr Richard Batchelor (Pilkington Group Research, Lathom) for ITO-coated glass electrodes and Johnson-Matthey for a loan of $RuCl_3{\cdot}nH_2O$.

** All potentials quoted in this paper are with respect to the ferrocene–ferrocenium redox couple, which was routinely monitored after electrochemical experiments. Conducting polymer films were grown by repetitive cyclic voltammetric scans from *ca.* −0.5 V, to a potential *ca.* 0.1 V beyond the potential at which heterocycle oxidation commenced, using Pt disk or indium-doped tin oxide (ITO)-coated glass working electrodes. The films were removed from the cell with the film in the neutral (reduced) state, washed thoroughly with $CH_2Cl_2$ to ensure that any Ru complex within the film is covalently anchored, dried and stored. Subsequent voltammetric experiments were conducted in 0.2 M $NEt_4BF_4$–MeCN. Other details of electrochemical methodology were as previously described.[6]

# Irreversible dinitrogen adsorption on Cu-ZSM-5 catalysts and *in situ* IR identification of the NO decomposition sites

**Dinitrogen chemisorbs on two neighbouring copper atoms of Cu-ZSM-5 catalysts that are demonstrated to be the active sites for NO decomposition.**

Dinitrogen chemisorption at room temperature on supported metal particles has been reported for rhodium on aluminium-rich zeolites and on titania.[1,2] On Cu/mordenite (Cu/NaM)[3–5] and $Cu^{I}$-ZSM-5[6] systems, IR evidence supports a simple physisorption of $N_2$ while the presence of a small amount of strongly adsorbed $N_2$ on Cu sites is only claimed.

We now report adsorption data and direct IR evidence of $N_2$ chemisorption on different Cu/zeolites systems, with correlation to their catalytic activity for NO decomposition to $N_2$ + $O_2$.

NaY (Si/Al = 2.4) and H-ZSM-5 (Si/Al = 17) zeolites were ion-exchanged at room temp. with dilute solutions of copper acetate. Dinitrogen adsorption isotherms were determined by a conventional volumetric apparatus at 273 K in the range 0–100 Torr. Samples were pretreated at $10^{-5}$ Torr for (*a*) 1 h at 788 K before the first $N_2$ adsorption and (*b*) 0.5 h at 273 K before the second $N_2$ adsorption. The $N_2$ adsorptions were calculated from the intercepts at $P = 0$ Torr of the straight lines in the high-pressure range of the first and the second isotherm, respectively.

With NaY, H-ZSM-5 and Cu/NaY the same behaviour reported for NaM[3–5] was observed: the intercepts of the straight lines are zero, corresponding only to $N_2$ physisorption. Moreover, the turnover frequency for NO decomposition on Cu/NaY is very low and quite insensitive of the copper loading.[7,8] The Cu-ZSM-5 systems, catalytically very active, show instead an irreversible $N_2$ coverage [0.03, 0.04, 0.12 mol $N_2$ (mol Cu)$^{-1}$ at 25, 65, 117% Cu exchange, respectively]. The adsorption process was also investigated in a flow cell by diffuse reflectance infrared FT spectroscopy (DRIFTS), in order to retain the working conditions of the catalyst and to avoid the diffusional limitations often encountered when the sample is a self-supporting wafer.

DRIFTS measurements were carried out at room temperature on Cu-ZSM-5 (98% Cu exchange), activated in flowing Ar [Fig. 1(*a*)]. A weak band at 2130 cm$^{-1}$ [Fig. 1(*b*)] appears in $N_2$ flow and does not change its intensity even after 12 h of Ar purging at room temp. The observed stretching frequency is much lower than the $\nu_{N-N}$ vibrations at 2299 and at 2295 cm$^{-1}$ attributed to physisorbed $N_2$ on Cu/NaM (150% Cu exchange)[3–5] and $Cu^{I}$-ZSM-5,[6] respectively, or the vibrations at 2334 and 2352 cm$^{-1}$ due to physisorbed $N_2$ on Brønsted- and Lewis-acid sites of H-ZSM-5.[9]

According to the reported relationship between $\nu_{N-N}$ and the N–N bond lengths,[10] the red shift of 201 cm$^{-1}$ with respect to the gaseous $N_2$ molecule (bond length = 1.098 Å) suggests a chemisorbed $N_2$ with a bond length of *ca*. 1.12 Å. Such a value is similar to those reported for the N–N bond distances in many $N_2$-dinuclear transition-metal complexes of [M–N≡N–M] type[10] and is in accord with an 'end-on' bridging coordination with the nitrogen molecule bonded to two different copper centers. The arrangement of two copper ions bridged by extra framework OH species was found by static atomistic simulation techniques to be particularly stable in ZSM-5 zeolite,[11] moreover, such binuclear species were independently proposed as the active sites for NO decomposition.[12,13]

Information about the nature of the sites responsible for this kind of $N_2$ chemisorption was gained through competitive adsorption of $N_2$ and CO experiments.

The spectrum in Fig. 1(*c*), obtained after carbonylation, shows a strong band at 2154 cm$^{-1}$ with a shoulder at 2138 cm$^{-1}$ and a weak band at 2107 cm$^{-1}$, all being commonly assigned to linearly chemisorbed CO on different $Cu^{+}$ intrazeolitic sites.[14]

Fig. 1(*d*) depicts the changes brought about by flowing $N_2$. The appearance of a new weak band at 2130 cm$^{-1}$ due to chemisorbed $N_2$ (partially overlapping the CO band at 2138 cm$^{-1}$), together with the marked decrease of the CO band at 2154 cm$^{-1}$, indicates an unexpected ability of $N_2$ to displace CO from that specific site. The driving force of this ligand-exchange reaction may be accounted for by the proposed bridging coordination of $N_2$ on two neighbouring copper sites.

Fig. 2 shows how the pattern of the 2154 cm$^{-1}$ carbonyl band intensity closely matches that of the catalytic activity at 773 K *vs*. % Cu exchange.[7] A direct correlation between the number of NO decomposition sites and the intensity of the 2154 cm$^{-1}$ CO band emerges from the comparison of these two profiles; as a consequence of such a correlation, the adsorption of $N_2$ is proved to occur only on these catalytically active sites.

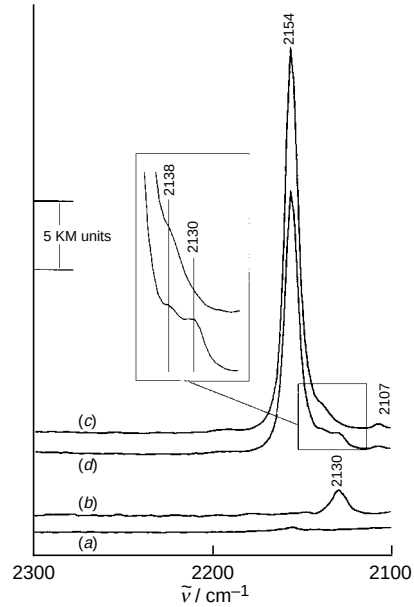

**Fig. 1** DRIFT spectra recorded at 293 K of 98% Cu exchanged Cu-ZSM-5 system: (*a*) after activation in flowing Ar from 293 K to 703 K for 1 h (ramp 3 K min$^{-1}$), (*b*) (*a*) after 3 h in flowing $N_2$ at 293 K, (*c*) activation as in (*a*) followed by 12 h in flowing CO at 293 K and subsequent Ar degassing, (*d*) (*c*) after 3 h in flowing $N_2$ at 293 K

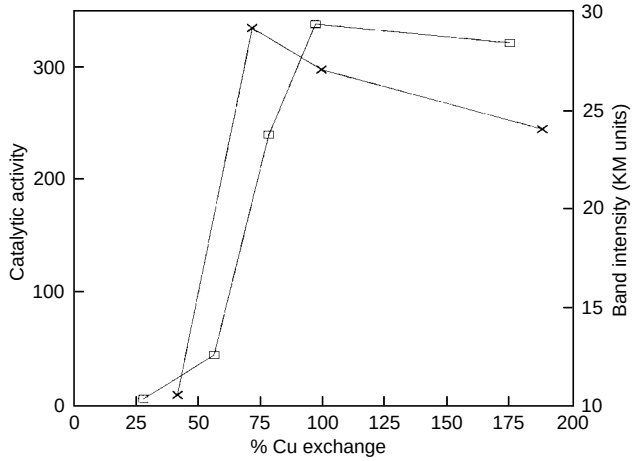

**Fig. 2** (×) Intensity of the CO band at 2154 $cm^{-1}$ of four Cu-ZSM-5 catalysts *vs*. % Cu exchange: spectra recorded in Ar after the same sequence reported in Fig. 1(*c*). (□) Catalytic activity at 773 K *vs*. % Cu exchange (ref. 6): the catalytic activity is expressed as $10^{-16}$ *x* (number of NO molecules converted to $N_2$) (g catalyst s)$^{-1}$.

The unique role of the ZSM-5 framework in the unusual catalytic activity of Cu-ZSM-5 systems can be therefore accounted for by its ability to provide the correct geometrical arrangement of dual copper sites for N≡N bond formation from two NO molecules.

We thank the Ministry of University and Scientific and Technological Research (MURST) for financial support.

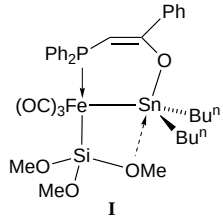
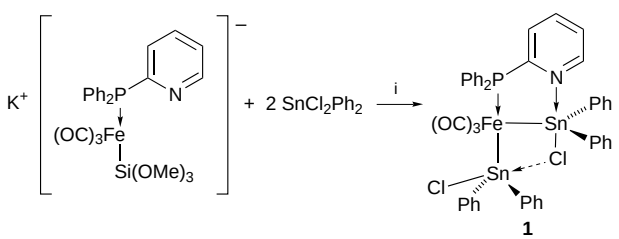
# Differing degrees of five-coordination for similar tin atoms in the polymetallic complex $[(OC)_3Fe(\mu\text{-}Ph_2Ppy)(SnPh_2)(\mu\text{-}Cl)(SnClPh_2)]$



**Pierre Braunstein,*[a] Chantal Charles,[a] Guido Kickelbick[b] and Ulrich Schubert[b]**

[a] *Laboratoire de Chimie de Coordination, URA 416 CNRS, Université Louis Pasteur, 4 rue Blaise Pascal, F-67070 Strasbourg Cedex, France*

[b] *Institut für Anorganische Chemie, Technische Universität Wien, Getreidemarkt 9/153, A-1060 Wien, Austria*



**The unusual iron–bistin complex, $[(OC)_3Fe(\mu\text{-}Ph_2Ppy)(SnPh_2)(\mu\text{-}Cl(SnClPh_2)]$, obtained by silicon–tin exchange from a Si–Fe–Sn precursor, contains two tin atoms showing different degrees of five-coordination, a unique feature of relevance to hypercoordination of main-group elements.**

The structural chemistry of tin in its complexes is diversified and the preferred geometries are tetrahedral, trigonal bipyramidal or octahedral.[1] Structural deformations encountered in crystallographically characterized molecules may often be analysed as representing snap-shots along the reaction coordinates of nucleophilic displacements at the tin centre.[2] It is also known that hypercoordination of a main-group element strongly influences its reactivity and may be used to promote catalytic behaviour. In transition-metal tin compounds M–Sn–R (R = alkyl or aryl), the bond angles decrease in the order M–Sn–R > R–Sn–R as there is more s character in the metal–tin bond.[3] Following our report of the structure of an unusual phosphinoenolate-bridged Si–Fe–Sn complex **I** in which the coordination at the tin centre was distorted tetrahedral, toward trigonal bipyramidal, with the oxygen donor ligands being *trans* to each other,[4] we have now observed that varying the nature of the assembling ligand led *via* a silicon–tin exchange reaction to a $FeSn_2$ complex in which the tin centres display different degrees of hypercoordination. This feature is of particular interest since it occurs in the same molecule, with tin ions in the same formal oxidation state.

**I**

The reaction of the iron metalate $K[Fe(CO)_3\{Si(OMe)_3\}(Ph_2Ppy\text{-}P)]$[5] [$Ph_2Ppy$ = 2-(diphenylphosphino)-pyridine] with $[SnCl_2Ph_2]$ (Scheme 1) required 2 equiv. to reach completion.† The product **1** was characterised by three $\nu$(CO) absorptions (2041m, 2001m, 1969s $cm^{-1}$) consistent with a *mer*-arrangement of the carbonyl ligands. Its $^{31}P\{^1H\}$ NMR spectrum contains a singlet at $\delta$ 77.9 attributed to the iron-bound P atom, coupled to two sets of $^{117,119}Sn$ isotopes with $^2J(P^{117,119}Sn)$ 161.7 and 217.6 Hz. This is consistent with the presence of two different tin atoms in the molecule, *cis* and *trans* to the P → Fe bond, respectively.[6a]

**1**

**Scheme 1** *Reagents and conditions*: i, thf, room temp., 30 min, − $SiCl(OMe)_3$, −KCl

A perspective view of the molecular structure of this complex is shown in Fig. 1.‡ The iron atom has a slightly distorted octahedral environment with three meridional carbonyl ligands, two *cis* tin atoms and the P atom of the bridging phosphinopyridine ligand. The nitrogen atom is coordinated to Sn(1) which has a trigonal-bipyramidal environment with the phenyl groups and the Fe atom in the equatorial plane, the sum of the corresponding bond angles being 359.2°. The Sn(1)–Cl(1) bond length of 2.557(2) Å is slightly longer than the average value for this bond.[7] This is probably due to the presence of a rather

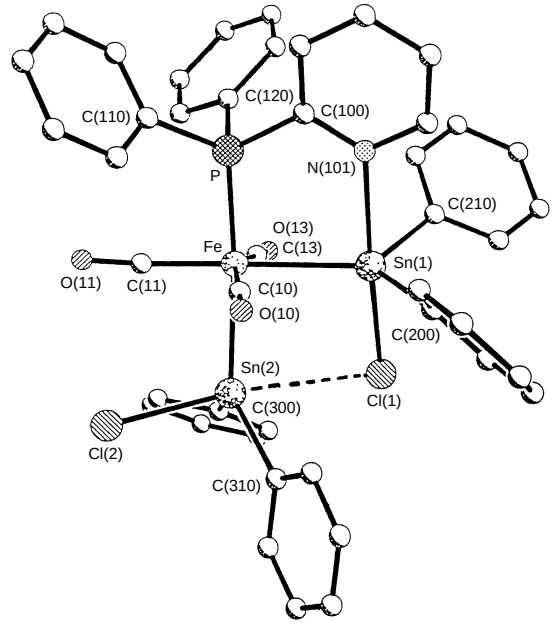


**Fig. 1** View of one molecule of **1**. Selected bond distances (Å) and angles (°): Fe–C(10) 1.796(9), Fe–C(11) 1.785(9), Fe–C(13) 1.799(9), Fe–P 2.241(2), Fe–Sn(1) 2.6111(12), Fe–Sn(2) 2.6026(12), P–C(100) 1.831(8), Sn(1)–Cl(1) 2.557(2), Sn(1)–C(200) 2.163(8), Sn(1)–C(210) 2.156(8), Sn(1)–N(101) 2.499(7), Sn(2)–Cl(2) 2.485(2), Sn(2)–C(300) 2.149(9), Sn(2)–C(310) 2.150(8), Sn(2)–Cl(1) 3.076(2); C(10)–Fe–C(11) 100.5(4), C(11)–Fe–C(13) 96.3(4), C(10)–Fe–C(13) 159.5(4), P–Fe–Sn(1) 92.73(6), P–Fe–Sn(2) 175.12(7), Sn(1)–Fe–Sn(2) 91.74(4), C(200)–Sn(1)–Fe 122.4(2), C(210)–Sn(1)–Fe 124.7(2), N(101)–Sn(1)–Fe 87.3(2), Cl(1)–Sn(1)–Fe 95.31(6), N(101)–Sn(1)–Cl(1) 176.4(2), C(200)–Sn(1)–C(210) 112.1(3), C(200)–Sn(1)–N(101) 88.2(3), C(210)–Sn(1)–N(101) 85.6(3), C(200)–Sn(1)–Cl(1) 92.6(2), C(210)–Sn(1)–Cl(1) 90.9(2), C(300)–Sn(2)–Fe 114.8(2), C(310)–Sn(2)–Fe 126.0(2), Cl(2)–Sn(2)–Fe 102.08(7), Cl(1)–Sn(2)–Cl(2) 171.6(3), Cl(2)–Sn(2)–Fe 102.08(7), Cl(2)–Sn(2)–C(300) 95.7(3), Cl(2)–Sn(2)–C(310) 92.5(2), C(300)–Sn(2)–C(310) 115.1(3).

strong N–Sn(1) bond [2.499(7) Å][7b,8] *trans* to it and to an intramolecular coordination of Cl(1) to Sn(2). Although the Sn(2)–Cl(1) separation of 3.076(2) Å is relatively long, it is only 0.04 Å longer than in the five-coordinated tin complex $[SnCl_2Me_3]^-$.[9] The bond angles around Sn(2) are consistent with a distorted trigonal-bipyramidal geometry, the Cl(1)–Sn(2)–Cl(2) angle of 171.6(3)° and the sum of the interligand angles involving Fe, C(200) and C(210) of 355.9(2)° being close to the ideal values for a trigonal bipyramid. The angles between Cl(2) and the three equatorial substituents [Fe, C(300), C(310)] [between 92.5(2) and 102.08(7)°] are again consistent with a distortion of the tetrahedral geometry around Sn(2) towards trigonal bipyramidal as a result of the Sn(2)–Cl(1) interaction. The value of the Cl(1)–Sn(2)–Cl(2) angle illustrates the view of this structure representing a snap-shot along the reaction coordinates of an intramolecular nucleophilic substitution at the Sn(2) centre.[2] Accordingly, the Sn(2)–Cl(2) distance of 2.485(2) Å is longer than in tetrahedral tin complexes. Complex **1** represents therefore a unique example where in the same molecule, two hypercoordinated tin atoms displaying different degrees of Sn–Cl interactions are present. It is also interesting that although the Fe–Sn(1) bond is supported by an assembling ligand in contrast to the Fe–Sn(2) bond, their lengths of 2.6111(12) and 2.6026(12) Å are only marginally different and compare well with those in relevant molecules.[6]

The reactivity of the Fe–Si bond, *trans* to P in the iron metalate, is dependent on the nature of the assembling ligand, as shown by the differences observed when $Ph_2Ppy$ (this work), dppm[6a] or $Ph_2PCH_2C(O)Ph$ are used. In the former cases, $FeSn_2$ complexes are formed whereas in the latter, spontaneous deprotonation of the Fe-coordinated ketophosphine ligand occurred to give a phosphino enolate bridging ligand.[4]

We are grateful to Dr J. Rocha (Aveiro, Portugal) for the solid-state NMR data, to the Ministère de l'Enseignement Supérieur et de la Recherche for a Ph. D. Grant for C. C. and to the Centre National de la Recherche Scientifique (Paris) and the Commission of the European Communities (contract ERBCHRXCT93 277) for financial support.

† All reactions were performed under purified nitrogen, using carefully dried solvents.

*Synthesis of mer*-$[Fe(CO)_3\{SnClPh_2\}_2(Ph_2Ppy)]$ **1**: to a stirred solution of $K[Fe(CO)_3\{Si(OMe)_3\}(Ph_2Ppy\text{-}P)]$ prepared *in situ* from the corresponding hydride (0.525 g, 1.0 mmol) and a slight excess of KH (0.05 g) in thf, was added $[SnCl_2Ph_2]$ (0.688 g, 2.0 mmol). Rapid formation of a white precipitate occurred. The solution was stirred for 30 min, slowly concentrated and filtered through Celite to eliminate KCl. The product was precipitated by addition of hexane and washed with hexane and a small amount of diethyl ether. Crystals were obtained by slow diffusion of hexane into a $CH_2Cl_2$ solution of **1**. Yield: 79%. IR $\nu$(C≡O) ($CH_2Cl_2$): 2041m, 2001w, 1969s cm$^{-1}$; (KBr): 2037m, 1994w, 1967s cm$^{-1}$. $^1$H NMR ($CDCl_3$): $\delta$ 6.90–8.35 (m, 34 H, aromatics), 8.85 [d, 1 H, $H_{ortho}$(py), $^2J$(HH) 4.7 Hz]. $^{31}$P{$^1$H} NMR ($CDCl_3$): $\delta$ 77.9 [s, P(Fe), $^2J$(P$^{119,117}$Sn) 161.7, $^2J$(P$^{119,117}$Sn) 217.6 Hz]. $^{31}$P NMR (solid state, CP MAS, 15 kHz) : $\delta$ 74.1. $^{119}$Sn NMR (solid state, CP MAS, 15 kHz): $\delta$ 2 and −65. Mass spectrum (FAB$^+$): 984 ($M^+$ − Cl, 84), 947 ($M^+$ − 2Cl, 32), 919 ($M^+$ − 2Cl − CO, 18), 891 ($M^+$ − 2Cl − 2CO, 15%).

‡ *Crystal data* for **1** (pale orange crystals, 0.24 × 0.20 × 0.14 mm): $C_{44}H_{34}Cl_2FeNO_3PSn_2\cdot CH_2Cl_2$, $M$ = 1104.75. The crystals were mounted on a Siemens SMART CCD area detector diffractometer. Mo-K$\alpha$ radiation was used for the measurement ($\lambda$ = 0.710 73 Å, graphite monochromated). Monoclinic, space group $P2_1/c$, $a$ = 11.4534(2), $b$ = 11.6281(3), $c$ = 34.1379(6) Å, $\beta$ = 97.643(1), $U$ = 4506 Å$^3$, $Z$ = 4, $D_c$ = 1.628 g cm$^{-3}$. The cell dimensions were refined with all unique reflections. The data collection at 293(2) K covered a hemisphere of the reciprocal space, by a combination of three sets of exposures. Each set had a different $\phi$ angle for the crystal and each exposure took 20 s and covered 0.3° in $\omega$. The collected data range was $1.20 \leqslant \theta \leqslant 25.00°$ ($-13 \leqslant h \leqslant 16$, $-16 \leqslant k \leqslant 15$, $-48 \leqslant l \leqslant 48$) by a crystal-to-detector distance of 3.85 cm. 25 359 reflections were collected and 7942 unique reflections ($R_{int}$ = 0.057) were obtained after correction of polarization and Lorentz effects and an empirical absorption correction (program SADABS, $\mu$ = 1.73 mm$^{-1}$).[10] The structure was solved by direct methods (SHELXS86). Refinement was performed by the full-matrix least-squares method based on $F^2$ (SHELXL93). All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were added in idealized positions and were refined with a riding model. The carbon atom of the solvent molecule was refined with constrained C–Cl distances. $R$ = 0.071, $R_w$ = 0.145 for 6395 reflections with $I$ = 2.0 $\sigma(I)$; $w = 1/[\sigma^2(F_o^2) + (0.1402P)^2 + 28.94P]$ [$P = (F_o^2 + 2F_c^2)/3$]. The largest residual electron density was 1.5 e Å$^{-3}$ at Sn(1) and Sn(2). CCDC 182/587.

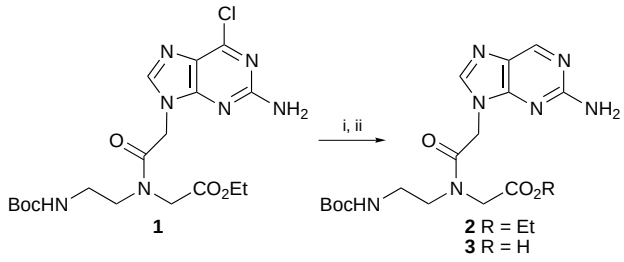
# 2-Aminopurine peptide nucleic acids (2-*ap*PNA): intrinsic fluorescent PNA analogues for probing PNA–DNA interaction dynamics

**Bargur P. Gangamani, Vaijayanti A. Kumar* and Krishna N. Ganesh*†**



*Organic Chemistry Synthesis Division, National Chemical Laboratory, Pune 411008, India*

**Peptide nucleic acids, containing intrinsically fluorescent 2-aminopurine in place of non-fluorescent adenine, are useful as fluorescent probes to study PNA–DNA interaction dynamics.**

Peptide nucleic acids (PNA) are DNA analogues in which the sugar–phosphate backbone is replaced by a peptide amide bond backbone.[1] PNAs exhibit unique properties that set them apart from other traditional DNA analogues. These properties are: (i) unprecedented strong binding to complementary, mixed DNA/RNA sequences to form duplexes, (ii) high specificity in discrimination of mismatched base pairs and (iii) 'strand invasion' at polypurine/pyrimidine stretches on a DNA duplex to form a $PNA_2$·DNA triplex.[2] This fact, coupled with their resistance to proteases and nucleases and chemical stability over a wide pH range, has led to the development of novel applications that cannot be satisfactorily executed with other DNA analogues. Such applications include blocking and activation of gene expression *via* D-loop complexes, identification of point mutations by PNA-directed PCR clamping, using fluorophore conjugated PNA as probes to locate individual genes in a DNA map and antisense drug development.[2,3]

Most of the structural changes to improve PNA properties so far have centred on backbone modifications to introduce conformational constrain and chirality.[1–4] Herein we report on a novel type of PNA analogue which has intrinsic fluorescence due to the presence of 2-aminopurine (2-*ap*),[5] an isomer of non-fluorescent adenine (6-aminopurine). The base 2-*ap* can be selectively excited in the presence of normal bases, making it an ideal real-time spectroscopic probe to study the dynamics and local environmental changes due to DNA binding with other molecules.[6] Incorporation of this into versatile PNA would therefore add a new dimension to the existing repertoire of PNA properties and potential applications. This is the first report of the synthesis of a PNA analogue which is intrinsically fluorescent, and also examines PNA–DNA complexation *via* fluorescence changes.

The desired PNA monomer **3** carrying a 2-aminopurine moiety was synthesised in two steps (Scheme 1) starting from the previously known compound ethyl *N*-(2-amino-6-chloropurin-9-ylacetyl)-*N*-(2-butoxycarbonylaminoethyl)glycinate **1**.[7] The 6-chloro group in **1** was first removed by hydrogenation over Pd–C to afford **2**, which was followed by hydrolysis of the ester with aq. NaOH to give the corresponding carboxylic acid **3**.‡ This monomer was used directly for incorporation into PNA oligomer **5** without protecting the 2-amino function, since it is inactive for normal peptide coupling conditions. The assembly of the PNA oligomers **4** and **5** was performed manually on Merrifield resin prior functionalised with β-alanine (0.3 equiv. $g^{-1}$) by standard solid phase peptide synthesis.[7] For the oligomer **5**, the 2-*ap* monomer **3** was used in place of A monomer in the indicated position (*A*). At the end of the synthesis, the oligomers were cleaved from the resin using $CF_3SO_3H$–TFA and the products assessed by reverse phase HPLC.§ The complementary oligonucleotides **6** and **7** designed for parallel and antiparallel PNA·DNA duplexes were synthesised on an automated DNA synthesiser.

***A*** = 2-aminopurine

The fluorescence spectra¶ of the monomer **3** was similar to that of the 2-aminopurine base, with emission at 367 nm upon excitation at 308 nm; the fluorescence intensity changed negligibly with increasing temperature in the range 10–60 °C. The fluorescent observables ($\lambda_{ex}$, $\lambda_{em}$) from 2-*ap*PNA **5** were similar to those of the monomer, but the fluorescence yield of 2-*ap* in PNA was significantly lower than that of the free base. The PNA oligomer **5** exhibited an increase in intensity as a function of temperature upto 40 °C (total 25%), after which a slight decrease in intensity was observed (Fig. 1). No meaningful changes in $\lambda_{ex}$/$\lambda_{em}$ (±1 nm) were seen with changes in temperature. However, the measurement of fluorescence anisostropy at different temperatures (15 °C, 0.073; 25 °C, 0.060; 35 °C, 0.040; 50 °C, 0.040) showed an appreciable decrease with increasing temperature until *ca*. 40 °C and remained constant thereafter. This behaviour indicates that 2-*ap*PNA, like PNA, is considerably self-organized at low temperatures and melts at higher temperature. Thus, the 2-*ap* residue in **5** senses the local changes in conformation/environment accompanying the self-melting of

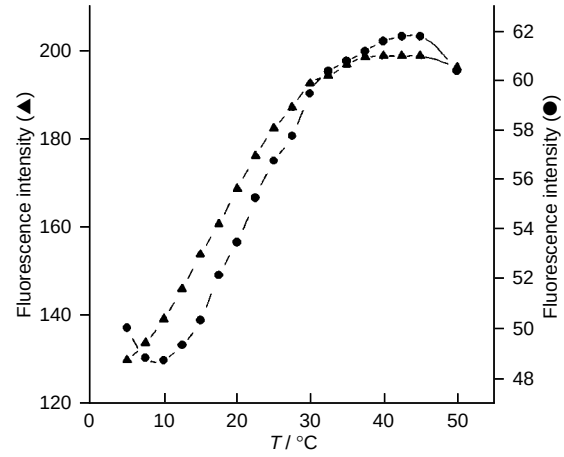

**Fig. 1** Fluorescence ($\lambda_{em}$ 365 nm) melting profiles of (●) 2-*ap*PNA **5** and (▲) 2-*ap*·DNA duplex **5·7**

PNA from an ordered chain to a random coil, a process that also reorients the fluorophore.

The mixed sequence PNAs form both parallel and antiparallel duplexes with appropriate complementary DNA sequences, with antiparallel duplexes being more stable than parallel duplexes.[2] The effect of incorporating 2*ap* in place of A on the thermal stability of duplexes is seen from the UV absorbance–temperature data for PNA·DNA duplexes ($T_m$; **5·6**, 25.5 °C; **5·7**, 25.0 °C; **4·6**, 28.0 °C; **4·7**, 28.5 °C). The single replacement of A by 2*ap* caused a lowering of $T_m$ by 2–3 °C for both parallel (N/5′, **5·6**) and antiparallel (N/3′, **5·7**) 2*ap*-PNA·DNA duplexes as compared to the corresponding unmodified control duplexes **4·6** and **4·7** respectively. The data indicate a relatively large increase in fluorescence intensity (60%) of 2 *ap* in duplex with temperature as compared to that in 2*ap*PNA alone (25%). Further, a slight blue shift in emission maxima (2 nm) was noticed at 50 °C compared to that at 5 °C, indicating a more hydrophilic environment for 2*ap* after melting. The fluorescence intensity showed a small decrease beyond 40 °C, similar to 2*ap*-PNA (Fig. 1). The parallel PNA·DNA duplex (**5·6**) gave temperature dependent fluorescence spectra (not shown) similar to those of the antiparallel (**5·7**) duplex. Surprisingly, the decrease in fluorescence anisotropy (10%) of the 2*ap* moiety in PNA upon PNA·DNA melting was less than that seen with 2-*ap*PNA alone (45%).

The fluorescence $T_m$ obtained from the data in Fig. 1 for 2*ap*-PNA·DNA melting (**5·7**, 27.5 °C) was less by 5 °C than the $T_m$ for self-melting of 2*ap*-PNA (**5**, 32.5 °C), consistent with the general observation that the thermal stability of the PNA·DNA duplex is lower than that of PNA.[2] It is interesting, but not unprecedented,[6a] to note that the fluorescence $T_m$ of the duplexes (**5·6**, 27.5 °C; **5·7**, 27.0 °C) were *ca*. 2.5 °C higher than the $T_m$ of the corresponding duplexes derived from UV absorbance changes. This difference may arise from the fact that the UV equilibrium melting curves monitor the global duplex dissociation while the fluorescent melting curve monitors local duplex perturbations in the vicinity of the fluorophore.[6] The temperature dependent fluorescence data is also influenced by transient kinetic states that are not reflected in equilibrium data.

The kinetics of the PNA·DNA hybridization process were examined by monitoring the fluorescence emission decay at 367 nm as a function of time after mixing of 2*ap*-PNA **5** with the complementary antiparallel DNA **7** (Fig. 2). The emission intensity decreased exponentially over a period of 6 min [Fig. 2, curve (*c*)] and thereafter remained constant. In contrast, either 2*ap*PNA **5** alone or its mixture with DNA $dA_{10}$, **8** having three mismatches with PNA, did not exhibit any effect on the PNA fluorescence [Fig. 2, curves (*a*) and (*b*)]. The time-dependent decrease in fluorescence of **5** immediately upon mixing with **7** may therefore be attributed to specific formation of a 2*ap*PNA·DNA hybrid (**5·7**). Similar kinetic behaviour has been previously observed for PNA·PNA hybrid by monitoring the evolution of a circular dichroism signal arising from helical propagation in a 10-mer lys-PNA upon mixing with a complementary PNA sequence[8] where signal saturation occurred at around 6 min. The decay profile observed could be fitted to a double exponential function with time constants of 46 and 290 s, indicating that the fluorescent base 2-*ap* in PNA monitors at least two types of local events, a fast duplex formation by complementary hydrogen bonding followed by a slow reorganization of the helix after duplex formation.

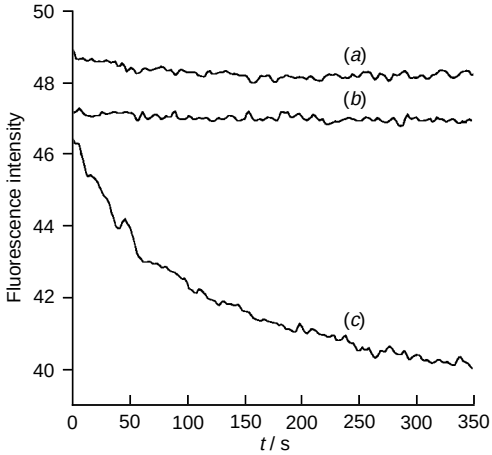

**Fig. 2** Fluorescence decay kinetics at 15 °C monitored by emission at 365 nm: (*a*) **5**, (*b*) **5·8** and (*c*) **5·7**

Structural studies of DNA/PNA using fluorescence are best performed without perturbing their structures, which is possible only with the use of intrinsic fluorescence from the base. In this context, 2*ap* is an ideal fluoroprobe since it senses both steady state and dynamic conformational changes. The present results clearly demonstrate that 2-*ap* is easily accommodated in a PNA chain and the intrinsic fluorescence can be employed to monitor PNA self-melting and PNA·DNA duplex transitions. The anisotropy changes suggest that the 2-*ap* residue in a PNA chain is more ordered than its environment in a PNA·DNA duplex. Since 2-*ap* can be placed at any point in a PNA·DNA helix to monitor local events, the type of probes reported here have potential for studying the consequences of backbone modifications on the PNA self-structure and on PNA·DNA duplex. Apart from their utility in diagnostics, these PNA probes may be applicable to other areas, such as the study of cellular uptake and intracellular distribution of PNA by employing fluorescence microscopy, and as sequence specific DNA biosensors.[9]

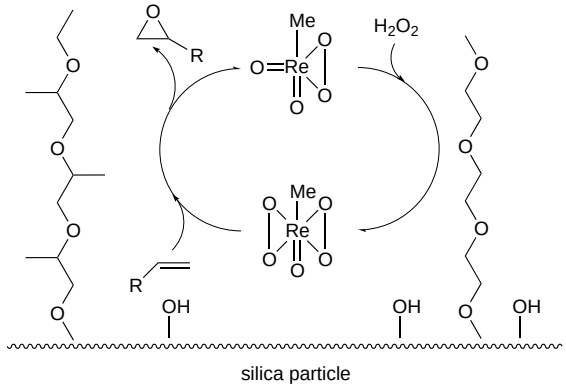
# Methyltrioxorhenium supported on silica tethered with polyethers as catalyst for the epoxidation of alkenes with hydrogen peroxide



**Ronny Neumann* and Tie-Jun Wang**

*Casali Institute of Applied Chemistry, Graduate School of Applied Science, The Hebrew University of Jerusalem, Jerusalem, Israel 91904*

**Methyltrioxorhenium has been supported on silica functionalized with polyether tethers; in the absence of an organic solvent, this catalytic assembly catalysed the epoxidation of alkenes with 30% aqueous $H_2O_2$ in high selectivity compared to the ring opening products observed in homogeneous media.**

Simplification of catalyst recovery procedures by immobilizing selective and highly active homogeneous catalysts on a insoluble support is an ongoing endeavour designed to increase the use of catalysis in industrial settings.[1] The most common method of covalent attachment of a catalyst to an insoluble support usually yields a catalytic assembly of reduced selectivity and activity. The method of supported liquid or aqueous phase catalysis, where a film of solvent containing the catalyst is adsorbed on an insoluble particle such as silica, is an important improvement because reactions occur at a liquid–liquid interface, somewhat reducing the mass transfer limitations.[2] However, leaching of the solvent and thus catalyst still remains an important concern in such systems. We recently improved this technique of supported liquid phase catalysis by covalently attaching polyethers to a silicate particle using sol-gel procedures.[3] The attached polyether phase acted as the solvent for the catalyst (polyoxometalate) and allowed contact with one or more substrate phases.

Here we extend this concept on the use of silica with polyether tethers to a different catalytic oxidation reaction, the supported methyltrioxorhenium (MTO) catalysed epoxidation of alkenes with 30% aqueous $H_2O_2$. MTO has been shown to be an excellent epoxidation catalyst, with the shortcoming that the use of the necessary protic solvent leads to ring-opened products rather than epoxides.[4] Here we show that the use of methyltrioxorhenium supported on silica tethered with polyethers gives epoxides in high yields by tailoring the hydrophilic–hydrophobic balance of the polyether phase. As represented in the schematic drawing, (Scheme 1), the hydrophobic poly(propylene oxide) (PPO) units may increase the solubility of the alkene substrate in the solvent anchored phase, whereas the poly(ethylene oxide) (PEO) units serve to dissolve the aqueous hydrogen peroxide oxidant and stabilize the peroxo intermediate responsible for catalytic activity.[5]

**Scheme 1**

The silica particles with tethered polyether units were prepared in two steps. First, the relevant trialkoxysilanes **1**, with the appropriate polyethers groups, $(MeO)_3SiC_6H_4$-$CH_2O(CH_2CHRO)_nMe$ (R = H, Me), were prepared.† Second, the funtionalized xerogels were prepared by copolymerizing the appropriate amount of the monomer **1** and the non-functionalized monomer, $Si(OEt)_4$.‡ Typical epoxidation reactions were carried out by mixing functionalized silica, 30% $H_2O_2$ and MTO in small magnetically stirred vials. After stirring vigorously for about 5 min, the alkene substrates were added. The reactions were quenched by adding either $CH_2Cl_2$ or $Et_2O$ to extract the substrate and products for GC and GC–MS analysis.

In order to probe the effect of the polyether tethers in the heterogeneous assembly, cyclohexene (which is known[4] to give *trans*-cyclohexane-1,2-diol as product in the homogenous aqueous–*tert*-butyl alcohol solvent system) was selected as model substrate in the current catalytic system. The results as presented in Table 1 show that MTO supported on non-functionalized silica demonstrated essentially no catalytic activity. MTO immobilized on polyether tethered silica showed several trends. Functionalization with only PEO showed increased conversion as a function of the amount of PEO, but low selectivities to epoxide. The low selectivity can be explained by the highly hydrophilic nature of the only-PEO assembly, which is similar to the homogeneous system. Use of only small amounts of PPO gave high yields but only moderate selectivities. Increased amounts of PPO without PEO reduced the conversion considerably, apparently due to the lower accessibility of the oxidant to the catalytic site. A balanced amount of both PEO and PPO gave the best results with almost quantitative (99.9%) conversion and high (86.4%) epoxide selectivity. The PPO is clearly shown to contribute to the

**Table 1** Epoxidation of cyclohexene catalysed by methyltrioxorhenium supported on polyether tethered silica[a]

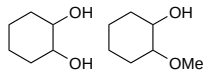
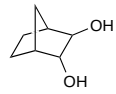
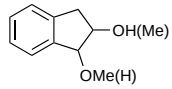
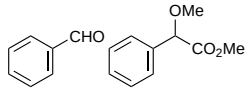
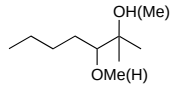
[a] Reaction conditions: cyclohexene (1 mmol), 30% $H_2O_2$ (2 mmol), MTO (0.02 mmol) and polyether tethered silica (100 mg), room temp. 3 h. [b] The amount of polyether is the mol% of the relevant monomer used in the preparation of the silica, as described in footnote.‡ [c] Selectivity to the epoxide product; the only other product was *trans*-cyclohexane-1,2-diol. [d] Non-functionalized silica prepared by the sol-gel method.











selectivity of the reaction whereas the PEO contributes to the conversion and thus a careful balance of hydrophobic–hydrophilic characteristics§ of a silica particle can be uniquely used to maximize both the activity and selectivity of a supported catalyst. Although the effect of the polyether composition on activity and selectivity clearly indicated that the reaction was occuring in the polyether phase, additional verification showing that MTO was not dissolved in either of the reactants was possible by mixing 10% PEO, 10% PPO-$SiO_2$, 30% $H_2O_2$ and MTO for 10 min. After filtration, the filtrate (30% $H_2O_2$) showed no catalytic activity upon addition of cyclohexene. Similarly, mixing 10% PEO, 10% PPO-$SiO_2$, cyclohexene and MTO for 10 min, followed by filtration and addition of 30% $H_2O_2$ to the filtrate, showed no cyclohexene conversion.

In order to demonstrate the generality of this reaction, the oxidation of various other alkenes using the optimal heterogeneous system (MTO on 10% PEO–10% PPO-$SiO_2$) was compared to a typical homogeneous reaction using MeOH as solvent, (Table 2). Compared to the homogeneous standard, where quantitative conversions were the norm, the polyether tethered silica support showed somewhat lower activity even with more oxidant (three-fold excess) but very considerable selectivity to the epoxide, even in the case of indene whose epoxide is believed unstable under acidic conditions.[6] Oxidation of styrene also yielded benzaldehyde, the product of carbon–carbon bond cleavage. The homogeneous reaction system gave almost exclusively the ring opened products which were identified by GC–MS, except in the case of norbornene where epoxide was also observed. Finally, initial experiments were carried out to test the possibility of catalyst recycling. At the end of each reaction period the catalytic assembly was filtered under vacuum and washed with 1 ml of cold $Et_2O$, followed by addition of more substrate and oxidant. For four cycles the catalytic activity (85 ± 7 mol% conversion) and selectivity (89 ± 6 mol% epoxide) remained high, although there were rather considerable fluctuations. From the fifth cycle onward, both conversion and selectivity dropped considerably. Analysis by GC–MS of the reaction mixture after each cycle showed some polyether remnants, indicating that deactivation was by polyether detachment from the silica particle.

MTO supported on silica particles with polyether tethers is an effective catalytic assembly for the epoxidation of alkenes with $H_2O_2$ under environmentally benign conditions, *i.e.* no organic solvent. The ability to design and control the hydrophobic–hydrophilic balance of the attached polyether phase holds much promise for the development of new heterogeneous catalytic systems, especially where reactants are immiscible.

This research was supported by grant No. 95-00076 from the United States-Israel Binational Science Foundation (BSF), Jerusalem, Israel.

† $(MeO)_3SiC_6H_4CH_2Cl$ (50 mmol) was reacted with poly(ethylene glycol) monomethyl ether (PEGME, MW = 350) (50 mmol) or poly(propylene glycol) monomethyl ether (PPGME, MW = 200) (50 mmol) in acetone (200 ml) in the presence of solid $K_2CO_3$ (250 mmol) at reflux for 18 h to form $(MeO)_3SiC_6H_4CH_2O(CH_2CHRO)Me$ **1a** (R = H) and **1b** (R = Me).

‡ A mixture of **1** and $Si(OEt)_4$ (total 10 mmol), water (100 mmol) and dibutyltin dilaurate (0.1 mmol) (polymerization catalyst) in acetone (40 ml) were heated at 60 °C for 3 h. The solution was kept in a beaker and the volatile organics were left to slowly evaporate over a period of two days at ambient temperature. The functionalized silica was then carefully washed twice with water and EtOH and dried *in vacuo*. Polymerization was quantitative (> 99%) as determined by microanalysis. The polymerization technique used is generally assumed to lead to a random (mixed) polymer (ref. 7). A detailed kinetic investigation of the rates of hydrolysis and self- and cross-condensation of **1** and $Si(OEt)_4$ would be required to verify this assumption and to exclude the formation of PEO and/or PPO enriched domains.

§ A wetting angle of 55° was measured for a 10% PEO–10% PPO-$SiO_2$ film. This wetting angle is indeed intermediate between hydrophilic (15–25°) and hydrophobic (80–100°).

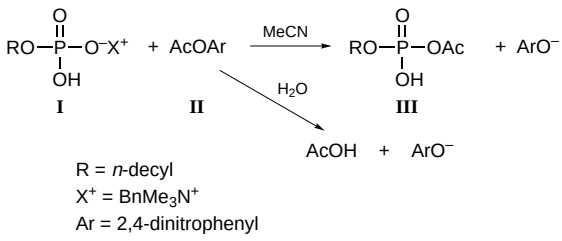
# Acyl transfer reactions in dipolar aprotic medium: desolvated phosphate ion as acyl acceptor in the formation of energy-rich phosphate compounds

**Vanderlei Gageiro Machado and Faruk Nome***



*Departamento de Química, Universidade Federal de Santa Catarina, Florianópolis, SC, 88040-900, Brazil*

**The reaction between an acetate ester and *n*-decylphosphate ions in dipolar aprotic medium provides a system which allows the facile formation of acetyl phosphate derivatives, by means of restricting the quantities of water available in the reacting system; the role of water is explained in terms of the inhibition of the nucleophilic attack of the phosphate group, which is disfavoured by its presence.**

In order to promote the interconversion of different forms of energy, cells use phosphate compounds such as ATP and acetyl phosphate as the currency of energy exchange.[1] The synthesis and the hydrolysis of these compounds are catalysed by enzymes able to perform energy transduction. During the last two decades, different laboratories have dedicated their efforts to the elucidation of this fascinating puzzle.[2–5] Lehn and co-workers[4] have demonstrated that a variety of macrocyclic polyamines mediate the phosphorylation of phosphate ion, *via* an energy-rich intermediate phosphoramidate, generating energy-rich compounds such as ATP and pyrophosphate. This model system was successful as a 'mimick' of enzymes responsible for the phosphorylation of many compounds. In all cases, the enzymatic models needed, in order to make the phosphoryl transfer, an energy-rich compound to phosphorylate the macrocycle.

Here we show that a dipolar aprotic medium allows the easy reaction of organic phosphate ions with an acetate ester to generate the corresponding energy-rich acetyl phosphate compound. Specifically, we found that addition of benzyltrimethylammonium *n*-decylphosphate **I**, in anhydrous MeCN, enables its facile reaction with 2,4-dinitrophenyl acetate **II** by nucleophilic addition to the carbonyl group. Compound **I** was used in order to increase the solubility of the organic phosphate to concentrations adequate for the acquisition of kinetic and spectroscopic data. In our experiment, the solubility limit of the salt in MeCN was *ca.* $1.2 \times 10^{-3}$ M. Acetyl *n*-decylphosphate **III** is then produced, and 2,4-dinitrophenolate is liberated. In aqueous solution the hydrolysis reaction is dominant, forming acetate and 2,4-dinitrophenolate ions as products (see Scheme 1).

The rate of acetyl transfer was determined at 40 °C by monitoring the formation of the 2,4-dinitrophenolate at 363 nm. The reaction is first-order in each of the reactants and proceeds quantitatively. The linear dependence of rate constants *vs.* the concentration of *n*-decylphosphate ions is maintained up to the solubility limit of the salt **I** in MeCN or MeCN–water mixtures (*ca.* $2 \times 10^{-3}$ M in MeCN containing 1% water). The second-order rate constant in anhydrous MeCN is $k_2 = 13.2$ l mol$^{-1}$ s$^{-1}$. The formation of **III** was followed by observation of the carbonyl region in the infrared spectra in MeCN, using a NaCl cell with a path length of 0.5 mm. While the peak corresponding to the ester carbonyl at 1786 cm$^{-1}$ disappears, a new band appears at 1754 cm$^{-1}$, a reasonable position for the carbonyl stretching vibration of **III**.[6] The product could be also trapped and quantified by an adaptation of the method of Lipmann and Tuttle.[7]†

R = *n*-decyl
$X^+ = BnMe_3N^+$
Ar = 2,4-dinitrophenyl

**Scheme 1**

The rate of the reaction under consideration shows a dramatic dependence on the water content of the aprotic solvent (Fig. 1). We observe a decrease of 68 times the value of the rate constant for the reaction when 6% of water is added to anhydrous MeCN ($[H_2O] = 2.65$ M), with a corresponding increase in the half-life of the reaction from 46 to 3136 s. Surprisingly, addition of 10% water in dry MeCN provokes a 660-fold inhibition. These results clearly show the primordial role of water in this particular acyl transfer reaction.

To verify the influence of water in the course of the reaction between the ester and the *n*-decylphosphate, the yields of the different products described in Scheme 1 were determined (Fig. 2). The data clearly demonstrates the strong influence of water in the course of the reaction under investigation. A reduction in yield of 50% of the acetyl phosphate is triggered by addition of 5% water to MeCN. Upon addition of 30% water, acetyl phosphate production could not be detected either by IR spectroscopy or by the adaptation of Lipmann's method.[7]† In this particular case, the only products are those resulting from ester hydrolysis. Clearly, for a mild, rapid and high yielding synthesis of energy-rich compounds such as **III**, an anhydrous microenvironment is needed.

Recently, de Meis has suggested[5] that energy-rich phosphate compounds can be synthesized on the enzymatic surface without the need of energy at a hydrophobic enzyme site. Indeed, the binding-change mechanism that is extensively used to describe ATP synthesis by ATP synthases[2] indicates that

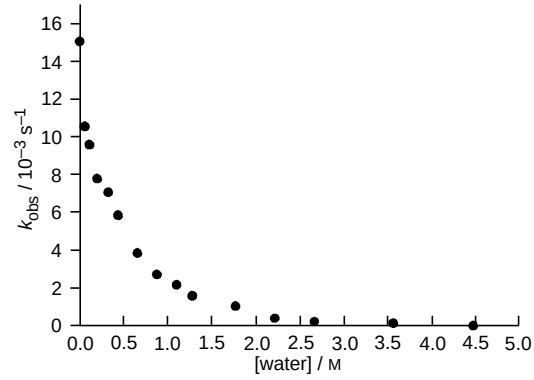


**Fig. 1** Effect of water on the first order rate constant for the reaction of 2,4-dinitrophenyl acetate ($3.0 \times 10^{-5}$ M) with benzyltrimethylammonium *n*-decylphosphate ($1.57 \times 10^{-3}$ M) in MeCN. The value corresponding to anhydrous MeCN was calculated using the experimental second-order rate constant.

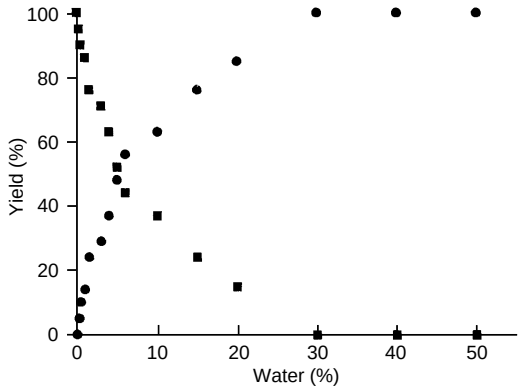

**Fig. 2** Effect of water on the yields of (■) acetyl phosphate and (●) hydrolysed ester for the reaction between 2,4-dinitrophenyl acetate and benzyltrimethylammonium *n*-decylphosphate in MeCN

ATP synthesis occurs spontaneously at the catalytic sites, and energy is needed only to release the ATP produced.

Analysis of the experimental results described above, although for a model system, is relevant in terms of the chemistry of living systems. The fundamental reason why water promotes the inhibition of the acyl transfer reaction is probably the fact that solvation of the phosphate anion decreases the nucleophilicity of this compound, allowing the simultaneous appearance of the ability of this compound to act as a general base in hydrolytic reactions.[8,9] An alternative explanation involving slow nucleophilic attack followed by relatively fast hydrolysis of the acyl phosphate was experimentally excluded, since **III** was stable under our experimental conditions. Indeed, the hydrolysis of acyl phosphates has been proven to be independent of solvent composition in water–MeCN mixtures, with a rate constant of *ca.* $7.3 \times 10^{-5}$ $s^{-1}$.[10] Thus, the predominance of the hydrolysis, or the formation, of a particular energy-rich compound is intrinsically related to the environment in which the reaction is taking place. Accordingly, the reversibility of these particular reactions should be achievable in normal solutions, under appropriate conditions, such as those described in this work. By analogy, if we are allowed to extrapolate these conclusions to enzyme catalysed reactions, a hydrolytic reaction which is spontaneous in aqueous media may well not be so on the surface of the enzyme (*e.g.* in a hydrophobic pocket).

The experimental fact that the reaction in anhydrous MeCN differs significantly from that in the presence of even small amounts of water, and completely from that observed in aqueous systems, shows, in our understanding, that the study of reactions of biochemical importance in purely aqueous systems may not adequately contribute to the understanding of enzyme catalysis. For reactions occurring in the hydrophobic pocket of a particular enzyme, water is certainly not an adequate standard state for the comparison of equilibrium and/or rate constants.[6] A typical example of this is that ionic intermediates are sometimes favoured in reactions occurring in polar solvents, but are considered to be of high energy in non-polar systems.[8,11] It may well be that this handling of the equilibrium thermodynamics of reactions is one of the factors that enzymes and nature use to promote the synthesis of energy-rich compounds.

In conclusion, we believe that the role of water, and particularly of its absence, in biochemically important events is a question still little explored. The present model represents, to the best of our knowledge, the first organic system that resulted in the facile formation of energy-rich compounds and, we hope, this fact will shed some light on the operational mode of some of the enzymes responsible for energy transduction. It provides an example that allows us to rationalize how water (or its absence) in the microenvironment of the active-site of an enzyme can determine both rate accelerations and changes in equilibrium constants.

The authors are grateful to CNPq and PADCT/FINEP for financial support of this work.

† The yield of acetyl phosphate was determined by mixing compound **I** (46.8 μmol) with 2,4-dinitrophenyl acetate (11.7 μmol) in MeCN (25 ml), with a known water concentration. The reaction mixture was then stirred at 25 °C in a stoppered flask until completion of the reaction. The solvent was removed and water (1 ml) was added to the residue. This aqueous solution was added to a mixture of aqueous hydroxylamine (1 ml) [all solutions were identical with those originally described by Lipmann and Tuttle (ref. 7)] and acetate buffer (1 ml), and the mixture was left to stand for 10 min. Then aqueous HCl (1 ml) and aqueous ferric chloride (1 ml) was added. The solution was filtered and the UV–VIS spectrum of the purple solution, caused by complexation of the quantitatively formed hydroxamic acid with $Fe^{3+}$, was determined at 500 nm ($\varepsilon$ = 925 $cm^{-1}$ $M^{-1}$).

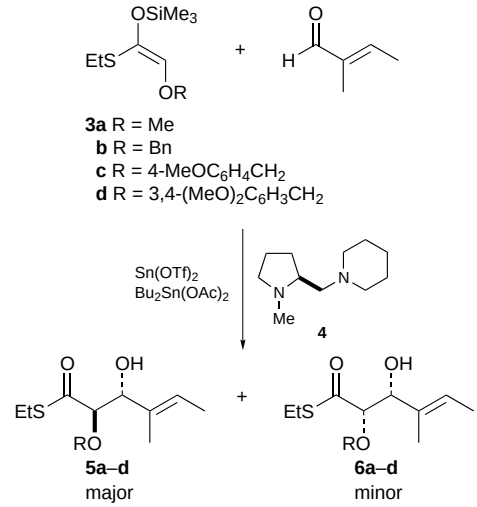
# Enhanced reactivity and *anti* selectivity in the asymmetric Lewis acid-mediated Mukaiyama aldol reaction of α-alkoxythiolketene acetals with α,β-disubstituted enals: synthesis of the C26–C33 segment of rapamycin

**James D. White* and Jörg Deerberg**

*Department of Chemistry, Oregon State University, Corvallis, OR 97331-4003, USA*



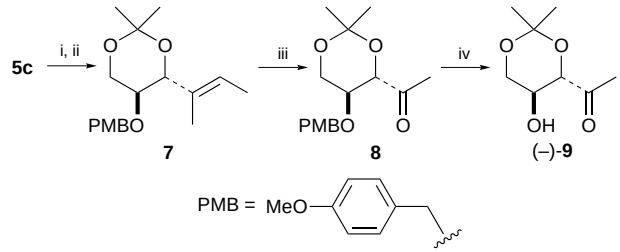
**The tin(II)-mediated reaction of α-alkoxythiolketene acetals 3a–d with *trans*-2-methylbut-2-enal and aldehyde 10 was found to give enhanced reactivity and high *anti* selectivity in the glycolate product when an α-benzyloxy substituent was present in 3, a finding which was applied to the synthesis of a segment (C26–C33) of the immunosuppressant rapamycin.**

In the course of our studies directed towards a total synthesis of the immunosuppressive agent rapamycin **1**,[1] a subunit was

required which contained functionality suitable for its incorporation as the C26–C33 segment of the macrolide. A difficulty associated with preparing such a fragment resides in controlling relative and absolute configuration of the vicinal *anti* diol moiety at C27–C28. In an attempt to solve this problem in the context of synthesis of a segment **2** required for rapamycin, we were attracted by the chiral Lewis acid-mediated *anti* glycolate aldolization methodology of Mukaiyama[2] and Fukuyama,[3] in which α-alkoxythiolketene acetals were reacted with aldehydes in the presence of tin(II) trifluoromethanesulfonate (triflate) and a proline-derived diamine ligand.[4] We now report that this methodology is readily extended to sterically demanding α,β-disubstituted enals, that both the reactivity and diastereoselectivity of the aldol process are controlled by the ketene acetal α-alkoxy substituent, and that appropriate selection of the *O*-protecting group of the ketene acetal allows differentiation of the adjacent oxygen functions in the aldol product.

Our initial studies were carried out with *trans*-2-methylbut-2-enal and the four α-alkoxythiolketene acetals **3a–d** (Scheme 1). The latter were synthesized from the corresponding thiol esters† by low temperature silylation [lithium tetramethylpiperidine (LTMP), −100 °C, $Me_3SiCl$] and were obtained predominantly as the (*Z*) isomer in each case. The reaction of ketene

**Scheme 1**



acetals **3a–d** with *trans*-2-methylbut-2-enal in the presence of (*S*)-1-methyl-2-[(1-piperidyl)methyl]pyrrolidine **4** under the conditions specified by Mukaiyama[2] gave aldol adducts **5** and **6** as a mixture of diastereoisomers‡ (Table 1). The *anti* adducts **5a–d** were found to be the major stereoisomers in each case;§ their optical purity was determined by chiral HPLC analysis¶ and by comparison with diastereoisomerically pure racemates synthesized independently. Absolute configuration was assigned in the case of **5c** by correlation with a substance of known stereochemistry (Scheme 2). Thus, reduction of thiol ester **5c** to the corresponding 1,3-diol, followed by acetonide formation, yielded **7** which after ozonolysis gave ketone **8**. Removal of the *p*-methoxybenzyl ether afforded (−)-**9** [$[\alpha]_D^{23}$ −24.8 (*c* 1.0, $CH_2Cl_2$)] which exhibited spectral data and analytical properties identical to those of its antipode (+)-**9** [$[\alpha]_D^{23}$ +23.6 (*c* 1.0, $CH_2Cl_2$)‖ prepared from D-glucose.[5]

The results in Table 1 indicate that an increase in both chemical yield *and* diastereoselectivity is observed in the aldol reaction of Scheme 1 when an electron-releasing α-alkoxy

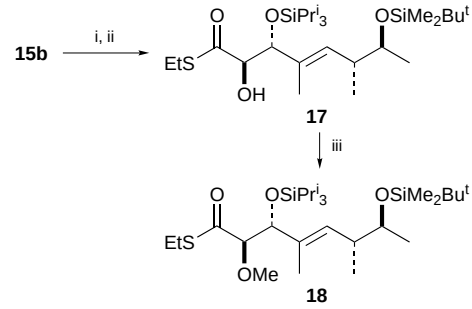
**Scheme 2** *Reagents and conditions*: i, $LiAlH_4$, THF, 0 °C → room temp., 3 h; ii, $Me_2C(OMe)_2$, TsOH, room temp., 2 h, 80%; iii, $O_3$, MeOH–pyridine (cat), −78 °C, 4 min, then $Me_2S$, 95%; iv, 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ): $CH_2Cl_2$–$H_2O$, 48%

**Scheme 3** *Reagents and conditions*: i, $Bu^tMe_2SiCl$, imidazole, $CH_2Cl_2$, room temp., 12 h; ii, $MgBr_2{\cdot}OEt_2$ (excess), $Et_2O$, 4 h, 93%; iii, $Pr_4NRuO_4$ (cat), 4-methylmorpholine *N*-oxide, $CH_2Cl_2$, room temp., 15 min, *ca*. 100%; iv, LDA, $Bu^tN{=}CHCH(Me)SiMe_3$ **14**, THF, −78 °C; v, $(HO_2C)_2$, $H_2O$; vi, $I_2$ (cat), $Bu^tNH_2$, hexane, 50 °C, 12 h, 62% from **13**; vii, **4**, $Sn(OTf)_2$, $Bu_2Sn(OAc)_2$, **3a**,**c**,**d**, $CH_2Cl_2$, −78 °C, 30–36 h



substituent such as 4-methoxybenzyl (PMB) or 3,4-dimethoxybenzyl (DMB) is present in the thiolketene acetal. Best results were obtained with DMB, whereas an α-methoxy substituent resulted in low diastereoselectivity and poor yield.

With this information in hand, our efforts focused upon α,β-unsaturated aldehyde **10** needed for synthesis of subunit **2**. Alcohol **11**, obtained from methyl (*R*)-3-hydroxy-2-methylpropionate,[6] was transformed to **12**[7] which was oxidized to aldehyde **13** with perruthenate.[8] Conversion of this labile substance to α,β-unsaturated aldehyde **10** was accomplished by the procedure of Corey *et al*.[9] in which condensation of **13** with the α-lithio derivative of imine **14** was followed by mild, acid-catalysed Peterson olefination. The initial *ca*. 2 : 1 mixture of (*E*) and (*Z*) isomers of enals was smoothly equilibrated to a > 99 : 1 ratio favouring (*E*) isomer **10** upon exposure to a catalytic quantity of iodine in warm hexane containing a trace (6 mol%) of *tert*-butylamine (Scheme 3).

**Table 2** Asymmetric Lewis acid-catalysed aldol reaction of **10** with α-alkoxythiolketene acetals

| Ketene acetal | Aldol Products (**15** and **16**) R | Yield (%) | *Anti* (**15**) : *syn*(**16**)[a] |
|---|---|---|---|
| **3a** | Me | 7 | 75 : 25 |
| **3c** | 4-$MeOC_6H_4CH_2$ | 54 | 90 : 10 |
| **3d** | 3,4-$(MeO)_2C_6H_3CH_2$ | 80 | 92 : 8 |

[a] See footnote §.

**Scheme 4** *Reagents and conditions*: i, $Pr^i_3SiOTf$, 2,6-lutidine, $CH_2Cl_2$, −40 → °C; ii, DDQ, $CH_2Cl_2$–$H_2O$, room temp., 1.5 h, 85% from **15b**; iii, $CH_2N_2$, $BF_3{\cdot}OEt_2$ (1 equiv.), $CH_2Cl_2$, 94%

The reaction of **10** with α-alkoxythiolketene acetals **3a**,**c**,**d** under the conditions employed with *trans*-2-methylout-2-enal yielded *anti* aldol products **15a**–**c** as the major diastereoisomers (Table 2). Again, PMB- and DMB-substituted ketene acetals **3c** and **3d** showed superior stereoselectivity, whereas α-methoxy derivative **3a** was virtually unreactive with **10**. Protection of **15b** as its triisopropylsilyl ether, followed by oxidative cleavage of the PMB ether,[10] gave **17** (Scheme 4), and treatment of the liberated alcohol with $CH_2N_2$ in $CH_2Cl_2$ containing $BF_3{\cdot}OEt_2$ furnished methyl ether **18**. This material now stands ready in conveniently protected form for connection at each terminus to other subunits required for the synthesis of **1**.

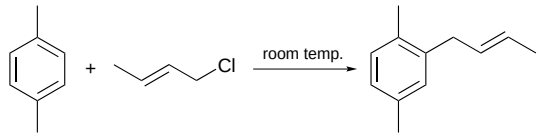
# Functional selectivity in Friedel–Crafts alkylations with allylic halides promoted by solid composite lead fluoride reagent

**Junko Ichihara***

*Institute of Scientific and Industrial Research, Osaka University, Mihogaoka, Ibaraki, Osaka 567, Japan*



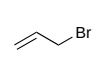
**The composite lead fluoride reagent prepared from $PbF_2$ and NaBr is a nonhygroscopic and efficient solid reagent for promoting Friedel–Crafts type reaction of aromatic compounds with allylic halides selectively to afford the monoallylated compounds.**

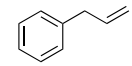
Friedel–Crafts type allylation of aromatic compounds using allylic alcohols or halides and Lewis acid catalysts has proved unsatisfactory, because the reaction occurs both at the double bond and at the allylic carbon to yield polyaryl-substituted alkanes.[1] The reactions with allylic halides liberates hydrogen halide, which further attacks the double bond of the products to induce the second reaction. Recently Kodomari *et al.* have reported successful selective monoallylation by using a combination of a solid acid and a solid base, $ZnCl_2$–$SiO_2$ and $K_2CO_3$–$Al_2O_3$.[2] The solid base operates as a scavenger of hydrogen halide liberated during the reaction and does not influence the catalytic activity of the solid Lewis acid because of the distance between both solid supported reagents. Solid acids such as acidic zeolites and clays has been applied to achieve functionally selective allylations with allylic alcohols.[3,4]

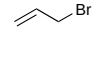
We have studied the use of synergistic interactions between diverse inorganic solid reagents for enhancing solid–liquid heterogeneous reactions with organic compounds dissolved in organic solvents. Recently we have observed that a combination of lead fluoride and a small amount of sodium bromide accelerates the fluorination of allylic and benzylic halides.[5,6] It was found that a new inorganic lead compound was formed from the solid reagents during the fluorination of organic halides, and that its formation process is associated with activation of the alkyl halides. This prompted us to examine it as a promoter for Friedel–Crafts alkylation reactions. Here we report that the composite lead fluoride reagent is a mild and efficient solid reagent for promotion of selective Friedel–Crafts type monoallylation when used in stoichiometric amounts.[7]

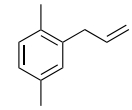
A composite lead fluoride reagent **A** ($Pb_3BrF_5$) was easily prepared by mixing aqueous NaBr and $PbF_2$ powder (3 equiv.).†

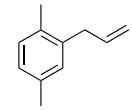
**Table 1** Friedel–Crafts allylation of *p*-xylene and 1-chlorobut-2-ene

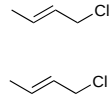


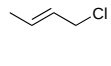


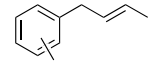


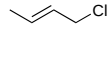


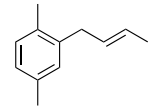


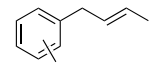


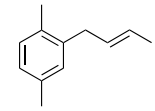


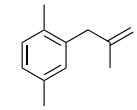


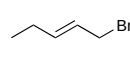


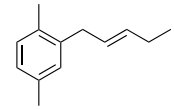


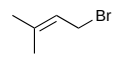


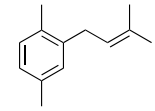












| Run | Reagent | GC Yield of **ArR** (%) (*t*/h)[a] | |
|---|---|---|---|
| 1 | Reagent **A** ($Pb_3BrF_5$) | 43 (1) | 86 (2) |
| 2 | Reagent **B** ($Pb_3ClF_5$) | 27 (1) | 80 (2) |
| 3 | NaBr–$PbF_2$ | 36 (1) | 48 (2) |
| 4 | $PbF_2$ | 0 (1) | 0 (2) |
| 5 | $TiCl_4$ (10 mol%) at 3–4 °C | 65 (1)[b] | |
| 6 | $ZnCl_2$–K10 (10 mol%) | 63 (0.5)[b] | |

[a] 1-Chlorobut-2-ene : *p*-Xylene: Reagent = 1 : *ca.* 20 : 0.6. [b] By-products were observed by GC.

Using the solid reagent **A**, an electrophilic substitution of *p*-xylene with 1-chlorobut-2-ene proceeded at room temp. to give the corresponding monosubstituted products (**ArR**) in 86% yield after 2 h (Table 1). The composite lead fluoride reagent **B**, prepared from NaCl and $PbF_2$, also showed high reactivity. Under the same reaction conditions, $PbF_2$ showed no reactivity, but a mixture of NaBr and $PbF_2$ promoted the reaction.

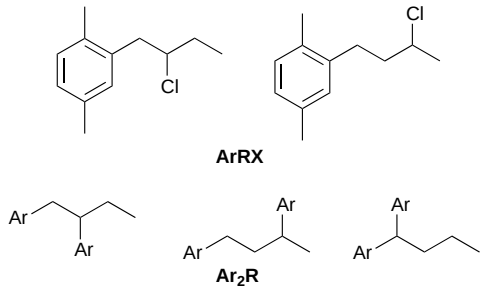


**Table 2** Friedel–Crafts allylation using $Pb_3BrF_5$ solid reagent[a]

| Allylic Halides | Aromatics | *T*/°C | *t*/h | Products | Yield (%) |
|---|---|---|---|---|---|
|  | Benzene | 60 | 2 |  | 94 |
|  | *p*-Xylene | 60 | 2 |  | 91 |
|  | *p*-Xylene | 60 | 10 |  | 91 |
|  | Benzene | room temp. | 3 |  | 45[b] |
|  | Toluene | room temp. | 2 |  | 99[c,d] |
|  | *p*-Xylene | room temp. | 2 |  | 77 |
|  | Toluene | room temp. | 2 |  | 85[d] |
|  | *p*-Xylene | room temp. | 2 |  | 77 |
|  | *p*-Xylene | room temp. | 48 |  | 87[c] |
|  | *p*-Xylene | room temp. | 2 |  | 93[c] |
|  | *p*-Xylene | room temp. | 1 |  | 70[b,c] |

[a] Alkyl halide : aromatic $Pb_3BrF_5$ = 1 : *ca.* 20 : 0.5. [b] Alkyl halide : aromatic : $Pb_3BrF_5$ = 1 : 140 : 1. [c] Isolated yields. The others are GC yields. [d] *opm*-isomer ratio = 1 : 1 : 0.1, determined by $^1H$ NMR spectroscopy.

Accordingly, in the latter case the reagent **A** or **B**, formed in the course of the reaction, was considered to participate in the reaction.

Catalytic activities of $TiCl_4$ and $ZnCl_2$–Montmollironite K-10 ($ZnCl_2$–K-10), well-known as mild Lewis acid catalysts, were compared with those of the lead reagents in the reaction.[8,9]‡ These catalysts showed higher reactivities but gave considerable amounts of by-products. In the presence of 10 mol% of $ZnCl_2$–K-10, a 63% yield of the monoallylated product **ArR** and a 24% yield of its hydrogen chloride adduct (**ArRX**) were formed as major products, with a 2% yield of diaryl substituted alkanes ($\mathbf{Ar_2R}$). Kodomari *et al.* have reported that **ArRX**- and $\mathbf{Ar_2R}$-type products are mainly formed in the reaction of benzene and allyl chloride with silica-supported $ZnCl_2$. On the contrary, in the case of our reagent **A** such by-products were scarcely detected by GC, and the desired product **ArR** was selectively formed and maintained intact in the reaction mixture even after prelonged. Thus, the reagent was found to have functional selectivity, in that it operates on the allylic carbon rather than on the double bond. The selective allylation occurs because the reagent behaves as both the Lewis acidic catalyst and a trap for the liberated halide, *via* exchange with fluoride.

The reaction required at least stoichiometric amounts of the reagent. It was shown by powder X-ray diffraction analysis that the reagent **A** is converted to PbClF during the reaction.

Table 2 shows typical examples for some allylic halides. In all cases the heterogeneous reaction of aromatic compounds and allylic halides using the $Pb_3BrF_5$ solid reagent proceeded smoothly under mild reaction conditions and the corresponding monoallylated compounds were obtained in good to excellent yields. The allylation of *p*-xylene by the more reactive 1-chloro-3-methylbut-2-ene was also performed without consecutive cyclization at C–C double bond. Further, our allylation method can be performed under the atmosphere, and requires simple isolation procedures, since the solid reagent is nonhygroscopic and easy to handle.

In conclusion, composite lead fluoride reagents were found to promote Friedel–Crafts allylation selectively and efficiently, thus demonstrating that they are a new and unique type of solid reagent exhibiting mild Lewis acidity and halide capture abilities.

† Powder X-ray diffraction analysis of the reagent **A** showed not a mixture of the known lead compounds $PbF_2$, PbBrF or $PbBr_2$, but the formation of a new lead compound. It was determined by X-ray fluorescence analysis that the reagent was composed of Pb, Br and F in 1.0 : 0.3 : 1.8 molar ratio. Therefore, the reagent **A** has the formula $Pb_3BrF_5$.

‡ $ZnCl_2$–K10 purchased from Fluka was used.

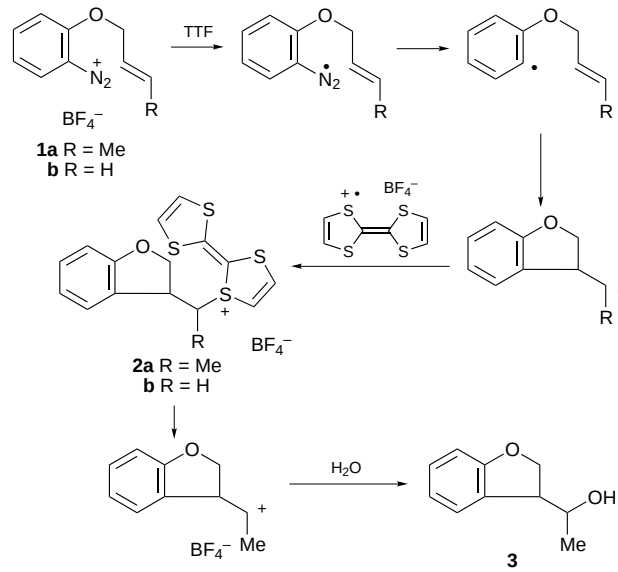
# Unprecedented electrophilic behaviour of tetrathiafulvalenium salts

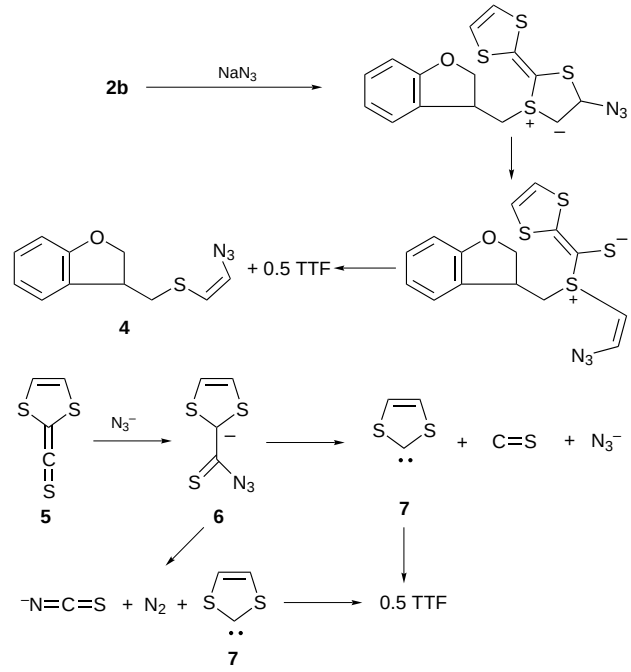
**Owen Callaghan, Xavier Franck and John A. Murphy***

*Department of Pure and Applied Chemistry, The University of Strathclyde, 295 Cathedral Street, Glasgow, UK G1 1XL*



**Primary tetrathiafulvalenium salts display a diverse and unprecedented reactivity towards nucleophiles.**

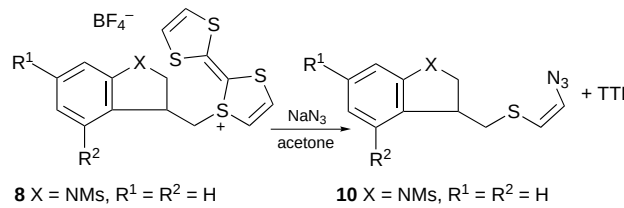
Tetrathiafulvalene (TTF) and its derivatives have attracted widespread interest in the preparation of novel materials.[1] Recently, the synthetic value of TTF has become apparent as a result of its catalysis of 'radical-polar crossover[2] chemistry'. This leads to the formation of tetrathiafulvalenium salts **2** (Scheme 1) which have been isolated. In appropriate cases, *e.g.* **2a**, these compounds undergo facile $S_N1$ substitution at room temperature by such nucleophiles as water, alcohols and MeCN. Since this happens *in situ*, TTF is regenerated and so functions as a catalyst. The catalyst is effective down to a concentration of *ca*. 5 mol% but, below this level incomplete conversions are seen. It is clear that the catalyst is slowly destroyed during such reactions.



One of the goals for the future of this research is to develop catalysts with greater efficiency, *i.e.* with greater turnover numbers. To achieve this, it is necessary to develop an understanding of what processes other than substitution can occur with TTF salts. In the case of salts such as **2a**, these processes can only compete poorly with the substitution chemistry. This means that side-products are formed in very small amounts in such cases, and hence it is difficult to determine the nature of the side-reactions which ultimately limit the catalytic life of TTF.

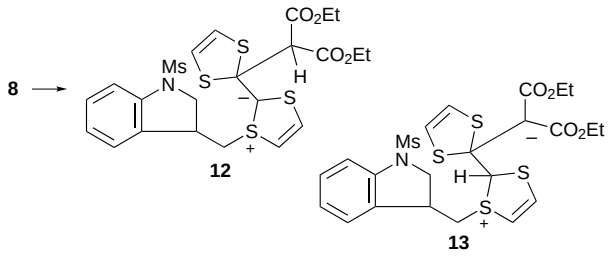
A logical way to determine the nature of side-reactions would be to study TTF salts where $S_N1$ substitution reactions are inhibited. Alternative reactions observed under such conditions then provide useful information on potential side-reactions in normal radical-polar reactions. We have previously described[1] that when the TTF moiety is attached to a primary carbon, as in **2b**, no substitution was observed. It is totally reasonable that substrates such as **2b** should not undergo $S_N1$ substitution, and we assumed that the mildness of the nucleophiles rendered any alternative reactions too slow to observe. We now report the results of exposing primary tetrathiafulvalenium salts to various nucleophiles.

The salt **2b** was subjected to attack by sodium azide in acetone (Scheme 2). The principal products from this reaction were tetrathiafulvalene (45%) and the vinyl azide **4** (46%). Although the appearance of tetrathiafulvalene initially suggested that an $S_N2$ substitution had occurred, this is clearly not the case. To explain the formation of these products, we propose the sequence of steps depicted in Scheme 2. The thioketene **5** has not been detected, but could suffer attack by azide, which in turn would lead to fragmentation to afford the stabilised carbene **7** together with either carbon monosulfide and azide ion or thiocyanate ion plus nitrogen gas. The carbene **7** is an established synthetic precursor of TTF in other contexts.[3]



**Scheme 1**

**Scheme 2**



To determine the generality of this process, two further primary tetrathiafulvalenium salts **8** and **9** were prepared and treated with sodium azide in acetone, producing the vinyl azides **10** (36%) and **11** (41%) respectively (Scheme 3). In both cases,

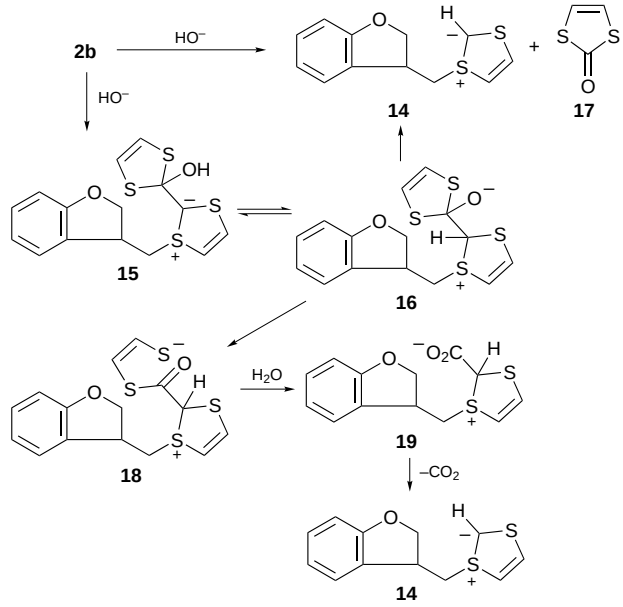
**8** X = NMs, $R^1 = R^2 = H$ **10** X = NMs, $R^1 = R^2 = H$

**9** X = O, $R^1 = CH_2OH$, $R^2 = OMe$ **11** X = O, $R^1 = CH_2OH$, $R^2 = OMe$

**Scheme 3**

**Scheme 4**

TTF was also produced (49 and 21%, respectively). Compound **11** was converted into its crystalline 3,5-dinitrobenzoate ester. However, attempts to produce a suitable crystal for X-ray structure determination were not successful.



The fragmentations seen above represent a previously unseen reaction of TTF salts. However, a completely different mode of reaction was seen when **2b** was treated with the anion of diethyl malonate (Scheme 4). In this case, the product **12** (38%) resulted from reaction at the central carbon–carbon double bond of the salt. The structure **12** rather than **13** is suggested for the product, since the $^1$H NMR spectrum exhibits a one-proton singlet at δ 3.1; this is in the expected region for a malonate proton but is considerably upfield of the expected shift for the proton in **13**. In this reaction, no attack on the peripheral double bonds of the TTF salt was observed. The reason for the complete change in selectivity for azide and malonate as nucleophiles is unknown.

Finally, the salt **2b** was treated with potassium hydroxide as base under different conditions (KOH in methanol, KOH in DMSO, KOH in acetone). In these cases, an alternative but very clean fragmentation to **14** (79% NMR yield, 66% isolated yield) was seen. Possible mechanisms for this reaction are proposed in Scheme 5. The base-sensitive dithiocarbonate **17** has not been detected, even when only 1 equiv. of base was used.

The ylide proton in **14** appeared as a singlet at $\delta$ 3.1, and this correlated with a methine carbon at $\delta_C$ 84. The chemical shift of both the carbon and the proton indicate that this structure is best viewed as an ylide *i.e.* featuring $^{-}$C–S$^{+}$ rather than a C=S π-bond. However, one interesting feature is that the $^1$H and $^{13}$C NMR spectra of **14** show no indications of the presence of diastereoisomers. This contrasts with **2b**, where signals due to diastereoisomers are clearly seen. This may indicate that inversion at the sulfonium sulfur in **14** occurs rapidly on the NMR timescale.[4]

In conclusion, primary tetrathiafulvalenium salts exhibit a rich and complex chemistry. The design of improved radical-polar crossover catalysts should take into account the observed nucleophilic attack on both the periphery and the internal alkene of these TTF salts.

These studies may also prove useful in materials chemistry.[1] A vast number of salts with intriguing electrical conductivity properties are known. These salts result from electron transfer from TTF to appropriate acceptor molecules, and hence the salts formally involve the TTF radical-cation, TTF$^{+\cdot}$. Although these

**Scheme 5**

cations are different from the alkylated TTF cations discussed here, it is clear that quenching of the conducting properties of these compounds could arise by attack by nucleophiles on the TTF nucleus.

We thank the EPSRC and Merck Ltd. for funding and the EPSRC National Mass Spectrometry Service Centre, Swansea, for mass spectra. We thank Dr Richard Hartley, University of Glasgow, for helpful discussions.

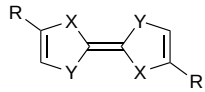
# New hybrid tetrachalcogenofulvalenes: diselenaditellurafulvalene and its dimethyl derivative

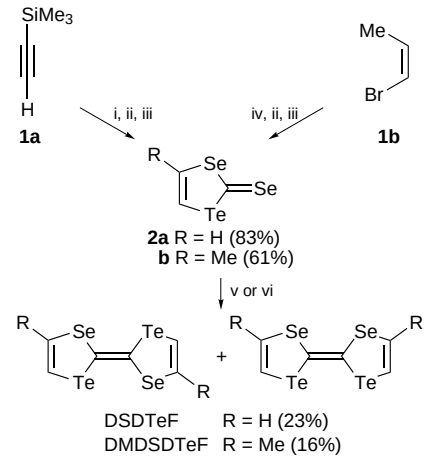
**Kazuo Takimiya, Atsushi Morikami, Yoshio Aso and Tetsuo Otsubo***



*Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Kagamiyama, Higashi-Hiroshima 739, Japan*

**A simple two-stage synthesis of hybrid tetrachalcogenofulvalenes containing two tellurium and two selenium atoms and the properties of their highly conductive TCNQ complexes are described.**

Since the discovery of the metallic conductivity of the TTF–TCNQ complex,[1] much effort has been devoted to the development of novel TTF-type electron donor molecules.[2] One of the successful structural modifications of TTF is to replace the skeletal sulfur atoms by selenium or tellurium atoms with large polalizabilities.[3] Thus the TCNQ complexes of tetra-



TTF X = S
TSF X = Se
TTeF X = Te

DSDTF X = S, Y = Se, R = H
DSDTeF X = Se, Y = Te, R = H
DMDSTeF X = Se, Y = Te, R = Me

selenafulvalene (TSF)[4] and tetratellurafulvalene (TTeF)[5] showed much higher conductivities (800 and 2200 S $cm^{-1}$, respectively) than TTF–TCNQ (500 S $cm^{-1}$). Of them, TTeF has attracted more attention, not only in that the complex has an extraordinarily high conductivity, but also in that it remains metallic down to a measurable low temperature (2 K). In contrast, the TTF–TCNQ and TSF–TCNQ complexes demonstrate a metal–insulator transition (Peierls transition) at 59 and 40 K, respectively, characteristic of a one-dimensional organic metal. In the TTeF–TCNQ complex, strong nonbonded tellurium–tellurium interactions are responsible for the suppression of the Peierls transition. Compared to TTF and TSF, a disadvantage of TTeF is its poor accessibility,[6] and the fact that only a limited number of its derivatives have been prepared.[7] Although a hybrid of TTF and TSF, diselenadithiafulvalene (DSDTF), has long been known,[8,9] no analogous tellurium-hybrid tetrachalcogenofulvalenes have been studied. Such hybrid compounds are expected not only to offer additional examples of tellurium-containing conductive complexes, but also to provide useful information on the contribution of the tellurium atoms to the design of organic metals. Here we describe the simple two-stage synthesis and properties of diselenaditellurafulvalene (DSDTeF) and its dimethyl derivative (DMDSDTeF) as the first tellurium-hybrid tetrachalcogenofulvalenes.

All the preceding TTeF donors were synthesized by a three-component reaction of 1,2-ditellurolate anion and tetrachloroethene. On the other hand, DSDTeF was obtained by the simple two-stage route as shown in Scheme 1, previously used for the syntheses of TSF[4] and DSDTF.[9] The precursor, 1,3-selenatellurole-2-selone **2a** was readily obtained in 83% yield by metallation of commercially available trimethylsilylacetylene **1a** with 1 equiv. of BuLi in THF at −78 °C followed by successive *in situ* treatment with 1 equiv. tellurium powder at −78 °C and then with 1 equiv. carbon diselenide at −90 °C, and finally quenching with water.[10] Subsequent triethyl phosphite-promoted homocoupling reaction of **2a** in refluxing toluene

**Scheme 1** *Reagent and conditions*: i, BuLi (1 equiv.), $Me_2NC_2H_4NMe_2$, THF, −78 °C, 0.5 h; ii, Te powder (1 equiv.), −78 °C then room temp., 3 h; iii, $CSe_2$ (1 equiv.), −90 °C, 3 min., then $H_2O$–THF (1 : 1, v/v); iv, BuLi (2 equiv.), THF, −78 °C, 2 h; v, excess $P(OEt)_3$, toluene, reflux, 2 h (for DSDTeF); vi, excess $P(OEt)_3$, benzene, reflux, 10 h (for DMDSDTeF)

afforded DSDTeF in 23% yield.† Similarly, 5-methyl-1,3-selenatellurole-2-selone **2b** was prepared in 61% yield from lithium 1-propynide, *in situ* generated by dehydrobromination of 1-bromopropene **1b** with BuLi, and subjected to a similar homocoupling reaction, producing DMDSDTeF in 16% yield.

The $^1H$ NMR spectrum of DSDTeF contains two sets of AB multiplets in a ratio of 4 : 6, indicating that it consists of a mixture of the *cis*- and *trans*- (*E* and *Z*) isomers, as seen in the case of DSDTF.[8,9] These geometrical isomers could not be separated by conventional purification methods. DMDSDTeF was also obtained as an isomeric mixture (3 : 7 ratio), but its recrystallization from benzene precipitated the pure main isomer. The cyclic voltammetry of DSDTeF showed two reversible one-electron oxidation waves at +0.43 and +0.73 V *vs.* Ag/AgCl; thus DSDTeF is a somewhat stronger electron donor than TSF ($E_{1/2}$ +0.49 and +0.78 V). Furthermore, DMDSDTeF has slightly lower oxidation potentials, as expected from the substituent effect of the methyl groups ($E_{1/2}$ +0.41 and +0.71 V).

Upon equimolar reaction of DSDTeF with TCNQ and $TCNQF_2$ in MeCN, crystalline 1 : 1 charge-transfer complexes were formed.‡ The room temperature conductivity of the DSDTeF–TCNQ complex measured on a single needle crystal was very high (1400 ± 300 S $cm^{-1}$, 10 samples), as was that of the DSDTeF–$TCNQF_2$ complex (900 ± 200 S $cm^{-1}$, 5 samples). DMDSDTeF also formed a conductive 1 : 1 complex with TCNQ ($\sigma_{rt}$ = 37 S $cm^{-1}$ measured on a compressed pellet). The conductivity of DSDTeF–TCNQ is just in between those of TSF–TCNQ and TTeF–TCNQ. In addition, variable temperature measurements demonstrate that, as shown in Fig. 1, the conductivity steadily increases to 2.5 times this value as the temperature drops to 4 K, and there is no metal-insulator transition as seen for TTeF–TCNQ.[5] These results clearly indicate that the two tellurium atoms of DSDTeF serve to

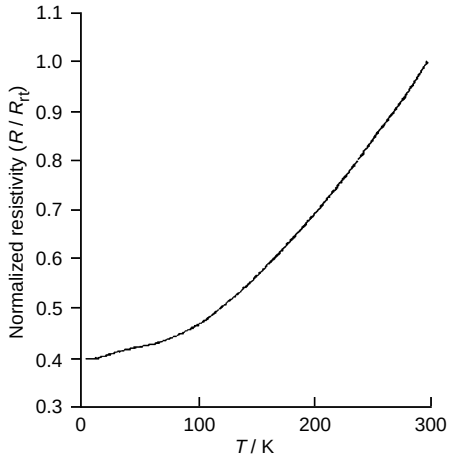


**Fig. 1** Electrical resistance of **1**–TCNQ

enhance intermolecular interactions enough not only to induce the high conduction of its charge-transfer complexes but also to suppress the Peierls transition. On considering their ready accessibility as compared to TTeF, the present tellurium-hybrid tetrachalcogenofulvalenes are electron donors of choice to study tellurium-containing organic metals.

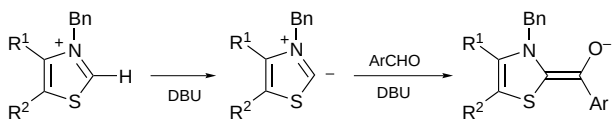
# Electron transfer properties of active aldehydes derived from thiamin coenzyme analogues



**Ikuo Nakanishi, Shinobu Itoh, Tomoyoshi Suenobu and Shunichi Fukuzumi***

*Department of Applied Chemistry, Faculty of Engineering, Osaka University, 2-1 Yamada-oka, Suita, Osaka 565, Japan*

**The rate constants and reorganization energies of electron transfer reactions between active aldehydes, derived from thiamin coenzyme analogues, and the corresponding one-electron oxidized radical species have been determined to demonstrate the efficient electron transfer properties of the active aldehydes.**

The conjugate base of 2-(α-hydroxyethyl)thiamin, a so called 'active aldehyde', derived from thiamin diphosphate coenzyme and pyruvate in the presence of a base is known to act as an efficient electron transfer catalyst which can mediate electron transport from pyruvate to various physiological electron acceptors. These include the lipoamide in pyruvate dehydrogenase multienzyme complex,[1] flavin adenine dinucleotide (FAD) in pyruvate oxidase[2] and the $Fe_4S_4$ cluster in pyruvate-ferredoxin oxidoreductase.[3] However, very little is known about the redox behaviour of active aldehydes because of their instability and tendency to undergo acyloin condensation with a second pyruvate molecule in the absence of oxidizing agents.[4] We report herein that active aldehyde **2**$^-$ derived from thiazolium salts **1a**–**c** and *o*-tolualdehyde in the presence of a strong base (Scheme 1) can be stabilized by the steric bulk of an *o*-methyl group and that the radical species produced by the one-electron oxidation of stabilized active aldehydes can be readily detected by EPR spectroscopy. The important electron transfer properties of the active aldehydes, such as reorganization energies of electron transfer reactions between the active aldehydes and the corresponding one-electron oxidized radical species, are determined by analysing linewidth variations in the EPR spectra.

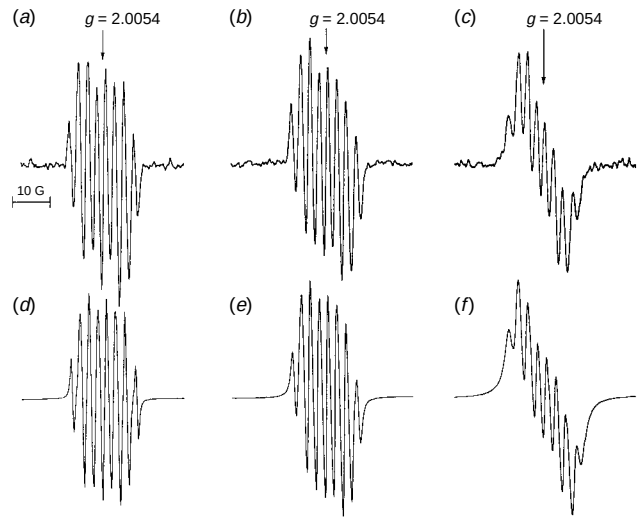
The active aldehyde **2a**$^-$ ($\lambda_{max}$ = 380 nm)[5] was prepared by the addition of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) to an MeCN solution of **1a** and *o*-tolualdehyde, keeping the ratio of the components constant (**1a** : *o*-tolualdehyde : DBU = 1 : 50 : 2). Then, the solution was partially electrolysed at −0.70 V *vs*. SCE, which is between the redox potentials for the **2a**$^-$/**2a**$^{\cdot}$ (−0.96 V *vs*. SCE in MeCN) and **2a**$^{\cdot}$/**2a**$^+$ couples (−0.52 V *vs*. SCE in MeCN),[6] to give the corresponding radical species **2a**$^{\cdot}$. EPR spectra for **2a**$^{\cdot}$ were obtained at different concentrations of **2a**$^-$, as shown in Fig. 1. The spectra of the radical species were persistent for several hours after the electrolysing potential had been switched off. The hyperfine splitting constants shown in Table 1 and the maximum slope linewidths ($\Delta H_{msl}$) were determined from a computer simulation of the EPR spectra (Fig. 1). The $\Delta H_{msl}$ value thus determined increases linearly with an increase in the concentration of **2a**$^-$, as shown in Fig. 2. Such linewidth variations of the EPR spectra can be used to investigate the rate processes involving the radical species.[7] The rate constants ($k_{et}$) of the electron transfer reactions between **2a**$^-$ and **2a**$^{\cdot}$ [eqn. (1)] were

**1a** $R^1$ = Me, $R^2$ = H
**b** $R^1$ = $R^2$ = Me
**c** $R^1$ = $R^2$ = H

Ar = *o*-$MeC_6H_4$

**2**$^-$

**Scheme 1**



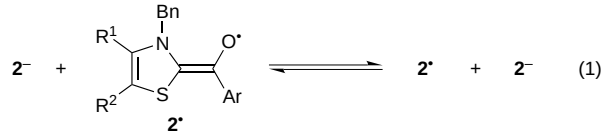


**Fig. 1** EPR spectra (X-band) of **2a**$^{\cdot}$ observed in the presence of different concentrations of **2a**$^-$: (*a*) 1.5 × $10^{-3}$, (*b*) 6.5 × $10^{-3}$ and (*c*) 3.0 × $10^{-2}$ M (in MeCN at 298 K, microwave frequency 9.21 GHz; modulation frequency 100 kHz; modulation amplitude 2.5 × $10^{-3}$ G; microwave power 10 mW; scan rate 19 G $min^{-1}$), and the corresponding computer simulation spectra using the hyperfine splitting values shown in Table 1 and linewidths of (*d*) 0.50, (*e*) 0.70 and (*f*) 1.55 G

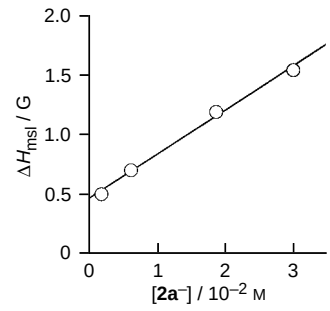

**Fig. 2** Plot of [**2a**$^-$] *vs*. $\Delta H_{msl}$ for EPR spectra of **2a**$^{\cdot}$ in MeCN at 298 K

determined using eqn. (2), where $\Delta H_{msl}$ and $\Delta H^0_{msl}$ are the

$$k_{et} = \frac{1.57 \times 10^7 (\Delta H_{msl} - \Delta H^0_{msl}}{(1 - P_i)[\mathbf{2}^-]} \quad (2)$$

maximum slope linewidth of the EPR spectra in the presence and absence of $\mathbf{2}^-$, respectively, and $P_i$ is a statistical factor which can be taken as nearly zero. The $k_{et}$ values for other active aldehydes $\mathbf{2b}^-$ and $\mathbf{2c}^-$ were determined in a similar manner and are listed in Table 1. The reorganization energies (λ) of the electron transfer reactions are obtained from the $k_{et}$ values using eqn. (3) ($Z = 10^{11}$ M$^{-1}$ s$^{-1}$),[8] and the λ values are also listed in

$$k_{et} = Z \exp(-\lambda/4kT) \quad (3)$$

Table 1. No prominent change in the $k_{et}$ or λ values is observed depending on the presence of methyl substituents on the thiazolium rings. The λ values are as small as those of fast electron transfer exchange systems such as *p*-benzoquinone/semiquinone radical anion (55 kJ mol$^{-1}$ in DMF) and naphthalene/radical anion of naphthalene (50 kJ mol$^{-1}$ in DMF) systems.[9]

The largely negative oxidation potentials of the active aldehydes derived from thiamin coenzyme analogues and the small reorganization energies for the electron transfer reactions indicate that the active aldehydes have strong electron donor abilities and that they are suitable for fast electron transfer systems where they can act as efficient electron transfer catalysts in electron transfer from pyruvate to physiological electron acceptors in enzymatic systems.

**Table 1** Hyperfine splitting values for $\mathbf{2}^{\cdot}$ produced by the one-electron oxidation of $\mathbf{2}^-$ and the observed rate constants ($k_{et}$) and the reorganization energies (λ) of the electron transfer reactions between $\mathbf{2}^-$ and $\mathbf{2}^{\cdot}$ in MeCN at 298 K[a]

| | Hyperfine splitting/G | | | | |
|---|---|---|---|---|---|
| Active aldehyde | $a_{N-}$ (N) | $a_{H-}$ (N–$CH_2$) | $a_{H-}$ (C–5) | $k_{et}/10^8$ M$^{-1}$ s$^{-1}$[b] | λ/kJ mol$^{-1}$[b] |

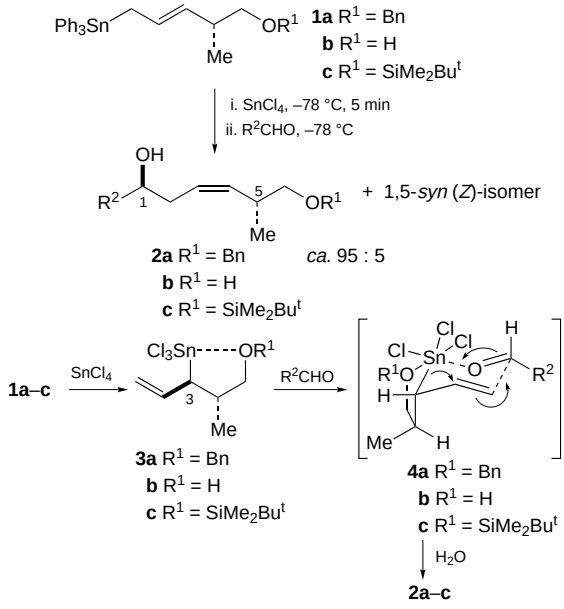
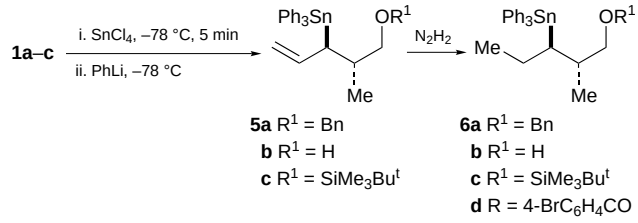
# On the mechanism of remote induction using (5-alkoxypent-2-enyl)stannanes: trapping the intermediate allyltin trihalides by phenyllithium and the X-ray crystal structure of [(2*SR*,3*RS*)-1-(4-bromobenzoyloxy)-2-methylpent-3-yl]-(triphenyl)stannane



**Roy L. Beddoes, Lindsay A. Hobson and Eric J. Thomas***

*The Department of Chemistry, The University of Manchester, Manchester, UK M13 9PL*



**Allyltin trihalides, intermediates in tin(IV) halide promoted reactions of 5-alkoxy-4-methylpent-2-enyl(triphenyl)-stannanes with aldehydes which proceed with 1,5-induction, have been trapped by phenyllithium to give [(3*RS*,4*SR*)-5-alkoxy-4-methylpent-1-en-3-yl](triphenyl)stannanes.**

Useful levels of 1,5-, 1,6- and 1,7-asymmetric induction have been found in reactions of (alkoxyalk-2-enyl)stannanes with aldehydes promoted by tin(IV) halides.[1] For example, treatment of [(4*R*)-5-benzyloxy-4-methylpent-2-enyl](triphenyl)stannane **1a** with tin(IV) chloride followed by addition of an aldehyde gives the 1,5-*anti* (*Z*)-alkenol **2a** (1,5-*anti* : 1,5-*syn* = 95 : 5) (Scheme 1).[2] To explain the stereo- and regio-selectivity of this reaction, it was suggested that transmetallation of the allylstannane **1a** is stereoselective and generates the allyltin trichloride **3a** in which the methyl and vinyl groups are *trans*-disposed about the oxastannane ring formed by coordination of the electron deficient tin by the oxygen of the benzyloxy group. This allytin trichloride then reacts with the aldehyde *via* the cyclic, chair-like transition structure **4a** in which the axial preference of the group next to tin determines the facial selectivity of the reaction with the aldehyde and introduces the double-bond into the product with (*Z*)-geometry.[1,3] Similar results were obtained using the 5-hydroxy- and 5-(*tert*-butyldimethylsilyloxy)-pent-2-enylstannanes **1b** and **1c** (1,5-*anti* : 1,5-*syn* = 80 : 20).[4] We now report evidence for the participation of allyltin trichlorides **3** in these reactions.

It was decided to attempt the conversion of the allyltin trichlorides into isolable products using a reaction which would

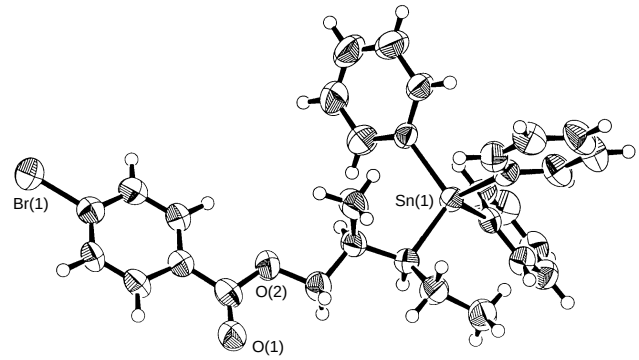
**Scheme 1**

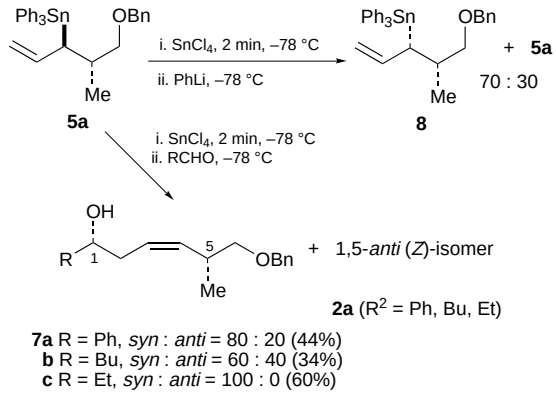
**Scheme 2**

retain their C(3)–Sn bonds. It was found that addition of an excess of phenyllithium to the reaction mixture formed by treatment of the racemic pentylstannanes **1a**–**c** with tin(IV) chloride for 5 min gave the pent-2-en-3-yl(triphenyl)stannanes **5a**–**c** with excellent stereoselectivity (*ca*. 95 : 5) (Scheme 2). These allylstannanes were isolated and characterised, and reduced using diimide to give the pentan-3-ylstannanes **6a**–**c** to avoid problems associated with 1,3-migration of the tin.[5]

The structure of the (hydroxypentan-3-yl)stannane **6b** was established by an X-ray crystal structure of its 4-bromobenzoate **6d**.† Fig. 1 shows a projection of a molecule of the 4-bromobenzoate which illustrates its stereochemistry. Benzylation and silylation of **6b** gave the benzyloxy- and silyloxypentan-3-ylstannanes **6a** and **6c**, confirming their structures.

The formation of the [(3*RS*,4*SR*)-pentenyl](triphenyl)stannanes **5a**–**c** in these reactions is consistent with stereoselective formation of the allyltin trichlorides **3a**–**c**, which are trapped by phenyllithium.‡§ To probe the mechanism of transmetallation, the [(3*RS*,4*SR*)-5-benzyloxypent-2-en-3-yl]stannane **5a** was treated with tin(IV) chloride followed by the addition of an aldehyde (Scheme 3). The 1,5-*syn* diastereoisomers **7a**–**c** were the major products from these reactions if 2 min was allowed between the addition of the tin(IV) chloride and addition of the aldehyde, although the yields were modest and the stereoselectivity varied with the aldehyde. The stereoselectivity was also dependent upon the time allowed between the addition of the tin(IV) chloride and addition of the aldehyde, *e.g.* with





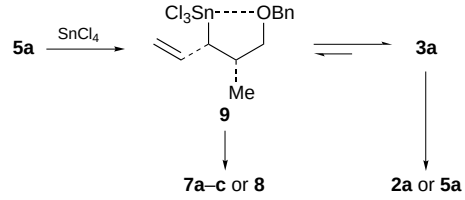


**Fig. 1** Projection of a molecule of the 4-bromobenzoate **6d** as determined by X-ray crystallography

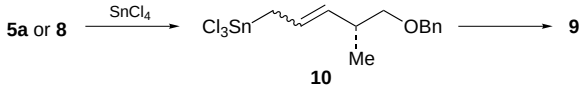
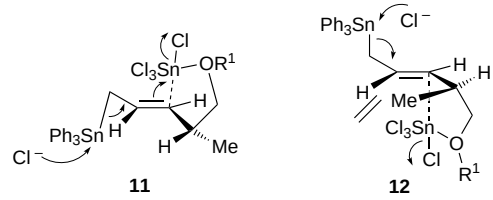
**Scheme 3**



benzaldehyde the stereoselectivity of 80 : 20 in favour of the 1,5-*syn* product **7a** was reduced to 60 : 40 if 5 min was left before addition of the aldehyde, and reversed to 80 : 20 in favour of the 1,5-*anti* product **2a** ($R^2$ = Ph; 40%) if the mixture was left for 10 min before the addition of the aldehyde. Addition of phenyllithium to the allyltin trichloride generated by transmetallation of the 5-benzyloxypentenylstannane **5a** for 2 min gave the (3*RS*,4*RS*)-5-benzyloxypentenylstannane **8** as the major product together with its (3*RS*,4*SR*)-isomer **5a** (ratio 70 : 30).¶

It would appear that the (3*RS*,4*RS*)-allyltin trichloride **9** is the major, kinetically-formed intermediate from transmetallation of the allylstannane **5a** (Scheme 4) and leads to the formation of the 1,5-*syn* products **7a**–**c** and the (3*RS*,4*RS*)-allylstannane **8** if 2 min only is allowed before addition of the aldehyde or phenyllithium. If, however, the addition of the aldehyde or phenyllithium is delayed, equilibration of **9** to **3a** takes place, leading to increased amounts of the 1,5-*anti* products **2a**.



**Scheme 4**

The formation of the (3*RS*,4*RS*)-allyltin trichloride **9** from the allylstannane **5a** corresponds to an electrophilic substitution with inversion of configuration at the more substituted end of an allylstannane when an SE′ process might have been expected. However, treatment of the (3*RS*,4*RS*)-allylstannane **8** with tin(IV) chloride for 3 min followed by addition of benzaldehyde also gives the 1,5-*syn* alcohol **7a** as the major product (1,5-*syn* : 1,5-*anti* = 73 : 27, 60% combined yield), and trapping the intermediate allyltin trichloride with phenyllithium returns the (3*RS*,4*RS*)-allylstannane **8** together with its epimer **5a** (ratio 70 : 30). The (3*RS*,4*RS*)-allyltin trichloride **9** is therefore involved in reactions of both allylstannanes **5a** and **8**. Perhaps transmetallation of the allylstannanes **5a** and **8** proceeds *via* formation of the terminal allyltin trichloride **10** (Scheme 5), in which, for the (*Z*)-isomer, the electron deficient tin would be coordinated by the alkoxy group, followed by rapid isomerisation to the (3*RS*,4*RS*)-allyltin trichloride **9**. This is then trapped by the aldehyde or phenyllithium or isomerises to the (3*RS*,4*SR*)-allyltin trichloride **3a** on standing.

**Scheme 5**

**Scheme 6**

The high stereoselectivities in reactions of allylstannanes **1a**–**c** promoted by tin(IV) chloride would appear primarily to be due to kinetic control of the transmetallation. Perhaps the tin(IV) chloride is delivered by the oxygen of the 5-substituent to the allylstannane at C(3) with transition structure **11** being preferred over the alternative transition structure **12** (Scheme 6) because of increased steric interaction between the terminal methyl group and H(2) in **12**.

We thank the University of Manchester and SmithKline Beecham for support (to L. A. H.) under the CASE Scheme, Dr M. Fedouloff of SmithKline Beecham for helpful discussions and Dr M. Helliwell for preparing the X-ray data for publication.

† *X-Ray crystal data* for **6d**: $C_{31}H_{31}BrO_2Sn$, $M$ = 634.18, triclinic, space group $P\bar{1}$, $a$ = 10.390(2), $b$ = 17.643(3), $c$ = 8.429(2) Å, $\alpha$ = 92.81(2), $\beta$ = 113.88(1), $\gamma$ = 90.83(1)°, $U$ = 1410.2(4) Å$^3$ (by least-squares refinement on diffractometer angles of 25 automatically centred reflections), $\lambda$ = 0.71069 Å, $Z$ = 2, $D_c$ = 1.493 g cm$^{-3}$, $\mu$ = 23.51 cm$^{-1}$, $F(000)$ = 636.00, colourless prism, crystal dimensions 0.2 × 0.2 × 0.25 mm. Data were collected at 293 K using a Rigaku AFC-5R diffractometer with graphite monochromated Mo-Kα radiation and a rotating anode generator. A total of 5290 reflections were measured in the $\omega$–2$\theta$ scan mode to a $2\theta_{max}$ of 50.1°, which gave 4987 independent reflections ($R_{int}$ = 0.024). A semi-empirical absorption correction was applied, based on the azimuthal scans of several reflections (transmission factors: 0.8958–1.00). A decay correction was also applied (3.16% decline). 3413 reflections had $I > 3\sigma(I)$. The structure was solved by Patterson methods using DIRDIF92 PATTY (ref. 6) and refined using full-matrix least-squares refinement using TEXSAN (ref. 7). All non-hydrogen atoms were refined anisotropically and hydrogen atoms were included in calculated positions. Refinement of the 316 variables converged with $R$ = 0.040, $R_w$ = 0.038 based on the 3413 reflections with $I > 3\sigma(I)$ and where $w = 1/[\sigma^2|F_o| + 0.00005|F_o|^2]$. Max/min peaks in the final difference map: 0.70/−0.38 eA$^{-3}$. CCDC 182/557.

‡ [(4*R*)-5-Benzyloxy-4-methylpent-2-enyl](tributyl)stannane also gave the triphenylstannane **5a** after transmetallation by tin(IV) chloride and addition of phenyllithium, so confirming that the phenyl substituents in **5a** are derived from the phenyllithium and not from the starting material **1a**. Trapping the allyltin trichloride **3a** with methyllithium also gave the trimethylstannyl analogue of **5a** (40%).

§ An alternative explanation would be that a mixture of rapidly equilibrating isomeric allyltin trichlorides is present after transmetallation of the pentenylstannanes **1a**–**c** but that the (2*SR*,3*RS*)-isomers are the most reactive. However this explanation is inconsistent with the formation of different products from the allyltin trichlorides **3a** and **9**.

¶ The isolation of both of the triphenylpentenylstannanes **5a** and **8** during this work meant that we knew we were able to distinguish them.

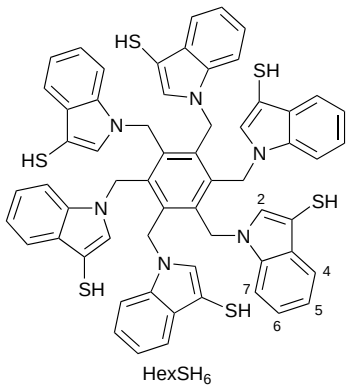
# A preorganised doubly tripodal hexathiol: syntheses and crystal structures of complexes with two 3 : 1 subsite-differentiated $Fe_4S_4$ clusters

**Christian Walsdorff,* Wolfgang Saak, Detlev Haase and the late Siegfried Pohl**



*Fachbereich Chemie der Carl von Ossietzky Universität, Postfach 2503, 26111 Oldenburg, Germany*

**Hexakis(3-sulfanylindolyl[1]methyl)benzene is highly preorganised to embed upon deprotonation two $Fe_4S_4$ clusters at a rigid separation of 12.8 Å.**

We have recently reported the convenient synthesis of 1,3,5-tris(3-sulfanylindolyl[1]methyl)-2,4,6-triethylbenzene ($TriSH_3$) from 1,3,5-tris(bromomethyl)-2,4,6-triethylbenzene.[1] This trithiol is highly preorganised to coordinate in the deprotonated form $TriS^{3-}$ to three iron subsites of $Fe_4S_4$ cluster cores thereby affording 3 : 1 subsite differentiated clusters. A key feature in the preorganisation of the molecular framework is the central hexasubstituted benzene ring that enforces a predominant *ababab*-conformation.† A detailed account of the design, underlying principles, synthesis and coordination properties has been given along with concise bibliographical reference.[1] Replacing 1,3,5-tris(bromomethyl)-2,4,6-triethylbenzene[2] with hexakis(bromomethyl)benzene[3] we have adapted the synthesis of $TriSH_3$ to obtain the novel ligand hexakis(3-sulfanylindolyl[1]methyl)benzene ($HexSH_6$), a doubly tripodal hexathiol that is preorganised to provide upon deprotonation two tripodal coordination spheres that are suitable to embed a single cluster core each.‡

$TriSH_3$

$HexSH_6$

Single crystals of $HexSH_6$ for X-ray structure analysis have not been obtained. By analogy with $TriSH_3$ rough $S_6$ or $D_{3d}$ symmetry should be expected for $HexSH_6$ in that the 3-sulfanylindolyl moieties point alternately above and below the plane of the central arene ring and the bulky annelated benzo groups are directed towards the periphery in order to avoid steric pressure while the HS groups in turn are all directed inward to provide two tripodal coordination spheres. This conformation is reflected in the $^1H$ NMR spectrum shown in Fig. 1. The indolyl $H^2$ protons are highfield shifted in the spectra of both $TriSH_3$ and $HexSH_6$ owing to shielding by the central arene ring. A similar shielding of the indolyl $H^7$ protons in $HexSH_6$ may be expected, since these protons are sandwiched between the neighbouring indolyl groups and should experience a shielding influence from them. Indeed a significant highfield shift is observed with one of the two pseudo-doublets whereas the other one appears in the normal range. This allows the unequivocal assignment of these signals that had remained ambiguous in the spectrum of $TriSH_3$. The sharp lines in the spectrum of $HexSH_6$ (actually dd were resolved instead of mere pseudo-doublets) further illuminate both the predominance and rigidity of the expected conformation.

The preorganisation of $HexSH_6$ is mirrored by the smooth reaction with $Fe_4S_4$ clusters to afford discrete double clusters. This has been established by X-ray structure analysis of the compounds $[PPh_4]_4[(Br)Fe_4S_4(HexS)Fe_4S_4(Br)]$ **1** and $[PPh_4]_4[(PhS)Fe_4S_4(HexS)Fe_4S_4(SPh)]$ **2**.§ Fig. 2 depicts the representative double cluster anion from **2**. Crystal inversion symmetry is imposed on the anion that renders both cluster cores equivalent. Coordination of the cluster cores closely resembles that in $[PPh_4]_2[Fe_4S_4(TriS)(SPh)]$,[1] *e.g.* the ligand deviates from trigonal symmetry, as can be seen from the non-equal thiolate-S···thiolate-S distances, to allow the slight tetragonal distortion that is typical of $Fe_4S_4$ clusters.[1] The cluster centroids are 12.83 Å apart, similar to the value of *ca*. 12 Å found by protein crystallography of *Peptococcuc aerogenes*,

a ferredoxin with two separate $Fe_4S_4$ clusters.[4] A series of model compounds for such two-cluster enzymes that employ bidentate thiolate ligands to link the cluster cores have been reported.[5] However, separation and relative orientation of the cluster cores are poorly defined in these compounds owing to the flexible bridging. On the contrary the rigid polydentate ligand $HexS^{6-}$ may be reasonably expected to control the relative arrangement of the cluster cores in solution, too. This very property makes us believe that the ligand as a prototype for further ligands of a similiar design deserves considerable interest also in various fields beyond iron–sulfur chemistry.

† The '*ab*' terminology was introduced by MacNicol *et al.*[5] According to force-field calculations for the closely related hexaethylbenzene and hexa(*n*-propyl)benzene the ground-state *ababab* conformation lies some 15–19 kJ mol$^{-1}$ below the conformers that are next higher in energy.[7]

‡ Typical synthetic procedures, purification of solvents and experimental techniques have been described elsewhere.[1] Yields are given for isolated, crystalline and $^1$H NMR spectroscopically pure compounds.

Hexakis(3-methoxymethylthioindolyl[1]methyl)benzene: (88%); $\delta_H$ ($CDCl_3$, 300 MHz) 3.43 (18 H, s, $OCH_3$), 4.70 (12 H, s, $SCH_2$), 5.27 (12 H, s, $NCH_2$), 6.79 (6 H, s, indolyl H$^2$), 6.90 (6 H, d, indolyl H$^7$), 7.21 (12 H, m, indolyl H$^{5,6}$), 7.76 (6 H, d, indolyl H$^4$); $\delta_C$ ($CDCl_3$, 75 MHz) 44.16, 56.06, 79.63, 106.64, 109.63, 120.05, 121.32, 123.36, 129.26, 130.23, 136.62, 138.75.

$HexSH_6$·0.5Et$_2$O: (20%); $\delta_H$ ($CDCl_3$, 300 MHz) 2.78 (6 H, d, *J* 1.3 Hz, SH), 5.25 (12 H, s, $NCH_2$), 6.47 (6 H, d, *J* 1.3 Hz, indolyl H$^2$), 6.84 (6 H, dd, $J_{12}$ 6.6 Hz; $J_{13}$ 1.5 Hz, indolyl H$^7$), 7.12 (12 H, m, indolyl H$^{5,6}$), 7.59 (6 H, dd, $J_{12}$ 6.8 Hz; $J_{13}$ 1.7 Hz, indolyl H$^4$); $\delta_C$ ($CDCl_3$, 75 MHz) 44.27, 98.49, 109.02, 119.77, 121.02, 123.22, 128.73, 130.44, 136.04, 138.58.

The electrochemical reduction of **2** was investigated by cyclic voltammetry (dmf, Pt electrodes *vs.* SCE, 100 mV s$^{-1}$, 0.1 M [$NBu_4$]$ClO_4$) in the range −460 to −1660 mV. The reduction is chemically reversible (no loss of current in successive cycles), but the reduction wave is broadened ($E_{pc}$ = −1000; $E_{pa}$ = −1210) owing to disproportionation equlibria in the two-electron process. Nevertheless no splitting into two separate potentials is observed, that might be caused by a strong electrochemical interdependence of the two cluster cores. However such a splitting should not be expected with two $Fe_4S_4$ clusters that far apart.[5]

§ Single crystals were grown by vapour diffusion of diethyl ether into the reaction solution (dmf). Suitable specimens were sealed in glass capilaries under an atmosphere of dinitrogen and mounted on a Siemens-Stoe AED 2 four-circle diffractometer. Intensity data collections were performed 296(2) K using Mo-K$\alpha$ radiation ($\lambda$ = 71.073 pm), a graphite monochromator and $\omega$ scan techniques. Both structures were solved (direct methods) and refined on $F^2$ using the SHELXTL package.[8] The anion of **2** has been drawn with the program SCHAKAL 92.[9]

*Crystal data*: **1**·6dmf, $C_{174}H_{164}Br_2Fe_8N_{12}O_6P_4S_{14}$, black plates, crystal size 0.49 × 0.34 × 0.15 mm, $M$ = 3698.51, triclinic, space group $P\bar{1}$, $a$ = 1679.8(2), $b$ = 1686.0(2), $c$ = 1712.6(2) pm, $\alpha$ = 68.82(1), $\beta$ = 73.54(1), $\gamma$ = 88.53(2)°, $U$ = 4.3213(9) pm$^3$, $Z$ = 1, $D_c$ = 1.421 Mg m$^{-3}$, $\mu$ = 1.378 mm$^{-1}$. 9241 independent reflections ($\theta_{max}$ = 20.98°) of which 6686 were observed [$I > 2\sigma(I)$]. A semi-empirical absorption correction from $\psi$ scans was applied. H atoms were refined on fixed positions. The phenyl groups of the cations and the dmf molecules were refined with idealized geometry. The dmf molecules and one cation phenyl group were disordered and refined on split positions with occupancy factors of 0.5 : 0.5. All other atoms were refined anisotropically. Refinement converged with GOF = 1.199 for 838 parameters, $R_1$ = 0.0652 and $wR_2$ = 0.1400 [$I > 2\sigma(I)$], $R_1$ = 0.1037 and $wR_2$ = 0.1820 (all data), $e_{max}$, $e_{min}$ = 762, = −687 e nm$^{-3}$.

**2**·4dmf·2Et$_2$O, $C_{188}H_{180}Fe_8N_{10}O_6P_4S_{16}$, black needles, crystal size 2.58 × 0.27 × 0.08 mm, $M$ = 3759.06, triclinic, space group $P\bar{1}$, $a$ = 1513.9(2), $b$ = 1752.1(3), $c$ = 1939.1(2) pm, $\alpha$ = 100.67(1), $\beta$ = 101.73(2), $\gamma$ = 110.94(1)°, $U$ = 4.5127(11) nm$^3$, $Z$ = 1, $D_c$ = 1.383 Mg m$^{-3}$, $\mu$ = 0.903 mm$^{-1}$. 11 043 independent reflections ($\theta_{max}$ = 22.02°) of which 8183 were observed [$I > 2\sigma(I)$]. A volume correction for a long needle was applied. H-atoms were refined on fixed positions. The phenyl groups of the cations and the solvent molecules were refined with idealized geometry. The solvent molecules were disordered and refined on split positions with occupancy factors of 0.5 : 0.5 but one dmf molecule (0.65 : 0.35). All other atoms were refined anisotropically. Refinement converged with GOF = 1.159 for 895 parameters, $R_1$ = 0.0659 and $wR_2$ = 0.1509 [$I > 2\sigma(I)$], $R_1$ = 0.0994 and $wR_2$ = 0.1936 (all data), $e_{max}$, $e_{min}$ = 831, = −680 e nm$^{-3}$. **Hydroxynitrile lyases (Hnls) catalyse enantioselectively both the cleavage and formation of cyanohydrins. Besides the well known (*R*)-selective enzyme from almonds, (*S*)-Hnls have recently become available in larger quantities by cloning and over-expression. The first three-dimensional structure of a Hnl has been established for the enzyme from *Hevea brasiliensis*. These results are the basis for a still broader application of Hnls for biocatalytic asymmetric syntheses on a preparative scale.**

## Introduction

Hydroxynitrile lyases (Hnls, EC 4.1.2.10, EC 4.1.2.11, EC 4.1.2.37, EC 4.1.2.39) are enzymes which catalyse the cleavage and formation of cyanohydrins.[1] Early work concentrated on the enzyme which is isolated easily from almond meal,[2] and which gives (*R*)-configured cyanohydrins from aromatic and aliphatic aldehydes. Although (*S*)-Hnls are also known (see below) their application for enantioselective biocatalytic syntheses has been hindered by the difficulty of obtaining sufficient amounts for larger scale preparations. Recently, the genes for the (*S*)-Hnls from *H. brasiliensis* and *Manihot esculenta* were cloned and over-expressed[3,4] and the first X-ray structure of a Hnl, the (*S*)-Hnl from *H. brasiliensis*, was elucidated.[5] Therefore, on the basis of suggestions on the mechanism of the enzyme catalysed cyanohydrin reaction (deduced from knowledge of the three-dimensional structure) and due to the availability of both (*R*)- and (*S*)-Hnls, the field now seems open to still broader synthetic applications. For this reason it is appropriate to summarise recent developments here. Although special emphasis is given to the Hnl from *H. brasiliensis* developed in this laboratory, a more general view is intended.

## Natural function and biochemical characterization of hydroxynitrile lyases

Cyanogenesis, the release of hydrogen cyanide (HCN) from the tissue of plants or other organisms which occurs upon tissue damage, has been extensively described to date. This source of HCN has been identified in over 2000 plants as being cyanogenic glycosides or cyanolipids. One group of enzymes involved in this catabolism are the hydroxynitrile lyases. Their natural function is the catalysis of cyanohydrin cleavage from cyanogenic glycosides to give HCN and the corresponding aldehydes or ketones.

Cyanogenic glycosides have been found to possess two main functions in nature. (i) Plant defence. If the subcellular structures are destroyed by herbivoral, fungal or mechanical means, the catabolic enzymes can act on the cyanogenic glycosides. The catabolism is initiated by cleavage of the carbohydrate moiety by one or more β-glycosidases. After cleavage of the carbohydrate moiety the intermediates (cyanohydrins) may decompose either spontaneously or enzymatically, in the presence of a hydroxynitrile lyase, which considerably accelerates the reaction velocity. (ii) Nitrogen source. Cyanogenic glycosides may also be catabolised without release of hydrogen cyanide. HCN is refixed by the enzyme β-cyanoalanine synthetase and forms β-cyanoalanine with L-cysteine. β-Cyanoalanine is then hydrolysed by β-cyanoalanine hydrolase to L-asparagine. Consequently, HCN can also be considered as a nitrogen source for amino acid synthesis.

Eleven different Hnls from six different plant families have been isolated to date.[1] Interesting preparative applications in organic synthesis have been described only for four enzymes: (*R*)-hydroxynitrile lyase from *Prunus amygdalus* and (*S*)-hydroxynitrile lyases from *Sorghum bicolor*, *H. brasiliensis* and *M. esculenta* (Table 1). The differences between these four enzymes lies not only in their biochemical characteristics and enantiospecificities, but also in their substrate specificities. The Hnl of *P. amygdalus* (Pa-Hnl) accepts aromatic as well as aliphatic, unsaturated and heterocyclic aldehydes.[2] The Hnl of *S. bicolor* (Sb-Hnl) accepts only aromatic and heterocyclic aldehydes.[6] On the contrary, the Hnl of *H. brasiliensis* (Hb-Hnl) catalyses the formation of cyanohydrins from aliphatic, aromatic and heterocyclic aldehydes.[7] The Hnl of *M. esculenta* (Me-Hnl) is very similar to the *H. brasiliensis* enzyme, and therefore a very similar substrate specificity is to be expected.

## Molecular cloning, characterization and overexpression of the *hnl*-gene from *Hevea brasiliensis*

Based on polyclonal antibodies and partial sequence information obtained from the Hnl which was purified to homogeneity from plant material,[11,12] the gene encoding for the Hb-Hnl enzyme could be cloned by antibody screening of a cDNA library prepared from leaves of the rubber tree.[4] Sequencing of the cDNA relevaed an open reading frame encoding for a polypeptide of 257 amino acids with a predicted molecular mass of 29 227 kDa (Fig. 1). This was in good agreement with the molecular weight of 30 kDa found for the natural Hnl, as determined by SDS polyacrylamide gel electrophoresis.

Detailed sequence homology studies were performed and revealed that Hb-Hnl is highly homologous to Hnl of cassava (*M. esculenta*)[10] but shows no significant homology to the (*R*)-hydroxynitrile lyase from *P. serotina*[13] or to the (*S*)-hydroxynitrile lyase from *S. bicolor*.[9a] Identification of distant relationships and homologies at the secondary structure level indicated that Hb-Hnl is a new member of the α/β-hydrolase fold family of enzymes.[14] The involvement of $Ser_{80}$ and $His_{235}$ in the catalytic action was clearly confirmed by replacing these amino acid residues of the predicted catalytic triad by site-specific mutagenesis. Both the $Ser_{80} \rightarrow Ala$ and the $His_{235} \rightarrow Ala$ mutant proteins were completely inactive.

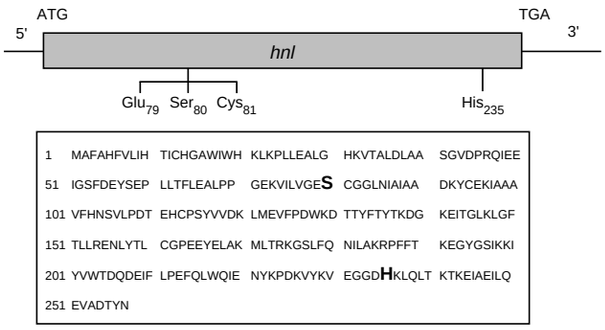

**Fig. 1** The *hnl* gene from *Hevea brasiliensis* and deduced amino acid sequence of the Hnl polypeptide. The active site $Ser_{80}$ and the $His_{235}$ of the catalytic triade are highlighted in the sequence by bold letters.

Replacing the residues adjacent to the active site, $Ser_{80}$, $Glu_{79}$ and $Cys_{81}$, resulted in low levels (1 and 3%) of the remaining specific Hnl activity of the mutant proteins $Glu_{79} \rightarrow$ Ala and $Cys_{81} \rightarrow$ Ser, which indicates that these residues may play an important role in enzyme function.[14]

The Hnl-encoding cDNA was used to construct expression vectors for overexpression of the *hnl* gene in different microorganisms. Overexpression in the bacterium *Escherichia coli* K12 resulted in efficient production of heterologous Hnl protein, however, the protein was intracellularly accumulated as insoluble inclusion bodies. Extraction of solubilized active Hnl enzyme was generally possible but resulted in low levels of specific activity. In contrast, expression in *Saccharomyces cerevisiae* resulted in efficient intracellular expression of soluble and highly active Hnl enzyme.[4] the specific activity of purified Hnl obtained by heterologous expression in *S. cerevisiae* (22 U $mg^{-1}$) was even slightly higher than the value of 18 U $mg^{-1}$ found for the Hnl enzyme purified from plant leaves. The most successful heterologous expression could be achieved by the methanol-inducible *Pichia pastoris* (methylotrophic yeast) expression system. High levels (up to about 60% of total cellular proteins) of intracellularly produced soluble Hnl protein, exhibiting specific activity of around 40 U $mg^{-1}$ (about twice the value found with the purified natural enzyme), were obtained. This expression system is also well developed for high cell density cultivation and yields more than 20 g of pure Hnl protein per litre of culture volume.[15] This high expression level represents an excellent basis for the establishment of efficient industrial processes for the production of recombinant *H. brasiliensis* Hnl enzyme.

## Three-dimensional structure of the Hnl from *Hevea brasiliensis*

Knowledge of the three-dimensional structure is a prerequisite for understanding the enzyme mechanism as well as for any attempt to alter enzyme properties by chemical or genetic means. Therefore, efforts to crystallize Hnls with the goal of determining their three-dimensional structures by X-ray crystallography have been undertaken.[16] These efforts have recently led to the successful conclusion of the structure analysis of Hb-Hnl, yielding the first three-dimensional structure of an enzyme with hydroxynitrile lyase activity.[5] Preliminary suggestions pertaining to the reaction mechanism could be derived from these recent results, which also form the basis for continued mutagenesis experiments.

### *The Hnl from* H. brasiliensis *belongs to the* α/β*-hydrolase fold family*

This is evident from the topology diagram [Fig. 2(*a*)] and from the three-dimensional structure [Fig. 2(*b*)]. The α/β-hydrolase fold is characterized by a well-conserved, large central β-sheet surrounded by α-helices in a less-well conserved arrangement, plus a variable 'cap' region. Other known members of this class of enzyme superfamily[17] have esterase, carboxypeptidase, dehalogenase and oxidoreductase activities, with somewhat related enzymatic mechanisms. Apart from their overall architecture, they also share a number of structurally conserved features in the vicinity of the active site, which can be used to identify the location of the active site as well as some of the residues involved in enzyme catalysis.

The active site is deeply buried inside the protein and connected to the surface by a narrow channel, as shown in Fig.3. This is consistent with the previously suggested ordered uni-bi mechanism[11,18] of hydroxynitrile lyases, which implies that substrates or products, depending on the reaction direction, access the active site in a sequential fashion. In the crystal structure, residual electron density interpreted as originating from a histidine molecule (presumably carried through from the buffer during enzyme purification) was observed within the active site region.

### *A (presumably) catalytic triad*

A triad consisting of residues $Ser_{80}$, $His_{235}$ and $Asp_{207}$ was identified by sequence and structure comparison with other α/β-hydrolase fold enzymes, and its catalytic relevance was assessed by mutagenesis studies.[4,14] Other characteristic features of α/β-hydrolases were identified ('nucleophile elbow') or at least tentatively assigned ('oxyanion hole') by structural

**Table 1** Biochemical characteristics of the hydroxynitrile lyases used for organic synthesis

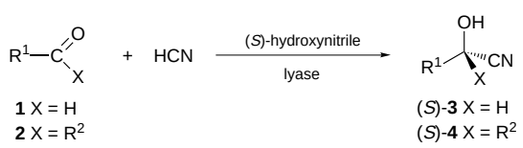
comparison with other enzymes of the superfamily, most notably acetyl cholineesterase.[19] Each of the structurally conserved features of α/β-hydrolases is likely to play a similar function in the catalytic mechanism of the corresponding enzyme. Thus, the terminal residue of the catalytic triad ($Ser_{80}$ in Hnl) is believed to act as an activated nucleophile, which typically attacks a carbonyl carbon atom (*e.g.* in serine carboxypeptidases[20]). The resulting negative charge on the oxygen of the thus formed tetrahedral intermediate is stabilized by accommodating this oxygen within what is frequently called the 'oxyanion hole'. The structural conservation of the catalytic triad in Hnl suggests a similar function. Therefore, it was proposed[5] that the catalytic cycle of Hnl also involves a tetrahedral intermediate formed by nucleophilic attack of the (activated) $Ser_{80}$ oxygen on the carbonyl group of the cyanohydrin. For the natural substrate (acetone cyanohydrin) of the Hb-Hnl, the structure of the tentative intermediate (filled into the Hnl crystal structure by molecular modelling) is shown in Fig. 4. The $Cys_{81}$ residue was proposed to be involved in proton transfer to and from cyanide[5] as deduced from the reduced catalytic activity of the $Cys_{81} \rightarrow$ Ser mutant.



## Enzyme catalysed synthesis of cyanohydrins

For preparative purposes, the (*R*)-Hnl from *P. amygdalus* can be easily isolated in sufficient quantities.[8] Its high stability made it possible to investigate its properties and substrate range. It was shown that aliphatic, aromatic and heteroaromatic aldehydes[21] as well as ketones[22] could be converted to the corresponding cyanohydrins in good yield and selectivity.

The first (*S*)-hydroxynitrile lyase employed for the synthesis of chiral cyanohydrins was isolated from four to eight day old shoots of *S. bicolor*.[6] For reactions on a larger scale this preparation is rather laborious. Broad application of this Hnl is not possible as only aromatic carbonyl compounds are accepted as substrates. In contrast to this, the hydroxynitrile lyase from *H. brasiliensis* was reported to be the first (*S*)-Hnl which also accepts aliphatic aldehydes as substrates.[7] This enzyme could be prepared in large quantities by over-expression in the yeast *P. pastoris*.[4] Recently, an (*S*)-Hnl has been isolated from *M. esculenta*,[10,23] which shows similar properties[24] to the enzyme from *H. brasiliensis*.[7,25] Regarding the (*S*)-cyanohydrins, the most thoroughly studied enzyme is Hb-Hnl. Therefore its use in organic synthesis will be concentrated on.

The hydrogen cyanide required for the cyanohydrin formation (Scheme 1) can be added directly into an organic reaction medium or created *in situ* by the addition of acid to an aqueous solution of alkali cyanide. Alternatively the method of transhydrocyanation can be employed.[7a,26,27] Here, HCN is set free from acetone cyanohydrin in a preequilibrium step. To obtain chiral cyanohydrins in good enantiomeric purity a fundamental prerequisite is the suppression of the spontaneous addition of HCN to the carbonyl group. The extent of this non-enzymatic reaction strongly depends on the conditions. An aqueous reaction medium is only suitable if pH values below 4.0 are employed.[28] It is also possible to suppress the non-enzymatic addition of hydrogen cyanide by the use of an organic solvent. This reaction system has the additional advantage that the isolated yields of the corresponding cyanohydrins are in general higher than in aqueous medium. The first results were obtained mainly with aliphatic aldehydes[7] and ketones employing an aqueous, buffered reaction medium at pH 3.75 to 4.0 (Table 2). The majority of the substrates investigated can be converted into the corresponding cyanohydrins with good to excellent enantiomeric excess. By this means (*S*)-cyanohydrins of aryl-substituted aliphatic aldehydes became enzymatically accessible for the first time using hydroxynitrile lyases.[25] Also the excellent selectivity of this Hnl for thiophene and furane aldehydes in comparison to hydroxynitrile lyases from other plant sources is remarkable.

Using an aqueous reaction system, the isolated yields of the cyanohydrins are only moderate, probably due in part to the low solubility of several substrates in water. This can be circumvented by employing an organic solvent. It is not necessary to immobilise the enzyme. One can also apply a crude, concentrated aqueous enzyme solution together with an organic solvent as a second phase. Solvents of choice are ethyl acetate and some ethers. After performing the reaction, the aqueous phase containing the enzyme can be reisolated by a simple phase separation step. The activity of the enzyme used is unchanged.

**Scheme 1**

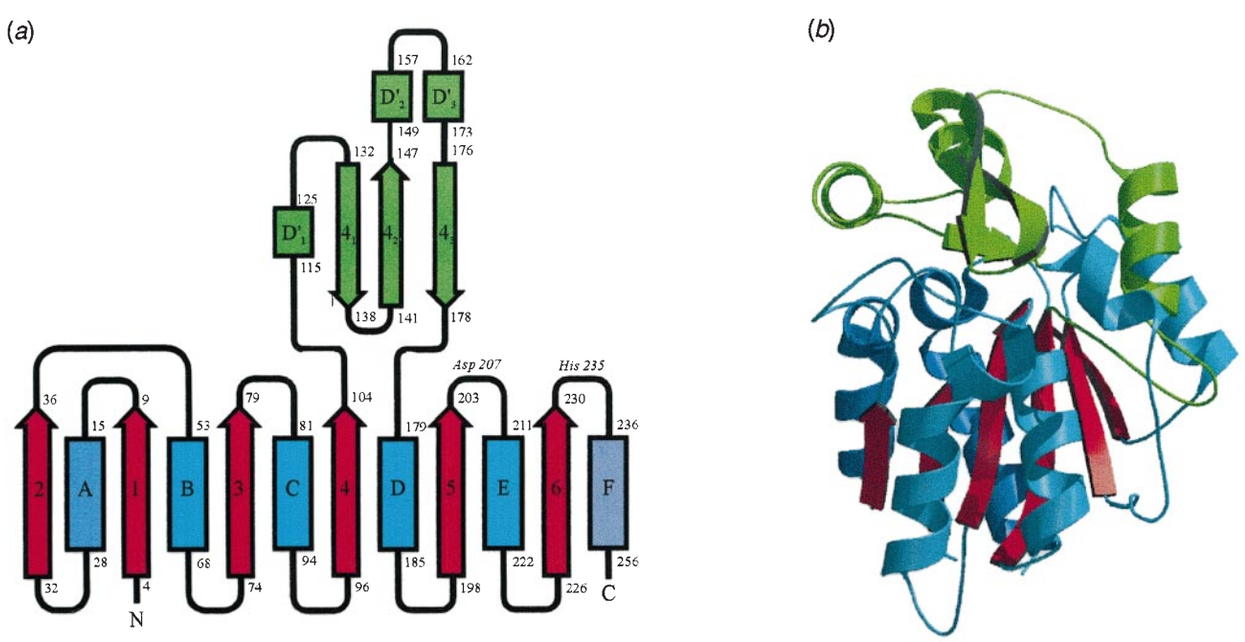


**Fig. 2** (*a*) Topology diagram and (*b*) three-dimensional and structure of the hydroxynitrile lyase from *Hevea brasiliensis*. The 'cap' region is colour-coded in green, helices are blue and β-strands are red.

Therefore, the same batch of enzyme can be reused several times without significant reduction in the isolated yield and the enantiomeric excess of the product. This fact is of importance with respect to industrial applications in order to enhance the productivity of the desired process. The pH value of the reaction mixture can be adapted to a certain substrate by adding an aqueous buffer solution to the aqueous enzyme solution. In order to obtain high yields of the corresponding cyanohydrins in short reaction times, concentrated solutions of the starting material (1 to 1.5 M) in the desired organic solvent can be employed. Furthermore, the temperature has a great influence on the course of the reaction. The reaction rate of the spontaneous addition of HCN, which will reduce the enantiomeric purity of the product, can be suppressed with respect to the enzymatic reaction if the reaction temperature is kept below 5 °C. At this temperature, the stability of the enzyme against denaturation is also enhanced. In almost all cases a reaction time of approximately 1 h at 0–5 °C was sufficient to obtain the corresponding chiral cyanohydrin in good yield and enantiomeric purity (see Table 3).

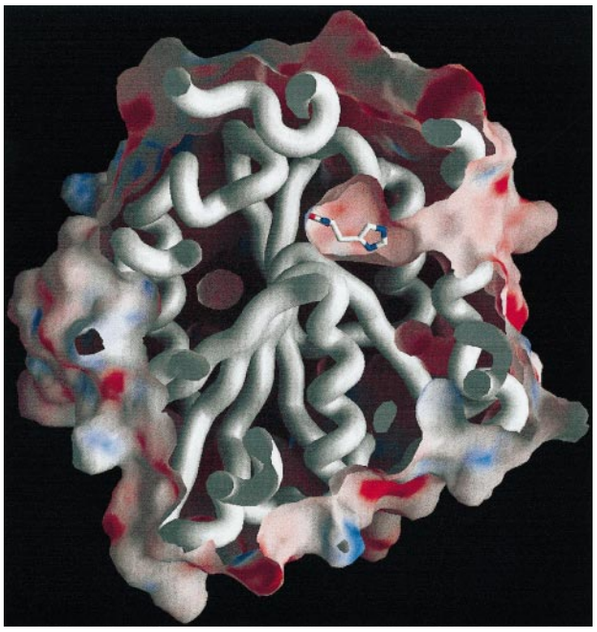

**Fig. 3** Section through a surface representation of the Hnl crystal structure. The colour coding is according to the electrostatic potential. The section passes through the active site cavity and the tunnel connecting it with the surrounding solvent. Also shown is a histidine molecule observed within the active site.

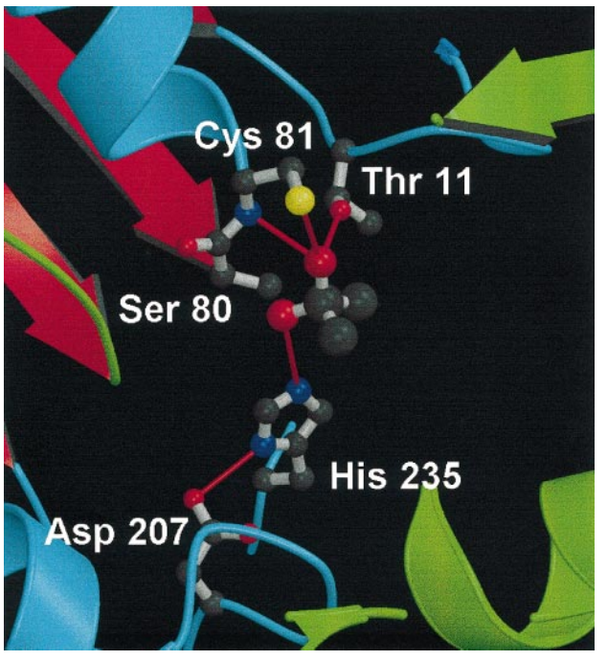

**Fig. 4** Structure of the tentative tetrahedral intermediate formed by nucleophilic attack of the $Ser_{80}$ oxygen on the carbonyl carbon of acetone. The structure of this intermediate was deduced by molecular modelling.

## Synthetic transformations of chiral cyanohydrins

Cyanohydrins, in particular those derived from aldehydes, are functionalised chiral units that possess broad synthetic utility. Scheme 2 summarizes some recent developments. Several synthetic routes are shown, each of which describes an alternative transformation of either the hydroxy or cyano moiety. Thus following route A, it can be seen that conversion of the hydroxy functionality to the silyloxy ether allows for a range of amino alcohols and hydroxy ketones to be generated, *via* nucleophilic addition of a Grignard reagent (*e.g.* methylmagnesium iodide) to the nitrile followed by reduction[29] or acidic hydrolysis[30] of the intermediate imine. This addition reaction has been further exploited by developing a transimination reaction[31] which yields an *N*-derivatized amino alcohol. When the hydroxy group is suitably protected (usually a silyloxy ether), the cyanohydrin can be converted to an

HCl

α-hydroxy aldehyde by treatment with excess diisobutylaluminium hydride followed by mild acidic hydrolysis (route B).[32] Alternatively, conversion of the hydroxy functionality into a suitable leaving group followed by nucleophilic displacement with various nucleophiles (*e.g.* acetate,[33] phthalimide[34] or fluoride[35]) introduces a new alternative functionality at the chiral centre with stereochemical inversion. The free cyanohydrins are particularly stable under anhydrous, strongly acidic conditions (*e.g.* dry hydrogen chloride), but treatment with an aqueous strong acid yields α-hydroxy acids.[6a] A more detailed coverage of the reactions presented in this scheme is given in recent reviews.[32,36]

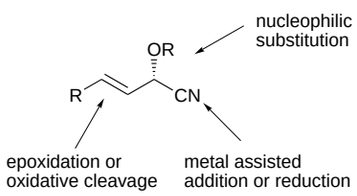
A representative example of the synthetic potential of Hnls is shown in Scheme 3, where the cyanohydrin **1** (prepared from benzaldehyde) is elaborated[37] to the β-hydroxy-α-amino acid **2**,

**Scheme 3** *Reagents*: i, DIBAL-H; ii, $NH_4Br$, MeOH; iii, $R^2NH_2$; iv, HCN; v, HCl; vi, 1,1′-carbonylbis(1*H*-imidazole); vii, $K_2CO_3$, EtOH; viii, HCl; ix, 2 M KOH

which has the structural features of the amino acid side chain of Taxol. Therefore, in the chiral cyanohydrins the provision of a single asymmetric centre with at least two different functionalities is of significant practical synthetic value for differential and selective chemical elaboration to bioactive compounds and natural products. These products include α-fluoro carboxylic acids (**3**),[35] ethanol amines (**4**),[29] tetronic acids (**5**)[38] and the Williams glycine template (**6**).[39]

*Unsaturated cyanohydrins from aldehydes*

The synthetic utility of the chiral cyanohydrins can be extended by employing unsaturated aldehydes as substrates. The subsequent unsaturated cyanohydrins represent enzymatic products from enzyme catalysed reactions with an enhanced synthetic potential. Such opportunities include oxidative cleavage or epoxidation of the unsaturated functionality, nucleophilic substitution at the hydroxy centre and metal assisted addition to, or reduction of, the nitrile functionality (Fig. 5). This versatility makes them an important tool for organic chemists.



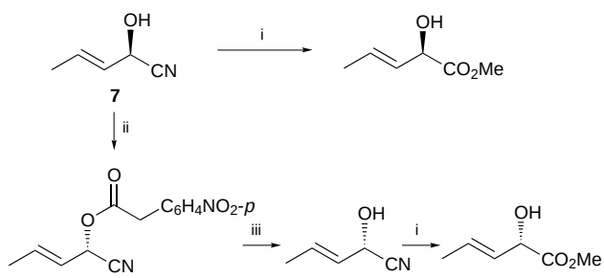


**Fig. 5** Opportunities for further transformation of unsaturated *O*-protected cyanohydrins

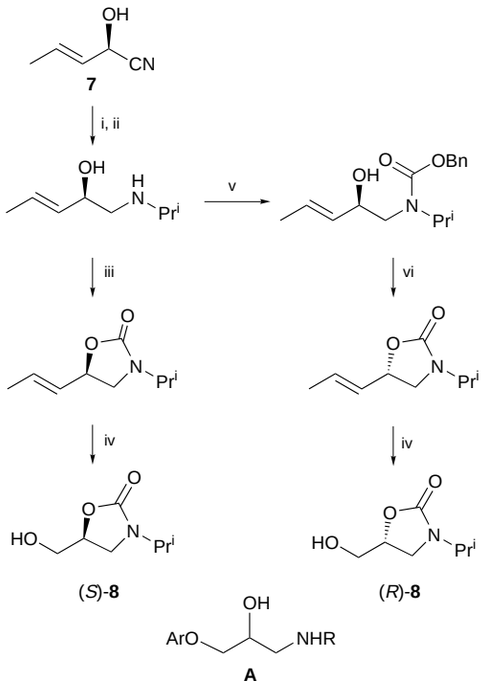
*Unsaturated hydroxy esters*[40]



On treatment with MeOH–$HCl_{(g)}$, the unsaturated cyanohydrins (*e.g.* **7**) are easily converted into the corresponding esters (Scheme 4). These compounds are the multifunctional chiral starting materials for a number of organic transformations. Inherent in their structures are the properties of an allylic alcohol combined with those of α-hydroxy esters and β,γ-unsaturated carboxylic esters. The hydroxy group facilities directed epoxidation whilst the unsaturated ester (or carboxylic acid) may be applied to a variety of addition reactions. The enantiomeric counterpart of **7** can also be prepared by inversion of the chiral hydroxy group, under Mitsunobu conditions, followed by acidic hydrolysis of the *p*-nitrophenyl acetate and application of the Pinner reaction once more (Scheme 4).

*Oxidative cleavage*[41]

(*R*,*E*)-(−)-2-hydroxypent-3-enenitrile **7** has proven to be particularly useful in a synthesis in which, at an appropriate juncture,

**Scheme 4** *Reagents*: i, HCl, MeOH–$Et_2O$, then $H_2O$, then $H_2O$; ii, $EtO_2CN{=}NCO_2Et$, $PPh_3$, *p*-nitrophenylacetic aicd; iii, MsOH, MeOH

the carbon–carbon double bond is broken *via* oxidative cleavage. The (*R*)-cyanohydrin **7** was converted into both enantiomers of oxazolidinone **8**, which is a key intermediate in the synthesis of β-blockers of the general structure A (Scheme 5).

*Synthesis of (*9E,11E,13S*)*-13-*hydroxyoctadeca*-9,11-*dienoic acid by chirality transfer*[42,43]

The stereoselective addition of HCN to unsaturated aldehydes to yield unsaturated (*S*)-cyanohydrins using the hydroxynitrile lyase from *H. brasiliensis* was first reported here in Graz in 1995.[7b] This work showed that the enantiomeric excess of the subsequent cyanohydrin increased with the chain length of the aldehyde. With this in mind, the synthesis of a natural product, (9*Z*,11*E*,13*S*)-13-hydroxyoctadeca-9,11-dienoic acid, was established[42] in which the key chiral synthon **9** (Scheme 6) is generated from the Hnl catalysed addition of HCN to octenal **10**. The cyanohydrin product **9** was derivatized to the butyrate **11** which was shown to possess an enantiomeric excess of 99%. The butyrate was then easily converted into the unsaturated nitrile **12** using a [3,3]-sigmatropic rearrangement catalysed by bis(acetonitrile)dichloropalladium **13** (Scheme 7). This rearrangement proceeded, as previously described,[44,45] in a stereospecific manner with complete retention of configuration and enantiomeric excess. Hydrolysis of the butyrate yielded the alcohol **14**, which was then protected with the *tert*-butyldiphenylsilyloxy functionality to yield the nitrile **15**. Chiral analysis

**Scheme 6** *Reagents*: i, Hnl from *Hevea brasiliensis*, HCN; ii, butyric anhydride, pyridine

**Scheme 7** *Reagents*: i, $Pd(MeCN)_2Cl_2$, **13**, THF; ii, $K_2CO_3$, MeOH; iii, $Bu^tPh_2SiCl$, imidazole, DMF; iv, DIBAL-H, then $H_3O^+$; v, $Ph_3P^+Br^-(CH_2)_8CO_2Me$, **17**, $(Me_3Si)_2NLi$, THF, HMPA, −78 °C; vi, $Bu_4NF$, THF; vii, LiOH, $H_2O$–$Pr^iOH$, then acidification to pH 7

(high performance liquid chromatography) revealed that the nitrile **15** possessed an enantiomeric excess of 99%. The synthesis was then completed in a straightforward fashion. Reduction of **15** with DIBAL-H followed by acidic workup gave the unsaturated aldehyde **16**, which was coupled with the phosphonium salt **17** using a Wittig reaction. Deprotection of the hydroxy group and hydrolysis of the methyl ester then followed, which yielded the desired compound **18** (Scheme 7).

## Conclusions and outlook

On the basis of the studies presented in this article it is expected that the enzyme catalysed cyanohydrin reaction will be further established as a versatile method to obtain enantiopure chiral intermediates. Investigations on the three-dimensional structure of Hnls from different source are in progress, together with genetic studies. The scope and limitations of the reaction are being clarified and the synthetic transformation of the enantiopure cyanohydrins to target structures of both scientific and industrial interest is in progress in several laboratories.

Taking into consideration the synthetic importance of enantiopure cyanohydrins, it is not surprising that methods other than the ones described above have been investigated to achieve this goal. With regard to enzymatic methods other than the use of hydroxynitrile lyases, the resolution of esters of racemic cyanohydrins has also been investigated.[46–48] Another approach uses cyclic dipeptides for asymmetric cyanohydrin synthesis,[36,49,50] or applies chiral Lewis acids.[36,50,51] However, regarding chemical yield, enantiopurity and substrate range accepted, the application of hydroxynitrile lyases at present seems to be the optimum choice.

## Acknowledgments

The names of colleagues and co-workers, other than the authors, engaged in research in the area of hydroxynitrile lyases are given in the respective references. We are deeply obliged to them for their enthusiasm, cooperation and support. Funding by the Austrian Science Foundation, Forschungsförderungsfonds der Gewerblichen Wirtschaft and DSM-Chemie Linz is gratefully acknowledged.

**Herfried Griengl received his chemical education in Graz, Heidelberg and Munich. He was a research fellow with Paul D. Bartlett at Harvard University (1968–1969) and is now Professor of Organic Chemistry at the Technical University, Graz. His main research area is biocatalysis.**

**Christoph Kratky was born in Graz, Austria, on December 25, 1946. He studied Chemistry at the Eidgenössischen Technische Hochschule in Zürich (Switzerland), where he also obtained his PhD under the supervision of J. D. Dunitz in the field of chemical crystallography. Following a post-doctoral year at Harvard University in the group of M. Karplus, he joined the University of Graz in 1977, where he now holds the position of Professor in Physical Chemistry. His research is mainly concerned with biophysics and the structure analysis of biological molecules with X-ray diffraction.**

**Dean V. Johnson was born in Welwyn Garden City, England on December 15, 1967, and received his batchelors degree (1989) followed by his doctoral degree (1992) in Chemistry from Exeter University. He was a research fellow with Carl Johnson at Wayne State University (Detroit), then with Irving Wainer at McGill University (Canada). He is currently a research associate at the Technical University, Graz.**

**Andrea Hickel was born in Graz, Austria, on September 6, 1967. She studied chemistry at the Technical University, Graz, where she received her doctoral degree under the supervision of Herfried Griengl in 1996. A post-doctoral research stay in the group of H. W. Blanch in Berkeley will follow.**

**Michael Schmidt was born in Graz, Austria, on November 26, 1964. In 1991 he received the degree of a Diplomingenieur at the Technical University, Graz. After several years in industry he returned to the Technical University, where he is currently working at his doctoral thesis, dealing with chiral syntheses.**

**Helmut Schwab was born in Feldbach, Austria in 1950. He studied biochemistry/biotechnology and received his doctoral degree at the Technial University, Graz, in 1980. After a post-doctoral period in industry, he returned to the Technical University, Graz, and is now heding the Genetics group at the Institute of Biotechnology. His interests are focussed on molecular biotechnology and include gene expression in industrial microorganisms, genetic stability, molecular enzymology and enzyme engineering.**

# A new type of alumoxane obtained by controlled hydrolysis of *N,N*-dialkylcarbamato complexes of aluminium; crystal and molecular structure of $[Al_4(\mu_3\text{-}O)_2(O_2CNPr^i{}_2)_8]$

**Ulrich Abram,[a] Daniela Belli Dell'Amico,[b] Fausto Calderazzo,*[b] Stefan Kaskel,[a] Luca Labella,[b] Fabio Marchetti,[b] Riccardo Rovai[b] and Joachim Strähle*[a]**

[a] *Institut für Anorganische Chemie der Universität Tübingen, Auf der Morgenstelle 18, D-72076 Tübingen, Germany*
[b] *Università di Pisa, Dipartimento di Chimica e Chimica Industriale, Via Risorgimento 35, I-56126 Pisa, Italy*

**The aluminium(III) *N,N*-diisopropylcarbamato derivative $[Al_2(O_2CNPr^i{}_2)_6]$ undergoes hydrolysis with a stoichiometric amount of water giving the $\mu_3$-oxo derivative $[Al_4(\mu_3\text{-}O)_2(O_2CNPr^i{}_2)_8]$, which is analytically, spectroscopically and structurally characterized.**

Hydrolysis of aluminium derivatives is an area of considerable interest, the ultimate goal being a better understanding of the processes leading to aluminium oxides[1] or aluminosilicates[2] from appropriate precursors. In this connection, halo-,[3] alkoxo,[1a,2] and alkyl derivatives[1d,4] of aluminium have been studied extensively. Some alkylalumoxanes[4] have been characterized crystallographically by Barron and coworkers, who obtained them by partial hydrolysis of aluminium alkyls; thus, hydrolysis of $AlBu^i{}_3$ gave[4b,c] the tetranuclear $[Al_4(\mu_3\text{-}O)_2Bu^i{}_8]$ together with the octanuclear $[Al_8(\mu_3\text{-}O)_8Bu^i{}_8]$.

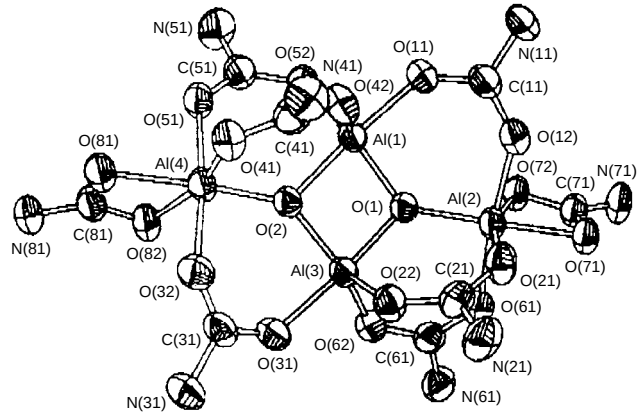
Our earlier work on homoleptic *N,N*-dialkylcarbamato complexes of aluminium[5] prompted us to study the hydrolysis of these compounds, and to verify their aptitude as alumoxane precursors. This paper reports the first case of a hydrolytic process involving an aluminium-bonded *N,N*-dialkylcarbamato group, and the first member of a new type of alumoxane.

The dinuclear[5] *N,N*-diisopropylcarbamato derivative $[Al_2(O_2CNPr^i{}_2)_6]$ undergoes hydrolysis with a stoichiometric amount of water [eqn. (1)] giving the $\mu_3$-oxo derivative $[Al_4(\mu_3\text{-}O)_2(O_2CNPr^i{}_2)_8]$.† An alternative, less satisfactory preparative procedure, consists of treating anhydrous $AlCl_3$ and $AlCl_3{\cdot}6H_2O$ in the appropriate molar ratio, with $Pr^i{}_2NH$–$CO_2$, [eqn. (2)].

$$2[Al_2(O_2CNPr^i{}_2)_6] + 2H_2O \rightarrow [Al_4(\mu_3\text{-}O)_2(O_2CNPr^i{}_2)_8] + 4Pr^i{}_2NH + 4CO_2 \quad (1)$$

$$11\ AlCl_3 + AlCl_3{\cdot}6H_2O + 24\ CO_2 + 60\ Pr^i{}_2NH \rightarrow 3[Al_4(\mu_3\text{-}O)_2(O_2CNPr^i{}_2)_8] + 36\ [NH_2Pr^i{}_2]\ Cl \quad (2)$$

In the latter case, the toluene soluble μ-oxo derivative is separated by filtration from the substantially insoluble dialkylammonium chloride. X-Ray diffraction‡ has established the molecular structure of the title compound, as the heptane solvated product, to consist of a tetranuclear assembly of aluminium atoms joined together by $\mu_3$-oxo ligands and by carbamato bridges (Fig. 1). The structure contains two $Al_2(\mu_3\text{-}O)(O_2CNPr^i{}_2)_4$ fragments with the Al(1)–O(1)–Al(2) and the Al(3)–O(2)–Al(4) sequences joined together by bridging carbamato groups and by the third coordination site of the $\mu_3$-oxo ligand. Bridging carbamato groups have also been found in the homoleptic dinuclear precursor $[Al_2(O_2CNPr^i{}_2)_6]$[5] and in the recently reported alkylcarbamato complexes $[(Me_2Al)_2\{\mu\text{-}O_2CNPr^i{}_2\}_2]$ and $[(Me_2Al)_2\{(\mu\text{-}O_2CNPr^i{}_2)_2\}_2Mg]$.[8] The present molecule contains five- [Al(1), Al(3)] and six-coordinate [Al(2), Al(4)] aluminium atoms with distorted trigonal-bipyramidal and octahedral geometries, respectively. It is worth noting that five-coordination to oxygen-containing ligands is uncommon for aluminium; known cases are found in andalusite, $Al_2SiO_5$[9a] and in an aluminium–barium glycolate.[9b] Drying *in vacuo* at room temp. converts the heptane solvated tetranuclear substance into the desolvated species, through a presumably topotactic process[9c,d] which maintains an elevated degree of crystallinity, as shown by X-ray powder diagrams.§



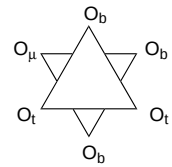


**Fig. 1** ZORTEP drawing of $[Al_4(\mu_3\text{-}O)_2(O_2CNPr^i{}_2)_8]{\cdot}0.5C_7H_{16}$ with the atom numbering scheme. Ellipsoids are at 50% probability, dialkyl groups and solvent are omitted for clarity. Relevant bond distances (Å) and angles (°). Five-coordinate aluminium: Al(1)–O(11) 1.863(2), Al(1)–O(42) 1.836(2), Al(1)–O(52) 1.811(2), Al(1)–O(1) 1.781(2) Al(1)–O(2) 1.832(2), O(42)–Al(1)–O(52) 106.4(1), O(1)–Al(1)–O(42) 119.3(9), O(1)–Al(1)–O(52), 134.3(1). Six-coordinate aluminium: Al(2)–O(12) 1.899(2), Al(2)–O(61) 1.935(2), Al(2)–O(72) 1.958(2), Al(2)–O(71) 1.937(2), Al(2)–O(1) 1.775(2); O(12)–Al(2)–O(72) 89.9(9), O(61)–Al(2)–O(72) 88.1(1), O(21)–Al(2)–O(61) 89.9(1), O(12)–Al(2)–O(21) 90.2(1), O(1)–Al(2)–O(71) 171.3(1). $\mu_3$-Oxygen; Al(1)–O(1)–Al(2) 134.0(1), Al(1)–O(1)–Al(3) 97.2(1), Al(2)–O(1)–Al(3) 120.9(1), Al(1)–O(2)–Al(3) 97.7(1), Al(1)–O(2)–Al(4) 120.9(1), Al(3)–O(2)–Al(4) 134.3(1).

To a first approximation, the six-coordinate aluminium can be regarded as asymmetric, as shown below in a view along two opposite triangular faces of the octahedron [$O_b$, $O_t$ and $O_\mu$ are the oxygen atoms belonging to bridging and terminal carbamato groups, and to the triply bridging oxo group, respectively]. As the tetranuclear aluminium compound crystallizes in the centrosymmetric space group $P\bar{1}$, the two enantiomers in the crystal are related by an inversion centre.

The spectroscopic data are consistent with the literature data for μ-oxo derivatives.[10–12] An intense IR band at 772 $cm^{-1}$ is attributed to the $(\mu_3\text{-}O)Al_3$ system. The presence of a single Al–

O stretching vibration in the tetranuclear aluminium compound suggests either accidental degeneracy or an almost planar ($\mu_3$-O)$Al_3$ system; the latter hypothesis is consistent with the solid-state data showing that the triply bridging oxides O(1) and O(2) are 0.28 and 0.27 Å, respectively, away from the plane of the three aluminium atoms to which they are connected. On the other hand, the $Al_4(\mu_4\text{-O})_2$ system is also almost planar, the dihedral angle between the Al(1)–Al(2)–Al(3) and Al(1)–Al(3)–Al(4) planes being only 8°. The $Al_4O_2$ frame closely resembles the tetranuclear alkylalumoxane $[Al_4(\mu_3\text{-O})_2Bu^i_8]$ with two $\mu_3$-oxo ligands and a substantially planar $Al_4O_2$ core. The $Al_4O_2$ frame is also known in a few cases, namely the anionic $[Al_4O_2Me_{10}]^{2-}$ [4a] and $[Al_4O_2Cl_{10}]^{2-}$ [3c] or the alkylalumoxane $[Al_4(\mu_3\text{-O})_2Bu^i_8]$.[4b] The $Al_3(\mu_3\text{-O})$ moieties in $[Al_5(Bu^t)_5(\mu_3\text{-O})_2(\mu_3\text{-OH})_2(\mu\text{-OH})_2(\mu\text{-O}_2CPh)_2]\cdot MeCN$,[1d] containing five-coordinate aluminium, show Al–O distances in the range 1.785(4)–1.827(3) Å, similar to those observed in our case; the Al–O–Al angles are 106.1(2), 107.1(2) and 130.0(2)°, corresponding to a greater deviation from planarity.

Despite the low symmetry of the aluminium environment, the NMR data are relatively simple. The broad $^{27}$Al NMR resonance at $\delta$ 4.0 with a shoulder at $\delta$ *ca*. 50 is suggestive of non-equivalent aluminium centres[13a] broadened by the large quadrupole moment of the metal.[13b] The $^{13}$C NMR spectrum shows three main $O_2CNR_2$ resonances due to non-equivalent carbamato groups. The $^1$H NMR spectra indicate the presence of non-equivalent alkyl groups within the tetranuclear compound; fast rotation around the C–N bond, on the NMR timescale, is further suggested by the observation of two main CH (multiplets) and four main $CH_3$ (doublets) resonances.

† Anhydrous $AlCl_3$ (7.65 g, 57.37 mmol) was added to a toluene solution (400 ml) of diisopropylamine (60.3 ml, 430 mmol) presaturated with $CO_2$. The mixture was stirred for 3 d under carbon dioxide at room temp. The dialkylammonium chloride was filtered off and washed with toluene (3 × 50 ml) and the colourless filtrate was hydrolyzed under a dinitrogen atmosphere by dropwise addition of water (0.5 ml, 27.78 mmol) dissolved in thf (350 ml), corresponding to a Al/$H_2O$ molar ratio of 2.07. Vacuum–dinitrogen cycles were repeated several times during the hydrolysis. The volatiles were then removed *in vacuo*; the solid residue was dried for 6 h at 50 °C and heptane (250 ml) was then added. The resulting suspension was filtered and the colourless μ-oxo derivative was dried *in vacuo* at room temp. for several hours. Yield 12.29 g, 66%. Anal. Calc. for $C_{56}H_{112}Al_4N_8O_{18}$: Al, 8.3; $CO_2$, 27.2. Found: Al, 8.0; $CO_2$, 26.7%. Samples of the vacuum-dried polycrystalline substance gave an X-ray diffraction diagram (dry argon, Siemens D5000 diffractometer) with the following parameters [spacings *d*/Å, intensities (%) in parentheses]: 14.091(21), 13.156(3), 12.079(75), 11.842(100), 10.659(44), 9.240(4), 8.634(12), 8.085(6), 7.352(3), 7.011(12), 6.429(9), 6.239(3), 5.894(6), 5.581(10), 5.412(8), 5.300(17), 5.143(8), 4.634(9), 4.530(4), 4.395(6), 4.316(5), 4.191(3), 4.040(4), 3.948(3), 3.790(3), 3.659(4), 3.605(3), 3.531(3), 3.119(3). *Selected spectroscopic data*, NMR (benzene, $\delta$); $^1$H: 1.09 (d), 1.27 (d), 1.34 (d), 1.45 (d), 3.86 (m), 4.40 (m); $^{27}$Al: 3.5 (s), *ca*. 50(sh), with respect to $[Al(H_2O)_6]Cl_3$; $^{13}$C: 160.2, 161.4, 167.1 ($O_2CNR_2$). # Thioether macrocycles as spacers for crystal engineering: synthesis and crystal structures of $[Ag_2([24]aneS_8)(CF_3SO_3)_2(MeCN)_2]_\infty$ and $[Ag([16]aneS_4)(BF_4)]_\infty$ ([24]aneS$_8$ = 1,4,7,10,13,16,19,22-octathiacyclotetracosane; [16]aneS$_4$ = 1,5,9,13-tetrathiacyclohexadecane)

**Alexander J. Blake, Wan-Sheung Li, Vito Lippolis and Martin Schröder***

*Department of Chemistry, The University of Nottingham, University Park, Nottingham, UK NG7 2RD*

**The polymeric complexes $[Ag_2([24]aneS_8)(CF_3SO_3)_2(MeCN)_2]_\infty$ and $[Ag([16]aneS_4)(BF_4)]_\infty$ show infinite ladder and layered structures respectively, with the thioether crown controlling the multi-dimensional architecture.**

The coordination chemistry of crown thioethers has been of great interest over the past decade.[1] Most studies have been focused on the coordination chemistry of these ligands to transition metal ions,[1–4] although very little information is available on $Ag^I$ complexes with crown thioethers containing four or eight S-donor atoms.[5] Parallel to this, the design of solid-state architectures has become an area of increasing interest,[6–9] with attention focused predominantly upon the use of supramolecular contacts (particularly hydrogen bonding) between suitable organic molecules to generate multi-dimensional arrays and networks.[6–9] In comparison, the design of inorganic networks,[10–12] particularly polymeric metal complexes, is less well developed[13] with most of the examples being based upon linear bridging ligands bound to tetrahedral metal ions such as $Cu^I$ and $Ag^I$.[11,12,14] Few polymeric structures for thioether crown complexes have been reported, dimensional control being achieved mainly by variation of the counter-anion.[2,5] We report herein two new polymeric thioether crown complexes of $Ag^I$ whose multi-dimensional architecture is controlled by the thioether crowns building blocks.

Reaction of [24]aneS$_8$ with 2 equiv. of $AgCF_3SO_3$ in $CH_2Cl_2$–$CH_3CN$ affords a white solid which can be recrystallised from $CH_3CN$–$Et_2O$.† A single crystal X-ray structure determination‡ confirms the product to be a one-dimensional polymer, $[Ag_2([24]aneS_8)(CF_3SO_3)_2(MeCN)_2]_\infty$, in which each $Ag^I$ ion is coordinated to four S-donors in a distorted tetrahedral geometry with S–Ag–S angles ranging from 85.83(5) to 127.36(5)° and Ag–S bond distances from 2.5400(14) to 2.627(2) Å. The four S-donors come from two different ligand molecules to generate an infinite ladder polymer along the *b* axis (Fig. 1). Within the ladder, pairs of symmetry-related $Ag^I$ ions are coordinated between two macrocyclic ligands, so that all eight S-donors of each [24]aneS$_8$ molecule are engaged in coordination. Each metal ion is also a spiro centre, being the common atom of two almost perpendicular $AgS_2C_2$ rings. The macrocycle adopts a unique pattern of alternate *endo*- and *exo*-orientated S-donors, with 9 out of 12 torsion angles less than 90° and all the S–C–C–S torsion angles having a *gauche* arrangement. Stacks of $CF_3SO_3^-$ ions and acetonitrile molecules are observed between the polymeric chains. Significantly, the use of $NO_3^-$ as counter-anion leaves the structure of the polymeric $Ag^I$ complex unchanged in $[Ag_2([24]aneS_8)(NO_3)_2(H_2O)]_\infty$.

Reaction of [16]aneS$_4$ with $AgBF_4$ in 1 : 1 molar ratio in $CH_3CN$–$CH_2Cl_2$ affords a white powder which can be recrystallised from hot dmf.† A single crystal X-ray structure determination‡ confirms the product to be a three-dimensional polymer, $[Ag([16]aneS_4)(BF_4)]_\infty$. Each $Ag^I$ ion occupies a crystallographic $\bar{4}$ ($S_4$) site and is coordinated by four symmetry-equivalent S-donor atoms in a tetrahedral geometry with S–Ag–S angles of 119.44(2) and 90.98(3)° and Ag–S bond distances of 2.6121(7) Å. The donor atoms are derived from four symmetry-related [16]aneS$_4$ molecules, each of which is bound to four different $Ag^I$ ions (Fig. 2). The mcrocycle adopts a [4444] conformation with all the sulfur atoms *exo*-oriented. The [16]aneS$_4$ molecules lie in sheets perpendicular to the *c* axis, within which 24-membered rings can be recognised: these comprise four $Ag^I$ ions and one S–C–C–C–S edge from four different thioether ligands (Fig. 2). Successive layers are stacked offset along *c* so that the [16]aneS$_4$ molecules and the 24-membered rings alternate, giving rise to channels within which the $BF_4^-$ anions lie at the centres of the larger rings. This compound represents the first structurally characterized complex of $Ag^I$ with an unfunctionalised tetradentate thioether

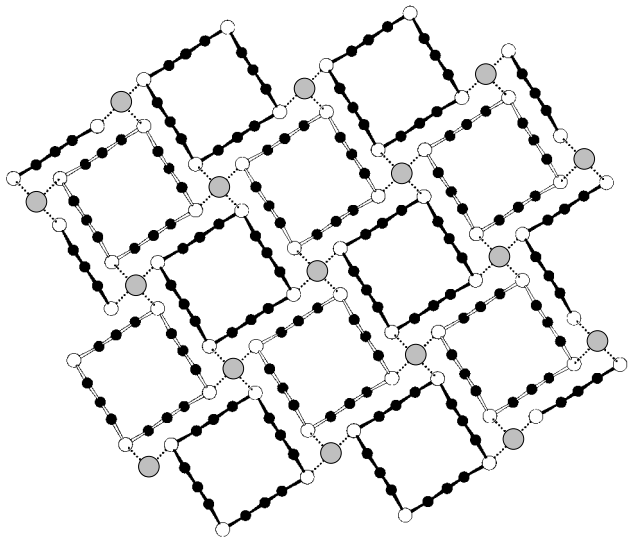

**Fig. 2** View of the packing diagram for the $\{[Ag([16]aneS_4)]^+\}_\infty$ polymeric complex along the *c* axis. Counter-anion omitted for clarity. Atoms shaded as in Fig. 1.

crown, although a polymeric structure has been reported with the ligand $(OH)_2$-[16]aneS$_4$[5] in which the OH groups play a major role in the crystal packing through extensive hydrogen bonding.

This work illustrates the potential of thioether crowns as building blocks for the synthesis of inorganic architectures using their *exo*-orientated S-donors. We are currently investigating how we may fine-tune the multi-dimensional architectures of polymeric Ag$^I$ complexes with tetradentate thioether crowns.

We thank the EPSRC for financial support.

# Realumination of dealuminated HZSM-5 zeolites by acid treatment

**Tsuneji Sano,* Rie Tadenuma, Zhengbao Wang and Kazuo Soga**

*School of Materials Science, Japan Advanced Institute of Science and Technology, Tatsunokuchi, Ishikawa 923-12, Japan*

**$^{27}$Al MAS NMR and FTIR spectroscopy shows that part of non-framework aluminiums in dealuminated HZSM-5 zeolites are reinserted into the framework upon treatment with aqueous hydrochloric acid.**

Physicochemical properties of zeolites such as catalytic, sorptive and ion-exchange abilities are strongly dependent on their framework (tetrahedrally coordinated) aluminiums in the zeolite structure. Dealumination from zeolite framework has been widely studied to alter the $SiO_2/Al_2O_3$ ratio of the framework. We have kinetically investigated the dealumination behavior of ZSM-5 zeolite and metallosilicate by thermal and hydrothermal treatments, and already reported that the dealumination rate by hydrothermal treatment has an apparent third-order dependence on the number of framework aluminiums.[1–3] As the framework aluminium atoms are isolated from each other in the case of highly siliceous zeolites such as ZSM-5, this indicates that the dealumination *via* hydrolysis of Si–O–Al bonds in the zeolite framework is catalyzed by acid (protons) which move freely in the zeolite pores. Realumination, the reverse reaction of hydrolysis of the Si–O–Al bond, as well as dealumination of zeolites has received considerable attention from the standpoint of regeneration of zeolite catalysts. There are several papers concerning the realumination of dealuminated zeolite by treatment with aqueous alkali solution, suggesting the reinsertion of non-framework aluminium into the framework (a decrease in the framework $SiO_2/Al_2O_3$ ratio).[4–10] However, no study of realumination by acid treatment has been reported in the literature. Here, the realumination of dealuminated HZSM-5 zeolites by treatment with aqueous HCl was investigated.

HZSM-5 zeolite was prepared following the procedure previously described.[1] A $SiO_2/Al_2O_3$ ratio of 71 was determined by X-ray fluorescence (XRF, Philips PW-2400) while a framework $SiO_2/Al_2O_3$ ratio of 78 was determined by $^{27}$Al MAS NMR spectroscopy (Varian VXP-400) using a calibration curve, which was produced by measuring $^{27}$Al MAS NMR spectra of HZSM-5 zeolites with various $SiO_2/Al_2O_3$ ratios.[2,3] Dealumination of the HZSM-5 zeolite was carried out by thermal and hydrothermal treatments at 600 °C using a muffle furnace and a quartz reactor tube. The water vapor pressure in the hydrothermal treatment was 10 kPa, generated using nitrogen as the diluent gas. HCl treatment (realumination) was carried out as follows: 1 g of dealuminated HZSM-5 zeolite was treated with 100 ml of aqueous 2 M HCl at 100 °C, stirring for a given time. The product was filtered off, washed thoroughly with deionized water, dried at 100 °C and calcined at 380 °C for 8 h. Characterization of dealuminated and realuminated HZSM-5 zeolites was achieved by $^{27}$Al MAS NMR spectroscopy, diffuse reflectance FTIR (JEOL JIR-7000), and nitrogen adsorption (Bel Japan Belsorp 28SA).

X-Ray diffraction diagrams of realuminated HZSM-5 zeolites after HCl solution treatment show no peaks other than those corresponding to ZSM-5 zeolite. The intensities of the peaks observed were almost the same as those of the dealuminated zeolite, indicating no structural degradation. This was also confirmed by the fact that no difference in the micropore volume $W_0(N_2)$ of 0.18 $cm^3$ (liquid) $g^{-1}$ obtained by the Dubinin–Raushkevich (DR) plot of the nitrogen adsorption isotherm was observed between dealuminated and realuminated zeolites. Fig. 1 shows FTIR spectra of the parent HZSM-5 (total $SiO_2/Al_2O_3$ ratio 71), the dealuminated HZSM-5 prepared by thermal treatment at 600 °C for 48 h (total $SiO_2/Al_2O_3$ ratio 72) and the realuminated HZSM-5 after HCl treatment (total $SiO_2/Al_2O_3$ ratio 78). The decrease in the peak at 3605 $cm^{-1}$ assigned to an acidic bridged OH of Si(OH)Al was observed in the spectrum of dealuminated HZSM-5 zeolite, while a clear increase in the peak intensity was observed in the spectrum of realuminated zeolite. This result suggests the reinsertion of non-framework aluminiums in the dealuminated zeolite into the framework.

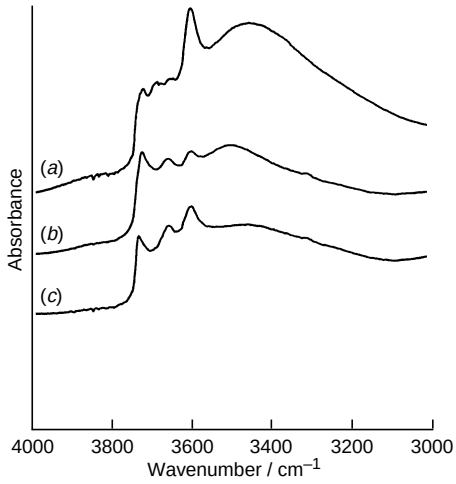

**Fig. 1** FTIR spectra of HZSM-5 zeolites of (*a*) parent, (*b*) after thermal dealumination at 600 °C for 48 h and (*c*) after realumination of (*b*) with 2 M HCl at 100 °C for 120 h

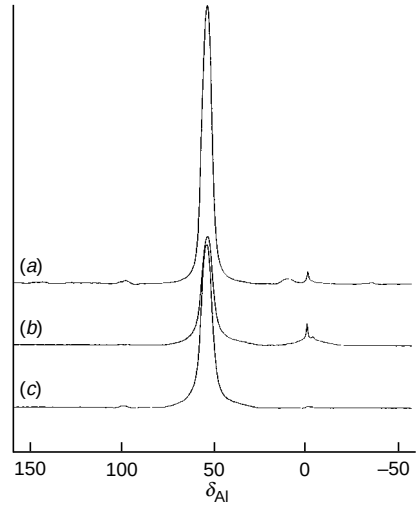

**Fig. 2** $^{27}$Al MAS NMR spectra of HZSM-5 zeolites of (*a*) parent, (*b*) after thermal dealumination at 600 °C for 48 h and (*c*) after realumination of (*b*) with 2 M HCl at 100 °C for 120 h

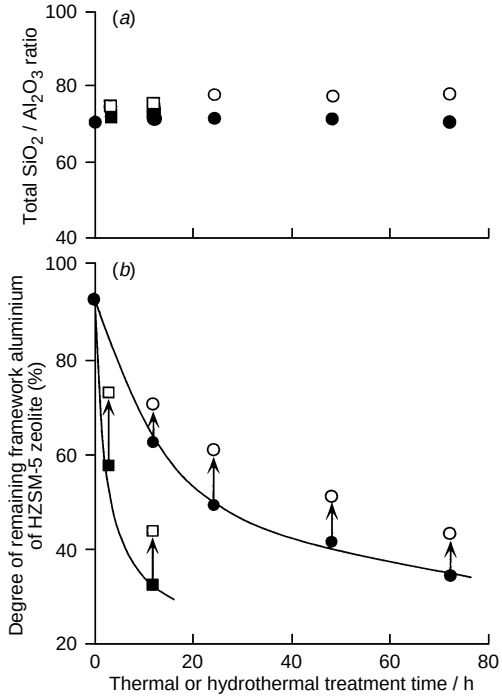

**Fig. 3** Total $SiO_2/Al_2O_3$ ratios and degrees of remaining framework aluminium of dealuminated and realuminated HZSM-5 zeolites. (●), HZSM-5 dealuminated by thermal treatment at 600 °C; (○), after treatment with 2 M HCl at 100 °C for 120 h; (■), HZSM-5 dealuminated by hydrothermal treatment at 600 °C and $P_{H_2O}$ of 10 kPa; (□), after treatment with 2 M HCl at 100 °C for 120 h.

To clarify this possibility of reinsertion, the $^{27}$Al MAS NMR spectra of these samples were measured. The normalized intensity of the peak at $\delta$ 53 assigned to framework aluminium of HZSM-5 zeolite was based on 1 g of zeolite. As shown in Fig. 2, the peak intensity of the dealuminated HZSM-5 zeolite definitely increased upon treatment with HCl. The calculated framework $SiO_2/Al_2O_3$ ratios of the dealuminated and the realuminated HZSM-5 zeolite were 173 and 140, respectively. As the total $SiO_2/Al_2O_3$ ratio of the realuminated zeolite was 78, dissolution of non-framework aluminium occurred during treatment with HCl; this indicates that some of the non-framework aluminium in dealuminated HZSM-5 zeolite is reinserted into the framework.

However, there is another possible explanation for the increase in the peak intensities of $^{27}$Al MAS NMR and FTIR spectra, namely that the increase is attributable to the removal of the framework silicon atoms.[12,13] To clarify this, therefore, silicon and aluminium concentrations in the liquid phase after HCl treatment were analyzed by inductively coupled argon emission spectroscopy (Seiko SPS7700). The degrees of elution of silicon and aluminium atoms from the dealuminated zeolite during the HCl treatment were 0.99 and 9.3%, respectively, indicating that the removal of framework silicon atoms scarcely takes place during this process. This is consistent with the result reported by Kooyman *et al.*[14] Therefore, we can conclude that realumination of dealuminated zeolite occurs during acid treatment.

To gain more information about the realumination, the realumination of several dealuminated HZSM-5 zeolites with different framework $SiO_2/Al_2O_3$ ratios was carried out at 100 °C for 120 h using 2 M HCl. Dealuminated HZSM-5 zeolites with different degrees of dealumination were prepared by varying the thermal treatment time. Fig. 3 shows the total $SiO_2/Al_2O_3$ ratios and the degree of remaining framework aluminium of dealuminated and the corresponding realuminated HZSM-5 zeolites. The total $SiO_2/Al_2O_3$ ratios of realuminated HZSM-5 zeolites were slightly higher than those of dealuminated zeolites. All framework aluminium ion concentrations of dealuminated HZSM-5 zeolite increased upon HCl treatment. Dealuminated HZSM-5 zeolites were also prepared by hydrothermal treatment at 600 °C under a water vapor pressure of 10 kPa and then treated with HCl and the result is also illustrated in Fig. 3 with reinsertion of non-framework aluminium into the framework also being observed.

From the above results, it is concluded that some of the non-framework aluminium in dealuminated HZSM-5 zeolite is reinserted into the framework in the presence of an aqueous solution of hydrochloric acid although the detailed mechanism of the realumination is not clear. As it is well known that non-framework aluminium is not uniform and exists in different states,[15] we primarily speculate that realumination proceeds mainly through reinsertion of non-framework aluminium species where the aluminium atom is connected to the zeolite framework by only one or two chemical bonds.

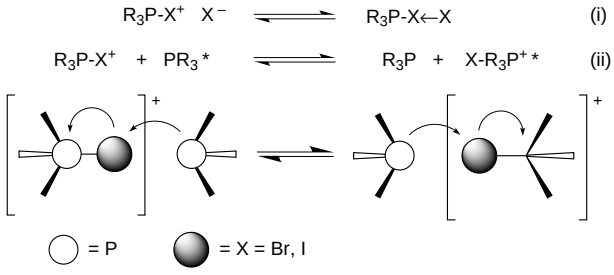
# ‘Soft–soft’ halogen–halogen interactions in solid ion pairs of solvent-free $Pr^i_3PCl_2$ and $CH_2Cl_2$-solvated $Pr^i_3PBr_2$: structural features of chloro- and bromo-triisopropylphosphonium salts

**Frank Ruthe, Wolf-W. du Mont* and Peter G. Jones**



*Institut für Anorganische und Analytische Chemie, Technische Universität Braunschweig, Postfach 3329, D 38023, Braunschweig, Germany*

**An X-ray crystallographic study of solvent-free $Pr^i_3PCl_2$ and dichloromethane-solvated $Pr^i_3PBr_2$ reveals that both halogenophosphonium halides exist as monomeric ion pairs $Pr^i_3P^+$–X···$X^-$; elongations of P–Cl and P–Br bonds are associated with Cl···Cl and Br···Br interactions.**

Iodine atoms and bromine atoms adjacent to phosphonium centers behave as soft electrophiles. Nucleophilic attack by tertiary phosphanes $R_3P$ at I (of $R_3PI^+$) or Br (of $R_3PBr^+$) leads to rapid $I^+$ or $Br^+$ transfer in solution (‘fluxional $P^{III}$–$P^V$ systems’), as detected by $^{31}P$ and $^1H$ NMR spectroscopy[1–3] (Scheme 1). In the solid state, I···I interactions of iodophosphonium ions $R_nPI_{4-n}^+$ with iodide counter ions lead, depending on the number of iodine atoms adjacent to phosphorus, to ‘spoke’ structures with approximately linear P–I···I units ($n$ = 3; $R_3PI_2$)[3–7] to rings, helices and zigzag chains ($n$ = 2, $R_2PI_3$),[8–11] or to interpenetrating puckered layers and three-dimensional networks ($n$ = 1, $RPI_4$).[12]

Evidence for related structures with Br···Br or even Cl···Cl interactions is still extremely scarce. McAuliffe *et al.* found that $Ph_3PBr_2$ also exists (as do $Ph_3PI_2$[4] and $Ph_3PIBr$[13]) as a ‘molecular charge-transfer-like spoke’;[14] dichloromethane-solvated $Ph_3PCl_2$, however, contains $[Ph_3PCl{\cdots}Cl{\cdots}ClPPh_3]^+$ cations that are well separated from $Cl^-$ anions.[15] Is there a general difference between the solid state structures of compounds $R_3PCl_2$ compared with $R_3PI{\cdots}I$ and $R_3PBr{\cdots}Br$, or is the structure of dichloromethane-solvated $Ph_3PCl_2$ an exceptional case? To determine whether ion–dipole interactions of the anion with dichloromethane or other effects contribute to the latter ‘exceptional’ structure, it was desirable to solve the structure of a related solvent-free species $R_3PCl_2$ and of a solvated species $R_3PBr_2$ (R = alkyl). Fortuitously, the crystallisation behaviour of triisopropylphosphane derivatives $Pr^i_3PX_2$ (X = Cl **1**,[17] X = Br **2**[16]) was found to meet just the above requirements.

Crystallisation from dichloromethane provided solvent-free **1**, which is, to the best of our knowledge, the first crystallographically characterised solvent-free compound of stoichiometry $R_3PCl_2$. **2**, however, gave crystals containing 0.5 equiv. of $CH_2Cl_2$ under comparable conditions. Both solid compounds contain $R_3P^+$–X···$X^-$ ion pairs with approximately linear P–X···X units;[3,4] the bromide ions of two such ion pairs of **2** are ‘bridged’ by a $CH_2Cl_2$ molecule (Figs. 1 and 2). We have

**Scheme 1** The positions of equilibria i and ii depend on R

since found that the corresponding P–I compound $[(Pr^i_3PI_2)_2{\cdot}CH_2Cl_2]$[18] is isostructural. The $Br^-{\cdots}H$–C–H···Br contacts can be understood as bromide solvation by ion–dipole interactions.

The Cl···Cl distance within ion pairs of **1** [3.234(1) Å] is slightly shorter than those of $Ph_3PCl{\cdots}Cl{\cdots}ClPPh_3]^+$ [3.279(6) Å];[15] the degree of interaction by (valence-shell expanding) $Cl \rightarrow Cl\ n \rightarrow \sigma^*$ overlap is obviously not very dependent on the coordination number of the donating chloride ion. Packing and anion solvation effects might both contribute to the structural difference between $Ph_3PCl_2{\cdot}CH_2Cl_2$[15] and **1**. A reinvestigation of the structure of $[Pr^i_3PCl]^+[N(SO_2CH_3)_2]^-{\cdot}CH_2Cl_2$[19] **3** reveals that here chlorine atoms of a well ordered $CH_2Cl_2$ approach the Cl atom of the $[Pr^i_3PCl]^+$ cation [3.407(2) Å] to satisfy its Lewis-acidic needs, which apparently cannot be met by the $[N(SO_2Me)_2]^-$ counter ion.

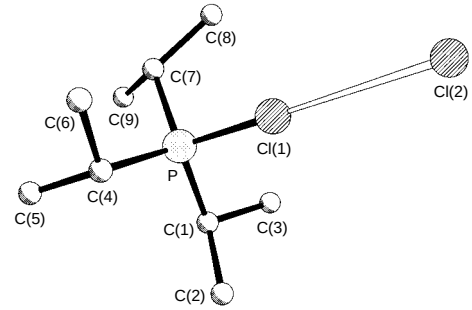


**Fig. 1** Molecular structure of **1**. H atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): P–Cl(1) 2.002(1), Cl(1)···Cl(2) 3.234(1); P–Cl(1)···Cl(2) 177.5(1).

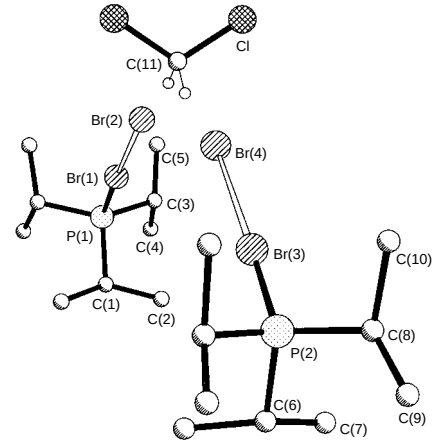

**Fig. 2** Molecular structure of **2**. H atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): P(1)–Br(1) 2.185(3), Br(1)···Br(2) 3.369(2), P(2)–Br(3) 2.174(3), Br(3)···Br(4) 3.315(2); P(1)–Br(1)···Br(2) 175.0(1), P(2)–Br(3)···Br(4) 176.5(1).

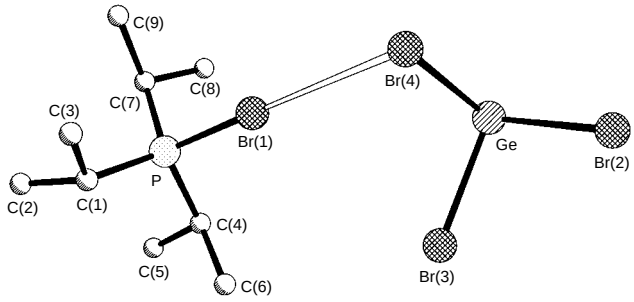

**Fig. 3** Molecular structure of **4**. H atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): P–Br(1) 2.155(2), Br(1)···Br(4) 3.415(1), Ge–Br(4) 2.556(1), Ge–Br(2) 2.481(1), Ge–Br(3) 2.480(1); P–Br(1)···Br(4) 177.8(1).

Bromotrialkylphosphonium tribromogermanates(II) and tribromostannates(II) have been identified spectroscopically as the products from reactions of bulky phosphanes with germanium and tin tetrabromides;[2] structural evidence by X-ray methods, however, has not yet been provided. In salts $[R_3PBr]^+[MBr_3]^-$ (M = $Ge^{II}$, $Sn^{II}$), cation–anion interactions might occur *via* Br···$M^I$ or Br···Br contacts. In the latter case, the Br···Br contacts would provide an interesting comparison with those of compound **2**. We therefore reacted $Pr^i_3P$ with $GeBr_4$: the new compound $Pr^i_3PBr^+GeBr_3^-$ **4**, formed in high yield, provides the first crystallographic characterisation of a product from a germanium or tin tetrahalide/tertiary phosphane redox reaction.[2,20,21] Consistent with the lower donor ability of the Br atoms of the $GeBr_3^-$ anion, cation–anion Br···Br contacts in **4** [3.415(1) Å] are slightly longer and the P–Br bond in **4** [2.155(2) Å] is slightly shorter than those in **2** (Fig. 2) or in $Ph_3PBr_2$ {*d*(Br–Br) 3.123(2), *d*(P–Br) 2.181(3) Å} (Fig. 3).[14]

P–I bonds of iodophosphonium ions are affected by $n \rightarrow \sigma^*$ overlap from nucleophiles attacking the I atoms. P–Br bond lengths [**2**, 2.185(3), 2.174(3) Å; **4**, 2.155(2) Å] are less affected by cation–nucleophile interactions than P–I bond lengths and the related impact on P–Cl bond lengths [**1**, 2.002(1) Å; **3**, 1.994(2) Å;[19] $Me_3PCl^+SbCl_6^-$, 1.986(2) Å[22]] is even smaller.

In contrast to the above-mentioned rapid $I^+$ or $Br^+$ transfer between phosphanes,[1,2] which is also observed in mixtures of **2** and $Pr^i_3P$ in $CH_2Cl_2$ solution at room temperature (1 : 1 mixture: $\delta_P$ 57), comparable $R_3PCl^+$–$R_3P$ systems do not give averaged $P^{III}$–$P^V$ NMR signals, indicating that transition states $[R_3P–X–PR_3]^+$ are of higher energy when X = Cl. $^{31}$P NMR shifts of the cations of **1**–**4** are only slightly anion dependent ($\delta_P$ in $CH_2Cl_2$ solution: **1**, 120.1; **2**, 114.9; **3**, 119.8;[19] **4**, 114.3).

In conclusion, phosphoranes with one I or Br atom bonded to pentacoordinated phosphorus are known;[23,24] however all as yet structurally characterised solid halogenophosphonium halides $R_3PX_2$ (X = Cl, Br, I) do not contain pentacoordinated phosphorus, but are ionic and exhibit similar types of cation–anion halogen–halogen interactions. The increasing significance of X···X interactions, the increasing extent of P–X bond lengthening and the increasing accessibility of $[R_3P···X···PR_3]^+$ transition states (Cl ≪ Br < I) associated with 'soft–soft' ($n \rightarrow \sigma^*$) interactions are all consistent with the known range of increasing electrophilicity and polarisability of the heavier halogens.

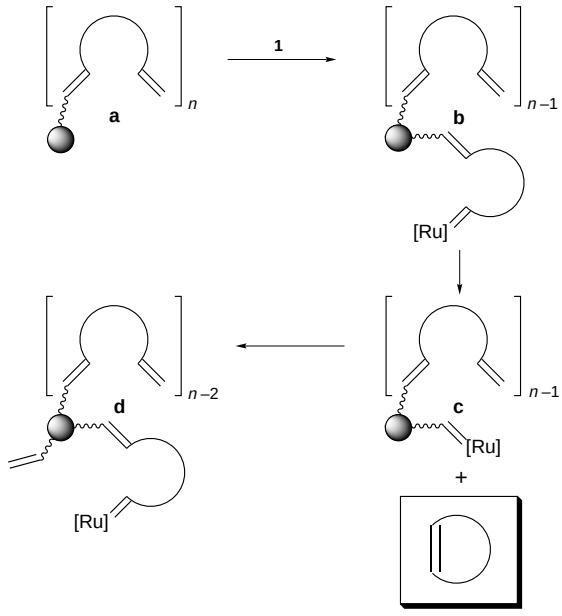
# Cyclisation/cleavage of macrocycles by ring-closing metathesis on solid support—conformational studies



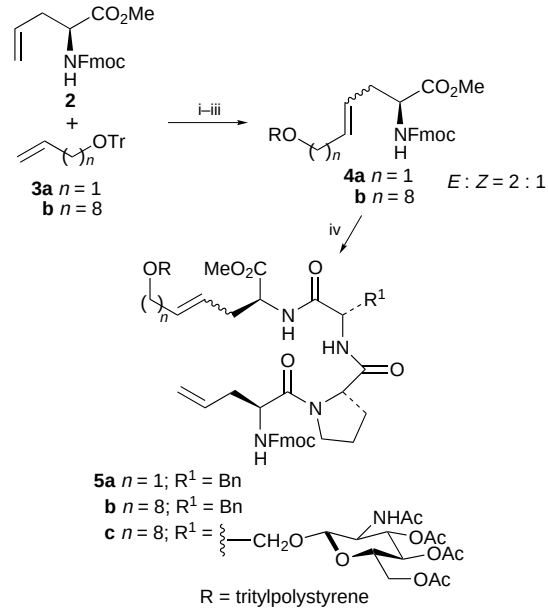
**Josef Pernerstorfer, Matthias Schuster and Siegfried Blechert***

*Institut für Organische Chemie, Sekr. C3, Technische Universität Berlin, Strasse des 17. Juni 135, D-10623 Berlin, Germany*

**Grubbs' ruthenium metathesis catalyst 1 was used to investigate the catalytic cyclisation/cleavage of tetrapeptide-derived macrocycles from a solid support; the rate dependence on substrate conformation has been studied.**

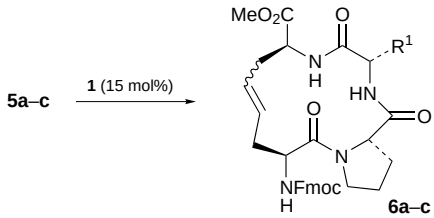
Recent developments in the field of alkene metathesis[1] were initiated by the introduction of catalysts[2] with unprecedented activities even in the presence of polar functional groups. In particular, ring-closing metathesis (RCM) has emerged as a powerful tool for the synthesis of different ring systems from five-membered rings to macrocycles.[3,4] Usually, cyclisations to large rings are performed in diluted solutions to supress competing acyclic diene metathesis (ADMET). RCM is also applicable to polymer-supported substrates.[5] In addition to ring closure, metathesis catalysts have been employed to facilitate catalytic binding[6] of alkenes to polystyrene-based resins as well as their catalytic cleavage.[7] A most interesting approach combines both RCM and the liberation of the cyclic alkene.[8]

Herein, we report investigations into the cyclisation/cleavage of macrocycles from solid support. Metatheses were performed using the well-established Grubbs' ruthenium initiator $Cl_2(PCy_3)_2Ru{=}CHPh$ **1** (Cy = cyclohexyl).[2] According to our concept (Scheme 1), **1** is expected to selectively attack a terminal double bond for steric reasons. This initial step (**a** → **b**) is followed by a RCM resulting in the liberation of one equivalent of the macrocycle and in the formation of polymer-bound metal–carbene complex **c**. Assuming sufficient flexibility, a transfer of the metal complex on the polymer surface (**c** → **d**) should take place, thus, enabling further catalytic cleavage cycles.[9] Byproducts resulting from quasi-intermolecular crossed metatheses of terminal double bonds remain bound to the resin during the entire process.

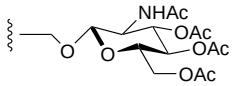


**Scheme 1**

We choose to perform our studies on peptide structures, since the sequence-dependence of their conformations is empirically well described.[10] Chlorotritylpolystyrene was used as the solid support, since solid-phase-bound reaction byproducts are easily monitored after cleaving the acid-labile trityl ether bond. Polymer-supported dialkenic tetrapeptides were obtained by standard Fmoc peptide chemistry using L-Fmoc-amino acids.



Under catalysis of **1** the side chain of Fmoc-allylglycine methyl ester **2** was selectively cross-coupled with *O*-trityl-protected hydroxy alkenes **3a,b** of different chain length.† To date, few comparable examples for synthetic applications of catalytic crossed metatheses have been described.[11] After deprotection, metathesis products were reacted with chlorotritylpolystyrene resin to give resin-linked, Fmoc-protected *C*-allylglycines **4** serving as starting materials for the solid phase synthesis of dialkenic tetrapeptides **5a–c** (Scheme 2). The terminal double bond was introduced by coupling Fmoc-*C*-allylglycine as the N-terminal amino acid. All resins described herein contained approximately 0.5 mmol $g^{-1}$ of tetrapeptide. The tetrapeptide motif of **5a** and **5b**, respectively, is closely related to disulfide bridge-stabilized β-turns found in redox-active proteins[12] and is, therefore, well suited for cyclisation as demonstrated by Miller *et al.* recently.[13] Results for ruthenium-catalysed cyclisations are given in Table 1.‡

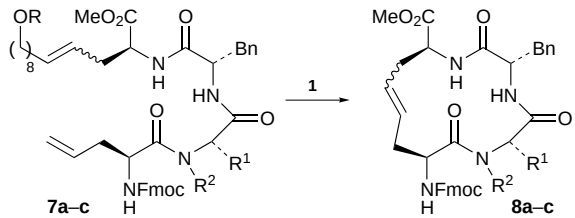


Remarkably, **5b** cyclised smoothly despite the high loading of 0.5 mmol $g^{-1}$. Comparison with the conversion of **5a** reveals that the extent of cyclisation/cleavage depends strongly on spacer length and, thus, mobility of the polymer-supported intermediates. Subsequent work was therefore carried out using the long spacer. Cyclisation of **5c** to cyclic glycopeptide **6c** with

**Scheme 2** *Reagents and conditions*: i, **1** (4 mol%); ii, TFA; iii, RCl; iv, piperidine–DMF, Fmoc-amino acid, PyBOP (iteratively) (PyBOP = benzotriazol-1-yloxytripyrrolidinophosphonium hexafluorophosphate)

**Table 1** Results of cyclisation/cleavage of acyclic **5** to macrocycles **6**

| Product | $R^1$ | *n* | Yield (%) | Purity (%) |
|---|---|---|---|---|
| **6a** | Bn | 1 | 30 | 65 |
| **6b** | Bn | 8 | 70 | 85 |
| **6c** |  | 8 | 30 | 85 |



good product purity demonstrates that highly functionalized dienes are also tolerated by our reaction system.

Since cleavage rates were expected to depend on the conformations of the acyclic precursors, we attempted to correlate the relative cyclisation/cleavage rates of different precursor dienes with their probability to form β-turn-like structures. Rate experiments are easily performed, since most byproducts formed during the metathesis reaction remain bound to the polymer. In **5a**–**c** a β-turn-like structure is induced by the proline residue. Consequently, the proline in **5b** was exchanged by alanine, sarcosine and glycine, respectively, all representing minimal structural analogues of proline. The resulting polymer-supported tetrapeptides **7a**–**c** are less likely to exhibit β-turn-like structures and are, therefore, expected to cyclise significantly slower than **5b** itself. To test this assumption, **5b**, **7a**, **7b** or **7c** were mixed with an equal amount of **5c** serving as an internal standard and reacted with **1**.§ The amounts of cyclic tetrapeptides formed relative to **6c** were determined by HPLC analysis. Relative rates are given in Table 2.

As expected, **7a**–**c** all exhibit significantly decreased cleavage rates as compared to **5b**. The higher rate of sarcosine-containing **7a** compared to **7c** may be explained by the *N*-methyl group expanding the conformational space by abolishing the partial double bond character of the X–Gly peptide bond. To characterize the reaction system polymer-bound byproducts formed during the cyclisation of **5b** (very fast) and **7c** (very slow) were analysed after acidic cleavage from the trityl resin. In case of **5b**, 25% of $\Delta^9$-octadecene-1,18-diol, resulting from dimerisation of the spacer after cleavage of the macrocycle, as well as negligible amounts of acyclic products were isolated. No starting material could be detected. In the case of **9**, besides open-chain byproducts (36%), 40% of the starting material also remained bound to the resin after cyclisation.¶ This latter finding suggests that intermolecular reaction of two terminal double bonds on the resin surface proceeds significantly slower than the cyclisation/cleavage.

**Table 2** Relative cyclisation/cleavage rates of polymer-supported tetrapeptides with different residues in the (*i* + 1)-position (R = tritylpolystyrene)

| Substrate | $R^1$ | $R^2$ | Cyclisation rate relative to **5c** |
|---|---|---|---|
| **5b** | | | 1.36 |
| **7a** | H | Me | 0.15 |
| **7b** | Me | H | 0.11 |
| **7c** | H | H | < 0.02 |

In summary, polymer-bound substrates cyclise rapidly when exhibiting favourable conformations. Macrocycles cleaved at lower rates are obtained in good purity, since byproducts remain bound to the polymer.

## Footnotes and References

* E-mail: sibl@wap0105.chem.tu-berlin.de

† Selective cross-metathesis: **2** (0.6 g, 17 mmol) was combined with **3** (34 mmol) in $CH_2Cl_2$ (10 ml) and reacted with **1** (50 mg, 0.062 mmol) at reflux for 12 h with exclusion of moisture and air. Cross-metathesis products were purified by flash chromatography and isolated in 75% yield each.

‡ Cyclisation/cleavage: polymer (200 mg) was suspended in $CH_2Cl_2$ (1.5 ml) and refluxed after addition of **1** (9 mg, 0.011 mmol). After 17 h the resin was filtered off and washed twice with $CH_2Cl_2$. The contents of the filtrate were analysed by analytical HPLC. A SEDEX 55 (ERC, Germany) Evaporative-Light-Scattering Detector (ELSD) was employed to ensure comparable mass responses for different analytes. Cyclic products were purified by semi-preparative HPLC and characterized by $^1$H NMR spectroscopy and HRMS. They were formed as *E*/*Z* mixtures, as indicated by HPLC and $^1$H NMR spectroscopy.

§ Competition experiments: **5c** and the diene to be tested (**5b**, **7a**, **b** or **c**) (30 mg of each) were suspended in $CH_2Cl_2$ and heated to reflux for 2 h after addition of **1** (2.5 mg, 0.003 mmol). Product mixtures were filtered and dried. The relative amounts of cyclic products formed were determined by HPLC. For product characterisation, cyclisation/cleavage of the tested diene was performed on a preparative scale using the procedure given above.

¶ Acyclic byproducts were unambigiously identified as cross-metathesis products between the double bonds of two tetrapeptide molecules or tetrapeptide and spacer arm.

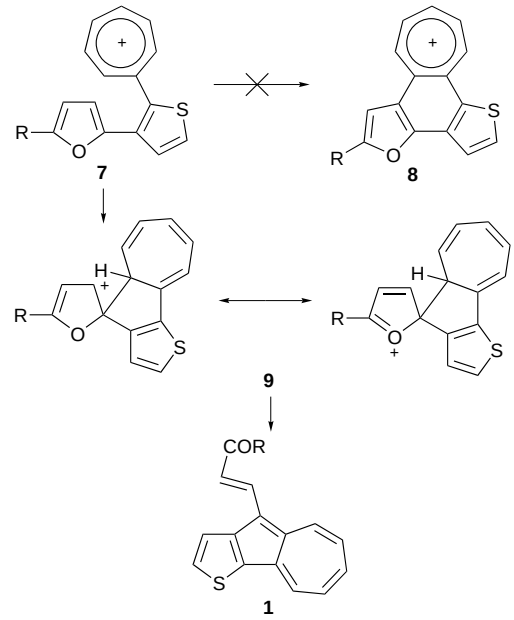
# A facile synthesis of β-(4-azuleno[1,2-*b*]thienyl) α,β-unsaturated ketones

**Naoki Kusuhara,[a] Yuka Sugano,[a] Hideki Takagi,[a] Hideyoshi Miyake[b] and Kimiaki Yamamura*[a]**



[a] *Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe 657, Japan*
[b] *Department of Biofunctional Chemistry, Faculty of Agriculture, Kobe University, Nada, Kobe 657, Japan*

**The facile and novel synthesis of β-(4-azuleno[1,2-*b*]thienyl) α,β-unsaturated ketones 1 from 2-tropylio-3-(2-furyl)thiophenes 7 is reported; a mechanism involving a novel ring cyclization by intramolecular attack of the tropylium ion at the 2-position of the furan ring is postulated.**

The azulenoid heterocyclic aromatic compounds which consist of the azulene ring condensed with heterocyclic aromatic nuclei are of interest not only for their physical and chemical properties, but also their pharmaceutical and physiological activity. Several azulene derivatives condensed with heteroaromatics such as thiophene, furan, pyrrole and pyridine rings are known.[1] Most of them were prepared by the heteroaromatization of the azulene derivatives, and were restricted to the parent compounds and alkyl-, aryl- or alkoxycarbonyl-substituted derivatives. Herein we disclose a novel and facile synthesis of azuleno[1,2-*b*]thiophenes having an α,β-unsaturated ketone group from the corresponding 2-tropylio-3-(2-furyl)thiophenes **7**.

**Scheme 1** *Reagents and conditions*: i, BuLi, $Me_3SnCl$, THF, −78 °C; ii, BuLi, $C_7H_7^+$, THF, −78 °C to room temp; iii, $PdCl_2(Ph_3P)_2$, THF, reflux; iv, xylene, reflux; v, $Ph_3C^+BF_4^-$, $CH_2Cl_2$, room temp; vi, $CH_2Cl_2$ or $CH_2ClCH_2Cl$

**Scheme 2**

The synthetic sequence leading to **1** from the readily available 2-substituted furans **2** is depicted in Scheme 1.† 2-Cycloheptatrienyl-3-(2-furyl)thiophenes **5** were prepared by the palladium(II)-catalysed Stille reaction[2] of 2-trimethylstannylfurans **3** with 2-cycloheptatrienyl-3-bromothiophene **4**. Thermal sigmatropic rearrangement of **5** to **6** and subsequent hydride abstraction using triphenylmethyl tetrafluoroborate gave 2-tropylio-3-(2-furyl)thiophenes **7** in 65–85% yields.‡ It might be expected that the intramolecular electrophilic substitution reaction of the tropylium moiety with the furan ring would afford the tetracyclic carbocations **8**, which are isoelectronic with triphenylene.[3] However, when a $CH_2Cl_2$ solution of **7a**§ was refluxed for 7 h, neutral red–black prisms were obtained instead of the expected carbocations **8a**. The structure of these prisms was confirmed to be 4-(4-azuleno[1,2-*b*]thienyl)but-3-ene-2-one **1a** *via* its spectral data,[5] together with elemental analysis. In the same manner, the chalcone-type compound **1b** and triphenylmethyl derivative **1c** were obtained as green–black needles (43%) and black needles (36%), respectively, from the corresponding tropylio derivatives **7b** and **7c**.

A possible mechanism for the formation of β-(4-azuleno-[1,2-*b*]thienyl) α,β-unsaturated ketones **1** from the corresponding 2-tropylio-3-(2-furyl)thiophenes **7** is illustrated in Scheme 2. The intramolecular electrophilic attack of the tropylium ion on the 2-poisition of the furan ring gives the spiro-type intermediate **9**, which can be converted to **1** by a ring-opening reaction. Although it is well-known that the 2-position of the furan ring is much more reactive towards electrophiles than the 3-position and that furans are readily ring-opened under acidic conditions,[4] this is to the best of our knowledge the first

tropylium ion-mediated furan ring-opening reaction to yield α,β-unsaturated carbonyl derivatives of azuleno[1,2-*b*]thiophene compounds. Since 2-substituted furans **2** are readily available and the procedure is simple and easy, it is considered that this is a valuable general synthetic route to various β-(4-azuleno[1,2-*b*]thienyl) α,β-unsaturated ketones.

The authors thank Miss Masuko Nishinaka for elemental analyses. The present work was supported in part by Grant-in-Aid for Scientific Research (C) (No. 08640685) from the Ministry of Education, Science, Sports and Culture, Japan.

# Evidence for the characterisation of the C–H··π interaction as a weak hydrogen bond: toluene and chlorobenzene solvates of 2,3,7,8-tetraphenyl-1,9,10-anthyridine

**N. N. Laxmi Madhavi,[a] Amy K. Katz,[b] H. L. Carrell,[b] Ashwini Nangia*[a] and Gautam R. Desiraju*[a]†**

[a] *School of Chemistry, University of Hyderabad, Hyderabad 500 046, India*
[b] *Fox Chase Cancer Center, 7701 Burholme Avenue, Philadelphia 19111, USA*

**The crystal structures of the toluene and chlorobenzene solvates of 2,3,7,8-tetraphenyl-1,9,10-anthyridine are nearly identical save for differences in the mode of solvent inclusion; these differences have an important bearing on the nature of the C–H··π interactions in these structures.**

During the synthesis[1] and purification of 2,3,7,8-tetraphenyl-1,9,10-anthyridine **1**‡ it was noticed that the compound failed to yield crystals for X-ray analysis from several solvents such as anisole, benzene, chloroform, ethyl acetate, mesitylene, nitrobenzene, pyridine and xylene, ill-defined powders being obtained in every case. Curiously, well-formed bright yellow crystals were obtained easily from toluene and analysis showed that they correspond to the 1 : 1 solvate **2**. Noting that the methyl

**1**

**2** = **1**•toluene
**3** = **1**•chlorobenzene

group is replaceable by the chloro group without a change in crystal structure (the so-called 'chloro–methyl exchange rule')[2] recrystallisation was attempted from chlorobenzene and we were not surprised to find that in this case too diffraction-quality crystals, now of the corresponding 1 : 1 solvate **3**, were obtained. The crystal structures of the toluene and chlorobenzene sovlates, **2** and **3**, were then determined at low temperature and to good precision.§ While the structures are very similar, with nearly the same unit cell dimensions and space group symmetry, there are small differences with respect to the positioning of the solvent molecules. Although small, these differences are significant and show that the C–H··π interactions found in these structures have the characteristics of weak hydrogen bonds.

Figs. 1 and 2 show the crystal structures of solvates **2** and **3**. The positioning of the heterocyclic molecule in the two unit cells is identical and so are the gross packing features.¶ Fig. 1 shows that the ordered toluene molecule in **2** is situated in a pocket formed by three molecules of **1**. Inspection of Fig. 2 shows that the ordered chlorobenzene molecule in **3** is situated in a nearly identical pocket. However, the Me and Cl substituents point in almost opposite directions in the two cases. This is unusual. When chloro–methyl exchange is obtained, the two substituents behave in an isosteric fashion with only shape and size factors controlling the packing.[2] The switching around of the substituent Me and Cl groups in **2** and **3** is indicative of the fact that electronic factors are involved in stabilisation of the solvent molecule in one or both cases.

A very short C–H··π interaction of 2.54(2) Å (all H-atom positions normalised in this and subsequently discussed contacts) in **2** (**a** in Fig. 1) is noteworthy. This interaction is clearly of the H··ring centroid type ($\theta$ = 151°),[3] the distances from the H-atom to the six ring atoms of the toluene molecule lying in the range 2.73–3.05 Å. Such H··centroid distances have been reported previously[3,4] but are definitely at the short end of the accepted distance range for this contact.[5] Accompanying contact **a** is a much longer contact of 3.01 Å ($\theta$ = 126°, **b** in Fig. 1) so that the toluene molecule may be said to be positioned at unequal distances from adjacent glide-related molecules of anthyridine **1**. In contrast, let us consider the two corresponding contacts, **g** [2.61(2) Å, $\theta$ = 143°] and **h** [2.62(2) Å, $\theta$ = 147°] in **3** (Fig. 2). These are formed by C–H groups that are chemically equivalent and therefore of the same acidity as the C–H group that forms contact **a** in **2**. However, contacts **g** and

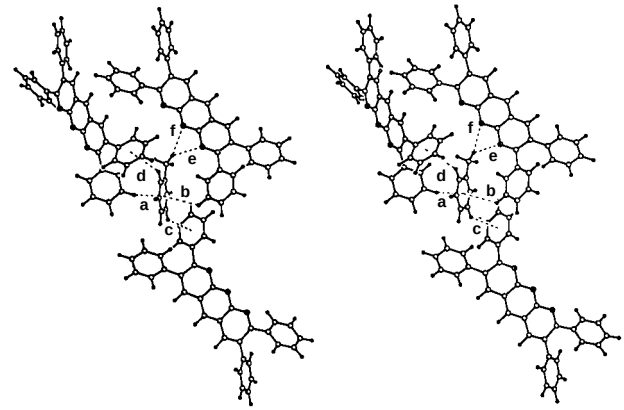

**Fig. 1** Stereoview of the crystal structure of solvate **2** approximately down [010], showing the binding of the toluene molecule. The anthyridine molecules are inversion- and glide-related. Interactions **a**–**f** are indicated. Notice the cooperative scheme of C–H··π hydrogen bonds and the positioning of the methyl H-atom between the two heterocyclic N-atoms. Interaction **a** is unusually short.

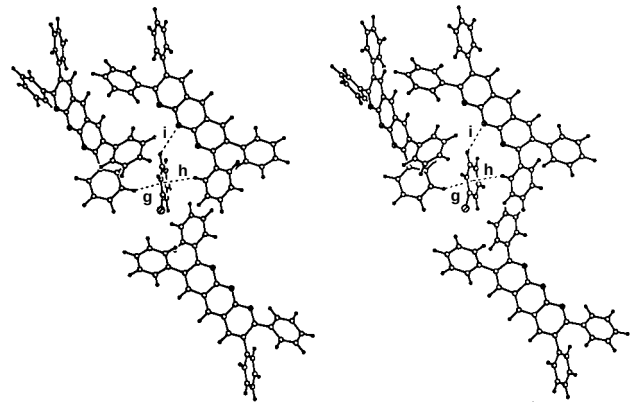

**Fig. 2** Stereoview of the crystal structure of solvate **3** showing the binding of the chlorobenzene molecule. Interactions **g**–**i** are indicated. Contrast this with Fig. 1. Notice that the Cl-atom is not involved in any specific intermolecular contact.

**h** are significantly longer than contact **a**. Unlike the toluene molecule in **2**, the chlorobenzene molecule in **3** may therefore be considered as being disposed at nearly equal distances to the adjacent molecules of **1**.

In general, short intermolecular distances such as **a** in **2** are taken as evidence of crystal stabilisation but it should be noted that shortness alone does not constitute proof of an attractive interaction. It is always possible that a short contact is repulsive and that it arises from the overall balance of interactions in a crystal structure.[6] However, when as in this case, the shortness of **a** with respect to **g** and **h** also correlates with the electron-rich character of the aromatic ring in toluene *vis-a-vis* chlorobenzene, and also given that there would be little steric problem were the toluene molecule to be placed symmetrically between the two approaching C–H groups, one may state with confidence that the C–H··π interaction **a** is stabilised by the electron rich aromatic ring in toluene. Hydrogen bonds of all types are fortified by increasing acidities and basicities of donor and acceptor groups, respectively,[7,8] and our observations here adduce evidence that the C–H··π interaction has structural properties of weak hydrogen bonds, similar to O–H··π and N–H··π interactions.[9] Because of its weakness, however, it is difficult in general to obtain clear evidence for the existence of this type of hydrogen bond. It is possible to do so in this case because structures **2** and **3** are similar in just about every respect except the interaction of interest.

Hydrogen bonds formed by carbon acids and π-bases are soft and this in turn can lead to the cooperative patterns of interactions.[10–13] Again, the structure of **2** is revealing. It would seem that the weak hydrogen bond **a** is able to activate the C–H groups in the toluene molecule at least to the extent that the long contacts **c**–**f** are possible. Interactions **c** (2.90 Å, $\theta$ = 140°) and **d** (3.01 Å, $\theta$ = 140°) formed by the aromatic C–H groups are the C–H··π type while interactions **e** (2.76 Å, $\theta$ = 146°) and **f** (2.83 Å, $\theta$ = 161°) formed by the methyl C–H groups are of the C–H··N type. Although long, these contacts are within the accepted distance ranges.[5,11] In contrast, there is just one extra interaction of the C–H··N type in the unactivated structure **3** (**i**; 2.87 Å, $\theta$ = 139°). All these interactions may make only small contributions to the crystal binding energy but they help in defining the structures of the solvates. For example, it is possible that these secondary interactions are the causes for the opposite orientations of the toluene and chlorobenzene molecules referred to above and also to the fact that the solvent molecules are ordered in **2** and **3**. It is pertinent to state here that of the 1171 toluene and 75 chlorobenzene solvates in the Cambridge Structural Database (CSD, April 1997, version 6.2, 167 797 entries) for which coordinates are available, the solvent is ordered in only 413 and 35 structures, respectively.‖ Although the binding of chlorobenzene in the anthyridine pocket is poorer than that of toluene, it is still not just shape-controlled; compound **1** failed to form diffraction-quality crystals with either fluorobenzene or bromobenzene. In this regard, the formation of solvates **2** and **3** is reminiscent of guest-induced host crystallisation of the type encountered in the benzene solvate of the mono-enol form of cyclohexane-1,3-dione.[14]

Since the pioneering work of Nishio, who first postulated the existence of the C–H··π interaction,[15] much work has been done in this area. With the current interest in crystal engineering and supramolecular chemistry, there is now a new appreciation for this form of intermolecular association. The hydrogen bond is an attractive, directional interaction which, though predominantly electrostatic, also has polarisation and charge transfer characteristics. While it has always been recognised that C–H··π interactions in highly activated systems such as terminal acetylenes are of the hydrogen bond type, the present work shows that even moderately activated systems such as tolyl rings participate in interactions that may be considered to be weak hydrogen bonds formed by soft acids and soft bases. In this regard, it could be stated that the grey area between the weak hydrogen bond and the herringbone interaction is gradually diminishing.

# Dissecting the effects of cooperativity on the stabilisation of a *de novo* designed three stranded anti-parallel β-sheet

**Gary J. Sharman and Mark S. Searle***

*Department of Chemistry, University of Nottingham, University Park, Nottingham, UK NG7 2RD.*

**Cooperative effects between two sets of weak interactions at different hydrogen bonded interfaces are shown to stabilise a *de novo* designed three-stranded anti-parallel β-sheet: NMR and CD (circular dichroism) spectroscopy have been used to compare and contrast the stability of the β-sheet (residues 1–24) and the isolated C-terminal β-hairpin (residues 9–24).**

Molecular recognition phenomena, including host–guest interactions in chemical systems and the processes by which complex structures self-assemble in biology, are fundamentally dependent on large numbers of weak, non-covalent interactions and their cooperative interplay.[1,2] Cooperativity frequently complicates attempts at quantitative analysis of such interactions because ligand binding constants are seldom only a measure of the interactions occurring at one particular molecular interface but reflect some property of the whole set of linked weak interactions within the ligand complex.[1–7] Here we describe a peptide system that has enabled us to investigate the interplay between two sets of weak interactions that occur at two different hydrogen bonded interfaces within a *de novo* designed anti-parallel three stranded β-sheet (Fig. 1). To dissect-out possible cooperative interactions we have synthesised two peptides. The first peptide (9–24) of 16 residues was designed to form a β-hairpin. The second peptide (1–24) ends with the same 16 residues but has a preceding 8 amino acid sequence designed to form a second β-turn and the third strand (S3) of the anti-parallel β-sheet. The first strand (S1 in Fig. 1) is in the same environment in both folded structures and undergoes the same changes in backbone solvation and hydrophobic interactions when it interacts with S2. Thus, the indirect influence of the third strand on the stability of the interaction between S1 and S2 can be assessed in this system. We report here evidence from CD and NMR studies that 1–24 folds into a three stranded sheet in which the C-terminal hairpin is cooperatively stabilised with respect to the isolated hairpin (9–24). There is much current interest in the autonomous folding of β-hairpin peptides for probing the sequence-dependent factors important in their stabilisation.[8]

In aqueous solution, the two peptides showed limited evidence of folding. Qualitative analysis of CD (circular dichroism) spectra suggested that substantial populations of random coil conformations persist with both peptides showing very similar molar ellipticity values (per residue) at 198 nm. Addition of methanol (in the range 0–50% v/v) to the aqueous peptide solutions was found to promote secondary structure formation. In 50% aqueous methanol peptide 1–24 showed only a small negative ellipticity at 198 nm, but a pronounced minimum around 216 nm, characteristic of a substantial population of β-sheet and β-turn conformation.[9,10] In contrast, the changes in molar ellipticity (per residue) on addition of methanol are less marked for the shorter peptide (9–24), with residual random coil structure still evident.

Both peptides were subsequently investigated under identical conditions by $^1$H NMR spectroscopy. $H_\alpha$ chemical shift deviations from random coil values have been shown to be an excellent probe of protein secondary structure.[11] In the mixed solvent system [50% $CD_3OD$–50% $D_2O$ (or 50% $H_2O$) solution at pH 3.9 and 2 mM concentration], $H_\alpha$ shifts for peptide 1–24 (Fig. 2) were indicative of three β-strands (downfield shifts of up to 0.7 ppm) separated by two β-turns (upfield shifts of $< 0.3$ ppm).[12] These structural features were confirmed by the pattern and intensity of NOEs: strong inter-residue and weak intra-residue $H_\alpha$–NH NOEs were observed within the strands, whereas these were of similar intensity within the turn regions. Also, the only significant sequential NH–NH NOEs were observed between residues 9–10 and 17–18, again characteristic of the two β-turns. The observation of long range NOEs provided the most conclusive evidence for the formation of folded structure in solution, consistent with the alignment of the peptide chain shown in Fig. 1(*a*). These included many of the

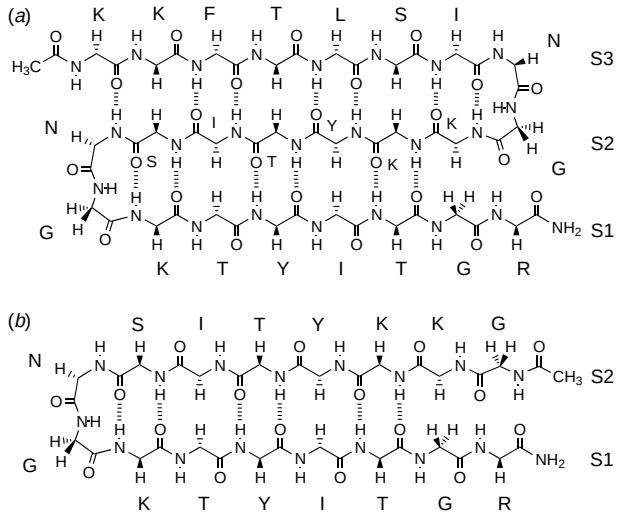

**Fig. 1** Structures and sequences of (*a*) the designed three-stranded β-sheet (residues 1–24) and (*b*) β-hairpin (residues 9–24). The first strand (S1) is in an identical environment in both folded structures.

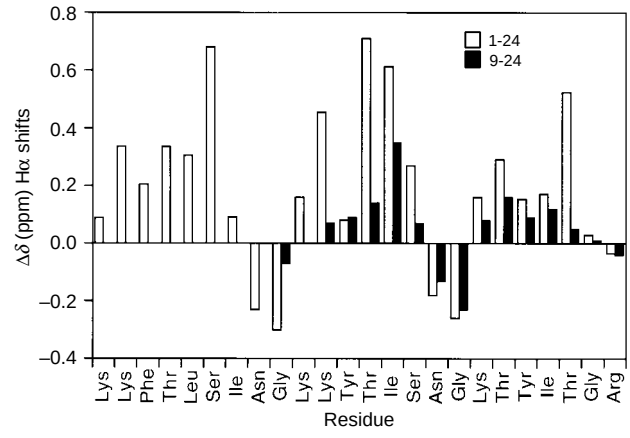

**Fig. 2** $H_\alpha$ chemical shift deviations from random coil values for sheet (1–24) and hairpin (9–24) in 50% v/v aq. methanol, 2 mM peptide, pH 3.9, 283 K

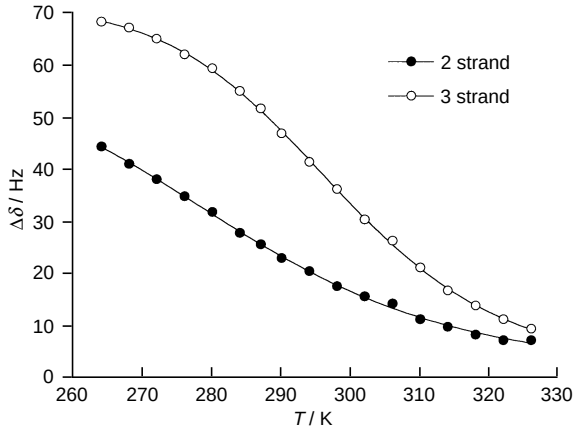

**Fig. 3** Melting curves for 1–24 and 9–24 determined from the temperature-dependence of the chemical shift difference ($\Delta\delta$/Hz) between the $H_\varepsilon$ resonances of Y12 and Y20. Data were fitted to a two-state model and the limiting values for $\Delta\delta$ determined iteratively. In both cases correlation coefficients ($R$) were > 0.99. At 298 K, peptide 1–24 was estimated to be 50% folded, while peptide 9–24 was only 25% folded.

expected cross-strand $H_\alpha$–$H_\alpha$ NOEs (K2→S15, T4→T13, S6→K11, K10→G23, I14→T19), NH–NH NOEs (F3→I14, I7→K10, T13→Y20, S15→K18) and interactions between side chains in close proximity (F3→I14 and L5→Y12→I21).

The shorter peptide (9–24) (Fig. 1) showed evidence of a rather less folded structure. Much less pronounced downfield shifts are observed for $H_\alpha$ resonances of residues within the strands (Fig. 2). NOE intensity measurements indicate a less ordered more dynamic structure than observed for the same residues in the three stranded sheet. In contrast to the large number of long range interstrand NOEs identified for peptide 1–24, no long range $H_\alpha$–$H_\alpha$ or NH–NH NOEs were detected, although the side chain interaction between Y12 and I21 was still apparent, suggesting a small population of a less well-ordered β-hairpin. Despite the apparently weak interaction between the two proposed β-strands, the observation of a strong NH–NH NOE between residues G17–K18, and similar shift perturbations for G17 $H_\alpha$ and K18 NH in both peptides, suggests that the β-turns may be populated to similar extents in the two structures.

To illustrate further the cooperative nature of the interactions, we have measured the temperature-dependence of the stability of both peptides (Fig. 3). The folded population in each case was conveniently monitored by measuring the chemical shifts of the aromatic protons of the two tyrosine residues (Y12 and Y20) which are common to both the hairpin and sheet, and whose chemical shifts diverge as the temperature is lowered. Sigmoidal melting curves are observed for both peptides indicative of a cooperative unfolding process. However, a sharper transition is evident for the three-stranded sheet, together with a higher mid-point transition temperature (298 *versus* 278 K). Thus, the larger number of hydrogen bonding interactions within the sheet gives rise to a greater degree of cooperativity.[2] The data are reminiscent of DNA melting curves where the transition also becomes sharper as the number of base pairs (interacting units) increases.[2]

The above data lead us to conclude that the stability of the C-terminal hairpin is cooperatively enhanced by interaction with the N-terminal portion of the sequence. This may in part be due to a chelate-like effect, in that the first strand can be envisaged to fold against a pre-ordered hairpin, such that the entropic cost of folding is reduced. In addition, this pre-organisation could lead to stronger hydrogen bonds through a restriction of backbone motions allowing shorter range interactions.[13,14] A further possibility is that electrostatic effects, mediated through the extended hydrogen bonding network, might further strengthen the interactions at the second interface through polarisation of amide bonds. Such a mechanism is supported by *ab initio* calculations on solvated hydrogen bonded amide dimers.[15] The effect of organic solvents in promoting intramolecular hydrogen bonding is generally regarded to have an electrostatic origin by weakening competing interactions between solute and solvent.[16–19] The experimental conditions described have proved ideal for monitoring this cooperative effect between the strands of a designed β-sheet; both the hairpin and sheet structures have only marginal stability, allowing even small perturbations to conformational equilibria between folded and unfolded states to be readily detected by measurable changes in NMR and CD parameters.

We thank the BBSRC for providing support to G. J. S. and gratefully acknowledge grants from The Nuffield Foundation and The Royal Society, and the support of The Department of Chemistry of the University of Nottingham. We are grateful to John Keyte for solid phase peptide synthesis and access to HPLC facilities in the Biochemistry Department, University of Nottingham.

***In vitro* immunization using a 5-membered ring iminocyclitol afforded antibodies that catalyse the hydrolysis of *p*-nitrophenyl glucopyranoside and *p*-nitrophenyl galactopyranoside with rate enhancements ($k_{cat}/k_{uncat}$) of greater than $10^4$.**

The generation and characterization of antibodies that catalyse glycosyl transfer reactions should provide insights into the mechanisms of naturally occuring glycosidases, and may lead to the development of glycosidases with novel specificities.[1–3] Previous efforts to generate antibodies with glycosidase activity made use of cyclic acetals as model substrates and antibodies generated against charged and conformationally restricted analogues of the oxocarbonium ion intermediate.[1–3] Rate accelerations of the order of $10^2$–$10^3$-fold were reported for these catalytic antibodies. More recently, an antibody that catalyses the hydrolysis of *p*-nitrophenyl galactopyranoside with a rate enhancement ($k_{cat}/k_{uncat}$) of $7 \times 10^4$ was isolated by screening a library of antibodies specific for a five-membered ring iminocyclitol using a suicide substrate.[4] We have independently used a similar positively-charged twist boat hapten to directly generate an antibody that catalyses the cleavage of *p*-nitrophenyl-β-D-glucopyranoside **3** with a rate enhancement ($k_{cat}/k_{uncat}$) of *ca.* $2 \times 10^4$. Antibodies were produced by *in vitro* immunization with free hapten, suggesting this might be a general method for generating catalytic antibodies, especially for unstable or toxic immunogens.[5]

The pyranoside ring is known to have a half-chair or twist-boat conformation in the transition state for glycosidic bond cleavage.[6] Another distinctive feature of the transition state is the development of partial positive charge at the anomeric position. Based on these structural and electronic characteristics, hapten **1** was used as a transition state analogue[7] to elicit antibodies that catalyse the cleavage of the β-glucosidic bond of *p*-nitrophenyl-β-D-glucopyranoside (Scheme 1). Hapten **1** was synthesized from 5-keto-D-fructose and benzhydrylamine in three steps.† The $NaBH_4$ dependent reductive amination of 5-keto-D-fructose with benzhydrylamine[8] afforded, after recrystallization, the indicated diastereoisomer (Scheme 1) of the corresponding *N*-benzhydryl azasugar. Removal of the protecting group by catalytic hydrogenation, and alkylation of the resulting secondary amine with 3-nitrobenzyl bromide, yielded hapten **1**. The nitro group was then reduced with $H_2$ using Lindlar catalyst, converted to the isothiocyanate and coupled to the carrier proteins keyhole limpet hemocyanin (KLH) and bovine serum albumin (BSA).[9] Sixteen hybridomas antibody specific for hapten **1** were generated by standard methods[10] and ascites from each cell line were generated. Antibodies were purified using Protein-A affinity chromatography[11] followed by ion-exchange chromatography using a mono S column,‡ and were tested using the following substrates: *p*-nitrophenyl-α- and -β-D-glucopyranosides, *p*-nitrophenyl-α- and -β-D- galactopyranosides and *p*-nitrophenyl-α- and β-mannopyranosides. HPLC analysis of the reaction products indicated that none of the antibodies showed any hydrolytic activity under a range of buffer conditions.‡

However, encouraged by recent progress in immunization methods, we decided to generate antibodies by *in vitro* immunization, wherein carrier free hapten is mixed directly with spleen cells in culture.[11] Using this method, fourteen hybridoma cell lines secreting antibodies specific for hapten **1** were identified by enzyme-linked immunosorbent assay and ascites were generated. The ascites were purified and assayed as described above. Two antibodies were found to be catalytic: Ab24 and AB21 catalysed the hydrolysis of *p*-nitrophenyl-β-D-glucopyranoside **3** and *p*-nitrophenyl-β-D-galactopyranoside **4**, respectively. These antibodies displayed saturation kinetics and their Michaelis constants were determined in 10 mM 2-(4-mor-

**1** X = $NO_2$
**2** X = NHC(S)–BSA or –KLH

**Scheme 1**

pholino)ethanesulfonic acid (MES), 100 mM NaCl, 0.02% $NaN_3$ buffer, pH 4.5, at 37 °C; rate constants for the uncatalysed reaction were determined under the same conditions.‡ Antibody Ab21 catalysed the hydrolysis of *p*-nitrophenyl-β-D-galactopyranoside **4** (and not **3**) with a $k_{cat}$ of 0.035 $h^{-1}$ and $K_m$ of 310 μM ($k_{cat}/k_{uncat}$ = 2.5 × $10^4$); antibody Ab24 catalysed the hydrolysis of *p*-nitrophenyl-β-D-glucopyranoside **3** (and not **4**) with a $k_{cat}$ of 0.02 $h^{-1}$ and $K_m$ of 160 μM ($k_{cat}/k_{uncat}$ = 2.2 × $10^4$). Antibodies purified from different preparations of ascites showed the same specific activities. Moreover, the catalytic activity could be stoichiometrically titrated by absorbing antibodies on increasing amounts of protein A agarose and analysing the activity of the filtrate *versus* the amount of bound antibody. The isolation of two antibodies, one specific for substrate **3** and the other for substrate **4**, also argues against enzymic contamination.

The antibodies were inhibited by hapten **1** with a $K_i$ value of 60 μM for the Ab21-catalysed hydrolysis of glucopyranoside **3**, and a $K_i$ value of 380 μM for the Ab24-catalysed hydrolysis of galactopyranoside **4**.[12] For both antibodies the rate acceleration does not correlate with the relative affinities of the antibody for substrate and hapten **1**. This behaviour suggests that a structural feature of the hapten (*i.e.* an amino or hydroxy group) results in the presence of a catalytic group, such as aspartic or glutamic acid, in the antibody combining site which can function as a general acid in catalysis but does not contribute substantially to the overall binding energy for the hapten. Indeed, diazoacetamide treatment of antibody Ab21 led to a 97% reduction in catalytic activity; 60% of the catalytic activity was retained when modification was carried out in the presence of 2 mM hapten **1**.[13] The relatively low affinities of the antibodies for hapten **1** resulting from the *in vitro* immunization likely reflect the absence of affinity maturation that normally occurs during an immune response.[14] In addition, antibodies generated against carbohydrates typically show relatively low affinities. It is of interest that both β-glucosidase and β-galacosidase activities were generated using hapten **1**. The five-membered ring in hapten **1** is flattened, mimicking a boat or twist-boat conformation of the pyranoside ring in the transition state. Either hapten **1** has some conformational flexibility or its geometry must map onto the critical recognition elements for both substrates and/or transition states.

Finally, Lerner[4] reported that direct immunization of a related hapten afforded catalytic antibodies with only 100-fold rate enhancements; we isolated no catalytic antibodies from direct immunization. This suggests that *in vitro* immunization, like antibody phage display methods, may complement conventional approaches for producing catalytic antibodies.

## Footnotes and References

† 5-Keto-D-fructose was synthesized by incubating D-fructose with *Gluconobactor cerinus* (ATCC catalogue number IFO 3267). Hapten **1** was purified on silica gel using $CH_2Cl_2$–MeOH (9 : 1 v/v) as eluent ($R_f$ = 0.37); $\delta_H$ (300 MHz, $CDCl_3$) 8.1 (s, 1 H), 8.0 (d, 1 H, *J* 3), 7.6 (d, 1 H, *J* 8), 7.45 (dd, 1 H, *J* 8, 3), 4.0–3.8 (m, 4 H), 3.6–3.3 (m, 8 H including 4H from 4 OHs), 3.1 (m, 1 H), 2.7 (m, 1 H); $\delta_C$ (75 MHz, [$^2H_6$]DMSO) 147.6 (3′ phenyl), 143.4 (1′ phenyl), 135.3 (6′ phenyl), 129.3 (4′ phenyl), 122.9 (2′ phenyl), 121.6 (4′ phenyl), 77.0, 76.1 (C3 and C4), 72.6 (C benzyl), 67.4, 62.0 (C2 and C5), 60.3, 57.4 (C1 and C6); *m/z* 299 ($MH^+$).

‡ Antibodies were purified using a SP-Separose® (HiLoad™ 16/10) column (Pharmacia). For the mobile phase, buffer A (50 mM MES, pH 5.5) and buffer B (50 mM MES, 1.0 M NaCl, pH 5.5) were co-eluted with a linear gradient of 0–50% B over 40 min and a flow rate of 2 ml $min^{-1}$. Assays were carried out by mixing 90 μl of antibody (2–3 mg $ml^{-1}$) and 10 μl of substrate (20 mM), each in reaction buffer, and then incubating at 37 °C for 3 days. The reaction was analysed by HPLC using a C18 microsorb column (4.6 mm × 15 cm, 5 μm), eluting with 50% aqueous MeOH at 0.8 ml $min^{-1}$ and monitoring a 315 nm. The rate was determined when less than 1% of the substrate was converted to product. The data were fitted directly to the Michaelis–Menten equation, $v = (V_{max}[S])/([S] + K_m)$, using the nonlinear curve fitting program from the Kaleidagraph software suite. The second order rate constants for the $H^+$, $OH^-$ and AcOH catalysed reactions and the psuedo-first order rate constant for the reaction in water are: $k_{H^+}$ = 1.1 × $10^{-3}$ $M^{-1}$ $h^{-1}$, $k_{OH^-}$ = 0.29 $M^{-1}$ $h^{-1}$, $k_{AcOH}$ = 1.2 × $10^{-6}$ $M^{-1}$ $h^{-1}$, and $k'_{H_2O}$ = 8.0 × $10^{-7}$ $h^{-1}$ for substrate **3**; $k_{H^+}$ = 3.8 × $10^{-3}$ $M^{-1}$ $h^{-1}$, $k_{OH^-}$ = 0.58 $M^{-1}$ $h^{-1}$, $k_{AcOH}$ = 2.0 × $10^{-6}$ $M^{-1}$ $h^{-1}$ and $k'_{H_2O}$ = 1.6 × $10^{-6}$ $h^{-1}$ for substrate **4**.

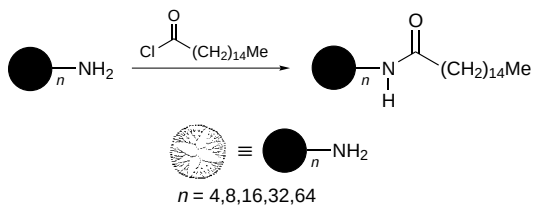
# Liquid–liquid extractions using poly(propylene imine) dendrimers with an apolar periphery

**Maurice W. P. L. Baars,[a] Peter E. Froehling[b] and E. W. Meijer*[a]**



[a] *Laboratory of Organic Chemistry, Eindhoven University of Technology, PO Box 512, NL-5600 MB Eindhoven, The Netherlands*
[b] *DSM Research, PO Box 18, NL-6160 MD Geleen, The Netherlands*

**The modification of poly(propylene imine) dendrimers with apolar endgroups yields effective and highly selective basic extractants of anionic dye molecules from water to solvents, like dichloromethane and toluene.**

Liquid–liquid extraction is a well known technique in the field of (preparative) organic, inorganic and analytical chemistry.[1a,b] The technique is based upon the transfer of a substance (solute) from one liquid (*e.g.* aqueous phase) to a second liquid (*e.g.* organic phase), the latter being reasonably immiscible with the first one. Extractants can influence the distribution of the solute molecules between the two phases to a large extent. It is well known that acidic extractants, like alkylphosphoric acids and alkylcarboxylic acids can extract positively charged (metal) ions[1a,b] while basic extractants are capable of extracting anionic species from water to the organic phase. Primary, secondary and tertiary amines are interesting extractants because of their organophilic nature (high solubility in organic solvents) and their basicity.[2a–c]

Recently, we have been investigating the endgroup modification of polar poly(propylene imine) ASTRAMOL™ dendrimers[3] with apolar endgroups, *e.g.* linear alkyl chains and adamantane.[4] These and other dendrimers are interesting molecules to study host–guest properties.[5a–g] In this paper we describe generations 1–5 (number of endgroups $n$ = 4–64) of the poly(propylene imine) dendrimers modified with palmitoyl chloride[6] yielding 'inverted unimolecular dendritic micellar' structures with a polar interior of tertiary amines and an apolar periphery (Scheme 1). The extraction properties of the dendritic structures were investigated, using different anionic xanthene dyes as solute molecules (**I** Fluorescein, **II** 4,5,6,7-tetrachlorofluorescein, **III** Erythrosin B, **IV** Rose Bengal).

The extraction yield,† using a fifth-generation palmitoyl dendrimer as a function of the pH of the aqueous solution (Fig. 1) indicated that at low pH all four solute molecules, as a 1 : 1 mol ratio of dye and dendrimer could be transferred to the organic layer, whereas at higher pH no extraction is possible, except for Rose Bengal. The sensitive and abrupt pH-dependent extraction yield describes the distribution ratio of the solute between the two phases. Differences in p$K_a$ and hydrophobicity of the solutes are likely to account for the different inflection points of the 'titration' curves. The (large) hydrophobicity of Rose Bengal seems a reasonable explanation for extraction of this probe by clathration even at high pH (pH > 12). From the fact that cationic probes, like Ethidium Bromide can not be extracted into the organic phase, we conclude that the interaction between solute and dendritic structure is mainly determined by their acid–base properties and that the dendritic structures behave as basic extractants.

**Scheme 1** Modification of poly(propylene imine) dendrimers

Under different pH conditions the relative absorption in UV–VIS of Rose Bengal in the aqueous layer was determined as a function of the dendrimer to dye ratio (Fig. 2). At pH = 7 the interaction between solute and dendrimer is much stronger than at pH = 11 and 14. From the inset in Fig. 2 (pH = 7) we can determine the dendrimer to dye ratio of the complex that is initially formed in the organic phase. It is concluded that approximately 50 (!) dye molecules ($M_{dye}$ = 1 × 10³) are

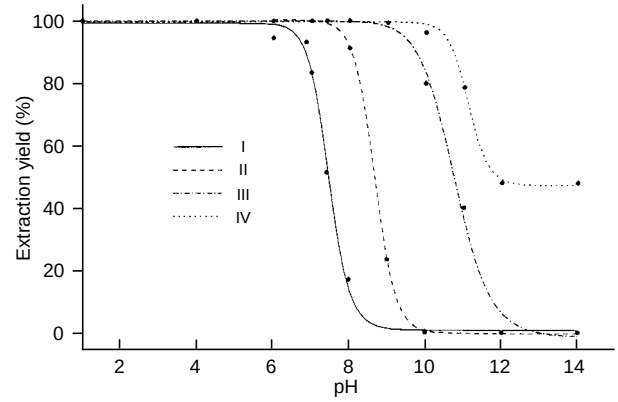


**Fig. 1** Extraction yield of fifth-generation palmitoyl dendrimer as a function of pH for different dye molecules **I**–**IV**. Dendrimer : dye ratio is 1 : 1 (mol/mol); [dendrimer] = 2.5 × 10⁻⁵ M. Equal volumes of both phases are used.

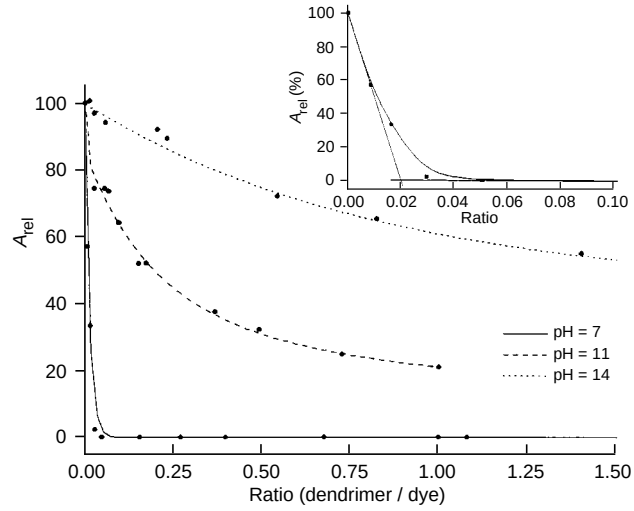

**Fig. 2** Relative absorbance of Rose Bengal **IV** in the aqueous layer as a function of the dendrimer to dye ratio. Fifth-generation palmitoyl dendrimer was used as dendritic extractant. Dye concentration was kept constant during measurement (2.5 × 10⁻⁵ M). Inset shows cut-off at a ratio ≈ 0.020, *i.e.* 50 dye molecules per dendrimer.

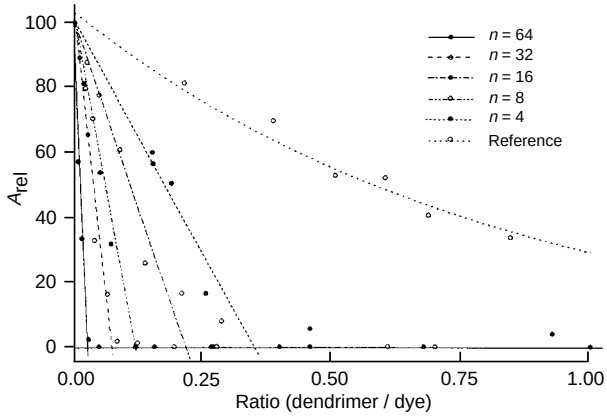

**Fig. 3** Relative absorbance of Rose Bengal **IV** in the aqueous layer as a function of the dendrimer to dye ratio for different generations of palmitoyl dendrimers ($n$ = 4, 8, 16, 32, 64). Tri-*n*-octylamine was used as reference compound. The concentration of extractant was kept constant [$2.5 \times 10^{-5}$ M] for all measurements.

extracted per fifth generation dendrimer ($M_{dendr} = 2.3 \times 10^4$). At pH = 7 all solute molecules can be extracted whereas at higher pH (pH > 10) there is an equilibrium and the dye is distributed over both layers. Even at higher ratios the extraction is not complete. The higher the extraction yield at a specific pH (Fig. 1), the faster is the (exponential) decrease in the absorption of the aqueous layer (Fig. 2).

Comparing all the generations of the palmitoyl dendrimers, we can conclude that the extraction is directly related to the number of tertiary amines in the dendritic interior (Fig. 3). The higher the generation of the dendrimer and the larger the number of tertiary amines in the interior, the more dye molecules can be extracted per dendrimer. Reference compound tri-*n*-octylamine (one tertiary amine) follows the same trend under these conditions as the dendritic extractants, but the extraction strength is less.

The dendritic extractant shows (almost) no difference in extraction yield of Fluorescein and Rose Bengal if the organic phase is changed from dichloromethane into toluene. Only in the case of Rose Bengal and high pH, is toluene less effective than dichloromethane. The extraction yield of tri-*n*-octylamine however deviates substantially when changing the organic phase; whereas in dichloromethane it is still possible to extract Fluorescein and Rose Bengal, Fluorescein can not be extracted into toluene using tri-*n*-octylamine. Rose Bengal still can be extracted, but the effectiveness is much smaller as is demonstrated by the inflection point that is several pH units lower. The results of tri-*n*-octylamine demonstrate that the strength of solvation decreases in the order dichloromethane > toluene, which is in full agreement with literature data.[26] Dendritic extractants, however, are not influenced by a change in solvent, probably due to their micellar character that shields the interior from the solvent.

The pH-dependent extraction behavior of the dendritic extractants (Fig. 1) enables us to perform back-extraction of the solute molecules. Fluorescein can be extracted into the organic phase at pH = 7 with a high extraction yield (*ca.* 90%). All Fluorescein in the organic phase can be recovered (extracted back) if an aqueous solution is used with pH = 10. In Fig. 1 it was already demonstrated that at pH = 10 no Fluorescein can be detected in the organic phase. Rose Bengal and Fluorescein show a pH region (pH *ca.* 8–10) in which there is maximum difference in extraction yield (Fig. 1). By adding Fluorescein and Rose Bengal in different ratios in the aqueous layer and determining the absorption of both layers, it was demonstrated that even in a 10 000 : 1 ratio, Rose Bengal could be selectively extracted into the organic layer. This high selectivity is only possible due to the specific topology of the dendritic extractant in the liquid–liquid extraction process.

In summary, we conclude that the extraction of anionic solutes by modified poly(propylene imine) dendrimers is related to their tertiary amine interior. As a consequence the behaviour of these dendrimers is that of acting as long chain tertiary amines. The dendritic molecules, however, are solvent-independent extractants, while the high local concentration of tertiary amines in the dendritic interior, typical for the poly(propylene imine) dendrimers, creates a high selectivity in the extraction of solutes with different p$K_a$ and hydrophobicity. As a consequence dendritic extractants might be very useful in the selective purification of anionic compounds.

This work has been supported by the Netherlands Foundation for Chemical Research (SON) with financial aid from the Netherlands Organisation for Scientific Research (NWO). We thank Marcel van Genderen, Albert Schenning and Bas de Waal for stimulating discussions and valuable assistance. Jørn Cristensen is gratefully acknowledged for synthetic input. Manon Muré-Mak and Ellen de Brabander-van den Berg are acknowledged for providing the poly(propylene imine) dendrimers.

## Footnotes and References

† The extraction yield is defined as the relative extraction of the solute into the organic phase and is determined by measuring the decrease and increase in absorption of the aqueous and organic layer, respectively in UV–VIS. The absorption is determined at $\lambda_{max}$ in both solvents for all dyes, where a small solvatochromic shift of $\lambda_{max}$ in organic solvents is observed. In all cases a decrease in absorption of the aqueous layer simultaneously gives a complementary increase in absorption of the organic layer. If no extractant is dissolved in the organic layer, the solute (dye molecule) shows no detectable distribution into the organic layer.

# The first structurally characterised solvent-free σ-bonded diorganocalcium, $Ca[C(SiMe_3)_3]_2$

**Colin Eaborn,* Simon A. Hawkes, Peter B. Hitchcock and J. David Smith***

*School of Chemistry, Physics and Environmental Science, University of Sussex, Brighton, UK BN1 9QJ*

**The monomeric solvent-free compound $CaR_2$ 1 [R = $C(SiMe_3)_3$] is obtained as colourless air- and moisture-sensitive crystals from the reaction between KR and $CaI_2$; in the solid the C–Ca–C axis is bent with Ca–C 2.459(9) Å and C–Ca–C 149.7(6)°; reactions of 1 with ethers ROEt give RH, ethene and $Ca(OEt)_2$.**

The structures of several bis(cyclopentadienyl) derivatives of the heavier group 2 elements have been determined[1] but to our knowledge the only structural determination of a σ-bonded diorgano derivative is that of bis[bis(trimethylsilyl)methyl] calcium which was characterised as a 1,4-dioxane adduct $Ca[CH(SiMe_3)_2]_2{\cdot}2C_4H_8O_2$.[2] Other σ-bonded dialkyls and diaryls have been characterised by the products of their reactions with electrophiles such as $CO_2$, carbonyl compounds, nitriles, or terminal alkynes.[3,4] We recently showed that the readily available reagent KR [R = $C(SiMe_3)_3$] reacts with $LnI_2$ (Ln = Yb, Eu) in benzene[5] or Sm in thf–heptane[6] (thf = tetrahydrofuran), to give solvent-free dialkyls $LnR_2$. Here we report a similar reaction with $CaI_2$ to give solvent-free bis[tris(trimethylsilyl)methyl]calcium, $Ca\{C(SiMe_3)_3\}_2$ **1** which was isolated as a colourless air- and moisture-sensitive solid.†

The structure of **1** (Fig. 1) was determined by an X-ray diffraction study‡ on a very thin plate that separated from heptane–benzene. Although the molecules lie across a crystallographic inversion centre there are three independent sites for the calcium atom, which is disordered over positions related by an approximate $\bar{3}$ axis. This indicates that the equilibrium structure in the solid is bent. (Refinement with a linear C–Ca–C skeleton led to unacceptably large anisotropic displacement parameters with electron density away from the molecular axis.) Although the atoms of the alkyl group R appear to be well defined, their positions must be an average of closely related sites corresponding to the various Ca positions. However, the values for the Ca–C distance, the C–Ca–C angle and probably the mean C–Si distances are reliable. The Ca–C distance, 2.459(9) Å, is similar to those in the adduct $Ca[CH(SiMe_3)_2]_2{\cdot}2C_4H_8O_2$ [2.483(5) Å], in which the Ca is four-coordinate.[2] It is significantly shorter than the Ca–C distances in cyclopentadienyl derivatives (*ca.* 2.65 Å), in the 2,3-dimethyl-1,4-diphenylbutadiene adduct Ca(PhCH=C-MeCMe=CHPh)$(thf)_4$ [2.588(7)–2.777(7) Å], in which the Ca is six-coordinate,[8] and in the electron-deficient methyl-bridged compound $[(C_5Me_5)_2CaAlMe_3(thf)]_2$ [2.948(7), 2.999(7) Å].[9] In **1** there are three Ca···Me contacts of *ca.* 3.08 Å for each position of the Ca atom [from Ca to C(4), C(7′), and C(9), *cf.* Ca···Me 2.98 Å in $Ca(C_5Me_5)_2$ **2**]. The most important feature of the structure is the C–Ca–C angle [149.7(6)°], which is almost the same as those (147 and 154°, respectively) in crystalline[10] and gaseous[11] **2**, a little smaller than that (162°) in the exceedingly crowded $Ca(C_5HPr^i_4)_2$[12] and similar to that (148°) reported for gaseous $CaI_2$.[13] (though the value for $CaI_2$ may be affected by the presence of dimers and shrinkage effects associated with the $\nu_2$ bending vibration[14]). Simple electron repulsion rules predict that the monomeric calcium compounds $CaX_2$ (X = halogen, alkyl, *etc.*) should be linear but bent structures have been suggested by recent modifications to the original theory.[15,17] High level *ab initio* calculations also indicate that many calcium compounds, including $CaMe_2$, are quasilinear, *i.e.* the plot of potential energy *vs.* bending angle is almost flat, at least out to 160°;[18,19] angles of 131 and 116°, respectively, are predicted for $SrMe_2$ and $BaMe_2$. For compound **1** in the crystalline state the bending could possibly be attributed to crystal packing forces influenced by the intramolecular Ca···Me interactions but, in contrast to the situation in **2**, there are no significant intermolecular interactions. It is noteworthy and perhaps important that the C–Ca–C angles in compounds **1**, **2** and gaseous $CaI_2$ are all in the range 148–154°. In the compound $Yb[C(SiMe_3)_3]_2$ **3** and the Eu analogue **4** the C–M–C angles are 136–137° but the Mg compound **5** is linear.[20]

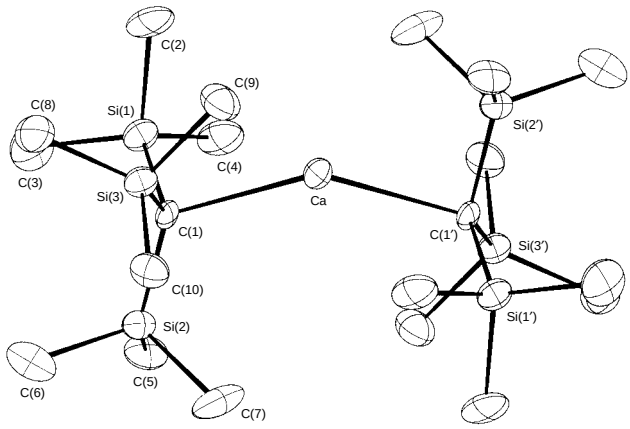

**Fig. 1** The molecular structure of **1**. Selected bond distances (Å) and angles (°): Ca–C 2.459(9), mean C(1)–Si 1.83(1), mean Si–Me 1.87(2); C–Ca–C 149.7(6), mean Si–C(1)–Si 114.8(6), mean Me–Si–Me 104.8(6).

The inner Si–C bond length in **1** is similar to those in **3** and **4** but shorter than that in **5**, suggesting that the metal–carbon bonds in the Ca, Yb and Eu derivatives are more ionic than those in the Mg compound.

We showed previously[5] that **3** reacted with diethyl ether to give the alkyl alkoxy compound $Yb[C(SiMe_3)_3](OEt)$, characterised by others as the diethyl etherate.[21] NMR-tube experiments showed that the analogous reaction of **1** with an excess of $Et_2O$ yielded RH [R = $C(SiMe_3)_3$], quantitatively, ethene, identified by its signal at $\delta_H$ 5.26, and insoluble $Ca(OEt)_2$ [eqn. (1)].

$$CaR_2 + 2Et_2O \rightarrow 2RH + 2C_2H_4 + Ca(OEt)_2 \qquad (1)$$

With 1 equiv. of $Et_2O$ only half of the $CaR_2$ was consumed, showing that the intermediate $Ca[C(SiMe_3)_3](OEt)$ reacts faster with $Et_2O$ than the dialkyl. Reactions with other ethers ROEt (R = $Bu^t$, Ph) proceeded in the same way but more slowly. No reaction was detected with PhOMe or $Pr^i_2O$. Compound **1** reacted rapidly with thf to give what appeared to be polymeric material (this was surprising since there are reports that organocalcium compounds are formed in much higher yield in thf than in $Et_2O$[4]). The reaction of **1** (1.99 mmol) with an excess of MeI gave RH (0.47 mmol), RI (0.96 mmol) and RMe (0.56 mmol), behaviour analogous to that of the ytterbium compound

**3** but different from that of $Mg[C(SiMe_3)_3]_2$ **5** which does not react with MeI under similar conditions.[20] The higher reactivity of **1** than of **4** is probably due in part to the structural differences. In **4** the Mg–C bond is short [2.116(2) Å], and the methyl groups interlock tightly round the linear C–Mg–C axis to protect the central atom.[20] In contrast the metal–carbon bond in **1** is longer, the skeleton is bent, and both the metal and the carbanionic centres are more exposed to attack.

The authors thank the EPSRC for financial support.

# An experimental and theoretical investigation of the electronic structure of Pd and Pt bis(carbene) complexes

**Jennifer C. Green,*[a] Robert G. Scurr,[a] Polly L. Arnold[b] and F. Geoffrey N. Cloke[b]**

[a] *Inorganic Chemistry Laboratory, South Parks Road, Oxford, UK OX1 3QR*
[b] *School of Chemistry, Physics and Environmental Science, University of Sussex, Brighton, UK BN1 9QJ*

**Photoelectron spectra and density functional calculations are reported for $M(CN_2R_2C_2H_2)_2$ (M = Pd, Pt); bonding occurs predominantly through σ donation from the carbene lone pairs into a metal ($d_{z^2}$ + s) hybrid; the corresponding ($d_{z^2}$ − s) is destabilised with respect to the other metal orbitals; there is little evidence for π bonding and the carbene π orbitals are essentially unperturbed on complexation.**

Isolation by Arduengo of stable carbenes by deprotonation of imidazolium salts[1] has opened up new routes to the synthesis of transition-metal carbene compounds.[2–6] The bis(carbenes) of the group 10 metals, Ni, Pd and Pt, are particularly striking being examples of stable neutral two-coordinate complexes. Together with the isoelectronic complexes of the group 11 metal ions, $Cu^+$, $Ag^+$ and $Au^+$, they show linear coordination,[5,6] which is common for $d^{10}$ metal ions. Though the bonding in the case of the monocations is likely to be predominantly σ donation from the nucleophilic carbene carbons, with the group 10 metals the question arises as to the degree of π-back donation from the metal to the carbene.

**1** M = Pd, R = Bu$^t$ **3** M = Pd, R = H
**2** M = Pt, R = Bu$^t$ **4** M = Pt, R = H

Crystal structure determinations on $M(CN_2Bu^t_2C_2H_2)_2$ (M = Pd **1**, Pt **2**) show the molecular framework to approximate to $D_{2d}$ symmetry with the two rings orthogonal to one another.[7] We consequently classify the molecular orbitals (MO) in this point group. It is also helpful to define their symmetry with respect to the local symmetry at the metal, $D_{\infty h}$. The primary bonding orbital ($a_1$ or $\sigma_g$) is expected to be a linear combination of the carbene lone pairs and a metal ($d_{z^2}$ + s) hybrid directed towards the ligands [Fig. 1(*a*)]. Interaction of the out-of-phase lone pair combination ($b_2$ or $\sigma_u$) with the metal $p_z$ orbital is expected to be less favourable on both energy and overlap grounds [Fig. 1(*b*)]. The metal orbitals which are possible candidates for π-back donation to the ligands are the $d_{xz}$ and $d_{yz}$ orbitals (e or $\pi_g$). They can interact with ligand $\pi_1$, $\pi_3$ or $\pi_5$ orbitals. The ligand $\pi_2$ and $\pi_4$ orbitals give linear combinations $b_1$ and $a_2$ in symmetry (δ and φ respectively). The remaining d orbitals which are δ in symmetry ($d_{xy}$ $b_2$ and $d_{x^2-y^2}$ $b_1$) are expected to have minimal interaction with the ligands. The ten metal electrons will occupy four metal d orbitals and a $d_{z^2}$ − s hybrid [Fig. 1(*c*)].

We have investigated the bonding in these compounds by a combination of photoelectron (PE) spectroscopy and calculations using density functional theory (DFT).

He I and II PE spectra were obtained for **1** and **2**.† The Ni compound was insufficiently volatile for PE spectroscopy. The spectra are shown in Fig. 2 and vertical ionisation energies ($E_i$) are given in Table 1 together with those of ($CN_2Bu^t_2C_2H_2$).[8]

[a] nb = non-bonding, b = bonding, lig. = ligand.

The spectrum of **1** shows one low lying ionisation band, A; in the He I spectrum, the first band lies under the sharp He self-ionisation band (He ionised by He II radiation) but is readily apparent in the He II spectrum. This is followed by a more complex band structure B. Intensity changes between the He I and He II spectra indicate that bands A and B arise from ionisation of metal localised electrons. Band A is assigned ionisation from the $d_{z^2} - s$ hybrid and band B to ionisation from the four Pd d orbitals. Bands C, D and E correspond closely in position to the first three ionisation bands of the free carbene (Table 1).[8] The band profile, however, differs in that band C is lower in intensity in the complex and bands D and E are less resolved. In the free carbene the first PE band is associated with ionisation of the carbene lone pair. The change in band profile on complexing is consistent with stabilisation of the $\sigma_g$ linear combination of the lone pairs in the complex. Band C in the Pd complex is assigned to ionisation of the $\sigma_u$ orbital. The lack of shift or apparent splitting of bands D and E suggest negligible metal–ligand $\pi$ interaction. From the spectrum there is no direct evidence of the location of the $\sigma_g$ ionisation band.

The PE spectrum of **2** is assigned by comparison with that of **1**. The first band A, the $\sigma_g$ ionisation lies at higher energy. Band B, assigned to the d ionisations, shows a significantly greater spread of $E_i$. Given an effective linear potential at Pt, the splitting is attributable to spin–orbit (SO) coupling, that of the $\delta$ orbitals, giving $J = 5/2$ and 3/2, being twice that of the $\pi$ orbitals, giving $J = 3/2$ and 1/2. In the absence of SO coupling the $\pi$ and $\delta$ $E_i$s would be *ca*. 6.2 eV, closely similar to those found for Pd. This suggests that the larger $E_i$ for band A is due to the relativistic stabilisation of the Pt 6s orbital. Band C of the Pd spectrum has no analogue in the spectrum of **2**. We infer that the $\sigma_u$ orbital is more tightly bound compared with the $\pi$ ligand bands which again give rise to bands D and E with similar $E_i$s to the free ligand. There is no direct evidence for the $\sigma_u$ and $\sigma_g$ ionisation bands but the changed intensities of bands D and E compared with the Pd spectrum suggests that the $\sigma_u$ ionisation may lie under band E.

DFT calculations have been carried out for $M(CN_2H_2C_2H_2)_2$ (M = Pd **3**, Pt **4**), assuming $D_{2d}$ symmetry.‡ The geometries were optimised for the ground-state molecules. The distances and angles thus found are compared with those from the crystal structures of **1** and **2**.§ Ionisation energies were calculated both by Slater's transition-state method[14] and by carrying out calculations for the molecular ions $\mathbf{3}^+$ and $\mathbf{4}^+$ in the ion ground state and the first eight excited states using the optimised geometry for the molecule. Though both methods gave a similar $E_i$ pattern the values by the former method were more satisfactory. They are compared with the $E_i$s measured for **1** and **2** in Table 1. The presence of the *tert*-butyl groups in the measured compounds means that precise agreement with theory is not anticipated; alkyl substitution is expected to lower the $E_i$ of a molecule. Good agreement between the pattern of calculated and experimental $E_i$ confirms the assignment of bands given above. Comparing **3** with **1** suggests that the calculation overestimates the ionisation energy of the $\sigma_u$ orbital. The calculations also suggest that for both **1** and **2** the $\sigma_g$ bonding ionisation lies under the main band which commences at 10 eV, and that for **2** the $\sigma_u$ ionisation lies in the envelope of bands D and E.

The combined weight of the experimental and theoretical evidence suggests that the bis(carbenes) of Pd and Pt have metal–ligand $\sigma$ bonds and $\pi$ bonding is minimal.

† PE spectra were measured using a PES Laboratories 0078 spectrometer and calibrated with He, Xe and $N_2$

‡ Calculations were performed using the density functional methods of the Amsterdam Density Functional (ADF) code Version 2.0.1.[9] The basis set used triple-$\zeta$ accuracy sets of Slater orbitals with a single polarisation function added to main group atoms, 2p on H, 3d on C and N. Cores of the atoms were frozen (C, 1s; N, 1s; Pd, 4p; Pt, 5p), those of Pd and Pt being relativistic. Vosko, Wilk and Nusair's local exchange correlation potential[10] was employed with non-local exchange corrections by Becke[11] and non-local correlation corrections by Perdew.[12,13]

# Square-prismatic *vs.* square-antiprismatic coordination in complexes of lead(II) with a simple bidentate chelating ligand; effects of intermolecular hydrogen bonding

**Elefteria Psillakis, John C. Jeffery,* Jon A. McCleverty and Michael D. Ward***

*School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS*

**Whereas the eight-coordinate complex cation of $[PbL_4][(MeO)_2PO_2]\cdot 2H_2O$ [L = 3-(2-pyridyl)pyrazole] has square prismatic geometry stabilised by hydrogen bonding between the pyrazolyl NH groups and the dimethylphosphate anion, the complex cation of $[PbL_4][PF_6]_2$, in which there are no significant hydrogen-bonding interactions, has a structure distorted towards square antiprismatic with a 22° twist between the planes.**

Eight-coordination in metal complexes is largely confined to two common geometries : square antiprismatic ($D_{4d}$) and dodecahedral ($D_{2h}$). Rather rarer, but also well represented, are other geometries such as bicapped trigonal prismatic and hexagonal bipyramidal.[1–3] In contrast, the simple cubic (or square prismatic, $D_{4h}$) geometries are very rare in discrete metal complexes, although well known in ionic solids with the CsCl or $CaF_2$ structures.

Regular cubic coordination requires monodentate ligands, as in $Na_3[MF_8]$ (M = Pa, U, Np)[4] and $[NEt_4]_4[M(NCS)_8]$ (M = U,[5] Th[6]). In the latter examples crystal packing forces are significant in imposing the cubic geometry on the complex anion, as $[U(NCS)_8]^{4-}$ is square-antiprismatic both in solution[7] and in crystals with $Cs^+$ as the cation.[8] $[NEt_4]_4[M(SCN)_7(H_2O)]$ (M = various lanthanoid ions) are also cubic.[9] In contrast, the bite-angle limitations of bidentate chelating ligands mean that regular cubic geometry is not possible. Instead, compressed square-prismatic structures arise with the bidentate chelating ligands lying along the four shorter edges, linking the two square planes.[10–13] Most of these examples have a lanthanide or actinide ion as the central metal, consistent with the requirement for f-orbital participation.[3]

We describe here two eight-coordinate complexes of lead(II) with the bidentate chelating ligand 3-(2-pyridyl)pyrazole (L), of which one is square prismatic and the other is skewed towards a square-antiprismatic geometry. This pair of structures is of interest for two reasons: firstly, they provide a very rare example of square-prismatic geometry outside of the f-block elements, and secondly, they show how intermolecular hydrogen-bonding interactions can overcome the steric problems associated with a square prismatic structure.

We recently reported the synthesis and crystal structure of $[PbL^1{}_2]\cdot H_2O$, containing the potentially tetradentate ligand bis[3-(2-pyridyl)pyrazol-1-yl]phosphinate ($L^1$).[14] On recrystallising a batch of this material from MeOH we found that it had been converted to $[PbL_4][(MeO)_2PO_2]\cdot 2H_2O$, *via* solvolysis of the phosphinate group.† The crystal structure of the centrosymmetric complex is shown in Fig. 1.‡ The four bidentate ligands L form a square-prismatic array about the $Pb^{II}$ centre with each ligand spanning one of the short edges of the square prism, as in $[U(bipy)_4]$.[10] The sides of each 'square' [N(21), N(41), N(11A), N(31A)] are all between 3.30 and 3.50 Å in length, with the distance between the parallel planes [*i.e.* N(11)–N(21) and N(31)–N(41)] being 2.78 Å. The angles within the square prism described by the eight N atoms all lie between 87.5 and 92.3°.

The disposition of the four asymmetric chelating ligands is 'up–up–down–down', such that each end of the complex has two *cis*-related pyridyl donors and two *cis*-related pyrazolyl donors. This allows the two pyrazolyl NH groups at each side of the complex to form an NH···O hydrogen-bonding interaction with O(3) of the dimethylphosphate anion, with the non-bonded O(3)···N(32) and O(3)···N(12) distances being 2.81 and 2.96 Å respectively. This hydrogen-bonding interaction is a significant factor in the adoption of square-prismatic geometry, since the two pyrazolyl NH groups need to be held close enough together to be able to hydrogen bond to the same oxygen atom; the non-bonded N(12)···N(32) separation is 3.73 Å.

To test this theory we prepared the complex cation $[PbL_4]^{2+}$ as its hexafluorophosphate salt.† The crystal structure of $[PbL_4][PF_6]_2$ is in Fig. 2.‡ There are three significant differences between this structure and that of $[PbL_4][(MeO)_2PO_2]\cdot 2H_2O$. Firstly, the four ligands all have the same 'head-to-tail' orientation such that all four pyridyl groups are at one end

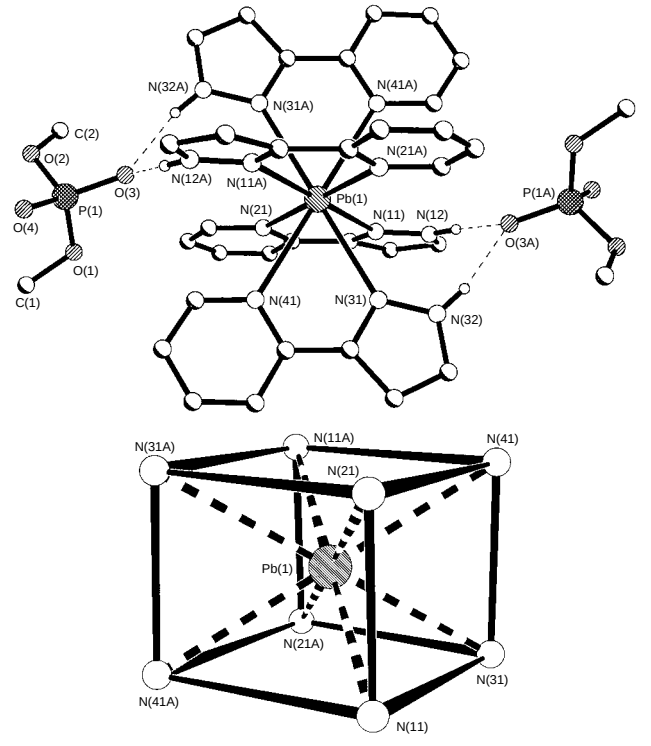

**Fig. 1** Crystal structure of $[PbL_4][(MeO)_2PO_2]\cdot 2H_2O$, showing (top) the complex cation and the hydrogen-bonded anions, and (bottom) the coordination geometry. Selected bond lengths (Å) and angles (°): Pb(1)–N(11) 2.765(6), Pb–N(21) 2.718(6), Pb–N(31) 2.760(6), Pb(1)–N(41) 2.794(6); N(11)–Pb(1)–N(21) 60.3(2), N(31)–Pb(1)–N(41) 59.9(2). Non-bonded N···N separations within the square prism (Å): N(11)···N(31) 3.37, N(31)···N(21A) 3.31, N(21)···N(41) 3.50, N(11)···N(41A) 3.34, N(11)···N(21) 2.78, N(31)···N(41) 2.78.

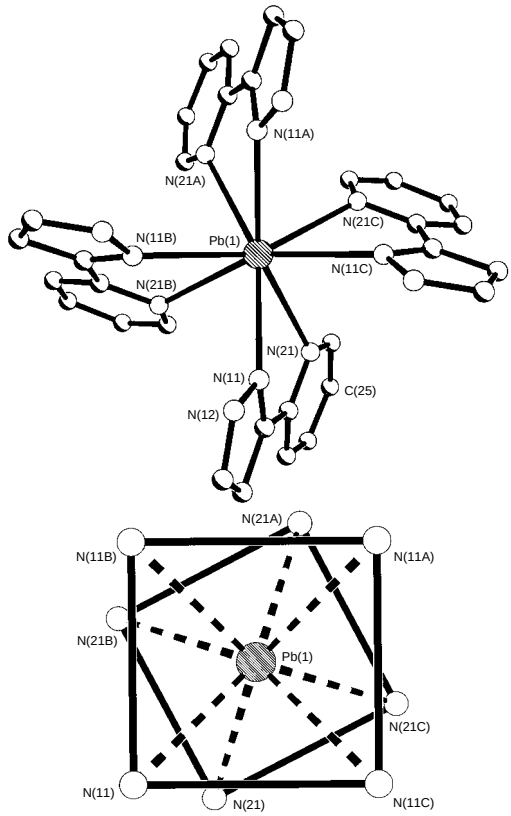

**Fig. 2** Crystal structure of $[PbL_4][PF_6]_2$, showing (top) the complex cation, and (bottom) the coordination geometry. Selected bond lengths (Å) and angles (°): Pb(1)–N(11) 2.702(4), Pb–N(21) 2.775(4); N(11)–Pb(1)–N(21) 60.80(13), N(11)–Pb(1)–N(11B) 80.23(7), N(21)–Pb(1)–N(21B) 75.07(7). Non-bonded N···N separations within the coordination polyhedron (Å): N(11)···N(11C) 3.48 Å, N(21)···N(21B) 3.38 Å, N(11)···N(21) 2.77 Å.

of the complex and the four pyrazolyl groups are at the other end. The complex has crystallographic $C_4$ symmetry with all four ligands equivalent. Secondly, the geometry is no longer square prismatic: the two mean planes are skewed with respect to one another by 22°, and the complex is therefore about half way between square prismatic and square antiprismatic. This twist brings the parallel planes closer together (2.52 Å, compared to 2.78 Å in the previous structure). This illustrates an important steric factor that does not occur in complexes with eight monodentate ligands, where the adoption of square-antiprismatic geometry to relieve the steric strain of an eclipsed prismatic structure does not have the unfavourable side-effect of also bringing the planes together. With four bidentate ligands of fixed length spanning the two planes this effect is inevitable and may explain why the offset of the two planes is only 22 rather than 45°. Thirdly, there are no significant hydrogen-bonding interactions between the complex cation and the hexafluorophosphate anions. An additional consequence of the 'skew' is that the adjacent pyrazolyl NH groups can move further apart; the separations between them [*e.g.* N(12)···N(12B)] have increased to 4.20 Å, as these groups are no longer held in proximity by forming hydrogen bonds to a common atom. The $N_4$ planes are perfect squares, with the square described by the four pyridyl groups (edge length 3.38 Å) being slightly smaller than that described by the four pyrazolyl groups (edge length 3.48 Å).

Crystal packing effects are known to be able to overcome the steric barrier to adoption of cubic geometries, as shown by comparison of $[NEt_4]_4[U(NCS)_8]$ and $Cs_4[U(NCS)_8]$.[5,8] We should be cautious in making comparisons between these two new structures. It does look however as if the hydrogen bonding in $[PbL_4][(MeO)_2PO_2]\cdot 2H_2O$ is partly responsible for the adoption of the very rare square-prismatic geometry, the first example of which we are aware for a main-group molecular species.

† *Preparations*. $[PbL_4][(MeO)_2PO_2]\cdot 2H_2O$: A sample of $[Pb(L^1)_2]$ (ref. 14) was dissolved in MeOH and allowed to crystallise by slow evaporation over several days, to give X-ray quality crystals of $[PbL_4][(MeO)_2PO_2]\cdot 2H_2O$ in 67% yield. $[PbL_4][PF_6]_2$: A mixture of L (ref. 15) (0.290 g, 2 mmol) and $Pb(ClO_4)_2\cdot 3H_2O$ (0.203 g, 0.5 mmol) in MeCN (15 $cm^3$) was vigorously agitated in an ultrasound cleaning bath for 30 min. To the resulting solution was added aqueous $NH_4PF_6$, resulting in precipitation of the product as a white powder in 43% yield. X-Ray quality crystals were grown by slow evaporation of a methanol solution. Both complexes gave satisfactory elemental analyses and FAB mass spectra.

‡ *Crystallographic data*. $[PbL_4][(MeO)_2PO_2]\cdot 2H_2O$: $C_{36}H_{48}N_{12}O_{10}P_2Pb$, $M$ = 1073.96, colourless blocks, crystal size 0.25 × 0.15 × 0.10 $mm^3$, triclinic, space group $P\bar{1}$, $a$ = 8.9120(13), $b$ = 9.462(2), $c$ = 13.394(2) Å, $\alpha$ = 102.17(2), $\beta$ = 101.508(14), $\gamma$ = 92.83(2)°, $U$ = 1076.9(3) $Å^3$, $Z$ = 1, $D_c$ = 1.656 g $cm^{-3}$, $F(000)$ = 536, $\mu$(Mo-K$\alpha$) = 4.060 $mm^{-1}$. 4995 data were collected with $2\theta_{max}$ = 46.5° at −100 °C, and merged to give 3079 unique data ($R_{int}$ = 0.0485). Refinement of 284 parameters converged at $R_1$ [selected data with $I \geqslant 2\sigma(I)$] = 0.041, $wR_2$ (all data) = 0.103. The Pb atom lies on an inversion centre.

$[PbL_4][PF_6]_2$: $C_{32}H_{28}N_{12}F_{12}P_2Pb$, $M$ = 1077.79, colourless blocks, crystal size 0.30 × 0.20 × 0.05 $mm^3$, tetragonal, space group $P4/ncc$, $a$ = 13.136(2), $c$ = 21.667(3) Å, $U$ = 3738.8(9) $Å^3$, $Z$ = 4, $D_c$ = 1.915 g $cm^{-3}$, $F(000)$ = 2096, $\mu$(Mo-K$\alpha$) = 4.703 $mm^{-1}$. 21236 data were collected with $2\theta_{max}$ = 55° at −100 °C, and merged to give 2145 unique data ($R_{int}$ = 0.0532). Refinement of 123 parameters converged at $R_1$ [selected data with $I \geqslant 2\sigma(I)$] = 0.032, $wR_2$ (all data) = 0.080. The Pb atom lies on a $C_4$ axis.

Both data sets were collected on a Siemens SMART diffractometer with an area detector. See refs. 15 and 16 for experimental details and software used. CCDC 182/586.

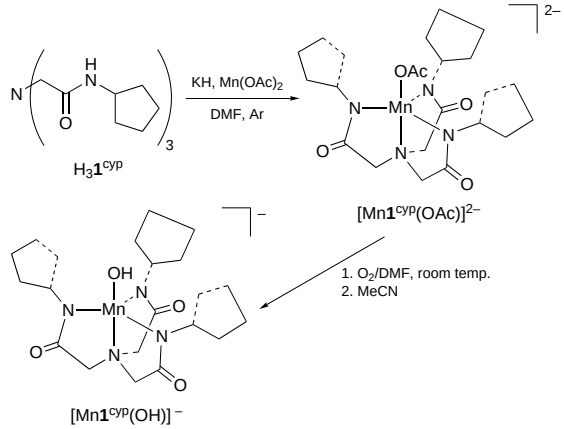
# Synthesis and structure of a $Mn^{III}$(OH) complex generated from dioxygen



**Zahida Shirin,[a] Victor G. Young, Jr.[b] and A. S. Borovik*[a]**

[a] *Department of Chemistry, University of Kansas, Lawrence, KS 66045, USA*
[b] *Department of Chemistry, University of Minnesota, Minneapolis, MN 55455, USA*

**Dioxygen activation at room temperature by a new $Mn^{II}$ complex having a cavity motif yields a monomeric $Mn^{III}$ complex with a terminally bonded hydroxo ligand whose oxygen atom is derived from $O_2$.**

The interactions of manganese ions with dioxygen are involved in a number of biological and synthetic processes.[1] In synthetic manganese complexes, dioxygen activation often leads to the isolation of multinuclear μ-oxo (hydroxo) bridged species having Mn–Mn separation of < 3.5 Å.[2,3] We recently developed a new class of tripodal ligands based on tris(*N*-alkylcarbamoylmethyl)amine that, when coordinated to a metal ion, create cavities that can regulate subsequent ligand binding.[4] Modeling studies (CPK) suggested that appending cyclopentyl groups from the amidate nitrogen ($H_3$**1**$^{cyp}$)[5] would afford a cavity that has space for binding only one exogenous donor to the metal, in addition to preventing the formation of multinuclear metal complexes with metal–metal distances of < 3.5 Å. Thus, while the binding and activation of dioxygen by $Mn^{II}$ complexes of [**1**$^{cyp}$]$^{3-}$ is possible, the formation of oxo(hydroxo)-bridge manganese complexes should be hindered, allowing us to study the formation of a new manganese complex derived from dioxygen.[6] Here, we report the room-temperature $O_2$ activation by a $Mn^{II}$ complex of [**1**$^{cyp}$]$^{3-}$ that produces a monomeric $Mn^{III}$ complex with a terminally bonded hydroxo ligand whose oxygen atom is derived from dioxygen. Preliminary mechanistic studies suggest a reaction pathway that involves C–H bond cleavage from solvent to form the hydroxo ligand.[7]

Treating an anhydrous dmf solution of $K_2$[Mn**1**$^{cyp}$(OAc)]† with 1 equiv. of dry $O_2$ at room temp. results in the formation of blue K[Mn**1**$^{cyp}$(OH)]‡ in 63% yield after washing with MeCN (Scheme 1). K[Mn**1**$^{cyp}$(OH)]18-crown-6 can be isolated in 90% yield when the reaction is carried out at room temp. in anhydrous MeCN. Initial assignment of the product as a monomeric $Mn^{III}$(OH) species is based on its room-temp. solid-state magnetic moment of 4.96 $\mu_B$ which is typical of a high-spin $Mn^{III}$ ion,[8] and its FTIR spectrum containing a sharp peak at 3643 $cm^{-1}$, within the range found for known M–OH complexes.[9]

**Scheme 1**

The presence of a monomeric $Mn^{III}$(OH) moiety in K[Mn**1**$^{cyp}$-(OH)] was confirmed by an X-ray diffraction study.¶ The solid-state molecular structure of [Mn**1**$^{cyp}$(OH)]$^-$ shows the Mn ion having a trigonal-bipyramidal coordination geometry (Fig. 1). The three amidate nitrogens of [**1**$^{cyp}$]$^{3-}$ bind in the trigonal plane with an average Mn–$N_{amide}$ distance of 2.069(2) Å and $N_{amide}$–Mn–$N_{amide}$ angle of 117.07(7)°. These Mn–$N_{amide}$ distances are significantly longer than those observed in the only other structurally characterized $Mn^{III}$ amidate complex where the amidate nitrogens coordinate in a square-planar arrangement [av. M–$N_{amide}$ 1.913(3) Å].[3] The Mn ion sits 0.355 Å out of the trigonal plane toward the hydroxo ligand. The hydroxo oxygen O(4) is positioned nearly *trans* to the apical nitrogen N(1) [N(1)–Mn–(O4) 177.7(2)°] with Mn–N(1) and Mn–O(4) distances of 2.036(2) and 1.816(4) Å. The Mn–O(4) distance observed in [Mn**1**$^{cyp}$(OH)]$^-$ is comparable to that reported for the only other known monomeric $Mn^{III}$(OH) complex {[Mn**1**(OH)];[5] Mn–O, 1.827(3) Å}.[10] The $OH^-$ is located in a cavity formed by the three cyclopentyl substituents which are oriented such that the methine hydrogens on each ring are positioned outside the cavity toward the amide carbonyl groups. This conformation of cyclopentyl groups leads to a cavity structure that enshrouds the $Mn^{III}$(OH) motif, preventing the OH ligand from binding to another Mn complex.

Complexes containing Mn(OH) moieties are rare: only four other structurally characterized synthetic complexes have been reported.[10,11] Of these four, only one contains a monomeric $Mn^{III}$(OH) unit which is obtained by treating [Mn**1**Cl] with NaOH to yield the six-coordinate complex [Mn**1**(OH)].[10] The structure most closely associated with that found in [Mn**1**$^{cyp}$-(OH)]$^-$ is the active site of the manganese superoxide dismutase (MnSOD) isolated from *Thermus thermophilus*; this site contains a trigonal-bipyramidal geometry around a $Mn^{III}$ center with an axially coordinated hydroxo ligand.[12] The hydroxo ligand in MnSOD, like those found in synthetic Mn(OH) complexes, is derived from a source other than dioxygen (*e.g.*, $OH^-$ or $H_2O$). Although $Mn^{III}$(OH) complexes have been proposed as either intermediates or products in several reactions involving $O_2$ and Mn ions there are no examples,[1,13] to our knowledge, where structural proof verifies the identity of these species.

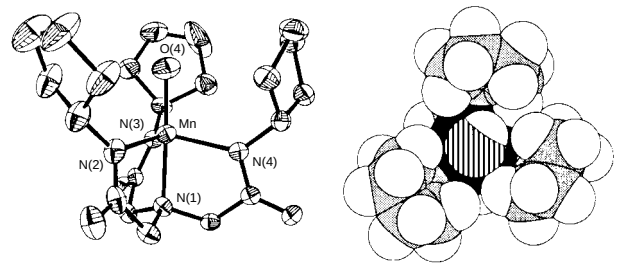


**Fig. 1** Thermal ellipsoid diagram of [Mn**1**$^{cyp}$(OH)]$^-$ and a space-filling representation of the complex. The ellipsoids are drawn at the 50% probability level and hydrogens are removed for clarity. Selected bond distances (Å) and angles (°): Mn–N(1) 2.036(3), Mn–N(2) 2.061(3), Mn–N(3) 2.053(3), Mn–N(4) 2.094(3), Mn–O(4) 1.816(4), N(2)–Mn–N(3) 125.43(1), N(2)–Mn–N(4) 113.5(1), N(3)–Mn–N(4) 112.3(1), N(1)–Mn–O(4) 177.7(2).

In [Mn**1**$^{cyp}$(OH)]$^{-}$ the oxygen atom of the hydroxo group originates from $O_2$: this was confirmed by treating $K_2$[Mn**1**$^{cyp}$(OAc)] with $^{18}O_2$ in MeCN to afford [Mn**1**$^{cyp}$($^{18}$OH)]$^{-}$ [FTIR; $\nu$($^{18}$OH) 3630 cm$^{-1}$, $\nu$($^{16}$OH)/$\nu$($^{18}$OH) = 1.004; calc. 1.003]. In addition, the stoichiometry of the $O_2$ reaction, as determined by manometry, gives Mn complex : $O_2$ = 2 : 1. In the presence of $PPh_3$P (1 equiv.), the oxidation of [Mn**1**$^{cyp}$(OAc)]$^{2-}$ with $O_2$ produces [Mn**1**$^{cyp}$(OH)]$^{-}$ and $Ph_3PO$ which is observed in 33% yield. Moreover, when the reaction is carried in $CD_3CN$ (99.5% D) the product is exclusively [Mn**1**$^{cyp}$(OD)]$^{-}$ [FTIR; $\nu$(OD) 2687 cm$^{-1}$, $\nu$(OH)/$\nu$(OD) = 1.356; calc. 1.374], demonstrating that solvent can serve as the source of the hydrogen (or deuterium) in the Mn$^{III}$[OH(D)] moiety. Similar results were obtained when the oxidation reaction was performed in [$^2H_8$]thf.

These observations are consistent with the formation of a dinuclear peroxo-bridge species during the reaction. A 1,2-μ-peroxo bridge species is postulated because the steric constraints of the cyclopentyl cavity prevents other modes of peroxide coordination.[14] Homolysis of the O–O bond can produce a Mn oxo intermediate whose oxo moiety is sufficiently buried inside the cavity that it is unable to react with other hindered Mn centers to form oxo-bridged clusters. With this pathway eliminated, the Mn oxo species is competent to react with solvent to form [Mn**1**$^{cyp}${OH(D)}]$^{-}$, a process that most likely occurs *via* a H atom abstraction. Support for an oxo intermediate comes from the observed oxygenation of $PPh_3$ to $Ph_3PO$: such oxo-transfer reactions have been proposed to be promoted by high-valent oxo species.[15] Further studies into the mechanism and oxo-transfer properties of this system are in progress.[16]

The $O_2$ reactivity exhibited by [Mn**1**$^{cyp}$(OAc)]$^{2-}$ is the first Mn complex of which we are aware that mediates the formation of a terminally bonded hydroxo ligand directly from $O_2$. In fact, this type of reactivity is rare for transition-metal complexes[17] and usually only occurs for reactions done at low temperatures (*e.g.*, Fe$^{II}$ porphyrins).[6*a*] The room-temperature activation process observed for [Mn**1**$^{cyp}$(OAc)]$^{2-}$ is controlled, in part, by the cavity motif provided by [**1**$^{cyp}$]$^{3-}$ that surrounds the $O_2$ binding site. This result contrasts with that reported by Floriani and coworkers for the room-temp. $O_2$ reactivity of a non-cavity containing Mn$^{II}$ Schiff-base complex.[18] In that system, a μ-OH bridged Mn$^{III}$ polymer is formed after $O_2$ activation with concomitant oxidation of the Schiff-base ligand where an imino group is converted to an amidato. We have not detected[19] any products that indicate modification of [**1**$^{cyp}$]$^{3-}$ during $O_2$ activation. A possible explanation for the lack of ligand oxidation in our system is the positioning of the methine C–H bonds of the cyclopentyl groups outside the cavity, away from the metal centers,[20] which protects these reactive sites from interacting with the activated (di)oxygen–Mn center(s).

Finally, Mn$^{III}$(OH) moieties have been recently proposed as key intermediates in the pathway for $O_2$ production from the oxygen evolving complex of photosynthesis.[21] Now that [Mn**1**$^{cyp}$(OH)]$^{-}$ is well characterized, reactivity studies will allow us to further evaluate the feasibility of this model,[22] efforts for which are underway.

We thank the NIH (GM50781 to A. S. B.) and the University of Kansas for financial support of this research, and Drs Charlie Riordan, Dan Stack, Eric Maatta and Tom Sorrell for helpful discussions.

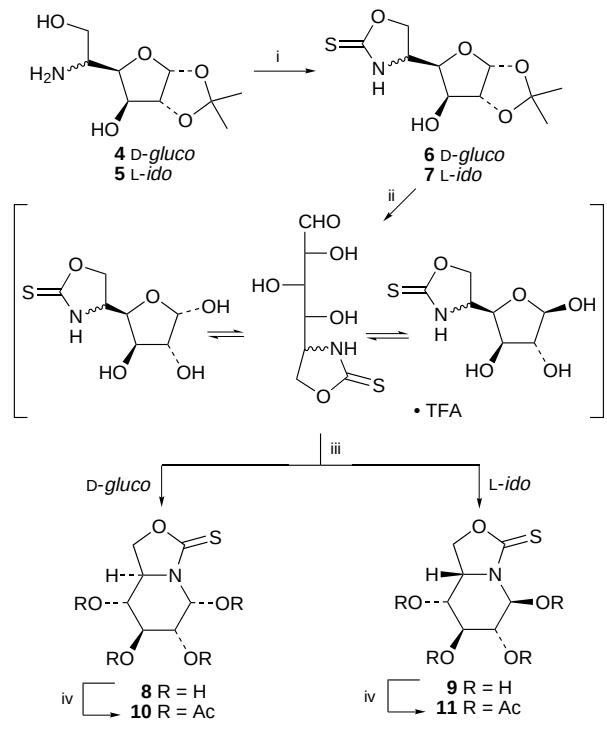
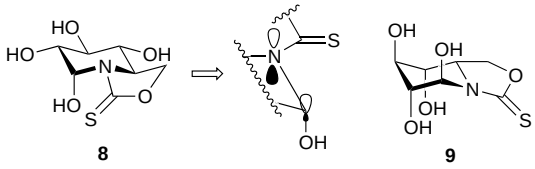
**Bicyclic azasugar glycomimetics structurally related to the polyhydroxy-indolizine and -piperidine series incorporating a stereoelectronically controlled pseudoanomeric axial hydroxy group have been prepared by tautomeric rearrangement of cyclic thiocarbamate precursors; preliminary enzyme inhibition tests show an increased selectivity towards yeast α-glucosidase for the α-D-glucopyranose analogue as compared with castanospermine or nojirimicin.**

Nitrogen-in-the-ring carbohydrate mimics (azasugars) represent an important group of tight-binding glycosyl hydrolase inhibitors useful for studies on glycoconjugate function, targeting and turnover.[1] An additional stimulus of great impact on the synthesis and use of these compounds comes from their application as chemotherapeutic agents for the treatment of several diseases such as diabetes, cancer, inflammation or viral replication, including the human immunodeficiency virus (HIV).[2] Although many potent azasugar glycosidase inhibitors are now available, they generally suffer from lack of specificity. Thus, nojirimycin **1**, a polyhydroxypiperidine derivative having an hydroxylation pattern of spatial similarity to that of D-glucose, and its 1-deoxy analogue **2** are good inhibitors of various α- as well as β-glycosidases. A higher enzyme specificity is observed for the configurationally related indolizidine alkaloid castanospermine **3**, which has been ascribed to the rigidity of the bicyclic structure that locks the homologous bond to C-5–C-6 in hexopyranoses.



nojirimycin **1** 1-deoxynojirimycin **2** castanospermine **3**



Neither of the above mentioned naturally occurring azasugars, nor virtually all the reported synthetic analogues, possess a defined configuration at the pseudoanomeric centre in aqueous solution. An ideal glycosidase ligand should, however, account for the stereocomplementarity of the leaving aglyconic oxygen atom with the key bilateral carboxylic acid and carboxylate groups in the active site of the enzyme, which is probably responsible for the α- or β-linkage specificity shown by many glycosidases.[3] Although the hydroxy group would be a universal surrogate for the natural glycosidic bond of the putative substrates, its hemiacetalic character results in rapid epimerization and low stability (*e.g.* **1**). In fact, indolizidine azasugars bearing a pseudoanomeric hydroxy substituent are unknown.[4]

We have previously shown that thioamide moieties in six-membered ring systems exert a definitive influence in the orientational properties of vicinal hydroxy groups.[5] Exclusively axial OH dispositions are allowed, probably due to a very efficient delocalization interaction between the π-type lone-pair orbital of the $sp^2$-hybridized N-atom in the ground state of *N*-thiocarbonyl functionalities and the σ* antibonding orbital of the contiguous C–O bond. We have now extended this concept to the preparation of carbohydrate mimics endowed with the favourable structural features of polyhydroxyindolizidines and incorporating a configurationally anchored pseudoanomeric hydroxy group.[6]

The synthetic strategy relies on the ability of the ambident *N*-thiocarbonyl group to act as a nitrogen nucleophile in coupling reactions with carbonyl compounds.[7] Thiocarbonylation of 5-amino-5-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranose **4**, available in eight steps from commercial D-glucofuranurono-3,6-lactone,[8] with carbon disulfide–DCC afforded the five-membered cyclic thiocarbamate **6** in excellent yield.§ Hydrolysis of the acetal protecting group under acidic conditions led to a mixture of the protonated α- and β-furanoses, as seen from a $^{13}C$ NMR spectrum of the crude reaction mixture, which after neutralisation rearranged to the fused bicyclic

**Fig. 1** Ring conformation of compounds **8** and **9** showing the OH orientational pattern. The π-electron stabilization interaction responsible of the strong anomeric effect is also represented for the pseudo $^4C_1$ chair conformation of the six-membered ring (*e.g.* **8**).

azasugar **8** by intramolecular nucleophilic addition of the thiocarbamate *N*-atom to the masked aldehydo group of the monosaccharide (Scheme 1).

The $^1$H and $^{13}$C NMR spectra of **8** in $D_2O$ showed the presence of a single tautomeric form having the *R* configuration at the pseudoanomeric centre, *i.e.* a molecular framework analogous to that of α-D-glucopyranose (Fig. 1). No traces of the *S*-epimer or furanoid tautomers were detected even after conventional acetylation (→ **10**), corroborating the total stereoelectronic control induced by the vicinal thiocarbamate segment. The potential of this approach to design glycomimetics bearing a pseudoanomeric oxygen atom with defined configurational and conformational properties is further illustrated by the preparation of the L-*ido* derivative **9** from the corresponding C-5 epimeric amino sugar[8] **5** following a similar reaction sequence (Scheme 1). The all-OH-axial bicyclic tautomer with *S* configuration at the pseudoanomeric centre (Fig. 1) was exclusively detected in $D_2O$ solution or after acetylation (→ **11**).¶ Both the vicinal $^3J_{H,H}$ coupling constants and computational calculations‖ support a rigid conformation for the bicyclic skeleton of **8** close to that of castanospermine **3**. Preliminary glycosyl hydrolase inhibition tests showed, however, a totally different scenario. Considering the most widely used glycosyl hydrolases, sweet almond β-glucosidase and yeast α-glucosidase, the inhibition constants for **8** (150 000 and 90 μmol dm$^{-3}$, respectively)** indicated a reverse linkage specificity as compared to **3** (1.5 and > 1500 μmol dm$^{-3}$) or **1** (0.89 and 6.3 μmol dm$^{-3}$).[1a] Although the latter is a one order of magnitude stronger inhibitor of yeast α-glucosidase than **8**, the selectivity ratio for **8** is above $10^4$-fold higher.

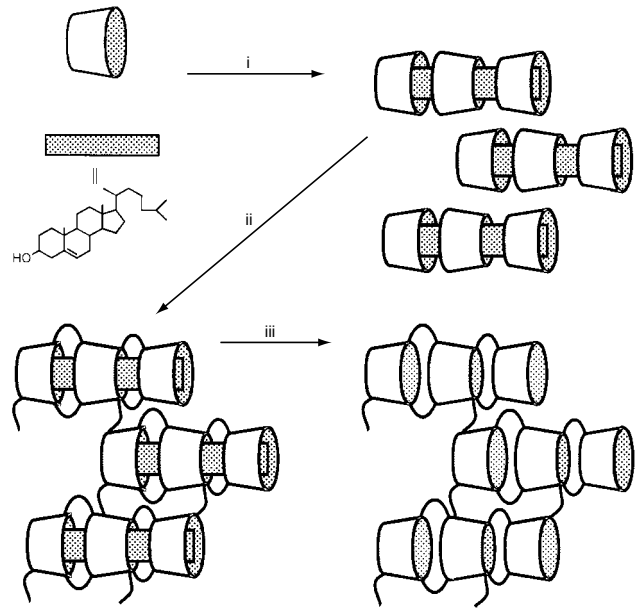
# Molecularly imprinted polymer of β-cyclodextrin for the efficient recognition of cholesterol

**Hiroyuki Asanuma, Masaya Kakazu, Masahiko Shibata, Takayuki Hishiya and Makoto Komiyama***

*Department of Chemistry and Biotechnology, Graduate School of Engineering, The University of Tokyo, Hongo, Tokyo 113, Japan*



**Polymeric receptors for cholesterol have been prepared by crosslinking β-cyclodextrin with diisocyanates in dimethyl sulfoxide in the presence of cholesterol as template.**

To date, a number of organic receptors which recognize small guest molecules have been synthesized.[1–3] Highly selective guest-binding was successfully achieved by placing appropriate functional residues at the required sites. Furthermore, a molecular imprinting method was developed to prepare tailor-made artificial receptors.[4–10] In this technique, the adducts between a guest and functionalized monomer(s) are polymerized, and hence the positions and orientations of the functional residues of the monomers in the adducts, which fit the physicochemical properties of the guest, are immobilized in the polymers. The studies on the recognition of small guest molecules have been so fruitful that the current interest is gradually focusing on receptors for still larger guests, such as steroids, oligopeptides, oligosaccharides, *etc*. Whitcombe *et al.* prepared a receptor for cholesterol by polymerizing a cholesterol-attached monomer, followed by the removal of the steroid residue.[11] Another promising strategy for the preparation of these receptors is to build up several host molecules, each of which binds a part of the large guest molecule, so that the resultant assembly of the hosts as a whole recognizes the guest.[12] However, the methodology for the construction of these ordered assemblies has not yet been established.

Recently, Breslow and Zhang[13] showed that cholesterol can be bound by a receptor in which two molecules of β-cyclodextrin (β-CyD: a cyclic oligomer of seven glucose units)[14–16] are connected to each other by an appropriate linker. These two β-CyD residues are precisely placed to bind cholesterol, which is too large to be accommodated in the cavity of a single β-CyD residue (free β-CyD forms a 3 : 1 complex with cholesterol).[17] Here we prepare polymeric receptors for cholesterol by crosslinking β-CyD molecules. The mutual orientations of the β-CyD residues are regulated by using the molecular imprinting technique. The crucial importance of the choice of both the crosslinking agent and the solvent for the templating is evidenced.

The templated β-CyD polymers were prepared as depicted in Scheme 1.† In dimethyl sulfoxide (DMSO), the β-CyD–cholesterol complex was treated with either hexamethylene diisocyanate (HMDI) or toluene 2,4-diisocyanate (TDI). After the crosslinking reaction, the cholesterol (used as the template) was removed from the polymer by treatment with acetone, THF and hot EtOH, and this was confirmed from $^{13}$C-CP/MAS NMR spectroscopy. These polymers were then dried and used for the adsorption experiments.

The templated β-CyD polymer, prepared using HMDI as the crosslinking agent (abbreviated as HMDI-Imp), efficiently adsorbed cholesterol, which was present in a water–THF mixture (5 : 6 v/v).‡ The adsorption reaction was completed within 5 min. By this simple procedure, 15% of the cholesterol was removed from the liquid phase (Table 1). The amount of adsorbed cholesterol was proportional to the amount of the polymer. Stigmasterol, a derivative of cholesterol, was also adsorbed by the polymeric receptor in a similar amount (10%). In contrast, non-templated β-CyD polymer (synthesized in the absence of the cholesterol template: HMDI-Non) did not adsorb cholesterol to a measurable extent. Thus, the 'templating' is essential to prepare the polymeric receptor which notably binds cholesterol. The templated polymer TDI-Imp showed an even greater adsorbing activity (70% of the cholesterol was adsorbed). This was probably due to the molecular rigidity of TDI being able to regulate the positions of β-CyD residues more precisely.

**Scheme 1** *Reagents and conditions*: i, hexane–$H_2O$; ii, diisocyanate in DMSO; iii, acetone, $H_2O$, THF, EtOH

All the adsorbed cholesterol was easily removed from the polymeric receptors by treating the polymer–cholesterol adducts with boiling EtOH. On the next run, both the rate of cholesterol adsorption and the adsorbing capacity were identical to those in the foregoing adsorption. Thus, the adsorption described here is totally reversible. The potential applicability

**Table 1** Adsorption of cholesterol from the water–THF mixture by crosslinked β-CyD polymers

| Crosslinking agent | Adsorbing activity[a] | | Templating effect[b] |
|---|---|---|---|
| | Templated | Non-templated | |
| HMDI | 0.15 | < 0.01 | > 15 |
| | (0.05)[c] | (0.05)[c] | (1.0)[c] |
| TDI | 0.70 | 0.19 | 3.7 |
| Epichlorohydrin | < 0.01 | < 0.01 | — |

[a] The ratio of the decrease in cholesterol concentration in the liquid phase to the initial concentration, under the adsorption conditions presented in footnote ‡. [b] The ratio of the adsorbing activity of the templated polymer to that of non-templated polymer. [c] Phenol is used as the guest, in place of cholesterol.

of these adsorbents to practical removal of cholesterol has been indicated.[18]

It is noteworthy that the β-CyD polymers, prepared by crosslinking with epichlorohydrin,[19]§ did not adsorb cholesterol (Table 1; a similar result was reported by Breslow and Zhang).[13] The templated polymer synthesized from the β-CyD–cholesterol complex (in place of free β-CyD) was also inactive. The use of DMSO is advantageous for the 'templating', since the β-CyD inclusion complexes are satisfactorily formed in this solvent.[14,15,20]¶ The formation of well-defined complexes under mild conditions is presumably responsible for the selectivity. The crosslinking of β-CyD by epichlorohydrin is achieved under highly alkaline conditions, where the β-CyD–cholesterol complexes mostly dissociate.

These arguments are further supported by the fact that the adsorbing activity of the HMDI-Imp on phenol was identical with the value of the HMDI-Non (see the numbers in parentheses in Table 1).[14,15]‖ The present finding indicates that artificial polymeric receptors for varieties of large guest molecules can be prepared by using the molecular imprinting technique for the immobilizaton of β-CyD.

## Footnotes and References

* E-mail: mkomi@chembio.t.u-tokyo.ac.jp

† The 3 : 1 β-CyD–cholesterol complex was prepared according to ref. 17, and was reacted with the diisocyanate agents in dry DMSO at 65 °C for a few hours ([diisocyanate]/[β-CyD] = 4.2). All the reactants (β-CyD, cholesterol and the diisocyanates) were satisfactorily soluble in DMSO. The polymer, obtained by pouring the mixture into acetone, was ground with a mortar and pestle, and then sufficiently washed with hot water, THF and hot EtOH to remove the cholesterol and free β-CyD completely. The ratios of the diisocyanate residue to β-CyD in the polymers were 3.4 for both HMDI and TDI, as estimated by elemental analysis. Non-templated β-CyD polymers were similarly prepared in the absence of the cholesterol template.

‡ The adsorption experiment was carried out by incubating the polymeric receptor (0.5 mmol of β-CyD residue) in 11 ml water–THF (5 : 6 v/v) containing 0.05 mmol of cholesterol. After being magnetically stirred at 25 °C, the mixture was centrifuged and the liquid phase was analysed by gas chromatography. The water–THF mixture was used as the solvent, since the solubility of cholesterol in water is too small and the addition of THF was required to provide homogeneous solutions.

§ The epichlorohydrin-immobilized β-CyD was prepared by reacting β-CyD (25 g) with the crosslinking agent (20 g) at 50 °C in 50 wt% of aqueous NaOH solution, according to ref. 19. The ratio of the crosslinking residue to β-CyD residue in the polymer was 3.6.

¶ The complex formation between β-CyD and cholesterol in DMSO was confirmed by $^1$H NMR spectroscopy using 3-(trimethylsilyl)[2,2,3,3-$^2H_4$]propionic acid as the internal standard. When β-CyD (30 mM) was added to a DMSO solution of cholesterol (2 mM) at 25 °C, the 18 methyl protons of cholesterol, for example, showed upfield shift (0.046 ppm) with respect to the value in the absence of β-CyD. The remarkable 'templating' efficiency is partially associated with the fact that, due to a proximity effect, the β-CyD residues in the cholesterol complex are crosslinked by the diisocyanates more quickly than are free β-CyD molecules in the solutions.

‖ In order to shed light on the role of the cavity of β-CyD in the present cholesterol binding, dextran was crosslinked by HMDI under the conditions employed for the immobilization of β-CyD. The resultant dextran polymer did not adsorb phenol at all. The possibility that phenol is simply adsorbed to either the outside of β-CyD or the crosslinking residue is unlikely. The complex formation between phenol and the templated polymer was further confirmed by solid-state $^{13}$C-NMR: C1 of β-CyD showed a downfield shift of 0.4 ppm on the complex formation, whereas the shift of C4 was marginal. The C2, C3 and C5 carbon atoms could not be sufficiently resolved under the conditions.

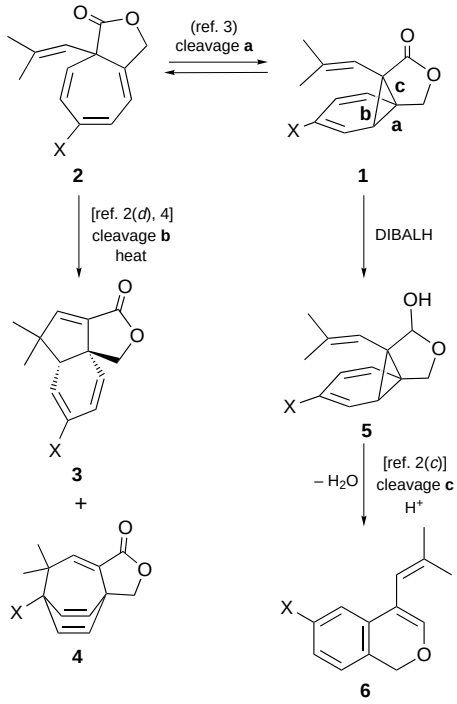
# Photospecific cleavage of one of the cyclopropyl σ-bonds of vinylnorcaradienes

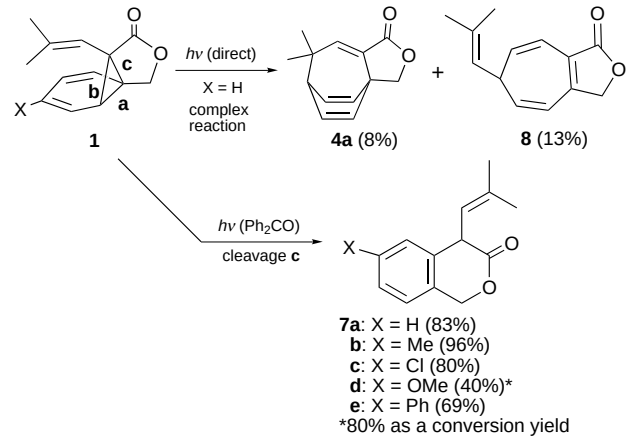
**Shigeo Kohmoto,* Hisao Yajima, Shin-ichi Takami, Keiki Kishikawa, Makoto Yamamoto and Kazutoshi Yamada**

*Department of Materials Science, Faculty of Engineering, Chiba University, Yayoi-cho, Inage-ku, Chiba 263, Japan*



**The benzophenone sensitised photochemical reaction of vinylnorcaradiene derivatives 1, 5-(2-methylprop-1-enyl)-3-oxatricyclo[4.4.0.0$^{1,5}$]deca-7,9-dien-4-ones, resulted in the regioselective cleavage of one of the cyclopropyl σ-bonds to afford the isochroman-3-one derivatives 7.**

With the release of the large ring strain as a powerful driving force, the cleavage and ring expansion of the cyclopropyl ring has been intensively studied and demonstrated to be a useful synthetic tool.[1] The selective cleavage of one of the three cyclopropyl σ-bonds is an interesting subject from both mechanistic and synthetic view points. If the cleavage is perfectly controlled, then one of the three modes of rearrangement can be utilised at choice starting from the same compound. To the best of our knowledge, such a control has never been cited.



In our study of stable tricyclic vinylnorcaradienes **1**,[2] we have been interested in the photo- and thermo-specific, and regioselective cleavage of the cyclopropyl σ-bonds in the norcaradiene structure. The following three types of cleavage are possible (Scheme 1). The cleavage of bond **a** results in the formation of cycloheptatriene **2**, which corresponds to the norcaradiene–cycloheptatriene equilibrium.[3] The cleavage of the bond **b** has been reported in the thermal rearrangements of vinylnorcaradienes to afford vinylcyclopropane–cyclopentene and Cope rearrangement products, **3** and **4**, respectively.[4] The third type of cleavage, the cleavage of bond **c**, has been shown in the acid-catalysed dehydrative aromatisation of lactols **5** derived from the reduction of **1** to afford **6**.[2c] Here we report on cleavage **c** of **1** which results in the formation of **7** directly.

Since the thermal reaction of **1** led to the cleavage of the cyclopropyl σ-bond **b**,[2d,4] we have investigated the photochemical reaction. In order to survey which part of the molecule, the diene or the carbonyl moiety, would act as the chromophore and be responsible for the photochemical reaction, a PM3 calculation of **1a** was carried out. The calculation showed that the lobe of the 1,3-diene moiety was much larger than the rest of the molecule in the LUMO of **1a**. The carbonyl moiety contributed to the excited state of **1a** in its next LUMO. The energy difference between the two states, the LUMO and the next LUMO, was large (0.94 eV). Therefore, the photochemical reaction of **1a** could possibly be initiated from the excited state of the 1,3-diene moiety.

Direct irradiation of a benzene solution of **1a** (X = H, $2.5 \times 10^{-2}$ M) in a Pyrex test-tube cooled in a water bath was carried out externally with a 400 W high pressure mercury lamp for 5 h through a Pyrex filter under argon bubbling. The photoreaction was complex and two products, **4a**[2d] (X = H, 8%) and **8** (13%) (Scheme 2),† were isolated in low yields by preparative HPLC purification together with 35% recovery of **1a**. The Cope rearrangement product **4a** was the result of the cleavage of bond **b** and **8a** was derived from the 1,5-shift of vinyl group from cycloheptatriene **2a**. The Cope rearrangement product **4a** can also be obtained thermally, however its formation requires heating at over 130 °C.[2d] Therefore, **4a** is almost certainly the photochemical product in the present case. No product corresponding to the rearrangement *via* the cleavage of bond **c** was found. However, when the reaction of **1a** (X = H, 0.12 mmol) was sensitised by the addition of benzophenone (1 equiv.) in benzene (10 ml) and irradiated with a 400 W high pressure mercury lamp for 70 min, **7a** (X = H) was obtained in 83% yield as a sole product.† The triplet excited state of the 1,3-diene moiety is probably responsible for the photorearrangement. This benzophone sensitised photorearrangement also worked well for other vinylnorcaradienes **1b** (X = Me), **1c** (X = Cl), **1d** (X = OMe) and **1e** (X = Ph) to give the

**Scheme 1**

**Scheme 2**

corresponding rearrangement products **7b**–**7e** in 96, 80, 40 (80% as a conversion yield) and 69% yields with irradiation times of 70, 80, 75, 60 and 720 min, respectively.† The reason for the relatively low photoreactivity of **1e** compared to the others is unclear. The phenyl substituent on the diene lowers the energy of the LUMO, from −0.31 eV for **1a** to −0.66 eV for **1e** as calculated by PM3, which might be responsible for inefficient energy transfer. The multiplicity dependent photochemical reaction of cyclohexa-1,3-diene derivatives has been reported.[5] In the present work, the selective cleavage of the cyclopropyl σ-bond **c** requires such a multiplicity dependent reaction of a cyclohexa-1,3-diene chromophore.

The results show a nice contrast to that of the reported thermolysis (cleavage of bond **b**) and provide useful information on the photochemistry of cyclopropane derivatives.[6]

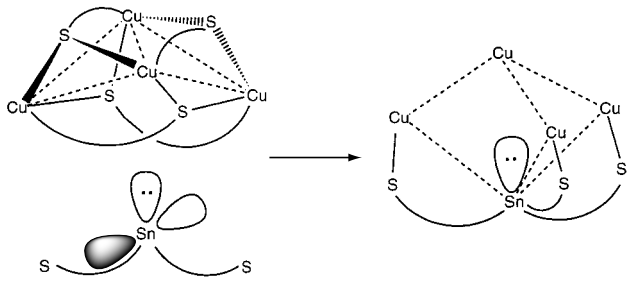
# Synthesis and structure of $[Sn(mit)_6Cu_4]$; a $[SnCu_4]$ cage supported by Sn–Cu cluster bonding [mit = $(\overline{CH)_2N(Me)C(=S)=N}$]

**Robert E. Allan,[a] Alan Bashall,[b] Julie S. Palmer,[a] Mary McPartlin,[b] Marta E. G. Mosquera,[a] Jeremy M. Rawson,[a] Andrew E. H. Wheatley[a] and Dominic S. Wright*[a]**

[a] *Chemistry Department, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW*
[b] *School of Applied Chemistry, University of North London, Holloway Road, London, UK N7 8DB*

**The reaction of $[Sn(mit)_2]_n$ with CuCl gives the heterobimetallic complex [{$Sn(mit)_6Cu_4$] 1, in which the *hypho*-hexagonal-bipyramidal $[SnCu_4]$ core is stabilised by $Sn^{II}$–$Cu^{I}$ cluster bonding between the *endo* lone pair of the Sn centre and the tetrahedral $Cu_4$ fragment.**



Much of our recent research has focused on the applications of a range of neutral and anionic p-block metal based ligands in the preparation of mixed-metal complexes.[1,2] The organometallic anions of group 14 metals ($[R_3E]^-$; E = Ge–Pb)[2b,3] and their metallo-organic relatives ($[\{RY\}_3E]^-$; Y = O, S, N, P)[1a,4] are a readily prepared and extensive class of ligands. Unfunctionalised tri(organo) metal anions have been employed as metal-centred monodentate ligands to a variety of main-group[3] and transition metals,[5] giving heterobimetallic complexes containing metal–metal bonds. In contrast, the metallo-organic derivatives [*e.g.* tris(alkoxy) and tris(amido) stannates] generally act as bidentate or tridentate ligands, utilising the heteroatoms in their coordination to metal ions.[4,6] However, the ability of these species to behave as multifunctional (metal- and heteroatom-centred) ligands has been utilised in the construction of mixed-metal complexes such as [{$(CO)_5MSn(\mu$-$OBu^t)_3In\{Mo(CO)_5\}$] (M = Cr, Mo).[7]

We report here that the addition of [CuCl] to a suspension of $[Sn(mit)_2]_n$[8] [mit = $(\overline{CH)_2N(Me)C(=S)=N}$] in thf gives the novel heterobimetallic cage complex $[Sn(mit)_6Cu_4]$ **1**.† The complex contains an unprecedented $SnCu_4$ cage arrangement in which a tris(amido) stannate unit supports the cluster by a combination of heteroatom and metal-centred donation. The synthesis of **1** can be conceived as occurring *via* the initial formation of $[Cu(mit)]_4$[9e] which is then complexed by a $[Sn(mit)_2]$ monomer (Scheme 1). The latter can be described as a synergic complexation reaction (*i.e.* resulting from a combination of N donation to Sn and lone pair donation from Sn to Cu).

A low-temperature (173 K) crystallographic study of **1**‡ shows it to be the heterobimetallic $Cu^{I}Sn^{II}$ complex $[Sn(mit)_6Cu_4]$ (Fig. 1), which has crystallised with four molecules of thf. The cage molecules of **1** are constructed from a $C_{3v}$ symmetric *hypho*-hexagonal $[SnCu_4]$ metal core linked together by a combination of N,S- and N,μ-S-chelating mit ligands.[9] The $Sn^{II}$ atom of **1**, which is bonded to the N centres of three mit ligands [Sn(1)–N(5a) 2.202(6) Å], adopts a typical-pyramidal geometry [N(5a)–Sn–N(5aa) 90.0(2)°] which is symptomatic of the presence of a stereochemically active *endo* lone pair, which is directed along the major axis of the $[SnCu_4]$ core, toward Cu(3). Three symmetry related mit ligands form bridges between the Sn atom and each of the equatorial Cu atoms of the core [S(7a)–Cu(2) 2.266(2) Å], with the remaining mit ligands N,μ-S-chelating the three available $Cu_3$ faces of the $Cu_4$ pyramid. The arrangement of the mit ligands in **1** results in identical trigonal planar geometries for the equatorial Cu centres and in a pyramidal coordination geometry for the apical Cu atom [S(7b)–Cu(3)–S(7ba) 113.78(5)°]. The remaining vacant coordination site of the latter corresponds to the shortest Sn···Cu contact made with the $Sn^{II}$ lone pair [Sn(1)···Cu(3) 2.727(2) Å being close to the sum of the metallic radii 2.69 Å,[10] Sn(1)···Cu(3)–S(7b) 104.72(7)°]. In addition, the Sn centre also has longer interactions with the equatorial Cu atoms of the $Cu_4$ fragment [Sn(1)···Cu(2) 2.902(1) Å].

Although no Ge–, Sn– or Pb–$Cu^{I}$ bonded complexes have been structurally characterised, bonds between the heavier group 14 elements and $Au^{I}$ have been observed in a number of simple σ-bonded complexes.[11] The presence of relatively short Sn···Cu contacts in **1** and the geometries of Cu(3) and Sn(1) strongly indicate that Cu–Sn bonding supports the core. In addition, the involvement of the Sn centre results in a large rearrangement in the $Cu_4$ core from the folded-square arrangement present in $[Cu(mit)]_4$ {Cu···Cu range 2.671(2)–3.132(2) Å in $[Cu(mit)]_4$;[9e] Cu(2)···Cu(3) 2.683(1) in **1**; *cf.* 2.56 Å in Cu metal}.[10]

In order to assess the extent to which Sn···Cu and Cu···Cu interactions support the cage of **1**, an extended Hückel molecular orbital (EHMO)[12] calculation was performed on its $[SnCu_4]^{6+}$ metal core.§ The lowest lying metal–metal bonding

**Scheme 1**

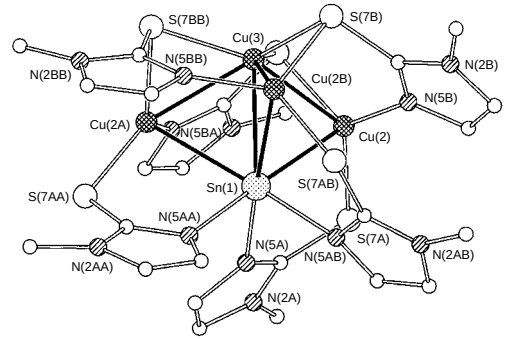


**Fig. 1** Cage structure of **1**, showing the $SnCu_4$ arrangement. Key bond lengths (Å) and angles (°); Sn(1)···Cu(2) 2.902(1), Sn(1)···Cu(3) 2.727(2), Cu(2)···Cu(3) 2.683(1), Sn(1)–N(5a) 2.202(6), Cu(2)–S(7a) 2.266(2), Cu(2)–S(7ba) 2.300(2), Cu(3)–S(7a) 2.315(2), Cu(2)–N(5b) 1.967(6), C(6a)–S(7a) 1.731(7), C(6a)–N(5a) 1.335(9), C(6b)–S(7b) 1.736(8), C(6b)–N(5b) 1.34(1); S(7b)–Cu(3)–S(7ba) 113.78(5), Sn(1)···Cu(3)–S(7b) 104.72(7), N(5a)–Sn–N(5aa) 90.0(2).

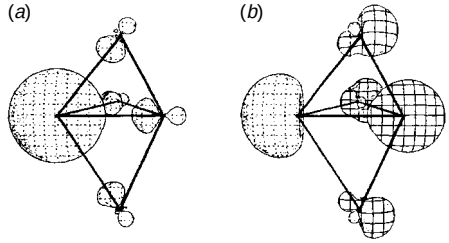

**Fig. 2** Extended Hückel molecular orbital calculation (EHMO) of $[SnCu_4]^{6+}$; (*a*) lowest metal-metal bonding MO, (*b*) the out-of-phase combination (LUMO)

orbital involves the totally in-phase interaction of the $Sn^{II}$ lone pair with all four Cu centres [Fig. 2(*a*)], with the corresponding out-of-phase interaction forming the LUMO [Fig. 2(*b*)]. The bonding between the metal centres is predominantly of s or s/p character, with less than 10% d character being contributed from the Cu centres. The strongest bonding interaction occurs between Sn and the apical Cu centre (overlap population 0.15), with weaker bonding occurring between the Sn and equatorial Cu atoms (overlap population 0.10) and with Cu···Cu interactions only being present between the apical and equatorial Cu ions (overlap population 0.07). The formation of the $[SnCu_4]^{6+}$ cluster is accompanied by the donation of charge from $Sn^{II}$ approximately equally to the $Cu^{I}$ centres (total 0.35 e). The magnitudes of the Cu···Cu interactions in **1** are similar to those calculated by Hoffman for naked $[Cu]_4^{4+}$ using the same EHMO parameters.[13] The small attraction between the Cu centres in the latter arises from mixing of the s and p orbitals with the d orbitals.[13] The cluster MO of **1** corresponds to a similar combination of Cu atomic orbitals as in $[Cu]_n^{n+}$ with the s orbital of Sn. Clearly, the geometric constraints and bonding preferences of the ligands are likely to have the largest effect on the metal core geometry of **1**. However, the structural and calculational findings support the view that weak Sn···Cu metal–metal cluster bonding reinforces the cage arrangement.

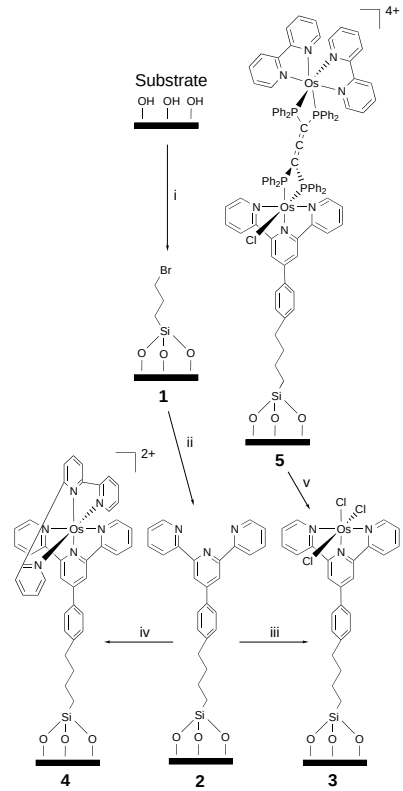
# Covalent surface confinement of osmium–terpyridine complexes: a UV–VIS and XPS study

**Mai Zhou, J. Mickey Laux, Kimberly D. Edwards, John C. Hemminger and Bo Hong***

*Department of Chemistry, University of California, Irvine, CA 92612, USA*

**Well defined monolayers of $–Si(CH_2)_4Ph–tpy–OsCl_3$, $–Si(CH_2)_4Ph–tpy–Os(tpy)$ and $–Si(CH_2)_4Ph–tpyOsCl–(PPh_2)_2C=C=C(PPh_2)_2–Os(bpy)_2$ (tpy = 2,2′:6′,2″-terpyridine, bpy = 2,2′-bipyridine) on polycrystalline quartz surfaces are prepared and studied by UV–VIS and X-ray photoelectron spectroscopy.**

Well defined monolayers and multilayers containing chromophores and redox-active centers are important owing to their diverse applications in photocatalysis, light-harvesting, nonlinear optical materials, and sensor technology.[1–5] We report here the preparation of monolayers and multilayers containing covalently confined osmium–terpyridine chromophores and the subsequent characterization using electronic absorption and X-ray photoelectron spectroscopy. Osmium–terpyridine complexes are known to be photostable and have well known solution-state absorption, luminescence, and redox properties.[6] Upon incorporation into the self-assembled organosilane monolayer structures *via* covalent linkage, surface-confined osmium–terpyridine units, in combination with other building block modifications, may allow the expedient assembly of robust monolayer and multilayer structures.



Scheme 1 illustrates the present approach to Os-containing monolayers and multilayers on polycrystalline quartz surfaces. It involves the initial direct reaction of a carbanion derived from a methyl-substituted terpyridine ligand with a preformed bromoalkylsilane surface,[4,5] giving a hydrocarbon tether to the quartz surface (Scheme 1, steps i and ii). The subsequent attachment of $OsCl_3$ to the modified surface was obtained by refluxing in aqueous ethanolic solution of $OsCl_3·3H_2O$ for 3 h. The surface treatment with $Os(tpy)Cl_3$ (tpy = 2,2′:6′,2″-terpyridine), in the presence of $NH_4PF_6$, step iv, was carried out in a similar way but with much longer refluxing time (up to 3 d) to ensure the completion of surface attachment. This results in the monolayer **4** with terminal –tpy–Os–tpy units.

Also shown in Scheme 1, the terminal $OsCl_3$ units in monolayer **3** can be used as structural motifs in the further construction of multilayer structures, since Cl ligands can be replaced by σ or π ligands such as phosphine or polypyridine units in other molecular building blocks. Step v shows a representative reaction of surface confined $–OsCl_3$ units with a monometallic building block $[Os(bpy)_2\{(PPh_2)_2C=C=C(PPh_2)_2\}][PF_6]_2$† (bpy = 2,2′-bipyridine) in refluxing thf for 24 h,[7] giving the bilayer thin film **5**.

Spectrophotometric changes are monitored during the surface treatment using UV–VIS spectroscopy. Polycrystalline quartz has no significant absorption above 250 nm. Upon surface modification, typically we observe a weak increase of absorption after attachment of $–Si(CH_2)_4Ph–tpy$. Broad absorption bands at about 280 and 320 nm are observed upon addition of Os centers. The intensity of these two peaks increases as a function of reaction time and reaches maximum after three days. No significant increase or decrease in absorbance is observed after 3 d, indicating that a stable monolayer with terminal $–CH_2Ph–tpy–Os–tpy$ units is obtained.

The UV–VIS spectrum of the solution sample of $Os(ttp)(tpy)(PF_6)_2$‡ (ttp = $CH_3Ph–tpy$) has absorption bands at 275 nm ($\varepsilon$ = 28 430 dm$^3$ mol$^{-1}$ cm$^{-1}$), 315 (43 100), 485 (11 490) and 665 (2840). When compared with the solution sample, the observed transition bands of the surface bound $–CH_2Ph–tpy–Os–tpy$ units in sample **4** are relatively broad and slightly shifted (shift *ca.* 5 nm towards longer wavelength), and tailed into 500 nm. However, no significant $^3$MLCT band in the range 500–700 nm is observed for the surface samples with attached Os centers owing to the much lower absorption coefficient of the band at 665 nm.§

The calculation of surface coverage, using UV–VIS spectroscopy, has also been carried out. The solution $\varepsilon_{max}$ values were assumed to be invariant in order to provide an approximation to the two-dimensional surface absorption coefficients ($\varepsilon_s$) in the calculations.[4,5] Using the lowest energy π–π* transition at 280 nm, the estimated values of monolayer surface coverages for modified surfaces with terminal $–CH_2Ph–tpy–Os–tpy$ ($\varepsilon_{s,280}$ = 2.8 × 10$^7$ cm$^2$ mol$^{-1}$) and $–CH_2Ph–tpy–OsCl_3$ ($\varepsilon_{s,280}$ = 1.2 × 10$^7$ cm$^2$ mol$^{-1}$) units are 2.0 × 10$^{-10}$ and 3.6 × 10$^{-10}$ mol cm$^{-2}$, respectively. These values are comparable with the reported values (typically, 1 × 10$^{-10}$ mol cm$^{-2}$) of the surface coverages for monolayers with complexes of Fe, Ru or Re.[4,5] The estimated surface coverage for bilayer with $–CH_2Ph–tpy–$

**Scheme 1** *Reagents and conditions*: i, $Br(CH_2)_3SiCl_3$, thf, ambient temp.; ii, 4′-tolyl-2,2′:6′,2″-terpyridine and LDA, thf, ambient temp.; iii, $OsCl_3·3H_2O$, EtOH–$H_2O$ (1:1), reflux 3 h; iv, $[Os(tpy)Cl_3]$, $NH_4PF_6$, EtOH–$H_2O$ (1:1), reflux for up to 3 d; v, $[Os(bpy)_2\{(PPh_2)_2C=C=C(PPh_2)_2\}][PF_6]_2$, thf, reflux 24 h

**Table 1** X-Ray photoelectron spectroscopic analysis of modified surfaces

| Surface-confined units[a] | Binding energy/eV | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | Si 2p | O 1s | C 1s | Br 3d | N 1s | Os 4f | Cl 2p | P 2p |
| –$Si(CH_2)_3$–Br **1** | 107.15 | 536.40 | 288.40 | 74.60 | | | | |
| –$Si(CH_2)_3$–ttp **2** | 106.20 | 535.80 | 287.85 | | 402.40 | | | |
| –$Si(CH_2)_3$–ttp–$OsCl_3$ **3** | 106.20 | 535.80 | 287.85 | | 402.40 | 53.85<br>56.45 | 200.00 | |
| –$Si(CH_2)_3$–ttp–Os–tpy **4** | 105.80 | 535.95 | 287.60 | | 402.75 | 53.80<br>56.40 | | |
| –$Si(CH_2)_3$–ttp–OsCl–$P_4C_3$–$Os(bpy)_2$ **5** | 106.00 | 535.50 | 287.85 | | 402.40 | 53.30<br>55.90 | —[b] | —[b] |

[a] $P_4C_3$ = $(PPh_2)_2C{=}C{=}C(PPh_2)_2$; ttp represents a –$CH_2$Ph–tpy unit. [b] Not observed; P peak position overlaps with Si.

$OsCl[(PPh_2)_2C{=}C{=}C(PPh_2)_2]Os(bpy)_2$ ($\varepsilon_{s,280}$ = $4.4 \times 10^7$ $cm^2$ $mol^{-1}$) units is $2.7 \times 10^{-11}$ mol $cm^{-2}$.

We have monitored each surface modification step by studying the modified surfaces by XPS (Fig. 1).[8] The elements involved in our modification procedures have their characteristic binding energies which can be clearly identified. Representative XPS data observed in each modification step are included in Table 1. Specifically, the successful modification of quartz surfaces by 3-bromopropyltrichlorosilane (step i) was verified by observation of Br 3d XPS (74.60 eV) in addition to Si 2p (107.15 eV), O 1s (536.40 eV) and C 1s (288.40 eV). Upon further reaction of terminal Br group with lithiated ttp ligand, step ii, N 1s (402.40 eV) is observed, while no significant Br 3d peak is found. After step iii or iv, XPS analysis gives Os 4f at 53.85 eV ($4f_{7/2}$) and 56.45 eV ($4f_{5/2}$) for sample **3** as well as 53.80 eV ($4f_{7/2}$) and 56.40 eV ($4f_{5/2}$) for sample **4**, all of which are characteristic of the Os 4f peaks.[9] Upon further addition of the $Os(bpy)_2[(PPh_2)_2C{=}C{=}C(PPh_2)_2]$ unit, the observed Os 4f peaks in sample **5** shifted to slightly lower energies, with 53.30 and 55.90 eV for $4f_{7/2}$ and $4f_{5/2}$, respectively. Since there are both $Os^{III}$ and $Os^{II}$ centers in **5** and the reported energies of 4f peaks of $Os^{II}$ are slightly lower than those of $Os^{III}$ {*i.e.*, with the same types of ligands, $4f_{7/2}$ is *ca.* 50.2–50.8 eV in $[Os^{II}Cl_2(PhPMe_2)_4]$ and *ca.* 51.4–52.0 eV in $[Os^{III}Cl_3(PhPMe_2)_3]$[9]}, the small shift of Os 4f peaks in **5** towards the lower energy region may be, partly, due to the overlapping Os 4f peaks of both $Os^{II}$ and $Os^{III}$ centers. No XPS peak corresponding to P can be unambiguously identified owing to the overlap of its peak with that of Si. Efforts have also been made to identify the peak corresponding to the inner Cl ligand on the $Os^{III}$ center in **5**, but no significant peak is observed.

A control experiment has been carried out in order to verify whether Os-based units could, instead of a covalent linkage, adsorb on quartz surfaces. After we refluxed $OsCl_3$ or $[Os(tpy)(ttp)(PF_6)_2]$ with clean quartz slides (no modification steps i–ii used) in EtOH–$H_2O$ for 3 d and followed the same cleaning procedures, no significant change was observed in either UV–VIS or XPS analysis of treated surfaces when compared with that of clean quartz surface. This indicates that without the modification steps i and ii, Os-based units cannot be attached to quartz surfaces.

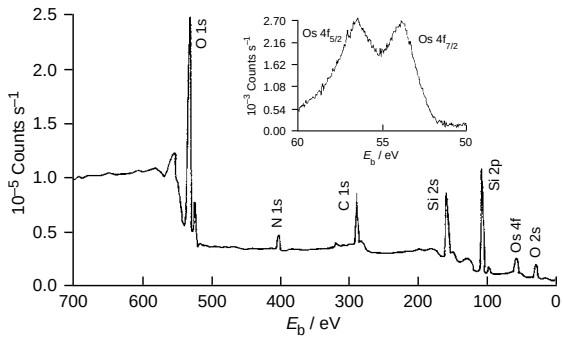


**Fig. 1** XPS spectra of modified surface with attached –$Si(CH_2)_4$Ph–tpy–Os–tpy after 3 d reaction (inset: high-resolution scan of the Os 4f region)

† Preparation of $Os(bpy)_2[(PPh_2)_2C{=}C{=}C(PPh_2)](PF_6)_2$. $(PPh)_2C{=}C{=}C(PPh_2)$[10] (296 mg, 0.38 mmol) in 15 ml thf was heated to reflux under $N_2$, and $[Os(bpy)_2Cl_2]\cdot 2H_2O$ (100 mg, 0.16 mmol) in ethylene glycol was added dropwise. The resulting solution was refluxed for 2 h, and excess $NH_4PF_6$ was added. The solution mixture was then refluxed for 60 h. Upon removal of thf, the solution was added dropwise to 100 ml of saturated aqueous $KPF_6$ solution. The precipitate thus formed was collected by vacuum filtration. Yield: 89%. $^{31}P\{^1H\}$ NMR ($CD_3CN$, 202 MHz, 22 °C): $\delta$ −30.49, −37.37. FABMS: *m/z* 1425 $(M - PF_6)^+$.

‡ *Preparation of* $[Os(tpy)(ttp)(PF_6)_2]$: $[Os(tpy)(H_2O)_3][PF_6]_3$ (50 mg, 0.09 mmol) and ttp (50 mg, 0.15 mmol) were heated at *ca.* 150 °C in ethylene glycol for 1 h. The resulting solution was added dropwise to 100 ml of saturated aqueous $KPF_6$ solution to induce precipitation. The brown product was collected *via* vacuum filtration and washed with distilled water (3 × 20 ml). FABMS: *m/z* 893 $(M - PF_6)^+$. $^1H$ NMR ($CD_3CN$): $\delta$ 2.56 (s, 3 H, $CH_3$), 7.06–9.01 (25 H, m, Ar-H).

§ For surface-confined Os(tpy)(ttp) units, $\varepsilon$ at 665 nm is only *ca.* 6–10% of the values at 275 or 315 nm. Hence, the expected absorbance would be a much lower value (*ca.* 0.0005–0.001) at 665 nm.

# Synthesis of a phthalocyanine derivative containing easily oxidised sterically-hindered phenolic substituents

**Guy J. Clarkson, Paul Humberstone and Neil B. McKeown***

*Department of Chemistry, University of Manchester, Manchester, UK M13 9PL*

**A novel phthalocyanine containing four redox-active 3,5-di-*tert*-butyl-4-hydroxyphenyl substituents is readily oxidised in aerated, basified solution to give a complex product mixture; the oxidation is apparently localised on the phenolic moieties without disturbing the structure of the phthalocyanine core.**

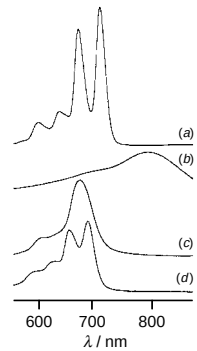
Phthalocyanines (Pcs) are of continuing interest as organic materials which possess interesting electronic and optical properties.[1] Recent synthetic work has sought to modify the electronic behaviour of the Pc macrocycle by the attachment of redox-active moieties based on ferrocene,[2] fullerene[3] and tetrathiafulvalene.[4] Sterically hindered phenols are readily oxidised to stable radical species (*e.g.* the galvinoxyl radical) and are used as radical scavengers for the stabilisation of monomers, polymers and solvents. They may also undergo further oxidation to form quinones. Previous studies concerning *meso*-tetrakis(3,5-di-*tert*-butyl-4-hydroxyphenyl)porphyrin **1** reveal that cooperative quinone formation occurs rapidly across the porphyrin ring system on addition of base to an aerated solution.[5] This process results in a dramatic distortion of the porphyrin ring system and loss of aromaticity.[6] It is of interest to establish whether similar cooperative processes may occur *via* the related Pc macrocycle. This communication describes the synthesis of a novel Pc derivative containing four 3,5-di-*tert*-butyl-4-hydroxyphenyl (DTBHP) substituents and the results of a preliminary examination of its behaviour under oxidative conditions.

**1**

Aromatic nucleophilic substitution of the nitro group of commercially available 4-nitrophthalonitrile **2**, using oxygen, nitrogen or sulfur nucleophiles, is a well established method of preparing phthalonitrile precursors to tetra-substituted Pc derivatives with enhanced solubility.[7] This is exemplified by the reaction between **2** and the anion of 3,5 di-*tert*-butylphenol **3** in DMF which gives 4-(3,5-di-*tert*-butylphenoxy)phthalonitrile **5** in 70–80% yield (Scheme 1). Several previous studies have illustrated the ability of the anion of 2,6-di-*tert*-butylphenol **4** to behave as a carbon nucleophile in the preparation of biphenyl derivatives *via* aromatic nucleophilic substitution.[8] Encouragingly, we found that the anion of **4** reacts with **2** as a carbon nucleophile efficiently displacing the nitro group to give the novel 4-(3,5-di-*tert*-butyl-4-hydroxyphenyl)phthalonitrile **6** in 75–85% yield. The structure of **6** was assigned using $^1$H NMR and IR spectroscopy and by a strong bathochromic shift from 345 to 505 nm in the $\lambda_{max}$ of its UV–VIS absorption spectrum on addition of base, which is characteristic of the formation of a conjugated phenolic anion.† In addition, its biphenyl structure was confirmed by a single crystal X-ray diffraction study. Cyclotetramerisation of phthalonitriles **5** or **6** is catalysed by lithium pentanolate in refluxing pentanol to give Pcs **7** and **8**, respectively, in 10–30% yield. These two isomeric Pcs are each composed of four inseparable regioisomers and give $^1$H NMR, UV–VIS absorption, IR, fast atom bombardment (FAB) mass spectra and elemental analyses which are consistent with their proposed structures.†

The cyclic voltammetry (CV) of deaerated solutions of Pcs **7** and **8** in $CH_2Cl_2$ give very similar results consistent with previous CV studies of soluble metal-free Pcs.[9] However, on the addition of excess tetrabutylammonium hydroxide (TBAH), Pc **8** exhibits a strong reversible redox transition ($E_{1/2}$ = 50 mV *vs.* $Ag^+/Ag$) of an intensity consistent with a four-electron oxidative process to give the tetra-phenolic radical species.

The UV–VIS absorption spectra of $CH_2Cl_2$ solutions of Pc **7** ($\lambda$ = 701 and 667 nm) and **8** ($\lambda$ = 715 and 683 nm) both exhibit the characteristic split Q-band of metal-free Pc [Fig. 1(*a*)]. On the addition of an excess of TBAH the Q-band of Pc **7** changes appearance to give a single sharp band at 690 nm [similar to Fig. 1(*c*)] consistent with the formation of a $Pc^{2-}$ anion due to the loss of the two protons from the central cavity. No change in this spectrum is seen over an extended period of time. However, the Q-band of Pc **8** exhibits an initial strong bathochromic shift to 796 nm on addition of the base [Fig. 1(*b*)]. This dramatic shift demonstrates that the deprotonated DBTHP substituents interacts strongly with the Pc macrocycle resulting in a Q-band position which is similar to that shown by naphthalocyanines, of interest as IR-absorbing dyes. If left to stand in aerated conditions the bathochromic shift gradually reduces until, after



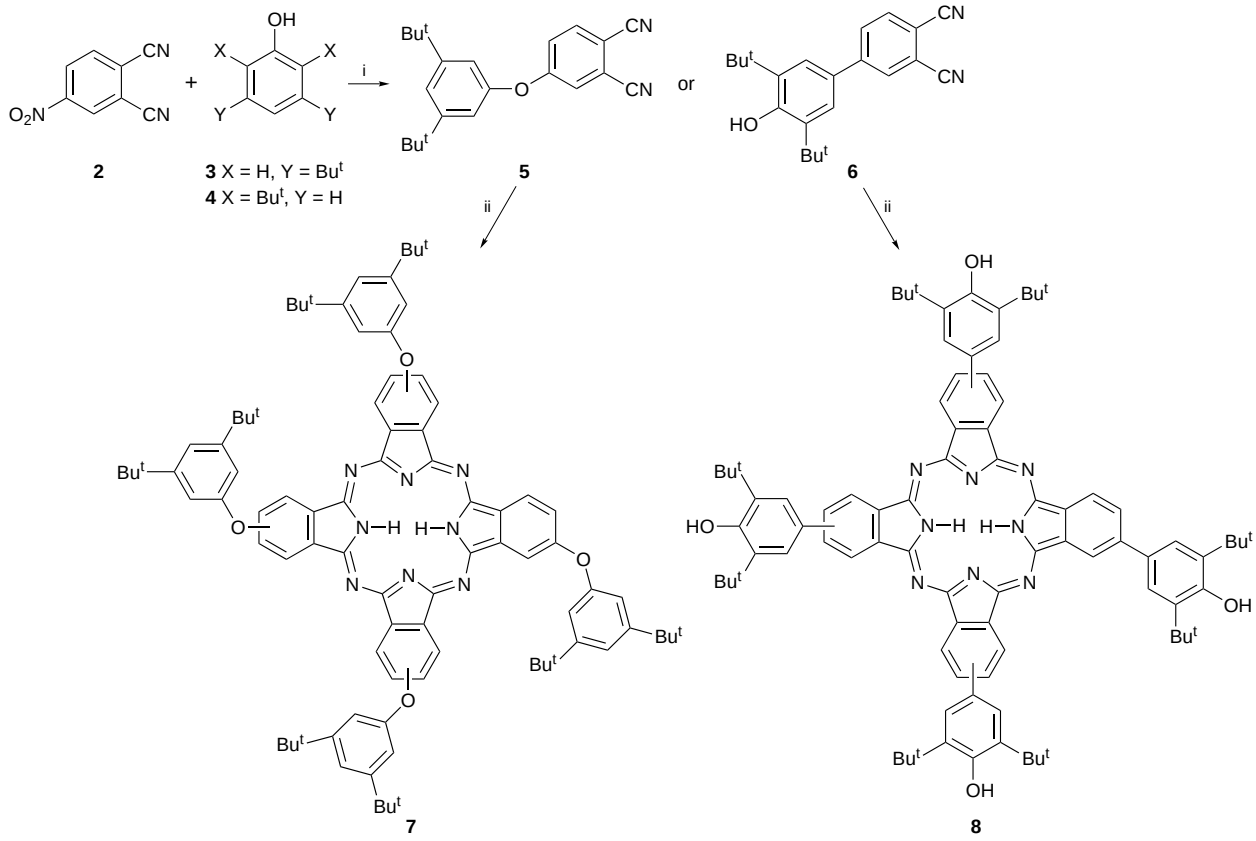


**Fig. 1** UV–VIS absorption spectra of Pc **8** in aerated $CH_2Cl_2$ (*a*) under neutral conditions; (*b*) immediately after the addition of excess TBAH; (*c*) after leaving the solution for 72 h; (*d*) upon addition of excess acetic acid

**Scheme 1** *Reagents and conditions*: i, anhydrous $K_2CO_3$, DMF, 40 °C; ii, $C_5H_{11}OLi$, $C_5H_{11}OH$, 135 °C

a period of 2–3 days, a characteristic $Pc^{2-}$ visible absorption spectrum [Fig. 1(*c*)] is obtained ($\lambda$ = 680 nm) similar to that observed for the $Pc^{2-}$ anion of **7**. On neutralisation with acetic acid, the familiar split Q-band of a metal-free Pc is regained [Fig. 1(*d*)], although slightly blue-shifted ($\lambda$ = 700 and 665 nm) relative to the original Q-band position of **8**. We conclude from these observations that, in contrast to the simple, rapid and cooperative oxidative process observed for porphyrin **1**, the structural integrity of the planar Pc macrocycle is retained and that oxidation is localised on the DTBHP subunits.

TLC and $^1$H NMR analysis of Pc **8** subsequent to the oxidation process suggests the formation of a highly complex product mixture from which no discrete compounds could be isolated by chromatography. FAB MS analysis of the product mixture was unhelpful due to the lack of ions with mass greater than 500 Da. However, the IR analysis (KBr disc) of the oxidised material indicates the presence of quinone type functionality ($\nu$ = 1640 and 1670 cm$^{-1}$). Elemental analyses, although irreproducible between different batches of oxidised **8**, indicate the presence of additional oxygen. It is highly likely that the DTBHP substituents undergo the various complex, but well understood, transformations of 4-aryl-2,6-di-*tert*-butylphenols in aerated basic solution.[10] These include the formation of 4-aryl-2,6-di-*tert*-butyl-4,5-epoxy-6-hydroxycyclohex-2-enones, 4-aryl-2,6-di-*tert*-butyl-5,6-epoxy-4-hydroxycyclohex-2-enones and 3-aryl-2,5-di-*tert*-butylcyclopenta-2,4-dienones *via* subsequent decomposition of the initially formed 2- and 4-hydroperoxycyclohexadienone anions. Each resulting Pc molecule would possess a combination of oxidised DTBHP fragments, hence the complex nature of the product mixture.

It is clear from this initial study that the synthesis of novel phthalonitrile precursor **6** allows the preparation of DTBHP containing metal-free or metal ion containing Pc derivatives, with symmetrical or unsymmetrical substitution.[11] Studies of the synthesis and redox properties of these Pcs under deaerated conditions are in progress.

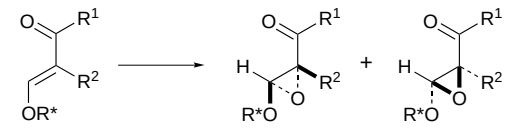
# Stereoselective epoxidations of vinylogous esters/carbonates directed by the 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl auxiliary: a route to near stereopure tertiary alcohols bearing functional arms

**Gurpreet S. Bhatia, Richard F. Lowe, Robin G. Pritchard and Richard J. Stoodley***

*Department of Chemistry, UMIST, PO Box 88, Manchester, UK M60 1QD*

**The 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl auxiliary is effective in directing the epoxidation of vinylogous esters/carbonates with dimethyldioxirane; the derived epoxides are convertible into a versatile class of 1,2,3-trifunctional chirons.**

As part of a programme to develop the 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl unit as an auxiliary in asymmetric synthesis, we have embarked on a study of vinylogous esters/carbonates of type **1**.[1,2] To date, we have established that such systems undergo stereoselective catalytic hydrogenations (to give mainly dihydro derivatives of type **2**) and regio- and stereoselective bromoalkoxylations (to furnish bromoalkoxy adducts of type **3** preferentially). Whilst the diastereomeric ratios were not high (generally, around 85 : 15), it was possible to isolate many of the major adducts in stereopure states and in acceptable yields simply by fractional crystallisation. Moreover, in selected cases, it was possible to remove the auxiliary under mildly acidic conditions to give chirons featuring tertiary stereogenic centres, *e.g.* **4** and **5**. Recognising the potential synthetic versatility of epoxides of type **6**, we have sought to prepare such compounds and to study their reactivity. Our findings are the subject of this communication.



After screening a variety of epoxidising agents, dimethyldioxirane (DMDO)[3,4] was found to be extremely effective in promoting the oxidation of vinylogous esters/carbonates† of type **1**. Table 1 summarises the outcome of the reactions. From the results, it is clear that better stereoselectivities are observed with the reactants **1a**,[1,5] **1b**,[2,6] **1c**,[1] **1e**[1] and **1f**[1] (*i.e.* $R^2$ = alkyl group) than with the reactants **1d**[7] and **1g**‡§ (*i.e.* $R^2$ = H). Moreover, in the former examples, the major epoxides **6a**§ {mp 126–127 °C, $[\alpha]_D$ −8.3 (*c* 0.5, $CH_2Cl_2$)}, **6b**§¶ (mp 106–107 °C), **6c**§ {mp 93–94 °C, $[\alpha]_D$ −40 (*c* 0.3, $CH_2Cl_2$)}, **6e**§ {mp 108 °C, $[\alpha]_D$ −33 (*c* 0.5, $CH_2Cl_2$)} and **6f**§ {mp 171–172 °C, $[\alpha]_D$ −46 (*c* 0.7, $CH_2Cl_2$)} could be isolated‖ in stereopure states and in reasonable yields simply by fractional crystallisation.

That the major epoxide arising from the reaction of the vinylogous ester **1a** with DMDO possessed the stereostructure **6a** was established by X-ray crystallography** (Fig. 1).

Seeking to detach the auxiliary and generate the dithiolane **8**, the epoxide **6a** was treated with ethane-1,2-dithiol under a range of acidic conditions. The best yield of the desired product (56% after chromatography) was achieved by heating the epoxide **6a** with the dithiol (120 mol%) and toluene-*p*-sulfonic acid monohydrate (*p*-TsOH·$H_2O$) (100 mol%) in toluene (*ca.* 72 °C, 3 h); however, the dithiolane **8**,§ $[\alpha]_D$ +35 (*c* 0.6, MeOH), was found to possess an ee of only 66% by HPLC analysis.†† Under similar conditions (1.5 h), the epoxide **6a** reacted with propane-1,3-dithiol to give the dithiane **9**§¶ (54% yield after chromatography), mp 80 °C, with an ee of 82%.†† Clearly, the dithioacetalisation reactions were accompanied by partial racemisation.

When subjected to methanolysis conditions [MeOH–$CH_2Cl_2$ (4 : 1), *p*-TsOH·$H_2O$ (cat.), 19 h], the epoxide **6a** was converted essentially quantitatively into a 90 : 10 mixture of the alcohols **12** and **14** (tentative stereostructures); crystallisation of the mixture provided the major diastereomer **12**,§ mp 112 °C, $[\alpha]_D$ −46 (*c* 0.3, $CH_2Cl_2$), in 58% yield. The mixture of the alcohols **12** and **14** reacted with propane-1,3-dithiol [$CHCl_3$, *p*-TsOH·$H_2O$ (100 mol%), $CF_3SO_3H$ (cat.), 21 h] to give the dithiane **9**¶ (55% yield based on **6a**), mp 102–103 °C, with an ee of 98%. Under the acidic conditions mentioned earlier

**Table 1** Epoxidation of vinylogous esters/carbonates of type **1** with DMDO[a]

| Reactant **1** | $R^1$ | $R^2$ | Products | Ratio[b] | Yield (%)[c] |
|---|---|---|---|---|---|
| **a** | Me | Me | **6a**,**7a** | 90 : 10 | 73 |
| **b** | Et | Me | **6b**,**7b** | 90 : 10 | 52 |
| **c** | $-CH_2CH_2CH_2-$ | | **6c**,**7b** | 91 : 9 | 64 |
| **d** | Me | H | **6d**,**7d** | 69 : 31 | — |
| **e** | OEt | Me | **6e**,**7e** | 91 : 9 | 74 |
| **f** | $-OCH_2CH_2-$ | | **6f**,**7f** | 86 : 14 | 70 |
| **g** | OEt | H | **6g**,**7g** | 67 : 33 | — |

[a] The oxidations were carried out using a distilled solution of DMDO in acetone (*ca.* 0.08 mol $dm^{-3}$). [b] The product ratio was determined by NMR spectroscopic and/or HPLC analysis. [c] The yield refers to the major epoxide isolated in a stereopure state after crystallisation.

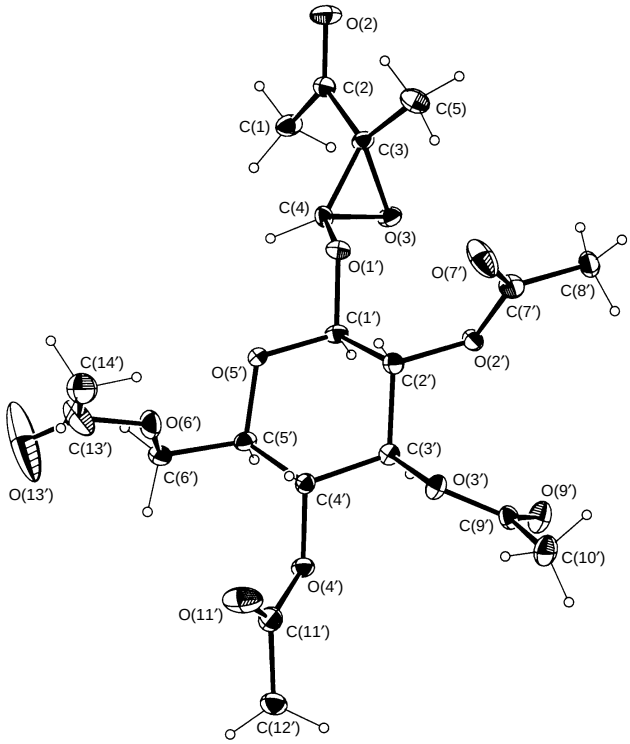


**Fig. 1** Molecular structure of compound **6a**

[PhMe, *p*-TsOH·$H_2O$ (100 mol%), *ca.* 72 °C, 4 h], the dithiane **9** underwent significant racemisation (98% → 29% ee). Presumably, the partial racemisations noted in the **6a** → **8** and **6a** → **9** transformations were the results of acid-induced α-ketol rearrangements[8] of the products **8** and **9**.

Conversion of the epoxide **6b**, by way of a 89 : 11 mixture of the alcohols **13** and **15**, into the dithiane **10**§ (48% yield), $[\alpha]_D$ +2.2 (*c* 0.5, MeOH), with an ee of 93%,†† was similarly effected.

Under the conditions used to effect the direct **6a** → **9** transformation, the epoxide **6e** was converted into the dithiane **11**§¶ (83% yield), mp 61–62 °C, with an ee of 98%.†† The lack of any significant racemisation in this process supports the notion that α-ketol rearrangements are implicated in the partial racemisation of compounds **8** and **9**.

The afore-cited findings are of note in several respects. They extend further the role of the 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl unit as an auxiliary in asymmetric synthesis. They reveal that the model used to explain the diastereofacial reactivity of vinylogous esters/carbonates of type **1** in catalytic hydrogenations[1] and bromoalkoxylations[2] is also applicable to epoxidation reactions. They illuminate a reactivity feature of vinylogous esters/carbonates that hitherto has not been exploited. Finally, compounds **6a**–**c**, **6e**–**f**, **8**–**11** and **12** are representatives of new classes of trifunctional chirons with notable synthetic potential.

We thank the EPSRC for a research grant (GR/J/65464), the Isle of Man Government for a research studentship (to R. F. L.), Dr C. M. Raynor for performing the HPLC analyses and Dr J. A. Whatley (Roche Products Ltd.) for help in devising the conditions used for the HPLC analyses.

† There appear to be relatively few studies of epoxidations of vinylogous esters/carbonates using DMDO (see ref. 9).

‡ The vinylogous carbonate **1g**, mp 116–118 °C, $[\alpha]_D$ −13 (*c* 1.1, $CHCl_3$), was prepared (53% yield after crystallisation) by the Wittig condensation of ethoxycarbonylmethylenetriphenylphosphorane with 1-*O*-formyl-2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose (see ref. 6).

§ This compound displayed analytical and spectral properties that supported its assigned structure.

¶ This compound possessed no significant optical rotation in a range of solvents.

‖ The thermal stability of epoxides of type **6** is striking. In general, epoxides derived from vinylogous esters/carbonates tend to decompose at ambient temperature (see ref. 9).

** *Crystal data* for **6a**: $C_{19}H_{26}O_{12}$, $M$ = 446.4, monoclinic, space group $P2_1$ (no. 4), $a$ = 11.621(3), $b$ = 7.500(2), $c$ = 12.855(3) Å, $\beta$ = 98.53(2)°, $Z$ = 2, $D_c$ = 1.338 g cm$^{-3}$, $F$(000) = 472, $\mu$(Mo-Kα) = 1.05 cm$^{-1}$, crystal size 0.40 × 0.25 × 0.25 mm. A total of 2022 reflections were measured, 1893 unique ($R_{int}$ = 0.0336), on a Siemens R3m/V diffractometer using the $\omega/2\theta$ scan method ($\lambda$ = 0.71069 Å) at 23 °C. The structure was solved by direct methods and refined by full-matrix least-squares based on $F^2$, with all non-hydrogen atoms anisotropic and hydrogen atoms constrained in calculated positions. The final cycle converged to $R$ = 0.053 and $wR^2$ = 0.115. CCDC 182/589.

†† The enantiomers were separated on a Chiralpak AD column, using hexanes–propan-2-ol (9 : 1) as eluent (flow rate: 1 cm$^3$ min$^{-1}$) in the cases of **8**/*ent*-**8** and **9**/*ent*-**9** and hexanes–ethanol (9 : 1) as eluent (flow rate: 1 cm$^3$ min$^{-1}$) in the case of **10**/*ent*-**10**.

# Ruthenium-catalysed conversion of triynes to benzene derivatives—a novel metathesis cascade

**Jens-Uwe Peters and Siegfried Blechert***

*Institut für Organische Chemie der Technischen Universität, Strasse des 17. Juni 135, D-10623 Berlin, Germany*

**In a novel application of [$PhCH_2$=$Ru(PCy_3)_2Cl_2$] 1, triynes are isomerised to benzene derivatives; a cascade of four metathesis reactions is proposed as a mechanistic explanation.**

Cyclotrimerisation of acetylenes is catalysed by a variety of transition metal catalysts[1] and provides easy access to highly substituted benzene derivatives.[2] Cobalt[3] and rhodium[4] catalysts have been used to make this reaction the key step in a number of elegant natural product syntheses. Metallacyclooligoolefins are believed to be pivotal intermediates in the acetylene trimerisation catalytic cycle.[5] An exception is the palladium-catalysed reaction *via* vinylpalladium intermediates.[6]

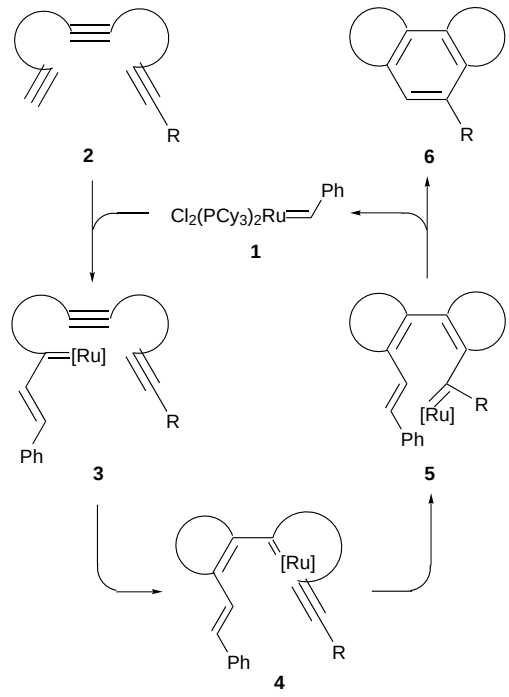
Another approach to transform acetylenes into benzene derivatives is the metathesis of mono-[7] or bis-acetylenic[8] compounds with stoichiometric amounts of transition metal carbonyl carbene complexes with subsequent CO insertion. These methodologies have also found ample application in efficient constructions of structurally complex synthetic targets.[9]

Mechanistically interesting is the conversion of an alkylidyne complex to a benzylidene complex with 3 equiv. of an acetylene by a metathesis cascade.[10]

However, a catalytic metathesis process for the isomerisation of triynes to benzene derivatives has not yet been described.

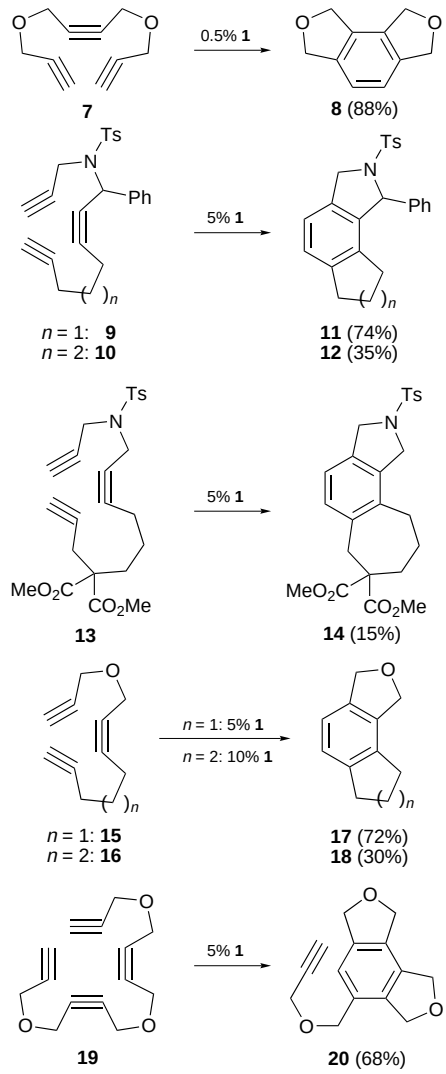
In several instances, it has been shown that ruthenium carbene complexes derived from Grubbs' metathesis catalyst **1**[11] insert intramolecular C≡C triple bonds regioselectively, with metallacyclobutenes as likely intermediates.[12] Recent work shows that intermolecular additions of such carbene complexes to C≡C triple bonds also proceed regioselectively.[13]

Ring-closing olefin metathesis employing **1** is a well established reaction.[14] In general, ruthenium-catalysed ring-closing olefin metatheses are initiated by the *in situ* transformation of the stable benzylidene complex **1** into a reactive methylidene complex as the active catalytic species.[15] However, far less reactive[15] ruthenium benzylidene complexes similar to **1** were also involved as catalytic species in ring-closing olefin metatheses.[16]



Metathesis catalytic cycles usually commence with a regioselective addition of the catalytic species to the substrate's least hindered site as is suggested by the outcome of conversions of substrates with differently substituted C≡C and C=C bonds.[17]

Based on these findings, we projected a metathesis cascade process for the isomerisation of acyclic triynes to benzene derivatives by **1** (Scheme 1).



In an initial intermolecular reaction, ruthenium benzylidene complex **1** adds to the least hindered triple bond of triyne **2**. The resulting vinyl carbene complex **3** undergoes an intramolecular metathesis reaction *via* **4** to produce a conjugated carbene complex **5**, with two of the newly formed double bonds embedded in ring structures and thus forced to be *Z*. This is a prerequisite for the final ring-closing olefin metathesis step which releases benzylidene complex **1**, thus making the entire process catalytic. The formation of an aromatic system **6** should provide a strong driving force for the overall reaction cascade.

To test our concept, we treated the easily accessible triyne **7**[18] as a 2 M solution in $CH_2Cl_2$ with 5 mol% of **1** (Scheme 2). The desired tetrasubstituted benzene derivative **8** was obtained in excellent yield after only seconds of vigorous reaction. Optimisation revealed that as little as 0.5 mol% of **1** is sufficient to convert all starting material of **7** as a 1 M solution in $CH_2Cl_2$ in an exothermic reaction within 2 h.† The small amount of catalyst necessary for this supposedly four-fold metathesis cascade is remarkable since most applications of catalyst **1** require several mol%;[14] *e.g.* 20 mol% of **1** has been used in macrocycle syntheses.[19]

To explore the scope of this novel acetylene oligomerisation to see which ring sizes might be accessible, acyclic triynes **9**, **10** and **13** were treated with **1** (Scheme 2). Compared to the formation of **8** from **7**, larger amounts of **1** and longer reaction times were required in all cases for complete conversion. Whereas indane derivative **11** was obtained in good yield from its acyclic precursor **9** after 12 h, the structurally similar **10** gave an only moderate yield of the tetralin **12**. Compound **13** was isomerised in poor yield to benzene derivative **14** with an annulated seven-membered ring. In the latter cases, the desired conversions proceeded slowly (2 d) and the competing formation of obviously polymeric byproducts explains the diminished yields. A similar trend was observed in the formation of indane derivative **17** and tetralin derivative **18** from their respective precursors **15** and **16**. Again, the indane

**Scheme 1** Cy = cyclohexyl

**Scheme 2** Ts = *p*-$MeC_6H_4SO_2$

derivative was obtained in good yield after 12 h, whereas the tetralin derivative was formed in a moderate yield along with polymeric byproducts in a sluggish reaction (2 d). We assume that benzene derivatives with two annulated five-membered rings are generally formed in good yields from acetylenic precursors by reaction with **1**. This was confirmed by further investigations with triynes similar to **7** (yields of 67% or higher).

The tetraacetylenic **19** could potentially be converted to either a cyclooctatetraene or a pentasubstituted benzene **20**. However, when **19** was treated with **1**, **20** was found to be the exclusive product. The long reaction time of 2 d for this conversion can be rationalised by the known susceptibility of the reactivity of ruthenium carbene complexes to steric hindrance;[15] in contrast to all other examples shown in Scheme 2, the final ring-closing olefin metathesis step of the catalytic cycle (Scheme 1) starts from a disubstituted carbene complex **5** (R ≠ H). Only a few examples of ring-closing olefin metatheses involving such ruthenium intermediates are known.[17] A sterically demanding and thus less reactive carbene complex **5** should make this final step slow and rate determining. Despite the slow reaction, **20** was isolated in good yield.

In conclusion, this novel application of **1** expands the scope of the versatile synthetic tool of acetylene cyclooligomerisation by employment of a catalyst which is commercially available and tolerates a wide range of functionalities.

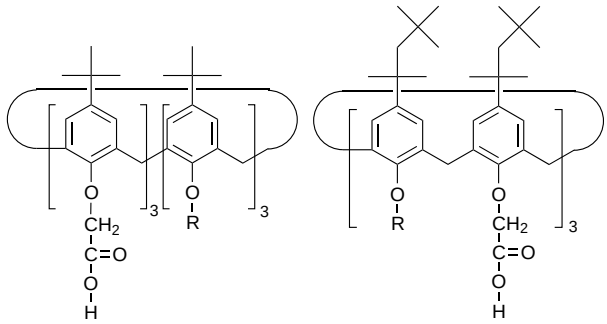
# A calixarene-based extractant with selectivity for $Am^{III}$ over $Ln^{III}$



**Rainer Ludwig,*[a] Kenji Kunogi,[a]† Nguyen Dung[a]‡ and Shoichi Tachimori[b]**

[a] *Institute for Inorganic and Analytical Chemistry, Radiochemical Division, Freie Universität Berlin, Fabeckstr. 34-36, 14195 Berlin, Germany*

[b] *Department of Chemistry and Fuel Research, Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki 319-11, Japan*

**Calix[6]arene-based extractant 4 shows high selectivity and extractability for $Am^{III}$ from weakly acidic solutions due to the cooperativity of different ligating groups.**

Among the [1$_n$]metacyclophane-based ligands[1,2] tested as extractants for metal ions, calix[4]arenes and, to a smaller extent, calix[6]arenes are two of the most popular to date.[3] While calix[4]arenes with ester, amide, carboxylic acid or other monodentate groups can extract alkaline, alkaline earth, several transition and noble metal ions selectively, the larger calix[6]-arenes often display a lower selectivity. We previously observed in the case of noble metal extraction that the selectivity can be greatly influenced by the presence of different donor groups, such as $CO_2H$ and amide in a calix[4]arene.[4] Although the mutual separation of lanthanides by calix[4]arenes bearing $CO_2H$ groups is improved by co-extracted sodium ions,[5,6] those ligands have a lower overall extractability towards lanthanides[4] and actinides, such as $Am^{III}$,[7] compared with calix[6]arenes. On the other hand, calix[6]arenes such as ligand **1a**, which serves as a reference compound in the communication, perform as good extractants for $Ln^{III}$ and $Am^{III}$, but with poor group and mutual separation factors. Conventional extractants such as liquid anion exchangers utilize the concurrent complexation by anions for achieving Ln/Am separation. We now report on the progress in achieving selectivity in the cation exchange-based extraction due to the introduction of mixed monodentate functional groups into calix[6]arenes. The emphasis will be on the relationship between ligand structure and complex formation–extraction.

**4** R = $CH_2C(O)NEt_2$

The distribution ratios $D$ ($D = c_{metal,\,org.}/c_{metal,\,aq.}$) of six selected lanthanide ions $Ln^{3+}$ (Nd, Eu, Tb, Dy, Er, Yb) in the competitive extraction from aqueous into $CHCl_3$ solutions containing ligand **1a** are shown in Fig. 1 on a logarithmic scale as a function of the equilibrium pH. The distribution ratio of $Am^{3+}$ (single element, trace amounts) with ligand **1a** is plotted in the same figure. There is no significant difference in the extractability between $Ln^{III}$ and $Am^{III}$ in these reference systems.

As a first step on the way to improve extractability as well as solubility, we changed *tert*-butyl to *tert*-octyl in the calix[6]arenes.[8] These highly branched ligands are very soluble in low polar organic solvents even without a modifier. The distribution ratios of $Am^{III}$ increase slightly with **1b**, compared with **1a** (Fig. 1). The slope of the plot log $D$ *vs*. pH is 3.0 in accordance to the metal ion charge.

Next, three carboxylic acid groups were introduced alternating with methoxy groups and the extraction into $CHCl_3$ by ligand **2** at 3 mM concentration was studied.§ The extractability decreased significantly [$pH_{0.5}$(Am) = 3.3, $pH_{0.5}$(Ln) > 4.5] due to the smaller number of carbonyl oxygen donor atoms and a less shielded ionophoric cavity, while the selectivity of $Am^{III}$ over $Ln^{III}$ improved, compared with **1b**. The calculated distribution ratios follow the order Am ⩾ Eu, Nd > Tb > Dy > Yb > Er. The slopes of the plots log $D$ *vs*. pH are lower than 3.0 which may be caused by the co-extraction of an anion in the metal ion coordination sphere.

At this point, we tested the influence of ligand geometry on the selectivity and extractability under the same conditions by using ligand **3**.¶ The extractability was low, with $pH_{0.5}$ being 3.5 for Am, Eu and Nd. The selectivity of Am over Ln at pH ⩾ 3, where more than 10% of Am is extracted, was low due to different slopes of the plots log $D$ *vs*. pH. It thus became clear that the geometrical arrangement of functional groups on the calixarene backbone is a key factor for the separation in the present system.

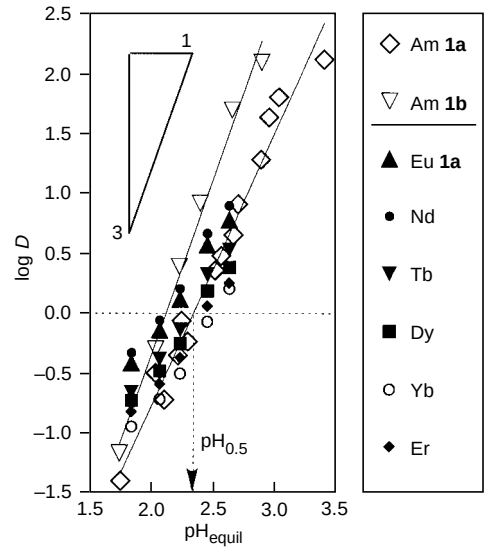

**Fig. 1** Distribution coefficients $D$ of trivalent Am and Ln in the extraction from aqueous to $CHCl_3$ solutions at 298 K by ligands **1a** and **1b**. Aq. phase (Am series): $^{241}Am^{III}$ activity 1 kBq ml$^{-1}$ ($3.3 \times 10^{-8}$ M), $HNO_3$ (various conc.); organic phase (Am series): 5 mM (◇, ▽) ligand, series (◇) contains 2% octan-1-ol as modifier, analysis by liquid scintillation counting of the aq. phase after extraction; aq. phase (Ln series): 0.6 mM $Ln(ClO_4)_3$ (Ln = Nd + Eu + Tb + Dy + Yb + Er, 0.1 mM each), $HClO_4$ (various conc.); organic Phase (Ln series): 3 mM ligand **1a**, 4% octan-1-ol, analysis by ICP-AES of aq. and back-extracted phase (stripping by titriplexIII, mass balance >99%).

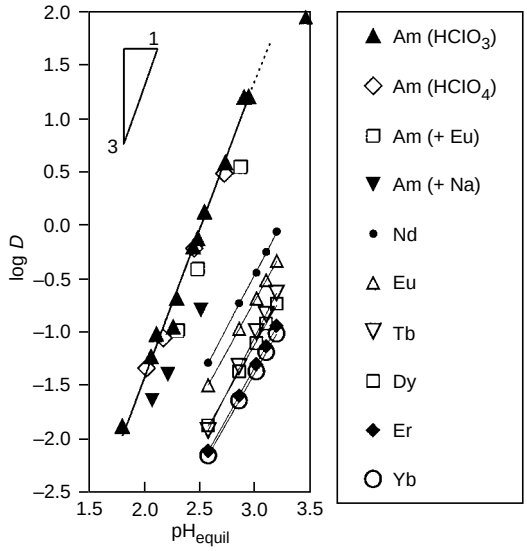

**Fig. 2** Distribution coefficients of trivalent Am and Ln for ligand **3**. Aq. phase (Am series): $^{241}Am^{III}$ (1 kBq ml$^{-1}$), $HNO_3$ (▲, ▼) or $HClO_4$ (◇, □), additional 0.3 mM $Eu(ClO_4)_3$ or 0.01 M $NaNO_3$ as indicated; aq. phase (Ln series) see Fig. 1; organic phase: $CHCl_3$ containing 3 mM ligand **4**.

In order to improve the extractability (expressed as log *D*), while keeping a good group separation, three amide groups were introduced alternating with three carboxylic acid groups and ligand **4** was obtained, thus avoiding an undesirable excess of ionizable groups over the metal ion charge, but having a sufficient number of carbonyl oxygen donor atoms.‖ The results are shown in Fig. 2. The extractability of $Am^{III}$ was high, thereby achieving high selectivity over $Ln^{III}$. A similar improvement in extraction was previously observed for $Pd^{II}$ and $Au^{III}$ upon substituting excessive $CO_2H$ groups by amide groups.[4] The proposed stoichiometry of the extracted complex is 1 : 1 (Am : **4**). The extractability of $Am^{III}$ is still high, when $Eu^{III}$ at a $10^4$ times higher or $Na^+$ at a $3 \times 10^5$ times higher concentration is present in the aqueous phase.

In conclusion, ligand **4** has an only slightly higher $pH_{0.5}$ value of 2.5 compared with reference ligand **1a** (2.35), but a much higher selectivity over trivalent lanthanides. The separation factors at pH = 3.0 are 66 (Am/Nd) and 118 (Am/Eu). Further studies will deal with competitive extraction of actinides at higher concentrations.

The authors appreciate the suggestions of Professor Y. Hasegawa (Science University of Tokyo). Financial support by Deutsche Forschungsgemeinschaft is gratefully acknowledged.

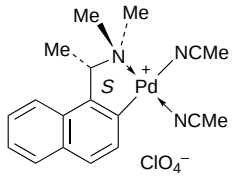
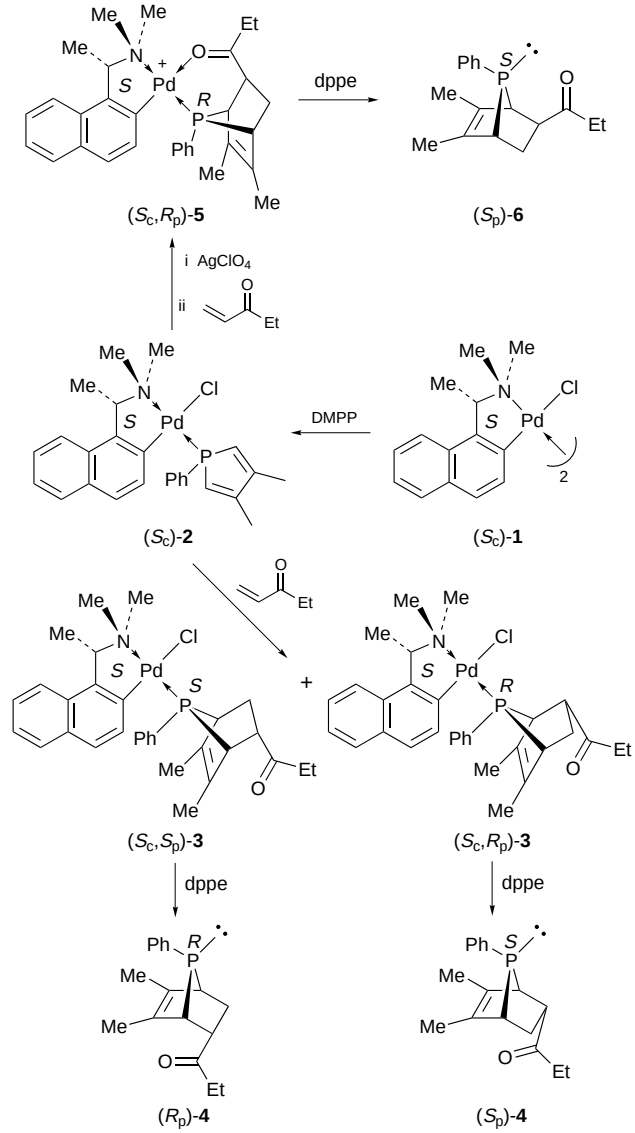
# Asymmetric synthesis of keto-substituted *P*-chiral phosphines by means of an unusual *exo*/*endo*-stereochemically controlled Diels–Alder reaction



**Pak-Hing Leung,*[a]† Soh-Kheang Loh,[a] Jagadese J. Vittal,[a] Andrew J. P. White[b] and David J. Williams[b]**

[a] *Department of Chemistry, National University of Singapore, Kent Ridge 119260, Singapore*
[b] *Department of Chemistry, Imperial College, London, UK SW7 2AY*

**An asymmetric Diels–Alder reaction between 1-phenyl-3,4-dimethylphosphole and ethyl vinyl ketone promoted by a chiral organopalladium complex gives the corresponding keto-substituted phosphine ligands in which the keto group can be stereospecifically located in the *endo*- or *exo*-positions of the phosphanorbornene skeleton.**



Asymmetric Diels–Alder reactions undoubtedly provide one of the most efficient and elegant methods for the synthesis of chiral 6-membered rings.[1] Since its discovery in 1928, this methodology has been used frequently in the synthesis of important chiral natural products such as antibiotics and prostaglandins. Using this method for carbon–carbon bond formation, we herein report the first asymmetric synthesis of keto-substituted *P*-chiral phosphines. Although ketophosphines are relatively common and their distinct chemistry as well as their synthetic applications are well established,[2] the number of such optically active P–O ligands is surprisingly low.[3] Certainly, no enantiomerically pure ketophosphines containing resolved tertiary phosphorus stereocentres have been reported hitherto.

Uncoordinated 1-phenyl-3,4-dimethylphosphole (DMPP) shows no reaction with ethyl vinyl ketone. The coordination of

($S_c$)-**7**

the phosphine ligand to the chiral reaction template ($S_c$)-**1**,[4] however, activates the cyclic diene towards [4 + 2] cycloaddition reactions (Scheme 1). Hence, treatment of the neutral complex ($S_c$)-**2** with ethyl vinyl ketone in $CH_2Cl_2$ at room temperature for 6 d gave a 1 : 2.5 diastereomeric mixture of the two *endo*-cycloaddition products, ($S_c$,$R_p$)-**3** and ($S_c$,$S_p$)-**3**, in quantitative yield. Prior to crystallization, the 202 MHz $^{31}$P NMR spectrum of the crude product in $CDCl_3$ exhibited two sharp singlets at $\delta_P$ 125.5 (major) and 126.6 (minor). The major isomer was subsequently crystallized from $CH_2Cl_2$–$Et_2O$ as pale yellow needles (70%), mp 135–136 °C, $[\alpha]_D$ +31.8 (*c* 1, $CH_2Cl_2$). An X-ray structural analysis revealed that this major isomer is ($S_c$,$S_p$)-**3** and the absolute configurations of the four new chiral centres at P, C(22), C(25) and C(27) are *S*, *R*, *S* and *R*, respectively (Fig. 1).‡ Treatment of ($S_c$,$S_p$)-**3** with 1,2-bis(diphenylphosphino)ethane (dppe) in $CH_2Cl_2$ liberated the optically pure ketophosphine, ($R_p$)-**4**, from the chiral metal template as an air-sensitive colourless oil in 85% yield, $[\alpha]_D$ −30.0 (*c* 1, $CHCl_3$), $\delta_P$ 109.0 (s). Stereospecific displacement of the ketophosphine was confirmed by the quantitative re-preparation of ($S_c$,$S_p$)-**3** from liberated ($R_p$)-**4** and ($S_c$)-**1**: the 202 MHz $^{31}$P NMR spectrum of the crude product indicated the diastereomer ($S_cS_p$)-**3** only. In a further test of optical purity, the diastereomer ($R_c$,$S_p$)-**3** was prepared from ($R_p$)-**4** and the equally accessible ($R_c$)-**1**: only one sharp singlet was observed at $\delta_P$ 126.6. Partially resolved ($S_p$)-**4** was liberated similarly from ($S_c$,$R_p$)-**3** by treatment with dppe. The free ligand was purified by re-coordination to ($R_c$)-**1** forming the highly crystalline complex ($R_c$,$R_p$)-**3** from which pure ($S_p$)-**4** was liberated. It is noteworthy that the intermolecular cycloaddition process could be completed in 16 h by heating the reaction mixture at 70 °C in 1,2-dichloroethane. Under these more vigorous reaction conditions, however, the product formation became non-selective and a 1 : 1 mixture of the two diastereomeric complexes was obtained.

**Scheme 1**

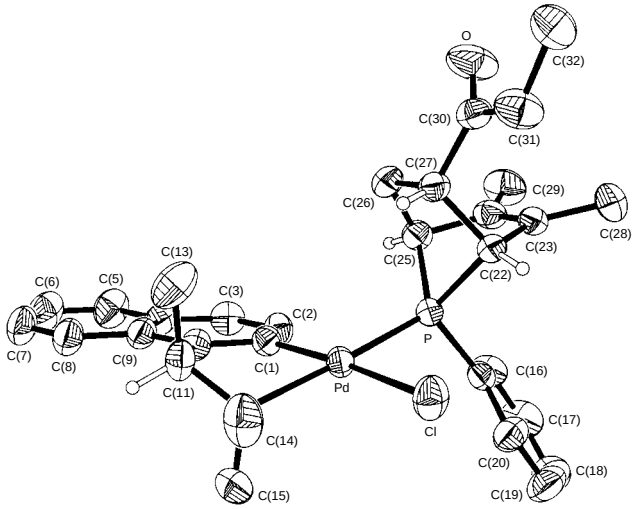


**Fig. 1** Molecular structure and absolute stereochemistry of complex ($S_c$,$S_p$)-**3**. Selected bond lengths (Å) and angles (°); Pd–P 2.241(0), Pd–Cl 2.411(1), Pd–C(1) 2.014(2), Pd–N(12) 2.151(1), P–C(22) 1.860(2), P–C(25) 1.858(2), O–C(30) 1.201(2), C(22)–C(27) 1.582(2), C(27)–C(30) 1.530(2), C(23)–C(24) 1.336(3); C(1)–Pd–N(12) 80.7(1), C(22)–P–C(25) 81.0(1), P–C(22)–C(27) 98.8(1), C(22)–C(27)–C(30) 110.3(1), C(27)–C(30)–O 121.3(2).

Interestingly, the removal of the chloro ligand in ($S_c$)-**2** clearly decelerates the cycloaddition process. Thus, when a $CH_2Cl_2$ solution of ($S_c$)-**2** was stirred with a stoichiometric quantity of $AgClO_4$, filtered, and then treated directly with ethyl vinyl ketone at room temperature, the corresponding cycloaddition reaction required 9 d for completion. Furthermore, the $^{31}P$ NMR spectrum of a $CDCl_3$ solution of the crude product obtained from this slow reaction indicated that both ($S_c$,$R_p$)-**3** and ($S_c$,$S_p$)-**3** were not formed. The spectrum included only a singlet at $\delta_P$ 107.3. This new product was crystallized from $CH_2Cl_2$–$Et_2O$ as yellow prisms (85%), mp 197–198 °C, $[\alpha]_D$ + 232.7 (*c* 1, $CH_2Cl_2$). An X-ray structural analysis confirmed that it is ($S_c$,$R_p$)-**5** and the absolute configurations of its four chiral centres at P, C(22), C(25) and C(27) are *R*, *S*, *R* and *R*, respectively (Fig. 2).‡ It is noted that, interestingly, the C=O bond distance [1.218(6) Å] in this cationic complex is longer than its counterpart [1.201(2) Å] in ($S_c$,$S_p$)-**3**. The lengthening

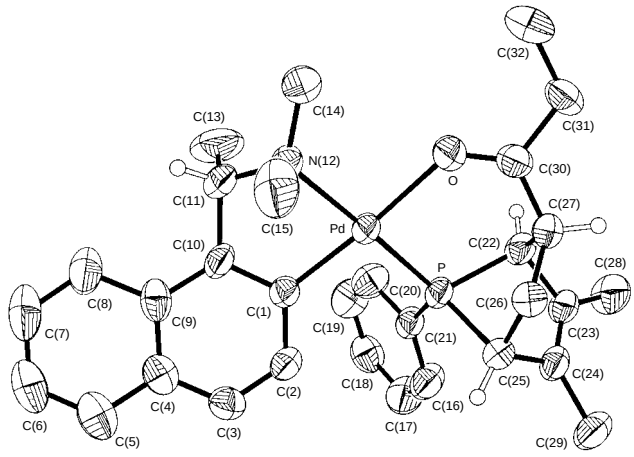

**Fig. 2** Molecular structure and absolute stereochemistry of the cation in ($S_c$,$R_p$)-**5**. Selected bond lengths (Å) and angles (°); Pd–P 2.226(1), Pd–O 2.156(4), Pd–C(1) 1.980(5), Pd–N(12) 2.134(4), P–C(22) 1.840(5), P–C(25) 1.853(5), O–C(30) 1.218(6), C(22)–C(27) 1.571(8), C(27)–C(30) 1.503(7), C(23)–C(24) 1.312(9); P–Pd–O 91.2(1), P–Pd–C(1) 95.7(1), P–Pd–N(12) 177.0(2), O–Pd–C(1) 172.4(2), O–Pd–N(12) 91.0(2), C(1)–Pd–N(12) 82.3(2), Pd–P–C(22) 112.1(2), Pd–P–C(25) 115.6(2), C(22)–P–C(25) 81.4(2), P–C(22)–C(27) 100.2(3), C(22)–C(27)–C(30) 109.1(4), C(27)–C(30)–O 123.1(5), C(30)–O–Pd 128.9(4).

of the C=O bond in the *O*-bonded complex is perhaps an indication of the weakening of the double bond character *via* coordination. Treatment of ($S_c$,$R_p$)-**5** with dppe liberated the optically pure ($S_p$)-**6** from the chiral metal template as an air-sensitive colourless oil in 73% yield, $[\alpha]_D$ −17.2 (*c* 1, $CH_2Cl_2$), $\delta_P$ 94.5 (s). The optical purity of ($S_p$)-**6** was confirmed by the quantitative re-preparation of ($S_c$,$R_p$)-**5** from the liberated ligand and ($S_c$)-**7**:[5] the 202 MHz $^{31}P$ NMR spectrum of the crude product indicated diastereomer ($S_c$,$R_p$)-**5** only. Consistent with this, the diastereomeric complex ($R_c$,$R_p$)-**5**, prepared from ($S_p$)-**6** and ($R_c$)-**7**, showed a sharp singlet at a clearly different $^{31}P$ chemical shift, *i.e.* at $\delta_P$ 110.0.

From a mechanistic standpoint, the transition state involved in the formation of ($S_c$,$R_p$)-**5** requires both the diene and the dienophile to be coordinated simultaneously on the cationic palladium template during the course of the intramolecular cycloaddition reaction. Such an intramolecular mechanism, however, is not involved in the synthesis of *endo*-diastereomers **3** which are clearly produced by an intermolecular cycloaddition reaction. Furthermore, we believe that the coordinated DMPP is electronically activated by the neutral palladium template throughout the intermolecular *endo*-cycloaddition process. Owing to the electron deficiency in the cationic transition state of the *exo*-cycloaddition reaction, the coordinated DMPP is less activated and hence a longer reaction time is required for the intramolecular process. Indeed, such a low activation prohibits the potential competing intermolecular cycloaddition reaction and hence the *exo*-cycloadduct is formed exclusively. Furthermore, as the diene and the dienophile of the *exo*-cycloaddition reaction are coordinated on the chiral template, their stereochemical orientations in the transition state are being controlled simultaneously by the naphthylamine auxilliary. Accordingly the slower *exo*-cycloaddition shows a much higher degree of stereoselectivity than the corresponding faster *endo*-process.

# Reductive etherification of substituted cyclohexanones with secondary alcohols catalysed by zeolite H-MCM-22

**Michel J. Verhoef, Edward J. Creyghton, Joop A. Peters and Herman van Bekkum***

*Laboratory of Organic Chemistry and Catalysis, Delft University of Technology, Julianalaan 136, 2628 BL Delft, The Netherlands*

**Zeolite MCM-22 is an active and regenerable catalyst for a remarkably shape selective reductive etherification of cyclohexanones with bulky substituents at the 4-position, employing secondary alcohols as reductants.**

Zeolite MCM-22 has recently been introduced as a unique biporous zeolite.[1] It has been shown that it contains two independent pore systems,[2,3] one defined by sinusoidal 10-membered ring channels extended in two dimensions, and the other by large 12-membered ring supercages (7.1 × 7.1 × 18.1 Å) connected by 10-membered ring channels. The material has a high thermal stability, a BET surface area of $> 400$ m$^2$ g$^{-1}$ and a sorption capacity of 0.16 ml g$^{-1}$,[4,5] which make it very interesting for catalysis. MCM-22 in its acidic form has already been claimed to be active in, for example, the conversion of lower alkenes to heavier hydrocarbons, and of aliphatic hydrocarbons to aromatics, the disproportionation of toluene and the alkylation of benzene.[6]

Here we report on the use of H-MCM-22 as a bifunctional catalyst in the reductive etherification of cyclohexanones having bulky substituents at the 4-position, using secondary alcohols as reductants. The zeolite appears to be active for both acid-catalysed conversion of the ketones to (hemi)acetals and consecutive Meerwein–Ponndorf–Verley (MPV)-type hydride transfer to yield ethers. Until now two catalysts were always required to achieve this, *i.e.* a strong acid for the acetalisation and a transition metal for the reduction step.[7,8] Various solid catalysts including zeolites have been applied in acid-catalysed acetal fomation[9] and the MPV reaction.[10,11] However, the combination of both properties in a single zeolite, enabling the direct synthesis of ethers from ketones, is novel.

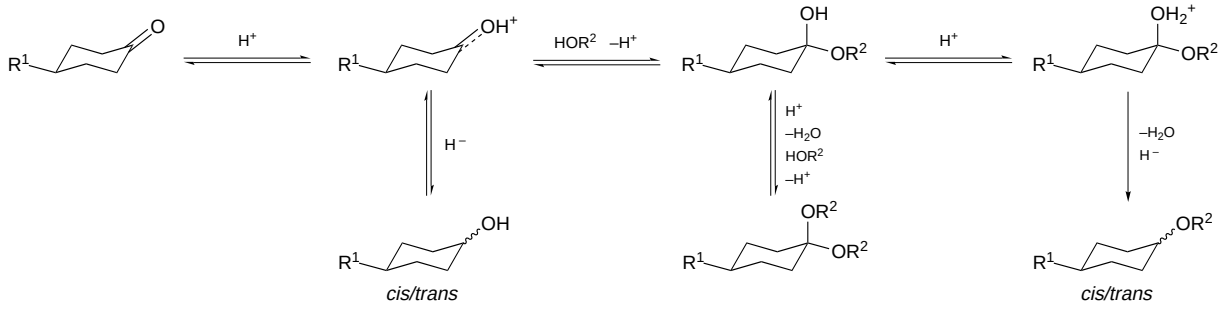
MCM-22 with a Si/Al ratio of 15 was synthesized following a literature procedure,[12] dried at 60 °C *in vacuo* and subsequently calcined in a flow of air at 540 °C for 12 h. The acidic form was obtained by four-fold ion-exchange with 1 M aqueous ammonium nitrate at 80 °C for 12 h, followed by calcination as described above. X-Ray diffraction studies and the NMR ($^{29}$Si and $^{27}$Al) spectra of the resulting material were in agreement with literature data.[13] The $^{27}$Al NMR spectra indicated the presence of some extra-framework aluminium ($\delta$ −1.0). Transmission electron microscopy measurements showed the material to consist of small disk-like particles (130 × 130 × 15 nm), in agreement with scanning electron microscopy data.[2]

Reactions were conducted by refluxing ketone (9 mmol), catalyst (1 g) and 1,3,5-tri-*tert*-butylbenzene (1.6 mmol) as internal standard in Pr$^i$OH or Bu$^s$OH (70 ml). The reactions were monitored by GC (CP wax 52 CB column).

H-MCM-22 proved to be active and selective in the reductive etherification of 4-*tert*-butylcyclohexanone with the above mentioned alcohols, giving the corresponding ethers with a *cis* : *trans* ratio of 60 : 40 ( Table 1). Only trace amounts ( < 5%) of 4-*tert*-butylcyclohexanol, formed by direct MPV reduction, were observed. Continuous removal of water from the reflux by a bed of zeolite Na-A significantly increased both the conversion and the selectivity to the ether (Table 1). The catalyst could be re-used, following regeneration at 450 °C for 12 h in air, without any loss in activity or crystallinity.

The size and the shape of the ketone substrate appears to be decisive for the course of the reaction. For example, 4-phenylcyclohexanone and 4-methylcyclohexanone could be etherified, although with poor conversions and selectivity. On the other hand, 4-trimethylsilylcyclohexanone, with a similar size and shape to 4-*tert*-butylcyclohexanone, reacted smoothly.

Secondary alcohols are found to be required as hydride donors. With MeOH only acetal formation occurred. Acid sites appear to be essential, since with Na-MCM-22 as catalyst in the etherification of 4-*tert*-butylcyclohexanone only a 5% yield was obtained after 24 h. The reductive etherification is irreversible. Starting from the ether, water and acetone in Pr$^i$OH in the presence of zeolite H-MCM-22, no reaction occurred.



Some zeolites, especially zeolite Beta, perform well in MPV reductions.[14] However, a mechanism involving MPV reduction of the cyclohexanone, followed by acid-catalysed etherification by the solvent, can be excluded, since no reaction occurred on starting from 4-*tert*-butylcyclohexanol under similar reaction conditions. It seems more likely that the reaction proceeds *via* Brønsted acid-catalysed formation of a hemiacetal followed by a Lewis acid-catalysed, MPV-like hydride transfer to yield the ether (see Scheme 1).

The involvement of (hemi)acetals is supported by the fact that when the reaction of 4-*tert*-butylcyclohexanone was performed with a mixture of MeOH and Pr$^i$OH (1 : 1 mixture) both the dimethyl and the mixed methyl isopropyl acetals were formed almost instantaneously. These acetals were slowly converted into the isopropyl and methyl ethers. With 4-phenyl- and 4-methyl-cyclohexanones, dissolved in a 1 : 1 mixture of MeOH and Pr$^i$OH in the presence of zeolite H-MCM-22, acetal formation also occurred; however, only trace amounts of ether were formed together with some cyclohexene derivatives. The

**Table 1** Reductive etherification of various 4-substituted cyclohexanones with secondary alcohols and H-MCM-22 as the catalyts[a]

| Substrate | Conversion (%) | Selectivity (%) Ether | Alcohol | TON[b] |

**Scheme 1**

diisopropyl acetal was not observed in any reaction although this acetal can easily be prepared homogeneously.[9] Steric strain might prevent its formation. It cannot be excluded, however, that formation of the diisopropyl acetal occurs in the zeolite supercages, from where it cannot escape.

The role of $Pr^iOH$ as hydride donor was demonstrated by a reaction in $Pr^iOD$ (25% labelling). GC–MS and $^2H$ NMR of the reaction product showed that the C(1)-position of the cyclohexane ring and the secondary carbon of the isopropoxy group were 25% deuterated.

It remains unclear why H-MCM-22 shows this unusual behaviour, while various other solid acids yield only the MPV reduction products.[14] Possibly the number of Brønsted acid sites in H-MCM- 22 greatly exceeds the number of sites capable of catalysing the MPV reduction, resulting in the fast formation of (hemi)acetals followed by a slow conversion to the ethers. An explanation for the remarkable shape selectivity of the reaction may be that it takes place in the zeolite supercages (see Fig. 1).

The aluminium site in MCM-22, required for the hydride transfer, is assumed to be located mostly at the positions marked with an arrow.[15] When 4-*tert*-butyl- (and 4-trimethylsilyl)-cyclohexanone is adsorbed into the zeolite cage, it is forced into an orientation which brings the carbonyl group into close proximity to that site. In this tentative mechanism the aluminium atom plays a three-fold role: activation of the ketone, hydride transfer and stabilisation of the carbocation intermediate formed after water elimination. In contrast, the 4-methyl- and 4-phenyl-cyclohexanones are not forced to adopt this specific orientation.

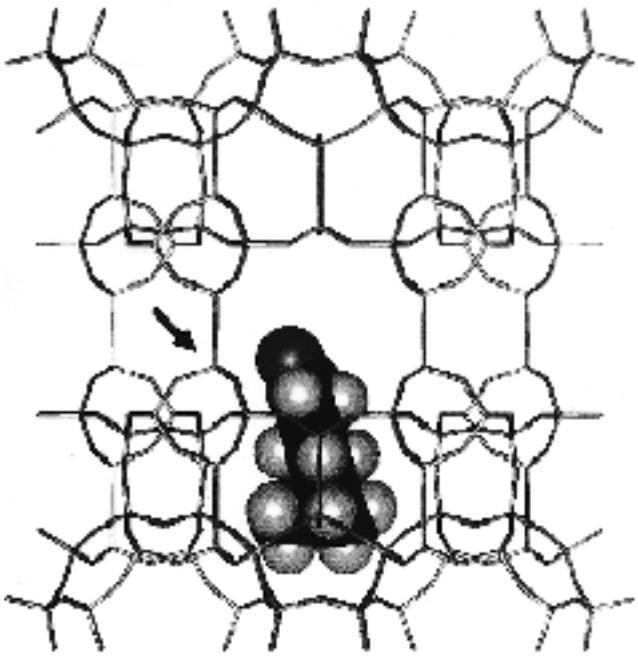

**Fig. 1** 4-*tert*-Butylcyclohexanone in an MCM-22 supercage

In conclusion, H-MCM-22 is an active catalyst in the reductive etherification of substituted cyclohexanones. The mechanism is proposed to proceed *via* the formation of a hemiacetal followed by an MPV-like reduction.

The authors thank Dr P. J. Kooyman of the National Centre for High Resolution Electron Microscopy, Delft University of Technology, Delft, The Netherlands, for performing the electron microscopy investigations and Ms S. L. Njo for her help with Fig. 1. The IOP Catalysis (Innovation Oriented Research Programmes) is gratefully acknowledged for financial support.

# Structural influence of hydrotalcite on Pd dispersion and phenol hydrogenation

**S. Narayanan* and K. Krishna**

*Catalysis Division, Indian Institute of Chemical Technology, Hyderabad 500 007, India*

**An interesting structure dispersion relationship of Pd/hydrotalcite is studied by changing the calcination temperature of hydrotalcite support and evaluated for phenol hydrogenation.**

Efforts are being directed towards searching for new and efficient supports for dispersing noble metals. Hydrotalcites (HTs) have brucite-like positively charged layers of magnesium and aluminium octahedra sharing edges and have interstitial carbonate anions.[1] Supported metal hydrotalcites have created much scientific interest because of their interesting properties in catalytic reforming.[2,3] However, not much attention has been paid to the characterization of hydrotalcite supported metals. We have investigated the high phenol hydrogenation activity of Pd/HT to cyclohexanone,[4] which is an important raw material for the production of caprolactam. Here we discuss, for the first time, the interesting changes in properties of the HT support with calcination and its influence on metal dispersion and hydrogenation activity.

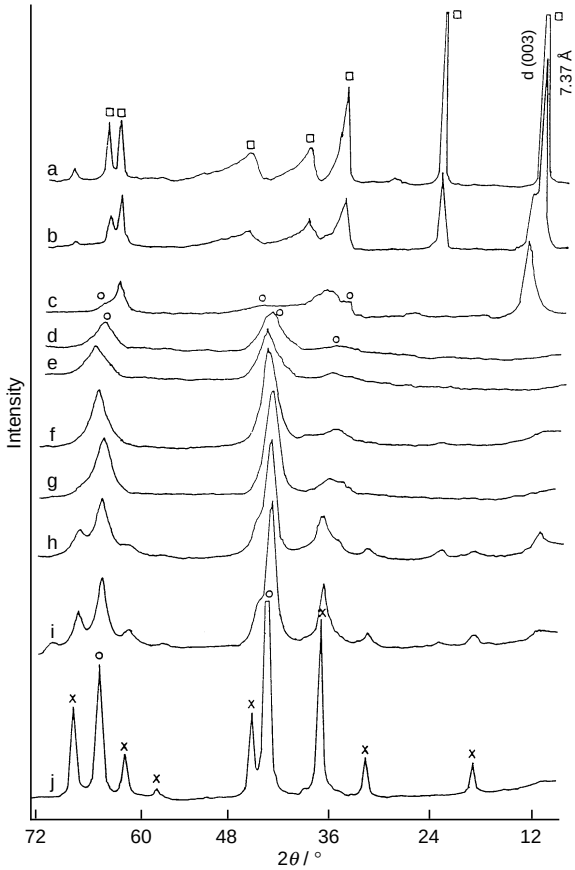

**Fig. 1** XRD patterns of the hydrotalcites calcined at different temperatures (K): (a) 373, (b) 473, (c) 573, (d) 673, (e) 773, (f) 873, (g) 973, (h) 1073, (i) 1173 and (j) 1273. (□) HT, (○) MgO, (×) $MgAl_2O_4$.

HT was prepared according to the method described by Reichle *et al.*[5] HT was calcined in air for 4 h in the temperature range 473–1273 K and XRD patterns were recorded in air. Apart from calcined HTs, γ-$Al_2O_3$ and $MgAl_2O_4$ were also used as supports for loading 1 mass% of Pd. Impregnation was done with a standard $PdCl_2$ solution acidified with HCl. Surface area of the support and CO chemisorption on 1 mass% Pd/HT were measured. Phenol hydrogenation was carried out at 453 K over *ca.* 0.2 g of the catalyst at a phenol WHSV of 0.037 mol $g^{-1}$ $h^{-1}$. The experimental details are given elsewhere.[4]

Fig. 1 shows XRD patterns of calcined HTs. The sample dried at room temperature (not shown) and 373 K showed the same diffraction patterns and $d_{(003)}$ basal spacing (7.37 A°) indicating retention of interlayer water. At 473 K, owing to the loss of gallery water, the basal spacing decreased by 0.56 Å. The patterns showed both anhydrous and hydrated HT, the latter might have formed owing to fast rehydration of HT.[6] The sample calcined at 573 K showed a basal spacing of 6.6 Å indicating dehydrated HT of low crystallinity along with MgO peaks. Between 373 and 573 K, the intensity of $d_{(003)}$ peak decreased, broadened and shifted towards higher $2\theta$ values indicating the progressive destruction of the layered structure. Beyond 573 K, broad and diffuse peaks corresponding to mixed oxides of MgO are observed. With increase in calcination temperature the MgO peaks intensify and at 1073 K HT showed peaks representing a mixture of crystalline MgO and spinel $MgAl_2O_4$. At 1273 K mainly $MgAl_2O_4$ along with crystalline MgO are formed.

The surface area remained almost the same (Fig. 2) up to a calcination temperature of 573 K, indicating that the layered structure of HT is predominantly present. Beyond 573 K and up to 773 K, there is an increase in surface area. This is due to the loss of water and $CO_2$ which creates craters in the metal oxide sheet.[5] Above 773 K, there is a progressive decrease in surface area as the crystallinity of the material increases.

Fig. 2 shows the effect of calcination temperature of HT on dispersion and catalytic activity of Pd. Two maxima in dispersion (*ca.* 60%) and conversion (≥90%) can be seen when

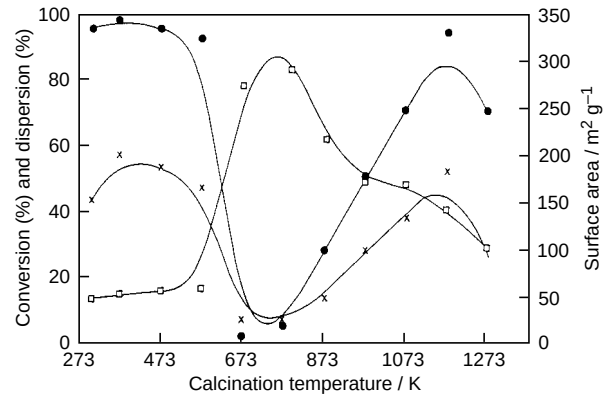

**Fig. 2** Effect of calcination on surface area of HT, metal dispersion and activity of 1 mass% Pd/HT. (□) Surface area, (●) conversion (%), (×) dispersion (%).

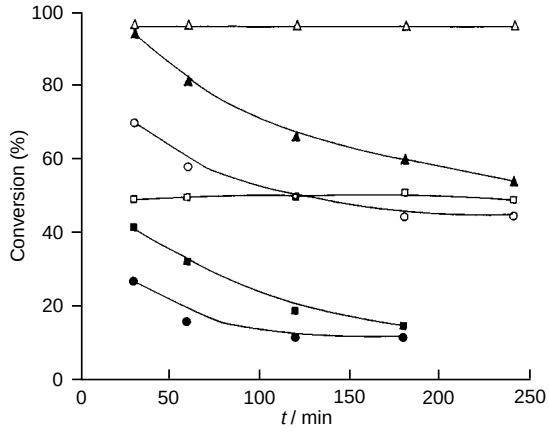

**Fig. 3** Effect of time on stream over 1 mass% Pd/support. HT support calcined at different temperatures (K): (△) 373, (□) 973, (○) 1073 and (▲) 1173, (●) 1 mass% $Pd/Al_2O_3$, (■) 1 mass% $Pd/MgAl_2O_4$.

the support is calcined in the region of room temp. to 573 K and at 973–1173 K. The dispersion of Pd slightly increases when the support is dried at 373 K and calcined at 473 K compared to the support dried at room temp. and calcined at 573 K. There is an abrupt decrease in CO uptake when the support is calcined between 673 and 773 K, and CO uptake progressively increases up to a calcination temperature of 1173 K and again decreases thereafter. Despite a large surface area of HT having the MgO phase, the dispersion of Pd is low on these supports. There is no direct relationship between surface area of the support, which exists in different phases, and Pd dispersion indicating that the structural properties are playing a major role in metal dispersion. Phenol conversion follows the same trend as that of dispersion and metal area. The selectivity towards cyclohexanone is ⩾95%.

Acidification of $PdCl_2$ leads to $PdCl_4^{2-}$ anion which on impregnation replaces the carbonate anion at the external edge surface of the non-porous HTs. This interaction results in a fine dispersion of palladium precursor which on reduction gives highly dispersed palladium. The replacement of carbonate anion in the internal surface sites can be ruled out as there is no change in the basal spacing of the palladium-loaded HT (XRD not shown). The physically adsorbed water in room-temperature dried HT inhibits $CO_3^{2-}$ access to $PdCl_4^{2-}$; therefore the deposition of the precursor is relatively more on the surface. This results in less dispersion of palladium compared to the sample dried at 373 K. The dispersion over HT dried at 373 K and calcined at 473 K is almost the same. This indicates that the structural water did not alter the dispersion as the precursor is mostly deposited by ion-exchange of $CO_3^{2-}$ on the external edge surface. The dispersion is less over HT which is partially decarbonated and dehydroxylated and includes both the phases of MgO and HT. Even though aluminium is distributed uniformly throughout the HT layer, on calcination, alumina segregates out to the surface and as the calcination temperature increases the concentration of alumina on the surface increases. The increase in crystallinity of MgO and the segregation of $Al_2O_3$ to the surface with increase in calcination temperature in the range 673–973 K, improves the dispersion of Pd though the role of these two phases is not very clear. The dispersion of Pd on HT calcined in the range 1073–1273 K increases with the increase in $MgAl_2O_4$ phase and decreases over the support containing a large amount of crystalline MgO and $MgAl_2O_4$. The decrease in dispersion could be due to sintering of Pd on this highly crystalline phase. From Fig. 1 and 2 it is observed that there exists a correlation between dispersion of Pd and $MgO/MgAl_2O_4$ ratio with a maximum dispersion at an optimum ratio.

Fig. 3 shows time on stream over Pd/HT, $Pd/Al_2O_3$ and $Pd/MgAl_2O_4$. $Pd/Al_2O_3$, $Pd/MgAl_2O_4$ deactivate due to the formation of coke by the acid sites of alumina.[7] Pd/HT in which the support was calcined upto to 973 K did not show any appreciable deactivation. Spectroscopic techniques show that, on calcination of HT, a small portion of octahedral Al is converted to tetrahedral Al possibly residing on the surface and the amount increases with calcination temperature.[8] This alumina is in a local oxidic environment that does not favor the acid-catalysed reaction that typically occurs over alumina.[9] The stability of the catalyst, in which the HT is calcined up to 973 K, against coke formation could be explained based on the above observation. The role of impurities which may surface during calcination in preventing the catalyst from deactivation can not be ruled out. Above calcination at 973 K the HT shows a spinel $MgAl_2O_4$ phase and there is appreciable deactivation. The rate of deactivation increases with increase in spinel phase in the support.

Some interesting observations have been made in this study. Pd dispersion depends on the HT structure. Palladium is highly dispersed over HT having a layered structure with carbonate interlayer anions and also on a mixture of crystalline MgO and $MgAl_2O_4$ spinel. In spite of partial segregation of alumina to the surface during calcination it did not show appreciable deactivation in phenol hydrogenation which is a problem with acidic alumina. In summary HTs are attractive alternative supports for noble metals.

K. K. thanks CSIR, New Delhi for the award of Senior Research Fellowship.

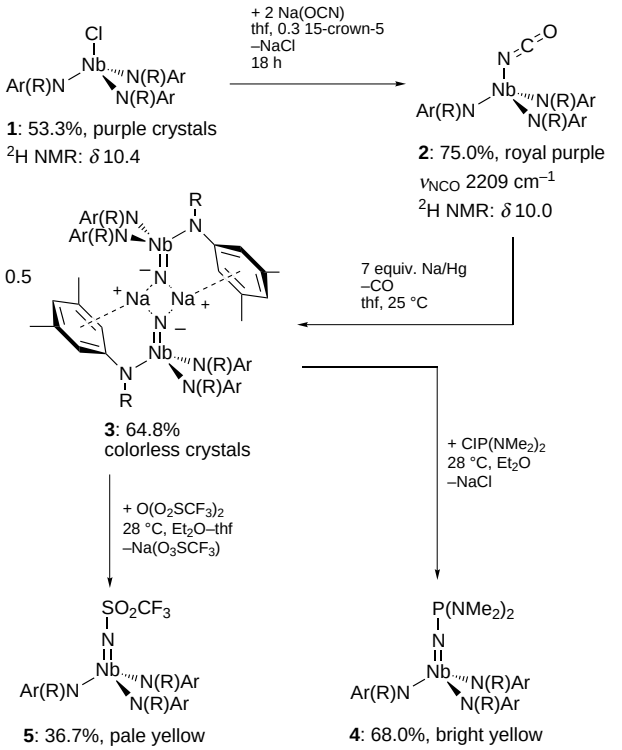
# A nucleophilic niobium(v) nitride prepared by isocyanate decarbonylation

**Michael G. Fickes, Aaron L. Odom and Christopher C. Cummins*†**

*Department of Chemistry, 2-227, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Cambridge, MA 02139-4307, USA*



**Carbon monoxide is lost upon sodium amalgam reduction of [(OCN)Nb{N(R)Ar}$_3$] [R = C(CD$_3$)$_2$CH$_3$, Ar = C$_6$H$_3$Me$_2$-3,5] to give crystallographically characterized [Na{NNb-[N(R)Ar]$_3$}]$_2$, a nucleophilic niobium(v) nitride which reacts with ClP(NMe$_2$)$_2$ and O(SO$_2$CF$_3$)$_2$ to give P- and S-substituted imido complexes, respectively.**

New synthetic routes to d$^0$ transition-metal complexes containing the terminal nitride functionality have emerged in recent years.[1] Various small molecules or ions, including $N_2$,[2,3] $N_2O$,[4] NO,[5] $N_3^-$,[6] and organic nitriles,[7] have been identified as N-atom sources for metal–nitrogen triple bond formation. This work describes the finding that cyanate ion $NCO^-$ can be added to the foregoing list in the context of niobium chemistry.

A handful of niobium complexes bearing sterically demanding amido ligands such as NPh$_2$,[8,9] N(SiMe$_3$)$_2$,[8,10] and N(c-C$_6$H$_{11}$)$_2$,[11] have been described in recent years. Given the demonstrated effectiveness of the N(R)Ar [R = C(CD$_3$)$_2$CH$_3$, Ar = C$_6$H$_3$Me$_2$-3,5) ligand in molybdenum chemistry,[2,4,12] and the convenience of the $^2$H NMR spectroscopic handle afforded by it,[13] this ligand was selected for our investigation of niobium isocyanate chemistry.‡ Accordingly, treatment of [NbCl$_4$(thf)$_2$] with 3 equiv. of Li[N(R)Ar](OEt$_2$) in hexane led to formation of purple [ClNb{N(R)Ar}$_3$] **1**, which was obtained in 53% yield as a hydrocarbon- and diethyl ether-soluble crystalline solid (Scheme 1). Toluene solutions of compound **1** exhibit an EPR signal ($g_{iso}$ = 1.966, $a_{iso}$ = 105.1 G) characteristic of a d$^1$ niobium ($^{93}$Nb, $I$ = 9/2) center, along with a single $^2$H NMR signal ($\delta$ 10.4, $\Delta\nu_{1/2}$ 116 Hz); the compound exhibits a $\mu_{eff}$ of 2.1 $\mu_B$ ([$^2$H$_6$]benzene).[14] The pseudotetrahedral monomeric nature of **1** has been confirmed in preliminary fashion by an X-ray diffraction study showing that **1** is isostructural with the related compound [SMo{N(R)Ar}$_3$],[15] with which **1** is isoelectronic.

Displacement of chloride by isocyanate was effected by treating, for 18 h, a 28 °C thf solution of **1** with an excess of sodium cyanate (2 equiv.) in the presence of 15-crown-5 (0.30 equiv). Compound **2** [(OCN)Nb{N(R)Ar}$_3$], was obtained subsequently as dark purple needles in 75% yield by recrystallization from pentane; the compound exhibits a $\mu_{eff}$ of 2.2 $\mu_B$ ([$^2$H$_6$]benzene). A strong band at 2209 cm$^{-1}$ in the IR spectrum of **2** is attributable to $\nu_{NCO}$,[16] consistent with the proposal of an N-bound, $\eta^1$ mode of ligation for the $NCO^-$ ion. The decarbonylation chemistry of **2** (see below) likewise is suggestive of its isocyanate character.

Decarbonylation occurred upon treatment of **2** with an excess of 0.5% sodium amalgam (7 equiv. Na, unoptimized) in thf for 18 h at 28 °C. Trapping experiments to be described in detail elsewhere confirmed that a substantial fraction of the carbon monoxide lost is evolved as free CO. The anionic niobium(v) nitride [Na{NNb[N(R)Ar]$_3$}]$_2$, **3**, was obtained as a thf-free, benzene-soluble, colorless solid in 65% yield subsequent to trituration with hexane and recrystallization from ether. Compound **3** was found by X-ray crystallography to adopt a dimeric structure in the solid state (Fig. 1),§ the dimer possessing a center of inversion about a central $Na_2N_2$ square core. The environment about sodium involves two nitrido nitrogens and $\eta^6$-aryl complexation, with Na–C$_{aryl}$ distances averaging 2.94 Å. Interaction of alkali-metal cations with benzene-like organic $\pi$ systems is a well documented phenomenon,[17] and in the present case this interaction serves to explain the ready isolation of **3** in thf-free form. NMR spectra of diamagnetic **3** are

**Scheme 1**

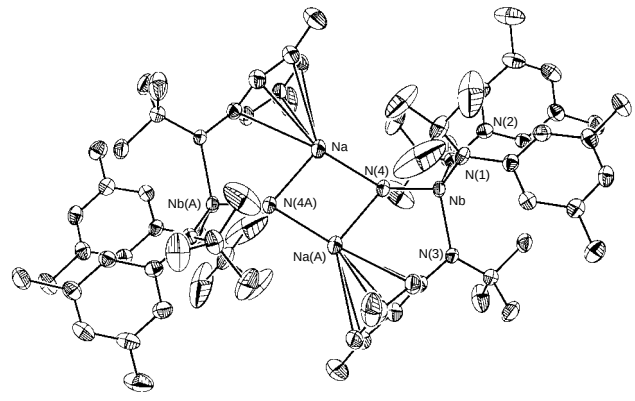


**Fig. 1** Structural drawing of **3** with thermal ellipsoids at the 35% probability level. Selected bond lengths (Å) and angles (°): Nb–N(4) 1.718(3), Nb–N(1) 2.041(3), Nb–N(2) 2.074(3), Nb–N(3) 2.089(3), N(4)–Na 2.351(4), N(4)–Na(A) 2.336(4); Nb–N(4)–Na 129.0(2), Nb–N(4)–Na(A) 148.5(2), N(4)–Na–N(4A) 96.62(12), N(4)–Nb–N(1) 104.3(2), N(4)–Nb–N(2) 105.7(2), N(4)–Nb–N(3) 101.3(2), N(1)–Nb–N(2) 115.61(14), N(1)–Nb–N(3) 113.40(13), N(2)–Nb–N(3) 114.42(13).

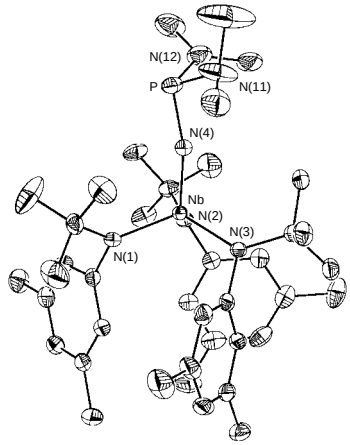

**Fig. 2** Structural drawing of **4** with thermal ellipsoids at the 35% probability level. Selected bond lengths (Å) and angles (°): Nb–N(4) 1.796(3), Nb–N(1) 2.010(3), Nb–N(2) 2.018(4), Nb–N(3) 2.021(3), N(4)–P 1.687(4), P–N(11) 1.744(5), P–N(12) 1.658(4); Nb–N(4)–P 166.5(2), N(4)–Nb–N(1) 108.0(2), N(4)–Nb–N(2) 109.5(2), N(4)–Nb–N(3) 108.0(2), N(4)–P–N(11) 99.4(2), N(4)–P–N(12) 106.5(2), N(11)–P–N(12) 99.0(3).

consistent with its solid-state structure if a fluxional process is invoked to explain the observed equivalence of the N(R)Ar ligands on the NMR timescale at 25 °C. The enthalpic driving force for the decarbonylation producing **3** is understandable in terms of formation of a very strong Nb–N multiple bond, free carbon monoxide, and solvated sodium ion. Despite its evident favorability the latter transformation appears to be unique in isocyanate coordination chemistry. The reverse reaction, isocyanate formation by intramolecular coupling of N and CO ligands, has been described in at least one report.[18]

The utility of **3** stems from its nucleophilic character as evinced by its reactions with chlorobis(dimethylamino)phosphine and triflic anhydride, producing the unusual imido derivatives **4** and **5**, respectively. (A related nucleophilic vanadium nitride anion, $[NV(NPh_2)_3]^-$, was reported recently.[9]) Compound **4**, $[(Me_2N)_2PNNb\{N(R)Ar\}_3]$, was obtained in 68% yield as a bright yellow lipophilic crystalline solid. Diamagnetic **4** exhibits a single broad $^{31}P$ NMR signal at $\delta$ 135.0 ($\Delta\nu$ 101 Hz), the breadth of which is attributable to $^{93}Nb$ coupling. X-Ray crystallography confirmed that **4** is a pseudotetrahedral monomer (Fig. 2) with a relatively linear Nb–N–P linkage (166.5°) and a Nb–$N_{imido}$ distance [1.796(3) Å] that is short by comparison with the Nb–$N_{amido}$ distances [av. 2.016(3) Å].§

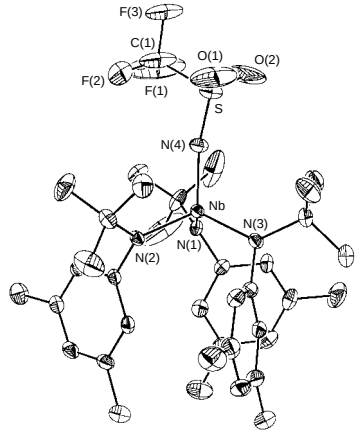

**Fig. 3** Structural drawing of **5** with thermal ellipsoids at the 35% probability level. Selected bond lengths (Å) and angles (°): Nb–N(4) 1.853(5), Nb–N(1) 1.978(5), Nb–N(2) 1.988(5), Nb–N(3) 1.983(5), N(4)–S 1.550(5), S–O(1) 1.415(7), S–O(2) 1.398(7), S–C(1) 1.807(12); Nb–N(4)–S 167.0(4), N(4)–Nb–N(1) 109.8(2), N(4)–Nb–N(2) 110.5(2), N(4)–Nb–N(3) 110.2(2), N(4)–S–O(1) 113.5(4), N(4)–S–O(2) 113.2(4), N(4)–S–C(1) 104.2(4), O(1)–S–O(2) 117.7(7), O(1)–S–C(1) 102.3(5), O(2)–S–C(1) 103.7(7).

'Triflimide' **5**, $[(CF_3SO_2)NNb\{N(R)Ar\}_3]$, was also characterized by X-ray diffraction (Fig. 3).§ The compound exhibits a relatively long Nb–$N_{imido}$ distance [1.853(5) Å] reflective of the highly electron-withdrawing nature of the trifluoromethanesulfonyl substituent. Interestingly, compound **5** appears to be the first example of a triflimide transition-metal complex. Although the formation of **5** appears to proceed smoothly according to the $^1H$ NMR spectrum of the crude reaction mixture, the compound, a pale yellow solid, was obtained in moderate (37%) yield after a diethyl ether wash.

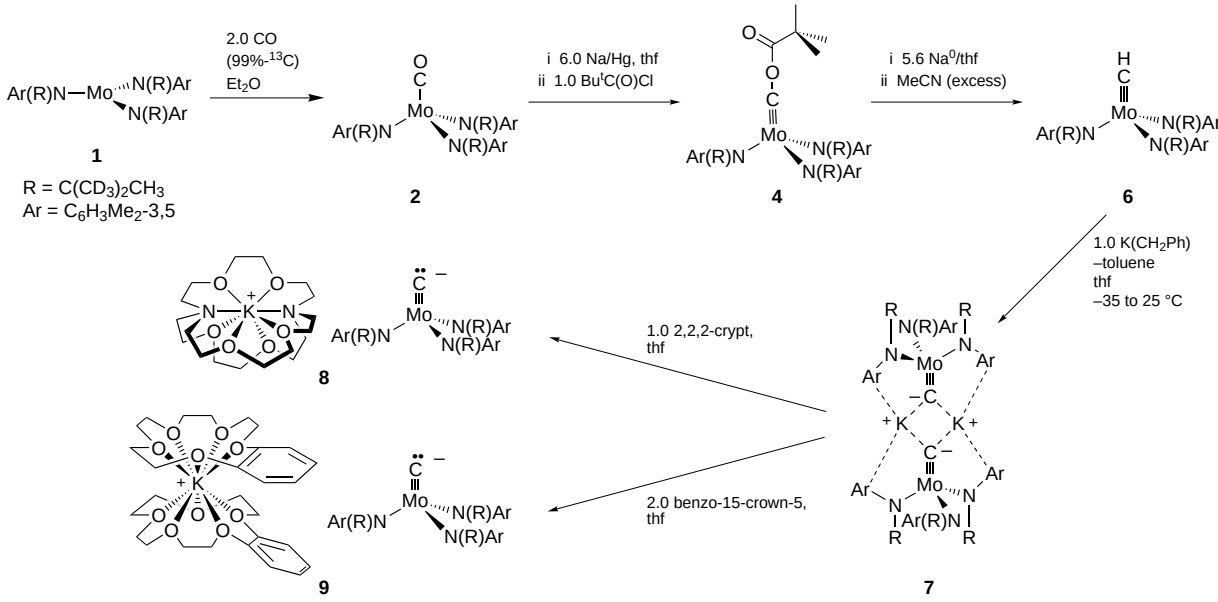
# A terminal molybdenum carbide prepared by methylidyne deprotonation

**Jonas C. Peters, Aaron L. Odom and Christopher C. Cummins*†**

*Department of Chemistry, Massachusetts Institute of Technology, 77 Massachusetts Avenue, Cambridge, MA 02139, USA*

**The carbide anion $[CMo\{N(R)Ar\}_3]^-$ [R = $C(CD_3)_2CH_3$, Ar = $C_6H_3Me_2$-3,5], is obtained by deprotonation of the corresponding methylidyne compound, $[HCMo\{N(R)Ar\}_3]$, and is characterized by X-ray diffraction as its $\{K(benzo\text{-}15\text{-}crown\text{-}5)_2\}^+$ salt, thereby providing precedent for the carbon atom as a terminal substituent in transition-metal chemistry.**



Recent work has shown that the molybdenum–nitrogen multiple bond in the nitride species $[NMo\{N(R)Ar\}_3]$ [R = $C(CD_3)_2CH_3$, Ar = $C_6H_3Me_2$-3,5] is exceedingly strong, and that this complex is quite robust.[1,2] Recognizing that the anionic carbide $[CMo\{N(R)Ar\}_3]^-$ would be isoelectronic with $[NMo\{N(R)Ar\}_3]$, we set out to synthesize it. As described herein, a successful synthesis was accomplished *via* deprotonation of the $d^0$ methylidyne complex $[HCMo\{N(R)Ar\}_3]$. Previously reported molecular carbide complexes feature carbon atoms with at least two nearest neighbors.[3–10]

Three-coordinate $[Mo\{N(R)Ar\}_3]$ **1** was treated with 99% $^{13}C$ carbon monoxide to give the paramagnetic ($\mu_{eff}$ = 1.73 $\mu_B$) carbonyl complex $[(O^{13}C)Mo\{N(R)Ar\}_3]$ **2** ($\nu_{CO}$ 1797 $cm^{-1}$) as a brown solid in 88% yield.‡§ One-electron reduction of **2** was effected with sodium amalgam in tetrahydrofuran (thf) giving $[(NaO^{13}C)Mo\{N(R)Ar\}_3]_2$ **3** [$\delta(^{13}C)$ 243.0] in essentially quantitative yield. **3** was obtained either as a solvent-free dimer or as an ether or thf solvate. *In situ* generated **3** was found to be sufficiently pure for synthetic purposes. Reaction of **3** with pivaloyl chloride[11] provided the 'carbido pivalate' complex $[Bu^tC(O)O(^{13}C)Mo\{N(R)Ar\}_3]$ **4** [$\delta(^{13}C)$ 217.2] in 82% yield as a beige crystalline solid.¶ Removal of the pivalate moiety in **4** was effected by treatment with sodium in thf giving, according to $^{13}C$ NMR analysis, a mixture of 'sodium carbide' $[Na(^{13}C\text{-})Mo\{N(R)Ar\}_3]_2$ **5** [$\delta(^{13}C)$ 474.2], methylidyne $[H(^{13}C)Mo\{N(R)Ar\}_3]$ **6** [$\delta(^{13}C)$ 287.5, $^1J_{CH}$ 157 Hz] and **3**. Treatment of the mixture with an excess of acetonitrile converted **5** to **6**, solubilized **3** and precipitated **6** in essentially pure form. Methylidyne **6**, an off-white solid, was isolated by this procedure in 53% yield from **2**.‖ Several other routes to the terminal methylidyne functionality have been documented.[12–17]

Deprotonation of **6** was effected by benzylpotassium in thf,[18] giving the potassium–molybdenum carbido complex $[K(^{13}C)Mo\{N(R)Ar\}_3]_2$ **7** [$\delta(^{13}C)$ 494.5][19,20] in 69% yield after recrystallization from pentane–thf.** In thf solution **7** presumably exists as a thf solvate, but the indicated thf-free, benzene-soluble dimer stabilized by intramolecular $K^+$–arene interactions[21] is readily obtained. Dimer **7** has been shown by X-ray crystallography to possess a central $K_2(carbide)_2$ square array situated about a crystallograpic inversion center.[22,23]

Treatment in thf of the potassium–molybdenum carbide **7** with 2,2,2-crypt[24] led to formation of the thf-soluble, benzene-insoluble salt $[K(2,2,2\text{-crypt})][^{13}CMo\{N(R)Ar\}_3]$ **8** [$\delta(^{13}C)$ 482.8].†† The $^1H$ NMR spectrum of **8** in $[^2H_8]$thf showed the expected four sharp resonances for the threefold-symmetric anion, along with the three signals characteristic of the $[K(2,2,2\text{-crypt})]^+$ cation. The curious fact that the $^{13}C$ NMR signal for the carbido carbon in **8** is broad ($[^2H_8]$thf, $\Delta\nu_{1/2}$ 1400 Hz) contrasts with the situation for **7**, which (in $C_6D_6$) exhibits a sharp signal.

A salt of the $[CMo\{N(R)Ar\}_3]^-$ anion amenable to X-ray crystallography, **9**, was obtained upon treatment of **7** with 2 equiv. (per K) of benzo-15-crown-5.[25] Crystals of salt **9**, which exhibited solubility characteristics similar to **8**, were obtained from thf–pentane.‡‡ The X-ray diffraction study of **9** revealed discrete and separate $[CMo\{N(R)Ar\}_3]^-$ anions and $[K(benzo\text{-}15\text{-}crown\text{-}5)_2]^+$ cations (Fig. 1).§§ The molybdenum–carbon distance in **9** was found to be 1.713(9) Å, at the low end of the known range for Mo–C multiple bonds.[26] The three N(R)Ar

**Scheme 1**

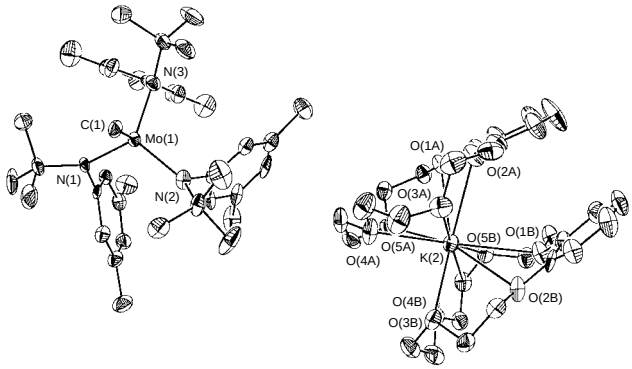


**Fig. 1** Structural representation of [K(benzo-15-crown-5)$_2$][CMo{N-(R)Ar}$_3$] **9** with thermal ellipsoids at the 35% probability level. Selected bond lengths (Å) and angles (°): Mo(1)–C(1) 1.713(9), Mo(1)–N(1) 2.008(6), Mo(1)–N(2) 2.010(7), Mo(1)–N(3) 2.013(6); C(1)–Mo(1)–N(1) 102.7(3), C(1)–Mo(1)–N(2) 103.9(3), N(1)–Mo(1)–N(2) 114.7(3), C(1)–Mo(1)–N(3) 103.8(3), N(1)–Mo(1)–N(3) 116.9(3), N(2)–Mo(1)–N(3) 112.6(3).

ligands in [CMo{N(R)Ar}$_3$]$^-$ adopt a propeller motif with the aryl rings π stacked[27] on one side of the molecule and the *tert*-butyl groups on the other side forming a protective 'pocket' about the Mo–C multiple bond. The gross structural and conformational features of [CMo{N(R)Ar}$_3$]$^-$ were anticipated based on structures of the related nitrido and phosphido derivatives [NMo{N(Bu$^t$)Ph}$_3$][1] and [PMo{N(R)Ar}$_3$].[28]

For funding this work we thank the Packard foundation, the Alfred P. Sloan Foundation, the National Science Foundation (CAREER Award CHE = 9501992), 3M, DuPont, and Union Carbide. J. C. P. is grateful for a Department of Defense Graduate Research Fellowship. This work is dedicated to the memory of Professor Jeremy K. Burdett.

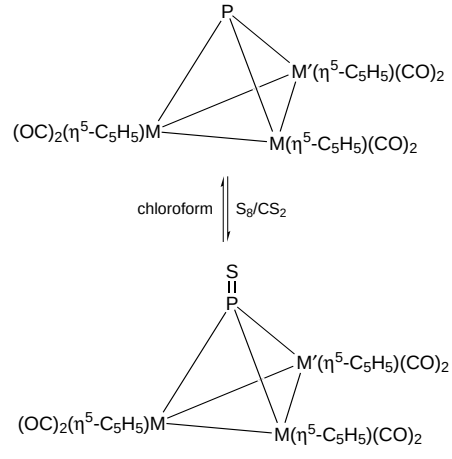
**The trimetallic tetrahedrane complexes $[Mo_nW_{3-n}(\eta^5\text{-}C_5H_5)_3(CO)_6(\mu_3\text{-}P)]$ ($n$ = 0–3) are oxidised in carbon disulfide solution by elemental sulfur to the corresponding $\mu_3$-PS complexes $[Mo_nW_{3-n}(\eta^5\text{-}C_5H_5)_3(CO)_6(\mu_3\text{-}PS)]$; the new complexes lose the sulfur atom upon standing in solution at room temp. to regenerate $[Mo_nW_{3-n}(\eta^5\text{-}C_5H_5)(CO)_6(\mu_3\text{-}P)]$; the X-ray crystal structure of $[W_3(\eta^5\text{-}C_5H_5)_3(CO)_6(\mu_3\text{-}PS)]$ is determined.**



The synthesis of complexes containing naked group 15 ligands has been the subject of much research over recent years.[1] The reported chemistry of such complexes is, however, rather sparse, being limited in the main to the further coordination of 16-electron organometallic fragments to lone pairs present on the group 15 atom.[2] We recently reported that the trimetallic complexes $[Mo_nW_{3-n}(\eta^5\text{-}C_5H_5)_3(CO)_6(\mu_3\text{-}P)]$ ($n$ = 0–3) could be oxidised to the respective $\mu_3$-PO complexes by standing in air,[3] although attempts to prepare the $\mu_3$-PS complexes by oxidation with sulfur using toluene as the solvent were unsuccessful. Complexes featuring the phosphorus sulfide ligand are extremely uncommon; to the best of our knowledge there exist only three previous examples with the PS ligand coordinated through phosphorus in the $\mu_3$ mode,[4–7] two examples in which it adopts the $\mu,\eta^2$ mode of coordination[6–8] and one example where the ligand is terminally coordinated through phosphorus.[9] We now report that the trimetallic species complexes $[Mo_nW_{3-n}(\eta^5\text{-}C_5H_5)_3(CO)_6(\mu_3\text{-}P)]$ ($n$ = 0–3) can be oxidised by sulfur in $CS_2$ solution to the complexes $[Mo_nW_{3-n}(\eta^5\text{-}C_5H_5)_3(CO)_6(\mu_3\text{-}PS)]$ ($n$ = 0–3) and that this oxidation may be reversed simply by dissolution in organic solvents in the absence of excess dissolved sulfur. None of the previously prepared PS complexes have been reported to undergo such a spontaneous self-reduction.

Reaction of elemental sulfur with carbon disulfide solutions of the phosphorus capped trimetallics $[Mo_nW_{3-n}(\eta^5\text{-}C_5H_5)_3(CO)_6(\mu_3\text{-}P)]$ ($n$ = 3 **1**, $n$ = 2 **2**, $n$ = 1 **3**, $n$ = 0 **4**)[3] affords in good yield the unstable trimetallic complexes $[Mo_nW_{3-n}(\eta^5\text{-}C_5H_5)_3(CO)_6(\mu_3\text{-}PS)]$ ($n$ = 3 **5**, $n$ = 2 **6**, $n$ = 1 **7**; $n$ = 0 **8**), featuring a capping phosphorus monosulfide ligand (Scheme 1).

All four $\mu_3$-PS complexes lose sulfur on standing in solution in common organic solvents in the absence of excess sulfur to give the corresponding $\mu_3$-P complex. The rate of this reverse reaction increases with an increasing number of molybdenum atoms in the complexes. Time-lapse $^1$H NMR studies on $[W_3(\eta^5\text{-}C_5H_5)_3(CO)_6(\mu_3\text{-}PS)]$ **8** revealed the formation of $[W_3(\eta^5\text{-}C_5H_5)_3(CO)_6(\mu_3\text{-}P)]$ **4** as the only significant cyclopentadienyl-containing product. The stabilities of the PS capped complexes in solution decrease in the order **8** > **7** > **6** > **5**. A study of the kinetics of this decomposition is being undertaken and will be the subject of a later paper. The oxidation of naked phosphorus ligands by sulfur has previously been reported both for ligands consisting of a single phosphorus atom[5,9] and for the $P_2$ ligand, this latter oxidation giving $P_2S_2$ coordinated to a tetrairon core.[10]

The spectroscopic data for the new complexes† are in accord with the proposed structures. All the complexes exhibit a similar IR absorption pattern in the carbonyl region, with the frequencies being similar to those observed for the corresponding phosphorus monoxide complexes.[3] The $^{31}$P NMR spectra of **5**–**8** show more positive chemical shifts and smaller $^1J_{PW}$ coupling constants as the number of tungsten atoms is decreased, as was also observed for the $\mu_3$-PO complexes.[3]

The molecular structure of $[W_3(\eta^5\text{-}C_5H_5)_3(CO)_6(\mu_3\text{-}PS)]$ **8** has been determined by X-ray diffraction,‡ and is shown in Fig. 1 along with selected bond lengths and angles. The complex crystallises along with 1 equiv. of $CH_2Cl_2$ in the space group $P2_12_12_1$, whereas $[Mo_3(\eta^5\text{-}C_5H_5)_3(CO)_6(\mu_3\text{-}PO)]\cdot CH_2Cl_2$ crystallises in space group $Pna2_1$.[3] Each $W(\eta^5\text{-}C_5H_5)(CO)_2$ fragment is distinct in the solid state on account of the differing relative geometry of the $\eta^5$-$C_5H_5$ and CO ligands with respect to the PS capping ligand, as also observed for $[Mo_3(\eta^5\text{-}C_5H_5)_3(CO)_6(\mu_3\text{-}PO)]$.[3] Only one cyclopentadienyl signal is observed in the $^1$H NMR spectrum of **8**, indicating a fluxional process in solution. The P=S bond is essentially perpendicular to the plane defined by the three tungsten atoms. The P=S separation of 1.992(7) Å is at the long end of the range for phosphorus–sulfur double bonds, these being typically observed to fall in the range 1.85–1.95 Å for alkyl and aryl phosphine sulfides,[11] and is in agreement with the observed weakness of this bond. As compared to the alkyl and aryl phosphine sulfides, back-donation from the filled metal d orbitals to vacant d orbitals on phosphorus is likely to reduce the effectiveness of the S → P π component of the PS bond. The W–W and W–P distances correspond to the presence of single bonds, as requires by simple electron counting schemes.

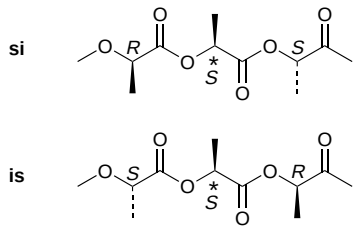
# Concerning the stereochemistry of poly(lactide), PLA. Previous assignments are shown to be incorrect and a new assignment is proposed

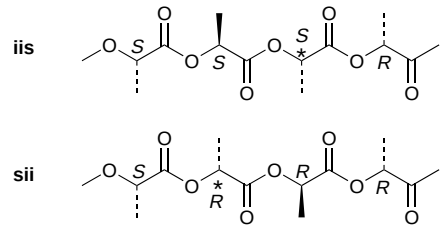
**Malcolm H. Chisholm*, Suri S. Iyer, Michael E. Matison, David G. McCollum and Marty Pagel**

*Department of Chemistry, Indiana University, Bloomington, IN 47405, USA*



**HETCOR NMR spectra reveal that previous assignments of the stereochemistry of poly(lactide) derived from *rac* and *meso*-lactide are incorrect; an alternative assignment is made at the tetrad level of resolution.**

Poly(lactide), PLA,[1] and its co-[2] and ter-polymers[3] provide an important class of biodegradable and biocompatible polymers with wide ranging applications from bulk commodity materials (Ecochem®)[4] to specialty medicinal products such as sutures, staples, fibers and rods (Dexon® and Vicryl®),[4] drug delivery agents (Leupron Depot® and Zoladex®)[5] and artificial tissue matrices.[6] The specific properties of these polymers relate directly to their microstructure and the latter is thus of considerable importance.[7] PLA is typically produced by ring-opening polymerization of the lactide cyclic dimers shown below by catalyst precursors such as tin octoate,[8] $Bu_3SnOMe$[9]



and $Al(acac)_3$[10] which allow for little kinetic selectivity in the ring-opening process. Attempts to establish the stereochemical microstructure of PLA have been based on NMR studies and Bernoullian statistics.[1a,2,10,11] Work has proceeded to infer stereochemical preferences in polymerization processes and by going to higher magnetic field strengths assignments of $^1H$ and $^{13}C\{^1H\}$ chemical shifts have been extended from the tetrad to the hexad level.[12] It is the purpose of this work to correct an error in the assignment of the microstructure and therefore to halt the propagation of errors relating to continuing studies of this polymer and assumptions and claims concerning stereo-preferential polymerizations.[11c,12,13]

In considering this polymer it is important to recognize that the ring opening of either an L- or D-lactide unit will generate an isotactic junction whereas opening a *meso*-lactide unit forms a syndiotactic unit. Thus at the triad level poly(L-lactide) and poly(D-lactide) will be denoted **ii** but polymerization of either racemic (50 : 50 D and L lactide) or *meso*-lactide will, in addition, contain both **si** and **is** units and unlike a poly(α-alkene) or poly(vinyl acetate) these two are not equivalent as shown below.†

At the tetrad level of assignment of PLA we are faced with the situation that the chemical shift of a given carbon or proton must be influenced by the stereochemistry of the polymer as read two to the left and one to the right, or two to the right and one to the left. There will always be ambiguity over the assignment **iis**/**sii**, shown below, because Bernoullian statistics renders them equivalent.

All previous assignments of PLA have followed from the work of Kriechldorf *et al.*[11a] based on (1) the homodecoupled methine proton and carbon resonances of polymers derived from the polymerization of *rac*- and *meso*-lactide and various mixtures thereof and (2) the assumption of Bernoullian statistics in polymer formation.[11b,c] These assignments of poly(*rac*-lactide) and poly(*meso*-lactide) are shown schematically in Fig. 1. In the absence of epimerization, which is effected by strong bases such as $KOBu^t$, poly(*rac*) will contain only **iii**, **iis**, **sii**, **sis** and **isi** tetrads whereas poly(*meso*) will be comprised of **sss**, **ssi**, **iss**, **sis** and **isi**. Thus common to both polymers are tetrad units **sis** and **isi**.

The assignments of **iii**, which can be identified independently from polymerization of either pure L-or pure D-lactide, and **sss**, which is favored statistically by polymerization of *meso*-lactide are correct but as shown by the HETCOR NMR spectra in Figs. 2 and 3 others are incorrect. The HETCOR spectra

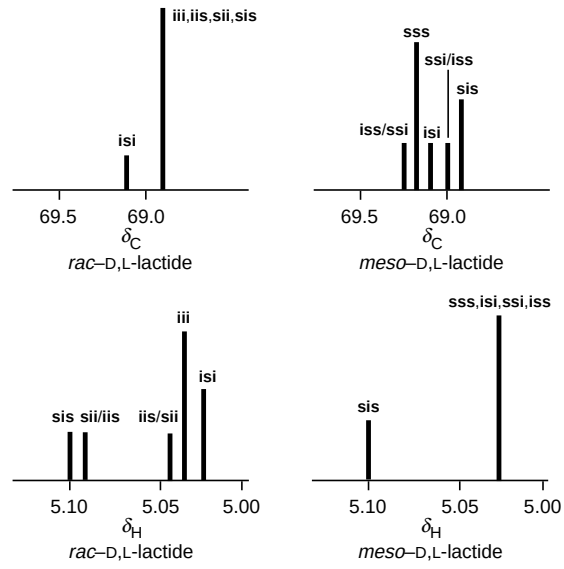


**Fig. 1** Schematic representation of the currently accepted assignments (CH) for PLA at the tetrad level following from ref. 11(*a*)

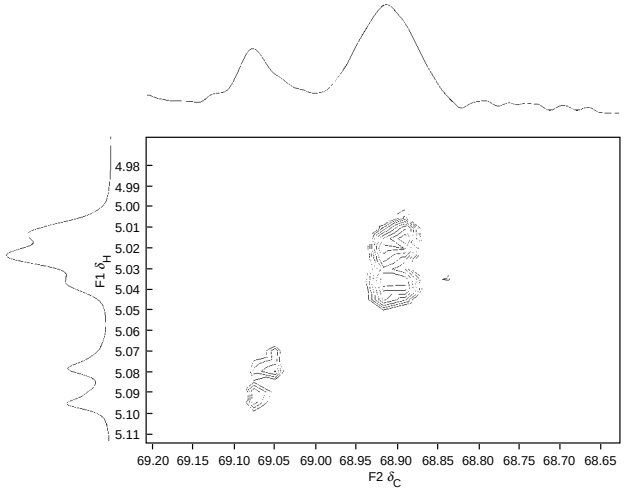

**Fig. 2** HETCOR spectrum showing the correlation of the homodecoupled methine protons with the methine carbon signals, $^{13}C\{^1H\}$, of poly(*rac*-lactide) in $CDCl_3$, 27 °C, recorded on a Brüker AM 500

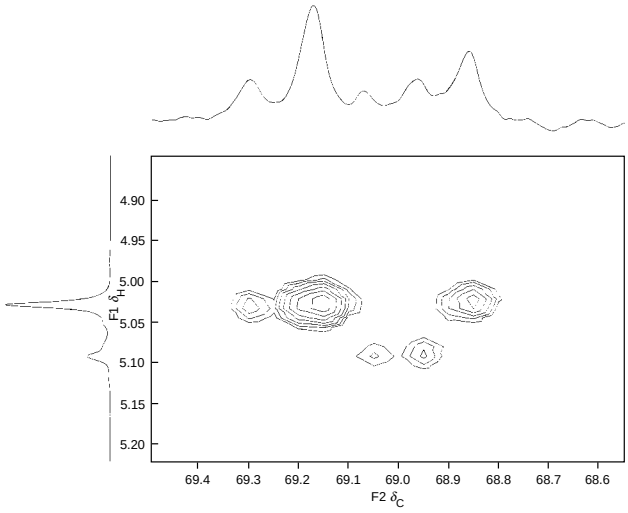

**Fig. 3** HETCOR spectrum showing the correlation of the homodecoupled methine protons with the methine carbon, $^{13}C\{^1H\}$, signals of poly(*meso*-lactide) in $CDCl_3$, 27 °C, recorded on a Varian I 400

correlate the homodecoupled methine protons with the methine carbons. We propose the alternate assignments shown in Fig. 4.

We have worked at field strengths of 400, 500, 600 and 750 MHz ($^1H$) and also employed long range HETCOR experiments. As other workers[12] have pointed out with higher magnetic field strengths resolution at the hexad level becomes possible but only when the correct assignment at the tetrad level is made will this be meaningful and useful in terms of microstructural analysis and in stereochemical preference in polymer formation, *i.e.* kinetic resolution of propagating steps. Work is in progress to elucidate further the microstructure of this polymer and to introduce stereospecificity into the polymer by use of chiral catalysts.

We thank the Department of Energy, Office of Basic Research, Chemical Sciences Division and the Petroleum Research Fund for support and Cargill Co., Minnesota for a gift of a sample of 93 : 7 *meso* : *rac* lactide.

† While the normal representation of m and r can be used in the polylactide system, the authors would like to spare the reader of the possible confusion arising from this nomenclature as the monomers used are also m(eso) and r(acemic). For this reason we choose to use **i** (isotactic) and **s** (syndiotactic).

# The reduction of $Nb_2Cl_6(tmeda)_2$ by $R_2NLi$. Formation of a diamagnetic niobium(II) cluster with short Nb–Nb triple bond and amide C–N bond cleavage

**Maryam Tayebani, Aparna Kasani, Khalil Feghali, Sandro Gambarotta* and Corinne Bensimon**

*Department of Chemistry, University of Ottawa, Ottawa, Ontario, Canada K1N 6N5*

**Reduction of trivalent $Nb_2Cl_6(tmeda)_2$ with either lithium diisopropylamide or *n*-butyllithium yields a novel $Nb^{II}$ cluster which performs oxidative addition into the amide C–N bond.**

Halide complexes of divalent Nb and Ta are particularly rare and limited to a few di- and poly-nuclear structures of halide derivatives mainly bridged by tetrahydrothiophene (THT) ligands.[1] The M–M triple bonds in these species are surprisingly long and thus to evaluate their properties it is important to prepare a variety of multiply bonded systems with the greatest possible diversity of ligand environments.

This work was prompted by the simple idea that low-valent niobium and tantalum amides may be able to form polymetallic structures with or without bridging ligands. The choice of these anions as supporting ligands was advised by their well established ability to stabilize highly reactive medium valent early transition metals.[2] With the dual purpose of bypassing the difficulties arising from the treatment of $MCl_5$ (M = Nb, Ta) starting materials with anionic amides[3] and possible complications arising from their subsequent reduction, and in an attempt to gain some insight into the stability of trivalent Nb and Ta amide, we have now reacted the dinuclear $[MCl_3(tmeda)]_2$ (M = Nb, Ta; tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine)[4] with $R_2NLi$ derivatives. Herein we describe our preliminary findings.

A stoichiometric 1 : 3 ratio of Nb to amide, as well as an extended reflux in thf, was always necessary to complete the reactions of $[NbCl_3(tmeda)]_2$ with RR′NM′ [RR′NM′ = $Ph_2NNa$, $Pr^i_2NLi$, $(C_6H_3Me_2$-3,5)(Ad)NLi (Ad = adamantyl)] and to avoid the presence of unreacted starting materials in the reaction mixtures. However, in the particular case of LDA (lithium diisopropylamide) the reaction was completed in a few hours at room temp. After suitable work-up, well formed, dark-brown, and air-sensitive crystals of a new diamagnetic product were isolated in poor yield. The IR and the NMR of the crystalline product clearly indicated that the complex contained two non-equivalent tmeda ligands. The presence of lithium, suggested by qualitative flame tests, was confirmed by $^7$Li NMR spectroscopy. Combustion analysis data were in agreement with the formulation $(tmeda)_3Nb_2Cl_5Li$ **1**. An X-ray structure confirmed the formula and elucidated the molecular connectivity (Fig. 1).†

The crystal structure of **1** provides a rare example of a dinuclear niobium(II) complex. The diamagnetism and the very short Nb–Nb distance [Nb–Nb 2.4001(5) Å], suggest the

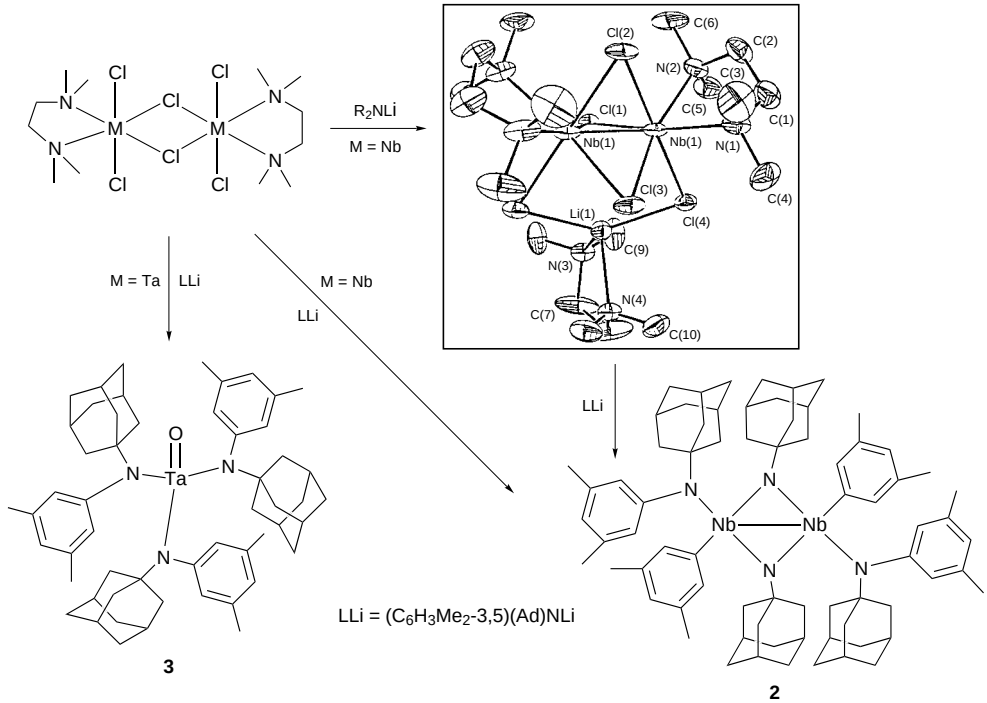

**Fig. 1** Selected bond distances (Å) and angles (°) for complex **1**: Nb(1)–Nb(1a) 2.4001(5), Nb(1)···Li(1) 3.217(8), Nb(1)–Cl(1) 2.5712(9), Nb(1)–Cl(2) 2.579(1), Nb(1)–Cl(3) 2.569(1), Nb(1)–Cl(4) 2.5583(9), Nb(1)–N(1) 2.390(2), Nb(1)–N(2) 2.366(3), Li(1)–Cl(4) 2.489(3), Li(1)···Cl(3) 2.840(8), Li(1)···Cl(1) 3.031(9), Li(1)–N(3) 2.199(9), Li(1)–N(4) 2.162(9), Cl(1)–Nb(1)–Cl(2) 95.90(3), Cl(1)–Nb(1)–Cl(3) 108.13(3), Cl(1)–Nb(1)–Cl(4) 84.39(3), Cl(1)–Nb(1)–N(1) 165.65(8), Cl(1)–Nb(1)–N(2) 85.83(7), Cl(2)–Nb(1)–Cl(3) 95.28(4), Cl(2)–Nb(1)–Cl(4) 84.16(3), Cl(2)–Nb(1)–N(1) 86.24(8), Cl(2)–Nb(1)–N(2) 85.45(8), Cl(3)–Nb(1)–Cl(4) 84.16(3), Cl(3)–Nb(1)–N(1) 85.73(8), Cl(3)–Nb(1)–N(2) 165.82(7), Cl(4)–Nb(1)–N(1) 93.60(8), Cl(4)–Nb(1)–N(2) 95.06(8), N(1)–Nb(1)–N(2) 80.2(1).

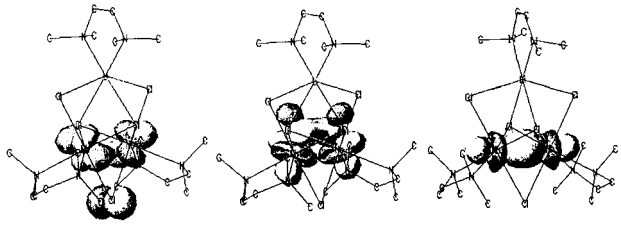

**Fig. 2** Pictorial view of the frontier orbitals of **1**

presence of a Nb–Nb triple bond.[5] However, the shortness of the intermetallic distance contrasts with those of the few previously reported divalent diniobium or ditantalum THF bridged complexes,[1] whose unusually long M–M distances were ascribed to an intrinsic weakness of the metal–metal bonds.[1b] Theoretical calculations carried out on the atomic crystallographic coordinates of **1** show that the three highest occupied molecular orbitals are mainly Nb–Nb centered with a metal atom contribution of predominantly d-orbital character and a minor but significant contribution from the p orbitals of the bridging chlorine atoms. The HOMO–LUMO gap (0.53 eV) is rather small yet sufficient to account for the observed diamagnetism in solution. The three MOs are formed by the overlap of hybrid atomic orbitals of the two niobium atoms. The shape of the HOMO (Fig. 2) is reminiscent of a M–M δ bond while the LUMO (−10.32 eV) is the corresponding out-of-phase combination. The next occupied molecular orbital, located at −11.24 eV is also M–M centered and has some π-bond character, while the third next orbital (−12.17 eV) is a regular σ bond lying symmetrically on the intermetallic vector. At this stage is not clear which factor (electronic or steric) is responsible for the short Nb–Nb distance. Certainly, we cannot rule out the possibility that the lithium cation may ultimately determine the intermetallic distance by bringing together the two vertices of the two octahedra.

The reduction of the metal center to the divalent state by LDA implies that the amide acted as a strong reductant.[6] Thus, it was possible to prepare **1** in higher yield by simply reacting $[NbCl_3(tmeda)]_2$ with 2 equiv. of $Bu^nLi$ in ether and in the presence of a small excess of tmeda. Even though the ability of amides to act as reductants is documented in the literature,[7] the fact that the same reaction with $Ph_2NNa$ (instead of LDA) gave the tetravalent derivative $(Ph_2N)_4Nb$ (45%)[8] suggests that the reduction of the metal center during the formation of **1** might occur through the disproportionation of an unstable niobium(III) intermediate. In addition, the reaction of $[NbCl_3(tmeda)]_2$ with $(C_6H_3Me_2$-3,5)(Ad)NLi yielded the tetravalent, dinuclear and diamagnetic $[C_6H_3Me_2$-3,5(Ad)N]Nb(3,5-$Me_2Ph)\}_2(\mu$-NAd)$_2\cdot 2Et_2O$ **2** (Fig. 1).† However, this product is likely to be originated by the further reaction of **1** with the lithium amide (the reaction requires reflux in thf for several hours in this case) to form a transient $[(C_6H_3Me_2$-3,5)(Ad)N]$_2$Nb species which generates **2** *via* oxidative addition into the C–N bond of the amide function.[9] Accordingly, direct reaction of **1** with 2 equiv. of $(C_6H_3Me_2$-3,5)(Ad)NLi also gave complex **2** in crystalline form.

The reaction of $[TaCl_3(tmeda)]_2$ with amides took a different pathway. While the majority of these reactions led to intractable materials, in the case of the reaction with $(C_6H_3Me_2$-3,5)(Ad)NLi the pentavalent $[(C_6H_3Me_2$-3,5)(Ad)N]$_3$Ta(O) **3** was isolated and characterized.‡ The complex is likely to be originated by the reaction of the initially formed $[(C_6H_3Me_2$-3,5)(Ad)N]$_3$Ta species with thf since reactions carried out in different solvent led to different results. This hypothetical intermediate obviously possesses a greater stability with respect to the niobium analogue and performs a two-electron reduction of thf. Accordingly, significant amounts of $CH_4$ and $CH_3CH_3$ (27 and 31%, respectively based on Ta) were recovered from the reaction mixture (Toepler pump and GC combined experiments).

**Thin films containing up to 30% endohedral Li@$C_{60/70}$ are dissolved in $CS_2$ and the purified endohedral material is isolated by HPLC.**

We have recently reported a new, general method for producing endohedral metal fullerenes using low-energy ion bombardment of fullerene films. The method has the advantage of limiting the endohedral species to one particular product, determined by the deposited fullerene film (in our case $C_{60}$ or $C_{70}$) and the ion used for the bombardment. We have shown that it is possible to produce films of a few hundred nanometres thickness which contain *ca.* 30% Li@$C_{60}$, as determined by laser desorption mass spectrometry (LD-TOF).[1,2] The efficiency of the method drops for larger alkali metals but the films still contain of the order of a few percent endohedrals.[2] The Li@$C_{60}$ films have been characterised by LD-TOF,[1,2] IR[1,3] and Raman spectroscopy[3] which all give convincing evidence for the endohedral nature of the product.

Here we show that it is possible to dissolve these endohedral films and to chromatographically purify the material. This will enable a full characterisation of the electronic and optical properties of these new materials to be carried out.

The method by which the thin films containing Li@$C_{60/70}$ are produced has been described in detail before.[2] Films of 400 nm thickness and surface areas of *ca.* 4 $cm^2$ were produced by successively depositing monolayers of fullerenes and ions on a conducting substrate. The ion energy was 30 eV which has been shown previously to produce the maximum amount of endohedral fullerenes.[2] Films were produced either with a Li : fullerene ratio of 6 : 1 which converts *ca.* 25–30% of the fullerenes in the film to endohedrals, or a ratio of 1 : 1 which converts *ca.* 4–6%, as determined by LD-TOF.[2]

We investigated many solvents for dissolving the films containing endohedral species and found $CS_2$ to yield the best results. The films could also be partly dissolved using pyridine and aniline. In both cases, in contrast to the results with $CS_2$, the endohedral species were more dominant than the empty $C_{60}$ in the solutions.

Once the films have been initially dissolved in $CS_2$ the dissolved material can be redissolved in a wide range of typical fullerene solvents.

The standard procedure used to dissolve the films was to place them in $CS_2$ and treat them with ultrasonic irradiation for 3 h. The $CS_2$ extract obtained was filtered through a 0.45 μm membrane. According to LD-TOF data the filtered solution contained only $C_{60}$ and Li@$C_{60}$. Analysis showed that up to 25% of the film material was dissolved in the $CS_2$ for the films produced with an ion to fullerene ratio of 6 : 1 increasing to over 90% for the films produced with a 1 : 1 ratio. The remaining non-dissolved material contained relatively more endohedral species with respect to empty fullerenes than the initial film and the resulting solution.

The HPLC separation of the $CS_2$ solutions was carried out using either a Cosmosil 5PBB analytical column or a Buckyprep column. Fig. 1 shows the chromatogram obtained from a 6 : 1 film with detection set at 405 nm, $CS_2$ eluent and a flow rate of 1.0 ml $min^{-1}$. Three well defined peaks (denoted as fractions **1**, **2** and **3**, respectively) can be clearly seen. The separated fractions were analyzed by LD-TOF (Brucker Biflex mass spectrometer with a 337 nm $N_2$ laser, detection of positive ions). As can be seen in the LD-TOF mass spectrum shown at the top of Fig. 2, the chromatographic fraction **1**, with the retention time of 4.5 min, corresponds to $C_{60}$, whereas the fractions **2** and **3**, with retention times peaking at *ca.* 5.8 and 7.9 min, respectively, can both be assigned to species comprised of Li@$C_{60}$. The latter fractions show small $C_{60}$ peaks in the mass spectra accompanied by very strong signals due to the endohedral Li@$C_{60}$. We have investigated the dependence of the relative intensity of peaks **2** and **3** on the amount of endohedral material in our sample. Fig. 1 was produced under conditions where we obtain the maximum yield of endohedral Li@$C_{60}$ (*ca.* 30% of the fullerenes in the film containing Li).[1] This corresponds to an ion energy of 30 eV and a ratio of $Li^+ : C_{60}$ of 6 : 1. If we reduce this ratio we obtain a smaller percentage of endohedral compounds in our films but better solubility. Practically all of the 'empty' fullerenes and a large proportion of the endohedral compounds could be dissolved from the films produced with $Li^+ : C_{60}$ = 1 : 1. We have carried out experiments for a range of $Li^+ : C_{60}$ ratios and been able to show that the relative intensity of peak **2** to peak **3** correlates very clearly with the percentage of endohedral compounds in the films. Fraction **3** is, however, less stable in solution over a timescale of a few days and its concentration decreases with respect to that of fraction **2**. The mass spectra obtained from the 1 : 1 fractions are very similar to those in Fig. 2 but have relatively more 'empty' $C_{60}$ (*ca.* 1 : 2 $C_{60}$ : Li@$C_{60}$). This may be due to the tail of the much larger $C_{60}$ fraction.

With $C_{70}$ we see only one clearly separated fraction which contains endohedral species. The HPLC retention time for this fraction as well as its LD-TOF mass spectrum and its long-time stability in solution are consistent with the $C_{60}$ results for fraction **3**.

The material was further purified by passing the separated fractions through a Buckyprep column with toluene–DCB eluent (11 : 1) which gives a better resolution of the peaks. The results are shown in Fig. 3. It should be noted that these chromatograms were obtained with a different wavelength (340

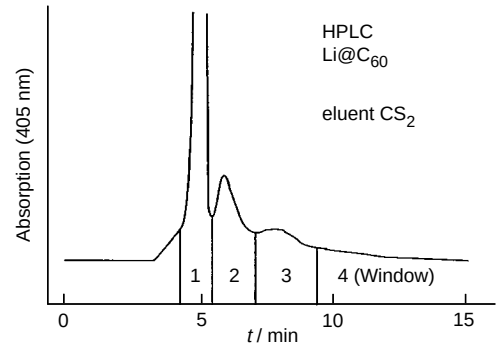

**Fig. 1** HPLC peak profiles of the $CS_2$ extract from the thin film containing Li@$C_{60}$. Obtained using a Cosmosil 5PBB analytical column, $CS_2$ eluent, 405 nm detection, 1.0 ml $min^{-1}$ flow rate. Thin film produced with $Li^+ : C_{60}$ = 6 : 1.

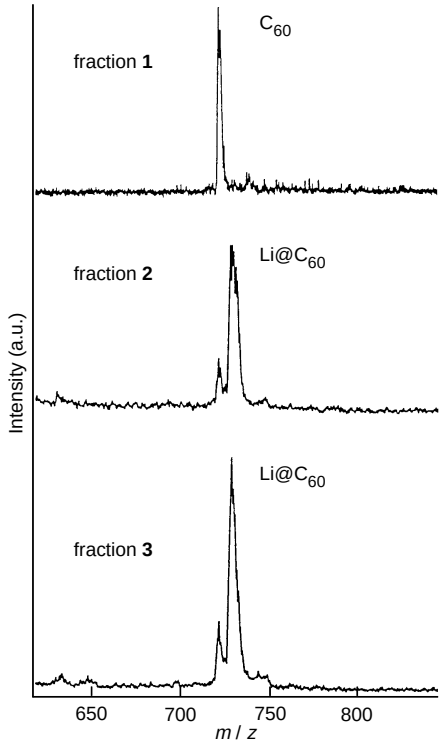

**Fig. 2** LD-TOF mass spectra of fractions **1**, **2** and **3** shown in Fig. 1

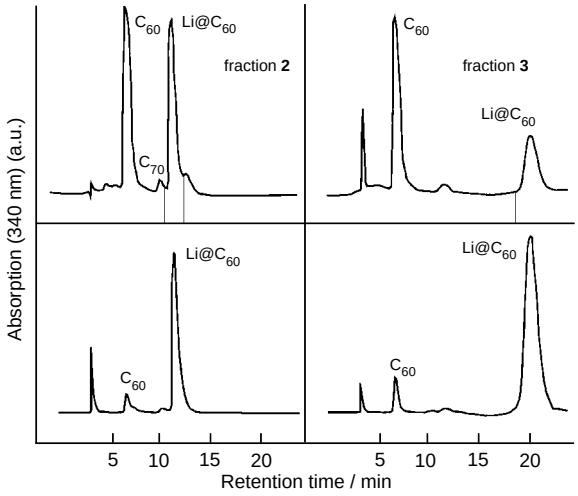

**Fig. 3** HPLC peak profiles of fractions **2** (left hand side) and **3** (right hand side) obtained from the PBB column with $CS_2$ eluent separated in a second stage with a Buckyclutcher column and toluene–DCB eluent (upper part). The endohedral fractions were again collected and separated once more with the Buckyclutcher column and toluene–DCB eluent yielding highly purified compounds (lower part).

nm instead of 405 nm in Figs. 1 and 3) which gives a much larger signal for $C_{60}$ than for the endohedral fractions as can be seen from the UV–VIS spectra of toluene solutions of the three different fractions in Fig. 4. The chromatograms of the endohedral fractions first separated by the PBB column (top half of Fig. 3) both show a fairly large $C_{60}$ peak, however, taking the higher detection efficiency into account, this is in keeping with the mass spectra of fractions **2** and **3** from films produced with a 1 : 1 ratio. Taking the endohedral fractions and

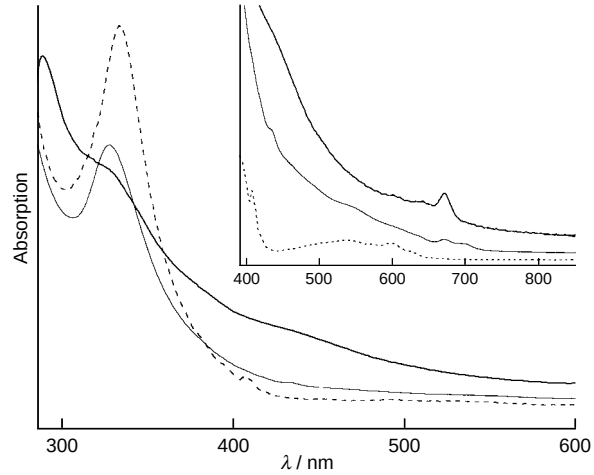

**Fig. 4** UV–VIS spectra of fractions **1**, **2** and **3** dissolved in toluene. Dashed line: fraction **1** ($C_{60}$); thin line: fraction **2**; thick line: fraction **3**.

again passing them through the Buckyprep column with the toluene–DCB eluent yields the two chromatograms shown in the bottom half of Fig. 3. In this way it is possible to almost completely isolate the Li@$C_{60}$ endohedral fraction.

The reason for having two separable endohedral fractions is not yet clear. Close inspection of the mass spectra reveals that fraction **2** has a considerably broader mass peak indicating the attachment of some H atoms to the fullerene cage. This fraction is also more dominant from films produced with large amounts of Li which also contain a range of interstitial reaction products of the intercalated Li with air. We also have reason to believe that the endohedral molecules show a strong propensity for forming oligomers and it is possible that fraction **2** is a dimer and fraction **3** the isolated monomer species. This is the subject of further work. The UV–VIS spectrum of fraction **2** is consistent with the dimer hypothesis.[4] The optical bands are broadened, reduced in peak intensity and shifted with respect to $C_{60}$. In addition, the typical $C_{60}$ features between 400 and 700 nm are lost and the absorption onset for both endohedral containing fractions lies much further in the IR. It is certainly the case that fractions **2** and **3** are two different chemical species since they have significantly different UV–VIS spectra, as clearly seen in Fig. 4, and also different solubilities and stability in solution. Fraction **2** dissolves more readily than fraction **3** and is stable in solution over a timescale of many days whereas fraction **3** decreases significantly in intensity.

Financial support from the BMBF (13N6652/7) for the MBI group and from the EU through the HCM network 'Formation, stability and photophysics of fullerenes' is gratefully acknowledged. We would also like to thank Prof. I.V. Hertel for his interest in and encouragement of this project.

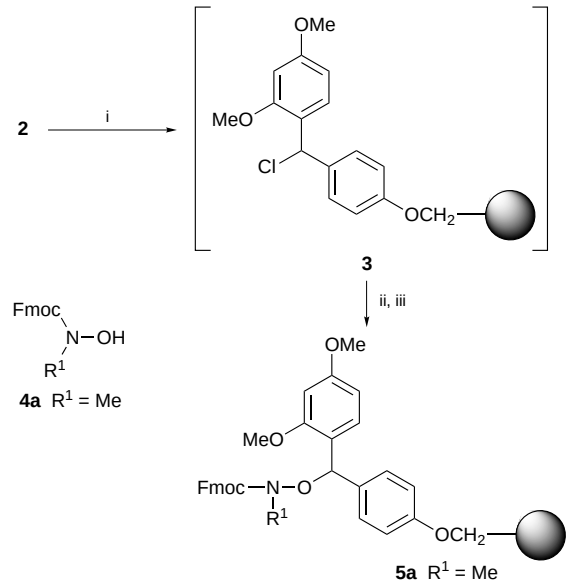
# 4-[2,4-Dimethoxyphenyl(*N*-fluoren-9-ylmethoxycarbonyl-*N*-alkylaminooxy)-methyl]phenoxymethyl polystyrene: a multiple solid-phase approach to *N*-alkylhydroxamic acids

**Sarah L. Mellor and Weng C. Chan***

*Department of Pharmaceutical Sciences, University of Nottingham, University Park, Nottingham, UK NG7 2RD*

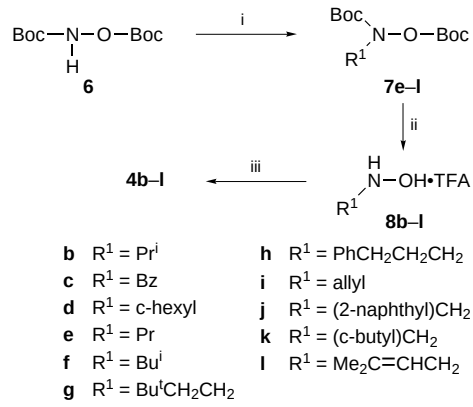
***N*-Fluoren-9-ylmethoxycarbonyl-*N*-alkylhydroxylamines, prepared *via* $K_2CO_3$-catalysed *N*-alkylation of *N*,*O*-bis(*tert*-butoxycarbonyl)hydroxylamine, undergo a highly efficient condensation with 4-[2,4-dimethoxyphenyl(chloro)methyl]-phenoxymethyl polystyrene (PS) to afford 4-[2,4-dimethoxyphenyl(*N*-fluoren-9-ylmethoxycarbonyl-*N*-alkylaminooxy)methyl]phenoxymethyl PS, which is used for the facile synthesis of structurally diverse *N*-substituted hydroxamic acids.**

Peptide hydroxamic acids, *e.g.* actinonin, foroxymithine and matlystatin B, isolated from microorganisms are known to be potent and selective inhibitors of many important metalloproteases.[1] The ability of the hydroxamic acid functionality to form a bidentate chelate with the zinc atom in the enzyme's active site is considered to be an important functional feature.[1] Recently, exploitation of this concept has led to the design and synthesis of α-alkylmalonyl and 2-phenyloxazoline hydroxamic acids as potent inhibitors of endothelin-converting enzyme and *E. coli* uridine 5′-diphosphate-3-*O*[3*R*)-3-hydroxymyristoyl]-*N*-acetyl-glucosamine deacetylase, respectively.[2]



The implication of combinatorial chemistry for high throughput generation of structurally diverse hydroxamic acids is self evident. Recently, several solid phase approaches for the synthesis of hydroxamic acids have been reported.[3,4] For example, we outlined a facile solid phase procedure using the high-loading resin, *N*-fluoren-9-ylmethoxycarbonylaminooxy-2-chlorotrityl polystyrene **1**.[3] However, these strategies are evidently not applicable for the synthesis of *N*-alkyl hydroxamic acids, which is necessary in order to provide a further dimension in chemical diversity, in a manner analogous to our previously reported[5] peptidyl *N*-alkyl amides. We report herein a novel parallel solid phase strategy to *N*-alkyl hydroxamic acids. The key feature of our strategy is the multiple synthesis of *N*-fluoren-9-ylmethoxycarbonyl-*N*-alkyl hydroxylamines **4**, followed by *O*-alkylation by the unique 4-[2,4-dimethoxyphenyl(chloro)methyl]phenoxymethyl PS **3** to afford 4-[2,4-dimethoxyphenyl(*N*-fluoren-9-ylmethoxycarbonyl-*N*-alkyl-aminooxy)methyl]phenoxymethyl PS **5**.

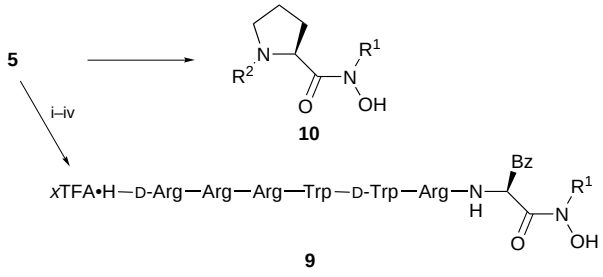
Preliminary investigations suggested that existing solid phase strategies[3,4] could not be adapted for the synthesis of *N*-alkyl hydroxamic acids for two reasons: (i) inefficient (65–80%) reduction was observed with *O*-benzylhydroxylamine-derived oximes using either $NaBH_3CN$ in 30–50% AcOH in MeOH–THF or $BH_3$·THF in THF, and (ii) negligible acylation ( < 5%) of NH(Me)O-2-chlorotrityl PS[3] was achieved as a result of considerable steric effect. In view of these results, we focused our efforts in the development of a new linker resin.



The acidolysis of 4-[2,4-dimethoxyphenyl(hydroxy)methyl]-phenoxymethyl PS **2** and its esters is well documented,[6] and since the linker group in **2** has significantly less steric hindrance than 2-chlorotrityl, we have established a facile solid phase procedure to the new linker resin **5** starting with commercially available **2**† (Scheme 1). Following evaluation of a series of chlorinating reagents and conditions, the conversion of **2** to the chloride **3** is best achieved by a simple $S_N1$ approach. Thus, treatment of **2** with 1% HCl in $CH_2Cl_2$–THF under continuous flow conditions gave **3** with typically *ca.* 70% efficiency.‡ In initial model experiments, the condensation of **3** with FmocN-(Me)OH[3] **4a** proceeded smoothly to afford **5a** with *ca.* 95% efficiency (0.38 mmol $g^{-1}$).† Any remaining reactive sites on the linker resin were 'eliminated' by treatment with MeOH and $Ac_2O$. We were then able to successfully acylate the Fmoc-deprotected **5a** with Fmoc-Phe-OH, carboxy-activated using HATU-based[7] method, with 89% efficiency, which on treatment with 1–5% TFA in $CH_2Cl_2$ yielded within 5 min the desired hydroxamic acid, Fmoc-Phe-N(Me)OH, in excellent purity ( > 95%).§

Furthermore, using commercially available **8b**–**d**·HCl, the Fmoc-derivatives **4b**–**d** were synthesized (Scheme 2) using our previously reported procedure[3] in excellent yields (71–86%), which on condensation with **3** yielded **5b**–**d** with good efficiencies (58–92%, 0.20–0.37 mmol $g^{-1}$). As expected, **4b** and **4d** were observed to react with lower efficiencies (58 and 73%, respectively) due to steric hindrance.

In order that the above strategy could be used as a generic solid phase approach to *N*-substituted hydroxamic acids, we went on to investigate synthetic methodology to chemically diverse Fmoc-N($R^1$)OH **4**. Following a systematic study, we have established a facile method to compounds **4** *via* *N*-alkylation of *N*,*O*-bis(*tert*-butoxycarbonyl) hydroxylamine[8,9] **6** in predominantly good overall yields (Scheme 2).¶ The alkylation of **6** was accomplished using the appropriate bromides in the presence of $K_2CO_3$ to furnish **7e**–**l** in typically 78–90% yields. In addition, we have also achieved alkylation of **6** using 3 equiv.



**Scheme 1** *Reagents and conditions*: i, 1% w/v HCl in $CH_2Cl_2$–THF; ii, **4** (1.5 equiv.), $Pr^i_2EtN$ (1.5 equiv.), $CH_2Cl_2$, 18 h; iii, MeOH–$CH_2Cl_2$, 30 min, then $Ac_2O$, $Pr^i_2EtN$, DMF, 4 h

**Scheme 2** *Reagents and conditions*: i, R′Br, $K_2CO_3$, DMF, 18 h; ii, 30% v/v TFA in $CH_2Cl_2$; iii, FmocCl, aq. $NaHCO_3$, 4 h

of a chloride, $Me_3C(CH_2)_2Cl$ in the presence of $K_2CO_3$ (1.25 equiv.) in DMF at 55 °C for 72 h, to give **7g** in 68% yield. The key building blocks **4e**–**l** were then readily obtained by, firstly, deprotection of **7e**–**l** with 30% v/v TFA–$CH_2Cl_2$, followed by introduction of the *N*-Fmoc protecting group using FmocCl to yield crystalline **4e**–**l** (65–81%).¶ In all cases, we observed high reaction efficiencies (78–97%) between **4e**–**l** and **3** to afford our key linker resins **5e**–**l** (0.26–0.30 mmol $g^{-1}$; 0.23 mmol $g^{-1}$ for **5j**.† In addition, the Fmoc-deprotected **5e**–**l** were readily acylated with HATU-activated Fmoc-Phe-OH (18 h) to yield the resin-bound Fmoc-Phe-(Fmoc-deprotected) **5e**–**l** in typically 93–100% yield, upon which 5% TFA-mediated cleavage afforded exclusively the desired hydroxamic acids Fmoc-Phe-N($R^1$)OH (> 95% purity judged by RP-HPLC§).

The utility of **5** was further illustrated by the synthesis of the model heptapeptidyl *N*-alkyl hydroxamic acids **9** (Scheme 3), using standard solid phase peptide chemistry.[10] The assembled peptidyl-(Fmoc-deprotected) **5e**–**l** following a two-step TFA treatment yielded **9e**–**l** in excellent purity and yield (80–90%).§ In addition, **5** was used for the solid phase synthesis of a biased 'small molecule' library comprising the generic template $N^1$-alkyl/acyl imino acyl *N*-alkyl hydroxamic acids, *e.g.* **10**; the $N^1$-alkylation step was typically accomplished using 4 equiv. of an alkyl bromide in the presence of 1 equiv. of DBU.

**Scheme 3** *Reagents and conditions*: i, 20% piperidine–DMF; ii, Fmoc-Phe-OH–HATU–HOAt–$Pr^i_2EtN$ (1 : 1 : 1 : 2, 10 equiv., *ca*. 0.3 M in DMF], 18 h; iii, standard Fmoc/$Bu^t$ solid-phase procedures (2.5 h acylation); iv, TFA–$Et_3SiH$–$CH_2Cl_2$ (5 : 1 : 94), 5 min, then TFA–$Pr^i_3SiH$–$HSCH_2CH_2SH$–$H_2O$ (90 : 1 : 4 : 5), 4 h, 30 °C

In summary, we have outlined a facile solid phase approach to *N*-substituted hydroxamic acids *via* the new linker resin **5** prepared from readily accessible building blocks **4**. The strategy allows the cleavage of target molecules from the solid support under exceptionally mild acidic conditions. The synthesized compounds **9** and **10** are currently being evaluated for biological activity.

† Compound **2** has a chemically reactive hydroxy loading of either 0.54 or 0.64 mmol $g^{-1}$. The derivatised resin loading is based on spectrophotometric determination of the Fmoc-derived chromophore liberated upon treatment with 20% piperidine–DMF using $\varepsilon_{290}$ = 5253 $M^{-1}$ $cm^{-1}$.

‡ The following reaction was performed using oven-dried glasswares. A solution of *ca*. 1% w/v HCl was prepared by the addition of $SOCl_2$ (2.50 ml) to THF–$CH_2Cl_2$(1 : 3, 100 ml) followed by MeOH (1.25 ml). The resin **2** (0.5 mmol), suspended in $CH_2Cl_2$ in a glass column (15 × 150 mm), was treated with the 1% w/v HCl solution (100 ml) at *ca*. 4 ml $min^{-1}$ and washed with $CH_2Cl_2$ (20 ml), THF–$CH_2Cl_2$ (5 ml) and $CH_2Cl_2$ (20 ml) to afford **3**, which was used immediately. To the suspension of **3** in $CH_2Cl_2$ (*ca*. 6 ml) was added **4** (0.75 mmol) followed by $Pr^i_2EtN$ (0.13 ml, 0.75 mmol), and the resultant mixture was gently stirred at ambient temperature overnight to yield **5**. MeOH (0.2 ml) was added to the reaction mixture, stirred for 30 min and the resin was then washed with DMF (30 ml). The resin, now suspended in DMF, was treated with $Ac_2O$ (5 mmol)–$Pr^i_2EtN$ (0.5 mmol) for 4 h, after which the resin was washed with DMF, filtered off, washed repeatedly with $CH_2Cl_2$ and MeOH, and dried *in vacuo*. The chloride loading in **3** was determined using an acid–base back-titration procedure.

§ Crude hydroxamic acids **9** and **10** were analysed by RP-HPLC on a Hypersil Pep $C_{18}$ columnn (4.6 × 150 mm). All purified synthetic compounds gave the expected ES-MS, *e.g.* **9d**: calc. $M^+$ 1259.52, found 1258.38; **9g**: calc. 1261.54, found 1261.34; **9h**: calc. 1295.54, found 1294.95; **10f** ($R^2$ = $CH_2CH_2CH_2Ph$): calc. $MH^+$ 305.43, found 305.3; **10k** [$R^2$ = $CH_2$(2-naphthyl)]: calc. $MH^+$ 339.44, found 339.5.

¶ A typical procedure for the synthesis of *N*-fluoren-9-ylmethoxycarbonyl-*N*-alkyl hydroxylamine FmocN(Php)OH **4h**: To a solution of **6** (5 mmol) in DMF (10 ml) was added $K_2CO_3$ (6.25 mmol) followed by portionwise addition of 1-bromo-3-phenylpropane (5.2 mmol), and the resultant mixture was vigorously stirred at room temperature overnight. Following a standard work-up procedure trituration with ice-cold pentane yielded **7h** (1.58 g, 90%) as a white crystalline solid [mp 75–76 °C; > 95% purity when analysed by RP-HPLC; ES-MS : $MH^+$ calc. 352.45, found 352.3].

A solution of **7h** (4 mmol) in TFA–$CH_2Cl_2$ (3 : 7, 10 ml) was left at ambient temperature for 3–4 h, and then evaporated to dryness to yield **8h** (1.05 g, 99%; mp 67–69 °C), which was dried *in vacuo* over KOH pellets and used without further purification.

Compound **4h** was obtained by treating a solution of **8h** in EtOAc–aq. $NaHCO_3$ (2.2 equiv.) with FmocCl (1.1 equiv.) using the procedure previously outlined (ref. 3) in 67% yield [mp 84–86 °C; $\delta_H$($CDCl_3$, 250 MHz) 1.98 (2 H, m, Php $CH_2CH_2CH_2N$), 2.64 (2 H, t, *J* 7.8, Php $CH_2CH_2CH_2N$), 3.59 (2 H, t, *J* 7.0, Php $CH_2CH_2CH_2N$), 4.26 (2 H, t, *J* 6.7, Fmoc C*H*), 4.50 (2 H, d, *J* 6.7, Fmoc $CH_2$), 7.12–7.47, 7.56, 7.81 (13 H, Fmoc and Ph ArH); ES-MS : $MH^+$ calc. 374.45, found 374.4].

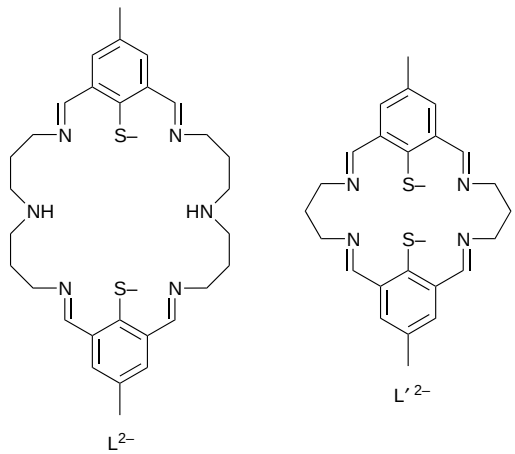
# First observation of non-bridging thiolates or tetrahedral geometries within thiolate-containing Schiff-base macrocycles: $[Zn_2L][CF_3SO_3]_2$



**Sally Brooker* and Tony C. Davidson**

*Department of Chemistry, University of Otago, PO Box 56, Dunedin, New Zealand*

**The structure determination of $[Zn_2L][CF_3SO_3]_2$ 1 reveals the first example of non-bridging thiolates within a thiolate-containing Schiff-base macrocyclic complex: the flexibility of such macrocycles is also clearly demonstrated as this is the first example of the provision of distorted tetrahedral metal ion binding sites.**

Thiolate-containing complexes are currently of great interest as model complexes for a number of metalloprotein active sites such as Fe–S clusters,[1] Ni–Fe hydrogenase,[2] $Cu_A$ site of cytochrome c oxidase[3] and Zn fingers.[4] The complexes are also of interest in their own right as they exhibit very different properties to those of complexes with other, more common donors such as oxygen or nitrogen. We have therefore incorporated the 'head unit' *S*-(2,6-diformyl-4-methylphenyl)dimethylthiocarbamate, which contains a masked thiolate, into a series of Schiff-base macrocycles:[5–7] the thiolate donor is best generated from the masked 'head unit' by base hydrolysis prior to the cyclisation reaction.[6] To date, the reported di- and tetra-nuclear Schiff-base macrocyclic complexes formed from this unmasked thiolate have exhibited a wide range of geometries, albeit predominantly square-based ones: from square planar, square pyramidal and octahedral through to one example of trigonal bipyramidal.[5–9] In all of the examples to date the thiolate donors bridge the two metal ions. Here we describe the synthesis and structure of a new dinuclear Schiff-base macrocyclic complex which exhibits very different features.

Hydrolysis of *S*-(2,6-diformyl-4-methylphenyl)dimethylthiocarbamate with NaOH, followed by reaction with *N*-(3-aminopropyl)-1,3-propanediamine in the presence of zinc(II) template ions, yields a yellow powder, $[Zn_2L][CF_3SO_3]_2$ **1**, in 85% yield (Scheme 1).† The IR spectrum of **1** was consistent with the presence of a Schiff-base macrocycle; an imine band was present at 1633 $cm^{-1}$ and there were no primary amine or carbonyl bands. Based on the geometry we observed for the zinc ions in a related macrocyclic complex $[Zn_2L'(H_2O)_2]^{2+}$ **2** (Scheme 1) we expected that the zinc ions in this new complex might also be trigonal bipyramidal, but that now *all* of the donors could be supplied by the macrocycle.[6] To test this proposal a structure determination was carried out on **1**.

**Scheme 1** Ligands $L^{2-}$ and $L'^{2-}$

Yellow single crystals were obtained by diethyl ether diffusion into an acetonitrile solution of **1**.‡ The X-ray structure determination revealed, in contrast to the predicted trigonal-bipyramidal geometry, the first example of a thiolate-containing Schiff-base macrocyclic complex containing metal ions with a distorted tetrahedral geometry (Fig. 1). Each of the two zinc atoms is bound to a single thiolate donor, two imine nitrogen donors and an amine nitrogen donor, and has adopted an approximately tetrahedral geometry. Tetrahedral coordination of zinc ions in mixed thiolate/nitrogen coordination environments is not uncommon[10] and presumably a trigonal-bipyramidal geometry is not observed in this case due to an unfavourable spatial arrangement of the required donors, due to the constraint of them all coming from a single polydentate macrocyclic ligand.[11] Another unique feature of this structure is that the thiolate donors do not bridge the two metal ions. This is in stark contrast with all of the related macrocyclic complexes prepared to date,[5–9,12] and with the well known ability of thiolates to bridge metal ions, a feature of thiolate chemistry which has often resulted in the uncontrolled (and usually undesired) formation of polymers.[13] We have found that the use of thiolate-containing macrocycles has allowed us to control this aspect of thiolate coordination chemistry (as well as a number of other common problems)[6,13] and has thus facilitated the formation of discrete complexes where the thiolate donors only bridge between the metal ions incorporated in the macrocycle.[5–7] However, in this new macrocyclic complex there is no thiolate bridging whatsoever.

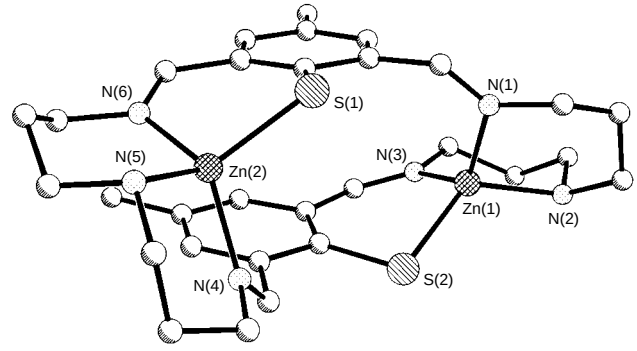


**Fig. 1** Perspective diagram of the cation of **1**, $[Zn_2L]^{2+}$. Selected bond lengths (Å) and angles (°): Zn(1)–N(3) 2.007(7), Zn(1)–N(1) 2.024(8), Zn(1)–N(2) 2.031(8), Zn(1)–S(2) 2.254(3), Zn(2)–N(6) 2.001(7), Zn(2)–N(4) 2.032(7), Zn(2)–N(5) 2.036(8), Zn(2)–S(1) 2.253(2), S(1)···S(2) 4.516(3), Zn(1)···Zn(2) 6.077(2); N(3)–Zn(1)–N(1) 126.1(3), N(3)–Zn(1)–N(2) 100.3(3), N(1)–Zn(1)–N(2) 98.6(3), N(3)–Zn(1)–S(2) 100.2(2), N(1)–Zn(1)–S(2) 108.5(2), N(2)–Zn(1)–S(2) 125.5(3), N(6)–Zn(2)–N(4) 123.9(3), N(6)–Zn(2)–N(5) 100.6(3), N(4)–Zn(2)–N(5) 98.6(3), N(6)–Zn(2)–S(1) 100.3(2), N(4)–Zn(2)–S(1) 110.5(2), N(5)–Zn(2)–S(1) 124.7(2), C(1)–S(1)–Zn(2) 99.7(3), C(16)–S(2)–Zn(1) 99.6(3).

The macrocycle has clearly adopted a very different conformation to those observed previously and in so doing reveals considerable flexibility. The use of an aromatic thiolate 'head unit' has allowed the formation of π–π interactions to influence the overall structure.[14] Specifically, favorable π–π interactions exist between the two aromatic rings within the macrocyclic unit: the two aromatic ring planes intersect at 6.8° and are 3.32–3.62 Å apart. Intermolecular π–π interactions are also observed and lead to the molecules packing together in chains. The two monodentate thiolate donors are relatively exposed but intermolecular bridging does not occur. The two triflate anions hydrogen bond to the two secondary amines (O···N 2.85, 2.89 Å), and destroy the otherwise approximate twofold symmetry of the complex.

Molar conductance measurements show that **1** is a 2:1 electrolyte in dimethylformamide (dmf) indicating that the cation $[Zn_2L]^{2+}$ is present in solution. $^1H$ and $^{13}C$ NMR spectra were obtained in both $[^2H_7]$dmf and $CD_3CN$. In each case the imine, aromatic and methylene resonances are chemically inequivalent which is consistent with the maintenance of the solid-state structure in solution. Preliminary cyclic voltammetry studies in MeCN show that **1** undergoes an irreversible, approximately two-electron, oxidation at $E_{pa}$ = +1.03 V *vs.* 0.01 M $AgNO_3$/Ag. This behaviour is very similar to that of complex **2** and is currently under further investigation.[6,7]

In summary, we have prepared a new thiolate-containing macrocyclic ligand, as a dizinc(II) complex, and it has very different characteristics from previous thiolate-containing Schiff-base macrocycles. Transmetallations and attempts to induce the thiolates to bridge to introduced metal ion complexes are underway. Further development of this and related systems will provide excellent opportunities to manipulate both the bridging tendency of the incorporated thiolates and the geometries adopted by the incorporated metal ions, giving us, in a controlled way, access to complexes of our own design.[7]

This work was supported by grants from the University of Otago. We thank Professor W. T. Robinson (University of Canterbury) for the X-ray data collection. S. B. thanks the University of Otago for the granting of study leave which has facilitated the writing of this paper, and gratefully acknowledges her host Professor K. Wieghardt and the financial support of the Alexander von Humboldt Stiftung.

**The high-nuclearity mixed-metal carbonyl clusters $[Os_5Pd_6(CO)_{13}(\mu\text{-}CO)_5(\mu\text{-}H)_2(\mu\text{-}dppm)_2]$ 1 and $[Os_5Pd_6(CO)_{13}(\mu\text{-}CO)_6(\mu\text{-}dppm)_2]$ 2 are synthesized from the reaction of $[Os_3(CO)_{10}(\mu\text{-}H)_2]$ with $[Pd_2(\mu\text{-}dppm)_2Cl_2]$; their molecular structures are determined by X-ray analysis.**

High-nuclearity mixed-metal clusters have attracted considerable interest due to their novel structural features and interesting chemical and physical properties.[1] Most of these mixed-metal clusters are the combination of late transition metals. For examples, Fe/Pd,[2] Fe/Pt,[3] Fe/Cu,[4] Ru/Pt,[5] Ru/Cu,[6] Os/Pt,[7] Os/Hg,[8] Co/Hg,[9] Rh/Ni,[10] Rh/Pt,[11] Ni/Pt[12] are well established. However, mixed-metal clusters of osmium and palladium are relatively rare.[13] We recently established some reliable synthetic routes to osmium and palladium mixed-metal clusters. These systems are all osmium rich. Herein we report the synthesis and structural characterization of two novel high-nuclearity Os/Pd mixed-metal carbonyl clusters containing an essentially, identical metal core.

The reaction of $[Os_3(CO)_{10}(\mu\text{-}H)_2]$ with a slight excess of $[Pd_2(\mu\text{-}dppm)_2Cl_2]$ in $CH_2Cl_2$ at room temp for 6 h affords two new osmium–palladium clusters: dark green $[Os_5Pd_6(CO)_{13}(\mu\text{-}CO)_5(\mu\text{-}H)_2(\mu\text{-}dppm)_2]$ **1** and brownish–green $[Os_5Pd_6(CO)_{13}(\mu\text{-}CO)_6(\mu\text{-}dppm)_2]$ **2** in 5 and 10% yields respectively. The major products isolated from this system are phosphine containing clusters $[Os_3(CO)_8(\mu\text{-}dppm)]$ (23%) and $[Os_4(CO)_{10}(\mu\text{-}dppm)]$ (18%) (confirmed by IR and $^1$H NMR spectroscopy). Both clusters **1** and **2** were isolated as air-stable solids upon thin layer chromatographic separation on silica. Spectroscopic† and analytical data are consistent with their formulations. In order to establish their molecular structures, X-ray analyses have been carried out on single crystals of **1** and **2**.‡ Suitable crystals of **1** and **2** were obtained as dark green prisms **1** and brownish–green blocks **2**, using $CH_2Cl_2$–*n*-hexane mixture at 0 °C for a period of 2 weeks, respectively. Clusters **1** and **2** were found to have an essentially identical metal core, see Fig. 1. Their full structures are depicted in Fig. 2 and Fig. 3 together with some important bond parameters. The cluster core geometry of **1** and **2** may be viewed as an 'inner' $Pd_6$ bicapped tetrahedron with several triangular faces asymmetrically capped by Os(1), Os(2), Os(4) and Os(5) on Pd(1)Pd(2)Pd(3), Pd(2)Pd(3)Pd(5), Pd(3)Pd(4)Pd(5) and Pd(4)Pd(5)Pd(6) respectively. In addition, the Os(3) capped onto Os(2)Pd(2)Pd(5) so that the cluster cores become asymmetric or otherwise a twofold axis is possible. The only significant Os–Os interaction is observed between Os(2) and Os(3) [3.0074(7) Å in **1** and 2.8861(9) Å in **2**]. This metal framework can be viewed as a distorted fragment of three close-packed layers of metal atoms and is unprecedented in both homo- and hetero-metallic clusters containing osmium. Of the 18 carbonyl groups in cluster **1**, 13 are terminally bonded and 5 are bridging the Os–Pd bonds. In **2**, the CO distributions are almost identical to that observed in **1**, except for an extra bridging C(10)–O(10) across Os(3)–Pd(5). In **1**, there are two hydride ligands. This was as evident from the $^1$H NMR spectroscopy. However, their positions cannot be determined by X-ray analysis directly. Detailed examination of the CO disposition on the ligand envelope and metal–metal bond distances suggested that one may bridge across the Os(2)–Pd(2) edge while the other one may bridge across Os(2)–Os(3). Both of these metal–metal distances are significantly longer than those observed in **2** where no hydride ligands are present.

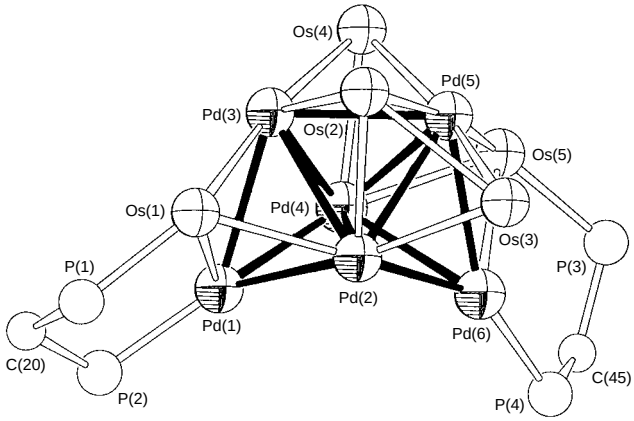

**Fig. 1** The metal core geometry of **1** and **2**

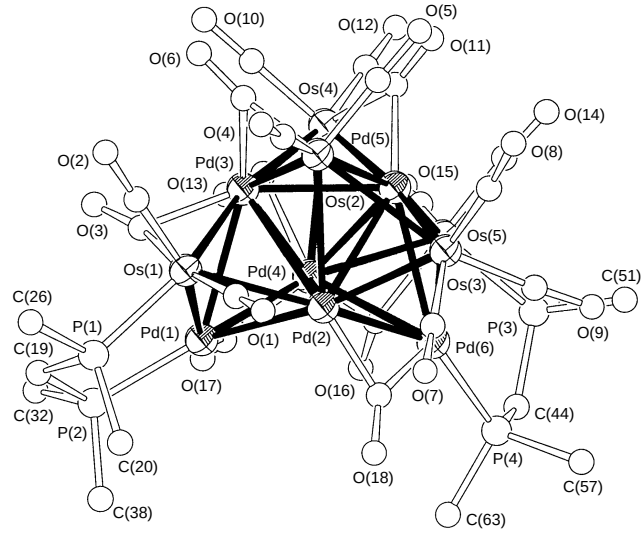

**Fig. 2** The molecular structure of **1** showing the atom numbering scheme (phenyl rings are omitted for clarity). Selected bond lengths (Å): Os(1)–Pd(1) 2.935(1), Os(1)–Pd(2) 2.833(1), Os(1)–Pd(3) 2.834(1), Os(2)–Os(3) 3.0074(7), Os(2)–Pd(2) 3.024(1), Os(2)–Pd(3) 2.725(1), Os(2)–Pd(5) 2.779(1), Os(3)–Pd(2) 2.774(1), Os(3)–Pd(5) 2.831(1), Os(4)–Pd(3) 2.890(1), Os(4)–Pd(4) 2.852(1), Os(4)–Pd(5) 2.730(1), Os(5)–Pd(4) 2.791(1), Os(5)–Pd(5) 3.030(1), Os(5)–Pd(6) 3.116(1), Pd(1)–Pd(2) 2.893(2), Pd(1)–Pd(3) 2.943(2), Pd(1)–Pd(4) 2.707(2), Pd(2)–Pd(3) 2.918(1), Pd(2)–Pd(4) 3.097(2), Pd(2)–Pd(5) 2.877(2), Pd(2)–Pd(6) 2.683(1), Pd(3)–Pd(4) 2.759(1), Pd(3)–Pd(5) 2.853(2), Pd(4)–Pd(5) 2.923(2), Pd(4)–Pd(6) 3.013(2), Pd(5)–Pd(6) 2.988(1).

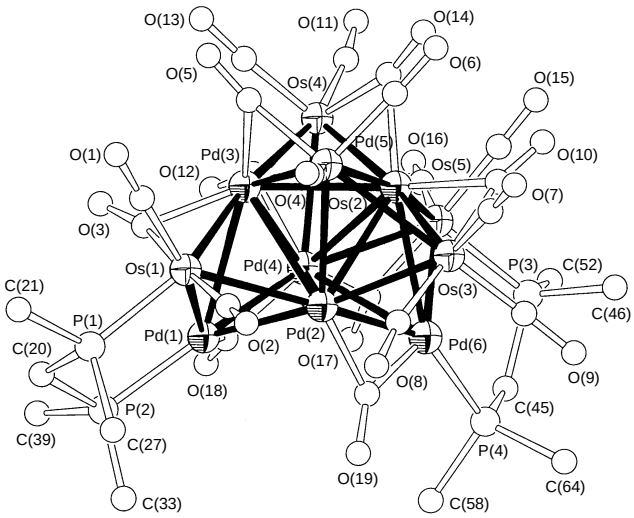

**Fig. 3** The molecular structure of **2** showing the atom numbering scheme (phenyl rings are omitted for clarity). Selected bond lengths (Å): Os(1)–Pd(1) 2.963(2), Os(1)–Pd(2) 2.868(1), Os(1)–Pd(3) 2.819(1), Os(2)–Os(3) 2.8861(9), Os(2)–Pd(2) 2.913(1), Os(2)–Pd(3) 2.716(1), Os(2)–Pd(5) 2.768(1), Os(3)–Pd(2) 2.756(1), Os(3)–Pd(5) 2.787(1), Os(4)–Pd(3) 2.841(1), Os(4)–Pd(4) 2.839(2), Os(4)–Pd(5) 2.747(1), Os(5)–Pd(4) 2.837(1), Os(5)–Pd(5) 3.016(1), Os(5)–Pd(6) 3.180(2), Pd(1)–Pd(2) 2.828(2), Pd(1)–Pd(3) 3.004(2), Pd(1)–Pd(4) 2.722(2), Pd(2)–Pd(3) 2.881(2), Pd(2)–Pd(4) 3.162(2), Pd(2)–Pd(5) 2.914(2), Pd(2)–Pd(6) 2.706(2), Pd(3)–Pd(4) 2.786(1), Pd(3)–Pd(5) 2.867(2), Pd(4)–Pd(5) 2.939(2), Pd(4)–Pd(6) 2.935(2), Pd(5)–Pd(6) 2.948(2).

It is a common observation that the metal–metal bond elongates as it is bridged by hydride.[14] Although the solid-state structure of **1** revealed two hydride environment, in solution some dynamic processes may be possible and a broad $^1$H NMR singlet is observed. Both **1** and **2** possess 146 CVE. However, their structures can not be rationalized by common electron counting rules.[15] This is not entirely unexpected as many Os/Pd or Os/Pt mixed–metal clusters do not obey simple electron counting rules owing to an alternative stable 16-electron configuration of Pd and Pt.

Our present results establish new examples of the high-nuclearity Os/Pd clusters. Although the yields are quite low, the syntheses under these experimental conditions are reproducible. At this stage, we do not detect any interconversion between **1** and **2** even though their molecular structures are very similar. Further studies would screen the experimental conditions and stoichiometry of the reactants to improve the yield of these novel species so that their chemical reactivities can be investigated.

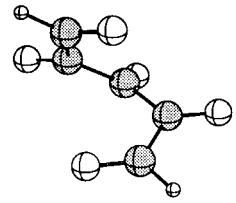
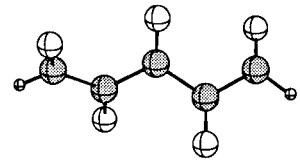
**State of the art *ab initio* calculations on R(CO)$_n$R (R = H, Me; $n$ = 1–11) indicate that the hypothetical polymer of carbon monoxide, poly-CO, would be energetically less stable than the molecular form only by a few kcal mol$^{-1}$, making it a plausible stable allotropic form of CO.**

Predictive quantum chemistry offers the opportunity to design new polymers with potentially interesting physical or structural properties. One can design these new materials by linking building blocks which sometimes can exist alternatively as stable monomers, dimers or even larger finite aggregates.[1–3] Our contribution in this field concerns the investigation of a hypothetical polymer of carbon monoxide by means of *ab initio* and density functional calculations. This polymer **1**, named



**1**



poly-CO throughout this paper, has the unusual property of having a repeat unit that is isoelectronic, albeit not isodesmic, to molecular CO: the [C=O] repeat units are linked together through C(sp$^2$)–C(sp$^2$) single bonds. Standard bond energy calculations[4] indicate that CO polymerization should be roughly thermoneutral, suggesting that poly-CO should be thermodynamically stable. Moreover, vicinal oligoketones, R(CO)$_n$R ($n$ < 6), have been shown to exist,[5] as well as one-dimensional (BC)$^{3-}$ chains, isoelectronic to poly-CO, which are encountered in several MBC (M = rare earth metal) solid state phases.[6] Previous semi-empirical calculations by some of us[7] and by Hoffmann[8] on poly-CO suggest that it should have an helical conformation.

We have evaluated the poly-CO total energy per repeat unit from calculations on a series of linear R(CO)$_n$R (R = H, Me) oligomers by using the finite difference method.[9] Assuming that, for a given $n$ value, $E_n$ is the total energy of the most stable conformer of R(CO)$_n$R, the difference function $\Delta E_n = E_{n+1} - E_n$ is expected to tend to the poly-CO energy per CO unit when $n$ becomes large enough. We have performed *ab initio* and DFT calculations§ on R(CO)$_n$R (R = H, Me) oligoketones, up to $n$ = 11.¶ The corresponding $\Delta E_n - E$(CO) energy values are shown in Fig. 1.

The potential energy surface was fully explored up to $n$ = 5 for R = H. In this case, for example, seven conformational isomers were identified, all differing from the relative rotational orientation of their CO groups. All these conformers lie in an energy range of *ca.* 8 kcal mol$^{-1}$, the four lowest in energy differing by less than 3 kcal mol$^{-1}$. It is worth noting that for R(CO)$_5$R (R = H, Me) the lowest energy corresponds to the helical form, **2a**, a conformation experimentally observed for Ph(CO)$_n$Bu$^t$.[5d,e] The second lowest in energy corresponds to the all-*trans* conformation **2b** lying above **2a** by less than 1.5 kcal mol$^{-1}$‖ From these results it is clear that the potential

**2a**, TCCT

**2b**, TTTT

energy surface associated with the conformational fluxionality of oligoketones is particularly soft.** For larger oligomers, the number of conformations becomes too large to allow a full structural investigation, and we restricted our research to isomers having the $C_2$ symmetry. It turns out that for $n$ > 2, all the optimized conformers are non-planar and typical C–C and C=O bond lengths are computed. The carbon atoms always maintain their expected (locally planar) sp$^2$ hybridization. Therefore, the conformation of the oligoketones can simply be described by the series of the dihedral angles ($\alpha$) between adjacent CO units, which are reported in supplementary material.‖

From Fig. 1, one may see that the $\Delta E_n$ variations computed at the HF and B3LYP geometries behave similarly, showing that optimized HF geometries can be used, allowing the study of longer H(CO)$_n$H chains up to $n$ = 11. Furthermore, the calculations performed with R = Me for smaller $n$ values provide evidence that no special end effect is present in the calculations with R = H. It is clear that for $n$ = 9 the parity oscillations due to the small-size effect are damped, as well as the asymptotic value of $\Delta E_n$ is nearly reached. When ZPVE corrections are included,§ poly-CO is computed to be less stable

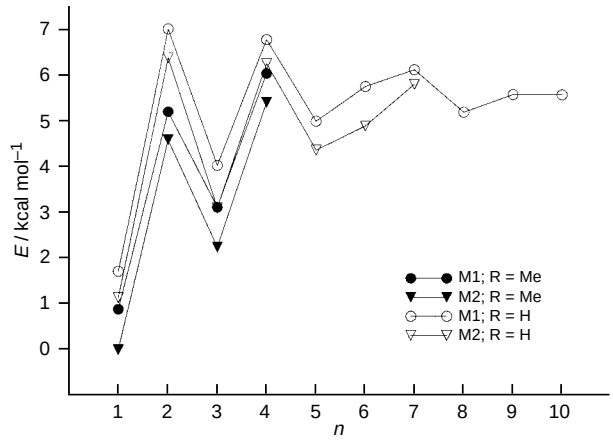


**Fig. 1** Plots of $E$[R(CO)$_n$R] − $E$[R(CO)$_n$R] − $E$[CO] (R = H, Me) with respect to $n$. Calculations are made at the B3LYP/6-311 + G**//HF/6-31G** (M1) and B3LYP/6-311 + G**//B3LYP/6-31G** (M2) levels, including ZPVE corrections. Filled and empty symbols are for (Me)-(CO)$_n$(Me) and H(CO)$_n$H oligomers, respectively.

than free CO monomer by only 5.5 kcal mol$^{-1}$. However, ZPVE terms are obtained assuming isolated molecules, while the hypothetical polymer is expected to exist as a solid in which the vibrational energy could be different. Discarding ZPVE corrections leads to an even smaller energy difference (3.5 kcal mol$^{-1}$). Dipole–dipole and van der Waals interactions, present in the solid-state phase of the polymer, are not taken into account in this study. They may reduce this energy difference or even perhaps change its sign. Moreover, as the potential energy surfaces of the studied oligoketones is particularly flat, the conformation of poly-CO in the hypothetical condensed phase (as under high pressure) may be different from the calculated gas phase helical conformation.[7] In any case, these calculations strongly suggest that poly-CO is a stable allotropic variation of carbon monoxide. The crucial point for its synthesis would be to overcome kinetic problems.

§ Geometry optimisations were carried out with the use of the GAUSSIAN 94 package[10] at the HF, MP2 and B3LYP levels, using the 6-31G** basis set. Harmonic vibrational frequencies and zero-point vibrational energies (ZPVE) were computed at HF level for all systems and in some cases, at the MP2 and B3LYP levels. Single point B3LYP calculations using the larger 6-311 + G** basis set were also performed on the optimised geometries. Since the three levels of calculations lead to similar qualitative conclusions, only single-point B3LYP/6-311 + G** energies on the optimised geometries [HF (M1) and B3LYP/6-31G** (M2)] are discussed here.
¶ The stability of finite oligomers, such as $C_2O_2$ or cyclic $C_nO_n$ molecules, has been discussed.[5a,11] Our preliminary calculations on these cyclic species indicate that they are significantly less stable than free CO, at least for $n < 9$ (to be published).
‖ Tables which summarize the main energetic and conformational data of the most stable $R(CO)_nR$ conformers can be requested from the authors.
** A critical factor related to the energy of these species in their planarity or non-planarity. Conjugation, *i.e.* $\pi$–$\pi^*$ mixing, tends to favor planarity. On the other hand, a second-order Peierls distortion away from planarity, associated to $\sigma_n$–$\pi$ mixing is expected for poly-CO. O··O lone pair repulsions also disfavour planar conformations. Finally, non-bonding interactions involving the terminal R groups can also play some role in the conformational choice, by forming weak intramolecular hydrogen bonds.[5,7,12]

# Ammoxidation of ethane to acetonitrile over Co-beta zeolite

**Yuejin Li and John N. Armor***

*Air Products and Chemicals, Inc., 7201 Hamilton Boulevard, Allentown, PA 18195-1501, USA*

**Co-beta zeolite selectively catalyzes the ammoxidation of ethane to acetonitrile with a rate that is 1–2 orders of magnitude higher than those over typical metal oxide catalysts.**

There is considerable interest in converting light alkanes directly to higher value organic chemicals because of the low cost and abundance of the alkanes. On the other hand, alkanes are chemically stable, which poses a tremendous challenge to achieve a high selectivity in their conversions. A commercially successful example of alkane activation is the manufacture of maleic anhydride by selective oxidation of butane[1] using V–P–O based catalyst. Another example is the recently announced production of acrylonitrile by reacting propane with $NH_3$ and $O_2$ (ammoxidation) over an Sb–V–Al mixed oxide catalyst.[2] In spite of these commercial advances, limited progress has been made for conversion of other alkanes. There were a few attempts to apply the propane ammoxidation catalysis on ethane to make acetonitrile. However, the propane ammoxidation catalyst, V–Sb–Al, was found ineffective for the ethane ammoxidation to acetonitrile. As postulated by Catani and Centi,[3] different mechanistic pathways are required for these two reactions because of the fundamental difference between propene, an intermediate for propane ammoxidation, and ethene, an intermediate for ethane ammoxidation.

Using $Al_2O_3$ supported Nb–Sb oxides, Catani and Centi investigated ethane ammoxidation between 480 and 540 °C with a contact time of 2.6 s.[3] They obtained ethane to acetonitrile selectivity of 50%, CO selectivity of > 20% and variable selectivities for $CO_2$ formation. HCN was also formed during this reaction with a constant selectivity of 5%. Earlier, a USSR patent[4] disclosed that ethane was converted to acetonitrile with a maximum yield of 10% over a Cr–Nb–Mo oxide catalyst at 350–500 °C with a contact time of 19 s. By-products of this reaction were not specified. Here, we report our recent discovery[5] using a metal exchanged zeolite as a superior catalyst for ethane ammoxidation with a very high reaction rate and selectivity to acetonitrile.

Some metal exchanged zeolites are known to activate small alkanes for selective reduction of $NO_x$.[6] In the case of $NO_x$ reduction with methane over Co-zeolites, $CH_4$ was activated by abstracting a proton with a $NO_2$ species which was adsorbed on $Co^{2+}$ sites.[7] Metal cations exchanged in zeolites are atomically dispersed on the coordinately unsaturated sites to balance the negative changes of the zeolite framework. These cations provide unique catalytic centers, as Lewis-acid sites, with a high site density which is usually not achievable by bulk or supported metal oxides.[8] We sought to utilize the unusual properties of metal-zeolite systems to activate ethane for its ammoxidation reaction [eqn. (1)].

$$C_2H_6 + NH_3 + 3/2O_2 \rightarrow CH_3CN + 3H_2O \qquad (1)$$

$NH_4$-beta zeolite (Si/Al = 14) (20 g) was exchanged with a 2 l, 0.02 M cobalt acetate aqueous solution at 70–80 °C for 24 h. After washing with 1 l of deionized water, the zeolite was dried overnight at 110 °C. Elemental analysis showed that the Co/Al atomic ratio was 0.35 (70% of the cation exchange capacity) or 2.2% Co by mass. The reactions were conducted in a microreactor system operating in a steady-state plug-flow mode at atmospheric pressure. The reactor is a U-shaped quartz tube with 0.25 in od at the inlet section and 0.375 in od at the outlet section. The catalyst was located in the outlet section at the center of the electrical furnace which surrounds the reactor tube. Quartz wool plugs were used to support and secure the catalyst bed. A typical feed consisted of 5% $C_2H_6$, 10% $NH_3$ and 6.5% $O_2$ in He with a total flow rate of 100 $cm^3\ mol^{-1}$. A 0.2 g catalyst sample sieved between 20/40 mesh was used for each run, which renders a GHSV of 15000 or a contact time of 0.24 s. The reactor effluent was analyzed by two on-line gas chromatograghs in series, each equipped with a thermal conductivity detector.

As shown in Fig. 1, $C_2H_6$ was selectively converted to acetonitrile over a Co-beta catalyst with a selectivity as high as 76%. The selectivity moderately decreased with increasing temperature. Major by-products for the ethane conversion are $CO_2$ and $C_2H_4$. The selectivity of $CO_2$ was *ca.* 20%, and the selectivity of $C_2H_4$ was generally low but increased linearly with increasing temperature. The conversion of $C_2H_6$ was strongly dependent on the reaction temperature and the availability of $O_2$. The highest conversion was 47% obtained at 475 °C.

An interesting observation for this reaction is that the total $C_2$ selectivity ($C_2H_4$ + $CH_3CN$) is relatively constant, 73 ± 3%. The mutually compensating effect between the formations of $C_2H_4$ and $CH_3CN$ suggests that $C_2H_4$ is the primary product of this reaction. Indeed, a reference reaction with $C_2H_4$–$NH_3$–$O_2$ under similar conditions tripled the nitrile yield. We believe that $C_2H_6$ is first converted to $C_2H_4$ *via* oxidative dehydrogenation on $NH_3$ moderated $Co^{2+}$ sites. Ammonia is strongly adsorbed on most of the $Co^{2+}$ sites as a Lewis base. The ethene molecule then adds on top of the adsorbed $NH_3$ forming an adsorbed

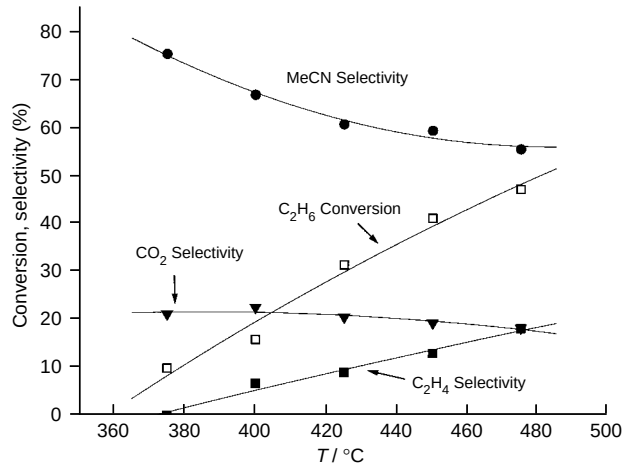

**Fig. 1** Ethane ammoxidation to acetonitrile over Co-beta catalyst as a function of temperature

**Table 1** Comparison between Co-beta and metal oxides for ethane $CH_3CN$ ammoxidation[a]

| Catalyst | Catalyst composition | Ref. | Catalyst mass/g | $CH_3CN$ yield (%) | $10^4$ $CH_3CN$ production rate/ mol $g^{-1}$ $h^{-1}$ |
|---|---|---|---|---|---|
| Co-beta | Si/Al = 14, Co/Al = 0.35 | This work | 0.2 | 26.4 | 160 |
| VPO | P/V = 0.10 (atomic ratio) | 9 | 0.2 | 0.2 | 1.2 |
| $SbVO_4$ | Sb/V = 1.0 (atomic ratio) | 2 | 0.2 | 0.06 | 0.4 |
| Nb–Sb oxides/$Al_2O_3$ | 70 mass% $Al_2O_3$ Nb/Sb = 1 : 5 | 3 | 0.5 | 1.2 | 3.0 |
| Cr–Zr–Mo oxides | Cr : Zr : Mo = 18.1 : 1 : 31.2 | 4 | 0.5 | 2.6 | 6.4 |

[a] All catalysts were tested at 500 °C, except for Co-beta (475 °C), under conditions described within the text.

ethylamine molecule, which is readily dehydrogenated to $CH_3CN$ in the presence of $O_2$.

The Co-beta catalyst was compared with a variety of metal oxide catalysts for the ethane ammoxidation reaction. As shown in Table 1, the $CH_3CN$ formation rate over Co-beta (at 475 °C) is 1–2 orders of magnitude higher than those over metal oxide catalysts (at 500 °C). Nb–Sb–Al and Cr–Zr–Mo were reported to be active for this reaction.[3,4] However, they were active only with a much longer contact time, 3–19 s. With a shorter contact time ($< 1$ s), the amount of $CH_3CN$ produced was barely detectable. It is obvious that Co-beta, a non-traditional selective ammoxidation catalyst, is superior in terms of reaction rate and selectivity to nitrile. In addition, our Co-zeolite catalysts were tested on stream for 100 h without significant deactivation.

In summary, we have found that Co-beta was a very good catalyst for converting ethane to acetonitrile with high rate and selectivity. We believe this to be a positive step towards utilizing ethane to make valuable chemicals.

# β-Peptides: a surprise at every turn

**Dieter Seebach* and Jennifer L. Matthews**

*Laboratorium für Organische Chemie, ETH-Zentrum, Universitätstrasse 16, CH-8092 Zürich, Switzerland*

**β-Peptides, *i.e.* oligomers of β-amino acids, containing as few as six residues may form surprisingly stable helices, with half-lives for the H/D exchange of the central NH protons of up to several days. Furthermore, these β-peptides (carrying the side chains of familiar α-amino acids such as Ala, Val, Leu, Phe, Lys in the 2- and/or 3-position of their 3-amino carboxylic moieties) have been shown to be stable to common peptidases for at least two days. In this article, a brief account of the results obtained since we started work in this area in early 1995 is given. The synthesis of enantiopure β-amino acids can be achieved by homologation of α-amino acids. The greater structural variability of β-amino acids leads to an even greater multitude of possible β-peptide primary and secondary structures. Circular dichroism, NMR and X-ray investigations have unveiled helical, pleated-sheet and tubular arrangements of linear and cyclic β-peptides composed of up to twelve β-amino acids. The prospects for the use of β-peptides as drugs, the construction of large, enzymatically-active β-proteins and their interaction with the natural, α-peptidic counterparts are discussed.**

Polymers derived from β-amino acids (so-called Nylon-3 derivatives[1]) have been the subject of many investigations in the past few decades. In particular, those[2] derived from aspartic acid (the only proteinogenic β-amino acid) have attracted much attention. There has also been some—rather speculative—conjecture concerning the possibility that β-peptides might form secondary structures.[3] Even given this, three years ago, whenever we succeeded in eliciting an opinion from specialists, they were convinced that the extra carbon atom and hence, the additional 'freely-rotating' C–C σ-bond in the β-amino acid building blocks would result in β-peptides having a lower tendency to form highly ordered structures than the analogous natural α-peptides.

This question had been frequently asked because, at the start of 1995, we began to tackle a project that we had been contemplating for a long time—namely, replacing the oxygens in the chain of oligo-(*R*)-3-hydroxybutanoates[4] (oligo-HB) by NH groups in the hope that we would see whether the helical substructures found[5] in the crystalline oligolides of HB [Fig. 1(*a*)] would be stabilised by hydrogen bonds. Since then, it has turned out that the first of the β-hexapeptides we prepared[6] (from homologated valine, alanine and leucine) formed a helix when dissolved in MeOH [Fig. 1(*b*)]. Furthermore, it was found[6,7] to be stable against the peptidase pepsin. The results of the last two years have sparked off a flurry of activity and reports have now appeared with titles such as

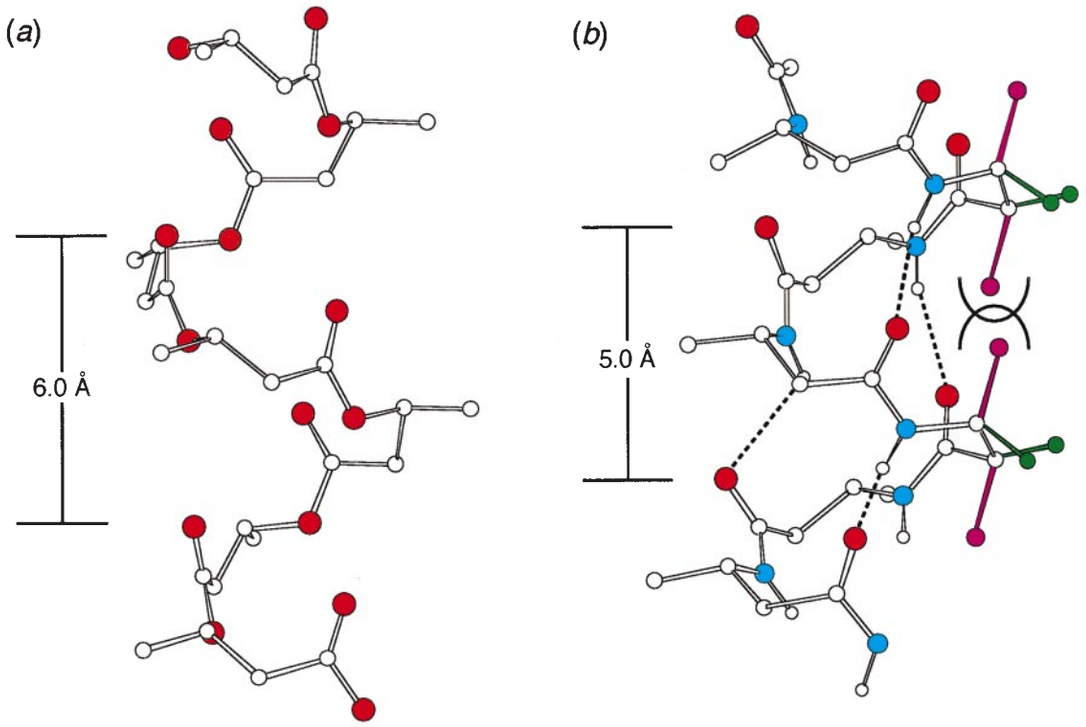

**Fig. 1** (*a*) Left handed or (*M*) $3_1$ helix of (*S*)-3-hydroxybutanoate (HB), modelled using X-ray structural parameters obtained from HB oligolides. The C=O bonds are approximately parallel to the helix axis and their oxygen atoms are close to the backbone oxygens. Top: O terminus, bottom: C terminus. (*b*) Idealised (*M*) $3_1$ helix (crystallographic nomenclature) or $3_{14}$ helix (peptide nomenclature) of a β-peptide; top: N terminus, bottom: C terminus. Lateral substitution (substituents coloured green) does not break up the helix; axial substitution (purple substituents) prevents helix formation. (Taken with permission from ref. 6.)

'Betas are brought into the fold', 'β-Peptides: Novel secondary structures take shape', 'β-Peptides: nature improved?' and 'Molecules without life: the search for artificial proteins'.[8]

In the following sections, we will first discuss the preparation of the β-amino acids and the β-peptides constructed from them. The subsequent sections will compare and contrast the properties and structures of β-peptides investigated to date with those of α-peptides (peptides consisting of natural and unnatural α-amino acids).

## β-Amino acid preparation

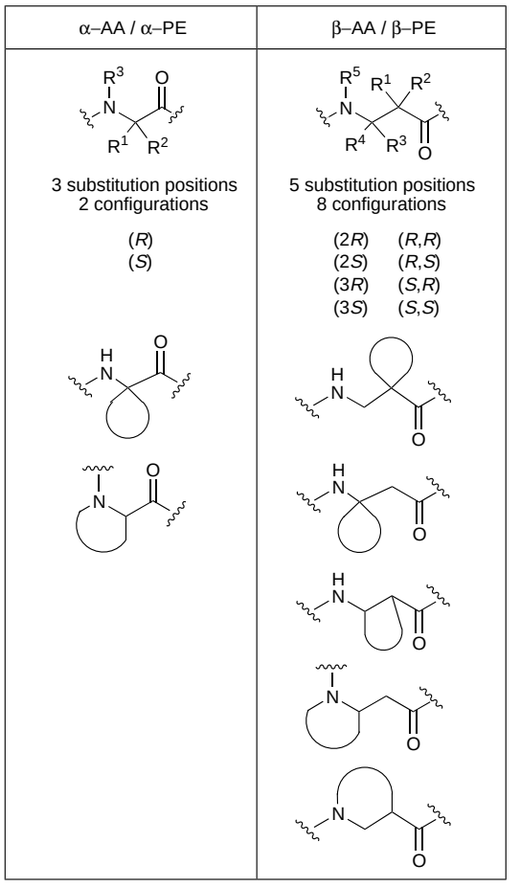
A glance through the eyes of a synthetic chemist at the formulae of an α- and β-amino acid immediately tells you that there is a much wider variety of possible strategies for the synthesis of the latter (Fig. 2). Furthermore, as you move from an α- to a β-amino acid (Fig. 3), the incorporation of an additional carbon atom between the carboxy and the amino groups results in an enormous increase in the number of possible constitutional and configurational isomers. A recently published book[9] reviews the methods available for the synthesis of β-amino acids and one of the chapters[10] deals with the method that we have made the most use of, namely, the Arndt–Eistert homologation [Scheme 1, route (*a*)]. Clearly, the big advantage of this reaction sequence is that the enantiomerically pure β-amino acid derivatives are readily prepared from the appropriate α-amino acid (for instance, with peptidic side chains[7]). Furthermore, reaction of the resulting β-amino acid derivatives leads[11] easily to the α,β-disubstituted compounds [Scheme 1, route (*b*)]. For the preparation of β-amino acids with the side chain in the α-carbonyl position [Scheme 1, route (*c*)], we turned to Evans' chiral auxiliary methodology.[12,13] Enantiomerically pure cyclic derivatives, such as *trans*-2-aminocyclopentanecarboxylic acid and *trans*-2-aminocyclohexanecarboxylic acid, have been prepared by other methods and also subsequently used in the construction of β-peptides.[14,15]

Before proceeding any further, we must first mention the nomenclature we have adopted for the description of β-amino acids and β-peptides. The derivatives with 'natural' side chains in the 2- or 3-position are described as H-β$^2$-Xxx-OH and H-β$^3$-Xxx-OH, respectively. β-Peptides built exclusively from one of these two types of β-amino acids are defined as β$^2$- or β$^3$-peptides, respectively [Fig. 4(*b*) and (*c*)].

## β-Peptide preparation

In our own work we have, in the main, incorporated the sequence β-HVal-β-HAla-β-HLeu into the β-peptides. This is due to the fact that α-peptides with the analogous sequence Val-Ala-Leu have been the subject of numerous structural investigations (above all, those[16] of Karle *et al.*). We also hoped that this approach would facilitate the best possible comparison between the two types of peptides without reference to the distorted picture that would result from a restriction of conformational freedom.[14,15]

We have used[6,7,17–20] the well-established methods of peptide synthesis for the coupling of the β-amino acids, making use of Z-, Boc- or Fmoc-protected amino groups, methyl or benzyl esters for the acid terminus and, usually, carbodiimide methods for the coupling step. We have principally performed



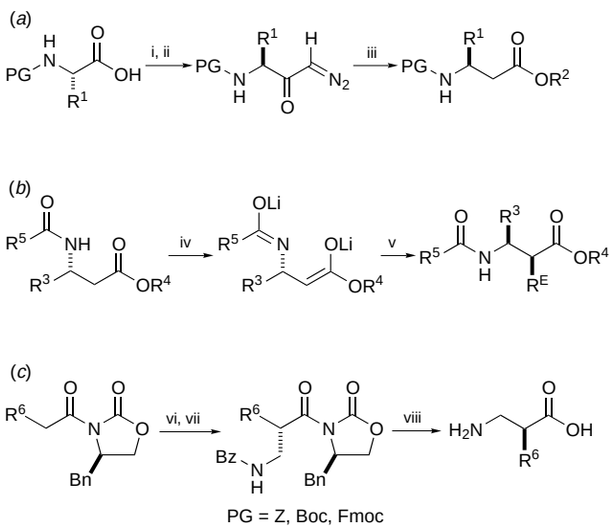


**Fig. 3** Contrasting substitution patterns and configurations of α- and β-amino acid residues in peptides

**Scheme 1** *Reagents and conditions*: i, $ClCO_2Et$, $NEt_3$, THF; ii, $CH_2N_2$, $Et_2O$; iii, $Ag^+$, $NEt_3$, $R^2OH$; iv, $LiNR_2$, LiCl; v, electrophile ($R^EX$); vi, $TiCl_4$, $NEt_3$; vii, $BzNHCH_2Cl$; viii, hydrolysis

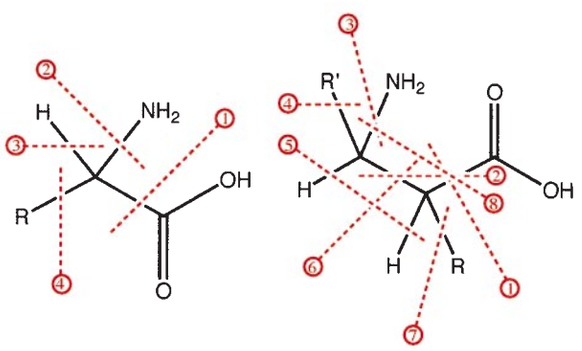

**Fig. 2** Retrosynthetic analysis of an α- and a β-amino acid. The numbers ①–⑧ indicate the bond(s) made in the corresponding synthesis. For literature on α- and β-amino acid syntheses, see textbooks, monographs and a book (ref. 9), which has appeared recently.

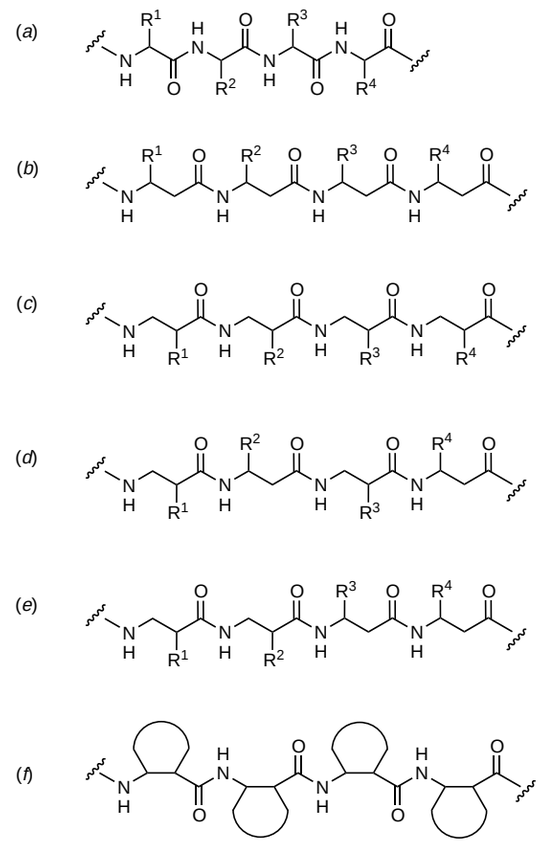
these procedures in solution but have recently begun to investigate the use of solid phase techniques.[21] The yields of the coupling steps are excellent; racemisation or epimerisation is not possible for the β³-amino acids and we only occasionally observe a loss of configurational purity with the β²-amino acids. The products have been purified by preparative HPLC and their composition has been determined by both mass spectrometry and degradation of the component amino acids. To date, β-oligopeptides built from up to twelve amino acids have been prepared (the different types are shown in Fig. 4) including the β-peptides **1**–**14**, which are the objects of discussion in the following sections.

### CD spectra of β-peptides

Circular dichroism is a powerful tool for the detection and determination of the secondary structures of α-peptides. Thus the most common, so-called α-helix of α-peptides[22] [a right handed or (*P*) $3.6_1$ helix with a pitch of 5.6 Å containing 13-membered hydrogen bonded rings] gives rise to CD minima at *ca*. 208 and 222 nm. A chain of at least 15 amino acid residues is required for this helix to be observed in protic solvents such as water or MeOH. Most helical substructures of proteins and enzymes consist of 10–15 amino acids. In contrast, and to everybody's great surprise, β³- and β²-oligopeptides (*e.g.* **1** and **9**, respectively) built of only six or seven (*S*)-β-amino acids† show[6,13,17,21] an intense CD minimum at *ca*. 215 nm, followed by a maximum at *ca*. 200 nm in MeOH [Fig. 5(*a*)], a pattern which is independent of the presence or absence of terminal protecting groups and of the concentration (0.02 to 1 mM). Within this series, the most intense CD absorptions were observed[23] with the β²,³-hexapeptide **3** consisting of β-amino acids with methyl groups in the 2-position and the side chains Val, Ala and Leu in the 3-position‡ [(*S*,*S*)-β³-HXxx(2-Me)] [Fig. 5(*a*)]. Yet another surprise came when we measured[20,25] the CD spectra of mixed β-peptides **4**–**8** containing β²- and β³-amino acid moieties: depending upon the sequence of these isomeric building blocks in the chain and upon the presence or absence of terminal protecting groups, the corresponding peptides showed either the familiar 215/200 nm extrema or a



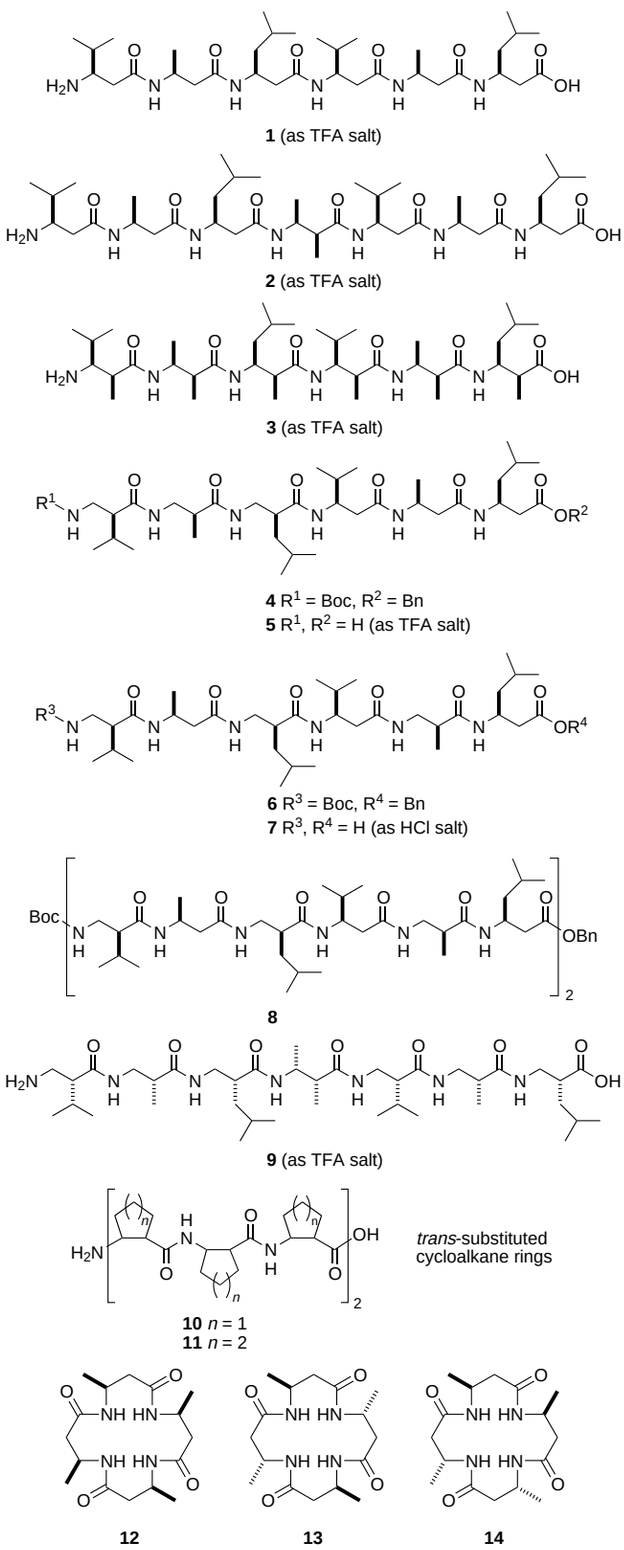


**Fig. 4** (*a*) An α-peptide. (*b*) A β³-peptide: a β-peptide consisting of β-substituted β-amino acids. (*c*) A β²-peptide: a β-peptide consisting of α-substituted β-amino acids. (*d*) A β-peptide consisting of alternating β²- and β³-amino acids. (*e*) A β-peptide consisting of block-coupled β²- and β³-amino acids. (*f*) A β-peptide consisting of aminocycloalkanecarboxylic acids.

single intense maximum at *ca*. 205 nm [Fig. 5(*b*) and (*c*)], which is again essentially concentration independent. From NMR investigations, we can conclude that the former CD pattern is caused by a left-handed helix and the latter one by an as yet unknown, different secondary structure (see following section). The CD spectrum of an oligomer **10** built from (*R*,*R*)-2-aminocyclopentanecarboxylic acid shows a concentration independent minimum at *ca*. 221 nm and a maximum at 204 nm.[15]

### Solution structures of β-peptides determined by NMR spectroscopy

Full NMR analyses (COSY, TOCSY, HSQC, HMBC, ROESY, NOE restrained modelling) have been performed[6,15,17,23,25] on the β$^3$-hexapeptides **1** and **2**, the β$^{2,3}$-hexapeptide **3**, the mixed β-hexapeptide **7**, the β$^2$-heptapeptide **9** and the derivative **10** containing cyclopentane rings. The result is that those β-peptides containing no ring and having identical configuration and substitution pattern of the amino acids adopt a $3_1$-helical conformation in both [$^2H_5$]pyridine or $CD_3OH$ solution [Fig. 6(*a*)]. These are left-handed or (*M*) helices for peptides containing amino acid residues with stereocentres of (*S*) configuration (*e.g.* **1**) and right-handed or (*P*) helices with amino acids of (*R*) configuration (*e.g.* **9**). The helix has a 5 Å pitch with the substituents in the 2- and 3-positions of the component amino acids and the hydrogens occupying lateral and axial positions, respectively [see Fig. 1(*b*)]. Lateral substituents at the *i* and (*i* + 3) position are directly aligned with a 5 Å distance between them and, if a substituent is forced into adopting an axial position, the $3_1$ helix breaks up.[17]

Molecular dynamics calculations (GROMOS96 program package) on the β-heptapeptide **2** in MeOH produced[26] a remarkable result: after a sudden temperature increase from 298 to 350 K, the $3_1$ helix unwinds. However, as the temperature is held at a constant 350 K, the helix is spontaneously restored within 400 ps and, even more amazingly, it is still stable after 2000 ps in this computational experiment which was performed without NOE restrictions. Such behaviour has never been observed with α-peptides.

In line with their different CD spectra, and most astonishingly for us, the mixed β-hexapeptides constructed from β$^2$- and β$^3$-amino acid building blocks (*e.g.* **6**–**8**, with β$^2$,β$^3$,β$^2$,β$^3$,β$^2$,β$^3$ sequences) form a different secondary structure. The NMR analysis shows strong NOEs between corresponding hydrogens of amino acids *i* and *i* + 2, rather than *i* and *i* + 3 as for the $3_1$ helix. This finding[20,25] caught us by surprise because these molecules could have formed the $3_1$ helix with all substituents in lateral positions. As Gellman has found,[15] the β-hexapeptide from *trans*-2-aminocyclopentanecarboxylic acid is present as a helix, but not a $3_1$ helix, when dissolved in both MeOH and pyridine [Fig. 6(*b*)]. It may be that the secondary structures of our mixed β$^2$,β$^3$-peptides **6**–**8** are similar to the helix shown in Fig. 6(*b*); however, at the time of writing, the NMR analysis is not conclusive.

Thus, in contrast to the analogous α-peptides, the short-chain β-oligopeptides are able to form helical secondary structures and, indeed, it has now been experimentally proven that they are able to form at least two different helices which result from rather subtle changes in structure. Investigations and calculations on compounds of the general formula, H[NHCH($CO_2$R)$CH_2$CO]$_n$OH (derived from aspartic acid) have revealed[2] that there might be additional stable β-peptide helices.

### Solid state structures of β-peptides from X-ray scattering

While we have, so far, not succeeded in crystallising any of the helix-forming β-peptides bearing the side chains of natural amino acids, the β-oligopeptides derived from *l*-2-aminocyclopentane- and *l*-2-aminocyclohexane-carboxylic acid§ gave crystals of sufficient quality for X-ray analysis.[14,15] In both cases, the structures found in solution were confirmed to be also present in the solid state: the cyclohexane derivative folds to a $3_1$ helix which is essentially superimposable with the NMR structures (the cyclohexane ring bonds occupy the two lateral positions). The $2.5_1$ helix of the cyclopentane derivative has an average NH–C–C–CO dihedral angle of 86° (with a spread of 75° to 109°) which compares with 55° in the crystal of the cyclohexane analogue acid.[14]

A pleated-sheet arrangement of a β-peptide fragment was found in the crystal structure of Boc-β$^3$-HVal-β$^3$-HAla-β$^3$-HLeu-OMe (Fig. 7), with intermolecular hydrogen bonding in 14-membered rings.

Finally, the steroisomeric cyclo-β-tetrapeptides **12**, **13** and **14** [with (*S*,*S*,*S*,*S*), (*R*,*S*,*R*,*S*) and (*R*,*R*,*S*,*S*) configuration, respectively] were found[28] to form tube-like, hydrogen-bonded stacks in the solid state (Fig. 8).

### Comparison of β-peptides with α-peptides—are they orthogonal to each other?

While the Gellman group approached the field of β-peptides from a supramolecular chemistry perspective[29] and hence made

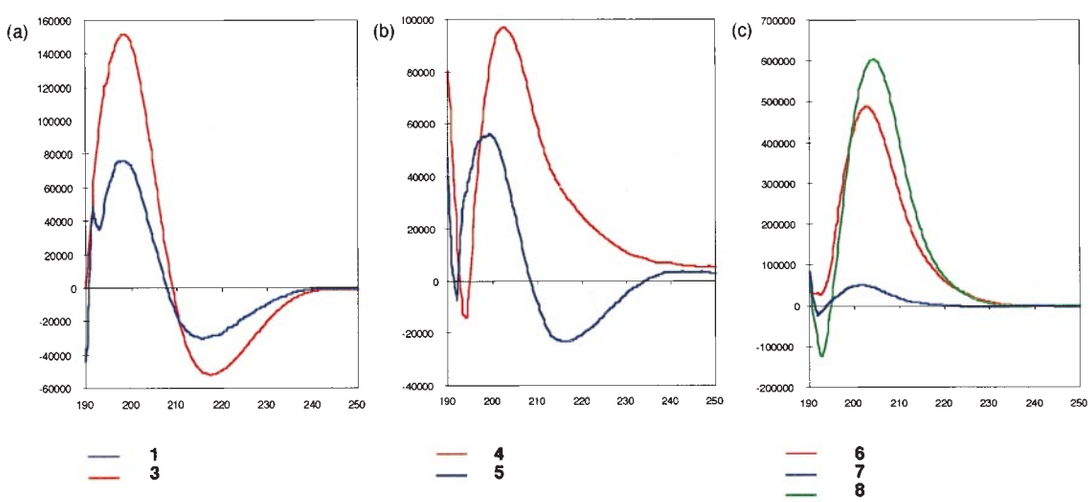

**Fig. 5** Circular dichroism (CD) spectra of β-peptides **1**,**3**–**8** in MeOH (0.2 mM). The typical CD pattern assigned to a left-handed $3_1$ helix [*cf*. Figs. 1(*b*) and 6(*a*)] is shown in (*a*) and the blue curve in (*b*). The characteristic CD pattern of a secondary structure which is, as yet, unassigned is shown in (*c*) and the red curve in (*b*). The most intensive Cotton effects were measured with disubstituted β-amino acid moieties [**3**, red in (*a*)], with a (β$^2$)$_3$(β$^3$)$_3$ (protected) sequence [**4**, red in (*b*)] and with the protected (β$^2$,β$^3$)$_6$ dodecapeptide [**8**, green in (*c*)].

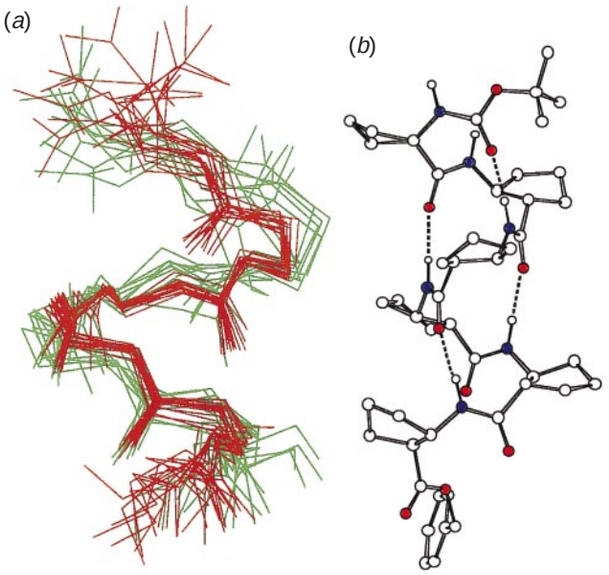

**Fig. 6** NMR structural determination. (*a*) The $3_{14}$ (peptide nomenclature) helical conformations of **1** in MeOH (green) and in pyridine (red) (taken with permission from ref. 17); (*b*) MacMoMo presentation of the $2.5_{12}$ helical conformation of a hexa-β-peptide **10** derived from (*S*,*S*)-2-amino-cyclopentanecarboxylic acid. The NMR structure determination of **10** was carried out on the (*R*,*R*)-isomer; the coordinates were inverted for the presentation shown here to allow a better comparison with other known β-peptide structures.

cycloalkane derivatives (which, as far as the side chains are concerned, bear no resemblance to natural peptidic structures), our entry was triggered by research on the biopolymer[4] poly(hydroxybutanoate) (PHB) and on peptide backbone modifications[30–32] (*e.g.* in cyclosporine), so that we actually prepared β-peptides from α-amino acids. This now puts us in a

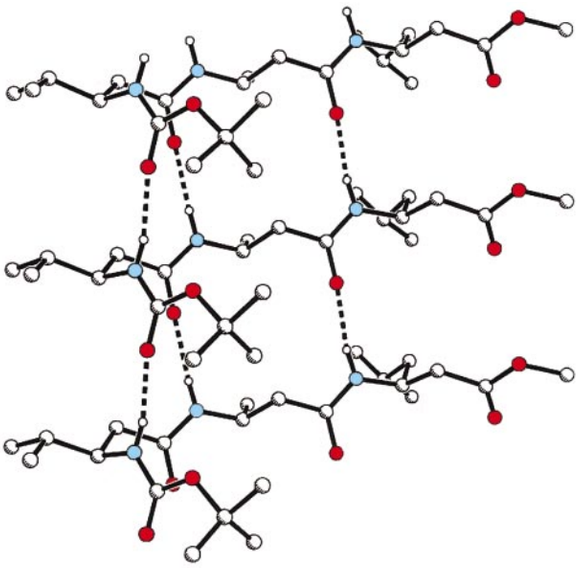

**Fig. 7** Section of the crystal structure of Boc-β$^3$-HVal-β$^3$-HAla-β$^3$-HLeu-OMe with the pleated-sheet type arrangement of two parallel β-peptide fragments

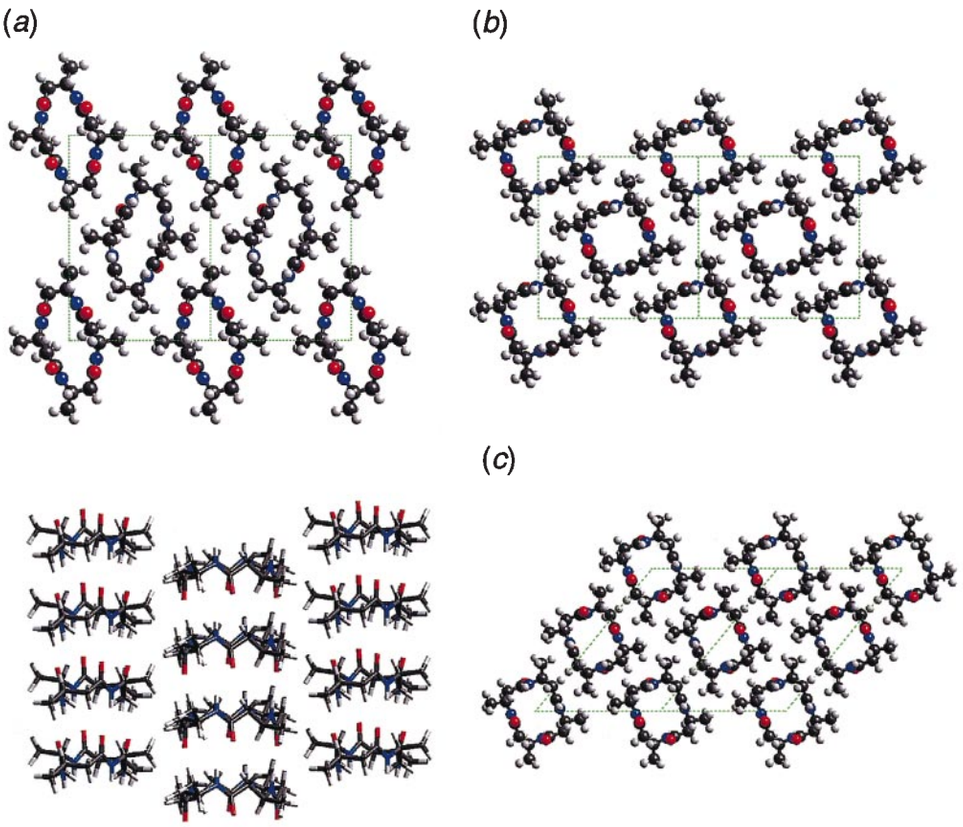

**Fig. 8** Tubular stacking of cyclo-β-tetrapeptides in the solid state (from powder diffraction data). (*a*) **12** [(*S*,*S*,*S*,*S*); top view (above), side view (below)]; (*b*) **13** [(*R*,*S*,*R*,*S*)], top view; (*c*) **14** [(*R*,*R*,*S*,*S*)], top view. In **12**, the ring adopts a rhomboidal shape, in **13**, a square and in **14**, a rectangular shape. All four C=O and N–H bonds are unidirectional in (*a*), two C=O and two N–H bonds point up and down on opposite faces in (*b*) and on adjacent faces in (*c*). (Taken with permission from ref. 28.)

position where we can closely compare related α- and β-peptides and learn something about the hydrogen bonding along the backbones, side chain interactions and possible interactions between α- and β-peptidic structures.

The comparative structural analysis of an α-peptidic $3.6_1$ helix with the $3_1$ and $2.5_1$ helices of β-peptides in Fig. 9 reveals the following points: (i) the helices have different polarities with respect to their C and N-termini; (ii) their shapes and sizes differ drastically; (iii) the $3_1$ β-peptide helix can exist only when its residues are homochiral or have 2,3-*l* relative configuration,§ and not with geminal disubstitution (in contrast, the α-helix is stabilised[33] by incorporation of geminally disubstituted α-amino acids such as Aib or Iva); (iv) the helices are stabilised by hydrophobic interactions between side chains, a contribution which may be responsible for the difference between $\beta^2$- and $\beta^3$-peptides ($3_1$ helix) on the one hand and the mixed $\beta^2/\beta^3$-peptides on the other hand.

From the crystal structure shown in Fig. 7, we are able to make a comparison of pleated sheets of α- and β-peptides (Fig. 10) and they differ in the following features: (i) the amide planes in an extended conformation are separated by one and two tetrahedral carbons, respectively; (ii) these planes are thus arranged in a zig-zag and in a parallel-displaced fashion; (iii) the C=O and N–H bonds are pointing up and down (approximately perpendicular to the chain) in the α-peptidic sheet, with O,O and O,H distances of 6.5, 3.6 and 2.8 Å, while they are unidirectional (all C=O up, all N–H down) in the β-peptidic case (O,O and H,H distances 4.9 Å); (iv) the antiparallel and the less common parallel pleated sheet of an α-peptide carry the side chains pointing perpendicular, above and below, the average plane of the sheet, while the sheet of a β-peptide built from homochiral§ (*all*-$\beta^2$ or *all*-$\beta^3$) components is obscured on only one face by the side chains; (v) while α-peptides containing the twenty proteinogenic amino acids may show a certain *tendency* for forming either a helix or a β-sheet (the Chou–Fasman algorithm[34]), the chain of a β-peptide can be *prevented* from forming a $3_1$ helix and *forced* to adopt an extended conformation, for instance, by constructing it from 2,3-disubstituted 3-amino acids of *u* configuration§¶ [$R^1$, $R^2 \neq$ H in Fig. 10(*b*)].

The additional versatility of β-peptides is further demonstrated by the cyclo-β-peptides: cyclic α-peptides are able to adopt a wide variety of conformations, but in order to exhibit regular tubular crystal packing each ring must be constructed from alternating (*R*)- and (*S*)-amino acid residues such that C=O and N–H bonds point alternately up and down and are parallel to the stacking direction[35] [Fig. 11(*d*)]. However, for cyclic β-peptides the extra $CH_2$ units remove these restrictions and more isomers are able to adopt a conformation suitable for the formation of tubular stacks [Fig. 11(*a*)–(*c*)].

Conformations other than extended chains, helices and circular stacks of β-peptides are yet to be found (*e.g.* turns or random coils); it will be interesting to see which conformation a β-peptide consisting of alternating (*R*)-$\beta^2$/(*S*)-$\beta^2$ or (*R*)-$\beta^3$/(*S*)-$\beta^3$ units[23] (sequences which should not be able to form either a $3_1$ helix or a pleated sheet) adopts. In this context, a couple of unusual CD curves of β-heptapeptides and analogues wait to be interpreted on the basis of NMR analyses.

The structural differences between α- and β-peptides, as outlined in the previous sections, suggest that they cannot exhibit supramolecular back-bone interactions with each other—something that is a prerequisite, for instance, for peptides to be accepted by peptidases as substrates. Thus, we have subjected six different β-tetra-, β-hexa- and β-heptapeptides to the action of the same number of various peptidases (20 different combinations): There was no indication of cleavage after two days but the peptidases had maintained activity towards their standard substrates.[7] The α- and β-peptidic structures in this experiment do not appear to interact in a way which would lead to the cleavage of peptide bonds. Furthermore, preliminary results of animal experiments with a water-soluble β-heptapeptide indicate that, in contrast to a common α-peptide, the β-peptide has an unusually long half-life in the blood serum of a rodent.

## Conclusion and outlook

At the outset of our work on β-peptides, the expectation of many a colleague and protein specialist was that insertion of a $CH_2$ group into each residue in a peptide backbone would lead to conformational chaos. Although we are convinced that we have by no means uncovered all secondary structures of β-peptides, we think that it is now justified to state that they have a much

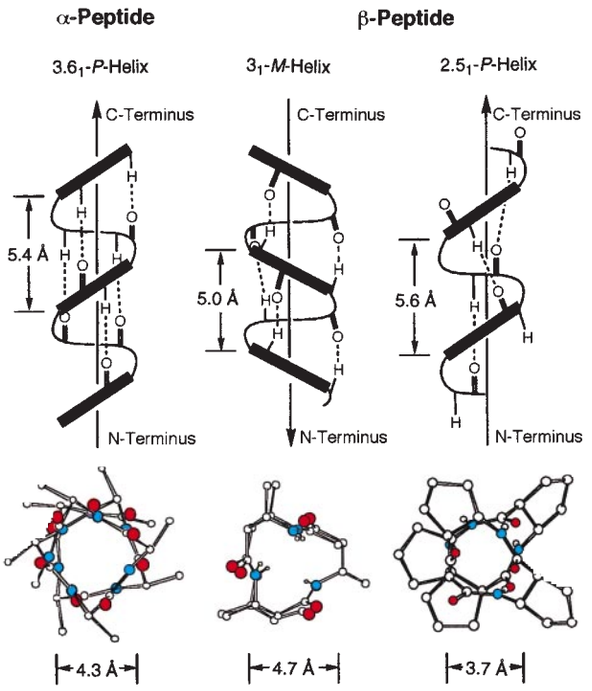

**Fig. 9** Polarities, pitches, diameters and positioning of the side chain in α- and β-peptide helices. (*a*) Schematic presentation of the three helices from (*S*)-α-, (*S*)-β- and (*S*,*S*)-β-amino acids. (*b*) View along the helix axes of the $3.6_{13}$, $3_{14}$ and $2.5_{12}$ helices (peptide nomenclature) as extracted from crystal or NMR structural data.

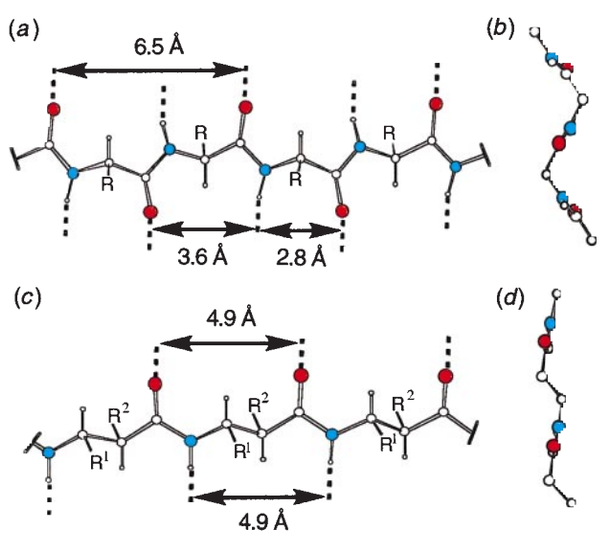

**Fig. 10** Models of the extended conformation of (*a*) an α-peptide and (*b*) a β-peptide which would permit pleated sheet formation. Geminal disubstitution is helix-breaking in both cases. The two types of peptides cannot possibly form 'mixed' sheets. (Taken with permission from ref. 7.)

richer conformational energy surface, with more stable secondary structures, than their α-peptide counterparts. The biological stability of β-peptides suggests that compounds of this type, with recognition-specific side chains attached to the backbone in the right geometry, will be able to bind to an α-peptidic receptor. Combined with their stability towards cleavage by peptidases, this could mean that β-peptides are candidates for useful drugs. Large β-peptides will probably be immunogenic, and it will be exciting to see how an α-peptidic globular protein such as an antibody copes with the challenge of specifically binding (recognising!) a β-peptide. Finally, with various secondary and tertiary β-peptidic structural building blocks in our arsenal (there will be more possible combinations than with conventional amino acid residues) we hope to be able to construct large, complex, protein-like molecules from β-amino acids, with properly arranged functional groups, to create active sites and generate enzymatic properties. The results of research in this area will undoubtedly lead to insights about natural proteins and it will be amusing to discuss the question 'why did nature use α- and not β-amino acids for the construction of the molecules central to life on earth?'‖

## Acknowledgements

It is a pleasure for us to acknowledge the efforts of our co-workers past and present—without them, many of the results described in this article would never have been realised and this article would never have taken shape. The help of Professor M. Dobler (crystallographic nomenclature), Karl Gademann (NMR structure figures), Beat Rheiner (X-ray crystal structure figures) and Paul Comina (proof-reading) is also greatly appreciated. We thank the many collaborators [B. Jaun, L. B. McCusker, C. Baerlocher, W. F. van Gunsteren (all ETH-Zürich), R. Amstutz and H. Widmer (Novartis Pharma, Basle) and all their respective co-workers] for their contributions to and interest in this work. Professor S. H. Gellman (Wisconsin-Madison) and Professor C. Alemán (Barcelona) are thanked for providing us with the coordinates resulting from their groups' work on β-peptides. Awards from the Royal Society, Great Britain (to J. L. M.), the Swiss National Science Foundation (Grant No. 21-40659.94) and the continuing support of Novartis Pharma AG, Basle, are appreciated.

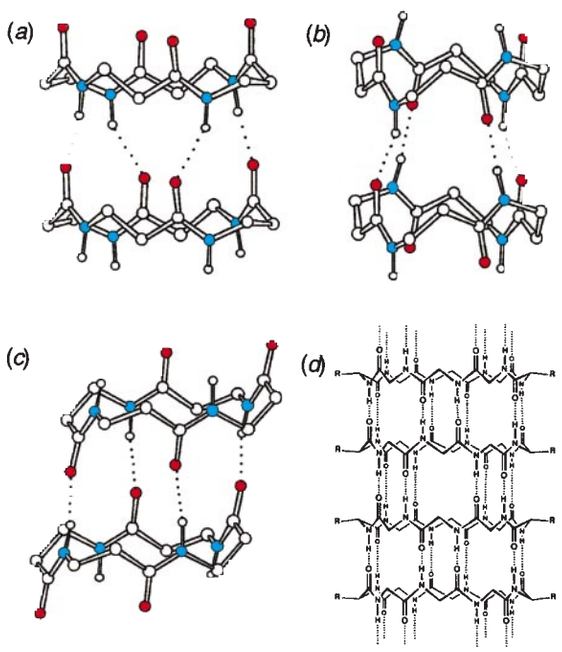

**Fig. 11** Arrangement of the cyclo-β-tetrapeptides (*a*) **12**, (*b*) **13** and (*c*) **14** as found in the solid state (*cf.* Fig. 8). All hydrogen-bonded rings are 14-membered with (7 + 7) and (8 + 6) combinations of the participating fragments. Me substituents and hydrogen atoms bound to carbon are omitted for clarity. For comparison, the stacking of a cyclo-α-octapeptide with alternating configuration of the residues is shown in (*d*). [Taken with permission from refs. 28 and 35(*c*).]

**Dieter Seebach was born in Karlsruhe, Germany, in 1937. He studied chemistry at the University of Karlsruhe and completed his PhD thesis on small rings and peroxides under the supervision of R. Criegee in 1964. After spending two years at Harvard University as postdoctoral co-worker (with E. J. Corey) and lecturer, he returned to Karlsruhe and, in 1969, completed his habilitation on the topic of S- and Se-stabilised carbanion and carbene derivatives. In 1971, he moved to the University of Giessen as a full professor and then in 1977 to the Eidgenössische Technische Hochschule in Zürich. He has received many prizes and titled lectureships, including the first Fluka Prize for Reagent of the Year (1987), the RSC Centenary Lectureship (1991) and the ACS Award for Creative Work in Organic Synthesis (1992), and he was the most recent Baker Lecturer at Cornell University (1997). His research has been directed towards the development of new synthetic methods and involves mechanistic studies and determination of structures. His attention is now focused on further developments of TADDOLs, on the short-chain oligomers of 3-hydroxybutanoic acid and the biopolymer PHB, on chiral dendrimers and on peptide modification.**

**Jennifer Matthews was born in Enfield, Middlesex in 1970. She studied chemistry at the University of Durham and after obtaining a BSc degree in 1991, remained there to complete a PhD on the preparation of asymmetric organosilicon compounds in 1994 under the supervision of Dr Patrick G. Steel. In January 1995, she joined Professor Seebach's group having obtained a Royal Society European Science Exchange Programme Fellowship. Throughout her stay in Zürich, her work has been in the β-peptide field. She has recently returned to the UK and is now a Royal Society Dorothy Hodgkin Research Fellow and Lecturer in Chemistry at the University of Glasgow.**

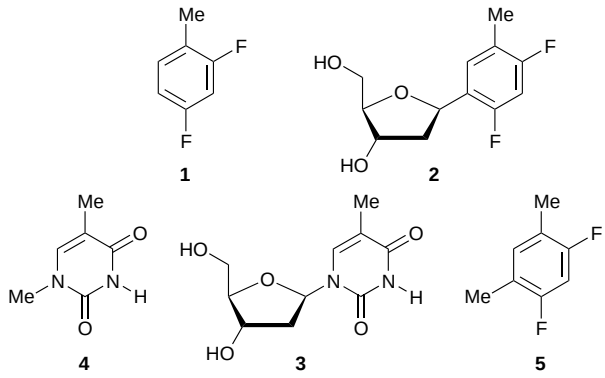
# Hydrogen bonding in DNA—a return to the *status quo*



**Timothy A. Evans and Kenneth R. Seddon***

*School of Chemistry, The Queen's University of Belfast, Stranmillis Road, Belfast, Northern Ireland, UK BT9 5AG*

**Recent claims that 'conventional hydrogen bonds may not be necessary for high efficiency and fidelity in DNA synthesis' and that 'DNA polymerase can exert high fidelity even when a base pair completely lacks conventional hydrogen bonds' are shown to be in error.**

Both Watson and Crick's original *Nature* paper,[1] and Watson's subsequent account of the discovery of the structure of DNA,[2] focus upon the central role of hydrogen bonds between base pairs in defining the formation of the double helix—a view which has become a paradigm, and has remained effectively unchallenged until the appearance this year of a communication (preannounced by Bradley)[3] from Kool,[4] in which the rôle of the hydrogen bond is questioned. Since such doubts as to the importance of hydrogen bonding to molecular recognition undermine not only many of the basic theories of biochemistry, but also the foundations of supramolecular chemistry[5] and crystal engineering,[6–8] it is particularly important that the basis for these radical criticisms be established beyond reasonable doubt. We describe here the reasons why we believe, despite its synthetic elegance, the work of Moran *et al.*[4] is flawed.

At the heart of the communication[4] is the contention that 2,4-difluorotoluene **1** is nonpolar, and incapable of forming hydrogen bonds: if this tenet of their approach is incorrect, the basis for their argument is fallacious. We demonstrate here that they have misunderstood the hydrogen bonding capabilities of such a molecule, that their basic experimental approach is thus flawed, and that there is no reason to change our fundamental understanding of the rôle of hydrogen bonding in the formation of the DNA double helix.

In the title of the paper ('Difluorotoluene, a Nonpolar Isostere for Thymine, Codes Specifically and Efficiently for Adenine in DNA Replication') and in the text it is stated that **1** is nonpolar.[4] However, AM1 calculations† give a dipole moment of 1.86 D (*cf.* AM1 calculations on 1,3-difluorobenzene give a dipole moment of 1.55 D; the experimental value is 1.58 D[9]), a value greater than that for water (1.82 D).[10] Thus, **1** is demonstrably polar, as is the derivative nucleoside **2** which is specifically mentioned[4] as 'a nonpolar shape mimic for natural thymidine' **3**. Furthermore, it is stated[4] that **2** 'would serve as a good test for the importance of thymidine's hydrogen bonding groups on fidelity, because [it] lacks the strongly localized charges but retains nearly the exact steric shape of the natural molecule'. Fig. 1 illustrates the charge distributions of 1-methylthymine **4**, an analogue of **3**, and **5**, an analogue of **2**, as obtained by *ab initio* calculations at the 6-31G** level (essentially similar results were produced by AM1). The pattern and relative magnitude of the localized charges in both molecules are essentially identical, and thus **1** or **2** should not be used for the test described.

The authors state[4] that **2** has a 'non-polar, non-hydrogen-bonding nature', and that their work provides evidence 'that a DNA polymerase can exert high fidelity even when a base pair completely lacks hydrogen bonds'. These statements apparently originate with their belief that the C–F··H–N hydrogen bond is 'unconventional' [*sic*],[4] and that C–H··N hydrogen bonds are not possible upon the observation that 'difluorotoluene is a highly hydrophobic species which does not pair with adenine even in chloroform'.[4] This latter statement is based upon an inconclusive experiment (9-ethyladenine has a very limited solubility in $CHCl_3$), in with 9-ethyladenine was titrated against a dilute (millimolar) solution of **2** in $CDCl_3$, and the N[4]–*H* resonance was monitored on the 9-ethyladenine:[11] the C–*H* resonances of the difluorotoluene do not appear to have been

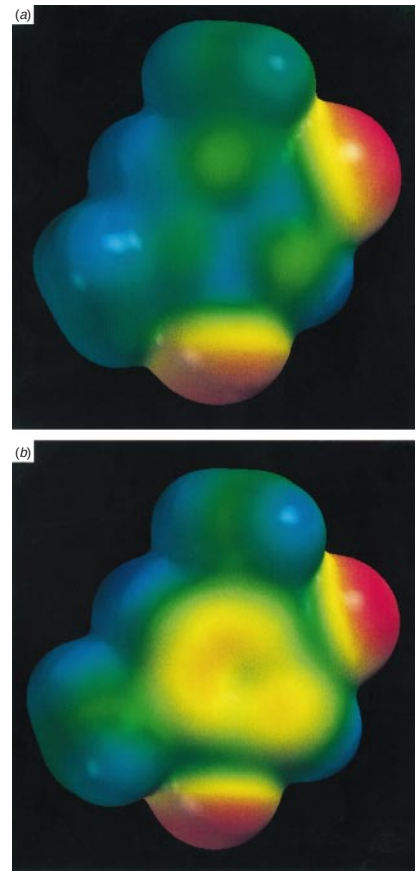


**Fig. 1** The total electron density isosurfaces for (*a*) **4** and (*b*) **5**, each being encoded with the value of its electrostatic potential (red = most negative, blue = most positive), calculated at the 6–31G** level. Both show essentially the same relative charge distribution, although the absolute values are smaller for **4** than for **5**. Calculations on **2** and **3** also reveal similar relative charge distributions.

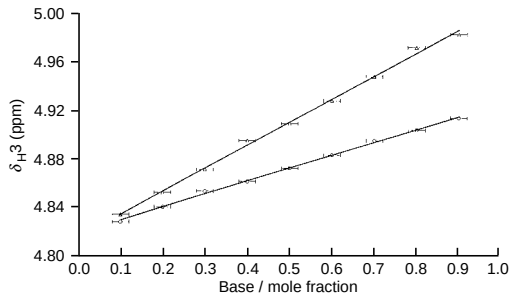
examined. In our hands, even the simple bases pyridine (p$K_a$ 5.18)[12] and 3-chloropyridine (p$K_a$ 2.84),[13] which are respectively stronger and weaker bases than adenine (p$K_a$ 4.20),[14] are capable of forming hydrogen bonds with **1**. Both pyridine and 3-chloropyridine are hydrogen-bond acceptors and, in both cases, the C–*H*$^3$ proton of **1** exhibits concentration dependent downfield shifts (see Fig. 2), both with respect to an internal reference ($SiMe_4$), and with respect to the methyl protons of **1**. Indeed, the AA′MXY spin system is converted, in the hydrogen-bonded base pair, into an ABMXY system. This is behaviour characteristic of hydrogen-bond formation in solution,[15–17] and provides hard evidence in direct contradiction of the recent claims.[4] Moreover, the phenomenon of C–H···X hydrogen bonds is well established,[8,18–22] and is no longer considered either controversial or 'unconventional'. In addition, in a study of hydrogen bonds formed by fluorinated hydrocarbons, Howard *et al.*[23] report (on the basis of exhaustive searching of the Cambridge Structural Database and high level *ab initio* calculations) that 'Encouraging for the bio-organic chemist is that substrate/protein interactions may offer an environment for optimal F···H bonding. [...] the F···H–X interaction may contribute to the overall binding energy, up to half of the strength of the original hydrogen bond to oxygen'. Our own gas-phase calculations (AM1, PM3 and 6-31G*) on the stabilization of base pairs between **4** or **5** and 9-methyladenine confirm this view, all resulting in the same fully-optimized co-planar structures **6** and **7**, respectively. Both these base pair structures have hydrogen-bonding motifs which encode identically as $N_1 = R_2^2(8)$ using Etter's topological analytical method for the comparison of hydrogen-bonding networks,[24,25] The calculated NH···F bond in **7** is only about 0.1 Å longer than the calculated NH···O bond in **6**, reflecting the smaller charges in **5** than in **4**, but representing significant hydrogen bonding. The CH···N bond in **7** is, as expected, significantly longer (0.4 Å) than the NH···N bond in **6**, but still represents a significant weak interaction. The difference in binding energies between the two structures represents a 60% decrease in substituting **5** for **4**. This energy difference is entirely in accord with the reported empirical measurements.[11,26,27] The existence of CH···N and NH···F hydrogen bonds in **7** explains the observed surprisingly high efficiency and fidelity in DNA synthesis: the choice of **2** as a replacement for **3** was inspired—it mimicked not only its shape, but also its relative charge distribution and hydrogen-bonding patterns.

In conclusion, the arguments presented elsewhere[4] are flawed: we have demonstrated here that 2,4-difluorotoluene is both polar and capable of acting as a hydrogen-bond donor and acceptor. It has been stated that 'conventional hydrogen bonds may not be necessary for high efficiency and fidelity in DNA synthesis' and that 'DNA polymerase can exert high fidelity even when a base pair completely lacks conventional hydrogen bonds'. These views contradict 'most if not all current models for replication fidelity'.[4] Using the well-established philosophical principle of Occam's Razor,[28] it is clear that these workers[4] have reported no results which disturb the *status quo*. Indeed, in



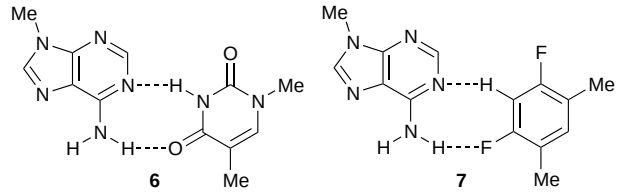


**Fig. 2** The chemical shift of the H$^3$ proton of **1** measured with respect to the methyl resonance, and plotted as a function of the mole fraction of added base, for the addition of (Δ) pyridine and (○) 3-chloropyridine

view of the expected hydrogen bonding ability of **2**, they may well have underlined the validity of the conventional model.

We are indebted to the EPSRC and Royal Academy of Engineering for the award of a Clean Technology Fellowship (to K. R. S.), to the EPSRC for the award of a ROPA grant, and to Richard Murphy, Mark Nieuwenhuyzen, and Drs John Holbrey, Martyn Earle, Yasmin Patell and John Wilson for their assistance and advice. We would particularly like to acknowledge a suggestion from a referee which prompted our use of 3-chloropyridine.

## Footnotes and References

† All the calculations reported here were performed using the Spartan 4.1.1 suite of software. The results cited correspond to the Hamiltonians quoted in the text, and all results represent fully optimized geometries with no applied constraints. In all cases, calculations were performed at the AM1, PM3, STO-3G, 6-31G* and 6-31G** levels, and full details of these calculations will be reported in a future manuscript. Inclusion of an aqueous solvation sheath in $AM1_{aq}$ calculations does not significantly perturb the conclusions.

# Engineering an atomically well defined active site for the catalytic epoxidation of alkenes

**Richard D. Oldroyd, John Meurig Thomas* and Gopinathan Sankar**

*Davy–Faraday Research Laboratory, The Royal Institution of Great Britain, 21 Albermarle Street, London, UK W1X 4BS*

**The improvement effected by replacing one of the three O–Si≡ groups to which a $Ti^{IV}$ ion is anchored (to a mesoporous silica support) by a O–Ge≡ group is described, as is the detailed structure retrieved by *in situ* X-ray absorption spectroscopy of the created active site.**

The immediate atomic environment of a catalytically active metallic ion may be determined by X-ray absorption spectroscopy.[1–3] Using this technique we find that, in the case of $Ti^{IV}$ ions anchored onto the walls of a high-area, crystalline mesoporous silica[4] (Ti ↑ MCM41) by condensing titanocene dichloride and pendant ≡Si–OH groups in a manner previously described,[5,6] the coordination numbers and spatially averaged bond distances for the epoxidation catalyst (see Fig. 1) are as shown in Table 1. It has hitherto been established[6,7] that this epoxidation catalyst functions in a radical-free fashion, and that it epoxidises cyclohexene with a selectivity as high as 95% and turnover numbers of *ca.* 35 $h^{-1}$ (under the conditions used in the cited study) with alkyl hydroperoxide oxidants. This performance is a good deal superior to that of the catalyst produced by incorporation of $Ti^{IV}$ ions into the interior of the walls during the synthesis of the MCM41 mesoporous silica from the parent gel (Ti→MCM41).[8–10]

Titanium and germanium K-edge extended X-ray absorption fine structure (EXAFS) spectroscopy, supplemented by FTIR spectroscopy and spatially resolved elemental analysis (using scanning transmission electron microscopy), show that the exposed active sties in the Ti ↑ MCM41 catalyst (Si : Ti = 44.7 : 1) are $Ti^{IV}$ centres tripodally attached to the support *via* three Ti–O–Si≡ linkages (Fig. 1). We have grafted $Ge^{IV}$ centres onto the MCM41 surface using a procedure similar to that of Nédez *et al.*[11] to which the catalytically active $Ti^{IV}$ centres have been subsequently attached. The synthesis entails exposing the dehydrated mesoporous silica (surface area = 1020 ± 10 $m^2\ g^{-1}$) to tetrabutylgermanium at 180 °C and then, after washing, calcining and dehydrating the resulting sample, introducing the $TiCp_2Cl_2$ in an analogous fashion to the procedure used for unmodified MCM41. The resulting atomic ratios are Si : Ge : Ti = 44.9 : 0.07 : 1 and 44.7 : 0 : 1 for the germanium-modified and Ti ↑ MCM41 catalysts, respectively. Full preparative and analytical details are to be given elsewhere.[12]

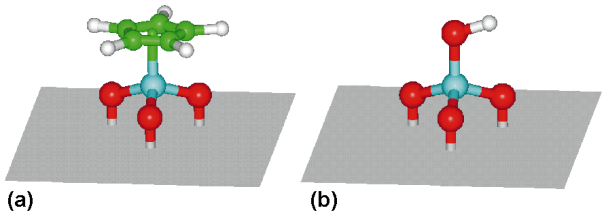

**Fig. 1** Illustration of the Ti environment in Ti ↑ MCM41 before (*a*) and after (*b*) removal of the Cp moiety by calcination. (Ti = cyan, C = green, O = red, H = white). For clarity, the $SiO_2$ background of the mesoporous support is not shown in atomic detail.

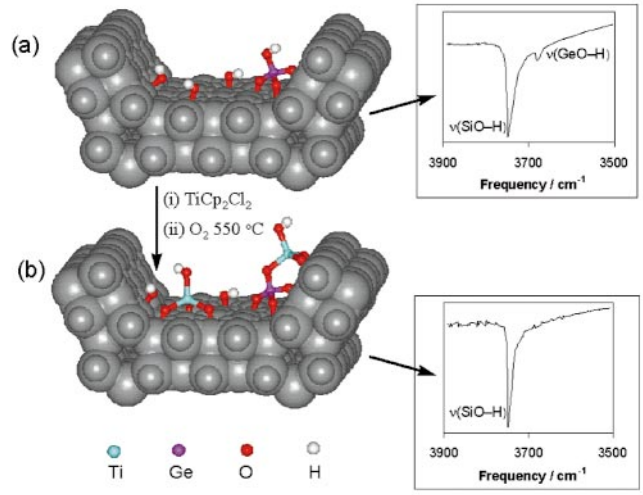

**Fig. 2** Representation of the derived structures of calcined Ge ↑ MCM41 (*a*) and Ti ↑ Ge ↑ MCM41 (*b*). The insets show the respective FTIR spectra. Most of the surface silanol groups have been omitted for clarity. (Note that the ratio of the different active sites shown here are not the same as in the real catalyst, but are purely illustrative.)

**Table 1** Bond distances and angles derived from analysis of Ti and Ge K-edge EXAFS data

| Material | Edge | Atom type | Occupancy | Distance/Å | $2\sigma^2$/Å$^2$ | Angle/° |
|---|---|---|---|---|---|---|
| Ti ↑ MCM41 (calcined) | Ti | O | 4.1 | 1.82 | 0.005 | Ti–O–Si(A) : 138 |
| | | Si(A)[a] | 2.3 | 3.19 | 0.006 | Ti–O–Si(B) : 160 |
| | | Si(B) | 0.8 | 3.37 | 0.006 | |
| Ge ↑ MCM41 (calcined) | Ge | O | 3.9 | 1.73 | 0.004 | Ge–O–Si : 132 |
| | | Si | 2.7 | 3.04 | 0.005 | |
| Ti ↑ Ge ↑ MCM41(calcined) | Ti | O | 3.8 | 1.81 | 0.002 | Ti–O–Si(A) : 139 |
| | | Si(A)[a] | 1.7 | 3.19 | 0.004 | Ti–O–Si(B) : 158 |
| | | Si(B) | 1.1 | 3.34 | 0.004 | |
| | Ge | O | 4.1 | 1.72 | 0.004 | Ge–O–Si : 136 |
| | | Ti | 0.8 | 2.80 | 0.003 | Ge–O–Ti : 106 |
| | | Si | 3.3 | 3.10 | 0.003 | |

[a] Self-consistent results pertaining to coordination numbers and bond lengths are best achieved by recognising two distinct Si shells.

The resulting so-called Ti ↑ Ge ↑ MCM41 catalyst was investigated by scanning transmission electron microscopy, X-ray absorption spectroscopy and also by IR spectroscopy. The salient results are given in Table 1, from which the representation of the created active sites (Fig. 2) is derived. It is evident that titanium attaches to the germanium centres (as well as unmodified regions of the MCM41 surface) from the disappearance of the $\nu$(GeO–H)[13] band at 3680 $cm^{-1}$ in the IR spectrum and the appearance of a Ge···Ti shell from the Ge K-edge EXAFS spectrum.

The difference in catalytic activity between the two catalysts is quite dramatic. Although the germanium loading on the MCM41 surface is low (only *ca.* 0.15 mass%) there is a substantial improvement in catalytic activity of as much as 18%. It can be calculated that for those titanium centres that are surrounded tripodally by two O–Si≡ and one O–Ge≡ there is a 140% increase in turnover frequency with *tert*-butyl hydroperoxide (TBHP) and some 80% increase with cumene hydroperoxide (CuHP) as oxidants at 30 °C compared to titanium centres bound to three O–Si≡ moieties. Turnover frequencies towards the epoxide were 33.8 and 39.8 $h^{-1}$ for Ti ↑ MCM41 and Ti ↑ Ge ↑ MCM41 respectively in the presence of TBHP, and 31.2 and 34.9 $h^{-1}$ using CuHP. In each case the selectivity towards cyclohexene oxide was > 75%, the remaining products being cyclohexenol and cyclohexan-1,2-diol.

Attempts to modify the active site with Sn (using $SnBu_4$ in place of $GeBu_4$)[14] prior to anchoring the titanium were not successful since there was a strong tendency for Sn–O–Sn linkages to form, and hence crystallites of extraframework $SnO_2$, which significantly inhibited catalysis. A detailed account of this work will be submitted elsewhere.[12]

We are grateful to the EPSRC for a rolling grant (to J. M. T.) and a ROPA award (to R. D. O.) and the staff at the Daresbury Laboratory for provision of facilities for the XAS experiments. We also acknowledge the efforts of Dr D. Lewis for preparing the figures.

# Polycatenated copper(I) molecular ladders: a new structural motif in inorganic coordination polymers

**Alexander J. Blake,[a] Neil R. Champness,*[a] Andrei Khlobystov,[a,b] Dmitri A. Lemenovskii,[b] Wan-Sheung Li[a] and Martin Schröder*[a]**

[a] *Department of Chemistry, The University of Nottingham, University Park, Nottingham, UK NG7 2RD*
[b] *Department of Chemistry, Moscow State University, 119899 Moscow, Russia*

**The complex $\{[Cu_2(MeCN)_2L_3](PF_6)_2\}_\infty$ [L = 1,4-bis(4-pyridyl)butadiyne] is prepared and characterised by X-ray diffraction studies which show an undulating polycatenated molecular ladder structure involving fully interwoven two-dimensional sheets.**

The study of inorganic coordination polymers and their use in constructing solid-state architectures has become an area of increasing interest.[1] Although the design of inorganic networks is less well developed than corresponding hydrogen-bonded systems,[2] recent examples have helped to extend the understanding of this rapidly expanding area.[1,3–8] Of particular interest in inorganic co-ordination polymers is the degree and nature of interpenetration or polycatenation[3] and to this end we have been investigating the effect of ligand functionality upon the construction of two- and three-dimensional arrays, and in particular adamantoid or super-diamondoid networks based upon copper(I) complexes.[4,5] We have established recently a degree of control over the assembly of these copper(I) adamantoid networks showing that the degree of interpenetration of independent networks can be increased or decreased by variation of the length[4] and steric bulk[5] of the linking ligand. During further investigations into such systems we have isolated a remarkable new structural motif for inorganic coordination polymers, a polycatenated undulating molecular ladder.

L

The reaction of $[Cu(MeCN)_4]PF_6$ with 1,4-bis(4-pyridyl)-butadiyne (L) in $MeCN–CH_2Cl_2$ yields a deep red solution from which red crystals of composition $\{[Cu_2(MeCN)_2L_3](PF_6)_2\}_\infty$ were isolated by layering with $Et_2O$.† The same product is isolated even in the presence of a large excess of ligand, with metal : ligand ratios of up to 1 : 4. X-Ray diffraction studies‡ of these crystals show that the compound exists as a network of molecular ladders in which the two independent $Cu^I$ centres are each coordinated in a tetrahedral geometry to three ligands L, Cu–N 1.993(9)–2.114(10) Å, and one MeCN ligand, Cu–N 1.980(13), 1.997(12) Å, (Fig. 1). The ladder structure is generated *via* the 1,4-bis(4-pyridyl)butadiyne ligands which each bridge two $Cu^I$ centres. This structure is particularly surprising as insoluble adamantoid networks have been previously observed from this type of reaction.[4–6] Molecular ladders have been observed for relatively few related systems although in all previous cases the metal junction of the ladder has been a pseudo-octahedral[7] or octahedral[8] centre generating what may be termed a flat ladder with all linking ligands coplanar.[7,8] In the case reported here the tetrahedral $Cu^I$ centres allow the ladder to undulate. The large cavities between the rungs of the ladder encourage the inclusion of discrete symmetry-related ladders. Examples of molecular ladders based upon cobalt(II)-bipyridyl complexes exhibit no interpenetration.[8] Interpenetration of symmetry-related ladders has been observed although this interpenetration was found to be perpendicular to the orientation of the original ladder, generating a three-dimensional polycatenated structure.[7] In the example reported here the ladders are polycatenated to give a remarkable two-dimensional layer structure involving undulating ladders which interweave in a parallel fashion (Fig. 2). These two-dimensional layers are flattened by a distortion of the N(1)–Cu(1)–N(5) and N(1′)–Cu(2)–N(4) angles from tetrahedral to 128.4(4) and 124.9(4)°, respectively, allowing a significant flattening of each ladder. Each ladder is polycatenated by a further four ladders which weave through the first ladder so as to fill the spaces between the ladders' rungs giving a fully polycatenated sheet (Fig. 3). Potential π–π interactions between adjacent, symmetry-related ladders at a distance of 3.484 Å may presumably contribute to the stability of the observed structural motif. The two-dimensional sheets of interwoven ladders are separated by $PF_6^-$ counter-anions and solvent molecules with the co-ordinated MeCN molecules pointing towards the next sheet in the crystal.

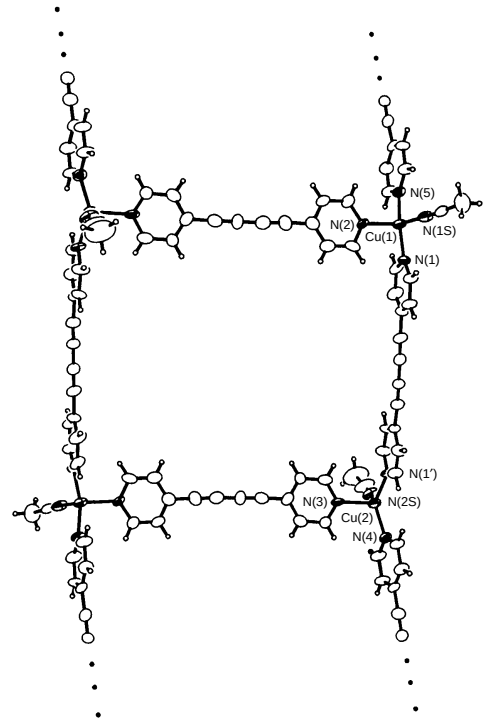

**Fig. 1** A view of part of one infinite undulating ladder. Cu(1)–N(1S) 1.997(12), Cu(1)–N(1) 1.997(9), Cu(1)–N(5) 1.998(9), Cu(1)–N(2) 2.087(9), Cu(2)–N(2S) 1.980(13), Cu(2)–N(4) 1.993(9), Cu(2)–N(1′) 2.032(9), Cu(2)–N(3) 2.114(10) Å.

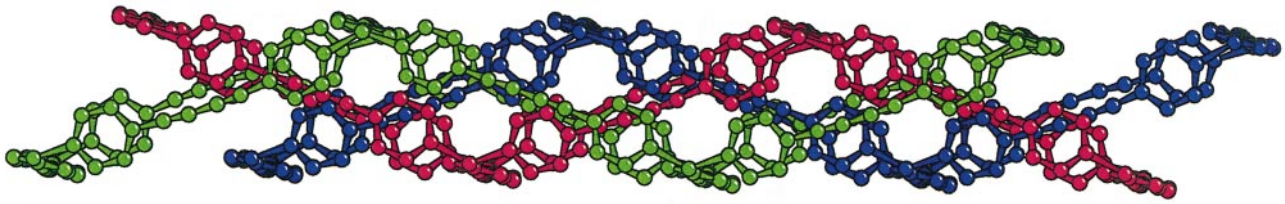

**Fig. 2** A lateral view of three undulating ladders distinguished by colour showing their interweaving. The $PF_6^-$ anions, solvent molecules and coordinated MeCN are omitted for clarity.

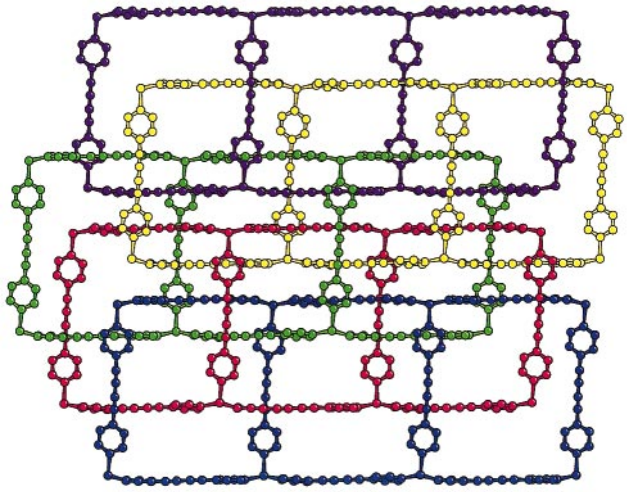

**Fig. 3** An orthogonal view whose central area shows the interpenetration of five ladders, which are distinguished by colour. The $PF_6^-$ anions, solvent molecules and coordinated MeCN are omitted for clarity.

In conclusion we have isolated a unique polycatenated undulating molecular ladder which forms interwoven two-dimensional sheets. We are currently investigating the factors that effect the formation of molecular ladders instead of the more common adamantoid networks in copper(I) bipyridyl arrays.

We thank the Nuffield Foundation and EPSRC for support.

† *Experimental*: $\{[Cu_2(MeCN)_2\{1,4\text{-bis(4-pyridyl)butadiyne}\}_3](PF_6)_2\}_\infty$. A solution of 1,4-bis(4-pyridyl)butadiyne (32 mg, 0.16 mmol) in MeCN (10 $cm^3$) was layered over a solution of $[Cu(MeCN)_4]PF_6$ (16 mg, 0.04 mmol) in $CH_2Cl_2$ (10 $cm^3$). Diffusion between the two phases over a period of days gave a homogeneous red solution. Diethyl ether was then diffused into the solution to give deep red crystals.

‡ *Crystal data* for $\{[Cu_2(MeCN)_2\{1,4\text{-bis(4-pyridyl)butadiyne}\}_3](PF_6)_2\}_\infty \cdot 0.5MeCN \cdot 0.5Et_2O$: $C_{49}H_{35}Cu_2F_{12}N_{8.5}O_{0.5}P_2$, $M$ = 1167.88, triclinic, space group $P\bar{1}$ (no. 2), $a$ = 12.789(6), $b$ = 15.139(6), $c$ = 16.192(8) Å, $\alpha$ = 110.59(5), $\beta$ = 91.36(4), $\gamma$ = 107.43(4)°. $U$ = 2771(2) Å$^3$, $Z$ = 2, $F(000)$ = 1177, $D_c$ = 1.400 g cm$^{-3}$, $\mu$(Mo-K$\alpha$) = 0.907 mm$^{-1}$. A red tabular crystal (0.30 × 0.16 × 0.15 mm) was used for data collection on a Stoe Stadi-4 four-circle diffractometer (graphite-monochromated Mo-K$\alpha$ radiation, $\omega$–$\theta$ scans, $\theta_{max}$ = 22.5°). No absorption correction was applied, 7210 unique reflections [$R_{int}$ = 0.0676], of which 4256 had $I \geqslant 2\sigma(I)$, were used in all calculations. A correction for crystal decay (37%) was applied during data reduction. The structure was solved using direct methods[9] and all non-H atoms were located using subsequent difference-Fourier methods.[10] Both $PF_6^-$ anions were found to be disordered, the first with each F atom split over two sites of occupancy 0.75 and 0.25, the second with the whole $PF_6^-$ disordered over two equally occupied sites. The MeCN and $Et_2O$ molecules were both found to have a half occupancy in their respective sites. Hydrogen atoms were placed in calculated positions and were allowed to ride on their parent atoms. The weighting scheme $w^{-1} = [\sigma^2(F_o^2) + (0.2P)^2]$, $P = [\text{max.}\ (F_o^2,0) + 2F_c^2]/3$ was adopted. At final convergence[10] $R_1$ [$I > 2\sigma(I)$] = 0.1232, $wR_2$ (all data) = 0.3699 for 649 parameters, $S$ = 1.219, $(\Delta/\sigma)_{max}$ = 0.008, $\Delta\rho_{max}$ = 0.94 e Å$^{-3}$. The high value for $R_1$ is attributed to the effects of crystal decay. CCDC 182/608.

# Stabilization of aragonite on thiol-modified gold surfaces: effect of temperature

**Jörg Küther and Wolfgang Tremel***

*Institut für anorganische und analytische Chemie, Johannes Gutenberg-Universität Mainz, J. J. Becherweg 24, D-55099 Mainz, Germany*

**While the slow crystallization of calcium carbonate at 22 °C on self-assembled ω-substituted alkylthiol surfaces yields in most cases, depending on the surface, the vaterite and calcite modifications, elevating the temperature to 45 °C allows the stabilization of the aragonite modification as well.**

The number of minerals known to be formed in biological systems has increased considerably during the past few years. The majority of these minerals contain Ca, and the precision by which these minerals are replicated in terms of structure, morphology and distribution indicates that the mechanisms of nucleation, growth and organization are specific for any biological system. Interest in the controlled crystallization of calcium carbonate is twofold. First, there is the geological and biological ubiquity of the various mineral modifications of $CaCO_3$, *viz*., calcite, vaterite and aragonite. Secondly these are interesting model systems for heterogeneous nucleation at organic–inorganic boundaries, such as those involved in natural biomineralization processes.[1] Extensive studies on $CaCO_3$ crystals grown under Langmuir films and in the presence of additives have been reported.[2,3] The crystallization of the calcite modification on self-assembled monolayers (SAMs) of substituted alkyl silanes on Si(001) has also been described.[4] We have been interested in the factors that determine why one modification is preferred over another, as well as crystal habit and how it can be controlled. To this end, we have studied the slow crystallization of $CaCO_3$ on well characterized SAMs of ω-substituted alkylthiols of different chain lengths, which build up highly ordered surfaces.[5] Depending on the ω-substituent, we are able to obtain calcite and vaterite phases at 22 °C either in pure form or as mixtures, with the actual proportions being determined by the Rietveld refinement of the powder X-ray profiles. In one case, to be described later, aragonite is also obtained. The focus of this work is our finding that by elevating the temperature at which the crystallization is carried out to 45 °C, we observe the stabilization of the aragonite modification as well. On certain surfaces, notably $HS(CH_2)_3SO_3Na$-modified Au, aragonite is the principal phase. This is of some importance since previous reports of aragonite crystallization under mild conditions have been carried out only in the presence of extraneous molecules or cations such as $Mg^{2+}$ or $Li^+$,[6,7] with the exception of a recent report on the template-directed synthesis of aragonite under Langmuir films of 5-hexadecyloxyisophthalic acid.[8] Here, we discuss the growth of $CaCO_3$ on a few surfaces, comparing the results of crystallization carried out at 45 °C with the results obtained on the same surfaces when the crystallization is carried out at 22 °C. We thus attempt to find factors that favour the formation of aragonite under these relatively mild conditions.

The glass/Cr/Au substrates used for crystallization were prepared by vacuum evaporation with film thickness being monitored using a quartz crystal oscillator. The SAMs were grown from ethanol solutions. Surface plasmon spectroscopy, contact angle measurements and reflectance FTIR spectroscopy were used to characterize the SAMs. Calcium carbonate crystallization was performed in a closed desiccator using solid $(NH_4)_2CO_3$ to raise, by diffusion,[9] the $CO_3^{2-}$ concentration of $CaCl_2$ solution.† The substrates were held downwards in solution to prevent gravitational precipitation. The whole apparatus was placed in an oven to control the temperature. Crystallization times were typically 48 h. The formation of crystals was followed by SEM (Zeiss DSM 962) and by PXRD (Siemens D5000) in transmission geometry with the crystals transferred from the substrates to Scotch™ tape. Fig. 1(*a*) shows an SEM micrograph of $CaCO_3$ crystals on the $HS(CH_2)_{15}CO_2H$-modified Au surface on which they have been grown. The three different crystal modifications are clearly seen, being small platelets of vaterite in the middle left, small well formed rhombs of calcite, and preponderantly, running diagonally across are clusters of aragonite needles.

Fig. 1(*b*) shows one such cluster of aragonite needles at higher magnification. The morphology is familiar from previous work, with the growth (needle) axis being in the *c* direction of the unit cell. Nucleation of the clusters take place along a line, as seen from panel (*a*) of this figure, and this

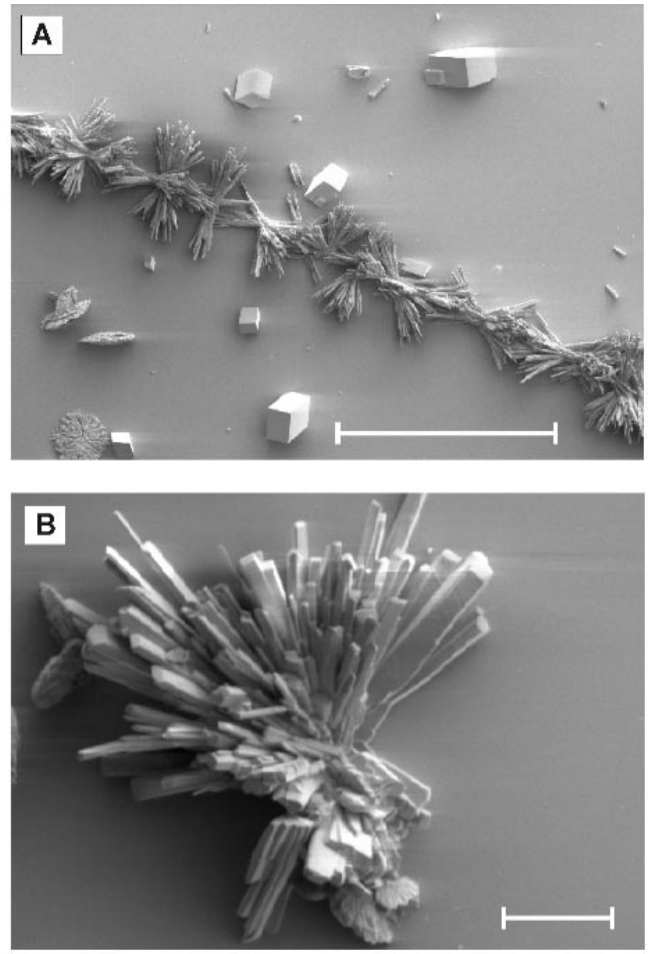

**Fig. 1** Scanning electron micrographs of calcium carbonate crystals on a $HS(CH_2)_{15}CO_2H$-modified Au surfaces. (*a*) Low magnification (bar = 200 μm), (*b*) high magnification (bar = 20 μm) of a cluster of aragonite needles.

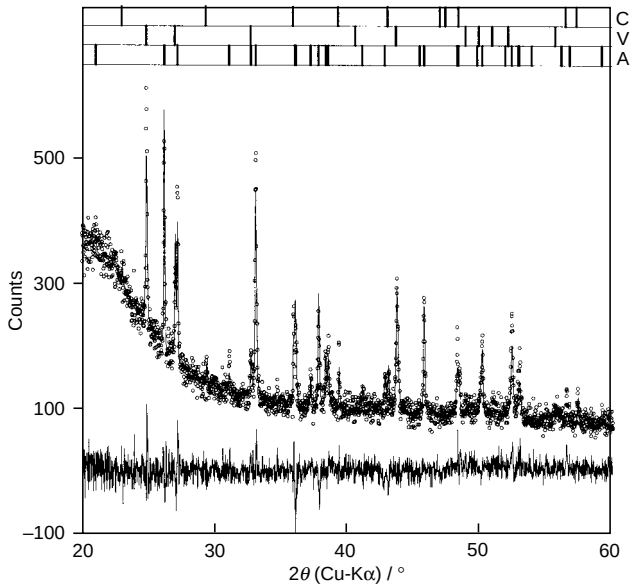

**Fig. 2** Powder X-ray data (points), Rietveld profile fits(lines) and difference profiles of $CaCO_3$ crystals grown on a $HS(CH_2)_3SO_3Na$-modified surface at 45 °C. The horizontal lines mark expected reflection positions for calcite (C), vaterite (V) and aragonite (A).

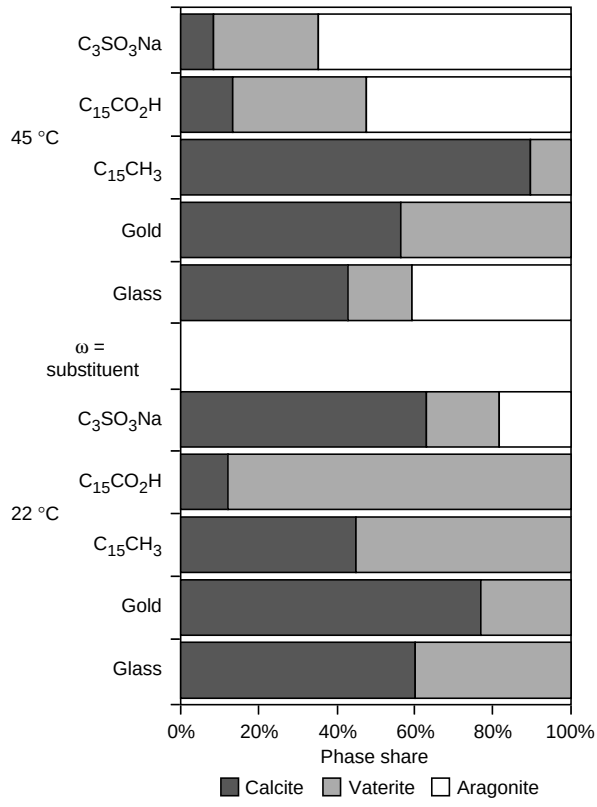

**Fig. 3** Histogram of phase composition obtained from Rietveld refinements of powder X-ray profiles from crystals of $CaCO_3$ grown at 22 and 45 °C on different substrates (indicated) $C_{15}CH_3$ refers to $HS(CH_2)_{15}CH_3$, ($C_{15}CO_2H$) to $HS(CH_2)_{15}CO_2H$ and $C_3SO_3Na$ to $HS(CH_2)_3SO_3Na$. We estimate the absolute errors to be < 10%.

provides some clues to factors that favour aragonite formation as discussed presently.

To improve quantification, we have acquired powder X-ray profiles and analyzed them using the Rietveld method[10] incorporated in the XND program.[11] Scale factors, lattice and profile parameters, including preferred orientations were refined. The structures were taken from the literature.[12–14] Actual mass fractions were estimated from the scale factors using the procedures discussed in ref. 15. Since estimating volumes of the crystallites is difficult in the present case, Brindley corrections were not applied.[16] These and other factors such as disparate crystallite sizes and poor powder averaging (due to the sub-milligram quantities used) are expected to decrease the reliability of such estimates. Fig. 2 shows a typical Rietveld profile fit for $CaCO_3$ grown on a $HS(CH_2)_3SO_3Na$-modified Au surface. Using this Rietveld procedure we illustrate in Fig. 3 histograms of the quantities of the different modifications of $CaCO_3$ grown on five different surfaces, clean glass, clean gold, and SAMs of $HS(CH_2)_{15}CO_2H$, $HS(CH_2)_3SO_3Na$ and $HS(CH_2)_{15}CH_3$, at 22 and at 45 °C. It is interesting that a small temperature difference can result in such large changes in the preference of one modification over others.

We now attempt to identify the factors that might favour aragonite growth. We note that aragonite formation in solution is generally favoured at higher temperatures.[17] Clearly, the fact that aragonite grows on clean glass disallows templating being invoked as the only responsible parameter in the present case. Since clean gold and the long chain alkyl terminated thiol do not show up any aragonite even at 45 °C, we believe that aragonite is not favoured on highly ordered surfaces. Polar, short-chain (and hence less ordered) SAMs on the other hand, seem to favour aragonite. Indeed of the ten or more surfaces examined, the SAM of $HS(CH_2)_3SO_3Na$ is the only one which is able to induce aragonite crystallization even at 22 °C. Going back to Fig. 1(*a*), we see that the nucleation in this case takes place along a line which is probably a step or a terrace boundary on the surface, where the local roughness might be high. The present observation of aragonite on certain surfaces and not on others at 45 °C thus is likely to be due to the combined effects of promotion on the one hand as well as inhibition on the surfaces where it is not observed.

We thank Professor W. Knoll (Max-Planck-Institut für Polymerforschung) for help and encouragement and Dr R. Seshadri for assistance with the Rietveld refinements and the Fonds der chemischen Industrie for financial support.

**Disubstituted, racemic, axially chiral compounds with true and isotopic chiralities have been discriminated through the differential ordering effect of enantiomers when dissolved in a chiral liquid crystal solvent made of organic solutions of poly(γ-benzyl L-glutamate).**

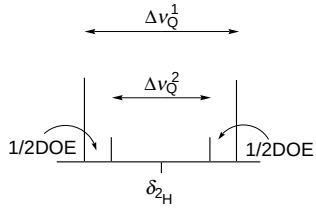
As a result of the widespread interest in the axial chirality found in allenes[1–4] and alkylidenecyclohexanes,[5] it is important to develop a general, reliable and precise method for the measurement of their enantiomeric excesses (ees).[1] It is already known that, for some disubstituted allenes, the use of $^1$H NMR chiral lanthanide shift reagents (CLSR)[1,6a–c] and $^{195}$Pt[1] and $^{31}$P[6d] NMR chiral derivatising agents (CDA), give good results. Recently, ees of trisubstituted allenes and bromoallenes were determined by $^1$H NMR[6e] using as a permethylated β-cyclodextrin a chiral solvating agent (CSA).

A direct and very efficient technique has been recently developed in our laboratory, using deuterium NMR in a chiral liquid crystal medium made of organic solutions of poly(γ-benzyl L-glutamate) (PBLG).[7a–c] This technique appears to be much more sensitive and more general than those previously described in which only the variation of a chemical shift is utilised. In our anisotropic environment, enantiomers have different averaged orientations towards the PBLG α-helix which results in a difference in the order-sensitive NMR interactions, noticeably the deuterium quadrupolar splitting ($\Delta\nu_Q$). Thus the proton-decoupled deuterium NMR [$^2$H-{$^1$H} NMR] spectrum of a chiral deuteriated substrate in a PBLG–organic solvent medium is evident and appears as two quadrupolar doublets, one for each enantiomer. A schematic illustration is given for a 50% ee mixture (Fig. 1).

The differential ordering effect[8] of enantiomers may be defined as the difference between the quadrupolar splittings of the *R* and *S* molecules: DOE = $|\Delta\nu_Q^R - \Delta\nu_Q^S|$. More conveniently the DOE value relative to the average splitting is used; eqn. (1). The NDOE may be seen as an enantiomeric discrimination measurement.

$$\text{NDOE} = (|\Delta\nu_Q^R - \Delta\nu_Q^S|)/[\tfrac{1}{2}(|\Delta\nu_Q^R| + |\Delta\nu_Q^S|)] \qquad (1)$$

This communication describes the application of the PBLG method to visualise axially chiral racemic compounds **1**–**4**§



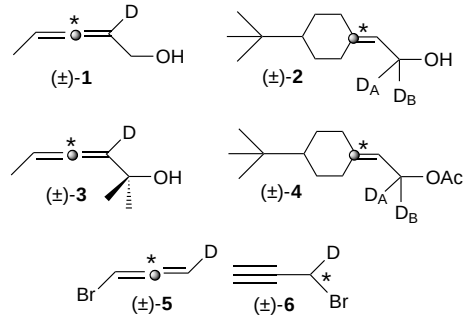


**Fig. 1** Enantiomer visualisation using $^2$H-{$^1$H} NMR in PBLG. When the enantiomers are not assigned, the superscripts *R* and *S* in eqn. (1) are replaced by 1 and 2.

bearing *polar* substituents. The $^2$H-{$^1$H} NMR spectra in PBLG–organic solvent media of products **1**–**4** have been recorded. For all of them the discrimination between enantiomers is large enough to allow an accurate ee measurement (Fig. 2). The enantiomers of primary alcohols **1** and **2** appeared as one and two pairs of doublets respectively. The deuterium of

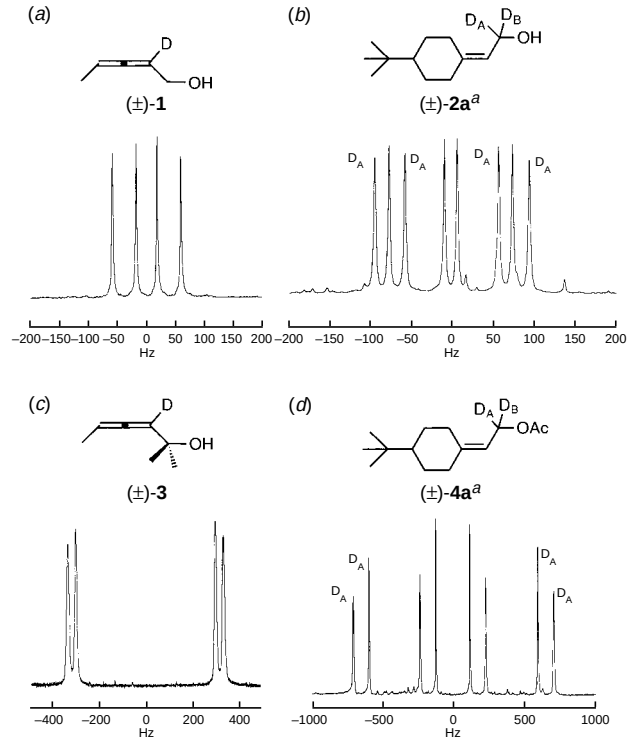

**Fig. 2** Visualisation of axial chiralities in compounds (±)-**1**–(±)-**4** using $^2$H-{$^1$H} NMR (64.1 MHz) in PBLG–organic solvent mixture. [a] For clarity, only diastereotopic deuteriums $D_A$ are quoted, the remaining signals belong to $D_B$.

**Table 1** Enantiomeric discrimination of racemic axially chiral compounds (±)-**1**–(±)-**5** using $^2$H-{$^1$H} NMR (64.1 MHz at 300 K) in PBLG–organic solvent

| Entry/ compound no. | Solvent | PBLG (%) | $\Delta\nu_Q^1$/ Hz[a] | $\Delta\nu_Q^2$/ Hz[a] | NDOE |
|---|---|---|---|---|---|
| **1** | $CH_2Cl_2$ | 14 | 118 | 36 | 1.06 |
| | | | 164 | 96 | 0.52 ($D_A$) |
| **2** | $CH_2Cl_2$ | 14 | | | |
| | | | 141 | 19 | 1.51 ($D_B$) |
| **3** | DMF | 30 | 664 | 595 | 0.11 |
| | | | 1413 | 1190 | 0.17 ($D_A$) |
| **4**[b] | DMF | 30 | | | |
| | | | 462 | 239 | 0.63 ($D_B$) |
| **5** | $CHCl_3$ | 19 | 231 | 174 | 0.28 |
| **6** | $CHCl_3$ | 19 | 951 | 631 | 0.40 |

[a] For racemic compounds (±)-**1**–(±)-**6**, quadrupolar splittings of the *R* and *S* enantiomers are not known at this stage, therefore, in the formula (see text) superscripts *R* and *S* are replaced by 1 and 2 [eqn. (1)]. [b] At 320 K.

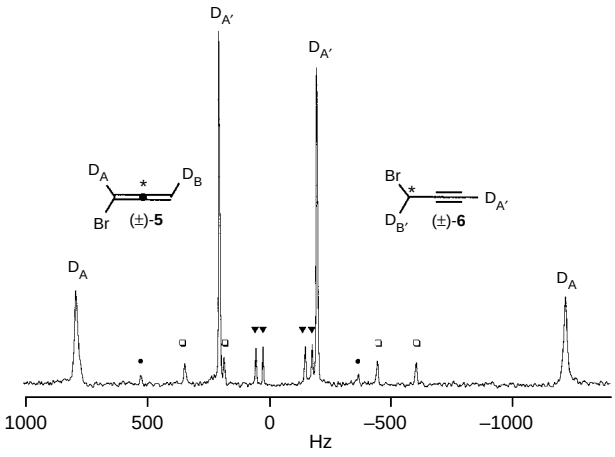

**Fig. 3** Visualisation of allenic and prop-2-ynylic isotopic chiralities in compounds (±)-**5** and (±)-**6** using $^2$H-{$^1$H} NMR (64.1 MHz) in PBLG, $CHCl_3$ at 300 K; (●) $CDCl_3$, (▼) $D_B$ in (±)-**5** and (□) $D_{B'}$ in (±)-**6**

allene **1** is split with an NDOE value of 1.06 (entry 1, Table 1) [Fig. 2(*a*)], whereas the $D_A$ and $D_B$ diastereotopic deuteriums of methylenecyclohexane **2**, are split with NDOEs of 0.52 and 1.51 respectively (entry 2, Table 1) [Fig. 2(*b*)]. The excellent visualisation of the enantiomers of alcohols **1** and **2** is probably due to a hydrogen-bond interaction between their primary hydroxy groups and the PBLG in $CH_2Cl_2$. Indeed, in this solvent, low or even no discrimination was observed with the corresponding tertiary alcohol **3** and primary acetate **4** respectively, which are known to give poor hydrogen-bonding associations. The enantiomers of **3** and **4**, are well-differentiated only when $CH_2Cl_2$ is replaced by DMF, together with a PBLG concentration increasing from 14 to 30%. Again, two and four doublets were observed for **3** and **4**, with NDOEs of 0.11, 0.17 and 0.63 respectively (entries 3 and 4, Table 1) [Fig. 2(*c*) and (*d*)]. In the methylenecyclohexanes **2** and **4**, the differentiation of diastereotopic deuteriums with no-discrimination through their chemical shifts ($\delta_A$ and $\delta_B$), mainly arises from a different orientation of the C–$D_A$ and C–$D_B$ bonds towards the magnetic field [Fig. 2(*b*) and (*d*)].

The efficiency of the PBLG technique may be emphasised by the result obtained with the allenic bromide **5**§ which is chiral only by virtue of an isotopic substitution. It is worth noting that the enantiomers of this compound, now, identically orientated but with an axis of isotopic chirality, are discriminated with an NDOE of up to 0.28 (entry 5, Table 1) (Fig. 3). Furthermore and as expected, enantiomers of an acetylenic counterpart **6**§ with a centro-symmetric isotopic chirality[7c] are also discriminated (entry 6, Table 1) (Fig. 3).

In conclusion, the $^2$H-{$^1$H} NMR spectra in PBLG successfully discriminate enantiomers with the axis of true chirality found in allenes **1**, **3** and methylenecyclohexanes **2**, **4** bearing *polar* substituents, whether or not the substituents interact strongly through hydrogen-bonding with PBLG. Whereas, enantiomers of bromoallene **5** with an axis of isotopic chirality are clearly visualised by our method.

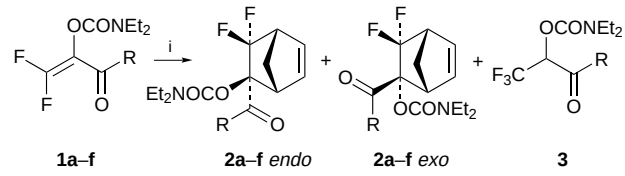
# On the Diels–Alder reactivity of β,β-difluorinated dienophiles

**P. J. Crowley,[b] J. M. Percy*[a] and K. Stansfield[a]†**

[a] *School of Chemistry, University of Birmingham, Edgbaston, Birmingham, UK B15 2TT*
[b] *Zeneca Agrochemicals, Jealotts Hill Research Station, Bracknell, Berkshire, UK RG12 6EY*



**A range of substituted β,β-difluoroenones and a β,β-difluoroalkenoate underwent [4 + 2] cycloadditions with cyclopentadiene, and other dienes, under thermal and Lewis acid-catalysed conditions.**

In the burgeoning area of the chemistry of fluorinated building blocks,[1] there are few concise ways of building ring systems that contain a fluorinated or difluorinated carbon atom. Diels–Alder cycloadditions of activated fluorinated dienophiles would therefore be extremely useful, but there are very few relevant reports. One tantalising example was provided by Leroy *et al.*[2] who described the [4 + 2] cycloaddition reaction between methyl 2,2-difluoropropenoate and furan in an approach to fluorinated analogues of shikimic acids. While the dienophile could be prepared *via* a reasonably short sequence, the cycloaddition and the manipulation of the cycloadducts were problematic and there do not appear to be any subsequent examples of applications of this chemistry.

Difluoroalkenyl compounds that contain electron-withdrawing groups undergo conjugate addition/elimination reactions which lead to loss of fluoride ion. Concomitant overall hydrofluorination follows, presenting a serious obstacle to the development of new chemistry. However, the presence of an *N*,*N*-diethylcarbamoyloxy group at the α-position in a β,β-difluoro dienophile offers some stabilisation against the side reaction.[3,4] Recently, we described some vinylcopper chemistry that allowed access to β,β-difluoroenones **1a**–**f**.[5] Heating the enones in sealed tubes in the presence of excess cyclopentadiene afforded inseparable mixtures of cycloadducts **2a**–**f** in moderate to good yields (Scheme 1, Table 1).‡ Stereoselectivities were low,[6] favouring the stereoisomer in which the π-acceptor group occupied the *exo* orientation. The *exo* : *endo* ratio increased as the ketonic alkyl group increased in size, while the yields of cycloadducts and hydrofluorination product **3** decreased and increased respectively. The stereoisomer ratios were determined by integrating $^{19}$F NMR spectra. Structural correlation was achieved by dihydroxylation[7] of the crude *exo*–*endo* mixture followed by separation and crystallisation of the major diol product; the crystal structure data will be reported elsewhere.

Thermal reactions with all other dienes failed and **3** was isolated as the sole product. In an attempt to achieve cycloaddition at lower temperatures, we examined the effect of added trimethylsilyl trifluoromethanesulfonate ($Me_3SiOTf$) on the reaction and found that cycloaddition occurred between −78 °C and ambient temperature, and that the reaction became highly stereoselective (*exo* : *endo* = 8 : 1). Although the yield of isolated cycloadduct was lower, the reaction was more efficient in diene, requiring only 1 equiv. under the catalytic conditions. Nevertheless, other dienes still failed to react and the formation of **3** predominated. Other Lewis acids [such as $TiCl_4$, $Sc(OTf)_3$, $Yb(OTf)_3$, $ZnI_2$] were ineffective promoters and **3** was formed instead.[8]

Palladium-catalysed coupling§ of our vinylcopper reagent with ethyl chloroformate[9] afforded **4**, a considerably more robust and (one order of magnitude) less reactive compound, which has undergone (to date) a limited number of Diels–Alder reactions affording cycloadducts with cyclopentadiene (**5a**, **5b**

[a] Conditions: A, neat cyclopentadiene (20 equiv.), 100 °C, 4 h, sealed tube; B, cyclopentadiene (1.0 equiv.), $Me_3SiOTf$ (0.1 equiv.), $CH_2Cl_2$, −78 °C to room temp.; C, neat cyclopentadiene (20 equiv.), 100 °C, 40 h, sealed tube; D, neat diene (20 equiv.), 100 °C, 72 h, sealed tube; E, neat furan (20 equiv.), $ZnI_2$ (0.5 equiv.), 80 °C, 48 h. [b] Isolated yields after chromatography are reported. [c] Determined by $^{19}$F NMR spectroscopy. [d] Starting material **4** was also recovered. [e] Ratio based on isolated yields after chromatographic separation of stereoisomers. [f] A 1 : 1 mixture of regioisomeric products was isolated.

74%), furan (**6a**, **6b** 20%, zinc iodide catalysis) and isoprene (**7**, 67%). Importantly, the alkenoate could be recovered from each reaction suggesting that considerable scope exists for the development of efficient catalytic conditions and thus, mild general syntheses of highly functionalised difluorinated cyclohexene derivatives. We should emphasise that the lower reactivity is acceptable because the problematic hydrofluorination reaction appears to be considerably slower in the case of **4**. We now wish to explore the effects exerted by the *N*,*N*-dialkylcarbamoyloxy group upon the stereoselectivity and reactivity of these transformations.

**The biodegradation of dialkyldimethylammonium compounds in aqueous solutions indicates that part of the degradation pathway includes the Cope elimination reaction, which does not occur under mild conditions in the absence of microorganisms.**

This report details the first report of the Cope reaction mediated by microorganisms and starting with long-chained quaternary ammonium compounds. This reaction appears to be a key step in the biodegradation of quaternary ammonium compounds ('quats'). The quats which are the subject of this study are either dialkylethoxymethylammonium, dialkylamidoammonium or dialkylmethylimidazolinium quats.

Long-chained quaternary ammonium compounds have found use in a variety of products and sometimes end their life-cycle by disposal into wastewater or surface waters. Thus the biodegradation of these compounds has been the subject of many studies. It has been found that a wide variety of microorganisms can utilise quats as energy sources. It is also known that many microorganisms can utilise alkylamines as a substrate and use an inducible monooxygenase (EC 1.14.13.8) which is capable of oxidising the substrate to the corresponding *N*-oxide.[1] We have discovered that a key step in the biodegradation of these quats is the formation of an *N*-oxide which is formed once the quats have first degraded to an alkyldimethylamine. During our investigations of the biodegradation of dialkydimethylammonium salts (DADMA X; X = F, Cl, Br, I, OH), and subsequent determination of the metabolic pathway by fermentation of these compounds, we isolated the corresponding *N*-oxides and cleavage products of these *N*-oxides, *e.g.* the $C_{18}$ alkene and the corresponding hydroxylamine. The *N*-oxide is converted to the corresponding trialkylamine and formaldehyde (which are mineralised to $CO_2$ and $H_2O$) by an amine *N*-oxide aldolase (EC 4.1.2-) functioning as a demethylase.[2] The degradation of the quats was done using acclimated bacterial strains, fungi and yeasts for fermentation, typical of those known to be present in the environment.

The Cope reaction is the cleavage of dialkylamine *N*-oxides to produce alkenes and hydroxylamines.[3] Mild conditions are used to reduce side reactions, and the generated olefins do not normally rearrange. In this report we show the transformation of dialkyldimethylammonium salts to *N*-oxides, followed by cleavage of the *N*-oxides to the corresponding alkenes in a Cope-like process using a crude enzymatic preparation from microorganisms of environmental origin. We also show an enhancement of the kinetics of olefin formation due to the presence of the DADMA X micelles (primarily for X = OH).

Fermentation was performed with 12 strains of microorganism§ known to be present in soil and aquatic systems, including waste treatment (*Xanthomonas compestis*, salt regulative #33951, *Bacillus subtilis vulgatus* #6984, *Torulopsis* spp. #34356, together with aerobic and faculative anaerobic bacterial genera *e.g. Actinobacter, Agrobacterium, Alcaligenes, Nocardia, Arthrobacter, Cellulomonas, Mycobacterium* and *Candida albicans*). The cells were harvested, centrifuged, washed with 0.1 M $KH_2PO_4$–$K_2HPO_4$, pH 7.5 and stored at −10 °C. The intracellular contents were purified by $(NH_4)_2SO_4$ fractionation (25–65% of a saturated solution at 5 °C). The portions containing the monooxygenase activity were found in the fractions collected in 48–60% saturated $(NH_4)_2SO_4$ solutions. These fractions were used to prepare the S-100 supernatant at 5 °C. The supernatant was used as a crude enzyme preparation and stored in 10% (v/v) glycerol in the presence of 0.01 M $KH_2PO_4$–$K_2HPO_4$, 5 mM $MgCl_2$ and 1 mM β-mercaptoethanol (pH 7.8, 20 °C). The S-100 fraction containing 10–15 mg $ml^{-1}$ protein was used in the enzymatic experiments in the presence of glycerol¶ and the distearyldimethylammonium salt (DSDMA OH; 5 mM) at pH 7.8 (37–40 °C) for studying enzyme mediated olefin formation, eqn. (1), where R = $C_nH_{2n+1}$ and $n$ = 8, 10, 12, 14, 16

$$(R)_2N^+CH_3{\rightarrow}O \longrightarrow (R)CH_3NOH + CH_2{=}CH(CH_2)_{15}CH_3 \quad (1)$$

or, as in the example given here, 18. The formation of the $(R)_2N(CH_3){\rightarrow}O$ compounds have also been studied at pH 6.0 in 0.01 M borate buffer at a protein concentration of 1 mg $ml^{-1}$, in the presence of 5 mM $NADH_2^+$ (or 3.5 mM $NAD^+$), and a $NADH_2^+$ ($NAD^+$) regenerating system at 37 °C.‖ Formation of the olefins has not been observed in the absence of the crude, enzymatic mixture at 37 °C under the same conditions. However, by refluxing the *N*-oxides in xylene in the presence of 1 mM NaOH for two hours the corresponding olefin can be obtained in an almost quantitative yield. Since the formation of *N*-oxides operates only at pH 6.0–6.5 (37 °C) and the olefin formation is seen mainly in the presence of 10% (v/v) glycerol and pH 7.5–8.0, both pathways can be studied separately. The *N*-oxides studied have also been prepared chemically by reacting the appropriate amine with 30% hydrogen peroxide at 0 °C for 10 min and characterised using standard methods. The *N*-oxides obtained from the enzymatic reactions were characterised in the same fashion.

Fig. 1 shows the yields of the olefin $CH_2{=}CHC_{16}H_{33}$ generated from distearylmethylamine *N*-oxide (10 mg $ml^{-1}$) using the crude enzymatic fraction in the presence of 5 mM DSDMA X (X = OH, F, Cl, Br, I) (pH 7.8, 37 °C) and 10% (v/v) glycerol. The most effective yield is obtained in the presence of 5 mM DSDMA OH [10% (v/v) glycerol], whereas at pH 6.5 the yield is very low as it was for the Br. Furthermore, addition of 1–10 mM NaCl to the reaction medium reveals inhibition of olefin generation ($C_i$ = 6 mM NaCl, 50% inhibition). The influence of NaCl can be related to: (i) the salt induced change of the colloidal state of DSDMA OH from vesicle to micelle,[4,5] and (ii) the shifting of the equilibrium of DSDMA OH + $Cl^-$ ⟷ DSDMA Cl + $OH^-$, toward the insoluble DSDMA Cl and colloidal state of both the hydroxide and chloride.

The biotransformation of DADMA X is strongly dependent on the critical micelle concentration (CMC) pH, temperature and ionic strength.[6] The initial rate constants for the anion exchange step where DSDMA X ⟶ DSDMA OH (X = Cl,

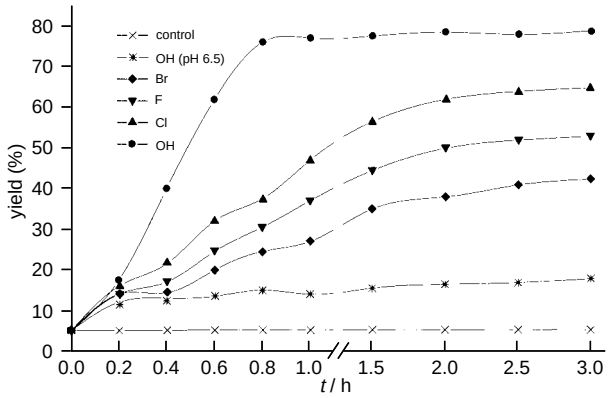

**Fig. 1** Olefin generation ($CH_2$=$CHC_{16}H_{33}$) from distearylmethylamine *N*-oxide in the presence of 5 mM DSDMA X (X = OH, F, Cl, Br) at pH 7.5, 37 °C in 0.01 M $K_2HPO_4$, 5 mM $MgCl_2$, containing 10 mg $ml^{-1}$ protein. Aliquots from the reaction vessel (10 ml) were taken after 15 min, analysed for remaining *N*-oxide and $CH_2$=$CHC_{16}H_{33}$ by GC–MS techniques.

Br) are strongly pH dependent, *e.g.* for DSDMA Cl at pH 5.0: $k^*_{app}$ = 20.1 × $10^3$ $M^{-2}$ $s^{-1}$ and at pH 8.0: $k^*_{app}$ = 0.105 $M^{-2}$ $s^{-1}$. Measurements below the CMC revealed a rate constant of $k$ = 6.79 × $10^9$ l $mol^{-1}$ $s^{-1}$ for $Cl^-$ ($OH^-$) and $k$ = 6.25 × $10^9$ l $mol^{-1}$ $s^{-1}$ for $Br^-$. These values are typical for a diffusion limited rate process between ions. Furthermore, a plot of log $k$ *vs.* $I^{1/2}$ reveals the influence of DSDMA Cl (Br) + $OH^-$ on the ionic strength, and is linear with a slope of 1.03 at pH 7.5–8.0 below the CMC, and 0.35 above the CMC. Furthermore, the fraction of exchange of $Cl^-$ ($\alpha$) by $OH^-$ at pH 6.0 (25 °C) at equilibrium is 1.56%, and at pH 7.5 it is 30.6%. So the second rate constant for exchange is $k_q\alpha$, which is the rate for forming the ternary complex (DSDMA Cl + $OH^-$ ⟷ DSDMA OH + $Cl^-$) times the fraction of that complex leading to exchange, *e.g.* at pH 6.0 (25 °C) to 318.6 $M^{-2}$ $s^{-1}$ and at pH 8.0 to 0.379 $M^{-2}$ $s^{-1}$, respectively.

Long chain ammonium salts having two different chain lengths and two methyl groups, *e.g.* $(C_{12}H_{25})(C_{18}H_{37})N^+(CH_3)_2$ $X^-$, particularly for X = OH, have also been studied. For these materials *N*-oxidation by this enzymatic transformation could yield the chiral (*S*)-(−)- and (*R*)-(+)-*N*-oxides. Chiral analysis

of the products** shows that the amounts of the two kinds of enantiomers are dependent on the chain length. Keeping $C_{18}$ and choosing the other chain length as between $C_8$ and $C_{16}$, the enantiomeric excesses (ees) were found to be of the order 60% (*R*) and 40% (*S*). When the second chain length was between $C_4$ to $C_6$, the ees changed to 40% (*R*) and 60% (*S*). In addition, when the *N*-oxides were reacted according to eqn. (1), it was found that the olefins produced were generated from the shorter chain length residue where the chiral *N*-oxide has the (*S*)-(−) conformatioin (80%), whereas the (*R*)-(+)-*N*-oxide generated only 10–15% alkene for $R^1$ = $C_{18}$, $R^2$ = $C_{12}$. Changing the chirality of the *N*-oxide from (*S*) to (*R*) for $R^1$ = $C_{18}$ and $R^2$ = $C_4$–$C_6$, the generated olefins are of the order of 80%. Racemic $R^1R^2$ *N*-oxides generated in the average 40–45% of the corresponding alkenes.

## Footnotes and References

§ The fermentation broth consisted of 10 g glucose, 2.5 g $KH_2PO_4$, 0.05 g peptone, 0.01 g urea and 10 mM DSDMA OH in 2.5 l HPLC grade water (pH 7.5, 20 °C). The broth was aerated and the $pO_2$ and $pCO_2$ were also computer controlled (100 Hz).

¶ The monooxygenase activity was measured through an $NADPH_2$ regenerating system, comprised of 10 mM NADP, 1.5 M glucose-6-phosphate and 75 mM of glucose-6-phosphate dehydrogenase (6-GPD)–10 ml 0.01 M $K_2HPO_4$ buffer, pH 7.8 (37 °C). The 6-GPD (EC 1,1,1,49) was from Baker's yeast and Torula (100 units). The activities for monooxygenase of the crude enzyme preparation were found to be of 14.2 ± 1.2 nmol $mg^{-1}$ for ethylmorphine *N*-dimethylase, 40.1 ± 4.2 nmol $mg^{-1}$ $min^{-1}$ for aminopyridine *N*-dimethylase and 45 nmol $mg^{-1}$ $min^{-1}$ for aniline hydroxylase, respectively, applying the Hantzsch reaction.

‖ Glucose dehydrogenase (GDH) from *B. cereus* was used for the cofactor regeneration (Sigma, St Louis, MO) since this enzyme can use glucose as a substrate and accepts either $NAD^+$ or $NADP^+$ as a cofactor. The regeneration of $NADH_2^+$ ($NADPH_2^+$) or synthesis of olefin can be maintained (37 °C) in a 10 ml solution containing glucose (0.35 M), 5 mM bromomercaptoethanol, GDH (700 units) in 0.01 M sodium borate buffer, pH 6.0, containing 0.05 M $MgCl_2$, 0.05 M NaCl and 0.05 M $CaCl_2$.

** The concentrations of (*S*)- and (*R*)-enantiomers of the *N*-oxides were measured by HPLC and NMR, using a Regis-DNB-phenylglycine Pirkle column, monitoring the change of the refractive index at 500 nm. Enantiomeric excess (ee) is defined as: ee = ([*R*]-[*S*])/([*R*] + [*S*]) × 100%. The NMR method used the derivatization of the protonated *N*-oxides with (*R*)-(+)-2-methoxy-2-trifluoromethylphenylacetic acid in pyridine.

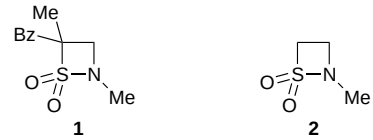
# Evidence for a trigonal bipyramidal intermediate during nucleophilic substitution at a sulfonyl centre and for a sulfonylium cation in the acid catalysed reaction

**Nicholas J. Baxter, Andrew P. Laws, Laurent Rigoreau and Michael I. Page***

*Department of Chemical and Biological Sciences, The University of Huddersfield, Queensgate, Huddersfield, UK HD1 3DH*

**The rate of alkaline hydrolysis of a substituted β-sultam shows a dominant term second-order in hydroxide ion, clearly indicating the reversible formation of a monoanionic trigonal bipyramidal intermediate; substituent effects and kinetic parameters for the acid catalysed hydrolysis are indicative of the formation of a sulfonylium ion intermediate.**

Direct substitution at sulfonyl sulfur is thought to occur with inversion of configuration.[1] Although this indicates that the geometry of the displacement probably involves one in which the entering and leaving groups occupy the two apical positions of a trigonal bipyramid, it does not distinguish between an $S_N2$ type transition state and an intermediate with a real life-time. In fact, unlike substitution at phosphonyl centres[2] there is no real good evidence for the formation of trigonal bipyramidal intermediates for reactions at sulfonyl sulfur.[3]



One of the most convincing pieces of evidence for the formation of tetrahedral intermediates during the hydrolysis of carboxylic acid amides is that terms second order in hydroxide ion have been observed for the hydrolysis of some anilides[4] and acetylpyrroles.[5] Important factors in determining the pathway of breakdown of tetrahedral intermediates are the basicity of the amine nitrogen leaving group and the acidity of the hydroxy group formed from the attacking nucleophilic hydroxide ion.[5]

We have studied the reactivity of β-sultams as potential mimics of the β-lactam antibiotics and shown that they undergo base-catalysed hydrolysis at a rate which is over $10^7$-fold faster than that of an analogous acyclic sulfonamide, but by a pathway which is first order in hydroxide ion.[6] We reasoned that β-sultams with electron-withdrawing groups α to the sulfonyl centre may generate a trigonal bipyramidal intermediate which requires a second hydroxide-ion to facilitate its breakdown.

The pseudo-first order rate constants ($k_{obs}$) for the alkaline hydrolysis of the β-sultam **1** are clearly second-order in hydroxide ion (Fig. 1) and a plot of $k_{obs}$/[OH$^-$] against [OH$^-$] (Fig. 2) shows that this is the dominant term in the rate law, equation (1). The values of $k_{OH1}$ and $k_{OH2}$ are $8.98 \times 10^{-3}$

$$k_{obs} = k_{OH1}[OH^-] + k_{OH2}[OH^-]^2 \quad (1)$$

dm$^3$ mol$^{-1}$ s$^{-1}$ and $3.87 \times 10^{-2}$ dm$^6$ mol$^{-2}$ s$^{-1}$ respectively at 30 °C and $I$ = 1.0 M (KCl).

The second-order term in hydroxide ion is strong evidence for the formation of a trigonal bipyramidal intermediate (TBPI) with a hypervalent sulfur. Initial but *reversible* attack of hydroxide ion on the β-sultam **1** generates a monoanionic TBPI$^-$, which requires deprotonation by a second hydroxide ion before the intermediate can collapse to products (Scheme 1). The third order rate constant $k_{OH2}$ would then be determined by eqn. (2), with $k_{-1} \gg k_2[OH^-]$.

$$k_{OH2} = (k_1k_2[OH^-]^2)/(k_{-1} + k_2[OH^-]) \quad (2)$$

Not only is the observation of the term second-order in hydroxide ion evidence for the formation of a TBPI, it

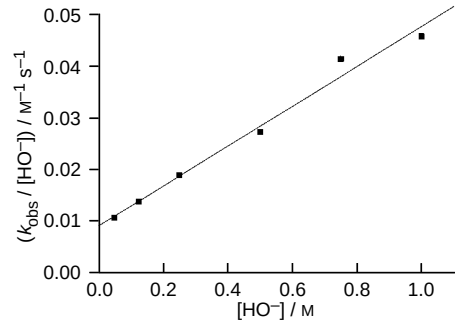


**Fig. 2** Plot of the apparent second order rate constants, $k_{obs}$/[OH$^-$], for the hydrolysis of the β-sultam, **1**, against hydroxide ion concentration at 30 °C, $I$ = 1.0 M (KCl)

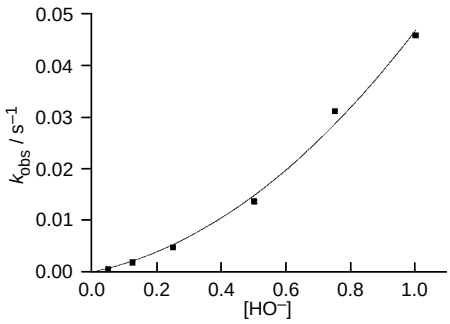

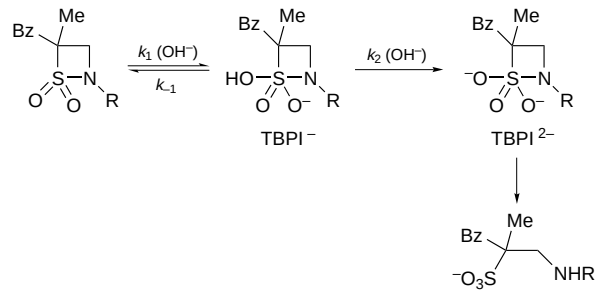

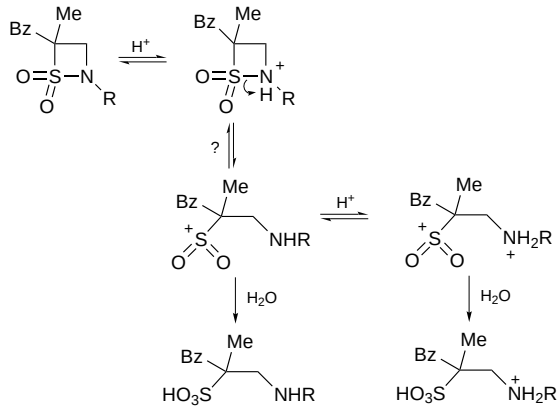

**Fig. 1** Plot of the observed pseudo-first order rate constant, $k_{obs}$, for the hydrolysis of β-sultam, **1**, against the hydroxide ion concentration at 30 °C, $I$ = 1.0 M (KCl)

**Scheme 1**

**Scheme 2**

demonstrates that $k_{-1}$, the rate constant for expulsion of hydroxide ion to regenerate starting material, is greater than ring opening of the strained four-membered β-sultam. It is a surprising fact that β-lactams do not undergo ring opening at a rate predicted by the release of strain energy in the four-membered ring.[7] It now appears that this is also the case for β-sultams. The rate limiting step for the alkaline hydrolysis of the β-sultam **1** could be either diffusion controlled deprotonation of the monoanionic TBPI$^-$, the subsequent breakdown of the dianionic TBPI$^{2-}$ or a concerted process involving both these steps. The solvent kinetic isotope effect for the term first order in hydroxide in $k_{OH1}^{H_2O}/k_{OD1}^{D_2O}$ is 0.49 whereas that for the term second order in hydroxide ion $k_{OH2}^{H_2O}/k_{OD2}^{D_2O}$ is 0.35. The latter is consistent with a stepwise process for product formation. For any process involving a proton in flight in the transition state the solvent kinetic isotope effect would be greater than unity. If formation of the dianionic TBPI$^{2-}$ is rate limiting this would be determined by the rate of the diffusion controlled encounter of hydroxide ion with the monoanionic trigonal bipyramidal intermediate TBPI$^-$. Alternatively, breakdown of the dianionic TBPI$^{2-}$ could be rate limiting. The entropy of activation for the third order rate constant $k_{OH2}$ is $-131$ J K$^{-1}$ mol$^{-1}$ which is similar to that for the second order rate constant, $k_{OH1}$, of $-121$ J K$^{-1}$ mol$^{-1}$ and is again indicative of a stepwise mechanism for the subsequent reaction of TBPI$^-$ rather than a concerted process.

The second-order rate constant for the *acid* catalysed hydrolysis of the β-sultam **1** is $1.90 \times 10^{-3}$ dm$^3$ mol$^{-1}$ s$^{-1}$ which is $1.5 \times 10^3$-fold less than that for the derivative lacking the α-benzoyl group **2**. This enormous rate retardation by electron-withdrawing substituents generates an apparent Hammett $\rho_I$ value for α-substitution of $-10$. By contrast, the effect of acyl substituents upon the rate of acid catalysed hydrolysis of amides is small, with electron-withdrawing substituents producing either a small increase or decrease in rate.[8] Although only based on a single substituent, this effect indicates a unimolecular A1-type process in which the N-conjugate acid of the β-sultam undergoes rate-limiting ring opening to form an electron-deficient sulfonylium ion which is then trapped by water to give the product β-amino sulfonic acid (Scheme 2).

Although sulfonylium ions are much more difficult to form than acylium ions[9] and there are no well established cases for their formation during substitution at sulfonyl centres,[3] the present case is compatible with the similar acylium ion mechanism suggested for the acid catalysed hydrolysis of β-lactams.[10]

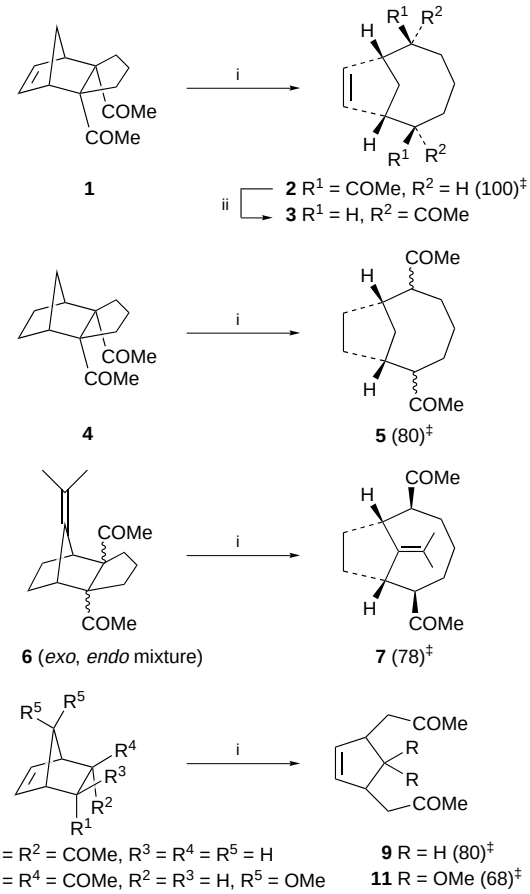
# Samarium(II) iodide promoted carbon–carbon bond fragmentation: a facile route to bridged eight membered rings and 1,3-disubstituted cyclopentanes

**Azizul Haque and Subrata Ghosh***

*Department of Organic Chemistry, Indian Association for the Cultivation of Science, Jadavpur, Calcutta-700032, India*

**Samarium(II) iodide has been found to induce carbon–carbon bond cleavage in a number of bicyclo[2.2.1]heptane derivatives having a 1,4-dicarbonyl moiety under conditions at which the 1,4-dicarbonyl moiety undergoes intramolecular pinacol coupling.**



The development of reactions promoted by samarium(II) iodide is of continued interest in organic synthesis. After its introduction as a powerful single electron transfer agent, it has been extensively used in C–C bond formation reactions.[1] Reactions involving fragmentation of carbon–heteroatom bonds[2] like dehalogenation, deoxygenation and deamination utilising samarium(II) iodide have also been widely investigated. However, little attention has been focused on fragmentation of C–C bonds. In 1982, Magnus and co-workers[3] reported a $SmI_2$-promoted reductive cleavage of a C–C bond of a six membered ring in a steroidal system. Subsequently C–C bond cleavage induced by $SmI_2$ has been observed in cyclopropanes[4] and cyclopentanes.[5] However, in the latter case, reduction was found to compete favourably with ring cleavage. To date these are the only rings reported to undergo cleavage promoted by $SmI_2$.

Hoffmann and co-workers[6] have recently demonstrated that 1,4-diketones undergo smooth pinacol coupling with $SmI_2$ to produce cyclobutane-1,2-diols. Even pinacol formation was found to be facile to produce cyclobutane-1,2-diols incorporated in highly strained ring systems. In connection with our interest in the synthesis of propellanes[7] of various ring sizes from the diketone **1**, we anticipated that its intramolecular pinacol coupling, according to Hoffmann *et al.*, would proceed smoothly to provide an easy access to [3.3.2]propellanes. Herein, we report our findings on attempted pinacol coupling of the 1,4-diketone embodied in norbornane derivatives leading to facile C–C bond cleavage.

Treatment of a solution of the diketone **1** (Scheme 1) in THF–HMPA (8 : 1) containing a catalytic amount of Bu$^t$OH at room temperature with 2.5 equiv. of $SmI_2$ (0.1 M in THF) afforded a liquid in quantitative yield. Surprisingly the product was found to contain carbonyl groups as evidenced by an IR absorption at 1700 $cm^{-1}$, and a COMe singlet at $\delta$ 2.15 integrating for six protons and a carbonyl carbon at $\delta$ 210.5 by $^1H$ and $^{13}C$ NMR spectra,† respectively. All these data indicated that the reaction did not follow the usual course of intramolecular pinacol coupling. Careful analysis of the $^1H$ and $^{13}C$ NMR spectra of the product revealed its structure to be that of **2**. The presence of two sets of methine carbons at $\delta$ 43.8 and 55.1 in the $^{13}C$ NMR spectrum of the product instead of only one set of methine carbons at $\delta$ 52.7 in the starting diketone **1** was a clear indication of the cleavage of the 2,6-bond. Conclusive evidence of the ring cleavage was obtained when the product epimerised on refluxing with NaOMe–MeOH to produce a mixture of the epimeric diketones **2** and **3** with the latter predominating. The stereochemical assignment of the ring cleaved product **2** was made by comparing the chemical shift of its bridgehead protons with that of the epimerised product. The bridgehead protons *syn* to the COMe group as in **2** must experience a deshielding effect of the carbonyl group. Thus, the diketone with the bridgehead protons appearing at $\delta$ 3.36 was assigned the structure **2** and the major component of the epimerised product with bridgehead protons at $\delta$ 3.06 was assigned the structure **3**.

The cleavage of the C–C bond in **1** having a 1,4-dicarbonyl functionality suitably oriented for intramolecular pinacol type coupling is remarkable. Pinacol reaction of the diketone **1** would probably involve an enormous increase in strain energy of the strained norbornene system. Hence the initially formed diketyl radical, instead of coupling, undergoes homolysis of the C–C bond to produce a relatively less strained system.

However, reduction of the strain of the parent system by structural modification left the reaction course unaltered. For example, the saturated diketone **4** underwent smooth ring cleavage under the same conditions. Similarly, a mixture of the *endo* and *exo* diketones **6** produced a single ring cleaved product **7** in excellent yield. Even the simple norbornene diketone **8** produced exclusively the ring cleaved product **9**. Finally, the diketone **10** in which the carbonyl groups are oriented *anti* to each other also underwent ring cleavage to produce the highly functionalised cyclopentane derivative **11**.

**Scheme 1** *Reagents and conditions*: i, $SmI_2$, THF, HMPA, Bu$^t$OH, room temp., 2–3 min, then 0.1 M HCl; ii, 2% NaOMe, MeOH, reflux, 7 h

The samarium(II) iodide promoted cleavage of C–C bonds in norbornene derivatives may be useful for application in organic synthesis. For example, the cleavage of the diketones **1**, **4** and **6** to provide the bridged eight membered ring derivatives **2**, **5** and **7**, respectively, may provide a convenient route for entry into taxanes.[8] The 1,3-disubstituted cyclopentenes have previously served as precursors[9] to cyclopentanoid natural products.

We are grateful to the Council of Scientific and Industrial Research, New Delhi, for financial support.

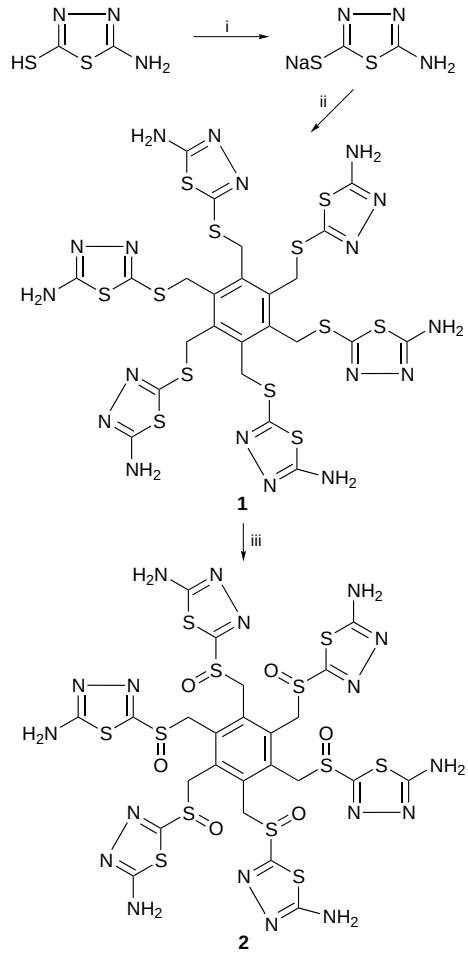
# First metal-encapsulating star polysulfoxide incorporating 2-amino-1,3,4-thiadiazole

**Chi Yang,*[a,b] Xiao-Ming Chen,*[b] Xiao-Quan Lu,[b] Qin-Hai Zhou[a] and Yan-Sheng Yang*[b]**

[a] *Department of Chemical Engineering, Guangdong University of Technology, 729 Dongfeng Road East, Guangzhou 510090, China*

[b] *Department of Chemistry, Zhongshan University, Guangzhou 510275, China*

**The first star polysulfoxide 2 is synthesized by selective oxidation of a new hexaaminohexathioether 1, which gives a novel binuclear bis-tripodant species by encapsulating a pair of $Cu^{II}$ ions.**



Suitably hexa-substituted benzene derivatives as new hosts and complex-forming ligands with a great underlying potential have received considerable attention in recent years.[1] A series of such macromolecules with specific enclathration properties have been uncovered, which are related to octopus,[2] hexa-host,[3] hexa-pedals,[4] aromatic propeller[5] and star polymers.[6] In particular, octopus polythioethers fitted with numerous donor atoms show unusual complexing tendency to metal cations owing to their conformational mobility being impeded by spatial crowding.[7] The binding of $Cu^{II}$ to polythioethers has led to a great understanding of Cu–S interactions in copper enzymes.[8] However, no report has yet appeared on the synthesis of octopus polysulfoxide or solid metal complexes of octopus ligands. We now report the synthesis and properties of novel $Cu^{II}$ complexes with a novel octopus polythioether **1** and the first star polysulfoxide **2**.

Synthesis of **1** was both straightforward and high yielding. Refluxing of hexakis(bromomethyl)benzene with the sodium salt of 2-amino-5-sulfanyl-1,3,4-thiadiazole gave **1** in > 93% yield.† Mild and selective oxidation of **1** with an excess of dilute hydrogen peroxide in dilute HCl solution at ambient temperature for 18 h afforded **2** in high yield ( > 90%),† with amino groups preserved and no over oxidation (see Scheme 1). Octopus compounds **1** and **2** can form inclusion compounds with DMF and $Me_2SO$ with host : guest = 1 : 1 and 1 : 2, respectively.

The hexasubstituted benzene octopus may form two possible types of metal complexes directed by suitable metal ions based on their preferential conformations: (*a*) a mononuclear species with the six arms of an octopus encapsulating a metal ion; (*b*) a binuclear bis-tripodant species with three arms of an octopus at 1,3,5-positions located above the phenyl plane encapsulating a metal ion, and the remaining three arms at 2,4,6-positions located below the plane encapsulating another metal ion. Copper(II) complexes of **1** and **2** were prepared in hot HCl solution in quantitative yield, giving a mononuclear species of **1**·$CuCl_2$ **3**,† and a binuclear species **2**·$Cu_2Cl_4$ **4**.† The $FAB^+$ mass spectrum of **3** which exhibits a peak at *m/z* 1011 ($[Cu\mathbf{1}]^{2+}$) is clearly indicative of the formation of a 1 : 1 complex. The presence of the characteristic molecular peak at *m/z* ($FAB^+$ MS) 1171 ($[Cu_2\mathbf{2}]^{4+}$) unambiguously shows complexation of two $Cu^{II}$ ions per molecule of **2** in **4**. The IR spectra suggest that the amino groups and exocyclic sulfur do not coordinate to the metal ions, only the 1,3,4-thiadiazole rings participate in coordination.[9] Thus, it is highly possible that in **3** one $Cu^{II}$ ion is encapsulated by six arms of **1**, and in **4**, two $Cu^{II}$ ions are each encapsulated by three arms of **2**.

Mononuclear complex **3** shows broad $^1H$ NMR peaks as usual for paramagnetic copper(II) complexes. In contrast, binuclear complex **4** produces very narrow $^1H$ NMR peaks, such an observation is similar to those found for some magnetically coupled dimeric copper(II) complexes.[10] The anisotropic X-band EPR spectrum of polycrystalline **3** at 100 K ($g_\perp$ = 2.263, $g_\parallel$ = 2.061) exhibits the usual line shape for mononuclear copper(II) complexes with a $d_{x^2-y^2}$ ground state. The EPR spectrum of **4** shows a unique quasi-isotropic, broad absorption centered at $g$ = 2.072 (100 K) with a half-weight width of *ca*. 300 G; the broadness of this EPR signal is typical of weak metal–metal interaction, and hence implies a dimeric structure.[11] Thermogravimetry of **4** shows a total mass loss of 87.1%, which correlates well with the expected loss of 87.9% for a metal : ligand molar ratio of 2 : 1.

There is no redox peaks observed for **1**, while cyclic voltammetry (CV) (Fig. 1) of **2** shows three quasi-reversible redox waves at $E_{1/2}$ = 0.052, −0.46 and −0.425 V *vs*. SCE, corresponding to the successive reduction waves of the three 2-amino-5-sulfinyl-1,3,4-thiadiazole arms located at the same side of the benzene plane (*i.e.* the groups at 1,3,5-positions),

**Scheme 1** *Reagents and conditions*: i, Na, EtOH, room temp.; ii, EtOH, 80 °C, Ar, 22 h; iii, $H_2O_2$, HCl–$H_2O$, room temp., 18 h

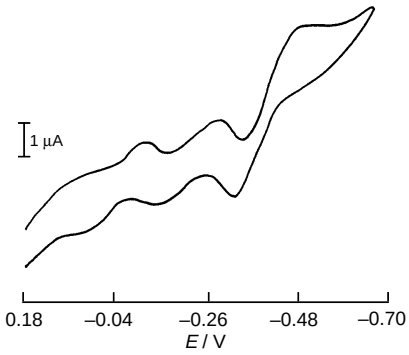


**Fig. 1** Cyclic voltammetry of **2** ($5 \times 10^{-5}$ M) on a carbon-glass electrode with $NBu_4Cl$ ($10^{-3}$ M) in HCl (3 M). Sweep rate: 100 mV $s^{-1}$.

leading to the overall formation of a hexa-anion. The shapes of the waves are in accordance with a six-electron transfer and each wave behaving as a two-electron wave, similar to those of cryptates.[12] These results indicate that the redox process of **2** is mainly ascribed to the presence of redox-active sulfinyl groups. CV studies of **3** and **4** show two similar quasi-reversible cathodic waves at $E_{1/2} = -0.121$ and $-0.225$ V, and at $E_{1/2} = 0.21$ and 0.295 V (*vs.* 10 mM $Ag^I/AgCl$), respectively, corresponding to the following reduction:[13]

$$[Cu^{II}\mathbf{1}]^{2+} \leftrightarrow [Cu^{I}\mathbf{1}]^{+} \leftrightarrow [Cu^{0}\mathbf{1}]^{0}$$

$$[Cu^{II}Cu^{II}\mathbf{2}]^{4+} \leftrightarrow [Cu^{II}Cu^{I}\mathbf{2}]^{3+} \leftrightarrow [Cu^{II}Cu^{0}\mathbf{2}]^{2+}$$

A possible reason for the observed behaviour of the binuclear species **4** is that only one $Cu^{II}$ ion, surrounded by three arms, can approach and be adsorbed by the electrode surface at a given time, resulting in similar behaviour to that observed for **3**.

We thank the State Commission of Science and Technology of China for financial support.

**Chiral 2,2′:6′,2″ : 6″,2‴-quaterpyridines bearing fused chiral groups in the 5,6- and 5‴,6‴-positions are prepared; these ligands preferentially form *P* or *M* dinuclear double helicates upon coordination to silver(I), one of which has been structurally characterised.**

Oligopyridines and oligopyridine metal-binding domains are a recurrent feature in metallosupramolecular chemistry[1] and it is now well established that the higher oligopyridines can give multiple-helical transition-metal complexes.[2] Although pre-organised chiral ligands bearing multiple oligopyridine domains have been previously studied[3,4] we have recently shown that the right- or left-handed chirality of the helix may also be controlled in true self-assembly processes by the use of chiral oligopyridines and have demonstrated that modest diastereomeric excesses (de, 75%) of the *P* or *M* double helicates are formed upon reaction of enantiomerically pure chiral 2,2′:6′,2″-terpyridines with copper(I).[5] Here, we show that acceptably high de values may be obtained by (*i*) varying the metal, (*ii*) increasing the number of donor atoms and (*iii*) increasing the number of chiral sites in the ligands.

2,2′ : 6′,2″:6″,2‴-Quaterpyridines react with silver(I) salts to give dinuclear double helicates.[6,7] A pair of enantiomeric 2,2′:6′,2″:6″,2‴-quaterpyridines (1*S*, 1*S*)-(+)-$L^1$ and (1*R*, 1*R*)-(−)-$L^2$ were prepared enantioselectively from (1*S*)-(−) or (1*R*)-(+) pinocarvone[8] by reaction with salt $L^3$ (ref. 9) and ammonium acetate in a mixture of acetic acid and acetic anhydride in near quantitative yield as white crystalline solids (Scheme 1).† The ligands were fully characterised and exhibited spectroscopic properties closely resembling those of analogous lower homologues first reported by von Zelewsky and co-workers.[10]

The reaction of $L^1$ or $L^2$ with silver(I) acetate in methanol followed by precipitation with ammonium hexafluorophosphate gave cream coloured precipitates of $[Ag_2L^1{}_2][PF_6]_2$ or $[Ag_2L^2{}_2][PF_6]_2$ as established by elemental analysis and mass spectrometry [*m*/*z* 1358 ($M^+ - PF_6$)] in 85–90% yield.‡ In principle, each ligand could give a pair of diastereomeric double helicates, for example $L^1$ could give *P*-$[Ag_2\{(1S, 1S)\text{-}L^1\}_2]^{2+}$ or *M*-$[Ag_2\{(1S, 1S)\text{-}L^1\}_2]^{2+}$. Unlike the case investigated earlier[5] the use of the symmetrically substituted ligands $L^1$ and $L^2$ eliminates any additional complications from head–tail isomerism. The $^1$H NMR spectrum of $CD_3CN$ solutions of the crude precipitates revealed a 0.024 : 1.00 ratio of diastereomers in each case [Fig. 1(*a*)]. This corresponds to a 95.3% de of one of the two diastereomers. A single recrystallisation from acetonitrile yielded good quality crystals which $^1$H NMR spectroscopy revealed to contain only the major diastereomer. Circular dichroism spectroscopy confirmed that the compounds prepared from $L^1$ and $L^2$ possessed equal and opposite chiroptical properties [Fig. 1(*b*)] as expected for an enantiomeric pair of (*S**,*S**,*S**,*S**)-P* and (*R**,*R**,*R**,*R**)-*M** helicates. After a single recrystallisation, a de of 100% has been obtained. The only question remaining was to determine which of the two helical conformations (*P* or *M*) was favoured in each case. In related systems, a large positive CD absorption at *ca.* 320 nm is characteristic of a *P* helicate, whereas a negative mode is seen for *M*-helicates.[10] On this basis, we propose *P*-$[Ag_2\{(1S, 1S)\text{-}L^1\}_2]^{2+}$ and *M*-$[Ag_2\{(1R, 1R)\text{-}L^2\}_2]^{2+}$ structures. Molecular modelling gave equivocal results and we have determined the X-ray structure of $[Ag_2\{(1S, 1S)\text{-}L^1\}_2]\text{-}[PF_6]_2$.§

Initial attempts to determine the structure revealed a very large unit cell [$U$ = 49 245(9) Å$^3$] and the structure was only solved using data from an area detector. The structure of the cation present in $[Ag_2\{(1S, 1S)\text{-}L^1\}_2][PF_6]_2$ is presented in Fig. 2(*a*). The double-helical geometry is confirmed and the double helix is revealed unambiguously to possess a *P* conformation [most easily seen in the space-filling representation in Fig. 2(*b*)]. The Ag–N distances [2.245(6), 2.343(6) Å] are unremarkable and closely resemble those in the parent 2,2′:6′,2″ : 6″,2‴-quaterpyridine complex (2.223–2.409 Å).[6,7] The Ag···Ag distance within the cation of 3.230(2) Å is slightly longer than observed in the parent 2,2′ : 6′,2″ : 6″,2‴-quaterpyr-

**Scheme 1**

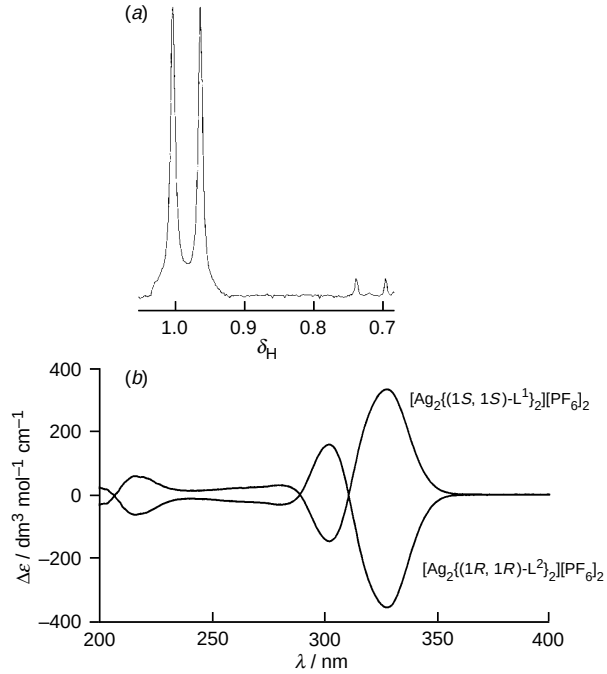

**Fig. 1** (*a*) Part of the $^1$H NMR spectrum of a $CD_3CN$ solution showing $H^{7PB}$ of the crude product [Ag$_2${(1*R*, 1*R*)-L$^2$}$_2$][PF$_6$]$_2$ showing the 95% de of one of the two diastereomers and (*b*) the CD spectra of the diastereomerically pure products obtained from the recrystallisation of [Ag$_2${(1*S*, 1*S*)-L$^1$}$_2$][PF$_6$]$_2$ and [Ag$_2${(1*R*, 1*R*)-L$^2$}$_2$][PF$_6$]$_2$

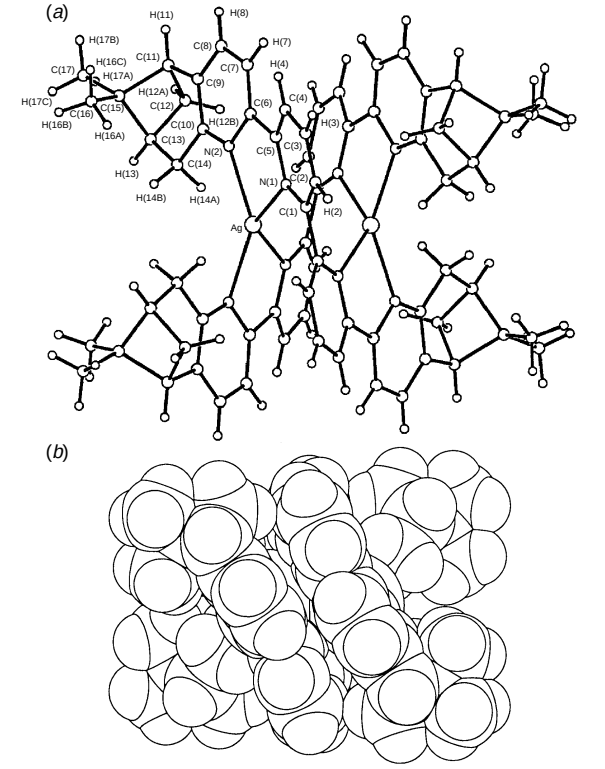

**Fig. 2** Crystal and molecular structures of (*a*) the double-helical cation with *P* chirality in the lattice of *P*-[Ag$_2${(1*S*, 1*S*)-**1**}$_2$][PF$_6$]$_2$ showing the numbering scheme and adopted and (*b*) a space-filling representation of the same cation

idine complex [3.107(2) Å][6,7] which presumably represents the repulsion between the fused chiral substituents. The principal twisting within the ligand occurs between the two central rings (41.4°) although a significant twist of 17.4° occurs between the outer rings (*cf.* 45–47 and 13.0–13.5° in the 2,2′:6′,2″:6″,2‴-quaterpyridine complex).[6,7] Interestingly, the (*S*,*S*,*S*,*S*)-*P* and (*R*,*R*,*R*,*R*)-*M* preference that is shown is opposite to the (*S*,*S*)-*M* and (*R*,*R*)-*P* preferences shown with monofunctionalised 2,2′:6′,2″-terpyridines.

In conclusion, we have demonstrated that 2,2′:6′,2″:6″,2‴-quaterpyridines bearing two fused chiral substituents give high diastereomeric excesses of *P* or *M* helicates upon reaction with silver(I). We are currently probing the origin of the diastereoselectivity and attempting to increase the selectivity further.

We should like to thank the Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung and the University of Basel (E. C. C., T. K.) for support. We should also like to thank Professor A. von Zelewsky for helpful discussions and for access to unpublished data.

# Application of triple-channel $^{13}C\{^{1}H,^{19}F\}$ NMR techniques to probe structural properties of disordered solids

**Alison Nordon,[a] Robin K. Harris,*[a] Lily Yeo[b] and Kenneth D. M. Harris*[b]**

[a] *Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE*
[b] *School of Chemistry, University of Birmingham, Edgbaston, Birmingham, UK B15 2TT*

**Triple-channel $^{13}C$ MAS NMR experiments are carried out to characterize intermolecular interactions in disordered molecular solids containing fluorinated *n*-alkanes; an approach involving a combination of $^{1}H \rightarrow {}^{13}C$ and $^{19}F \rightarrow {}^{13}C$ cross-polarization experiments, with both single-channel ($^{1}H$) and double-channel ($^{1}H$,$^{19}F$) decoupling is developed to assign resonances for a given type of $^{13}C$ nucleus in different intermolecular environments.**

In molecular crystals, structural disorder often arises when the molecules are able to take up more than one orientation (not necessarily with equal energy) within the space available to them. Fundamentally, such disorder raises important issues concerning the intermolecular interactions within the crystal. Although the space- and time-averaged crystal structure, as determined by diffraction-based techniques, can generally indicate the existence of disorder, it is often unable to provide information at a sufficiently detailed level. Techniques that can be used to study local structural and/or dynamic properties of solids must then come to the fore, and in this regard solid-state NMR spectroscopy proves to be a versatile and powerful approach. As described here, the application of triple-resonance techniques[1,2] can enhance considerably the scope and potential of solid-state NMR in this field. In particular, this paper reports solid-state $^{13}C$ NMR studies carried out to characterize intermolecular interactions in disordered molecular solids containing organofluorine compounds. Selective cross-polarization from $^{1}H$ or $^{19}F$, together with decoupling of $^{1}H$ and/or $^{19}F$, have been exploited to probe the local structure around organic functional groups that are disordered between local intermolecular environments that either contain fluorine or do not contain fluorine. The approach is applied to orientational disorder of 1-fluorotetradecane [$FH_2C(CH_2)_{12}CH_3$] 'guest' the molecules within the crystalline urea tunnel structure[3] in 1-fluorotetradecane–urea inclusion compound.

Carbon-13 CP MAS spectra recorded for the 1-fluorotetradecane–urea inclusion compound are shown in Fig. 1. An initial assignment of the resonances in the $^{1}H \rightarrow {}^{13}C$ CP MAS spectrum [Fig. 1(*a*)], acquired using $^{1}H$ and $^{19}F$ double-decoupling, was made, in part, on the basis of a previous study of alkane–urea inclusion compounds.[4] There are two resonances for $CH_2F$ ($\delta$ 84.1, 83.9) and two for $CH_3$ ($\delta$ 14.7, 14.4), whereas all other $^{13}C$ positions within the molecule give rise to only one distinguishable resonance (note that an italic letter is used to specify the assignment of resonances). As first proposed and demonstrated by Hollingsworth *et al.*[5,6] (see also ref. 3), such chemical shift differences for the end-groups of unsymmetric guest molecules $X(CH_2)_nY$ (abbreviated to X–Y) in urea inclusion compounds can arise from the existence of the different end-group interactions X···X, X···Y and Y···Y (rather than other possible sources such as conformational disorder). On this basis, the observation of two resonances for $CH_2F$ in 1-fluorotetradecane–urea may be attributed tentatively to the $CH_2F\cdots FH_2C$ and $CH_2F\cdots H_3C$ end-group environments and the observation of two resonances for $CH_3$ may be similarly assigned to the $CH_3\cdots H_3C$ and $CH_3\cdots FH_2C$ end-group environments. Previously, assignments of such resonances to the different end-group situations have been made by comparing the spectrum for the urea inclusion compound containing X–Y guest molecules with: (*a*) spectra for urea inclusion compounds containing the corresponding symmetric guest molecules X–X and/or Y–Y; and/or (*b*) spectra for urea inclusion compounds containing mixtures of the guest molecules X–Y and X–X, and/or mixtures of the guest molecules X–Y and Y–Y.

In the approach devised here, the two resonances for $CH_3$ carbons in the 1-fluorotetradecane–urea inclusion compound can be assigned using two complementary experiments which exploit the $^{13}C$–$^{19}F$ dipole–dipole interaction. First, we consider a $^{19}F \rightarrow {}^{13}C$ CP MAS experiment with the spectrum [see Fig. 1(*b*)] acquired using both $^{1}H$ and $^{19}F$ decoupling; clearly, $^{19}F \rightarrow {}^{13}C$ CP gives rise to signals only from $^{13}C$ nuclei that have a dipolar interaction with (and therefore proximity to) $^{19}F$. Second, we discuss a $^{1}H \rightarrow {}^{13}C$ CP MAS experiment with the spectrum [see Fig. 1(*c*)] acquired using only $^{1}H$ decoupling; although all $^{13}C$ nuclei will cross-polarize from $^{1}H$, resonances arising from $^{13}C$ nuclei that experience $^{13}C$–$^{19}F$ dipole–dipole interactions will be broadened significantly in this experiment (note the absence of $^{19}F$ decoupling). In Fig. 1(*b*), the resonance at $\delta$ 14.4 is present, whereas the resonance at $\delta$ 14.7 is absent. In Fig. 1(*c*), the resonance at $\delta$ 14.4 is broadened severely, whereas the resonance at $\delta$ 14.7 is a narrow peak. These observations imply that the resonance at $\delta$ 14.4 arises from $CH_3\cdots FH_2C$ end-group environments, whereas the resonance at $\delta$ 14.7 arises from $CH_3\cdots H_3C$ end-group environments.

Clearly, the resonances for $CH_2F$ cannot be assigned using the above experiments, as the $^{13}C$ nucleus of interest is directly bonded to $^{19}F$. Instead, the classic approaches[5,6] may be used. Thus, $^{1}H \rightarrow {}^{13}C$ CP MAS spectra, acquired using both $^{1}H$ and $^{19}F$ decoupling, for the 1,10-difluorodecane–urea and 1,12-di-

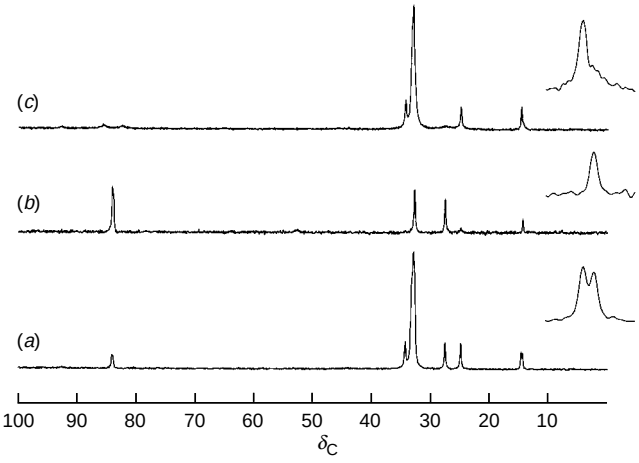

**Fig. 1** Carbon-13 CP MAS spectra (guest region only) of the 1-fluorotetradecane–urea inclusion compound: (*a*) $^{1}H \rightarrow {}^{13}C$ cross-polarization spectrum acquired with $\{^{1}H,^{19}F\}$ double-decoupling; (*b*) $^{19}F \rightarrow {}^{13}C$ cross-polarization spectrum acquired with $\{^{1}H,^{19}F\}$ double-decoupling; (*c*) $^{1}H \rightarrow {}^{13}C$ cross-polarization spectrum acquired with only $^{1}H$ decoupling. In each case the inset shows the $CH_3$ signals on expanded scale.

**Table 1** Carbon-13 chemical shifts and assignments for the 1-fluorotetradecane–urea inclusion compounds

| $\delta_C$ | Assignment |
|---|---|
| 14.4 | $CH_3\cdots FH_2C$ |
| 14.7 | $CH_3\cdots H_3C$ |
| 25.0 | $CH_2CH_3$ |
| 27.6 | $CH_2CH_2CH_2F$ |
| 32.8 | $CH_2CH_2F$ |
| 33.0 | 'inner' $CH_2$ |
| 34.3 | $CH_2CH_2CH_3$ |
| 83.9 | $CH_2F\cdots H_3C$ |
| 84.1 | $CH_2F\cdots FH_2C$ |

fluorododecane–urea inclusion compounds have single resonances due to $CH_2F$ at $\delta$ 84.1 for 1,10-difluorodecane–urea and at $\delta$ 84.2 for 1,12-difluorododecane–urea (in these inclusion compounds, all end-group interactions are of the type $CH_2F\cdots FH_2C$). This suggests that the resonance at $\delta$ 84.1 for 1-fluorotetradecane–urea arises from $CH_2F\cdots FH_2C$ end-group interactions. This assignment has been corroborated by considering the change in relative intensities of the two resonances in $^1H \rightarrow {}^{13}C$ CP MAS spectra for a urea inclusion system containing a mixture of 1-fluorotetradecane and tetradecane (for which the relative proportion of $CH_2F\cdots H_3C$ end-group environments should be higher than that in the 1-fluorotetradecane–urea inclusion compound).

All our assignments of isotropic chemical shifts for 1-fluorotetradecane in the urea tunnel structure are summarized in Table 1.

Although $^{19}F$ NMR has several advantages over $^{13}C$ NMR (including substantially greater sensitivity), it is noteworthy that we have been unable to distinguish different intermolecular environments for $^{19}F$ in the 1-fluorotetradecane–urea inclusion compound using $^{19}F$ MAS NMR (with $^1H$ decoupling). Presumably the $^{19}F$ chemical shift difference between the $CH_2F\cdots H_3C$ and $CH_2F\cdots FH_2C$ end-group environments is too small to be resolved, which in turn probably arises because $^{13}C$ linewidths are significantly smaller ($\Delta\nu_{\frac{1}{2}}$ *ca.* 12 Hz) than $^{19}F$ widths ($\Delta\nu_{\frac{1}{2}}$ *ca.* 125 Hz) for these systems.

The research described here has demonstrated that selective cross-polarization experiments in solid-state $^{13}C$ NMR can provide local structural information on intermolecular arrangements in disordered solids. This shows how triple-resonance solid-state NMR techniques may be exploited to extend our understanding of fundamental structural properties of solids.

Carbon-13 MAS NMR spectra were recorded on a Chemagnetics CMX200 NMR spectrometer operating at 50.33 MHz for $^{13}C$, 200.13 MHz for $^1H$ and 188.27 MHz for $^{19}F$. A Chemagnetics HFX triple-resonance probe was used, with the sample contained in zirconia rotors (7.5 mm outer diameter) fitted with boron nitride spacers and a Kel-F drive tip and end-cap. For $^{13}C$ CP MAS experiments, typical spectral conditions were: $\pi/2$ pulse duration, 4.5 μs; contact times, 1.0 ms ($^1H \rightarrow {}^{13}C$ CP) and 3.0–12.0 ms ($^{19}F \rightarrow {}^{13}C$ CP); spectral width, 20 kHz; recycle delay, 5–10 s; acquisition time, 102.4–153.6 ms; $^1H$ and $^{19}F$ decoupler powers, 56 kHz; MAS frequencies, 1.0–3.0 kHz. Chemical shifts were referenced externally, by rotor replacement, to the high-frequency resonance of adamantane ($\delta$ 38.4 with respect to the signal for tetramethylsilane). All urea inclusion compounds were prepared by slow cooling of solutions containing the guest molecules and urea in either methanol or a mixture of methanol and *tert*-amyl alcohol.

We thank EPSRC for the award of a studentship and ICI for a scholarship to A. N. and EPSRC also for financial support under research grant L02906. Ciba Specialty Chemicals Ltd and the University of Birmingham are thanked for the award of studentships to L. Y. We are grateful to Dr Paul Coe for synthesis of the 1,10-difluorodecane and 1,12-difluorododecane samples used in this work.

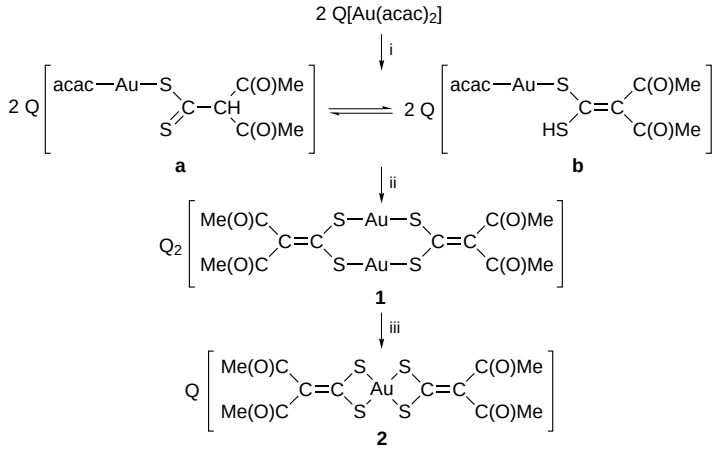
**The reaction of $[N(PPh_3)_2][Au(acac)_2]$ (acac = acetylacetonate) with $CS_2$ gives $[N(PPh_3)_2]_2[Au_2\{\mu^2:\eta^2\text{-}S_2C{=}C(COMe)_2\}_2]$, which reacts with $PhICl_2$ to give $[N(PPh_3)_2][Au\{\eta^2\text{-}S_2C{=}C(COMe)_2\}_2]$, for which the crystal structure is determined; these are the first characterized 2,2-diacetylethylene-1,1-dithiolato complexes of any element.**



Interest in gold complexes containing S-bonded ligands stems from their potential application in the glass and ceramic industries[1] and, more importantly, in medicine (chrysotherapy).[2] Thiolatogold(I) complexes such as the commercial Myocrisin, Allochrysine, Solganol, or Auranofin, are among the most efficient antiarthritic drugs.[2] In addition, Solganol and Auranofin show *in vitro* inhibitory effects on Human Immunodeficiency Virus 1,[3] high cytotoxicity to tumor cells[4] and activity against i.p. P388 leukaemia.[5]

We have found that $CS_2$ reacts with $[N(PPh_3)_2][Au(acac)_2]$[6] to give $[N(PPh_3)_2]_2[Au_2\{\mu^2:\eta^2\text{-}S_2C{=}C(COMe)_2\}_2]$ **1** (Scheme 1). As far as we are aware, this is the first fully characterized 2,2-diacetylethylene-1,1-dithiolato complex of any element.

In the absence of any mechanistic data, we assume that the $CS_2$ inserts into one of the gold–carbon bonds to produce a dithiocarboxylato complex **a** (see Scheme 1), likely to be in tautomeric equilibrium with the ethylene-1,1-dithiolato form **b**, the remaining acac ligand being responsible for intermolecular deprotonation and subsequent dimerization to give **1** with concomitant formation of acetylacetone.

Insertion reactions of $CS_2$ into transition-metal–H, –C, –N, –P, –S, or –Cl bonds are known to produce dithioformiato, dithiocarboxylato, dithiocarbamato, phosphinodithiocarboxylato, trithio- or perthio-carbonato, or chlorodithioformiato complexes, respectively.[7] However, in the case of gold these reactions have scarcely been studied and thus only two other $CS_2$ insertion reactions have been described so far, namely those into the Au–C bond in $[Au\{\eta^1\text{-}C_5Me_5\}(PR_3)]$ complexes to give dithiocarboxylato complexes $[Au\{\eta^1\text{-}S_2CC_5Me_5\}(PR_3)_n]$ (R = Ph, *n* = 2; R = Pr$^i$, *n* = 3)[8] or into an Au–Cl bond of $[Au_2Cl_6]$ to give the chlorodithioformate complex $[AuCl_2(\eta^2\text{-}S_2CCl)]$.[9] We have ourselves described the insertion of $CS_2$ into an Au–S (or S–H) bond in $[N(PPh_3)_2][Au(SH)_2]$ to produce the first trithiocarbonatogold complex.[10] In the reaction of $CS_2$ with $[Au(C_6F_5)(PPh_2CHPPh_2Me)]$ the complex $[Au^{III}\{PPh_2C(PPh_2Me)CS_2\}_2][Au^I(C_6F_5)_2]$, resulting from a carbon–carbon coupling reaction, is obtained.[11]

The reaction of methylene active compounds with $CS_2$ and $LiNR_2$, NaH,[12] or $K_2CO_3$,[13] led to the synthesis of the corresponding 2,2-disubstituted ethylene-1,1-dithiolate salts, which were treated *in situ* with MeI to give ketene dithioacetals. In this context acetylacetone has been used to prepare the 2-acetyl-2-oxopropylidene-*S*,*S*-acetal $[(MeS)_2C{=}C\{C(O)Me\}_2]$.[13–15] Our synthetic method is, therefore, unprecedented. Ketene dithioacetals are of current interest because the double carbon–carbon bond they present is amenable to both nucleophilic and electrophilic attack.[14] Indeed, they are very versatile starting materials for the synthesis of a wide variety of fused heterocycles,[13,16] polysubstituted pyridines,[17] pyrazoles,[18] *etc.* On the other hand, the interest in ketene dithioacetals with electron-withdrawing substituents stems from some of their physical properties as push–pull polarized ethylenes. Thus, the effect of chiral substituents or hydrogen bonding on second-order non-linearity,[19] the free energy of activation for rotation around the carbon–carbon double

**Scheme 1** Q = $[N(PPh_3)_2]$, acac = acetylacetonate. *Reagents and conditions*: i, $CS_2$ (excess) in acetone, 1 h, room temp; ii, −2 Hacac; iii, + $Cl_2IPh$ − PhI − $Q[AuCl_2]$, $CH_2Cl_2$, 45 min, room temp.

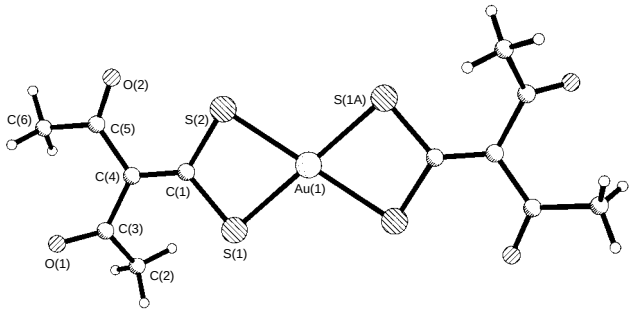


**Fig. 1** Structure of one of the two independent anions of **2**. Selected bond lengths (Å) and angles (°): Au(1)–S(1) 2.3234(13), 2.3375(13), Au(1)–S(2) 2.3479(12), 2.3217(12), C(1)–S(1) 1.758(4), 1.748(4), C(1)–S(2) 1.744(4), 1.755(4), C(1)–C(4) 1.353(6), 1.365(6); S(1)–Au(1)–S(2) 74.16(4), 74.46(4), S(2)–Au(1)–S(1A) 105.84(4), 105.54(4), S(1)–C(1)–S(2) 107.0(2), 107.2(2), S(1)–C(1)–C(4) 125.8(3), 126.1(3), S(2)–C(1)–C(4) 127.2(3), 126.8(4).

bond,[15,20] or the influence of the double bond twisting on the position of the IR $\nu_{C=C}$ stretching band[21] or on the photoionization energy[22] have been studied. Our synthesis opens a new access for such studies. The only 2,2-diacetylethylene-1,1-dithiolato complexes (of $Mn^{II}$, $Co^{II}$, $Ni^{II}$, $Cu^{II}$ and $Zn^{II}$) mentioned in the literature were prepared from the corresponding sodium salt of the ligand and their composition was only established by elemental analysis, while amperometric and potentiometric titrations were unsuccessful.[23]

Many dinuclear gold(I) complexes are known to undergo oxidative addition reactions with halogens, pseudohalogens or alkyl halides to give gold(II) complexes containing a gold–gold bond.[24] However, when complex **1** is treated with an equimolar amount of $Cl_2IPh$ in dichloromethane a disproportionation reaction takes place, giving $[N(PPh_3)_2][AuCl_2]$ along with the gold(III) complex $[N(PPh_3)_2][Au\{\eta^2\text{-}S_2C{=}C(COMe)_2\}_2]$ **2**. The same behaviour has previously been observed for other dithiolato,[25] dialkyldithiocarbamato,[26] or trithiocarbonato[27] gold(I) complexes.

The isolated complexes **1** and **2** have been fully characterized by C, H, N, S analyses, IR spectroscopy and $^1H$ and $^{13}C$ NMR. The X-ray crystal structure of complex **2** (Fig. 1),‖ shows it to crystallize with two independent half-anions and one $[N(PPh_3)_2]$ cation in the asymmetric unit. Both anions show almost identical inversion-symmetric $[Au\{\eta^2\text{-}S_2C{=}C(COMe)_2\}_2]$ *E*,*Z*-conformations. The gold atoms are in distorted square-planar environments, the angles around gold differing from the ideal value of 90° because of the small bite of the dithiolate ligand [S(1)–Au(1)–S(2) 74.16(4), 74.46(4)°; S(1)–Au(1)–S(2′) 105.84(4), 105.54(4)°, respectively]. The Au(1), S(1), S(2), C(1) and C(2) atoms are coplanar (mean deviation 0.054, 0.044 Å), with both acetyl groups twisted out of this plane, one of them considerably (torsion angle 55, 48°), the other one slightly (torsion angle 9, 13°, respectively). The C(1)–C(4) bond distances [1.353(6), 1.365(4) Å] lie in the range expected for $C(sp^2){=}C(sp^2)$ double bonds (1.294–1.392)[28] and are similar to that found in the closely related ketene *S*,*S*-dithioacetal $(MeS)_2C{=}C\{C(O)Me\}_2$ (1.351 Å) which shows a twisted (torsion angle 14°) *E*,*E*-conformation.[29]

Apart from bands due to the cation, the solid-state IR spectrum of **1** shows two strong $\nu$(C=O) bands at 1698 and 1678 $cm^{-1}$ and a strong $\nu$(C=C) band at 1580 $cm^{-1}$, while the $\nu$(AuS) band(s) cannot be assigned unequivocally because of the presence of bands from the $[N(PPh_3)_2]$ cation in the 400–300 $cm^{-1}$ region. The position of the $\nu$(C=O) band suggest that conjugation plays at best a marginal role.[29] The IR spectrum of **2** shows two strong $\nu$(C=O) bands at 1664 and 1636 $cm^{-1}$ and a medium $\nu$(AuS) band at 370 $cm^{-1}$. The frequency of the $\nu$(C=C) band is expected to decrease because of conjugation with one of the acetyl groups and cannot be unequivocally assigned.

We thank DGICYT (PB92-0982C) and the Fonds der Chemischen Industrie for financial support. P. G.-H. is grateful to Ministerio de Educación y Cultura for a Grant.

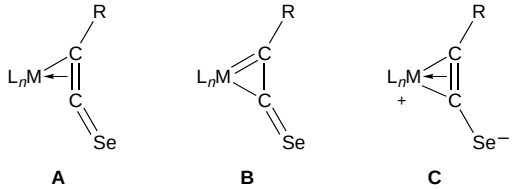
# Selenoketenyl and selenoalkyne complexes *via* the reactions of ketenyl complexes with Woollins' reagent

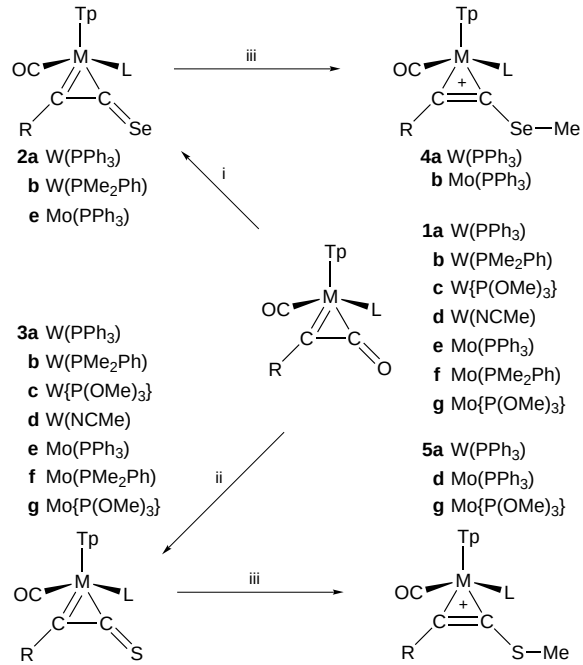
**Ian Baxter, Anthony F. Hill,* John M. Malget, Andrew J. P. White and David J. Williams**

*Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY*



**The complexes [ML(η²-OCCR)(CO)(Tp)] [M = W, Mo; L = $PMe_2Ph$, $PPh_3$, $P(OMe)_3$; R = $C_6H_4Me$-4; Tp = hydrotris(pyrazol-1-yl)borate] react with 'Woollins' reagent' [$4(PPh)_5/5Se_8$] to provide the first examples of selenoketenyl complexes [ML(η²-SeCCR)(CO)(Tp)], alkylation of which provides selenoalkyne complexes; the crystal structures of [W(η²-SeCCR)(CO)($PMe_2Ph$)(Tp)] and [W(η²-MeSeCCR)(CO)($PPh_3$)(Tp)]I are also reported.**

The study of ligands featuring carbon–selenium multiple bonds is hampered by the shortage of suitable ligand precursors, with the majority of studies involving $CSe_2$ and CSSe as source molecules. Thioketenyl ligands have recently begun to attract attention[1–3] however no reports have appeared concerning the preparation of selenoketenyl complexes (Scheme 1). This report is concerned with (*i*) the development of synthetic routes to the first examples of selenoketenyl complexes; (*ii*) the structural characterisation of one such complex, [W(η²-SeCCR)(CO)($PMe_2Ph$)(Tp)] **2b** [hereafter R = $C_6H_4Me$-4, Tp = hydrotris(pyrazol-1-yl)borate]; (*iii*) alkylation of selenoketenyl ligands to provide rare examples of mononuclear selenoalkyne complexes; (*iv*) structural characterisation of one example in the salt [W(η²-MeSeC≡CR)(CO)($PPh_3$)(Tp)]I **4a**.



We have recently described two routes for the conversion of ketenyl complexes of tungsten to their sulfur congeners.[3] The first involves the initial conversion of a ketenyl ligand to a chloroalkyne and then treatment with sodium hydrosulfide. In our hands, this approach has so far failed in the case of sodium hydroselenide or lithium selenide, with intractible mixtures being obtained. The second approach involves the reaction of a ketenyl ligand with Lawesson's oxygen/sulfur transfer reagent and appeared attractive except that the selenium analogue has yet to be reported.[4,5] Woollins has prepared a range of organophosphorus selenides from the reaction of cyclopolyphosphines with selenium.[5] For brevity, we shall refer to as Woollins' reagent, the compound which is presumed to be 2,4-bis(phenyl)-1,3-diselena-2,4-diphosphetane-2,4-diselenide, obtained from $(PPh)_5$ and elemental selenium (P : Se ratio 1 : 2). Studies to date suggest a similar reactivity profile, at least in part, to that of Lawesson's reagent.[5] The ketenyl complex [W(η²-OCCR)(CO)($PPh_3$)(Tp)] **1a**[6] reacts cleanly with Woollins' reagent to provide [W(η²-SeCCR)(CO)($PPh_3$)(Tp)] **2a** in high yield as the only isolable species (Scheme 2). The formulation follows from spectroscopic data† which are comparable to those for the related thioketenyl complexes[3] and the complexes [ML(η²-SeCCR)(CO)(Tp)] [ML = $WPMe_2Ph$, $MoPPh_3$, $MoP(OMe)_3$] which may be obtained in a similar manner from Woollins' reagent and [ML(η²-OCCR)(CO)(Tp)] (Scheme 2). The series of complexes **1a**, **3a** and **2a** shows a steady increase in the IR frequency of the carbonyl-associated absorption [**1a**, 1883; **2a**, 1909; **3a**, 1919 $cm^{-1}$], suggesting that the π-acidity of chalcoketenyl ligands increases in the order O, S, Se.

One example, **2b**, of this new class of compound was characterised by X-ray crystallography (Fig. 1).‡ The overall structure is remarkably similar to that of [W(η²-OCCR)(CO)($PPh_3$)(Tp)].[6] The bonding of the selenoketenyl ligand is dihapto through C(1) and C(36), the C=C=Se grouping lying in the equatorial coordination plane which also contains the carbonyl ligand. The W–N distances are unremarkable and in the range 2.188(9)–2.251(8) Å, the shortest of these being that *trans* to the phosphine, whilst the N–W–N angles are similar [79.8(3)–82.2(3)°]. The binding of the selenoketenyl ligand is best described by three resonance forms **A**–**C** (Scheme 1). There is clearly multiple bonding between W and C(1) [2.003(11) Å], W and C(36) [2.078(10) Å] and C(1) and C(36) [1.328(13) Å]. Furthermore, whilst there is little appropriate crystallographic precedent,[7] the C(36)–Se(37) separation [1.834(11) Å] clearly indicates a degree of partial double bond character.

Consistent with their alternative formulation as chalcogenoxyalkyne complexes (**C**, Scheme 1), the new complexes **2** and the related thioketenyl complexes [ML(η²-SCCR)(CO)(Tp)][3] are readily alkylated at the chalcogen to provide complexes of selenolato and thiolato alkynes (Scheme 2). Thus the new complexes **4** and **5** were readily obtained from the reaction of

**Scheme 1** Valence bond descriptions for selenoketenyl ligands

**Scheme 2** *Reagents*: i, $4(PPh)_5/5Se_8$; ii, $(S_2PC_6H_4OMe\text{-}4)_2$; iii, MeI; M = Mo, W; R = $C_6H_4Me$-4; L = $PPh_3$, $P(OMe)_3$, $PMe_2Ph$, MeCN; Tp = hydrotris(pyrazol-1-yl)borate

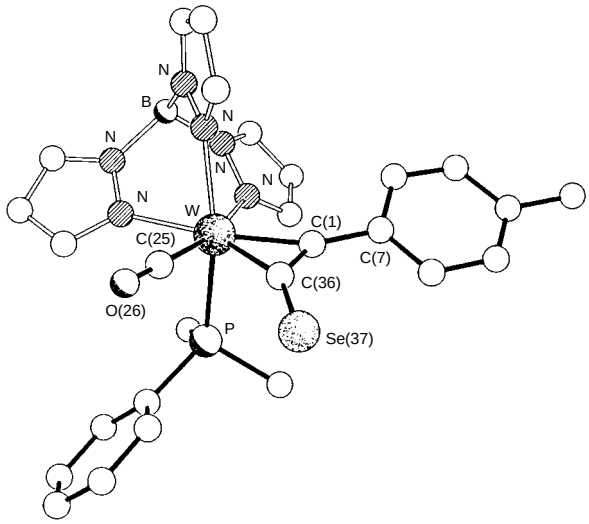


**Fig. 1** Molecular geometry of **2b** (hydrogen atoms omitted)

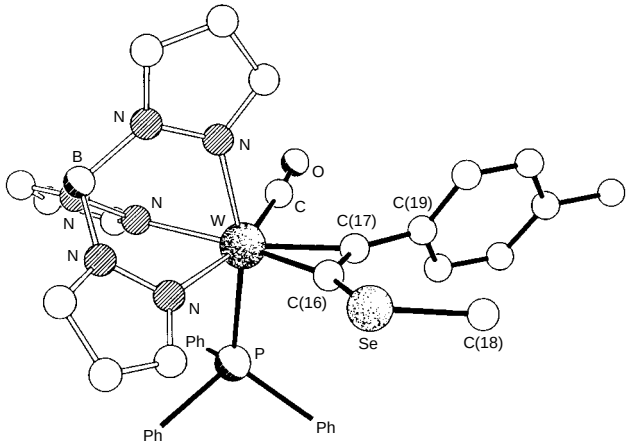

**Fig. 2** Molecular geometry of **4a** (phenyl groups, hydrogen atoms and iodide counter-anion omitted)

selected examples of **2** or **3** with iodomethane. The salts **4**† provide rare examples of mononuclear selenoalkyne complexes.[8] Notably, alkylation of **2** is considerably more rapid than for **3** and the ketenyl complexes **1** fail to react with alkyl halides.

The tungsten salt [W($\eta^2$-MeSeCCR)(CO)($PPh_3$)(Tp)]I **4a**, has been structurally characterised.‡ The molecular geometry of the cation (Fig. 2) is topologically similar to that of **2b** with the notable exception that the alkyne orientation now places the tolyl group *syn* to the carbonyl ligand *cf*. the *anti* arrangement of these groups in **2b**. Within the Tp scorpionate, the W–N bond *trans* to the carbonyl [2.172(13) Å] is somewhat shorter that the other two W–N distances [2.216(13), 2.218(12) Å]. The dimensions associated with the selenoalkyne coordination are somewhat similar to those of **2b**. Once again there is multiple bonding between W and C(17) [2.05(2) Å], and between W and C(16) [2.02(2) Å], however there is a notable loss of double bond character between C(16) and C(17) [1.39(2) Å] *cf*. **2b**. The C(16)–Se separation [1.81(2) Å] suggests that the partial double bond character observed in **2b** is retained upon alkylation, this being shorter than for the Se–C(18) separation [1.97(2) Å] which is typical for a Se–C($sp^3$) bond. The modest perturbation of these dimensions on alkylation lends further support to the significant contribution of resonance form **C** to the bonding description of **2b**.

The successful deployment of Woollins' reagent for the oxygen/selenium transfer conversion of coordinated organometallic ligands bodes well for the elaboration of further unsaturated organoselenium ligands, an avenue we are currently investigating. Ketenyl complexes are typically formed from the often reversible coupling of alkylidyne and carbonyl ligands. It remains to be seen if thioketenyl and selenoketenyl ligands may decouple to serve as precursors for chalcocarbonyl co-ligated alkylidyne complexes, $L_nM(\equiv CR)(CA)$ (A = S, Se).

We gratefully acknowledge the EPSRC (UK) for the award of a studentship (to J. M. M.) and the provision of a diffractometer. A. F. H. wishes to thank the Leverhulme Trust and the Royal Society for the award of a Senior Research Fellowship.

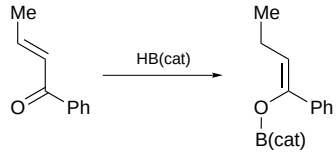
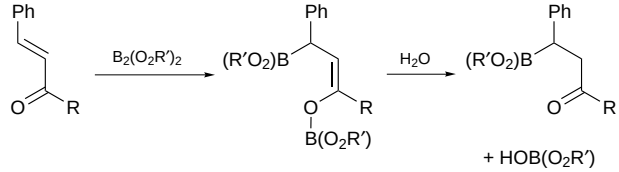
# Platinum catalysed 1,4-diboration of α,β-unsaturated ketones



**Yvonne G. Lawson,[a] M. J. Gerald Lesley,[a] Todd B. Marder,*[b]† Nicholas C. Norman*[a] and Craig R. Rice[a]**

[a] *The University of Bristol, School of Chemistry, Cantock's Close, Bristol, UK BS8 1TS*
[b] *The University of Waterloo, Department of Chemistry, Waterloo, Ontario, Canada N2L 3G1*

**Diborane(4) compounds react with α,β-unsaturated ketones to give the 1,4-addition product in the presence of a platinum catalyst at 80 °C.**



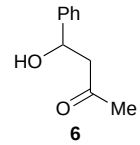
In contrast with the rhodium-catalysed hydroboration of alkenes, alkynes and α,β-unsaturated carbonyl compounds, which is now well established,[1] the related topic of metal-catalysed diboration reactions has only recently been studied in any detail. Thus the groups of Baker and Marder,[2] Miyaura[3] and Smith[4] have shown that alkenes can be diborated in the presence of rhodium,[2] gold[2] or platinum[3,4] catalysts affording 1,2-bis-(boronate) ester products, whilst platinum catalysed alkyne diboration yielding *cis*-1,2-bis(boronate) alkenes has been demonstrated by Miyaura and coworkers,[5a,b] Iverson and Smith[5c,d] and Norman and coworkers.[5e] Additional studies by Miyaura and coworkers[6] have also demonstrated 1,4-addition of a B–B bond to 1,3-dienes. In all cases, key steps are thought to involve oxidative addition of the B–B bond of a diborane(4) compound to the metal centre followed by coordination and insertion of the organic precursor and subsequent reductive elimination of the product.[7]

To date, however, the reaction of α,β-unsaturated carbonyl compounds with diborane(4) compounds has not been studied, although previous work has shown that HB(cat) (cat = 1,2-$O_2C_6H_4$) reacts with α,β-unsaturated carbonyl compounds in a 1,4 fashion[8] to give a synthetically useful[9] boron enolate as shown in Scheme 1. Here we report the reaction of α,β-unsaturated ketones with the diborane(4) compounds $B_2(pin)_2$ **1**[10] (pin = $OCMe_2CMe_2O$) and $B_2(cat)_2$ **2**.[11]

**Scheme 1**

Reaction of *trans*-4-phenylbut-3-en-2-one **3a** or *trans*-1,2-diphenylprop-2-en-1-one **3b** with 1 equiv. of **1** in the presence of 5 mol% of $[Pt(C_2H_4)(PPh_3)_2]$ at 80 °C gave, after 12 h, the 1,4-bis(boronate) ester products **4a**,**b** quantitatively as judged by $^1$H NMR spectroscopy (Scheme 2).‡ Furthermore, the $^1$H NMR spectra of **4a** and **4b** showed that each was present as only a single isomer which, in the case of **4a** and, by implication **4b**, is assumed to be the *Z*-isomer on the basis of a $^1$H NMR NOE signal enhancement (13.1%) between the vinylic and methyl protons; both hydroboration of α,β-unsaturated ketones[8] and diboration of dienes[5] also produce only the *Z*-isomer. Compounds **4a** and **4b** are both sensitive to hydrolysis and exposure to $H_2O$ affords the hydrolysis products **5a** and **5b** (Scheme 2).§

**3a** R = Me
**b** R = Ph



**4a** R = Me, $O_2R'$ = pin
**b** R = Ph, $O_2R'$ = pin
(**c** R = Me, $O_2R'$ = cat)

**5a** R = Me, $O_2R'$ = pin
**b** R = Ph, $O_2R'$ = pin
**c** R = Me, $O_2R'$ = cat

**Scheme 2**

In the corresponding reaction between **3a** and **2**, the 1,4-bis(boronate) ester **4c** analogous to **4a**,**b** was not observed but the hydrolysis product, **5c**, was identified by $^1$H NMR spectroscopy.¶ This observation indicates that the initial products formed from reactions involving **2** are more susceptible to hydrolysis than those involving **1** in keeping with observations made in the diboration of alkynes.[5e]

As further confirmation of the nature of the products formed in these reactions, compounds **5a** and **5c** were oxidised using $NaOH–H_2O_2$ to give the corresponding alcohol **6**‖ which was identified by the comparison of the spectra obtained with lit. values.[12]

**6**

Comparison of **4a**,**b** with the products formed from the hydroboration of similar α,β-unsaturated ketones shows that the regiochemistry is similar in both reactions, *i.e.* 1,4-addition occurs. However the reaction of diborane(4) compounds with α,β-unsaturated ketones results in the effective formation of a hydroxyl group in the β position (*i.e.* compound **6** in the case of **4a**), in contrast to hydroboration where no hydroxyl group is formed but in which the alkene function is effectively reduced.

We note finally that boron enolates such as **4a**,**c** are likely to be useful intermediates in organic synthesis providing starting materials in processes such as aldol condensations with aldehydes.[9] Reactions, of α,β-unsaturated ketones with chiral diborane(4) compounds will be reported elsewhere.

# Efficient synthesis of a molecular knot by copper(I)-induced formation of the precursor followed by ruthenium(II)-catalysed ring closing metathesis

**Christiane Dietrich-Buchecker, Gwénaël Rapenne and Jean-Pierre Sauvage***

*Laboratoire de Chimie Organo-Minérale, URA 422 CNRS, Université Louis Pasteur, Institut Le Bel, 4, rue Blaise Pascal, F-67070 Strasbourg, France*

**A double-stranded helix constructed around two copper(I) centres used as templates and bearing four terminal alkenes, is converted into a trefoil knot in 74% yield by ruthenium(II)-catalysed ring closing methathesis (RCM); the cyclic alkenes can be quantitatively reduced by catalytic hydrogenation to afford the copper(I)-complexed 82-membered knotted ring.**

In molecular biology, knots constructed on double-stranded DNA have been described more than twenty years ago.[1] Recently, the trefoil knot, but also more complex topologies, have been generated from single-stranded DNA.[2] Some proteins have also been shown to adopt knotted topologies.[3] The planned synthesis of chemical knots was first reported a few years ago,[4] but clearly the yield had to be increased both for the synthetic challenge that this improvement represented and for the interesting properties of this new family of compounds.[5] A more preparative procedure (30% yield) was recently described,[6] but we still looked for a more efficient and chemically milder method. The ring-closing metathesis approach (RCM)[7] which we now describe seems to be close to ideal: not only is the yield excellent considering the complexity of the reaction but the procedure takes place under very gentle conditions (without any acid or base, in $CH_2Cl_2$ at room temp.).

The strategy (Fig. 1) relies on (*i*) quantitative formation and high stability of the helical precursor composed of copper(I) bisphenanthroline units with 1,3-phenylene linkers between the phenanthroline nuclei,[5c,6] and (*ii*) the highly efficient RCM methodology developed by Grubbs and coworkers.[7]

Ligand **2** was obtained in 97% yield by reaction of **1** with 2-(2-chloroethoxy)ethanol in DMF at 80 °C, in the presence of $Cs_2CO_3$. It could be quantitatively converted to **3** by generating the dialcoholate with NaH and reacting it with an excess of allyl bromide in refluxing THF. The helical precursor $\mathbf{4}^{2+}$ was

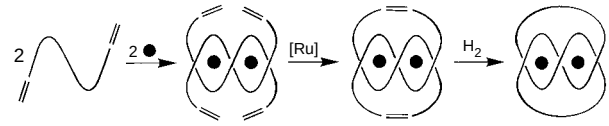

**Fig. 1** Synthetic strategy. Two coordinating fragments bearing terminal alkenes are gathered and interlaced around two copper(I) centres. RCM with ruthenium catalyst affords the knot.

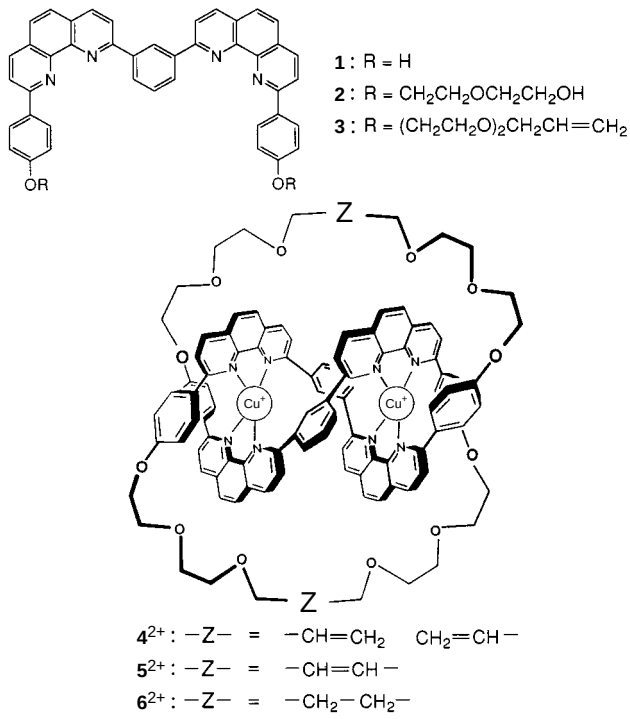

**Fig. 2** Chemical structure of the organic precursors and of the knots

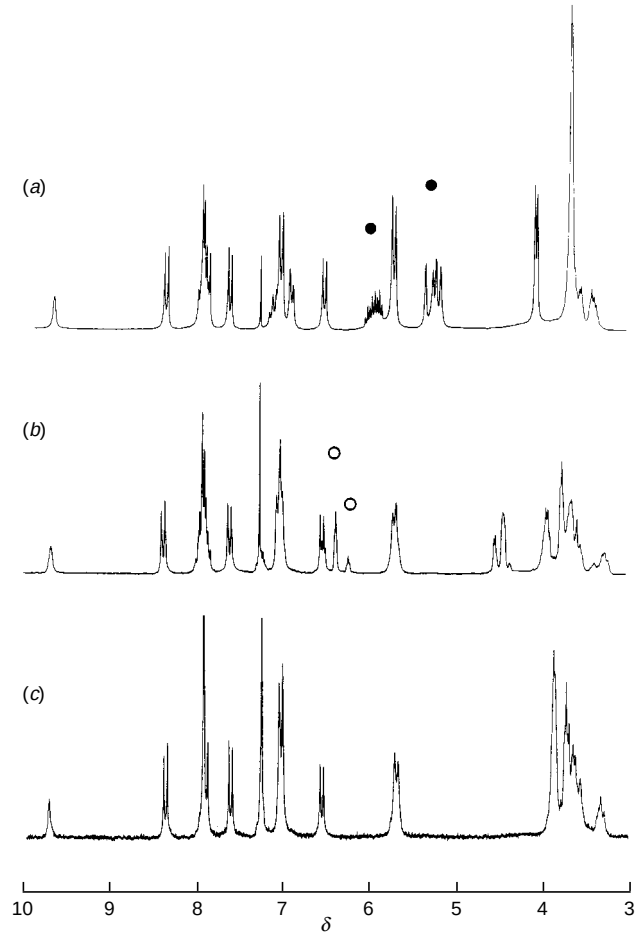

**Fig. 3** $^1$H NMR spectra of (*a*) the helical precursor $\mathbf{4}^{2+}$ with the signals corresponding to the four terminal alkenes (●), (*b*) the trefoil knot $\mathbf{5}^{2+}$ with the signals corresponding to the two alkenes incorporated in the molecule (○) and (*c*) the trefoil knot $\mathbf{6}^{2+}$ after catalytic reduction of the alkenes

formed quantitatively by the classical way: addition under argon of $[Cu(MeCN)_4]PF_6$ dissolved in MeCN onto a solution of the bis-chelate **3**. The metathesis was catalysed by $[RuCl_2\{P(C_6H_{11})_3\}_2(=CHPh)]$ (0.05 mol. equiv.) at a substrate concentration of 0.01 M in $CH_2Cl_2$ at room temp. The double coupling of the terminal alkenic groups afforded the trefoil knot $\mathbf{5}^{2+}$ in 74% yield after column chromatography (Fig. 2). The only other products were oligomers arising from intermolecular metathesis reactions.

The dicopper(I) trefoil knot $\mathbf{5}^{2+}$ is thus obtained in seven steps from commercially available 1,10-phenanthroline, with an overall yield of 35%.

The two cyclic alkenes remaining in $\mathbf{5}^{2+}$ appeared originally as a mixture of *cis* and *trans* alkenes in a 80 : 20 ratio, according to the $^1$H NMR spectrum. We thus obtained the *cis–cis*, *cis–trans* and *trans–trans* products [compare the broad signals in the spectrum in Fig. 3(*b*) to the narrow and well resolved ones of the spectrum in Fig. 3(*c*)]. The alkene functionalities could be easily and quantitatively reduced at room temp. by catalytic hydrogenation in EtOH–$CH_2Cl_2$ (1 : 1) with Pd/C (5 mol% Pd). Cyclisation and reduction could both be monitored by $^1$H NMR spectroscopy in the alkenic region, the signals corresponding to the cyclic alkenic groups in knot $\mathbf{5}^{2+}$ being sharply different from those of the terminal alkenic groups in the precursor $\mathbf{4}^{2+}$ (see Fig. 3). Moreover, the $^1$H NMR spectrum of the knot after reduction is clearly simplifed.

The knotted topology of $\mathbf{5}^{2+}$ could be unambiguously established by $^1$H NMR spectroscopy, the signals of the aromatic protons as well as those of the polyoxyethylenic chains in the 3–4 ppm region being highly characteristic.[8] Further evidence was obtained from FABMS which confirmed the absence of any starting material and displayed the expected mass: a peak at 1965.3 corresponding to $[\mathbf{5}(PF_6)]^+$ and a peak at 910.1 corresponding to $\mathbf{5}^{2+}$.

The here-described latest improvements now allow an easy access to trefoil knots and hence render the extensive study of their specific properties possible. It can also be envisaged that the two alkene functionalities of $\mathbf{5}^{2+}$, disposed in an antipodal fashion, can be utilized for further functionalization.

We thank the CNRS for financial support and the French Ministry of Research for a fellowship to G. R.

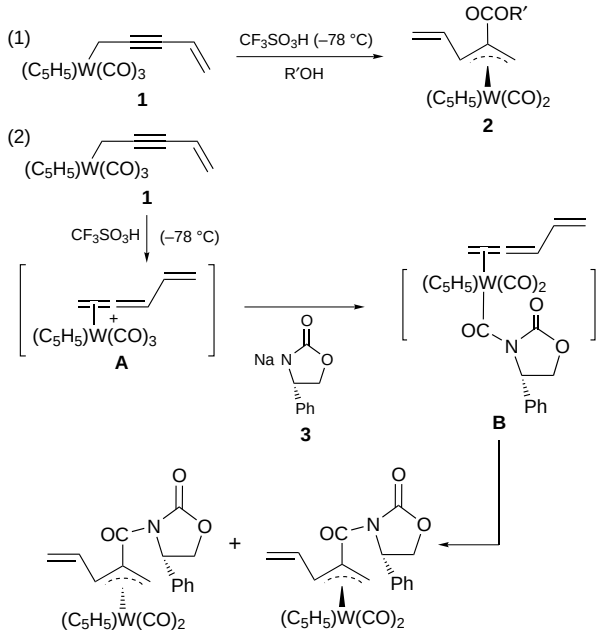
# Enantioselective syntheses of α-methylene butyrolactones *via* asymmetric aminocarbonylation of tungsten–prop-2-ynyl compounds



**Lin Hung Shiu,[a] Sue-Lein Wang,[a] Ming-Jung Wu[b] and Rai-Shung Liu*[a]**

[b] *Department of Chemistry, Kaoshiung Institute of Medical College, Kaohsiung, Taiwan, ROC*

**A tungsten–η¹-vinylprop-2-ynyl compound undergoes enantioselective aminocarbonylation to afford an optically pure tungsten–π-γ-lactone; this π-allyl complex is useful for the efficient synthesis of optically pure α-methylene butyrolactone.**

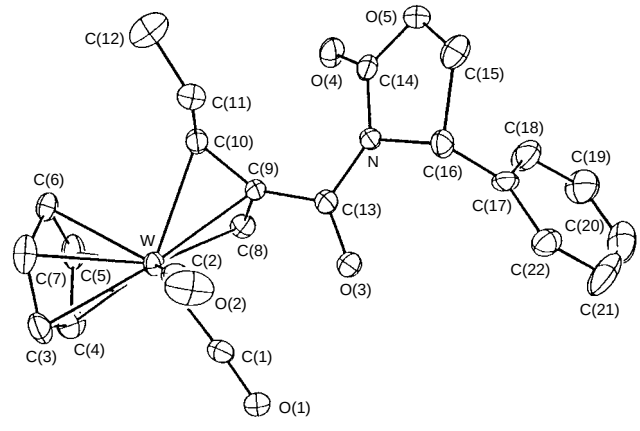
In the last twenty years, utilization of stoichiometric transition-metal reagents in organic syntheses has undergone considerable progress.[1–3] The unique electronic properties of transition metals can direct and facilitate carbon–carbon bond formation of unusual types, providing easy access to useful organic substructures.[1–3] Nevertheless, most of these reactions[1–3] are carried out with racemic organometallic reagents although naturally occurring compounds often exist in optically pure forms. [M(η⁵-$C_5H_5$)(CO)$_2$(π-allyl)] (M = Mo, W) complexes have proved to be very useful in organic synthesis.[4,5] In this laboratory, we recently reported the use of complexes of this type for stereoselective syntheses of various oxygen heterocycles, 1,3-diols and 1,3,5-triols.[6] To further enhance the synthetic applications of these π-allyl complexes, we report herein an enantioselective aminocarbonylation of tungsten–vinylprop-2-ynyl complexes to afford an optically pure tungsten–π-γ-lactone that can be elaborated for asymmetric synthesis of α-methylene butyrolactones.

Although tungsten–prop-2-ynyl complexes are prone to alkoxycarbonylation[6b,c] to yield π-2-alkoxycarbonylallyl complexes **2** [Scheme 1, eqn. (1)], attempts to use chiral secondary alcohols such as (+)-menthol and (+)-neomenthol to induce enantioselective alkoxycarbonylation of **1** were unsuccessful.

**Scheme 1**

The resulting products **2** consisted of 1:1 diastereomeric mixtures that were inseparable by fractional crystallization and column chromatography. We found that (*S*)-4-phenyl-2,5-oxazolidinone[7] **3** was an effective chiral auxiliary for enantioselective aminocarbonylation of **1**. In a typical operation, $CF_3SO_3H$ acidification of **1** (*ca.* 1.50 g) in cold diethyl ether yielded a dark orange precipitate **A**, presumbly being containing η²-vinylallene cations.[8] After replacement of diethyl ether with THF, precipitate **A** was treated with the sodium oxazolidinonate **3** (1.2 equiv.) at −40 °C and 15-crown-5 (1.2 equiv.), followed by slowly warming the solution to 0 °C (*ca.* 12 h), yielding a mixture of **4a** {$[\alpha]_D$ −53.4 (*c* 0.5, $C_6H_6$)} and **4b** {$[\alpha]_D$ 282.1 (*c* 0.5, $C_6H_6$)} in 81% yield (**4a**/**4b** = 3.8). Further separation of these two diastereomers on a silica column gave **4a** and **4b** in 51 and 16% yields, respectively. In this aminocarbonylation, **3** initially attacks the coordinated carbonyl of **A** to yield tungsten–η¹-aminocarbonyl species **B** which subsequently undergoes insertion of the aminocarbonyl group into its central allene carbon, yielding the two isomers **4a**,**b**. The crystal structure of **4a** has been determined by an X-ray diffraction study† to clarify its absolute configuration; the ORTEP drawing is shown in Fig. 1.

As shown in Scheme 2, further treatment of **4a** with $CF_3SO_3H$ (1.1 equiv.) in cold ether (−40 °C) produced an orange precipitate **C**; subsequent hydrolysis of this salt with a saturated $Na_2CO_3$ solution yielded an optically active π-ε-lactonylallyl complex **5** {$[\alpha]_D$ 157.8 (*c* 0.5, $C_6H_6$)} in 80% yield. Fig. 2 shows the the crystal structure† of this optically active complex **5** which has an *anti*-configuration, *i.e.* the methyl group lies away from W(η⁵-$C_5H_5$)(CO)$_2$ fragment. The configuration of the tungsten–π-allyl fragment of **5** is retained relative to that of **2a**. To rationalize the stereochemical transformation of **4a** into **5**, we propose that η⁴-*s-trans*-diene **C** was first formed in the acidification of **4a** with $CF_3SO_3H$; subsequent attack of water at the η⁴-diene intermediate **C** occurs



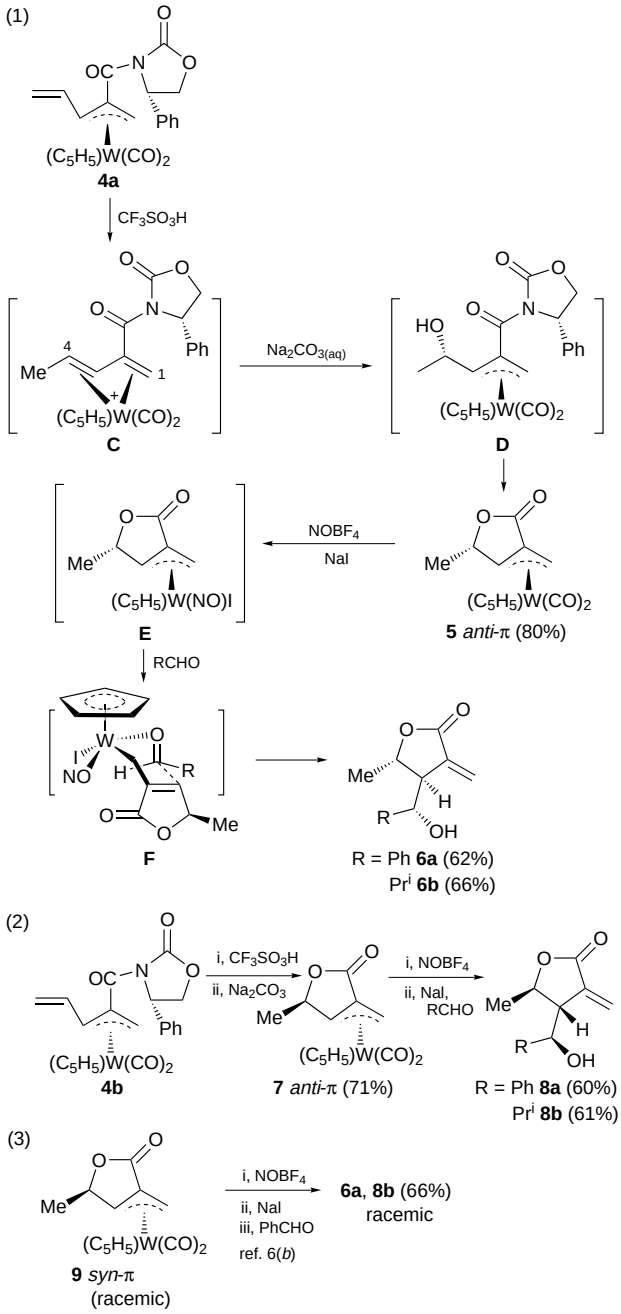


**Fig. 1** ORTEP drawing of the optically active tungsten–π-allyl complex **4a**. Pertinent bond lengths (Å): W–C(8) 2.252(7), W–C(9) 2.251(6), W–C(10) 2.321(6), C(8)–C(9) 1.427(9), C(9)–C(10) 1.411(8), C(10)–C(11) 1.459(9), C(11)–C(12) 1.320(10).

**Scheme 2**

regioselectively at the C(4)-carbon opposite W($\eta^5$-$C_5H_5$)$(CO)_2$ to yield an α-hydroxyallyl complex **D.** In aqueous $Na_2CO_3$ species **D** is prone to undergo base-catalyzed intramolecular lactonization, yielding the π-*anti*-allyl stereoisomer **5**.

To realize the synthetic utility of this asymmetric aminocarbonylation, compound **5** was sequentially treated with $NOBF_4$ (1.0 equiv.) and NaI (1.0 equiv.) in MeCN to generate the W($\eta^5$-$C_5H_5$)(NO)I derivative **E** that functions as an allyl anion;[9] this anion reacted *in situ* with RCHO (R = Ph, Pr$^i$) to afford optically active α-methylene butyrolactones **6a** {$[\alpha]_D$ −71.1 (*c* 0.5, $C_6H_6$)} and **6b** {$[\alpha]_D$ −90.2 (*c* = 0.5, $C_6H_6$)} in 62 and 66% yields, respectively. The ee values of **6a** and **6b** were 93 and 94% according to HPLC analysis (column: Chirasphere). Following the same procedure, the chiral π-allyl complex **4b** was converted to π-allyl–γ-lactone **7** {$[\alpha]_D$ −157.2 (*c* 0.5, $C_6H_6$)} in 71% yield. Sequential treatment of **7** with $NOBF_4$ and NaI, and then RCHO afforded α-methylene butyrolactones **8a** {$[\alpha]_D$ 70.3 (*c* = 0.5, $C_6H_6$)} and **8b** {$[\alpha]_D$ 90.4 (*c* 0.5, $C_6H_6$)} in 60 and 61% yields, respectively. HPLC analyses of **8a** and **8b** gave the ee values of 92 and 94%, respectively. Herein, a chair-like-transition state **F** is likely involved to control the stereochemistry of the products. We previously reported[6b] that the racemic form of **6a** (or **8a**) could also be produced from the π-*syn*-γ-lactone **9** following the same operation; the reaction mechanism was similarly elucidated to involve the transition state **F**.[6b] An interesting observation of this study is that two π-*anti* and -*syn*-stereoisomers **5** and **9** have the same transition states **F** for generation of α-methylene-γ-lactone **6a** (or **8a**).

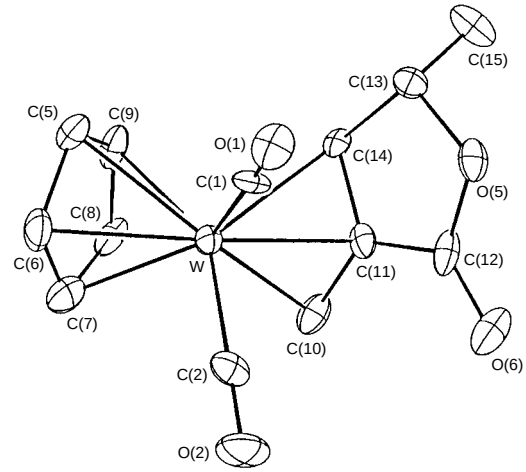

**Fig. 2** ORTEP drawing of the optically active tungsten–π-γ-lactone **5**. Pertinent band lengths (Å): W–C(10) 2.292(15), W–C(11) 2.241(14), W–C(14) 2.330(16), C(10)–C(11) 1.392(15), C(11)–C(14) 1.407(24), C(12)–O(6) 1.201(22).

# Alternating ring-opening metathesis copolymerization of bicyclo[2.2.1]hept-2-ene and cyclopentene

**Basma Al Samak, Andrew G. Carvill, James G. Hamilton,* John J. Rooney and Jillian M. Thompson**

*School of Chemistry, The Queen's University of Belfast, Belfast, UK BT9 5AG*

**Almost alternating copolymers of bicyclo[2.2.1]hept-2-ene and cyclopentene have been formed by ring-opening metathesis polymerization using a $RuCl_3$–phenol catalyst system; this highly novel result is attributed to differential steric influences exerted by a hydrogen-bonded solvent cage which encloses the catalyst site.**

Copolymerization is an aspect of polymer chemistry that continues to attract widespread interest, not only because it affords the opportunity to prepare and study polymers with a wide variety of main chain architectures but also because of the mechanistic insights which may be gained from a detailed analysis of the microstructure of such materials.[1,2]

The primary microstructural variant in copolymers of a given comonomer composition is the distribution of the different monomer units in the chain and this variable depends to a large extent on the choice of monomer pairs. For example, in the field of coordination polymerization, monomers of similar polarity generally give rise to statistical copolymers, although block copolymers may be obtained by the sequential addition of a variety of monomers to living catalyst systems. Alternating distributions may be obtained either by copolymerization of monomers of dissimilar polarity; for example, the Ziegler–Natta copolymerization of CO[3] or styrene[4] with ethylene, or they may result from regiospecific ring-opening metathesis polymerization (ROMP)[5] or acyclic diene metathesis (ADMET)[6] homopolymerizations. Alternating copolymerization of olefinic monomers which have the same olefinic double bond polarity is extremely rare.[7–9]

We now report the alternating ring-opening metathesis copolymerization of cyclopentene and norbornene, two non-polar monomers, using a simple $RuCl_3$-based catalyst system.

Although readily available and remarkably tolerant of a wide range of monomer functionality, classical Ru-based ROMP initiators are rather sluggish, so a number of studies have been directed towards increasing the activity whilst retaining the robust properties of this class of catalyst.[10–12] The working catalytic species in metathesis polymerization is a metallacarbene[13] and a strategy we have employed is to increase the polarity of the Ru=C π-bond, and hence its activity, by providing harder acidic ligands at the Ru centre. A measure of success has been achieved using isolated complexes such as Ru(trifluoroacetate),[14] or $RuCl_3$ in the presence of acidic diol solvents, such as dimethyl tartrate,[15] and in these cases an enhanced catalyst activity, judged by the increased incorporation of the relatively unreactive cyclopentene in cyclopentene (CPE)–bicyclo[2,2,1]hept-2-ene (norbornene, NBE) copolymerizations, was noted. In continuation of these studies we have been examining the role of phenolic solvents both as reaction media and as potential ligands and we have found, not only a greatly enhanced catalyst activity, but remarkably, a highly alternating distribution of CPE and NBE units which is maintained throughout a range of yields (~2% to ~20%).† It is also significant that the final concentration of CPE in these copolymerizations, even at higher yields, exceeds its equilibrium monomer concentration.[7]

The alternating nature of these copolymers is unambiguously shown by the olefinic region of their rather simple $^{13}C$ NMR spectra, Fig. 1(*a*). Here the predominant signals at 128.2 and 135.13 ppm arise from isolated cyclopentene $M_2\mathbf{M}_1M_2$ (CPE = $M_1$) and norbornene $M_1\mathbf{M}_2M_1$ (NBE = $M_2$) units respectively,‡ the low intensity signals arising from homopolymer sequences, $M_1M_1M_1$ and $M_2M_2M_2$.[16] Fine structure is attributed to the effects of double bond isomerism and it is noteworthy that the *cis* double bond content (~30%) is higher than for less reactive Ru-based catalysts.[16]

The formation of such a copolymer requires that propagation occurs at a novel catalyst site and although its structure is at this stage a matter of some speculation we believe it to be based on

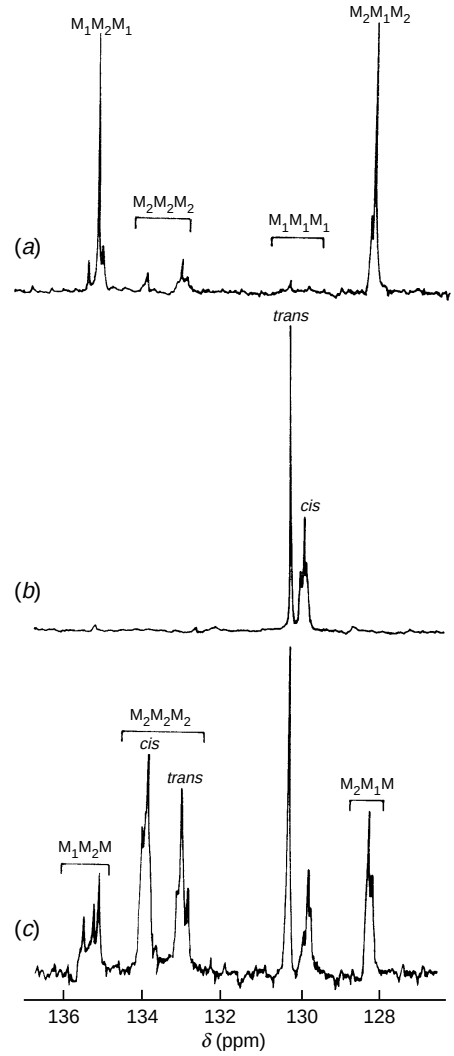

**Fig. 1** The olefinic regions of the 125 MHz $^{13}C$ NMR spectra (in $CDCl_3$ with $Me_4Si$ internal standard) of polymers prepared from NBE ($M_2$) and CPE ($M_1$) at a molar feed ratio of 1 : 8; (*a*) a highly alternating copolymer prepared using the $RuCl_3$–dry phenol catalyst, (*b*) a CPE homopolymer prepared using a $OsCl_3$–dry phenol catalyst and (*c*) a random copolymer prepared using the $OsCl_3$ catalyst in a 100 : 1 phenol–water solvent

$$\mathbf{P_C} + \text{CPE} \xrightarrow{k_{CC}} \mathbf{P_C} \qquad \mathbf{P_N} + \text{CPE} \xrightarrow{k_{NC}} \mathbf{P_C}$$

$$k_{CN} >> k_{CC} \qquad k_{NC} >> k_{NN}$$

$$\mathbf{P_C} + \text{NBE} \xrightarrow{k_{CN}} \mathbf{P_N} \qquad \mathbf{P_N} + \text{NBE} \xrightarrow{k_{NN}} \mathbf{P_N}$$

**Scheme 1**

a Ru-carbene complex bearing $\eta^1$-coordinated phenoxide ligands, formed *in situ* by the action of excess phenol on $RuCl_3$. Phenol (solvent) molecules are then associated with this complex through the medium of hydrogen bonding, in a manner analogous to that described recently for other Ru–phenoxy complexes,[17] forming, in effect, a cage around the catalyst site such that the differential steric effects of cyclopentylene and pentylene chain ends are greatly emphasised with respect to access of incoming monomer, NBE and CPE respectively.

The process is therefore governed primarily by the steric demands of the chain end coupled with the different steric and electronic properties of the approaching monomers and it is envisaged that propagation involves different forms of the metallacarbene, $\mathbf{P_N}$ and $\mathbf{P_C}$, (**N** = cyclopentylene, **C** = pentylene). Thus, with $\mathbf{P_N}$, the bulky norbornene is denied access to the site and the much less bulky cyclopentene has then the opportunity to react, leading to $\mathbf{P_C}$. The less sterically constrained $\mathbf{P_C}$ is now relatively accessible to both monomers but reacts preferentially with norbornene due to its electronically much more reactive double bond, and thus a $\mathbf{P_N}$ site is generated. This sequence of events may be described by the above kinetic scheme, Scheme 1, where the apparent reactivity ratios, $r_1 = k_{CC}/k_{CN}$, and $r_2 = k_{NN}/k_{NC}$, estimated from the spectra of the copolymers, are numerically very small, as demanded by an alternating mechanism.

We have accumulated several pieces of experimental evidence which support the existence of the proposed catalyst site and propagation mechanism. For example, the other noble metal-based metathesis catalysts, $IrCl_3$ and $OsCl_3$, behave in an analogous manner when used in phenolic solvents with the same monomer feed. $IrCl_3$, gives a somewhat less alternating product than $RuCl_3$ but significantly $OsCl_3$, Fig. 1(*b*), yields essentially a CPE homopolymer. This seemingly inconsistent result may however still be explained by the above mechanism if it is assumed that the hydrogen-bonded cage is now very tightly arranged around the Os-centred catalyst site, primarily as a consequence of the stronger ligand field exerted by the third row metal ion,[14] and that NBE is therefore denied access (Scheme 1, $k_{CN} = k_{NN} = 0$).

As expected, copolymers become less alternating as the solvent system is changed progressively from pure phenol to non-hydrogen bonded solvents such as chlorobenzene, but the essentially hydrogen-bonded nature of the cage is best illustrated by the effect of the addition of small quantities of water (1.0 wt% phenol) to the catalyst. Now with each metal a random copolymer is formed, illustrated here by reference to the $OsCl_3$, Fig. 1(*b*) and (*c*); we believe that random copolymer is formed as a result of propagation at a much less crowded site at which the hydrogen-bonding water has profoundly altered the nature of the solvent cage so that both monomers have now equal access. The high level of incorporation of CPE in these random copolymers however indicates that although water may have disrupted the solvent cage, a very active Mt(phenoxide) complex is still the propagating species.

Finally, we have noted that the *cis* double bond content of the polymer is essentially the same whether or not water is present in the system, and typically, in both $OsCl_3$ cases, Fig. 1(*b*) and (*c*), $M_1M_1$ units are 35% *cis*. We believe that this indicates that the solvent cage, which is not directly bonded to the metal, exerts a second order effect, merely helping to control monomer access but does not control the orientation of the intermediate metallacycle and hence the stereochemistry of the [2 + 2] cycloaddition step,[13] a first order effect. We have previously emphasised that these latter effects, *e.g.* a dramatic increase in the *cis* content of the polymer, may be caused by steric crowding due to various bulky spectator ligands directly bonded to the metal.[2] Examples are the addition of esters to $WCl_6$ and $MoCl_5$-based systems and various dienes and acetylenes to noble metal catalysts and can be used to modify catalyst systems and produce high *cis* content polymers.[2]

## Footnotes and References

* E-mail: j.g.hamilton@queens-belfast.ac.uk

† Catalyst systems were prepared by dissolving commercial samples of $RuCl_3{\cdot}xH_2O$, $OsCl_3$ or $IrCl_3{\cdot}3H_2O$ (8 mg) in phenol (2 ml) distilled from $P_2O_5$. A mixture of cyclopentene (1.7, 24 mmol) and norbornene (0.3, 3 mmol), both dried by distillation from $CaH_2$, was then added and the reaction mixture kept at room temperature overnight. Polymer was recovered by dissolving the gel in chloroform followed by precipitation in methanol and vacuum drying to yield typically 240 mg copolymer, $M_w$ 1.3 $\times$ $10^6$ (polystyrene standards). When other phenolic solvents such as *p*-chloro- and *p*-fluoro-phenol, as well as trifluoroethanol are used in the same manner, alternating copolymers are also produced.

‡ Taking into account variations due to *cis* and *trans* double bonds there are eight possible, closely positioned and partially overlapping, heterotriad resonances for the olefinic carbon atoms centred on $M_2$ units: $M_1t\mathbf{M_2}tM_1$, $M_1c\mathbf{M_2}tM_1$, $M_1t\mathbf{M_2}cM_1$, $M_1c\mathbf{M_2}cM_1$ and $M_2t\mathbf{M_2}tM_1$, $M_2c\mathbf{M_2}tM_1$, $M_2t\mathbf{M_2}cM_1$, $M_2c\mathbf{M_2}cM_1$. We have previously identified most of these[2] and are now confident that the three peaks labelled as $M_1M_2M_1$ in Fig. 1(*a*) are the first three of these with the central peak, $M_1tM_2tM_1$, the most abundant as expected from the higher *trans* content of the largely alternating copolymer. The corresponding resonances for the heterotriads centred around $M_1$ are less well resolved, but those labelled $M_2M_1M_2$ in Fig. 1(*a*) also agree with previous assignments as being $M_2tM_1M$ (major peak) and $M_2cM_1M$ (minor peak) (M is either $M_1$ or $M_2$).

# Heterogeneous electron transfer at the polarised water/1,2-dichloroethane interface studied by *in situ* UV–VIS spectroscopy and differential cyclic voltabsorptometry

**Zhifeng Ding, Pierre F. Brevet and Hubert H. Girault***

*Laboratoire d'Electrochimie, Département de Chimie, Ecole Polytechnique Fédérale de Lausanne, CH-1015 Lausanne, Switzerland*

**The heterogeneous electron transfer reaction between the redox couple ferricyanide–ferrocyanide in water and 7,7,8,8-tetracyanoquinodimethane (TCNQ) in 1,2-dichloroethane (DCE) is studied by combining conventional electrochemical measurements and UV–VIS absorption spectroscopy in total internal reflection (TIR) geometry.**

Heterogeneous electron transfer reactions are of biological interest, and polarised liquid/liquid interfaces represent a rather simple model system to study this type of reactions where reactants and products are located in their respective adjacent phases.[1–6] However, there is a paucity of reliable experimental data as electrochemical methods suffer from the difficulty of differentiating between currents originating from electron- and ion-transfer reactions occurring across the interface.[7–9] To circumvent the limitations of electrochemical studies, we have developed a novel spectroelectrochemical methodology.

Very few reports of spectroelectrochemical studies on electron transfer at liquid/liquid interfaces have been published.[10,11] *In situ* EPR has been used to study the product formation for the reduction of TCNQ and the oxidation of tetrathiofulvalene (TTF) by the ferro–ferricyanide redox couple at the water/DCE interface.[10] Time-resolved laser-induced fluorescence spectroscopy in TIR mode has been used to study photoinduced electron transfer between europium(III) in water and anthracene in DCE.[11] TIR fluorescence spectroscopy[12–14] and TIR UV–VIS spectroscopy[15] have recently been applied to the field of ion-transfer reactions across the water/DCE interface. The work outlined here shows that UV–VIS spectroscopy in TIR geometry can be used to detect interfacial changes of the products of electron-transfer processes at liquid/liquid interfaces.

The spectroscopic measurements involved the use of a 150 W xenon arc lamp (Applied Photophysics) which supplied white light within the UV–VIS spectral range. The output of the lamp was directed to the bottom face of the interface between water and DCE. The use of a 250 mm focal length lens and several aluminium mirrors then ensured that the light was focused on the interface in TIR mode and also allowed accurate adjustment of the light path to guarantee the optimum conditions for the spectroscopic measurements. An angle of approximately 75° was maintained in all of the experiments which allowed clear observation of the reflected beam at the opposite wall of the cell.[15] The spectroelectrochemical cell which held the solutions was a conventional four-electrode liquid–liquid electrochemistry cell modified to allow unhindered passage of the light beam. The reflected beam was either collected using a optical fibre of 400 μm in diameter attached to a spectrophotometer (Ocean Optics, Inc.) for *in situ* measurement of the whole spectrum, or collected using a water-filled optical waveguide of 1 cm in diameter attached to a high-voltage photomultiplier tube (PMT) *via* a monochromator (Applied Photophysics) equipped with a wavelength stepping motor for voltabsorptometry. The signal measured by either the fibre optic spectrophotometer or the PMT was then sampled and recorded directly on a microcomputer where further processing took place. The cell chosen for the simultaneous investigation of the electrochemistry and the absorptometry was cell 1,[5] where BTPPA represents bis(triphenylphosphoranylidene)ammonium, TPBCl represents tetrakis(4-chlorophenyl)borate. For the experiments conducted here the product of the electron-transfer reaction was $TCNQ^{\cdot-}$ in the DCE phase and was monitored spectroscopically. The potential difference imposed on the water/DCE interface and the whole data acquisition process were driven by LabView(Version 4, National Instruments). Using this set-up, the data acquisition program allowed the straightforward measurement of the whole absorption spectrum from the fibre optic spectrometer at frequencies up to 10 Hz or the signal intensity from the PMT, together with the applied interfacial potential and the corresponding electrochemical current at frequencies up to 20 kHz.

Cyclic voltammograms were recorded using a four-electrode potentiostat[16] which uses the positive feedback method for the compensation of potential drop due to solution resistance. All the potentials are absolute values obtained by comparison of the formal transfer potential of the tetramethylammonium cation: $\Delta_O^W\phi^0_{TMA^+}$, 0.160 V.

To obtain a whole spectrum, the raw data were processed in the following way. Since the data were in transmittance form which is effectively the final intensity incident at the fibre optic spectrometer, taking the negative logarithm of the ratio of signal data over the reference data at the beginning applied potential where there is no electron-transfer reaction gave the corresponding absorption spectrum directly. Fig. 1 shows the interfacial absorption spectra of the product *i.e.* $TCNQ^{\cdot-}$ in DCE following the application of a potential to the water/DCE interface, which drives the reduction of TCNQ in DCE by ferrocyanide in the aqueous phase. The acquisition frequency of a whole spectrum is 1 Hz. The electronic absorption spectrum of the $TCNQ^{\cdot-}$ following electroreduction of the parent TCNQ (the absorption maximum at 390 nm) by a platinum electrode in DCE exhibits clearly major absorption bands at 842, 744, 760,

cell 1

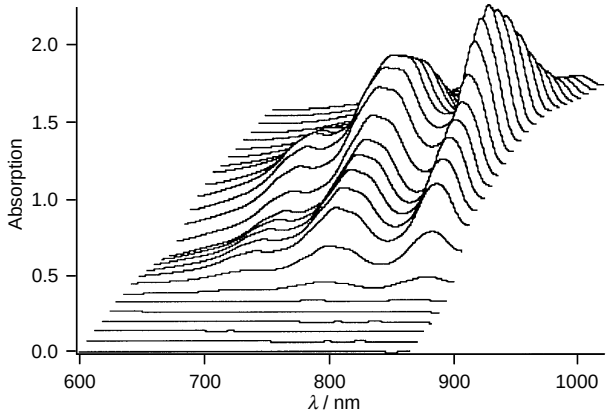

**Fig. 1** *In-situ* absorption spectra measured in TIR mode when the applied potential is scanned at 25 mV $s^{-1}$. From bottom to top, the applied potential $\Delta_O^W\phi$ varies from 0.187 to −0.26 V (forward scan) and from −0.26 to 0.187 V (backward scan) with a potential difference of *ca.* 40 mV between two spectra.

670 and 650 nm. This is similar to the spectrum reported for $TCNQ^{\cdot-}$ in acetonitrile.[17] The spectra shown in Fig. 1 can be attributed to the heterogeneous reduction of TCNQ to $TCNQ^{\cdot-}$ on forward sweep as the water phase becomes increasingly negative and the re-oxidation of the $TCNQ^{\cdot-}$ on the reverse sweep as the water becomes more positive relative to the DCE phase. TCNQ is totally water insoluble. The appearance and disappearance of the $TCNQ^{\cdot-}$ proves without any doubt that a heterogeneous electron-transfer process does take place at the water/DCE interface. The success of the experiment relies on the choice of the redox couple which must have distinct absorption spectra in the two oxidation states. The resolution of the experiment depends on the molar absorption coefficient of the product. A background spectrum was measured before and after addition of 0.6 mM TCNQ to the DCE phase and no absorption could be measured at any wavelength between 600 and 900 nm when the applied interfacial potential was held at a potential (0.258 V for example) far away from the formal electron transfer potential($\Delta_O^W\phi^0$ = −0.105 V).

The dependence of the absorbance waveform on scan rate has been established for the system in Fig. 2(*a*). By monitoring the absorbance of the $TCNQ^{\cdot-}$ species at 670 nm during a potential

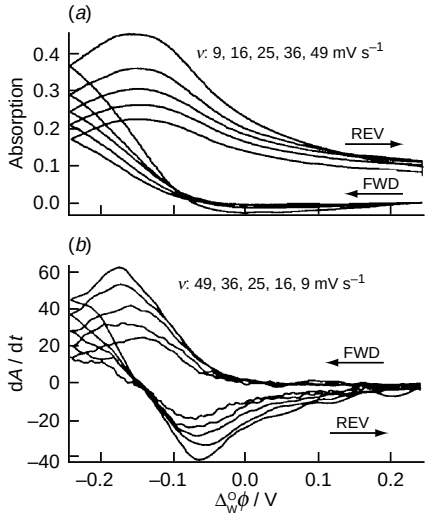

**Fig. 2** (*a*) Absorption data for cell 1 measured simultaneously during the voltammetry, and (*b*) corresponding differential cyclic voltabsorptograms. The monochromator was set to 670 nm and the scan rates (from top to bottom) are indicated.

sweep, an increase in absorbance until the zero current point and then a decrease in absorbance is observed at applied potentials corresponding to those of the electron-transfer voltammogram. Following the theory we have described elsewhere,[15] the shape is similar to that of an integrated voltammogram. The slower the scan rate, the larger the absorbance, because the absorption represents the amount of electron-transfer product which is formed during the electron-transfer reaction or the charge which has passed across the interface. Then differentiation of the absorbance data against time gave a voltammetric shape when plotted against applied potential. The results shown in Fig. 2(*b*) for several different scan rates corresponding to Fig. 2(*a*) are analogous to the measured electrochemical voltammograms with the observed peak height exhibiting a linear response as a function of the square root of scan rate. Because the concentration of ferrocyanide is very high in this case, the water phase acted analogously to a solid electrode and the electron-transfer rate was mainly controlled by the diffusion of TCNQ in DCE.

This study confirms the ability of *in situ* TIR UV–VIS spectroscopy to follow heterogeneous electron transfer at the liquid/liquid interface. The technique provides more information than conventional electrochemical techniques in mechanistic and kinetic studies. The kinetics of electron transfer for this system is currently under investigation based on spectroscopic approaches, such as chronoabsorptometry[15] and potential modulated reflectance spectroscopy.[18]

# Photo- and thermo-chromism of a ruthenium(II) complex and viologen-containing polymer film

**Masahiro Suzuki, Mutsumi Kimura, Kenji Hanabusa and Hirofusa Shirai***

*Department of Functional Polymer Science, Faculty of Textile Science and Technology, Shinshu University, Ueda, Nagano 386, Japan*

**A ruthenium(II) complex and a viologen-containing partially quaternized poly(1-vinylimidazole) film demonstrates both photochromism and thermochromism as a result of photosensitized and thermosensitized charge separations.**

1,1′-Dialkyl-4,4′-bipyridinium dications, so called viologens, are one of a group of electrochromic materials.[1,2] Electrochromism takes place in bipyridinium segments because the positive charge in radical cations formed by one electroreduction is delocalized. Electrochromic devices (ECDs) have been fabricated by electrostatic incorporation of such viologens into anionic polyelectrolyte films.[3–7] On the other hand, viologen radicals can be readily formed by photoinduced electron transfer from ruthenium(II) complexes to viologens in sacrificial systems.[8–12] The facts indicate that photochromism using photoinduced electron transfer is possible. Under an air atmosphere, however, the lifetime of viologen radicals is very short owing to reaction with $O_2$. Recently, we have reported that the viologen radical is efficiently formed by a photosensitized charge-separation reaction using a partially quaternized poly(1-vinylimidazole)-bound ruthenium(II) complex as a photosensitizer, alkylviologen and triethanolamine (TEOA) as a sacrificial donor.[13] In this work a ruthenium(II) complex and a viologen containing partially quaternized poly(1-vinylimidazole) is synthesized and the photo- and thermo-chromic properties of this polymer film are investigated.

Poly(1-vinylimidazole) and ruthenium(II) complex-containing poly(1-vinylimidazole) (RuPIm) were prepared as described elsewhere.[13,14] 1-(6-Bromohexyl)-1′-hexadecyl-4,4′-bipyridinium dibromide was prepared by refluxing of an acetonitrile solution of 1,6-dibromohexane and 4-(4′-pyridyl)-1-hexadecylpyridinium bromide[15] and identified by elemental analysis, $^1$H NMR and FTIR spectroscopy. Ruthenium(II) complex and viologen-containing partially quaternized poly(1-vinylimidazole) (RuVQPIm) was prepared by refluxing RUPIm and 1-(6-bromohexyl)-1′-hexadecyl-4,4′-bipyridinium dibromide in ethanol for 24 h under an argon atmosphere. After addition of *n*-hexadecyl bromide, the solution was further refluxed for 24 h. The RuVQPIm was purified by reprecipitation from methanol into acetone and identified by its UV–VIS absorption spectrum and $^1$H NMR spectroscopy (Fig. 1). The RuVQPIm film casting on a glass plate was *via* a methanol solution of RuVQPIm (5–10 mass%). The resulting film thickness was *ca.* 0.15 mm.

Upon light irradiation on an RuVQPIm film in air, the film changed from orange to blue, and reverted to orange on standing in the dark. Similarly, changes in film colour to blue with heating and to orange upon standing (cooling) were also observed. These colour change reactions were reversible† with the responses being more rapid for the irradiated relative to the thermal system. In both systems, the blue to orange response was slower. These results indicate that the colour change to blue is caused by formation of viologen radicals which are formed by electron transfer from the photoexcited ruthenium(II) complex residue to the viologen. Absorbances at 611 and *ca.* 400 nm, corresponding to absorption maxima of the viologen radical,[16] increased upon light irradiation or heating as shown in Fig. 2. The absorption spectrum of RuVQPIm showing an absorption maximum at 490 nm does not change even when viologen radicals are formed, indicating that the photo- and thermo-sensitized charge separation reactions take place in the film. In

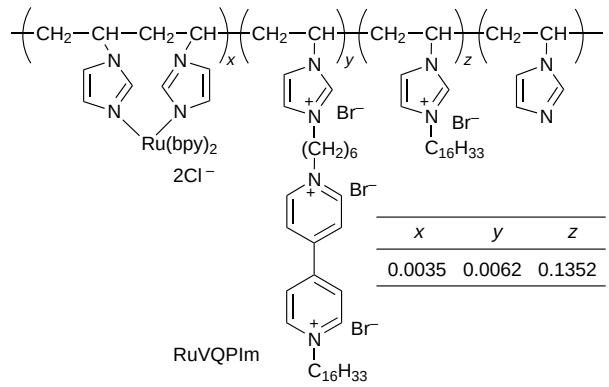

**Fig. 1** Chemical structure of RuVQPIm

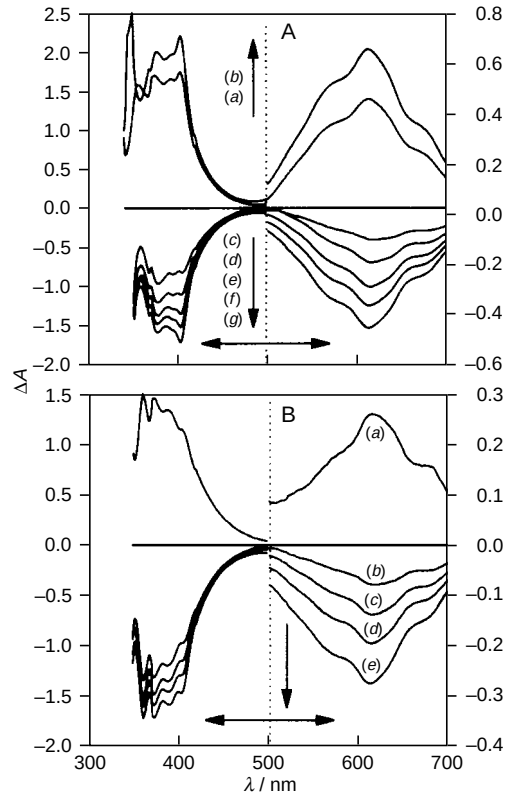

**Fig. 2** UV–VIS absorption spectral changes for photochromism (A) and thermochromism (B) of RuVQPIm film. (A): (*a*) light irradiation for 5 min, (*b*) 10 min, (*c*) standing in the dark for 5 min, (*d*) 10 min, (*e*) 20 min, (*f*) 30 min, (*g*) 50 min. (B): (*a*) heating at 120 °C for 2 min, (*b*) standing at room temp. for 10 min, (*c*) 20 min, (*d*) 30 min, (*e*) 50 min.

methanol solution, charge separation is observed in the presence of the sacrificial donor triethanolamine under an argon atmosphere, but not in the absence of triethanolamine in air.[13] In Fig. 2, the absorbance at *ca.* 350 nm, which is independent of viologen radical and RuVQPIm, increases with formation of viologen radicals. We have reported that the reaction product in intra-polymer electron-transfer between a cobalt(II) Schiff-base complex and quaternized imidazolium residue would be 3-ethylimidazoline(4−) having $\lambda_{max}$ at *ca.* 340 nm.[17] Considering this fact, 3-hexadecylimidazoline(4−) would also be formed in the charge separation reaction; the quaternized imidazolium residue acting as an electron donor.

On the other hand, the colour change to orange in air is caused by decrease in the viologen radical species concentration as shown in Fig. 2. It is likely that a reaction between 3-hexadecylimidazoline(4−) and viologen radical residues takes place. In addition, viologen radical reacts with dioxygen in air, although this is slow since the rate of colour change is little different from that in an argon atmosphere.‡ This is supported by the fact that the absorbance at *ca.* 350 nm corresponding to the 3-hexadecylimidazoline(4−) roughly disappears and little colour change was observed after 24 h under dioxygen.

The thermal blue to orange colour change is slow in comparison to the system under irradiation. Since the glass transition temperature of the RuVQPIm film is *ca.* 220 °C, a phase transition does not occur upon heating at 120 °C for 2 min. However, the DSC curve of the RuVQPIm film shows endothermic behavior at 120–150 °C, suggesting that a conformational change takes place in the film. The heating treatment brings about charge separation in addition to conformational change. Therefore, the reverse colour change after heating is caused by decrease in viologen radical concentration through electron transfer and a concomitant conformational change.

The present results reveal orange to blue photo- and thermochromism using a new polymer film. The blue colour arises from viologen radicals formed by charge separation in which the quaternized imidazolium residue acts as an electron donor in the film. A detailed investigation on the photo- and thermochromism is now in progress in our laboratory.

† The film is very stable for repeated experiments with light on and off as well as heating and cooling. Even after 30 repetitions, the spectroscopic properties of the film were unchanged.

‡ The decrease in viologen radical concentration after standing for 30 min in air was 1.2 times larger than that under Ar.

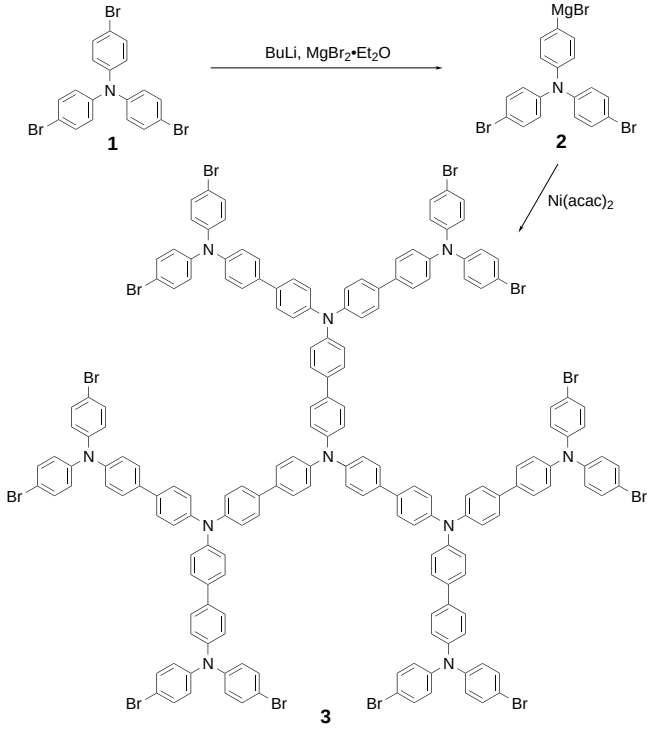
# Preparation of new branched poly(triphenylamine)

**Susumu Tanaka,*[a] Tomoaki Iso[b] and Yasuo Doke[a]**



[a] *National Institute of Materials and Chemical Research, 1-1 Higashi, Tsukuba, Ibaraki 305 Japan*
[b] *Ibaraki Prefectural Industry and Technology Center, 189 Kanakubo, Yuhki, Ibaraki 307 Japan*

**New branched poly(triphenylamine) is conveniently prepared by the Grignard reaction of tris(4-bromophenyl)-amine.**

Oligomeric and polymeric materials based on triphenylamine have attracted much attention because of their stability and useful properties such as electrical conductivity and electroluminescence.[1–3] Typical conductive polymers have a linear conjugated system like polythiophene, polyphenylene and polypyrrole. Until now, only a few reports have appeared on three dimensionally conjugated polymers.[4–6]

We report here the first preparation of a branched conjugated polymer containing triphenylamine, *via* the coupling of *N*,*N*-bis(4-bromophenyl)-*N*-(4-bromomagnesiophenyl)amine **2**, by the Grignard reaction of tris(4-bromophenyl)amine **1** (Scheme 1).

Branched polymers can be prepared through two distinct synthetic approaches. One is a stepwise growth process,[7,8] in which a protection–deprotection step is required at every stage. Although this approach yields monodisperse polymers with well-defined structure, it usually requires extensive purification of the products at every protection–deprotection step of the growth process. Another approach is the one-step process[9,10] where an $AB_x$-type monomer undergoes self-condensation polymerization, as first discussed theoretically by Flory in 1952,[11] which results in a branched product. The advantage of this one-pot $AB_x$ approach lies in its simple preparation process. But this method involves the loss of control in molecular weight, accompanied by a broad molecular weight distribution.

**Scheme 1**

Polymer **3** was prepared by monolithiation with $Bu^nLi$ at −78 °C in THF, followed by reaction with magnesium bromide–diethyl ether, and coupling the resulting Grignard reagent with the catalytic amount of $Ni(acac)_2$. Grignard reagent **2** reacted as an $AB_2$-type monomer to give branched conjugated polymer **3** in a one-step process. Polymer **3** had an average molecular weight of $4.0 \times 10^3$ and was found to be soluble in organic solvents such as THF and $CHCl_3$, which implies that the branched polymer is processable.

A FTIR spectrum of monomer **1** showed three bands at 510, 817 and 1269 $cm^{-1}$, assignable to the C–Br stretching vibration; the C–H deformation vibration of 1,4-disubstituted benzene rings and the C–N stretching vibration of tertiary amines, respectively. Polymer **3** had all these bands, but the band at 510 $cm^{-1}$ was weak, due to the C–Br stretching vibration of the terminal benzene rings. These results indicate that a C–C bond was formed between the monomers at the carbon atoms coupled with bromine originally and a highly conjugated system was formed.

The UV–VIS spectra of monomer **1** had a band at 307 nm assignable to the conjugation between benzene units and nitrogen atoms. In polymer **3** a new π–π* transition band was clearly observed at 360 nm, possibly brought about by the conjugation between biphenylene units and nitrogen atoms.

The $^{13}C$ NMR spectrum of polymer **3** had three bands at 124.4, 127.5 and 129.3 ppm, which were assignable to biphenylene carbon resonances. Monomer **1** did not have these bands.

GPC was performed in THF at 40 °C using a TOSOH TSKgel $G3000H_{XL}$ column which was calibrated with polystyrene standards. Fig. 1 shows a fully reproducible GPC trace. The molecular weight of the lowest oligomeric peak was *ca*. 1000, indicating that the lower oligomers had been removed in the course of the work-up. The GPC trace had another interesting feature; the splittings of the low oligomeric peaks reflect the resolution of the repeating unit of polymer **3**, $C_{18}H_{12}NBr$. The results of GPC indicated that the degree of polymerization was *ca*. 12. Considering that the repeating unit of polymer **3** contains three benzene rings, this degree of polymerization signifies that the polymer contained *ca*. 36 benzene rings, which was sufficient to show electroactivity as described below. The degree of polymerization estimated from the bromine content of polymer **3** was *ca*. 10, which implies that the value obtained by GPC was likely to be an overestimate of the real molecular weight.

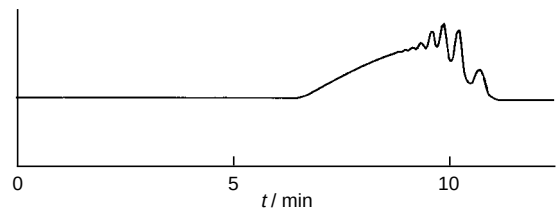


**Fig. 1** GPC of polymer **3** in THF

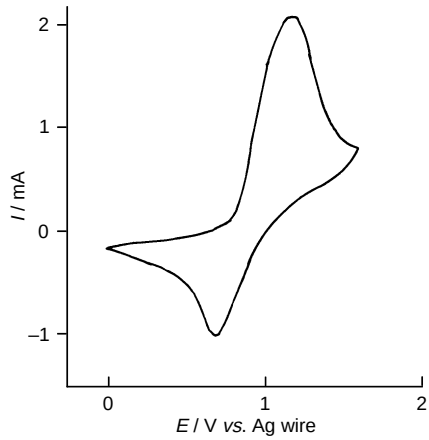

**Fig. 2** Cyclic voltammogram of polymer **3** in PC with 0.1 mol $l^{-1}$ $Bu_4NBF_4$; sweep rate, 100 mV $s^{-1}$

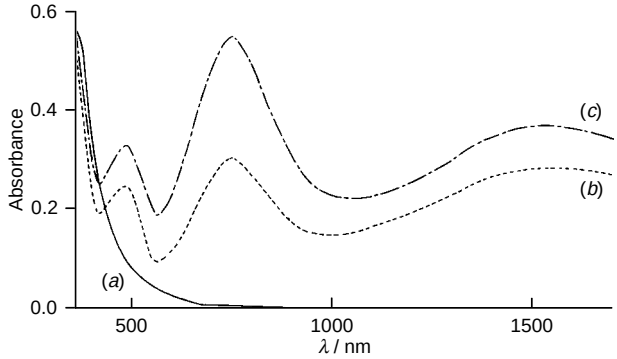

**Fig. 3** Spectral change during electrochemical $BF_4^-$ doping of polymer **3**. Applied voltage: (*a*) 0 , (*b*) 1.0 and (*c*) 1.2 V.

A cast film deposited on a platinum plate was used for cyclic voltammetry. The polymer showed a cathode-activity at applied voltages higher than 0 V; an anodic peak was observed at 1.20 V (Fig. 2). The film was dark blue above the oxidation potential and brown–yellow in the neutral state. The amount of charge, *Q*, exchanged during the redox cycle, was calculated from the integration of the absolute value of the current in Fig. 2 with respect to sweep time. The value of *Q* was found to be 0.20 electron per monomeric unit, which indicated that the polymer would be useful as a charge storage material.

Fig. 3 shows the change in the VIS–near IR spectra during electrochemical doping of polymer **3**. When the applied voltage was 0 V, the polymer film had only one band at 360 nm (3.44 eV) assigned to a π–π* transition. At 1.0 and 1.2 V, three new bands were observed around 500, 750 and 1500 nm (2.48, 1.65 and 0.83 eV). The first and last bands were considered to be assigned to the transition from the valence band to the higher and lower polaron bands,[12] respectively. The second band would be due to the transition from the lower to the higher polaron band. Electrochemically created charge carriers would be identified as polaron species in this case. The stability of the charge carriers would be brought about by the resonance effect of charged triphenylamine moiety.

Many conductive polymers are insoluble in organic solvents due to the rigid main chains but the introduction of a long alkyl or alkoxy group to the main chains is one way of enhancing solubility. However these groups do not contribute to an increase in π-conjugation length. A new branched conjugated polymer containing triphenylamine has been designed which has both a hyperbranched and conjugated backbone, and was found to be soluble in organic solvents without the addition of a long alkyl or alkoxy group. It showed a distinct anode-activity, indicating that it has a highly developed conjugated system.

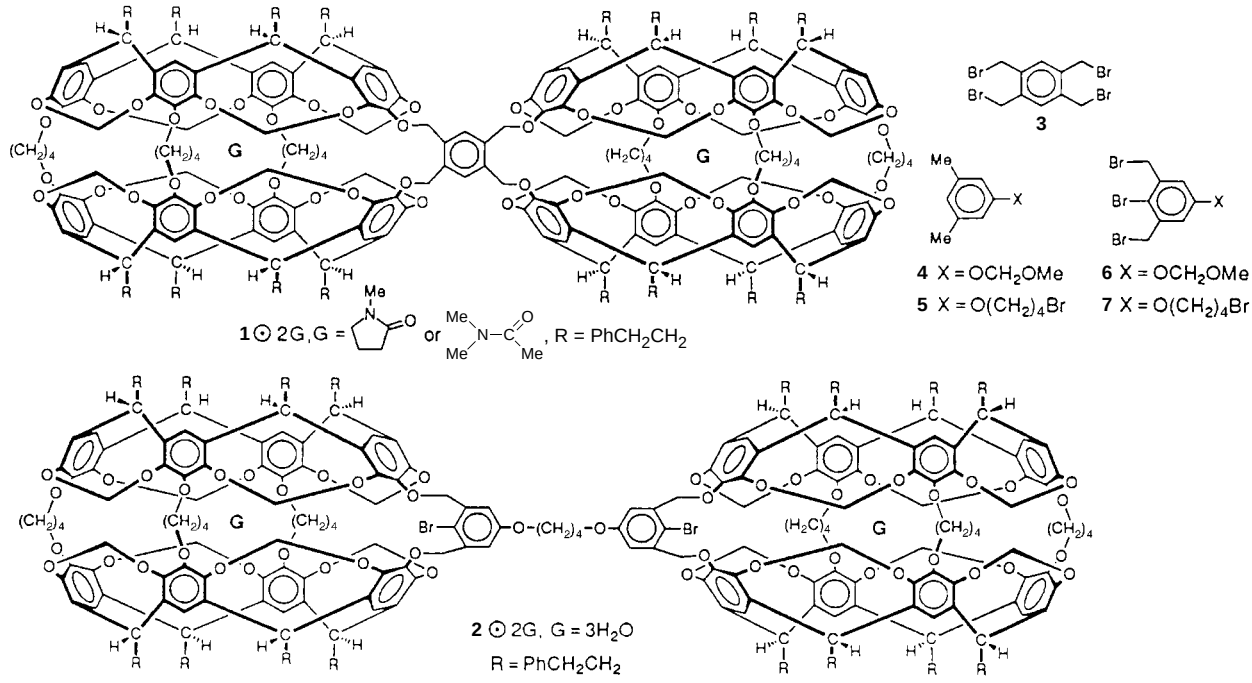
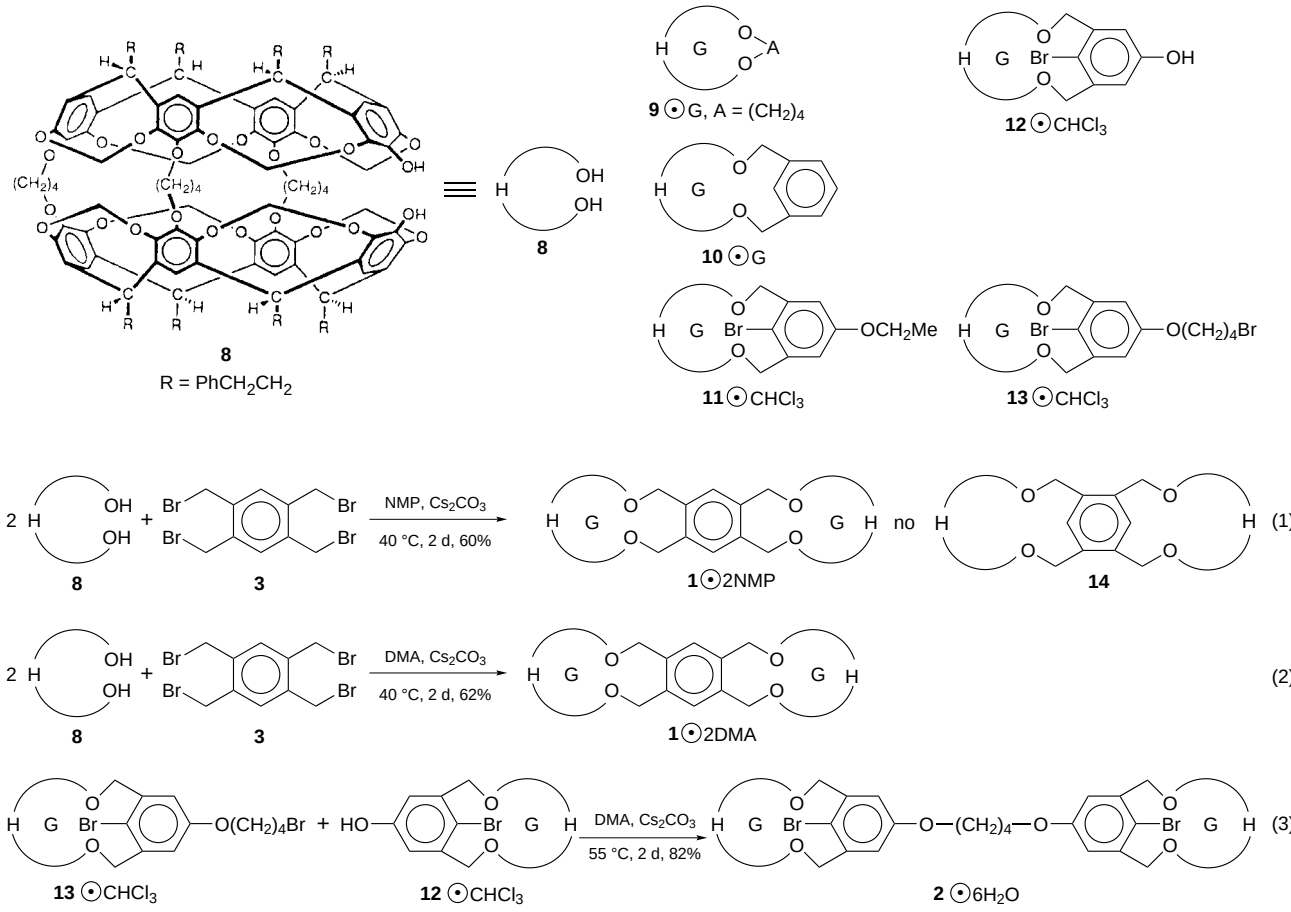
# Syntheses of two kinds of dimeric hemicarcerand systems

**Juyoung Yoon and Donald J. Cram***

*Department of Chemistry and Biochemistry, University of California at Los Angeles, Los Angeles, CA 90095-1569, USA*



**The first dimeric hemicarcerand systems are reported, whose synthesis allows either identical or nonidentical cavities and their guests to be tethered at designed distances from one another.**



The objective of this research was to establish synthetic feasibility for the synthesis of hemicarcerands covalently attached to one another through groups of designable lengths and saturation, of which **1** and **2** are examples. We reported earlier that appropriate guests incarcerated in **9** underwent oxidation and reduction reactions in bulk solution containing a variety of reducing and oxidizing agents. Electron and water transfers through shells without physical contact between guest and reagent were demonstrated.[1] These results suggest the possibility of electron transfers occurring between two or more designable guests whose hosts of appropriate character are located at controllable distances from one another. We imagine the possibility of ultimately preparing robust polymer chains whose core of guests is conducting, whose proximate shells are electron-permeable, and whose R groups are insulating. Earlier papers report the easy synthesis of diol **8**,[2] and its convertibility to eight different hosts of general structure **9** that differ only in their A groups.[2–4] This family of hosts forms stable complexes with over 50 characterized guests representing a wide variety of structural types.[2–5]

The synthesis of **1**⊙2NMP† (NMP = *N*-methylpyrrolidinone) and of **1**⊙2DMA† (DMA = dimethylacetamide) was accomplished by the reaction of tetrabromide **3** with two moles of diol **8** under the conditions of eqns. (1) and (2), respectively.‡ Earlier, **8** had been shown to react with 1,3-$(BrCH_2)_2C_6H_4$ to give **10**⊙G, suggesting the possibility that a dimer might be formed in which each of the two shell closures involved *m*-xylyl rather than *o*-xylyl type reactions, as in **14**.[2] No evidence for formation of **14** was obtained. The rates of the product-determining steps involve formation of the second ether group which closes to form a 26-membered ring leading to **1** or to form a 27-membered ring to provide **14**. Apparently the former rate is faster than the latter.

The final step in the synthesis of **2**⊙6$H_2O$† is formulated in eqn. (3). The two hemicarceplexes, **12**⊙$CHCl_3$† and **13**⊙$CHCl_3$†, were prepared as follows. The hydroxy group of 3,5-$Me_2C_6H_3OH$ was protected by treating it with $BrCH_2OMe$–NaH–THF to give **4**† (95%), which was brominated with *N*-bromosuccinimide (NBS)–$CH_2Cl_2$–AIBN to give **6**† (40%). Shell closure of diol **8** with **6** in NMP–$Cs_2CO_3$ (40 °C, 2 d) gave **11**⊙$CHCl_3$† (NMP exchange with $CHCl_3$ solvent occurred during chromatography). Deprotection of the $ArOCH_2OMe$ group of **11**⊙$CHCl_3$ (THF–HCl, 35 °C, 4 h) gave **12**⊙$CHCl_3$.† Alternatively, 3,5-$Me_2C_6H_3OH$ was treated with excess $Br(CH_2)_4Br$–$K_2CO_3$–DMF (50 °C, 4 h) to provide **5** (60%) (characterized only by $^1H$ NMR), which was brominated with NBS–$CH_2Cl_2$–AIBN to give **7**† (40%). Shell closure of diol **8** with **7** in NMP–$Cs_2CO_3$ (30 °C, 2 d) resulted in **13**⊙$CHCl_3$† (72%), NMP again being exchanged for $CHCl_3$ as guest during chromatography. As indicated in eqn. (3), the DMA–$Cs_2CO_3$ catalyzed coupling of **13**⊙$CHCl_3$ and **12**⊙$CHCl_3$ gave **2**⊙6$H_2O$† (82%), the $CHCl_3$ guest of the starting materials being replaced by water during chromatography with $CH_2Cl_2$, drying and absorbing water from the atmosphere.‡

Corey–Pauling–Koltun model examinations of **1**, **2** and **14** provide the following estimates for the respective maximum and minimum distances the centres of the two cavities can be

from one another: **1**, 13–15; **2**, 13–26; **14**, 12.5–16 Å. For all three models, low-energy conformations appear to exist in which the outsides of the two shells contact one another. We believe it is more likely for electrons to pass from an appropriate guest in one shell of **1** to a second appropriate guest in the other shell of **1** than it is for electrons to pass between oxidizing or reducing agents and incarcerated guests dissolved in dilute solvent, an observed phenomenon.

† These new compounds gave C and H elemental analyses within 0.30% of theory, $M^+$ *m/z* signals of 80–100% intensity (including guest) in their FAB-MS and $^1$H NMR spectra consistent with their structures.

‡ The procedures were patterned after those that are standard in the literature. All products were purified by chromatography (E. Merck silica gel 60, 70–230 mesh). The shell closures required reagent grade DMA or NMP, freshly distilled and stored over 3 Å molecular sieves (activated at 320 °C) and degassed just prior to use. The shell closures involved medium dilution and inert atmospheres, and were similar to those reported in refs. 2 and 5.

# Dendritic solution viscosity behaviour in core terminated hyperbranched poly(amidoamine)s

**Lois J. Hobson and W. James Feast***

*I.R.C. in Polymer Science & Technology, University of Durham, Durham, UK DH1 3LE*

**A poly(amidoamine) hyperbranched $AB_2/B_6$ copolymer displays a viscosity/molecular weight profile similar to that shown by perfectly regular dendrimers.**

The physical properties of a polymer are heavily dependent upon its topology.[1–6] Dendrimers, prepared by stepwise iterative syntheses, represent a particularly interesting class of materials which are attracting considerable attention at present. A characterising feature of dendritic polymers is that past a critical point, their intrinsic viscosity decreases with increasing molecular weight.[7] It is often argued that the properties which distinguish dendrimers from other structures are associated only with those materials whose molecular weight is above this peak in the viscosity *versus* molecular weight curve.[8]

We have recently established a simple 'one-pot' route to the hyperbranched analogues of Tomalia's poly(amidoamine) dendrimers.[9,10] These polymers, prepared by the melt polymerisation of *N*-acryloyl-α,β-diaminoalkane hydrochlorides[11] $H_2C{=}CHCONH(CH_2)_nNH_3^+Cl^-$ ($n$ = 2–7), exhibit a degree of branching approaching one in the case where $n$ = 2. The observation of near perfect branching for this monomer is very unusual indeed; so far it is the only example we have found in more than twelve $AB_2$ polymer systems studied. Near perfect branching in $AB_n$ systems does not, of course, imply the formation of materials with dendritic topology. This is illustrated in Fig. 1, where structure (*b*) represents one possible topology in the spectrum between the linear structure (*a*) and the perfect dendritic wedge (*c*), all of which display a branching factor of one.

The peak in the log (molecular weight) *versus* log (intrinsic viscosity) relationship is widely believed to be a specific characteristic of dendritic materials and the possibility of regulating the molecular weight *versus* viscosity relationship within the limits defined by linear and true dendritic systems has technological attractions.

Here we report the preparation of a series of $AB_2/B_6$ copolymers, using the monomer *N*-acryloyl-1,2-diaminoethane hydrochloride ($n$ = 2) in conjunction with the $B_6$ core, tris(2-aminoethyl)amine. The polymerisations were carried out under dry nitrogen in the melt and it was readily shown by $^1$H NMR spectroscopy that the vinyl unit was rapidly and completely consumed in this system. For related monomers where $n > 2$ this did not occur and vinyl units remained after several hours reaction time. The high reactivity and high branching factor appears to be unique to the monomer where $n$ = 2. Since consumption of the monomer was complete, variation of the molar ratio of core terminating tris(2-aminoethyl)amine to $AB_2$ *N*-acryloyl-1,2-diaminoethane hydrochloride monomer allows regulation of product molecular weight. Unfortunately the water soluble polyelectrolytes produced in this work are not amenable to reliable molecular weight analysis by either GPC or MALDI–TOF MS, which prevents a direct check on their molecular weights and molecular weight distributions. However the knowledge that all the $AB_2$ wedges are terminated by cores and that all the monomers are consumed, taken with our earlier experience with less highly branched core-terminated polyesters,[12] gives some confidence in the calculated molecular weights used below. Our earlier work with $CHCl_3$ and THF soluble polyesters had established that the homo-$AB_2$ hyperbranched polyesters conformed to the Mark–Houwink relationship and that molecular weights calculated from $AB_2$ monomer to $B_n$ core molar ratios for the core terminated samples fell between the *M*n and *M*w values determined by GPC (see Fig. 2 in ref. 12), thus establishing a correlation between the molecular weight of the products and the $B_n$ core: $AB_2$ monomer molar ratio used in the polymerisation. Following this precedent, we have polymerised $AB_2/B_6$ mixtures with the molar ratios appropriate to the formation of successive generations of ideal dendrimers. Solution viscosity measurements on the resultant polyelectrolytes were carried out in 1% aqueous LiCl at 25 °C over a range of dilutions, using a Laude/Schott automated system. A plot of reduced viscosity against concentration allows extrapolation to zero concentration to give a value for intrinsic viscosity ($cm^3\ g^{-1}$).

The logs of the observed intrinsic viscosities were plotted against the logs of molecular weights calculated from the monomer to core terminator molar ratios and are shown in Fig. 2 in comparison with Tomalia's PAMAM dendrimer data.[13] We

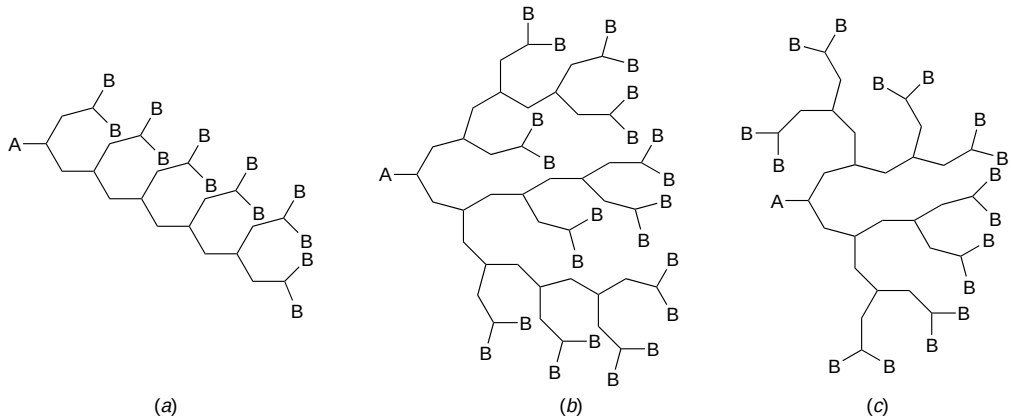

**Fig. 1** Possible structures of an $AB_2$ hyperbranched polymer with a branching factor of one

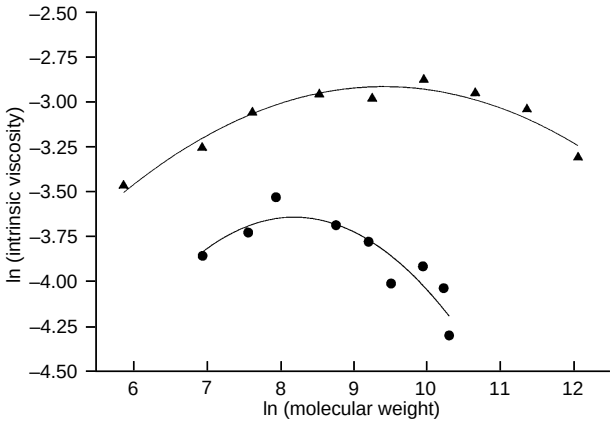

**Fig. 2** The molecular weight *vs.* intrinsic viscosity relationship for $AB_2/B_6$ copolymers: (●) $AB_2/B_6$ copolymers and (▲) Tomalia's PAMAM dendrimers (ref. 13)

do not expect that this simple 'one pot' synthesis will produce perfect monodisperse dendrimers; indeed, a distribution in both molecular weight and structure is to be expected. However it is clear that in the system examined the peak in the graph of log (intrinsic viscosity) *versus* calculated molecular weight is demonstrated and is consistent with the formation of polymeric materials with topologies giving rise to solution viscosity behaviour resembling that of dendrimers. These observations imply that at least some of the attractive materials properties of dendrimers may be obtained in materials synthesised by less laborious procedures than those reported to date.

We thank the EPSRC for support of this work through a ROPA grant.

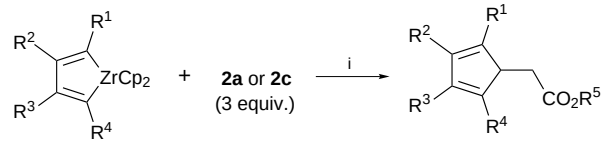
# 1,1-Cycloaddition of zirconacyclopentadienes to propynoates

**Tamotsu Takahashi,* Wen-Hua Sun, Chanjuan Xi and Martin Kotora**

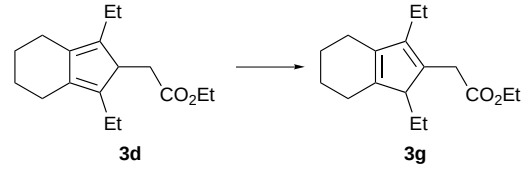
*Catalysis Research Center and Graduate School of Pharmaceutical Sciences, Hokkaido University, Kita-ku, Sapporo 060, Japan*



**Zinconacyclopentadienes react with propynoates in a 1,1-cycloaddition manner to give pentasubstituted cyclopentadiene derivatives in high yields.**

Metallacycles are convenient starting materials for the construction of carbocyclic compounds.[1] The formation of carbocycles can be accomplished by the addition reaction to (or insertion reaction of) unsaturated compounds such as alkenes, alkynes, CO and RNC. It is well documented that CO or its synthetic equivalents act as one-carbon units. For alkenes or alkynes, two types of addition reaction, *i.e.* 1,2-cycloaddition or 1,1-cycloaddition, are considered to be possible as shown in Scheme 1. There have been many examples of the 1,2-cycloaddition of metallacycles to alkynes, in which the alkynes behave as two-carbon units.[2] In contrast, 1,1-cycloaddition to alkynes or related reactions in which alkynes act as a one-carbon unit is very rare.[3,4] Here we report the 1,1-cycloaddition of zirconacyclopentadienes to propynoates to afford cyclopentadiene derivatives.

**Scheme 1**



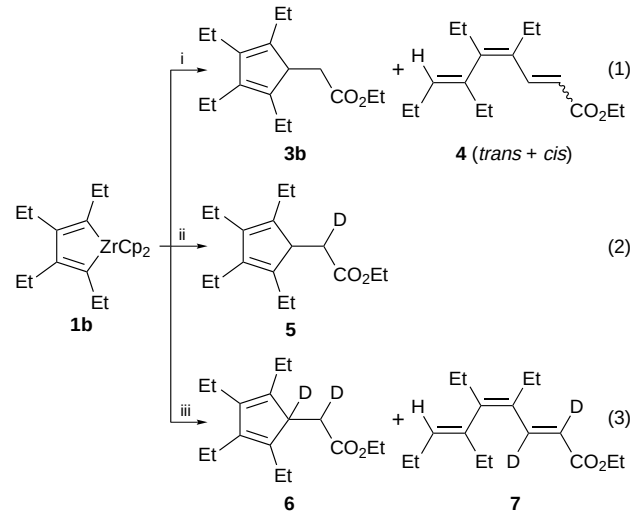
In a typical example, the reaction of tetraethylzirconacyclopentadiene **1b** with ethyl propynoate **2a** (3 equiv.) provided the cyclopentadiene **3b** in 97% (GC) yield (Scheme 2). The best results were obtained by stirring the reaction mixture first at −78 °C for 1 h followed by stirring at 0 °C for 1–3 h. Some further examples are presented in Scheme 2. In all cases yields of products were high. Monocyclic zirconacyclopentadienes afforded only the corresponding cyclopentadienes. In the case of bicyclic zirconacyclopentadiene **1d**, the desired product **3d** was easily isomerized to the more stable **3g** (Scheme 3) under the conditions used here. The reactions of

**1a** $R^1 = R^2 = R^3 = R^4 = Me$
**b** $R^1 = R^2 = R^3 = R^4 = Et$
**c** $R^1 = R^2 = R^3 = R^4 = Pr$
**d** $R^1 = R^4 = Et$, $R^2–R^3 = –(CH_2)_4–$

**3a** ($R^5$ = Et): 93% (73)
**b** ($R^5$ = Et): 97% (74)
**c** ($R^5$ = Et): 96% (78)
**d** ($R^5$ = Et): 93% (68)
**e** (from **1b**, $R^5$ = Me): 95% (78)
**f** (from **1c**, $R^5$ = Me): 93% (78)

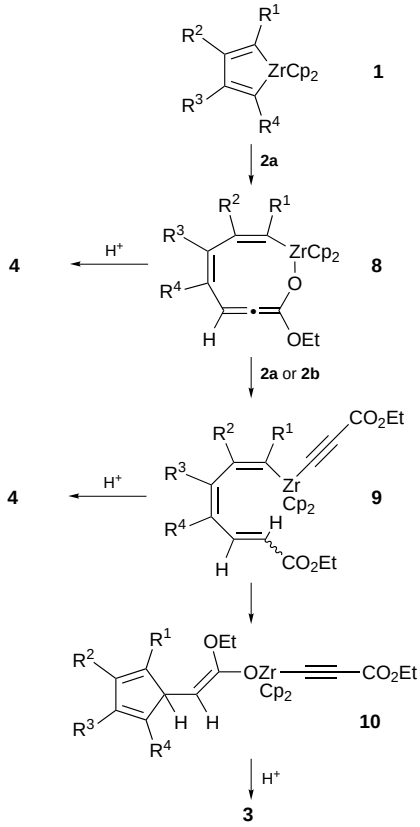
**Scheme 2** *Conditions*: i, −78 to 0 °C, 1–3 h; $H^+$. GC yields. Isolated yields are given in parentheses.

**3d** **3g**



**Scheme 3**

zirconacyclopentadienes **1b**,**c** with methyl propynoate **2c** gave similar products **3e** and **3f**, respectively. Thus, the formation of cyclopentadiene derivatives proceeds under relatively mild conditions in high yields. Although its scope is limited only to zirconacyclopentadienes bearing alkyl substituents, and zirconacyclopentadienes bearing phenyl or trimethylsilyl substituents at the α-position did not react, clarification of the mechanism of 1,1-cycloaddition of **1** to **2** should be informative.



**2a** **2b** **2c**

To elucidate the reaction mechanism, the following experiments were conducted (Scheme 4). Firstly, the reaction was carried out at −78 °C. Interestingly, trienes **4** were obtained in 78% yield (*trans*-**4** 38% + *cis*-**4** 40%) as major products along with **3b** (18%), whereas at −40 °C the reaction gave a different ratio of the products: **3b** (49%), *trans*-**4** (29%) and *cis*-**4** (16%). Secondly, the reaction of the zirconacyclopentadiene **1b** with ethyl propynoate at −78 °C for 1 h and then 0 °C for 1 h afforded the monodeuterated cyclopentadiene **5** after deuterolysis with 3 M DCl. This result shows that the product of the reaction of **1b** with **2a** before hydrolysis contains only one Zr–C bond or one Zr-enolate moiety. One hydrogen atom must be transferred to the intermediate during the reaction. Obviously,

**1b** **3b** **4** (*trans* + *cis*) **5** **6** **7**

**Scheme 4** *Reagents and conditions*: i, **2a**, −78 °C, $H^+$; ii, **2a**, −78 to 0 °C, $D^+$; iii, **2b**, −78 to 0 °C, $H^+$

**Scheme 5** Proposed reaction mechanism of the cyclopentadiene formation

the only compound capable of acting as a possible hydrogen donor is the propynoate having a weakly acidic hydrogen atom bound to the sp carbon of the triple bond. This is consistent with the fact that 3-substituted propynoates, which do not have the acidic hydrogen, do not give the desired products. To clarify this point, the reaction of the zirconacyclopentadiene **1b** with ethyl [3-$^2$H]propynoate **2b**[5] was carried out. Hydrolysis of the reaction mixture with 3 M HCl afforded the dideuterated cyclopentadiene **6** in 61% yield and the *trans* triene **7** in 17% yield. This clearly indicates that Michael addition of one Zr–C bond of the zirconacyclopentadiene to propynoate is the first step. It is noteworthy that this is the first example of direct Michael addition of organozirconocene compounds. So far, the Michael addition was observed only after transmetallation of organozirconium compounds to Cu[2,6] or Ni[7] compounds. This demonstrated that a hydrogen (deuterium) atom is indeed transferred from the second propynoate (deuterated propynoate). It also explains why an excess of propynoate was necessary for this reaction and why 3-substituted propynoates did not give the desired products.

From these results, it is possible to propose the following reaction mechanism (Scheme 5). In the first step, the zirconacyclopentadiene **1** adds to the propynoate **2a** forming the nine-membered oxazirconacycle **8**. Hydrolysis of **8** gives the trienes **4**. Then, protonolysis **8** with the propynoate **2a** takes place forming the alkenylalkynyl zirconium compound **9**. Hydrolysis of **9** also affords trienes **4**. The intermediate **9** undergoes an intramolecular conjugate addition and forms **10** which, upon hydrolysis, affords **3**.

In conclusion, zirconacyclopentadienes unprecedentedly reacted with propynoates *via* inter- and intra-molecular Michael addition, resulting in a 1,1-cycloaddition to afford cyclopentadienes. This is in contrast to the reactions of late transition metal metallacyclopentadienes (*e.g.* Ir) which react with propynoates *via* vinylidene intermediates to yield stable organometallic compounds.[4,8]

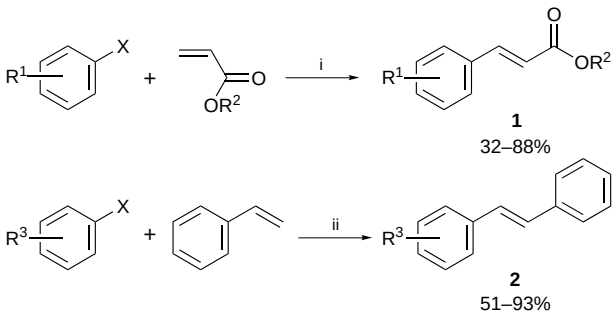
# Pd–Cu–Exchanged montmorillonite K10 clay: an efficient and reusable heterogeneous catalyst for vinylation of aryl halides

**R. K. Ramchandani, B. S. Uphade, M. P. Vinod, R. D. Wakharkar, V. R. Choudhary and A. Sudalai***



*National Chemical Laboratory, Pune 411 008, India*

**Palladium and copper exchanged montmorillonite K10 clay has been found to catalyse very efficiently the reaction between aryl halides (X = Br, I) and acrylates, and styrenes affording alkyl (*E*)-cinnamates and (*E*)-stilbenes respectively in high yields.**

The palladium-catalysed vinylation of aryl halides (X = Br, I) (Heck reaction) provides a very convenient and powerful method for forming carbon–carbon bonds at unsubstituted vinylic positions.[1] Major improvements in Heck-type reactions over the last decade have been brought about by the introduction of tetraalkylammonium salts, silver(I) or thallium(I) salts as promoting additives or by use of organotrifluoromethanesulfonates.[2] Two recent promising approaches involve reactions in aqueous (or water–organic solvent) media[3] and the use of vinyl iodonium salts.[4] For the Heck reaction, a $Pd^{II}$ salt or complex is employed which is reduced *in situ* to an active zero valent palladium species under homogeneous conditions. The $Pd^{II}$ species that is subsequently regenerated in the reaction[2] is very difficult to separate and reuse for the reaction directly without further processing. In view of the practical and industrial applications, improvements in catalyst efficiency and catalyst recycling are essential. To overcome these problems, heterogeneous catalysts such as polymer-supported palladium catalysts and Pd–$Ph_2$P–Si supported on clay have been reported for the arylation of alkenes.[5] However, these catalysts suffer from drawbacks such as (i) their preparation involves many steps and the use of expensive phosphorus and silicon compounds and (ii) deactivation of the catalyst on its reuse. We report here our preliminary results on the use of Pd and Cu exchanged montmorillonite K10 (Mont.K10) clay catalysts for the vinylation of aryl halides (X = Br, I) (Scheme 1).

Pd, Cu and Pd–Cu exchanged clay catalysts were prepared by exchanging the clay with dilute aqueous $PdCl_2$, $Cu(NO_3)_2$ or a mixture of two respectively. For example, Pd (0.29 wt%)–Cu (0.36 wt%)-exchanged Mont.K10 clay catalyst was prepared by treating Mont.K10 clay (25 g) with 600 ml aqueous $PdCl_2$ and $Cu(NO_3)_2$ under vigorous stirring at room temperature for 24 h, centrifuging and washing the Pd–Cu exchanged clay with distilled deionised water repeatedly until the discarded filtrate was free from $Cl^-$ and $NO_3^-$ ions, and drying the resulting mass at 110 °C for 12 h. The metal content of the catalysts was determined using an electron disperse X-ray microscope (EDX) (Kevex, US) connected to a JEOL (JSM-5200) scanning electron microscope (SEM). The surface area of Pd (0.29 wt%)–Cu (0.36 wt%)–Mont.10 and Cu (0.39 wt%)–Mont.K10 being 262.9 and 238.9 $m^2\ g^{-1}$ respectively (BET method). The XRD pattern and FT-IR spectra of these samples show that they are crystalline, however no significant differences were observed among their structures. Definite information about the nature of the metal species present in the catalyst could be obtained from cyclic voltammetry (CV). Fig. 1 shows the CV of Cu–Pd exchanged Mont.K10 clay at a scan rate of 50 mV $s^{-1}$. It clearly indicates two reversible peaks with $E_{1/2}$ (*vs.* saturated calomel electrode) at −0.119 and +0.117 V. We attribute, after comparing the potential values from literature,[6] the peak at +0.117 to a Pd/$Pd^{2+}$ process and the one at −0.119 V to a Cu/$Cu^{2+}$ process. Although two one-step electron processes (*i.e.* $Cu^{2+}/Cu^+$ and $Cu^+/Cu$) are possible, separate experiments with Cu and Pd exchanged Mont.K10 clay have shown that the CV behaviour corresponds to $Cu^{2+}/Cu$ and Pd/$Pd^{2+}$ redox processes. Hence the presence of Pd is mediating the Cu redox process (Fig. 2). This explains the high activity of the Pd–Cu exchanged catalyst compared to the Cu or Pd exchanged catalyst.

Results of the reaction of iodobenzene with acrylates, over different catalysts and over the best catalyst Pd (0.29 wt%)–Cu (0.36 wt%)-exchanged Mont.K10 clay catalyst are presented in Tables 1 and 2 respectively.† A comparison of the results in

| 1 | Cu (0.07 wt%)–Mont.K10 | 0 | 0 |
| 2 | Cu (0.39 wt%)–Mont.K10 | 30 | 51 |
| 3 | Pd (0.33 wt%)–Mont.K10 | 41 | 56 |
| 4 | Pd (0.29 wt%)–Cu (0.36 wt%)–Mont.K10 | 83 | 88 |
| 5 | Pd (1.73 wt%)–Cu (0.16 wt%)–Mont.K10 | 56 | 61 |
| 6 | Cu (0.32 wt%)–kaolin | 0 | 0 |

[a] *Reaction conditions*: iodobenzene (3 mmol), methyl acrylate (6 mmol), anhydr. $K_2CO_3$ (8 mmol), catalyst (10% m/m), DMF (5 ml), reflux, 2 h. [b] Isolated yield obtained after chromatographic purification.

Table 1 shows that among the catalysts, the Pd (0.29 wt%)–Cu (0.36 wt%)-exchanged Mont.K10 clay catalyst gives the best results for the Heck reaction. The higher activity of this catalyst seems to be due to a synergistic effect produced by the presence of Pd and Cu in close vicinity. The results also indicate that for this catalyst to be more active, enough copper must be present along with the palladium. It is remarkable that Cu (0.39 wt%)–Mont.K10 clay also catalyses the Heck reaction leading to the formation of (*E*)-cinnamate esters. The choice of solvent for the arylation reaction catalysed by the Pd (0.29 wt%)–Cu (0.36 wt%)–Mont.K10 clay catalyst is also critical as the reaction fails when carried out in MeCN under reflux. Among the different bases tried for this reaction, *viz.* $NaHCO_3$, K or Na acetate, $K_2CO_3$, $Et_3N$ and $Bu_3N$, $K_2CO_3$ gave the best results (*i.e.* high yields with 100% selectivity).

Table 2 lists the results for different types of aryl halides (X = Br, I) that have been vinylated with methyl or ethyl acrylate to afford the corresponding cinnamates in high yields using the Pd (0.29 wt%)–Cu (0.36 wt%)–Mont.K10 clay catalyst. In all the substrates examined, exclusive formation of the (*E*)-cinnamate was observed (GC, $^1$H and $^{13}$C NMR and mass spectroscopy). Table 3 shows the results of the reaction of various aryl halides (X = Cl, Br, I) with styrene producing (*E*)-stilbenes in high yields using Pd–Cu–Mont.K10 catalyst (15% m/m). A remarkable feature of these catalytic systems is that even less reactive substituted bromobenzenes react with styrene to give (*E*)-stilbenes in excellent yields. The reaction however did not proceed using aryl iodides with substituents such as nitro, amino, chloro *etc.* The reaction also failed when methyl vinyl ketone and cyclohexenone were used as alkenylating agents instead of acrylate. Mechanistically, it is proposed that aryl halides react with copper presumably to yield an organocopper species, which then transmetallates to $Pd^{II}$ followed by olefin insertion, β-hydride elimination and dissociation of palladium hydride species[2] (Scheme 2).

**Table 2** Results of the reaction of aryl halides with acrylates over Pd (0.29 wt%)–Cu (0.36 wt%)–Mont.K10 clay catalyst

**Scheme 2**

The catalyst from the reaction mixture was recovered by simple filtration and was successfully reused three times without loosing its activity in the alkenylation of 4-methoxyiodobenzene with methyl acrylate.

In conclusion, the Pd (0.29 wt%)–Cu (0.36 wt%)–Mont.K10 clay catalyst has high activity for the Heck reaction in which aryl halides (X = Br, I) are reacted with acrylates and styrenes to form the corresponding (*E*)-cinnamates and (*E*)-stilbenes respectively in high yields. The high activity of the catalyst is attributed to a synergistic effect produced by the presence of Pd and Cu species in the catalyst.

† In a typical reaction procedure, iodobenzene [580 mg, 2.8 mmol (1 : 1 styrene)], methyl acrylate (500 mg, 5.8 mmol), anhydr. $K_2CO_3$ (1 g, 7.2 mmol) and catalyst (58 mg, 10% by weight of PhI) in DMF (5 ml), were refluxed for 2 h. After completion of the reaction (TLC monitoring), the catalyst was separated by filtration and the reaction mixture was poured into water followed by its extraction with ethyl acetate to give the crude product which was subsequently purified by column chromatography to afford methyl (*E*)-cinnamate (380 mg, 83%), $\delta_C$ (50.3 MHz, $CDCl_3$) 51.6, 117.9, 127.9, 128.3, 128.9, 129.2, 130.3, 134.4, 144.8 and 167.3; *m/z* 162 ($M^+$, 65%), 161 (45), 131 (100), 117 (5), 103 (82) and 73 (91).

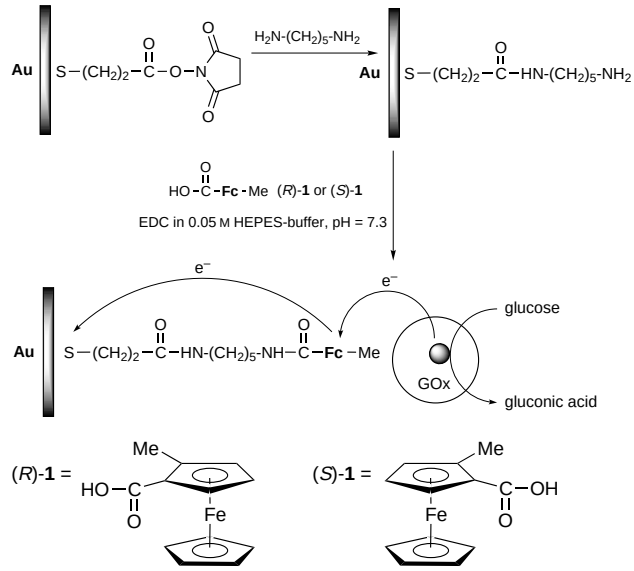
# Enantioselective bioelectrocatalyzed oxidation of glucose by glucose oxidase at chiral-monolayer-electrodes

**Guoliang Tao, Eugenii Katz and Itamar Willner***



*Institute of Chemistry, The Hebrew University of Jerusalem, Jerusalem 91904, Israel*

**(*R*)- or (*S*)-2-Methylferrocenecarboxylic acid monolayers assembled onto Au-electrodes stimulate chiroselective bioelectrocatalysed oxidation of glucose in the presence of glucose oxidase**

Chiral discrimination in electron transfer or energy transfer processes in biological assemblies has been a subject of extensive research.[1,2] Chiroselectivity was observed in the association of optically-active transition metal complexes to DNA[3] and enantioselective electron transfer in the DNA microenvironment was reported.[4] Chiroselective electron transfer between transition metal complexes and redox proteins such as plastocyanine,[5] cytochrome c,[6] plant ferredoxin[7] and reconstituted $Zn^{II}$-myoglobin[8] was reported, although in low discrimination yields. Mediated electron transfer between low molecular-weight redox-relays and redox proteins has been studied in the general context of electrochemical biosensors.[9,10] In particular, ferrocenyl cation-mediated[11] oxidation of oxidoreductases was extensively explored, and the mediated electron transfer rates were controlled by the ferrocene substituent groups and the redox potentials of the relays. As the association rate of ligands to proteins is lower than diffusion-controlled (*k ca.* $10^7$–$10^8$ $M^{-1}$ $s^{-1}$) it is anticipated that chiral discrimination could play an important role in the affinity interactions of ligands and proteins. Indeed, we have reported the first example of enantioselective, diffusionally mediated, bioelectrocatalysed oxidation of glucose in the presence of chiral ferrocene mediators.[12] These results were later criticized by Alzari *et al.*,[13] though recent examples by Sadeghi and co-workers[14] nicely support the concept of chiroselective, diffusionally mediated, electron transfer within enzymes. Mediated bioelectrocatalytic transformations at redox-relay functionalized monolayer electrodes was recently exemplified.[15] Chiral monolayer-modified electrodes were developed for some electrochemical,[16] but not bioelectrochemical applications. Here we report on the assembly of chiral monolayers consisting of (+)-2-methylferrocene carboxylic acid, (*R*)-**1** and (−)-2-methylferrocenecarboxylic acid, (*S*)-**1**.[17] The resulting chiral monolayer interfaces stimulate the enantioselective mediated bioelectrocatalysed oxidation of glucose. Mechanistic analysis of the electron transfer process using a rotating disc electrode (RDE), reveals chiral discrimination in the affinity associative interactions between the chiral monolayer and the redox enzyme glucose oxidase (from *Aspergillus niger* type X-S, E.C. 1.1.2.4, Sigma).

The assembly of the amide-functionalized chiral ferrocene monolayers on Au-electrodes is shown in Scheme 1. The ferrocene monolayer-functionalized electrodes exhibit a reversible cyclic voltammogram, $E^\circ$ = 0.235 V *vs.* SCE, and the surface coverage of the two enantiomers is similar, $6 \times 10^{-11}$ mol $cm^{-2}$ (±2%). The electron transfer rates to the two chiral ferrocene relays was determined by Laviron's method[18] and were found to be identical, $k_{et}$ *ca.* 18.0 $s^{-1}$. Fig. 1 shows the cyclic voltammograms of the chiral ferrocene-functionalized electrodes, in the presence of glucose oxidase, GOx, in the electrolyte solution in the absence of glucose [curves (*a*) and (*b*)] and in the presence of added glucose, $5 \times 10^{-2}$ M [curves (*c*) and (*d*)]. In the presence of glucose electrocatalytic anodic currents are observed in the presence of the two redox-functionalized electrodes. The electrocatalytic anodic current in the presence of the (*S*)-**1**-functionalized monolayer is higher by *ca.* 90% as compared to the electrocatalytic current in the presence of the (*R*)-**1**-functionalized monolayer electrode. These results clearly demonstrate that chiroselective bioelectrocatalysed oxidation of glucose occurs at the functionalized electrodes.

To understand the origin of chiroselective mediated electron transfer at the chiral monolayer electrodes, the bioelectro-

Background electrolyte, 0.1 M phosphate buffer, pH 7.0. Potential scan rate, 5 mV $s^{-1}$.

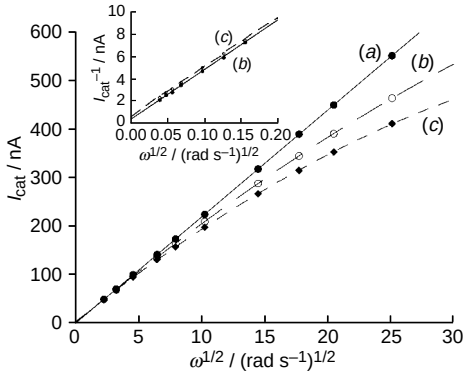

**Fig. 2** Currents generated at the chiral ferrocene monolayer-modified Au-electrodes (Au-disk, 0.16 cm² geometrical area, roughness coefficient, *ca.* 1.3) in the presence of $1 \times 10^{-5}$ M GOx and $5 \times 10^{-5}$ M glucose at applied potential +0.4 V *vs.* SCE. (*a*) Theoretical Levich plot, (*b*) **(*S*)-1** monolayer-modified electrode, (*c*) **(*R*)-1** monolayer-modified electrode. Background electrolyte, 0.1 M phosphate buffer, pH 7.0. Inset: Koutecky–Levich plots for the experimental results shown.

catalysed process was examined at a rotating disc electrode (RDE).[19] The two chiral ferrocenes, (*R*)-**1** and (*S*)-**1** were assembled on an Au-disc electrode as described in Scheme 1, and the resulting catalytic currents were monitored at a low glucose concentration, $5 \times 10^{-5}$ M, and under Ar in order to preserve the flavo enzyme redox centres in their reduced states, GOx$^{red}$. Fig. 2 (*b*) and (*c*) shows the experimental Levich plots for the electrocatalysed oxidation of GOx$^{red}$ by the (*S*)-**1** and (*R*)-**1** monolayers, respectively. For comparison, the theoretical Levich plot for the oxidation of GOx$^{red}$ by the ferrocene monolayer is shown in curve (*a*) (assuming the transfer of 2 electrons, $n = 2$; and the diffusion coefficient $D_{GOx} = 4 \times 10^{-7}$ cm² s$^{-1}$). The inset in Fig. 2 shows the related Koutecky–Levich plots for the electrocatalysed oxidation of GOx$^{red}$ by (*R*)-**1** and (*S*)-**1** monolayers, respectively. The slopes of the two plots are identical and correspond to the transfer of two-electrons (Fig. 2, inset). Thus, even though GOx consists of a dimer and the oxidation of each of the FAD sites in the subunits involves two electrons, the transfer of only two electrons is observed in the RDE experiments. This is rationalized by the fact that only one subunit is appropriately aligned in respect to the monolayer within the electron transfer event. It should be noted that in the RDE experiments, analysing the electron transfer rate between the chiral ferrocene monolayers and GOx, a *low* concentration of glucose was used under anaerobic conditions. The use of a low glucose concentration is essential to derive the electron transfer rate constant from reduced GOx, GOx$^{red}$, to oxidized ferrocene under conditions where the regeneration of GOx$^{red}$ by glucose is impossible (very slow) during monolayer and enzyme interaction time. From the intercepts of the respective Koutecky–Levich plots, the electrochemical electron transfer rates from the (*R*)-**1** and (*S*)-**1** monolayer were derived to be $0.51 \times 10^{-2}$ and $0.9 \times 10^{-2}$ cm s$^{-1}$, where the overall rate constants ($k_{overall} = k_{el}/\Gamma_{ferrocene}$, where $\Gamma_{ferrocene}$ is the surface coverage of the electron mediator) correspond to $0.85 \times 10^5$ and $1.5 \times 10^5$ M$^{-1}$ s$^{-1}$, respectively. The overall electron transfer rates for the oxidation of GOx by the two chiral monolayer-electrodes depend inversely on the concentration of GOx. This indicates that the electrocatalysed oxidation of GOx by the ferrocene monolayer proceeds via the formation of a complex between the monolayer and GOx$^{red}$, rather than by outer sphere electron transfer,[19] Scheme 2.

$$\left|-Fc^{+} + GOx^{red} \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}}\right| -Fc^{+} \cdots GOx^{red} \xrightarrow{k_{+2}} \left|-Fc + GOx^{ox}\right.$$

**Scheme 2**

Following Scheme 2, the overall rate constant is given by eqn. (1), where $K_M$ is given by eqn. (2). We find that the electron transfer rates from the GOx$^{red}$ to the (*R*)-**1** and (*S*)-**1** monolayer differ substantially, $k_{+2}$(*R*)-**1** = 0.3 s$^{-1}$, $k_{+2}$(*S*)-**1** = 0.5 s$^{-1}$, while the $K_M$ values characterizing the chiral monolayer and GOx$^{red}$ are identical, $K_M = 1.2 \times 10^{-5}$ M.

$$k_{overall} = k_{+2}/(K_M + [GOx^{red}]) \quad (1)$$

$$K_M = (k_{-1} + k_{+2})/k_{+1} \quad (2)$$

We thus conclude that the affinities for the association of GOx$^{red}$ to the chiral ferrocenyl cation monolayer are similar. The electron transfer rates between the reduced flavin centre and the chiral ferrocenyl cations differ substantially. The diastereoisomeric nature of the complexes between GOx$^{red}$ and the chiral ferrocenyl cations could yield different electron transfer distances to the flavin sites, thereby stimulating the enantioselective bioelectrocatalysed oxidation of glucose.

This research was supported by the Bundesministerium für Bildung, Wissenschaft, Forschung und Technologie, BMBF, Germany, and a Consortium with Wacker Industries, München.

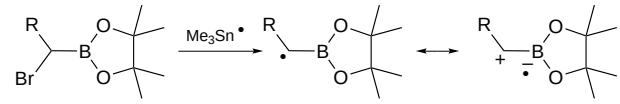
# First EPR characterisation of the structures and reactivities of α- and β-boryl radicals derived from boronic esters

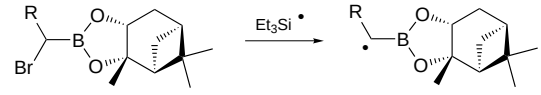
**Andrew McCarroll,[a] John C. Walton,*[a]† Roger Nziengui[b] and Bertrand Carboni*[b]‡**



[a] *University of St Andrews, School of Chemistry, St Andrews, Fife KY16 9ST, UK*
[b] *Université de Rennes I, Avenue du Général Leclerc, 35042 Rennes CEDEX, France*

**The first EPR observations of carbon-centred radicals with α- and β-boronic ester substitutents indicated moderate thermodynamic stabilisation for the former whereas the latter had an inclination towards β-scission.**

Boronic acids and esters are convenient synthetic intermediates which have been widely applied in stereocontrolled reactions.[1] Recent research has shown that α-boryl radicals, generated by addition of carbon-centred radicals to alkenyl-[2] and alkynylboronic esters,[3] can take part in inter- and intra-molecular chain addition reactions. α-Boryl radicals have also been generated by iodine abstraction from α-iodoboronic esters[4] and high yields of useful homoallylboronic esters were obtained in allylation reactions. These developments led us to apply EPR spectroscopy to identify the radical intermediates and examine key reaction rates for several types of carbon-centred radicals possessing a boronic ester functionality. Little is known about the EPR spectra of boron-containing species in solution, apart from the impressive spectroscopic experiments of Roberts and co-workers with amine–boryl and other ligated-boryl radicals,[5] a report on the $Me_2BCH_2^{\bullet}$ radical in the solid state[6] and some aminoxyl species.[7]



The α-bromoboronic esters **1a**,**b** were prepared according to the protocols developed by Matteson and co-workers from $B(OPr^i)_3$, $CH_2Br_2$ and $Bu^nLi$ for **1a**,[8] from pinacol *n*-hexyl boronate, $CH_2Br_2$ and $Pr^i_2NLi$ for **1b**.[9] EPR spectra, recorded during abstraction of the bromine atoms of these boronic esters by photochemically generated $Me_3Sn^{\bullet}$ radicals (or $Et_3Si^{\bullet}$ radicals) in *tert*-butylbenzene, cyclopropane or propane could be positively assigned to the corresponding α-boryl radicals **2a**,**b** (EPR parameters in Table 1). The hyperfine splittings (hfs) from the α-Hs are somewhat smaller than in analogous unsubstituted primary and secondary alkyl radicals [*e.g.* for $^{\bullet}CH_2CH(OEt)_2$ $a(H_\alpha)$ = 22.2 G][10] which suggests there is some electron delocalisation into the vacant boron p-orbital (**3**). This is also consistent with the comparatively large $^{11}B$ hfs.

If **3** makes a significant contribution to the ground state there should be an appreciable barrier to rotation about the $C_\alpha$–B bond. To try and detect this we examined the EPR spectra of radicals generated from the unsymmetrical boronic esters **4a**,**b** prepared by transesterification of **1a**,**b** with (+)-pinanediol.

**1** **2** **3**

**a** R = H, **b** R = n-$C_6H_{13}$

**4** **5**

**a** R = H, **b** R = n-$C_6H_{13}$

In the resulting radical **5a** the two α-Hs will be magnetically non-equivalent in the slow exchange limit. The spectrum of **5a** at 150 K [(Fig. 1(*a*)] shows hfs from $^{11}B$, the single δ-H of the pinane ring and two equivalent $H_\alpha$. Between 150 and 100 K selective line broadening occurred [Fig. 1(*b*)] due to restricted rotation about the $C_\alpha$–B bond with a coalescence temperature ($T_c$) of < 100 K. The $C_\alpha$–B torsion barrier ($E_t$) is therefore significantly greater than the analogous $C_\alpha$–$C_\beta$ barrier in alkyl radicals like $^{\bullet}CH_2CHR_2$ which show no exchange broadening.[11,12] Due to freezing of the propane solvent at lower temperatures, we were unable to determine the hfs of the non-equivalent $H_\alpha$. However, in analogous radicals $^{\bullet}CH_2$—X, (X = OH, OMe, $CHR_2$, SMe),[13–15] δ*a* is always in the range 0.5–1.5 G. Computer simulations[16] of the exchange broadened region (160–110 K) gave best fit with δ*a* = 0.6 G and led to log ($A_t$/s$^{-1}$) = 11.9, $E_t$ = 12.2 ± 3.0 kJ mol$^{-1}$. This established that alkyl radicals with α-boronic ester substituents possess a small but significant thermodynamic stabilisation and supports the contention that boron stabilises neighbouring radical centres.

Additional data on the stabilising influence of an α-boronic ester group was obtained *via* methyl boronic ester **6**. $Bu^tO$ radicals were known to displace alkyl radicals from trialkylboranes with comparative ease (homolytic substitution at boron)[17–19] and therefore a similar homolytic displacement of $Me^{\bullet}$ was expected from **6**. In fact, however, photolysis (150–160 K) of a solution of **6** and $Bu^tOOBu^t$ in cyclopropane

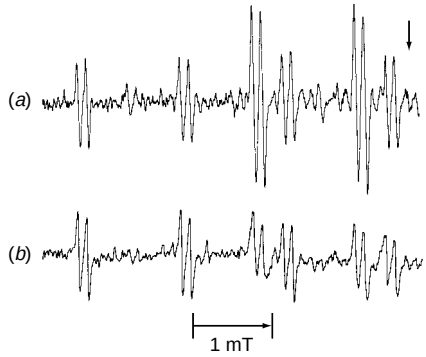

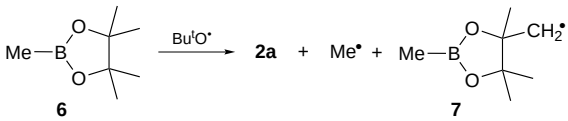

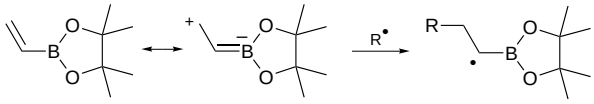

**Fig. 1** Low field halves of 9.4 GHz EPR spectra of radical **5a** in *n*-propane solution at (*a*) 150 and (*b*) 110 K. Arrow indicates spectrum centre.

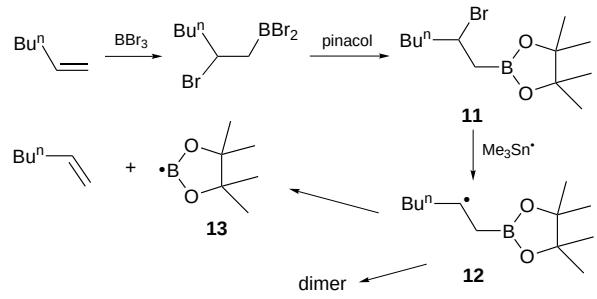
gave a spectrum containing Me•, **2a** and a primary radical [*a*(2H) = 22.7 G] which we identify as **7**. Measurements of the relative concentrations of **2a** and $CH_3$• showed that abstraction of hydrogen adjacent to boron by $Bu^tO$• was about a factor of five more rapid than displacement of $CH_3$• from boron at 160 K.

**6** **7**

Addition to vinylborane **8** by a range of free radicals including $Bu^tO$•, Ph•, $CCl_3$•, $Ph_2N$• and BnS• was examined by EPR spectroscopy. However, only the radicals $Et_3Si$• and $Me_3Sn$• added efficiently enough, under EPR conditions (200–250 K), for adduct radicals **10a**,**b** to be detected (see Table



**8** **9** **10**

**a** R = $Et_3Si$, **b** R = $Me_3Sn$

1). These observations do not conflict with reports on the production of adducts from a variety of radicals at higher temperatures, where all rates of addition will be faster, but they do suggest that nucleophilic radicals add most efficiently. This conclusion is in good accord with the idea that structures such as **9** make an appreciable contribution to the ground state.[20]

The β-bromoboronic ester **11** was prepared in good yield by bromoboration of hex-1-ene followed by esterification with pinacol. Although this reaction was reported to give mixtures of products,[21] in our hands, and under different experimental conditions, addition proceeded in good yield.§ Bromine atom abstraction from ester **11** afforded a spectrum of the β-boryl radical **12** (see Table 1) in the temperature range 180–220 K. As expected, the hfs of the β-B-atom was larger than that of an α-B-atom, due to a hyperconjugative effect. At temperatures above *ca*. 220 K the spectrum of **12** unexpectedly disappeared leaving only noise. GC–MS analysis of the photolysate at 250 K showed hex-1-ene as the major product together with minor amounts of a dimer and other unidentified components. Product analysis of a photolysis at 180 K showed the dimer to be the main product with only minor amounts of hex-1-ene. A mechanism (Scheme 1) in which dimerisation of radical **12** gives way to β-scission producing hex-1-ene and radical **13** at higher temperatures is consistent with the known facts. Boron-centred radical **13** was EPR 'silent' probably because of extensive broadening. Attempts to spin trap **13** with 2-methyl-2-nitrosopropane and *tert*-butyl hyponitrite were unsuccessful. Radical **13** might become EPR visible when ligated with a suitable donor. However, when **12** was generated in the presence of excess pyridine, no signals due to [$C_5H_5N \rightarrow$ **13**]• were obtained.

# A new type of allyl- and prop-2-ynyl-manganese species: generation and reactions with electrophiles

**Makoto Hojo, Hajime Harada, Hajime Ito and Akira Hosomi***

*Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305, Japan*

**Tetrabutylmanganese ate complex '$Bu_4MnLi_2$' reacts with allylic and prop-2-ynylic bromides to generate the corresponding allyl- and prop-2-ynyl-manganese species which further react with electrophiles such as aldehydes, ketones, epoxide and chlorosilanes to afford the corresponding allylated and prop-2-ynylated and/or allenylated products in high yields.**

Reactions of many kinds of allyl- and prop-2-ynyl-metals have been reported so far while new types of such reagents will attract much attention.[1] The creation of these new species may provide new methods for selective allylation and prop-2-ynylation. We report here reactions of a new type of allyl- and prop-2-ynyl-manganese reagent generated by the direct reduction of allyl and prop-2-ynyl bromides using manganese ate complex [eqn. (1)]. All of these reagents react with electrophiles efficiently.

Tributylmanganate '$Bu_3MnLi$' reacted with allyl bromide **1a** in THF at −78 °C, and upon addition of benzaldehyde **2a** to the mixture, the allylated product, 1-phenylbut-3-en-1-ol **3a** was obtained in 50% yield. Even if the amount of the manganate was increased to 1.5 equiv. the yield of the product **3a** was at most 66% [eqn. (1), $R^1$ = Ph, $R^2$ = H]. In sharp contrast to these facts, tetrabutylmanganate '$Bu_4MnLi_2$' showed high reactivity and the allylated product **3a** was produced in 80% yield using an equimolar amount of the reagent.† These results deserve comment. Considering this stepwise procedure, an allylmanganese reagent is possibly generated from allyl bromide by the action of the manganese ate complex as a reductant.[2] Hitherto, two methods for the generation of allylmanganese reagents, by transmetalation[3,4] and direct reduction of allyl halides with low valent manganese (Grignard-type procedure),[5] have been reported.[6]‡ The present reaction is clearly different from these reactions, in view of both the procedure and the reductant used. The substantial difference between the reducing ability of tributylmanganate and that of tetrabutylmanganate is also interesting. Tributylmanganate seems possibly to be in equilibrium between dibutylmanganese and tetrabutylmanganate. Our experiments showed that even reaction with tributylmanganate gave allylated product, but the yield of the product did not exceed 50% based on manganese. These results are likely due to the disproportionation of tributylmanganate, and the present reaction is the first example showing the peculiar reactivity of tetraalkylmanganate, although comparable relative reactivities of tetraalkylmanganates and trialkylmanganates have previously been reported.[7]§ Selected results for the allylation of carbonyl compounds are summarized in Table 1.¶ Aliphatic and aromatic aldehydes as well as ketones are allylated in high yield under mild conditions.

A characteristic feature of the reactivity of the allylmanganese reagent also emerged, as shown in eqns. (2)–(4). From chalcone **2e**, the 1,4-adduct **3e** was obtained as the major product. This is in marked contrast to previously reported reactions using low valent manganese, where only the 1,2-adduct was produced.[5,6]‖ This selectivity may possibly be due to the ate character of the allylmanganese reagent.[8] The allylation even took place with cyclohexene oxide,[9]** while with the keto ester **2g**, the keto moiety was allylated rather than the ester function.[6b]

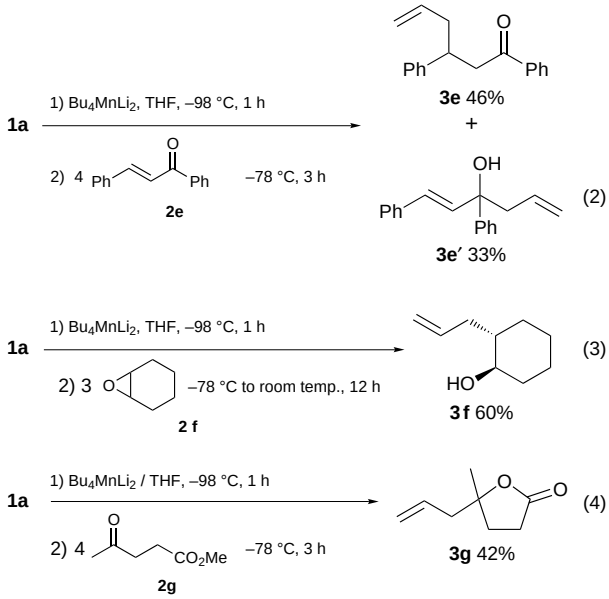
Tetrabutylmanganate also reduced prop-2-ynylic bromides [eqn. (5)]. In this case, allenic and/or prop-2-ynylic products were produced depending on the bulkiness of the electrophiles and the substituent R on the prop-2-ynyl bromides (Table 2). From prop-2-ynyl bromide **1d** (R = H), only the prop-2-ynylic adduct **3o** was obtained in quantitative yield [eqn. (6)].††

As shown here, tetrabutylmanganate reacts with allyl and prop-2-ynyl bromides to generate allyl- and prop-2-ynyl-

**Table 1** Generation of an allylmanganese reagent from allyl bromide **1a** *via* reduction with manganese ate complexes and its reaction with carbonyl compounds **2**[a]

| Manganese ate complex (equiv.) | Reduction conditions | Carbonyl compound **2** $R^1$ | $R^2$ | | Allylation conditions | Product | Yield (%)[b] |
|---|---|---|---|---|---|---|---|
| '$Bu_3MnLi$' (1.0) | −78 °C, 1 h | Ph | H | **2a** | −78 °C to room temp., 4 h | **3a** | 50 |
| '$Bu_3MnLi$' (1.5) | −78 °C, 1 h | Ph | H | **2a** | −78 °C to room temp., 4 h | **3a** | 66 |
| '$Bu_4MnLi_2$' (1.0) | −98 °C, 1 h | Ph | H | **2a** | −78 °C, 0.5 h | **3a** | 80 |
| '$Bu_4MnLi_2$' (1.0) | −98 °C, 1 h | Pr | H | **2b** | −78 °C, 3 h | **3b** | 70 |
| '$Bu_4MnLi_2$' (1.0) | −98 °C, 1 h | Ph | Me | **2c** | −98 °C to room temp., 4 h | **3c** | 76 |
| '$Bu_4MnLi_2$' (1.0) | −98 °C, 1 h | -$(CH_2)_5$- | | **2d** | −78 °C, 3 h | **3d** | 84 |

[a] Conditions: allyl bromide **1a** (0.50 mmol) was added to a mixture of manganese ate complex (0.50 mmol) in THF at the temperature shown in the column 'reduction conditions', and the mixture stirred for 1 h. An electrophile was added to the flask, and the resultant mixture was further stirred under the conditions shown in the column 'allylation conditions'. After quenching with saturated $NH_4Cl$ and extraction with $Et_2O$ (30 ml × 3), an organic layer was washed with saturated EDTA and saturated $NaHCO_3$, and the organic layer was dried over $MgSO_4$. After evaporation of solvents, the crude mixture was subjected to chromatography to give the pure product. [b] Isolated yield.



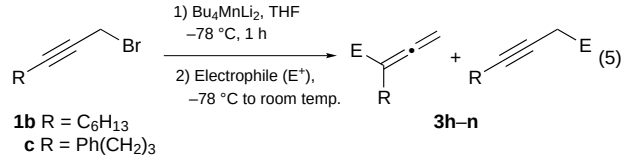


**Table 2** Generation and reaction of allenyl- and prop-2-ynyl-manganese species[a]

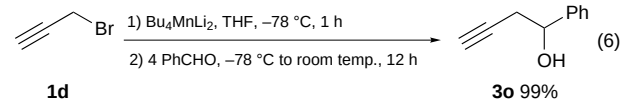

| Prop-2-ynyl bromide | Electrophile | Product | Yield (%)[b] (allenic : prop-2-ynylic) |
|---|---|---|---|
| **1b** | PhCHO **2a** | **3h** | 82 (100 : 0) |
| **1b** | EtCHO **2h** | **3i** | 75 (100 : 0) |
| **1b** | PhCOMe **2c** | **3j** | 74 (100 : 0) |
| **1b** | $Et_2CO$ **2i** | **3k** | 82 (67 : 33) |
| **1c** | $PhMe_2SiCl$ **2j** | **3l** | 80 (0 : 100) |
| **1c** | $Me_3SiCl$ **2k** | **3m** | 94 (1 : 99) |
| **1c** | $Me_2HSiCl$ **2l** | **3n** | 86 (61 : 39) |

[a] Conditions: prop-2-ynyl bromide (0.50 mmol) was added to a mixture of '$Bu_4MnLi_2$' (0.50 mmol) in THF at −78 °C, and the mixture was stirred for 1 h. An electrophile was added to the flask, at −78 °C and the temperature was allowed to rise to room temp. over > 4 h. After quenching was saturated $NH_4Cl$ and extraction with $Et_2O$ (30 ml × 3), the organic layer was washed with saturated EDTA and saturated $NaHCO_3$, and the organic layer was dried over $MgSO_4$. After evaporation of solvents, the crude mixture was subjected to chromatography to give the pure product. [b] Isolated yield.

manganese reagents where the manganate serves as a reducing agent, not as an alkylating agent. This is a new approach to allylic and prop-2-ynylic manganese reagents which react with aldehydes, ketones, oxirane and chlorosilanes to give the corresponding allylated and prop-2-ynylic and/or allenic products. Further study on the generation and reaction of these reagents is now under investigation.

## Footnotes and References

* E-mail: hosomi@staff.chem.tsukuba.ac.jp

† The formulae '$Bu_3MnLi$' and '$Bu_4MnLi_2$' and the terms 'tributylmanganate' and 'tetrabutylmanganate' are used tentatively, since the precise structures of the species are not clear at present.

‡ Barbier-type allylations with metallic manganese were also reported (ref. 6).

§ It is known that the reactions of tetraalkylmanganates with acyl chlorides to produce ketones proceed at lower temperature, compared to the reactions of trialkylmanganates, while the yields in these reactions are equally good [ref. 7(*a*)].

¶ A solution of BuLi in hexane (1.6 M; 1.25 ml, 2.0 mmol) was added at −20 °C to a suspension of manganese(II) chloride in THF (63 mg, 0.50 mmol in 5 ml) and the mixture was stirred at −40 to −20 °C for 30 min. Allyl or prop-2-ynyl bromide (0.50 mmol) was added at −98 or −78 °C (at the specified temperature), and the mixture was stirred for 1 h. An electrophile (1.5–2.5 mmol) was added to the mixture, which was further stirred under the conditions shown. After quenching with saturated $NH_4Cl$ and extraction with $Et_2O$ (30 ml × 3), the organic layer was washed with saturated ethylenediaminetetraacetic acid (EDTA) and saturated $NaHCO_3$. The organic layer was dried over $MgSO_4$. After evaporation of solvents, the crude mixture was subjected to chromatography to give the pure product.

‖ The selective 1,4-addition to ethylidenemalonate, which is a good acceptor for the 1,4-addition [*cf.* refs. 3(*c*), 5, 6 and 8], using allylmanganese chloride was also reported [ref. 3(*c*)].

** It was reported that alkylmanganese chloride reacted with oxiranes in the presence of a copper chloride catalyst (ref. 9).

†† This is to the best of our knowledge, the first case of the generation and reaction of prop-2-ynylic manganese reagents.

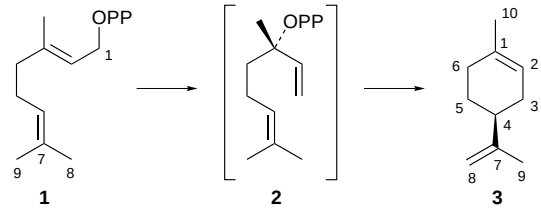
# Stereochemistry of the methyl→methylene elimination in the enzyme-catalysed cyclization of geranyl diphosphate to (4*S*)-limonene

**Robert M. Coates,*[a] Charles S. Elmore,[a] Rodney B. Croteau,[b] David C. Williams,[b] Hiromi Morimoto[c] and Philip G. Williams[c]**

[a] *Department of Chemistry, University of Illinois, 600 S. Mathews Avenue, Urbana, IL 61801, USA*
[b] *Institute of Biological Chemistry, Washington State University, Pullman, WA 99164-6340, USA*
[c] *National Tritium Labelling Facility, E.O. Lawrence Berkeley National Laboratory, One Cyclotron Road, Berkeley, CA 94720, USA*

**The cyclization of (*R*)-[9-$^2H_1$,$^3H_1$]geranyl diphosphate catalysed by a recombinant form of (4*S*)-limonene synthase from spearmint leaf (*Mentha spicata*) is terminated predominantly by *re*-facial, *anti* proton elimination at the *cis* methyl group, producing (4*S*, 8*E*)-[8-$^2H_1$,$^3H_1$]limonene.**

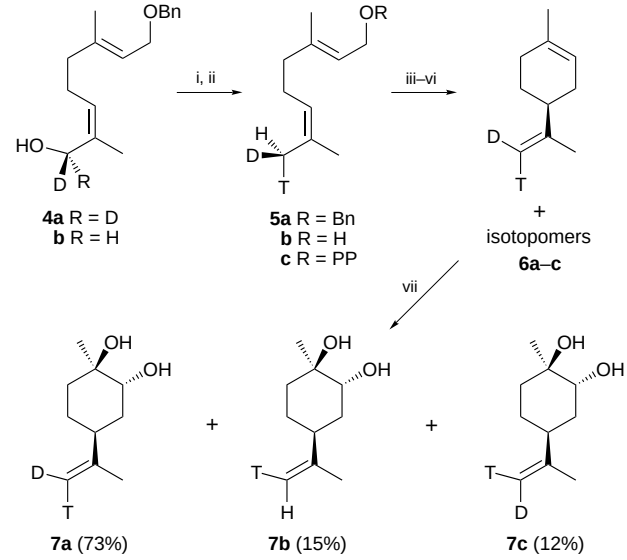
(4*S*)-Limonene synthase from *Mentha* species catalyses the coupled isomerization–cyclization of geranyl diphosphate **1** (GPP) to (4*S*)-limonene **3** by way of the enzyme-bound intermediate, (3*S*)-linalyl diphosphate **2** (LPP) (Scheme 1).[1] (4*R*)-Limonene synthase in *Citrus* species is responsible for producing the enantiomeric component of peel oil.[2] (4*S*)-Limonene synthase has been purified from both peppermint (*M. piperita*) and spearmint (*M. spicata*) and characterized.[3]



The mechanism of action and structural features of both (4*S*)- and (4*R*)-limonene synthases have been investigated using enzymes from *Mentha*, *Citrus* and other plant species.[4–6] The reaction leading to (4*S*)-limonene proceeds *via* stepwise, suprafacial isomerization of **1** to **2** followed by *anti*, *endo* $S_N'$ cyclization with overall retention of configuration at C(1)[4] and terminating proton transfer from the *cis* methyl group [C(9)].[4,5] Here we report evidence that establishes the stereochemistry of the final $CH_3 \rightarrow CH_2$ elimination.

A protein-based cloning strategy was employed to isolate a cDNA encoding (4*S*)-limonene synthase from a spearmint leaf cDNA library.[7] The 1800 nucleotide open-reading frame translates a 500 amino acid protein bearing a putative plastidial targeting peptide. The cDNA isolate was functionally expressed in *E. coli* to give catalytically active protein that affords (*S*)-limonene and its minor co-products [2% each of myrcene, (−)-α-pinene and (−)-β-pinene]. The recent development of a high level heterologous expression system[8] provided sufficient quantities of the crude recombinant protein for product analyses by $^3H$ NMR spectroscopy.

Substrate bearing a chiral methyl group of (*R*) configuration at the *cis* C(9) position (**5c**) was synthesized as outlined in Scheme 2. Z-Selective condensation of (*E*)-6-benzyloxy-4-methylhex-4-enal with ethyl 2-(diethoxyphosphoryl)propionate followed by $AlD_3$ reduction afforded dideuterio alcohol **4a**. Catalytic ruthenate oxidation and asymmetric reduction of the labile *Z*-aldehyde with (*S*)-Alpine-Borane[9] provided **4b**, the expected *R* configuration and enantiomeric purity (≥97%) of which were confirmed by $^1H$ NMR analysis of its (1′*S*)-camphanate derivative.[10]† Evidence that the methanesulfonate (MsO) of **4b** undergoes nucleophilic substitution with inversion was obtained by its conversion to the *S* enantiomer of **4b** (≥97% *S*) with $Bu_4NOAc$ in $Et_2O$ followed by $LiAlH_4$ cleavage and $^1H$ NMR analysis of the (1′*S*)-camphanate.



Reduction of **4b**–OMs with $LiBEt_3T$[11] (THF, 0 °C) was assumed to proceed with inversion, creating an *R* chiral methyl group in **5a** (1.0 Ci, *ca*. 6.7 Ci mmol$^{-1}$). Conversion to (*R*)-[9-$^2H_1$,$^3H_1$]GPP **5c** (23 mCi, 66%) was accomplished by literature procedures[12] adapted for radiochemical operations. The radiochemical purity of (*R*)-[9-$^2H_1$,$^3H_1$]geraniol **5b** (114 m Ci, 88%) was established by radio TLC, $^3H$ NMR spectroscopy and isotopic dilution analysis as the 3,5-dinitrobenzoate derivative.†

Incubation of **5c** with the crude recombinant (*S*)-limonene synthase[8]‡ afforded, after dilution with 1 mg of cold carrier and filtration over silica gel, [8-$^2H$,$^3H$]limonenes **6a**–**c**, (4.1 m Ci, 21%). Regioselective epoxidation followed by acid-catalysed hydrolysis and chromatographic purification gave [8-$^2H$,$^3H$]-menth-7-ene-1,2-diols **7a**–**7c** (1.0 m Ci, 24%), judged to be of high radiochemical purity by radio TLC and dilution analysis. Assignments of the isopropenyl vinyl proton signals at $\delta$ 4.81 and 4.77 in the 500 MHz $^1H$ NMR spectrum ($C_6D_6$) of unlabelled diol to $H_Z$ and $H_E$, respectively, were secured by

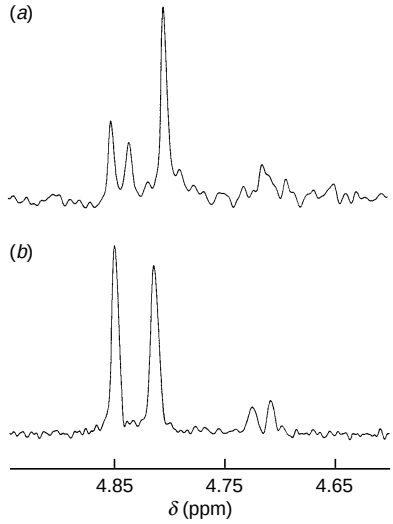

**Fig. 1** (*a*) Vinyl proton region of the 640 MHz $^3H\{^1H\}$ NMR spectrum of [8-$^3$H]menth-7-ene-1,2-diols (**7b**, **7c** and **7a**) in $C_6D_6$. (*b*) The same region of the 600 MHz $^1$H NMR spectrum of the unlabelled carrier diol for comparison. A slight impurity appears in the $^1$H NMR spectrum at $\delta$ 4.71 and 4.73.†

NOE measurements. The magnitude of the intramolecular primary kinetic isotope effect for the $CH_3 \rightarrow CH_2$ elimination ($k_H/k_D$ = 4.6 ± 0.5) was independently determined by GC–MS analysis of [8-$^2$H]limonene biosynthesized similarly using [9-$^2H_2$]-**1** as substrate.

The 640 MHz $^3$H NMR spectrum (Fig. 1) of [8-$^2$H,$^3$H]diols **7a**–**c** ($C_6D_6$) shows peaks at $\delta_T$ 4.849 (0.15 T), 4.833 (0.12 T), and 4.802 (0.73 T).† The most intense peak is assigned to the doubly labelled species **7a** generated by kinetically favored proton elimination. The signal at $\delta_T$ 4.849 is ascribed to the singly labelled species **7b** arising from deuteron elimination since its downfield position relative to **7a** ($\Delta\delta_T$ = +0.047) corresponds to the chemical shift difference between the vinyl protons ($\Delta\delta_H = \delta_{H_Z} - \delta_{H_E}$ = +0.037) plus a typical upfield deuterium isotope shift for **7a** of ($\Delta\delta_T$ = − 0.10).[13] The ratio of integrals (0.73/0.15 = 4.9) for the high and low field peaks is consistent with the primary deuterium isotope effect. The small centre peak is attributed to the minor doubly labelled form **7c** (isotope shift $\Delta\delta$ − 0.016 ppm from $\delta^{H_E}$ 4.849).

The results establish that the major doubly labelled product **6a** has arisen by proton elimination from the *R* chiral methyl group *anti* to the C(3)–C(4) bond formed in the cyclization step (Scheme 3). It is unclear whether the minor doubly labelled product **6c** is formed by competing *syn* elimination from **5c** or by *anti* elimination from a contaminant of the *S* chiral methyl enantiomer. The predominant *anti* $S_E'$ stereochemistry of this cyclization–elimination sequence is the same as that observed for the bridging cyclization–elimination in the formation of (+)- and (−)-α-pinene catalysed by pinene cyclases I and II from sage.[14] A plausible explanation for the *anti* elimination producing limonene is the preservation of a through-space bonding interaction between C(4) and C(7) of the presumed (*S*)-terpinyl ion intermediate required for cyclization to the pinenes.

The identity and radiochemical purity of all [$^3$H] compounds were verified by radio TLC analyses and comparisons with the unlabelled substance. All compounds were characterized by $^1$H and/or $^3$H NMR spectroscopy and other appropriate data.†

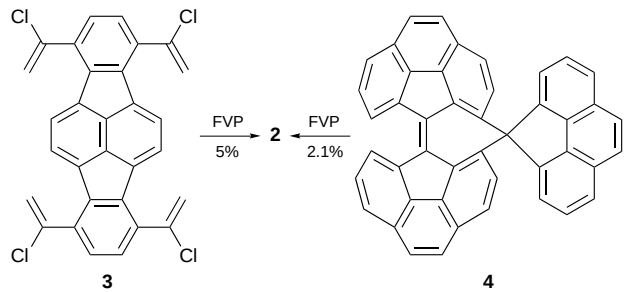
# Buckybowls: a simple, conceptually new synthesis of $C_{2v}$-semibuckminsterfullerene ($C_{30}H_{12}$, [5,5]-fulvalene circulene)

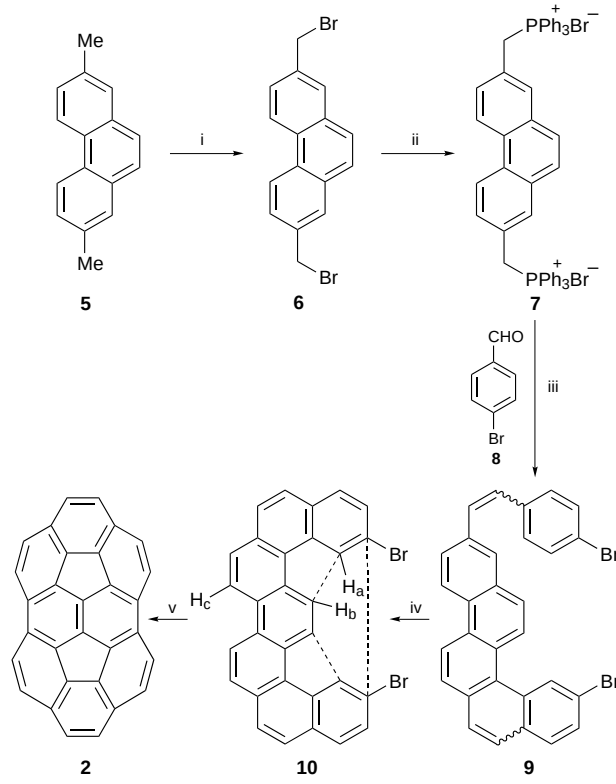
**Goverdhan Mehta* and Gautam Panda**



*Molecular design and synthesis laboratory of JNCASR, School of Chemistry, University of Hyderabad, Hyderabad 500 046, India*

**An extremely simple synthesis of decacyclic, $C_{30}H_{12}$ 'buckybowl' 2 from *m*-xylene, employing a strategy of wider applicability for the synthesis of diverse curved aromatic surfaces, is described.**

The onset of the fullerene era, following the discovery of buckminsterfullerene **1**, has generated a great deal of interest in the synthesis and chemistry of 'bowl-shaped' polycyclic aromatic hydrocarbons (PAHs), particularly those representing a dominant motif on the fullerene surface.[1] Such PAHs, with curved surfaces, can be expected to exhibit novel physicochemical characteristics and mimic some of the properties of fullerenes. Since buckybowls have never been encountered during the graphite vapourization processes, the only way to access them is through logically orchestrated synthetic methodologies. Efforts in this direction have been mounted in several laboratories during the past few years[1] and among the notable successes is the synthesis of $C_{2v}$-semibuckminsterfullerene **2**,[2] representing half the carbon content of **1** and endowed with substantial curvature (calculated bowl depth 2.7 Å).[2a]



Rabideau *et al.*[2a] were the first to report the synthesis of **2** *via* flash vacuum pyrolysis (FVP) of **3**, following a variant of the Scott's seminal synthesis of corannulene (Scheme 1).[3] Very recently, in 1997, the groups of Scott and Zimmermann accomplished[2b] a synthesis of **2** *via* FVP of **4**, a compound obtained serendipitously from cyclopenta[*def*]phenanthrene. We now report a new synthesis of **2** which is conceptually different from the earlier efforts and notable for its simplicity and brevity.[4]

**Scheme 1**

Readily available 2,7-dimethylphenanthrene **5**[5] was transformed to the bis-ylide precursor **7** *via* the bis(2,7-bromomethyl)phenanthrene **6** (Scheme 2). Two-fold Wittig coupling between the ylide derived from **7** and *p*-bromobenzaldehyde **8** furnished **9** as a mixture of *E*- and *Z*-isomers. On irradiation, **9** underwent facile two-fold oxidative photocyclization with high regioselectivity to furnish the desired **10** as the only characterizable product. The symmetry of **10** and its structure followed from its characteristic $^1$H NMR spectrum [bay-region protons: $\delta$ 9.41 (s, $H_a$), 9.02 (s, $H_b$), 8.93 (d, $J$ 9 Hz, $H_c$)] and 15 line $^{13}$C NMR spectrum [$\delta$ 132.0, 131.4, 131.3, 130.6, 130.0(2C), 129.3, 128.1, 127.2(2C), 127.0(2C), 125.7, 122.7, 120.6]. We had planned to effect in tandem, three-fold cyclization in **10** (see dotted lines) as the pivotal step and for that purpose strategically positioned the two bromine atoms as promoters of such a process.[2b] To our great delight, we found that **10** on FVP furnished **2**, which was isolated from the pyrolysate through

**Scheme 2** *Reagents and conditions*: i, NBS, $CCl_4$, heat, 4 h, 80%; ii, $PPh_3$, benzene, room temp., 2–3 days, 79%; iii, $K_2CO_3$, THF, 18-crown-6, 10 h, 40%; iv, *hv* (450 W), Pyrex, benzene, 2 h, 60%; v, FVP, 1150 °C, 0.5 mm, $N_2$, 2–3%

extensive chromatography (alumina) and characterized through its mass spectrum [*m*/*z* 372 ($M^+$)] and diagnostic three line $^1$H NMR spectrum [$\delta$ 7.92 (d, *J* 9 Hz, 4 H), 7.55 (d, *J* 9 Hz, 4 H), 7.42 (s, 4 H)] which was found to be identical with the reported values.[2] Admittedly, the yield (2–3%) of **2** in the FVP step is low and as yet unoptimised, but it compares well with the earlier reports (2.1 and 5% in FVP).[2]

Our approach to **2** from dimethylphenanthrene **5** involves the following sequence: NBS bromination–Wittig olefination–photocyclization and pyrolysis. Interestingly, the phenanthrene precursor **5** itself is assembled from *m*-xylene through the same sequence involving NBS bromination–Wittig olefination–photocyclization.[5] Thus, in an overall sense, through an iterative three step sequence and a final pyrolysis step, *m*-xylene is elaborated into the decacyclic, $C_{30}H_{12}$, aromatic 'bowl' **2**. We believe that the simple strategy outlined here can be adapted towards the synthesis of several bowl-like non-planar PAHs. Efforts along these lines are currently underway.

We thank CSIR for the research support and a fellowship to G. P. We also appreciate the help of Mr Anirban Banerjee in performing some important preliminary experiments. We also thank Professor L. T. Scott and Dr S. Hagen, Boston College, USA, for sending the $^1$H NMR spectrum of [5,5]-circulene for comparison.

**The propargylic carbonates (*S*)-6 and (*R*)-9 are converted into the chiral allenes 10, 11, 13 and 14 (ee 82–85%) using organozinc reagents and tetrakis(triphenylphosphine)-palladium as catalyst.**

The importance of allenes is well-established and the variety of chemical reactions that they undergo is documented.[1] Recently, methods have been reported for the construction of allenes of the type $R^1CH{=}C{=}CHR^2$, in optically active form.[2]

In this paper, we report the enzymatic resolution of secondary[3] and the classical resolution of tertiary propargylic alcohols, their conversion into chiral allenes of the type $R^1R^2C{=}C{=}CR^3R^4$ *via* the corresponding carbonates[4] and their activation with palladium catalysts[5] in the presence of a zinc derivative.[6]

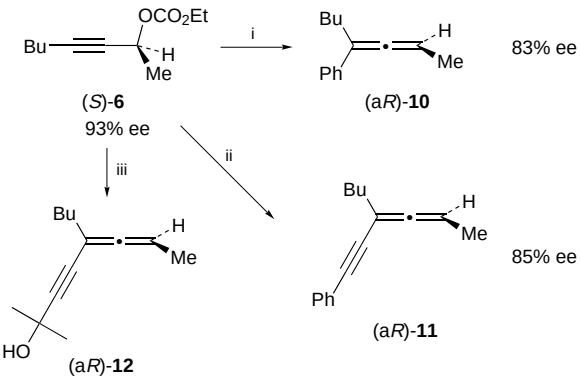
The optically active compounds required as starting materials for this study were obtained by a variety of methods. The alcohols **1** and **2** were prepared in high enantiomeric purity using enzymatic resolution methods (Table 1), while the alcohol (*R*)-**3** (99% ee) was obtained from the racemate by fractional crystallisation of the brucine salt from acetone.[7] Treatment of alcohol (*R*)-**3** with bromobenzene, piperidine and a catalytic amount of tetrakis(triphenylphosphine)palladium(0) in DMF at 80 °C furnished the alcohol (*S*)-**4** (86%).[8] Finally, the alcohol (*S*)-**5** (99% ee) was prepared by enzyme-catalysed acetylation of racemic material (Table 1),[9] while the alcohol (*R*)-**5** (92% ee) was prepared from 1-phenyl-3-(trimethylsilyl)prop-2-ynone by selective reduction using dipinanylborane,[10] followed by desilylation with potassium carbonate in methanol.

The alcohol (*S*)-**1** was converted quantitatively into the corresponding carbonate (*S*)-**6** using ethyl chloroformate in pyridine, in the presence of a catalytic amount of 4-*N*,*N*-dimethylaminopyridine (DMAP). Alcohols (*S*)-**2** and (*R*)-**5** afforded the carbonates (*S*)-**7** and (*R*)-**9** after similar treatment, while the alcohol (*S*)-**4** furnished the carbonate (*S*)-**8** (97%) on treatment with butyllithium for one hour followed by treatment with methyl chloroformate at low temperature.

The carbonate (*S*)-**6** was treated with phenylzinc bromide† and a catalytic amount of tetrakis(triphenylphosphine)palladium (TTPP) in THF to provide the (a*R*)-allene **10** in 84% yield and 83% ee (Scheme 1). This reaction is very similar to one

**Table 1** Resolution of alcohols **1**, **2** and **5** using *Pseudomonas amano* sp. AK and *Candida antarctica* lipases[a]

| Substrate | Enzyme | *t*/h | Alcohol Yield (%) (ee) (%) configuration | Ester Yield (%) (ee) (%) configuration |
|---|---|---|---|---|
| **1** | *P. amano* | 4 | 41 (93) *S* | 41 (97) *R* |
| **1** | *C. antarctica* | 2 | 39 (99) *S* | 42 (94) *R* |
| **2** | *P. amano* | 3 | 45 (86) *S* | 42 (99) *R* |
| **5** | *C. antarctica* | 3.5 | 46 (99) *S* | 50 (98) *R* |



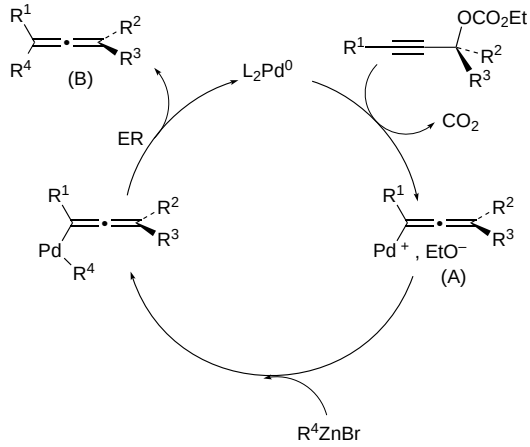
[a] The substrate, enzyme and vinyl acetate were reacted for the specified time in hexane.

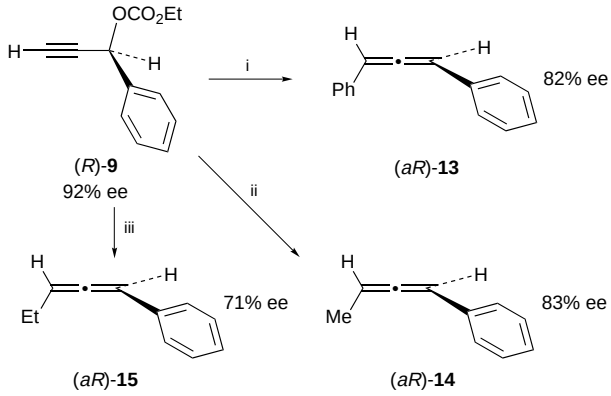
**1** $R^1$ = Bu; $R^2$ = H; $R^3$ = Me; $R^4$ = Et **6**
**2** $R^1$ = Ph; $R^2$ = H; $R^3$ = Me; $R^4$ = Et **7**
**3** $R^1$ = H; $R^2$ = $Bu^t$; $R^3$ = Ph
**4** $R^1$ = $R^3$ = Ph; $R^2$ = $Bu^t$; $R^4$ = Me **8**
**5** $R^1$ = $R^2$ = H; $R^3$ = Ph; $R^4$ = Et **9**

performed by Vermeer *et al.*[6] The Dutch group reported a lower degree of stereocontrol, but these earlier studies were hampered by having a starting material of low optical purity (28% ee) and by having an uncertain amount of biphenyl in the product allene. Similarly, reaction of (*S*)-**6** with phenylacetylene in the presence of diisopropylamine, zinc chloride and catalytic amounts of copper(I) iodide and TTPP furnished the trisubstituted (a*R*)-allene **11** in 63% yield and 85% ee. The enantiomeric excesses of the products **10** and **11** were assessed by $^1$H NMR spectroscopy using a mixture of a silver salt and a chiral ytterbium salt (ratio 1 : 1) as recommended previously.[11] The enantiomeric purity of the starting material and products suggests a high degree of control in the transfer from point to axial chirality. While the enantiomeric excess of the (a*R*)-dienynol **12**, obtained from the carbonate (*S*)-**6** and 2-methylbut-3-yn-2-ol, could not be assessed by physical methods, a high degree of stereocontrol in the reaction could be anticipated.

The absolute configuration of the allenes **10**–**12** has not been established conclusively but is assumed on the basis of the established mechanism of the reaction (Fig. 1). The palladium(0) is expected to activate the chiral carbonate by nucleophilic attack antiperiplanar to the leaving group, forming the chiral allenylpalladium intermediate (A). A cross-coupling on the intermediate (A) affords the chiral allene (B), regenerating the palladium(0) catalyst.

**Scheme 1** *Reagents and conditions*: i, PhZnBr–Pd($PPh_3$)$_4$, THF–$Et_2O$, 84%; ii, CuI–$ZnCl_2$–$Pr^i_2NH$–Pd($PPh_3$)$_4$–THF–PhC≡CH, 63%; iii, CuI–$ZnCl_2$–$Pr^i_2NH$–Pd($PPh_3$)$_4$–THF–$Me_2C(OH)C{\equiv}CH$, 59%





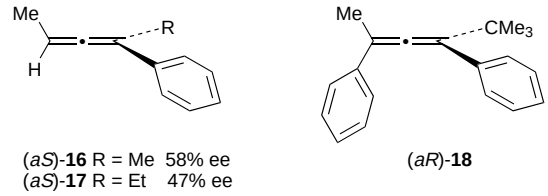


**Fig. 1** Mechanism

**Scheme 2** *Reagents and conditions*: i, $PhZnBr–Pd(PPh_3)_4–THF–Et_2O$, 65%; ii, $Me_2Zn–KBr–Pd(PPh_3)_4–THF$, 40%; iii, $EtZnBr–Pd(PPH_3)_4–THF–Et_2O$, 67%

In agreement with this proposal, the carbonate (*R*)-**9** (92% ee) reacts with phenylzinc bromide† in the presence of TTPP (Scheme 2) to furnish the (a*R*)-diphenylallene **13** (82% ee) {$[\alpha]_D^{22}$ −932 (*c* 1.0, $CHCl_3$); lit.[12] $[\alpha]_D$ +1137 ($CHCl_3$), for the (a*S*) enantiomer}. This carbonate (*R*)-**9** also reacts with dimethylzinc–potassium bromide or ethylzinc bromide in the presence of TTPP to give allenes **14** and **15** in 83 and 71% ee respectively (Scheme 2), as confirmed by $^1$H NMR spectroscopy (Yb/Ag salts).

Incorporation of a phenyl group at the alkyne terminus, such as in compound (*S*)-**7**, leads to a poorer transfer of chirality on reaction with dimethylzinc–TTPP or diethylzinc–TTPP as shown with the allenes **16** and **17** being formed in 58 and 47% ee respectively. Thus, while the carbonate (*R*)-**8** reacts smoothly with dimethylzinc and TTPP in the presence of potassium bromide to give the allene **18** in 78% yield, the optical rotation of the product, $[\alpha]_D$ −250 (*c* 0.96, $CHCl_3$), may reflect only a moderate enantiomeric excess. (The optical purity of this tetrasubstituted allene could not be established by $^1$H NMR spectroscopy using the silver–ytterbium chiral shift reagent.)

In summary, the preparation of highly substituted allenes of good to excellent optical purity can be accomplished by transformations involving secondary and tertiary propargylic carbonates.

We thank the CROUS de Rennes for support (to T. G.).

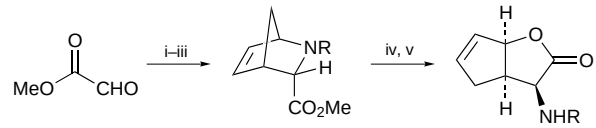
**The carbocyclic analogue 11 of nikkomycin C 1 is prepared by a sequence involving allylic rearrangement of the imino ester adduct 3, palladium-mediated substitution of the allylic lactone 4c with uracil bis(trimethylsilyl)ether 6, and osmylation of the double bond.**

The imino Diels–Alder reaction is a versatile tool for the preparation of a variety of natural products.[1–4] As part of a programme to investigate the synthesis of amino acid derivatives, we were interested in elaboration of the azabicyclo-[2.2.1]heptene skeleton *via* acid catalysed rearrangement.[5] We have investigated the scope of these rearrangements, and the palladium catalysed allylic substitutions of the resulting lactones, to prepare cyclopentene amino acid derivatives. The methodology has been exemplified in the synthesis of a carbocyclic nikkomycin analogue.[6,7]



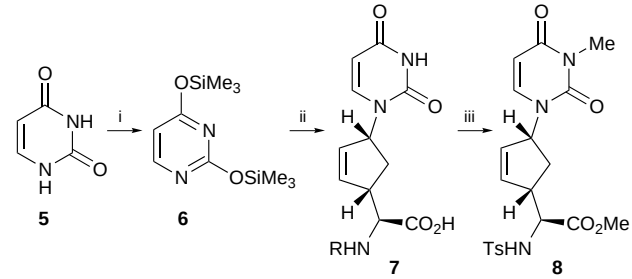
**1**

The nikkomycins and polyoxins are a family of nucleoside-type antibiotics which exhibit a broad spectrum of biological activity.[8–12] Carbocyclic nucleosides display comparable biological activity to the natural furanose materials, whilst maintaining an inherent stability towards β-glycosidase hydrolysis *in vivo*.[13–15] Our synthesis of a carbocyclic nikkomycin analogue **11** using bicyclic lactones illustrates a general approach to carbocyclic nucleosides.

The required lactone **4** was synthesised from the imino Diels–Alder adduct **3**. The stereochemistry of the amino acid side chain of nikkomycin necessitated use of the *endo* cycloadduct. The *endo* adducts are inherently more difficult to prepare than their *exo* diastereoisomers, since the imines required for the Diels–Alder reactions with unactivated dienes need to be activated by the presence of electron withdrawing groups on the nitrogen terminus. These electron withdrawing groups then appear to exert a greater requirement to adopt the *endo* conformation in the transition state and so give rise to the *exo* adducts. The solution to this problem is to use iminium salts as dienophiles[5] and to effect a resolution to produce enantiomerically pure material.

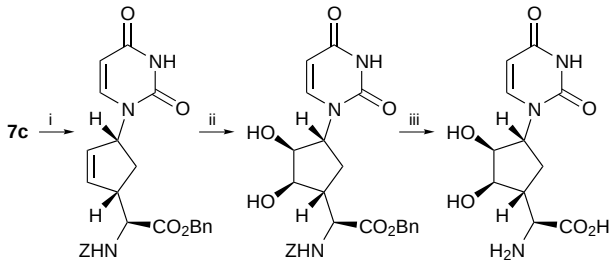
Cycloaddition of the iminium ion derived from methyl glyoxylate[16] to cyclopentadiene gave the azabicyclo-[2.2.1]heptene **3** (R = H) (Scheme 1). Derivatisation of the nitrogen with an electron withdrawing group [*e.g.* Ts, Bz, BnOCO (Z)] enables the acid-catalysed allylic rearrangement to occur. This is effected in good yield by treatment of the derived carboxylic acids with trifluoroacetic acid to give the lactones **4a**–**c**.

Treatment of the lactones with a variety of palladium(0) reagents effected efficient conversion into the π-allyl palladium complexes. Initial attempts to couple uracil as its sodium salt



**2** **3** **4a** R = Ts **b** R = Bz **c** R = Z

**Scheme 1** i, $NH_4Cl$ (aq.); ii, cyclopentadiene; iii, *N*-derivatisation (see text) (70–82% overall); iv, LiOH, $H_2O$–THF; v, trifluoroacetic acid, $CH_2Cl_2$ (80–85% overall)



using a palladium-catalysed π-allyl substitution reaction proved fruitless.[17] More positive results were achieved using uracil bis(trimethylsilyl)ether† following the report of Benneche and co-workers for the preparation of a thymidine-substituted cyclopentene (Scheme 2).[18] Treatment of the *N*-tosyl lactone **4a** with tetrakis(triphenylphosphine)palladium(0) in the presence of DIPHOS at 25 °C in acetonitrile gave rise to a moderate yield (31%) of the required substitution product **7** (R = Ts). Somewhat unexpectedly, treatment of this product with (trimethylsilyl) diazomethane[21] gave the dimethylated derivative **8**, where the uracil nitrogen had also been methylated.[22] The uracil substitution reactions can be considerably improved by the use of chlorotrimethylsilane to promote formation of the π-allyl palladium intermediate.[7] It is thought that the function of the chlorotrimethylsilane is to trap the carboxylate species produced during formation of the π-allyl complex, and thus favour this in the equilibrium with the starting lactone. Repetition of the uracil substitution reaction under these conditions with the *N*-benzyloxycarbonyl derivative **4c** afforded the analogous cyclopentene **7c**. Benzylation of **7c** gave the ester **9** from which the protecting groups were later cleaved by hydrogenolysis (Scheme **3**). Dihydroxylation of the alkene **9** afforded an approximately 2 : 1 mixture of the diol **10** and its all-*cis* diastereoisomer. The poor selectivity of cyclopentene dihydroxylations can be rationalised on steric[23] or electronic[24] grounds.[7] Finally, hydrogenolysis of the benzyl protecting groups gave the required target molecule **11** in good yield.‡

In summary, this route has therefore demonstrated a rapid assembly of the nikkomycin skeleton and has further demonstrated the synthetic versatility of cycloadducts of imino Diels–Alder reactions.

† Preparation of the bis(trimethylsilyl)uracil **6** using Vorbrüggen[19] or Cossy[20] methodology was, in our hands, difficult to reproduce consistently. Development of the Benneche protocol using refluxing hexamethyldisilazane with a catalytic quantity of ammonium sulfate gave reproducibly good results, provided the reflux time was prolonged to 3–4 h.

‡ All new compounds exhibited spectroscopic and combustion analysis (or high resolution mass spectrometry) properties in accordance with the assigned structures.

# Synthetic carbohydrate-based vaccines: synthesis of an L-*glycero*-D-*manno*-heptose antigen–T-epitope–lipopeptide conjugate

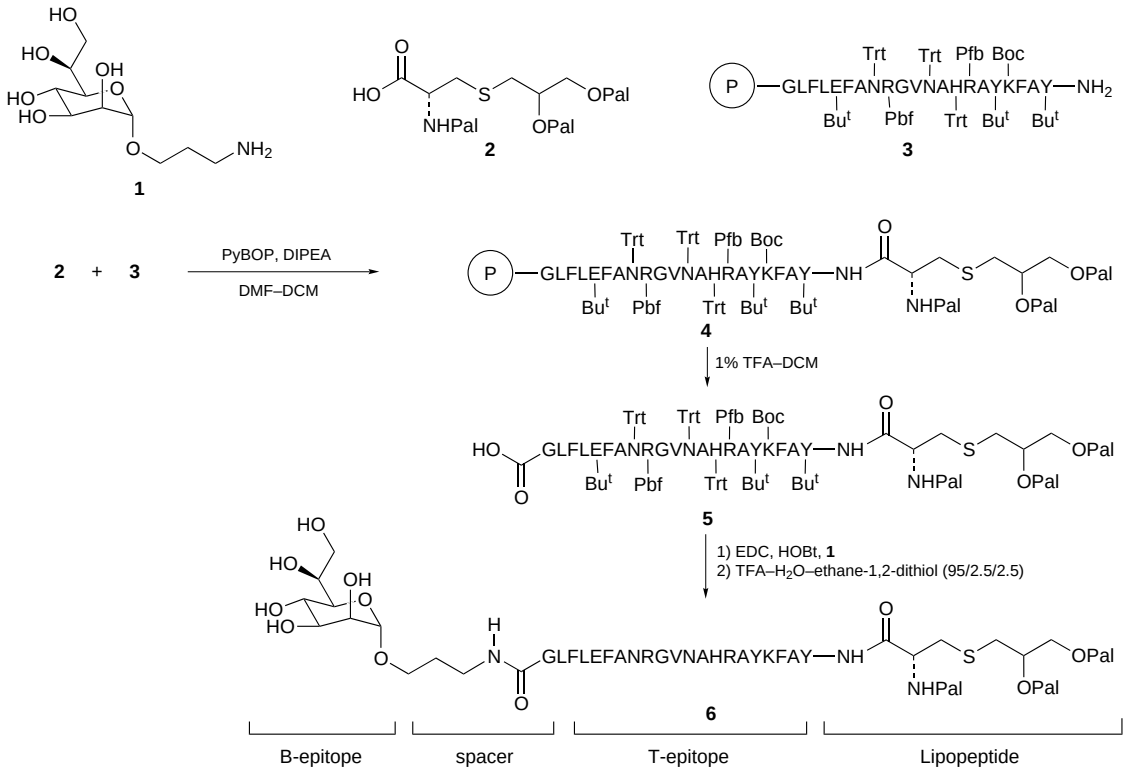
**Frank Reichel, Peter R. Ashton and Geert-Jan Boons***

*School of Chemistry, The University of Birmingham, Edgbaston, Birmingham, UK B15 2TT*

**A facile and highly efficient synthesis of a glycopeptidolipid containing a heptose sugar, a synthetic T-epitope and a synthetic immunoadjuvant is presented which represents an important step towards the development of a fully synthetic vaccine against *Neisseria meningitidis*.**

*Neisseria meningitidis* can cause a severe form of meningitis and bacteriamia and is the only bacterium that is capable of generating epidemics of meningitis.[1] Although it is more than a century since meningococcus was discovered, no vaccine has been developed that matches requirements such as safety, long-lasting immunity to all age groups and cross-protection against meningococcal serotypes and sub-serotypes.

Saccharides representing partial structures of the inner-core oligosaccharide of meningococcal lipopolysaccharides (LPS) have been synthesised.[2] These structures were equipped with an artificial spacer which enabled controlled conjugation to tetanus toxoid (TT). The conjugates were used to immunise mice and evoked an L-2 or L-3,7,9 specific immune response.[3] Thus, small synthetic saccharides derived from meningococcal LPS functioned as effective B-epitopes. Furthermore, tetanus toxoid acted as a carrier protein as well as a source of T-epitopes to give immunological memory.



The use of TT as a carrier protein is problematic in several respects. For example, the antibody response to a haptan which is coupled to a carrier protein can be ineffective when vaccines have previously been immunised with the carrier protein.[4] Furthermore, heterologous memory T-cells (for example induced with TT conjugates) may not be reactivated during infection. Therefore, incorporation of homogeneous (*i.e.* meningococcal-derived) T-cell epitopes into a vaccine will be advantageous as the memory response will be more effective.[5] In addition, the advantages of the use of synthetic peptides derived from immunodominant T-cell epitopes compared to bacterial protein carriers are obvious: the immune response is directed selectively towards effective determinants, whereas sequences homologous to human self-protein can be excluded from the vaccine. The feasibility of the use of synthetic T-epitopes as vaccine components has recently been shown[6] by a conjugate composed of a *Heamophilus influenzae* capsular polysaccharide and functional T-helper cell peptide epitope, that elicited protective levels of antibodies in rabbits.

We report here a synthetic methodology that makes it possible to construct fully synthetic glycopeptidolipids that contain a carbohydrate-based B-epitope, a peptide T-epitope and a lipopeptide. Such a conjugate constitutes the minimal structural features required for an effective immunological response. We have synthesised a compound (**6**) that contains a L-*glycero*-D-*manno*-heptose sugar that will act as a B-epitope, the peptide sequence YAFKYARHANVGRNAFELFL that has been identified as a MHC class II restricted site for human T-cells and is derived from an outer-membrane protein of *N. meningitidis*[7] and the lipopetide *S*-[(*R*/*S*)-2,3-dipalmitoyloxypropyl]-*N*-palmitoyl-(*R*)-cysteine ($Pam_3Cys$). The lipopeptide $Pam_3Cys$ is a highly potent B-cell and macrophage activator derived from the immunologically active N-terminal sequence of the principal lipoprotein of *Escherichia coli*[8] and has been used in synthetic peptide-based vaccine and cancer vaccine development.[9] The lipid moiety will also serve as a membrane anchor in the lipid layer of cell membranes which will ensure efficient and long-term delivery of the antigen.

The synthesis of the complex target compound **6** requires a highly convergent strategy and the synthetic methods selected should be compatible with the requirements of carbohydrate, peptide and lipid chemistry. It was envisaged that the artificial spacer containing saccharide building block **1**, the lipopeptide **2** and solid supported peptide **3** would be suitable starting materials. As can be seen in Scheme 1, they will be coupled by well-established amide-bond forming reactions. Thus, the carboxylic acid of the glycolipid **2** will be coupled to the amino terminus of a peptide (**3**) that has been assembled on a solid support. Next, cleavage of the lipopeptide from the solid support followed by coupling of the released C-terminus to the amino containing spacer of saccharide **1** will afford a fully protected conjugate. An additional glycine residue has been incorporated at the C-terminus of the peptide to avoid epimerisation during the latter coupling step. The proposed assembly and deprotection requires only four synthetic steps and extensive purification procedures are avoided since most of the reactions have been performed on a solid support.

The preparation of the spacer containing saccharide unit **1** is rather straightforward and was performed as described previously.[2] Lipopeptide **2** was prepared from cysteine in five steps according to the procedure of Wiesmüller *et al.*[10] The peptide **3** was prepared by automated continuous flow solid-phase peptide synthesis on a commerically available HMPB–MBHA-resin using $N^{\alpha}$-fluorenylmethoxycarbonyl (Fmoc) amino acid derivatives, according to standard procedures.[11] The hyper acid sensitive linker allows the cleavage of the lipopeptide from the solid support without removal of the side-chain protecting groups. This feature is important since the unprotected side chains of aspartic acid, glutamic acid and lysine will interfere with the incorporation of the saccharide unit. The following side chain protecting groups were selected: Trt for Asn and His, Pbf for Arg, Boc for Lys and $Bu^t$ for Tyr and Glu. Deprotection can be performed under mild acid conditions without affecting the glycosidic linkages and palmitoyl ester moieties.

The N-terminus of the solid supported peptide **3** was linked to the carboxylic acid unit of the $Pam_3Cys$ **2** to give lipopeptide **4**. Model studies had established that the benzotriazol-1-yloxytris-(pyrrolidino)phosphonium hexafluorophosphate–$Pr^i_2EtN$ coupling reagents allowed highly efficient and fast coupling. Furthermore, this method required less of the rather precious $Pam_3Cys$ **3** compared to the use of a carbodiimide–1-hydroxybenzotriazole (HOBT) coupling system. Next, the conjugate was released from the solid support by treatment with 1% TFA in $CH_2Cl_2$ followed by immediate neutralisation with 10% pyridine–MeOH. The crude product was purified by size-exclusion column chromatography (Sephadex LH-20, $CH_2Cl_2$–MeOH 1 : 1, v/v) and 2D NMR and mass spectrometric analysis of the product obtained showed that the side-chain protecting groups had not been effected. Compound **5** was isolated in a yield of 75% based on a resin loading of 30 μmol. The revealed carboxylic acid at the C-terminus of the lipopeptide **5** was

**Scheme 1**

coupled with the amino-containing spacer moiety of the sugar unit **1** and in this case the coupling was best performed with EDC and HOBT in the presence of $Pr^{i}_{2}EtN$. Purification was accomplished by gel filtration and the fully protected conjugate was isolated in a yield of 91%. The molecular structure was confirmed by 1D and 2D NMR spectroscopy and mass spectrometry. FAB mass analysis of **5** showed a peak at *m*/*z* 5108 corresponding to $[M + Na]^+$. Scanning was also performed over a narrow mass range between 4800 and 5200. Peaks were present at *m*/*z* 5086 and 5108 corresponding to $[M + H]^+$ and $[M + Na]^+$, respectively. Further peaks at *m*/*z* 4843 and 4865 correspond to a fragment lacking one trityl protecting group and its sodium adduct, respectively. It is noteworthy that the hydroxy groups of the sugar moiety were unprotected and did not interfere with the coupling reaction. This feature is important because the most commonly used permanent protecting groups in carbohydrate chemistry are benzyl ethers or acetyl or benzoyl esters. Removal of these protecting groups would cause problems as base-catalysed deacylation of a product may result in the loss of the palmitoyl moieties. Furthermore, catalytic hydrogenation of benzyl ethers would be difficult because of poisoning of the palladium catalyst by the sulfur residues in the compound. Finally, the side chain protecting groups of the peptide were removed by treatment with TFA–water in the presence of ethane-1,2-dithiol as a scavenger. The obtained compound was purified by HPLC on a phenogel 5 μ 100 Å column (eluent: DMSO) and after freeze drying the structural integrity of **6** was confirmed by FAB mass spectrometry and 1D and 2D NMR spectroscopy. FAB mass analysis of **6** showed a peak at *m*/*z* 3586 corresponding to $[M + H]^+$.

In conclusion, we have developed a highly convergent strategy for the assembly of compounds that contain a carbohydrate B-epitope, a peptide T-epitope and a lipopeptide adjuvant. The use of these glycoconjugates as vaccines will have several advantages compared to conventional polysaccharide-protein conjugate vaccines. They are well-defined and can be purified to homogeneity and are chemically stable. The incorporation of homogeneous T-epitopes will enhance the immunological response.

Financial support for this project was provided by the Medical Research Council.

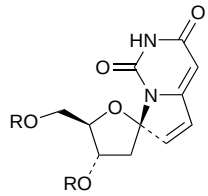
# A new class of anomeric spironucleosides

**Thanasis Gimisis,[a] Carlo Castellari[b] and Chryssostomos Chatgilialoglu*[a]**



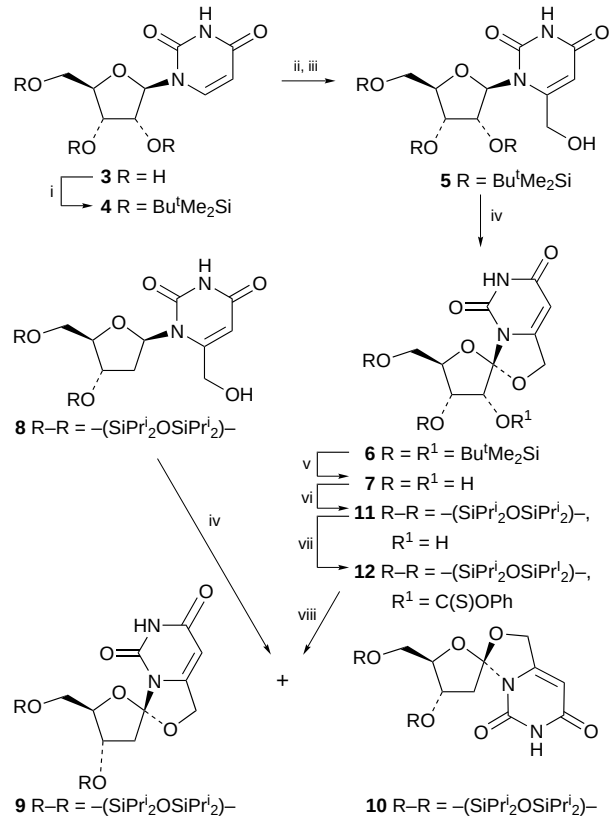
[a] *I.Co.C.E.A., Consiglio Nazionale delle Ricerche, Via P. Gobetti 101, I-40129 Bologna, Italy*
[b] *Dipartimento di Chimica 'G. Ciamician', Università di Bologna, Via Selmi 2, I-40126 Bologna, Italy*

**A 1,5-hydrogen migration of a conveniently situated alkoxyl radical affords spironucleosides which possess an unusual orthoamide structure at the anomeric position; X-ray crystallography establishes the configuration of the C-1′ position.**

Anomeric spironucleosides are useful modifications of natural nucleosides in that they contain the base unit in a fixed conformation around the *N*-glycosidic bond.[1] In recent years, they have gained in importance with the discovery of hydantocidin[2] **1**, a natural spironucleoside with herbicidal and plant growth regulatory activities, and generally, with the notion that important pharmaceutical leads can be found among modified nucleoside analogues.

**1**

**2**



The first anomeric spironucleosides to be synthesized were derivatives of psiconucleosides.[3,4] All recent developments on the synthesis of anomeric spironucleosides are based on free-radical chemistry.[3b,5,6]

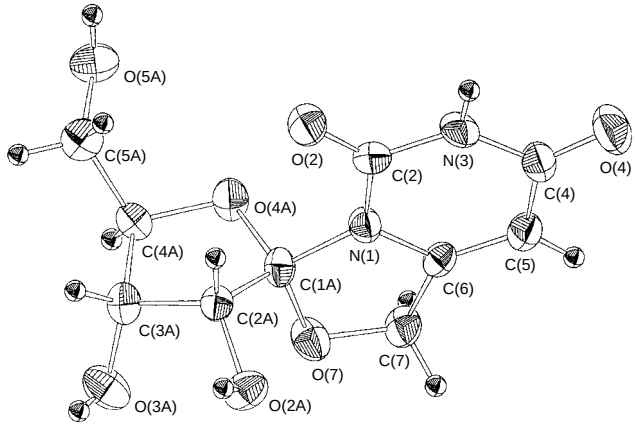
Modification of the anomeric position of nucleosides can also be attained *via* the intermediacy of C-1′ radicals.[7] We recently reported the first example of this kind of transformation for the preparation of compound **2**.[8] We report herein the synthesis of a new class of anomeric spironucleosides *via* a [1,5]-radical translocation of alkoxyl radicals to the anomeric position.

When the protected 6-hydroxymethylribouridine **5**, prepared from the corresponding protected uridine **4** by fine tuning of literature procedures,[9] was treated under the standard Suárez conditions[10] a major product was obtained in moderate (36%) yield after flash column chromatography (Scheme 1). The structure of the product could be assigned to compound **6** based on its $^1$H NMR spectrum, in which 2′-H appeared as a doublet and the 7-Hs appeared as a well resolved AB quartet. This, coupled with the lack of a 1′-H or 7-OH signal, corroborated the assignment of an orthoamide function to the product nucleoside, although the configuration of the anomeric centre remained ambiguous. Deprotection of the silyl groups provided the water soluble compound **7**. A single crystal of this material grown from MeOH–$H_2O$ with mp 172–173 °C was subjected to X-ray diffraction analysis in order to determine unambiguously the stereochemistry of the C-1′ position.

The independent part of the cell contains two formula units. An ORTEP diagram of **7** (molecule 1) is shown in Fig. 1. All atoms in molecule 1 were well defined, while atom O(5A) in molecule 2 exhibited a split image, as a consequence of two-fold rotational disorder around the C(4A)–C(5A) axis. An occupation factor for the latter was refined for O(5A) and the accompanying hydrogens, the final value being 0.57(1). The two independent molecules have strictly comparable parameters. In both molecules the stereogenic centre C(1A) is in the *R* configuration. The oxazolo[3,4-*c*]pyrimidine moiety is flat [maximum deviation from the average plane is 0.137(3) and 0.171(3) Å for atom O(7) in molecules 1 and 2, respectively]. The dihedral angle between the five membered ring and the fused pyrimidine moiety is 82.3(2) and 86.5(2)° for molecules 1 and 2, respectively.

When the Suárez conditions,[10] were applied to the 2′-deoxynucleoside analogue **8**, prepared from the corresponding protected 2-deoxyuridine,[9] two spironucleoside products were isolated in 71% combined yield and in a 1.1 : 1 ratio after flash column chromatography (Scheme 1). The structures of the products were assigned to compounds **9** and **10** based on their $^1$H NMR spectra, in which the two diastereotopic 2′-Hs appeared as well resolved doublets of doublets and the 7-Hs appeared as an AB quartet. The determined absolute configuration of the anomeric centre in the spiroribonucleoside **7** was linked with that of the 2′-deoxy analogues through a straightfor-

**Scheme 1** *Reagents and conditions*: i, Bu$^t$Me$_2$SiCl (5.0 equiv.) imidazole (7.0 equiv.), DMF, room temp., overnight, 98%; ii, LDA, THF, −70 °C, 3 h; $HCO_2Et$, −60 °C, 2 h; iii, $NaBH_4$, MeOH, room temp., 30 min, 68% based on consumption of **4**; iv, PhI(OAc)$_2$, $I_2$, cyclohexane, *hv*, 28 °C, 5 h, 36% for **6**, 71% for **9** and **10**; v, $Bu_4NF$ on $SiO_2$, THF, room temp., 2 h, 90%; vi, (Pr$^i_2$SiCl)$_2$O, pyridine, room temp., overnight, 61%; vii, PhOC(S)Cl, DMAP, $CH_2Cl_2$, 1 h, room temp., 84%; viii, (Me$_3$Si)$_2$SiH, AIBN, toluene, 80 °C, 6 h, 95%



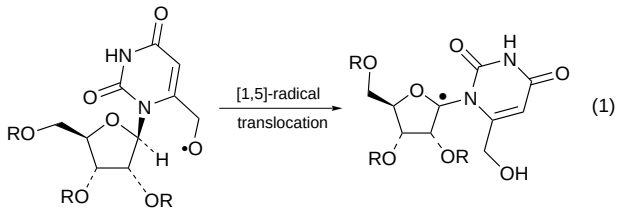


**Fig. 1** ORTEP drawing of one of the independent molecules of **7** (molecule 1) in the unit cell

ward, three-step chemical transformation, as outlined in Scheme 1. Standard regioselective protection of the 3′- and 5′-positions with the 1,1,3,3-tetraisopropyldisiloxane-1,3-diyl group to afford **11**, followed by transformation of the 2′-hydroxy group to give the thiocarbonate **12**,[11] and finally Barton–McCombie radical deoxygenation in the presence of $(Me_3Si)_3SiH$[12] produced the chromatographically less polar stereoisomeric 2′-deoxyspironucleoside **9**. These transformations, apart from establishing unequivocally the configuration of the C-1′ anomeric centre in **9** and **10**, also demonstrated the inherent stability of the orthoamide structure.

The mechanism for the formation of the spironucleoside involves generation, under the Suárez conditions, of the alkoxyl radical intermediate **13** which undergoes a [1,5]-radical translocation reaction[13] to yield the anomeric C-1′ radical intermediate **14** [eqn. (1)], which in turn produces the observed

**13** **14** (1)

orthoamide **6** after oxidation and cyclization. It is worth pointing out that the steric hindrance induced by the bulky 2′-substituent in the ribo series is likely responsible for the stereospecificity of the cyclization. The absence of the epimeric spironucleoside with *S* configuration in the reaction product can be attributed to the steric interaction between the carbonyl in the 2-position of the base and the bulky-2′ substituent as can be envisaged by inspection of the crystal structure in Fig. 1.

The spironucleosides reported herein correspond to the first spiro[tetrahydrofuran-2,3′-(1,5,6,7-tetrahydro-3*H*-[1,3]-oxazolo[3,4-*c*]pyrimidine)] nucleosides, possessing a remarkably stable orthoamide modification of the C-1′ anomeric position. Further work on the preparation and chemical transformations of this class of compounds is in progress.

We are grateful to the European Commission for a ‘Marie Curie’ post-doctoral fellowship to T. G.

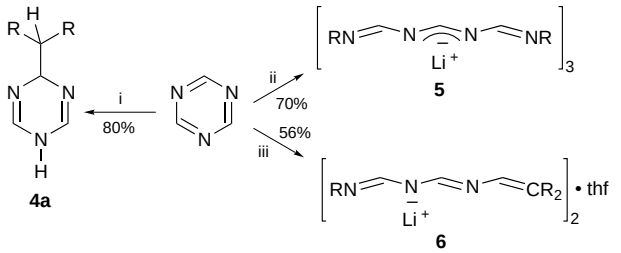
# Reactions of 1,3,5-triazine with organolithium compounds yielding 1,4-dihydrotriazines or the ring-opened products, a 3-lithio-1,3,5,7-tetraazaheptatriene or -1,3,5-triazaheptatriene†

**Willem M. Boesveld, Peter B. Hitchcock and Michael F. Lappert***

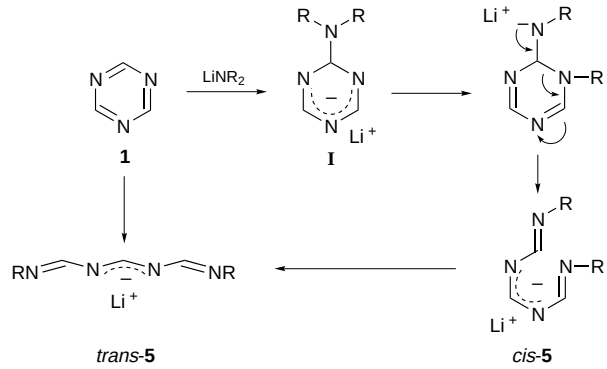
*The Chemistry Laboratory, University of Sussex, Falmer, Brighton, UK BN1 9QJ*

**1,3,5-Triazine 1 reacts with the lithium alkyl LiR′ (R′ = $CHR_2$, $CH_2R$, Me, $Bu^n$ or Ph; R = $SiMe_3$) to give 1,4-adducts which on hydrolysis yield the first simple 1,4-dihydrotriazines; however, 1 with $LiNR_2$ or $LiCR_3(thf)_2$ gives the crystalline ring-opened 3-lithio-1,3,5,7-tetraazaheptatriene 5 or -1,3,5-triazaheptatriene 6 $[Li\{RNC(H)NC(H)NC(H)ER\}]_n$(μ-L) (E = N, *n* = 3 and L is absent 5, or E = CR, *n* = 2 and L = thf = tetrahydrofuran 6).**



As part of our study of the reactions of nitriles free from α-hydrogen with organometallic reagents such as $LiCH(SiMe_3)_2$,[1] we now describe our initial findings with $(HCN)_3$, the 1,3,5-triazine **1**. The behaviour of **1** towards organometallic reagents is largely unexplored,[2] in contrast to its 2,4,6-triphenyl-derivative NC(Ph)NC(Ph)NC(Ph) **2**.[3] In rare cases **1** behaved as an HCN-synthon, but no intermediates were isolated.[4] For example, **1** with 2 $LiNR_2$ and subsequent treatment with RCl gave on sublimation the formamidine $RNC(H)NR_2$ (R = $SiMe_3$).[5]

We now report on the reactions of lithium hydrocarbyls or bis(trimethylsilyl)amide with **1**. Treatment of **1** in benzene with LiR′ (R′ = **a** $CHR_2$, **b** $CH_2R$, **c** Me, **d** $Bu^n$ or **e** Ph) at ambient temperature produced 1,4-adducts **1**·LiR′ **3a**–**e** which, because of their insolubility, were not adequately characterised, but presumably are analogues of 1-lithio-4-alkyltriphenyldihydrotriazines derived from **2**.[6] Hydrolysis of a diethyl ether slurry of each of the compounds **3a**–**e** with 1.1 equiv. of $H_2O$ and drying of the filtrate ($Na_2SO_4$) yielded the first 'simple' (*i.e.* monosubstituted) 1,4-dihydrotriazines, the colourless, crystalline **4a** (mp 104–106 °C) (or crystalline **4b** or the liquids **4c**–**e**), (Scheme 1, i). Such simple dihydrotriazines were hitherto believed merely to be transients[7] unlike the stable 1,4-dihydro adducts of **2** such as 1-*n*-butyl-2,4,6-triphenyl-1,4-dihydrotriazine.[3] Compound **4a**, possibly stabilised by the bulky $CH(SiMe_3)_2$-substituent (**4b** was markedly less robust), gave satisfactory microanalysis, $^1H$ and $^{13}C\{^1H\}$ NMR spectroscopic‡ and EI MS (parent molecular ion) data; the molecular structure of crystalline (boat-shaped) **4a** was also established by its X-ray structure (to be reported in the full paper). In $C_6D_5CD_3$ **4a** was in equilibrium with its 1,2-dihydro tautomer (*ca.* 50 : 1 at 295 K), a previously observed behaviour of substituted dihydrotriazines.[8]



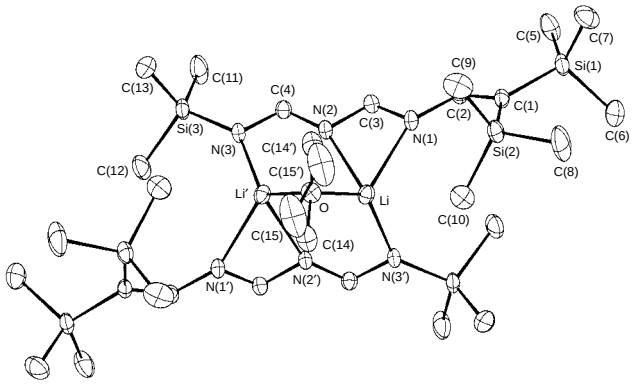
Reaction of **1** with $LiNR_2$ or $LiCR_3(thf)_2$ under similar conditions, however, took a different course: the triazine ring opened and, formally, an α → ω migration of an $Me_3Si$ group occurred; thus the 3-lithio-1,3,5,7-tetraazaheptatriene **5** or -1,3,5-triazaheptatriene **6** was obtained (Scheme 1, ii and iii). Compounds **5** and **6** were air- and moisture-sensitive both in the solid state and in solution and, in marked contrast to **3**, extremely soluble in hydrocarbons. Both have been characterised by microanalysis, $^1H$ and $^{13}C\{^1H\}$ NMR spectroscopy,‡ EI MS (parent molecular ion) and single-crystal X-ray analysis.

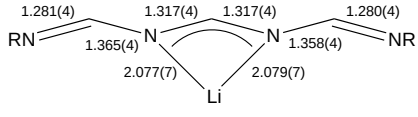
The pathway leading stereospecifically to the *trans*-product **5** or **6** is believed to implicate initially a 1,4-adduct analogous to **3**, followed successively by a 1,3-$Me_3Si$ shift from $NR_2$ or $CR_3$ and then its ring scission. This is illustrated for the system **1** + $LiNR_2$ → **5** in Scheme 2. Evidence for the Meisenheimer complex **I** (or its $CR_3$ analogue for **6**) is supported by NMR-scale experiments, which revealed intermediates having chemical shifts and coupling patterns resembling those of dihydrotriazine **4a**. Relevant precedents exist for anionic 1,3-$Me_3Si$ shifts from N → N[9] or C → N.[1] This migration might be stereoelectronically promoted, since for the case of **1** + $LiCHR_2$ the adduct **3a** was transformed into Li[RNC(H)NC(H)NC(H)CHR] **7** upon heating to 140 °C.

The X-ray molecular structure of crystalline **6** (Fig. 1) shows it to be dinuclear and lying on a crystallographic twofold rotation axis.§ The lithium atoms are bridged by a thf molecule, a rare phenomenon.[10] The atoms C(2), N(1), C(3), N(2), C(4) and N(3) are coplanar, largest deviation from least-squares plane is 0.048, and comparison of the bond lengths with known formamidinates[11,12] suggest that the NC(H)NC(H)N unit has some degree of delocalisation, while the values of 1.406 Å for N(1)–C(2) and 1.351 Å for C(2)–C(1) are unexceptional for a $N(sp^2)$–$C(sp^2)$ and $C(sp^2)$=$C(sp^2)$ bond, respectively.[13] The X-ray molecular structure of the crystalline, trinuclear compound **5** will be discussed in more detail in the full paper, but representative fragments of the molecular structures of **5** and **6**

**Scheme 1** *Reagents and conditions*: i, $LiCHR_2$, $Et_2O$, 4 h, −40 to *ca.* 20 °C, then 1.1 $H_2O$ and drying ($Na_2SO_4$); ii, $LiNR_2$, $C_6H_6$, 2 h, *ca.* 20 °C; iii, $LiCR_3(thf)_2$, $C_6H_6$, 2 d, *ca.* 20 °C

**Scheme 2** Proposed pathway for formation of **5**





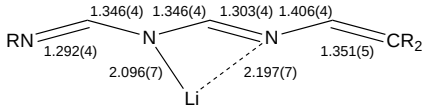


**Fig. 1** ORTEP representation of the molecular structure of **6**. Selected bond lengths (Å) and angles (°): Li–O 2.133(7), Li–N(1) 2.197(7), Li–N(2) 2.096(7), Li–N(3′) 2.058(7), C(1)–C(2) 1.351(5), C(2)–N(1) 1.406(4), N(1)–C(3) 1.303(4), C(3)–N(2) 1.346(4), N(2)–C(4) 1.346(4), C(4)–N(3) 1.292(4); N(2)–Li–N(1) 63.9(2), N(2)–Li–O 86.9(2), N(1)–Li–O 114.0(3), N(3′)–Li–O 129.4(3), N(3′)–Li–N(2) 125.4(3), N(3′)–Li–N(1) 115.3(3), Li′–O–Li 77.4(4), C(1)–C(2)–N(1) 124.6(4), N(1)–C(3)–N(2) 118.2(3), N(2)–C(4)–N(3) 120.5(3).

**5**

**6**

**Fig. 2** Bond lengths of selected fragments of the molecular structures of **5** and **6**

(Fig. 2) show that for **5**, unlike **6**, there is complete delocalisation of the central NC(H)N moiety with a bond length of *ca*. 1.32 Å.

On the basis of further exploratory experiments we consider that the results here reported have significant implications in that (*i*) compounds such as **4** upon hydrolysis in acidic or basic media are sources of aldehydes, (*ii*) compounds **5**–**7** are of interest as both sources of unusual tetra- or tri-azaheptatrienyl ligands and of nitrogen macrocycles.

**A new tetranuclear FePdFeSn four-membered ring cluster, which could be viewed as a bent chain complex FePdFe bridged by a stannylene ligand, is obtained from a $Fe_2Sn_2$ precursor by $Ph_2PCH_2PPh_2$ (dppm)-assisted palladium incorporation; it provides the first example of a Sn–Fe–Pd linkage.**

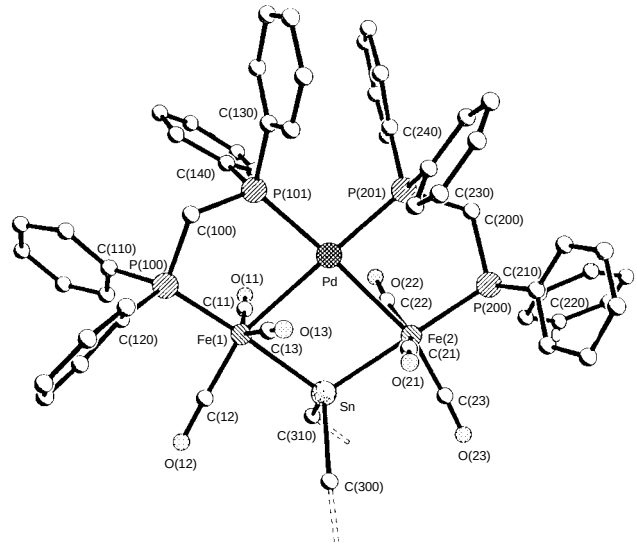
Molecules which associate transition metals with group 14 elements currently enjoy increased attention because they provide opportunities for the formation of unusual structures and new bonds between transition metals and main-group elements, they are used as single-source precursors for new materials and display interesting catalytic properties.[1]

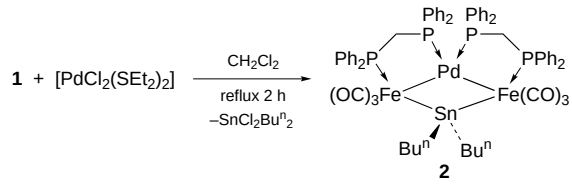
We have recently reported the synthesis of $[Fe(CO)_3(\eta^1\text{-dppm})(SnBu^n_2)]_2$ **1** (dppm = $Ph_2PCH_2PPh_2$) from $K[Fe(CO)_3\{Si(OMe)_3\}(\eta^1\text{-dppm})]$ and $[Sn(OAc)_2Bu^n_2]$ where a silicon/tin exchange reaction has taken place.[2] The silyl ligand may be considered as a protecting group for the unknown dianion $[Fe(CO)_3(\eta^1\text{-dppm})]^{2-}$.[3] Since the uncoordinated phosphorus lone pair in **1** can be used for further metal complexation,[2] we considered using a palladium educt with two labile ligands which could lead to an inorganic cyclic or a linear polymer.

Addition of 1 equiv. of $[PdCl_2(SEt_2)_2]$ to the solution of **1** in $CH_2Cl_2$ at −40 °C, gave after 2 h a dark-red solution which was filtered at −30 °C and yielded a bright-red powder which should be kept below −30 °C.‡ Its IR spectrum [$\nu$(CO) region] is similar to that found for **1**. However two main products, in approximately 1 : 1 ratio, were detected by $^{31}P\{^1H\}$ NMR and have very similar data. The former is characterized by two doublets at $\delta$ 58.0 and 35.3 with $^2J$(PP) 70.5 Hz and the latter by two other doublets at $\delta$ 56.7 and 34.7 with $^2J$(PP) 69.1 Hz. Further stirring of this red solution for 2 h at −30 °C did not result in any change and there was no evolution from one product to the other. However, if the reaction mixture is left standing in $CH_2Cl_2$ at room temp. for 2 d, $^{31}P\{^1H\}$ NMR monitoring shows the progressive formation of two new products and the disappearance of those described above. After one week, the solution became bright-green and contained only the two new products. Product **2** is characterized by a pair of doublets at $\delta$ 64.2 and 28.8 with $^2J$(PP) 107.2 Hz, and product **3** by a pair of triplets centered at $\delta$ 63.1 and 21.7 with $^2J$(PP) 99.8 Hz. Very dark single crystals of **2** were obtained by fractional crystallisation (slow diffusion of hexane into a concentrated solution in $CH_2Cl_2$) and their structure was determined by X-ray diffraction (Fig. 1).§

This rhombus-like molecule provides the first structure of a SnFePd ring. The Pd, two Fe and four P atoms are nearly coplanar and the four membered ring $PdFe_2Sn$ is folded by 9.97(9)° along the Fe–Fe axis. The sum of the angles around the Pd atom is exactly 360°, *i.e.* the coordination sphere around this atom is perfectly planar. The Fe(1)–Pd–Fe(2) angle is 93.51(8)° whereas the opposite Fe(1)–Sn–Fe(2) angle of 106.89(8)° reflects the nearly tetrahedral arrangement around the Sn atom. The coordination sphere around the Fe atoms is distorted octahedral.[1l,n,4] The Fe–Sn distances are 2.517(3) and 2.520(3) Å and are smaller than those found in **1** [2.6736(9) and 2.645(1) Å]. The Fe–Pd distances [2.763(3), 2.791(3) Å] are longer than those found in related dppm bridged complexes such as $[Fe(CO)_3\{\mu\text{-}Si(OMe)_2(OMe)\}(\mu\text{-dppm})PdCl]$ [2.582(1) Å] or $[Fe(CO)_3\{Si(OMe)_3\}(\mu\text{-dppm})Pd(\eta^3\text{-}C_3H_4Me\text{-}2)]$ [2.6994(7) Å] or $[Fe(CO)_3\{Si(OMe)_2(OMe)\}(\mu\text{-dppm})Pd(SnPh_3)]$ [2.6655(5) Å].[5] Neither the Pd–Sn (3.389(2) Å) nor the Fe(1)–Fe(2) distances [4.046(3) Å] indicate a metal–metal interaction across the ring.

During attempts to optimize the yield of **2**, we have reacted a solution of **1** with 1 equiv. of $[PdCl_2(SEt_2)_2]$ in refluxing





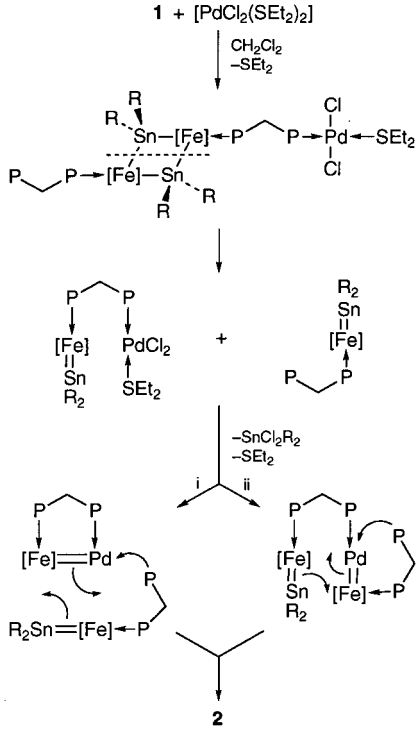


**Fig. 1** View of the structure of **2**. The dotted lines at C(300) and C(310) indicate the disorder of the butyl groups. Selected bond distances (Å) and angles (°): Pd–Fe(1) 2.763(3), Pd–Fe(2) 2.791(3), Sn–Fe(1) 2.520(3), Sn–Fe(2) 2.517(3), Pd–P(101) 2.347(4), Pd–P(201) 2.325(4), Sn–C(300) 2.421(12), Sn–C(310) 2.31(2), Fe(1)–C(11) 1.79(2), Fe(1)–C(12) 1.74(2), Fe(1)–C(13) 1.79(2), Fe(1)–P(100) 2.210(5), Fe(2)–C(21) 1.76(2), Fe(2)–C(22) 1.78(2), Fe(2)–C(23) 1.76(2), Fe(2)–P(200) 2.201(5); Fe(1)–Pd–Fe(2) 93.51(8), Fe(1)–Sn–Fe(2) 106.89(8), Sn–Fe(1)–Pd 79.69(7), Sn–Fe(2)–Pd 79.20(7), P(201)–Pd–P(101) 97.1(2), P(101)–Pd–Fe(1) 83.52(12), P(201)–Pd–Fe(2) 85.91(11), C(300)–Sn–C(310) 106.9(8), C(13)–Fe(1)–C(11) 147.6(8), C(21)–Fe(2)–C(22) 149.7(8).

**Scheme 1**

$CH_2Cl_2$ for 2 h. The solution became green and a dark-green powder of **2** was isolated in 51% yield (Scheme 1).

The first step of this unusual reaction is likely to be palladium coordination to a phosphorus lone pair of **1** (Scheme 2). The subsequent steps can only be speculative at this stage. Fragmentation of the $Fe_2Sn_2$ ring would occur and it is conceivable that replacement of one 'Fe=$SnR_2$' unit with an isolobal 'Fe=PdLL' moiety with elimination of $SnCl_2Bu^n_2$ would be followed by combination of this moiety with the remaining equivalent iron–stannylene.

**Scheme 2** Tentative pathways to the formation of **2**. Alternatives i and ii correspond to formal intra- or inter-molecular elimination of $SnCl_2R_2$. R = $Bu^n$; [Fe] = $Fe(CO)_3$.

During attempts to extend the formation of this complex to other metal centers we have found that reaction of **1** with $[PtCl_2(NCPh)_2]$ under similar conditions ($CH_2Cl_2$, 2 h, reflux) appears less selective but yields a product **4** similar to **2** on the basis of spectroscopic data.‡

We are grateful to the Ministère de l'Enseignement Supérieur et de la Recherche for a PhD Grant for C. C., the CNRS, the Ministère des Affaires Etrangères (Paris) (Amadeus 1996) and the Commission of the European Communities (contract ERBCHRXCT93 277) for financial support.

† Dedicated to Professor Pascual Royo (Universidad de Alcala) on the occasion of his 60th birthday.

‡ All reactions were performed under purified nitrogen, using carefully dried solvents.

*Syntheses*: $[(OC)_3\overline{Fe(\mu\text{-}SnBu^n_2)(\mu\text{-}dppm)Pd}(\mu\text{-}dppm)Fe(CO)_3]$ **2**: to a solution of **1** in $CH_2Cl_2$ (0.258 g, 0.17 mmol) was added $[PdCl_2(SEt_2)_2]$ (0.061 g, 0.17 mmol). The solution was refluxed for 2 h, then filtered and concentrated. Yield: 51%. IR ($CH_2Cl_2$) $\nu$(C≡O) 1980m, 1949m, 1918vs $cm^{-1}$; (KBr) 1959m, 1925s, 1895vs, 1884vs $cm^{-1}$. NMR $^1H$ ($CD_2Cl_2$): $\delta$ 0.88 (t, 3 H, $CH_2CH_3$), 0.98 (t, 3 H, $CH_2CH_3$), 1.20–2.05 (m, 12 H, $CH_2$), 3.56 [t, 2 H, $PCH_2P$, $^2J$(PH) 9.48 Hz], 3.57 [t, 2 H, $PCH_2P$, $^2J$(PH) 9.56 Hz], 6.79–7.40 (m, 40 H, Ph). NMR $^{31}P\{^1H\}$ ($CD_2Cl_2$): $\delta$ 64.2 [d, P(Fe), $^2J$(PP) 107.2, $^2J(P^{117,119}Sn)$ 212.9 Hz], 28.8 [d, P(Pd), $^2J$(PP) 107.3 Hz].

$[(OC)_3\overline{Fe(\mu\text{-}SnBu^n_2)(\mu\text{-}dppm)Pt}(\mu\text{-}dppm)Fe(CO)_3]$ **4**: to a solution of **1** in $CH_2Cl_2$ (0.300 g, 0.20 mmol) was added $[PtCl_2(NCPh)_2]$ (0.095 g, 0.20 mmol). The solution was refluxed for 2 h, then filtered and concentrated. The brown powder was precipitated by addition of hexane. Yield: 55%. IR ($CH_2Cl_2$) $\nu$(C≡O) 1990w, 1955m, 1920s $cm^{-1}$. NMR $^{31}P\{^1H\}$ ($CD_2Cl_2$): $\delta$ 77.5 [d, P(Fe), $^2J$(PP) 49.3 Hz], 20.5 [d, P(Pd), $^2J$(PP) 49.3 Hz].

§ *Crystal data* for **2**. Dark red crystals (0.4 × 0.3 × 0.2 mm) were mounted on a Siemens SMART CCD area detector diffractometer. Mo-K$\alpha$ radiation ($\lambda$ = 0.710 73 Å, graphite monochromated). Monoclinic, space group $P2_1/n$, $a$ = 17.5349(7), $b$ = 18.6137(7), $c$ = 17.8860(7) Å, $\beta$ = 90.781(1)°, $U$ = 5837.3(4) $Å^3$, $Z$ = 4, $D_c$ = 1.797 g $cm^{-3}$. The cell dimensions were refined with all unique reflections. The data collection at 303(2) K covered a hemisphere of the reciprocal space, by a combination of three sets of exposures. Each set had a different $\phi$ angle for the crystal and each exposure took 20 s and covered 0.3° in $\omega$. The collected data range was $1.58 \leqslant \theta \leqslant 23.00°$ ($-25 \leqslant h \leqslant 24$, $-22 \leqslant k \leqslant 26$, $-16 \leqslant l \leqslant 25$) with a crystal-to-detector distance of 5.85 cm. 27 071 reflections were collected, and 8134 unique reflections ($R_{int}$ = 0.136) were obtained after correction of polarization and Lorentz effects ($\mu$ = 2.09 $mm^{-1}$). An empirical absorption correction with the program SADABS was carried out.[5] The structure was solved by direct methods (SHELXS86). Refinement was performed by the full-matrix least-squares method based on $F^2$ (SHELXL93). All non-hydrogen atoms were refined with anisotropic thermal parameters with exception of the $Bu^n$ carbon atoms. The hydrogen atoms were added in idealized positions and were refined with a riding model. We were not able to refine the two $Bu^n$ groups due to their strong disorder. Only the anchor C atoms were found and were refined isotropically. The positions C(2)–C(4) were totally smeared over the whole cone angle opened by the vector originating in the Sn atom. Various routines and ways of modelling the disorder of the Bu groups were attempted without success. There was neither convergence of the refinements nor an improvement of the $R$ factors. The missing $Bu^n$ groups cause the relatively high $R$ values [$R$ = 0.103, $R_w$ = 0.28 for 5265 reflections with $I \geqslant 2.0\,\sigma(I)$; $w = 1/[\sigma^2(F_o^2) + (0.1437\,P)^2 + 118.83\,P]$ [$P = (F_o^2 + 2\,F_c^2)/3$]. The largest residual electron density was 2.486 e $Å^{-3}$. CCDC 182/588.

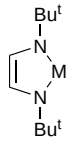
# Cyclic phosphenium and arsenium cations with 6π electrons and related systems

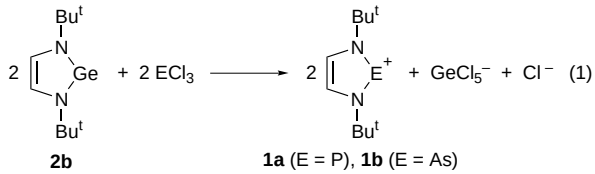
**Claire J. Carmalt, Viviana Lomeli, Brian G. McBurnett and Alan H. Cowley***



*Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, Texas 78712, USA*

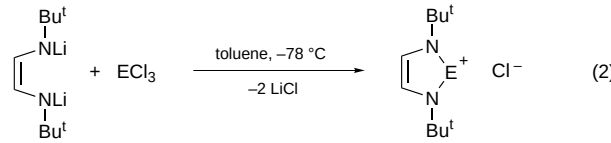
**Cyclic phosphenium (1a) and arsenium (1b) cations are formed either by treatment of germylene 2b with $ECl_3$ (E = P, As) or *via* the metathetical reaction of LiN(Bu$^t$)C=CN(Bu$^t$)Li with $ECl_3$ and the structures of 1a and 1b are compared with those of pertinent saturated analogues.**

Cyclic phosphenium (**1a**) and arsenium (**1b**) cations are isoelectronic with the corresponding silylenes **2a**[1] and germylenes **2b**.[2] As such, they raise interesting questions concerning



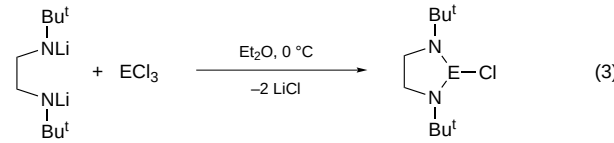
**1a** (E = P), **1b** (E = As)

**2a** (M = Si), **2b** (M = Ge)



circumannular delocalisation since, in principle, **1a**,**b** and **2a**,**b** possess six π electrons. Given that the group 15 systems bear a formal positive charge at the phosphorus or arsenic centre, it might be expected that these species would exhibit more extensive delocalisation than their neutral group 14 counterparts. (For a similar argument for nitrenium ions *vis-à-vis* carbenes, see ref. 3). A cyclic phosphenium ion with the same skeleton as **1a** was structurally characterised several years ago;[4] however, this cation features a 2-chloro substituent thus potentially complicating interpretations of bonding. More recently, **1a** has been synthesised and identified spectroscopically.[5] We report the following new developments in this field: (*i*) a novel synthetic route to **1a** and **1b** based on the redox reactions of **2b** with $ECl_3$ (E = P, As); (*ii*) X-ray crystallographic data for **1a** and **1b** and (*iii*) syntheses and X-ray crystallographic data for pertinent saturated analogues of **1a** and **1b**.

The reaction of **2b** with $PCl_3$ or $AsCl_3$ takes place under mild conditions and affords moderate yields of the corresponding phosphenium or arsenium ions [eqn. (1)].† The reaction



**2b** **1a** (E = P), **1b** (E = As)

mechanism has not been elucidated; however, it is clear that germanium is oxidised from the +2 to the +4 state and that **1a** and **1b** crystallise with equimolar quantities of $GeCl_5^-$ and $Cl^-$ anions. A noteworthy feature of **1b** is that it is monomeric in contrast to the previously reported cyclic arsenium cation, $MeNCH_2CH_2N(Me)As^+$, which is dimeric.[6,7] Since it was not obvious from the foregoing whether autoionisation of the E–Cl bonds of the products would occur, we sought a system free of chloride ion acceptors. It was found that the metathetical reactions summarised in eqn. (2) proceed in good yields.†

**1a** (E = P), **1b** (E = As)

Analogous metathetical reactions were employed for the synthesis of the related saturated systems [eqn. (3)].

**3a** (E = P), **3b** (E = As)

The structures of **1a**,**b** (Fig. 1) and **3a**,**b** (Fig. 2) have been determined by X-ray crystallography.‡ Autoionisation is observed in the case of **1a**. While shorter than the van der Waals radii, the P···Cl separation in **1a** [2.715(2) Å] is nevertheless considerably longer than those of typical covalent P–Cl bonds *e.g.* $PCl_3$ 2.043 Å, mes*NPCl 2.142(4) Å.[9] Anion–cation interactions which are less than the sum of the van der Waals radii are common for non-metals and certain phosphenium salts.[10] It has been observed previously that such anion–cation interactions have little or no effect on the structural features within the cation or anion.[11] Indeed, the structural features of **1a** derived from either the germanium exchange or metathetical route are identical within experimental error. Interestingly, the P–Cl distance in the corresponding C–C saturated analogue, **3a** [2.425(4) Å] is also longer than that of typical P–Cl bonds but shorter than that in **1a** thus implying that this compound is partway along the P–Cl heterolysis pathway. There is therefore an interesting parallel with carbene chemistry in the sense that the unsaturated imidazol-2-ylidenes (Arduengo type)[12] are more stable than the C–C saturated imidazol-2-ylidenes (Wanzlick type).[13] The case of the analogous arsenic system is not as clear because we have only been successful in isolating X-ray quality crystals of the mixed anion species, $[\mathbf{1b}]_2[GeCl_5]Cl$.

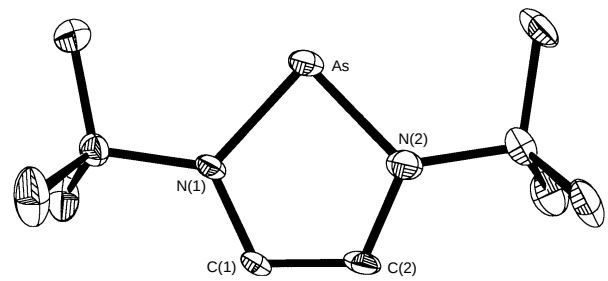


**Fig. 1** Molecular structure of **1b** showing the atom numbering scheme. Selected distances (Å) and angles (°) for **1b** (corresponding values for **1a** shown in parentheses): As–N(1) 1.810(9) [P–N(1) 1.650(4)], As–N(2) 1.812(9) [P–N(2) 1.651(4)], N(1)–C(1) 1.38(1) [1.370(6)], N(2)–C(2) 1.38(2) [1.383(6)], C(1)–C(2) 1.36(2) [1.330(6)], N(1)–As–N(2) 86.2(4) [N(1)–P–N(2) 90.4(2)].

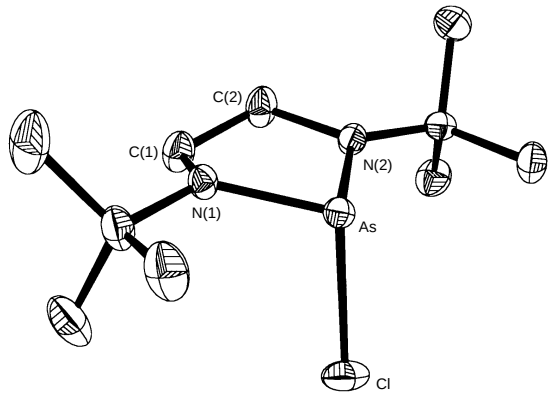

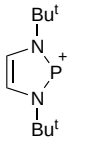

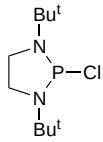

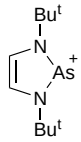

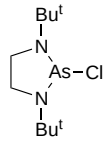

**Fig. 2** Molecular structure of **3b** showing the atom numbering scheme. Selected distances (Å) and angles (°) for **3b** (corresponding values for **3a** shown in parentheses): As–N(1) 1.773(6) [P–N(1) 1.629(9)], As–N(2) 1.789(6) [P–N(2) 1.645(9)], As–Cl 2.375(2) [P–Cl 1.425(4)], N(1)–C(1) 1.468(9) [1.41(1)], N(2)–C(2) 1.464(9) [1.43(1)], C(1)–C(2) 1.44(1) [1.43(1)], N(1)–As–N(2) 88.7(3) [N(1)–P–N(2) 90.6(5)], N(1)–As–Cl 103.7(2) [N(1)–P–Cl 103.1(4)], N(2)–As–Cl 101.8(2) [N(1)–P–Cl 101.9(3)].

However, it is interesting to note that the C–C saturated chloride, **3b**, also possesses an elongated As–Cl bond with a bond length of 2.375(2) Å, a feature which is also observed in the related compounds, MeNCH$_2$CH$_2$N(Me)AsCl [2.390(5) Å] and MeN(CH$_2$)$_3$N(Me)AsCl [2.357(2) Å].[8]

The metrical parameters for **1a**,**b** and the C–C saturated analogues **3a**,**b** (Table 1) are pertinent to the question of electron delocalisation in these systems. One of the first points to note is that the P–N bond distance in **1a** is longer than that in the acyclic phosphenium cation, [P(NPr$^i_2$)$_2$]$^+$ [av. 1.613(4) Å].[14] Moreover, the P–N and As–N bond lengths in **1a,b** are longer than those in the corresponding saturated derivatives **3a,b,** and the C–C bond lengths in **1a** and **1b** correspond to localised double bonds. The EN$_2$C$_2$ rings of **1a** and **1b** are planar within experimental error, as are the geometries at the nitrogen centres. However, it is interesting that the PN$_2$C$_2$ ring of **3a** is planar whilst the AsN$_2$C$_2$ ring of **3b** is not. Thus, in contrast to the view[5] that **1a** 'possesses aromatic 6π-stabilisation,' the foregoing metrical parameters indicate that the cyclic phosphenium and arsenium cations **1a** and **1b** possess relatively localised electronic structures.

**Table 1** Metrical parameters for compounds **1a**,**b** and **3a**,**b**

| |  **1a** |  **3a** |  **1b** |  **3b** |
|---|---|---|---|---|
| E–N(av.)/Å | 1.651(4) | 1.637(9) | 1.812(9) | 1.781(6) |
| N–CH(av.)/Å | 1.376(6) | 1.42(1) | 1.38(2) | 1.466(9) |
| C–C/Å | 1.330(6) | 1.43(1) | 1.36(2) | 1.44(1) |
| N–E–N/° | 90.4(2) | 90.6(5) | 86.2(4) | 88.7(3) |

† *Experimental procedures*: the experimental procedures outlined below relate to the preparations of **1a** and **3a**; however, similar methods were employed for the preparations of **1b** and **3b**.

[**1a**]$_2$[GeCl$_5$]Cl: a solution of PCl$_3$ (0.433 g, 3.16 mmol) in thf (20 cm$^3$) was added dropwise to a stirred solution of **2b** (0.76 g, 3.16 mmol) in thf (30 cm$^3$) resulting in the formation of an orange coloured solution and precipitate. The reaction mixture was stirred overnight and then filtered through Celite resulting in a dark orange solution which was reduced *in vacuo* to a volume of approximately 20 cm$^3$. Cooling of this solution to −20 °C overnight afforded a 40% yield of orange, crystalline [**1b**]$_2$[GeCl$_5$]Cl.

[**1a**]Cl: a toluene solution (40 cm$^3$) of LiN(Bu$^t$)C=CN(Bu$^t$)Li (2.09 g, 11.47 mmol) was added dropwise to a solution of PCl$_3$ (1 cm$^3$, 11.47 mmol) in toluene (20 cm$^3$) at −78 °C. The reaction mixture was stirred overnight with slow warming to room temp. After filtering through Celite, the volume of the filtrate was reduced to 20 cm$^3$ and cooling of the solution to −20 °C afforded a 55% yield of orange crystalline [**1a**]Cl.

Further experimental details can be obtained as supplementary material upon request from the authors.

‡ *Crystal data*: [**1a**]$_2$[GeCl$_5$]Cl: $C_{20}H_{40}Cl_6GeN_4P_2$, $M$ = 683.79, monoclinic, space group $P2_1/c$, $a$ = 10.445(2), $b$ = 17.059(2), $c$ = 19.846(3) Å, $\beta$ = 93.35(2)°, $U$ = 3530(1) Å$^3$, $Z$ = 4, $D_c$ = 1.287 g cm$^{-3}$, $T$ = 298(2) K, $\mu$ = 1.428 mm$^{-1}$. $wR_2$ = 0.2347 (6187 independent reflections), $R$ = 0.0995 [$I > 2\sigma(I)$].

[**1b**]$_2$[GeCl$_5$]Cl: $C_{20}H_{40}As_2Cl_6GeN_4$, $M$ = 771.69, monoclinic, space group $P2_1/c$, $a$ = 10.567(4), $b$ = 16.954(5), $c$ = 19.675(7) Å, $\beta$ = 93.02(2)°, $U$ = 3520(2) Å$^3$, $Z$ = 4, $D_c$ = 1.456 g cm$^{-3}$, $T$ = 183(2) K, $\mu$ = 3.207 mm$^{-1}$. $wR_2$ = 0.2433 (4364 independent reflections), $R$ = 0.0765 [$I > 2\sigma(I)$].

[**1a**]Cl·0.5C$_7$H$_8$: $C_{13.5}H_{24}ClN_2P$, $M$ = 280.77, monoclinic, space group $C2/c$, $a$ = 20.535(4), $b$ = 11.356(4), $c$ = 13.939(4) Å, $\beta$ = 97.30(2)°, $U$ = 3224(2) Å$^3$, $Z$ = 8, $D_c$ = 1.157 g cm$^{-3}$, $T$ = 298(2) K, $\mu$ = 0.322 mm$^{-1}$. $wR_2$ = 0.2320 (2835 independent reflections), $R$ = 0.0686 [$I > 2\sigma(I)$].

**3a**: $C_{10}H_{22}ClN_2P$, $M$ = 236.72, orthorhombic, space group *Pbca*, $a$ = 11.978(2), $b$ = 11.439(3), $c$ = 19.533(3) Å, $U$ = 2676.4(8) Å$^3$, $Z$ = 8, $D_c$ = 1.175 g cm$^{-3}$, $T$ = 298(2) K, $\mu$ = 0.375 mm$^{-1}$. $wR_2$ = 0.1603 (2348 independent reflections), $R$ = 0.0883 [$I > 2\sigma(I)$].

**3b**: $C_{10}H_{22}AsClN_2$, $M$ = 280.67, orthorhombic, space group *Pbca*, $a$ = 12.140(1), $b$ = 11.405(1), $c$ = 19.907(3) Å, $U$ = 2756.3(6) Å$^3$, $Z$ = 8, $D_c$ = 1.353 g cm$^{-3}$, $T$ = 298(2) K, $\mu$ = 2.631 mm$^{-1}$. $wR_2$ = 0.1275 (2419 independent reflections), $R$ = 0.0529 [$I > 2\sigma(I)$]. # Stereoselectivity in the mass-spectral fragmentation of palladium phosphinamine complexes

**Robin T. Aplin, Henri Doucet, Mark W. Hooper and John M. Brown***

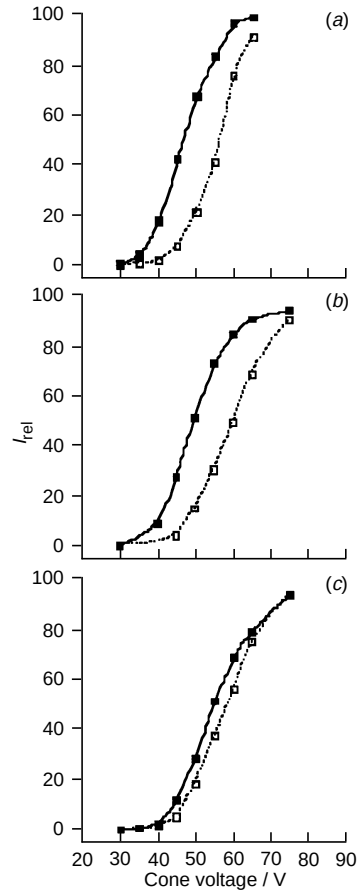
*Dyson Perrins Laboratory, South Parks Rd., Oxford, UK OX1 3QY*

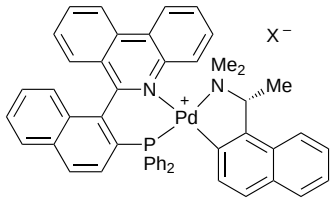
**The diastereoisomers of cyclopalladated 1-naphthyldimethylethylamine complexes of several phosphinoarylisoquinolines demonstrate distinct fragmentation in their electrospray MS, diagnostic of the ligand enantiomer.**

In previous work we have described the synthesis and resolution of a class of P–N chelating ligands based on 2-aza-1,1′-binaphthyl, the parent being **1a**.[1] These P–N chelates have proved useful for catalytic hydroboration and for allylic alkylation and considerable structure variation in the ligand is afforded by minor synthetic variations.[2] The chloropalladium complex derived (*R*)- or (*S*)-*N*,*N*-dimethyl-1-naphthylethylamine[3] proved to be uniquely effective for resolution of the racemic ligand, and this was rationalised in terms of an enforced conformational rigidity in the chelate ring of the complexed resolving agent.[4]

With a number of the resolution intermediates isolated in pure state as chloride or hexafluorophosphate salts, we were interested in making fuller spectroscopic comparisons. A difference became apparent on comparing electrospray MS of the diastereomeric pairs of the parent (*R*,*R*)-**2a** and (*R*,*S*)-**2a** at a standard cone voltage of 55 V. For the (*R*,*R*)-diastereomeric salt, the parent peak of the cation is evident, and a fragment $[LPdH]^+$ where the naphthylamine entity has been lost is also present with around twice the intensity of the parent peak. For the (*R*,*S*)-diastereomer, the same two peaks are observed but now the parent peak is about twice the intensity of the fragment peak. This pattern is repeated with related complexes at the same cone voltage, and under these conditions the spectrum is clean. More profound fragmentation to $[Ar_2PPd]^+$ occurs above 90 V.

In order to obtain more systematic information, three pairs of complexes of known configuration were subjected to electrospray MS over a range of cone voltages where both $[M^+]$ and $[M - 197]^+$ were evident, and the results are shown in Fig. 1. For **2a**, the parent compounds in the series, it can be seen that fragmentation is more pronounced for the (*R*,*R*)-enantiomer than for the (*R*,*S*)-enantiomer across the range of cone voltages [Fig. 1(*a*)]. The diastereomers of the phenanthridine analogue **3** behave quite similarly [Fig. 1(*b*)], although here the counter ion is $Cl^-$ for the (*R*,*R*)-isomer and $PF_6^-$ for the (*R*,*S*)-isomer.[5] For the phenylethylamine analogue **4** [Fig. 1(*c*)], where both complexes are $PF_6^-$ salts, it can be seen that the (*R*,*S*)-diastereomer fragments to a lesser degree than does the (*R*,*R*)-diastereomer.† However the difference is much smaller here; the ease of fragmentation is comparable for all the (*R*,*S*)-diastereomers in the series but the (*R*,*R*)-diastereomer of **3** is





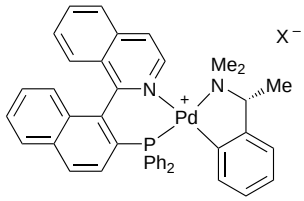


**Fig. 1** Relative signal intensity $I_{rel}$ *vs*. cone voltage for complexes **2a** (*a*), **3** (*b*) and **4** (*c*); intensity expressed as $(M - 197)^+/[M^+ + (M - 197)^+]$ for the $^{106}Pd$ isotopomer. The upper trace is the (*R*,*R*)-diastereomer (■) and the lower trace the (*R*,*S*)-diastereomer (□).

(*R*,*R*)- or (*R*,*S*)-**3**

$X^- = Cl^-$ or $PF_6^-$

(*R*,*R*)- or (*R*,*S*)-**4**

more stable to ESI cone voltage fragmentation than the other (*R*,*R*)-complexes.

A series of related ligands **1b–e** have been prepared in order to elucidate aryl substituent effects on asymmetric catalysis.[6] The resolution protocol was successful in separating enantiomers of each ligand, but the order of crystallisation was not predictable and in some cases the $PF_6^-$ salt was formed but in others the $Cl^-$ salt was isolated. Whilst it was possible to infer the absolute configuration in other cases by an accumulation of evidence (sign of optical rotation, sense of rhodium catalytic asymmetric hydroboration[7]) the furylphosphine **1d** proved anomalous. The (+)-isomer gave closely similar results in rhodium-catalysed asymmetric hydroboration to the (*R*)-(+)-isomer of **1a**, but the opposite hand of secondary alcohol was formed, indicating the (*S*)-(+) configuration for **1d**. This was confirmed by comparative CD spectra of (*S*)-(−)-**1a** and (−)-**1d** in $CHCl_3$ which are similar but mirror-related. It was observed that all the four pairs of diastereomeric complexes **2b–e** showed clear-cut behaviour in their electrospray mass spectra of 55 V; one of the pair was dominated by the parent $M^+$ and the other by the fragment $[M - 197]^+$. In each case it was the compound inferred to be the (*R*,*S*)-diastereomer which showed the strong parent peak and correspondingly the compound inferred to be the (*R*,*R*)-diastereomer which showed the strong fragment (Fig. 2). Hence the electrospray MS provides a simple and general method for defining the absolute configuration of the ligand. This is consistent with our earlier suggestions that the success of the palladium–naphthylamine resolving agent is due to enforced rigidity in the resolution complexes which specifically destabilises one diastereomer through unfavourable steric interactions.[4] Although these examples relate to P–N chelate ligands, some preliminary observations have been made which indicate that chiral diphosphines exhibit similar behaviour.[8]

The application of mass spectrometry to stereochemical problems is uncommon, although there are established cases where diastereomers can be identified from differences in their fragmentation patterns. For example, collision-induced dissociation is capable of defining ring-junction stereochemistry where that is the site of a retro-Diels–Alder reaction.[9] Electrospray MS in tandem with cone-voltage CID has been used to distinguish between $C_2$-epimeric pairs of ammine–nickel glycoside complexes.[10] The present case provides a simple method for direct assay of the configuration of a family of ligands useful in asymmetric catalysis, which may have more general applicability.

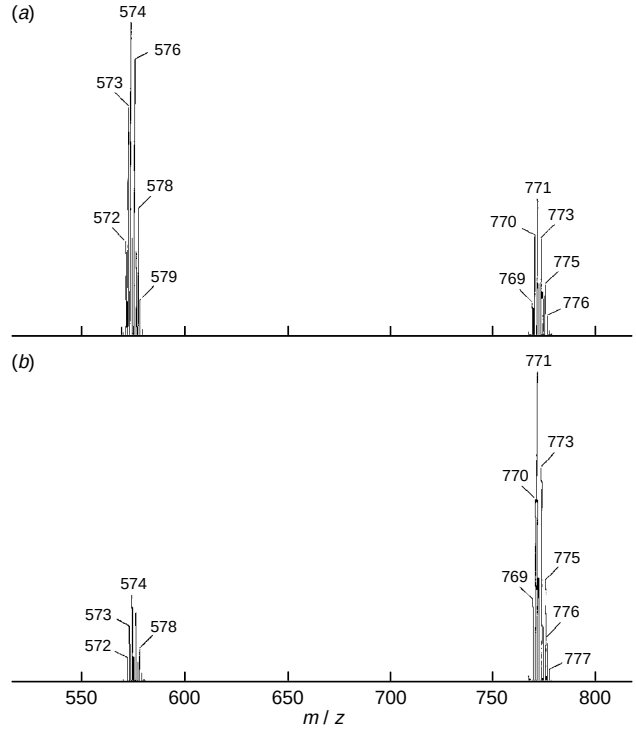

**Fig. 2** The electrospray mass spectra of (*a*) the (*R*,*R*) and (*b*) the (*R*,*S*) isomers of complex **2b** taken at a cone voltage of 55 V from a *ca.* 1% solution in MeCN–MeOH

We thank the EPSRC for support under the Catalysis Initiative to (H. D.) and for a Quota Studentship to (M. W. H.). Johnson-Matthey kindly provided a loan of Pd salts. Supporting CD spectra from the EPSRC Chiroptical Spectroscopy Service are gratefully acknowledged.

# Synthesis and characterization of high-nuclearity osmium–rhodium mixed-metal carbonyl clusters; molecular and crystal structures of $[Os_{12}Rh_9(CO)_{44}(\mu_3\text{-}Cl)]\cdot 2CH_2Cl_2$ and $[Os_4Rh_3(\mu_3\text{-}H)(CO)_{14}(\mu_3\text{-}CO)(\eta^4\text{-}C_7H_8)_2]$

**Sarah Yeuk-Wah Hung and Wing-Tak Wong***

*Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong, PR China*

**The anionic triosmium cluster $[N(PPh_3)_2][Os_3(\mu\text{-}H)(CO)_{11}]$ reacts with $[Rh(nbd)Cl)_2$ (nbd = norbornadiene) in the presence of $AgPF_6$ to give two new high-nuclearity osmium–rhodium clusters $[Os_{12}Rh_9(CO)_{44}(\mu_3\text{-}Cl)]$ 1 and $[Os_4Rh_3(\mu_3\text{-}H)(CO)_{14}(\mu_3\text{-}CO)(\eta^4\text{-}C_7H_8)_2]$ 2 in moderate yields.**

Mixed-metal clusters of osmium and rhodium are of interest as the rhodium tends to have a stable, coordinatively unsaturated 16 electron configuration,[1] while the osmium clusters display very rich chemistry and are kinetically stable. In addition, both osmium and rhodium metals have a well established background of catalytic applications.[2–6] One route to synthesize the mixed-metal osmium clusters is *via* nucleophilic addition of rhodium reagents to the coordinatively unsaturated cluster $[Os_3(\mu\text{-}H)_2(CO)_{10}]$ which has been extensively applied for the development of Os–Rh clusters.[7] An obvious alternative route into these systems is the interaction of the anion $[Os_3(\mu\text{-}H)(CO)_{11}]^-$ and cationic rhodium fragment but this has previously met limited success. However, this kind of ionic coupling strategy works well in many other mixed-metal systems.

Herein we report the reaction of a cationic mononuclear rhodium complex, $[Rh(nbd)]^+$,[8] (nbd = norbornadiene) with the anionic carbonyl cluster, $[Os_3(\mu\text{-}H)(CO)_{11}]^-$, which results in a novel class of high-nuclearity mixed-metal osmium–rhodium clusters. A mixture of $[Rh(nbd)Cl]_2$ and $AgPF_6$ (1 : 1) in thf was filtered and then treated with $[N(PPh_3)_2][Os_3(\mu\text{-}H)(CO)_{11}]$ under nitrogen at room temp.[9] An immediate change from red to brown was observed. Separation of the brown solution by TLC on silica [eluent: *n*-hexane–dichloromethane (1 : 4)] gave red $[Os_{12}Rh_9(CO)_{44}(\mu\text{-}Cl)]$ **1** (20%) and brown $[Os_4Rh_3(\mu_3\text{-}H)(CO)_{14}(\mu_3\text{-}CO)(\eta^4\text{-}C_7H_8)_2]$ **2** (10%) together with two uncharacterized products in low yield. Complexes **1** and **2** were fully characterized by spectroscopic techniques† and X-ray crystallography.‡

Single crystals of $\mathbf{1}\cdot 2CH_2Cl_2$ suitable for X-ray analysis were obtained by slow evaporation of a $CH_2Cl_2$–*n*-hexane solution. Its molecular structure, together with some important bond parameters, is depicted in Fig. 1. The structure of **1** [Fig. 1(*a*)] can be viewed as four '$Os_3(CO)_{11}$' units clipping onto the nanorhodium cluster metal core so that an asymmetric metal core results as illustrated in Fig. 1(*b*). The $Rh_9$ core geometry may be described as the fusion of an octahedron, Rh(1)Rh(2)Rh(3)Rh(4)Rh(5)Rh(6), with another virtual octahedron, Rh(4)Rh(5)Rh(6)Rh(7)Rh(8)Rh(9), in which there is no direct bonding between Rh(7) and Rh(9) or Rh(8) and Rh(9).

(*b*) The metal core geometry of **1**.

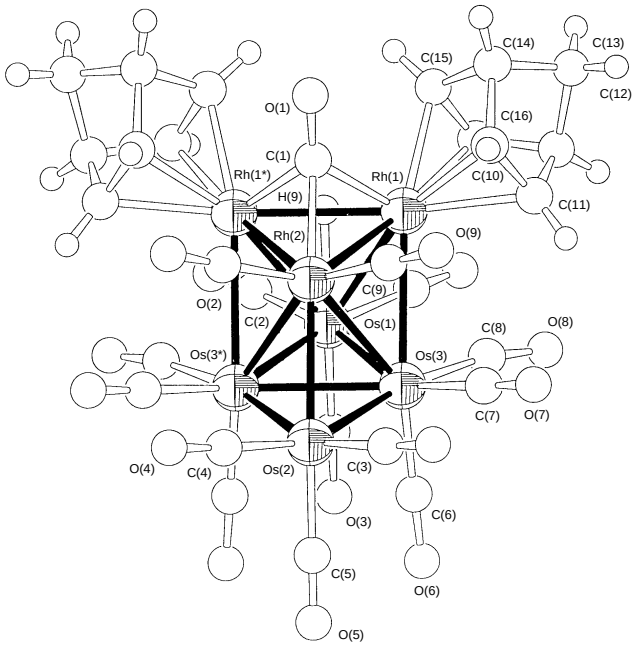

**Fig. 2** Molecular structure of the cluster $[Os_4Rh_3(\mu_3\text{-}H)(CO)_{14}(\mu_3\text{-}CO)(\eta^4\text{-}C_7H_8)_2]$ **2** showing the atom numbering scheme. Selected bond lengths (Å) and angles (°): Os(1)–Os(3) 2.839(1), Os(2)–Os(3) 2.800(1), Os(3)–Os(3*) 2.795(2), Os(1)–Rh(1) 3.003(2), Os(2)–Rh(2) 2.741(3), Os(3)–Rh(1) 2.915(2), Rh(1)–Rh(1*) 2.847(4), Rh(1)–Rh(2) 2.761(3), Rh(1)–C(1) 2.15(2), Rh(2)–C(1) 2.11(3), Rh(1)–C(10) 2.22(2), Rh(1)–C(11) 2.24(3), Rh(1)–C(15) 2.19(2), Rh(1)–C(16) 2.21(2), Os(1)–H(9) 2.03, Rh(1)–H(9) 1.85, O(1)–C(1) 1.19(3); Rh(1)–C(1)–Rh(1*) 83.1(9), Rh(1)–C(1)–Rh(1*) 83.0(9), Rh(1)–C(1)–Rh(2) 80.9(8), Os(1)–H(9)–Rh(1) 101.5, Rh(1)–H(9)–Rh(1*) 100.8.

In the $Rh_9$ core, one chloro-ligand caps onto three rhodium atoms, Rh(7), Rh(8) and Rh(9), and the rest of rhodium atoms, Rh(1), Rh(2), Rh(3), Rh(4), Rh(5) and Rh(6), have no ligand groups attached to them but are coordinated to metal atoms only. A salient structural feature of **1** is these relatively exposed Rh atoms which may facilitate the coordination of nucleophiles. All the carbonyl ligands are essentially terminally bonded to the osmium atoms except an incipient bridging CO interaction which is found between Os(4) and Rh(3), [Rh(3)···C(12) 2.44(3) Å]. However, in solution all carbonyls are terminally bonding as suggested by IR spectroscopic data. We do not detect any hydride in the variable-temperature $^1$H NMR studies [−50 to 25 °C]. Although satisfactorily elemental analysis was obtained, a satisfactory mass spectrum of **1** cannot be obtained by either EI, FAB or ESI techniques. If the triosmium units are each considered to have a formal 2− charge, $[Os_3(CO)_{11}]^{2-}$, each rhodium atom should be in an oxidation state of +1. Cluster **1** contains 50 metal–metal bonds and 268 cluster valence electrons (CVE) and hence does not obey the simple electron counting rules.[10–12] This is not entirely unexpected as it is common for rhodium to have a stable 16 electron configuration.

Brown crystals of **2** were grown from a $CH_2Cl_2$–*n*-hexane solution of the complex. A perspective drawing of cluster **2** with atomic numbering scheme is shown in Fig. 2 together with some selected bond parameters. Cluster **2** is much more symmetrical and consists of a crystallographic mirror plane that relates the two halves of the molecules. The metal framework contains a mixed-metal monocapped octahedron with four osmium atoms and three rhodium atoms. A $\mu_3$-bridging hydride capping the Os(1)–Rh(1)–Rh(1*) face is suggested by potential-energy calculations[13] and supported by $^1$H NMR spectroscopic measurements and difference Fourier synthesis based on log-angle data in the X-ray analysis. The metal core geometry of cluster **2** is similar to that of $[Os_7(CO)_{21}]$,[14] where both compounds have 98 CVE. This can be rationalised by the polyhedral skeletal electron pair theory[15] and the condensed polyhedral approach.[16] The mechanisms of formation of **1** and **2** have not been established. However, it seems reasonable to suggest that $[Rh(nbd)Cl]_2$ undergoes chloride dissociation upon reaction with silver(I) salts to give the active rhodium reagent, $[Rh(nbd)]^+$,[8] which reacts with the osmium cluster anion, $[Os_3(\mu\text{-}H)(CO)_{11}]^-$ *via* a complicated redox condensation, instead of a simple ionic coupling reaction. Cyclic voltammetric studies of $[N(PPh_3)_2][Os_3(\mu\text{-}H)(CO)_{11}]$ in thf at 25 °C showed an irreversible oxidation at +0.66 V *vs*. $Ag/AgNO_3$ while the preformed $[Rh(nbd)]^+$ cation showed an irreversible reduction at −0.02 V in thf *vs*. $Ag/AgNO_3$.[17] Further work on the mechanistic details and the chemical reactivities of these new high-nuclearity clusters is in progress.

# Toward lanthanide-containing metallomesogens with tridentate ligands

**Homayoun Nozary,[a] Claude Piguet,*[a] Paul Tissot,[a] Gérald Bernardinelli,[b] Robert Deschenaux*[c] and Maria-Teresa Vilches[c]**

[a] *Department of Inorganic, Analytical and Applied Chemistry, University of Geneva, 30 quai E. Ansermet, CH-1211 Geneva 4, Switzerland*

**Tridentate aromatic receptors L¹–L⁴ containing the 2,6-bis-(benzimidazol-2-yl)pyridine chelating unit are designed to exhibit thermotropic calamitic liquid-crystalline phases; the mesomorphic behaviour is essentially retained in the complex [LuL²(NO₃)₃].**

We have recently launched into a research program aimed at developing lanthanide building blocks with tailored tridentate binding units.[1] It is now possible to finely control and tune the thermodynamic, structural, electronic and magnetic properties of the resulting mononuclear 1 : 1 and 1 : 3 complexes.[2–4] The incorporation of these building blocks into extended organized polynuclear architectures has been demonstrated,[4–6] but this approach is severely limited by the large amount of structural information required by segmental ligands for the selective recognition of 4f-block metal ions.[5,6] An alternative approach could take advantage of the molecular order associated with liquid-crystalline phases. Only a few lanthanide-containing metallomesogens have been prepared[7] and none with tridentate ligands, most likely as a consequence of their bent arrangement which results upon coordination.

**Scheme 1** *Reagents*: i, $EtNH_2$, EtOH; ii, pyridine-2,6-dicarbonyldichloride, $NEt_3$, $CH_2Cl_2$; iii, Fe, HCl–EtOH–$H_2O$; iv, $BBr_3$, $CH_2Cl_2$; v, $CH_2Cl_2$; vi, $NBu_4OH$, $CH_2Cl_2$

We report here on the design of semi-rigid tridentate receptors tailored for the preparation of calamitic lanthanide-containing liquid crystals. Substituted 2,6-bis(1′-ethylbenzimidazol-2′-yl)pyridine binding units (L¹–L⁴) have been selected for their peculiar electronic and structural properties which fit the $Ln^{III}$ stereochemical preferences, leading to stable complexes with predetermined properties.[3,8] Semi-rigid lipophilic substituents have been connected to the 5-positions of the benzimidazole rings in order (*i*) to extend the rigid core and the axial anisotropy, (*ii*) to improve intermolecular interactions and (*iii*) to limit the stability of the crystalline phase owing to flexible lipophilic chains. The spacers between the tridentate unit and the *para*-substituted phenyl side-arms are crucial since they must be flexible enough to allow the ligands to adopt suitable conformations in the free form (*trans–trans*)[5] and in the complexes (*cis–cis*), and rigid enough to ensure a rod-like shape compatible with the formation of calamitic mesophases. The synthons **1** and **2** are obtained in satisfying yields (28 and 38%, respectively) according to a multistep strategy based on the recently developed cyclisation of unsymmetrical benzimidazole rings from *N*-(2-nitroaryl)arenecarboxamide (Scheme 1).[9] Nucleophilic substitutions using **1** as electrophile give L¹, L² and L⁵. Deprotonation of **2** with $NBu_4OH$ followed by alkylation or acylation provides the ligands L³ and L⁴.

$^1H$ NMR nuclear Overhauser enhancement effects (NOE) in solution suggest that the tridentate units adopt the expected *trans–trans* conformation in all free ligands L¹–L⁵, which is confirmed in the solid state by the crystal structure of the non-mesogenic model compound L⁵ [N(4) is *trans* to N(3) and N(1) is *trans* to N(3), Fig. 1].† All C–C, C–N and C–O bonds are standard[10] and the $C_{ar}$–C–O–$C_{ar}$ atoms of the two spacers adopt all-*trans* conformations leading to an approximate rod-like shape of the receptor (Fig. 1). Reaction of L² with stoichiometric amounts of $Ln(NO_3)_3$ (Ln = La, Lu) in acetonitrile produces quantitatively the complexes $[LnL^2(NO_3)_3]\cdot nH_2O$ (Ln = La, *n* = 3; Ln = Lu, *n* = 1) where $Ln^{III}$ is nine-coordinated by the tridentate aromatic unit which adopts the *cis–cis* conformation (NOE effects observed between $H^{38}$–$H^{17}$) and three bidentate nitrate anions as similarly reported for the analogous complexes with unsubstituted 2,6-bis(1′-alkylbenzimidazol-2′-yl)pyridine ligands.[8,11]

The thermal and liquid-crystal properties were investigated by a combination of differential scanning calorimetry (DSC)

**Table 1** Phase-transition temperatures and enthalpy and entropy changes for ligands $L^1$–$L^4$ and complex $[LuL^2(NO_3)_3]\cdot H_2O$

| Compound | Transition[a] | $T$/°C | $\Delta H$/kJ mol$^{-1}$ | $\Delta S$/J mol$^{-1}$ K$^{-1}$ |
|---|---|---|---|---|
| $L^1$ | K–I | 107 | 80 | 211 |
| $L^2$ | K–$S_A$ | 132 | 50 | 122 |
| | ($S_C$–$S_A$)[b] | 98 | —[c] | — |
| | $S_A$–I | 188 | 17 | 37 |
| $L^3$ | K–$S_C$ | 131 | 35 | 86 |
| | $S_C$–$S_A$ | 217 | —[c] | — |
| | $S_A$–N | 223 | —[d] | — |
| | N–I | 226 | 7[e] | 14[e] |
| $L^4$ | K–$S_A$ | 144 | 28 | 66 |
| | ($S_C$–$S_A$)[b] | 107[f] | — | — |
| | $S_A$–I | 193 | 18 | 39 |
| $[LuL^2(NO_3)_3]$ | K–$S_A$ | 133 | 72 | 176 |
| | ($S_C$–$S_A$)[b] | 98 | —[c] | — |
| | $S_A$–I | 188 | 23 | 50 |

[a] K = crystal, $S_C$ = smectic C phase, $S_A$ = smectic A phase, N = nematic phase, I = isotropic fluid; temperatures are given as the onset of the peak (Seiko DSC 220C differential scanning calorimeter, 5 °C min$^{-1}$, under $N_2$); the liquid crystalline phases were identified from their optical textures: $S_C$ = broken focal-conic fan and *schlieren* textures; $S_A$ = focal-conic fan texture and homeotropic zones; N = *schlieren* and marbled textures. [b] Monotropic transition. [c] Second-order transition determined by polarized optical microscopy. [d] Masked by isotropization. [e] Cumulated enthalpies and entropies. [f] Approximate value: the $S_C$ phase formed during the crystallization process.

and polarized optical microscopy (Table 1). The ligand $L^1$ (three-atom spacers) does not show mesogenic behaviour. However, the ligands $L^2$–$L^4$, which possess two-atom spacers, display interesting mesomorphism: they all present disordered smectic C and smectic A phases. An additional nematic phase is obtained for $L^3$. Interestingly, the mesomorphic behaviour of $L^2$ is essentially retained in the lanthanide complexes. In $[LaL^2(NO_3)_3]\cdot 3H_2O$, the melting process (130 °C) is associated with a fast decomposition which prevents an unambigous characterization of the mesophase(s), but the analogous complex $[LuL^2(NO_3)_3]\cdot H_2O$ melts at 133 °C to give a stable $S_A$ phase which isotropizes at 188 °C. Although the temperatures of the $K \rightarrow S_A$ and $S_A \rightarrow I$ transitions are similar for $L^2$ and its complex $[LuL^2(NO_3)_3]\cdot H_2O$, the enthalpy and entropy changes are significantly larger for the latter compound.

In conclusion, two-atom spacers as in $L^2$–$L^4$ are suitable for the incorporation of bent tridentate units into rod-like shape receptors exhibiting thermotropic calamitic behaviours. A fine tuning of the thermal properties results from the nature of the spacer, while metallic size effects are responsible for the larger stability of the Lu complex as previously reported for other lanthanide-containing metallomesogens.[7] The introduction of spectroscopically and magnetically active $Ln^{III}$ into smectic phases is currently under investigation.

# The first synthetic microporous yttrium silicate containing framework sodium ions

**João Rocha,* Paula Ferreira, Zhi Lin, Paula Brandaõ, Artur Ferreira and Júlio D. Pedrosa de Jesus**

*Department of Chemistry, University of Aveiro, 3810 Aveiro, Portugal*

**The synthesis and structural characterization of AV-1, the first synthetic microporous yttrium silicate containing stoichiometric amounts of framework sodium cations, are reported.**

Recently, much research has been carried out aimed at preparing inorganic microporous framework solids containing metal atoms in different coordination geometries. Two such families of materials are of considerable interest, microporous titanosilicates (known at ETS materials) and derivatives contain $Ti^{4+}$ usually in octahedral coordination,[1,2] while porous molybdophosphates display an amazing variety of crystal structures.[3] We have been interested in the synthesis of microporous framework silicates of several elements of the Periodic Table.[4,5] When attempting to prepare yttrium silicates we have obtained a synthetic analogue (named AV-1, Aveiro microporous solid no. 1) of the rare mineral montregianite (Mont St-Hilaire, Québec, Canada), $Na_4K_2Y_2Si_{16}O_{38}\cdot 10H_2O$, which possesses a most unusual structure.[6,7] In montregianite the sodium (and yttrium) cations are an integral part of the framework. In sharp contrast, in zeolites and zeolite-type materials the charge-balancing sodium cations usually reside within the channels and, thus, are not part of the framework.

AV-1 of composition (determined by bulk chemical analysis and TG) $Na_2KYSi_8O_{19}\cdot 5H_2O$, was prepared in Teflon-lined autoclaves under hydrothermal conditions. An alkaline solution was prepared by mixing 5.07 g sodium silicate solution (27% m/m $SiO_2$, 8% m/m $Na_2O$, Merck), 18.26 g $H_2O$, 0.20 g KOH (Carlo Erba), 0.29 g NaOH (Merck) and 0.22 g NaCl (Aldrich). $Y_2(SO_4)_3\cdot 8H_2O$ (Aldrich) (1.73 g) was added to this solution and stirred thoroughly. The gel with composition 0.53 $Na_2O$ : 0.078 $K_2O$ : 1.0 $SiO_2$ : 0.12 $Y_2O_3$ : 44 $H_2O$ was autoclaved for 6 d at 230 °C. The crystalline product was filtered, washed with distilled water and dried at ambient temperature, the final product being an off-white microcrystalline powder.

The crystal structure of montregianite consists of two different types of layers alternating along the [010] direction (Fig. 1): (*a*) a double silicate sheet, where the single silicate sheet is of the apophyllite type with four- and eight-membered rings, and (*b*) an open octahedral sheet composed of $[YO_6]$ and three distinct $[NaO_4(H_2O)_2]$ octahedra. The layers are parallel to the (010) plane. The K atoms are ten-coordinate and the six water molecules (not shown) are located within large channels formed by the planar eight-membered silicate rings.

The powder X-ray diffraction patterns of AV-1 and montregianite[6] (Fig. 2) are similar. The small differences observed are mainly due to the fact that extensive framework substitution of Y and Si by Ca, Mg, Ba and Al, respectively, occurs in the mineral.[6] The unit-cell parameters of AV-1 have been calculated assuming a monoclinic unit cell ($P2_1/n$, $Z = 2$)[7] and cell dimensions $a = 9.595$, $b = 23.956$, $c = 9.583$ Å, $\beta = 93.850°$.

The AV-1 $^{29}Si$ solid-state MAS NMR spectrum (Fig. 3) displays two groups of resonances in the ranges $\delta -96$ to $-102$ and $-105$ to $-108$. The spectrum can be deconvoluted into eight peaks with equal intensities, revealing the presence in AV-1 of eight non-equivalent Si sites. In accord with this observation, the crystal structure of montregianite calls for the

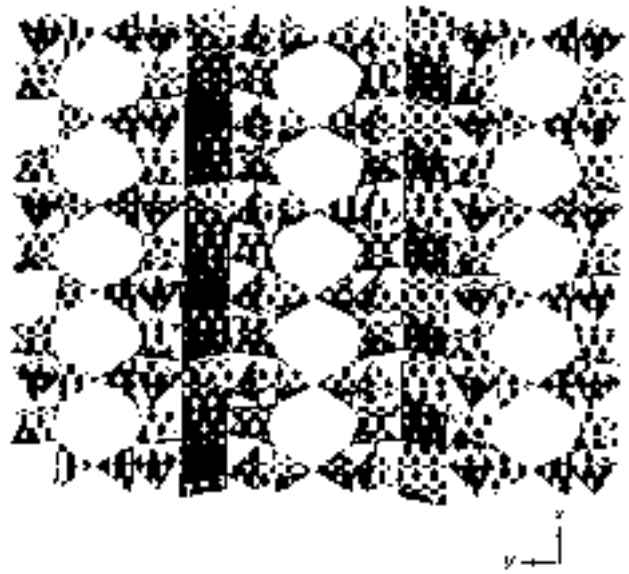

**Fig. 1** Polyhedral representation of the montregianite (and AV-1) structure viewed along [001] showing the alternating octahedral sheet and double silicate sheet along [010]

presence of eight unique Si sites with equal populations.[7] Two silicate tetrahedra [Si(1) and Si(4)], one each within the four-membered rings belonging to a single sheet, have upward-pointing apices [O(1)] which are shared with the apices of the two downward-pointing corresponding tetrahedra [Si(4) and Si(1), respectively] in the second silicate sheet.[7] Clearly, Si(1) and Si(4) are Si(4Si) environments (Si linked to four other Si *via* oxygen bridges) and the $^{29}Si$ MAS NMR resonances at $\delta -105.5$ and $-106.9$ are attributed to them. The assignment of the peaks at high frequency is more difficult. Si(6) is of the type Si(3Si, 1Y). Si(6)–O(12) is the shortest non-bridging bond length (1.562 Å) involving the most charge-deficient oxygen which is bonded to a Y atom.[7] Considering the well known correlation between the $^{29}Si$ chemical shifts and the SiO bond lengths in silicates,[8] we tentatively assign the peak at $\delta -100.8$

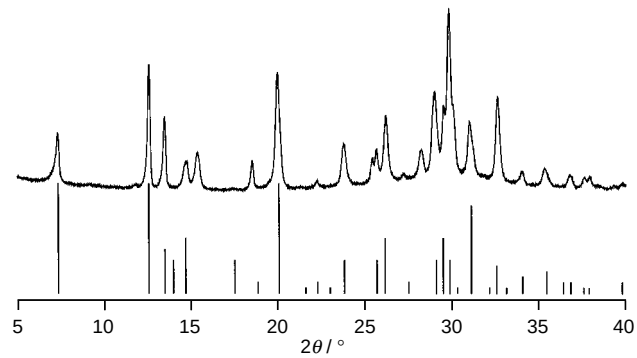

**Fig. 2** Powder XRD pattern of AV-1. For comparison, the solid lines depict the montregianite reflections.[6]

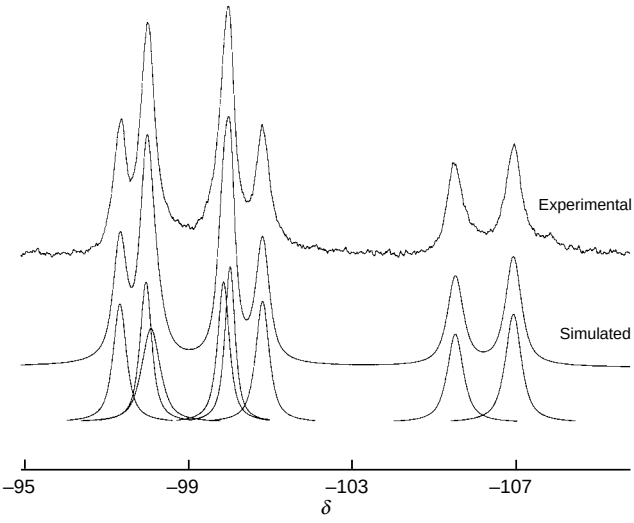

**Fig. 3** Experimental and simulated $^{29}$Si MAS NMR spectrum of AV-1 recorded at 79.5 MHz on a Bruker MSL 400P. Chemical shifts are quoted in ppm from $SiMe_4$.

to Si(6). The other five unique Si atoms are connected to three other silicons *via* bridging oxygens.[7] However, the fourth oxygen atom is non-bridging and is bonded to one Y and two Na atoms. [Si(2a) and Si(2b)] and [Si(5a) and Si(5b)] have very similar local environments and thus the resonances overlapping at $\delta$ *ca.* −98 and *ca.* −100 are probably associated with these sites. The resonance at $\delta$ −97.3 is assigned to the remaining Si(3) site.

The $^{23}$Na triple-quantum (3Q) MAS NMR spectrum[9] of AV-1 (not shown) displays two resonances with intensities close to 1 : 1. Although montregianite contains three non-equivalent Na sites the $[Na(2A)O_4(H_2O)_2]$ and $[Na(2B)O_4(H_2O)_2]$ octahedra (populations 0.47 and 0.45, respectively) are very similar in configuration and it is unlikely that they can be distinguished by solid-state $^{23}$Na NMR.[7] The $[Na(1)O_4(H_2O)_2]$ site (population 0.95) forms a weak seventh bond with O(5B) and is, thus, distorted. The 3Q peak S1 displays a relatively broad powder pattern and, hence, is ascribed to the distorted Na(1) site. S2 is assigned to sites Na(2A) and Na(2B). The single-quantum ('normal') spectrum (not shown) can be simulated assuming the presence of two resonances, ascribed to sites Na(1) and [Na(2A) and Na(2B)], with intensities of *ca.* 1 : 0.9 and the following parameters: isotropic chemical shifts: $\delta$ 1.8 and 9.0 (from 1 M aqueous NaCl); quadrupole coupling constants 1.92 and 1.24 MHz; asymmetry parameters 0.50 and 1.0, respectively.

The Raman spectrum of AV-1 (not shown) displays a main, strong and sharp, peak at 607 $cm^{-1}$ which we assign to relatively undistorted $[YO_6]$ octahedra. Indeed, in montregianite the $[YO_6]$ octahedron is fairly regular.[7]

The Fourier transform infrared spectra of AV-1 (not shown) and montregianite[6] are very similar. In particular, the medium intensity band at 1630 $cm^{-1}$, due to the H–O–H bending, confirms that water is present in the structure. Three O–H stretching bands are observed at 3610, 3510 and 3460 $cm^{-1}$.

Thermogravimetry (TG) and differential scanning calorimetry (DSC) data (not shown) provide further evidence that the structures of AV-1 and montregianite[6] are very similar. The dehydration of AV-1 is essentially complete at *ca.* 450–500 °C and the total mass loss is 11.4%. AV-1 materials calcined at 650 °C and rehydrated overnight at room temperature display TG and DSC curves similar to the parent solid. Three stages of dehydration occur, at *ca.* 20–80 °C (loss of disordered zeolitic water molecules adsorbed within the channels), 80–200 °C and 200–450 °C.

In conclusion, the novel synthetic microporous yttrium-silicate AV-1 and the rare mineral montregianite possess the same structure. These materials contain stoichiometric amounts of sodium cations which are an integral part of the framework and, thus, are fundamentally different from zeolites and other zeolite-type solids.

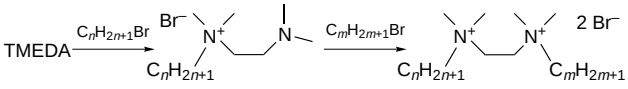
# Gemini surfactants, the effect of hydrophobic chain length and dissymmetry



**Reiko Oda,*[a] Ivan Huc[b] and Sauveur J. Candau[a]**

[a] *Laboratoire d'Ultrasons et de Dynamique des Fluides Complexes, 3 rue de l'Université 67084 Strasbourg Cedex, France*

**The synthesis of a new series of dimeric surfactants is reported; chain length and dissymmetry are shown to be critical factors for the richness of phases observed in water.**

In recent years, bis(quaternary ammonium) gemini surfactants have received increasing attention. Dimeric compounds with the structure $C_sH_{2s}$-α,ω-$(Me_2N^+C_mH_{2m+1}Br^-)_2$ which are referred to as *m*-*s*-*m*, show very low critical micellar concentrations (cmc) compared to the corresponding monomeric surfactants.[1] Some have been found to form giant worm-like micelles[2] at low concentration without any salt or hydrophobic counterions as was the case for the classically studied systems.[3,4] Zana and co-workers have reported detailed studies about the effect of the spacer chain length on the cmc of these surfactants as well as on the morphology of their aggregates.[5] Trimeric quaternary ammonium surfactants have also been prepared.[6] In this communication, we report on a new series of surfactants *n*-2-*m*, and on the effect of the dissymmetry of surfactant molecules on their self-assembled structures in aqueous solutions.

Their synthesis proceeds in two steps from *N*,*N*,*N*′,*N*′-tetramethylethylenediamine and two *n* and *m*-alkyl bromides. Thus, the diamine (0.1 mol) and the first alkyl bromide (0.8 equiv.) were heated in MeCN (250 ml) at 40 °C for 3 days. After evaporation and crystallisation from $Et_2O$, the corresponding pure alkyl dimethyl[1-(2-dimethylamino)ethyl] ammonium bromide was isolated in 70–80% yield. This compound (20 mmol) and the second alkyl bromide (4 equiv.) were refluxed in EtOAc (250 ml) for 2 days. After evaporation, the residue was recrystallised several times from $CHCl_3$–acetone yielding the *n*-2-*m* surfactant (50–60%).

When dissolved in water, the different surfactants assemble into various phases depending on their structure (Fig. 1). The symmetrical surfactants 14-2-14, 16-2-16, 18-2-18, as well as the almost-symmetrical surfactants 16-2-14 and 18-2-16 form turbid and rather viscous solutions which present a transition to isotropic and strongly viscoelastic phases upon heating. Rheometric studies (see below) allowed this latter phase to be characterised as entangled worm-like micelles. For the symmetrical surfactants, the solutions at room temperature are slightly birefringent. As shown in Fig. 2, DIC microscope observations reveal the presence of aggregated clusters of long and entangled tubule-like structures above 0.4, 0.2 and 0.1% for 14-2-14, 16-2-16 and 18-2-18 respectively. These tubules are quite stable and static, and their diameters do not exceed a micron. The phase observed with 16-2-14 at room temperature is somewhat different. It is also viscous, but shows much higher birefringence than those mentioned above. Microscopic observations show some indication of a lamellar phase. The phase observed with 18-2-16 also shows high birefringence, but the structure observed under the microscope was more reminiscent of a tubular phase. These structures as well as the nature of the transparent phase in-between are currently being investigated in detail by neutron scattering as well as with cryo-TEM.

The transition temperatures of these tubular/lamellar phases to worm-like micelles strongly depend on the overall length (*n* + *m*) as well as on the dissymmetry (*n* − *m*) of the surfactants (Fig. 1). The tubular/lamellar phases are more stable for longer chain lengths. In the symmetrical series, we observed a 15 °C drop in the transition temperature when both chains of a surfactant are shortened by two carbons, leading to transitions at 60, 45 and 30 °C for 18-2-18, 16-2-16 and 14-2-14 respectively.† Interestingly, the same 15 °C drop in transition temperature occurs when only one chain of a symmetrical surfactant is shortened by two carbons (*e.g.* from 18-2-18 to 18-2-16 or from 16-2-16 to 16-2-14). For example, 18-2-16 and 16-2-16, or 16-2-14 and 14-2-14 have almost identical transition temperatures. Thus, symmetry is a critical factor for the formation of the tubular/lamellar phases. In the range of *n* and *m* studied, these phases were never observed for $n - m > 2$ even for 18-2-14 which has the same overall chain length as 16-2-16.

Rheometric studies of the worm-like micellar phases obtained at high temperatures were performed, and we investigated the concentration dependence of the viscosity at low shear rate for various surfactants to determine the crossover concentration (overlap concentration) between dilute and semi-dilute regimes. Here, the crossover between these two regimes occurs when the micellar lengths become comparable to the screening length of electrostatic interactions. For salt-free worm-like micellar solutions, this happens approximately at the concentration at which the average distance between micelles equals the average length of micelles. As shown in Fig. 3, the overlap concentration of 16-2-16 is ten times lower than that of 14-2-14, which is itself ten times lower than that of 12-2-12. This can be

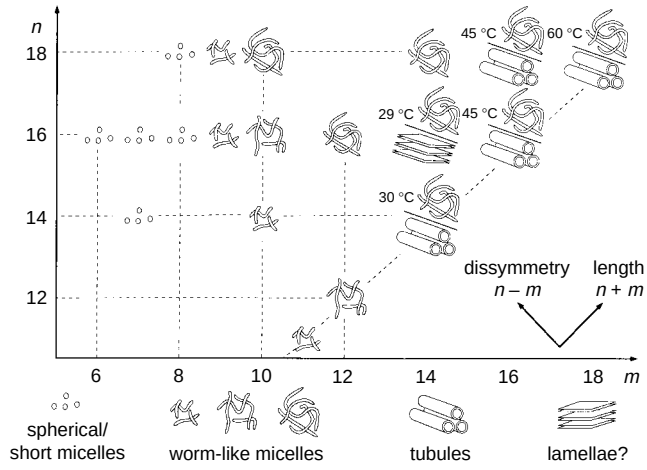

**Fig. 1** Phases observed in aqueous solutions of *n*-2-*m* surfactants as a function of *n* and *m*. The investigated concentrations were between 0.1 and 10% w/w (*ca.* 1.6–160 mM). Transition temperatures are indicated whenever a phase transition was observed upon heating. The worm-like micelles are divided into three categories according to their overlap concentrations: (*i*) lower than 0.5% w/w for the longer micelles; (*ii*) between 0.5 and 2%; (*iii*) between 2 and 10%.

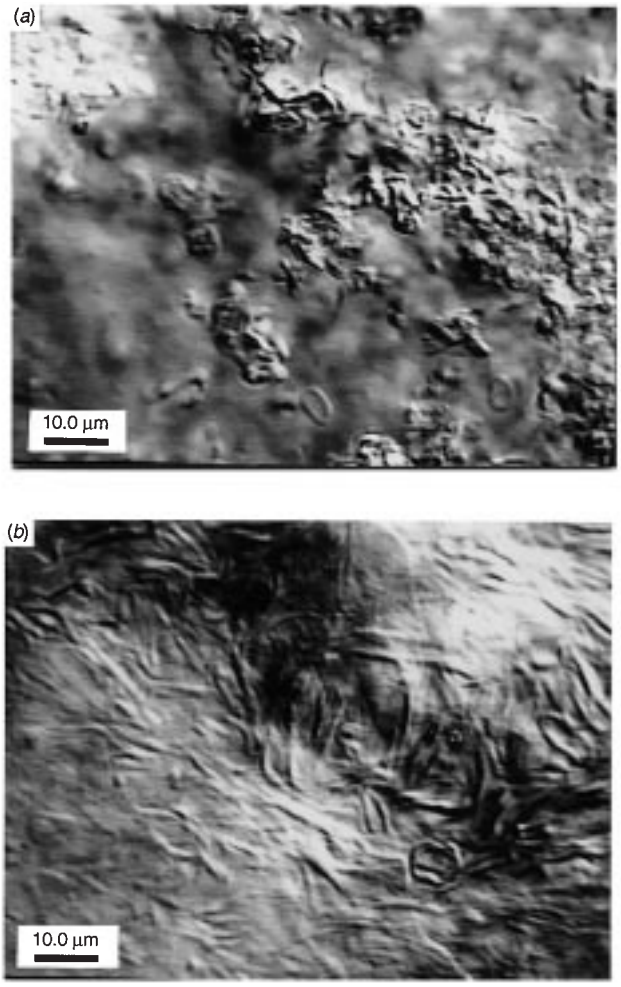

**Fig. 2** Tubule-like structures at room temperature in 1% solutions of (*a*) 16-2-16 and (*b*) 18-2-18. Observations were made with a video-enhanced differential interference contrast (DIC) Zeiss Axiovert 135 Microscope using a 100× objective (numerical aperture 1.3). The images were processed using a Hamamatsu CCD camera (C2400-77) and an Argus20 real time image processor.

understood geometrically as an increase of the spontaneous curvature for shorter hydrophobic chains.[7] A higher curvature reduces the cap-energy and favours the formation of shorter micelles.[8] It is striking that a 0.1% solution of 16-2-16 (1.6 mM) shows a viscosity of 0.15 Pa s at temperatures as high as 45 °C! In order to study the effect of the dissymmetry, we compared surfactants with the same $n + m$, but with different $n - m$: 12-2-12 *vs*. 14-2-10, 14-2-14 *vs*. 16-2-12 and 16-2-16 *vs*. 18-2-14. In all these cases, the symmetric surfactants showed higher viscosity and lower overlap concentrations. Thus, the dissymmetry also causes an increase of the spontaneous curvature. This effect is particularly pronounced when one chain is less than half the length of the other. The solutions are then fluid at all temperatures and at concentratons as high as 20%, indicating the presence of spherical or short micelles only. Rather than being true geminis, these surfactants feature a single hydrophobic chain linked to a very voluminous and polar head, which leads to a large spontaneous curvature.

The cmcs of the surfactants were measured by conductimetry. They show a monotonous decrease as the overall hydrophobic chain length is increased. The smallest measured cmc was that of 16-2-18, at 17 μM. The cmc of 18-2-18 was too low to be evaluated accurately with this technique. Surfactants with equal $n + m$ such as 12-2-12, 10-2-14 and 8-2-16, or 14-2-18 and 16-2-16 have similar cmcs. Unlike the other properties of the surfactant aggregates presented above, the cmc

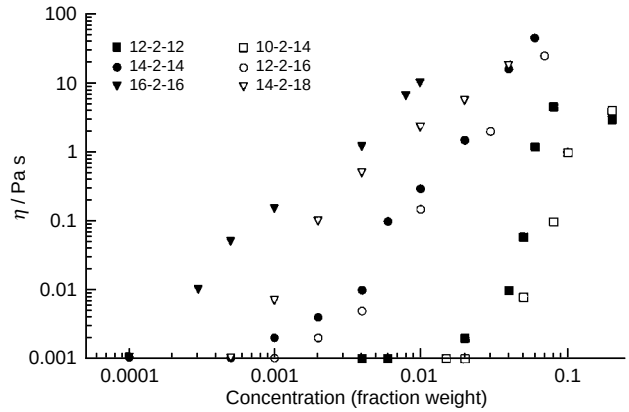

**Fig. 3** The low-shear viscosity ($\eta$) of 12-2-12, 14-2-14, 16-2-16, 14-2-10, 16-2-12 and 18-2-14 as a function of concentration at 45 °C. Measurements were performed with a Rheometrics Fluid Spectrometer RFS II.

does not depend on the symmetry but only on the overall hydrophobicity of the surfactant.

In conclusion, we have been able to correlate the morphology and the physical properties of the phases formed by new gemini surfactants with structural elements such as overall chain length and symmetry. Both decreasing the chain length and decreasing the symmetry result in larger spontaneous curvatures. This latter factor is particularly significant, allowing one to assess the arrangement of the surfactant hydrophobic chains in the various phases. Indeed, the increase in curvature for dissymmetric surfactants implies that in an aggregate, two diametrically opposed surfactant molecules cannot compensate their dissymmetry by overlapping their longer hydrophobic chains (see Graphical Abstract). The formation of pairs of surfactants spanning across a membrane in an arrangement comparable to that of bolamphiphiles is probably entropically disfavoured, and the thermal disorganisation of the hydrophobic chains proscribes such an overlap at the low concentrations studied. We are currently pursuing investigations to see whether interdigitation is possible in concentrated solutions of surfactants as was observed for hydrated dissymetrical phospholipids in the gel state.[9]

# New hydrotalcite-like anionic clays containing $Zr^{4+}$ in the layers

**S. Velu,[a] Veda Ramaswamy,[a] A. Ramani,[b] Bhanu M. Chanda[b] and S. Sivasanker*[a]**

**New hydrotalcite-like anionic clays containing $Zr^{4+}$ in the brucite-like layers are synthesised by a simple coprecipitation technique; these materials show very interesting properties as catalysts for liquid-phase hydroxylation of phenol with $H_2O_2$.**

Hydrotalcite (HT)-like anionic clays are a new family of interesting materials with applications as catalysts, catalyst supports, ion exchangers and composite materials.[1–3] The structure of these compounds can be visualised as being made of brucite [$Mg(OH)_2$]-like octahedral layers in which a part of $Mg^{2+}$ is isomorphously substituted by trivalent cations. The excess positive charge of the layer is compensated by hydrated anions, such as $CO_3^{2-}$, present in the interlayer. The materials are represented generally by the formula: $[M^{II}_{1-x},M^{III}_x,(OH)_2]^{x+}[(A^{n-})_{x/n}\cdot yH_2O]^{x-}$, where $M^{II}$ = $Cu^{2+}$, $Ni^{2+}$, $Co^{2+}$, $Zn^{2+}$, $Mn^{2+}$; $M^{III}$[4,5] = $Al^{3+}$, $Fe^{3+}$, $Cr^{3+}$, $Ga^{3+}$, $V^{3+}$, and more recently,[6] $Ru^{3+}$ and $Rh^{3+}$. A large number of HT-like compounds with a wide variety of cation pairs including a Co–$Ti^{IV}$ layered double hydroxide[7] have been reported in recent years. We now report the synthesis of a $Zr^{4+}$ containing HT-like material using a simple coprecipitation technique. The importance of Zr or Ti containing HT-like compounds stems from the fact that, similar to zeolites containing Zr (Zr-silicalites) or Ti (Ti-silicalites), they can be used as catalysts for liquid-phase hydroxylation/oxidation of various organic substrates.[8–11] In the present investigation, we report our preliminary studies on the synthesis of new Zr-containing anionic clays and their catalytic performance in the liquid-phase hydroxylation of phenol.

Zr-containing hydrotalcites with various Mg : Al : Zr atomic ratios were synthesized by a coprecipitation method at room temperature by reacting aqueous solutions containing a mixture of $Mg(NO_3)_2$, $Al(NO_3)_3$ and $ZrO(NO_3)_2$ and a mixture of NaOH and $Na_2CO_3$ at a constant pH (*ca.* 10). The resulting precipitate was filtered, washed with distilled water several times until the pH of the filtrate was 7 and then dried at 373 K overnight. The incorporation of Zr in the brucite-like layers was confirmed by powder X-ray diffraction (PXRD/Rigaku, D-MAX III VC model, with Ni-filtered Cu-K$\alpha$ radiation), UV–VIS diffuse reflectance spectroscopy (UV–VIS DRS; Shimadzu, UV–VIS Spectrophotometer 2101 PC model) and catalytic hydroxylation of phenol using hydrogen peroxide ($H_2O_2$) as the oxidant.

Fig. 1 shows the PXRD patterns of Mg : Al : Zr-HT with Mg : Al : Zr atomic ratio ranging from 3 : 1 : 0 to 3 : 0 : 1. A single phase corresponding to HT is obtained for all the samples although the crystallinity of the samples decreases with increasing Zr content (Table 1). A binary Zr containing HT without Al forms a poorly crystalline $ZrO_2$ phase [Fig. 1(*k*)] rather than a HT phase, indicating that the presence of Al favours the formation of a pure HT-like phase. The crystallographic parameters were evaluated employing least-squares refinement assuming a hexagonal crystal system for samples Zr0.0-HT–Zr0.6-HT whose PXRD peaks were intense and sharp enough for accurate determination. The increase in lattice parameters *a* and *c* with a concomitant increase in the unit cell volume *U* (Table 1) with increasing Zr content clearly demonstrates the effective incorporation of $Zr^{4+}$ in the HT framework. The increase in *a* can be attributed to the isomorphous substitution of $Al^{3+}$ (Shannon ionic radius 0.53 Å)[12] in the octahedral coordination by $Zr^{4+}$ (Shannon ionic radius 0.72 Å) in the HT matrix. The increase in *c* may be due to the weakening of the interaction between the brucite-like layer and the interlayer anions or due to the larger number of anions. Furthermore, since a part of the trivalent cation $Al^{3+}$ is being substituted by the tetravalent cation $Zr^{4+}$, the interlayer should accommodate more $CO_3^{2-}$ anions for charge compensation. This is supported by an increase in carbon content from 2.44% for Zr0.0-HT to 3.55% for Zr0.6-HT (Table 1). Hence, based on the chemical composition presented in Table 1, the Zr containing HT-like compounds with Mg/Al + Zr = 3 can be represented by the following general formula: $Mg_6Al_{2-x}Zr_x(OH)_{16}\cdot[(x + 2)/2]CO_3\cdot yH_2O$, where *x* can vary from 0 to at least 1.2.

Thermal calcination of these samples at 723 K results in the formation of an MgO phase whose *d*(200) value increases from 2.0934 Å for Zr0.0-HT to 2.1174 Å for Zr0.5-HT, indicating the dissolution of $Zr^{4+}$ in the MgO lattice. However, a poorly crystalline $ZrO_2$ phase, in addition to an MgO phase is noticed in the PXRD of the samples above Zr0.5-HT.

The dispersion of Zr in the HT framework was studied by UV–VIS DRS (Fig. 2). All these samples, including that

[a] Determined by X-ray fluorescence spectroscopy. [b] Determined by CHN microanalysis. [c] Refined using least square fitting method for hexagonal crystal system.

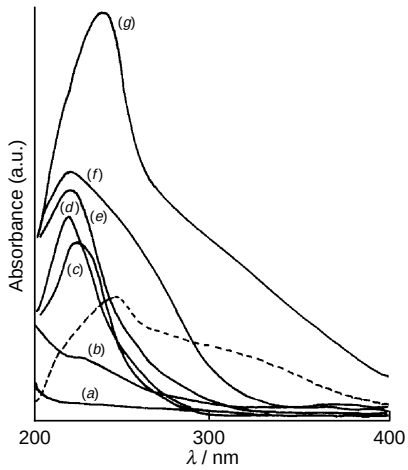

**Fig. 2** UV–VIS diffuse reflectance spectra of MgAlZr-HT: (*a*) Zr0.0-HT, (*b*) Zr0.1-HT, (*c*) Zr0.3-HT, (*d*) Zr0.3-CHT, (*e*) Zr0.5-HT, (*f*) Zr0.8-HT, (*g*) pure $ZrO_2$, (---) Zr0.0-HT + pure $ZrO_2$ (physical mixture)

calcined at 723 K [Fig. 2(*d*)], exhibited a single narrow band around 210 nm. This absorption band is attributed to charge transfer involving isolated $Zr^{IV}$ species.[9,10] Both pure $ZrO_2$ and a physical mixture of Zr0.0-HT and $ZrO_2$ exhibited bands around 240 and 320 nm. These results clearly demonstrate the absence of any $ZrO_2$ species within the sample and indicate that the $Zr^{4+}$ cations are well dispersed in the HT matrix, similar to that in Zr-silicates.[9–11]

Some of the Zr containing hydrotalcites have been tested as catalysts in the hydroxylation of phenol using $H_2O_2$ as the oxidant. Preliminary studies with $H_2O_2$/phenol ratios from 0.5 to 8 using solvents such as water, $CCl_4$ or MeOH did not show any catalytic activity. However, appreciable activity (up to around 10% conversion of phenol) was observed when light petroleum (bp 60–80 °C) was used as the solvent. Table 2 summarizes the results of hydroxylation of phenol over various Zr containing hydrotalcites. It is interesting to note from the Table that the turnover number (TON; moles of phenol converted per mole of Zr atom) increases four-fold (1.0 to 3.8) when $H_2O_2$ is added dropwise using a syringe pump. Similarly, a two-fold increase (1.0 to 1.9) in catalytic activity is noticed if the sample is calcined at 723 K for 5 h. In all these cases, catechol is obtained as a unique product (100% selectivity). Upon increasing the $H_2O_2$/phenol ratio, the TON also increases considerably, but the selectivity of catechol decreases at the expense of hydroquinone. The absence of catalytic activity in the case of pure MgAl-HT without Zr (Zr0.0-HT) or pure $ZrO_2$ clearly indicates that the Zr incorporated in the HT framework plays a pivotal role in catalytic activity. Surprisingly, under similar experimental conditions, the Zr-containing silicalite (ZrS-1) which showed appreciable conversion in aqueous medium,[8] is found to be inactive in the hydroxylation of phenol. Further work is in progress in order to investigate the above differences and also to compare the catalytic performance with new Ti-containing hydrotalcites.

**Table 2** Hydroxylation of phenol with $H_2O_2$ over MgAlZr-HT

| Catalyst | $H_2O_2$/phenol molar ratio | TON[a] | Product selectivity (mass%) | |
|---|---|---|---|---|
| | | | Catechol | Hydroquinone |
| Zr0.0-HT | 5.0 | — | — | — |
| Zr0.1-HT | 5.0 | 1.4 | 100 | — |
| Zr0.3-HT | 5.0 | 1.0 | 100 | — |
| Zr0.3-HT[b] | 5.0 | 3.8 | 100 | — |
| Zr0.3-CHT[c] | 5.0 | 1.9 | 100 | — |
| Zr0.3-HT | 7.0 | 29.1 | 73.8 | 26.2 |
| Zr0.3-HT | 10.0 | 40.5 | 65.1 | 34.9 |
| ZrS-1 | 5.0 | — | — | — |
| $ZrO_2$ | 5.0 | — | — | — |

[a] TON = Turnover number (mole of phenol converted per mole of Zr atom). [b] $H_2O_2$ was added dropwise using a syringe pump at a rate of 0.5 ml $h^{-1}$. [c] Sample calcined at 723 K for 5 h. *Reaction conditions*: solvent light petroleum (bp 60–80 °C) 30 ml; phenol, 1 g; catalyst, 100 mg; temperature 353 K; time 8 h.

Based on the above experimental evidence, we report that pure and crystalline Zr containing HT-like compounds can be easily synthesized by a simple coprecipitation method. The Zr atoms are highly dispersed in the HT matrix and the resulting Zr-HT-like compounds are active in the catalytic hydroxylation of phenol to catechol.

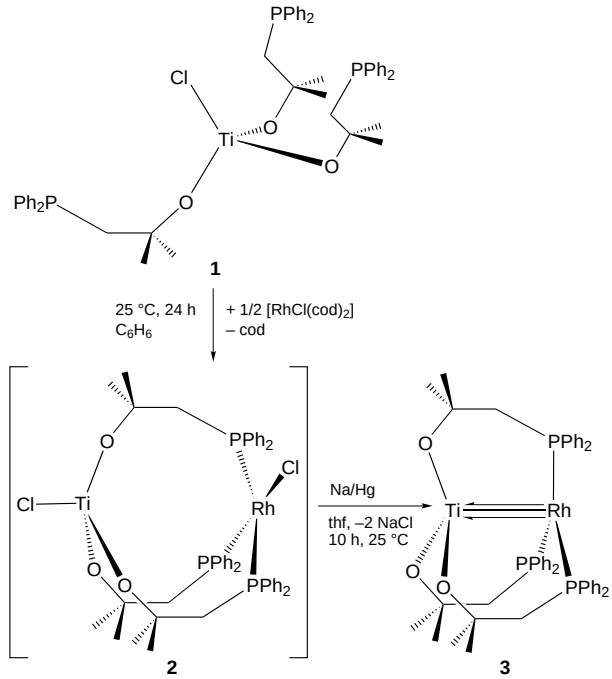
# Ti(μ : η¹,η¹-$OCMe_2CH_2PPh_2)_3$Rh has a cylindrically symmetric triple bond

**LeGrande M. Slaughter and Peter T. Wolczanski***

*Cornell University, Baker Laboratory, Department of Chemistry, Ithaca, New York, USA 14853*

**The cylindrical symmetry of Ti(μ : η¹,η¹-$OCMe_2CH_2PPh_2)_3$Rh permits maximum $Rh(d_\pi) \rightarrow Ti(d/p_\pi)$ overlap, resulting in a 2.2142(11) Å metal–metal triple bond.**



Aspects of heterogeneous materials exhibiting the strong metal–support interaction (SMSI)[1] have been modeled by homogeneous systems,[2–6] some containing M–M′ bonds of disparate metals.[5,6] Previously, we conducted an X-ray structural study of Cp*Zr(μ : η¹,η¹-$OCH_2PPh_2)_2RhMe_2$ (Cp* = η⁵-$C_5Me_5$) that revealed a short 2.444(1) Å ZrRh bond which was evaluated *via* extended Hückel molecular orbital (EHMO) calculations of an appropriately configured model, $Cp(HO)_2ZrRh(PH_3)_2Me_2$.[5] The metal–metal interaction, which is approximately 0.25 Å shorter than the sum of Zr (1.454 Å) and Rh (1.252 Å) covalent radii, was described in terms of a σ bond and a $Rh(d_\pi) \rightarrow Zr(d_\pi)$ bond. While the geometry of the alkoxyalkylphosphine bridges and the single critical π interaction resulted in a strong bond, at least by bond length criteria, the low symmetry of the complex prevented a second π interaction from being significant. As a consequence, we turned our attention to the synthesis of a cylindrically symmetric metal–metal bond in order to increase and perhaps maximize the strength of π interactions between group 4 and 9 metal centers.[5,7,8]

Treatment of $TiCl_4(thf)_2$ with 3 equiv. of $LiOCMe_2CH_2PPh_2$[4] in benzene at 25 °C for 3 h afforded $(Ph_2PCH_2CMe_2O)_3TiCl$ **1**† as a viscous, clear yellow oil in 80% yield. Although **1** was typically contaminated with *ca*. 5% $HOCMe_2CH_2PPh_2$, this was of sufficient purity to continue. Upon stirring a benzene solution of tris(alkoxyphosphine)-titanium chloride **1** and 0.5 equiv. of $[RhCl(cod)]_2$[9] for 24 h at 25 °C, a color change from yellow to deep red was noted, and an amorphous red solid was isolated from hexane. The major product displayed broad resonances in its $^1H$ and $^{31}P\{^1H\}$ NMR spectra at 23 °C in $C_6D_6$, the latter implying a 2 : 1 ratio of bound and free phosphines, while the $^{31}P\{^1H\}$ NMR spectrum at −8 °C exhibited broad, complex multiplets at $\delta$ 52.17 and 56.42 in a 2 : 1 ratio corresponding to bound phosphines. At −80 °C, we postulate the complex as ClTi(μ : η¹,η¹-$OCMe_2CH_2Ph_2P)_3RhCl$ (**2**, Scheme 1),† but suggest that dimerization to $[ClTi(OCMe_2CH_2Ph_2P)(\mu : \eta^1,\eta^1\text{-}OCMe_2CH_2Ph_2P)_2Rh]_2(\mu\text{-}Cl)_2$ is plausible at room temperature. Recrystallization and chromatographic purification efforts failed, and the chemical shifts attributed to impurities (*ca*. 20–25% integrated intensity) were consistent with the formation of various aggregates with bridging alkoxyalkylphosphines {*i.e.* $[TiCl(\mu : \eta^1,\eta^1\text{-}OCMe_2CH_2Ph_2P)_2ClRh(\mu : \eta^1,\eta^1\text{-}PPh_2CH_2CMe_2O)]_n$}.

Since **2** or any oligomeric variant could be a useful precursor to the desired heterobinuclear metal–metal bonded species, the red powder was reduced with 2 equiv. of Na/Hg in thf for 10 h at 25 °C. After separation from the salt and Hg, the resulting red–orange solid was dissolved in thf and chromatographed on basic alumina (activity I). The solid generated upon removal of thf was dissolved in toluene (60 °C) and crystallized at −78 °C to afford deep red Ti(μ : η¹,η¹-$OCMe_2CH_2Ph_2P)_3Rh$ **3**† as a $C_7H_8$ solvate in 24% overall yield. Reactivity studies implicated a robust titanium–rhodium bond: (*i*) no reaction with $H_2$ (10 equiv.) was observed upon heating in $C_6D_6$ at 140 °C for 2 weeks (sealed tube); (*ii*) reversible formation of a CO adduct, Ti(μ : η¹,η¹-$OCMe_2CH_2Ph_2P)_3RhCO$ **4**† was noted [ν(CO) 1956 $cm^{-1}$] and (*iii*) within 12 h, 2 equiv. of HCl converted **3** to precursor **2**, generating $H_2$ and a significant amount of impurities (*ca*. 50%) in the process.

An X-ray crystallograpic investigation of Ti(μ : η¹,η¹-$OCMe_2CH_2Ph_2P)_3Rh\cdot 0.5C_7H_8$, **3**·$0.5C_7H_8$, revealed a $C_3$ symmetry for the $O_3TiRhP_3$ core of **3** [dihedral angle $OTiRhP_{av}$ 15.8(20)°] that is broken when the external framework is included (Fig. 1). The OCCP bridge conformations adjust to maximize the number of favourable edge-to-face phenyl–phenyl interactions, thereby skewing the periphery.[10] A distorted trigonal monopyramidal geometry is evident for Rh, with Ti positioned apically and P–Rh–P angles of 113.22(5), 120.59(5) and 124.18(5)° describing an equatorial plane approximately perpendicular to the TiRh vector [Ti–Rh–P(1–3) 96.29(5), 89.72(5), 97.30(5)°]. The Ti center is roughly tetrahedral [O–Ti–O 107.7(2), 109.8(2), 112.4(2)°; $O–Ti–Rh_{av}$ 108.9(5)°] and the titanium–oxygen [$d(Ti–O)_{av}$ 1.830(3) Å] and rhodium–phosphine bond lengths [$d(Rh–P)_{av}$ 2.319(3) Å] are normal.

The titanium–rhodium bond distance of 2.2142(11) Å characterizes an extremely short heterobimetallic metal–metal bond. When compared to the sum of Ti (1.324 Å) and Rh covalent radii, the 0.362 Å reduction in bond length represents a large deviation (FSR = 0.860)[11] that supports formulation of a Ti≡Rh bond comprised of one $Ti(d/p_\sigma)–Rh(d/p_\sigma)$ and two $Rh(d_\pi) \rightarrow Ti(dTp_\pi)$ interactions. This appraisal is in accord with our EHMO investivations of Cp*Zr(μ : η¹,η¹-$OCH_2PPh_2)RhMe_2$,[5] and more recent Fenske–Hall calculations

**Scheme 1**

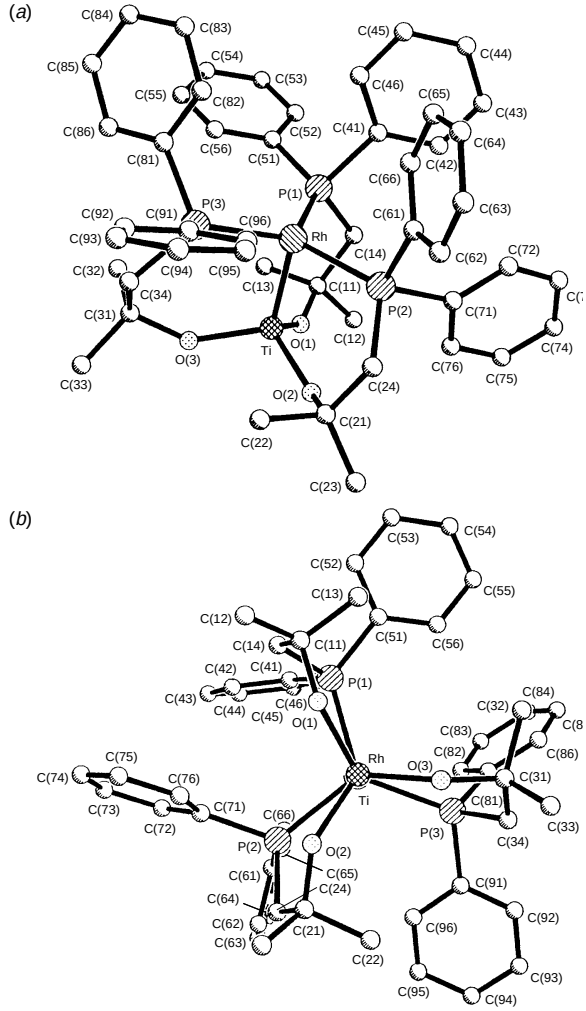


**Fig. 1** Side (*a*) and Ti–Rh parallel (*b*) views of Ti(μ : η¹,η¹-OC-$Me_2CH_2PPh_2)_3$Rh **3**. Selected (see text) interatomic distances (Å) and angles (°): Ti–Rh 2.2142(11), Ti–O(1) 1.833(4), Ti–O(2) 1.831(4), Ti–O(3) 1.827(4), Rh–P(1) 2.318(2), Rh–P(2) 2.316(2), Rh–P(3) 2.322(2); O(1)–Ti–Rh 109.5(1), O(2)–Ti–Rh 108.5(1), O(3)–Ti–Rh 108.9(1), Ti–O(1)–C(11) 143.8(3), Ti–O(2)–C(21) 137.9(4), Ti–O(3)–C(31) 144.1(3), O(1)–C(11)–$C_{av}$ 108.3(14), O(2)–C(21)–$C_{av}$ 109.0(25), O(3)–C(31)–$C_{av}$ 108.4(12), (O)C–C–$P_{av}$ 117.3(25), O(1)–Ti–Rh–P(1) 17.5(2), O(2)–Ti–Rh–P(2) 13.7(2), O(3)–Ti–Rh–P(3) 16.2(2).

on models of $\{MeC(CH_2NSiMe_3)_3\}MFe(CO)_2Cp$ (M = Ti, Sn) by Gade and coworkers.[7] While it is difficult to assess the influence of the alkoxyalkylphosphine bridges on *d*(Ti–Rh), none of the bond angles and distances are characteristically strained while imparting the desired cylindrical symmetry.

We thank the National Science Foundation and Cornell University for support of this research, and Emil B. Lobkovsky for experimental assistance in the X-ray crystallographic study.

# A simple synthesis for donor-stabilized $Ga_2I_4$ and $Ga_3I_5$ species and the X-ray crystal structure of $Ga_3I_5{\cdot}3PEt_3$

**Andreas Schnepf, Clemens Doriat, Evelyn Möllhausen and Hansgeorg Schnöckel***

*Institut für Anorganische Chemie, Universität Karlsruhe, Engesserstraße, 76128 Karlsruhe, Germany*

**The reaction of 'GaI' synthesized by ultrasonic irradiation of gallium and diiodine in the presence of phosphanes leads to new gallium subhalides in which gallium–gallium bonds are involved.**

The molecular chemistry of the heavier low-valent group 13 elements has gained special interest during recent years.[1] One reason for this rapid development is the cryochemical preparation method in which the high-temperature molecules AlX and GaX (X = Cl, Br, I) are trapped in suitable cooled solvents.[2] By this method donor-stabilized $Al_4I_4$[2] and $Ga_8I_8$[3] compounds can be synthesized.

A much more convenient starting material for many low-valent gallium species is $Ga_2Cl_4$, which consists of $Ga^+GaCl_4^-$ ions in the solid[4] as well as in the molten state.[5] By addition of arenes a series of $Ga^+$–arene compounds with interesting Ga–π interactions has been prepared.[6] On the other hand geniune gallium(II) species with Ga–Ga bonds are formed by addition of special donor compounds. $Ga_2Cl_4{\cdot}2$dioxane[7] was the first prominent example which was followed by the analogous bromides and very recently by two examples of donor-stabilized $Ga_2I_4$ compounds.[3,8] Here we present a new route to low-valent donor-stabilized, gallium iodides, based on a method described by Green *et al.*, in which pale green 'GaI' is formed from a reaction of gallium with iodine in toluene under ultrasonic conditions at *ca.* 35 °C;[9] however, no definite species have, as yet, been isolated.

On treating 'GaI' in toluene with $PEt_3$ at −78 °C a yellow solution was obtained which exhibited $^{31}P$ NMR signals at $\delta$ −24 and −8 (doublet, triplet, coupling constants of 35 Hz) and a singlet at $\delta$ −20, which provides evidence for new molecular species.

The solid metallic residue was analyzed to be elemental gallium. This means that the soluble compound cannot be a pure GaI species since the amount of gallium and iodine was originally 1 : 1.

When the yellow solution was concentrated two new species could be isolated. The first was obtained as a white solid at −78 °C. The white powder can be recrystallized from toluene to provide colourless crystals. X-Ray analysis indicates the formation of $(GaI_2{\cdot}PEt_3)_2$ **1**, the third example of donor-stabilized $Ga_2I_4$, $Ga_2I_4{\cdot}2AsEt_3$ **2**[8] and $Ga_2I_4{\cdot}2NEt_3$ **3**[3] having been characterized very recently.

These iodides exhibit the expected structure with tetrahedrally coordinated gallium atoms and gallium–gallium bonds, Fig. 1.

The gallium–gallium distances are nearly identical for **1** [243.6(2) pm] and **2** [242.8(2) pm] but are shorter than in **3** [249.8(7) pm]. These changes in bond length may be explained with a decrease of donor strength in the series $NEt_3 \rightarrow PEt_3 \rightarrow AsEt_3$. This interpretation is based on an increase of the I–Ga–I bond angle in the same direction [**3**, 101.83(5)°, **1** 107.64(4)°; **2**, 109.0(1)°], which demonstrates that a weaker donor bond is in line with a more $sp^2$-like geometry at the Ga atom.[10]

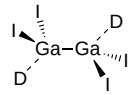

**Fig. 1** Schematic presentation of $GaI_2$ compounds (D = donor group)

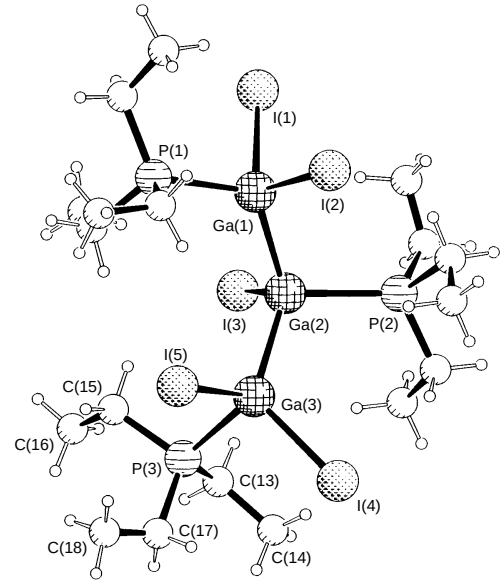
However, steric interaction may also influence the Ga–Ga distance since $Ga_2I_4{\cdot}2PPh_3$ **4**, which has been synthesized by ultrasonic treatment of 'GaI' with $PPh_3$ exhibits a Ga–Ga distance of 244.4(2) pm.

The second compound isolated from the yellow solution is $Ga_3I_5{\cdot}3PEt_3$ **5** and its molecular structure is shown in Fig. 2. It is the first neutral compound containing a $Ga_3$ unit (similar to $B_3F_5$[11]).

In **5** a $Ga^I$ centre is the bridging entity for two $Ga^{II}$ units with Ga–Ga distances of 245.1(1) and 246.0(1) pm. As expected, the Ga–I distances in the terminal $GaI_2$ units [261.0(1) pm], are shorter than for the central GaI [262.7(1) pm], a fact which is in line with the larger size of $Ga^I$ relative to $Ga^{II}$. The same argument is valid for the corresponding Ga–P distances: 242.7(3) and 240.5(3) pm. More unexpected are the $^{31}P$ NMR shifts in comparison with that of uncoordinated $PEt_3$ ($\delta$ −19). The shifts of the $PEt_3$ groups at the $Ga^{II}$ centers are observed at $\delta$ −24 and of $PEt_3$ at the central $Ga^I$ unit at $\delta$ −8. Owing to the more positively polarized P atom coordinated to $Ga^I$ ($\delta$ −8) and to a more tetrahedral like geometry at phosphorus [sum of C–P–C bond angles is 310.3(13)° cf. 320.5(7)° for terminally coordinated $PEt_3$ ligands] a stronger donor bonding from $PEt_3$ to $Ga^I$ than to $Ga^{II}$ is concluded.

The overall reaction pathway may be described by Scheme 1. This scheme demonstrates the easy synthesis of donor-



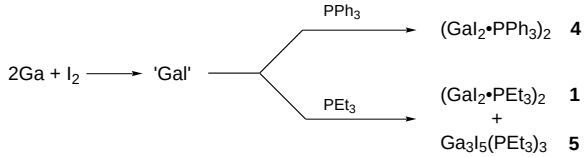


**Fig. 2** Perspective view of the molecular structure of $Ga_3I_5(PEt_3)_3$ **5**. **Scheme 1** Overall reaction pathway

stabilized low-valent gallium iodides, although it does not explain the reaction pathway. However, the results presented here are a strong encouragement to apply this simple synthetic method, besides co-condensation techniques, in order to prepare uncoordinated gallium subhalides.

# Synthesis of pure clinoptilolite without the use of seed crystals

**Craig D. Williams**

*School of Applied Sciences, University of Wolverhampton, Wulfruna Street, Wolverhampton, UK WV1 1SB*

**The present work re-examines the work of Chi and Sand together with that of Satokawa and Itabashi and reports the modifications required to obtain a pure clinoptilolite using conventional reagents, in the absence of seed crystals, at temperatures between 150 and 175 °C under autogeneous pressure.**

The natural zeolite clinoptilolite is widely distributed in nature, being the most abundant of natural zeolites.[1] However it has proved quite difficult to synthesise clinoptilolite under laboratory conditions. This has been ascribed to the rather narrow ranges of gel Si/Al and OH/Si ratios found to produced an acceptable final product. There have been three principal contributions to the synthesis of clinoptilolite in the laboratory. Hawkins *et al.*[2] produced Na,K-clinoptilolite, with the aid of seeds, at temperatures between 130 and 150 °C using volcanic glass as a reagent and high pressures, the final product was impure. Goto[3] produced Na,K-clinoptilolite from more standard chemical reactants at temperatures of 200 °C and autogeneous pressure, however the products were contaminated with mordenite. Chi and Sand[4] produced both Na,Na,K and K-clinoptilolite from standard laboratory reagents at temperatures between 120 and 200 °C and autogeneous pressure, using seed crystals. Recently Satokawa and Itabashi[5] reported the formation of Na,K-clinoptilolite, without the addition of seeds, using conventional chemical reagents.

The materials used in this work were as follows: Silica sources were fumed silica, 99.8 mass% [Cab-o-sil M5 (Carbot Corp; supplied by BDH)], colloidal silica, 40 mass% [Ludox AS40 and HS40 (Du Pont, supplied by Aldrich)]. Alumina sources were aluminium wire, 99.9 mass% (BDH), Versal 900 alumina, 72 mass% [pseudoboehmite (La Roche)], reagent-grade sodium and potassium hydroxide, 98+ mass% (Scientific & Chemical Supplies) and deionised water. The seed crystals (if used) were natural Anaconda 1010A clinoptilolite. Syntheses were carried out in 250 or 500 ml stainless steel autoclaves, stirred at 100 rpm at temperatures between 150 and 175 °C under autogeneous pressure. The reaction gels were prepared as follows; the alkali hydroxide was weighed out into a Teflon beaker and the required mass of aluminium wire or Versal 900 was added together with water (50 ml). This solution was stirred by hand and allowed to cool for 15 min. After this time the silica source was added, together with the outstanding water and the resultant gel was stirred electrically for 5 min until a fluid homogenised gel was obtained. If seed crystals were to be added they were added at this stage. The gel was then transferred to the autoclave and allowed to react for the required time. Both autoclaves were fitted with sampling devices to allow the degree of crystallization to be monitored. Once the gel had fully crystallized the products were recovered by filtration on a Buchner funnel and washed with water ($3 \times 50$ ml), they were then dried in air at 40 °C for 16 h. The synthesised samples were analysed by powder X-ray diffraction using a Philips PW1710 diffractometer utilizing Cu-K$\alpha$ radiation. The scan was run between $2\theta$ 3.5 and 50°, using a scan speed of 1° min$^{-1}$. The diffractometer is linked to a DEC 3100 MicroVAX using Sandman Search and Match routines to search the ICDD database. The purity of the natural and synthesised clinoptilolite was determined using Philips computerised quantitative software in conjunction with the ICDD database. Scanning electron microscopy (SEM) was performed on the samples using a Philips SEM 515 microscope.

[a] Derived by quantitative XRD analysis. [b] Reaction time.

The molar compositions used in this work and their original reference are detailed in Table 1. All experimental synthesis procedures were repeated three times to check for reproducibility. The powder X-ray diffractogram for the pure clinoptilolite sample is shown in Fig. 1. The mass% of the various phases formed are given in Table 2. Chemical analysis was carried out on the pure clinoptilolite sample using X-ray fluorescence analysis and thermal analysis, the results are shown in Table 3.

As can be seen, several attempts were made to repeat the work outlined by Chi and Sand, however, for each attempt the required phase, clinoptilolite, appeared elusive. It would appear that the substitution of Ludox AS40 for Ludox HS40 can lead to the successful synthesis of a pure clinoptilolite without the need to use seed crystals. It is well known that clinoptilolite has a high affinity for the ammonium ion and Ludox AS40 is stabilised by the ammonium ion, as opposed to Ludox HS40 which is sodium stabilised. It can also be seen that the fast dissolution characteristics of aluminium wire favour the formation of denser phases, with all reaction runs producing

**Table 3** Elemental compositions fo the pure clinoptilolite obtained

| Elemental oxide[a] | Conc. (%) |

[a] Determined by XRF and TG.

mixed final products. Therefore it would seem expedient to use an alumina source which dissolves into solution more slowly, such as the Versal 900 or similar hydrated aluminium oxides. Finally it can be concluded that it is difficult to synthesise clinoptilolite in the laboratory free from impurities and that pure clinoptilolite is transitory in nature. This observation may explain why so few reports of a successful pure clinoptilolite synthesis method can be found in the literature.

The author would like to thank Dr Mick Morris of British Gas for the gift of the 250 ml autoclave, Dr Alan Dyer for supplying the Anaconda 1010A natural clinoptilolite and La Roche for the Versal 900 alumina source.

# Peroxo-bridged dinuclear cobalt(III) complexes containing *N*-glycoside ligands from tris(2-aminoethyl)amine and D-glucose and their reversible dioxygen binding properties

**Tomoaki Tanase,*[a] Tomoko Onaka,[a] Masako Nakagoshi,[a] Isamu Kinoshita,[b] Kozo Shibata,[b] Matsumi Doe,[b] Junko Fujii[b] and Shigenobu Yano*[a]**

*Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630, Japan*
*Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 662 Japan*

**Peroxo-bridged dinuclear cobalt(III) complexes containing *N*-glycoside ligands from tris(2-aminoethyl)amine (tren) and D-glucose (D-Glc), $[\{Co[(D\text{-}Glc)_2tren]\}_2O_2]X_3\cdot 5H_2O$ (X = Cl 2, Br 3), and their reversible dioxygen binding properties are reported [$(D\text{-}Glc)_2$tren = bis(*N*-D-glucosyl-2-aminoethyl)(2-aminoethyl)amine].**

Interactions of carbohydrates with metal ions have become an important subject in bioinorganic chemistry, since many sugar-processing enzymes have been revealed to function with redox non-active metal ions such as $Mg^{2+}$, $Mn^{2+}$ and $Zn^{2+}$ in the active sites.[1] Elucidation of reactivity and behavior of sugars around redox active metal ions is also potentially important in relevance to ribonucleotide reductases which utilize non-haem diiron or coenzyme $B_{12}$ functional units.[2]

We have recently reported mononuclear cobalt(II) complexes ligated by a heptadentate *N*-glycoside formed from tris(2-aminoethyl)amine (tren) and mannose-type aldohexoses, $[Co\{(aldose)_3tren\}]X_2$ **1**, where $(aldose)_3$tren = tris(*N*-aldosyl-2-aminoethyl)amine, aldose = D-mannose (D-Man), L-rhamnose (L-Rha), and X = Cl, Br, $1/2SO_4$. Complex **1** showed a dynamic chiral inversion around the metal centre ($\Delta\leftrightarrow\Lambda$) induced by the interaction of sugars with the sulfate anion.[3] In general, mannose-type aldoses such as D-Man and L-Rha have 2,3-*cis* configuration and the sugar ring is axially oriented with respect to the chelate ring upon coordination through the 1,2-functional groups with the β-anomeric form being adopted.[4] The axial orientation of D-Man and L-Rha enables close sugar–sugar interactions around the metal centres.[5] The present study was carried out by utilizing D-glucose (D-Glc) as the sugar component, which has 2,3-*trans* configuration and was equatorially oriented on ligating through the 1,2-functional groups with the β-anomeric form being adopted.[4] We report herein novel μ-peroxo dicobalt(III) complexes supported by β-D-glucosyl polyamine ligands and their reversible dioxygen binding properties.

A methanolic solution of $Co^{II}X_2\cdot 6H_2O$ (X = Cl, Br) was treated in air with tris(*N*-D-glucosyl-2-aminoethyl)amine [$(D\text{-}Glc)_3$tren], which was prepared from D-glucose (D-Glc) and tris(2-aminoethyl)amine (tren) *in situ*. The resultant dark brown solution was chromatographed on a Sephadex LH-20 gel permeation column, eluted with methanol, and the brown band was collected. Slow evaporation of the solution yielded brown crystals formulated as $[\{Co[(D\text{-}Glc)_2tren]\}_2O_2]X_3\cdot 5H_2O$ (X = Cl **2**, Br **3**) in low yields, where $(D\text{-}Glc)_2$tren is bis(*N*-D-glucosyl-2-aminoethyl)(aminoethyl)amine.† Elemental analyses indicated that complexes **2** and **3** contained a *N*-glycoside ligand, $(D\text{-}Glc)_2$tren, formed by a loss of one D-glucose residue from $(D\text{-}Glc)_3$tren, per metal. The presence of a peroxo bridge between the two cobalt ions is demonstrated by the intense electronic absorption band around 400 nm (log $\varepsilon$ 3.46–3.58), corresponding to a peroxo–metal charge-transfer band, and the IR peak at 888 $cm^{-1}$ assignable to $\nu_{O-O}$. Two environmentally different D-glucose moieties were confirmed by the $^1H$ and $^{13}C$ NMR spectra of **3** in $D_2O$ assignments being carried out by combination of $^1H$–$^1H$ and $^{13}C$–$^1H$ COSY, HMBC, and HMQC NMR spectra. The *N*-glycosidic bond formation was unambiguously determined by the isotopic multiplets observed in the $^{13}C$ NMR spectrum in $D_2O$–$H_2O$ (1 : 1). Two resonances for the C(1) carbon atoms of D-glucose were observed as doublets owing to the isotope induced shifts of the neighboring N–H and N–D species.[6]†

ORTEP diagrams for the complex cation of **2** are illustrated in Fig. 1 and 2.‡ The complex cation consists of two $Co^{III}$ ions bridged by a peroxo unit [O(1)–O(2) 1.452(10) Å]. The cation has a pseudo-$C_2$ symmetry with respect to an axis passing through the middle of the O–O bond (Fig. 2). The metal–metal separation is 4.114(2) Å. Each cobalt ion is ligated by the *N*-glycoside, $(D\text{-}Glc)_2$tren, through the four nitrogen atoms and the C(2) oxygen atom of a sugar moiety together with the peroxide to give distorted *cis*-(O,O)-$[CoN_4O_2]$ octahedral geometry. The other D-glucose residue is anchored on the metal by only the *N*-glycosidic nitrogen atom; hydroxyl groups of the sugar lie away from the coordination sphere of the metal.[5] The $Co^{III}_2(\mu\text{-}O_2)$ core is supported by hydrogen bonds between the sugar moieties [O(112)···O(212) 2.42(1) Å, O(113)···O(213) 2.70(1) Å, O(122)···N(23) 2.95(1) Å, O(222)···N(13) 2.92(1)

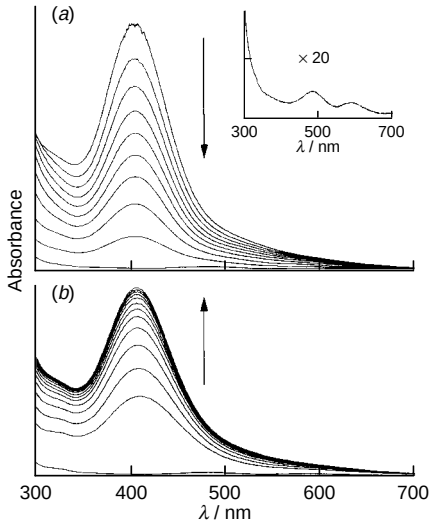

**Fig. 3** (*a*) An electronic absorption spectral change of **2** in $CH_3OH$ upon irradiation with a high-pressure mercury lamp at room temp. under a nitrogen atmosphere, monitored every 5 min. The final spectrum is expanded in the upper-right. (*b*) Absorption spectral changes measured in air every 5 min after the irradiation.

Å]. In particular, the short interatomic distance O(112)···O(212) suggests the presence of O$^-$···H–O type strong hydrogen bond, similar to that observed in the dinuclear nickel(II) complex bridged by a β-D-mannofuranoside residue.[7] This hydrogen-bonding system distorts the Co–O–O–Co torsional angle from planarity to 100.4(6)°, between 0–65° found in $Co^{III}_2(\mu\text{-}O_2)(\mu\text{-}X)$ double-bridged complexes (X = OH, NH) and 145–180° in $Co^{III}_2(\mu\text{-}O_2)$ single-bridged structures.[8]

The electronic absorption spectrum of **2** in methanol rapidly changed upon irradiation with a high-pressure mercury lamp at room temp. under a nitrogen atmosphere [Fig. 3(*a*)]. The absorption intensity around 400 nm, characteristic of a μ-peroxo dicobalt(III) complex, decreased and finally very weak absorptions around 480 and 590 nm were observed. This spectral change could correspond to deoxygenation of **2** leading to a cobalt(II) species and $O_2$, by analogy with the photolysis of $[(en)_2Co^{III}(\mu\text{-}OH)(\mu\text{-}O_2)Co^{III}(en)_2]^{3+}$ (en = 1,2-diaminoethane).[9]

When the resultant solution was exposed to air after irradiation, the absorption peak at 400 nm was immediately restored, and finally, almost 80% of complex **2** was recovered on the basis of its absorbance [Fig. 3(*b*)]. These spectral changes clearly indicated an almost reversible dioxygen binding through the μ-peroxo dimer **2**.§

The sugar units dramatically influence the redox property of the cobalt centre, which was demonstrated by the differential reactivity toward dioxygen molecule between the complex with mannose-type aldoses (D-Man, L-Rha) and that with D-glucose. Studies using other glucose-type aldoses are now in progress.

# Synthesis of *meso* substituted porphyrins in air without solvents or catalysts

**Charles M. Drain* and Xianchang Gong**

*Department of Chemistry, Hunter College of the City University of New York, 695 Park Avenue, New York, NY 10021, USA*

***meso*-Tetraarylporphyrins are synthesized from pyrrole and aryl aldehydes cleanly and efficiently in one step without solvents or catalysts by reactions at temperatures 10–15 °C above the boiling point of the starting aldehydes using air as oxidant.**

The remarkably diverse photo-, electro- and bio-chemical properties of the porphyrins continue to attract the attention of researchers even after well over a hundred years. In this century porphyrin research has gone from Hans Fischer's pioneering synthesis of hemin in the 1920s,[1] to their use as redox catalysts,[2] molecular electronic devices[3] and photodynamic therapy agents. In order to exploit their chemistry and fine tune their properties, a variety of synthetic methods have been developed for non-natural porphyrins, especially for the *meso* tetra-substituted porphyrins.[4–8] We have developed a simple way to synthesize many *meso* substituted porphyrins without solvents, catalysts or man-made oxidants, and the reaction is complete in minutes. This is the synthesis of porphyrins at high temperatures and/or in the gas phase.

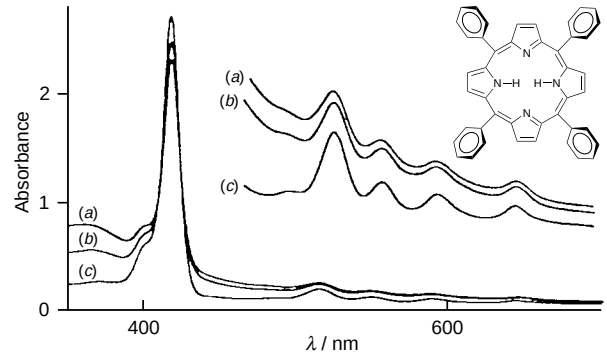
Previous syntheses using pyrrole and aromatic aldehydes are typified by the Ruthemund sealed-tube anaerobic reaction in pyridine at 200 °C (*ca*. 5% yield),[4] the Adler–Longo reaction in propionic or acetic acid under aerobic conditions (10–30% yield),[5] the MacDonald coupling of dipyrroles (10–20% yield)[6] and most recently the Lindsey, anaerobic condensation to form the porphyrinogen followed by oxidation to the porphyrin (10–60% yield).[7] The rapid appearance of water and what is now known to be the porphyrinogen[8] in a pseudo zero-order reaction in the Adler–Longo method, the equilibrium conditions of the Lindsey method, and the stability of the porphyrin to high temperatures of the Rothemund method, led us to attempt porphyrin synthesis at high temperatures and in the gas phase.

Although solventless mixtures of the pyrrole and aldehyde rapidly heated to > 200 °C form the corresponding porphyrins,[9] better yields but similar side product distributions are observed by mixing the two reagents in the gas phase at the same temperature.† Whether the porphyrin is formed entirely in the gas phase is unknown at present, but a brown–purple vapour is observed within *ca*. 2 s of adding the pyrrole to gaseous aldehyde, and a blue–black tar begins to condense on the sides of the reaction vessel soon afterwards. In the rapid heating experiments, porphyrins condense at the top of the reaction vessel, which is below the reaction temperature, with the same purity as that found in the bottom containing the original solution.

High temperature gas phase conditions allow for the rapid aldehyde–pyrrole condensation, for the removal of water from the proximity of the intermediate and for an increase in the rate of oxidation by dioxygen. This latter reaction is proposed to be the rate limiting step in the Adler–Longo method.[5] Examination of yield and products *versus* time indicates that oxidation of the porphyrinogen, or its intermediates, occurs very rapidly, since we detect no porphyrinogen and no chlorin in the UV–VIS spectra (Fig. 1) even after reaction times of a few seconds. Anaerobic reaction conditions result in very low porphyrin yields and only traces of porphyrinogen, indicating the crucial role of dioxygen in trapping the porphyrin products. Studies show that the reaction temperature must be above the boiling point of benzaldehyde to result in yields of *meso*-tetraphenylporphyrin (TPP) greater than a few percent, but the yield levels off by 210 °C. That the rapid removal of water from the condensing porphyrin (intermediates) is one key to these reaction conditions is shown by the decreased yield (*ca*. 12%) when a 5 : 1 water : aldehyde mixture is used.[10] Consistent with the known chemistry of aryl aldehydes, benzaldehyde can serve as an oxidant, since greater than 20% yields are obtained in experiments where the ratio of benzaldehyde to pyrrole is 3 : 1 and the amount of dioxygen is limiting. Catalytic amounts ( < 5 mol%) of HCl or $NH_3$ block porphyrin formation almost entirely, but washing the reaction vessel with 1.0 M HCl or KOH and thorough drying has no effect. TFA diminishes the formation of TPP, but increases the yield of tetramesityl-porphyrin from trace amounts to about 7% for reasons still under investigation.

This method is general enough to make a wide variety of *meso* substituted porphyrins in yields ranging from 7 to 23% (not optimized) (Table 1). For those reactions using aldehydes that have boiling points greater than *ca*. 250 °C at 1 atm, where the pyrrole begins to decompose too rapidly, a thin film of the melted or liquid aldehyde is coated into the reaction vessel sides at *ca*. 220 °C before the pyrrole is injected. Thus a 15% yield of tetrakis(4′-*tert*-butylphenyl)porphyrin are obtained.

We are currently examining the complex balance between temperature, pressure and concentrations of all three reactants in order to maximize the yield and gain a deeper understanding of the reaction mechanism and thermodynamics. Porphyrin formation is believed to be driven by enthalpic changes[9] and the macrocycle is preferred over the polymer for entropic reasons ($\Delta H$ −212 kcal mol$^{-1}$, $\Delta G$ −166 kcal mol$^{-1}$, and $\Delta S$ −153 e.u.).[7–9] If this data is correct, then the favourable $\Delta G$ is dominated by the entropy term, and cooler temperatures should favour porphyrin formation. However, the porphyrin yield increases with temperature up to *ca*. 250 °C, thus under these conditions the high temperature gas phase formation of porphyrins represents a kinetically controlled reaction dominated by the reactivity of dioxygen—as the oxidation studies suggest. The glass walls of the vial do not directly participate in



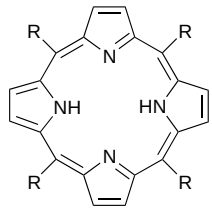


**Fig. 1** Unpurified $CHCl_3$ rinses from two gas phase reactions: (*a*) a 3 : 1 and (*b*) a 1 : 1 ratio of benzaldehyde to pyrrole are compared to (*c*) the UV–VIS absorption spectra of known pure $H_2$TTP from a large gas phase reaction, showing the purity of the soluble materials and the lack of dipyrromethanes and chlorins in the product mixture. The inset absorbance scale is ×10.

the reaction since control experiments, whereby glass wool is inserted into the reaction vial or the vial has been silanated, show similar yields and reactivities. We are further investigating the possibilities of surface catalysis.

Our results show that the commercially important *meso* arylporphyrins may be synthesized without catalysts or solvent, and using only dioxygen as an oxidant. The polymeric byproducts are insoluble, so washing the reaction vessel with minimal amounts of solvent followed by a short silica gel column results in pure porphyrin. Dioxygen is a key requirement for porphyrin synthesis under these conditions. While the unoptimized 7–23% isolated yields resulting from our high temperature gas phase method are typically not as good as the Lindsey method and on a par with the Adler–Longo and MacDonald methods, the great advantages of this method are its simplicity and minimal waste production. Purification is generally easier since there is virtually no chlorin formation and the tarry byproducts are less soluble than other byproducts from other procedures. We have been able to scale up this method for the synthesis of 0.1–0.3 g of several porphyrins using a glass tube wrapped with heating tape (or in a zone refining furnace) whereby the aldehyde is slowly injected at one end, and the pyrrole is slowly added at the other end, of a 1.5 × 60 cm tube closed with glass wool to allow sufficient dioxygen for the reaction. The product is removed with 100–200 ml $CHCl_3$ and a very short silica gel column yields pure material. Thus, this method is quite amenable for industrial-type reactors.

We thank D. Mauzerall for his consistently insightful ideas. Financial support from MBRS (GM08176-18) and Research Centers in Minority Institutions (RR-03037) grants to Hunter College are acknowledged, as is a Eugene Lang Faculty development award to C. M. D.

† Synthesis of *meso*-tetraphenylporphyrin is used as an example. A 5 ml vial is closed by a cap fitted with a rubber septum, placed in a temperature controlled sand bath and heated to *ca*. 200 °C, at which time benzaldehyde (10 μl, 0.1 mM) is injected into the system. After a few minutes, when the aldehyde is in the gas phase, 1 equiv. of pyrrole is injected slowly into the vial. (Alternatively both reagents can be placed in the vial, stirred and placed in the sand bath, but the yields are 25–30% lower.) The vial is kept at *ca*. 200 °C for another 15 min. Rinsing the reaction vessel sparingly with $CH_2Cl_2$ or $CHCl_3$ removes most of the porphyrin in *ca*. 80% purity as measured by UV–VIS spectroscopy,[7] while the remaining insoluble material contains < 1% of the porphyrin yield. Isolated yields are listed in Table 1. All compounds had satisfactory $^1H$ NMR, UV–VIS and FAB mass spectra. **Caution**: the rapid formation of gases and the flash point of all compounds should be considered. Under these conditions there is some benzaldehyde decomposition, and little decomposition of the pyrrole.

‡ A plethora of methods result in spectroscopically detectable quantities of porphyrins, including gamma ray irradiation, supercritical fluids, very high pressures, DC plasmas and fluidized bed reactors (ref. 9).

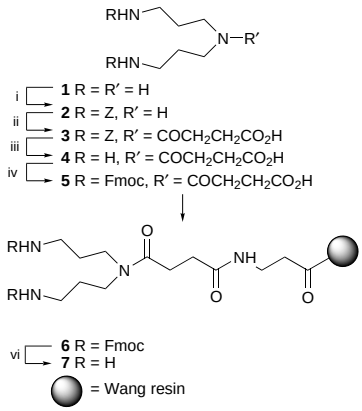
# Multivalent neoglycoconjugates: solid-phase synthesis of N-linked α-sialodendrimers

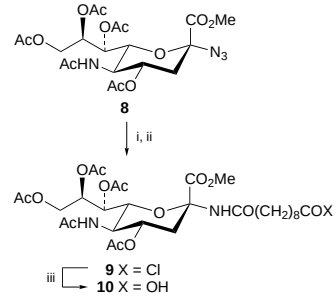


**Muriel Llinares and René Roy***

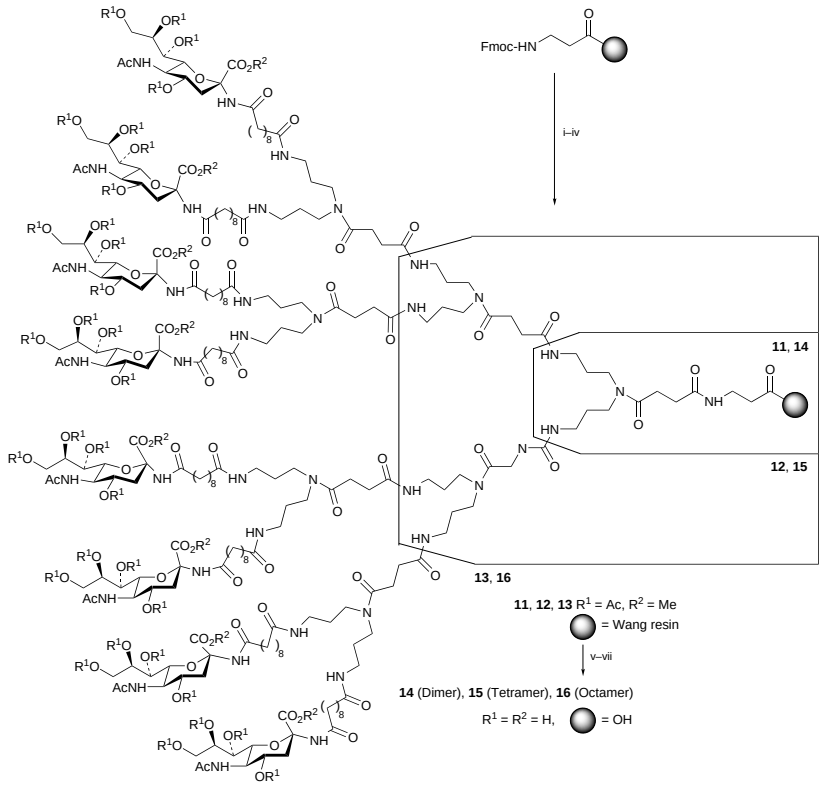
*Department of Chemistry, University of Ottawa, Ottawa, ON, K1N 6N5 Canada*

**A series of N-linked α-sialodendrimers with valencies of 2, 4 and 8 has been scaffolded on an *N*,*N*-bis(3-aminopropyl)succinamic acid core using Wang resin and 9-fluorenylmethoxycarbonyl and 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium tetrafluoroborate solid-phase chemistry.**

Dendrimers are attractive monodispersed macromolecules with broad spectrum applications from physics to medicine.[1] The design of novel dendrimers represents an active research area and their syntheses are considered challenging owing to their size and highly branched structures. Traditionally, divergent[2] and convergent[3] strategies have been used to synthesize dendrimers. However, more recently a double exponential growth strategy[4] and a self-assembling method[5] have been developed. To date, the synthesis of most dendrimers has been carried out in solution, although Tam[6] has built hyperbranched L-lysine dendrimers on a solid-phase for multiple antigen peptide (MAP) presentation. Because of the critical role of carbohydrate-containing macromolecules in many cellular proceses, glycodendrimers have also become a growing research area.[7] There is increasing evidence that the multivalent effect displayed by these novel biopolymers may overcome the characteristic low-affinity binding interactions between carbohydrate ligands and proteins.[8,9]



Potent L-lysine-based dendritic α-thiosialoside inhibitors of *Influenza* virus's hemagglutination to human erythrocytes have been previously described.[10] Similarly, different series of symmetrical dendrimers containing *N*-acetylneuraminic acid (NeuAc or sialic acid), representing one of the most widespread mammalian cell surface carbohydrate ligands,[11] have been successfully synthesized in solution.[12,13] Therefore, it was attractive to build a new series of sialodendrimers on a solid-phase. The present approach differs from previous S-linked sialosides[10,11] by the use of N-linked sialylated derivatives which are also expected to be sialidase resistant. Thus, the solid-phase synthesis of a new family of symmetrical N-linked sialodendrimers based on *N*,*N*-bis(3-aminopropyl)succinamic acid **4** core is described.



**Scheme 1** *Reagents and conditions*: i, $BnO_2CCN$, $CH_2Cl_2$, 2 h, 72%; ii, succinic anhydride, $Et_3N$, $CH_2Cl_2$, 1 h, 96%; iii, $H_2$, 10% Pd–C, MeOH, 2 h, quant.; iv, FmocCl, 10% $Na_2CO_3$–dioxane, 12 h, 72%; v, H-βAla-Wang resin, TBTU, $Pr^i_2EtN$, DMF, 30 min; vi, 20% piperidine–DMF (1 × 5 min, 1 × 15 min)

In order to provide a strategy which could be used with other carbohydrate ligands, a divergent approach was used to build these novel poly(amidoamine) dendrimers on a solid-phase. Suitably acid-functionalized carbohydrate derivatives could then be added onto polyamino dendrimers to afford glycodendrimes with even valencies. The dendritic core was prepared as follows (Scheme 1). The primary amine groups of *N*-(3-aminopropyl)propane-1,3-diamine **1** were regioselectively protected with benzyloxycarbonyl (Z) groups using benzyl cyanoformate in $CH_2Cl_2$[14] to give secondary amine **2** in 72% yield. Acylation of the residual amine with succinic anhydride (triethylamine, $CH_2Cl_2$, 96%) provided key building block **3** having a divalent structure with a bis-Z-protected monoacid core. In order to use the Fmoc strategy, the Z-protecting groups were removed by catalytic hydrogenation (10% Pd–C, MeOH) to give **4**, which was then treated with 9-fluorenylmethyl chloroformate (FmocCl, 10% $Na_2CO_3$–dioxane, 0 °C) to afford **5**† in 72% yield. The dendritic polyamine scaffolds were built on a β-alanine spacer attached to Wang resin [4-(hydroxymethyl)phenoxymethyl–*co*-poly(styrene–1% divinylbenzene), 0.58 mmol $g^{-1}$], using the Fmoc-strategy and performing the deprotection–coupling cycles as follow: (i) Fmoc deprotection by treatment with 20% piperidine in DMF (1 × 5 min, 1 × 15 min), (ii) coupling of Fmoc–protected acid **5** (2 equiv.) using 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium tetrafluoroborate (TBTU) (2 equiv.) as activating agent and $Pr^i_2EtN$ (4 equiv.) in DMF during 30 min. Coupling completion was determined by a ninhydrin test for residual amino groups.[15] To characterize the dendrimers, 30 mg of resin from each sequential generation was Fmoc-deprotected and the dendrimers were released from the solid support following conventional acid treatment (95% aq. TFA, 2 h, 30–79% yield).

Glycodendrimer synthesis required sialic acid residues suitably functionalized at the anomeric position for coupling with amine-terminated dendrimers. The readily available α-sialic acid azide derivative **8**[16] was reduced by catalytic hydrogenation (10% Pd–C, MeOH) to provide α-sialic acid amine in quantitative yield (Scheme 2). To minimize anomerisation, the next acylation step was performed within 1 h. To

**Scheme 2** *Reagents and conditions*: i, $H_2$, 10% Pd–C, MeOH, 1 h, quant.; ii, $ClCO(CH_2)_8COCl$, $Pr^i_2EtN$, $CH_2Cl_2$, 3 h; iii, $H_2O$, 53% overall yield

**Scheme 3** *Reagents and conditions*: i, 20% piperidine–DMF (1 × 5 min, 1 × 15 min); ii, **5**, TBTU, $Pr^i_2EtN$, DMF, 30 min; iii, repeat cycle or 20% piperidine–DMF; iv, **10**, TBTU, $Pr^i_2EtN$, DMF, 0.5–8 h; v, 95% aq. TFA, 2 h; vi, 1 M NaOMe, MeOH, 2–8 h; vii, 0.05 M NaOH, 2–8 h

offer suitable carbohydrate accessibility, introduction of a spacer arm between the sialic acid residues and the dendrimer was carried out using excess $ClCO(CH_2)_8COCl$ ($CH_2Cl_2$, $Pr^i_2EtN$, 0 °C) to give unstable monoacid chloride **9** which was immediately hydrolysed to afford **10** in 53% overall yield. Attempts to isolate **9** for subsequent attachment to the resin were unsuccessful. α-Sialic acid derivative **10** was then ready to be coupled to the dendritic polyamine core on the solid-phase using the same TBTU coupling strategy described to scaffold the dendrimer generations. After coupling, peracetylated sialodendrimers with the valencies of 2, 4 and 8 (**11**, **12** and **13**) were released from the resin by treatment with 95% TFA. The sialodendrimers were then deprotected by sequential ester hydrolysis [(i) de-*O*-acetylation with 1 M NaOMe in MeOH, (ii) 0.005 M NaOH]. Purification of each independent generation by size exclusion chromatography over Biogel-P2 ($H_2O$ as eluent) provided pure deprotected glycodendrimers **14**, **15** and **16** in moderate yields (25–56%) (Scheme 3). The purity of each compound was readily established from the relative integration of key signals in the $^1H$ NMR spectrum. MALDI-TOF mass spectral data (negative mode) further confirmed the integrity of the dendrimers. Biological properties of these novel N-linked sialodendrimers will be reported in due course.

We thank Qing Quan Wu and Denis Carrière for providing α-sialic acid azide derivative **8**. We are also grateful to Drs P. Thibault and D. Krajcarski from NRC, Ottawa, for running the MALDI-TOF experiments on a Perspective Elite-STR instruments.

# Dendroids: a building block for the synthesis of polymodal dendritic structures

**Joanne V. Allen, David C. Horwell,* Julia A. H. Lainton, Jacqueline A. O'Neill and Giles S. Ratcliffe**

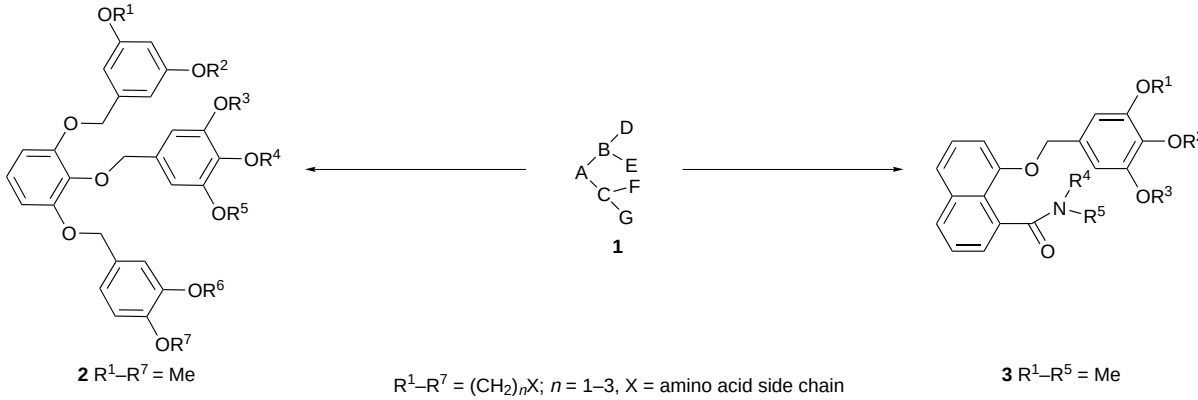
*Parke-Davis Neuroscience Research Centre, Cambridge University Forvie Site, Robinson Way, Cambridge, UK CB2 2QB*

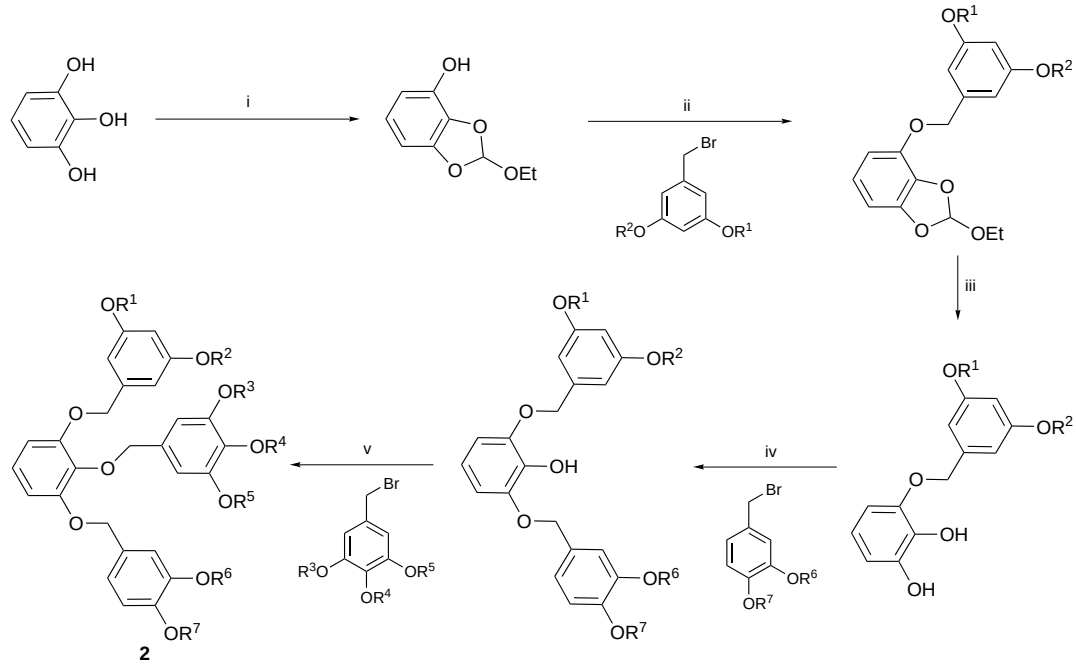
**Differentially substituted 1,8-naphthalene and 1,2,3-trihydroxybenzene derivatives are synthesised and termed 'dendroids'; these may be differentially derivatised with mimetics of amino acid side chains.**

Dendritic polymers are synthetic polymers that are characterised by a non-linear array of monomeric species. They are self-organising moieties that have unique physico-chemical properties with respect to their linear counterparts and have a range of potentially novel industrial applications.[1–5]

The topographical features of starburst dendrimers have been compared with those found in globular proteins.[1] However, proteins display heterogeneous functional moieties on their surfaces, such as the constituent amino acid side-chains or the peptide backbone.

We describe here the synthesis of simple aromatic compounds with low molecular weight ( < 1000 Daltons) which can serve as a structural motif that is able to display *different* functional groups which correspond to the side-chains of amino acids. Such polymodal 'dendritic wedges'[2] we term 'dendroids' (**1**, Fig. 1). The dendroid motif is anticipated to facilitate *intramolecular* self-organisation (*cf. intermolecular* self-assembly associated with nanostructures[6,7]) by choice of suitable spacer groups B and C, which may non-covalently interact with each other by steric crowding, hydrophobic collapse and stereoelectronic attractive or repulsive effects. For example,





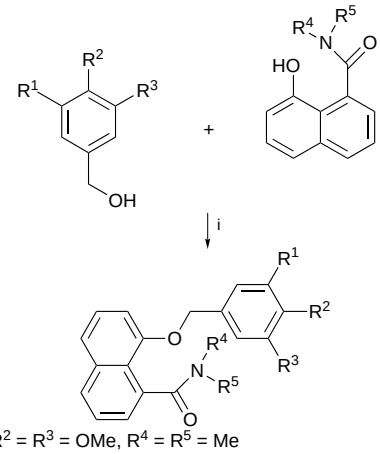


**Fig. 1** Dendroid motif **1** exemplified by 1,2,3-trialkoxybenzenes **2** and 1,8-disubstituted naphthalenes **3**

**Scheme 1** *Reagents and conditions*: i, $CH(OEt)_3$, Amberlyst-IR-120(plus), reflux, 28 h, 92%; ii, $K_2CO_3$, 18-crown-6, room temp., 18 h, 92%; iii, TsOH, room temp., 20 h, 90%; iv, $K_2CO_3$, 18-crown-6, room temp., 21 h, 32%; v, $K_2CO_3$, 18-crown-6, room temp., 21 h, 46%

**3a** $R^1 = R^2 = R^3 = OMe$, $R^4 = R^5 = Me$
**b** $R^1 = R^3 = H$, $R^2 = OBn$, $R^4 = R^5 = Me$
**c** $R^1 = R^3 = H$, $R^2 = OBn$, $R^4 = Pr^i$, $R^5 = (R,S)$CHMe-(indol-3-yl)
**d** $R^1 = R^3 = H$, $R^2 = OBn$, $R^4 = Bn$, $R^5 = CH_2C_6H_4OMe$-*p*
**e** $R^1 = R^3 = H$, $R^2 = OBn$, $R^4 = Bn$, $R^5 = CH_2CH_2$-(indol-3-yl)
**f** $R^1 = R^3 = H$, $R^2 = OBn$, $R^4 = CH_2C_6H_4OMe$-*p*, $R^5 = CH_2CH_2$-(indol-3-yl)
**g** $R^1 = R^3 = H$, $R^2 = OBn$, $R^4 = CH_2CH_2C_6H_4OMe$-*p*, $R^5 = CH_2$-(indol-3-yl)

**Scheme 2** *Reagents and conditions*: i, $PPh_3$ (1 equiv.), diisopropyl azodicarboxylate (1 equiv.), THF, 0 °C to room temp., 4 h

1,2,3-trisubstituted benzenes[8–11] and 1,8-disubstituted naphthalenes[12–15] have been shown to adopt non-planar arrangements by X-ray, NMR and chemical reactivity analysis. As one example, the dendroid motif **2**† may be synthesised from 1,2,3-trihydroxybenzene (Scheme 1). This type of molecule is able to achieve a non-planar structure by virtue of the electronic repulsion between the crowded 1,2,3-aryl ether oxygen atoms, so that the central 2-aryl ether oxygen substituent is forced out of plane with respect to the benzene ring.[8,9]

The 1,8-disubstituted naphthalene dendroids **3a**–**g** are prepared from 8-hydroxy-*N*,*N*-dimethylnaphthalenecarboxamide[12] (Scheme 2). Such 1,8-naphthalenes have been shown by X-ray analysis to exhibit a non-planar preference *via* a truly remarkable stereoelectronic attraction between the 8-naphthalene oxygen substituent atom and the 1-substituted carbonyl group of the amide moiety,[12] allowing the attached groups $R^1$–$R^5$ in **3** to be splayed into a polymodal surface. Examples of where this dendroid motif has been derivatised to give amino acid side-chains include the mimetics of phenylalanine **3b**, β-methyltryptophan **3c**, tyrosine (as its *O*-methyl ether) **3d** and tryptophan **3e**. The examples **3f** and **3g**† also mimic tryptophan and tyrosine side-chains bearing differing methylene spacer groups.

In these cases, the synthetic schemes allow *separate* functionalisation of the dendroid motif, which can be converted by further synthesis into separate amino acid side-chains. Hence the polymodality of part protein structures can be mimicked by use of the dendroid motif. The elaboration of the dendroid motif to give protein mimetics of the 'hot spots' of key amino acids in interleukin-Ira,[16] interleukin-8[17] and the conotoxin derivative SNX-III[18] is under investigation in our laboratory.

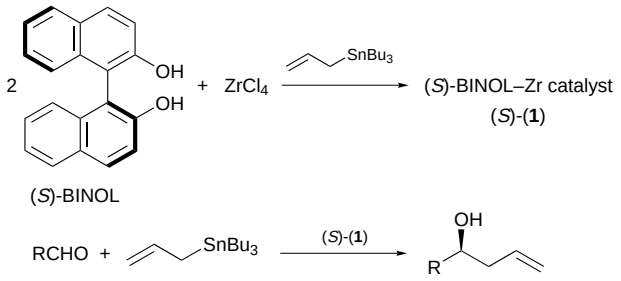
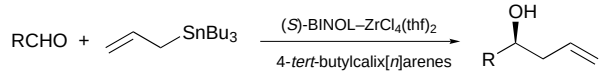
**4-*tert*-Butylcalix[4]arene activates the enantioselective allylation of aldehydes catalyzed by a new zirconium–BINOL Lewis acid system allowing the use of less than 2% of the catalyst.**



Enantioselective allylation reaction is becoming an important methodology in the total synthesis of complex chiral molecules. In order to enhance the broad applicability and the efficiency of this process for catalytic applications, a large number of groups have published different allylation methodologies which have been realized through the use of different metal–BINOL complexes.[1] The major drawback in all the reported methods is the high loading of the catalyst employed in the reaction (10–20%) which reduces the interest of this simple methodology.

Recently, an acceleration effect on the catalytic cycle of the allylation reaction was discovered whereby an additive, $R_2MSR$ (where M = Al, B), was introduced *in stoichiometric amount* into the reaction mixture.[2]



In searching for more active and efficient catalysts, we discovered that zirconium–BINOL Lewis acid **1** can be prepared by dissolving the $ZrCl_4$ in MeCN in the presence of BINOL, followed by the addition of allyltributyltin in $CH_2Cl_2$ (Scheme 1).[3]† After stirring the reaction mixture for 1–2 h at room temperature, the aldehyde was successively added at lower temperature (Scheme 1). The resulting data from this reaction are collected in Table 1. The drawback of this method is that two equivalents of BINOL (with respect to the zirconium) are needed to obtain high enantiomeric excesses (ees). Furthermore good reproducibility was difficult to obtain. We realized that another catalyst which could be prepared from commercially available $ZrCl_4(thf)_2$[4] could considerably enhance the applicability and the reproducibility of the procedure. Moreover, the higher solubility of $ZrCl_4(thf)_2$ in organic solvent, as compared to $ZrCl_4$, simplifies the procedure for the preparation of the catalyst. In fact, the catalyst can be simply prepared starting from BINOL and $ZrCl_4(thf)_2$ in $CH_2Cl_2$ or in $Et_2O$. As shown in Table 1 high ees were achieved by employing $Et_2O$ as the reaction solvent. Despite the high ees which we obtained, those reported for the same reactions promoted by $Zr(OiPr)_4$·$^i$PrOH–BINOL Lewis acid[5] were higher. Moreover, at least 10% mol of the zirconium catalyst was necessary to achieve good levels of ees.

Recently Mikami and Matsukawa reported that certain titanium–BINOL Lewis acids, capable of promoting the ene reaction, are activated by the addition of chiral phenols.[6] In particular, they showed that the presence of enantiopure BINOL enhances the reactivity of racemic titanium–BINOL catalysts and increases the ees of ene[6] and Diels–Alder reactions.[7]

We report here a spectacular activation of the zirconium–BINOL catalyst by adding achiral 4-*tert*-butylcalix[4]arene,[8] a phenol derivative, to the reaction mixture (Scheme 2). This new Lewis acid system is generated *in situ* by treating a mixture of BINOL, $ZrCl_4(thf)_2$ and 4-*tert*-butylcalix[4]arene with allyltributyltin.‡ The 4-*tert*-butylcalix[4]arene has low solubility in the reaction solvent ($Et_2O$) and the addition of allyltributyltin to

[a] All reactions were run by the employment of 10% catalyst based on Zr. Reactions performed with lower % of the catalyst gave lower yield and enantioselectivity. [b] The catalyst was prepared by dissolving $ZrCl_4$ (0.1 mmol) and BINOL in MeCN followed by the evaporation of the solvent. The solid residue was suspended in $CH_2Cl_2$ and allyltributyltin (2 mmol) was added. The resulting mixture was stirred for 1 h followed by the addition of the aldehyde (1 mmol). [c] The catalyst was prepared in $CH_2Cl_2$ or $Et_2O$ by stirring $ZrCl_4(thf)_2$ (0.1 mmol) and BINOL for 1 h followed by the addition of allyltributyltin (1.7 mmol) in the same solvent. The resulting yellow solution was stirred for another hour at room temp., then the mixture was cooled to the temperature reported in the Table and the aldehyde was added (1 mmol). [d] Isolated yield after chromatographic purification. [e] The ees were determined by GC analysis with a chiral Megadex-5 column.
