[a] All reactions were carried out in $Et_2O$ at −20 °C. [b] For all reactions the molar ratio between $ZrCl_4(thf)_2$ and BINOL was 1 : 1. [c] Isolated yield after chromatographic purification. [d] The ees were determined by GC analysis with a chiral Megadex-5 column. [e] The reaction was performed at 0 °C. [f] The reaction was performed in $CH_2Cl_2$.

**Table 3** Enantioselective allylation promoted by BINOL–zirconium–phenol systems[a]

| Entry | Phenol | Yield (%)[b] | ee (%)[c] |
|---|---|---|---|
| 1 |  | 30 | 66 |
| 2 |  | 40 | 71 |
| 3 |  | 47 | 19 |
| 4 |  | 0 | — |
| 5 |  | 0 | — |

[a] All reactions were performed employing the following stoichiometric ratio: BINOL : $ZrCl_4(thf)_2$ : phenol : allyltributyltin : aldehyde; 0.1 : 0.1 : 0.1 : 1.6 : 1.0 at −20 °C for 48 h. [b] Isolated yield after chromatographic purification. [c] The ees were determined by GC analysis with a chiral Megadex-5 column.

the mixture solubilizes the complex with the appearance of a yellow colour only in the case of low catalyst loading (2–3%). In addition, the experimental procedure is simple, all the reagents are commercially available, and no particular drying procedure is required for the calixarene.

The remarkable aspect of this procedure is that, even without the use of molecular sieves, it is possible to obtain very high ees (up to 96% with linear aldehydes) using only 2% of the chiral promoter. Our results indicate that the amount of calixarene added to the mixture can be reduced (entries 3 and 4, Table 2). As shown in Table 2, the results are generally good with both aliphatic and aromatic aldehydes. Only in the case of cinnamaldehyde the yield and the ees are not satisfactory. Other calixarenes can be used with comparable results (entries 9 and 10, Table 2). It is noteworthy that this dramatic activation is obtained specifically with the calixarenes, whereas other phenols do not show the same activating effect (Table 3). Our system is interesting not only from the point of view of low catalyst loading giving high ees, but from the perspective that new frontiers can be opened in the field of metal–BINOL complexes in asymmetric catalytic applications.

Future work in our laboratory will address the general scope of Lewis acid catalyst activation and the characterization of the species responsible for the performance of the catalyst.

We thank MURST and CNR (Rome) for financial support. We wish to thank the University of Bologna for funds for selected research topics.

† Preliminary spectroscopic investigations have shown that the catalyst formation probably occurs through the proton abstraction from an initial adduct between the $ZrCl_4$ and BINOL due to the allylating reagent, as previously described by Carreira and co-workers[3] for the $TiF_4$–BINOL system. Tributyltin chloride and propene are the products of the reaction.

‡ Typical experimental procedure: a suspension of (*S*)–BINOL (0.05 mmol), 4-*tert*-butylcalix[4]arene (0.05 mmol) and $ZrCl_4(thf)_2$ (0.05 mmol) was stirred for 1 h in $Et_2O$ (1.5 ml), then allyltributyltin (1.7 mmol) was added at room temperature. After stirring for 1 h and cooling to −20 °C, the aldehyde (1 mmol) was added. The mixture was stored in the freezer at −20 °C for 50–90 h, then diluted with $Et_2O$ and quenched with a saturated solution of $NaHCO_3$. The insoluble materials were filtered and the organic phase separated. The aqueous phase was extracted with $Et_2O$. The organic phases were collected, dried, evaporated under reduced pressure and purified by flash chromatography.

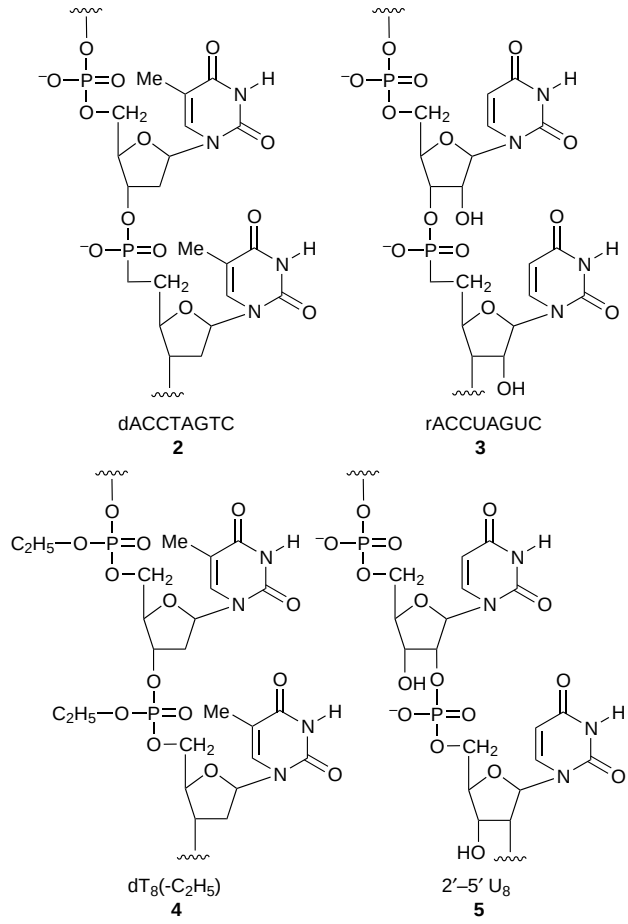
# A 24 mer peptide derived from RecA protein can discriminate a single-stranded DNA from a double-stranded DNA

**Naoki Sugimoto* and Shu-ichi Nakano**

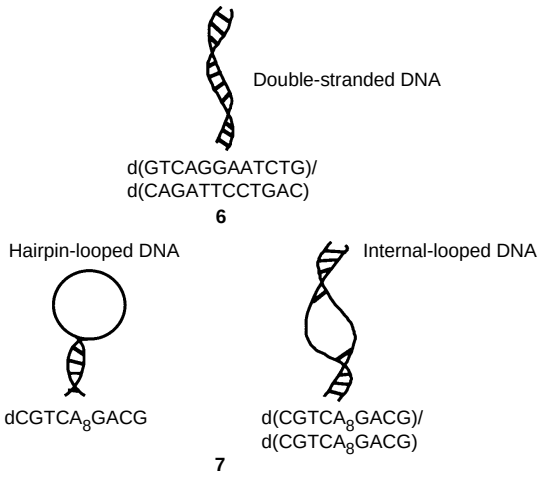


*Department of Chemistry, Faculty of Science, Konan University, 8-9-1 Okamoto, Higashinada-ku, Kobe 658, Japan*

**A novel 24 residue peptide, Ile-Arg-Met-Lys-Ile-Gly-Val-Met-Phe-Gly-Asn-Pro-Glu-Thr-Thr-Thr-Gly-Gly-Asn-Ala-Leu-Lys-Phe-Tyr, derived from RecA protein can discriminate a single-stranded DNA (ssDNA) from a double-stranded DNA (dsDNA) and a new developed support with this peptide recognizes ssDNA but not dsDNA.**

RecA protein plays an essential role for homologous DNA recombination and DNA repair in prokaryote.[1–3] The X-ray structure of 352 amino acids of *E. coli* RecA protein in the absence of DNA showed that two disordered loop domains, L1 (157–164) and L2 (195–209), composed of highly conserved amino acids project towards the polymer axis near DNA strands.[4] Based on several investigations of mutated RecA proteins, it was proposed that L1 and L2 are dsDNA and ssDNA binding domains, respectively. Helix G (210-218) lying next to loop L2 amino acids is a conserved domain including two Gly residues (211 and 212) which are absolutely invariant among bacterial RecA proteins, T4 UvsX, yeast Dmc 1 and mouse Rad 51 proteins.[5] Recently, it was reported that a 20 amino acid peptide (named FECO peptide) derived from *E. coli* RecA protein, which contains L2 and the conserved amino acids at both L2 termini including the invariant Gly residues (193–212), showed an enzymatic activity for the homologous recombination of DNA strands without any cofactors.[6] However, the FECO peptide which lacks the full helix G amino acids except both Gly residues, bound both ssDNA and dsDNA with similar affinity. Here, we have synthesized a 24 amino acid peptide including L2 and all helix G residues (195–218), Ile-Arg-Met-Lys-Ile-Gly-Val-Met-Phe-Gly-Asn-Pro-Glu-Thr-Thr-Thr-Gly-Gly-Asn-Ala-Leu-Lys-Phe-Tyr **1**, and investigated its recognition ability specific to ssDNA.[7]

Binding behaviors of the synthesized L2-G peptide **1** with four single-stranded octanucleotides, dACCTAGTC **2**, rACCUAGUC **3**, $dT_8(\text{-}C_2H_5)$ **4**, and 2′–5′ $U_8$ **5**, a double-stranded DNA (dsDNA) d(GTCAGGAATCTG)/d(CAGATTCCTGAC) **6**, and a hairpin-looped DNA $dCGTCA_8GACG$ **7** were investigated by surface plasmon resonance (SPR) analysis. Octamers **2** and **3** are unmodified ssDNA and ssRNA, respectively. Octamers **4** and **5** are unnatural strands; **4** has neutral charges on its backbone and **5** is linked by a phosphodiester bond between 2′ and 5′ positions. The DNA sequences of **6** and **7** were confirmed to form double-stranded and hairpin-looped structures, respectively, with an alternative secondary structure of two molecules of **7** forming an internal-looped one also being possible.



The L2-G peptide was immobilized on the SPR sensorchip,[8] and the octanucleotides were flowed across the sensorchip.† After the injection of 320 μM octanucleotides **2**–**5** to the flowcell, the response of the refractive index increased as the sample was flowed. Final intensities were approximately 1200, 400, 50 and 200 RU (resonance unit) for **2**, **3**, **4** and **5**, respectively, at 300 seconds after the injection. Although the refractive index for the ssDNA seems only three-fold greater than that for the ssRNA, the signal for **2** continued increasing even 300 seconds after the injection. Thus, affinity of **2** for the L2-G peptide is much greater than **3**. These results indicate **3** and **5** have much lower binding abilities to the peptide on the sensorchip than **2**, although these three nucleotides possess the same negative charges. Apparently, the neutral nucleotide of **4** could not bind to the L2-G peptide, suggesting the L2-G peptide recognizes nucleotides not only by their electronegativity but also by their backbone structure. A lower dissociation process for **2** was observed when the running buffer was flowed at 300 seconds after the injection, suggesting the interactions for the ssDNA with the L2-G peptide are not simple.

Ac-Ile-Arg-Met-Lys-Ile-Gly-Val-Met-Phe-Gly-Asn-Pro-Glu-Thr-Thr-Thr-Gly-Gly-Asn-Ala-Leu-Lys-Phe-Tyr-$NH_2$

L2 site — Helix G

**1**

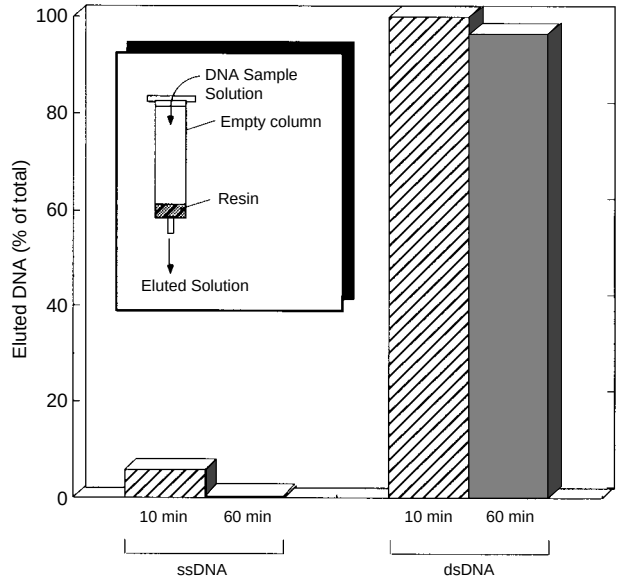


**Fig. 1** Binding properties of the control and L2-G columns to ssDNA of d(TAATACGACTCACTATAGGG) and dsDNA of d(TAATACGACTCACTATAGGG)/d(CCCTATAGTGAGTCGTATTA) at room temperature. Percentages of the eluted DNAs through these columns against the total DNA amount were calculated with absorbance differences at 260 nm of the eluted solutions through the control and the L2-G columns.

When **6** was flowed over the sensorchip with the L2-G peptide, only an increment of 100 RU was observed. Even if a high concentration of this dsDNA (up to 6 mM) was examined, the response was at most 200 RU. Thus, the L2-G peptide bound to ssDNA, but not to ssRNA, unnatural nucleotides or structured DNAs. This binding affinity was also supported by circular dichroism (CD) spectra (data not shown). On the other hand, as we expected, **7** had a smaller signal (450 RU) than **2**, because this DNA strand was designed to form a hairpin-looped structure easily. However, there was a relatively larger response of **7** than that of the ssRNA **3**. This result might be due to its ability to form not only a hairpin-looped structure but also an internal-looped structure of the self-complementary duplex which would be bound by the L2-G peptide.

Furthermore, we prepared an ssDNA affinity column by using the ssDNA recognizing peptide (L2-G peptide). The peptide was attached to a polystyrene supported PEG-PS resin (PerSeptive Biosystems). This resin was put in an empty column (L2-G column), then ssDNA, d(TAATACGACTCACTATAGGG), or dsDNA, d(TAATACGACTCACTATAGGG)/d(CCCTATAGTGAGTCGTATTA), was poured into the column.‡ In addition, a control resin without attached amino acid residues on the PEG-PS resin was prepared as a control column.

Absorbance at 260 nm of the elution buffers was compared. In the case of the ssDNA, no decrement of absorbance was observed for elution through the control column. However, through the L2-G column, much less absorbance ($Abs_{260}$ = 0.04) compared to that before pouring ($Abs_{260}$ = 0.73) was found. The percentages of the eluted DNA strand flowing through these resins against the total DNA amount are shown in Fig. 1. This indicates that most ssDNAs bound to the L2-G resin even after mixing for 10 min. When the dsDNA was poured into these columns, no significant difference of the measured absorbance was observed between the control column and the L2-G column. Thus, there is no specific interaction of the L2-G resin with the dsDNA. These results indicate that the L2-G resin is very useful as an ssDNA binding support.

In summary, the 24 amino acid peptide (L2 and helix G domains of RecA protein) discriminated ssDNA from ssRNA, unnatural nucleotides, and dsDNA. The helix G amino acids were required for the discrimination property of the L2-G peptide. A useful support recognizing DNA secondary structures was able to be developed with the L2-G peptide derived from the DNA binding protein.

We would like to thank Drs H. Mihara (Tokyo Institute of Technology), H. Aoyagi and T. Niidome (Nagasaki Univ.) for advice on the synthesis of the peptide, Dr H. Sawai (Gunma Univ.) for providing 2′–5′ linked $U_8$, and Dr Y. Hayakawa (Nagoya Univ.) for providing ethoxy-$dT_8$. We also acknowledge Dr P. C. Bevilacqua at Penn. State University for critical reading of the manuscript and helpful comments. This work was supported in part by Grants-in-Aid from the Ministry of Education, Science, Sports and Culture, Japan, and from the 'Research for the Future' Program of the Japan Society for the Promotion of Science.

† Nucleotide concentrations are expressed as base concentrations. All experiments were conducted in a buffer including 100 mM NaCl, 10 mM $Na_2HPO_4$ and 1 mM $Na_2EDTA$ (pH 7.0).

‡ 100 mg of the L2-G resin and the PEG-PS resin without attached amino acid residues was prepared. The quantity of the peptide bound to the resin was calculated to be 1.7 mmol if the synthesis was completed with 100% yield. The L2-G resin or the PEG-PS resin was put into a empty column (named L2-G column or control column, respectively). The single-stranded DNA of d(TAATACGACTCACTATAGGG) or double-stranded DNA of d(TAATACGACTCACTATAGGG)/d(CCCTATAGTGAGTCGTATTA) was dissolved in a buffer including 100 mM NaCl, 10 mM $Na_2HPO_4$ and 1 mM $Na_2EDTA$ (pH 7.0) to a concentration of 1.3 nmol. These DNA solutions were poured into the two columns and the percentages of the bound DNA on the resin were estimated from the absorbance at 260 nm of the eluted solution.

# New titanium imido chemistry

**Philip Mountford***

*Department of Chemistry, The University of Nottingham, Nottingham, UK NG7 2RD*

**A general entry point to new titanium imido chemistry is gained *via* the readily prepared synthons [Ti(NR)Cl$_2$(py)$_3$] (R = Bu$^t$ or aryl) and their homologues, from which straightforward metathesis reactions afford a wide range of derivatives. The structures, solution dynamics and reactivity of these new compounds are reviewed.**

## Introduction

Transition metal imido chemistry is one of the growth areas of inorganic research and has been reviewed up to the end of 1993.[1–4] The dianionic terminal imido ligand in complexes of the general formula [M(NR)$_n$(L)$_m$] [R = alkyl or aryl usually; (L)$_m$ = ancilliary ligand set] can act as a four-electron donor that is capable of forming a strong triple bond to the metal centre.† As such the M=NR linkage is valence isoelectronic with the terminal oxo group M=O, and the {NR}$^{2-}$ moiety is isolobal with {C$_5$R$_5$}$^-$.[5,6] The π-donor imido functional group gives rise to chemistry that is generally dominated by medium to high metal oxidation states; this contrasts with the familiar low to medium oxidation state chemistry that is characteristic of transition metal complexes supported by the neutral, π-acceptor carbonyl ligands.

While there has clearly been a strong curiosity-driven element to the development of transition metal imido chemistry, the importance of imido compounds and of their isolobal analogues in industrial processes, organic synthesis and catalysis is now very well recognised.[3,4,7] Generally speaking, by the end of the 1980s the chemistry of terminal imido compounds of Group 5–8 transition metals was firmly (although by no means comprehensively) established. By way of contrast, well defined derivatives for Groups 4 and 9 did not appear until about this time.[4] The primary objective of this article is to highlight the more recent advances in titanium imido chemistry. However, it will be helpful to begin by summarising some of the early developments in order to set the later work in context.

Structurally characterised terminal titanium imido complexes were only first described in 1990. These were the five-coordinate [Ti(NPh)(OC$_6$H$_3$Pr$^i_2$-2,6)$_2$(py′)$_2$] (py′ = 4-pyrrolidinopyridine) and six-coordinate [Ti{NP(S)Ph$_2$}Cl$_2$(py)$_3$], prepared by Rothwell and coworkers[8] and Roesky *et al.*[9] respectively [Fig. 1(*a*) and (*b*)]. In 1991 Wolczanski and coworkers described the preparation and chemistry of the highly reactive transient species [Ti(NSiBu$^t_3$)(NHSiBu$^t_3$)$_2$] [Fig. 1(*c*)] which can activate benzene C–H bonds.[10] Other reactive transient titanium imido species were also described around this time.[11] By 1993 a number of five- and six-coordinate complexes analogous to those shown in Fig. 1(*a*) and (*b*) had been reported,[4] but the range of titanium imido reaction chemistry appeared to be very polarised. In other words, it looked as though titanium imido compounds could either be isolated but were (apparently) unreactive, or could be generated *in situ* and were extremely reactive. In 1994 we started work in titanium imido chemistry by identifying a synthetic strategy that we hoped would allow us to extend significantly the range of ancilliary ligand environments for the Ti=NR functional group, and hence to find new reaction chemistry.[12] The remainder of this article describes this general entry to new titanium imido chemistry, an overview of the scope and range of new compounds that can be prepared, and some aspects of their structures, solution dynamics and reactivity.

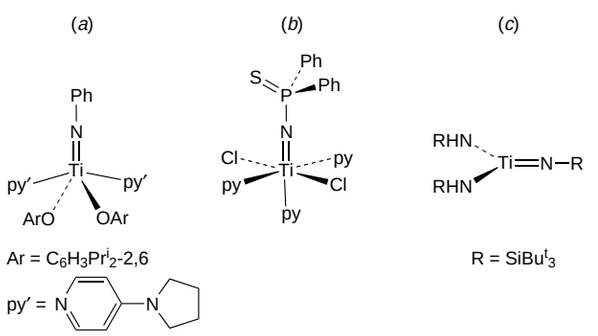

**Fig. 1** The first crystallographically characterised (*a*) five-[8] and (*b*) six-coordinate[9] titanium imido complexes, and (*c*) a highly reactive transient species[10]

## A convenient entry point to new titanium imido chemistry

### *Syntheses*

Being aware of the fairly facile reduction of Ti$^{IV}$ to Ti$^{III}$ in much of the element's chemistry, we decided to introduce the titanium imido group first, and any desired ancilliary ligands last. We have found that the compounds [Ti(NR)Cl$_2$(L)$_n$] (R = Bu$^t$ or aryl; L = py or NC$_5$H$_4$Bu$^t$-4; *n* = 2 or 3; see Fig. 2) are excellent synthons in this regard.[12,13] The success of these complexes as entry points to new titanium imido derivatives (*vide infra*) may partly be attributed to the π-donor imido ligand's ability to stabilise higher oxidation states. Hence almost none of the anion metathesis reactions described herein are complicated by reduction of the Ti$^{IV}$ centre.

The *tert*-butyl imido complexes [Ti(NBu$^t$)Cl$_2$(L)$_n$] (**1a** L = py, *n* = 3; **2a** L = py, *n* = 2; **3** L = NC$_5$H$_4$Bu$^t$-4, *n* = 2) are readily and efficiently obtained from TiCl$_4$, Bu$^t$NH$_2$ and the appropriate L (Fig. 2).‡ Compound **1a** in particular is available on a 35–40 g scale in near-quantitative yield.[12,13] Analogous aryl imido pyridine derivatives cannot be obtained directly from ArNH$_2$ and TiCl$_4$, but arylamine/*tert*-butyl imide exchange reactions of [Ti(NBu$^t$)Cl$_2$(py)$_3$] **1a** readily afford the desired [Ti(NAr)Cl$_2$(py)$_3$] (Ar = C$_6$H$_3$Me$_2$-2,6 **1**b; C$_6$H$_3$Pr$^i_2$-2,6 **1c**; C$_6$H$_5$ **1d**; C$_6$H$_4$Me-4 **1e**; C$_6$H$_4$NO$_2$-4 **1f**).[13,14] These were the first such exchange reactions for Group 4 imido compounds. The 2,6-disubstituted aryl derivatives **1b** and **1c** are by far the most stable and readily prepared; compounds **1a** and **1d**–**1f** have been crystallographically characterised. Five-coordinate bis(pyridine) derivatives [Ti(NAr)Cl$_2$(py)$_2$] (Ar = C$_6$H$_3$Me$_2$-2,6 **2b**; C$_6$H$_3$Pr$^i_2$-2,6 **2c**) are also easily obtained, reflecting the *trans*-labilising ability of the imido group.

The homologous series [Ti(NR)Cl$_2$(py)$_3$] (R = Bu$^t$ **1a**, Ph **1d**, C$_6$H$_4$Me-4 **1e** or C$_6$H$_4$NO$_2$-4 **1f**) provided the first opportunity to use crystallographic results to compare the general structural and *trans* influence [the average difference between the *cis*-Ti–N(py) and *trans*-Ti–N(py) bond lengths] of different imido ligands within a series of simple six-coordinate, d$^0$ complexes as a function of the imido N-substituent. The

absence of aryl ring 2,6-substituents in **1d–f** meant that steric effects were minimised as far as possible. Interestingly, despite the significantly different nitrogen substituents in **1a** and **1d–f**, there is no experimental difference in *trans* influence between them.[13,14]

### *Bi- and tri-dentate amine adducts*

Early transition metal, $d^0$ complexes with *cis*-dichloride ligands are potential precursors to alkene polymerisation catalysts.[15,16] As shown in Fig. 2, the bis- and tris-pyridine adducts **2a** and **1a** afford fourteen- and sixteen-electron, bi- and tri-dentate amine adducts $[Ti(NBu^t)Cl_2(tmeda)]$ (**4**; tmeda = tetramethylethylenediamine),[17] $[Ti(NBu^t)Cl_2(pmdeta)]$ (**5**; pmdeta = pentamethyldiethylenetriamine) and $[Ti(NBu^t)Cl_2(Me_3[9]aneN_3)]$ (**6**; $Me_3[9]aneN_3$ = 1,4,7-trimethyl-1,4,7-triazacyclononane) in good yields.[13,18] The crystallographically characterised compounds **5** and **6** are isolobal analogues of $[Ti(\eta^5\text{-}C_5H_5)_2Cl_2]$. The open-chain triamine adduct $[Ti(NBu^t)Cl_2(pmdeta)]$ **5** is highly labile in solution whereas the cyclic triamine analogue $[Ti(NBu^t)Cl_2(Me_3[9]aneN_3)]$ **6** is rigid on the NMR timescale and generally more easily handled. Compound **6** is the first structurally characterised, triazacyclonane-supported transition metal imido complex. Studies of the substitution chemistry and polymerisation activity of **4–6** and their heavier Group 4 and Group 5 analogues are currently in progress.

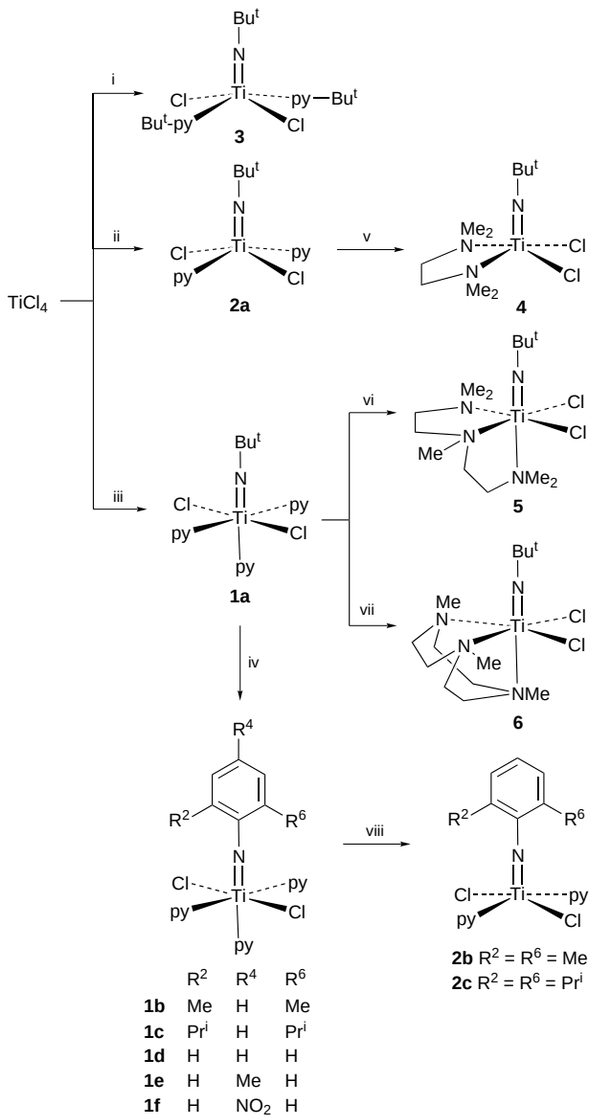

**Fig. 2** Versatile synthons for new titanium imido compounds and some pyridine substitution reactions.[13,18] *Reagents and conditions*: (i) $Bu^tNH_2$ (6 equiv.), py-$Bu^t$ (2.2 equiv.); (ii) $Bu^tNH_2$ (6.0 equiv.), py (2.3 equiv.); (iii) $Bu^tNH_2$ (6.3 equiv.), py (4.1 equiv.); (iv) aniline or substituted aniline; (v) tmeda; (vi) pmdeta; (vii) $Me_3[9]aneN_3$; (viii) 65 °C, dynamic vacuum. py-$Bu^t$ = $NC_5H_4Bu^t$-4.

## Cyclopentadienyl and indenyl derivatives

### *Half-sandwich compounds*

Straightforward metathesis reactions of $[Ti(NBu^t)Cl_2(NC_5H_4R\text{-}4)_n]$ (**1a**, **2a** or **3**) with sodium or lithium cyclopentadienides gives the range of half-sandwich derivatives $[Ti(\eta^5\text{-}C_5R'_5)(N\text{-}Bu^t)Cl(NC_5H_4R\text{-}4)]$ (**7–14**, Fig. 3).[12,19,20] Similarly, treatment of **3** with lithium trimethylindenide afforded the first Group 4 indenyl imido derivative $[Ti(\eta^5\text{-}C_9H_4Me_3)(NBu^t)Cl(NC_5H_4\text{-}Bu^t\text{-}4)]$ **15** for which a pentahapto coordination of the indenyl ligand was inferred from $^{13}C$ NMR data. Compound **15** is relatively labile and ring non-substituted indenyl analogues could not be isolated. The structurally characterised compound $[Ti(\eta^5\text{-}C_5Me_5)(NBu^t)Cl(py)]$ **12** was first obtained *via* dehydrohalogenation of $[Ti(\eta^5\text{-}C_5Me_5)(NHBu^t)Cl_2]$ in the presence of pyridine.[21] The ring non- or mono-substituted compounds **9** and **10** lose pyridine in solution or the solid state forming μ-imido bridged dimers. However, the ring penta-substituted homologues **12–14** are stable to pyridine loss under comparable conditions.

Bis(pyridine), half-sandwich titanium imides analogous to those of zirconium and hafnium[22] were not isolated, but variable temperature NMR measurements identified $C_s$-symmetric complexes $[Ti(\eta^5\text{-}C_5Me_4R)(NBu^t)Cl(py)_2]$ as intermediates in the free/coordinated pyridine exchange reactions of **7–14**; $^{13}C$ NMR lineshape and coalescence measurements for $[Ti(\eta^5\text{-}C_5Me_4C_4H_7)(NBu^t)Cl(py)]$ **14** yielded activation parameters for this process.

### *Sandwich compounds*

The Bergman group has developed an extensive reaction chemistry of zirconocene imido derivatives.[23,24] We were thus interested to find an entry point to analogous titanium imido systems.§

*Syntheses*: Fig. 3 shows that addition of two equivalents of sodium cyclopentadienide to $[Ti(NBu^t)Cl_2(py)_3]$ **1a** gave reasonable yields of $[Ti(\eta^5\text{-}C_5H_5)_2(NBu^t)(py)]$ **17**. Mixed ring analogues $[Ti(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_5Me_4R)(NBu^t)(py)]$ (R = Me **18** or Et **19**) were prepared from $Na[C_5H_5]$ and **12** or **13**. Attempts to prepare bis(pentamethylcyclopentadienyl)titanium imides from **12** and $Li[C_5Me_5]$ were unsuccessful and appeared to result in reduction to $Ti^{III}$.¶ The X-ray structure of **17** confirmed the pentahapto coordination of the cyclopentadienyl rings in the solid state and revealed a near-linear Ti=$NBu^t$ linkage. The sandwich titanium imido compounds are considerably more air- and moisture-sensitive than their half-sandwich analogues.

At first sight, the titanocene imido complexes **17–19** are twenty valence electron species. However, it appears that in these and related metallocene imido and oxo compounds[25,26] two of the 'excess' electrons are located in a ligand-based, non-bonding orbital having both $C_5H_5$ carbon and $NBu^t$ nitrogen character. Thus the actual Ti=$NBu^t$ bond order in compounds **17–19** is probably somewhere between two and three, with the titanium–cyclopentadienyl interactions presumably also somewhat weakened relative to 'normal' sixteen- and eighteen-electron titanocene derivatives. The Ti–$Cp_{cent}$ distances and $Cp_{cent}$–Ti–$Cp_{cent}$ angles ($Cp_{cent}$ = computed $C_5H_5$ centroid) for **17** are consistent with this hypothesis. Furthermore, reaction of lithium indenide with $[Ti(\eta^5\text{-}C_5H_5)(NBu^t)Cl(py)]$ **9** afforded the eighteen-electron, ring-slipped derivative $[Ti(\eta^5\text{-}C_5H_5)(\eta^3\text{-}C_9H_7)(NBu^t)(py)]$ **20**. Moreover, an equimolar mixture of $[Ti(NBu^t)Cl_2(py)_2]$ **2a** and $[Ti(\eta^5\text{-}C_5H_5)_2(NBu^t)(py)]$ **17** in $C_6D_6$ underwent a very facile, room temperature redistribution reaction in $C_6D_6$ to give **9** quantitatively, again indicative of $C_5H_5$ ligand labilisation in the bis(cyclopentadienyl) com-

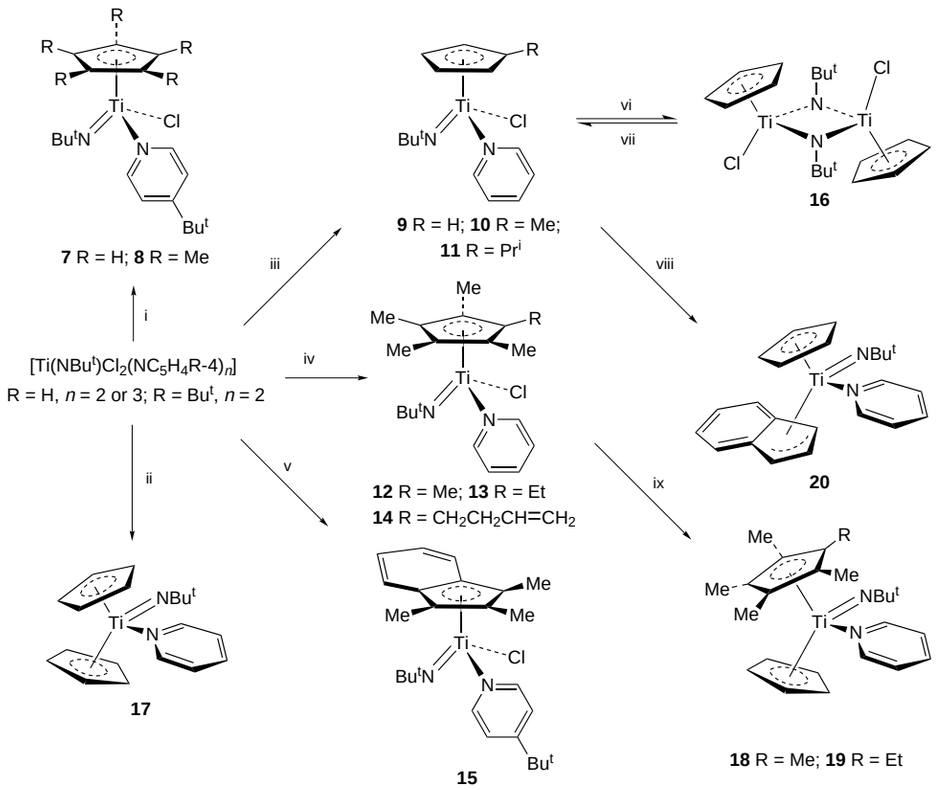

**Fig. 3** Sandwich and half-sandwich titanium imido derivatives.[20] *Reagents and conditions*: (i) for **7**: Na[$C_5H_5$], for **8**: Li[$C_5Me_5$]; (ii) Na[$C_5H_5$] (2 equiv.); (iii) for **9**: Na[$C_5H_5$], for **10**: Li[$C_5H_4Me$], for **11**: Li[$C_5H_4Pr^i$], (iv) for **12**: Li[$C_5Me_5$], for **13**: Li[$C_5Me_4Et$], for **14**: Li[$C_5Me_4C_4H_7$]; (v) Li[$C_9H_4Me_3$]; (vi) $1 \times 10^{-2}$ mbar, 85 °C; (vii) py (3 equiv.); (viii) Li[$C_9H_7$]; (ix) Na[$C_5H_5$].

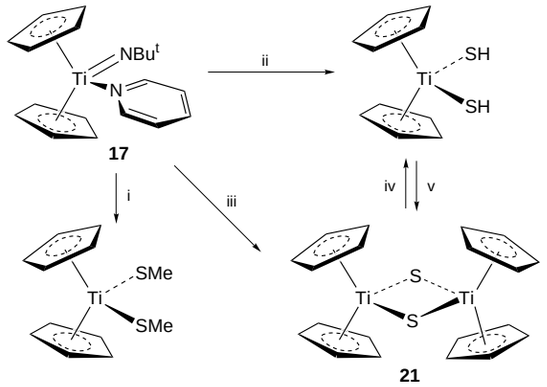

**Fig. 4** Reactions of [$Ti(\eta^5\text{-}C_5H_5)_2(NBu^t)(py)$] **17** with S–H bonds.[28] *Reagents*: (i) MeSH (excess); (ii) $H_2S$ (excess); (iii) $H_2S$ (1 equiv.); (iv) $H_2S$ (excess); (v) **17** (1 equiv.).

plexes. By way of comparison, the analogous $C_5H_5$ ring redistribution reaction between [$Ti(\eta^5\text{-}C_5H_5)_2Cl_2$] and $TiCl_4$ required elevated temperatures and longer reaction times.[27]

*Reactions with S–H bonds:* Tetraazamacrocycle-supported titanium *tert*-butyl imido derivatives (*vide infra*) undergo facile exchange of Ti=NBu$^t$ for terminal Ti=E (E = O, S, NAr or $NNPh_2$) groups on treatment with $H_2E$. We have investigated possible analogous routes to titanocene mono(sulfide) complexes (Fig. 4).[28] Not surprisingly, reaction of [$Ti(\eta^5\text{-}C_5H_5)_2(NBu^t)(py)$] **17** with an excess of MeSH affords the previously described [$Ti(\eta^5\text{-}C_5H_5)_2(SMe)_2$]. An intermediate species formulated as [$Ti(\eta^5\text{-}C_5H_5)_2(NHBu^t)(SMe)$] was observed by $^1$H NMR spectroscopy but was not isolated. With an excess of $H_2S$, **17** gives high yields of [$Ti(\eta^5\text{-}C_5H_5)_2(SH)_2$], but with one equivalent of $H_2S$ the new bis(μ-sulfide) [$Ti_2(\eta^5\text{-}C_5H_5)_4(\mu\text{-}S)_2$] **21** was obtained. Compound **21** may also be prepared by reaction of **17** with [$Ti(\eta^5\text{-}C_5H_5)_2(SH)_2$]. In neither of these reactions was evidence for a titanocene terminal sulfido derivative found.¶ The thermally labile compound **21** is a possible intermediate in the formation of [$Ti(\eta^5\text{-}C_5H_5)_2(SH)_2$] since treatment of **21** with an excess of $H_2S$ gave a quantitative yield of [$Ti(\eta^5\text{-}C_5H_5)_2(SH)_2$].

These reactions comprised the first reports of S–H bond 'activation' for Group 4 metal imido complexes. Furthermore, the complex [$Ti_2(\eta^5\text{-}C_5H_5)_4(\mu\text{-}S)_2$] **21** represents a kind of 'missing link' both in the titano- and zircono-cene bis(μ-chalcogenido) series [$M_2(\eta\text{-}C_5R_5)_4(\mu\text{-}E)_2$] (M = Ti or Zr; E = S or Se) and in the bis(titanocene) μ-(poly)sulfido series [$Ti_2(\eta\text{-}C_5H_4R)_4(\mu\text{-}S_x)_2$] ($x$ = 1, 2 or 3), which have been the subject of considerable research activity.

## Mono- and bi-nuclear derivatives with aryloxide ligands: fine control by *ortho*-substituents

As mentioned, five-coordinate aryloxide-supported derivatives were among the first terminal titanium imido compounds to be structurally characterised.[8,29] The transient imido complex [$Ti(NSiBu^t)(OSiBu^t)_2$] has been proposed as a reactive intermediate.[30] We were interested in extending these studies by exploring in detail the dependence of the structures, nuclearity and metal coordination number of aryloxide-supported titanium imides upon the steric demands of the ligand O- and N-substituents.[31]

The reaction products of [$Ti(NBu^t)Cl_2(py)_3$] **1a** with lithium aryloxides (Fig. 5) show the relationship between the product nuclearity and coordination number and the steric bulk of the aryloxide ligand *ortho*-substituents. The structure of [$Ti_2(\mu\text{-}NBu^t)_2(OC_6H_3Me_2\text{-}2,6)_4$] **22** was confirmed by X-ray crystallography and [$Ti(NBu^t)(OC_6H_3Bu^t_2\text{-}2,6)_2(py)$] **24** was established as a monomer by solution molecular mass determinations. The {$Ti(\mu\text{-}NBu^t)_2Ti$} core in compound **22** can be

cleaved by an excess of pyridine to form mononuclear $[Ti(NBu^t)(OC_6H_3Me_2\text{-}2,6)_2(py)_2]$ **25a**. Although the *tert*-butyl imido compound **25a** slowly dimerises to **22** over time, the aryl imido homologues $[Ti(NC_6H_3R_2\text{-}2,6)(OC_6H_3Me_2\text{-}2,6)_2(py)_2]$ [R = Me **25b** (X-ray structure) or $Pr^i$ **25c**] are stable.

We have analysed the bonding in $[Ti_2(\mu\text{-}NBu^t)_2(O\text{-}C_6H_3Me_2\text{-}2,6)_4]$ **22** using extended Hückel molecular orbital (EHMO) calculations and reached two important conclusions.[31] First, symmetry constraints mean that the Ti centres in **22** can only ever achieve a valence electron count of sixteen, even though the formal hybridisation of the imido N- and terminal aryloxide O-atoms suggests that metal electron counts of eighteen are apparently possible. Second, the deviation of the μ-imido $Bu^t$ substituents from coplanarity with the $Ti_2N_2$ unit in both **22** and related species such as $[Ti_2(\mu\text{-}NBu^t)_2(NMe_2)_4]$ can be attributed to a second-order Jahn–Teller distortion which arises because of competition between the terminal and bridging π-donor ligands for metal $d_\pi$-acceptor orbitals.

## Amidinate derivatives

In contrast to other areas of main group and transition metal chemistry, amidinate ligands[32,33] have been little used in metal imido systems.[34–38] We have recently reported new niobium imido (and oxo) benzamidinate derivatives,[39] and this work is complemented by the titanium imido amidinate chemistry summarised below.

The steric and solubility properties of amidinate ligands $R'C(NR)_2$ may be modified by changing the R′ and R groups. We have compared (Fig. 6) the reactions of lithium *N*,*N*′-bis(trimethysilyl)benzamidinate and lithium *N*,*N*′-bis(cyclohexyl)acetamidinate with $[Ti(NR)Cl_2(py)_3]$ (R = $Bu^t$ **1a**, $C_6H_3Me_2$-2,6 **1b** and $C_6H_3Pr^i_2$-2,6 **1c**).[40] Reaction of $Li[PhC(NSiMe_3)_2]$ with **1a**–**1c** afforded the corresponding mononuclear compounds $[Ti(NR)\{PhC(NSiMe_3)_2C\}l(py)_2]$ **26a**–**c** as confirmed by X-ray crystallography for **26b**. In contrast, reaction of $Li[MeC(NC_6H_{11})_2]$ with **1a** led to the structurally characterised binuclear derivative $[Ti_2(\mu\text{-}NBu^t)_2\{MeC(NC_6H_{11})_2\}_2Cl_2]$ **27** which contains no pyridine coligands. Attempts to prepare aryl imido analogues of **26** or **27** from $Li[MeC(NC_6H_{11})_2]$ and $[Ti(NC_6H_3Me_2\text{-}2,6)Cl_2(py)_3]$ **1b** were unsuccessful.

All three compounds **26a**–**c** form six-coordinate bis(pyridine) adducts in the solid state, but in solution they exist in temperature-dependent dynamic equilibrium with the fourteen valence electron, mono(pyridine) homologues **26a′**–**c′** (Fig. 6). Thermodynamic parameters (Table 1) associated with these equilibria have been determined by NMR spectroscopy and

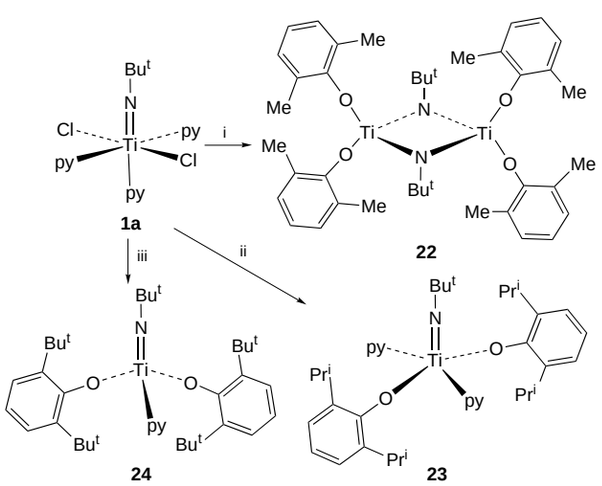

**Fig. 5** Reactions of $[Ti(NBu^t)Cl_2(py)_3]$ **1a** with $Li[OC_6H_3R_2\text{-}2,6]$: fine control by *ortho*-substituents.[31] *Reagents*: (i) $Li[OC_6H_3Me_2\text{-}2,6]$ (2 equiv.); (ii) $Li[OC_6H_3Pr^i_2\text{-}2,6]$ (2 equiv.); (iii) $Li[OC_6H_3Bu^t_2\text{-}2,6]$ (2 equiv.).

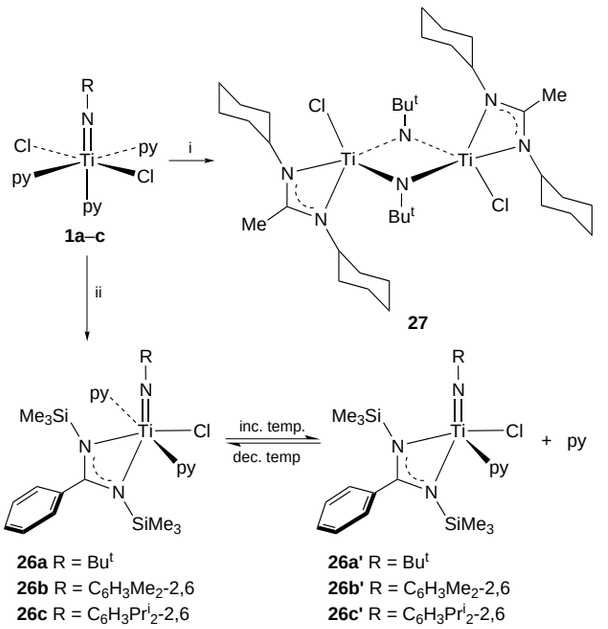

**Fig. 6** Mono- and bi-nuclear titanium imido complexes with amidinate ligands.[40] *Reagents*: (i) $Li[MeC(NC_6H_{11})_2]$; (ii) $Li[PhC(NSiMe_3)_2]$.

reveal the underlying effects of the different imido N-substituents. Activation parameters for the forward (*i.e.* **26a** or **26b** → **26a′** or **26b′** + py) and reverse (**26a′** or **26b′** + py → **26a** or **26b**) processes have also been measured. The differences between the derived $\Delta G^{\ddagger}_{258\,K}$ values for the forward and reverse steps compare very well with the equilibrium thermodynamic $\Delta G_{258\,K}$ values which show that all three equilibria are effectively thermochemically neutral. The large positive $\Delta S$ values are consistent with the dissociative equilibria as written and nearly compensate for the endothermic $\Delta H$ term at higher temperatures.

Very recent results for $[Ti(NBu^t)\{PhC(NSiMe_3)_2C\}l(py)_2]$ **26a** promise an extensive reaction chemistry for the amidinate-supported titanium imido compounds.[18] Straightforward metathesis reactions afford a range of organometallic and inorganic derivatives in good to excellent yields (Fig. 7). The half-sandwich compound **29** can also be prepared from $Li[PhC(NSiMe_3)_2]$ and $[Ti(\eta^5\text{-}C_5Me_5)(NBu^t)Cl(NC_5H_4Bu^t\text{-}4)]$ **8**.[18]

## Tris(pyrazolyl)hydroborate derivatives

Fig. 8 summarises the synthesis of sixteen valence electron tris(pyrazolyl)hydroborate derivatives $[Ti(L)(NBu^t)Cl(NC_5H_4Bu^t\text{-}4)]$ (L = $Tp^{Me2}$ **34**, $Tp^{Pri}$ **35** or $Tp^{Pri,Br}$ **36**) *via* reaction of $[Ti(NBu^t)Cl_2(NC_5H_4Bu^t\text{-}4)_2]$ **3** with one equivalent of $K[Tp^{Me2}]$, $K[Tp^{Pri}]$ or $K[Tp^{Pri,Br}]$ [$Tp^{Me2}$ = tris(3,5-dimethylpyrazolyl)hydroborate; $Tp^{Pri}$ = tris(3-isopropylpyrazolyl)hydroborate; $Tp^{Pri,Br}$ = tris(3-isopropyl-4-bromopyrazolyl)hydroborate] respectively.[41] Compounds **34**–**36** are the first Group 4 tris(pyrazolyl)hydroborate-supported imido complexes and are isolobal analogues of the half-sandwich

**Table 1** Thermodynamic parameters for the dissociative equilibria of $[Ti(NR)\{PhC(NSiMe_3)_2\}Cl(py)_2]$ [R = $Bu^t$ **26a**, $C_6H_3Me_2$-2,6 **26b** or $C_6H_3Pr^i_2$-2,6 **26c**][40]

complexes [Ti($\eta^5$-$C_5R'_5$)(NBu$^t$)Cl($NC_5H_4$R-4)] (**7**–**14**). Unlike the cyclopentadienyl compounds, however, the tris(pyrazolyl)hydroborate species are fluxional on the $^1$H and $^{13}$C NMR timescales, the spectra indicating restricted rotation about the Ti–($NC_5H_4$Bu$^t$-4) bond. Activation parameters were determined for **34** and the barrier to pyridine rotation obtained from coalescence measurements ($\Delta G^{\ddagger}_{267\,K}$ = 51.1 kJ mol$^{-1}$) compared very well with that calculated (51.4 kJ mol$^{-1}$) from the $\Delta S^{\ddagger}$ and $\Delta H^{\ddagger}$ values using lineshape analysis.

## Diamidoamine and diamidopyridine derivatives

The tetradentate, triamidoamine (tren) ligands [(RNCH$_2$CH$_2$)$_3$N]$^{3-}$ have been used with spectacular success for developing the metal–ligand multiple bond chemistry of groups 5–7.[42] We have started to explore the potential of tridentate diamidoamine[43] and diamidopyridine[44] ligands in Group 4 imido chemistry. While being related to the triamidoamines, the dianionic diamidoamine and diamidopyridine ligands have a dative nitrogen donor 'arm' which can in principle readily detach from the metal centre to open up reversibly a more reactive site. Furthermore, they require only two d electrons for metal–ligand bonding, thus enabling neutral imido derivatives for the Group 4 metals. Although our work in this area is at a very early stage, some important results have already been obtained (Fig. 9).[18,45]

Reaction of Li$_2$[Me$_3$SiN(CH$_2$CH$_2$NSiMe$_3$)$_2$] with [Ti(NBu$^t$)Cl$_2$(py)$_3$] **1a** gave the crystallographically characterised derivative [Ti(NBu$^t$){Me$_3$SiN(CH$_2$CH$_2$NSiMe$_3$)$_2$}py)] **37** in good yield. Similarly, addition of [Li$_2${MeC($C_5H_4$N-2)(CH$_2$NSiMe$_3$)$_2$}]$_2$ to **1a** in benzene gave [Ti(NBu$^t$){MeC($C_5H_4$N-2)(CH$_2$NSiMe$_3$)$_2$}(py)] **38** which has also been crystallographically characterised. Compounds **37** and **38** are the first fully characterised examples of terminal titanium imides supported by amido ligands, although the complex [Ti(NSiBu$^t_3$)(NHSiBu$^t_3$)$_2$] has been proposed as a reactive transient in C–H bond activation reactions.[10] Fig. 9 shows the product of the remarkable reaction between **38** and methyl isocyanide, namely [Ti{MeC($C_5H_4$N-2)(CH$_2$NSiMe$_3$)$_2$}{N(Me)N(Bu$^t$)-1,2-($C_4H_3N_2$Me-3)}] **39**, which has been structurally characterised. The Ti=NBu$^t$ linkage of **1a** has clearly undergone a C–N and C–C coupling reaction (with concomitant C–H bond migration) with three molecules of MeNC to form a coordinated 3-methyl-5,6-diamino-2,3-dihydropyrimidine derivative. The type of reaction giving rise to **39** is unprecendented in Group 4 imido chemistry. It is also highly selective with **39** being the only new species formed when the reaction was

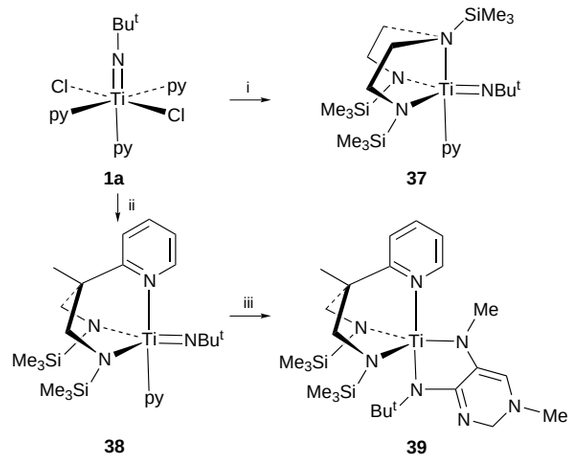

**Fig. 9** Titanium imido complexes with diamidoamine and diamidopyridine ligands.[18,45] *Reagents*: (i) Li$_2$[Me$_3$SiN(CH$_2$CH$_2$NSiMe$_3$)$_2$]; (ii) [Li$_2${MeC($C_5H_4$N-2)(CH$_2$NSiMe$_3$)$_2$}]$_2$; (iii) MeNC (3 equiv.).

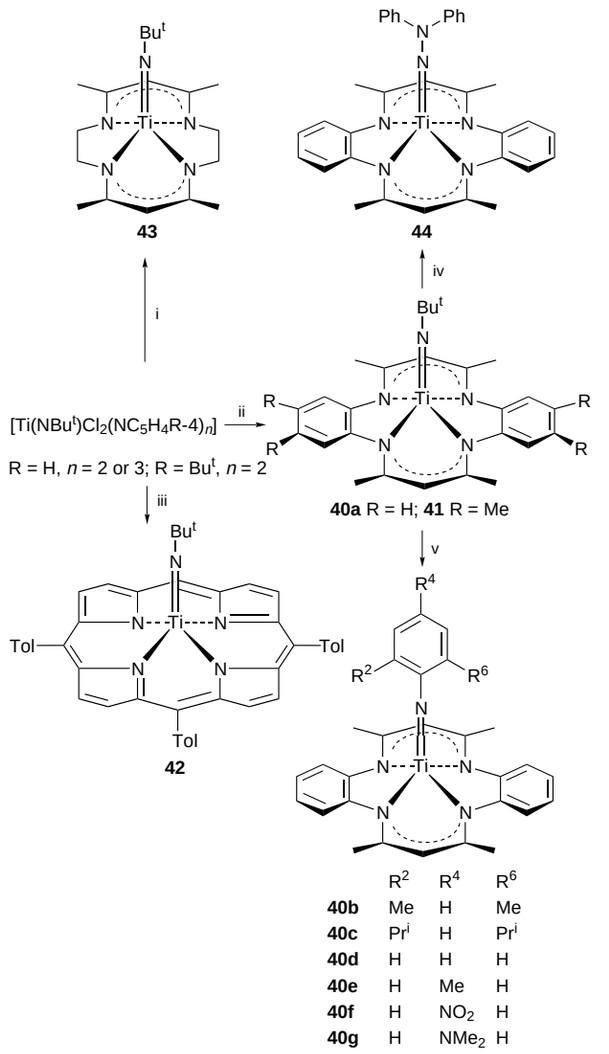

**Fig. 10** Titanium imido complexes with dibenzotetraaza[14]annulene and some other tetraazamacrocyclic ligands.[12,18,52] *Reagents*: (i) $Li_2[Me_4taen]$; (ii) for **40a**: $Li_2[Me_4taa]$, for **41**: $Li_2[Me_8taa]$; (iii) $Li_2[ttp]$; (iv) $Ph_2NNH_2$; (v) aniline or substituted aniline.

followed by $^1$H NMR spectroscopy. The Ti=NBu$^t$ functional group in **38** also reacts with a range of other unsaturated organic substrates and work is in progress to determine the scope of this chemistry.

## Tetraazamacrocycle-supported derivatives

### *Syntheses*

Prompted by reports that the Ti=O linkage in the tetraazamacrocycle-supported compound [Ti(O)($Me_4$taa)][46] ($H_2Me_4$taa = tetramethyldibenzotetraaza[14]annulene) is reactive towards a range of organic and inorganic substrates,[47] we prepared (Fig. 10) the titanium *tert*-butyl imido analogues [Ti(NBu$^t$)($Me_n$taa)] (*n* = 4 **40a** or 8 **41**; $H_2Me_8$taa = octamethyldibenzotetraaza[14]annulene) from [Ti(NBu$^t$)$Cl_2(L)_n$] and $Li_2[Me_n taa]$.[12,48] Compounds **40a** and **41** were the first reported macrocycle-supported Group 4 imido compounds. Woo and coworkers subsequently reported the synthesis of [Ti(NR)(ttp)] (R = Bu$^t$ **42**, Ph, $C_6H_4$Me-4 or $C_6H_{11}$; $H_2$ttp = tetratolylporphyrin) from [Ti(ttp)$Cl_2$].[49] We have shown that **42** can also be obtained in good yield by treating [Ti(NBu$^t$)$Cl_2(py)_3$] **1a** with $Li_2$[ttp].[18] In related studies (Fig. 10) we found that reactions of $Li_2[Me_4taen]$ ($H_2Me_4$taen = 5,7,12,14-tetramethyl-1,4,8,11-tetraazacyclotetradeca-4,6,11,13-tetraene) with **1a** gives [Ti(NBu$^t$)($Me_4$taen)] **43**. We have also recently prepared related $Me_4$taa-supported zirconium imido and amido complexes.[50,51]

Exchange reactions (Fig. 10) of [Ti(NBu$^t$)($Me_4$taa)] **40a** with a range of anilines or *N*,*N*-diphenylhydrazine afforded the homologues [Ti(NAr)($Me_4$taa)] (Ar = $C_6H_3Me_2$-2,6 **40b**, $C_6H_3Pr^i_2$-2,6 **40c**, Ph **40d**, $C_6H_4$Me-4 **40e**, $C_6H_4NO_2$-4 **40f** or $C_6H_4NMe_2$-4 **40g**) and [Ti($NNPh_2$)($Me_4$taa)] **44** respectively.[18,52] Although most of these reactions were quantitative by $^1$H NMR spectroscopy, they were noticeably slower than those of [Ti(NBu$^t$)$Cl_2(py)_3$] **1a** (Fig. 2). Indeed, the 2,6-diisopropylphenyl imido derivative **40c** was only obtained in trace quantities after long reaction times. The X-ray structures of **40b**[52] and **41**[12] have been determined. No bis(amide) intermediates were observed when the reactions of [Ti(NBu$^t$)($Me_4$taa)] **40a** with anilines were followed by $^1$H NMR spectroscopy and no evidence was found for equilibrium concentrations of [Ti($NHR)_2$($Me_4$taa)] in solutions containing [Ti(NR)($Me_4$taa)] and $H_2$NR (R = Bu$^t$ or $C_6H_3Me_2$-2,6). In contrast, the zirconium aryl imido homologue (which is obtained as a pyridine adduct) [Zr($NC_6H_3Pr^i_2$-2,6)(py)($Me_4$taa)] reacts immediately and irreversibly with $H_2NC_6H_3Pr^i_2$-2,6 to form the bis(anilide) [Zr($HNC_6H_3Pr^i_2$-2,6)$_2$($Me_4$taa)].[50] Interestingly, we note that [Ti(NBu$^t$)(ttp)] **43** does not undergo exchange reactions with anilines.[49] This underlines the importance of the choice of macrocyclic ligands.

### *Reactions of [Ti(NBu$^t$)($Me_4$taa)]* **40a** *with O–H and S–H bonds*

Treatment of **40a** with $H_2E$ (E = O or S) gave the previously described[46] [Ti(E)($Me_n$taa)] in quantitative yield (Fig. 11). Compound **40a** also undergoes protonolysis with aryl and alkyl alcohols and diols to form [Ti($OR)_2$($Me_4$taa)] (R = Me **45** or $OC_6H_3Me_2$-2,6 **46**; $(OR)_2 = O_2C_2Me_4$ **47** or $O_2C_6H_4$ **48**[46]), and with MeSH to form [Ti($SMe)_2$($Me_4$taa)] **49** by $^1$H NMR spectroscopy. Reaction of **49** with $H_2S$ forms [Ti(S)($Me_4$taa)] and MeSH. By analogy with the *tert*-butyl imide/aniline exchange processes (Fig. 10), when reactions of [Ti(NBu$^t$)($Me_4$taa)] **40a** with $HOC_6H_3Me_2$-2,6, MeSH or $H_2S$ were followed by $^1$H NMR spectroscopy, no six-coordinate intermediates [Ti(ER)(NHBu$^t$)($Me_4$taa)] (ER = $OC_6H_3Me_2$-2,6, SMe or SH) were observed. Furthermore, reaction of **40a** with one equivalent of $HOC_6H_3Me_2$-2,6 gave a *ca.* 50% yield of [Ti($OC_6H_3Me_2$-2,6)$_2$($Me_4$taa)] and unreacted **40a**.

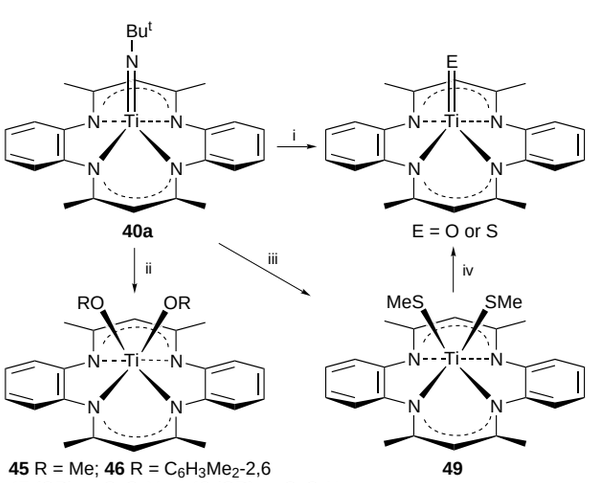

**Fig. 11** Reactions of [Ti(NBu$^t$)($Me_4$taa)] **40a** with O–H and S–H bonds.[12,18] *Reagents*: (i) $H_2E$ (E = O or S); (ii) ROH (2 equiv. of OH functional group); (iii) MeSH (2 equiv.); (iv) for [Ti(S)($Me_4$taa)]: $H_2S$ (excess).

### *Reactions of [Ti(NAr)(Me$_4$taa)] (Ar = Ph* **40d** *or Tol* **40e**) *with isocyanates, CO$_2$ and carbodiimides*

We have studied the cycloaddition and metathesis reactions of the compounds [Ti(NR)(Me$_4$taa)] **40** with a range of organic substrates.[18,50] Fig. 12 summarises some of the reactions of [Ti(NAr)(Me$_4$taa)] (Ar = Ph **40d** or Tol **40e**), along with some new, comparative reactions of [Ti(O)(Me$_4$taa)].

Reaction of **40d** or **40e** with isocyanates PhNCO or TolNCO gave the *N*,*N*′-bonded ureates [Ti{N(Ar)C(O)N(Ar)}(Me$_4$taa)] (Ar = Ph **50** or Tol **51**, respectively) in good yields.[50] The mixed N-aryl substituent ureate [Ti{N(Ph)C(O)N-(Tol)}(Me$_4$taa)] **52** was prepared similarly from **40e** and PhNCO. In related studies, [Zr(N-C$_6$H$_3$Pr$^i_2$-2,6)(py)(Me$_4$taa)] reacted with Bu$^t$NCO to give the crystallographically characterised *N*,*N*′-bound ureate [Zr{N(C$_6$H$_3$Pr$^i_2$-2,6)C(O)N(Bu$^t$)}-(Me$_4$taa)].[50] The titanium congener **52** exhibits novel reactivity such that treatment with an excess of PhNCO gave [Ti{N(Ph)-C(O)N(Ph)}(Me$_4$taa)] **50** with extrusion of TolNCO from the ureate ligand. $^1$H NMR crossover experiments eliminated [Ti(NPh)(Me$_4$taa)] **40d** as an intermediate, thus suggesting that the PhNCO–TolNCO exchange involves an unusual associative mechanism proceeding *via* a biuret-type species, [Ti{N(Ph)C(O)N(Ph)C(O)N(Tol)}(Me$_4$taa)]. The exchange reaction of **52** was the first example of the reversible insertion of an isocyanate into the metal–N bond of a ureate ligand.

Reaction of [Ti(NTol)(Me$_4$taa)] **40e** with di-*p*-tolylcarbodiimide gave [Ti{N(Tol)C(NTol)N(Tol)}(Me$_4$taa)] **53** which is a rare example of a triazatrimethylene methane metal complex.[53] Reaction of **40e** with $CO_2$ gave the *O*,*O*′-bonded carbamate species [Ti{OC(NTol)O}(Me$_4$taa)] **54**. Compound **54** is presumably a thermodynamic (as opposed to kinetic) product since the expected first-formed product would be the *N*,*O*-bonded linkage isomer [Ti{N(Tol)C(O)O}(Me$_4$taa)]. In comparative studies, we found that treatment of [Ti(O)(Me$_4$taa)] with TolNCO also formed **54** exclusively. This is again consistent with compound **54** being the thermodynamically favoured isomer. Thus rearrangements of the macrocycle-supported titanium-imido and -oxo cycloaddition products appears to be facile, as emphasised by the reaction of [Ti(O)(Me$_4$taa)] with di-*p*-tolylcarbodiimide (Fig. 12). This gave the *N*,*N*′-bound ureate **51** (also obtained from **40e** and TolNCO) rather than the *N*,*O*-bonded linkage isomer [Ti{OC(NTol)N(Tol)}(Me$_4$taa)] which would presumably form as a first intermediate in a Ti=O + TolN=C=NTol [2 + 2] cycloaddition reaction. Furthermore, even if the reactions in Fig. 12 proceed *via* nucleophilic attack of the imido N- or oxo O-atom at the central cumulene carbon E=C=E′ (*i.e.*, instead of going *via* direct cycloaddition), the formation of **54** from **40e**, and of **51** from [Ti(O)(Me$_4$taa)], still require rearrangement processes involving Ti–N and Ti–O bond cleavage respectively.

### Titanium imides with other dianionic ligands

Ongoing work in our group with other dianionic ligands has established further new classes of organometallic and coordination titanium imido compounds. As with the syntheses of the tetraazamacrocyle-supported derivatives [Ti(NBu$^t$)(Me$_4$taa)] **40a**, [Ti(NBu$^t$)(ttp)] **42** and [Ti(NBu$^t$)(Me$_4$taen)] **43**, straighforward reactions of disodium or dilithium salts Li$_2$[C$_8$H$_6$-(SiMe$_3$)$_2$], [Na$_2$(L)]$_2$ (LH$_2$ = 1,3-dimethyl ether *p*-*tert*-butylcalix[4]arene) or Na$_2$[Bu$^t_4$salen] [H$_2$Bu$^t_4$salen = tetrakis(*tert*-butyl)salen] with [Ti(NBu$^t$)Cl$_2$(py)$_3$] gave good yields of the corresponding new imido complexes [Ti(NBu$^t$){$\eta^8$-C$_8$H$_6$(SiMe$_3$)$_2$}] **55**, [Ti(NBu$^t$)(L)] **56** or [Ti(NBu$^t$)(Bu$^t_4$salen)] **57** repectively.[18,48,54] Studies of these and related systems are currently underway.

### Concluding remarks

Over the last three years we have shown that many new types of titanium and other Group 4 metal imido complex can be readily accessed through high-yielding, straightforward synthetic methods. A variety of both new and familiar reaction types have already been found for the new compounds. It is very likely that the next phase of Group 4 imido chemistry will focus much more on developing new reactions towards organic substrates and catalytic processes.

### Acknowledgements

I am indebted to my current and former graduate and postdoctoral coworkers for their contributions to the chemistry described in this article. I thank also my collaborators and colleagues in Nottingham and elsewhere for many valuable discussions, and the EPSRC, Leverhulme Trust, British Council, Nuffield Foundation, University of Nottingham, Royal Society and NATO for funding.

† Although for ease of representation all metal–imido or –oxo linkages are drawn M=NR or M=O, the formal metal–ligand multiple bond order in the Group 4 imido compounds described herein is probably best thought of as three (pseudo-$\sigma^2\,\pi^4$; triple bond) rather than as two.[4] Formal bond orders for the imido linkage in the bis($\eta^5$-cyclopentadienyl)titanium imido and related compounds have been addressed.[4,20] General bond order assignments in a number of poly(imido) transition metal compounds have been proposed.[55]

‡ Throughout this review the suffixes **a**, **b** and **c** for homologous series of imido compounds $[Ti(NR)(L)_n]_m$ refer to those with R = $Bu^t$, $C_6H_3Me_2$-2,6 and $C_6H_3Pr^i_2$-2,6, respectively.

§ Vinylimido titanocene derivatives have been described but their reactions invariably involve [4 + 2] cycloadditions. Hence the reactivity of the non-conjugated Ti=NR functional group cannot be studied in these systems.[56]

¶ Although bis(pentamethylcyclopentadienyl) derivatives cannot be obtained *via* our route, Andersen and co-workers have recently found that reaction of $[Ti(\eta\text{-}C_5Me_5)_2(\eta^2\text{-}C_2H_4)]$ with $ArN_3$ or with $S_8$ and pyridine affords $[Ti(\eta\text{-}C_5Me_5)_2(NAr)]$[57] and $[Ti(\eta\text{-}C_5Me_5)_2(S)(py)]$ respectively.[58]

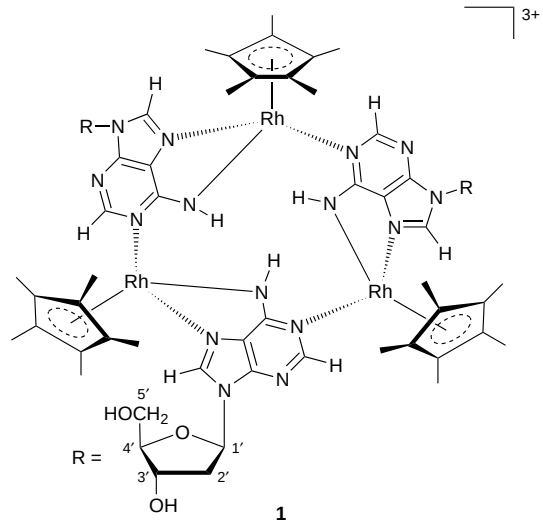
# Gas phase molecular recognition of aromatic amino acid and aromatic carboxylic acid guests with a supramolecular [(η$^5$-pentamethylcyclopentadienyl)rhodium(2′-deoxyadenosine)]$_3^{3+}$ cyclic trimer host *via* non-covalent π–π interactions utilizing electrospray ionization mass spectroscopy†

**Ray Bakhtiar,[a] Hong Chen,[b]‡ Seiji Ogo[b]§ and Richard H. Fish*[b]**



[a] *Department of Chemistry, Stevens Institute of Technology, Castle Point on The Hudson, Hoboken, NJ 07030, USA*
[b] *Lawrence Berkeley National Laboratory, University of California, Berkeley, California 94720, USA*

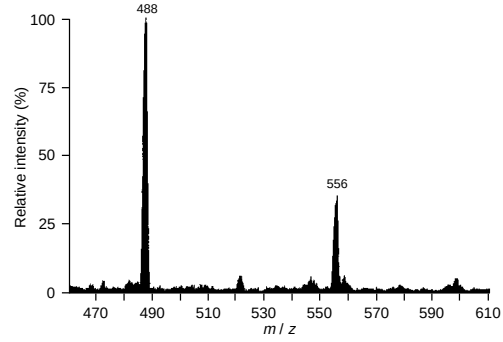
**A novel, gas phase, host–guest molecular recognition process, detected by electrospray ionization mass spectrometry, using guests that encompass aromatic amino acids and aromatic and aliphatic carboxylic acids with a supramolecular, bioorganometallic host, [Cp*Rh(2′-deoxyadenosine)]$_3$[OTf]$_3$ (Cp* = η$^5$-C$_5$Me$_5$), is found to occur predominately *via* non-covalent π–π interactions; non-covalent hydrophobic forces apparently being weak or non-existent.**

Molecular recognition is the cornerstone of many important biological processes; for example, drug and protein interactions with selective DNA sequences.[1–3] Recently, we reported on the molecular recognition of aromatic and aliphatic amino acids, as well as aromatic and aliphatic carboxylic acid guests with supramolecular, bioorganometallic (η$^5$-pentamethylcyclopentadienyl)rhodium (Cp*Rh)–nucleobase/nucleoside/nucleotide cyclic trimer hosts in aqueous solution at pH 7.2.[4] More importantly, in that study, the non-covalent hydrophobic interactions were found to be fully operational in aqueous solution by solvophobic forces that enhanced host–guest complexation, along with the equally important non-covalent π–π interactions.

It was intriguing to extend these above-mentioned aqueous molecular recognition studies to the gas phase, to compare and to better understand the role of water and its effect on the important π–π, hydrophobic, and hydrogen-bonding parameters, including steric, electronic, and conformational effects, that we found controls the host–guest process; to our knowledge, this is the first reported gas phase, host–guest molecular recognition study using a bioorganometallic host. Moreover, it has been clearly demonstrated that the soft electrospray ionization mass spectroscopy (ESIMS) technique was ideally suited for detecting such gas phase host–guest complexes in the absence of solvent.[5–11]

We started our gas phase molecular recognition ESIMS studies with a perusal of the various triangular, bowl-shaped Cp*Rh–nucleobase/nucleoside/nucleotide cyclic trimer molecular receptors we had studied in water, using L-tryptophan (L-Trp) as the guest in all cases.[4] To our surprise, we found that the best host in water, [Cp*Rh(2′-deoxyadenosine)]$_3$(OTf)$_3$ **1**, was also the best host in the gas phase. Thus, when we mixed equimolar amounts of host **1** with guest L-Trp in an aqueous 10 mM $NH_4OAc$ solution at pH 7.0, ions for **1** and the host–guest complex (**1**·L-Trp) were observed at *m/z* 488 (100%) and *m/z* 556 (35%), respectively (Fig. 1). As well, by further increasing the orifice potential from 45 to 80 V, we are able to follow the dissociation of the *m/z* 556 ion for the **1**·L-Trp host–guest complex in the gas phase. From these latter results, we had our first indication of favorable non-covalent π–π interactions in the gas phase between host **1** and L-Trp, as in aqueous solution [association constant, $K_a$ = 607 dm$^3$ mol$^{-1}$; free energy of complexation, $\Delta G^0$ = −3.8 kcal mol$^{-1}$ (1 cal = 4.184 J) in $H_2O$].[4]

We also conducted additional gas phase, ESIMS host–guest experiments with L-Phe and G1–G5 (see Guest structures) in the presence of host **1**. Table 1 contains the results, and what was very interesting, was the fact that G4, which had an association constant, $K_a$ = 760 dm$^3$ mol$^{-1}$, and a free energy of complexation, $\Delta G^0$ = −3.9 kcal mol$^{-1}$, with **1** in water, provided no detectable host–guest complex in the gas phase. Thus, initial indications clearly show that non-covalent hydrophobic interactions between G4 and **1** appear to be weak in the gas phase, and opposite to what occurred in water.[4,9,10]



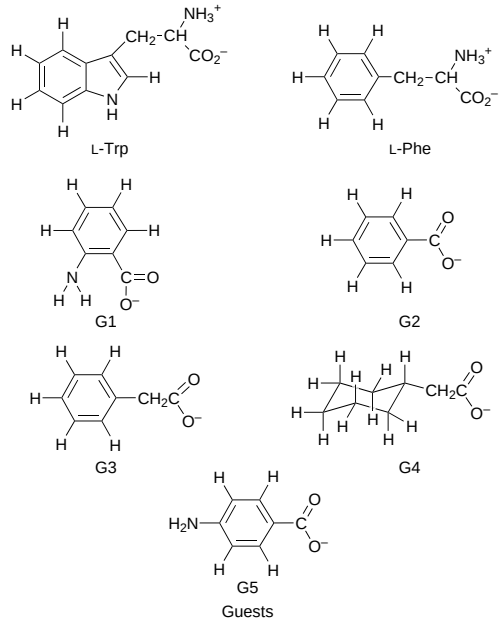


**Fig. 1** ESIMS of host **1** (*m/z* = 488) and host–guest, **1**·LTrp (*m/z* = 556) (experimental conditions, Table 1 footnotes)

Additionally, guest L-Phe, an aromatic amino acid that had a $K_a$ value of 456 dm$^3$ mol$^{-1}$ ($\Delta G^0$ = −2.8 kcal mol$^{-1}$) with **1** in aqueous solution, provided no corresponding detectable gas phase host–guest complex. Therefore, in water, L-Phe is in the prevalent zwitterion form at pH 7, and is more soluble in water and has a favorable Hansch partition coefficient, log $P_{octanol}$, in comparison to L-Trp; these factors appear to further demonstrate the solvophobic effect of water on the ability of L-Phe to form a strong host–guest complex in the aqueous phase.[4] Interestingly, in the gas phase, the water desolvated zwitterion form of L-Phe must inhibit host–guest complexation, apparently for reasons associated with its pronounced hydrophilicity.

In contrast, *o*-aminobenzoic acid ($K_a$ = 810 dm$^3$ mol$^{-1}$; $\Delta G^0$ = −4.0 kcal mol$^{-1}$, in $H_2O$ with **1**), G1, provides a detectable host–guest complex with **1** in the gas phase, since the free $NH_2$ group, in this instance, provides electron-donation to the aromatic ring thereby increasing π-electron density, and further facilitating non-covalent π–π interactions in the absence of solvent. Moreover, a positional isomer of G1, G5, which was found in the aqueous phase to sterically inhibit π–π interactions with host **1**, also did not provide a detectable host–guest complex in the gas phase, thus verifying a similar inhibition with the desolvated guest. Furthermore, aromatic carboxylic acids, G2 and G3, also readily provide detectable host–guest complexes in the gas phase with **1**, and again, dramatizes the dominance of the aromatic π electron effect in the gas phase molecular recognition process with the electron deficient host **1**.

**Table 1** Host–guest complexes in the gas phase with host **1**[a]

| Guest | Host ion, *m/z* (%) | Host–guest ion, *m/z* (%) |
|---|---|---|
| L-Trp | 488 (100) | 556 (35) |
| L-Phe | 488 (100) | ND[b] |
| G1 | 488 (100) | 534 (25) |
| G2 | 488 (100) | 528 (36) |
| G3 | 488 (100) | 533 (40) |
| G4 | 488 (100) | ND |
| G5 | 488 (100) | ND |

[a] An API III plus triple quadrapole spectrometer (PE-Sciex), equipped with an ion spray interface, was used for these ESIMS experiments. Host **1** and the guests in equimolar concentrations were dissolved in an 10 mM ammonium acetate solution at pH 7.0 and then delivered at 2.5 μl min$^{-1}$ to the ion-spray tip *via* a 50 μm id fused silica capillary. The ion-spray tip was held at a potential of 4.8 kV and compressed air (45 psi) was employed to assist liquid nebulization. Interface temperature (55 °C); orifice potential (45 V); positive ion detection mode; 5–10 scans summed for each host–guest experiment (±5–10%), which were performed three times. [b] Not detected.

The ESIMS literature with organic hosts and various guests has reported few comparisons of aqueous solution and gas phase molecular recognition chemistry.[5–11] However, the limited reported studies also demonstrate that the aqueous solvent is an important parameter especially for hydrophobic effects.[4,9,10] Thus, in the absence of water; *i.e.* under ESIMS conditions, this solvophobic force is missing, and therefore, non-covalent hydrophobic effects are greatly weakened in the gas phase, as is corroborated in this ESIMS study.

Future ESIMS molecular recognition studies will focus on the gas phase host–guest complexes of substituted aromatic carboxylic acid guests with **1** for a further understanding of steric and electronic effects involving non-covalent π–π interactions. As well, we will also focus on the molecular recognition of peptides containing terminal Trp or Phe groups with host **1**, and a comparison of the gas phase results with similar peptide–host **1** non-covalent π–π interactions in water, as analyzed by $^1$H NMR spectroscopy. In a preliminary experiment in both the gas phase (ESIMS) and in water ($^1$H NMR spectroscopy), it was found that the Trp–Met–Asp–Phe tetrapeptide with host **1** formed a host–guest complex in water that is detected in the gas phase; $^1$H NMR shows π–π interactions with the both terminal Trp or Phe groups.[12] Thus, complex **1** can be thought of as a simplified model DNA host which selectively binds peptides with terminal Trp or Phe groups *via* non-covalent π–π interactions in aqueous solution that are detected in the gas phase.

The studies at LBNL were generously supported by the Department of Energy under Contract No. DE AC03-76SF00098. R. B. wishes to acknowledge Merck Research Laboratories for the use of the ESIMS equipment and facilities.

# Syntheses of phosphate diesters having *p-tert*-butylcalix[4]arene and alkyl group as ester moieties, and their selective lithium cation transport abilities through liquid membranes

**Sadatoshi Akabori,* Hideyuki Itabashi, Hisako Shimura and Masayuki Inoue**

*Department of Chemistry, Faculty of Science, Toho University, Funabashi-shi, Chiba 274, Japan*

**Phospate diesters, 2a, 2b and 2c, having *p-tert*-butylcalix-[4]arenes and alkyl groups as ester moieties exist as an equilibrium of cone and partial-cone conformations in solution and selectively transport $Li^+$; however, the conformations of the calix[4]arene moieties in the Li and Na complexes of 2a as the methyl ester and/or 2b as the ethyl ester in solution are cone only, although that of the K complex exists as a mixture of cone and partial-cone conformers.**

Calix[4]anene derivatives show highly selective complexing abilities, toward transition metal,[1–3] Na,[4–7] K[6–8] and Cs[9,10] cations. However, reports of selective complexing ability for the $Li^+$ are rare.[11] Also, the relationship between the complexing ability for metal cations and the conformation of calix[*n*]arene derivatives has been reported.[12] In previous papers, we reported that photoresponsive azocrown ethers,[13] benzocrown ethers,[13] dibenzocrown ethers[15,16] and crown ethers[17] having alkylphosphoric acid groups as side arms are useful as selective and efficient $Li^+$ carriers for liquid–liquid extraction and liquid membrane transport. In connection with these findings, we have synthesized phosphate diesters, **2a**, **2b** and **2c** having 25,26,27-trimethoxy-28-hydroxy-*p-tert*-butylcalix[4]arenes and alkyl groups (R = Me, Et, $Pr^n$) as ester moieties and studied the complexing abilities with alkali metal cations.

**2a** R = Me
**b** R = Et
**c** R = $Pr^n$

The host molecules **2a**, **2b** and **2c**, were prepared by the treatment of 25,26,27-trimethoxy-28-hydroxy-*p-tert*-butylcalix[4]arene **1**[18] with alkyldichlorophosphate followed by hydrolysis in 37, 22 and 35% yields, respectively.† The $^1$H NMR spectra of **2a** showed the signals of the methyl protons of the $Bu^t$ groups as singlets at $\delta$ 1.27, 1.30 and 1.33, the signals of the methylene protons as doublets at $\delta$ 3.20, 3.25, 4.32 and 4.65, the signals of the methoxy protons of the anisole moieties as singlets at $\delta$ 3.81 and 3.88 together with the other proton peaks. These results show the presence of the cone conformers of **2a**. In addition to these peaks, the $^1$H NMR spectra arising from the partial-cone of **2a** contained the signals of the methyl protons of the $Bu^t$ groups as singlets at $\delta$ 1.06, 1.33 and 1.41, the signals of the methylene groups as a doublet at 3.14 and 4.57 and a singlet at 3.73 (4 H), and the signals of the methoxy protons of the anisole moieties as singlets at 3.14 and 3.67 together with other proton peaks. The $^{31}$P NMR spectra‡ of **2a** showed two peaks at $\delta$ −5.77 and −6.29. From these data and other NMR measurements (COSY, DEPT, NOSY), **2a** in solution at 25 °C exists as an equilibrium between the cone and partial-cone conformations. As shown in Fig. 1, in order to convert the cone to partial-cone only the *p-tert*-butyl anisole moiety, which is *trans* to the phosphate ester substituted ring, needs to invert. The conformation of **2b** and **2c** were determined by similar methods. The spectral data showed that **2a**, **2b** and **2c** exist as a mixture of cone and partial-cone isomers (5 : 3) in $CD_3CN$–$CDCl_3$ (7 : 3) at 25 °C (2 : 3 ratio in $CDCl_3$). These results suggest that the equilibrium between the cone and partial-cone isomers in **2a**, **2b** and **2c** is sensitively affected by the solvent polarity; the cone % increases with solvent polarity. These findings are consistent with the result obtained for 25,26,27,28-tetramethoxy-*p-tert*-butylcalix[4]arene by Iwamoto *et al.*[12] In the cone conformation, four dipoles in **2** are forced to orient into the same direction whereas in the partial-cone conformation, one dipole is reversed.

The comparative complexing abilities of **2a**, **2b**, **2c** and **1** toward alkali metal cations ($Li^+$, $Na^+$ and $K^+$) were evaluated using solvent extraction and competitive liquid membrane transport experiments[13–17] and results are summarized in Table 1. The extraction abilities of **1** toward $Li^+$, $Na^+$ and $K^+$ are very low (9.3–11.7%) compared with those of **2a**, **2b** and **2c** and the selectivities for $Li^+/Na^+$, $Li^+/K^+$ and $Na^+/K^+$ are nearly of the same order (0.79–1.15). However, **2a**, **2b** and **2c** showed much higher cation extraction abilities (57–67%) toward alkali metal cations compared with those of **1**, although **2** did not show remarkable selectivities toward alkali metal cations. These results suggest that the alkylphosphoric acid moiety of **2** plays an important role in the complexation of **2** with alkali metal cations under our experimental conditions. Therefore, the selective extraction of **2** toward alkali metal cations could not observed. Next, in order to investigate the selectivity of the complexing abilities toward alkali metal cations in more detail, competitive liquid membrane transport experiments were carried out. In this experiment, practically no ion transport occurred in the absence of **2a**, **2b** or **2c**. The host molecule **1** also exhibited no transport abilities toward the alkali metal cations under these conditions, owing to its hydrophilic character. In contrast, drastic enhancement in the transport abilities was observed by introduction of an alkylphosphoric acid moiety into **1**. These results suggest that the transport ability order of **2a**, **2b** and **2c** toward alkali metal cations was $Li^+ > Na^+ > K^+$, although the alkali cations transport tendency of **2a**, **2b** and **2c** are very similar. $Li^+$ selectivity (4.55) over $K^+$ by **2b** was superior to those of **2a** and **2c**. However, **2a** showed higher selectivity of $Li^+$ over $Na^+$ compared with those of **2b** and **2c**.

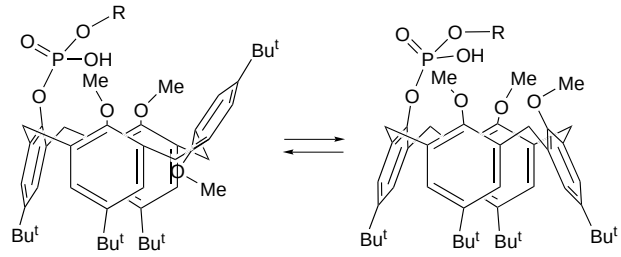

**Fig. 1** Equilibrium of **2** between cone and partial-cone conformers

**Table 1** Competitive extraction and competitive facilitated transport with **1, 2a, 2b** and **2c**

| | Extractability[a] (%) | | | Selectivity | | | Transported amount[b]/ $10^{-3}$ mol | | | Selectivity | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Compound | $Li^+$ | $Na^+$ | $K^+$ | $Li^+/Na^+$ | $Li^+/K^+$ | $Na^+/K^+$ | $Li^+$ | $Na^+$ | $K^+$ | $Li^+/Na^+$ | $Li^+/K^+$ | $Na^+/K^+$ |
| **1** | 11 | 9 | 12 | 0.91 | 0.79 | 0.0 | 0.0 | 0.0 | 0.0 | — | — | — |
| **2a** | 60 | 57 | 65 | 1.05 | 0.93 | 0.89 | 4.33 | 2.90 | 1.80 | 1.49 | 2.41 | 1.61 |
| **2b** | 63 | 66 | 67 | 0.95 | 0.93 | 0.97 | 5.89 | 4.36 | 1.30 | 1.35 | 4.55 | 3.35 |
| **2c** | 55 | 57 | 62 | 0.97 | 0.89 | 0.92 | 3.41 | 2.62 | 1.41 | 1.30 | 2.42 | 1.30 |

[a] The extraction abilities of the host molecule with alkali metal cation was examined by the extraction method described previously.[13–17] [b] Conditions: [membrane phase] = $1.0 \times 10^{-3}$ M of the host molecule in $CH_2Cl_2$ (6.0 $cm^3$). [Source phase] = aqueous solution (3 $cm^3$) containing 1.0 M MOH (M = Li, Na, K); [receiving phase] = 1.0 M HCl (3 $cm^3$).

Furthermore, **2b** showed the highest selectivity for $Na^+/K^+$ (3.35) among the investigated host molecules. Therefore, the effects of the length of alkyl groups on transport abilities were negligibly small, however, the length of the alkyl groups affected the selectivity for $Li^+/Na^+$, $Li^+/K^+$ and $K^+/Na^+$.

In order to investigate the conformations of the host moiety in the complexes of **2** with alkali metal cations, the following experiments were carried out. A solution of **2** ($3.0 \times 10^{-6}$ mol) in $CD_2Cl_2$ (0.45 $cm^3$) was shaken 100 times with a $D_2O$ solution (0.45 $cm^3$) containing an alkali metal deuteroxide ($1.5 \times 10^{-5}$ mol) at 25 °C and then the $^1H$ and $^{31}P$ NMR spectra of the organic layer were measured. As shown in Fig. 2, the methoxy and methyl protons peaks of the methylphosphoric acid moieties in the Li and Na complexes of **2a** due to the cone conformer shifted down- and up-field by *ca*. 0.25–0.33 and 0.24–0.31 ppm, respectively, while all of the proton peaks due to the partial-cone conformer disappeared. Also, the $^{31}P$ NMR spectra of $Li^+$ and $Na^+$ complexes of **2a** showed only one peak at $\delta$ −5.87 and −6.22, respectively, despite the fact that for **2a** itself two peaks were observed. In contrast, the $^1H$ NMR spectra of the complex of **2a** with $K^+$ showed the presence of both cone and partial-cone conformers, although the methoxy protons of the anisole moiety due to the cone and partial-cone conformers were shifted down- and up-field by *ca*. 0.03 and 0.01 ppm, respectively; the $^{31}P$ NMR spectra also showed two peaks at $\delta$ −6.13 and −6.40. These results suggest that the host moieties in the complexes of **2a** and/or **2b** with $Li^+$ and $Na^+$ adopt only the cone conformation, although the host moiety of the $K^+$ complex exists as a mixture (1 : 2) of the cone and partial-cone conformers together with a very small amount of other conformers.

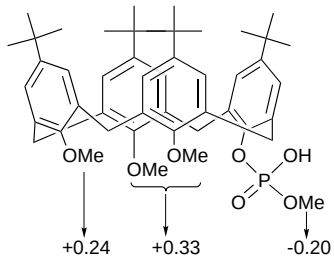

**Fig. 2** $^1H$ NMR chemical shift changes between **2a** and the $Li^+$ complex of **2a**. Positive and negative values mean down- and up-field shifts, respectively.

Furthermore, titration experiments in $CD_3CN$–$CDCl_3$ (7 : 3) were carried out by adding 0.25–3.0 equiv. of alkali metal thiocyanate to **2**. Remarkable chemical shift changes appeared in the $^1H$ and $^{31}P$ NMR spectra. The downfield shift of the methoxy protons in the cone conformer increases almost linearly with increase in $Li^+$ and/or $Na^+$ salt until addition of 1 equiv. relative to **2a**; further addition of alkali metal salt results in only a slight downfield shift change, which suggests the formation of a 1 : 1 complex of **2a** with $Li^+$ or $Na^+$. Also, all of the proton peaks in the $^1H$ NMR spectra due to the partial-cone conformer of **2a** disappeared, and the $^{31}P$ NMR spectra showed only one peak of the cone conformer when 1 equiv. of the thiocyanate was added. However, when KSCN was added to **2a** and/or **2b**, no chemical shift changes in the $^1H$ and $^{31}P$ NMR spectra were observed. This suggests that the host molecules **2a** and **2b** did not complex KSCN, although **2a** and **2b** complex with KOD.

In summary, we have shown that the phosphate diesters, **2a** and **2b**, containing calix[4]arene and alkyl groups as ester moieties selectively complexed $Li^+$ among the investigated alkali metal cations and the most moieties in the complexes of **2a** and/or **2b** with $Li^+$ and $Na^+$ cations adopt only a cone conformation, although the host moiety of the $K^+$ complex exists as a mixture (1 : 2) of cone and partial-cone conformations.

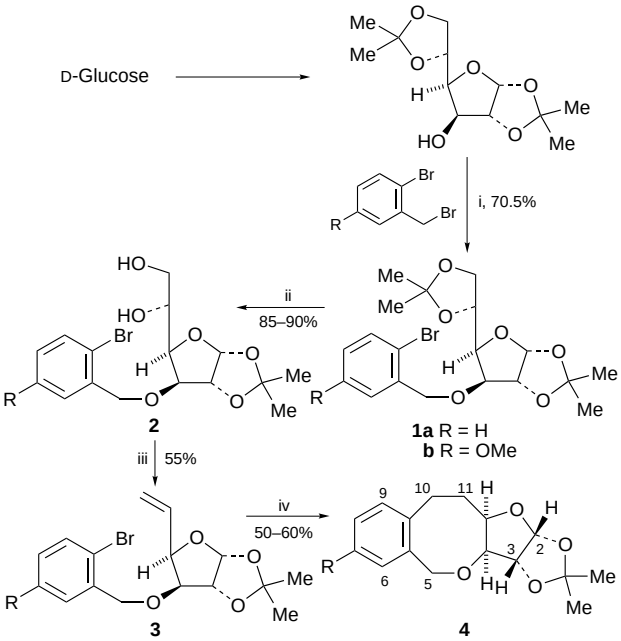
# A simple construction of chiral fused benzoxocine ring ethers from D-glucose by regioselective 8-*endo*-aryl radical cyclisation



**Partha Chattopadhyay,*[a] Monika Mukherjee[b] and Soma Ghosh[b]**

[a] *Indian Institute of Chemical Biology, Calcutta-700 032, India*
[b] *Department of Solid State Physics, Indian Association for the Cultivation of Science, Jadavpur, Calcutta-700 032, India*

**A regioselective 8-*endo-trig* aryl radical cyclisation of the 5,6-deoxy-D-*xylo*-5-enofuranosides 3a and 3b with tri-*n*-butyltin hydride provides the chiral furo[3,2-*c*][2]benzoxocines 4a and 4b in good yields; the crystal structure of 4a is reported.**

The synthesis of condensed cyclic ethers incorporating medium size rings, a unique structural feature present in some highly bioactive marine natural products,[1] is a challenging problem. The development of new and general methodology for the synthesis of this class of compound,[2,3] especially in chiral form, has become an attractive area for investigation in recent years. The syntheses of chiral 5-, 6- and 7-membered cyclic ethers have been achieved from D-glucose by intramolecular nitrone cycloaddition reactions.[4] More recently, functionalised 9-membered chiral ethers have been prepared from D-glucose through oxy-Cope rearrangement.[5] We report herein a simple and convenient conversion of D-glucose to highly functionalised chiral condensed tricyclic benzoethers incorporating a *cis* 8-5 bicyclic system by regioselective 8-*endo-trig* aryl radical cyclisation.[6]

The transformation of the easily accessible 5,6-deoxy-*O*-isopropylidene-3-*O*-(*o*-bromobenzyl)-α-D-*xylo*-5-enofuranose **3a** and the corresponding 5′-methoxy derivative **3b** to the tricyclic furo[3,2-*c*][**2**]benzoxocines **4a** and **4b** is shown in Scheme 1. D-Glucose was converted to the 3-*O*-(*o*-bromobenzyl) ethers **1a**† and **1b** through *O*-benzylation of 1,2 : 5,6-diisopropylidene-α-*D*-glucofuranose with 50% aq. NaOH in a biphasic medium ($CH_2Cl_2$–$H_2O$) using $Bu_4NBr$ as phase transfer catalyst. Under mild acidic condition, the 5,6-*O*-isopropylidene group in **1a**,**b** was selectively deprotected to give **2a**,**b** which on treatment with $Ph_3P$, $I_2$ and imidazole in boiling toluene[7] gave the desired dideoxy furanose derivatives **3a** and **3b**. Radical cyclisation of each of the alkenes **3a** and **3b** in refluxing benzene (0.008 mol $dm^{-3}$) for 8–10 h with $Bu_3SnH$ (1.5 equiv.) and a catalytic amount of AIBN furnished the respective crystalline tricyclic ethers **4a** and **4b** in 50–60% yield as the only isolable products in each case after separation of the tin compounds[8] followed by chromatography on silica gel. The assigned structures of the products **4a** and **4b** resulting from 8-*endo-trig* aryl radical cyclisation were based upon spectroscopic data. Unequivocal confirmation of the structure of **4a** was obtained from an X-ray crystal structure‡ determination (Fig. 1).

**Scheme 1** *Reagents and conditions*: $Bu_4NBr$, 50% NaOH, $CH_2Cl_2$, 25 °C, 12 h; ii, 75% AcOH, 25 °C, 12 h; iii, $PPh_3$, $I_2$, imidazole, PhMe, reflux, 2 h; iv, $Bu_3SnH$, AIBN, benzene, 200 W lamp, reflux, 10 h

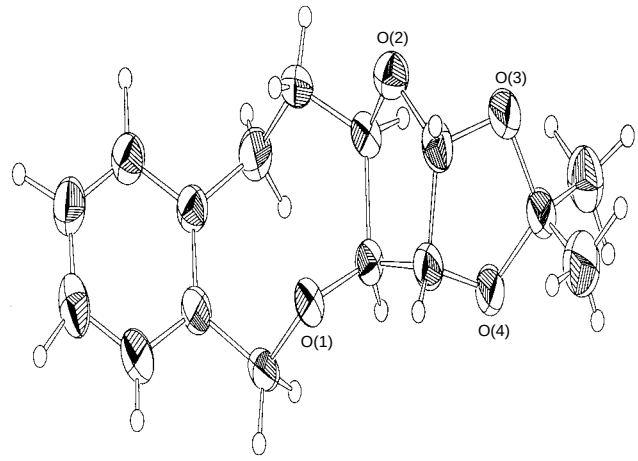


**Fig. 1** ORTEP diagram of **4a**

In conclusion, the present investigation clearly shows the potential of regioselective aryl radical cyclisation from carbohydrate derived substrates in the synthesis of chiral condensed cyclic ethers incorporating medium sized rings.

Grateful acknowledgement is due to Professor U. R. Ghatak, INSA Senior Scientist, for his kind interest and valuable suggestions. We also extend our thanks to the Regional Sophisticated Instruments Center, Bose Institute, Calcutta, India, for the use of its single crystal diffractometer facility.

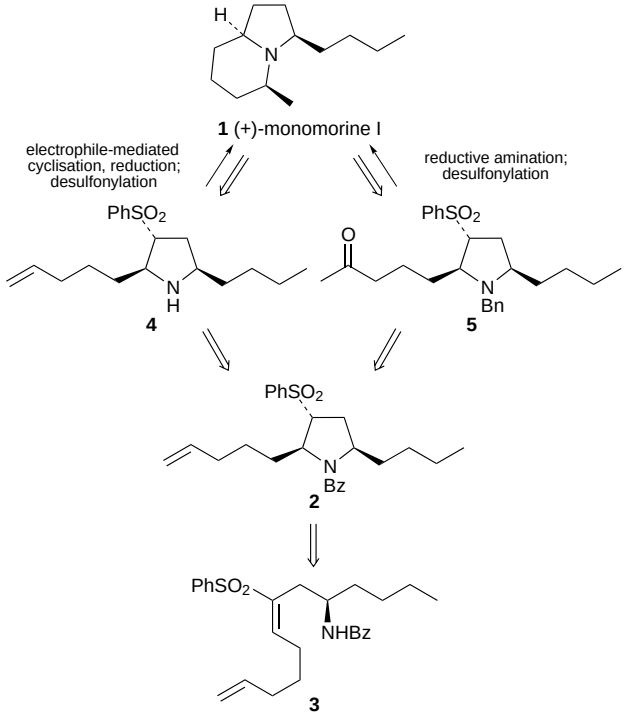
# 5-*endo-trig* Cyclisations in heterocycle synthesis: enantiospecific synthesis of (+)-monomorine I

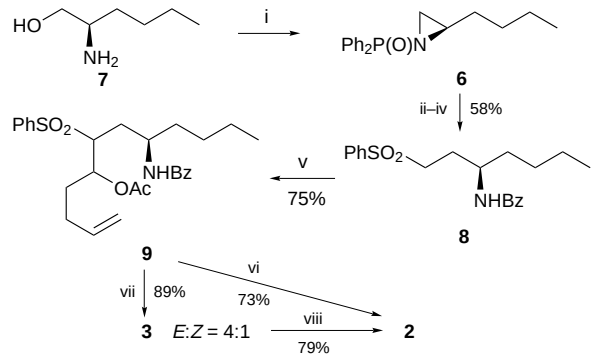
**Malcolm B. Berry,[a] Donald Craig,*[a] Philip S. Jones[b] and Gareth J. Rowlands[a]**

[a] *Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY*
[b] *Roche Discovery Welwyn, Broadwater Road, Welwyn Garden City, Hertfordshire, UK AL7 3AY*



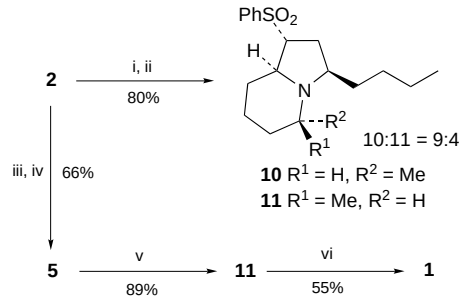
**The indolizidine alkaloid monomorine I is synthesised from D-norleucinol using 5-*endo-trig* cyclisation and intramolecular reductive amination as the key ring-forming steps.**

Pyrrolidines occur widely in nature as pheromones, venoms and toxins, and as structural motifs in more complex molecules such as pyrrolizidines and indolizidines.[1] As part of our programme investigating 5-*endo-trig* cyclisation reactions[2] for heterocycle construction[3] we have been looking at sulfone-mediated assembly of pyrrolidines, and have discovered that 2,5-disubstituted pyrrolidines may efficiently and stereoselectively be prepared from amino acid-derived precursors.[4] Here we report the application of this methodology to the total synthesis of the indolizidine alkaloid monomorine I **1**, the trail pheromone of the Pharaoh worker ant *Monomorium pharaonis*.[5,6]



Our synthetic plan for **1** involved initial assembly of the pyrrolidine ring in **2** by 5-*endo-trig* cyclisation reaction of a substrate such as **3**. Closure of the remaining, six-membered cycle would be effected either by electrophile-induced addition of the pyrrolidine nitrogen atom to the distal double bond, as in **4**, or by intramolecular reductive amination of a derived side-chain ketone moiety, as in **5** (Scheme 1).

Retrosynthetic analysis of the cyclisation substrate **3** indicated *N*-protected aziridine **6** as the starting material. This was synthesised in two steps from commercially available D-norleucine;† reduction using the $NaBH_4$–iodine reagent system described by Meyers[7] gave D-norleucinol **7**, which was converted directly into **6** by treatment with diphenylphosphinic chloride and triethylamine in THF followed by excess sodium hydride according to the method of Sweeney (Scheme 2).[8] Addition of **6** to a THF–*N*,*N*,*N*′,*N*′-tetramethylethylenediamine solution of lithio(phenylsulfonyl)methane followed by proton quench gave the expected product of aziridine ring-opening at the less substituted carbon atom. This was dephosphinylated and reprotected as the benzamide **8** in good overall yield for the three steps from **6**.[9] Exposure of **8** to 2 equiv. of base followed by hex-5-enal, and *in situ* trapping of the intermediate alkoxides, gave ester **9**, mostly as one diastereoisomer.‡ Pyrrolidine formation was effected *in a single step* by treating a dilute THF solution of **9** with 2 equiv. of potassium *tert*-butoxide in the presence of *tert*-butyl alcohol, which effected one-pot elimination to give **3** followed by cyclisation. Pyrrolidine **2** formed in this way was a single, 2,5-*syn* diastereoisomer as evidenced by single-crystal X-ray diffraction analysis.§ Interestingly, treatment of **9** with 1 equiv. of base followed by *immediate* proton quench gave in 89% isolated yield a 4:1 *E*:*Z* mixture of geometric isomers of **3**, which could be converted into **2** in a separate operation by treatment with a further 1 equiv. of base. Compound **2** prepared in this way was identical in all respects to material made in the one-pot reaction.



Initial attempts to complete the assembly of the indolizidine nucleus by closure of the six-membered ring involved mercury(II)-assisted cyclisation. Thus, debenzoylation of **2** using Super-Hydride®,[10] and treatment of the resulting free amine with $Hg(OAc)_2$ followed by *in situ* reduction with $NaBH_4$,[11] gave in 90% yield a 9 : 4 mixture of **10** and the desired

C-2 epimer **11**. The stereochemical assignment of **11**, and therefore that of **10** followed from the nuclear Overhauser enhancements of the signals corresponding to the α-hydrogen atoms at C-6 and C-9 observed on irradiation of the C-2 methyl group. In view of this adverse selectivity, the reductive amination route was pursued. Partial reduction of **2** to the *N*-benzyl analogue using DIBAL-H, and oxidation of the side-chain double bond in the product using a modified Wacker procedure[12] gave ketone **5**. This was subjected to catalytic transfer hydrogenation,[13] which effected sequential hydrogenolytic debenzylation and intramolecular reductive amination[14] to give exclusively **11**, which was identical in all respects to material prepared *via* the mercury-mediated cyclisation route. Finally, *brief* exposure¶ of **11** to sodium naphthalenide in THF followed by $NH_4Cl$ work-up gave (+)-monomorine I **1** (Scheme 3), which showed $^1H$ and $^{13}C$ NMR, IR and mass spectral and optical rotation characteristics in agreement with published values.[6]

In summary, the synthesis of (+)-monomorine I has been achieved in nine steps from aziridine **6**, which is available in two steps by known methods from D-norleucine. Both ring-forming steps are highly stereoselective, and our synthesis compares favourably with published approaches.[6] The complete selectivity of the pyrrolidine-forming reaction is particularly notable, and should be applicable to the synthesis of other pyrrolidine-containing alkaloids, and related pyrrolizidines and indolizidines.

We thank the SERC/EPSRC (CASE Studentships to M. B. B. and G. J. R ) and Roche Discovery Welwyn for financial support of this research.

# Self-assembling of bis-*ortho* chelated diaminobenzyl- (NC′N) and butyl-lithium units to give 2 : 2 mixed alkyllithium aggregates $(NC'N)Li_2Bu_2Li_2(NC'N)$ with a ladder structure

**Peter Wijkens,[a] Johann T. B. H. Jastrzebski,[a] Nora Veldman,[b] Anthony L. Spek[b] and Gerard van Koten*[b]**

**The lithiation reaction of 1,3-bis(dimethylaminomethyl)-4,6-dimethyl-2-(trimethylsilylmethyl)benzene 2 with $Bu^nLi$ (2 equiv.) affords a unique aggregated species 3 of the parent lithiated compound and $Bu^nLi$ in a 2 : 2 ratio in which the bridging carbon atoms and the lithium atoms are arranged in an unprecedented ladder-type arrangement with exclusively bridging alkyl groups.**

Heteroatom-assisted lithiation of the bis(*ortho*-amino) substituted 2-methyl group in 1,3-bis(dimethylaminomethyl)-2,4,6-trimethylbenzene (NC′N–H)† with $Bu^nLi$ resulted in the formation of an unprecedented 2 : 2 mixed alkyllithium aggregate $(NC'N)_2Li_4Bu_2$ **1**.[1] The structure of **1** suggests considerable stability for the $[(NC'N)_2Li_4]^{2+}$ dication, which comprises a lithium tetrahedron of which two faces are capped by two NC′N terdentate monoanionic ligands, leaving two faces open for the binding of a C-monoanion *via* $\eta^3$-coordination (in **1**, two $\eta^3$-bonded Bu groups).

As a possible approach to overcome the formation of tetrahedral $Li_4$ aggregates like **1** we explored the effect an $\alpha$-$Me_3Si$ group would have on the aggregate formation. We now report that lithiation of 1,3-bis(dimethylaminomethyl)-4,6-dimethyl-2-(trimethylsilylmethyl)benzene **2** (NC′N–$SiMe_3$)[1] with $Bu^nLi$ likewise results in the formation of a 2 : 2 mixed alkyllithium aggregate having $(NC'N–SiMe_3)_2Li_4Bu_2$ stoichiometry, but with a novel structure comprising a ladder type frame-work with exclusively bridging alkyl groups.

The 1 : 2 molar reaction of **2** with $Bu^nLi$ in pentane afforded a pale yellow crystalline solid. According to its $^1H$ NMR spectrum this material appeared to be a mixed alkyl species **3** of $\alpha$-lithiated **2** and $Bu^nLi$ in a 1 : 1 molar ratio (Scheme 1), suggesting that **3** would have a similar 2 : 2 mixed alkyl aggregate structure as found earlier for **1**. Interestingly, the X-ray crystal structure determination‡ of **3** revealed that the 2 : 2 mixed aggregate was comprised of four lithium atoms and four carbon atoms, but now arranged in a unique ladder-type C–$Li_2$–C′$_2$–$Li_2$–C framework [see Fig. 1(*a*)]. It should be noted that X–Li–C–Li structural units have been reported before,[2–4] but **3** is the first heteroleptic organolithium aggregate containing a ladder framework consisting of only lithium and carbon atoms.§

**Scheme 1**

The 2 : 2 mixed alkyllithium aggregate **3** may be regarded as consisting of two (NC′N–$SiMe_3$)$Li_2$ cationic units linked together by two butyl anions. The two cationic units are symmetry-related by a crystallographic centre of symmetry. In the (NC′N–$SiMe_3$)$Li_2$ unit the benzylic carbon atom, C(7), is asymmetrically bonded to Li(1) [2.456(6) Å] and Li(2) [2.152(7) Å], while the two nitrogen atoms of the NC′N–$SiMe_3$ anion are each coordinating to one lithium atom, *i.e.* Li(1) [2.140(6) Å] and Li(2) [2.032(7) Å].

The two butyl anions connecting the two (NC′N–$SiMe_3$)$Li_2$ cationic units are each binding to three lithium atoms in an asymmetric manner: C(19) to Li(1) 2.386(9) Å, to Li(1a) 2.274(8) Å and to Li(2) 2.088(8) Å. As a consequence of different bonding modes of the NC′N–$SiMe_3$ and butyl bridging carbon atoms the coordination geometry of Li(1) is distorted tetrahedral and that of Li(2) more or less trigonal [see Fig. 1(*b*)]. This difference in coordination number and geometry is nicely

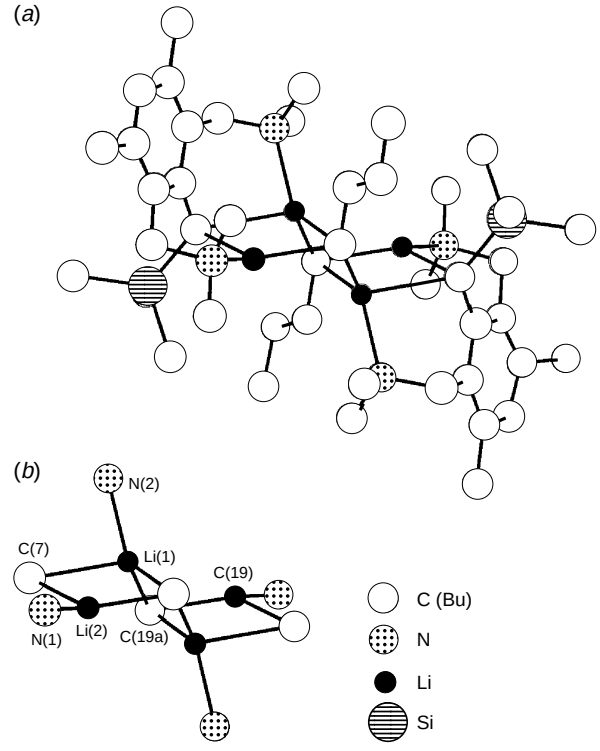

**Fig. 1** (*a*) Overall molecular geometry of **3**. (*b*) Schematic structure showing the ladder type structure with the arrangement of the lithium atoms, the multi-centre bonded carbon atoms and the coordinating nitrogen atoms. Important bond lengths (Å): Li(1)–C(7), 2.456(6); Li(1)–C(19), 2.386(9); Li(1)–C(19a), 2.274(8); Li(1)–N(2), 2.140(6); Li(2)–C(7), 2.152(7); Li(2)–C(19), 2.088(8); Li(2)–N(1), 2.032(7).

reflected in the shorter bonding interactions ($\Delta$Li–$C_{av}$, 0.23 Å; $\Delta$Li–N, 0.1 Å) around Li(2) as compared to Li(1).

Comparison of the closed tetrahedral–$Li_4$ **1** and the open ladder-$Li_4$ structure **3** leads to the following conclusions. α-Substitution leads to a change of the **4c**–**2e** $CLi_3$ bonding in **1** to **3c**–**2e** $CLi_2$ bonding in **3**. Although the charge at the α-C anion changes considerably on introduction of the α-$Me_3Si$ substituent it is most likely for steric reasons that instead of three (see **1**), only two lithium cations are bonded by the NC′N–$SiMe_3$ anion. This makes the NC′N–$SiMe_3$ anion unsuited to forming a well-defined dicationic species $[(NC'N–SiMe_3)_2Li_4]^{2+}$ similar to **1**, but stabilises $[(NC'N–SiMe_3)Li_2]^+$ monocationic building blocks instead.

The observed single resonance pattern in the $^{13}C$ NMR spectrum of **3** at room temperature comprises two $CH_2N$ resonances ($\delta$ 58.0 and 59.6), two ArMe resonances ($\delta$ 21.7 and 21.9) and four NMe resonances ($\delta$ 42.6, 43.1, 46.7 and 47.5). These observations indicate the lack of a symmetry plane, both in-plane and perpendicular to the plane of the aryl moiety of the benzylic ligand, and is, moreover, evidence that Li–N coordination is inert on the NMR timescale at this temperature. Also the $^1H$ NMR spectrum of **3** clearly illustrates the asymmetric fashion in which the benzylic ligand is bonded to two lithium atoms. Two AB patterns were observed for the two $NCH_2$ groups ($\delta$ 3.00 and 3.40, $^2J_{HH}$ 14 Hz, and $\delta$ 3.10 and 3.95, $^2J_{HH}$ 14 Hz). In the region between $\delta$ 1.60 and 2.10 several overlapping broad lines, attributed to the two $NMe_2$ and two ArMe groups were observed. $^1H$, $^{13}C$ and $^6Li$ NMR spectra recorded at lower temperatures (+10 down to −80 °C) did not provide further information, and only extensive line broadening was observed. At higher temperatures a fluxional process becomes operative on the NMR timescale, generating a symmetry plane perpendicular to the aryl moiety of the benzylic ligand. The observation of only one resonance pattern for the two $NMe_2$ groups (one singlet) and the $NCH_2$ (one AB pattern) indicates that a process involving Li–N dissociation/association becomes fast on the NMR timescale. However, the fact that the $CH_2$ protons are still diastereotopic is proof for the configurational stability of the stereogenic α-C atom which is bound to the lithium atoms.

During the lithiation of **2** a stereocentre at the benzylic position, having either (*R*) or (*S*) stereochemistry, is formed in equal amounts. The observation of only one resonance pattern in the $^1H$ and $^{13}C$ NMR spectra of **3** indicates that, most likely as a consequence of differences in thermodynamic stability of the possible aggregates, a diastereoselective aggregation to **3** [*i.e.* (*R,S*)] as found in the solid state has occurred.

That anionic organic groups other than primary alkyl anions are also capable of linking two cationic $(NC'N–SiMe_3)Li_2$ units to a ladder type arrangement may be concluded from the independent synthesis of the corresponding $Bu^t$ and 4-$MeC_6H_4$ aggregates **4** and **5**, respectively (see Scheme 1). The observed $^1H$ and $^{13}C$ NMR spectra of **4** and **5** are almost identical (with respect to the benzylic ligand) to that of **3**, suggesting a close structural resemblance. Obviously, the formation of these mixed hetero-aggregates from the homo-aggregates is driven by the difference in their thermodynamic stability. The observed selectivity of the self-assembling process in the present study is connected to the use of well-designed heteroatom-containing ligands such as NC′N in **1** and NC′N–$SiMe_3$ in **2**.

For synthetic purposes the present findings are relevant as ample evidence exists in the literature[5] that for the *in situ* preparation of various LiR species excess metallating reagent is often required.¶ When this is due to the formation of stable aggregates like **1** or **3**, subsequent reactions will be hampered as a consequence of the presence of trapped, but still reactive, Bu groups, *e.g.* with transition metals both MR as well as often unstable MBu may be formed. The use of $Bu^tLi$, for example, can sometimes solve this problem, most probably not because of the higher nucleophilicity of the $Bu^tLi$ anion but because of the lower stability of species such as **1** and **3** containing bridging $Bu^t$ instead of $Bu^n$ groups as compared with the respective parent alkyllithiums.

Enraf-Nonius CAD4T/rotating anode diffractometer, graphite monochromated Mo-Kα radiation, $\lambda$ = 0.71073 Å, $T$ = −123 °C. Solution by direct methods (SHELXS86), refinement on $F^2$ with SHELXL-93 converged at $R_1$ ($wR_2$) = 0.066 (0.1779), $w = 1/[(\sigma^2(F_o) + (0.0736P)^2 + 1.0293P]$, $P = (F_o^2 + 2F_c^2)/3$, for 260 refined parameters (anisotropic temperature factors for the non-hydrogen atoms). Hydrogen atoms were included on calculated positions, riding on their carrier atoms. The structure contains some unresolved disorder as indicated by the anisotropic displacement parameter of C(19), the nature of which is unclear. CCDC 182/578.

§ One example of a homoleptic alkyllithium compound exhibiting a cyclic 'ladder' structure is $(c\text{-}HexLi)_6$ (ref. 6).

¶ In this respect it should be noted that we have proposed earlier, based on chemical evidence, that a mixed aryl-butyl aggregate $[2\text{-}Me_2NCH(Me)C_6H_4]_2Bu_2Li_4$ **6** is formed during the heteroatom assisted lithiation of $Me_2NCH(Me)C_6H_5$, irrespective the molar ratio of amine and BuLi used, *i.e.* excess amine is not reacting further with **6** (ref. 7). Furthermore $(C_6H_2Bu^t_3\text{-}2,4,6)_2Li_4Bu_2$, obtained as one of the products from the reaction of $C_6H_2BrBu^t_3$-2,4,6 with $Bu^nLi$, represents the first example of a well characterised mixed aryl-alkyllithium aggregate (ref. 8).

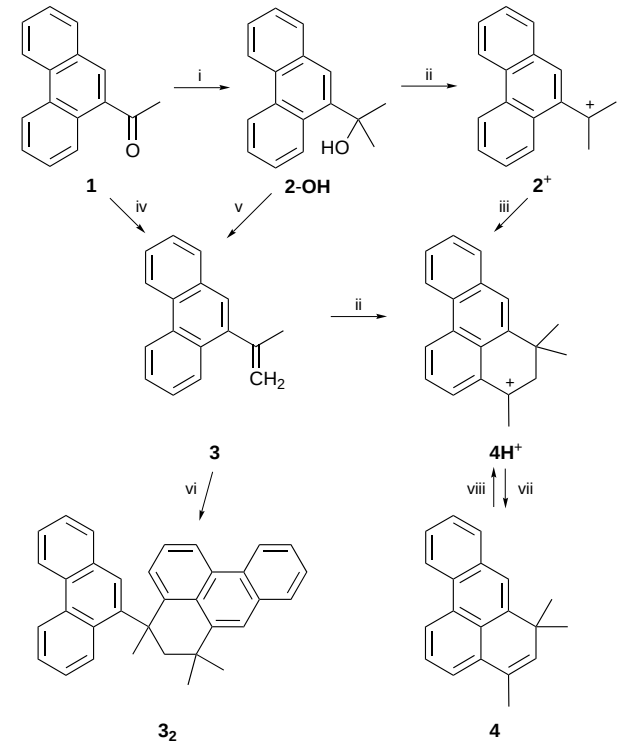
*Received in Liverpool, UK, 27th June 1997; 7/04548D*

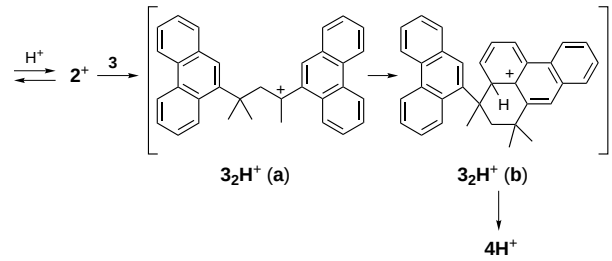
# Efficient conversion of 9-Isopropenylphenanthrene to 4,6,6-trimethyl-6*H*-benz[*de*]anthracene in $FSO_3H$; 5,6-dihydro-4*H*-benzanthracen-4-ium ion and its charge delocalization mode

**Sandro Hollenstein and Kenneth K. Laali***



*Department of Chemistry, Kent State University, Kent, OH 44242, USA*

**Low temperature protonation of 9-isopropenylphenanthrene in $FSO_3H$–$SO_2ClF$ (or $FSO_3H$–$CH_2Cl_2$) leads to direct observation of 5,6-dihydrobenzanthracenium cation $4H^+$ from which the corresponding benz[*de*]anthracene is obtained in 92% yield upon quenching.**



In the course of our work on charge delocalization mapping in arenium ions of polycyclic aromatic hydrocarbons (PAHs) and on various classes of PAH–$C^+R_2$ carbocations as models of epoxide ring opening,[1] we had prepared several regioisomeric phenanthrylpropane-2-carbenium ions including $\mathbf{2}^+$ which was stable up to room temperature. Attempted conversion of **2-OH** to the chloro derivative (**2-Cl**) led only to elimination to give the isopropenyl derivative **3**,[2] which was also independently synthesized by a Wittig type reaction[3] from **1** (Scheme 1).

Surprisingly, the expected quantitative conversion to $\mathbf{2}^+$ did not occur by low temperature protonation with $FSO_3H$–$SO_2ClF$; a mixture of the benzanthracene cation $\mathbf{4H}^+$ and 2-(9-phenanthryl)propane-2-carbenium ion $\mathbf{2}^+$ were formed, even if highly diluted PAH solutions were added to a large excess of the superacid. Raising the temperature led to increased formation of $\mathbf{4H}^+$ at the expense of $\mathbf{2}^+$ (NMR) and complete conversion to $\mathbf{4H}^+$ occurred at room temp. Quenching of the superacid solution furnished the benzanthracene **4** in 92% yield.†

The mechanistic scheme outlined in Scheme 2 is suggested, with intermediate formation of the dimer cation $\mathbf{3_2H}^+$**(a)** and the cycloalkylation product $\mathbf{3_2H}^+$**(b)**, converting rapidly to $\mathbf{4H}^+$. The proposed pathway requires the formation of a stoichiometric amount of phenanthrene. However, no protonated

**Scheme 1** *Reagents and conditions*: i, MeLi, $Et_2O$, 92%; iii, $FSO_3H$, $SO_2ClF$ or $CH_2Cl_2$, −78 °C–room temp.; iii, cat. phenanthrene; iv, $MePr(Ph)_3Br$, $NaNH_2$–THF, 94%; v, $SOCl_2$, $CH_2Cl_2$; vi, $TiCl_4$, $CH_2Cl_2$ (ref. 5); vii, NaOH–$H_2O$, 92%; viii, $FSO_3H$, $SO_2ClF$ or $CH_2Cl_2$

**Scheme 2**

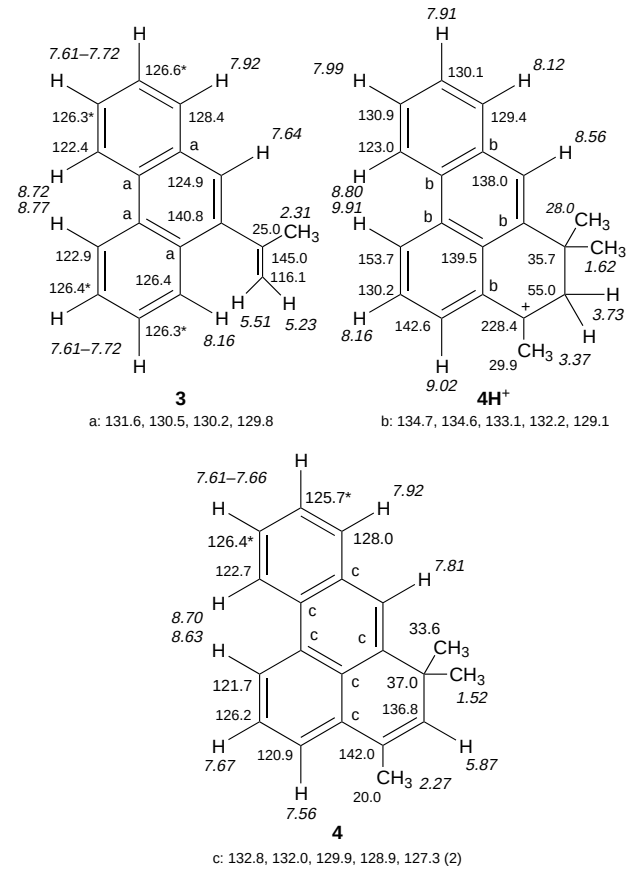


**Fig. 1** $^1H$ NMR (300 MHz, *italic*) and $^{13}C$ NMR (75 MHz) chemical shifts, referenced to internal $CHCl_3$ (7.26 ppm, 77.0 ppm, **3** and **4**) or $CH_2Cl_2$ (5.32 ppm, 53.8 ppm, $\mathbf{4H}^+$) *assignment may be interchangeable

phenanthrene was observed in the superacid solution and no phenanthrene could be isolated on work-up. This can be rationalized since in line with previous studies, the parent phenanthrenium ion is elusive;[4] furthermore control experiments confirm that once phenanthrene is reacted with $FSO_3H$, no intact phenanthrene can be isolated on work-up ($\rightarrow$polymer). An important question that remained was why $\mathbf{2}^+$ generated from the propan-2-ol would not undergo dimerization and cyclization. Addition of catalytic amounts of phenanthrene to a solution of $\mathbf{2}^+$ (generated *via* **2-OH**) gave $\mathbf{4H}^+$, demonstrating that either phenanthrene or its polymer induces *in situ* deprotonation forming **2** in equilibrium, which can then react with $\mathbf{3}^+$, cyclize and eliminate ($\rightarrow\mathbf{4H}^+$).

The $TiCl_4$-mediated dimerization of **3** to give an isolable dimer $\mathbf{3_2}$[5] and similar dimerization of other isopropenyl-PAHs[6*a–c*] have been reported where depending on the regioisomer, isopropenyl-PAHs would either undergo polymerization or dimerization. The observed facile dimerization, cyclization and cleavage in the superacid, offers synthetic potential for preparation of various benzophenalenes in simple one-pot reactions. Another noteworthy feature of this chemistry is facile access to 1-phenanthryl-substituted carbocations which are otherwise not available due to difficulties associated with synthesis of 1-substituted phenanthrene derivatives by electrophilic chemistry.

In the $^{13}C$ NMR, the $C^+$ centre in $\mathbf{4H}^+$ is at 228.4 ppm which is slightly shielded if compared to the $C^+$ of $\mathbf{2}^+$ (230.1 ppm),[1*c*] indicating a similar degree of charge delocalization into the phenanthrene moiety and therefore comparable $C^+$–C(*ipso*) double bond character (Fig. 1). Charge delocalization mapping in $\mathbf{4H}^+$ as deduced from $\Delta\delta^{13}C$ values shows arene $\pi$-participation primarily *via* a naphthalenium ion (AB ring of phenanthrene moiety) and is in qualitative agreement with the overall mode of charge delocalization deduced based on the AM1-calculated[7] carbon charges.[1]

We are grateful to the NCI of NIH (R15 CA63595-01A1) for financial support.

# An extreme water exchange rate: the europium(II) aqua ion

**P. Caravan and André E. Merbach***

*Institut de Chimie Minérale et Analytique, Université de Lausanne-BCH, CH-1015 Lausanne, Switzerland*

**The rate of water exchange at the europium(II) aqua ion is measured by a combined variable-temperature $^{17}O$ NMR and EPR study; it is the fastest aqua exchange rate ever directly measured by magnetic resonance for a non Jahn–Teller ion, $3.5 \times 10^9$ s$^{-1}$ at 25 °C.**

Water exchange on an aqua ion is one of the most fundamental chemical processes. An established field, water exchange rates have been measured on many of the aqua ions across the Periodic Table and span 20 orders of magnitude.[1] To date, no solvent exchange rates have been reported for the divalent lanthanides. The most easily accessible divalent lanthanide is europium(II). This report describes water exchange on $Eu^{2+}_{(aq)}$ as a function of temperature determined by a combined $^{17}O$ NMR and EPR study. Apart from its intrinsic interest, and to develop an understanding of ligand substitution kinetics at $Eu^{II}$, this work sheds light on two other areas. Europium(II) is very similar in size to $Sr^{II}$ and exhibits a similar chemistry (excluding electron transfer).[2] Since water exchange on the heavier group 2 elements cannot be directly measured, $Eu^{II}$ may provide insight as a spectroscopic probe in the chemistry of $Ca^{II}$ and $Sr^{II}$.[3] Also, $Eu^{II}$ is isoelectronic with $Gd^{III}$; we, and others, have extensively studied the factors influencing water exchange on $Gd^{III}$ based contrast agents for magnetic resonance imaging (MRI).[4] Europium(II) being another $f^7$ ion allows us to further understand relaxation processes in $^8S$ ions.

The approach taken was the same as in our previous analyses† of $Gd^{III}$ water exchange kinetics.[5] The source of $Eu^{II}$ was the triflate salt, $Eu(O_3SCF_3)_2{\cdot}H_2O$.‡ From the measured relaxation rates and angular frequencies of $Eu^{2+}_{(aq)}$ solutions, $1/T_1$, $1/T_2$ and $\omega$, and of a dilute triflic acid reference solution, $1/T_{1A}$, $1/T_{2A}$ and $\omega_A$, the reduced relaxation rates and chemical shift $1/T_{1r}$, $1/T_{2r}$, and $\omega_r$ can be calculated, eqns. (1)–(3). Here,

$$\frac{1}{T_{1r}} = \frac{1}{P_m}\left[\frac{1}{T_1} - \frac{1}{T_{1A}}\right] = \frac{1}{T_{1m} + \tau_m} \tag{1}$$

$$\frac{1}{T_{2r}} = \frac{1}{P_m}\left[\frac{1}{T_2} - \frac{1}{T_{2A}}\right] = \frac{1}{\tau_m}\,\frac{T_{2m}^{-2} + \tau_m^{-1}T_{2m}^{-1} + \Delta\omega_m^2}{\left(\tau_m^{-1} + T_{2m}^{-1}\right)^2 + \Delta\omega_m^2} \tag{2}$$

$$\Delta\omega_r = \frac{1}{P_m}\left(\omega - \omega_A\right) = \frac{\Delta\omega_m}{\left(1 + \tau_m T_{2m}^{-1}\right)^2 + \tau_m^2\Delta\omega_m^2} \tag{3}$$

the subscript m refers to the relaxation rates of bound water and the chemical shift difference between bound and bulk water, $P_m$ is the mole fraction of bound water, and $\tau_m = k_{ex}^{-1}$ is the residency time of a bound water molecule. The chemical shift of bound water is given by eqn. (4), where $A/\hbar$ is the

$$\Delta\omega_m = \frac{g_L\mu_B S(S+1)B}{3k_BT}\,\frac{A}{\hbar} \tag{4}$$

hyperfine coupling constant and the other symbols are constants.§ The longitudinal relaxation rate is dominated by the dipole–dipole and quadrupolar mechanisms, eqn. (5).

$$\frac{1}{T_{1m}} = \left[\frac{2}{5}\left(\frac{\mu_0}{4\pi}\right)^2 \frac{\hbar^2\gamma_I^2\gamma_S^2}{r_{EuO}^6}\,S(S+1) + Q\right]\tau_R \tag{5}$$

The rotational correlation time is given by $\tau_R$ which has an exponential temperature dependence with an activation energy $E_R$, eqn. (6). The dipole–dipole mechanism is dependent on

$$\tau_R = \tau_R^{298}\exp\left[\frac{E_R}{R}\left(\frac{1}{T}\,\frac{1}{298.15}\right)\right] \tag{6}$$

the Eu–O bond length ($r^6_{EuO}$) which we have set to 2.65 Å.[6] The reduced transverse relaxation rate allows the determination of the rate constant by eqn. (7), where $1/\tau_{1S} = k_{ex} + 1/T_{1e}$.

$$\frac{1}{T_{2sc}} = \frac{(A/\hbar)^2}{3}\,S(S+1)\tau_{1S} \tag{7}$$

The transverse electronic relaxation rates have been determined by EPR linewidth measurements, denoted $\Delta_{Hpp}$. Eqns. (8) and (9) introduce three more parameters, $\Delta^2$, the trace of the square

$$\frac{1}{T_{2e}} = \frac{g_L\mu_B\pi\sqrt{3}}{h}\,\Delta H_{pp} = \Delta^2\tau_v\left[\frac{5.26}{1 + 0.372\omega_S^2\tau_v^2} + \frac{7.18}{1 + 1.24\omega_S\tau_v}\right] \tag{8}$$

$$\tau_v = \tau_v^{298}\exp\left\{\frac{E_V}{R}\left(\frac{1}{T} - \frac{1}{298.15}\right)\right\} \tag{9}$$

of the zero field splitting (ZFS) tensor $\tau_v$, the correlation time modulation of the ZFS, and $E_v$, the activation energy defining the temperature dependence of $\tau_v$. The longitudinal electronic relaxation rate can then be determined by the following relationship, eqn. (10). Finally, the temperature dependence

$$\frac{1}{T_{1e}} = \frac{1}{25}\,\Delta^2\tau_v\left\{4S(S+1) - 3\right\}\left(\frac{1}{1 + \omega_S^2\tau_v^2} + \frac{4}{1 + \omega_S^2\tau_v^2}\right) \tag{10}$$

of the exchange rate follows the Eyring equation (11). The

$$\frac{1}{\tau_m} = k_{ex} = \frac{k_BT}{h}\exp\left\{\frac{\Delta S^\ddagger}{R} - \frac{\Delta H^\ddagger}{RT}\right\} = \frac{k_{ex}^{298}T}{298.15}\exp\left\{\frac{\Delta H^\ddagger}{R}\left(\frac{1}{298.15} - \frac{1}{T}\right)\right\} \tag{11}$$

reduced relaxation rates, reduced chemical shifts, and electronic transverse relaxation rates were fitted simultaneously as a function of temperature using eqns. (1)–(11). The fitted parameters are given in Table 1, and the fitted data shown in Fig. 1.

**Table 1** Comparison of parameters for $Gd^{III}$[a] and $Eu^{II}$ water exchange

| Parameter | $[Eu(H_2O)_8]^{2+}$ | $[Gd(H_2O)_8]^{3+}$ |
|---|---|---|
| $10^{-9}\ k_{ex}^{298}/s^{-1}$ | 3.5 ± 0.4 | 0.80 ± 0.06 |
| $\Delta H^{\ddagger}$/kJ mol$^{-1}$ | 18.2 ± 2 | 15.3 ± 1 |
| $\Delta S^{\ddagger}$/J mol$^{-1}$ K$^{-1}$ | −0.2 ± 6 | −23.1 ± 4 |
| $10^{-6}\ (A/\hbar)$/rad s$^{-1}$ | −3.70 ± 0.07 | −5.3 ± 0.1 |
| $\tau_R^{298}$/ps | 12 ± 1 | 41 ± 2 |
| $E_R$/kJ mol$^{-1}$ | 18.2 ± 0.6 | 15.0 ± 1.3 |
| $\tau_v^{298}$/ps | 0.4 ± 0.1 | 7.3 ± 0.5 |
| $E_v$/kJ mol$^{-1}$ | 8.6 ± 0.8 | 18.4 ± 1.4 |
| $10^{-20}\ \Delta^2$/ s$^{-2}$ | 5.4 ± 1.4 | 1.19 ± 0.09 |

[a] Ref. 4.

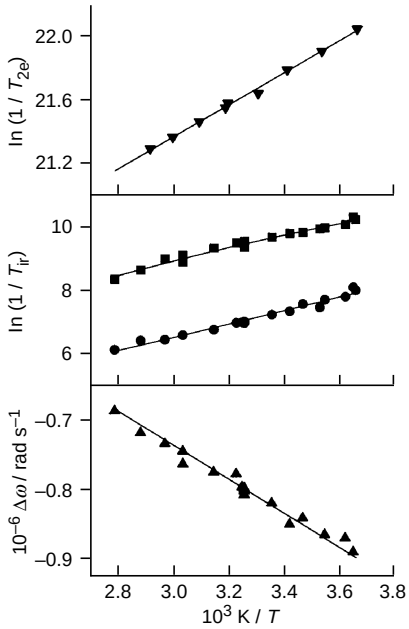

**Fig. 1** Temperature dependence of the reduced $^{17}O$ chemical shifts (bottom), reduced $^{17}O$ longitudinal (circles) and transverse (squares) relaxation rates (middle), and of the transverse electronic relaxation rates (top)

As expected, the larger, less highly charged $[Eu(OH_2)_8]^{2+}$ ion undergoes water exchange faster than $[Gd(OH_2)_8]^{3+}$. The hyperfine coupling constant is lower for $Eu^{II}$, again, as expected since $A/\hbar$ is determined by the degree of interaction between the electron spin of the metal and the $^{17}O$ nucleus; the larger, less charged ion should interact less strongly with the oxygen donor atom. The rotational correlation time is very short for the $Eu^{II}$ aqua ion. Although the precision associated with this number is very good, the actual error could be much larger since the measured $T_1$ of the sample was close to the $T_1$ of the reference (within 90%). Hence the rotational correlation time is based on the small difference between two large numbers, and $\tau_R$ should not be considered too meaningful. In contrast, the transverse relaxation rates provide a very good representation of the exchange rate. The value of $1/T_{2m}$ is dependent on contributions from electronic relaxation and chemical exchange. Since $Eu^{II}$ has a longer electronic lifetime than $Gd^{III}$ (shorter $\tau_v$, larger $\Delta^2$), the contribution of $1/T_{1e}$ to $1/T_{2m}$ is much less for the $Eu^{II}$ aqua ion (only about 10%). The differences between measured $T_2$ values for $Eu^{II}$ and reference are more than ten times greater than for the $T_1$ difference leading to increased accuracy.

The coordination number of the $Eu^{II}$ aqua ion is not known. This report assumes a coordination number of eight based on analogy with $Sr^{II}$.[7] A coordination number of nine would lead to a value 8–9 times lower for $k_{ex}^{298}$, which is within the experimental error.

This report describes the second fastest water exchange rate ever measured [behind $Cu^{2+}_{(aq)}$] and its represents the fastest rate of water exchange measured on a non-Jahn–Teller ion.[8] Currently, this work is being expanded to examine the effects of magnetic field strength on both the NMR and EPR data, the effect of pressure on the rate of water exchange, and a molecular dynamics study on $Eu^{II}$ solvation and water exchange.

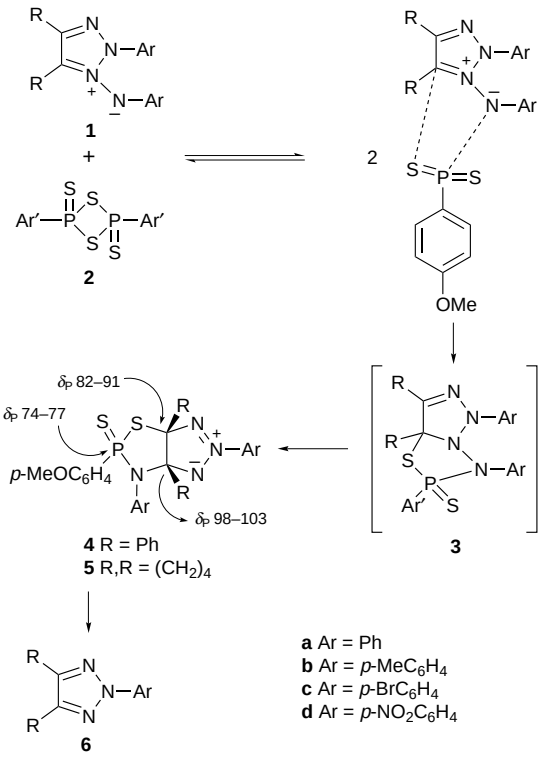
# [1,2,3]Triazolo[4,5-*d*][1,3,2]thiazaphospholes: a new fused NPS ring system from a cycloaddition–rearrangement sequence with Lawesson's reagent, a super dipolarophile

**Richard N. Butler,* Elaine C. McKenna and (in part) Denise C. Grogan**

*Chemistry Department, University College, Galway, Ireland*

**A new fused NPS ring system has been obtained from the reaction of substituted 1,2,3-triazolium-1-imide 1,3-dipoles with Lawesson's reagent**



Recently there has been renewed interest in sulfur–nitrogen and sulfur–nitrogen–phosphorus containing ring systems.[1,2] The use of Lawesson's reagent as a possible P=S 1,3-dipolarophile has been established by Bertrand.[2] The cycloaddition–1,4-sigmatropic rearrangement sequences which we developed[3,4] for the triazolium imide 1,3-dipole system **1** opened the prospect of possible new fused nitrogen–phosphorus–sulfur ring systems such as **4** if these would be stable. Herein we describe routes to the new ring system **4** and the new tricyclic structure **5**, both of which proved to be reasonably stable in the solid state but unstable in solution, where they broke down rapidly to 1,2,3-triazoles **6** and uncharacterised N–P–S compounds. Kinetic studies on the rate of consumption of the dipole **1** by Lawesson's reagent showed it to be 2000 times faster than for acrylonitrile and twice as fast as the C=S dipolarophile of MeSC(S)CN, indicating that Lawesson's reagent is a super-dipolarophile comparable to thiones.[5–7]

Solutions of the dipoles **1** (*ca.* 0.4 mmol) in dry THF under an atmosphere of dry nitrogen were treated with Lawesson's reagent **2** (0.5 equiv.) and stirred at ambient temperature for *ca.* 1 h. The solvent was removed under reduced pressure and the flaky residue leached with cold $Et_2O$ until the ethereal extracts were colourless. Evaporation of the ethereal extracts gave the products **4** and **5** as low melting yellow–orange solids. A single product only was obtained in each case. Due to the instability of the fused ring system in solution low temperatures (−30 °C) and a carefully chosen number of scans were necessary to obtain good NMR spectra since the products **4** and **5** readily broke down to **6** in NMR solvents. The compounds were fully characterised by their $^1$H and $^{13}$C NMR spectra measured in $CDCl_3$, which showed all of the expected signals. Key signals were the two bridgehead carbon signals (see Table 1 and Scheme 1). We have previously established[4] that the N–C–N fused bridgehead $^{13}$C NMR signal for related systems without P occurs at $\delta$ 95–105 and the N–C–S bridgehead occurs at $\delta$ 80–95. These quaternary bridgehead signals were particularly weak and were made more difficult to detect because of the ongoing decomposition of the products. Small splittings (*ca.* 3–10 Hz) of the bridgehead carbon signals were observed due to the phosphorus. This is in agreement with the structures **4** and **5**, where P is not bonded directly to the bridgehead carbons. The *endo* or *exo* alignment of the substituents on the P atom has not been established. The $^{31}$P signal for **4** and **5** appeared at $\delta$ 74–77 (downfield from $H_3PO_4$) and the P-bonded *p*-methoxyphenyl group showed the expected $^{31}$P splittings although precise $J_{PC}$ values could not be measured in all cases due to signal spreading caused by the ongoing decomposition. Despite the fact that they could not be recrystallised and only cold washing procedures could be used for purification, the solid compounds **4** and **5** gave satisfactory CHN microanalyses. Energy dispersive X-ray analyses (EDAX) of the solid compounds using a scanning electron microscope confirmed the presence of sulfur and phosphorus in **4** and **5** in the expected atomic ratio of 2 : 1.

UV spectral measurements of the disappearance of the dipole **1a** (R = Ph) at 37 °C in acetone were carried out using pseudo-first-order conditions with 10–1000-fold excesses of dipolarophile giving $k_1$ values. Second-order rate constants $k_2$ were obtained from plots of these $k_1$ values against the dipolarophile concentration, giving the following $k_2$ values at 37 °C: dimethyl maleate = $0.108 \times 10^{-3}$; ethyl acrylate = $0.57 \times 10^{-3}$, acrylonitrile = $1.47 \times 10^{-3}$, dimethyl acetylene-

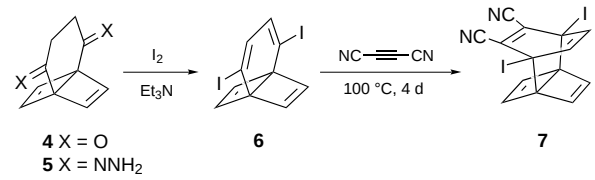
# Tricyclo[4.2.2.2$^{2,5}$]dodeca-1,3,5,7,9,11-hexaene: generation and chemical trapping of the 3,4-dicyano derivative

**Takashi Tsuji,* Masahiro Okuyama, Masakazu Ohkita, Toshiro Imai and Takanori Suzuki**

*Division of Chemistry, Graduate School of Science, Hokkaido University, Sapporo 060, Japan*

**The 3,4-dicyano derivative of hitherto unknown tricyclo-[4.2.2.2$^{2,5}$]dodeca-1,3,5,7,9,11-hexaene, in which six double bonds are uniquely arranged, is generated and chemically trapped with 1,2-dimethylenecyclopentane and *tert*-butyllithium.**

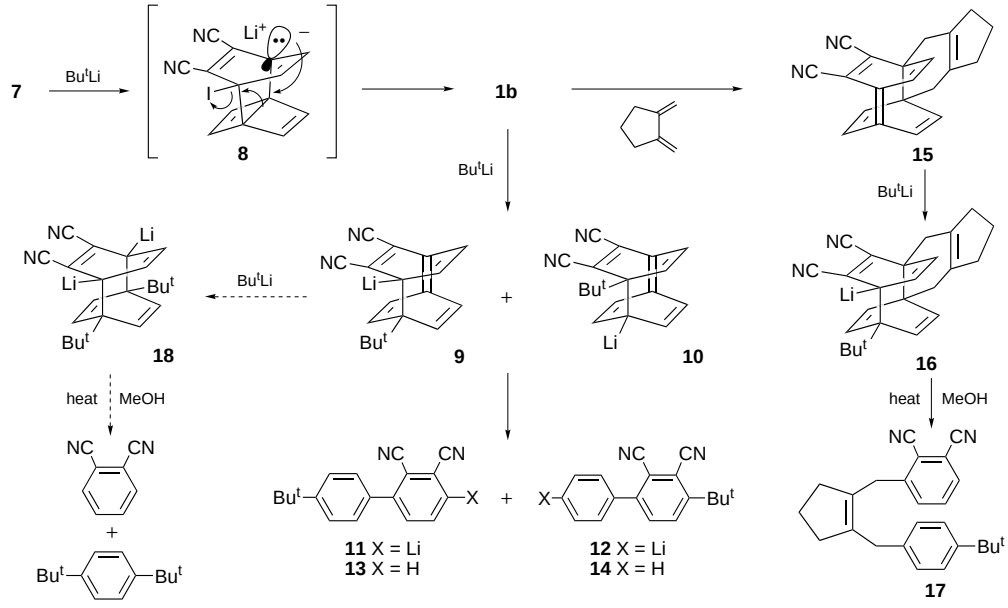


The title compound **1a** is a highly strained and symmetrical, fully unsaturated hydrocarbon[1] in which four double bonds are arranged longicyclically[2] and the residual two doubly bridgehead unsaturated bonds are disposed face-to-face in close

**1a** R = H
**b** R = CN

**2** **3**

proximity. It is also of interest that the species may be regarded as a π-bond-shift isomer of [0.0]paracyclophane **2** although, according to theoretical calculations, the latter appears neither to represent a local energy minimum on the potential energy surface nor to appreciably contribute to the molecule as a canonical form.† To the best of our knowledge, the tetrabenzo derivative **3**[3] is the only known compound closely related to **1a**. We envisaged that the title hexaene structure might be accessible *via* 1,4-elimination in **7** in which the cleaving bonds are ideally disposed antiperiplanar to each other.[4] Moreover, strain release by the concomitant cleavage of the highly strained central σ-bond is expected to facilitate the reaction. Here the generation of the 3,4-dicyano derivative **1b** from **7** and its chemical trapping is reported.



**4** X = O
**5** X = $NNH_2$

**6** **7**

**Scheme 1**

The preparation of **7** started with tricyclic diketone **4**,[5] from which diiodo[4.2.2]propellatetraene **6** was obtained *via* the bis(hydrazone) **5** using Barton's procedure (Scheme 1).[6] The [2 + 4] cycloaddition of dicyanoacetylene to **5** furnished **7** in 45% yield after 4 d at 100 °C.‡ Treatment of **7** with 3.3 equiv. of *tert*-butyllithium in the presence of 1,2-dimethylenecyclopentane (0.33 mol dm$^{-3}$) in THF at −78 °C followed by the addition of MeOH after 1 h provided **13** (40%), **14** (5%) and **17** (10%), along with several minor unidentified products. The formation of these products seems to be best explained by postulating the generation of **1b** *via* **8** as a short lived intermediate (Scheme 2), which undergoes [2 + 4] cycloaddition with 1,2-dimethylenecyclopentane[7] to give **15**, in competition with the regioselective addition of *tert*-butyllithium to give **9** and **10**. The addition of alkyllithium to strained carbon–carbon double bonds is well documented[1] and the observed regioselectivity is in accord with the expected electronic polarization of the double bond and/or the steric effect exerted by the cyano substituents. The resulting adducts **9** and **10** would suffer rapid ring-cleavage to give **11** and **12**, respectively, being facilitated by an enormous gain in energy, and end up as **13** and **14** after protonation by MeOH. According to semiempirical

**11** X = Li
**13** X = H

**12** X = Li
**14** X = H

**Scheme 2**

calculations (PM3),[8] the isomerization of the 1,2-dihydro derivative of **1a** to biphenyl is exothermic by 93 kcal mol$^{-1}$.§

Conspicuously absent in the product mixture were the substituted benzenes expected from the addition of another molecule of *tert*-butyllithium to **9** and **10** followed by ring fission, *e.g.* 1,4-di-*tert*-butylbenzene and phthalonitrile. Thus, the further addition of *tert*-butyllithium to **9** and **10** must be unimportant. The cycloadduct **15**, which is still highly strained but restrained from isomerizing to a biphenyl derivative by the side chain, would eventually be converted to **17** *via* the addition of *tert*-butyllithium,¶ followed by the fission in the benzene *p*,*p*-dimer moiety of the resultant adduct and protonation by MeOH under the reaction conditions or during the isolation.[9] When 1.1 equiv. of *tert*-butyllithium was used in an attempt to suppress its addition to **1b**, only one third of **7** was consumed and the residual two thirds were recovered intact. Apparently, the lithiation of **7** is rate-determining and the subsequent elimination of LiI from **8** and the addition of *tert*-butyllithium to the resulting **1b** must be much faster.‖ The reported isolation of highly strained alkenes whose alkenic carbons are more highly pyramidalized than the central carbons of **1a**,[10–12] however, suggests that the title hexaene may well become isolable if a generation method not requiring the use of strongly nucleophilic or electrophilic reagents is devised, or the skeleton is kinetically stabilized by the introduction of suitable substituents.

† The structure of **1a** optimized at the B3LYP/6-31G* level of theory is $D_{2h}$ symmetric; the interatomic distances C(1)–C(2), C(2)–C(3), C(3)–C(4) and C(1)–C(6) are 1.369, 1.515, 1.345 and 2.399 Å, respectively, and the angle between the bond C(1)–C(2) and the plane C(1)–C(8)–C(9) is 37.0°.

‡ *Selected data* for **6**; $\delta_H(CDCl_3)$ 5.86 (2 H, s), 6.38 (4 H, s); $\delta_C(CDCl_3)$ 65.20, 98.04, 129.88, 143.25; Calc. for $C_{10}H_6I_2$: 379.8559. Found: 379.8535. For **7**: $\delta_H(CDCl_3)$ 6.26 (2 H, s), 6.29 (2 H, s), 6.42 (2 H, s); $\delta_C(CDCl_3)$ 32.08, 66.00, 113.53, 136.08, 140.14, 140.64, 141.70; Calc. for $C_{14}H_6N_2I_2$: 455.8620. Found: 455.8616.

§ The formation of 10-methylbianthryl upon treatment of **3** with methyllithium has recently been reported. The addition of methyllithium in a transannular fashion, however, predominates in the reaction: R. Herges, H. Neumann and F. Hampel, *Angew. Chem., Int. Ed. Engl.*, 1994, **33**, 993.

¶ According to semiempirical calculations (AM1 and PM3) (ref. 8), the degree of pyramidalization around the central alkenic carbons of the 1,2-dihydro derivative of **1a** is slightly more pronounced than around those of **1a**.

‖ It seems that *tert*-butyllithium also rapidly reacts with *tert*-butyl iodide arising from the lithiation of **7**. Thus, 3 equiv. of *tert*-butyllithium at least are consumed in the reaction with **7**.

# A three stranded β-sheet peptide in aqueous solution containing *N*-methyl amino acids to prevent aggregation

**Andrew J. Doig***

*Department of Biomolecular Sciences, UMIST, PO Box 88, Manchester, UK M60 1QD*

**A three stranded β-sheet peptide of *de novo* design with *N*-methyl amino acids to prevent aggregation folds upon heating.**

Peptides which fold in isolation provide a useful way to study protein secondary structure and stability. The α-helix has been studied in this way for a number of years since the discovery that *de novo* designed peptides of 15–20 amino acids in length, composed primarily of alanine, form isolated α-helices in water.[1] In contrast to the mature field of α-helical peptides, β-sheet peptides are much less well understood. A challenge is to synthesise a peptide which will fold into a β-sheet in aqueous solution without aggregation. Synthetic polypeptides that form β-sheets generally form large, insoluble structures comprising many polypeptide chains that are intractable for further study in aqueous solution. However, success has been achieved using both peptides containing natural amino acids[2–13] and with β-sheet formation promoted by non-peptide units.[14–20] Here a peptide designed to fold into a three-stranded β-meander is synthesised, and the fact that it folds into a β-sheet is demonstrated by circular dichroism (CD) spectroscopy.

The β-meander, sequence Ac-YGD(*N*-Me-A)A(*N*-Me-A)APGVVDDVVPGD(*N*-Me-A)AVA(*N*-Me-A)-$CONH_2$, was designed to fold into the structure shown in Fig. 1. Aggregation is avoided in two ways. Firstly, negatively charged Asp side chains are located on both faces of the sheet to introduce intermolecular charge repulsions. Secondly, both outer edges of the sheet have two *N*-methylated amino acids. The *N*-methyl bonds are unable to participate in intermolecular hydrogen bonding and hence the peptides will remain monomeric. These residues are also restricted in their backbone conformations to the β-sheet geometry, which further facilitates folding.[21] *N*-Methylation has previously been used to prevent dimerisation of Interleukin-8 by blocking intermolecular hydrogen bonding.[22] Ghadiri *et al*. have *N*-methylated peptide nanotubes on one side so that they form dimers tractable to NMR spectroscopy and X-ray crystallography.[23]

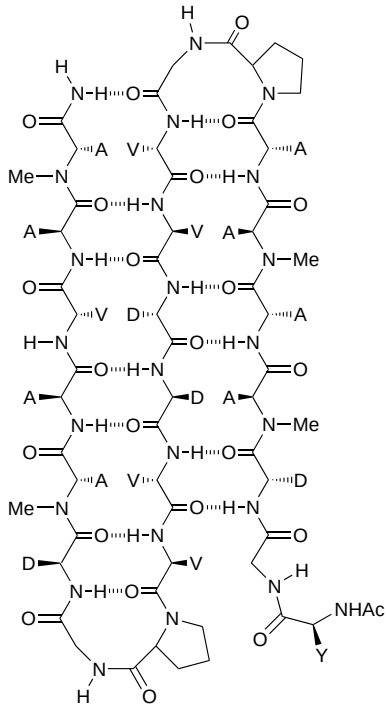

**Fig. 1** Design of the three stranded β-meander peptide

The other amino acids in the sheet were chosen as follows: Pro-Gly is the most commonly observed turn sequence in proteins,[24] while valine residues have a strong preference for β-sheets.[25,26] The formation of the N–Me to C=O bond is synthetically challenging.[27] This is generally made easier by forming *N*-Me-Ala to Ala bonds where possible. In particular, β-branched amino acids are avoided preceding *N*-methyl amino acids. The Gly-Tyr sequence is designed to give the peptide a UV absorbance unperturbed by secondary structure for accurate concentration determination.[28]

The syntheses of peptides containing *N*-methyl amino acids or those that form β-sheets are particularly difficult. The peptide designed here is therefore doubly challenging to synthesise. Peptides were synthesised by the solid phase method using Fmoc chemistry. Success was first achieved with Rink resin and Fmoc amino acids and the reagent TBTU [(benzotriazol-1-yloxy)tris(pyrrolidino)phosphonium hexafluorophosphate] in four-fold excess in the presence of $Pr^i_2EtN$, as judged by analytical fast protein liquid chromatography (FPLC) on the crude yield and confirmed by mass spectrometry. The yield was too low for further analysis so the powerful new reagents, HATU [*O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate] and HOAt (1-hydroxy-7-azabenzotriazole)[29,30] were used with Fmoc-PAL-PEG-PS resin and double coupling cycles for the N–Me to C=O bonds. *N*-Termini were acetylated using pyridine and $Ac_2O$. Cleavage from the resin was achieved with TFA–anisole (19 : 1). After precipitation of the peptide–TFA mixtures into dry ice-coooled $Et_2O$, the peptides were purified by $C_{18}$ reverse-phase FPLC (Pharmacia) using a $H_2O$–MeCN gradient of 10–30% containing 0.1% TFA, followed by size-exclusion chromatography, giving a 10% yield (10 mg) of the target product.

The peptide is soluble in aqueous solution up to at least 2 mM concentration and appears to be monomeric by size exclusion chromatography and 1D NMR line shape analysis (data not shown). CD spectra were acquired at 18 μM concentration, pH 7, 5 mM phosphate buffer, 10 mM NaCl. Fig. 2 shows the CD spectra acquired at 293, 313 and 333 K. At 293 K the peptide is a mixture of random coil and β-sheet. Remarkably, it folds upon heating, giving a classic β-sheet spectrum at 333 K, with a minimum at 219 nm.[31] Hence, β-sheet formation is endothermic. The isodichroic point at 212 nm suggests that the sheet/coil transition is two-state.

It is proposed that *N*-methylation of NH groups on the outer edges of a β-sheet is a general solution to the problem of β-sheet aggregation. The peptide developed here may provide a suitable model system for investigating a range of aspects of β-sheet stability and folding.

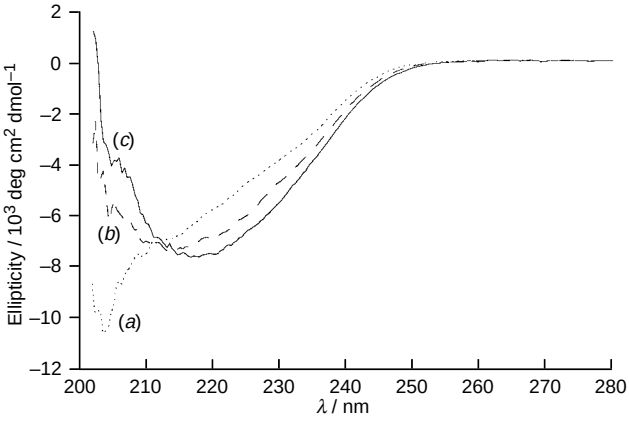

**Fig. 2** CD Spectra of the β-meander (pH 7, 5 mM phosphate, 10 mM NaCl) at (*a*) 20, (*b*) 40 and (*c*) 60 °C

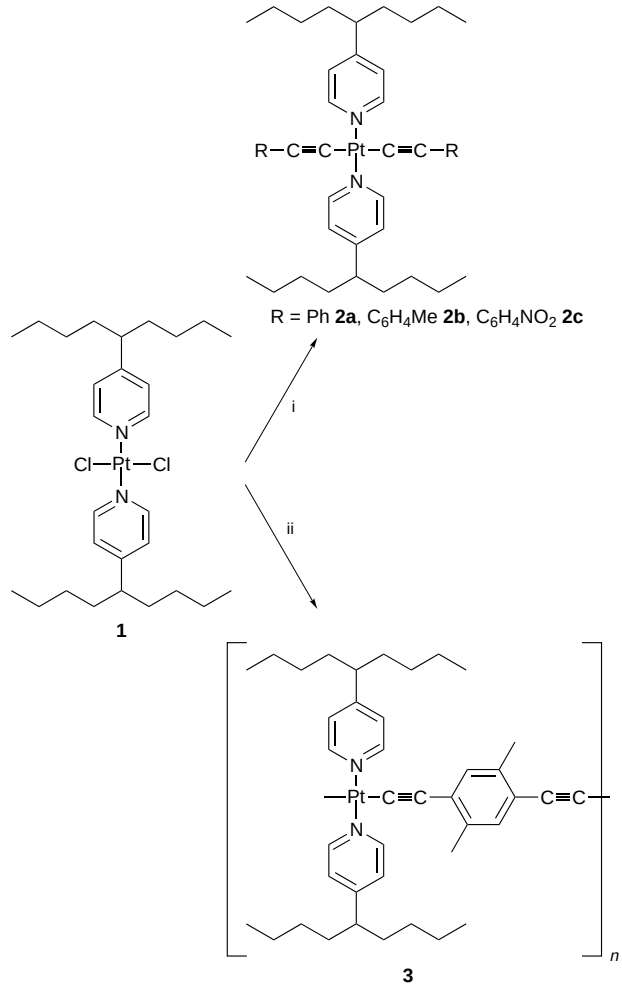
# Novel pyridyl-stabilised rigid-rod organometallic polymers and their monomeric precursors

**Christopher J. Adams, Stuart L. James and Paul R. Raithby***

*Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge, UK CB2 1EW*



**Reaction of *trans*-[Pt(NC$_5$H$_4$CHBu$^n$$_2$)$_2$Cl$_2$] 1 with an excess of HC≡CR (R = Ph, C$_6$H$_4$Me, C$_6$H$_4$NO$_2$) affords the monomeric complex *trans*-[Pt(NC$_5$H$_4$CHBu$^n$$_2$)$_2$(C≡CR)$_2$] (R = Ph 2a, C$_6$H$_4$Me 2b, C$_6$H$_4$NO$_2$ 2c), the *trans* arrangement of the alkynyl ligands being confirmed from spectroscopic data and by an X-ray analysis of 2c; when 1 is treated with 1 equiv. of HC≡CC$_6$H$_2$(Me)$_2$C≡CH the polymer [Pt(NC$_5$H$_4$CHBu$^n$$_2$)$_2$C≡CC$_6$H$_2$Me$_2$C≡C]$_n$ is formed, which is soluble in a range of organic solvents.**

There is considerable current interest in σ-alkynyl transition-metal complexes and in the polymers formed from them because of their potential for use as non-linear optical, low-dimensional conducting, luminescent or liquid-crystalline materials.[1] Within this group the 'rigid-rod' *trans*-bis(σ-alkynyl) systems with the general formula [ML$_x$–C≡C–R–C≡C]$_n$ (M = Fe, Ru, Os, Ni, Pd, Pt; L = phosphine, arsine, *n* = 2,4; R = C$_6$H$_4$, C$_6$H$_2$Me$_2$, C$_6$H$_2$F$_2$, C$_4$H$_4$S, C$_{14}$H$_8$)[2] have been shown to exhibit a variety of novel electronic properties.[3] The ancillary ligands, L, in these metal-containing polymers are almost always phosphines, and this derives from the overwhelming proportion of monomeric platinum-group alkynyl precursor complexes which are stabilised by phosphines.[4] Imine donors are expected to impart different properties to both monomeric and polymeric systems, particularly with regard to their optical and redox behaviour.[5] We have, therefore, embarked on the development of platinum-group alkynyl chemistry with nitrogen donor ligands, and have recently reported the preparation of the *cis*-diimine stabilised complexes [(Me$_2$bipy)Pt(C≡CC$_6$H$_4$R-4)$_2$] (bipy = bipyridyl; R = H, Me, NO$_2$).[6] We now report the synthesis of the first diimine stabilised *trans*-bis(σ-alkynyl) platinum complex [Pt(NC$_5$H$_4$CHBu$^n$$_2$)$_2$(C≡CR)$_2$] (R = Ph **2a**, C$_6$H$_4$Me **2b**, C$_6$H$_4$NO$_2$ **2c**) and the formation of the novel polymer [Pt(NC$_5$H$_4$CHBu$^n$$_2$)$_2$C≡CC$_6$H$_2$Me$_2$C≡C]$_n$ **3**.

A frequent problem in the synthesis of σ-alkynyl complexes and the subsequent formation of the polymers is their insolubility in common organic solvents. In order to reduce this problem *trans*-[Pt(NC$_5$H$_4$CHBu$^n$$_2$)$_2$Cl$_2$] **1**, prepared by an adaption of the literature method,[7] was used as the starting material; the long hydrocarbon chains attached to the 4-position of the pyridine group greatly enhance the solubility. The reaction of **1** with 3 equiv. of HC≡CR (R = Ph, C$_6$H$_4$Me, C$_6$H$_4$NO$_2$), in the presence of catalytic amounts of CuI, in CH$_2$Cl$_2$ solution containing Pr$^i$$_2$NH, afforded [Pt(NC$_5$H$_4$CHBu$^n$$_2$)$_2$(C≡CR)$_2$] (R = Ph **2a**, C$_6$H$_4$Me **2b**, C$_6$H$_4$NO$_2$ **2c**) in high yield, after stirring for 1 h (Scheme 1). The products were isolated as crystalline solids after purification by column chromatography on alumina using CH$_2$Cl$_2$–hexane (1 : 1) as eluent. The products were characterised initially by IR, $^1$H and $^{13}$C NMR spectroscopy, and by mass spectrometry.† The single ν(C≡C) stretching frequency in the range 2102–2098 cm$^{-1}$ in the IR spectrum confirmed the presence of the σ-alkynyl ligands, consistent with the *trans* geometry.

In order to confirm the *trans* geometry of the products a single-crystal X-ray analysis of **2c** was undertaken. The molecular structure‡ is illustrated in Fig. 1 which includes selected bond parameters. The Pt atom sits on a crystallographic centre of symmetry, which imposes exact planarity at the metal centre, and requires the two alkynyl groups and the two substituted pyridine ligands to occupy mutually *trans* positions, respectively. The Pt–C(21)–C(22) alkynyl unit is essentially linear. The geometry is similar to that found in a number of *trans*-bis(phosphine) stabilised platinum bis(alkynyl) complexes,[8] and the Pt–C(21) distance lies within the range 1.98(1)–2.06(1) Å found in the other complexes.

The reaction of **1** with 1 equiv. of HC≡CC$_6$H$_2$Me$_2$C≡CH, under the same reaction conditions as described above, afforded, after purification, the polymer *trans*-[Pt(NC$_5$H$_4$CHBu$^n$$_2$)$_2$C≡CC$_6$H$_2$Me$_2$C≡C]$_n$ **3** as a brown solid in moderate yield (Scheme 1). The polymer was characterised by spectroscopic techniques,† and the presence of the σ-alkynyl confirmed by the presence of the ν(C≡C) stretching vibration in

**Scheme 1** i, 3 equiv. HC≡CR (R = Ph **2a**, C$_6$H$_4$Me **2b**, C$_6$H$_4$NO$_2$ **2c**), catalytic amount of CuI in Pr$^i$$_2$NH, CH$_2$Cl$_2$, stirred at room temp. for 1 h; ii, 1 equiv. HC≡CC$_6$H$_2$Me$_2$C≡CH, catalytic amount of CuI in Pr$^i$$_2$NH, CH$_2$Cl$_2$, stirred at room temp. for 1 h

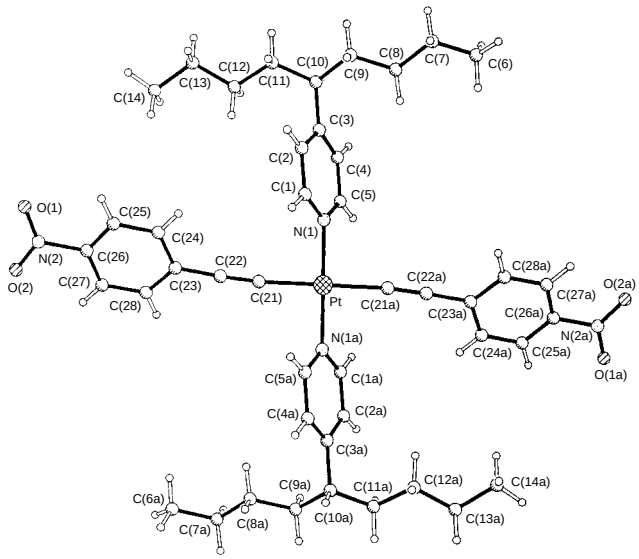


**Fig. 1** Molecular structure of **2c** showing the atom numbering scheme. Selected bond lengths (Å) and angles (°): Pt–N(1) 2.001(10), Pt–C(21) 2.02(2), C(21)–C(22) 1.21(2), C(22)–C(23) 1.42(2), C(26)–N(2) 1.49(2), N(2)–O(1) 1.22(2), N(2)–O(2) 1.22(2); N(1)–Pt–C(21) 88.2(4), N(1)–Pt–C(21A) 91.8(4), Pt–C(21)–C(22) 174.8(11), C(21)–C(22)–C(23) 174(2), O(1)–N(2)–C(26) 118.2(13), O(2)–N(2)–C(26) 116.1(14), O(1)–N(2)–O(2) 125.6(14).

the IR spectrum. As in other σ-alkynyl polymers[9] this $\nu$(C≡C) stretch does not show a significant shift from the position in the precursor complex. The $^{13}$C NMR spectrum confirmed the presence of both the arene spacer group and the substituted pyridine ligands, but in common with other 'rigid-rod' polymers chemical shifts corresponding to the σ-alkynyl carbons were not observed.[2,3]

Unlike many of the phosphine-stabilised 'rigid-rod' polymers **3** is soluble in a range of organic solvents. Therefore, it has been possible to run a series of electronic spectra to observe the shift in the absorption consistent with the greater delocalisation of electron density through the extended π-system along the polymer chain. In the free ligand, $HC{\equiv}CC_6H_2Me_2C{\equiv}CH$, two strong absorptions are observed at $\lambda_{max}$ = 263.8 nm ($\varepsilon$ = 1.9 × 10$^4$ dm$^3$ mol$^{-1}$ cm$^{-1}$) and $\lambda_{max}$ = 273.3 (2.31 × 10$^4$) in the UV region. For the precursor complex *trans*-[Pt(NC$_5$H$_4$CHBu$^n$$_2$)$_2$Cl$_2$] **1** one broad absorption is observed at $\lambda_{max}$ = 252.5 nm ($\varepsilon$ = 9.39 × 10$^3$ dm$^3$ mol$^{-1}$ cm$^{-1}$), while in the alkynyl-substituted monomer [Pt(NC$_5$H$_4$CHBu$^n$$_2$)$_2$-(C≡CPh)$_2$] **2a** the absorption is slightly shifted to $\lambda_{max}$ = 281.0 nm ($\varepsilon$ = 3.53 × 10$^4$ dm$^3$ mol$^{-1}$ cm$^{-1}$). In contrast, for the polymer there is a considerable shift in absorption to $\lambda_{max}$ = 342.2 nm ($\varepsilon$ = 2.92 × 10$^4$ dm$^3$ mol$^{-1}$ cm$^{-1}$), again a very broad band being observed. This shift in the position of the absorption is consistent with the greater delocalisation along the polymer chain. Similar shifts in the absorption spectra have been observed previously for related systems.[10]

We thank the EPSRC for support (to C. J. A. and S. L. J.), and Dr J. E. Davies for assistance with X-ray data collection.

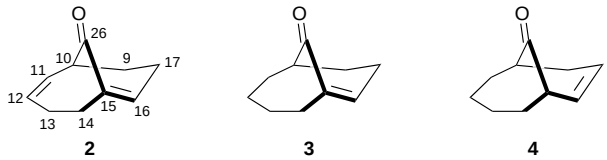
# Synthesis of the carbobicyclic substructure of CP-225,917 and CP-263,114

**Paulo W. M. Sgarbi and Derrick L. J. Clive***

*Chemistry Department, University of Alberta, Edmonton, Alberta, Canada T6G 2G2*

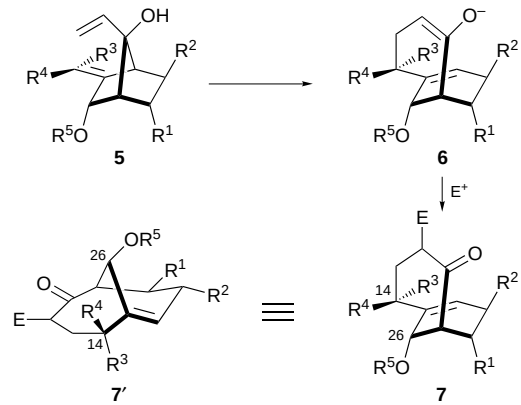


**The bridgehead alkenic ketones 22a and 22b, representing the carbobicyclic substructure of the squalene synthase and farnesyl transferase inhibitors CP-225,917 (1) and CP-263,114 (23), have been synthesized from the 7-norbornenone acetal 8, using an anionic oxy-Cope rearrangement of 21a and 21b in the key step; the synthesis serves as a test of a potential route to both natural products.**

The structurally complex anhydride **1** was isolated from the fermentation broth of an unidentified fungus, and described recently by chemists at Pfizer Central Research.[1,2] The substance is related to the nonadrides[3]—at least on the basis of its proposed[2] biosynthetic origin. It was given the designation CP-225,917, and was found[1] to inhibit squalene synthase[4] (from rat liver) and Ras farnesyl transferase[5] (from rat brain). Inhibition of these enzymes represents an opportunity for controlling serum cholesterol levels[6] as well as certain types of abnormal cell growth,[5] and so **1** may serve as a lead in the design of cholesterol-lowering and anticancer drugs.

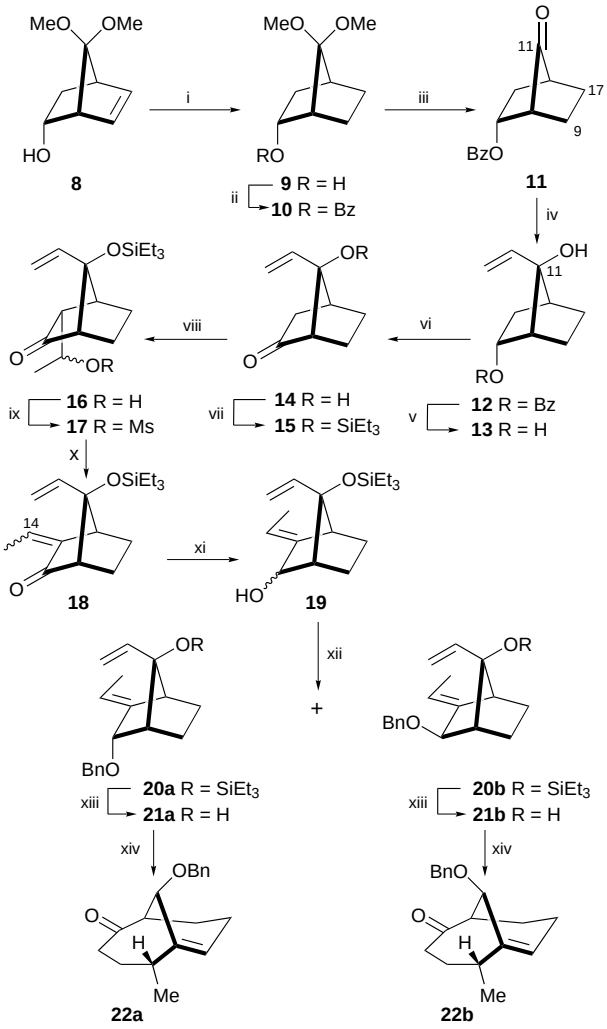
**1**

CP-225,917 is the hemiacetal of a bicyclo[4.3.1]decadienone substructure **2**,† and one of its notable features is the bridgehead double bond. Although the related olefinic ketone **3** (which was obtained in admixture with the isomer **4**) has been prepared,[7] the method used to make that particular compound does not seem well-suited to the task of synthesizing the natural product. We report a model study[8,9] that establishes a route to **22a** and **22b** (see Scheme 2), both of which we take to represent the [4.3.1]-carbobicyclic substructure of CP-225,917.



**2** **3** **4**

Our approach is based on the idea that anionic oxy-Cope rearrangement‡ of compounds such as **5** (Scheme 1) should lead to enolates **6**, which have a number of features that are appropriate for further elaboration in the desired manner (**6**→**7**/**7′**). In particular, the C(26) oxygen function of **7**/**7′** could provide the corresponding acetal unit of **1**, and the enolate **6** would offer several opportunities for constructing the anhydride, perhaps by initial capture with an electrophile, such as Mander's reagent.[11] The route summarized in Scheme 1 should also be able to accommodate introduction of two substituents at C(14) (see **7**/**7′**), which is a quaternary centre in the natural product.



Our model study (Scheme 2) began with the readily available norbornene **8**.[12] The double bond was first saturated (**8**→**9**; Pd–C, $H_2$; 92%), and the resulting alcohol was then benzoylated (BzCl, pyridine; 98%) and treated with aqueous acetic acid to hydrolyse the acetal (**9**→**10**→**11**). When esterification was omitted, extensive decomposition occurred during attempts at deacetalization, presumably by a retroaldol process. Ketone **11** is quite sensitive, and so it was used without purification. While we had originally planned to introduce a vinyl group at C(11) (*cf.* **11**→**12**) by an intramolecular Barbier reaction, we wondered if adequate facial selectivity would be observed for a simple intermolecular process[13] and, in the event, treatment of crude **11** with vinylmagnesium bromide in $Et_2O$ gave a ≥5 : 1 mixture of tertiary alcohols, with the desired isomer **12** being the major product. In the present study, carbons C(9) and C(17) of **11** are unsubstituted; in a more advanced model those carbons would carry alkyl groups, and steric factors may improve the already satisfactory product ratio. Separation of the C(11) isomers could be performed chromatographically after hydrolysis of the benzoyl group (**12**→**13**; LiOH, 9 : 1 THF–water, 60 °C; 44% overall from **10**; 9% of C(11) isomer of **13**). Oxidation of the major diol (**13**) was initially problematic, until we tried the Dess–Martin reagent,[14] which smoothly converts **13** into keto alcohol **14** (93%).

The next task was to protect the tertiary hydroxy group (**14**→**15**) in order to avoid retroaldol fragmentation.[15] $Et_3$-SiOTf in the presence of 2,6-lutidine proved to be a satisfactory combination of reagents (84%); attempts to introduce *tert*-butyldimethylsilyl or *p*-methoxybenzyl groups were unsuccessful. The remainder of the hexa-1,5-diene subunit required for the anionic oxy-Cope rearrangement was assembled by a short sequence, beginning with aldol condensation (**15**→**16**; LDA, THF, −78 °C; excess of MeCHO; > 76%), so as to form the β-hydroxy ketones **16** as an isomer mixture. Without separation, these alcohols were converted into the corresponding mesylates **17** (MsCl, $Et_3N$, $CH_2Cl_2$, 0 °C) and, again without isomer separation, the mesylates were treated with DBU (THF, room temperature), affording the desired enones **18**, which were easily separable (*E*-isomer, 60% overall from **15**; *Z*-isomer, 11% overall from **15**).§ As a matter of convenience, only the major ketone was taken further. Reduction (**18**→**19**; $NaBH_4$,

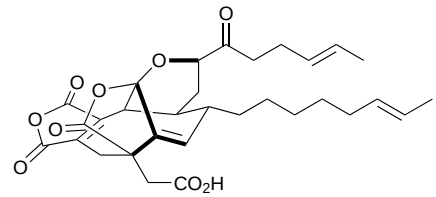

**Scheme 1**

**Scheme 2** *Reagents and conditions*: i, $H_2$, 10% Pd–C, MeOH, room temp., *ca*. 5 h, 92%; ii, BzCl, pyridine, room temp., 10 h, 98%; iii, 6 : 1 AcOH–$H_2O$, 150 °C, 40 min; iv, $H_2C$=CHMgBr, $Et_2O$, 0 °C, 40 min; v, LiOH·$H_2O$, 9 : 1 THF–$H_2O$, 80 °C, 12 h, 53% over 3 steps [44% for **13**, 9% for C(11) isomer of **13**]; vi, Dess–Martin periodinane, 33 : 1 $CH_2Cl_2$–DMSO, room temp., 12 h, 93%; vii, $Et_3SiOSO_2CF_3$, 2,6-lutidine, $CH_2Cl_2$, room temp., 1 h, 84%; viii, LDA, THF, −78 °C, 1 h, then MeCHO, −78 °C, 1 h; ix, $MeSO_2Cl$, $Et_3N$, $CH_2Cl_2$, 0 °C; x, DBU, THF, room temp., 1 h, 71% over 3 steps [60% isolated yield of (*E*)-alkene and 11% isolated yield of (*Z*)-alkene]; xi, $NaBH_4$, $CeCl_3$·$7H_2O$, MeOH, room temp., 1.5 h, 86% (*endo*-**19**, 42%; *exo*-**19**, 44%); xii, BnBr, NaH, THF, 70 °C, 24 h, 94% for **20a**, 70% for **20b**; xiii, $Bu_4NF$, THF, room temp., 2 min, 89% for **21a**, 89% for **21b**; xiv, $(Me_3Si)_2NK$, PhMe, 100 °C, 20 h, 95% for **22a**, 82% for **22b**

MeOH, $CeCl_3$·$7H_2O$; 86%) gave a 1 : 1 mixture of *endo*- (42% isolated yield) and *exo*-alcohols (44%), which were easily separated and individually protected by benzylation (*endo*-**19**→**20a**, 94%; *exo*-**19**→**20b**, 70%). At this point, desilylation of both **20a** and **20b** was accomplished under standard conditions ($Bu_4NF$, THF, room temperature; 89% for each compound) and finally, the resulting alcohols were subjected to anionic oxy-Cope rearrangement [$(Me_3Si)_2NK$, PhMe, 100 °C, *ca*. 20 h]. *endo*-Benzyl ether **21a** gave the bridgehead keto alkene **22a** (95%) and the *exo* isomer (**21b**) gave **22b** (82%), whose structures were confirmed by extensive $^1H$–$^1H$ COSY and ROESY NMR measurements. In neither case was the rate of oxy-Cope rearrangement noticeably increased by addition of 18-crown-6.

Formation of **22a** and **22b** (which is crystalline) serves as an initial test of the plan summarized in Scheme 1.

**23**

A closely related natural product (CP-263,114, **23**) was isolated along with CP-225,917, and found to have similar biological properties, although of a lower potency with respect to squalene synthase inhibition. The present work is, of course, equally relevant to the synthesis of the congener.

All new compounds, except **11**, one epimer of **16**, **17** and the C(11) epimer of **12**, were satisfactorily characterized by spectroscopic methods, including high resolution mass spectroscopic measurements.

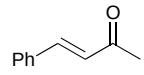
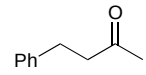
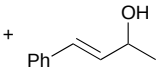
# Copper(I) salt mediated 1,4-reduction of α,β-unsaturated ketones using hydrosilanes

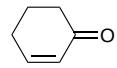
**Atsunori Mori,* Akinori Fujita, Yasushi Nishihara and Tamejiro Hiyama**

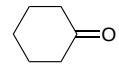
*Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Nagatsuta, Yokohama 226, Japan*

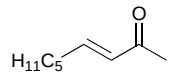


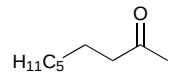


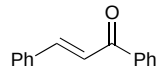


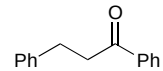


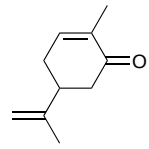


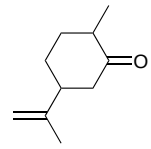






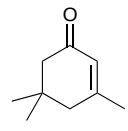






**Reduction of α,β-unsaturated ketones with $HSiPhMe_2$ in the presence of $CuF(PPh_3)_3{\cdot}2EtOH$ proceeds in a 1,4-selective manner to give the corresponding saturated ketones in excellent yields.**

Transfer of the organic groups of organosilanes to metallic species, *transmetalation*, has been our recent concern since a number of metal mediated synthetic reactions involve transmetalation as a key step.[1] The organometallic species thus formed may undergo further transformations, such as carbon–carbon or carbon–heteroatom bond formation, *via* reaction with several organic substrates.[2] We have disclosed that organosilicon compounds such as alkenyl-, aryl- and alkynyl-silanes induce homo-coupling reactions to yield the corresponding 1,3-dienes, biaryls and 1,3-diynes, respectively, in the presence of a copper(I) salt in a polar solvent.[3] The findings suggest that transmetalation of the organosilanes to copper occurs to give the organocopper species, the novel transmetalation being remarkable since an organic group on silicon is assumed to transfer onto copper without using an additional activator.[4,5] Our interest has accordingly turned to the transmetalation of hydrosilanes to copper to generate *copper hydride* species, with which reduction of a variety of organic molecules has been reported.[6] Although the combination of a copper salt and hydrosilane has rarely been studied when compared with reagents made from copper salts and the hydrides of metals such as aluminium and tin,[7] the desired reaction, we considered, would proceed with the proper choice of the counter ion and a ligand of copper. After screening several $Cu^I$ species, we found that the $CuF(PPh_3)_3$–$HSiPhMe_2$ system could effect 1,4-selective reduction of α,β-unsaturated ketones under mild conditions.



The reaction was studied using 1-phenylbut-1-en-3-one **1a** as substrate and HSiPhMe **2a** as the reducing agent in the presence of a copper(I) salt. The molar ratio of the substrate, hydrosilane and copper salt, as well as solvent, reaction temperature and reaction time were examined. We found that the use of 2 equiv. of **2a** and 1 equiv. of $CuF(PPh_3)_3{\cdot}2EtOH$[8] in *N*,*N*-dimethylacetamide (DMA) were the optimum conditions to yield 1-phenylbutan-2-one **3a** in a quantitative yield.† Results are summarized in Table 1. The yield decreased to 63% when 1 equiv. of **2a** was used. Using a catalytic amount of $CuF(PPh_3)_3{\cdot}2EtOH$, the reaction similarly proceeded with a slight decrease in yield, along with the formation of a small amount of unidentified product as well as a trace amount of 1,2-reduction product **4a**. Concerning the hydrosilane, **2a** and triethylsilane **2b** exhibited high 1,4-selectivities to give the corresponding ketone in excellent yields, but diphenylsilane **2c** considerably decreased the selectivity to give **3a** and **4a** in 49 and 36% yields, respectively, in contrast with the results on rhodium-catalysed hydrosilylation of α,β-unsaturated ketones.[9] No reaction occurred with $HSiPhCl_2$ **2d**.

Reactions using several other α,β-unsaturated ketones were carried out using similar optimized condition, as shown in Table 1. The reactions of **1a**–**e** proceeded in excellent yields with high 1,4-selectivity. However, sterically congested enones such as **1f**–**h** were recovered unchanged.‡ The results also contrast with those from the reactions catalysed by a rhodium complex,[9] which reduced enones **1f**–**h** smoothly in a highly 1,4-selective manner. In this sense, our systems appears to be highly chemoselective. Indeed, the reaction of a 1 : 1 mixture of **1a** and **1f** with **2a** in the presence of $CuF(PPh_3)_3{\cdot}2EtOH$ cleanly produced **3a** (99%), along with complete recovery of **1f** (97%) [eqn. (1)].

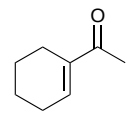


**Table 1** Copper(I) salt mediated reactions of α,β-unsaturated ketones with hydrosilanes in the presence of $CuF(PPh_3)_3{\cdot}2EtOH$[a]

| Substrate | Hydrosilane | Product (% yield) | |

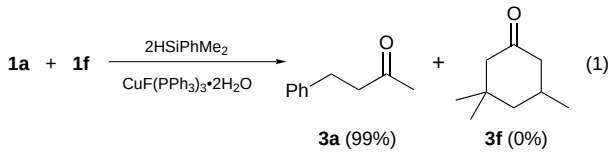
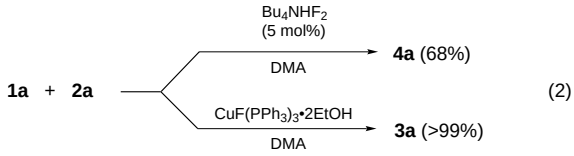
[a] Reactions were carried out using enone **1** (1.0 mmol), silane **2** (2.0 mmol) and $CuF(PPh_3)_3{\cdot}2EtOH$ **3** (1.0 mmol) unless otherwise specified. The yields are based on $^1H$ NMR analyses using $Cl_2C{=}CHCl$ as an internal standard. [b] One equiv. of **2a** was used. Accompanied by recovery of **1a** (21%). [c] $CuF(PPh_3)_3$ (5 mol%) was used. [d] 4 equiv. of **2a** was used. [e] Diastereoisomeric ratio was *ca.* 8 : 1.



**1f**



**1g**

**1h**

Although a mechanistic study of the transmetalation of organosilane to copper has yet to be undertaken, the activation of hydrosilanes by $CuF(PPh_3)_3{\cdot}2EtOH$ seems to be rather different from that by $Bu_4NF$ or the related reagents. The reaction of **1a** and **2a** in the presence of 5 mol% of $Bu_4NHF_2$[12] resulted in predominantly 1,2-reduced product **4a** in 68% yield. Thus, 1,4- and 1,2-selective reduction of α,β-unsaturated ketones with hydrosilanes are accessible by a suitable choice of copper(I) fluoride or $Bu_4NHF_2$ in a highly selective manner, respectively [eqn. (2)].

The authors thank Shin-Etsu Chemical Co. Ltd. for the generous donation of organosilicon reagents. This work was partially supported by a Grant-in-Aid for Scientific Research on Priority Areas (No. 09239102) from the Ministry of Education, Science, Sports and Culture, Japan.

† *Typical experimental procedure*: $CuF(PPh_3)_3{\cdot}2EtOH$ (0.25 mmol) was dissolved in 2 ml of DMA to give a colourless clear solution, to which was added $HSiPhMe_2$ **2a** (0.5 mmol) at 0 °C to give a red homogeneous solution. The colour of the solution gradually changed to yellow after the addition of 1-phenylbut-1-en-3-one (**1a**, 0.25 mmol). The temperature of the reaction mixture was gradually raised to room temperature, and stirring was continued for 6 h to furnish **4a** in a quantitative yield after workup.

‡ The reaction of an α,β-unsaturated ester (methyl cinnamate) also resulted in no reaction. On the other hand, an α,β-unsaturated aldehyde (cinnamaldehyde) was found to effect 1,2-reduction, predominantly.

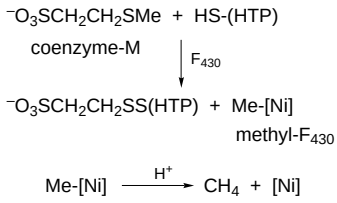
# Biomimetic methane generation and disulfide formation by catalysis with a nickel complex

**Masaru Tada* and Yoshihide Masuzawa**

*Department of Chemistry, Advanced Research Center for Science and Engineering and Materials Research Laboratory for Bioscience and Photonics, Waseda University, Shinjuku, Tokyo 169, Japan*

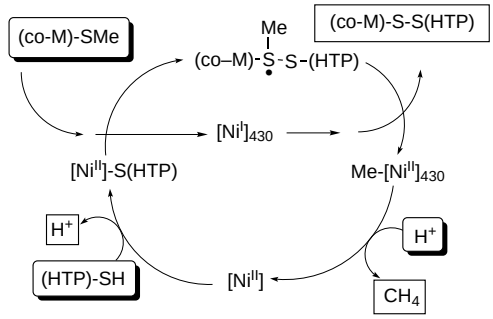


**The final metabolic process of *methanogen*, methane generation and simultaneous disulfide formation, is simulated by the reaction of thioanisole with a toluenethiyl radical in the presence of a nickel complex, which is generated by the photolysis of a toluenethiolato–nickel complex.**

Methanogens[1] are unique bacteria belonging to the Archae bacteria, which constitute the third domain of terrestrial life in addition to Eukaryotes and Prokaryotes.[2] A methanogen produces methane and water as metabolites to produce energy from hydrogen and carbon dioxide[3] [eqn. (1)]. The final step

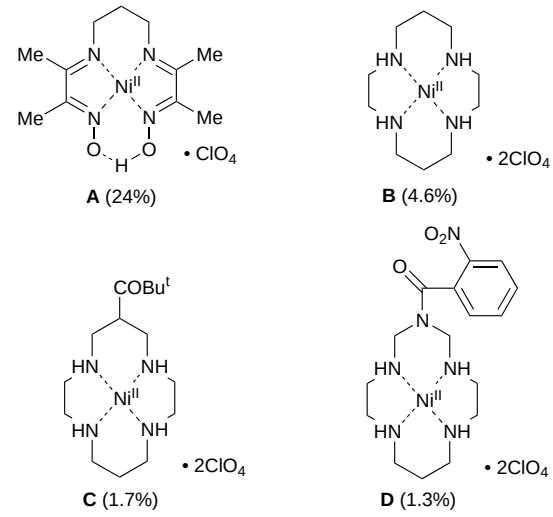
$$4H_2 + CO_2 \xrightarrow{methanogen} CH_4 + 2H_2O \qquad (1)$$

$$\Delta G^0 = -131 \text{ kJ mol}^{-1}$$



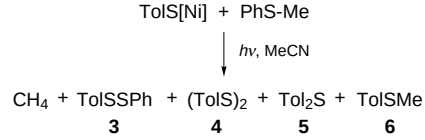
of this $C_1$-unit transformation is the generation of a mixed disulfide and methane (or methyl-$F_{430}$) from methyl-coenzyme M and 7-mercaptoheptanoylthreonine phosphate (HTP-SH) (Scheme 1).[3]

**Scheme 1**



We have no analogy for this in organic or inorganic chemistry, and the main purpose of the present study is to establish a biomimetic reaction analogous to the biological methane production and gain insight into the biochemical reaction mechanism. Reported here is the first successful example of biomimetic production of methane and a mixed disulfide by catalysis with a nickel(II) complex, an $F_{430}$ model.[4] $F_{430}$ is a nickel complex having a modified corrin nucleus which is more flexible than the corrin nucleus in coenzyme $B_{12}$. This flexibility of $F_{430}$ is considered to enable variation in coordination number during the catalysis.

On starting the experimental study, we adopted the working hypothesis shown in Scheme 2, which was originally proposed by Jaun[5a] and Berkessel.[5b] Thus the formation of a thiolato–nickel complex [Ni]–S(HTP) and a sulfuranyl radical (co-M)S•Me– S(HTP)and a final methyl transfer from the sulfuranyl radical to the nickel complex ($F_{430}$) are the crucial features of this mechanism.



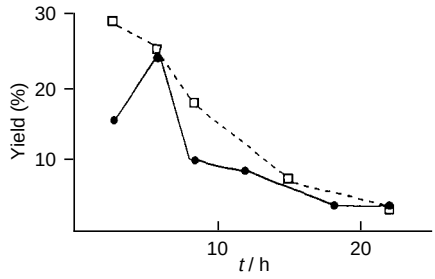
**Scheme 2**

Nickel(I) species have been reported to be active in an enzyme system;[6] therefore, we planned to produce the sulfuranyl radical and nickel(I) complex by the photolysis of the thiolato–nickel complex formed by the reaction of a nickel(II) complex and a thiolate ion. The colour of the MeCN solution of the nickel(II) complex **A** changed from orange to blue–violet on addition of the toluene-*p*-thiolate anion, which was prepared *in situ* from toluenethiol and NaH. A mixture of the toluene-*p*-thiolate ion ($1.5 \times 10^{-2}$ mol $l^{-1}$) and the nickel complex **A** ($5.0 \times 10^{-3}$ mol $l^{-1}$) was added to thioanisole ($1.5 \times 10^{-2}$ mol $l^{-1}$) in MeCN, and the mixture was irradiated at 350 nm under argon.†

Product analyses showed the formation of a mixed disulfide **3** in addition to ditolyl disulfide **4** and ditolyl sulfide **5** (Scheme 3). The time course of the formation of the mixed disulfide **3** and ditolyl disulfide **4** is shown in Fig. 1, which shows that the initial products **3** and **4** decompose on continuous irradiation. Reference irradiation showed the decomposition of these disulfides into the corresponding sulfides, and thus the initial products are the disulfides **3** and **4**.

Gas chromatography–mass spectral analysis (utilizing peaks at *m/z* 12 and 15 to avoid contamination by oxygen) of the top

**Scheme 3**



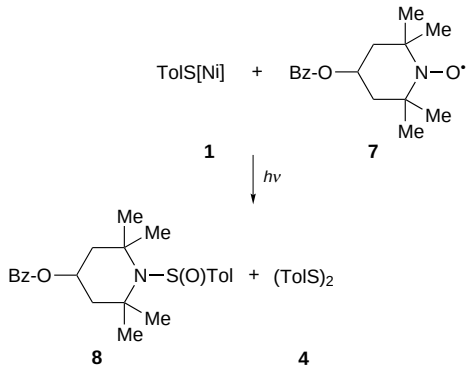


**Fig. 1** The time course of the formationn of disulfides (●) **3** and (□) **4**

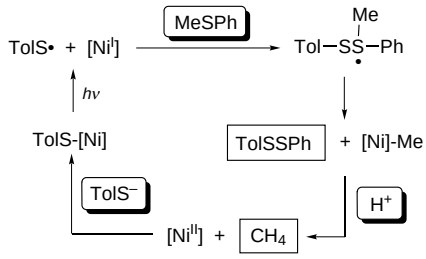
gas of the reaction vessel showed the evident formation of methane, although the yield could not be determined due to the solubility of methane in MeCN. Irradiation of the same mixture containing an equivalent amount of compound **7** gave compound **8**‡ in 12% yield. The formation of **8** and ditolyl disulfide **4** shows the intervention of the toluenethiyl radical (Scheme 4).



**Scheme 4**

Other nickel(II) complexes **B**–**D** showed some catalytic activity, although with less efficiency, and the yields of **3** after 6 h irradiation are shown in parentheses beneath their structures. Neutral complexes such as bis(dimethylglyoximato)nickel(II) and tetraphenylporphyrin–nickel(II) showed no activity.§ Formation of the mixed disulfide was not observed when either the nickel(II) complex or irradiation was absent. This reaction catalysed by the nickel(II) complex **A** is summarized by Scheme 5 and the net reaction is written as eqn. (2).

$$\mathrm{TolS^-} + \mathrm{MeSPh} + \mathrm{H^+} \rightarrow \mathrm{TolSSPh} + \mathrm{CH_4} \qquad (2)$$

There are two possible action modes of the nickel complex as shown in Fig. 2; (*a*) an $S_H2$ type substitution on the methyl group or (*b*) a ligand coupling on the hypervalent state sulfur.[7] We prefer mode (*a*) because the use of ω-phenylalkyl phenylsulfide instead of thioanisole yields no mixed sulfide and

**Scheme 5**

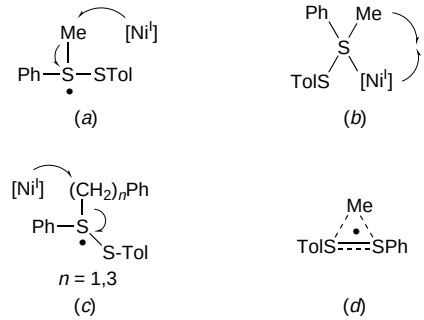


**Fig. 2** Possible reaction modes of the sulfuranyl radical

phenylalkane. Thus the transition state (*c*) of the nickel attack must be more hindered than the transition state (*a*) in which the least bulky methyl group is the reaction centre, and the present reaction seems to be under severe steric control. On the other hand, steric control is less important for mode (*b*) because the reaction centre is a sulfuranyl radical.

Finally, we detected a trace amount of methyl tolyl sulfide **6** from the present model reaction, and the methyl group on the sulfuranyl radical (*a*) seems to swing to some extent through a transition state (*d*). We are studying the effect of this methyl migration on the present intramolecular methyl transfer of biomimetic type.

We thank Waseda University and the Ministry of Education, Sports, and Culture of Japan for their financial support through the Annual Project Program (95A-252) and a 1997 Grant-in-aid (09640649) respectively.

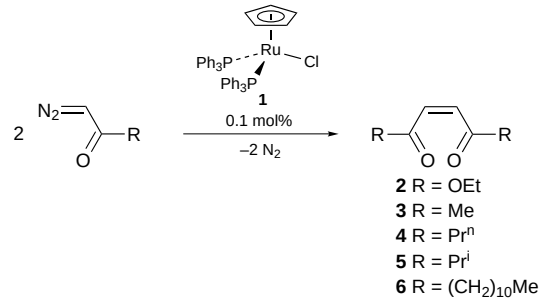
# Highly stereoselective formation of *cis*-enediones from α-diazo carbonyl compounds catalysed by [RuCl(η$^5$-$C_5H_5$)($PPh_3$)$_2$]

**Walter Baratta, Alessandro Del Zotto and Pierluigi Rigo***



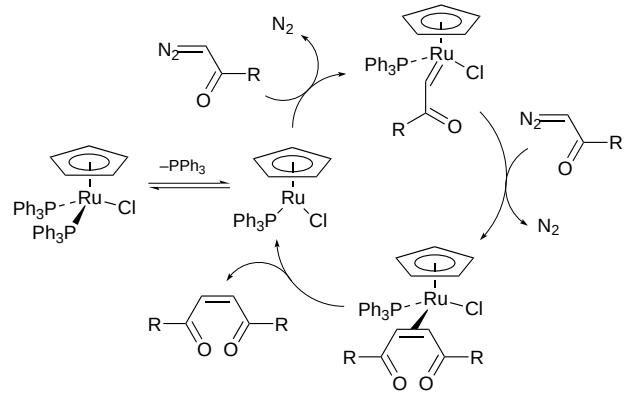
*Dipartimento di Scienze e Tecnologie Chimiche, Università di Udine, Via Cotonificio 108, I-33100 Udine, Italy*

**Stereoselective decomposition of the α-diazo carbonyl compounds $N_2CHCOR$ [R = Me, Pr$^n$, Pr$^i$, $(CH_2)_{10}CH_3$] catalysed by [RuCl(η$^5$-$C_5H_5$)($PPh_3$)$_2$] (0.1 mol%) in toluene at 65 °C affords quantitatively RCOCH=CHCOR carbene dimers, the *cis* isomers being formed in 95–97% yield; under the same experimental conditions $N_2CHCOEt$ gives diethyl maleate in a purity of greater than 99%, the highest value for a stereoselective carbene–carbene dimer formation reported to date.**

The metal-catalysed reactions of α-diazo carbonyl compounds have attracted a great deal of attention in recent years and have been used in an increasing number of syntheses, such as alkene cyclopropanation, carbene dimerisation and C–H insertion.[1] It is generally accepted that transition-metal complexes react with diazo compounds to generate transient metal–carbenes, although a few catalytically active species have been isolated.[2] Tuning of the electronic and steric properties of the catalyst has been proved to strongly affect the product distribution in reactions with diazo compounds, the control of both chemo- and stereo-selectivity still remaining an important goal.[3]

It has been reported that the metal-catalysed decomposition of diazo compounds occurs with loss of nitrogen to give alkenes, and both yield and *cis* : *trans* ratio vary according to the catalyst employed. We have now found that the readily available ruthenium(II) complex [RuCl(η$^5$-$C_5H_5$)($PPh_3$)$_2$] **1** catalyses the highly stereoselective formation of *cis*-enediones[4] from α-diazo carbonyl compounds. Thus, **1** in toluene at 65 °C converts ethyl diazoacetate (EDA) into diethyl maleate **2** quantitatively and in a purity of greater than 99%, diethyl fumarate being the only byproduct.† A comparison with other group 8 metal complexes shows that the metal–porphyrins [Ru(TMP)][1c] and [Os(TTP)]$_2$[5] induce formation of diethyl maleate in 94 and 96% purity, respectively, the highest values reported to date. Moreover, other complexes such as [$Rh_2(OAc)_4$], [$RuCl_2(PPh_3)_3$] and [$Ru_2Cl_4$(p-cymene)$_2$] also catalyse the conversion of EDA into alkenes, but with a considerably lower *cis* : *trans* ratio. Complex **1** has been previously used as a catalyst for the coupling of terminal alkynes with allyl alcohols,[6] but no investigations concerning its catalytic activity towards diazo compounds decomposition have been reported to date.

In order to explore the potential of **1** in the stereocontrolled carbene dimerisation reaction, other substrates have been tested (see Scheme 1). The conversion into alkene is always quantitative and the *cis* isomer is present in the reaction mixture in yields higher than 95%. Thus, when a toluene solution of $N_2CHCOR$ [R = Me, Pr$^n$, Pr$^i$, $(CH_2)_{10}CH_3$] is treated with 0.1 mol% of **1** under an inert atmosphere, dinitrogen evolution takes place rapidly (within 10 min) at 65 °C with quantitative formation of the product, as monitored by NMR spectroscopy. After removal of toluene, the *cis*-enediones **3**–**5** were distilled off *in vacuo* and isolated in 81–87% yield, while **6** was chromatographed on $SiO_2$ (84% isolated yield).† No cyclopropanation products, or other byproducts except *trans*-enediones were detected in the reaction mixtures by NMR and GC–mass spectrometry.



**Scheme 1** *Reaction conditions*: toluene, 65 °C, argon atmosphere

The catalytic carbene dimer formation has been extended to α,ω-bis(diazo carbonyl) compounds. For example, $N_2CHCO(CH_2)_4COCHN_2$ reacts in THF solution at 60 °C in the presence of **1** to give a mixture of cyclic *cis*-enediones, the *trans*-isomers being formed in less than 5% yield. The mononuclear *cis*-cyclooct-2-ene-1,4-dione[7] was distilled off from the reaction mixture and isolated in 19% yield. The solid residue, obtained in 60% yield, is a mixture of dicarbene dimer and trimer (in *ca.* 2 : 3 molar ratio), as inferred by $^1$H and $^{13}$C NMR and mass spectrometry.

Other ruthenium(II) cyclopentadienyl complexes obtained by substitution of one or both $PPh_3$ of **1**, such as [RuCl(η$^5$-$C_5H_5$)(CO)($PPh_3$)], [RuCl(η$^5$-$C_5H_5$)(CNBu$^t$)($PPh_3$)], [RuCl(η$^5$-$C_5H_5$){$P(OPh)_3$}$_2$] and [RuCl(η$^5$-$C_5H_5$)-($Ph_2PCH_2CH_2PPh_2$)], have been shown not to be catalytically active for the decomposition of EDA. In contrast, the indenyl complex [RuCl(η$^5$-$C_9H_7$)($PPh_3$)$_2$] **7** decomposes all the $N_2CHCOR$ compounds reported above, at a temperature (45 °C) lower than that necessary with **1**, but with similar high selectivity for the *cis*-enedione.

The decomposition of EDA catalysed by **1** has been examined in some detail and a plausible mechanism for the *cis*-enedione formation is depicted in Scheme 2. Since at room temperature no catalytic activity is shown by **1**, it is likely that the diazo compound decomposition takes place on the 16-electrons species [RuCl(η$^5$-$C_5H_5$)($PPh_3$)], which is formed upon

**Scheme 2** Proposed mechanism and catalytic cycle

$PPh_3$ dissociation induced by high temperature and concomitant reaction of the phosphine with EDA. In fact, it is known that EDA and $PPh_3$ give in an equilibrium reaction the phosphazine $EtOCOCHN_2{=}PPh_3$, and traces of this product were always found in our reaction mixtures. Furthermore, solutions containing equimolar amounts of EDA and $PPh_3$ and **1** as catalyst do not show dinitrogen evolution at 65 °C. At 90 °C only traces of diethyl maleate ( < 1%) are detected after 2 h reaction, the ylide $EtOCOCH{=}PPh_3$ being the major product present in solution.

As stated above, the indenyl complex **7** decomposes EDA at a lower temperature (45 °C) then **1** (65 °C), and this result is consistent with the kinetic studies of Gamasa *et al*.,[8] who found that complex **7** dissociates $PPh_3$ an order of magnitude faster than **1** to form [RuCl($\eta^5$-ligand)($PPh_3$)].

In the proposed catalytic cycle a neutral $Ru^{II}$ cyclopentadienyl carbene complex is involved, which is similar to [RuCl($\eta^5$-$C_5H_5$)($CPh_2$)($PPh_3$)], recently reported by Braun *et al*.[9] The high stereoselectivity observed for the nucleophilic attack of the α-diazo carbonyl compound on the coordinated carbene is probably related to the preferred orientation of the carbene moiety caused by the cyclopentadienyl ligand.[10] Furthermore, the steric constraint of the RuCl($\eta^5$-$C_5H_5$)($PPh_3$) fragment may favour the formation of the less sterically demanding *cis* alkene.[11]

The extension of this research towards the synthesis of unsymmetrical *cis*-enediones by using two different α-diazocarbonyl compounds is in progress. In particular, decomposition of a 1 : 1 mixture of EDA and $N_2CHCOMe$ yields **2**, **3** and *cis*-EtOCOCH=CHCOMe in *ca*. 1 : 1 : 3 molar ratio, respectively. The double coupling between carbene units derived from mono- and α,ω-bis-diazo carbonyl compounds is also under investigation and seems to give promising results.

This work was supported by the Italian Ministero dell'Università e della Ricerca Scientifica e Tecnologica (Rome). The authors thank Professor Giancarlo Verardo of the Dipartimento di Scienze e Tecnologie Chimiche, Università di Udine, for recording the mass spectra.

# Efficient method for the one-pot azidation of alcohols using bis(*p*-nitrophenyl) phosphorazidate

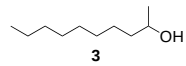
**Masanori Mizuno[a,b] and Takayuki Shioiri*[a]**

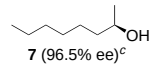
[a] *Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467, Japan*
[b] *Research and Development Department, Eisai Chemical Co. Ltd, Sunayama, Hasaki, Kashima-gun, Ibaraki 314-02, Japan*

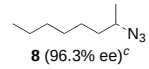
**The direct stereoselective conversion of various alcohols and hexopyranoses into the corresponding alkyl azides and glycosyl azides, respectively, is efficiently accomplished by using bis(*p*-nitrophenyl) phosphorazidate and DBU.**

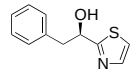
Azides have been used extensively in organic synthesis, especially for the introduction of primary amino groups and the construction of heterocyclic structures.[1] In most cases, aliphatic azides are prepared by nucleophilic substitution of the corresponding halides or sulfonates by the azide anion.[2] The only known methods for the direct conversion of alcohols into azides are the Mitsunobu reaction,[3] in which removal of the by-products is troublesome, and the diphenyl phosphorazidate (DPPA)–DBU method[4] which is effective only for activated alcohols. In the course of our investigation on the reactivity of some analogs of DPPA, we have discovered that bis(*p*-nitrophenyl) phosphorazidate (*p*-$NO_2$DPPA), prepared easily by nitration of DPPA,[5] in combination with DBU is quite useful and efficient for the direct conversion of alcohols into azides, as shown in Scheme 1.

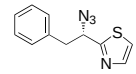
**Scheme 1**

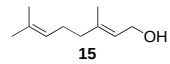


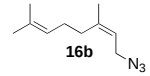


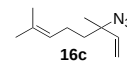


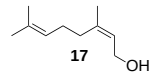


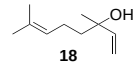








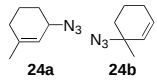


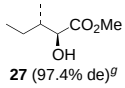


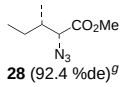
Treatment of decan-1-ol **1** or decan-2-ol **3** with *p*-$NO_2$DPPA (1.2 equiv.) and DBU (1.2 equiv.) in toluene (1 mol $l^{-1}$) smoothly afforded the corresponding azides **2** and **4** in good yield. Superior features of this method are that the reactions proceed with considerably faster rates than when DPPA–DBU is used (5 and 3% yields, respectively), and there are fewer byproducts to struggle with than in the Mitsunobu reaction. In the azidation of decan-2-ol **3**, DBU (81% yield) was much superior to triethylamine (28%), triethylamine with 0.1 part of DMAP (44%) and diisopropylethylamine (32%) under analogous reaction conditions. Toluene was the solvent of choice though THF and DMF can also be used.

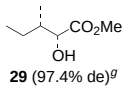
Various azides prepared from alcohols according to this method are listed in Table 1. High stereoselectivity was observed in the reaction of optically active alcohols; for instance, (*R*)-(−)-octan-2-ol **7** and (*R*)-(+)-1-phenylethanol **9** afforded (*S*)-(+)-2-azidooctane **8** and (*S*)-(−)-1-phenylethyl azide **10**, respectively, in good yield with inversion of configuration without loss of stereochemical integrity. (*R*)-(+)-2-Phenyl-1-(thiazol-2-yl)ethanol **11** was also conveniently converted to the (*S*)-azide **12**, which was an intermediate for the synthesis of dolaphenine [(*S*)-(−)-2-phenyl-1-(thiazol-2-yl)ethylamine],[6] the C-terminal unit of dolastatin 10 having strong anticancer activity. Allylic alcohols gave a mixture of the isomeric azides (entries 8–11 and 13) due to rapid 1,3-rearrangement of the allylic azides.[7] However, the azidation of alicyclic alcohols such as cyclohexanol **31** and (−)-menthol **32** were unsuccessful under the same reaction conditions.

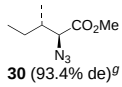
This method was extended to the preparation of glycosyl azides, key intermediates in the synthesis of glycosyl amino acids.[8] The results summarized in Table 2 demonstrate that this method selectively gives 1,2-*trans*-glycosyl azides. The stereochemical outcome of these direct azidations may be rationalized on grounds similar to those proposed by Sabesan and Neira[9] for the preparation of anomerically enriched glycosyl phosphates from hexopyranoses, *i.e.* probably the azidation occurs *via* initial formation of the thermodynamically stable 1,2-*cis*-glycosyl phosphate which subsequently undergoes the azide displacement with inversion of configuration.











In summary, compared to other methods[2–4] that have been reported, this present method for the stereoselective synthesis of

# Facilitated transport of amino acids by fixed-site jumping

**Tracey A. Munro and Bradley D. Smith***

*Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN 46556, USA*

**Amino acids are transported with high fluxes through plasticized cellulose triacetate membranes containing large amounts of quaternary tetraalkylammonium salts; similar results are obtained using analogous polymer-supported liquid membranes.**

The main aim in facilitated transport research is to develop selectively permeable, high-flux membranes with long-term durability. A major impediment to the industrial exploitation of this technology is the problem of membrane instability.[1] Recently, we discovered that plasticized cellulose triacetate (CTA) membranes containing large amounts of trioctylmethylammonium chloride (TOMAC) are selectively permeable to small, neutral carbohydrates.[2] The plastic films, which were originally designed as anion exchange membranes,[3] exhibit high saccharide fluxes and high membrane stabilities. Mechanistic studies produced evidence in favour of a fixed-site jumping mechanism, where the TOMAC acts as fixed 'stepping stones' and the sugar permeates through the membrane by jumping from one fixed-site to another.[2,4] These findings raise the possibility that facilitated transport through plasticized membranes by fixed-site jumping is a general way of improving membrane stability while still retaining high and selective permeability. As a consequence we have investigated the facilitated transport of other hydrophilic solutes through lipophilic CTA membranes. This report focuses on the neutral amino acids, phenylalanine, leucine and alanine.

Previous work has shown that liquid organic membranes incorporating TOMAC act as anion exchange membranes for amino acids at basic pH.[5,6] Under these conditions (relatively low concentration of TOMAC dissolved in the liquid membrane), transport occurs by membrane-diffusion of lipophilic ion-pairs of TOMA cation and amino acid anion.[7] At neutral pH very little of the amino acid is present in its anionic form, and transport enhancement is very weak.[8,9] We now report that amino acid transport can be greatly enhanced if the membrane contains enough TOMAC to induce fixed-site jumping.

Two related membranes were examined: plasticized CTA films and polymer-supported liquid membranes.† The plasticized films were prepared by evaporating a chloroform solution of CTA, 2-nitrophenyl octyl ether (2-NPOE) and TOMAC in a flat-bottomed glass petri dish.[3] The resulting plastic film (*ca.* 50 μm thick, depending on composition) was peeled off, trimmed and clamped into a cylindrical transport cell.† The supported liquid membranes were solutions of TOMAC dissolved in 2-NPOE that were absorbed by thin sheets of microporous polypropylene (Celgard 2500™, 25 μm thick). A selection of the transport fluxes observed with the plasticized CTA films is listed in Table 1. Even at neutral pH, the amino acid fluxes are very high, whereas the membranes are only weakly permeable to metal cations and hydrophilic organic cations such as dopamine.

**Table 1** Non-competitive transport through cellulose triacetate membranes at neutral pH

| Solute[a] | Flux/$10^{-8}$ mol m$^{-2}$ s$^{-1}$ TOMAC present[b] | TOMAC absent[c] |
|---|---|---|
| L-Phenylalanine | 1590 | 0.12 |
| L-Leucine | 520 | 0.12 |
| L-Alanine | 290 | 0.76 |
| Dopamine | 25 | 0.31 |
| NaCl[d] | 12 | 0.81 |

[a] Initially source contained 100 mM solute. Both aqueous phases contained 100 mM sodium phosphate, pH 7.3, $T$ = 298 K. [b] Membrane: 0.10 g CTA, 0.20 g 2-NPOE, 0.20 g TOMAC. [c] Membrane: 0.10 g CTA, 0.20 g 2-NPOE. [d] Source: 100 mM NaCl in deionised water; receiving: deionised water.

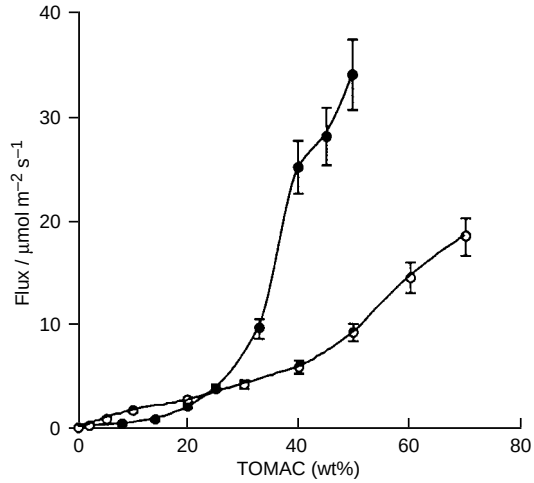

**Fig. 1** Initial phenylalanine flux *versus* wt% TOMAC in (●) plasticized membrane that also included CTA (0.1 g) and 2-NPOE (0.2 g) and (○) liquid membrane of 2-NPOE supported by a 25 μm thick sheet of Celgard 2500™. Both aqueous phases contained sodium phosphate (60 ml, 100 mM, pH 7.3), $T$ = 298 K. The source phase also contained phenylalanine (100 mM). To account for changes in flux due to changes in membrane thickness, the fluxes have been multiplied by the ratio (membrane thickness in presence of TOMAC)/(membrane thickness in absence of TOMAC).

Plots of phenylalanine flux *versus* wt% of TOMAC for both membranes with aqueous phases at neutral pH are shown in Fig. 1. The profiles do not exhibit the linear relationship that is typically found with transport systems that operate by carrier-diffusion.[4,12] Rather the profiles are non-linear, with the flux increasing dramatically at high TOMAC levels. This is indicative of a transport process that uses fixed-site jumping (Fig. 2).[4] In the case of the CTA films there is clear evidence of a percolation threshold at around 20% TOMAC. We postulate that below the threshold concentration, flux is negligible because the distance between the relatively immobile quaternary ammonium sites is too great ( > *ca.* 15 Å) to allow solute

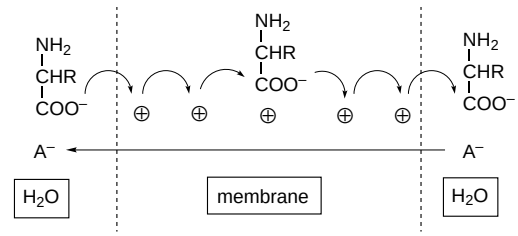

**Fig. 2** A transport process using fixed-site jumping

jumping and the high membrane viscosity greatly inhibits transport by carrier-diffusion. In the case of the supported liquid membrane, the flux *versus* percentage of TOMAC is first-order until about 40% TOMAC and then increases at a higher power. The difference in curve shape is attributed to a change in the relative contributions of the two transport pathways, *i.e.* carrier-diffusion at lower TOMAC concentrations and fixed-site jumping at higher TOMAC levels. The lower viscosity associated with a liquid membrane makes carrier-diffusion a more favourable pathway compared to a plasticized membrane, and the TOMAC concentration has to reach 40% before any flux enhancement due to fixed-site jumping is observed.

Amino acid flux through the CTA films is dependent on membrane thickness. Stacking multiple membranes together or preparing a single membrane of additional thickness lowers the flux in a linear fashion. Additional transport mechanism studies are ongoing, however, three pieces of evidence implicate an anion exchange process. (i) When the source phase but not the receiving phase contains sodium phosphate (100 mM, pH 7.3), phenylalanine flux is very low, but when the situation is reversed, (*i.e.* receiving phase contains sodium phosphate and the source phase does not) the flux is quite high. (ii) A plot of phenylalanine flux as a function of pH shows very low flux at pH $< 5.5$ (the isoelectric point for phenylalanine) and dramatically increasing flux after pH 5.5. At pH 10 the flux is five times higher than at pH 7.3. (iii) Changing the TOMA counter-anion from chloride to phosphate leads only to a 30% drop in initial flux, whereas changing the counter-anion to lipophilic bis(2-ethylhexyl)phosphate results in complete loss of phenylalanine permeability.

Previous work by others has shown that a crown–boronic acid mixture is a better transporter of phenylalanine through bulk, liquid membranes than TOMAC at neutral pH.[8] With CTA films containing high concentrations of transporting agent we find that TOMAC is superior. It appears that the crown–boronic acid mixture uses a carrier-diffusion process and, unlike TOMAC, does not switch to a fixed-site jumping mechanism at high membrane concentrations. A similar conclusion was recently reached by Lamb concerning metal cation transport mediated by crown carriers.[12] We have also examined the facilitated transport of dopamine through plasticized membranes using crown–boronic acid mixtures that are known to be effective dopamine carriers in supported liquid membranes.[13] Again there is no evidence for the onset of fixed-site jumping at high carrier concentrations. Thus, it remains to be seen if this remarkable transport effect, which we attribute to fixed-site jumping (*i.e.* the solute is rapidly relayed along a sequence of relatively immobile carriers), can be duplicated with transport agents other than quaternary alkylammonium salts.[4]

This research was supported by the National Science Foundation (USA) and the Herman Frasch Foundation of the American Chemical Society.

† The transport cell consisted of two identical, water-jacketed cylindrical halves (half-cell volumes 60 ml, membrane area 16 $cm^2$) that were stirred by turbines which in turn were driven by externally situated magnets (ref. 10). The side of the plastic film exposed to the air during the evaporation process was placed facing the source solution. Amino acid concentrations were determined by ninhydrin assay (ref. 11). Phenylalanine concentrations were also monitored spectrometrically at $\lambda = 262$ nm ($\varepsilon = 139$ l $mol^{-1}$ $cm^{-1}$) as were the dopamine levels ($\lambda = 279$ nm, $\varepsilon = 2675$ l $mol^{-1}$ $cm^{-1}$). Metal cation concentrations were determined by conductivity or inductively coupled plasma emission. All CTA films were prepared from CTA (0.10 g) and 2-NPOE (0.20 g). In the absence of TOMAC the films were 30 μm thick. Addition of TOMAC thickened the films up to 75 μm for a membrane containing 50 wt% TOMAC.

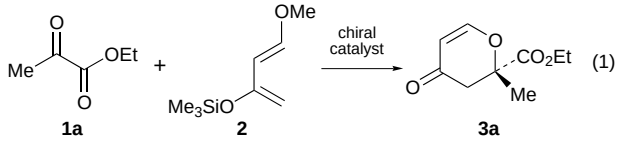
# The first highly enantioselective catalytic hetero-Diels–Alder reaction of ketones

**Mogens Johannsen, Sulan Yao and Karl Anker Jørgensen***

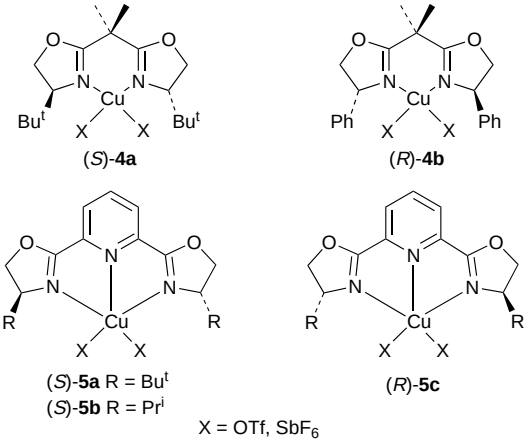
*Center for Metal Catalyzed Reactions, Department of Chemistry, Aarhus University, DK-8000 Aarhus C, Denmark*



**The first highly enantioselective catalytic hetero-Diels–Alder reaction of various aliphatic and aromatic ketones with an activated conjugated diene catalysed by chiral copper(II) complexes with enantiomeric excesses up to 99% is presented.**

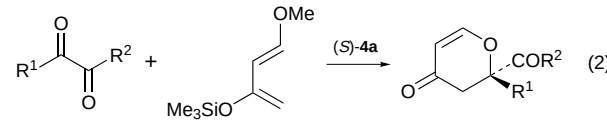
The hetero-Diels–Alder (HDA) reaction of carbonyl compounds with conjugated dienes is one of the cornerstone reactions in organic chemistry and has wide application for the synthesis of important compounds.[1] One of the most useful reactions in this field is the HDA reaction of aldehydes with activated conjugated dienes, such as Danishefsky's diene, leading to highly valuable oxygenated products.[2]

In recent years interest has been focused on the development of metal-catalysed enantio- and diastereo-selective HDA reactions of aldehydes with conjugated dienes.[3] Great progress has been made in the HDA reaction between activated conjugated dienes and simple unactivated aldehydes.[4] Recently, we have been involved in developing highly enantioselective HDA reactions of aldehydes, such as glyoxylates, with unactivated conjugated cyclic and acyclic dienes catalysed by bisoxazoline–copper(II) and –zinc(II) complexes[5] and BINOL-aluminium(III) complexes.[6]



The challenge is to develop the metal-catalysed enantioselective HDA reaction of ketones with conjugated dienes, as this reaction will have wide potential in organic chemistry. Here we present the first highly enantioselective HDA reaction of both aliphatic and aromatic ketones with an activated conjugated diene using chiral catalysis.[7]

The reaction of ethyl pyruvate **1a** with *trans*-1-methoxy-3-(trimethylsilyloxy)buta-1,3-diene (Danishefsky's diene) **2** [eqn. (1)] has been studied in the presence of various bidentate



**1a** **2** **3a** (1)

bisoxazoline and tridentate bisoxazoline–pyridine ligands in combination with copper(II) salts [(*S*)-**4a**, (*R*)- **4b**, (*S*)-**5a**,**b** and (*R*)-**5c**, respectively] in order to investigate the catalytic properties of the different ligands on the HDA reaction. The reaction of **1a** with **2** in the presence of (*S*)-**4a**, (*R*)-**4b**, (*S*)-**5a**,**b** or (*R*)-**5c** (X = OTf) (10 mol%) as the catalyst in $CH_2Cl_2$ at room temperature gives the HDA product **3a** in various yields and enantiomeric excesses (ees) depending on the catalyst used. By application of (*S*)-**4a** as the catalyst, **3a** is isolated in 85% yield, with an ee of 92% (reaction time, 8 h), while (*R*)-**4b** gave the same yield of **3a**, but with an ee of only 26% (reaction time, 8 h). It should be noted that both catalysts give the same enantiomer of the HDA product **3a**.[5a,c] The catalysts (*S*)-**5a**,**b** and (*R*)-**5c** are less effective and much longer reaction times are required (*ca.* 100 h); with (*S*)-**5a**,**b**, the HDA product **3a** is isolated in 29 and 15% yield, and with an ee of 9 and 27%, respectively, while (*R*)-**5c** gave nearly the same yield (23%), but a slightly higher ee (55%).

It turned out the catalyst (*S*)-**4a** was the most promising chiral catalyst, both in terms of yield and ee of the HDA product formed. This catalyst was therefore applied for the reaction of different α-keto esters and an α-diketone **1a**–**d** with *trans*-1-methoxy-3-(trimethylsilyloxy)buta-1,3-diene **2** [eqn. (2)]

[a] Isolated yield. [b] Ee determined by GC on a Chrompack Chirasil-DEX CB column. [c] Ee determined by HPLC on a Daicel Chiralpak AD column, eluent: hexane–$Pr^iOH$ (99 : 1).

Ethyl pyruvate **1a** reacts with *trans*-1-methoxy-3-(trimethylsilyloxy)buta-1,3-diene **2** in the presence of the catalyst (*S*)-**4a** having triflate as the anion at room temperature to give the HDA product in 85% yield with 92% ee (Table 1, entry 1). Performing the reaction at −40 °C leads to an improvement of the ee of **3a** to 99% without affecting the yield significantly (entry 2). Exchange of the anion from triflate to antimonate leads to a decrease in the yield of **3a** to only 22%, and also to a reduction of the ee (80%) (entry 3). Performing the reaction between **1a** and **2** in the presence (*S*)-**4a** (X = $SbF_5$) at −40 °C slightly increases the ee of the HDA product (entry 4). The ester substituent is of minor importance for the highly enantioselective HDA reaction as methyl pyruvate **1b** reacts with **2** in the presence of (*S*)-**4a** (X = OTf) as the catalyst to give **3b** in high yield (95%) and with high ee (91%) (entry 5). The reaction of the aromatic ketone **1c** with **2** in the presence of (*S*)-**4a** (X = OTf) also proceeds well, giving a 77% yield of the HDA product **3c** with an ee of 77%. The enantiomeric HDA reaction is not only restricted to α-keto esters such as **1a**–**c**; the α-diketo compound butane-2,3-dione **1d** also reacts with **2** in the presence of (*S*)-**4a** (X = OTf) as the catalyst to give **3d** in high yield (89%) and with very high ee (94%).

The potential of this new enantioselective HDA reaction for the various ketones is obvious from entries 2, 5–7 in Table 1. The HDA products are formed in high yields for both the aliphatic and aromatic ketones and, furthermore, the aliphatic ketones give up to 99% ee in these reactions, whereas 77% ee is found for the aromatic ketone. Work is in progress to develop this HDA reaction further and to understand the mechanistic aspects of the reaction.

† *Typical procedure*: (*S*)-**4a** (X = OTf) was prepared by addition of $Cu(OTf)_2$ (36 mg, 0.1 mmol) to 2,2′-isopropylidenebis[(4*S*)-4-*tert*-butyl-2-oxazoline] (31 mg, 0.105 mmol) dissolved in dry $CH_2Cl_2$ (2 ml) under an inert atmosphere and stirred for 2 h. The catalyst was cooled to −40 °C, ethyl pyruvate **1a** (110 μl, 1 mmol) and *trans*-1-methoxy-3-(trimethylsilyloxy)buta-1,3-diene **2** (250 μl, 1.2 mmol) were added, and the solution stirred for 30 h at this temperature. Then TFA (0.1 ml) dissolved in $CH_2Cl_2$ (20 ml) was added at −40 °C and the solution stirred for 1 h at 0 °C. The solution was then neutralised with saturated $NaHCO_3$ and the solution was filtered through a plug of cotton. The organic phase was separated and the water phase was extracted twice with $CH_2Cl_2$. The combined organic phases were dried, filtered and the solvent evaporated. Purification of the crude product using flash chromatography (EtOAc–light petroleum, 1 : 4) gave **3a** in 78% yield and 99% ee (chiral GC); $[\alpha]_D^{25}$ + 149 (*c* 1.1, $CHCl_3$).

# Effects of lanthanide complexes on the facial reactivity of 2-(2′,3′,4′,6′-tetra-*O*-acetyl-β-D-glucopyranosyloxy)benzaldehyde in hetero-Diels–Alder reactions and a model to account for such effects

**Richard P. C. Cousins,[a] Woan Chee Ding,[b] Robin G. Pritchard[b] and Richard J. Stoodley*[b]**

[a] *Medicinal Science, Glaxo Wellcome Medicines Research Centre, Stevenage, Hertfordshire, UK SG1 2NY*
[b] *Department of Chemistry, UMIST, PO Box 88, Manchester, UK M60 1QD*

**Changes in the facial reactivity of 2-(2′,3′,4′,6′-tetra-*O*-acetyl-β-D-glucopyranosyloxy)benzaldehyde towards (*E*)-1-methoxy-3-(*tert*-butyldimethylsiloxy)buta-1,3-diene in the presence of lanthanide(fod)$_3$ complexes can be correlated with the ionic radius of the lanthanide metal.**

Recently, we reported notable 1,5-asymmetric inductions in the reaction of the salicylaldehyde derivative **1** with Danishefsky's diene **2** in the presence of Lewis acids.[1] The use of $BF_3{\cdot}OEt_2$ and $SnCl_4$ (100 mol% of each) in THF led to *ca.* 27 : 3 : 63 : 7 mixtures of compounds **4**–**7**, which were transformed by the action of TFA into 90 : 10 mixtures of the dihydropyranones **6** and **7**. With $ZnCl_2$ (100 mol%) in THF and Eu(fod)$_3$ (5 mol%) in toluene, the cycloadducts **8** and **10** were produced in ratios of 86 : 14 and 25 : 75; the cycloadducts **8** and **10** were converted into the dihydropyranones **6** and **7** in the presence of TFA. Clearly, $BF_3{\cdot}OEt_2$ and $ZnCl_2$ in THF promoted attack mainly at the *si*-face of the aldehyde moiety of compound **1** whereas Eu(fod)$_3$ in toluene induced preferential *re*-face addition.

Here we describe efforts that have led to improvements in the practicality and stereoselectivity of the hetero-Diels–Alder reaction; we also propose a model to account for the variation in the facial reactivity of the salicylaldehyde derivative **1**.

Seeking initially to increase the stabilities of the cycloadducts† (compounds **8** and **10** were very prone to undergo desilylative eliminations to give the pyranones **6** and **7**), we investigated the reaction of the aldehyde **1** with the diene **3**[2]‡ under the afore-cited cycloaddition conditions. The use of $ZnCl_2$ in THF and Eu(fod)$_3$ in toluene afforded the cycloadducts **9** and **11** in ratios of 67 : 33 and 18 : 82. From the latter reaction, it was possible to isolate the cycloadduct **11**,§ mp 175–176 °C, $[\alpha]_D$ +53 (*c* 0.3, $CH_2Cl_2$), in 75% yield after crystallisation. In accord with its structure, the cycloadduct **11** was transformed into the dihydropyranone **7** (82% yield after crystallisation).

Expecting that a 'matched' chiral europium(III) complex would improve the diastereoselectivity, the use of (+)-Eu(hfc)$_3$, (−)-Eu(hfc)$_3$, (+)-Eu(tfc)$_3$ and (−)-Eu(tfc)$_3$ (5 mol% of each) as promoters was studied in toluene. Surprisingly, there was little difference in the effects of the enantiomeric catalysts and the selectivities were poor. Thus, the cycloadducts **9** and **11** were produced in ratios of 59 : 41 and 61 : 39 with (+)-Eu(hfc)$_3$ and (−)-Eu(hfc)$_3$, and in ratios of 45 : 55 and 47 : 53 with (+)-Eu(tfc)$_3$, and (−)-Eu(tfc)$_3$.

The importance of the metal in lanthanide(fod)$_3$ complexes in determining the facial reactivity of the aldehyde **1** towards the diene **3** is illustrated by the results shown in Table 1. In the first

**Table 1** Outcome of the reaction of aldehyde **1** and diene **3** in the presence of lanthanide(fod)$_3$ complexes[a]

| Catalyst | Lanthanide ionic radius/Å[b] | Ratio **9** : **11**[c] |
|---|---|---|
| La(fod)$_3$ | 1.06 | < 5 : 95 |
| Ce(fod)$_3$[d] | 1.03 | < 5 : 95 |
| Pr(fod)$_3$ | 1.01 | < 5 : 95 |
| Nd(fod)$_3$ | 0.99 | < 5 : 95 |
| Eu(fod)$_3$[e] | 0.95 | 18 : 82 |
| Gd(fod)$_3$ | 0.94 | 26 : 74 |
| Dy(fod)$_3$ | 0.91 | 55 : 45 |
| Ho(fod)$_3$ | 0.89 | 61 : 39 |
| Er(fod)$_3$ | 0.88 | 69 : 31 |
| Yb(fod)$_3$ | 0.86 | 66 : 34 |

[a] Typically, the reactions were conducted using aldehyde **1** (0.1 mmol), diene **3** (0.2 mmol) and the complex (*ca.* 4 mol%) in dry toluene (2 cm$^3$). [b] Ref. 3. [c] The ratio was determined by 300 MHz $^1$H NMR spectroscopic analysis of the crude product and/or the derived pyranones **6**/**7**. [d] The reaction involving Ce(fod)$_3$ was significantly slower than the others (requiring *ca.* 48 h for completion compared with *ca.* 5 h). [e] The use of different concentrations of Eu(fod)$_3$ (*ca.* 10 and *ca.* 0.5 mol%) did not affect the ratio of cycloadducts produced.

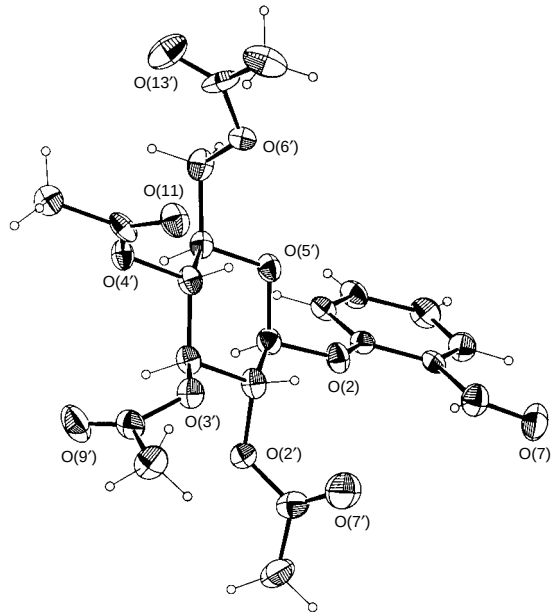

**Fig. 1** Molecular structure of compound **1**

four examples, essentially complete ( > 95 : 5) *re*-face selectivity of the aldehyde **1** was observed. In the remaining examples, there was (in the main) a gradual increase in *si*-face selectivity as the ionic radius of the lanthanide metal decreased. Significantly, from a synthetic standpoint, it was possible to isolate the cycloadduct **11** in 90% yield after crystallisation from the reaction of the salicylaldehyde **1** (11 mmol) and the diene **3** in the presence of $Pr(fod)_3$.

In the hope that its solid-state structure would reveal 'preorganisation' that might shed light on the stereoinductions, compound **1** was subjected to an X-ray crystallographic analysis. The molecular structure,¶ shown in Fig. 1 with its atomic labelling, indicates that the *re*-face of the aldehyde moiety is shielded by the 2′-*O*-acetyl group of the sugar.‖

Evidence that the solid-state conformation of compound **1** was maintained in solution ($C_6D_6$) was adduced from an NOED spectroscopic study. Thus, irradiation of the anomeric hydrogen atom (1′-H) caused an 8% enhancement of the aryl 3-hydrogen atom (3-H); similarly, irradiation of 3-H enhanced 1′-H by 6%.

From the afore-cited findings, we propose that compound **1** can be activated by Lewis acids in two ways. The formation of a monodentate complex of type **12**, in which the Lewis acid is coordinated to the aldehyde carbonyl O-atom *syn* to the aldehyde H-atom, is postulated to be the basis of the *si*-face reactivity; this pattern is predominant in aldol reactions induced by $BF_3{\cdot}OEt_2$ and $SnCl_4$ and in hetero-Diels–Alder reactions promoted by $ZnCl_2$ and the 'late' lanthanides. The generation of a chelated complex, *e.g.* of type **13** in which the Lewis acid is coordinated to the aldehyde carbonyl O-atom and the glycosidic O-atom, provides a possible explanation for the *re*-face selectivity; this behaviour is a feature of cycloaddition reactions initiated by the 'early' lanthanides. Presumably, because of the 'lanthanide contraction' (in which the radii of lanthanide cations decrease with increasing atomic number),[3] the 'late' lanthanides favour heptacoordination (and, therefore, the formation of monodentate complexes) whereas the 'early' lanthanides prefer octacoordination (and, as a consequence, are able to form chelated complexes).[4]

The results reported herein are of both mechanistic and synthetic note. Although the catalytic activity of lanthanide complexes in hetero-Diels–Alder reactions has been extensively investigated since Danishefsky's foundation studies,[5] the finding that the nature of the cation can have a significant impact upon the facial reactivity of a chiral aldehyde is novel.** The possibility that this effect is linked to the ionic radius of the lanthanide cation and its ability to form a monodentate *versus* a bidentate complex warrants further study. From a synthetic context, the technology permits the efficient assembly of compounds **7** and **11** in multi-gram quantities; earlier, only the dihydropyranone **6** was accessible in high yield.[1]

We thank the CVCP for an ORS award (to W. C. D.) and a referee for drawing our attention to ref. 8.

† Our interest in such cycloadducts stems from the expectation that their dihydropyran rings can be elaborated into glycopyranose-like structures; such products, which may be regarded as 'scaffolded' disaccharides, represent a novel and potentially interesting class of compounds.

‡ The diene **3** was prepared by a modification of the literature route (see ref. 2) in which (*E*)-4-methoxybut-3-en-2-one was treated with *tert*-butyldimethylsilyl triflate and triethylamine (see ref. 6).

§ New compounds displayed analytical and spectral properties that supported their assigned structures.

¶ *Crystal data* for **1**: $C_{21}H_{24}O_{11}$, $M$ = 452.4, monoclinic, space group $P2_1$ (no. 4), $a$ = 12.625(6), $b$ = 6.929(5), $c$ = 13.262(4) Å, $\beta$ = 97.89(3)°, $U$ = 1149(11) Å$^3$, $Z$ = 2, $D_c$ = 1.307 g cm$^{-3}$, $F(000)$ = 476, $\mu$(Mo-K$\alpha$) = 1.00 cm$^{-1}$, crystal size 0.40 × 0.15 × 0.15 mm. A total of 1947 reflections were measured, 1658 unique ($R_{int}$ = 0.084) after an empirical absorption correction (max., min. transmission = 1.00, 0.84), on a Rigaku AFC6S diffractometer using $\omega$–2$\theta$ scans ($\lambda$ = 0.71069 Å) at 20 °C. The structure was solved by direct methods and refined by full-matrix least-squares based on $F^2$, with all non-hydrogen atoms anisotropic and hydrogen atoms constrained in calculated positions. The final cycle converged to $R$ = 0.054 and $wR^2$ = 0.138 based on 679 observed reflections [$I > 2\sigma(I)$] and 293 variables ($R$ = 0.190, $wR^2$ = 0.210 for all data). CCDC 182/579.

‖ A related shielding effect was noted in the X-ray structure of 5-(2′,3′,4′,6′-tetra-*O*-acetyl-β-D-glucopyranosyloxy)-1,4-naphthoquinone and invoked to account for the high facial reactivity of the dienophile in Diels–Alder reactions (see ref. 7).

** The enantioselectivities of Diels–Alder reactions catalysed by complexes of lanthanide(OTf)$_3$ and (*R*)-binaphthol can be influenced by added achiral ligands and by the lanthanide metal (see ref. 8).

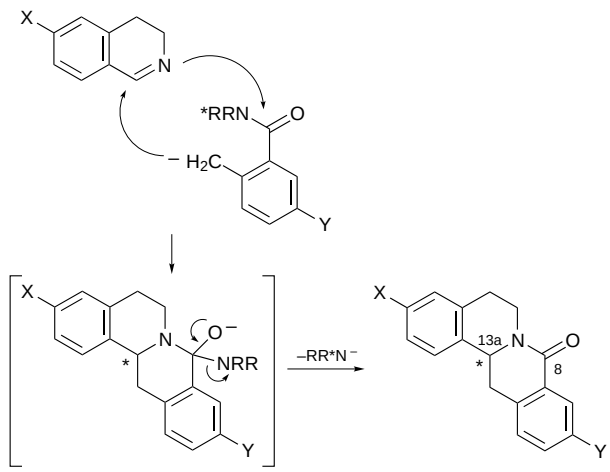
# Asymmetric synthesis of protoberberine alkaloids *via* a tandem nucleophilic addition and intramolecular cyclisation of a chiral *o*-toluamide anion with 3,4-dihydroisoquinoline

**Ronald N. Warrener,* Ligong Liu and Richard A. Russell*†**

*Centre for Molecular Architecture, Central Queensland University, Rockhampton, Qld, Australia, 4702*



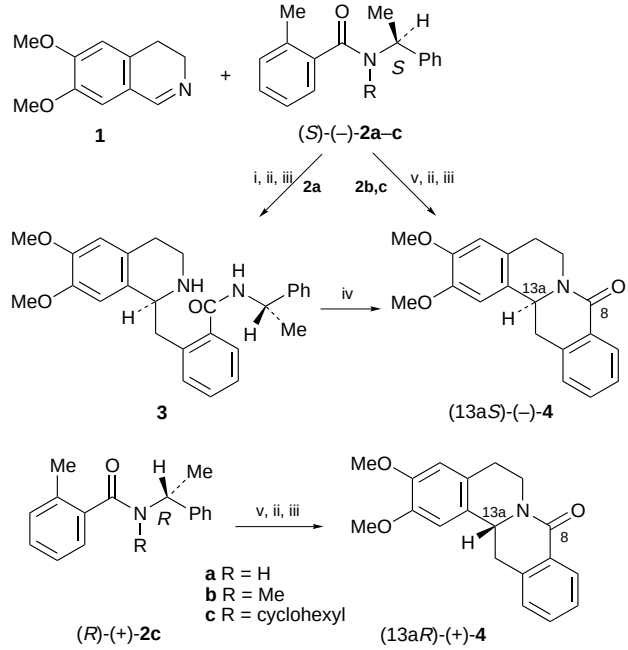
**The reaction of *o*-toluamide anions, derived from the (*S*)-(−)- and (*R*)-(+)-1-phenylethylamine, with 6,7-dimethoxy-3,4-dihydroisoquinoline gives (13a*S*)-(−)- and (13a*R*)-(+)-8-oxoprotoberberine, respectively, with enantiomeric excesses > 96%.**

The protoberberine alkaloids display a broad diversity of biological activities[1,2] and feature predominently as active components in many folkloric medicines especially in China and other Asian countries. A wide range of synthetic methods have been reported for the preparation of protoberberines and these have been the subject of several reviews.[2,3] In spite of this only a few methods deal with the enantioselective synthesis of protoberberines. Most asymmetric methods involve multi-step procedures, use of special reagents and occur in relatively low optical yields.[4,5] Recently, lateral metallation methodology has been developed for the synthesis of racemic heterocyclic compounds, including protoberberines, and shown to exhibit exceptional regiochemical control.[6] This feature, coupled with a direct approach to the products, offers efficient entry to the protoberberine skeleton and related structures.

In this communication we report the first successful application of lateral metallation to the efficient asymmetric synthesis of protoberberines *with* a chiral *o*-toluamide (Scheme 1).

The commercial availability of the two enantiomers of 1-phenylethylamine made this an attractive chiral auxiliary to incorporate into the *o*-toluamides. Our initial study, which involved the reaction the anion derived from the secondary *o*-toluamide **2a** (R = H) with the isoquinoline **1**, failed to afford any of the cyclised protoberberine **4** and only the ring-opened intermediate **3** could be detected. Whilst this intermediate could be cyclised by heating in refluxing toluene, the final product **4** exhibited very low enantiomeric purity (1.5% ee) (Table 1).

Since anions of tertiary amides, *e.g. N*,*N*-diethyl-*o*-toluamide, are known to condense with dihydroisoquinolines and



**Scheme 1** An approach to the asymmetric synthesis of protoberberines based upon lateral metallation

**Table 1** Chemical and optical yields of protoberberine **4** from reactions involving the toluamides **2a**–**c** with dihydrosioquinoline **3**

| | Yield (%)[a] | $[\alpha]_D^{20}$[b] | Ee (%)[c] |
|---|---|---|---|
| (*S*)-**2a** | 39 | −5.6 | 1.5 |
| (*S*)-**2b** | 14 | −19.9 | 5.2 |
| (*S*)-**2c** | 48 | −372.4 | 97 |
| (*R*)-**2c** | 51 | +366.6 | 96 |

[a] Chemical yields have not been optimised and refer to the sole product which was isolated by chromatography. [b] Rotations: *c* 0.359, $CHCl_3$. [c] Optical yields were calculated by comparison of the rotation with the reported data, *i.e.* rotations (in $CHCl_3$) of 10, 50, 67 and 73 corresponding to 3, 13, 18 and 19% ee.[5]

subsequently cyclise in the one pot,[7] we turned our attention to the chiral amide **2b**. Whilst reaction of **1** with **2b** afforded the 8-oxoprotoberberine in one step, there was only a slight improvement of the enantiomeric selectivity (5.2% ee) of the reaction. These rather disappointing results, we reasoned, were due to too great a conformational mobility of the chiral auxiliary and accordingly the more sterically demanding cyclohexyl group was introduced as a non-chiral substituent on the amide nitrogen atom, *i.e.* **2c**. The reaction of (*S*)-(−)-**2c** with the dihydroquinoline **1** gave as the product (*S*)-(−)-**4** (97% ee) in 48% chemical yield. Similarly pure (*R*)-(+)-**4** (96% ee) was prepared by replacement of the chiral auxiliary in the amide **2c** with (*R*)-(+)-1-phenylethylamine (Scheme 2), thereby provid-

**Scheme 2** *Reagents and conditions*: i, $Bu^nLi$ (2 equiv.), THF, 0 °C, 1 h; ii, **1**, THF, −78 to −30 °C, 1 h; iii, aq. $NH_4Cl$, −30 °C; iv, PhMe, 110 °C, 15 h; v, $Pr^i_2NLi$ (1 equiv.) THF, −78 °C, 25 min

ing the desired one-pot synthesis of the protoberberine ring system.

Although our research is at an early stage, it is clear that we have developed an efficient asymmetric synthesis for chiral 8-oxoprotoberberines based upon the regiospecific addition–cyclisation reaction of chiral *o*-toluamide anions with 3,4-dihydroisoquinolines. The extension of this methodology to other heterocyclic compounds and the understanding of the mechanism leading to chiral induction is an ongoing study in our laboratories.

# One-step synthesis of tris(butylsulfanyl)sexithiophene from 3-butylsulfanyl-2,2′-bithiophene

**Francesca Goldoni, Dario Iarossi, Adele Mucci and Luisa Schenetti***

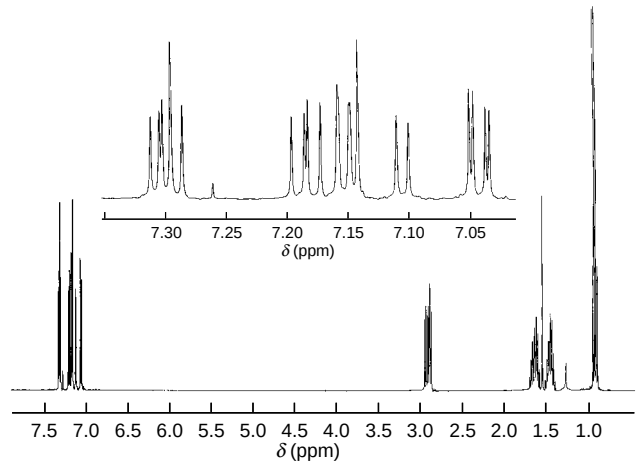
*Dipartimento di Chimica Università di Modena, Via Campi, 183, 41100 Modena, Italy*

**$FeCl_3$ converts, in high yield, 3-butylsulfanyl-2,2′-bithiophene into a tris(butylsulfanyl)sexithiophene, which shows interesting optical properties and forms a stable radical cation and dication.**

Oligothiophenes with defined structure are gaining increasing attention as a new class of organic π-electron systems. Among them, α-sexithiophene (α-6T) is a very promising material for field-effect transistors.[1] The optical and electrical properties as well as the processability of these materials can be modulated by adding substituents on the oligothiophene backbone. Recently, interesting methylsulfanylsexithiophenes with UV maximum absorption wavelengths near to, but lower than, those of sexithiophene have been reported.[2] Among alkylsulfanyl groups, butylsulfanyl shows interesting solubility and structural properties in poly(3-butylsulfanyl)thiophene[3] and in 4,4′-bis(butylsulfanyl)-2,2′-bithiophene.[4] To minimize the steric effect due to the bulky substituent we chose to build a sexithiophene from 3-butylsulfanylbithiophene.

Here, we report preliminary results on 3,3‴,3⁗-tris(butylsulfanyl)-2,2′ : 5′,2″ : 5″,2‴ : 5‴,2⁗ : 5⁗,2‴′-sexithiophene **1**, obtained by oxidative coupling of 3-butylsulfanyl-2,2′-bithiophene with $FeCl_3$ in $CHCl_3$–$MeNO_2$ (Scheme 1).† The product was identified by $^1H$ and $^{13}C$ NMR, mass and UV spectra. Mass analysis confirmed a molecular formula of $C_{36}H_{38}S_9$: *m/z* (70 eV) 762 (10%, $[M^+ + 4]$), 761 (15, $[M^+ + 3]$), 760 (41, $[M^+ + 2]$), 759 (43, $[M^+ + 1]$), 758 (100, $[M^+]$), 506 (18, $[M^+ - C_{12}H_{12}S_3]$).

$^1H$ NMR data enabled the regiochemistry of **1** to be determined. In the aromatic region of the $^1H$ NMR spectrum (Fig. 1), the presence of four doublets characterized by $^3J$(H-α,H-β) 5.2–5.3 Hz (H-4, H-5, H-4⁗ H-5⁗), six doublets characterized by $^3J$(H-β, H-β′) 3.7–3.9 Hz (H-3′, H-4′, H-3″, H-4″, H-3‴, H-4‴) and a singlet (H-4‴) demonstrates that the compound under investigation is actually a sexithiophene. Compound **1** proposed in Scheme 1 is the only structure compatible with the absence of monosubstituted terminal thiophenes. Three distinguishable triplets for $CH_2$(α) are found in the aliphatic region of the proton NMR spectrum, at δ 2.92, 2.88 and 2.87. Two further triplets, corresponding to the terminal methyls, are found at δ 0.92 (double intensity) and 0.90. Signals corresponding to $CH_2$(β) and $CH_2$(γ) are superimposed. Complete NMR characterization was achieved through $^1H$ and $^{13}C$ NMR inverse-detection techniques, HMQC[5] and HMBC.[6]



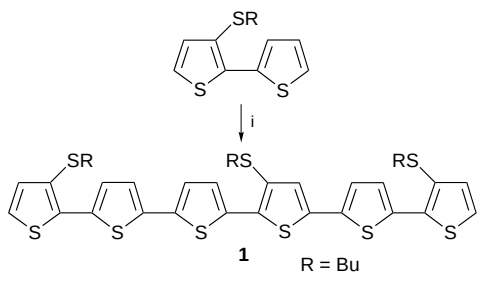


**Fig 1** $^1H$ NMR spectrum of sexithiophene **1**. The upper trace shows the expanded aromatic region.

The formation of the regioisomer **1**, out of the possible four that could in principle derive from the starting bithiophene, can be explained by considering the deactivation effect of the 3-methylsulfanyl group on the 5-position of thiophene or bithiophenes in oxidative coupling reactions with $FeCl_3$.[7] Another important result is the high reaction yield (70% of pure product) probably due to the stability of radical cation $\mathbf{1}^{+\cdot}$ in the reaction conditions. This stability was confirmed by a cyclic voltammetry investigation (Fig. 2) which showed the presence of two reversible oxidation peaks at 0.89 and 1.02 V (0.1 M $Bu_4NBF_4$–$CH_2Cl_2$, glassy carbon electrode, scan rate 100 mV $s^{-1}$, SCE) corresponding to the formation of the cation radical $\mathbf{1}^{+\cdot}$ and the dication $\mathbf{1}^{2+}$. Compound **1** shows $\lambda_{max}(CHCl_3)$ 449 nm, 17 nm higher than that reported for α-6T[8] and 19–43 nm higher than that reported for methylsulfanylsexithiophenes.[2] A further 19 nm bathochromic effect is observed in $CS_2$. In fact, $\lambda_{max}$ changes from 443 in MeOH, to 446 in MeCN, to 449 in $CHCl_3$ and to 468 nm in $CS_2$. The lowering of the optical gap with respect to α-6T and to methylsulfanylsexithiophenes is probably the consequence of a good balance between steric and

**Scheme 1** *Reagents and conditions*: i, $FeCl_3$, $CHCl_3$–$MeNO_2$ 1 : 1, room temp., 30 h

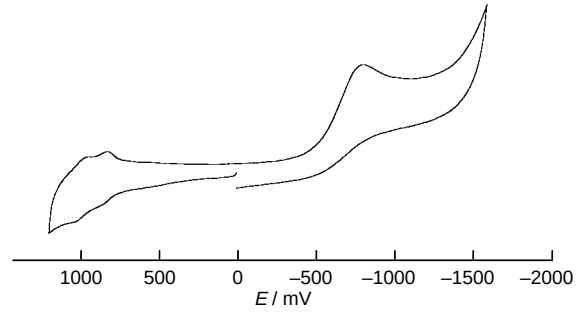

**Fig. 2** Cyclic voltammogram of sexithiophene **1**

electronic effects. The conjugational ability of the butylsulfanyl group acts on a π-conjugated system in which the steric hindrance, due to the bulky β-alkylsulfanyl groups, is diluted by the presence of unsubstituted rings. The regiochemistry of substitution should play a fundamental role in determining the optical characteristics of **1**. In fact, the lone pairs of the two sulfur atoms in the 3- and 3′′′′-positions can be delocalized onto the whole molecular skeleton. The sulfur lone pair could not exert the same conjugative effect if the outer butylsulfanyl groups were placed in the 4- and 4′′′′-positions. The 3′′′-butylsulfanyl group can only give rise to a less extended conjugation pattern (over four rings). In conclusion, through the accurate choice of the starting monomer we were able to synthesize a substituted sexithiophene with butylsulfanyl groups on the 3-, 3′′′- and 3′′′′-positions, having a $\lambda_{max}$ at a longer wavelength than that of α-6T and forming a stable radical cation and dication.

This work was supported by the Italian National Research Council (CNR). Thanks are due to the Centro Interdipartimentale Grandi Strumenti for the use of the Bruker AMX-400 WB spectrometer, and to Dr M. Borsari for electrochemical measurements.

† *Preparative details*: A solution of anhydrous $FeCl_3$ (10.4 g, 64 mmol) in dry nitromethane (240 ml) was added dropwise over a period of 2 h to a solution of 3-butylsulfanyl-2,2′-bithiophene (4.0 g, 15.7 mmol) in distilled $CHCl_3$ (240 ml) under a flow of dry nitrogen. The reaction mixture, stirred 30 h at room temperature, was evaporated and the residue was stirred with a solution of HCl acidified methanol (100 ml). The filtered dark product was washed with methanol (40 ml) and dissolved in $CHCl_3$ (150 ml). The chloroform solution was washed with a 3% hydrazine solution (100 ml) and then with water, and evaporated. The crude red oil was washed with pentane (400 ml). The pentane solution was evaporated and the product (3.7 g) chromatographed on silica gel (neutralized with a 2% solution of triethylamine) using light petroleum (bp 40–70 °C)–diethyl ether (90 : 10) as the eluent. The compound isolated (2.8 g, 70%) is a red oil identified as 3,3′′′,3′′′′-tris(butylsulfanyl)-2,2′ : 5′,2′′ : 5′′,2′′′ : 5′′′,2′′′′,: 5′′′′,2′′′′-sexithiophene **1**.

**$H_2O_2$ reacts with rutile $TiO_2$ powder forming not only surface $O_2^-$ anions but also two newly identified surface $S = 1$ triplet radical anion pairs composed of two interacting $O^-\cdots O^-$ centers characterised by the EPR spin Hamiltonian parameters of $g_{iso} = 2.0104$ and $D = 13.7$ mT for triplet 1 and $g_{iso} = 2.0064$ and $D = 12.7$ mT for triplet 2.**

The role of free radical intermediates in the heterogeneous decomposition of organic substrates over metal oxides and zeolitic systems has been investigated for many years. In particular, the catalytic oxidation by $H_2O_2$ over $TiO_2$ or $V_2O_5$ has been studied in depth with a view to understanding the role of the active peroxo or peroxoacid species in the decomposition mechanism.[1] Despite the extensive literature available in this field, a well defined description of the basic phenomena occurring at the interface of the $H_2O_2$–oxide system is far from complete. Some of us have previously explored the reactivity of the $H_2O_2$–oxide system by EPR spectroscopy and a rich abundance of trapped radical species were identified.[2–5] It was found that for $H_2O_2$–MgO, a variety of oxygen based and protonated oxygen radicals including $O^-$, $O_2^-$ and $OH^\bullet$ were formed.[3] Here, we present preliminary results on the nature of the various radical centers, which are generated by interaction of $H_2O_2$ with rutile $TiO_2$. Evidence will be presented for the direct observation of a novel $S = 1$ triplet radical pair on the $TiO_2$ surface.

The $TiO_2$ powder (Rutile, ICI Tioxide) was stirred for 2 h at room temp. with an aqueous solution of $H_2O_2$ (27.5 mass%, Aldrich). The resulting slurry was then filtered and gently dried in air at 308–313 K for *ca.* 1 h. The EPR spectrum of the fresh sample (100 K) is shown in Fig. 1(*a*). This spectrum is clearly dominated by the presence of an intense orthorhombic signal with $g_1 = 2.0036$, $g_2 = 2.0095$, $g_3 = 2.0243$ and assigned to the superoxide $O_2^-$ anion. This anion is usually stabilised at a positive cationic site such that the electrostatic interaction splits the $2\pi^*$ antibonding orbitals by an amount ($\Delta$) depending on the local cationic crystal field. The magnitude of the $g_{zz}$ component ($g_3$ in this case) will give a measure of the cationic crystal field since $g_{zz} = g_e + 2\lambda/\Delta$ where $\lambda$ is the spin–orbit coupling constant of oxygen.[6] A $g_3$ value of 2.0263 clearly indicates that the $O_2^-$ anion is stabilised at a $Ti^{4+}$ cation in agreement with the $g$ values reported in the literature for $O_2^-$ adsorbed on $TiO_2$.[6]

Evacuation of the sample (30 min at 298 K, to $10^{-5}$ Torr) leads to the EPR spectrum shown in Fig. 1(*b*). Two very distinguishing features can be noted. First, the intensity of the $O_2^-$ signal has increased by a factor of about 40. This can be explained by the detection of predominantly surface $O_2^-$ anions with a much smaller abundance of bulk/subsurface superoxide. Only the bulk $O_2^-$ anions are visible in Fig. 1(*a*) since the surface $O_2^-$ anions undergo dipolar broadening with $O_2$ at low temperatures and so are not visible in the non-evacuated sample.

The second notable feature of Fig. 1(*b*) is the appearance of a new signal characterised by two low field and high field lines. The paramagnetic center(s) responsible for this signal are clearly stabilised on the rutile surface, since the signal is absent in the presence of $O_2$ due to the dipolar broadening. We propose that these new features correspond to the $\Delta M_s = 1$ transition of an $S = 1$ surface triplet arising from two interacting $S = 1/2$ species. This assignment is based on the following:

(*i*) the presence of a low field $\Delta M_s = 2$ transition at the expected magnetic field position of 165 mT [Fig. 1(*c*)];

(*ii*) it is not related in any way to the $O_2^-$ anions (*e.g.* as a superhyperfine interaction), since their respective saturation profiles are different and also the intensity of the new surface center varies slightly from one experiment to the next independent of the superoxide concentration.

Careful inspection of the new triplet signal reveals a 'splitting' of the two low field lines into an apparent doublet which is absent in the two high field lines. Assuming mutual orientation of the spin–spin and spin–nuclear axes with respect to the applied magnetic field, then simulation of the signal based on an $S = 1$ system with isotropic symmetry and $m_I = 1/2$ does not satisfactorily account for the line shape. In that case all $\Delta M_S = 1$ lines were split into doublets. The intensities of the

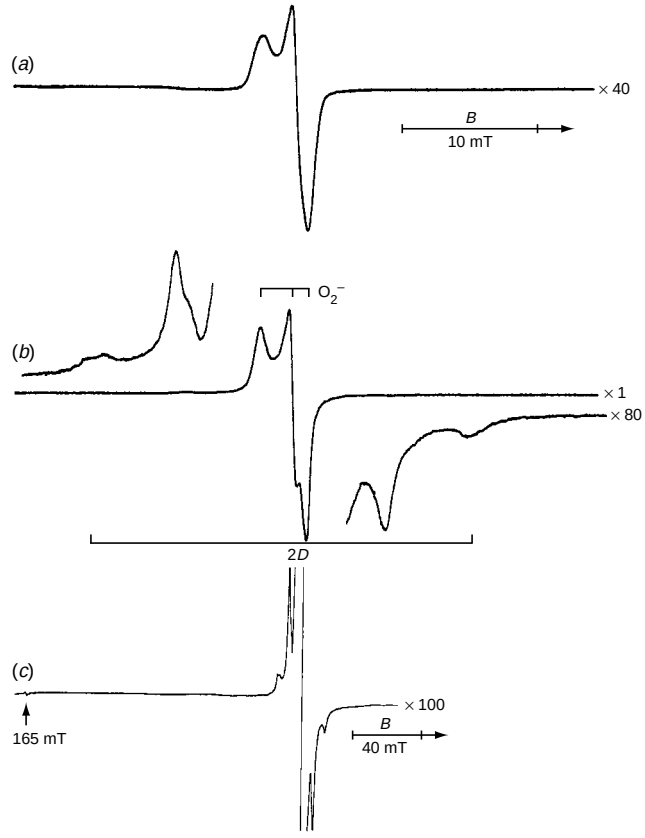

**Fig. 1** EPR spectrum (100 K) of rutile $TiO_2$ after contact with an aqueous solution of $H_2O_2$. (*a*) Sample prior to evacuation, (*b*) sample after evacuation at 298 K for 30 min, (*c*) sample as in (*b*) but recorded over wide scan range to show the half field feature at 165 mT.

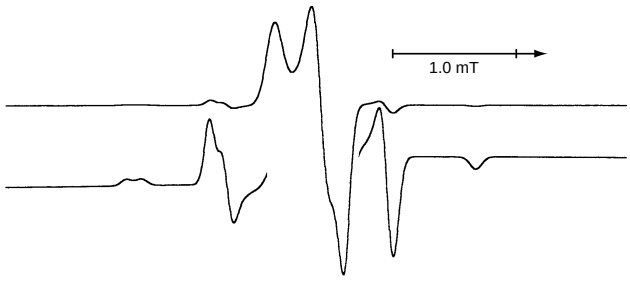

**Fig. 2** Computer simulation of Fig. 1(*b*) revealing the $O_2^-$ and the triplet $S = 1$ radical pair

apparent low field doublets also vary from one experiment to the next, suggesting the splitting arises from two separate signals rather than a hyperfine doublet. The best simulation obtained (Fig. 2) was based on two separate $S = 1$ centers having slightly different spin Hamiltonian parameters; *i.e.* triplet 1, $g_{iso} = 2.0104$ and $D = 13.7$ mT and triplet 2, $g_{iso} = 2.0064$ and $D = 12.7$ mT.

$D$ is the zero field splitting term and for randomly oriented triplets the separation between the $\Delta M_S = 1$ outer vertical lines is just $2D$ [Fig. 1(*b*)] so $D$ is easily extracted from the experimental spectrum.[7] The symmetry of the $g$ tensor, although reported as isotropic, may be slightly axial since small changes in the $g$ values did not produce drastic alterations to the simulation. Even though the individual $S = 1/2$ centers may have significantly lower symmetry (*e.g.* axial), in the coupled $S = 1$ state they appear to have a different symmetry, close to isotropic. Because the intensity of the $S = 1$ signal is so weak, precise analysis of the symmetry is not possible at present. Assuming $D$ is due entirely to a dipole–dipole interaction between two $S = 1/2$ species, then the distance $r$ separating the two species may be calculated using the equation $D = 3g^2\mu_B^2/2r^3 = -1.949 \times 10^{-4} g^2/r^3$ MHz.[8] This leads to a value of $r = 5.9$ and 6.0 Å riplet 1 and 2, respectively.

Based on the above EPR data, an assignment on the nature of the triplet center may be proposed. The absence of any hyperfine structure on the fine structure disfavours the possibility of any protonated $S = 1/2$ centers such as pairwise interacting $OH^\bullet$ or $H_2O^\bullet$ radicals. These radicals are involved in the homogeneous and heterogeneous decomposition of $H_2O_2$ and have been observed by EPR. $H_2O_2$ decomposition on MgO produces trapped $OH^\bullet$ radicals[3] and the pairwise trapping of $HO_2^\bullet$ radicals in aqueous glasses of $H_2O_2$ produce radical pairs with characteristic triplet state spectra.[9] Photoadsorption of $O_2$ on hydrated $TiO_2$ has also been reported to lead to the formation of surface trapped $HO_2^\bullet$ radicals but there was no observation of any $S = 1$ triplet centers.[10] However both $OH^\bullet$ and $HO_2^\bullet$ have appreciable hyperfine couplings of $a_{iso} \approx 2.7$ mT[3] and $a_{iso} \approx 1.1$ mT[11] respectively which should be visible in Fig. 1(*b*) where the line width of the $\Delta M_S = 1$ transition is only 0.9 mT. Furthermore ENDOR experiments failed to reveal the presence of any $^1H$ ENDOR lines. This would then indicate that the individual $S = 1/2$ species of the triplet pair do not contain a proton suggesting $O_2^-$ or $O^-$ as alternative candidates. A large number of oxide systems containing surface stabilised superoxide anions have been studied in the past. Despite the high concentrations of $O_2^-$ that may be formed, the pairing of two $O_2^-$ anions to produce a net $S = 1$ spin state has never been reported. Surface stabilised $O^-$ anions, with axial symmetry, have been reported on MgO but always as independent monomeric $S = 1/2$ centers.[12,13] However triplet state $O^-$ radical ion pairs have been observed in bulk monocrystals of alkaline earth oxides with $D$ terms ranging from 22.7 mT for MgO to 13.5 mT for SrO and spin–spin distances comparable to the lattice parameters of the oxides.[14] The observed $D$ terms in the present case (13.7 and 12.7 mT) are similar to those observed for other $O^-\cdots O^-$ radicals in oxides.

The formation of the triplet pair $O^-$ centers on the surface of rutile $TiO_2$ most likely occurs *via* the decomposition of the peroxide radical anion ($O_2^{2-} \rightarrow 2O^-$), the peroxide itself being formed directly or *via* the disproportionation of superoxide ($2O_2^- \rightarrow O_2 + O_2^{2-}$).[4] Indeed a similar mechanism has been proposed in the decomposition of surface $O_2^{2-}$ anions into active oxygen species, likely $2O^-$, over barium–lanthanum–oxygen mixed oxides, which have been postulated to be active in the oxidative coupling of methane.[15] We do not however speculate on any possible catalytic relevance of the $O^-\cdots O^-$ radical pair on $TiO_2$.

To summarise, a number of paramagnetic radicals have been observed following the heterogeneous decomposition of $H_2O_2$ over rutile $TiO_2$. Apart from the dominant presence of surface $O_2^-$ anions, a triplet state ($S = 1$) surface radical pair has been identified. This paramagnetic center arises from a pair of surface $O^-\cdots O^-$ anions in mutual interaction on rutile $TiO_2$ producing a net $S = 1$ triplet state. The observation of this surface centre is interesting since, despite the complex nature of the $H_2O_2$ interaction and the heterogeneous morphology of polycrystalline rutile $TiO_2$, the reproducibility of the results evidences the preferential stabilisation of $O^-$ anions at very specific surface sites consistently 5.9 or 6.0 Å apart. Similar surface triplet centers were not observed by us on anatase $TiO_2$ treated under similar conditions. This is to the best of our knowledge the first reported EPR spectrum of an $S = 1$ $O^-\cdots O^-$ radical anion pair stabilised on an oxide surface.

Funding of the National ENDOR center (by EPSRC) is gratefully acknowledged. E. W. G. would like to thank ICI Katalco and EPSRC for a CASE studentship.

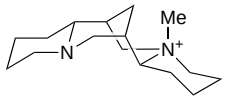
# CIT-5: a high-silica zeolite with 14-ring pores

**Paul Wagner,[a] Masahito Yoshikawa,[a]† Mark Lovallo,[b] Katsuyuki Tsuji,[a] Michael Taspatsis[b] and Mark E. Davis*[a]**



[a] *Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, CA 91125, USA*
[b] *Department of Chemical Engineering, University of Massachusetts, Amherst, MA 01003, USA*

**The synthesis and structure of a new zeolite, CIT-5 (California Institute of Technology Number Five), is described, which possesses one-dimensional pores comprised of 14 T-atoms (tetrahedrally coordinated silicon or aluminium atoms).**

Zeolites with pores comprised of larger than 12 T-atoms (extra-large pores) are much in demand[1–4] and have been so for many years.[4–7] The reason for this is the desire to perform catalysis/adsorption on molecules > 8 Å in size.

The first molecular sieve with extra-large pores was VPI-5 that is an aluminophosphate material with 18-ring pores.[8] Subsequently, other phosphate-based extra-large pore materials have been reported, *e.g.* cloverite.[2] All of the phosphate-based molecular sieves lack the desired properties of combined high acidity and thermal/hydrothermal stability and thus limit the practical potential. Recently, the first extra-large pore zeolite, UTD-1, was reported and shown to possess good acidity and thermal/hydrothermal stability.[9,10] Additionally, there have been numerous disclosures of ordered, aluminosilicate mesoporous materials with pore sizes of 20–100 Å.[11,12] Because the inorganic portions of the mesoporous materials are not crystalline, they lack the acidity and thermal/hydrothermal stability of high-silica zeolites.[13]

Here, we report a new extra-large pore zeolite denoted CIT-5. CIT-5 is synthesized under hydrothermal conditions. A reaction mixture of composition 0.2 ROH : 0.1 LiOH : 0.02 $Al_2O_3$ : 1 $SiO_2$ : 40 $H_2O$ is heated to 175 °C at autogenous pressure for *ca.* 12 d in order to produce CIT-5. In the absence of aluminium, pure-silica CIT-5 can be prepared in 5 d. The organic structure-directing agent (SDA), R, is *N*(16)-methylsparteinium **I** and is prepared as previously reported.[14] In the absence of lithium, **I** can form pure-silica or borosilicate SSZ-24.[13,14] Thus, the key to the successful preparation of CIT-5 is both the SDA **I** and the inclusion of lithium. Further synthetic details are forthcoming.[15]

**I**

Indexation[16] of the synchrotron powder X-ray diffraction (SPXRD) data from the pure-silica sample of CIT-5 revealed the presence of a small amount of an impurity phase together with the predominant CIT-5 phase. The CIT-5 material indexed in the orthorhombic crystal class with refined lattice constants $a$ = 13.694(2), $b$ = 5.0213(5), and $c$ = 25.4970(3) Å ($U$ = 1753.2 Å$^3$). The lattice constants for the impurity hexagonal phase were found to be $a$ = 13.63 and $c$ = 8.30 Å. The unit cell parameters and scanning electron micrographs helpd to identify the impurity phase as SSZ-24 (International Zeolite Association Code AFI).[17] Systematic absences for the orthorhombic CIT-5 phase indicate body-centering consistent with six possible space groups.

The starting model for Rietveld refinement of CIT-5 was obtained by an iterative process of model building, distance-least squares (DLS)[18] refinement of the atomic positions for the model, and comparison of the simulated powder X-ray pattern (CERIUS[19]) to the experimental pattern. The model with the closest match between the simulated X-ray powder pattern and the experimental XRD was found to have maximal topological symmetry of space group *Imma* (no. 74, standard setting) (consistent with the systematic absences).

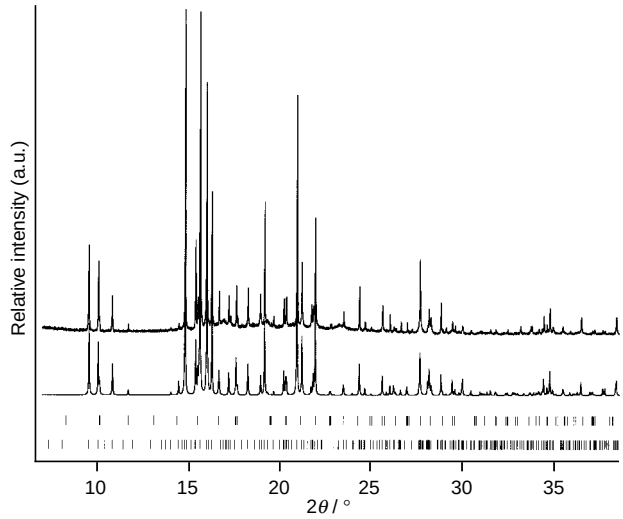


**Fig. 1** Experimental (top) and simulated (bottom) powder XRD data of CIT-5, $\lambda$ = 1.200 28(5) Å. The upper tick marks represents peak positions for the impurity phase, SSZ-24, while the bottom set of tick marks represents peak positions for CIT-5.

A two phase Rietveld refinement[20] was carried out using the structural parameters previously reported for the SSZ-24 impurity phase.[13] The background, scale factor and zero shift were refined, followed by refinement of the lattice parameters, peak shape function parameters and atomic positions for both

**Table 1** Crystallographic and refinement data

| | |

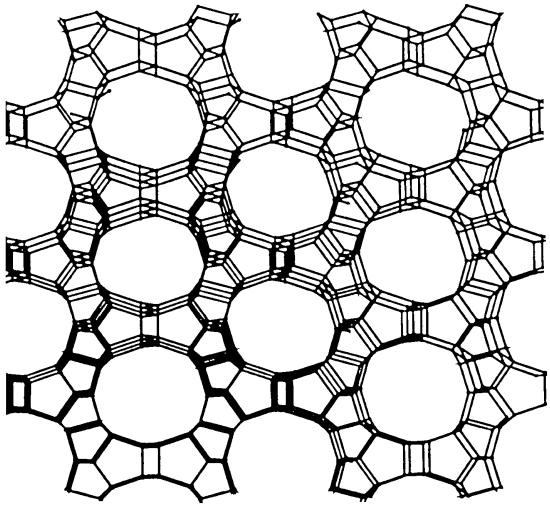

**Fig. 2** The [010] projection of CIT-5 showing the 14MR pores

CIT-5 and SSZ-24. Isotropic thermal parameters for the CIT-5 phase were also refined. The phase fraction refinement indicated *ca.* 4% SSZ-24 impurity. The low values of the residuals ($R_p$ = 8.7% and $R_{wp}$ = 11.4%) indicate close agreement between the calculated intensities from the refinement and the experimentally observed intensities (Fig. 1). Further details of the refinement results can be found in Table 1.

The structure of CIT-5 viewed down the *b*-axis is shown in Fig. 2 and is composed of one-dimensional, extra-large pores of nearly circular cross section (center of oxygen to center of oxygen distance 10.0 × 9.9 Å) circumscribed by 14-T-atom-membered rings (14MRs). The asymmetric unit contains 5 T-atoms and 8 oxygens resulting in a unit cell content of $[Si_{32}O_{64}]$, a framework density (FD) of 18.3 T-atoms/1000 Å$^3$, and a density of 1.821 g cm$^{-3}$. Table 2 contains the final atomic positional parameters and isotropic temperature factors obtained from the Rietveld refinement.

Comparison of the simulated, experimental and image processed experimental high resolution transmission electron micrographs (HRTEM) of CIT-5 viewed down the pores ([010] projection) are shown in Fig. 3, and confirm the topology of the structure. The primary building unit of CIT-5 is a zigzag ladder of four-membered rings (4MRs) with pendant five-membered rings (5MRs). These units are interconnected through single zigzag chains to form the body centered structure shown in Fig. 2. Electron diffraction patterns of CIT-5 show no signs of streaking indicating that the structure is not faulted or disordered.

Thermogravimetry showed an 11.2 mass% loss from **I** by 700 °C (in air). This amount of organic gives a pore volume of

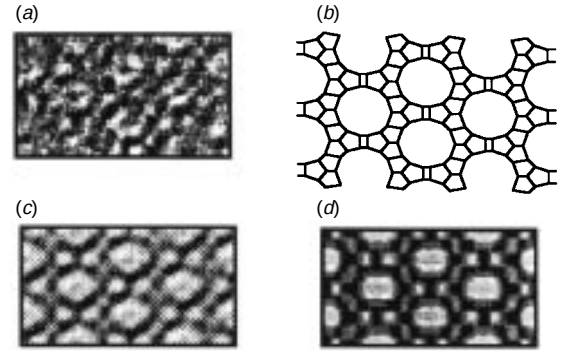

**Fig. 3** High-resolution transmission electron micrographs (HRTEM): (*a*) experimental, (*b*) [010] projection of CIT-5, (*c*) processed experimental image and simulated image (*d*). Samples for HRTEM were prepared by microtomy and images were recorded using a Phillips 430 electron microscope operating at 200 kV.

0.128 ml g$^{-1}$ and is consistent with the pore volume calculated from the structure (0.135 ml g$^{-1}$). While CIT-5 contains extra-large 14MR pores, temperature dependent powder XRD studies show that it has very high thermal and hydrothermal stability. The calcined material remains crystalline to over 900 °C, both under pure nitrogen atmosphere and under nitrogen atmosphere containing *ca.* 23 Torr $H_2O$.

Financial support for this work was provided by Chevron. We gratefully acknowledged R. Medrud and D. E. Cox for their assistance in collecting the synchrotron powder XRD data. The data were collected at the X7A beamline at the National Synchrotron Light Source at Brookhaven National Laboratory (Upton, NY), that is supported by the Department of Energy, Division of Material Science and Division of Chemical Sciences. P. W. thanks Air Products and Chemicals Inc. for financial support.

# Electronic energy transfer between ruthenium(II) and osmium(II) polypyridyl luminophores in a hydrogen-bonded supramolecular assembly

**Nicola Armaroli,[a] Francesco Barigelletti,*[a] Giuseppe Calogero,[a] Lucia Flamigni,[a] Claire M. White[b] and Michael D. Ward*[b]**

**Complexes Ru–C and Os–G are derivatives of $[Ru(bipy)_3]^{2+}$ and $[Os(bipy)_3]^{2+}$ bearing peripheral cytosine (C) or guanine (G) nucleobases respectively; in $CH_2Cl_2$ these undergo association ($K_A$ > 5000 dm$^{-3}$ mol$^{-1}$) by hydrogen bonding between the complementary C/G groups, and Ru → Os photoinduced energy-transfer occurs within Ru–C···G–Os associated pair.**

Many complexes are now known which display inter-component photoinduced energy transfer.[1–3] The study of such compounds is of fundamental interest both in relation to the mechanism of photosynthesis in nature,[2] and to recent efforts to prepare artificial molecular-scale electronic devices.[3] In virtually all cases the interacting components are covalently linked by a suitable bridging group, as this allows control of the inter-component separation, orientation, and the nature of the pathway between them through which the interaction can occur.

More recently supramolecular complexes have been prepared in which interacting components are associated by non-covalent interactions, in particular hydrogen bonding,[4] and photoinduced energy-transfer has been observed between metalloporphyrins and hydrogen-bonded organic fragments.[5] Although hydrogen bonding is widely used to promote self-assembly processes and to assist molecular recognition with organic compounds,[6] the association of metal complexes in the same way has received much less attention.[7,8]

Here we report on the association of ruthenium(II)– and osmium(II)–polypyridine units[3] driven by a triple hydrogen bond, and which results in photoinduced $Ru^{II} \rightarrow Os^{II}$ energy transfer across the hydrogen-bonded bridge. This was accomplished using metal complex components functionalised with the nucleotide bases cytosine (C) and guanine (G); the C/G pair gives Watson–Crick three-point hydrogen-bonding association with high constants (*ca.* $10^4$ dm$^3$ mol$^{-1}$) in low polarity solvents.[9]

The ligands bpy-C and bpy-G (Scheme 1) were prepared by alkylation of 5-bromomethyl-2,2′-bipyridine directly with cytosine at position $N^1$ to give bpy–C, or with 2-amino-6-chloropurine at position $N^9$ followed by acid hydrolysis to give bpy-G.[10]† Reaction of these with $[M(Bu^t_2bpy)_2Cl_2]$ [M = Ru, Os; $Bu^t_2bpy$ = 4,4′-di(*tert*-butyl)-2,2′-bipyridine][8] afforded $[Ru(Bu^t_2bpy)_2(bpy\text{-}C)][PF_6]_2$ (**Ru–C**) and $[Os(Bu^t_2bpy)_2(bpy\text{-}G)][PF_6]_2$ (**Os–G**).‡ The use of $Bu^t_2bpy$ ancillary ligands ensures good solubility in low-polarity solvents, to maximise association by hydrogen bonding. $[Os(Bu^t_2bpy)_2(bpy)][PF_6]$ (denoted **Os**) was also prepared.

**Scheme 1** Structure of the **Ru–C··Os–G** associate

The absorption properties in the visible region of **Ru–C** and **Os–G** dissolved in $CH_2Cl_2$ are as expected for ruthenium(II)– and osmium(II)–polypyridyl chromophores,[3] with band maxima occurring at 459 nm ($\varepsilon$ = 14 200 dm$^3$ mol$^{-1}$ cm$^{-1}$) and 484 (11 600), respectively, for population of the lowest-lying $^1$MLCT excited state. The luminescence band maxima of **Ru–C** and **Os–G** obtained in $CH_2Cl_2$ solvent are well separated with $\lambda_{max}$ = 626 and 744 nm, respectively. **Ru–C** is a much stronger emitter than **Os–G**, with $\Phi = 3.6 \times 10^{-2}$ ($\tau$ = 350 ns) and $2.9 \times 10^{-3}$ ($\tau$ = 44 ns), respectively.

We have demonstrated formation of a **Ru–C··G–Os** associate (where ··· signifies the triple cytosine/guanine hydrogen-bond; Scheme 1) by luminescence spectroscopy, comparing results obtained on 1 : 1 mixtures of **Ru–C** and **Os–G** in $CH_2Cl_2$ solution, before (*a*) and after (*b*) addition of drops of EtOH to break the hydrogen bonding between the components. The experiment was performed at three different concentrations: $[\mathbf{Ru–C}]_0 = [\mathbf{Os–G}]_0 = 1.0 \times 10^{-4}$ M, case (*i*); $2.2 \times 10^{-4}$ M, case (*ii*); and $4.5 \times 10^{-4}$ M, case (*iii*). Fig. 1 compares luminescence spectra recorded for case (*i*) (before and after additional of EtOH to break the hydrogen bonds), and those observed for a mixture of the reference couple **Ru–C** and **Os**. From Fig. 1 we see that EtOH addition causes an increase of the Ru-based luminescence intensity ($I_b/I_a$ = 1.4) for the **Ru–C**/**Os–G** pair, but has no effect on the Ru-based luminescence intensity for the **Ru–C**/**Os** pair. The absorption spectra of the mixtures are unaffected by the addition of EtOH. It follows that in the **Ru–C··G–Os** associate the Ru-based emission is

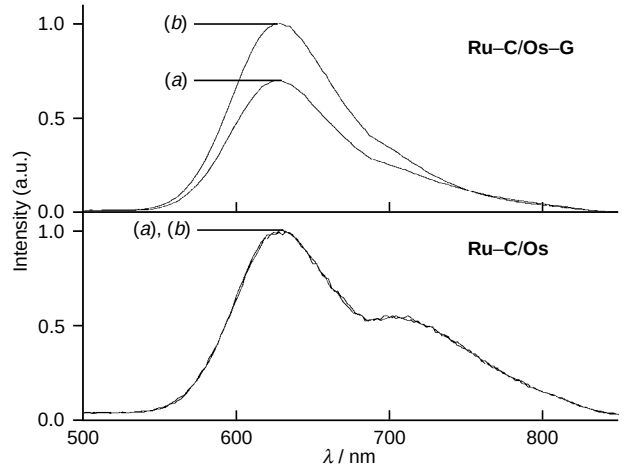

**Fig. 1** Upper: luminescence spectra of a $CH_2Cl_2$ solution of **Ru–C** and **Os–G** (both $1.0 \times 10^{-4}$ M), before (*a*) and after (*b*) EtOH addition. Lower: luminescence spectra of a $CH_2Cl_2$ solution of **Ru–C** ($3 \times 10^{-4}$ M) and **Os** ($7 \times 10^{-4}$ M), before (*a*) and after (*b*) EtOH addition. Excitation was at 458 nm.

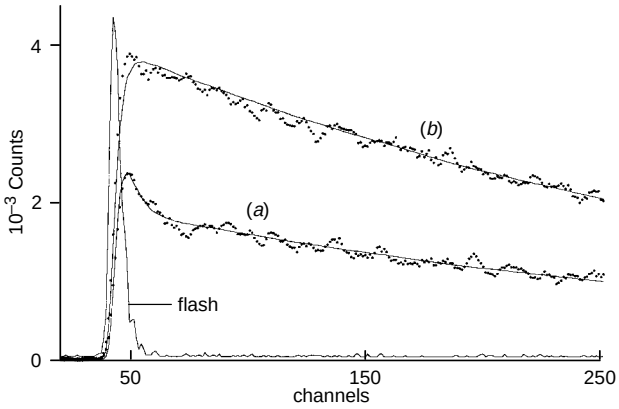

**Fig. 2** Decay of the luminescence intensity for a $CH_2Cl_2$ solution of **Ru**–**C** and **Os**–**G** (both $1.0 \times 10^{-4}$ M), before (*a*) and after (*b*) EtOH addition. Time axis was 1.03 ns/channel. Excitation was at 337 nm.

quenched, and this quenching is removed when the hydrogen bond is broken. In the latter case (**Ru**–**C**/**Os** pair) no hydrogen-bonding associate can be formed, so addition of EtOH had no effect on the emission properties of the mixture. For cases (*ii*) and (*iii*), the relative increases in luminescence intensity after addition of EtOH ($I_b/I_a$) were 1.6 and 4.0, respectively.

Fig. 2 shows the Ru-based time-resolved luminescence decay observed for case (*i*), as monitored at $\lambda_{em}$ = 626 nm. In neat $CH_2Cl_2$, case (*i*) (*a*), the decay follows a dual exponential law, $I(t) = B_1[\exp(-t/\tau_1)] + B_2[\exp(-t/\tau_2)]$, with $\tau_1$ = 10.5 ns, $\tau_2$ = 290 ns and $B_1/B_2$ = 0.7. EtOH addition, case (*i*) (*b*), results in a single exponential decay, $I(t) = B[\exp(-t/\tau)]$, with $\tau$ = 270 ns. Similar behaviour was shown for cases (*ii*) and (*iii*). From comparison of the luminescence intensity observed in $CH_2Cl_2$ before [cases (*a*)] and after [cases (*b*)] EtOH addition, and by entirely ascribing the residual Ru-based luminescence intensity of cases (*a*) to the unassociated **Ru**–**C** complex,§ it is possible to estimate an association constant $K_A > 5 \times 10^3$ dm$^3$ mol$^{-1}$ for formation of **Ru**–**C**··**G**–**Os**.¶

Use of time-resolved luminescence results allows estimates of the rate constants for both intermolecular and intra-associate quenching of the Ru-based luminescence of **Ru**–**C** by **Os**–**G**. Thus, for case (*i*), (*a*) intermolecular quenching controlled by diffusional processes results in $\tau_2$ = 290 ns as compared to $\tau$ = 400 ns for **Ru**–**C** alone in dilute solution.‖ The much more efficient quenching, resulting in $\tau_1$ = 10.5 ns, we ascribe to the process taking place within the **Ru**–**C**··**G**–**Os** associate because addition of EtOH [case (*i*), (*b*)], which is expected to cause disruption of the hydrogen bonds, results both in recovery of the Ru-based luminescence intensity at 626 nm (Fig. 1) and loss of the shorter-lived component of the luminescence decay (Fig. 2). Based on $k_{en} = 1/\tau_1 - 1/\tau$, the rate constant for this step is $k_{en} = 9.3 \times 10^7$ s$^{-1}$. For cases (*ii*) and (*iii*), $k_{en}$ was likewise found to be $9.5 \times 10^7$ s$^{-1}$ ± 10%. Attempts to obtain evidence for sensitization of the Os-based luminescence were unsuccessful because the Os-based luminescence ($\lambda_{max}$ = 744 nm) is hidden by the tail of the much stronger Ru-based luminescence (Fig. 1).

Energy transfer within the **Ru**–**C**··**G**–**Os** associate could in principle occur by the Förster (dipole–dipole)[11] or Dexter (exchange or through-bond)[12] mechanisms. Although the Förster mechanism is feasible at the shortest possible metal-to-metal separation,** estimated at *ca.* 13 Å from CPK models, the Dexter mechanism must be invoked for the greater metal–metal separations which are energetically favoured because of electrostatic repulsion. This implies a double electron exchange[13] *via* the hydrogen-bond interface, consistent with the recent finding that single electron transfer can be effectively mediated by H bonds.[14]

We thank the EPSRC (UK) for a Ph.D studentship (C. M. W.) and Johnson Matthey for the loan of ruthenium and osmium salts. We thank L. Ventura and M. Minghetti for technical support.

† bpy-C: NaH (1 mmol) was added to a suspension of cytosine (111 mg, 1 mmol) and KI (30 mg, a catalytic amount) in dry, degassed *N*,*N*-dimethylformamide (dmf) and stirred for 0.5 h. A solution of 5-bromomethyl-2,2′-bipyridine (250 mg, 1 mmol) in dry dmf (2 cm$^3$) was added slowly to this mixture and the reaction was then stirred under $N_2$ at 50 °C overnight. Addition of water (100 cm$^3$) resulted in precipitation of clean bpy–C (175 mg, 62%).

bpy–G: a mixture of 1-amino-6-chloropurine (170 mg, 1 mmol), $K_2CO_3$ (276 mg, 2 mmol) and KI (30 mg, a catalytic amount) in dry $Me_2SO$ (10 cm$^3$) was stirred under $N_2$ for 10 min. A solution of 5-bromomethyl-2,2′-bipyridine (620 mg, 2.5 mmol) in dry $Me_2SO$ was then added slowly and the reaction was stirred under $N_2$ at room temp. for 3 h. Addition of water (50 cm$^3$) precipitated the intermediate 2-amino-6-chloro-9-{5-(2,2′-bipyridyl)methyl}purine (bpy–ACP) as an off-white solid (218 mg, 64%). bpy–ACP (215 mg, 0.6 mmol) was then heated to reflux in 0.1 M HCl (20 cm$^3$) for 4 h. After cooling and neutralisation (KOH), bpy-G precipitated as a white solid (156 mg, 77%). Satisfactory mass and $^1$H NMR spectroscopic data, and C, H, N, analyses, were obtained for both ligands and the intermediate bipy–ACP.

‡ The complexes were prepared in *ca.* 50% yield by reaction of $[M(Bu^t_2bpy)_2Cl_2]$ (M = Ru, Os, 1 mmol) with bpy-C or bpy-G as required (1 mmol) in ethylene glycol (10 cm$^3$) at 160 °C for 2 h followed by precipitation with aqueous $KPF_6$, followed by chromatography on alumina (Brockmann activity III) with $CH_2Cl_2$ containing 2–5% MeOH. ESMS of **Ru**–**C**: *m*/*z* 1062 $\{Ru(Bu^t_2bpy)_2(bpy–C)(PF_6)\}^+$, 459 $\{Ru(Bu^t_2bpy)_2(bpy–C)\}^{2+}$. ESMS of **Os**–**G**: *m*/*z* 1192 $\{Os(Bu^t_2bpy)_2(bpy–G)(PF_6)\}^+$, 523 $\{Os(Bu^t_2bpy)_2(bpy–G)\}^{2+}$. Satisfactory elemental analyses were also obtained.

§ For instance in case (*i*), $(B_1\tau_1)/(B_2\tau_2)$ = 0.014 (see text), so the contribution of the short-lived component to the steady state luminescence spectrum of Fig. 1 is < 2%.

¶ For instance, for case (*i*) and by using $[\mathbf{Ru}–\mathbf{C}]_0 = [\mathbf{Os}–\mathbf{G}]_0 = 1.0 \times 10^{-4}$ M and $[\mathbf{Ru}–\mathbf{C}]_0/[\mathbf{Ru}–\mathbf{C}]$ = 1.4 from Fig. 1, one may calculate [**Ru**–**C**··**G**–**Os**]; then $K_A$ = [**Ru**–**C**··**G**–**Os**]/([**Ru**–**C**][**Os**–**G**]) is evaluated.

‖ According to $\tau/\tau_2 = 1 + k_q\tau[\mathbf{Os}–\mathbf{G}]$, this is consistent with a second-order quenching constant $k_q = 9.5 \times 10^9$ dm$^3$ mol$^{-1}$ s$^{-1}$.

** According to the Förster treatment[11] the dipole–dipole rate constant for an intermetal separation of 13 Å is $k_F = 1.2 \times 10^8$ s$^{-1}$, to be compared with the experimental value $k_{en} = 9.3 \times 10^7$ s$^{-1}$, see text.

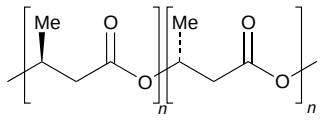
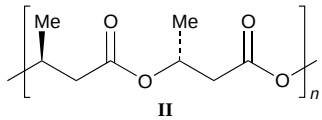
**The reaction of $[Bu^tAl(\mu_3\text{-}O)]_6$ with 2 equiv. of (*R*,*S*)-β-butyrolactone resulted in the formation of the alumoxane, (*R*,*S*)-$[Al_6Bu^t_6(\mu_3\text{-}O)_4\{\mu_3\text{-}O_2CCH_2C(H)(Me)O\}_2]$, with a molecular structure consisting of two ring-opened lactone moieties inserted into, and bridging, the edge of the $Al_6O_6$ alumoxane. The role of this alumoxane in the latent Lewis acid catalyzed ring-opening polymerization of β-butyrolactone is discussed.**



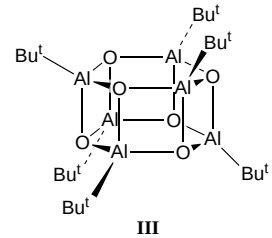
Alkylalumoxanes, $(RAlO)_n$, have been demonstrated to be catalysts for the ring opening polymerization of racemic β-butyrolactone, yielding a crystalline, high molecular mass polymer: poly-β-butyrolactone [eqn. (1)].[1]



(1)

A range of alumoxane compounds have been investigated for this type of polymerization, including methylalumoxane (MAO), ethylalumoxane (EAO), and isobutylalumoxane (IBAO).[2] The activities of these alumoxane catalysts have been found to be highly dependent on the identity of the alkyl substituent, with the polymerization rates in the following order IBAO > EAO > MAO.

We have recently reported that the individual isolable *tert*-butylalumoxanes, $[Bu^tAl(\mu_3\text{-}O)]_n$ ($n$ = 6, 9), are also catalysts, as is a mixture of *tert*-butylalumoxanes (TBAO).[3] However, the stereoregular polymers prepared using MAO, EAO and IBAO are generally found to be isotactic in structure,[4] and it has been proposed that they consist of diads of isotactic sequences of approximately 5–10 repeating units of each configuration of (*R*)- and (*S*)-β-hydroxybutyrate unit sequences, **I**.[3] In contrast, the polymers formed using $[Bu^tAl(\mu_3\text{-}O)]_n$ were found to be predominantly syndiotactic in structure **II**.[3]



**I**

**II**

Irrespective of the details of the polymer microstructure obtained, it is clear that all alumoxane catalysts are able to convert a racemic mixture of (*R*,*S*)-β-butyrolactone into a stereoregular polymer by some type of stereospecific or steroselective propagation step; most likely one involving chain end control. The propagation process is generally agreed to occur by a coordination polymerization mechanism in which the monomer is insertion between the active site on the alumoxane and the growing, covalently bound, polymer chain. However, given the lack of understanding of the structure of alumoxanes in general it is not surprising that the initiation and propagation steps of polymerization are poorly understood.

We have previously demonstrated that the catalytic and co-catalytic activity of the isolable *tert*-butylalumoxanes, $[Bu^tAl(\mu_3\text{-}O)]_n$, is due to the opening of the $Al_nO_n$ cage, and we have postulated the term 'latent Lewis acidity' to describe this reactivity.[5] On the basis of these earlier results it is possible that the ring opening polymerization reaction of (*R*,*S*)-β-butyrolactone involves the alumoxane cage itself rather than the aluminium alkyl substituents. In that regard, our isolation of individual alkylalumoxanes[6,7] with proven catalytic activity has allowed us to investigate the initiation step in the ring opening polymerization of (*R*,*S*)-β-butyrolactone and we report herein the product formed from the reaction of hexameric alumoxane, $[Bu^tAl(\mu_3\text{-}O)]_6$ **III** with this monomer.

**III**

Addition of 2 equiv. of (*R*,*S*)-β-butyrolactone to a hexane solution of $[Bu^tAl(\mu_3\text{-}O)]_6$ at 25 °C, resulted in the formation of crystalline (*R*,*S*)-$[Al_6Bu^t_6(\mu_3\text{-}O)_4\{\mu_3\text{-}O_2CCH_2C(H)(Me)O\}_2]$ in *ca*. 30% yield. Use of only 1 equiv. of (*R*,*S*)-β-butyrolactone gave a lower yield of the same product. Although stable as a solid, (*R*,*S*)-$[Al_6Bu^t_6(\mu_3\text{-}O)_4\{\mu_3\text{-}O_2CCH_2C(H)(Me)O\}_2]$ decomposes in solution at room temp., producing unidentified products. However, X-ray quality crystals were obtained from the reaction mixture under suitable conditions. For example, reaction of $[Bu^tAl(\mu_3\text{-}O)]_6$ (650 mg) in hexane (25 $cm^3$) mixed with (*R*,*S*)-β-butyrolactone (0.18 $cm^3$) and allowed to stand, undisturbed, for 24 h.

The molecular structure of (*R*,*S*)-$[Al_6Bu^t_6(\mu_3\text{-}O)_4\{\mu_3\text{-}O_2CCH_2C(H)(Me)O\}_2]$, which resides on a crystallographic twofold axis, was determined by X-ray crystallography and is shown in Fig. 1.† The core structure consists of an $Al_6O_4$ ladder in a curved conformation, bridged by two $[O_2CCH_2C(H)(Me)O]^-$ ligands. The structure may be described as being derived from the opening of two adjacent edges of the hexagonal prismatic core of $[Bu^tAl(\mu_3\text{-}O)]_6$ and insertion of two

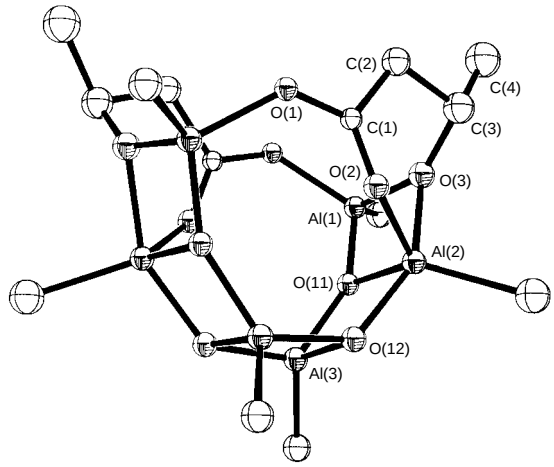


**Fig. 1** Molecular structure of (*R,S*)-[$Al_6Bu^t_6(\mu_3\text{-}O)_4\{\mu_3\text{-}O_2CCH_2C(H)(Me)O\}_2$]. Thermal ellipsoids are shown at the 30% level. All hydrogen atoms and *tert*-butyl methyl groups are omitted for clarity. Selected bond lengths (Å) and angles (°): Al(1)–O(1a) 1.82(1), Al(1)–O(3) 1.77(1), Al(1)–O(11) 1.71(1), Al(2)–O(2) 1.887(9), Al(2)–O(3) 1.99(1), Al(2)–O(11) 1.91(1); Al(2)–O(12) 1.807(9), Al(3)–O(11) 1.800(9), Al(3)–O(12) 1.84(1), Al(3)–O(12a) 1.79(1), C(1)–O(1) 1.29(1), C(1)–O(2) 1.23(1); O(1a)–Al(1)–O(3) 104.1(5), O(1a)–Al(1)–O(11) 108.6(5), O(3)–Al(1)–O(11) 85.9(5), O(2)–Al(2)–O(3) 85.4(4), O(2)–Al(2)–O(11) 118.2(4), O(2)–Al(2)–O(12) 89.1(4), O(3)–Al(2)–O(11) 75.0(4), O(3)–Al(2)–O(12) 152.1(5), O(11)–Al(2)–O(12) 83.7(4), O(11)–Al(3)–O(12) 85.7(4), O(11)–Al(3)–O(12a) 122.0(4), O(12)–Al(3)–O(12a) 86.7(4), Al(1a)–O(1)–C(1) 131.1(8), Al(2)–O(2)–C(1) 131.8(8), Al(1)–O(3)–Al(2) 96.8(5), Al(1)–O(3)–C(3) 138(1), Al(2)–O(3)–C(3) 119(1), Al(1)–O(11)–Al(2) 102.1(5), Al(1)–O(11)–Al(3) 155.1(5), Al(2)–O(11)–Al(3) 94.2(5), Al(2)–O(12)–Al(3) 96.2(5), O(1)–C(1)–O(2) 122(1).

molecules of β-hydroxybutyrate between the sides of the ladder. In this regard the cage opened core of (*R,S*)-[$Al_6Bu^t_6(\mu_3\text{-}O)_4\{\mu_3\text{-}O_2CCH_2C(H)(Me)O\}_2$] is unlike our previously characterized products from the latent Lewis acid reactions of [$Bu^tAl(\mu_3\text{-}O)]_6$ in which opposite edges are ordinarily opened.[5]

The geometries and bond distances around the Al and O atoms† are similar to those we have previously reported for other *tert*-butyl alumoxane compounds.[6,7] One unusual feature of the structure, however, is the presence of the two five-coordinate aluminium centers, Al(2) and Al(2a). As is common for five-coordinate aluminium, the geometry about Al(2) is that of a distorted trigonal bipyramid; O(3)–Al(2)–O(12) 152.1(5)°, and $\Sigma(X_{eq}\text{–Al–}X_{eq})$ = 359.3(6)°. The $[O_2CCH_2C(H)(Me)O]^-$ ligands, formed from the ring opening of the β-butyrolactone, each cap three of the aluminium atoms. The carboxylate moiety bridges atoms Al(1a) and Al(2), while the alkoxide terminus bridges atoms Al(1) and Al(2). The bond lengths and angles within the carboxylate unit are typical of such moieties[8] and are indicative of delocalization within the carboxylate group. The O–C–O angle [122(1)°] is similar to that in 'free' carboxylic acids. The carboxylate bite distance [Al(1a)···Al(2) 4.78 Å] is, however, significantly longer than previously observed for aluminium carboxylates (3.26–4.18 Å).[8] Unlike other types of bridging alkoxide compounds the Al(μ-OR)Al unit is asymmetrical, presumably due to the presence of both four- and five-coordinate aluminium centers and/or the ring strain within the cage.

Based on the structure described above, we can conclude that the ring-opening reaction of a β-butyrolactone by an alumoxane occurs by attack on the lactone's carbonyl group by the basic alumoxane oxo-ligands rather than by the alumoxane's alkyl substituents. This proposal is in line with our previous results which have shown that while the alkyl groups are relatively inert, the oxide ligands are basic, *e.g.*, they are readily protonated by even relatively weak acids.[9] Thus, it is clear from the structure of (*R,S*)-[$Al_6Bu^t_6(\mu_3\text{-}O)_4\{\mu_3\text{-}O_2CCH_2C(H)(Me)O\}_2$], and its activity as a polymerization catalyst, that the latent Lewis acid mechanism previously proposed for the ring opening of propylene oxide[10] is most likely involved in the initiation step in the polymerization of β-butyrolactone by *tert*-butylalumoxane. In addition, similar derivatives may be involved in the polymerization reactions of this monomer with other alkylalumoxanes.

Financial support of this work was provided by the Office of Naval Research (A. R. B.), and Robert A. Welch Foundation (S. G. B. and A. R. B.), and the Materials Research Laboratory of the University of Massachusetts funded by the National Science Foundation (R. W. L.).

# Post-synthesis grafting of Al onto MCM-41

**Robert Mokaya* and William Jones**

*Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge UK CB2 1EW*

**Al-containing MCM-41 materials are prepared by grafting Al onto purely siliceous MCM-41; the resulting materials retain the hexagonal order and physical properties of the purely siliceous parent MCM-41 and exhibit higher Brønsted acid content compared to Al-MCM-41 prepared by direct hydrothermal synthesis.**

The recent synthesis of the M41S family of siliceous solids with sharply distributed pores of diameter in the mesoporous regime (20–100 Å) has greatly increased the range of heterogeneous catalysts.[1–3] Of particular interest is MCM-41 which possesses a hexagonally arranged array of uniform pores. Brønsted acid sites may be generated in MCM-41 by isomorphous substitution of Al for Si.[2,3] However, the direct synthesis of aluminium containing MCM-41 has proved to be challenging; the incorporation of even small amounts of aluminium in the MCM-41 framework causes a decrease in hexagonal ordering.[4,5] It has also been observed that when compared to zeolites, the concentration of Brønsted acid sites in such aluminosilicate MCM-41 is very low even at high aluminium concentrations.[2,3,6] It is therefore desirable to prepare aluminosilicate MCM-41 which exhibits both higher Brønsted acid content and long range order similar to that of the purely siliceous material. An alternative synthetic approach which may address both these challenges is the post synthesis grafting/incorporation of aluminium into MCM-41. This is possible due to the presence of a high density of silanol groups on the pore surface of MCM-41 to which guest species may be attached.[7–9] Here we report a grafting method which consists of reacting the silanol groups present in MCM-41 with discrete amounts of aluminium alkoxide in a non-aqueous environment, followed by calcination to anchor the Al.

The starting material, a purely siliceous MCM-41 (designated PSMCM), was prepared by adding tetramethylammonium hydroxide (TMAOH) and sodium hydroxide (NaOH) to an aqueous solution of hexadecyltrimethylammonium chloride (CTACl) of appropriate concentration with stirring for 10 min. Tetraethylorthosilicate (TEOS) was combined with the resulting solution at room temp. under stirring to give a gel of molar composition 0.25 TEOS : 0.06 NaOH : 0.03 TMAOH : 27.8 $H_2O$ : 0.06 CTACl which was left to react for 24 h at room temp. The solid product was obtained by filtration, washed with distilled water, dried in air at room temp. and finally calcined at 550 °C for 16 h. For alumination, 2.0 g of PSMCM was dispersed in 50 ml dry hexane, and added to 150 ml dry hexane containing the appropriate amount of aluminium isopropoxide, $Al(OPr^i)_3$, to give Si : Al ratio in the range 40–5 : 1. The resulting mixture was stirred for 10 min and allowed to react at room temp. for 24 h. The obtained powder was filtered, washed with dry hexane, dried at room temp. and calcined at 550 °C for 4 h. Four samples (designated Al-PSMCMX, where X is the Si : Al ratio) were prepared from PSMCM at Si/Al ratio 40, 20, 10 and 5.

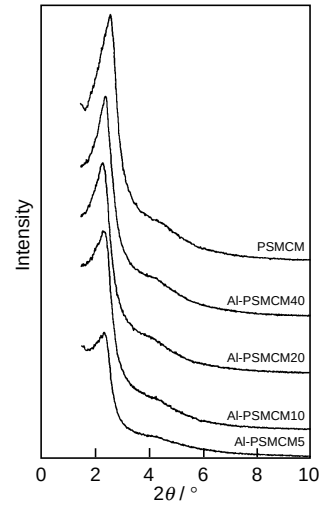

**Fig. 1** Powder XRD patterns of calcined purely siliceous sample (PSMCM) and Al-grafted (Al-PSMCM) samples

Fig. 1 shows that the powder X-ray diffraction patterns of the Al grafted materials are similar to that of the parent MCM-41 which is an indication that hexagonal order is maintained. TEM shows that, despite the gradual reduction in the intensity of the (100) peak, the hexagonal arrangement of the pores remains the same in all cases. Chemical analysis given in Table 1 shows that the Si/Al molar ratios of the Al-grafted samples are close to the expected bulk Si/Al ratios which is an indication of the potential of the present method in introducing discrete amounts of heteroatoms to purely siliceous MCM-41. $^{27}$Al MAS NMR spectra (of the calcined samples) shown in Fig. 2 indicate that all the samples contain tetrahedral (framework) and octahedral (non-framework) Al with resonances at $\delta$ 53.0 and 0, respectively. The amount of tetrahedral Al is always higher than the octahedral Al and generally increases with increasing Al content. For the dry samples, octahedral Al was always higher

**Table 1** Elemental composition, *d* spacing and textural properties and acidity of the study materials (CHA = cyclohexylamine)

| Sample | Si/Al | $d_{100}$/Å | Surface area/m$^2$ g$^{-1}$ | Pore volume/ cm$^3$ g$^{-1}$ | APD[a]/Å | $a_0$[b]/Å | Wall thickness/Å | Acidity/ mmol CHA g$^{-1}$ |
|---|---|---|---|---|---|---|---|---|
| PSMCM | | 33.8 | 1110 | 0.93 | 26.3 | 39.0 | 12.7 | |
| Al-PSMCM40 | 38.5 | 34.8 | 1000 | 0.82 | 26.8 | 40.2 | 13.4 | 0.16 |
| Al-PSMCM20 | 19.8 | 36.4 | 1004 | 0.81 | 26.7 | 42.0 | 15.3 | 0.29 |
| Al-PSMCM10 | 11.2 | 36.0 | 996 | 0.78 | 26.6 | 41.6 | 14.9 | 0.48 |
| Al-PSMCM5 | 6.1 | 35.7 | 980 | 0.77 | 26.5 | 41.2 | 14.7 | 0.51 |

[a] APD = Average pore diameter (determined using BJH analysis). [b] $a_0$ = Lattice parameter from XRD data using the formula $a_0 = 2d_{100}/\sqrt{3}$.

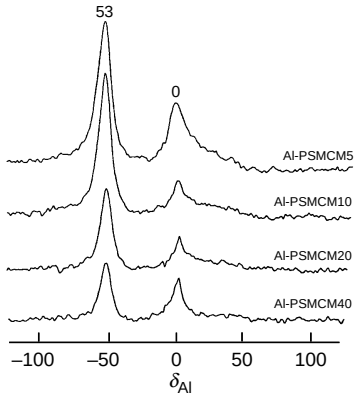

**Fig. 2** $^{27}$Al MAS NMR spectra of calcined Al-PSMCM samples. To ensure quantitative reliability all samples were hydrated and equilibrated with room air prior to measurement.

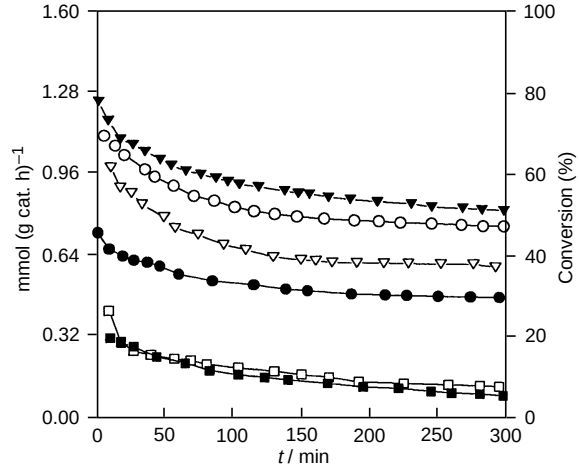

**Fig. 3** Cumene conversion over Al-PSMCM samples and reference materials compared at 300 °C and WHSV of 5.5. Al-PSMCM5 (▼), Al-PSMCM10 (○), Al-PSMCM20 (▽), Al-PSMCM40 (●), H$^+$-MCM41-20 (□), and SA10 (■)

than tetrahedral Al and therefore calcination serves to anchor some (octahedral) Al to the framework.

The *d* spacing of the Al-grafted materials was in all cases higher than that of the parent MCM-41 (see Table 1). This is consistent with the presence of tetrahedral Al in the framework. Table 1 also gives the textural properties obtained for the calcined Al-PSMCM materials. The surface area and average pore diameter (obtained by BJH analysis of the sorption data) of the Al-PSMCM materials are similar to that of the parent MCM-41 while the pore volume is lower probably due to the presence of non-framework Al in the pores. The pore wall thickness of the Al-grafted samples was in all cases higher than that of the parent purely siliceous MCM-41 sample in agreement with the incorporation of Al into the framework.

The acid content of the Al-PSMCM materials was obtained using thermally programmed desorption of cyclohexylamine.[3] Prior to analysis the base containing samples were heat treated at 250 °C for 2 h. This method principally determines the proton concentration which is of interest to catalysis. It is clear from the acidity values in Table 1 that the Al-grafting process generates acid sites and that the number of acid sites generated increases as the amount of framework aluminium increases. The acid content of Al-PSMCM10 and Al-PSMCM5 are very close in agreement with the $^{27}$Al MAS NMR which shows them to possess almost similar amounts of tetrahedral Al. We found that for similar bulk Si/Al ratios, the acidity of Al-PSMCM samples is higher than that of equivalent (protonic) aluminosilicate MCM-41 prepared using the conventional direct synthesis method (for example H$^+$-MCM-41-20 (see ref. 3 for sample details) had an acid content of 0.19 mmol g$^{-1}$ compared to 0.29 mmol g$^{-1}$ for Al-PSMCM20. We also prepared Al-grafted amorphous silica (designated SA10) at a Si/Al ratio of 10; the resulting material had an acid content of 0.22 mmol g$^{-1}$ compared to 0.48 for the equivalent (in terms of Al content) Al-PSMCM10 sample. Confirmation of the higher acid content of Al-grafted samples was provided by their activity in the cracking of cumene as shown in Fig. 3. The reaction, performed at 300 °C and a WHSV of 5.5 using a tubular stainless steel, continuous flow fixed-bed microreactor system with helium (25 ml min$^{-1}$) as carrier gas after activating the catalyst bed (100 mg; 30–60 mesh) for 1.5 h at 500 °C under helium (25 ml min$^{-1}$) proceeded almost exclusively *via* catalytic cracking to benzene and propene with only trace amounts of α-methylstyrene (product of dehydrogenation over Lewis acid sites) indicating that the active sites are of the Brønsted type.[10] The curves in Fig. 3 indicate that Al-PSMCM materials possess considerable catalytic activity, with the conversion of cumene increasing with increasing acid content and amount of framework aluminium. In particular we note that the activity of the Al-PSMCM materials is superior to that of equivalent MCM-41 prepared by direct synthesis (see comparison between H$^+$-MCM-41-20 and Al-PSMCM20). The Al-grafted amorphous silica (SA10), in line with the acid content, had a much lower activity compared to the equivalent Al-grafted MCM-41 (Al-PSMCM10). The purely siliceous material exhibited no catalytic activity.

We have demonstrated that Al-containing MCM-41 of good order can be prepared by post-synthesis grafting of Al by reacting purely siliceous MCM-41 with an Al–alkoxide in non-aqueous media. The Al is incorporated into the framework to generate materials with Brønsted acid sites whose content is higher than in equivalent Al-MCM-41 materials prepared *via* the conventional direct synthesis method. We attribute the higher acid content in the Al-grafted materials to the presence of Brønsted acid generating Al in accessible sites on the pore walls.

R. M. is grateful to the EPSRC for an Advanced Fellowship. The assistance of Laporte Absorbents in surface area measurements and Dr H. Y. He for NMR measurements is appreciated.

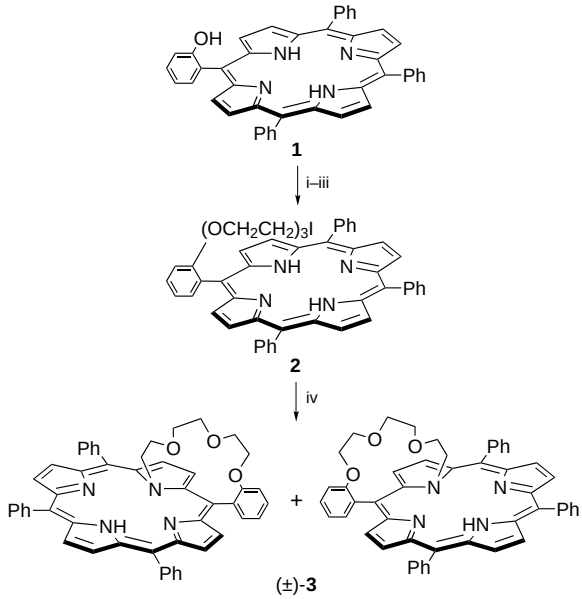
# Synthesis and characterization of intramolecular *N*-strapped porphyrins

**Yoshihiro Ishimaru,* Shigeki Sumida and Takeaki Iida**



*Department of Functional Materials Science, Faculty of Engineering, Saitama University, 255 Shimo-ohkubo, Urawa 338, Japan*

**The first successful synthesis and characterization of intramolecular *N*-strapped porphyrins and the separation of a set of enantiomers are described.**

The functionalization of porphyrin macrocycles has become of interest in the field of supramolecular and biomimetic chemistry. Moreover, current investigations of porphyrin chemistry have led to the construction of new structural motifs using porphyrin rings.[1,2] *N*-Alkylporphyrins have been synthesized as biologically important compounds, after having been found to be formed by the reaction of alkenes with the cytochrome P-450 in the liver of mice. The aim of the present investigation was to synthesize the *N*-alkylporphyrins with new structural properties. Accordingly, we decided upon the preparation of intramolecular *N*-strapped porphyrins, that is, with one nitrogen atom alkylated by a tris(3-oxapropylene) bridge the other end of which was joined at the 2-position of a *meso* phenyl group.

The proposed intramolecular *N*-alkylation introduced three structural motifs into the porphyrin ring. (i) The generation of an asymmetric nitrogen atom. (ii) The steric distortion of the porphyrin ring. (iii) The construction of a half crown ether type bridge. To the best of our knowledge, despite the development of various methods for the alkylation of inner nitrogen atom(s),[3] no practical synthetic methods have yet been proposed for intramolecular *N*-alkylation. Accordingly, we propose here the synthetic method shown in Scheme 1.

Compound **1** was synthesized by condensation of pyrrole, benzaldehyde and 2-hydroxybenzaldehyde in a 4 : 3 : 1 molar ratio according to the method of Little *et al.*[4] The alkyl halide, 5-[2′-(9″-iodo-1″,4″,7″-trioxanonyl)phenyl]-10,15,20-triphenylporphyrin **2** was synthesized from **1** in 73% overall yield.

**Scheme 1** *Reagents and conditions*: i, NaOH, $I(CH_2CH_2O)_3THP$, dry DMSO, room temp., 12 h; ii, TsOH, MeOH–$CH_2Cl_2$, room temp., 12 h; iii, imidazole, $I_2$, $PPh_3$, benzene, room temp., 0.5 h; iv, $AgBF_4$, MeCN, reflux, 3 days

The detailed reaction conditions are shown in the caption to Scheme 1. The starting material **2** (0.3 mmol) and $AgBF_4$ (0.6 mmol) were stirred in refluxing dry MeCN (30 ml) for 3 days. After chromatographic purification, the desired product could be collected as a second purple band ($R_f$ 0.2, chloroform–methanol, 97 : 3) in 50% yield. Compound **3** has a UV–VIS spectrum that is fairly typical of *N*-alkylporphyrin free base derivatives.†

The reaction of **2** with $AgBF_4$ gave carbonium ion intermediates formed by the precipitation of AgI. The resulting intermediates were readily attacked by the intramolecular pyrrolic nitrogen atom *in situ* to give the proposed compound.

Fig. 1 shows $^1$H NMR spectrum of **3**. Extraordinarily up-field shifted signals at −4.08 and −4.31 ppm due to *N*-$CH_2$ protons and twelve multiplet signals due to the CH protons were evidence of the intramolecular conjugation of the tris(1-oxapropylene) bridge with asymmetric nitrogen atom. Signals at 8.78 (2 H), 8.67, 8.54, 8.47, 8.44, 7.61 and 7.52 ppm were assigned to the eight β-pyrrole protons on the basis of their peak intensity and coupling constants ($J$ 4.5 Hz). In particular, the signals at 7.61 and 7.52 ppm were strictly assigned to the *N*-alkylated β-pyrrole protons as explained by Kuila *et al.*[5] Signals at 7.66, 7.40 and 7.25 ppm were assigned to the *o*′-, *m*- and *m*′-protons of the 5-phenyl group, respectively, by 2D COSY measurement. This evidence suggested that the porphyrin ring was restrictively distorted by the introduction of an intramolecular strap.

As a result of the introduction of an intramolecular strap, two sets of enantiomers were expected to be formed at the different possible *N*-alkylation positions. Thus, a detailed two-dimensional NMR study (HMBC method) was performed to confirm which nitrogen atom is alkylated. The signal at 122.24 ppm† is correlated with the signals at 7.61 ppm due to the *N*-alkylated β-pyrrole proton and 7.66 ppm due to the *o*′-phenyl proton of the 5-phenyl group. Thus, we concluded that either the N(21) or N(22) atom of the pyrroles, which are adjacent to the 5-phenyl

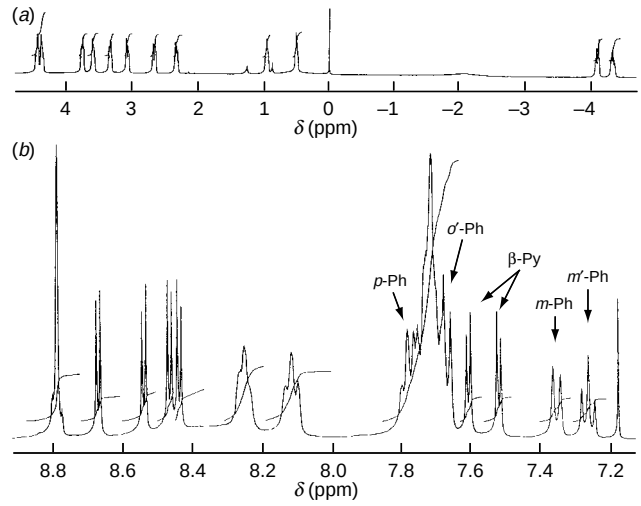


**Fig. 1** Portions of the $^1$H NMR spectrum of **3** in $CDCl_3$; (*a*) the tris(1-oxapropylene) region; (*b*) the aromatic region

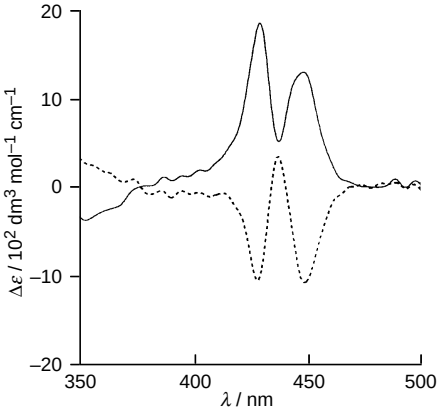

**Fig. 2** CD spectra of (+)-**3** (—) and (−)-**3** (- - -) in $CHCl_3$

group attached to the tris(1-oxapropylene) side chain, were alkylated. The length of the tris(1-oxapropylene) side chain is especially well-suited for connecting the 5-phenyl group and the nitrogen atom of the adjacent pyrrole rings.

It is considered that compound **3** is a set of enantiomers with an asymmetric nitrogen atom. Consequently, separation of racemic compound **3** was attempted using chiral HPLC (CHIRALCEL OD; Daisel Co. Lt. in Japan) eluted by *n*-hexane–propan-2-ol (7 : 3). Two fractions each of 100% ee were obtained.

The separated enantiomers, (+)-**3** and (−)-**3**, show mirror-image circular dichroism spectra and a split Cotton effect in the Soret region as shown in Fig. 2.

In summary, a new type of *N*-alkylporphyrin has been synthesized and characterized. The present work provides a unique technique for controlling the distortion of porphyrinoid macrocycles through intramolecular *N*-strapping. *N*-Alkylation studies with chains of different lengths is now under way.

We thank Dr J.-i. Setsune of Kobe university for useful discussions, Mr K. Fujikura of Varian Japan Limited for measurement of HMBC spectra and Mr T. Koyama for measurement of FAB mass spectra.

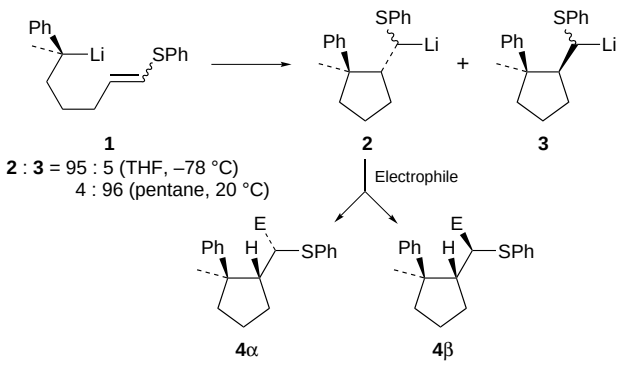
# Stereochemistry of the intramolecular carbolithiation of vinyl sulfides

**Reinhard W. Hoffmann,*[a] Ralf Koberstein,[a] Bruno Remacle[b] and Alain Krief[b]**



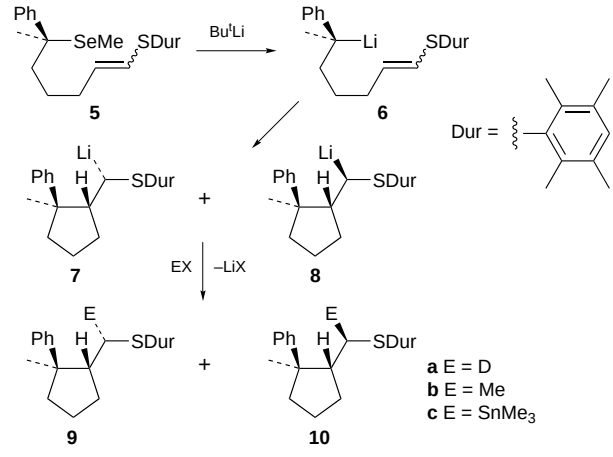
[a] *Fachbereich Chemie der Philipps-Universität Marburg, Hans-Meerwein-Strasse, 35032 Marburg, Germany*
[b] *Department of Chemistry, Facultés Universitaires Notre-Dame de la Paix, 61, rue de Bruxelles, 5000 Namur, Belgium*

**Intramolecular carbolithiation of vinyl sulfides to generate configurationally stable α-durylthioalkyllithium compounds at −105 °C in THF showed carbolithiation to be non-stereospecific regarding the newly formed lithium bearing stereocentre.**

The intramolecular carbolithiation of alkenes,[1] *i.e.* the addition of an organolithium entity across a C=C double bond is of interest, because it leads to carbo- and hetero-cycles with a stereochemically defined substitution pattern.[2] The detailed mechanism of the carbolithiation reaction is as yet not well-understood.

Cyclization of **1** in THF led to the *trans*-isomer **2** in high diastereoselectivity[3,4] (Scheme 1). Trapping of **2** by electrophiles generated two diastereoisomeric products **4α** and **4β**, the ratio of which depended on the electrophile used.[3] This demonstrates that the configurational stability of the α-phenylthioalkyllithium species **2** is too low to allow any conclusions regarding the initial configuration of the lithium-bearing stereocentre in **2**. Such information could, however, be obtained if a lithium-bearing stereocentre of higher configurational stability could be generated in the carbolithiation reaction. Previous studies[5] have indicated that α-durylthioalkyllithium compounds (duryl = 2,3,5,6-tetramethylphenyl) have a significantly higher barrier to enantioisomerization than α-phenylthioalkyllithium compounds. We therefore prepared the (*E*)- and (*Z*)-durylthio compounds **5**,† hoping to uncover further stereochemical details of the carbolithiation reaction of the derived benzyllithium compounds **6** (Scheme 2).

In order to preserve the initial configuration at the newly formed lithium-bearing stereocentre in **7** and **8**, we treated the seleno compound **5** with *tert*-butyllithium at −105 °C in THF. Quenching after 10 min with precooled $CD_3OD$ in a two compartment reaction vessel[6] showed that cyclization of **6** to **7** and **8** had occurred. The relative configuration of **9** at the ring carbon atoms corresponds to that of **4**, as supported by a crystal structure analysis of **9c**. The relative configuration of **9a** and **10a** at the exocyclic carbon atom is assigned by the similarity of their $^1$H NMR spectra to that of **4** (E = D). The ratio of the two diastereoisomeric deuterated compounds **9a** and **10a** was determined by $^2$H NMR spectroscopy.

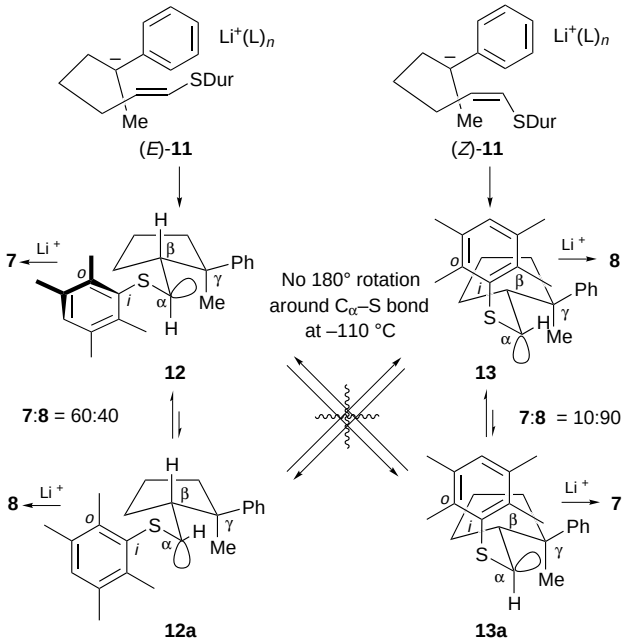


**Scheme 1**

Entries 1 and 2 of Table 1 show that carbolithiation occurred in an essentially stereospecific manner, when starting from a sample enriched in (*Z*)-**5**. Carbolithiation in the *E* series (entries 3 and 4) led to the α- and β-diastereoisomers **9a** and **10a** in a 4 : 6 ratio. The differences between the two series of experiments, and the fact that the time between carbolithiation and trapping had no influence on the diastereoisomer ratio of **9a** : **10a** indicates that the α-durylthioalkyllithium compounds **7** and **8** are configurationally stable under the reaction conditions. The diastereoisomer ratio is therefore kinetically controlled. Warming of the reaction mixture to −78 °C before quenching led to equilibration of **7** and **8**. Subsequent trapping then reflects the thermodynamic ratio of **7** and **8** (*cf.* entries 11–13 of Table 1). Moreover, dilution (entry 5) or trapping with methyl iodide to give **9b** and **10b** (entries 6 and 7) had no effect on the **9** : **10** ratio. For the carbolithiation reactions to occur at these low temperatures and with this stereochemistry, THF (a lithium-coordinating solvent) is essential. The reaction does also proceed in pentane at low temperatures, but only in the presence of at least one equivalent of THF.

The seemingly stereospecific cyclization of (*Z*)-**6** to **7** is in line with a concerted *syn*-addition of carbon and lithium to the double bond, but does not prove such a mechanism. The non-stereospecific cyclization of (*E*)-**6** suggests, however, a different scenario for the carbolithiation reaction in THF.

Carbolithiation reactions are greatly facilitated by all factors which help to detach the lithium from the carbon atom at the migration origin, *e.g.* an allyl-[7] or benzyl-lithium[3,4,8] entity at the migration origin, complexation assisted carbolithiation[9,10] and addition of lithium coordinating co-solvents.[10,11] This suggests that the carbon–lithium bond at the migration origin has to be broken first, in the extreme with the formation of a solvent separated ion pair **11**, a process favoured at lower temperatures.[12] C–C Bond formation, *i.e.* the cyclization, then proceeds in the carbanion part of the ion pair to give the ion pairs **12** and **13** (Scheme 3). The choreography of the cyclisation is probably such that $C_i$, S, $C_\alpha$ and the lone pair are initially antiperiplanar in **12** and **13**, in order to stabilize the transition state of the cyclization by delocalization of the negative charge



**Scheme 2**

**Table 1** Results of some carbolithiation experiments

| Entry[a] | *T*/°C[b] | Solvent | Substrate **5** *E* : *Z* | Electrophile | *t*/min[c] | Product Yield (%) | **9** : **10** |

| 8 | −107 | THF + HMPA (4 equiv.) | 15 : 85 | $CD_3OD$ (0.95 M in THF) | 15 | 67 | 86 : 14 |
| 9 | −104 | THF + HMPA (1 equiv.) | 98 : 2 | $CD_3OD$ (1.06 M in THF) | 20 | | 41 : 59 |
| 10[e] | −103 | Pentane + THF (1 equiv.) | 98 : 2 | $CD_3OD$ (1.06 M in THF) | 50 | 70 | 42 : 58 |
| 11 | −78 | THF | 13 : 87 | $CD_3OD$ (neat) | 90 | 62 | 94 : 6 |
| 12 | −78 | THF | 98 : 2 | $CD_3OD$ (neat) | 90 | | 94 : 6 |
| 13 | −78 | THF | 13 : 87 | MeI (2.01 M in THF) | 90 | 81 | 94 : 6 |

[a] Reactions were normally carried out with a 0.20 M solution of **5** in THF and with 1.2 equiv. of a 1.6 M solution of Bu$^t$Li in pentane. [b] All reactions were carried out with Bu$^t$Li and substrate solutions precooled to the given temperature. [c] Time between the start of the reaction and the addition of the electrophile ('15 + 30' means that the substrate was added over 15 min to the Bu$^t$Li solution and stirred for further 30 min before $CD_3OD$ was added). [d] Substrate concentration: 0.02 M, Bu$^t$Li concentration: 0.08 M. [e] Substrate concentration: 0.10 M.

**Scheme 3**

into the S–$C_i$ σ*-orbital. Next, a rotation about the $C_\alpha$–$C_\beta$ bond ensues to render the groups S–$C_\alpha$–$C_\beta$–$C_\gamma$ antiperiplanar, due to the quaternary nature of $C_\gamma$. Thus, the cyclization of (*E*)-**11** and (*Z*)-**11** leads to two distinct ion pairs **12** and **13**. Interconversion between the ion pairs **12** and **13** would require carbanion inversion and rotation about the $C_\alpha$–S bond, a process which should be slow at −110 °C,[5] but could be viable at −78 °C. The change in the stereochemistry of the carbolithiation reaction is then attributed to an inversion at the carbanion centre, which is calculated to have a rather low (< 2.5 kcal mol$^{-1}$) activation barrier.[13] This inversion to give **12a** and **13a** could therefore be competitive with or faster than the collapse of the ion pairs **12** and **13** to the configurationally stable organolithium compounds **7** and **8**. It should be noted, however, that the same stereoselectivity is observed in the absence or presence of HMPT and that further experiments may be needed to prove or to modify the interpretation given.

The carbolithiation of vinyl sulfides in THF was found to be non-stereospecific regarding formation of the new lithium-bearing stereocentre. This suggests that carbolithiation proceeds in a non-concerted fashion, in which collapse of an ion pair determines the configuration of the lithium-bearing centre at the migration terminus.

We are grateful to the Deutsche Forschungsgemeinschaft (SFB 260) and the Fonds der Chemischen Industrie for support of this study. We thank Professor H. J. Reich, Madison, Wisc., USA, for stimulating discussions and Dr N. Huser for carrying out preliminary studies.

# Novel polycyclic polyprenoid sulfides in sediments

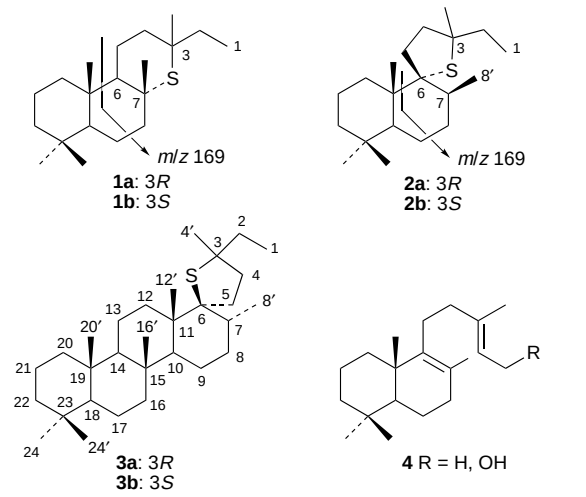
**Jacques Poinsot, Patrick Schneckenburger, Pierre Adam, Philippe Schaeffer, Jean Trendel and Pierre Albrecht*†**

*Institut de Chimie, URA 31 du CNRS, Université Louis Pasteur, 1 rue Blaise Pascal, 67000 Strasbourg, France*

**A series of polycyclic sulfides ($C_{15}$, $C_{20}$, $C_{25}$, $C_{30}$) deriving from regular isoprenoids has been characterized in sediments by mass spectrometry, synthesis of $C_{20}$ members, and NMR structural elucidation of two $C_{30}$ isomers isolated from a geological sample.**

The structure of numerous organo-sulfur compounds identified in sediments clearly indicates that incorporation of sulfur into biomolecules of decaying organisms takes place at the earliest stages of diagenesis.[1] Sulfurization most likely occurs by reaction of inorganic sulfur species (elemental S, $H_2S$, polysulfides) generated by bacterial processes with either organic components directly inherited from organisms or their functionalised derivatives. However, the precise mechanisms of these low-temperature sulfurization reactions still remain unclear and are at present the subject of many studies.[2] Structural determination of organo-sulfur components can give very useful information on their origin and their mode of formation. We report here the identification of a series ($C_{15}$, $C_{20}$, $C_{25}$, $C_{30}$) of novel polycyclic polyprenoid sulfides in immature sediments, the structures of which imply sulfur incorporation into partially cyclised regular isoprenoids.

Several organic extracts from sulfur-rich sediments were studied[3] and the aliphatic sulfide fraction was analysed by GC with a sulfur-specific FPD detector and by GC–MS. In all the samples selected, the *m/z* 169 mass fragmentogram shows the presence of two major isomeric compounds, the mass spectra of which exhibit a molecular ion at *m/z* 444 corresponding to an elemental composition of $C_{30}H_{52}S$ (verified by high resolution mass spectrometry) and a fragment triplet at *m/z* 156, 169 (base peak) and 185, all containing the sulfur atom as demonstrated by tandem mass spectrometry. In the peculiar case of an Italian Triassic marl, however, the *m/z* 169 mass fragmentogram highlighted four repetitive patterns of eight isomeric structures comprising two major, two minor and four extremely minor compounds more or less well resolved depending on the pattern considered. The molecular ions of each group,‡ respectively at *m/z* 240 ($C_{15}H_{28}S$), 308 ($C_{20}H_{36}S$), 376 ($C_{25}H_{44}S$) and 444 ($C_{30}H_{52}S$)—the two major $C_{30}$ skeletons being identical to that of the other samples—obviously point towards regular polyprenic structures differing by one isoprenic unit ($\Delta m/z$ = 68, respectively). Moreover, each compound displays the same fragment triplet as for the previous $C_{30}$ sulfides, thus suggesting the presence of a common sulfurized moiety. Small quantities of an almost pure major $C_{30}$ compound were obtained after argentation TLC fractionation of a particularly simple sulfide fraction where the two $C_{30}$ species were by far the major components. Desulfurization of the isolated product was achieved under drastic conditions with lithium–ethylamine and afforded a tetracyclic alkane, the mass spectrum of which shows a similar fragmentation pattern to that of scalarane, a tetracyclic sesterterpenoid which results from the cyclisation of a regular $C_{25}$ isoprenoid skeleton. Additional valuable information was obtained from the sulfone formed by treatment of the $C_{30}$ sulfide with OXONE®.[4] The lack of H–D exchange (BuLi, $CD_3SOCD_3$)[5] observed by MS showed the absence of any acidic proton α to the sulfur. These preliminary data indicated that all these closely related unknown compounds could result from sulfur incorporation into partially cyclised regular isoprenoids, leading to structure types **1**–**3** shown in Fig. 1.§



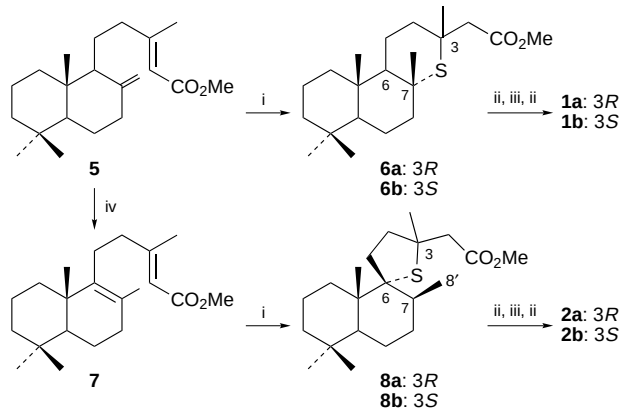


**Fig. 1** Postulated (**1**–**3**) and identified (**2** and **3**) structures of the geological sulfides and probable precursors **4** for **2**

Focusing first on the $C_{20}$ sulfide group of the Italian marl which comprises eight well-resolved isomers in the *m/z* 169 mass fragmentogram, we undertook the synthesis of reference compounds (Scheme 1), starting from methyl copalate here represented as its *ent*-isomer **5** for uniformity with other structures. Hence, sulfurization of **5**, achieved in DMF by means of $S_8$–NaSH in a 1 : 4 molar ratio ($HSSS^-$ major species),¶ gave exlusively a mixture of the two thiane epimers at position 3, **6a** and **6b**, which were fully characterised by 2D NMR after TLC separation. Complete reduction of the methoxycarbonyl function of **6a** and **6b** led to the corresponding thianes **1a** and **1b** whose mass spectra were markedly different from that of the sedimentary compounds, therefore allowing us to exclude this kind of structure for the naturally occurring components. Other suitable candidates were spiro-

thiolanes **2**, which could account for the presence of eight isomers with regard to the possible configurations at C-3, C-6 and C-7. Two of them, **2a** and **2b**, were successfully obtained with the same reaction sequence as above, starting from the methyl copalate isomer **7**, the sulfurization of which specifically afforded, although in moderate yield, compounds **8a** and **8b** epimeric at C-3. Again, their structures were unambiguously determined by 2D NMR studies on the corresponding alcohols which were easily separated by HPLC. Based on comparison of mass spectra and GC retention times, thiolanes **2a** and **2b** were conclusively identified with two of the very minor sedimentary structures.

We finally isolated the two major ubiquitous $C_{30}$ sulfides **3a** and **3b** from the organic extract of a sedimentary rock (Toarcian, Paris basin, France) using a combination of liquid chromatographies. Their structures were established by NMR studies which led to the complete assignment of proton and carbon signals listed for **3a** in Table 1. For each compound, the basic carbon framework was deduced, with the help of the DEPT spectrum, from the HMBC spectrum correlation ($^{2,3}J_{CH}$ 7 Hz) network clearly showing that these structures indeed result from the cyclisation of a regular $C_{30}$ isoprenoid. Stereochemical information was obtained from the NOESY spectra which showed that **3a** and **3b** are epimeric at C-3 and bear the same *trans-transoid-trans* arrangement of the fused rings with axial ring-junction methyl groups on the same side of the mean plane of the molecule, a 6*S* configuration—*i.e.* the inverse of that of the synthetic references **2**—and a Me-8′ in the thermodynamically stable equatorial position.

In the light of these results, it was inferred that the eight structures belonging to a same molecular pattern are spirothiolanes isomeric at C-3, C-6 and C-7, the four extremely minor compounds being those which bear the 8′-methyl group at C-7 in the thermodynamically unfavourable axial position. Their formation most likely involves sulfur incorporation into partially cyclised regular isoprenoids, such as **4**, still possessing two double bonds in their skeleton. This implies that this process must operate at the earliest stages of diagenesis. Remarkably, apart from the case of the Italian marl, their distribution in all the geological samples investigated is almost exclusively restricted to the two $C_{30}$ members **3a** and **3b**, the other components, if any, being hardly detectable. This could reflect either a stereoselectivity in sulfur incorporation due to the mechanism itself—either linked or not to the existence of particular precursors—or that the 6*R* isomers formed initially are thermodynamically less stable and/or more susceptible to further geochemical transformations than their 6*S* epimers. Moreover, in most cases, the $C_{30}$ thiolanes overwhelmingly dominate the whole sulfide fraction, a fact which could indicate a major input of their biological precursors in sediments—although these $C_{30}$ tetracyclic terpenoids derived from regular isoprenoids are not known today in living organisms‖—or, more speculatively, that these sedimentary sulfides are directly inherited from producing oganisms.

We thank E. Mastio and P. Wehrung for their assistance in GC–MS analyses and R. Graff for recording NMR spectra.

‡ *MS data* (Finnigan MAT TSQ 700) EI (70 eV), *m/z* (rel. int.) for the first-eluting major sulfide of each group. $C_{15}H_{28}S$: 240 ($M^+$, 58%), 183 (3), 169 (100), 156 (22); $C_{20}H_{36}S$: 308 ($M^+$, 38%), 185 (3), 169 (100), 156 (22); $C_{25}H_{44}S$: 376 ($M^+$, 41%), 185 (18), 169 (100), 156 (38); $C_{30}H_{52}S$: 444 ($M^+$, 56%), 429 (8), 415 (3), 259 (12), 185 (38), 169 (100), 156 (40).

§ Since absolute configurations of the geological compounds are unknown, structures are arbitrarily drawn in the most usual way for terpenoid geochemical markers. All configurations subsequently discussed are relative to that represented on the drawings. Carbon numbering derives from that of the corresponding uncyclised regular isoprenols.

¶ Detailed mechanistic considerations concerning this sulfurization process will be included in an article on sulfur incorporation into unsaturated compounds (P. Schneckenburger, J. Poinsot, P. Adam and P. Albrecht, in preparation).

‖ Other polycyclic terpenoids derived from higher regular isoprenoids and of controversial or unknown origin have been identified in sediments: they are ubiquitous tricyclic hydrocarbons (D. Heissler, R. Ocampo, P. Albrecht, J.-J. Riehl and G. Ourisson, *J. Chem. Soc., Chem. Commun.*, 1984, 496) and optically-active highly cyclised hydrocarbons of more restricted distribution (P. # Preparation and characterization of titanocene silyl hydrides $[Cp_2Ti(\mu\text{-}HSiH_2)]_2$ and $[Cp_2Ti(\mu\text{-}HSiH_2)(\mu\text{-}H)TiCp_2]$

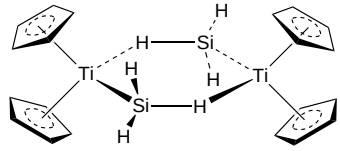
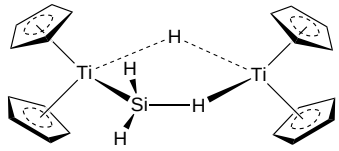
**Leijun Hao,[a] Anne-Marie Lebuis,[a] John F. Harrod*[a] and Edmond Samuel[b]**

[a] *Department of Chemistry, McGill University, Montreal, Canada H3A 2K6*
[b] *Laboratoire de Chimie Organométallique de l'ENSCP (URA 403 CNRS), 11 rue P. et M. Curie, 75005 Paris, France*



**The structure of a complex previously assigned as $[Cp_2Ti(\mu\text{-}SiH_2)]_2$ is shown to be $[Cp_2Ti(\mu\text{-}H\text{–}SiH_2)]_2$.**

Titanocene(IV) complexes containing a Ti–Si bond are extemely rare. To our knowledge, only three examples have been reported with convincing structural characterization.[1–3] We have previously reported the titanocene(III) hydrosilyl complexes $[Cp_2Ti(\mu\text{-}HSiHPh)]_2$ **1** and $[Cp_2Ti(\mu\text{-}HSiHPh)(\mu\text{-}H)TiCp_2]$ **2**, which are derived from intermediates in the polymerization of phenylsilane catalyzed by dimethyltitanocene (DMT).[4] The individual steps involved in the latter reaction are very complex and the mechanisms are still poorly understood.[5] Our experience in determining the structures of **1** and **2** sensitized us to the ease with which hydrogen atoms can be missed in the X-ray structures of such compounds. This in turn led us to consider the structure of $[Cp_2Ti(\mu\text{-}SiH_2)]_2$ **3**, reported two decades ago by Hencken and Weiss.[3]



Our interest in this question was rekindled recently by the isolation of the complex $[Cp_2Ti(\mu\text{-}HSiH_2)]_2$ **4**, from the reaction of dimethyltitanocene (DMT) with trialkoxysilanes. In this reaction, the DMT catalyses the extremely rapid redistribution of $(RO)_3SiH$, according to eqn. (1).[6] The $SiH_4$ produced then reacts further to give the titanocene(III) silyl complex.

$$4\ (RO)_3SiH \rightarrow SiH_4 + 3\ (RO)_4Si \qquad (1)$$

The reaction of DMT with excess, chlorine-free,† $(MeO)_3SiH$ or $(EtO)_3SiH$ in dry hexane under argon gives **4** in good yield as air- and moisture-sensitive dark blue crystals.‡ Solutions of **4** in benzene, or toluene, under an argon atmosphere at room temperature are stable for several hours, decomposing slowly to a new compound $[Cp_2Ti(\mu\text{-}HSiH_2)(\mu\text{-}H)TiCp_2]$ **5**.§ This decompostition was evident from changes in the $^1H$ NMR spectrum of the solution and from a color change from greenish blue to dark yellowish green. Essentially the same result was obtained by the direct reaction of $SiH_4$ with $Cp_2TiMe_2$.

**4**

**5**

Complex **4** was readily characterized by comparison of its $^1H$ NMR spectrum to that of the known complex **1**.[4] At both room temperature and low temperature, the $^1H$ NMR spectrum of **4** in $[^2H_8]$toluene shows a single resonance at $\delta$ 4.58 for all four Cp rings, owing to a plane of symmetry containing the two titanium atoms, two silicon atoms and two hydrides in the six-membered ring, and a $C_2$ axis perpendicular to and through the center of the six-membered ring. The bridging hydride resonance appears as a triplet at $\delta$ −10.07, owing to coupling with the terminal $SiH_2$ protons. A doublet at $\delta$ 4.69 is assigned to the terminal $SiH_2$ protons. Similarly, **5** was characterized by comparison of its $^1H$ NMR spectrum to that of **2**.[4] At ambient temperature, **5** gives a broad single resonance at $\delta$ 5.50 due to the four Cp ligands. However, upon lowering the temperature to −20 °C the resonance splits into two equal intensity peaks, and a high-field hydride resonance appears at $\delta$ −13.22 assignable to the Si–H–Ti proton.[4] The coalescence temperature for the Cp resonances is at *ca.* 0 °C. A second high-field hydride was observed at $\delta$ −19.32 at −60 °C assignable to the Ti–H–Ti proton.[4] Integration of this spectrum indicates the formula $[Cp_2Ti(\mu\text{-}HSiH_2)(\mu\text{-}H)TiCp_2]$.

$^1H$ NMR measurements on the product prepared by reaction of $[Cp_2TiCl_2]$ with $SiH_3K$, carefully following the published procedure,[3] gave the same $^1H$ NMR specrum as **4**, indicating that the product of this reaction is not the $SiH_2$-bridged titanocene(IV) dimer **3**, originally proposed, but the titanocene(III) silyl dimer **4**. This result is consistent with the reported single crystal X-ray structure analysis.[3] The reported *R* value was high (*ca.* 9%) and disordering of the Si–H bridges would make detection of the third hydrogen unlikely.¶

We are continuing attempts to make higher quality crystals of **4** and **5** for X-ray diffraction to unequivocally assign their solid state structures. Further investigation of the chemistry of **4** and **5** is also under way.

We thank NSERC (Canada) and the Fonds FCAR de Quebec for financial support.

† Most commercial samples of alkoxysilanes are adulterated with chlorosilanes to inhibit $SiH_4$ formation.

‡ $^1H$ NMR (200 MHz) data for **4** in $[^2H_8]$toluene: $\delta$ 4.69 [d, 4 H, $^2J$(HH) 5.4 Hz, $SiH_2$], 4.58 (s, 20 H, Cp), −10.07 [t, 2 H, $^2J$(HH) 5.4 Hz, SiHTi].

§ $^1H$ NMR (270 MHz) data for **5** in $[^2H_8]$toluene at 20 °C: $\delta$ 5.80 (br, 2 H, $SiH_2$), 5.50 (s, br, 20 H, Cp); at −20 °C, $\delta$ 5.65 (br, 1 H, SiH), 5.58 (s, br, 10 H, Cp), 5.41 (br, 1 H, SiH), 5.36 (s, br, 10 H, Cp), −13.22 (m, 1 H, SiHTi); at −60 °C, $\delta$ 5.64 (br, 1 H, SiH), 5.56 (s, br, 10 H, Cp), 5.38 (br, 1 H, SiH), 5.29 (s, 10 H, Cp) −13.3 (m, 1 H, SiHTi), −19.32 (m, 1 H, TiHTi).

¶ A problem with the reported structure is the extreme shortness of the Ti–Si bond (*ca.* 2.1 Å) compared to other values (ref. 2 and 4; *ca.* 2.5–2.7 Å) and the anomalously high temperature factor for the Si. Both of these problems disappear if it is assumed that the bridging group is OH, or O. The fact that the reported elemental analysis corresponds well to a product with an $SiH_2$ (or $SiH_3$) bridge, together with our NMR observations showing the presence of the $SIH_3$ bridged dimers in solution, suggests that the authors may have been unlucky in choosing a crystal of oxidized material.

# Sodium springs another surprise

**C. Dennis Hall,* Thi-Kim-Uyen Truong, James H. R. Tucker† and Jonathan W. Steed**

*Department of Chemistry, King's College London, Strand, London, UK WC2R 2LS*

**The X-ray crystallographic structures of the novel redox-active cryptand 1 and its homobinuclear complex with sodium perchlorate are reported and discussed.**

The synthesis, structure, electrochemistry and complex formation of cryptands containing metallocene units have attracted considerable attention in recent years.[1] A common synthetic procedure to the compounds involves the condensation of 1,1′-ferrocene bis-acid chloride with diazamacrocycles which generally produces a mixture of monomeric and dimeric cryptands containing amide functions.[2] All the available solution NMR data and X-ray crystallographic data show that the amide functions are disposed *trans* to each other.[3–5] Complex formation with a range of mono-, di- and tri-valent cations then involves rotation of the amide carbonyl groups to *cis* orientations which allows their coordination to the guest cation usually in conjunction with other oxygen atoms of the polyether chains or heterocyclic units within the macrocyclic structure.[6,7] Recent work has involved the synthesis of analogous cryptands incorporating nitrogen ligands in the form of phenanthroline units which also have the carbonyl groups within the host cryptand disposed *trans* to each other.[8,9] These cryptands were designed with the objective of complexing lanthanide cations in order to create redox-active luminescent cryptates and the work reported here represents an extension of this concept to the synthesis of the dimeric cryptand **1** containing four 2,2′-bipyridyl units.

**1**

Cryptand **1**‡ was synthesised in the usual way from ferrocene bis-acid chloride and the appropriate diamine, prepared by a modification§ of the literature procedure.[10] No trace of the monomeric species was found but a trimeric amide was separated and characterised.¶ The $^{13}C$ NMR of **1** in $CDCl_3$ showed a total of 16 signals consisting of four ferrocene C–H carbons, one carbonyl carbon, two $CH_2N$ signals, six CH bipyridyl signals and three quaternary bipyridyl signals. The *ipso*-ferrocene carbons and one of the quaternary bipyridyl carbons were not observed but the spectrum is consistent with a structure in which the carbonyl groups on each ferrocene unit are either *cis* or *trans* to each other. The $^1H$ NMR data were also consistent with this conclusion. The definitive evidence, however, is provided by the X-ray crystal structure of the cryptand (Fig. 1).‖ It is immediately obvious that the carbonyl groups, located on the periphery of the cryptand, are mutually *trans* to each other with two of the bipyridyl units on the outside of the cryptand virtually orthogonal to the two corresponding bipyridyl units filling the cavity. Thus π–π stacking interactions are minimal and the crystal adopts a configuration which appears to minimise the dipole moment and maximise close packing.

Downfield shifts of most of the $^1H$ NMR signals of **1** were indicative of complex formation with $Na^+$ but at NMR concentrations (*ca.* $5 \times 10^{-2}$ M) complexes with other cations (*e.g.* $Ca^{2+}$ or $Eu^{3+}$) precipitated thus making it difficult to achieve a complete NMR analysis of the latter cryptates which is still in hand. The sodium complex was sufficiently soluble, however, to achieve a full analysis (by 2D NMR) and in summary, twice as many $^{13}C$ signals were observed in the complex as in the parent compound, a result which is entirely consistent with the crystal structure reported below. The binuclear sodium perchlorate complex of **1** crystallised from $CH_2Cl_2$–MeCN solution and the resultant single crystal was found to contain four molecules of solvent acetonitrile per molecule of the complex. Far more interestingly however, X-ray crystallography revealed the two sodium cations each bound in a centrosymmetrical structure by the four bipyridyl nitrogen atoms of one macrocyclic ring and one carbonyl oxygen of the other macrocyclic system in an approximate square pyramidal configuration (Fig. 2). Each uncomplexed amide function remained *trans* to its partner but was not involved in binding the cation. The sodium–nitrogen bond distances varied from 2.373(7) to 2.579(7) Å and the Na–O distance was unusually short at 2.191(6) Å. The N–Na–N bond angles in the square pyramid varied from 67.7(2) to 84.8(2)° and the O–Na–N bond angles from 105.2(2) to 136.0(2)°. The configuration achieved in the crystal enabled all the amide groups to remain planar and in the plane of the cyclopentadienyl rings in each case. This

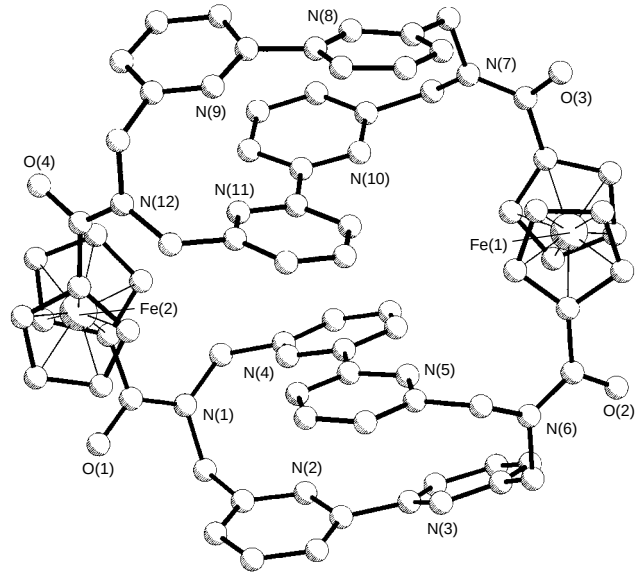

**Fig. 1** X-Ray crystallographic structure of ligand **1** showing all four amide carbonyl bonds *trans* relative to each other

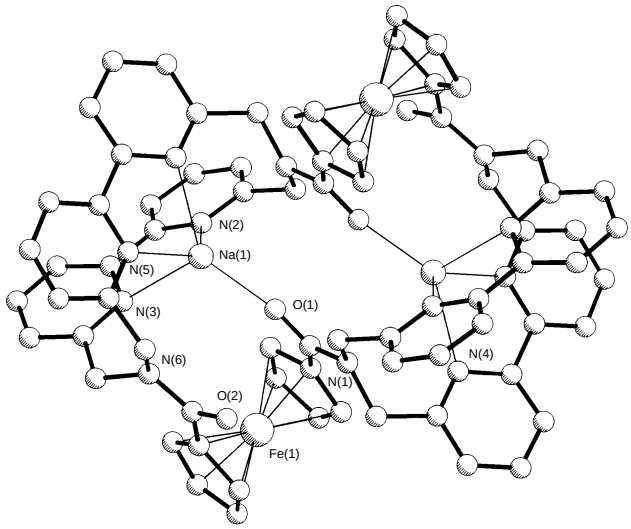

**Fig. 2** X-Ray crystallographic structure of the homo-binuclear complex of **1** with sodium perchlorate (counter-ions not included)

leaves a distance of 5.57 Å between the complexed sodium cations, a feature which should enable a suitable anion (*e.g* cyanate) or dianion (*e.g.* oxalate) to be accommodated within the cleft of the cryptate. This aspect of the complexation will be the subject of future work. The perchlorate counter ions are a considerable distance from the sodium cations with the nearest Na···Cl distance of $ClO_4$ at 7.88 Å and the nearest Na···O distance of $ClO_4$ at 6.66 Å. This confirms that the sodium cations are fully encapsulated by the cryptand which should therefore be effective as a redox-active phase transfer host. Finally, the highly unusual feature of sodium a 'hard' cation, complexed by four pyridyl nitrogens and an amide carbonyl oxygen in a five-coordinate square pyramidal configuration should be addressed. Preorganized rather than predisposed oligopyridine ligands are known to form helical complexes with sodium cations,[11,12] and macrocycles or cryptands containing phenanthroline[13] or bipyridyl[14] units are also known to complex sodium albeit in the latter case as a cryptatium species. There are very few examples, however, of sodium complexed by four nitrogen and one oxygen donor atoms and none in which the configuration of the complex is a square pyramid. Nelson and coworkers have characterised a mononuclear cryptate with a distorted trigonal bipyramidal configuration about the sodium composed of four nitrogen donors and a water molecule situated in an equatorial position.[15] The Na–N bond length varies from 2.520 to 2.636 Å and the Na–O distance is 2.241 Å significantly longer than that observed in the cryptate from **1**. It seems that sodium is indeed capable of more than one surprise.[11]

We thank King's College London for a Junior Research Studentship (to T.-K.-U. T.) and for financial support in purchasing X-ray equipment. Thanks are also due to Jane Hawkes and Jon Cobb (KCL/ULIRS) for NMR data and Dr K. Welham (School of Pharmacy/ULIRS) for mass spectra.

‖ *Crystal data* for **1**. $C_{74}H_{60}Cl_4Fe_2N_{12}O_4$, $M$ = 1434.84, monoclinic, space group $P2_1/n$, $a$ = 14.450(1), $b$ = 28.621(1), $c$ = 16.181(1) Å, $\beta$ = 103.05(1), $U$ = 6517.51(6) Å$^3$, $Z$ = 4, $D_c$ = 1.462 Mg m$^{-3}$, $\mu$ = 0.67 mm$^{-1}$, $T$ = 293(2) K, 9856 unique reflections.

Refinement converged with $wR_2$ = 0.2278, which corresponds to a conventional $R$-factor of 0.081 for data with $I > 2\sigma(I)$.

*Crystal data* for the Na complex of **1**. $C_{72}H_{56}Fe_2N_{12}O_4{\cdot}2NaClO_4{\cdot}4CH_3CN$, $M$ = 1674.08, monoclinic, space group $P2_1/c$, $a$ = 9.3880(2), $b$ = 29.2720(8), $c$ = 13.2400(4) Å, $\beta$ = 97.895(1), $U$ = 3603.9(2) Å$^3$, $Z$ = 2, $D_c$ = 1.543 Mg m$^{-3}$, $\mu$ = 0.57 mm$^{-1}$, $T$ = 293(2) K, 3604 unique reflections.

*Experimental*: orange prismatic crystals (0.4 × 0.1 × 0.1 mm) were prepared by slow evaporation of an MeCN–$CH_2Cl_2$ solution of the compound (as the triflate salt) in the presence of excess $NBu_4ClO_4$ and mounted on a thin glass fibre using a fast setting epoxy resin. A total of 360 oscillation frames of 45 s exposure time with 0.5° rotation in $\phi$ were recorded using a Nonius Kappa CCD diffractometer, with a detector to crystal distance of 35 mm. The crystal was indexed from the first ten frames using the DENZO package[16] and positional data were refined along with diffractometer constants to give the final unit cell parameters. Integration and scaling of the whole data set resulted in a total of 3604 unique data which were corrected for Lorentz and polarisation effects and were used in subsequent refinement. The structure was solved using the direct methods option of SHELXS-86[17] and developed *via* alternating least squares cycles and difference Fourier synthesis (SHELXL-93).[18] All non-hydrogen atoms were modelled anisotropically except those of the two disordered molecules of acetonitrile and the oxygen atoms of the disordered perchlorate. Hydrogen atoms are assigned an isotropic thermal parameter 1.2 times that of the parent atom and allowed to ride. Hydrogen atoms were not included for the acetonitrile solvent molecules within the lattice as a consequence of their severely disordered nature. This disorder was eventually modelled in terms of a total of twelve different atom positions with refined occupancies ranging from 1.0 to 0.25. Even this model proved chemically unsatisfactory but since the solvent exhibits no significant interactions with the complex it was accepted as giving the best fit to the diffraction data. The disorder of the perchlorate anion was successfully modelled in terms of rotation about the Cl(1)–O(40) axis resulting in a total of nine different positions for the three oxygen atoms. Refinement converged with $wR_2$ = 0.2533, which corresponds to a conventional $R$-factor of 0.077 for data with $I > 2\sigma(I)$. CCDC 182/619.

# Novel ionogenic heterometal alkoxide derivatives

**Michael Veith,* Sanjay Mathur* and Volker Huch**

*Institute of Inorganic Chemistry, University of Saarland, D-66041 Saarbrücken, Germany*

**First examples of hydrocarbon soluble heterometal cation–anion systems containing metal alkoxide clusters as isolated ions, are reported.**

Although a few cationic alkoxides of yttrium against non-metallic counter ion $BPh_4^-$ have been reported,[1] the cation–anion systems based on different metals and discrete ions are unprecedented in heterometal alkoxide chemistry.[2] In view of the above, the title derivatives containing separated poly-metallic alkoxide ions, as solution and solid-state stable species, represent a new subset in alkoxide chemistry.

The equimolar interaction of $SnI_4$ with $KTi(OPr^i)_5$[2e] or $KTi_2(OPr^i)_9$[2c] in toluene–isopropyl alcohol, followed by removal of precipitated KI and leaving the deep orange solution at room temperature for a few hours, leads to crystallisation of the only isolable ionic complex $[\{Ti_3(OPr^i)_{11}\}^+][\{Sn_2I_6(OPr^i)_3\}^-]$ **1**, in both cases. **1** could be obtained in higher yield by the reaction of $SnI_4$, $KOPr^i$ and $Ti(OPr^i)_4$ in 2 : 2 : 3 molar ratio.†

The solid-state structure‡ of **1** consists of distinct $\{Ti_3(OPr^i)_{11}\}^+$ cations and $\{Sn_2I_6(OPr^i)_3\}^-$ anions (Fig. 1). The trinuclear cation, $Ti_3(OPr^i)_{11}^+$ is formed by three edge-sharing distorted octahedra, built about Ti(1), Ti(2) and Ti(3), which are also mutually confacial. The trimetallic $Ti_3$ core forms an equilateral triangle (non-bonding Ti···Ti distances = 3.082 Å) capped at both the faces by triply bridging $\mu_3$-$OPr^i$ ligands [O(8), O(9)], while the three doubly bridging $\mu$-$OPr^i$ ligands [O(6), O(7), O(12)] bridge the edges of the triangular frame. The cationic unit in **1** is a modification of the $M_3X_{11}$ structure type, well known among trimetallic alkoxides of the general formula $M_3(O)(OR)_{10}$.[3,4] Whereas one of the eleven ligands in $M_3O(OR)_{10}$ derivatives is dianionic ($O^{2-}$), the presence of only univalent anions in $Ti_3X_{11}$ unit produces a cationic species which acts as a stable entity due to the preferred six-coordination achieved by all the Ti atoms. The Ti–O bond lengths follow the trend $\mu_3$-$OPr^i$ (2.157 Å) > $\mu$-$OPr^i$ (2.044 Å) > terminal-$OPr^i$ (1.753 Å) and are in harmony with Ti–O bond lengths observed in molecular titanium isopropoxide derivatives.[2c,5] The anionic part in **1** is a bioctahedron formed by the two octahedral tin atoms [Sn(1), Sn(2)] sharing a face defined by the oxygen atoms of $\mu$-$OPr^i$ groups [O(1), O(2), O(3)]. It can be visualised as a modification of cluster anion $M_2(OPr^i)_9^-$ (M = Sn,[6] Ti,[2c] Zr,[2a] Hf,[2e]) observed as a versatile chelating metallo-ligand in a variety of hetero bi- and tri-metallic alkoxides. The Sn–I distances (av. 2.765 Å) are comparable with the Sn–I contacts observed in the crystal structures[7] of non-ionic compounds $[I_2Sn\{Ti(OPr^i)_5\}_2]$ (2.778 Å), $[I_2Sn\{Al(OPr^i)_4\}_2]$ (2.736 Å) and $[I_3Sn\{Zr(OPr^i)_5\text{-}(Pr^iOH)\}]$ (2.774 Å). It is noteworthy that bonding parameters of both the ions in **1** show no significant deviation when compared with analogous molecular compounds. The ambient-temperature $^1H$ NMR spectrum§ of **1** exhibits methyl resonances in the integrated ratio 6 : 3 : 3 : 2 which is consistent with the total number of alkoxide ligands observed in the solid-state structure; the methine protons are observed as several associated septets which overlap to give four multiplets in approximate intensity ratio 6 : 2 : 4 : 2. The solution $^{13}C$ NMR data corroborates the above observation. Although all the $OPr^i$ ligands in the solid-state structure of **1** are unique, the solid-state $^{13}C$ CP MAS NMR spectrum reveals only six signals of relative intensities 6 : 3 : 2 : 1 : 1 : 1, which possibly occur from an accidental overlapping of some of the alkoxy ligands [*e.g.* 6 terminal, 3 $\mu$- and 2 $\mu_3$-$OPr^i$ groups in $Ti_3(OPr^i)_{11}^+$], resonating at almost similar frequencies. The presence of a tin(IV)-based anionic species in the solution of **1** is evident in the significant lower frequency shift of the $^{119}Sn$ resonance ($\delta$ −1734.7) when compared with the $^{119}Sn$ NMR chemical shifts observed for neutral iodo-functionalised alkoxides $\{[I_2Sn\{Ti(OPr^i)_5\}_2]$, $\delta$ −1245.0; $[I_2Sn\{Al(OPr^i)_4\}_2]$, $\delta$ −1540.7$\}$ which also contain six-coordinate tin(IV) centers in an environment of terminal iodide and bridging isopropoxide ligands.[7] Various attempts to record a $^{119}Sn$ CP MAS NMR spectrum were thwarted by low signal to noise ratio which precluded an unambiguous assignment of anisotropic shifts.

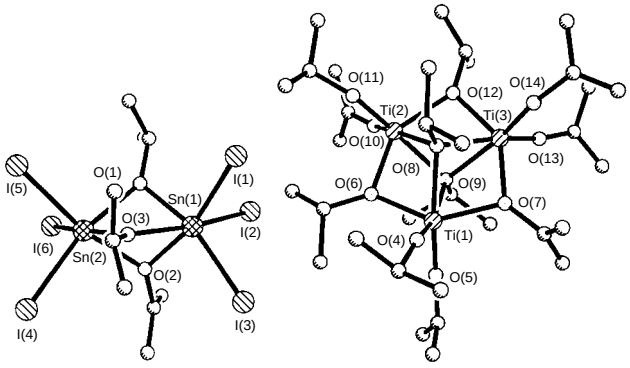

**Fig. 1** Crystal structure of **1**. Hydrogen atoms of isopropyl moieties are not drawn. Representative bond lengths (Å) and angles (°): Sn(1)–O(2) 2.104(8), Sn(1)–O(1) 2.108(9), Sn(1)–O(3) 2.164(8), Sn(2)–O(1) 2.119(8), Sn(2)–O(2) 2.140(9), Sn(2)–O(3) 2.103(8), Sn–I(1) 2.779(2), Sn–I(2) 2.776(2), Sn–I(3) 2.742(2); O(1)–Sn(1)–I(3) 164.8(2), O(2)–Sn(1)–I(2) 97.0(2), O(3)–Sn(1)–I(1) 97.8(2), I(2)–Sn(1)–I(3) 95.45(6), I(1)–Sn(1)–I(2) 93.39(5), I(1)–Sn(1)–O(1) 95.4(2), O(6)–Ti(1)–O(7) 140.7(3), O(5)–Ti(1)–O(9) 98.3(4), O(4)–Ti(1)–O(9) 162.3(3), O(4)–Ti(1)–O(5) 99.2(4), O(4)–Ti(1)–O(6) 100.6(4), O(4)–Ti(1)–O(8) 93.7(3).

The unique arrangement of large bi- and tri-metallic alkoxide clusters as distinct ions in **1**, inspired us to explore similar systems. Ionogenic heterometal alkoxide derivatives could be rationally constructed by abstracting halide ligand from the well defined heteroleptic heterometal alkoxides [eqn. (1)].

$$[ClSn\{M_2(OPr^i)_9\}]_2 + 2\ SnCl_2 \xrightarrow{\text{toluene}} 2\ [\{SnM_2(OPr^i)_9\}^+][SnCl_3^-] \quad (1)$$

M = Ti **2** M = Ti **4**
M = Zr **3** M = Zr **5**

The halide heterobimetallic precursors, **2** and **3** are obtained in nearly quantitative yields on treating anhydrous $SnCl_2$ with stoichiometric amount of alkali metal reagent $KM_2(OPr^i)_9$ (M = Ti, Zr[8]). Both **2** and **3** react [eqn. (1)] with 1 equiv. of $SnCl_2$ to afford **4** and **5**, respectively. In contrast to the fluxional behaviour of **3**, which could not be frozen to a static structure at even −70 °C, the room. temp. spectral data of **5** are structurally diagnostic. Both $^1H$ and $^{13}C$ NMR spectra show 4 : 2 : 1 : 2 pattern of resonances, characteristically observed for hetero-bimetallic alkoxides based on tetradentate interaction of the

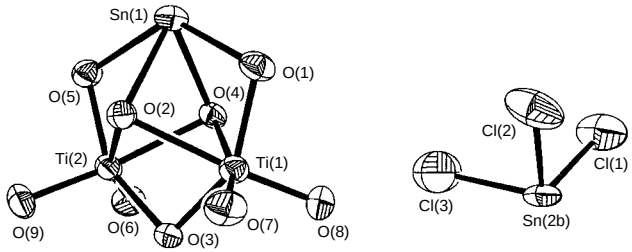

**Fig. 2** An ORTEP diagram of **4**. Displacement ellipsoids are drawn at 30% probability levels. $SnCl_3^-$ unit shows only one of the partially occupied tin sites. All oxygen atoms bear isopropyl groups which are not drawn from clarity. Pertinent bond lengths (Å) and angles (°): Sn(1)–O(1) 2.321(4), Sn(1)–O(2) 2.214(4), Sn(1)–O(4) 2.164(4), Sn(1)–O(5) 2.422(4), Ti(1)–O(3) 2.014(4), Ti(2)–O(3) 2.027(3), Ti(1)–O(8) 1.755(4); O(5)–Sn(1)–O(1) 131.58(12), Sn(1)–O(4)–Ti(1) 94.19(13), Ti(1)–O(1)–Sn(1) 97.7(2), Sn(1)–O(2)–Ti(1) 92.54(14), Ti(1)–O(3)–Ti(2) 102.7(2). Sn–Cl bond lengths and Cl–Sn–Cl angles in the $SnCl_3^-$ unit are in the range 2.329–2.488 Å and 93.1–99.4°, respectively.

bioctahedral $M_2(OPr^i)_9^-$ alkoxide sub-structure with a cationic fragment and possessing molecular $C_{2v}$ symmetry in solution.[2b,c] The $^{119}Sn$ NMR spectrum of **5** exhibits two resonances at $\delta$ −180.29 and −297.41 which according to the published data indicate the presence of two tin(II) species with coordination number at tin differing by one.[9] Ambient-temperature NMR data¶ of compound **4** shows a non-rigid behaviour, however, cooling a [$^2H_8$]toluene solution to −40 °C results in a static structure with spectral features essentially similar to that of **5**. The $^{119}Sn$ NMR chemical shifts ($\delta$ −147.2 and −281.3), similar to that observed for **5**, indicate a compositional similarity among the tin(II) species present in the solutions of both **4** and **5**.

The formulation of **4** and **5** suggested on the basis of spectroscopic and analytical data was established for **4**, by X-ray crystallography.‡ The crystal structure consists of discrete $\{SnTi_2(OPr^i)_9\}^+$ cation and $SnCl_3^-$ anion (Fig. 2). The heterobimetallic fragment based on the interaction of monoanionic $\{Ti_2(OPr^i)_9\}^-$ unit to $Sn^{2+}$, is of special interest as no $Sn^{II}Ti^{IV}$ mixed-metal species is formed in the reaction of neutral constituent alkoxides.[9b] Curiously, all the four alkoxide arms of $Ti_2(OPr^i)_9^-$ unit are used to cradle $Sn^{2+}$ in the $Sn\{Ti_2(OPr^i)_9\}^+$ unit, whereas only bidentate interaction of $\{M_2(OPr^i)_9\}^-$ moieties toward an $SnCl^+$ fragment is observed in $[ClSn\{M_2(OPr^i)_9\}]_2$ (M = Zr, Hf) derivatives.[8] The tin atom, in both cases, is present in a pseudotrigonal bipyramidal geometry. Whereas the lone pair of electrons occupies an equatorial position in the $SnTi_2(OPr^i)_9^+$ unit, the presence of a terminal halide ligand at tin in $[XSn\{M_2(OPr^i)_9\}]_2$ compounds[8] directs the lone pair of electrons to an axial position which inhibits the coordination of remaining isopropoxy ligands to tin(II).[6,8]

The 'bare' coordination hemisphere of tin(II) atom (no terminal ligands) makes the $Sn\{Ti_2(OPr^i)_9\}^+$ unit comparable, in a structural sense, with the molecular derivatives $K\{U_2(OBu^t)_9\}$[10] and $Na\{Th_2(OBu^t)_9\}$,[4] in which the alkali metals are devoid of any terminal ligands. Further, the Sn–$\mu_3$-OR (av. 2.189 Å) distances are significantly shorter than Sn–$\mu$-OR contacts which contrasts the usual trend ($\mu_3$-OR > $\mu$-OR > terminal OR) observed among $M'M_2$ heterobimetallic alkoxides containing a $M_2X_9^-$ unit. The repulsive forces between the Sn–O bonding electrons and the tin(II) electron lone pair along with the geometric constraints of the bioctahedral $Ti_2(OPr^i)_9^-$ unit result in a strained pseudotrigonal bipyramidal geometry at the tin center [O(2)–Sn(1)–O(4) 67.44(12)°, O(1)–Sn(1)–O(5) 131.58(12)°]. The ligand geometry about tin in $SnCl_3^-$ anion is trigonal pyramidal implying a stereochemically active lone pair; the tin atom, in the crystal structure, is disordered at two sites with partial site occupancy factors 0.66 : 0.34 [Sn(2A): Sn(2B)]. The Sn–Cl distances (av. 2.427 Å) fall in the range typically observed for $SnCl_3^-$ species.

This work was supported by the German Science Foundation (research programme SFB-277) and the Alexander von Humboldt Foundation, Germany.

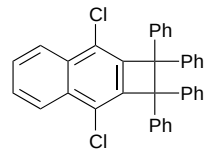
# Consistencies between experiments and quantum calculations of strained C–C single bond lengths

**Cheol Ho Choi and Miklos Kertesz***

*Department of Chemistry, Georgetown University, Washington, DC 20057-1227, USA*

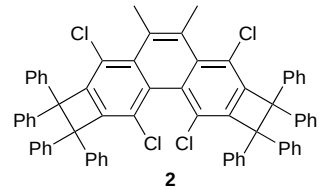
**Modern electron correlated methods can accurately predict the unusually stretched C–C single bond lengths substantiating experimental structural information.**

Typical covalent bond lengths, such as 1.54 Å for C–C single bonds[1] have been one of the fundamental parameters in chemistry. At the same time, the possibility of unusually long C–C bond lengths has attracted much attention for its challenging nature raising the questions: is there an upper limit to the length of a stretched C–C single bond?



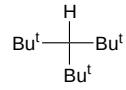
Recently, Toda *et al.*[2] have reported unusually long C–C bond lengths such as 1.720(4) Å in **1**, and 1.710(5) as well as 1.724(5) Å in **2**. They are considered the longest C–C single bonds accurately determined to date.[3] However, semiempirical methods have underestimated the length of the long bond in **1** by about 0.05 Å showing that special bonding effects exist that are not suitably covered by the current semiempirical parameters.[2]

In order to resolve these discrepancies between experiments and theories, full geometry optimizations[4] based on Hartree–Fock (HF) and density functional theory (DFT)[5] have been performed on **1**, as well as on other representative molecules (**3**, **4**, **5**) having strained long C–C bonds. Becke's 1988 (B)[6] and his three parameter hybrid (B3)[7] functionals incorporating exact exchange were used as gradient-corrected density functionals in combination with the Lee, Yang, and Parr (LYP)[8] correlation functional in the calculations.



Hagler *et al.*[9] have shown that high-level quantum calculations, including HF and DFT in combination with available gas electron diffraction data, can assign a unique structure of **3** in which C–C bond length between the center methane carbon and that of a *tert*-butyl group is as long as 1.622(6) Å[10] (see Table 1). It can be seen that while HF slightly underestimates and BLYP overestimates the stretched bond length in **3**, our B3LYP/6-31G* calculation agrees perfectly with experiment.

The crystal structure of **4** has been refined by Choi and Marinkas[11] at room temperature and by Abboud *et al.*[12] at 198 K. They have shown that its two bridge bonds connecting the two anthracene components are 1.624[11] and 1.618(3)[12] Å, respectively. MNDO calculations[13] underestimate this long single bond by 0.04 Å. Again, while the B3LYP value is in perfect agreement with the experimental long C–C single bond length, HF underestimates and BLYP overestimates it. The same trend can also be found in the calculations for **5**. The C–C bond length, 1.77 Å for the two bridging bonds of **5** determined by Ehrenberg[14] has been disputed by several studies.[13,15] They have concluded that Ehrenberg had investigated a mixture of two photodimers[13] and found the bond lengths to be 1.663(4)[15*a*] and 1.648(3)[15*b*] in their X-ray diffraction studies. Our B3LYP/6-31G* calculation as well as the earlier two DFT calculations are in excellent agreement with Harata *et al.*'s experiment. However, BLYP/6-31G* calculation overestimates it by 0.035 Å.



The overlong C–C bond length in **1** as calculated with B3LYP/6-31G* is in very good agreement with experiment showing excellent consistency between experiment and modern quantum calculations. The fact that HF systematically underestimates the stretched single C–C bond lengths indicates that

electron correlation effects in describing the lengthened bonds are essential. Since extreme bond lengthening is accompanied by large changes in electron correlation at the beginning of bond breaking, the underestimation of the bond length by HF is not surprising. Furthermore, our results show that incorporating the exact exchange term *via* Becke's three parameter methods (B3) is also very important to obtain accurate results in these kinds of chemical bonds.

In summary, on the basis of first principle calculations, the existence of the unusually long bond length of **1** has been further substantiated. The consistencies between experiments and modern quantum calculations have been demonstrated by comparing four representative molecules. It is clearly seen that electron correlation effects have to be included in the calculations to correctly describe lengthened bonds.[16]

We thank the National Science Foundation (CHE-9601976) for support and the National Center for Supercomputing Applications (NCSA, No. DMR-950029N) for the use of supercomputing facilities. An interdisciplinary grant from Georgetown University for support the Georgetown Molecular Modeling Center is also acknowledged.

# Novel low-valent zirconium porphyrin complexes: syntheses, characterization and X-ray crystal structures of ($\eta^5$-cyclopentadienyl)zirconium tetraphenylporphyrin and ($\eta^2$-diphenylacetylene)zirconium octaethylporphyrin

**Hee-Joon Kim, Sungkyung Jung, You-Moon Jeon, Dongmok Whang and Kimoon Kim***

*Department of Chemistry and Center for Biofunctional Molecules, Pohang University of Science and Technology, San 31 Hyojadong, Pohang 790-784, South Korea*

**Reactions of (por)$ZrCl_2$ [por = octaethylporphyrinato (oep) or tetraphenylporphyrinato (tpp) dianion] with TlCp and diphenylacetylene in the presence of Na/Hg or Mg produce novel low-valent zirconium porphyrin complexes (por)Zr($\eta^5$-Cp) 1 and (por)Zr($\eta^2$-PhC≡CPh) 2, respectively; spectroscopic and/or structural data for 1 and 2 are consistent with a formalism in which 1 is a resonance hybrid of a zirconium(III) metal-centered radical and a zirconium(IV) porphyrin radical anion while 2 is a zirconium(II) complex stabilized by a four-electron-donor alkyne ligand.**

Low-valent zirconium complexes have led to the development of novel routes to the functionalization of unsaturated organic molecules.[1] For example, zirconium(II) compounds have proved to be effective in converting a variety of enynes and diynes into the corresponding zirconabicycles in zirconocene chemistry.[2] We and others have been interested in development of zirconium porphyrin chemistry which has been, however, mainly focused on high-valent zirconium(IV) complexes.[3–5] In fact, there is no well characterized zirconium-(III) or -(II) porphyrin complex except for (oep)$ZrCH_2SiMe_3$.[3e] Extremely high sensitivity to air and moisture of such low-valent zirconium porphyrin complexes makes their synthesis and characterization challenging. Here we report the syntheses, characterization and X-ray crystal structures of the novel zirconium-(III) and -(II) porphyrin complexes (tpp)Zr($\eta^5$-Cp) **1** and (oep)Zr($\eta^2$-PhC≡CPh) **2**. The former is only the second example of formally zirconium(III) porphyrin complexes and the latter is the first zirconium(II) porphyrin complex.†

The cyclopentadienyl complex (tpp)Zr($\eta^5$-Cp) **1** was first obtained from the reaction of [(tpp)Zr(C≡CPh)$_3$][Li(thf)] **3**[6] and $Cp_2Ti(Me_3SiC{\equiv}CSiMe_3)$ **4** in toluene [eqn. (1)].[6]

$$\underset{\mathbf{3}}{[(tpp)Zr(C{\equiv}CPh)_3][Li(thf)]} + \underset{\mathbf{4}}{Cp_2Ti(Me_3SiC{\equiv}CSiMe_3)} \rightarrow \underset{\mathbf{1}}{(tpp)Zr(\eta^5\text{-}Cp)} + [Cp_2Ti(C{\equiv}CPh)]_2 + \textit{etc.} \quad (1)$$

Complex **1** can also be synthesized directly by reacting (tpp)$ZrCl_2$ with TlCp in the presence of Na/Hg [eqn. (2)].‡

$$(tpp)ZrCl_2 + TlCp + Na/Hg \rightarrow (tpp)Zr(Cp) \quad (2)$$

Complex **1** is paramagnetic as indicated by its broad $^1$H NMR peaks at $\delta$ 22.6, 11.0, 0.6 and −5.0. The mass spectrum of **1** shows a cluster of peaks centered at *m/z* 767.1 corresponding to the molecular mass of **1**. The structure of **1** was characterized by single crystal X-ray diffraction (Fig. 1).§ The zirconium ion is coordinated by the four nitrogen atoms of tpp and the $\eta^5$-Cp ligand in a sandwich fashion with the average Zr–N, and Zr–C bond distances being 2.177(10) and 2.49(2) Å, respectively. The four-nitrogen plane and the Cp plane are parallel (dihedral angle, 0.9°). The zirconium atom is 0.773(5) Å displaced out of the four nitrogen plane, and 2.206(6) Å away from the centroid of the Cp ligand. These values are almost the same as those found in (oep)Sc(Cp) (0.80 and 2.196 Å, respectively).[7]

The EPR spectrum of **1** in thf at 77 K is very similar to that of (oep)$ZrCH_2SiMe_3$;[3e] it shows a signal typical of a metal-centered radical, with $g_\perp$ = 2.004 and $g_\parallel$ = 1.991 but with no $^{14}$N hyperfine splitting. However, an isotropic signal with $g$ = 2.001, typical of an organic radical, is observed at room temperature. The electronic absorption spectrum of **1** recorded at room temperature exhibits a broad band centered at *ca*. 638 nm which is characteristic for a porphyrin anion radical. The electronic structure of **1** is therefore best described as a resonance hybrid of a zirconium(III) metal-centered radical and a zirconium(IV) porphyrin radical anion, as in the case of (oep)$ZrCH_2SiMe_3$.[3e]

The diphenylacetylene complex (oep)Zr($\eta^2$-PhC≡CPh) **2** was synthesized from the reduction of (oep)$ZrCl_2$ with equimolar amounts of magnesium in the presence of PhC≡CPh in thf at room temperature [eqn. (3)].‡

$$(oep)ZrCl_2 + PhC{\equiv}CPh + Mg \rightarrow (oep)Zr(\eta^2\text{-}PhC{\equiv}CPh) \quad (3)$$

Product **2** is diamagnetic exhibiting sharp $^1$H NMR signals. The $^1$H NMR spectrum of **2** is similar to that of the Ti analogue (oep)Ti($\eta^2$-PhC≡CPh).[8] The C≡C stretching frequency in **2** observed at 1697 cm$^{-1}$ is also similar to that of the Ti analogue (1701 cm$^{-1}$). The $\eta^2$-coordination of the alkyne ligand in **2** has been confirmed by X-ray crystallography (Fig. 2).§

The overall appearance of the molecular structure of **2** resembles that of (oep)Ti($\eta^2$-PhC≡CPh).[8] A crystallographic two-fold rotation axis passes through the Zr atom and the midpoint of the alkyne C–C bond. The geometry around the Zr atom is square pyramidal, with the four pyrrole nitrogens forming the basal plane and the alkyne triple bond at the apical position. All the metal to ligands distances, Zr–C [2.160(4) Å] and Zr–N [2.203(4), 2.205(4) Å] distances, are longer than the corresponding values for (oep)Ti($\eta^2$-PhC≡CPh) [Ti–C 2.016(5), 2.015(5) Å; Ti–N 2.083(8)–2.099(7) Å] apparently due to the larger ionic radius of Zr than that of Ti. The metal atom is displaced 0.90 Å out of the mean 24-atom porphyrin plane, which is larger than in the Ti analogue (0.54 Å). The alkyne C–C distance [1.333(8) Å] is comparable to that in the Ti complex [1.30(1) Å]. The bending of the alkyne ligand [C(19′)–C(19)-C(20) 133.4(3)°] is more severe than that (143°) in (oep)Ti($\eta^2$-PhC≡CPh).

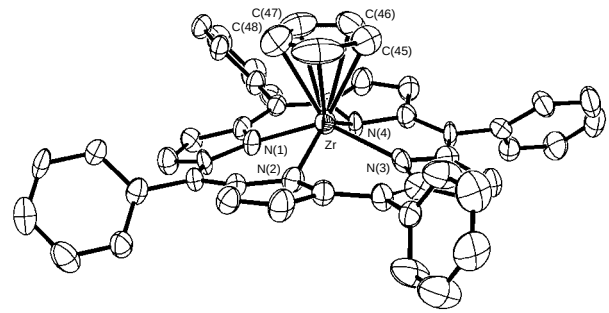

**Fig. 1** X-Ray crystal structure of (tpp)Zr($\eta^5$-Cp) **1**. Selected bond distances (Å): Zr–N(1) 2.183(10), Zr–N(2) 2.190(10), Zr–N(3) 2.169(10), Zr–N(4) 2.166(10), Zr–C(45) 2.47(2), Zr–C(46) 2.51(2), Zr–C(47) 2.50(1), Zr–C(48) 2.47(2), Zr–C(49) 2.50(1).

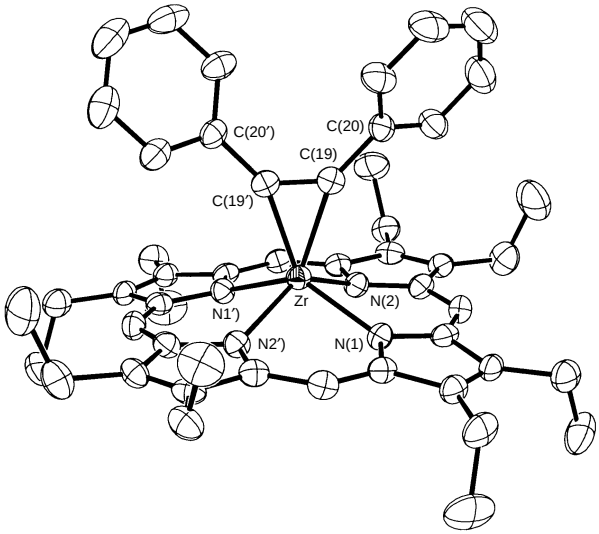

**Fig. 2** X-Ray crystal structure of (oep)Zr($\eta^2$-PhC≡CPh) **2**. Selected bond distances (Å) and angles (°) for **2**: Zr–C(19) 2.160(4), Zr–N(1) 2.203(4), Zr–N(2) 2.205(4), C(19)–C(19′) 1.333(8), C(19′)–C(19)–C(20) 133.4(3), N(1)–Zr-N(1′) 138.0(2), N(1)–Zr–N(2), 83.90(14).

Comparison of (oep)Zr($\eta^2$-PhC≡CPh) **2** with $Cp_2Zr(\eta^2$-PhC≡CPh)$(PMe_3)$[9] supports that the alkyne ligand in **2** behaves as a four-electron donor. According to the 18-electron rule the alkyne ligand is formally a two-electron donor in $Cp_2Zr(\eta^2$-PhC≡CPh)$(PMe_3)$. The longer Zr–C distances [2.20(4), 2.25(4) Å] in $Cp_2Zr(\eta^2$-PhC≡CPh)$(PMe_3)$ are in accord with this formalism. The $^{13}$C chemical shifts for the alkyne carbons in the two complexes are consistent with a two-electron-donor alkyne ($\delta$ 141.61, 156.42) in $Cp_2Zr(\eta^2$-PhC≡CPh)$(PMe_3)$ and a four-electron-donor alkyne ($\delta$ 218.4) in **2**.[10] Taking these into account, the alkyne complex **2** is best described as a zirconium(II) porphyrin complex stabilized by the $\eta^2$ four-electron $\pi$-donor ligand.

Preliminary reactivity studies of **2** also support the $Zr^{II}$ formalism. Stirring a [$^2H_8$]thf solution of **2** for several hours results in a change to brown. The $^1$H NMR spectrum of the resulting solution shows only sharp peaks corresponding to free diphenylacetylene with a broad background. This indicates that the diphenylacetylene ligand is displaced by thf to generate a paramagnetic zirconium porphyrin complex, which has not been fully characterized. When the solvent is removed by evaporation and the residue is taken up in $C_6D_6$ the original complex **2** is recovered as indicated by $^1$H NMR spectroscopy.

In summary, we have synthesized and characterized novel low-valent zirconium porphyrin complexes (tpp)Zr($\eta^5$-Cp) **1** and (oep)Zr($\eta^2$-PhC≡CPh) **2**. Spectroscopic and/or structural data for **1** and **2** are consistent with a formalism in which **1** is a resonance hybrid of a zirconium(III) metal-centered radical and a zirconium(IV) porphyrin radical anion while **2** is a zirconium(II) complex stabilized by a four-electron-donor alkyne ligand. Further studies on the reactivities of these novel complexes and their utilities in organic and organometallic syntheses are underway.

This work was supported by the Korea Research Foundation (Non Directed Research Fund, 1996) and in part by Center for Biofunctional Molecules.

† Generation of a zirconium(II) porphyrin by photolysis of (tpp)$ZrMe_2$ has been clamed.[5b] However, neither its isolation nor characterization was reported to substantiate the claim.

‡ (tpp)Zr($\eta^5$-Cp) **1**: in a glove box a mixture of (tpp)$ZrCl_2$ (144 mg, 0.19 mmol), TlCp (75 mg, 0.28 mmol) and 6% Na/Hg (150 mg, 0.39 mmol) in thf (*ca*. 25 ml) was stirred for 1 d at room temp. After the solvent was removed *in vacuo*, the residue was taken up with diethyl ether. Insoluble salts were removed by filtration and the filtrate was concentrated to *ca*. 5 ml under reduced pressure. The violet crystalline product was filtered and dried *in vacuo* (110 mg, 77%). $^1$H NMR ($C_6D_6$): $\delta$ 22.6 (br s, 5 H, Cp), 11.0 (br s, 8 H, $H_\beta$), 0.6 (br s, 8 H, Ph), −5.0 (br s, 12 H, Ph). UV–VIS (toluene): $\lambda_{max}$ (log $\varepsilon$) 420 (4.76), 456 (4.10), 544 (3.10), 638 (3.43), 734 (2.91) nm. EPR (thf, 77 K): $g_\perp$ = 2.004, $g_\parallel$ = 1.991; (thf, 298 K) $g$ = 2.001. FABMS: *m/z* 767.1 ($M^+$). Despite numerous attempts with crystalline products no satisfactory elemental analysis has been obtained owing to extreme air sensitivity of the compound.

(oep)Zr($\eta^2$-PhC≡CPh) **2**. A mixture of (oep)$ZrCl_2$ (523 mg, 0.75 mmol), Mg powder (50 mesh, 19 mg, 0.78 mmol), and PhC≡CPh (135 mg, 0.76 mmol), in thf (*ca*. 50 ml) was stirred at room temp. in a glove box. The initially purplish red solution turned to dark green within 1 h. After 24 h, the solvent was removed *in vacuo*. The residue was extracted with toluene. The dark red extract solution was filtered and the filtrate was slowly concentrated to *ca*. 5 ml. Layering pentane (*ca*. 5 ml) over the solution yielded the microcrystalline product in 2 d, which was filtered, washed with pentane and dried *in vacuo* (329 mg, 54%). $^1$H NMR ($C_6D_6$): $\delta$ 10.42 (s, 4 H, *meso*-H), 6.34 (m, 6 H, *m*, *p*-Ph), 4.93 (d, 4H, *o*-Ph), 3.92 (m, 16 H, $CH_2CH_3$), 1.81 (t, 24 H, $CH_2CH_3$). $^{13}$C NMR ($C_6D_6$): $\delta$ 218.4 (C≡C), 147.6 (α-pyrrole), 144.2 (β-pyrrole), 132.1 (Ph), 126.9 (Ph), 126.0 (Ph), 125.1 (Ph), 101.5 (*meso*), 20.4 ($CH_2$), 18.6 ($CH_3$). IR (KBr): $\nu_{C\equiv C}$ 1697 $cm^{-1}$. UV–VIS (toluene): $\lambda_{max}$ (log $\varepsilon$) 408 (4.70), 458 (2.99), 534 (3.57), 570 (3.76) nm. Anal. Calc. for $C_{50}H_{54}N_4Zr$: C, 74.85; H, 6.80; N, 6.98. Found: C, 74.83; H, 6.39; N, 6.45%.

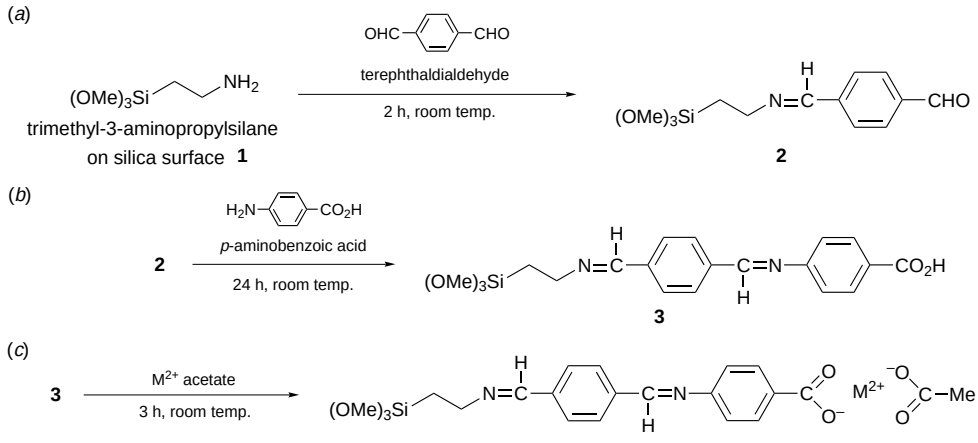
# Liquid phase oxidations using novel surface functionalised silica supported metal catalysts

**Janet Chisem (neé Bovey), Ian C. Chisem, John S. Rafelt, Duncan J. Macquarrie and James H. Clark***

*Department of Chemistry, University of York, Heslington, York, UK YO1 5DD*



**Metal species supported on a surface functionalised silica gel are active heterogeneous catalysts for the liquid phase, room temperature epoxidation of cyclohexene and the aerobic oxidation of ethylbenzene.**

The oxidation of organic substrates leads to the production of many functionalised molecules which are of great commercial and synthetic importance. The oxidation of alkyl aromatic substrates is one such example, enabling the production of key groups such as ketones, aldehydes and esters. Epoxides are useful synthetic intermediates because they readily undergo ring-opening reactions to form bifunctional molecules. Alkene oxidation is a common method of epoxide synthesis. Use of a so-called sacrificial aldehyde as an oxygen transfer agent is a convenient and effective way of facilitating the epoxidation reaction.[1–5] However, in general, direct oxidation using organic oxygen donors such as peroxyacids and peroxides is the most important method of oxidation in industry.[6] The formation of by-products and decomposition of the desired product are often problems in these systems. The heterogenisation of reagents and catalysts and the use of molecular oxygen or air in place of homogenous oxidants is clearly desirable in economic and environmental terms.[6–7] However, air and oxygen are weak, non-selective oxidation reagents and suitable heterogeneous catalysts therefore need to be developed that work effectively in conjunction with these oxidants. Heterogeneous catalysts which have been used for liquid phase oxidations are often based on active species (notably transition metals, metal ions or metal complexes) adsorbed on supports (such as carbon, aluminas, silicas, zeolites, clays and ion exchange resins).[8] Chemically modified support materials offer great scope for the development of new catalysts.[5,9–11] Here we report on a new range of active oxidation catalysts based on chemically modified mesoporous silica with metal ions immobilised on a hydrophobic chain which, unusually, are capable of facilitating both alkene epoxidation and alkylaromatic oxidation reactions.

The preparation of the catalysts is illustrated in Scheme 1 and was carried out at room temperature. Silica with an average pore diameter of 100 Å (Kieselgel 100) was suspended in ethanol. Trimethyl-3-aminopropylsilane was added such that a ratio of 1.0 mmol silane (g silica)$^{-1}$ was obtained and the mixture was stirred for 24 h. The solid was then separated by filtration and washed thoroughly with diethyl ether to yield aminopropylsilica (AMPS). The AMPS was suspended in excess ethanol and terephthaldialdehyde added at a ratio of 1 mmol (g silica)$^{-1}$. The mixture was stirred for 2 h before being filtered and washed with diethyl ether. The resulting solid was then suspended in ethanol and *p*-aminobenzoic acid was added at a ratio of 1 mmol (g silica)$^{-1}$. The mixture was stirred for *ca.* 24 h. The solid was again separated by filtration and washed with diethyl ether. The product was resuspended in ethanol and the metal acetate (Cr, Mn, Co, Ni or Cu) was added at a ratio of 1.0 mmol metal (g silica)$^{-1}$ and the mixture stirred for 3 h. The excess solvent was removed using a rotary evaporator and the catalyst thoroughly washed with ethanol until the washings were colourless. Finally, the catalyst was dried under vacuum at *ca.* 95 °C for 16 h.

The epoxidation of cyclohexene to cyclohexene oxide was carried out as follows. A reaction flask under an $O_2$ atmosphere was charged with 17.5 mmol of cyclohexene, 60 mmol of isobutyraldehyde and 0.6 g of catalyst. Dichloromethane was used as the solvent and *tert*-butylbenzene as an internal standard. The reaction was run for 6 h at room temperature with constant stirring using a magnetic stirrer. The oxidation of ethylbenzene to acetophenone was carried out in a baffled flask with overhead stirring (1500 rpm). Air was used as the oxidant at a rate of 800 ml min$^{-1}$. 1.5 g of the Cr catalyst was added to 500 ml of neat substrate and the reactions carried out at reflux (130 °C) for 24 h. Water produced during the reaction was collected in twin Dean Stark traps. Both reactions were analysed by gas chromatography (GC) and the amount of product (mmol) thus determined.

The loading of metal on the catalysts was determined by atomic absorption spectroscopy (AAS). The solids were first dissolved in concentrated sulfuric acid and the resulting solution diluted with deionised water. Loadings were found to be in the

**Scheme 1** Diagrammatic representation of the functionalisation of the silica support (*a*,*b*) and the addition of the active metal species (*c*)

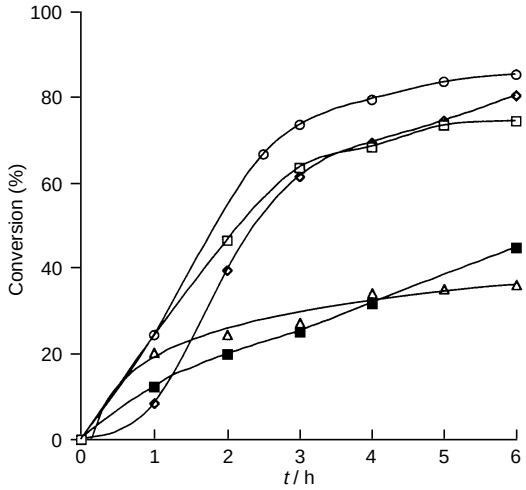


**Fig. 1** Percentage conversion of cyclohexene to cyclohexene oxide by various supported metals: Cr (□), Mn (△), Co (■), Ni (○) and Cu (◊)

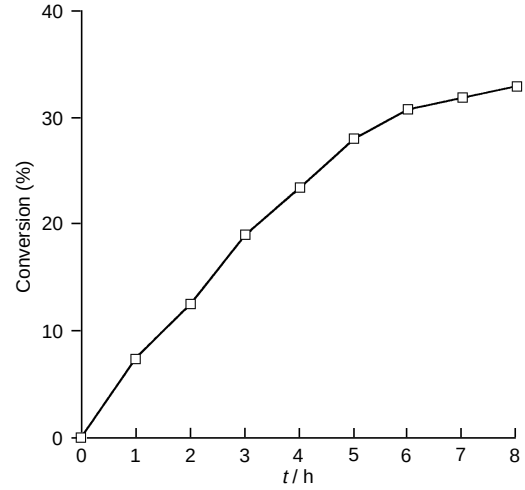

**Fig. 2** Percentage conversion of ethylbenzene to acetophenone by supported Cr catalyst

range 0.36–0.46 mmol $g^{-1}$, depending on the metal, which is typical of supported metal catalysts.[8] The loadings of metal are lower than the initial aminopropyl groups which may be due to incomplete metal binding during synthesis. Furthermore, the stoichiometry of the binding of the metal complexes has not yet been confirmed. Fourier-transform infrared spectroscopy revealed a band at 1684 $cm^{-1}$ which is indicative of the imine group, as shown in the proposed structure of the catalyst (see Scheme 1). Bands at 1584 and 1456 $cm^{-1}$ were attributed to the antisymmetric and symmetric stretching modes of the carboxylate group respectively. Preliminary leaching studies were carried out by performing AAS on the Ni catalyst following reaction. The loading of Ni was 0.36 mmol $g^{-1}$ for both the spent and fresh catalysts. This suggests that metal leaching is not occurring, which in turn is indicative of chemical bonding between the metal and the support of the catalyst.

In the cyclohexene epoxidations, all the catalysts showed excellent selectivity for the epoxide with only trace amounts (in total $< 1.0\%$) of by-products being detected by GC. Under homogeneous conditions, Murahashi *et al.*[1] obtained cyclohexenone as a by-product in the epoxidation of cyclohexene, in accordance with a peracid mechanism. Whilst we see only trace quantities of by-products in the heterogeneous reaction, we cannot rule out the possibility of cyclohexenone production. Fig. 1 shows the conversions (epoxide yields) achieved by each catalyst plotted *vs.* time. It should be noted that these activities have not been corrected for metal loadings but the range of loadings is narrow. It can be seen that the activity of the catalyst is dependent upon the identity of the supported cation, with high conversions being achieved for the Cr, Ni and Cu catalysts. The most active catalyst is the supported Ni variant which gives a conversion of 85% epoxide yield after 6 h. 80 and 74% epoxide yields are obtained with the Cu and Cr catalysts respectively. The fastest rates achieved are by the Ni and Cu catalysts and are 28 and 26.5% $h^{-1}$ respectively, over the first 3 h. These rates correspond to a frequency of 12 and 11 turnovers $h^{-1}$ per catalytic site (at an average loading of 0.41 mmol $g^{-1}$), respectively. Fig. 2 shows the conversion of ethylbenzene to acetophenone by the Cr catalyst *vs.* time. It can be seen that the catalyst showed excellent activity for the reaction, reaching 33% conversion after 8 h. A rate of *ca.* 5.5% $h^{-1}$ was reached over 5 h which is equivalent to $> 370$ turnovers $h^{-1}$ per catalytic site (assuming a loading of 0.41 mmol $g^{-1}$). After 5 h the rate decreased significantly which may be attributed to the inefficient removal of water from the system which leads to poisoning of the catalyst. The catalyst was highly selective to the ketone and no induction period was observed.

These new catalysts show remarkable and unusual versatility as they are capable of selectively catalysing reactions which proceed *via* very different mechanisms.[6] Further work is being directed at the use of other alkylaromatic and alkene substrates as well as Baeyer–Villiger systems. Catalyst re-use studies and the activities of other metal variants including Ti, V and Fe are also being investigated.

# Guest-responsive structural changes of porphyrinogen inclusion crystals: a long-range cooperative effect on guest inclusion

**Yoshio Furusho and Takuzo Aida***

*Department of Chemistry and Biotechnology, Graduate School of Engineering, The University of Tokyo, Hongo, Tokyo 113, Japan*

***meso*-Octaethylporphyrinogen inclusion crystals with lower alcohols undergo reversible guest-responsive structural changes, for which a long-range cooperative effect with a Hill coefficient of 40 is observed.**

Although porphyrinogen is a well known precursor of porphyrin, its chemistry has not been investigated until recently. Floriani *et al.* have extensively studied the chemistry of metal complexes of *meso*-octaalkylporphyrinogens,[1] and Sessler and co-workers have reported that free bases of porphyrinogens bind anions and neutral substrates in the solid state and in solution.[2] We have independently found that *meso*-octaethylporphyrinogen (hereafter OEP)[3] forms inclusion crystals with lower alcohols.[4] Herein we report guest-responsive structural changes of their inclusion crystals, and wish to highlight a long-range cooperative effect on the guest selection.

The crystalline inclusion compounds were obtained by recrystallization of OEP from alcoholic solutions, where the two host : guest mole ratios, 1 : 1 and 1 : 2, depending on the guest alcohol, were observed: 1 : 1 for MeOH, $HOCH_2OH$ [DHM] (from formalin–acetone), and $HOCH_2CH_2OH$ (EG) (from EG–acetone); 1 : 2 for EtOH, $Pr^nOH$ and $Pr^iOH$.† Crystallization of OEP from hexane gave crystals without guest molecules.

The crystal structures of some of the above inclusion compounds were successfully determined by X-ray crystallography (Fig. 1),‡ in which the porphyrinogen itself always adopts an $S_4$-saddle shape with the pyrrole units pointing up and down alternately. In the crystal of OEP without guest [Fig. 1(*a*)] the OEP molecules are stacked in an 'offset' geometry to fill cavities for guest inclusion, and form oblique columns, which are oriented in two directions perpendicular to each other. No intra- and inter-molecular hydrogen bonds were observed between OEP molecules in the crystal lattice. On the other hand, in the OEP·MeOH crystal [Fig. 1(*b*)], the OEP molecules are stacked along the crystallographic *b*-axis, and provide the cavity for MeOH. IR spectroscopy showed the presence of a hydrogen-bonding interaction between OEP and MeOH, for which the pyrrolic N–H serves as proton donor: A $\nu_{N-H}$ at 3440 $cm^{-1}$ for the OEP crystal without guest was observed at 3310 $cm^{-1}$ ($\Delta\nu_{N-H}$ −130 $cm^{-1}$) for the OEP·MeOH crystal. Interestingly, the oxygen atom of the guest MeOH is disordered along the *b*-axis,§ suggesting that it is hydrogen bonded with upper and lower OEP molecules. The packing mode of the OEP·EG crystal is very similar to that of the OEP·MeOH crystal, where the guest EG is not disordered due to simultaneous hydrogen bonding interaction with the upper and lower host molecules. The OEP·DHM crystal showed a virtually identical powder X-ray diffraction pattern to that of the OEP·MeOH crystal. On the other hand, in the OEP·2$Pr^iOH$ crystal [Fig. 1(*c*)], the OEP molecules are stacked tilting alternately to the left and right to give a cavity for two molecules of $Pr^iOH$, where each guest molecule is hydrogen bonded to the upper or lower OEP molecule. A similar packing mode was observed for the OEP·2EtOH crystal, although the crystal structure was not completely refined owing to its partial decomposition.

When finely pulverized OEP crystals without guest were exposed to an alcoholic vapor, the alcohol was included in the crystal. Likewise, the guest exchange of the inclusion crystals also took place reversibly. The guest inclusion or exchange under alcoholic vapors was usually complete within 48 h to furnish host : guest mole ratios identical to those for the clathrates grown from alcoholic solutions.¶ Of particular interest here is the fact that the OEP crystal exhibits guest-responsive structural changes of the lattice: from the powder X-ray diffraction pattern interconversions among the different crystals of OEP without guest, OEP·MeOH, OEP·2EtOH and

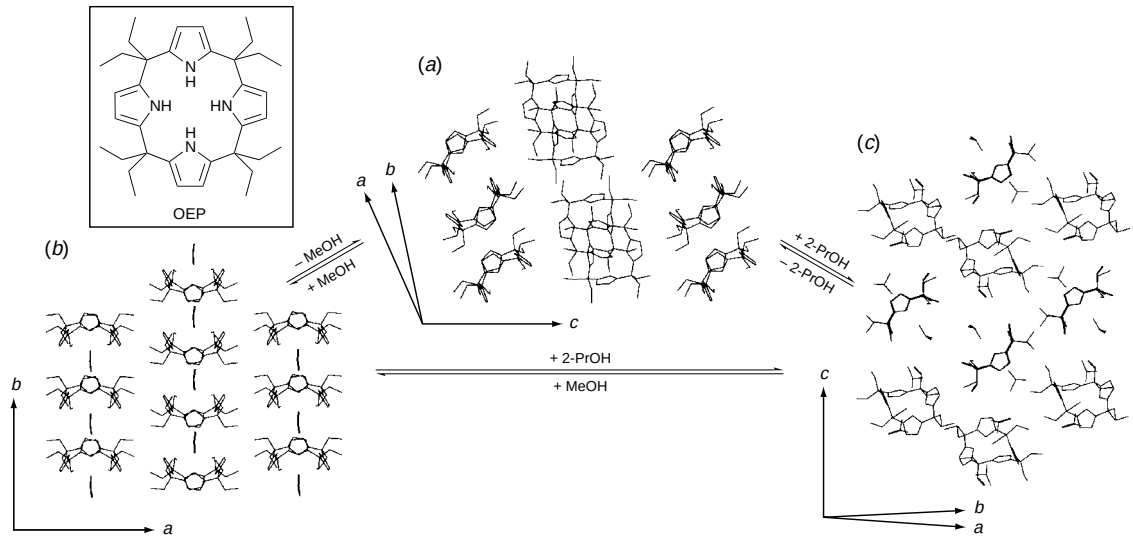

**Fig. 1** Crystal packing diagrams of OEP without guest (*a*), OEP·MeOH (*b*) and OEP·2$Pr^iOH$ (*c*)‡

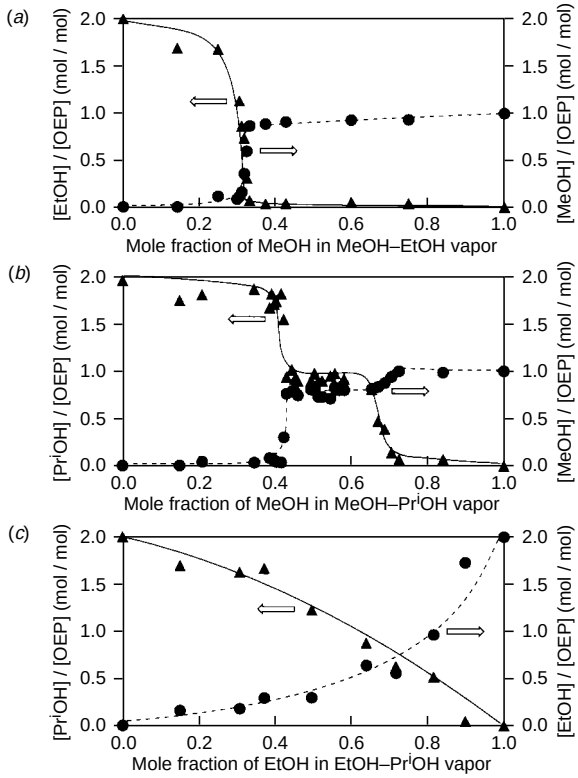

**Fig. 2** Relationships between mole ratios [guest]/[OEP] and vapor composition in competitive guest inclusion into OEP crystals without guest under mixed alcoholic vapors of MeOH–EtOH (*a*), MeOH–Pr$^{i}$OH (*b*) and EtOH–Pr$^{n}$OH (*c*) at 20 °C‖

OEP·2Pr$^{i}$OH took place without decomposition. Such a guest-responsive crystal-to-crystal transformation is rare, and has been reported for the inclusion crystals of cholic acid[5] and orthogonal aromatic triads.[6]

When powdery OEP crystals without guest were exposed to a mixed alcoholic vapor, a very clear cooperative (allosteric) effect, leading to a selective guest inclusion, was observed (Fig. 2).‖ In MeOH–EtOH vapor [Fig. 2(*a*)], MeOH was highly selectively incorporated into the host crystals over a wide range of vapor composition. However, at a mole fraction of MeOH below 30%, the selectivity was discretely reversed to EtOH. From Fig. 2(*a*), the Hill coefficient** was evaluated to be 40, which means that forty host molecules are cooperative for the guest inclusion.[7] The result was virtually identical to the above when started either from the inclusion crystals of OEP·MeOH or OEP·2EtOH. In MeOH–Pr$^{i}$OH vapor, the guest inclusion into the OEP crystals also showed a clear allosteric response [Fig. 2(*b*)]. However, an intermediate crystalline phase with [OEP]:[MeOH]:[Pr$^{i}$OH] of about 1:1:1 appeared, which is not a mixture of the OEP·MeOH and OEP·2Pr$^{i}$OH crystals, as judged from the powder X-ray diffraction pattern. In sharp contrast, in EtOH–Pr$^{i}$OH vapor, where the host:guest mole ratio was almost constant at 1:2 irrespective of the vapor composition, no allosteric response was observed for the guest inclusion [Fig. 2(*c*)].

From Fig. 2 together with the packing modes of the crystals (Fig. 1), the cooperative effect appears to operate when the guest inclusion or exchange requires a considerable structural change of the crystal lattice. For example, in the competition of MeOH and EtOH [Fig. 2(*a*)], the packing modes of the OEP·MeOH and OEP·2EtOH crystals are very different from each other, so that they may be unfavorable to coexist in a single crystal. As a consequence, either MeOH or EtOH is incorporated into the crystal depending on the vapor composition. Consistently, the exchange of $CH_3OH$ with $CD_3OD$ in the OEP crystal, which should require no structural change of the crystal lattice, took place extremely slowly ( < 10% in 48 h) compared with the exchange of MeOH with EtOH or Pr$^{i}$OH. Thus, the crystalline host of *meso*-octaethylporphyrinogen may be called an 'allosteric crystal'.

In conclusion, we have clearly demonstrated a long-range cooperative effect on the inclusion of lower alcohols into *meso*-octaethylporphyrinogen crystals. Although inclusion crystals have recently attracted particular attention as 'organic zeolites',[8] guest removal or exchange is very likely to result in decomposition of the crystal structure because of a low flexibility of the crystal packing. In contrast, the porphyrinogen inclusion crystal is a 'soft' organic zeolite, which is able to change its packing mode cooperatively depending on the guest molecule, leading to selective guest inclusion.

† Determined by $^{1}$H NMR, thermogravimetry and elemental analyses.

‡ *Crystal structure analysis* of OEP without guest, OEP·MeOH, OEP·EG and OEP·2Pr$^{i}$OH: Intensity data were collected on a Mac Science MXC18 diffractometer equipped with a graphite monochromator by using Cu-K$\alpha$ radiation ($\lambda$ = 1.541 78 Å) at room temperature with the $2\theta$–$\omega$ scan method. Structure solution and refinements were performed by using the SIR92 program package.

*Crystal data*: OEP ($C_{36}H_{52}N_4$, $M$ = 540): crystals from hexane, monoclinic, $C2/c$, $a$ = 19.038(2), $b$ = 16.655(3), $c$ = 22.937(3) Å, $\beta$ = 110.12(1)°, $U$ = 6829(2) Å$^3$, $Z$ = 8, $D_c$ = 1.05 g cm$^{-3}$, $F(000)$ = 2368, $R$ = 0.0560, $R_w$ = 0.0557. OEP·MeOH ($C_{37}H_{56}N_4O$, $M$ = 572): crystals from methanol, monoclinic, $C2/c$, $a$ = 23.129(6), $b$ = 6.894(2), $c$ = 23.045(6) Å, $\beta$ = 112.32(2)°, $U$ = 3399(2) Å$^3$, $Z$ = 4, $D_c$ = 1.12 g cm$^{-3}$, $F(000)$ = 1255, $R$ = 0.0804, $R_w$ = 0.0782. OEP·EG ($C_{38}H_{58}N_4O_2$, $M$ = 602): crystals from ethylene glycol, monoclinic, $C2/c$, $a$ = 27.52(1), $b$ = 16.510(5), $c$ = 20.462(6) Å, $\beta$ = 130.17(2)°, $U$ = 7105(4) Å$^3$, $Z$ = 8, $D_c$ = 1.13 g cm$^{-3}$, $F(000)$ = 2640, $R$ = 0.0717, $R_w$ = 0.0806. OEP·2Pr$^{i}$OH ($C_{42}H_{68}N_4O_2$, $M$ = 660): crystals from Pr$^{i}$OH, monoclinic, $P2_1/c$, $a$ = 17.239(4), $b$ = 11.513(2), $c$ = 20.793(5) Å, $\beta$ = 93.41(2)°, $U$ = 4119(2) Å$^3$, $Z$ = 4, $D_c$ = 1.07 g cm$^{-3}$, $F(000)$ = 1456, $R$ = 0.0775, $R_w$ = 0.0724. CCDC 182/622.

§ The disordered molecules are related by a twofold axis.

¶ In alcoholic solutions, the guest inclusion and exchange took place very rapidly and was complete within 1 h.

‖ Finely pulverized OEP crystals without guest were exposed for 48 h to a mixed alcoholic vapor at 20 °C in a 50 ml closed glass bottle, and the host:guests molar ratio was determined by $^{1}$H NMR in $CDCl_3$. The vapor composition was estimated from the vapor pressures at 20 °C (mmHg) for MeOH (91.8), EtOH (44.0) and Pr$^{i}$OH (32.4).

** The Hill coefficient ($n$) was calculated on the basis of the following equation: $\log [(x/(1-x)] = n \log P_{MeOH} - n \log P_{50}$, where $x$ is the molar ratio of OEP·MeOH to OEP·2EtOH; $P_{MeOH}$ and $P_{50}$ represent the partial pressure of MeOH and that of MeOH when a half of OEP molecules binds MeOH, respectively.

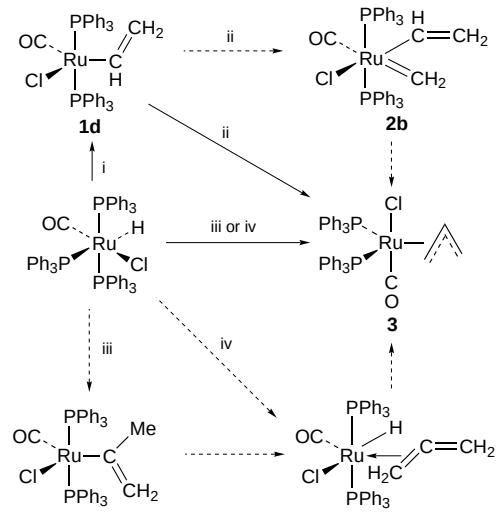
# The coupling of methylene and vinyl ligands at a ruthenium(II) centre

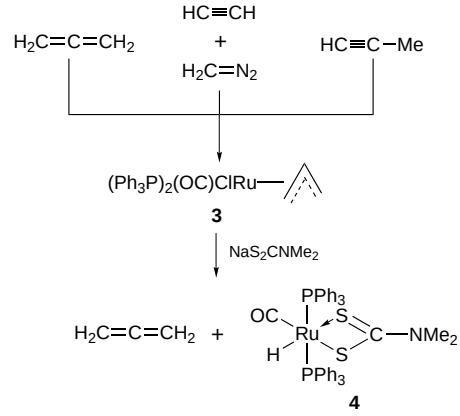
**Anthony F. Hill,* Chean T. Ho and James D. E. T. Wilton-Ely**

*Department of Chemistry, Imperial College of Science Technology and Medicine, South Kensington, London, UK SW7 2AY*



**The reaction of $[Ru(CH{=}CH_2)Cl(CO)(PPh_3)_2]$ with diazomethane provides the allyl complex $[Ru(\eta^3\text{-}CH_2CHCH_2)Cl(CO)(PPh_3)_2]$ which is also the product of the reactions of $[RuHCl(CO)(PPh_3)_3]$ with either allene or propyne and which reacts subsequently with $NaS_2CNMe_2$ to provide $[RuH(S_2CNMe_2)(CO)(PPh_3)_2]$ and allene.**

In a recent review,[1] Maitlis *et al*. drew attention to the potential significance of the coupling of vinyl and methylene groups in the Fischer–Tropsch synthesis. In particular the oxidation of $[Rh_2(\mu\text{-}CH_2)_2(CH{=}CH_2)_2(\eta\text{-}C_5Me_5)_2]$ by $AgBF_4$ in acetonitrile was shown to provide $[Rh(\eta^3\text{-}CH_2CHCH_2)(NCMe)(\eta\text{-}C_5Me_5)]BF_4$,[2] whilst diazomethane addition to the diruthenium complex $[Ru_2(\mu\text{-}CH{=}CH_2)(CO)_3(\eta\text{-}C_5H_5)_2]^+$ followed by deprotonation provides $[Ru_2(\mu\text{-}CHCH{=}CH_2)(\mu\text{-}CO)(CO)(\eta\text{-}C_5H_5)_2]$.[3] The operation of these couplings on bimetallic systems, whilst clearly significant in understanding Fischer–Tropsch processes, begs the question do they occur on monometallic systems? Werner and coworkers have reported that the reaction of $[RuCl(=CPh_2)(PPh_3)(\eta\text{-}C_5H_5)]$ with vinyl magnesium bromide provides the allyl complex $[Ru(\eta^3\text{-}CH_2CHCPh_2)(PPh_3)(\eta\text{-}C_5H_5)]$.[4] The complex $[Ru(CH{=}CH_2)(=CPh_2)(PPh_3)(\eta\text{-}C_5H_5)]$ is an attractive intermediate, however as the authors point out, the product is also consistent with direct nucleophilic attack at the carbene carbon. Such a process is typical of coordinatively saturated carbene complexes of divalent ruthenium.[5] Here, we report the unambiguous observation of the coupling of a vinyl and a methylene ligand on a ruthenium system. Furthermore, we show an unusual β-elimination process of the resulting $\eta^3$-allyl ligand which may be induced by dithiocarbamate coordination.



Roper and coworkers have shown that the coordinatively unsaturated complex $[Ru(Ph)Cl(CO)(PPh_3)_2]$ **1a** reacts with diazomethane to provide a remarkably stable methylene complex $[Ru(\eta^2\text{-}OCPh)Cl(=CH_2)(PPh_3)_2]$ **2a**, but that such a reaction has so far failed for the corresponding *trans* β-styryl analogue $[Ru(CH{=}CHPh)Cl(CO)(PPh_3)_2]$ **1b**.[6] An intriguing feature of the reactivity of **2a** is the apparent reluctance of the phenyl and methylene ligands to couple, despite the anticipated stability of the hypothetical product $[Ru(CH_2Ph)Cl(CO)(PPh_3)_2]$ **1c**. We find that the parent vinyl complex $[Ru(CH{=}CH_2)Cl(CO)(PPh_3)_2]$ **1d**[7] reacts readily with diazomethane in dichloromethane–diethyl ether to provide high yields of the $\eta^3$-allyl complex $[Ru(\eta^3\text{-}CH_2CHCH_2)Cl(CO)(PPh_3)_2]$ **3** (Scheme 1), the identity and stereochemistry of which follows unambiguously from spectroscopic data† and two unequivocal syntheses (*vide infra*). Whilst the reaction leading to **3** is unique, the class of compounds has precedent. Related examples, *e.g.* $[Ru(\eta^3\text{-}CH_2CHCH_2)Cl(CO)(PMe_2Ph)_2]$ have been obtained from the reaction of $[RuCl_2(CO)_2(PMe_2Ph)_2]$ with $Bu^n_3SnCH_2CH{=}CH_2$,[8]‡ whilst $[RuHCl(CO)(PPh_3)_3]$ hydroruthenates 1,3-dienes to provide substituted examples.[9] Although this result is surprising, the methylene complex $[Ru(CH{=}CH_2)Cl(=CH_2)(CO)(PPh_3)_2]$ **2b** is an obvious intermediate in the formation of **3**. It remains unclear to us why, in the case of **1a** methylene coordination is followed by (reversible) migration of a phenyl group to a carbonyl ligand, but in the case of **1d**, migration of the vinyl ligand occurs selectively and irreversibly to the introduced methylene ligand. Maitlis' studies of C–C bond forming processes for organorhodium species certainly point to a greater migratory aptitude for vinyl than phenyl ligands.[1] However, since the phenyl complex **2a** has been shown to be in equilibrium with $[Ru(Ph)Cl(=CH_2)(CO)(PPh_3)_2]$[6] the relative mobility of vinyl and phenyl ligands appears not to be the limiting factor here, but more likely one of product development control.

Complex **3** also results from two other approaches. Santos and coworkers have shown that in general, terminal alkynes RC≡CH (R = Ph, $Bu^t$, $Bu^n$) react with $[RuHCl(CO)(PPh_3)_3]$ to provide coordinatively unsaturated σ-vinyl complexes $[Ru(CH{=}CHR)Cl(CO)(PPh_3)_2]$.[10] We anticipated that a similar hydroruthenation of allene might provide **3** which indeed it does in high yield (Scheme 1). Somewhat surprisingly however, **3** is also the product of the reaction of $[RuHCl(CO)(PPh_3)_3]$ with propyne! This result can be explained by the formation of the usually less favoured α-substituted σ-vinyl complex $[Ru(C(Me){=}CH_2)Cl(CO)(PPh_3)_2]$, which can undergo β-Ru–H elimination to provide $[RuH(\eta^2\text{-}CH_2CCH_2)Cl(CO)(PPh_3)_2]$ followed by hydroruthenation to provide **3**.

The chemistry of $\eta^3$-allyl ligands is enriched by their ability to assume a monohapto coordination mode. We therefore attempted to induce monohapto coordination by replacing the chloride ligand in **3** with a potentially bidentate dithiocarbamate ligand. Surprisingly, the reaction of **3** with $Na[S_2CNMe_2]$ in dichloromethane–ethanol led to the formation of $[RuH(S_2CNMe_2)(CO)(PPh_3)_2]$ **4** with the organometallic ligand being lost from the coordination sphere. When the reaction was carried out in $CDCl_3$–MeOH (10 : 1), $^1H$ NMR integration confirmed allene as the organic product. The most reasonable course for this reaction would appear to be dissociation of chloride followed by the β-RuH elimination of allene to provide the coordinatively unsaturated, though presumably solvent-stabilised species '$[RuH(CO)(PPh_3)_2]^+$'. Although this type of elimination is unusual, we have observed[11] that treating

**Scheme 1** *Reagents and conditions*: i, HC≡CH ($CH_2Cl_2$, 25 °C); ii, $CH_2N_2$ ($Et_2O$, $CH_2Cl_2$, 25 °C); iii, $CH_3C{\equiv}CH$ (thf, 25 °C then heating); iv, $H_2C{=}C{=}CH_2$ (thf, 25 °C then heating)

**Scheme 2**

$[Ru(CH{=}CHCH_2PPh_3)Br(CO)(PPh_3)_2]^+$ with $Na[S_2CNMe_2]$ also leads to formation of **4**.

The above transformations taken together constitute the metal-mediated conversion of ethyne or propyne to allene (Scheme 2). The reactions are clearly not catalytic in nature, however they do add a further viewpoint to the complex picture of chain growth in Fischer–Tropsch processes, complimenting recent results obtained by Werner *et al*. for the coupling of vinyl ligands with vinylidenes on mononuclear rhodium centres.[12]

# Generation of stable and persistent carbocations from 4-vinylanisole within zeolites

**V. Jayathirtha Rao,[a] Nicolette Prevost,[a] V. Ramamurthy,*[a] Masanobu Kojima[b] and L. J. Johnston[c]**

[a] *Department of Chemistry, Tulane University, New Orleans, LA 70118, USA*

**Stable and ultrastable carbocations from 4-vinylanisole are spontaneously generated within zeolites; these reactive intermediates are stable for several weeks within the confined environments of zeolites.**

Spontaneous generation of long-lived organic cation radicals on the surfaces of zeolites has been known for over three decades.[1] However, only during the last few years has this phenomenon been widely recognized and the technique has been developed into a routine laboratory tool to generate stable cation radicals.[2,3] Simultaneous formation of carbocations may occasionally complicate the characterization of organic cation radicals within zeolites. This discrepancy prompted the present investigation. Our efforts to characterize stable reactive intermediates generated by inclusion of 4-vinylanisole within a number of zeolites are presented here. The behavior of 4-vinylanisole is typical of the many styrenes we have investigated. Persistent carbocations are formed more readily than cation radicals in all these cases.

Inclusion of 4-vinylanisole into activated Na ZSM-5 (Si/Al ≈ 15, the PQ Corporation-CBV 3010; Si/Al ≈ 25, Chemie Utikon) turned the zeolite blue–purple, as reported by Pollak *et al.*[4] The diffuse reflectance spectrum of the purple solid displayed in Fig. 1 consists of three maxima (*ca.* 280, 580 and *ca.* 640 nm). Of these the short-wavelength absorption is due to 4-vinylanisole. The appearance of an intense red–violet color and a visible absorption (*ca.* 580 nm) were general within a number of zeolites (Ca Y, H Y, Na omega-5, Na ZSM-11 and Na-beta). Of the zeolites examined, only Na X was totally inert. The appearance of a maximum at 640 nm was unique to ZSM zeolites. In no other zeolites was this peak recorded. The absorption spectrum of the 4-vinylanisole radical cation in solution consists of two maxima, one in the UV and the other in the visible region.[5] Close examination of the spectrum recorded for zeolite samples revealed that the absorption in the UV range (340–380 nm) in solution, was absent. To be sure that the zeolites do not influence the electronic transitions, the diffuse reflectance of the 4-vinylanisole radical cation included within Na Y was recorded by generating such a species by photoionization. The spectrum of such a generated 4-vinylanisole radical cation within Na Y was similar to that in solution. This indicated to us that no stable radical cation of 4-vinylanisole is generated under our conditions.

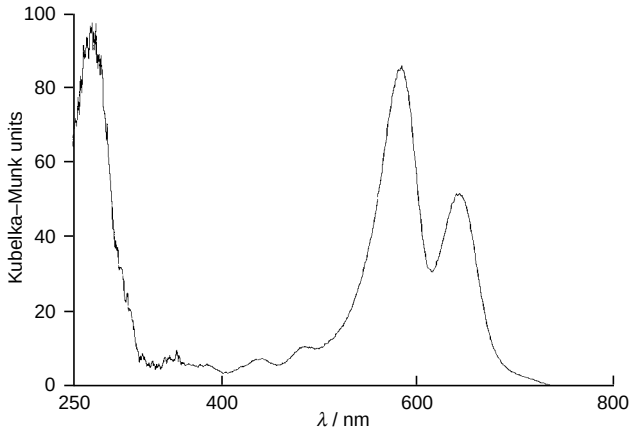

**Fig. 1** Diffuse reflectance spectrum of 4-vinylanisole upon inclusion in Na ZSM-5 (Si/Al ≈ 25)

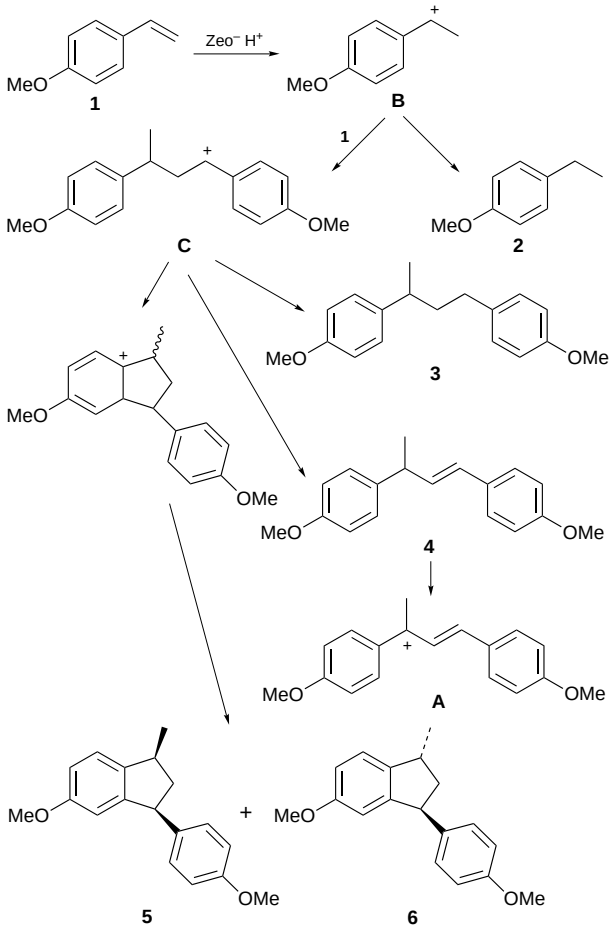


Extraction of the red–violet zeolite with either $CH_2Cl_2$ or tetrahydrofuran–$H_2O$ gave several products. The yields of products in various zeolites are summarized in Table 1. Since the total isolated yields of the products and the reactant after extraction amounted to *ca.* 90%, the species responsible for the red–violet color must be present only in small amounts within a zeolite. The formation of products **2**–**6** can be mechanistically rationalized on the basis of a primary step involving a proton transfer from the zeolite to 4-vinylanisole (Scheme 1). We believe that the acid sites, generated upon calcination, are directly involved in the formation of products **2**–**6**.[6]

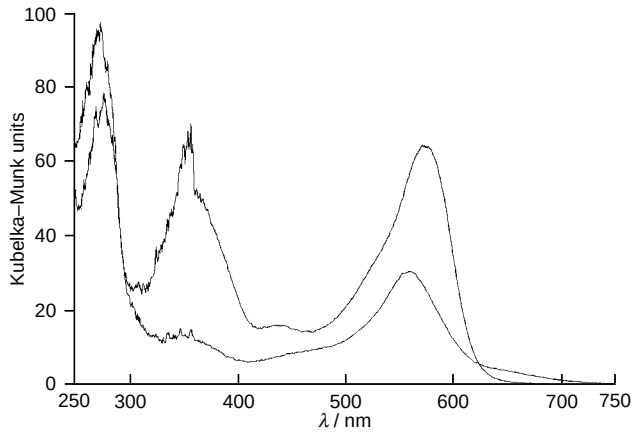
Support for the involvement of the postulated reactive intermediates in Scheme 1 was obtained by recording the diffuse reflectance absorption spectrum of the colored zeolites. For example, activated Ca Y when dropped into a solution of 4-vinylanisole in hexane, developed a vibrant red–violet color. The diffuse reflectance spectrum of the solid zeolite sample presented in Fig. 2 consists of two broad absorption centered at 340 and 580 nm (note the absence of the transition at 640 nm). Of the two absorptions, the one at 580 nm was found to be permanent; the zeolite retained the red color and the absorption at 580 nm remained under all conditions including refluxing in HCl or NaOH solutions. The diffuse reflectance spectrum of the zeolite that has been extracted with a polar solvent did not show the absorption at 340 nm (Fig. 2). This leads us to suggest that an intermediate absorbing at 340 nm is responsible for the formation of products **2**–**6**. We attribute the absorption at *ca.* 340 nm to the carbocation(s) **B** and/or **C**. The absorption spectrum for the 4-methoxy phenylethyl cation has been reported in solution and that remarkably coincides with the

**Table 1** Product distribution (%) upon inclusion of vinylanisole within zeolites

| | Compound | | | | |
|---|---|---|---|---|---|
| Conditions[a,b] | **2** | **3** | **4** | **5 + 6** | Conversion |
| Ca, Y, oven, 500 °C | 22 | 36 | 37 | 6 | > 80% |
| Ca Y, vac. line, 400 °C | 10 | 78 | 6 | 6 | > 90% |
| H Y, oven 500 °C | 12 | — | 76 | 12 | > 90% |
| ZSM-5, oven, 500 °C | 4 | — | 5 | 65 | > 90% |
| Na Y, oven, 500 °C | 5 | — | 63 | 32 | < 20% |
| Na X, oven, 500 °C | — | — | — | — | — |

[a] Ca Y and H Y were prepared from Na Y obtained from Aldrich & Co; Na X was an Aldrich sample; Na Y received from Aldrich showed the most thermal reaction. Samples obtained from Zeolyst International (CBV-100) showed the least thermal reaction. [b] ZSM-5 samples were obtained from PQ Corporation and Chemie Utikon. Both samples showed similar behavior.

**Scheme 1** Mechanism of proton-transfer mediated reactions within zeolites



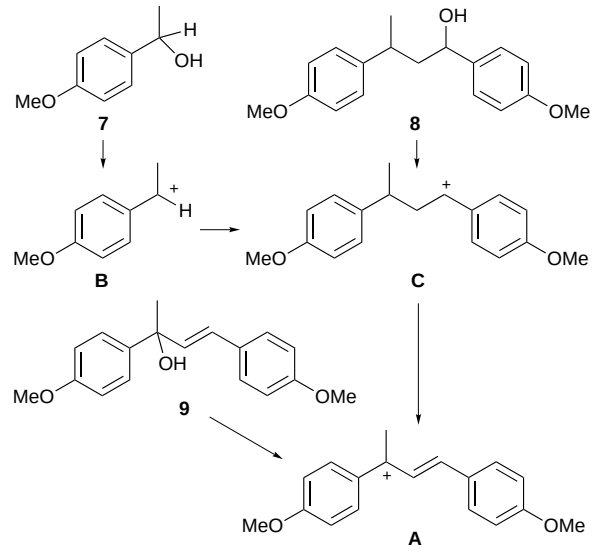


**Fig. 2** Diffuse reflectance spectrum of 4-vinylanisole upon inclusion into Ca Y. The spectrum with two maxima is before washing and that with one maximum is after washing.

absorption maximum observed in zeolite.[7] We propose that the absorption at *ca.* 580 nm is due to the persistent carbocation **A** shown in Scheme 1. This suggestion is consistent with the expected absorption for the 1,3-diphenyl propenyl cation.[8]

Support for the above assignment was obtained by generating the same carbocations from an independent source, from carbinols **7**, **8** and **9** (Scheme 2). Addition of activated Ca Y, H Y and Na ZSM-5 to hexane solutions of **7**, **8** and **9** resulted in an immediate development of a bright red–pink color. The diffuse reflectance spectrum, independent of the carbinol, possessed

**Scheme 2** Generation of carbocations from the corresponding carbinols

absorptions at 580 nm, identical to the one obtained when 4-vinylanisole was included into these zeolites. This suggested to us that independent of the source, within a zeolite, the cations **B** and **C** readily transform themselves into the persistent carbocation **A**.

It is clear from the above presentation that zeolites, when properly prepared, can generate and stabilize 'reactive' intermediates from neutral molecules. On the basis of the behavior of 1,2-diarylethylenes which yield stable cation radicals, we had expected the formation of cation radicals from these systems as well.[3] It is surprising to note that 1-arylethylenes yield persistent carbocations.[9] At this stage the origin of such a difference is not obvious.

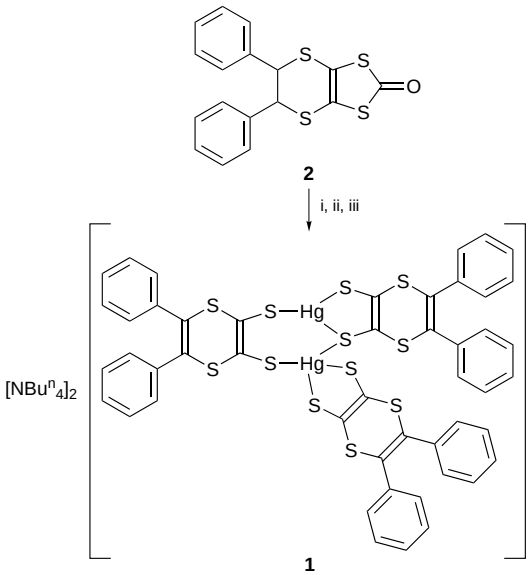
# Synthesis and crystal structure of an unusual bimetallic mercury–dithiolene complex



**Dong-Youn Noh,[a] Allan E. Underhill*[b] and Michael B. Hursthouse[c]**

[a] *Department of Chemistry, Seoul Womens University, Seoul 139-774, Korea*
[b] *Department of Chemistry, University of Wales, Bangor, Gwynedd, UK LL57 2UW*
[c] *Department of Chemistry, University of Wales, Cardiff, PO Box 912, UK CF1 3TB*

**A bimetallic mercury(II) dithiolene complex in which the ligand exhibits three different modes of coordination to the mercury atoms within the same molecular species is reported.**

Metal dithiolene complexes have been widely studied because of their potential in applications such as molecular conductors, ferromagnets, IR dyes, liquid crystals and catalysis.[1–3] As part of an extensive programme of research into these unusual compounds we have been studying the synthesis and properties of metal complexes of ligands derived from dmit (dmit = 1,3-dithiol-2-thione-4,5-dithiolate). During the course of these studies we have prepared a bimetallic mercury(II)–dithiolene complex **1**, which has a most unusual structure involving three differing modes of coordination by the same dithiolene ligand and contains a three-coordinate $Hg^{II}$. Here we report the synthesis and X-ray crystal structure of **1**.

The synthesis of the mercury–dithiolene complex **1** is outlined in Scheme 1. The 1,3-dithiole-2-one **2** was treated with KOH dissolved in MeOH under $N_2$ to open the five-membered ring.[5] To the solution were added separate solutions of $HgCl_2$ and TBABr in MeOH. The yellow precipitate was filtered off and washed with MeOH. The precipitate was recrystallised from acetone–ethyl acetate in a freezer to yield **1**† in 32% yield. Surprisingly, the precursor (or an intermediate thereof) has undergone oxidative dehydrogenation during this reaction to yield the fully conjugated system 1,4-dithiacyclohexadiene observed in **1**.

**Scheme 1** *Reagents and conditions*: i, KOH, MeOH, room temp.; ii, $HgCl_2$, MeOH then [$NBu^n_4$]Br, MeOH; iii, recrystallization from acetone–ethyl acetate, 32% yield

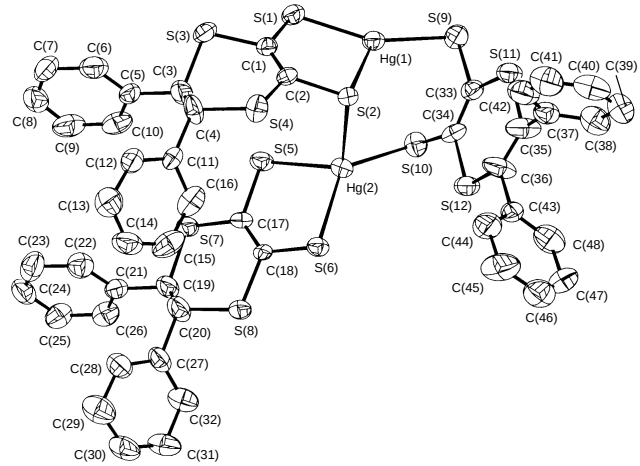


**Fig. 1** The single-crystal X-ray structure of [$NBu^n_4$][$Hg_2$(dithiolene)$_3$], with ellipsoids shown at 50% probability and [$NBu^n_4$]$^+$ ions omitted. For clarity only mercury and sulfur atoms are labelled, with all other atoms being carbon. Selected bond lengths (Å) and angles (°): Hg(1)–S(1) 2.367(3), Hg(1)–S(2) 2.609(2), Hg(1)–S(9) 2.348(3), Hg(2)–S(2) 2.748(2), Hg(2)–S(5) 2.502(2), Hg(2)–S(6) 2.484(2), Hg(2)–S(10) 2.481(3); S(1)–Hg(1)–S(2) 88.31(8), S(1)–Hg(1)–S(9) 155.40(8), S(2)–Hg(1)–S(9) 115.24(7), S(2)–Hg(2)–S(5) 108.31(8), S(2)–Hg(2)–S(6) 114.44(8), S(2)–Hg(2)–S(10) 95.26(9), S(5)–Hg(2)–S(6) 88.52(7), S(5)–Hg(2)–S(10) 120.97(8), S(6)–Hg(2)–S(10) 129.47(10).

The crystal structure of **1**‡ and selected interatomic parameters are presented in Fig. 1 and show two mercury atoms bridged and chelated by three dithiolene ligands, each of which have different binding modes. One ligand simply chelates a mercury ion, [Hg(2)], whilst another ligand acts as a normal $\mu_2$ bridge between Hg(1) and Hg(2) and the final ligand chelates Hg(1) and further bridges *via* one sulfur to Hg(2). As far as we are aware these variations in ligand behaviour (and indeed the resulting formations of oligomers) are unique in the area of dithiolate chemistry, but similar features are known in β-diketonate clusters.[6] The two mercury centres are in different coordination environments. Hg(1) is three coordinate with a very distorted trigonal planar geometry which is due to the ligand bonding constraints. Hg(2) however is four coordinate with very distorted tetrahedral geometry. These multiple forms of coordination have introduced considerable strain into the complex, as may be seen upon investigation of the Hg–S bond lengths. the conventionally coordinated ligand produces expected bond lengths [Hg(2)–S(5), Hg(2)–S(6)]. However around Hg(1) a longer bond is observed for the bridging sulfur [S(2)] and a shortening is seen for the chelating sulfur atoms [S(3), S(9)]. A lengthening is also observed for the Hg(2)–S(2) bridging sulfur, whilst the Hg(2)–S(10) bond has the expected length.

We thank the EPSRC and KOSEF for financial support.

# Infrared spectroscopic evidence for an attractive intramolecular 1,5-CH···O interaction in 1-methoxy-2-(methylthio)ethane

**Hiroshi Yoshida, Takanori Harada, Keiichi Ohno and Hiroatsu Matsuura***

*Department of Chemistry, Faculty of Science, Hiroshima University, Kagamiyama, Higashi-Hiroshima 739-8526, Japan*

**An attractive intramolecular 1,5-CH··O interaction is evidenced in a conformer of 1-methoxy-2-(methylthio)ethane, in which the distance between a hydrogen atom of the SMe group and the oxygen atom is significantly shorter than the van der Waals separation.**

In 1992, we showed the importance of an intramolecular 1,5-CH··O interaction for determining the conformational stabilities of 1,2-dimethoxyethane (DME) in an argon matrix.[1] Since this work was reported, a considerable number of theoretical studies have been published, which dealt with the conformational properties of this molecule by paying special attention to this peculiar interaction.[2–6] These theoretical studies have shown the importance of this interaction in the conformational stabilisation of the DME molecule, in agreement with the experimental results by gas-phase electron diffraction[7] and matrix-isolation and gas-phase IR spectroscopy.[1,8] These experimental findings for the intramolecular 1,5-CH··O interaction were, however, not necessarily decisive because of the complexity involved in the analysis of the experimental data owing to the presence of many conformers. Here we report definitive detection by matrix-isolation IR spectroscopy of a conformer of 1-methoxy-2-(methylthio)-ethane (MMTE), $MeOCH_2CH_2SMe$, which is stabilised by an intramolecular 1,5-CH··O interaction. The characteristics of this intramolecular interaction should be similar in many respects to those of the well-recognised intermolecular CH··O interactions in organic crystals.[9]

The matrix-isolation IR spectra of MMTE were measured by depositing the premixed gases (Ar/MMTE = 2000) onto a caesium iodide plate kept at 11 K. Further experimental details are the same as described previously.[10] *Ab initio* molecular orbital calculations were performed using the GAUSSIAN 94 program[11] on all of the 14 possible conformers of MMTE by the second-order Møller–Plesset perturbation theory (MP2) using the 6-31G* basis set to evaluate the energies, optimized structures, partial charges, vibrational wavenumbers and IR intensities. The calculated wavenumbers were scaled by a uniform factor of 0.95 in the light of the previous systematic studies dealing with a large number of experimental wavenumbers.[12,13]

The IR spectrum of MMTE in an argon matrix at 11 K is shown in Fig. 1. The intensity behaviour of the bands with varying temperature has revealed that the spectrum consists of the bands arising from two conformers. To identify these conformers, the observed spectrum was critically compared with the *ab initio* calculated theoretical spectra of all the possible conformers. The observed bands coincide only with the bands of the TGG′ and TTG conformers.† The theoretical spectra of these conformers are shown in Fig. 1, in comparison with the observed spectrum. The existence of the TGG′ and TTG conformers in an argon matrix agrees with the calculated energies given in Table 1, corresponding as they do to the two lowest-energy conformers of MMTE.

It is noted that the TGG′ conformer, whose optimized structure is shown in Fig. 2, is highly stabilized in the isolated state. In this conformer, the distance (indicated by dots) between one of the hydrogen atoms of the SMe group and the oxygen atom is 0.244 nm, which is significantly shorter than the expected van der Waals separation of *ca*. 0.270 nm. It is obvious that an attractive intramolecular 1,5-CH··O interaction occurs between these non-bonded atoms and greatly stabilizes the TGG′ conformer. The H··O distance in MMTE is shorter than the corresponding distance in DME by 0.002 nm, indicating that the interaction in the former molecule is stronger than in the latter.

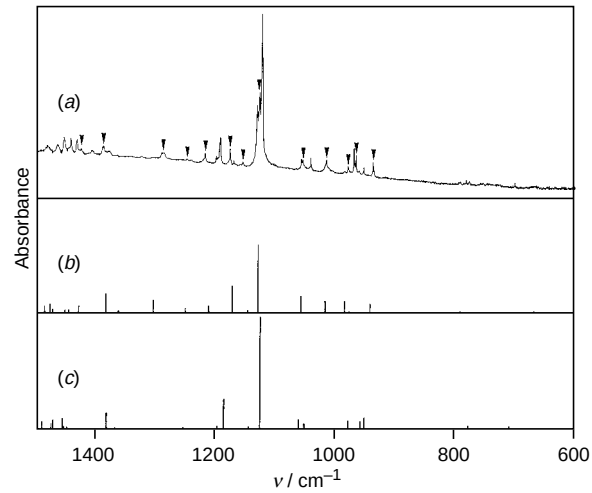

**Fig. 1** Observed and calculated IR spectra of MMTE: (*a*) observed matrix-isolation spectrum at 11 K, (*b*) calculated spectrum of the TGG′ conformer and (*c*) calculated spectrum of the TTG conformer. In the observed spectrum, the bands which are assigned exclusively to the TGG′ conformer are marked with an arrow.

The calculated partial charges of atoms are shown in Fig. 2. It is noteworthy that the methyl carbon atom bonded to the sulfur atom carries a large negative charge (−0.63 *e* units), which is comparable to the partial charge (−0.62 *e*) of the oxygen atom. The positive partial charge (+0.22 *e*) of the methyl hydrogen atom that interacts with the oxygen atom is larger than the partial charges (+0.18 and +0.19 *e*) of other hydrogen atoms

**Table 1** Energies of the 14 possible conformers of 1-methoxy-2-(methylthio)ethane (MMTE)

| Conformer[a] | Energy/ kJ mol$^{-1}$[b] | Conformer[a] | Energy/ kJ mol$^{-1}$[b] |
|---|---|---|---|
| TGG′[c] | 0.000 | GGG | 8.633 |
| TTG | 3.042 | GTG | 8.647 |
| TTT | 5.848 | GGT | 8.851 |
| GGG′[c] | 6.167 | GTT | 11.094 |
| TGT | 6.514 | G′GG[d] | 13.447 |
| G′TG | 7.662 | G′GT[d] | 14.745 |
| TGG | 7.688 | G′GG′[c,d] | —[e] |

[a] Conformation around the MeO–$CH_2$–$CH_2$–SMe bonds (T = *trans*, G = *gauche*). [b] Relative energies with respect to the energy of the TGG′ conformer, calculated at the MP2/6-31G* level. [c] 1,5-CH··O interaction is involved. [d] 1,5-CH··S interaction would be possible. [e] Transformed into the TGG′ conformer during structure optimization.

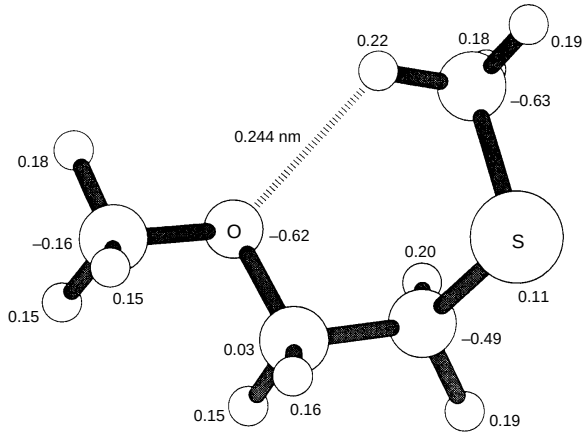

**Fig. 2** Optimized structure of the TGG′ conformer of MMTE. The intramolecular 1,5-CH··O interaction occurs between the methyl hydrogen atom and the oxygen atom as indicated by dots; the H··O distance is 0.244 nm and the C–H··O angle is 118.0°. The values shown are the partial charges of atoms in *e* units.

belonging to the same methyl group. These results indicate that the (S)C–H bond in the TGG′ conformer is like an alcoholic O–H bond in respect of partial charges and interacts attractively with the oxygen atom; this electrostatic interaction can therefore be described as $C^{\delta-}$–$H^{\delta+}\cdots O^{\delta-}$. In the MMTE molecule, an analogous intramolecular interaction may be anticipated to occur between one of the hydrogen atoms of the OMe group and the sulfur atom. The calculated energies (Table 1) indicate, however, that conformational stabilisation by this interaction is unlikely to occur.

The salient result in this work is that we have convincingly detected a conformer, TGG′, of MMTE which is highly stabilised by an intramolecular 1,5-CH··O interaction. Before the importance of this interaction was recognized, the conformers such as TGG′ of MMTE were thought to be unstable owing to apparent heavy steric repulsions between the relevant atoms which are in close proximity to each other. The comparison of the results for MMTE and DME indicates that the (S)CH··O interaction is stronger than the (O)CH··O interaction. The substituent atom, sulfur or oxygen, bonded to the C–H bond may change the strength of the 1,5-CH··O interaction.

# Palladium-grafted mesoporous MCM-41 material as heterogeneous catalyst for Heck reactions

**Christian P. Mehnert and Jackie Y. Ying***

*Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, MA 02139, USA*

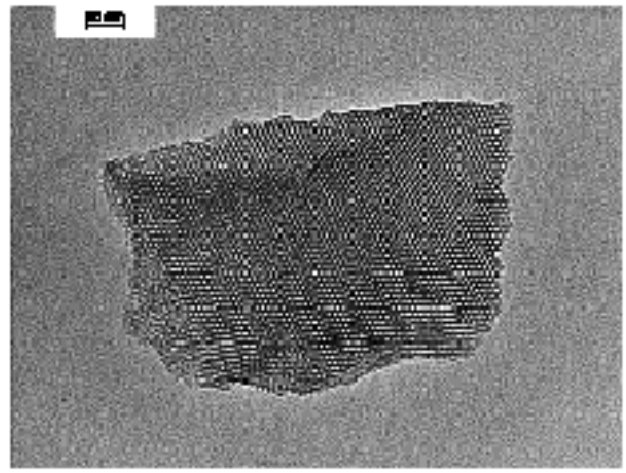
**Palladium grafted mesoporous MCM-41 materials, prepared by vapor grafting, show remarkable activity in Heck carbon–carbon coupling reactions.**

Current research focuses on the synthesis and application of modified mesoporous MCM-41 materials[1,2] that have an active species attached to the framework *via* host–guest interactions, creating discrete and uniform catalyst sites on the inner walls of the porous systems. Herein we report the synthesis of palladium-grafted mesoporous materials, designated Pd-TMS11, and their application as heterogeneous catalysts in Heck reactions. Palladium catalyzed carbon–carbon bond formation, the Heck reaction,[3] represents one of the most versatile tools in modern synthetic chemistry and has great potential for industrial applications. Although recent advances in homogeneous[4] and heterogeneous[5] Heck catalysis have attracted considerable attention, the properties and activities of the existing catalysts have, as yet, limited industrial application. Here we report the synthesis of a highly active heterogeneous palladium catalyst, Pd-TMS11, that exhibits excellent activity towards activated and non-activated haloarene substrates.

Palladium-grafted mesoporous material (Pd-TMS11) is synthesized by vapor deposition of a volatile palladium complex onto the inside walls of the porous framework, followed by reduction. The success of grafting the inside of a porous material with a highly dispersed metal film is strongly dependent on the properties of the volatile complex and the reaction conditions.† To maintain the uniform structure, high surface area and accessibility of the molecular sieves, it is important to minimize the cluster growth inside and outside of the porous material. The concept of vapor grafting enables a uniform distribution of a volatile complex and ensures the discrete deposition of metal fragments throughout the porous structure of the material without cluster formation, giving metal-grafted molecular sieves.

The palladium grafting of the degassed silicate-based MCM-41 material‡ was carried out *via* sublimation of the volatile organometallic complex[6] [Pd($\eta$-$C_5H_5$)($\eta^3$-$C_3H_5$)] under vacuum through the porous material. After the palladium complex is deposited onto the inside walls of the pores, the material is reduced under a stream of hydrogen gas, giving an air-stable, black powder.

The prepared catalyst,§ Pd-TMS11, retains its hexagonally-packed porous structure as shown in X-ray diffraction (XRD) pattern. Although the diffraction patterns of Pd-TMS11 and the MCM-41 starting material are almost identical, the peak intensity for Pd-TMS11 is reduced owing to radiation diffusion caused by the grafted palladium metal. The XRD pattern of palladium metal has major diffraction peaks at $2\theta = 40.1°$ (111) and 46.7° (200), which are not found in the XRD pattern of Pd-TMS11, indicating that the palladium metal is highly dispersed in the latter. Further evidence is provided by transmission electron micrograph¶ (TEM) that shows the hexagonally packed porous structure of Pd-TMS11 (Fig. 1), with no noticeable palladium clusters. In addition, scanning transmission electron micrographs (STEM) and energy dispersive analysis by X-ray (EDAX) studies have been conducted on Pd-TMS11 particles, indicating that palladium is uniformly



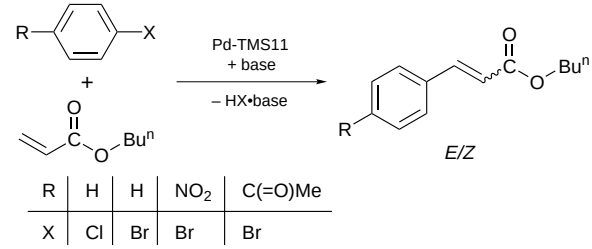


**Fig. 1** TEM of Pd-grafted mesoporous catalyst, Pd-TMS11, showing the hexagonal array of 26 Å pores

dispersed over the pore surface of the mesoporous support. Elemental analysis of Pd-TMS11 samples shows palladium metal contents of 10–30 mass%, depending on the amount of volatile complex [Pd($\eta$-$C_5H_5$)($\eta^3$-$C_3H_5$)] used in the vapor grafting process. The BET surface area of a typical sample of Pd-TMS11 with a palladium content of 19.1 mass% is 750 $m^2\ g^{-1}$. The BJH (Brunauer–Joyner–Halenda) pore size distribution of Pd-TMS11 illustrates a narrow peak centered at 26 Å for the pore diameter which is, as expected, slightly smaller than that determined for the MCM-41 starting material (27.4 Å) owing to the grafted palladium metal. The CO adsorption studies of Pd-TMS11 show metallic surface areas between 120 and 140 $m^2\ g^{-1}$ (Pd metal) with a metal dispersion of more than 30%. In comparison, commercially available Pd/$\gamma$-$Al_2O_3$ (Aldrich) shows a metallic surface area of only 60 $m^2\ g^{-1}$ (Pd metal) with a metal dispersion of 15%.

The Pd-TMS11 materials catalyze the Heck carbon–carbon coupling reaction of aryl halides (Scheme 1). The catalytic activity of these materials was investigated using activated and non-activated aryl halides and butyl acrylate as the vinylic substrate (Table 1). The yields for the activated aryl halides, with respect to reaction time and amount of catalyst, showed that the Pd-TMS11 catalysts have an excellent activity especially in view of other palladium-based heterogeneous systems.** Full conversion and a yield of 99% was obtained after

only 1 h for the reaction of *n*-butyl acrylate and 4-bromoacetophenone using as little as 0.02 mol% catalyst. The Pd-TMS11 material therefore provides an extremely simple and efficient Heck catalyst that even rivals some of the best homogeneous catalysts.[7,††] A moderate conversion of non-activated aryl halides was observed, and a conversion of 67% for bromobenzene has been achieved (see Table 1).

The new catalyst system Pd-TMS11, prepared by vapor grafting, has successfully been used in carbon–carbon coupling reactions. Remarkable activity, easy accessibility and exceptional stability of the described material provides an excellent example for a new generation of heterogeneous Heck catalysts.

† MCM-41 material was degassed at 60 °C under reduced pressure to prevent decomposition of the palladium complex due to air oxidation or hydrolysis *via* surface adsorbed water. To achieve a uniformly grafted Pd-TMS11 it is necessary that the surface of the MCM-41 be water-free and only consist of surface bound oxo and hydroxo groups.

‡ Modified synthesis of mesoporous MCM-41. Hexadecyltrimethylammonium bromide (15.9 g, 44.9 mmol) was dissolved in $H_2O$ (1.2 l) and treated with sodium silicate (14% NaOH/27% $SiO_2$) and 1 g (3.14 mmol) $Nb(OEt)_5$ in $H_2O$ (0.4 l) to give a white precipitate.‡‡ The pH value of the mixture was adjusted to pH = 11.5 using sulfuric acid (30%). The gel was aged at room temp. for 12 h before it was heated in pressure tubes to 100 °C for 7 d. The supernatant of the aged gel was decanted off and the resulting white residue washed with $H_2O$ (1 l) and EtOH (1 l). The isolated solid was dried in air at room temp. for 12 h before the material was calcined at 560 °C for 6 h giving MCM-41 with a hexagonally-packed cylindrical mesoporous structure.

§ Synthesis of palladium-grafted mesoporous material (Pd-TMS11). MCM-41 (0.5 g) [XRD (100) 39.9 Å, (110) 22.5 Å, (200) 19.6 Å, (210) 14.8 Å; BET surface area of 997 $m^2\ g^{-1}$, BJH adsorption pore size of 27.4 Å] was degassed at 600 °C under reduced pressure ($10^{-2}$ Torr) for 6 h. The resulting material was loaded into a short path frit and contained with glass wool under an inert gas atmosphere. A small round-bottom flask was filled with the red complex [Pd($\eta^3$-$C_3H_5$)($\eta$-$C_5H_5$)] (0.25 g, 1.2 mmol) and connected to a prepared frit that was further attached to a condensation bridge with a round-bottom flask. The apparatus was evacuated, and a constant pressure ($10^{-2}$ Torr) was maintained by cooling the empty round-bottom flask to −196 °C. The small round-bottom flask containing the volatile palladium complex and the loaded frit were heated to 120 °C (ramp 1 °C $min^{-1}$) using an oil bath. During the heating process, the white MCM-41 starting material turned black and the excess volatile organometallic complex was condensed into the cooled round-bottom flask. The resulting solid was reduced under a stream of hydrogen (50 ml $min^{-1}$) at 300 °C, giving a black powder designated Pd-TMS11 [XRD (100) 39.6 Å, (110) 22.4 Å, (200) 19.4 Å].

¶ An average of 50 particles per sample was investigated *via* TEM. No palladium clusters were observed on the as-synthesized Pd-TMS11 material, even at high magnification. TEM investigation of used Pd-TMS11 catalyst showed the formation of palladium clusters (*ca*. 50 Å diameter).

‖ Catalyst deactivation is noted in the form of palladium metal agglomeration, fracturing of the MCM-41 support material and coking of the catalyst surface. Pd-TMS11 recovered from the reaction of *n*-butyl acrylate and 1-bromo-4-nitrobenzene showed reduced activity in the second and third catalysis cycles under identical condition. The total lifetime of the catalyst is *ca*. 3000 TON for the latter reaction.

** Control experiments using commercially available $Pd/Al_2O_3$, $Pd/SiO_2$ and Pd/carbon (all containing *ca*. 10 mass% palladium) were conducted giving TONs which were 60% lower than those obtained for Pd-TMS11 with respect to activated aryl substrates. No activity was observed for non-activated aryl substrates in commercial supported catalysts.

†† Reaction between bromobenzene and *n*-butyl acrylate using homogeneous catalysts showed a TON of 96. In comparison, a TON of 624 was obtained for Pd-TMS11 at 170 °C in the same reaction. Unlike the existing homogeneous catalysts, our Pd-TMS11 is not air-sensitive and can be easily recovered by filtration after usage.

‡‡ The prepared MCM-41 had a niobium content of 1.5 mass% which contributed to the larger wall thickness of the material (18 Å). The dopant had no effect on the catalysis results.

# A solid state artificial muscle based on polypyrrole and a solid polymeric electrolyte working in air

**J. M. Sansiñena,[a] V. Olazábal,[a] T. F. Otero,[a] C. N. Polo da Fonseca[b] and Marco-A. De Paoli[b]**

[a] *Laboratorio de Electroquímica, Facultad de Química, Universidad del País Vasco, Apd 1072, 20080 San Sebastián, Spain*
[b] *Laboratório de Polimeros Condutores, Instituto de Química, Unicamp, C. Postal 6154, 13081-970 Campinas, SP, Brazil*

**A solid state artificial muscle based on polypyrrole(PPy) and poly(epichlorohydrin-co-ethylene oxide) [P(ECH-co-EO)]/$LiClO_4$ (solid polymeric electrolyte) is developed; an angular movement in air with rate, direction and electrical control similar to those obtained in a liquid electrolyte (aqueous solution of $LiClO_4$) is registered when an electrical current was applied.**

Conducting polymers like polypyrrole, polythiophene and polyaniline, can be electrochemically oxidized and reduced in a continuous and reversible way. Simultaneous changes in conductivity,[1] colour,[2] volume[3–5] and other parameters are observed. All these properties are linked to movement of ions and solvent inside and outside the conducting polymer. These movements are accompanied by conformational changes along the polymeric chains, driving the opening and closure of the polymeric entanglements. Artificial muscles based on reversible stress gradients linked to these reverse conformational changes have been developed in recent years.[6–14] All these prototypes are in the liquid configuration, usually a lithium salt dissolved in an aqueous solution.

In this work, we have investigated the construction of a new solid state artificial muscle, fully polymeric, based on two polypyrrole (PPy) film electrodes and a new polymeric electrolyte, poly(epichlorohydrin-co-ethylene oxide) [P(ECH-co-EO)]/$LiClO_4$.

Polypyrrole films were electrogenerated from 0.2 M pyrrole and 0.1 M $LiClO_4$ organic solutions (acetonitrile with a water content of 2%). Three AISI 304 stainless steel plates, having a surface area of 3.50 $cm^2$, were used as electrodes, one of them as the working electrode and the other two as counter electrodes. The electrogeneration was performed under an inert atmosphere of argon. Potential square waves were applied between −0.300 V (2 s) and 0.850 V (8 s) to control the morphology of the film and its adherence to the metal. A saturated calomel electrode (SCE) was used as reference electrode.

Polymer electrolytes were prepared from a tetrahydrofuran solution containing 2.5% (w/w) of [P(ECH-co-EO)] and $LiClO_4$. An elastomeric solid with high ionic conductivity is obtained after evaporation of the solvent (casting). Higher ionic conductivity was attained when the salt concentration, defined as $\eta$ = [O]/[$Li^+$], was fixed at $\eta$ = 6.[15]

The artificial muscle prototype was prepared by dripping the electrolyte solution on two polypyrrole films (mass = 3 mg, thickness = 6 μm) grown on two different stainless steel electrodes, followed by evaporation of the solvent under atmospheric pressure at room temperature. Two [steel ‖ PPy ‖ P(ECH-co-EO)/$LiClO_4$] systems were obtained. The evaporation of the THF gives increasingly viscous and adherent films. Once the polyelectrolyte was viscous and adherent enough, the two electrodes covered by the polyelectrolyte film (thickness = 3 μm) were put in contact and a [steel ‖ PPy ‖ P(ECH-co-EO)/$LiClO_4$ ‖ PPy ‖ steel] system was performed. After 30 min the polyelectrolyte is dry and the triple layer [PPy ‖ P(ECH-co-EO)/$LiClO_4$ ‖ PPy] was then peeled off the stainless steel plates. The two films of polypyrrole were held at the top with a metallic clamp to allow independent electrical contract to the PPy films. One polypyrrole film was connected as working electrode and the other as counter electrode short-circuited with the reference electrode contact of the potentiostat. The movement of the triple layer was studied at room temperature with a controlled humidity (60%).

The solid polymeric electrolyte provided the ionic contact between the two polypyrrole electrodes with a face to face

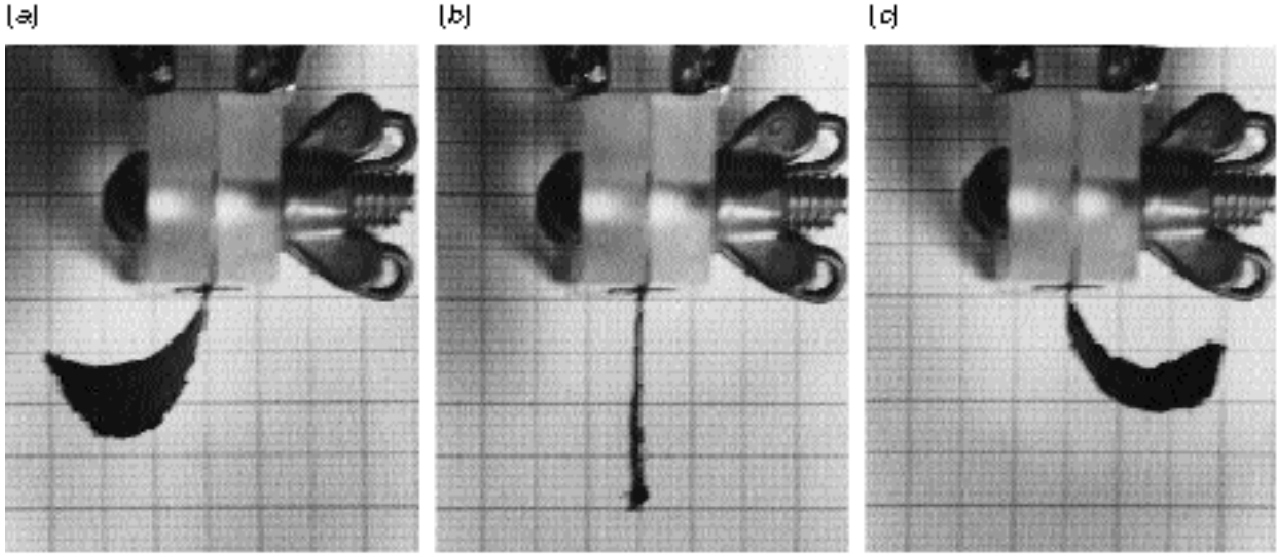

**Fig. 1** Movement of the solid artificial muscle during the application of an electric current: (*a*) position after 108 mC of reduction charge, (*b*) position at neutral electrical state and (*c*) position after 108 mC of oxidation charge

configuration. All experiments began from the vertical position as can be seen in Fig. 1(*b*) with the two PPy films in a semi-oxidised state (250 mV *vs.* SCE). The right face of the triple layer was the working electrode and the left side worked as a counter electrode.

The flow of a constant current through PPy films promotes an angular movement of the free end of the triple layer. An anodic current applied to the PPy film connected as working electrode produced an angular movement of the free end in the direction of the counter electrode, Fig. 1(*c*). A movement in the opposite direction was observed when a cathodic current was applied, Fig. 1(*a*). The triple layer bent in the direction of the working electrode. Under a constant current of 20 mA the free end of the artificial muscle delay 5.4 s to cross 90°.

The angular movement in air was similar to that obtained in a liquid medium.[10–12] The direction of the movement during the oxidation or reduction of the working electrode was the same to that obtained when a liquid electrolyte ($LiClO_4$ aqueous solution) was used. In this liquid electrolyte, $ClO_4^-$ anions enter into the PPy film during the oxidation process and the volume of PPy increases. These anions leave the film during reduction and the film volume decreases. In the solid configuration the flow of the current between both PPy films is supported by ionic movements inside the polymer electrolyte.

On the other hand, the electrical charge consumed during the movement of the solid state artificial muscle to cover 90° (36 mC per mg of PPy) was the same as that consumed when an aqueous $LiClO_4$, solution was used.

Taking into account that the covered angle depends directly on the volume change of the PPy film,[11,12] the PPy volume variation (covered angle) was the same for a similar electrical charge consumed when an aqueous $LiClO_4$ solution or a solid polymeric electrolyte (containing $LiClO_4$) was used.

The movement rate was also recorded. This parameter remained constant while the electrical current applied did not change. A linear relationship between movement rate and applied electrical current (similar to that showed in liquid configuration) was obtained [eqn. (1)].

$$\text{Movement rate rad s}^{-1} = 0.042\ I/\text{mass (mA mg}^{-1}) \quad (1)$$

Under these conditions both rate and direction of the angular movement are controlled by the intensity and direction of the current flow, respectively.

All the results obtained in this work show the feasibility of electrochemomechanical devices based on polypyrrole and a solid polyelectrolyte P(ECH-co-EO)/$LiClO_4$ film able to work in air. This fact starts a new development toward actuators and microrobotic applications.

The authors wish to express their gratitude to Gobierno Vasco, Iberdrola S.A., CNPq and FAPESP for their financial support. We also thank Oscar K. Kozima for the photographic work.

# Pore size regulation of $TiO_2$ by use of a complex of titanium tetraisopropoxide and stearic acid

**Satoshi Sato,* Satomi Oimatsu, Ryoji Takahashi, Toshiaki Sodesawa and Fumio Nozaki**

*Department of Applied Chemistry, Faculty of Engineering, Chiba University, Yayoi, Inage, Chiba 263, Japan*

**The pore size distribution of $TiO_2$ can be controlled by changing the molar ratio of stearic acid to titanium tetraisopropoxide.**

Materials with a controlled pore size, in addition to high specific surface areas, are attractive for use as catalysts and catalyst supports. Mesoporous amorphous silicas such as MCM-41[1] and FSM-16[2] have been recently synthesized, and have specific surface areas $> 1000$ m$^2$ g$^{-1}$ together with uniform mesopores. Interest in the synthesis of mesoporous materials are also focused on other oxides such as $Al_2O_3$, $WO_3$, and PbO.[3–7] Mesoporous aluminas with specific surface areas $> 500$ m$^2$ g$^{-1}$ have been prepared from aluminium alkoxide in the presence of a surfactant.[6,7] On the other hand, the pore size distribution of alumina can be regulated by a pH-swing process.[8] In the process, the particle size of aluminium hydroxide was controlled by altering the pH of the solution containing aluminium hydroxide gel. Here we demonstrate the control of pore size of titania by using stearic acid as a pore regulating reagent.

A measured amount of stearic acid ($C_{17}H_{35}CO_2H$, STA) was dissolved in propan-1-ol at 50 °C and titanium tetraisopropoxide [$Ti(OPr)_4$] dissolved in propan-1-ol at room temp. was added to the STA solution at room temp. The molar ratios of $Ti(OPr)_4$, STA, and propan-1-ol were $1:X:26$, where $X$ was varied from 0 to 2. After the mixed solution was stood at room temperature in an open container for at least 24 h, a white precipitate was formed. The solution was allowed to stand until no further precipitate was formed (up to 264 h). The precipitate was separated by decantation from the solution, and dried at 170 °C for 1 h. The dried sample was calcined at 400 °C for 4 h to obtain $TiO_2$. The pore size distribution of each $TiO_2$ sample was calculated from its $N_2$ adsorption isotherm at −196 °C according to a calcination method reported by Cranston and Inkray.[9]

Preliminarily, it was found that the addition of water to the starting solution decreased both the specific surface area and pore volume. Thus, we prepared samples without adding water to the solution. Since no STA was observed in the supernatant solution, almost all the added STA was included in the precipitate. When the samples were dried at 170 °C, the precipitates became yellow granules up to a molar ratio of STA/Ti ($X$) of 0.9, and melted above $X = 1.2$. Above $X = 0.2$, a white $TiO_2$ solid was obtained by calcining the dried sample at 400 °C, and the mass of the sample decreased. The mass decrease in the sample was nearly equal to the amount of added STA. For $X = 0.3$, the $TiO_2$ sample calcined at 400 °C had a specific surface area of 92 m$^2$ g$^{-1}$. For $X < 0.2$, however, carbon species remained in the samples calcined at 400 °C. The crystal structure, as confirmed by XRD, was anatase titania which at 500 °C, became a mixture of anatase and rutile (2.6 m$^2$ g$^{-1}$). At 600 °C, the crystal structure was completely converted to rutile and the specific surface area of the rutile titania was as low as 1 m$^2$ g$^{-1}$. Consequently, a calcination temperature of 400 °C was adopted.

The structural properties of the resulting $TiO_2$ altered with the amount of STA added in the starting solution (Figs. 1 and 2). At $X < 0.1$, specific surface areas of the samples were lower than 10 m$^2$ g$^{-1}$. A sample prepared without STA ($X = 0$) had a broad distribution of pore volume with a maximum at 5 nm, while the total volume was only 0.01 cm$^3$ g$^{-1}$. The specific surface area as well as the pore volume increased with increase in $X$ up to 1.2 (Fig. 1), and the pore size distribution could be regulated; the pore diameter was shifted from 5 to 15 nm in the STA/Ti ($X$) range between 0.3 and 1.2 (Fig. 2). At $X > 1.2$, no change was observed in the structural properties including the pore size distribution. In the calculation of the pore size distribution of $TiO_2$ samples, cumulative surface areas calculated from the pore volume and the pore diameter were consistent with the specific surface areas obtained by the BET method. Therefore, the pore size distribution of $TiO_2$ is controlled by changing the molar ratio of STA to $Ti(OPr)_4$ in the range $0.3 < X < 1.2$.

For different $X$ values, both the trend of the variation in structural properties and the behavior of the samples in the

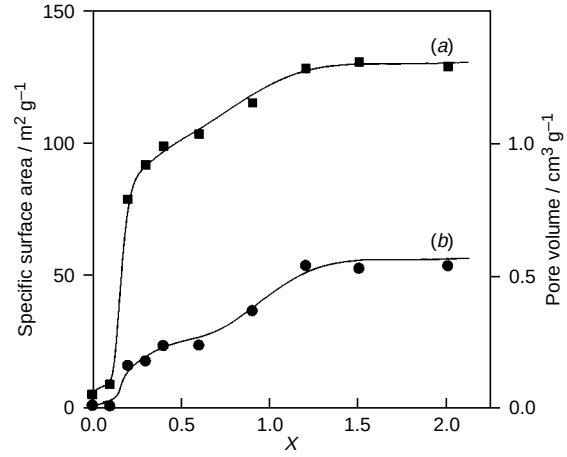

**Fig. 1** Structural properties of $TiO_2$ prepared with different amounts of stearic acid. The molar ratios of $Ti(OPr)_4$, stearic acid, and propan-1-ol were $1:X:26$; (*a*) specific surface area, (*b*) pore volume.

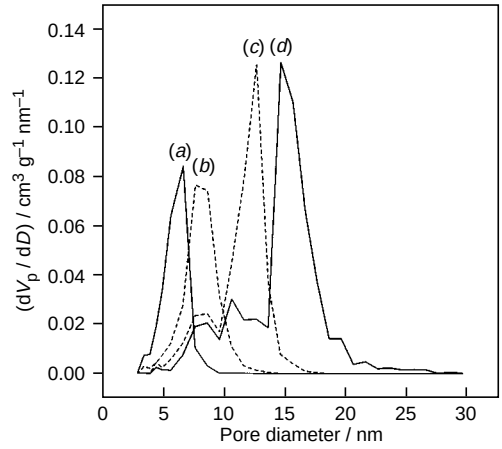

**Fig. 2** Pore size distribution of $TiO_2$ prepared from a $Ti(OPr)_4$–STA complex. The molar ratios of $Ti(OPr)_4$, stearic acid, and propan-1-ol were $1:X:26$; (*a*) $X = 0.3$, (*b*) 0.6, (*c*) 0.9, (*d*), 1.2.

preparation process were clearly altered at $X$ *ca*. 1. In the $Ti(OPr)_4$–$MeCO_2H$ system, two acetic acid molecules are known to coordinate with a titanium isopropoxide dimer to form a 2 : 2 complex.[10] In the $Ti(OPr)_4$–STA system, it is considered that the same type of complex is formed. In the IR spectrum of the precipitate dried at 170 °C, three characteristic absorption peaks were observed at 1450–1470, 1540–1560 and 1740 $cm^{-1}$. The broad peaks at 1450–1470 and 1540–1560 $cm^{-1}$ are assigned as stretching vibrations of a bidentate carboxylate ($CO_2^-$) ligand, and the sharp peak at 1740 $cm^{-1}$ as a stretching vibration of C=O in an ester bond of stearate. Because free STA was not detected in the sample dried at 170 °C, excess STA reacted with the solvent propan-1-ol to form *n*-propyl stearate.

For $X < 1.2$, the precipitates is a mixture of the $Ti(OPr)_4$–STA complex and titanium hydroxide contained residual alkoxide groups. For $X > 1.2$, the precipitate is a mixture of the $Ti(OPr)_4$–STA complex and *n*-propyl stearate. The results, for samples with $X > 1.2$, that the excess STA does not contribute to the formation of pore structure imply that the $TiO_2$ pores are formed upon decomposition of the $Ti(OPr)_4$–STA complex. In other words, an appropriate amount of STA acts as a template while excess of STA acts simply as a solvent. In conclusion, the pore size distribution of $TiO_2$ can be controlled by calcining the precipitate containing the $Ti(OPr)_4$–STA complex with different STA/Ti ratios.

# A novel aluminophosphate precursor that transforms to $AlPO_4$-5 molecular sieve at high temperature

**A. M. Prakash,[a] Martin Hartmann[b] and Larry Kevan*[a]**

[a] *Department of Chemistry, University of Houston, Houston, Texas 77204, USA*
[b] *Institute für Chemische Technologie, Universität Stuttgart, 70550 Stuttgart, Germany*

**A novel aluminophosphate microporous compound, denoted UHM-5, synthesized from an aqueous aluminophosphate gel at 150 °C in the presence of cyclohexylamine as the template, transforms upon calcination above 300 °C into $AlPO_4$-5 molecular sieve.**

Hydrothermal synthesis of microporous materials using organic structure directing templates normally leads to a crystalline solid (precursor) that possesses a three dimensional framework of $TO_4$ tetrahedra, where T is a tetrahedral atom, and the subsequent elimination of the template by calcination occurs without significant structural variation. Surprisingly, this is not the case for the precursor reported in this work. However, partial removal of the organic species from the precursor by calcination above 300 °C leads to the AFI type structure. A similar behavior has been reported recently in the structural transformation of JDF-20, an extra large pore molecular sieve with a 20-membered ring, to $AlPO_4$-5.[2] JDF-20 has been reported to be crystallized from a predominantly non-aqueous synthesis medium using triethylamine which is also a template for $AlPO_4$-5. Although both UHM-5 and JDF-20 exhibit similar transformation to $AlPO_4$-5, these materials differ significantly in their structural and compositional details. From various characterization results on UHM-5, we believe that this is a new member of the extra-large pore molecular sieve family.

Synthesis of UHM-5 was achieved from an aqueous aluminophosphate gel using cyclohexylamine (CHA) as the structure directing template. UHM-5 was prepared by a modification of a synthesis procedure which would otherwise yield $AlPO_4$-5 molecular sieve. Typically the molar composition of the gel was: 1 CHA : 1 $Al_2O_3$ : 1 $P_2O_5$ : 50 $H_2O$. In a typical synthesis procedure aluminium isopropoxide (Aldrich, 98+%) was slurried in deionized water. While stirring, orthophosphoric acid (Merck, 85%) diluted with water was added. After stirring for 10 min, cyclohexylamine (Aldrich, 99%) was added slowly. The mixture was then heated at 70 °C for 30 min using a water-bath. The final gel was crystallized at 150 °C for 74 h.

Fig. 1 shows the X-ray powder diffraction patterns of a sample in the as-synthesized form and after heating this sample in $O_2$ at 300 °C. The observed crystalline pattern for the as-synthesized material is novel. The very low $2\theta$ value ($d$ = 17.96 Å) of the most intense line in the XRD pattern is indicative of an extra-large pore molecular sieve. The weak line at $2\theta$ 7.57° is probably due to a very small amount of $AlPO_4$-5 which can probably crystallize along with UHM-5. After heating the sample at 300 °C, the structure changes to that of well crystallized $AlPO_4$-5 as also shown in Fig. 1. This structural transformation is brought about by the partial removal of the organic template. There is an extra line at $2\theta$ 21.80° in the XRD pattern which does not belong to $AlPO_4$-5. Note that a line at $2\theta$ 21.85° is also present in the XRD pattern of the as-synthesized sample. Thus, we believe that this extra line is possibly due to a small amount of a dense impurity phase present in the sample. By considering the first 15 lines after excluding the lines due to $AlPO_4$-5 ($2\theta$ 7.57°) and the impurity phase ($2\theta$ 21.85°) the powder pattern of UHM-5 has been indexed as a tetragonal unit cell with lattice parameters of $a$ = 18.15, $c$ = 20.59 Å and $U$ = 6786.3 Å$^3$.

To remove the organic template without effecting structural transformation, ion-exchange with $NH_4Cl$ was attempted. As in the case of thermal treatment, this procedure also leads to transformation of UHM-5 to $AlPO_4$-5 with significant loss in crystallinity. This suggests strong interaction between cyclohexylamine and the framework of UHM-5. The interaction between template and framework is further evidenced from thermal analysis results. Thermogravimetry (TG) and differential thermal analysis (DTA) of the material (Fig. 2) show two exothermic mass losses; a sharp loss at *ca*. 300 °C and a gradual loss between 300 to 500 °C due to the desorption and decomposition of the organic template. The total mass loss of 34 mass% observed on UHM-5 is significantly higher than the mass loss reported for any of the extra large pore molecular sieve materials and indicates the very high internal volume confined by the aluminophosphate framework. For example, both JDF-20 and VPI-5 show about 25% mass losses.[2,3] Interestingly, the material contains a very low amount of water as only < 1% of the total mass loss is accounted for by water desorption.

The product composition was estimated from electron microprobe analysis and TG results as 0.36 CHA $(Al_{0.5}P_{0.5})O_2 \cdot x\ H_2O$. The observed Al/P ratio of unity in UHM-5 is characteristic of three dimensional microporous solids with

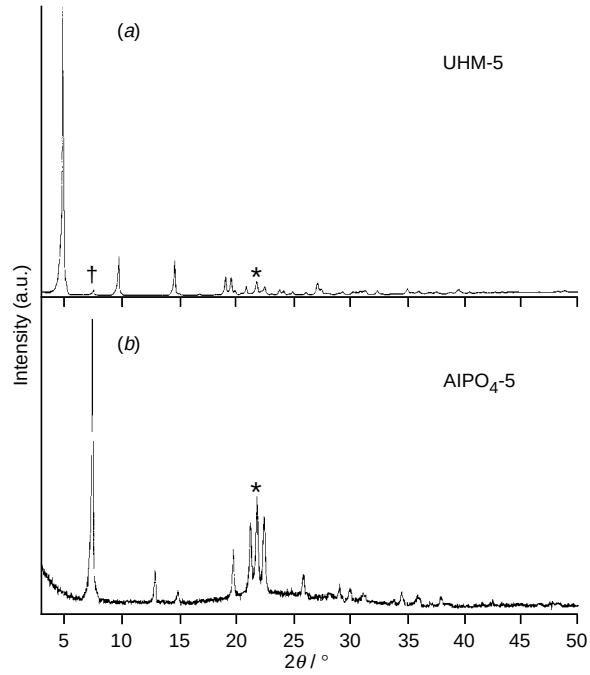

**Fig. 1** X-Ray powder diffraction patterns of (*a*) as-synthesized UHM-5 and (*b*) $AlPO_4$-5 obtained after calcination of UHM-5 at 300 °C in oxygen. In the as-synthesized sample the line marked with † is due to a small amount of $AlPO_4$-5 phase present. In both the as-synthesized and calcined samples, the lines marked by * are due to an impurity phase.

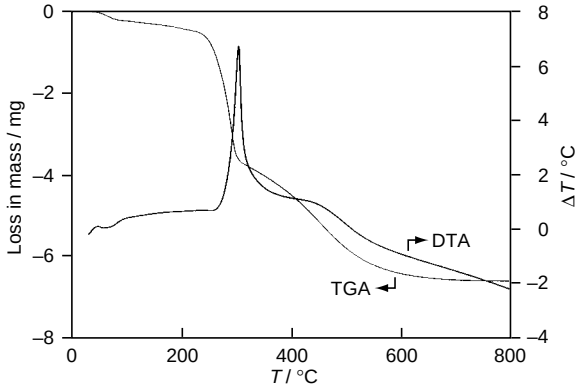

**Fig. 2** Thermogravimetry (TG) and differential thermal analysis (DTA) results on UHM-5. The data were recorded with a heating rate of 5 °C $min^{-1}$ in $O_2$ atmosphere. The initial mass of the sample was 17.418 mg.

alternate Al and P in the framework and is not observed in layered aluminophosphate materials. Previously synthesized layered aluminophosphates have a framework Al/P ratio of 0.75 and consist of vertices sharing $AlO_4$ and $PO_4$ tetrahedra with all of the vertices of the $AlO_4$ units being shared but only three-quarters of the $PO_4$ units being shared thus leaving formally a P=O group. It has been shown that these structure types can be related to two dimensional nets with the inclusion of a capping $PO_4^{3-}$ group.[4]

Fig. 3 shows the $^{27}Al$ and $^{31}P$ NMR spectra recorded on UHM-5 and after heating at 300 °C. The as-synthesized UHM-5 exhibits a single asymmetrical resonance in the $^{27}Al$ MAS NMR spectrum at $\delta$ 41.2 (reference: aqueous aluminium nitrate) characteristic of tetrahedral aluminium.[5] After the solid state transformation an additional peak is detected at $\delta$ 36.8. As-synthesized and calcined $AlPO_4$-5 is reported to exhibit a single resonance centered at $\delta$ *ca.* 35.[5] The fact that the line at $\delta$ 41.2 did not completely disappear during the transformation indicates that only a fraction of the Al sites undergo changes in environment during the transformation. The $^{31}P$ MAS NMR spectrum of as-synthesized UHM-5 exhibits a single sharp line at $\delta$ −4.6 and an additional broad line at $\delta$ −30 (reference 85% $H_3PO_4$). After the transformation, the line at $\delta$ −4.6 completely disappears while the line at $\delta$ −30 increases substantially. A $^{31}P$ line at $\delta$ −28.1 has been determined for $AlPO_4$-5.[6] Tetrahedral phosphorus in microporous materials generally exhibits resonances in the range $\delta$ −25 to −35 range characteristic of $P(OAl)_4$ environments.[5] The resonance at $\delta$ *ca.* −30 in UHM-5 is clearly due to tetrahedral phosphorus as found in several other microporous materials. The fraction of $AlPO_4$-5 present in the

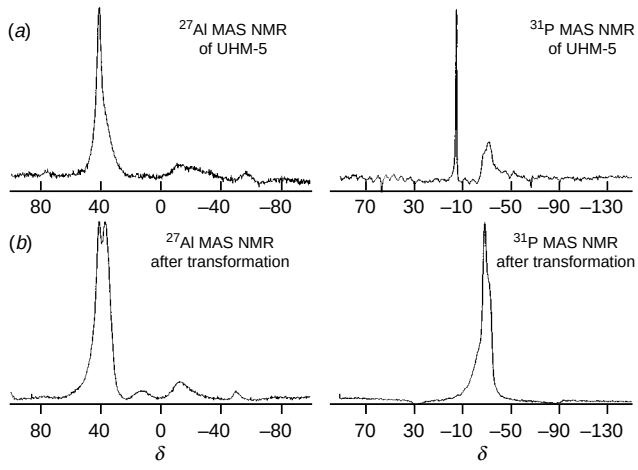

**Fig. 3** $^{27}Al$ and $^{31}P$ MAS NMR spectra recorded (*a*) for as-synthesized UHM-5 and (*b*) after heating UHM-5 at 300 °C in oxygen

original as-synthesized sample is very small. Thus, the relatively strong NMR signal at $\delta$ *ca.* −30 in an as-synthesized sample cannot be fully accounted for by an $AlPO_4$-5 phase, although a small contribution of this phase to the observed signal is obvious. In $AlPO_4$-based materials, the interaction of the framework phosphorus with extraframework species such as water or organic molecules can modify or shift the resonance signal considerably.[7] A wide range of chemical shifts spanning from $\delta$ 30 to −85 has been reported for five-coordinate phosphorus compounds.[8] A framework P/Al ratio of unity in UHM-5 implies an alternate arrangement of Al and P units in the framework. The observed resonance at $\delta$ −4.6 could be due to five-coordinate phosphorus of the form $P(OAl)_4(OH)$ formed by coordinating with four framework Al and an extraframework species such as a hydroxyl group. The presence of hydroxyl groups was observed in UHM-5 by FTIR measurements which show an intense sharp band at 3650 $cm^{-1}$ normally assigned to hydroxyl stretching vibrations.[9] The disappearance of the resonance at $\delta$ −4.6 after heating above 300 °C can be viewed as a consequence of phase transformation where the five-coordinated phosphorus transforms to tetrahedral to form $AlPO_4$-5 molecular sieve. Associated with each $P(OAl)_4(OH)$ unit one would expect a protonated template species. $AlPO_4$ units in which both Al and P are in tetrahedral coordination are neutral and do not require amine to balance any framework charge. From the observed chemical composition of UHM-5, it can be seen that for every ten P atoms there are about seven CHA species. This suggests that out of ten P atoms of the framework, roughly seven are in five-coordination and three in tetrahedral coordination consistent with the two $^{31}P$ NMR signals.

The observations made above suggest that the framework of UHM-5 probably consists of both $AlPO_4$ and $(AlPO_4)OH$ units. The framework structure of UHM-5 is stable in the presence of the organic species and transforms upon heating to the $AlPO_4$-5 structure. UHM-5 crystallizes in small 4–6 μm platelets bunched together to form large clusters of *ca.* 100 μm as revealed by scanning electron microscopy. Because of the small crystal size, single crystal analysis would be difficult. All the characterization results so far obtained on UHM-5 indicate an extra large pore material. Additional experiments are necessary for a better understanding of the transformation mechanism and work is in progress to determine the structure of UHM-5.

**The crystal structure of an amine phenol complex of gallium(III), [{1,12-bis(2-hydroxy-3-methoxybenzyl)-1,5,8,12-tetraazadodecane}gallium(III)] [Ga(madd)]$^+$, a potent new antimalarial which selectively targets chloroquine-resistant organisms is reported; the compound is shown to directly inhibit heme polymerization.**

Chloroquine, the mainstay of treatment and prophylaxis of malaria, disrupts polymerization of heme (ferriprotoporphyrin IX) released during catabolism of host hemoglobin within the causative organism, *Plasmodium falciparum*.[1–3] Given the importance attributed to iron metabolites in parasite toxicity, a variety of metal chelating agents such as deferoxamine and reversed siderophores have been explored as potential antimalarial chemotherapeutics.[4–6] We recently identified a class of Schiff-base and reduced amine phenol metal(III) complexes with $N_4O_2$ donor cores having potency as novel antimalarials.[7] We report herein the chemical characterization including crystal structure and direct demonstration of inhibition of heme polymerization by one distinctive complex, [{1,12-bis-(2-hydroxy-3-methoxybenzyl)-1,5,8,12-tetraazadodecane}gallium(III)] {[Ga(madd)]$^+$ **1**}. While the action of chloroquine is now circumvented by widely disseminated resistant organisms, **1** paradoxically possesses antimalarial activity only against chloroquine-resistant *P. falciparum* in whole cell assays. Thus, **1** may provide a lead for further development of analogous iron(III) antimalarials and, in addition, the crystal coordinates provide a structural template for exploration of the molecular determinants of chloroquine resistance in *P. falciparum*.

Large spectral linewidths and the accompanying poor resolution produced by high spin iron(III) pose difficulties for spectroscopic characterization of iron(III) complexes in solution through NMR studies. Thus, we have chosen diamagnetic gallium(III) as a template for iron(III), since both ions have the same charge and nearly identical six-coordinate ionic radii which typically result in similar coordination chemistry.[8] Furthermore, neither high spin $d^5$ iron(III) nor $d^{10}$ gallium(III) possess any crystal field stabilization energy and therefore often result in similar ligand exchange kinetics.[9] For analysis, the desired amine phenol ligand, $H_2$madd **2**, was obtained through *in situ* potassium tetrahydroborate reduction of the condensation product derived from appropriate stoichiometric amounts of bis(*N*,*N*′-aminopropyl)ethylenediamine and 3-methoxysalicylaldehyde.[10,11] [Ga(madd)]$^+$ **1** was obtained by dissolving **2** in methanol and treating with base and the hydrated salt of gallium(III) perchlorate.† The $^1$H NMR spectrum of **1** recorded in $(CD_3)_2SO$ demonstrated overlapping signals for the hydrocarbon backbone consistent with complex formation and a single set of signals for the aromatic protons consistent with chemically equivalent aromatic environments. The proton-decoupled $^{13}$C NMR spectrum recorded under similar conditions also revealed 12 resonances out of a possible 24 further indicating the maintenance of a high degree of symmetry around the ethylene moiety upon coordination of the metal to ligand **2**.

Definitive evidence that $Ga^{III}$ was coordinated simultaneously and symmetrically with the $N_4O_2$ donor core was provided by X-ray crystallography.‡ Crystals suitable for X-ray structure determination were grown through slow evaporation of methanol over a period of 2–3 d. An ORTEP drawing of **1** is shown in Fig. 1 along with selected bond angles and interatomic distances. The central $Ga^{III}$ is six-coordinate involving two phenolate oxygens and four amine nitrogens providing overall octahedral geometry. Furthermore, the structure reveals formation of four six-rings and one five-membered ring upon coordination of the metal. The smallest angle, N(2)–Ga–N(3), is attributable to restrictions by the five-membered chelate ring involving N(2), C(11), C(12), N(3) and Ga. The *trans* angles involving N(1)–Ga–N(3), N(2)–Ga–N(4) and O(1)–Ga–O(2) averaged 175.4°, whereas the *cis* angles involving O–Ga–N averaged 90.0°, providing minimally distorted octahedral

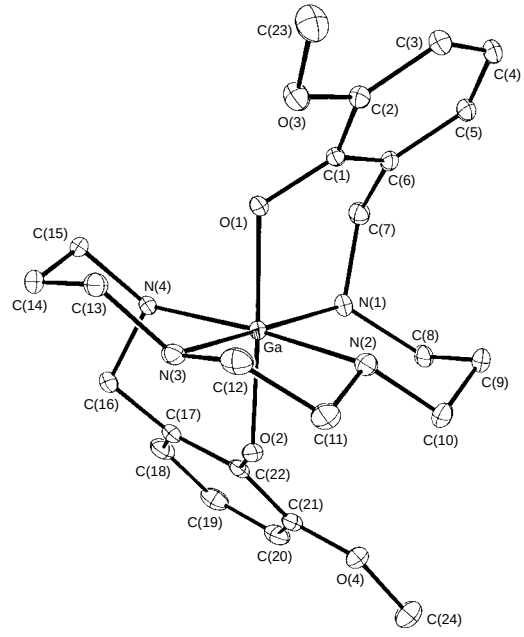

**Fig. 1** ORTEP drawing of the [Ga(madd)]$^+$ cation (**1**) in [Ga(madd)]$ClO_4$ showing the crystallographic numbering scheme. Atoms are represented by thermal ellipsoids corresponding to 20% probability. Selected bond angles (°) and interatomic distances (Å) for **1**: N(1)–Ga–N(2) 92.15(11), N(2)–Ga–N(3) 83.22(11), N(3)–Ga–N(4) 90.62(11), N(4)–Ga–N(1) 94.08(10), O(1)–Ga–O(2) 177.99(8), N(1)–Ga–N(3) 174.87(10), N(2)–Ga–N(4) 173.43(10), O(1)–Ga–N(1) 90.29(10), O(1)–Ga–N(4), 88.59(10), O(2)–Ga–N(2) 87.87(10), O(2)–Ga–N(3) 90.87(10), C(1)–O(1)–Ga 122.4(2), C(22)–O(2)–Ga 119.1(2); Ga–O(1) 1.911(2), Ga–O(2) 1.950(2), Ga–N(1) 2.130(3), Ga–N(2) 2.103(3), Ga–N(3) 2.109(3), Ga–N(4) 2.105(3), O(1)–C(1) 1.345(4), O(2)–C(22) 1.340(4).

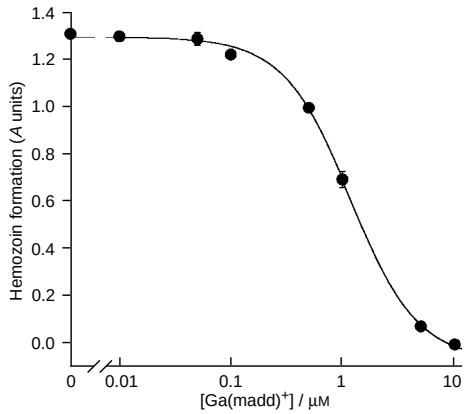

**Fig. 2** Inhibition of heme polymerization by $[Ga(madd)]^+$ **1**. Heme polymerization was assayed by the preformed hemozoin nucleation reaction[7] in the absence or presence of various concentrations of **1**. Data are shown as the mean ±SEM (when larger than symbol) of six determinations.

geometry around the central metallic core. Angles and distances of atoms directly participating in the coordination sphere of **1** are similar to those recently reported for the gallium(III) complexes of a 5-bromo substituted amine phenol[12] and an analogous substituted Schiff-base phenol.[13]

Chloroquine concentrates within the parasitic digestive vacuole[14] an acidic organelle wherein the host's hemoglobin is digested as a source of amino acids, releasing monomeric heme.[15] Toxic to parasites,[2,16,17] heme is polymerized by the organisms into a crystalline matrix known as hemozoin, a black insoluble pigment which constitutes heme units coordinated through iron–carboxylate linkages.[1] Chloroquine inhibits heme polymerization, resulting in accumulation of the toxic monomeric heme moiety.[2,3] Resistance appears to be mediated by an acquired ability of the parasite to reduce uptake[18] or pump chloroquine out of the digestive vacuole.[19,20] Because hemozoin formation is unique to the malaria organism, inhibition of heme polymerization has remained an attractive target for drug development, providing an agent can be designed to bypass the organism's chloroquine-evading mechanisms.

Among dozens of analogues, including the above 5-bromo complex[21] and several Schiff-base analogues,[7] **1** was found to be unique in possessing selective antimalarial activity against chloroquine-resistant Dd2 clones of *P. falciparum*. To further determine the potency of **1** to inhibit additional chloroquine-resistant lines of *P. falciparum*, growth of trophozoites in intra-erythrocyte culture was assayed by the hypoxanthine incorporation method.[7,22] Compared to a half-maximal inhibitory concentration ($IC_{50}$) value $>>20$ μM in the chloroquine-sensitive HB3 line, the $IC_{50}$ values for **1** were 0.5 and 0.6 μM in the chloroquine-resistant FCR-3 and Indo-1 lines, respectively, and further supported a general collateral selectivity of **1** for chloroquine-resistant *P. falciparum*.

However, the potency of **1** to directly inhibit heme polymerization *in vitro* was found to be similar to other agents in this class (Fig. 2). For example, to simulate the parasitic digestive vacuole environment,[16] heme was incubated along with preformed hemozoin nucleates under acidic conditions in the absence or presence of various concentrations of **1**.[2,7]§ Complex **1** was found to be a potent inhibitor of heme polymerization ($IC_{50}$ = 1.2 ± 0.08 μM; mean ±SEM; $n$ = 6), two- to three-fold more potent than chloroquine under identical conditions.[7] Thus, while **1** is not susceptible to the chloroquine resistance mechanism(s) in whole cell assays, it inhibits the same final molecular target as chloroquine *in vitro*. Careful evaluation of **1** revealed that the angles Ga–O(1)–C(1) and Ga–O(2)–C(22) which incorporate the aromatic rings averaged 120.8°, *ca*. 2.5° more acute than the reported 5-bromo complex, thereby suggesting that the unique targeting properties of **1** likely reside in the spatial orientation of the peripheral regions of the aromatic moieties, including the methoxy functionalities, rather than the central metal core.

The gallium(III) complex, $[Ga(madd)]^+$ **1**, is the first amine phenol metal(III) complex to show antimalarial activity selectively against chloroquine-resistant organisms. While important considerations regarding optimization of selectivity and bioavailability are under active investigation, **1** represents a significant step forward in the development of a novel antimalarial.

We thank George Gokel for critical review of the manscript, Ilya Gluzman and Anna Oksman for technical assistance. This work was funded in part by a grant from the US Department of Energy (ER61885) and by grants from the NIH (AI31615 and CA65735).

# Generalised route to the preparation of mesoporous metallosilicates *via* post-synthetic metal implantation

**Ryong Ryoo,* Shinae Jun, Ji Man Kim and Mi Jeong Kim**

*Materials Chemistry Laboratory, Department of Chemistry and Center for Molecular Science, Korea Advanced Institute of Science and Technology, Taejon, 305-701, Korea*

**A post-synthesis route, through which various metal elements can be grafted onto siliceous frameworks using non-aqueous solutions of $AlCl_3$, $Al(NO_3)_3$, $SnCl_2$, $Zn(O_2CMe)_2$ $Mn(O_2CMe)_2$, *etc.*, is developed as a generalised means to obtain mesoporous metallosilicates molecular sieves with various structures such as MCM-41 (hexagonal), MCM-48 (cubic *Ia*3*d*), SBA-1 (cubic *Pm*3*n*), KIT-1 (disordered) and MSU-1 (disordered) with superior structural integrity, acidity and catalytic activity to those of materials having metals incorporated during synthesis.**

During the past five years, various kinds of mesoporous silica so-called MCM-41,[1,2] MCM-48,[1,2] SBA-1,[3] MSU-1,[4] KIT-1,[5,6] FSM-16,[7] *etc.* have been synthesized using surfactant micelles as the structure-directing agent. A large number of papers have reported the incorporation of aluminium and other metal elements within the siliceous frameworks of the mesoporous materials by adding metal precursors prior to hydrothermal synthesis reaction in order to improve ion exchange capacity, acidity and catalytic activity.[8] However, the method incorporating Al precursors into the surfactant–silicate gel requires specialised synthesis conditions depending on the respective structures of the materials being synthesised, incorporating metals, and silica sources. Besides, the synthesis method is often hindered by a severe decrease in the structural order as the metal content increases.

Here we report a generalised route through which various metal elements such as Al, Sn, Zn and Mn can be incorporated within various mesoporous materials such as MCM-41 (hexagonal), MCM-48 (cubic *Ia*3*d*), MSU-1 (disordered), SBA-1 (cubic *Pm*3*n*) and KIT-1 (disordered), after the synthesis of pure silica forms. We show that the resultant mesoporous aluminosilicates can have not only high ion exchange capacity due to tetrahedral Al, but also superior structural integrity, acidity and catalytic activity to those obtained by the mixed-gel approach.

The silica forms of MCM-41, MCM-48, MSU-1, SBA-1 and KIT-1 were obtained by hydrothermal synthesis following methods reported in the literature.[1–6] The as-synthesized materials except SBA-1 were washed with slurrying in EtOH–HCl at room temp.; less than 1 g of sample was washed with a mixture of 0.5 ml of 37% HCl and 20 ml of 95% EtOH. The sample was immediately dried in an oven at 393 K. The washing resulted in the removal of more than 95% of the surfactant, which was confirmed by IR absorption spectroscopy. The surfactant in SBA-1 was removed by calcination in $O_2$ flow at 823 K since the structure collapsed upon washing with EtOH–HCl. The mesoporous materials after the removal of surfactant, either by solvent extraction or calcination, were slurried in absolute EtOH solutions containing the anhydrous form of various metal compounds such as $AlCl_3$, $Al(NO_3)_3$, $SnCl_2$, $Zn(O_2CMe)_2$ and $Mn(O_2CMe)_2$, with magnetic stirring for 1 h at 298–333 K. The mesoporous materials were then washed with absolute EtOH, dried and calcined in air using a muffle furnace. The calcination temperature was increased to 823 K over 10 h and maintained there for 5 h.

The obtained materials were characterised by X-ray powder diffraction (XRD), BET surface area measurement, $^{27}Al$ MAS NMR, temperature programmed desorption (TPD) of $NH_3$, and $K^+$ ion exchange. XRD patterns and NMR spectra were obtained in the same manner reported in our recent papers.[9,10] Ammonia TPD and $K^+$ ion exchange capacity were measured following refs. 11 and 12, respectively.

All mesoporous metallosilicates obtained by the present metal-implantation route gave the same XRD patterns as those for their pure-silica analogues, as shown in Fig. 1. There were no significant changes in the XRD peak intensities and linewidths resulting from the implantation of Al, Sn, Zn and Mn throughout the investigated range of Si/Al $\geqslant$ 8, Si/Sn $\geqslant$ 20, Si/Zn $\geqslant$ 10 and Si/Mn $\geqslant$ 20. No additional XRD peaks appeared beyond the $2\theta$ region shown in Fig. 1, indicating that the implanted metal elements were well dispersed. The BET areas of the various samples ranged from 900 to 1200 $m^2\ g^{-1}$, and showed no more decreases than those attributable to increases in the sample mass due to the addition of the metal elements.

Recently, aluminosilicate forms of MCM-41 have been clarified to exhibit ion exchange capacity comparable to that for aluminosilicate zeolites whereas little ion exchange occurs with pure-silica MCM-41.[12] The ion exchange capacity can then be used as a means to probe the incorporation of metal elements with oxidation states less than +4. We have therefore measured the $K^+$-ion exchange capacity of our various metal-containing samples, and summarised results in Table 1. Note that the present Al-implanted samples showed a $K^+$-ion exchange capacity comparable to a result of 0.4 $K^+$/Al which was reported previously[12] with an AlMCM-41 (Si/Al = 39) sample prepared by the addition of sodium aluminate into the surfactant-silicate gel. The ion exchange capacity of the present Al-implanted samples depended more or less on structures and Si/Al ratios. The $K^+$/Al ratios decreased, in general, as the Si/Al ratios decreased. Sn-, Zn- and Mn-implanted samples also showed remarkable $K^+$ ion exchange capacity. It is thus evident that the

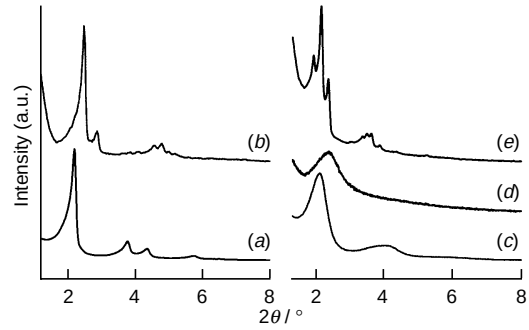

**Fig. 1** X-Ray diffraction patterns for various mesoporous molecular sieves obtained after calcination with metal implantation: (*a*) AlMCM-41 (Si/Al = 32), (*b*) AlMCM-48 (Si/Al = 8), (*c*) AlKIT-1 (Si/Al = 33), (*d*) AlMSU-1 (Si/Al = 53) and (*e*) AlSBA-1 (Si/Al = 11). The XRD patterns of the calcined samples with and without the metals were indistinguishable from each other.

**Table 1** Potassium ion exchange on mesoporous metallosilicates prepared by the metal-implantation method

| | Al implanted | | Sn implanted | Zn implanted | Mn implanted |
|---|---|---|---|---|---|
| Samples | Si/Al (K/Al[a]) | Si/Al (K/Al) | Si/Sn (K/Sn) | Si/Zn (K/Zn) | Si/Mn |
| KIT-1 | 47.7[b] (0.15) | 10.3[c] (0.07) | 71.7 (0.12) | 20.4 (0.09) | 68.5 |
| MCM-41 | 48.9[b] (0.20) | 8.3[c] (0.18) | 218 (0.39) | 21.1 (0.13) | 56.1 |
| MCM-48 | 37.1[b] (0.24) | 6.9[c] (0.10) | 56.7 (0.23) | 18.7 (0.26) | |
| SBA-1 | 56.3[b] (0.49) | 10.8[c] (0.27) | 79.2 (0.13) | 23.6 (0.29) | |
| MSU-1 | 53.4[b] (0.52) | 27.1[c] (0.33) | 230 (0.34) | | |

[a] Numbers in parentheses denote the atomic ratio between the ion exchanged $K^+$ and the implanted metal, determined by ICP emission spectroscopy. Metal leaching during ion exchange treatment occurred much less than $K^+$ exchange. Release of $H^+$ was also confirmed, indicating that the $K^+$ was exchanged with $H^+$. The pure-silica sample gave a K/Si ratio of 0.0004. [b] For Al incorporation, siliceous material was slurried in ethanol containing $AlCl_3$ at 298 K. [c] Slurry and filtration repeated three times using an excess of $AlCl_3$.

ion exchange capacity of the metal implanted samples arises from the incorporation of the metal elements within the silica framework, or at least in the form closely associated with it.

The incorporation of Al within the silica framework is consistent with a remarkable increase in the $^{27}$Al MAS NMR peak intensity for Al with tetrahedral coordination, upon calcination as shown in Fig. 2. The NMR spectrum before calcination shows a much lower peak intensity for the tetrahedral Al ($\delta$ 52) than that for octahedral aluminium ($\delta$ 0). The intensity order was reversed after calcination, throughout the range of Si/Al = 10 to infinity for the various mesoporous materials after calcination. This result indicates that a considerable proportion of the Al achieves tetrahedral coordination after calcination and probably becomes implanted within the silica framework.

Fig. 3 shows $NH_3$ TPD for the resulting Al-implanted samples. The other aluminosilicate samples also gave two TPD peaks which were centered around 430 and 830 K, respectively. The relative peak intensities and positions depended more or less on the structures and Si/Al ratios. The low temperature peak is similar to the TPD results reported previously for AlMCM-41. However, the high temperature peak was not reported previously.[9,13] The high temperature peak may be due to strong Lewis acidity of the extraframework Al species. The Al-

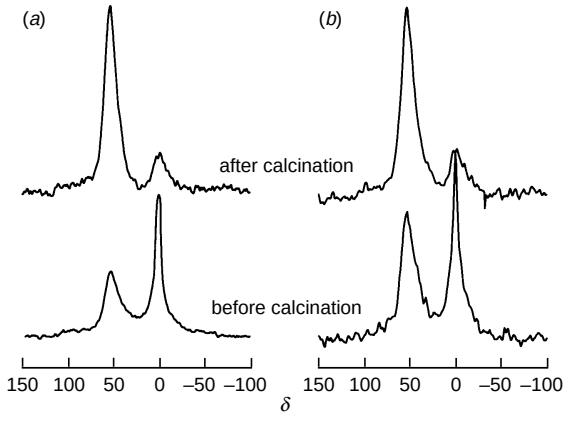

**Fig. 2** $^{27}$Al MAS NMR spectra for Al-implanted samples: (*a*) AlMCM-41 (Si/Al = 32) and (*b*) AlKIT-1 (Si/Al = 33). The NMR spectra show transition from octahedral to tetrahedral Al upon calcination.

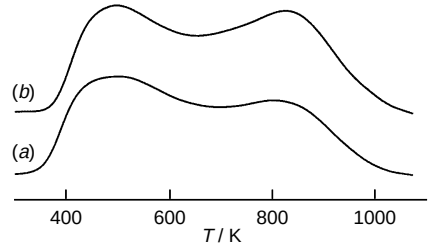

**Fig. 3** $NH_3$TPD spectra for Al-implanted samples: (*a*) AlKIT-1 (Si/Al = 33) and (*b*) AlMCM-41 (Si/Al = 32)

implanted samples exhibited 2–3 times higher catalytic activity for *n*-butane cracking under 0.5 kPa butane and 110 kPa He at 801 K. This can be due to the presence of a relatively large amount of Al on the framework surface of the implanted samples, while much A is imbedded within the pore wall of the samples which were synthesized with the addition of Al sources into the surfactant–silicate gel. Upon extrapolation to zero conversion, the turnover frequency for freshly calcined KIT-1 (Si/Al = 33) catalyst after Al implantation was 0.13 $s^{-1}$. This result is comparable to 0.30 $s^{-1}$, which was obtained for HZSM-5 (Si/Al = 25) based on the total number of Al sites under the same measurement conditions. Further details of the catalytic activity measurements will be reported in a full paper.

We have confirmed that it is important to use moisture-free EtOH or MeOH and anhydrous metal compounds since the presence of water inhibited metal implantation. It is believed that the metal species in the moisture-free solution was grafted onto silanol groups on the silica framework. The metal became probably incorporated within the siliceous framework *via* thermal activation during calcination. The resulting metallosilicate samples showed superior structural integrity, acidity and catalytic activity, compared to the materials obtained by the addition of a metal source into the surfactant-silicate gel. Thus, our metal implantation method can be useful for the preparation of various existing and new mesoporous metallosilicates.

The authors thank KOSEF for a grant supporting the present work.

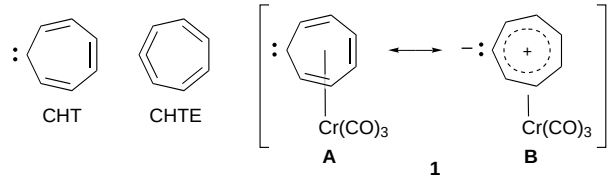
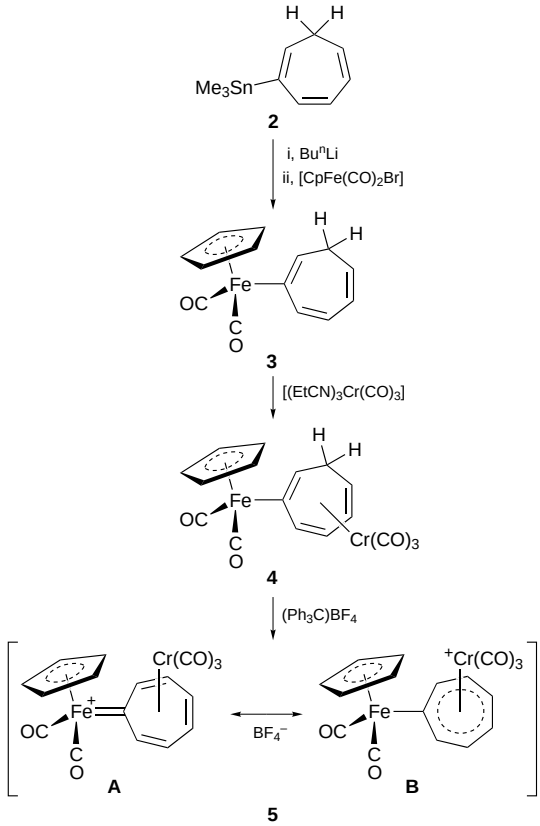
# Heterobimetallic cycloheptatrienyl and cycloheptatrienylidene complexes



**Matthias Tamm,* Alexander Grzegorzewski, Irene Brüdgam and Hans Hartl**

*Institut für Anorganische und Analytische Chemie, Freie Universität Berlin, Fabeckstraße 34-36, D-14195 Berlin, Germany*



**The heterobimetallic μ-(η¹ : η⁶-1,3,5-cycloheptatrien-2-yl) complex 4 is obtained from 2-trimethylstannyl-1,3,5-cycloheptatriene 2 and [CpFe(CO)$_2$Br] followed by reaction with [(EtCN)$_3$Cr(CO)$_3$]; hydride abstraction results in the formation of the first heterobimetallic cycloheptatrienylidene (CHT) complex [CpFe(CO)$_2${μ-(η¹ : η⁷-CHT)}Cr(CO)$_3$]BF$_4$ 5; the crystal structure of 4 is reported.**

Cycloheptatrienylidene (CHT) and 1,2,4,6-cycloheptatetraene (CHTE) are well known isomers of the $C_7H_6$ potential-energy surface. Experimentally[1] and theoretically,[2] CHTE is the most stable species among the monocyclic $C_7H_6$ isomers. On the other hand, in transition metal complexes the ground state varies with the metal, and several η¹-CHT and η²-CHTE complexes have been reported by Jones and coworkers.[3]

In addition, these ligands offer the option to synthesize heterobimetallic complexes by coordination of the seven-membered ring to a second metal fragment.[4] Whereas the first heterobimetallic CHTE complex, [(PPh$_3$)$_2$Pt{μ-(η² : η⁶-CHTE)}Mo(CO)$_3$], has been reported only recently,[5] heterobimetallic CHT complexes have not yet been prepared. Attempts to generate and trap free [(η⁷-CHT)Cr(CO)$_3$] **1** were unsuccessful.[6] In the course of our work on ligands containing cycloheptatrienylium rings,[7] we have recently synthesized 2-trimethylstannyl-1,3,5-cycloheptatriene **2**,[7c] which can be used in a Stille coupling reaction. Here, we wish to report on the suitability of **2** for the preparation of heterobimetallic 1,3,5-cycloheptatrien-2-yl and cycloheptatrienylidene complexes.

Complex **3** was prepared by lithiation of **2** with Bu$^n$Li and reaction with [CpFe(CO)$_2$Br] in THF at low temperature (Scheme 1).†,[8] The $^1$H NMR spectrum clearly shows the exclusive formation of the 1,3,5-cycloheptatrien-2-yl derivative exhibiting a doublet of doublets for the allylic protons and five resonances for the vinylic protons in a 2 : 1 : 1 : 1 : 1 : 1 ratio. In order to avoid isomerization, **3** was treated with [(EtCN)$_3$Cr(CO)$_3$] at room temp., to form heterobimetallic **4** as stable red–orange crystals.† The $^1$H NMR spectrum exhibits five resonances due to the vinylic protons and two resonances due to the allylic *exo*- and *endo*-protons. As **4** is a racemic mixture of two enantiomers, two $^{13}$C NMR resonances are observed for the diastereotopic FeCO carbon atoms. The molecular structure of **4** is depicted in Fig. 1.‡ The 1,3,5-cycloheptatriene-2-yl ring is coordinated in a μ-(η¹ : η⁶)-fashion. The bond lengths and angles about the iron atom fall in the range observed for other alkenyl complexes,[9] and the Cr(CO)$_3$ coordination is similar to that reported for a manganese–chromium hydrosesquifulvalenyl complex.[7c]

**Scheme 1**

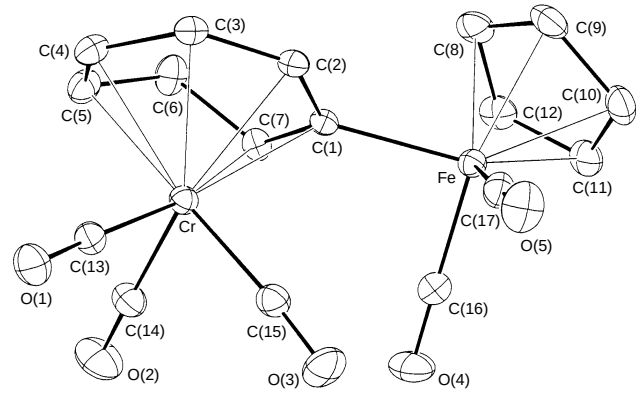


**Fig. 1** ORTEP drawing of **4**. Selected bond lengths (Å) and angles (°): Fe–C(1) 2.014(4), Fe–C(8) 2.139(6), Fe–C(9) 2.110(6), Fe–C(10) 2.117(4), Fe–C(11) 2.116(4), Fe–C(12) 2.125(5), Fe–C(16) 1.767(5), Fe–C(17) 1.761(5), Fe–C(17) 1.761(5), Cr–C(1) 2.272(3), Cr–C(2) 2.233(4), Cr–C(3) 2.220(5), Cr–C(4) 2.223(5), Cr–C(5) 2.386(6), Cr–C(7) 2.317(4), Cr–C(13) 1.847(4), Cr–C(14) 1.859(5), Cr–C(15) 1.848(5), O(1)–C(13) 1.151(5), O(2)–C(14) 1.138(7), O(3)–C(15) 1.139(7), O(4)–C(16) 1.132(6), O(5)–C(17) 1.140(7), C(1)–C(2) 1.446(5), C(1)–C(7) 1.397(7), C(2)–C(3) 1.406(5), C(3)–C(4) 1.449(7), C(4)–C(5) 1.385(7), C(5)–C(6) 1.514(5), C(6)–C(7) 1.516(7), C(8)–C(9) 1.434(9), C(8)–C(12) 1.434(7), C(9)–C(10) 1.458(8), C(10)–C(11) 1.415(8), C(11)–C(12) 1.425(8); C(1)–Fe–C(16) 90.8(2), C(1)–Fe–C(17) 94.3(2), C(16)–Fe–C(17) 95.7(2), Fe–C(1)–C(2) 119.3(3), Fe–C(1)–C(7) 118.2(2), Fe–C(16)–O(4) 178.5(4), Fe–C(17)–O(5) 176.2(4), Cr–C(13)–O(1) 177.4(4), Cr–C(14)–O(2) 178.5(3), Cr–C(15)–O(3) 175.7(4).

In **4** the 7-*exo*-hydrogen atom is easily accessible for hydride abstraction, and the carbene complex $[CpFe(CO)_2\mathbf{1}]BF_4$ **5** was formed quantitatively upon reaction with $(Ph_3C)BF_4$.† To the best of our knowledge, **5** represents the first heterobimetallic cycloheptatrienylidene complex. The carbene carbon resonance ($\delta$ 159.1) is observed at high field due to coordination of the $Cr(CO)_3$-unit to the μ-($\eta^1:\eta^7$-CHT) ligand. A direct relationship between the chemical shift of the cyclopentadienyl group and the degree of electron richness at the metal site has been suggested.[10] Consequently, the $^1$H cyclopentadienyl resonance of **5** is observed at substantially higher field ($\delta$ 5.14) than that of $[CpFe(CO)_2(\eta^1\text{-CHT})]PF_6$ ($\delta$ 5.50),[3a] thus indicating that $[(\eta^7\text{-CHT})Cr(CO)_3]$ **1** is a weaker π-acceptor than cycloheptatrienylidene and that the canonical form **B** contributes more strongly to the ground-state electronic structure of **5**.

Here, we have presented a new route for the preparation of isomerically pure mono- and bi-metallic cycloheptatrienyl complexes as suitable precursors for the synthesis of cycloheptatrienylidene complexes. In continuation of this program, we are currently studying the possibility to synthesize various bimetallic mono- and poly-carbene complexes by this method.

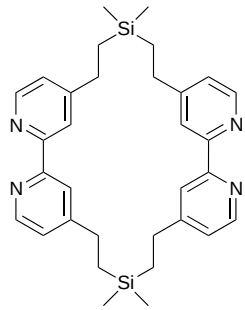
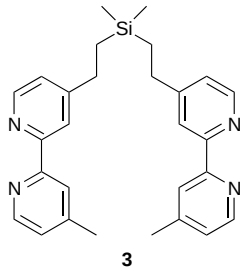
# Synthesis and structural analysis of a *exo*-ditopic macrocyclic ligand bearing 2,2′-bipyridine units interconnected by silane spacers and of its binuclear ruthenium complex

**Christian Kaes,[a] Mir Wais Hosseini,*[a] André De Cian[b] and Jean Fischer[b]**



[a] *Université Louis Pasteur, Laboratoire de Chimie de Coordination Organique (UMR 7513 CNRS), F-67000 Strasbourg, France*
[b] *Université Louis Pasteur, Laboratoire de Cristallochimie et Chimie Structurale (UMR 7513 CNRS), F-67000 Strasbourg, France*

**The synthesis and structural analysis of a macrocyclic *exo*-ditopic ligand bearing two 2,2′-bipyridine units interconnected at the 4 and 4′ positions by two $-(CH_2)_2Si(CH_2)_2-$ spacers and of its acyclic analogue is achieved; for both compounds ruthenium homobinuclear complexes were prepared; for the complex obtained with the cyclic ligand, both diastereoisomers were separated and the structure of the *meso* form was elucidated by X-ray analysis.**



Whereas considerable effort has been invested in designing *endo*-di- and poly-topic ligands affording discrete *endo* complexes in which metal centres are located in close proximity, over the last few years much interest seems to be focused on *exo* ligands in which the coordination sites are outwardly oriented.[1] This increase in interest is related to the development of coordination polymers in which *exo*-ditopic ligands play the role of connectors between metallic centres. Although many examples of coordination polymers are available, most of the reported cases deal with bis-monodentate ligands.[2] Only few coordination polymers based on bridging of metallic centres by bis-tridentate ligands have been published so far.[3] Our approach to the formation of coordination polymers is based on the use of bis-bidentate ligands. 2,2′-Bipyridine derivatives are the most widely used chelates for metal binding.[4] We have previously reported *exo*-ditopic ligands based on two 2,2′-bipyridine units interconnected at the 4 and 4′ positions imposing the divergent orientation of the binding sites either by $(CH_2)_n$[5] or by $CH_2SiCH_2$ fragments (compound **1**).[6] In the latter case, probably owing to the presence of fragile benzylic positions, we were unable to prepare the ruthenium binuclear complexes.

**1**

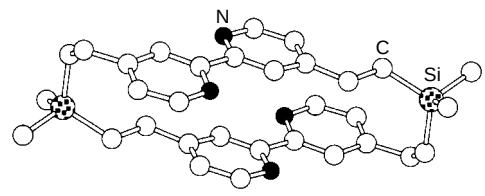
**2**

**3**

In order to overcome this problem, ligand **2**, in which the two 2,2′-bipy chelates are interconnected at the 4 and 4′ positions by two $(CH_2)_2Si(CH_2)_2$ fragments was designed. Introduction of two silicon atoms within the macrocyclic framework has been previously reported for silacrown ether derivatives.[7] The silane moieties might be used either as connecting groups or as reactive centres allowing further structural modification. Prior to elaboration of coordination polymers using ligand **2**, a detailed structural analysis of discrete binuclear complexes based on such a ligand is needed. Here, we present the synthesis of both the free ligand **2** and its acyclic analogue **3** and of their homobinuclear ruthenium(II) complexes **2**-$Ru_2$ and **3**-$Ru_2$. For the **2**-$Ru_2$ complex, we also report a solid state structural analysis. The synthesis of ligand **2** was achieved by reacting the dilithium derivative of 4,4′-dimethyl-2,2′-bipyridine,[8] prepared by treating at 0 °C the latter with lithium diisopropyl amide (LDA) in dry THF, with bis(chloromethyl)dimethylsilane in dry THF at 25 °C (slow addition, 4–5 h and further stirring at room temp. overnight). To the blue–violet solution thus obtained a few drops of MeOH were added to quench the excess LDA before it was evaporated to dryness. In order to separate polymeric species, the residue was taken up in $CHCl_3$ and filtered. The solid was further washed with $CHCl_3$. The filtrate and washes were combined and evaporated to dryness affording a mixture of ten different products. Both compound **2** and **3** were obtained as a mixture after chromatography [$SiO_2$, $CH_2Cl_2$–MeOH (0–3%)]. Their separation (3% yield for compound **2**) appeared to be only feasible upon crystallisation from a hexane–$CH_2Cl_2$ mixture. However, compound **3** was also prepared in 50% yield by treating the monolithium derivative of 4,4′-dimethyl-2,2′-bipyridine with bis(chloromethyl)dimethylsilane in dry THF at 25 °C.

The X-ray analysis (Fig. 1) of the free ligand **2** revealed the following features:† (*i*) the two bipy units, both in *transoid* conformation, were almost parallel to each other leading thus to a cyclophane type situation (box dimension of 2.9 × 11.6 Å); (*ii*) the coordination geometry around both silicon atoms was tetrahedral with an average Si–C distance of 1.86 Å and C–Si–C angle of 109.5°; (*iii*) on each silane moiety, both methyl groups were pointing towards the exterior of the macrocycle.

The homobinuclear complexes $(\mathbf{2}\text{-}Ru_2)^{4+}4PF_6^-$ and $(\mathbf{3}\text{-}Ru_2)^{4+}4PF_6^-$ were obtained upon treatment under reflux of **2** or **3** with $Ru(bipy)_2Cl_2\cdot 2H_2O$ in degassed EtOH followed by addition of $NH_4PF_6$ which caused the precipitation of both



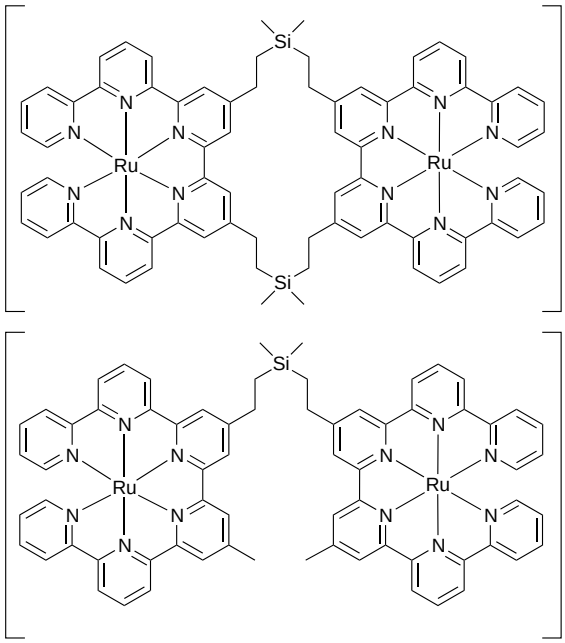


**Fig. 1** X-Ray crystal structure of ligand **2**; H atoms are not shown for clarity (for distances and angles see text)

stereoisomeric (Δ,Δ; Λ,Λ) and *meso* (Δ, Λ) complexes in a 1 : 1 mixture. The latter was further recrystallised from acetone–ether. For (**2**-$Ru_2$)$^{4+}$4$PF_6^-$, the 1 : 1 ratio of stereoisomers was deduced from the $^1$H NMR spectrum (300 MHz, $CD_3CN$, 25 °C) of the mixture which revealed that among the signals present, three singlets corresponding to MeSi fragments were the most differentiated. The diastereomeric separation of the mixture was achieved by crystallisation of the *meso* form by slow diffusion of benzene into a nitromethane solution. The assignment of singlets corresponding to MeSi groups was based on the $^1$H NMR study of both the pure *meso* form which showed two singlets at $\delta$ 0.02 and 0.1 and of the remaining mixture of enantiomers which revealed only one singlet at $\delta$ 0.06.

In the solid state (Fig. 2), the structure of the *meso* form of (**2**-$Ru_2$)$^{4+}$4$PF_6^-$ was studied by X-ray diffraction† which revealed the following features: (*i*) in addition to (**2**-$Ru_2$)$^{4+}$4$PF_6^-$ complex, six MeCN and two MeOH molecules are present in the solid state but without any interaction with the metallic centres; (*ii*) in marked contrast with the free ligand **2**, both bipy units in the complex adopt a *cisoid* conformation allowing, as expected, the chelation of $Ru^{II}$ cations; (*iii*) the cationic moiety of the complex possesses a centre of symmetry; (*iv*) the coordination geometry around Si atoms was tetrahedral with an average Si–C distance and C–Si–C angle of 1.86 Å and 109.4° respectively; (*v*) owing to the conformation of the $(CH_2)_2Si(CH_2)_2$ fragments (CCCSi, and CSiCC dihedral angles of 171.0 and −87.2 °, respectively), in marked contrast with the free ligand adopting a cyclophane type conformation, the two bipy units oppositly oriented are almost parallel but not coplanar; (*vi*) both Me groups of both silane moieties are, as in the case of the free ligand, outwardly oriented; (*vii*) for both $Ru^{II}$ centres, the coordination sphere is composed of six nitrogen atoms amongst which four are belonging to the two auxiliary bipy units and the remaining two are part of the macrocyclic ligand **2**. The coordination geometry around each $Ru^{II}$ was almost octahedral with an average Ru–N distance of 2.05 Å; (*viii*) the two $Ru^{II}$ centres were separated by 13.58 Å; (*ix*) quite interestingly and unexpectedly, among the four $PF_6^-$ anion present, two of them were localised below and above the mean plane of the macrocyclic core and pointing almost towards the centre of the macrocycle.

It is worth noting that a systematic Cambridge Database search revealed that only three homobinuclear ruthenium complexes bearing three bipyridine type ligands have been structurally characterised (KIKHOB,[9] ZADLAR,[5a] ZELCIC[1d]). Preparation of linear coordination polymers based on compound **2** is under current investigation.

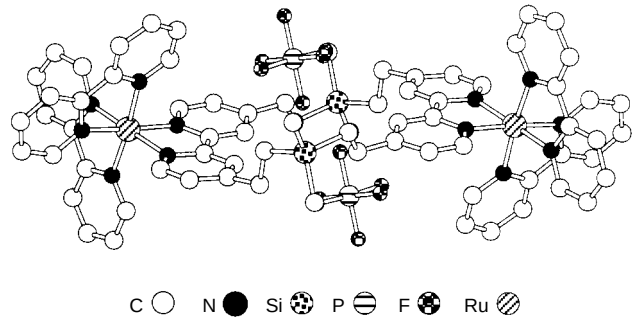

**Fig. 2** Crystal X-ray structure of the *meso* form of the ruthenium binuclear complex obtained with ligand **2**; solvent molecules as well as H atoms are not shown for clarity (for distances and angles see text)

We thank the CNRS and the Institut Universitaire de France (IUF) for financial support. C. K. thanks the Ministry of Education of Luxembourg for a scholarship.

**Reaction of ligand 2 with Cu$^{I}$ ions leads to the self-assembly of the distorted [2 × 2] grid complex 1 of box-like shape, featuring a well defined cavity and trapping of guest molecules.**

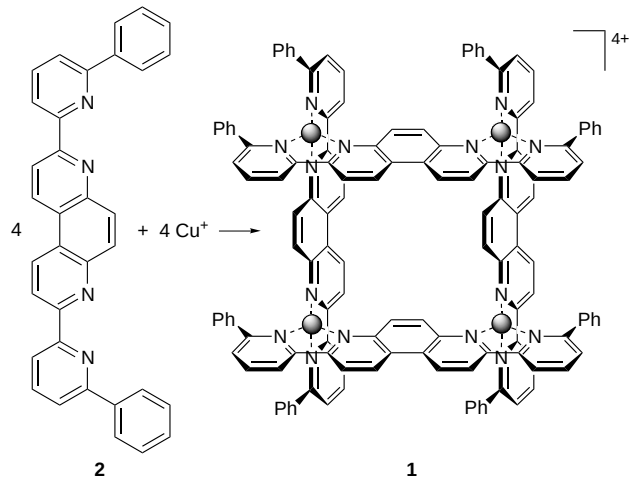
The controlled generation of molecular entities that contain geometrically precisely defined arrangements of metal ions is of considerable current interest within the fields of supramolecular chemistry and materials science.[1] The presence of metal ions in such coordination arrays may result in the development of many varied physicochemical properties such as electrochemical, optical, magnetic, mechanical and catalytic activity for example.

Metal ion-directed self-assembly currently provides a very efficient method of access to coordination arrays of predetermined nuclearity and spatial composition[2] such as helicates,[3] pseudorotaxane racks,[4] grids,[5,6] rings[7] and cages.[8] The inorganic grids represent a particularly intriguing class of coordination arrays which may potentially function as components of systems such as molecular memory devices, in which information might be stored in the form of electron holes or occupancies at specific sites or areas within the architecture.

With ligands presenting a greater spatial separation between the metal ion binding sites than previously reported,[5,6] a cavity of controlled dimensions would be opened up within the grid structure. Such a cavity may exhibit selective guest inclusion, which if combined with redox activity of the grid itself, may result in a class of electrochemical guest sensors. Towards this goal, the linear ditopic tetradentate ligand **2** was constructed. A grid composed of four **2** ligands and four metal ions of tetrahedral coordination geometry should possess an internal box-shaped cavity lined by aromatic rings, of suitable dimensions for the inclusion of small molecules.

We herein report the structural characterisation and some physicochemical features of the self-assembled symmetric [2 × 2]G tetracopper grid (**1**) which is generated from **2**† and copper(I) ions; it is electrochemically active and exhibits guest inclusion in the solid state.

The tetracopper grid **1** forms in almost quantitative yield‡ in nitromethane solution upon admixture of a 1 : 1 stoichiometric ratio of the linear ligand **2** and $[Cu(MeCN)_4PF_6$. The structure of **1** both in solution and in the solid state has been established on the basis of $^1$H and $^{13}$C NMR, FAB and ES mass spectroscopy, microanalysis and X-ray crystallography.



The $^1$H NMR spectrum‡ of the above reaction product in nitromethane solution consisted of a very simple pattern of peaks corresponding to ligand **2** in a single magnetic and chemical environment, and suggestive of the formation of a highly symmetrical species. The $^{13}$C spectrum also consisted of the expected fifteen peaks.

FAB and ES mass spectroscopy were found to be especially informative in identifying the above reaction product as **1**. The highest *m*/*z* peaks observed in the FAB mass spectrum, were assignable to the tetracopper grid **1** with succesive loss of $PF_6^-$ counter ions, *i.e.* 2635.2 $\{[Cu_4(\mathbf{2})_4](PF_6)_3\}^+$, 2490.2 $\{[Cu_4(\mathbf{2})_4](PF_6)_2\}^{\cdot+}$ and 2345.3 $\{[Cu_4(\mathbf{2})_4]PF_6\}^{\cdot\cdot+}$. Peaks at lower *m*/*z* ratios corresponded to mono- and di-nuclear species which arise through fragmentation/dissociation of **1**. The EMS peaks (recorded at $10^{-4}$ in $MeNO_2$) of the reaction product at *m*/*z* 1245.3, 781.9 and 550.3 were assignable to the species $\{[Cu_4(\mathbf{2})_4](PF_6)_2\}^{2+}$, $\{[Cu_4(\mathbf{2})_4]PF_6\}^{3+}$ and $[Cu_4(\mathbf{2})_4]^{4+}$, respectively. Upon dilution to $10^{-6}$ M, the peaks corresponding to counter ion loss from **1** decrease in intensity and peaks which arise from the dissociation of **1** increase in height showing that **1** undergoes dissociation at high dilution.

An X-ray crystal structural analysis finally provided unambiguous evidence that the identity of the above reaction product was that of **1**.§ The cation is indeed a tetranuclear distorted square grid composed of four copper(I) ions and four **2** ligands, with overall external dimensions (including van der Waals radii) of 22.5 × 15.4 × 12.5 Å (depth). The ligands are divided into two parallel pairs, one of which lies above and the other below the mean plane through the four copper ions. The grid is not a square but a rhombus (inner angles, *i.e.* angles between the mean planes of **2** of 74.5 and 105.5°) owing to deviation from perfect tetrahedral coordination geometry about each metal centre, with the ligands forming the sides and the copper(I) ions (7.7 Å apart) lying at the corners. The Cu–N bond lengths, 2.055–2.002 Å and N–Cu–N angles are unexceptional. The complex cation possesses an internal box-shaped void of area 4.2 × 3.8 Å and 12.5 Å depth.[9] Six guests, four benzenes and two nitromethane molecules are trapped in the grooves defined by the parallel pairs of the ligands, with a benzene lying in the mouth of the cavity on each side of the cation (Fig. 1).

Cyclic voltammetric measurements showed **1** to be electrochemically active, giving a single reversible oxidation wave at 0.44 V, and three closely spaced reversible reduction waves at −1.56, −1.65 and −1.79 V (*vs.* $Fc/Fc^+$).¶

The [2 × 2]G symmetric tetracopper grid **1** forms by the self-assembly of eight articles, four metal ions and four ligand components. It exhibits multiple guest inclusion in its box-

**Scheme 1** Self-assembly of the inorganic [2 × 2] box-grid **1**

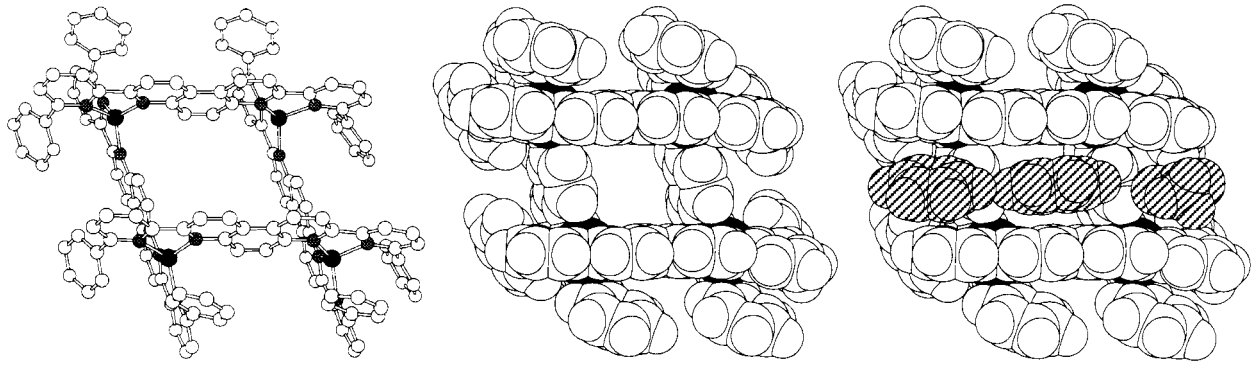


**Fig. 1** Crystal structure of the grid-type complex **1**; ball and stick representation (left); space-filling representation (centre); space-filling representation of **1** with guests in upper groove (right); guests in lower groove omitted for clarity

shaped cavity in the solid state. The presence of the phenyl rings on the ligands appears to be essential for its formation. If the phenyl rings of **2** are replaced by H or Me groups, then 1 : 1 mixtures with $[Cu(MeCN)_4]PF_6$ under identical conditions to the formation of **1** yield oligomeric mixtures and insoluble coordination polymers as the only products.

In addition to their possible use as components of molecular electronics devices, inorganic grids capable of trapping guest species may be of potential interest for chemical catalysis and selective guest sensing. They could therefore find various applications in materials science and nanotechnology.

We thank Annick Dupont-Gervais, Emmanuelle Leize and Alain Van Dorsselaer for the ES Mass spectroscopic and Marcel Mayor for the electrochemical measurements.

† Ligand **2** was prepared from 2-trimethylstannyl,6-phenylpyridine and 3,8-dibromo-4,7-phenanthroline *via* a Stille coupling protocol.

‡ *Experimental*: to a mixture of 0.030 g ($6.17 \times 10^{-5}$ mol) of **2** and 0.023 g ($6.17 \times 10^{-5}$ mol) of $[Cu(MeCN)_4]PF_6$ under an atmosphere of argon was added 4 ml of $MeNO_2$ *via* syringe, and the dark-brown solution stirred at ambient temperature for 48 h. All solvent was then removed under vacuum and the remaining solid purified by gel permeation chromatography on a column of SX-1 biobeads using nitrobenzene as eluent. The product was collected in one fraction, reduced in volume to 3 ml under vacuum at 70 °C and precipitated by the addition of an excess of toluene. The solid was collected by filtration under vacuum, washed with toluene, recrystallised twice from $MeNO_2$–toluene and finally dried under vacuum at 90 °C/2 × $10^{-6}$ mmHg. The above work-up yielded 0.039 g (91%) of the product complex **1** $(PF_6)_4$ as a dark-brown microcrystalline solid. $^1$H NMR spectral assignments were made on the basis of $^1$H–$^1$H COSY and ROESY measurements.

# Synthesis of tetrasubstituted derivatives of $[Fe_3(CO)_{12}]$

**Xuetai Chen and Brian E. Mann**

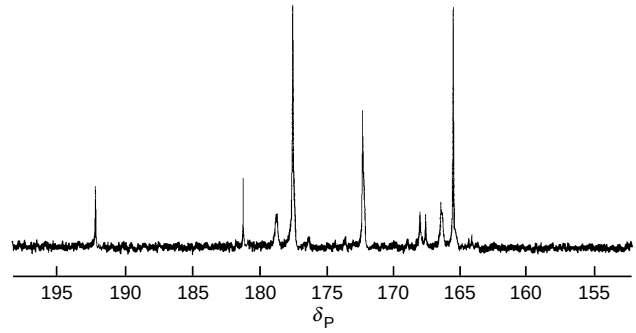
*Department of Chemistry, The University of Sheffield, Sheffield, UK S3 7HF*

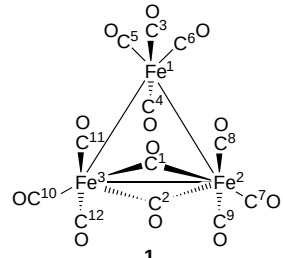
**The treatment of $[Fe_3(CO)_{10}L^1L^2]$ [$L^1$, $L^2$ = CO, $P(OMe)_3$, $P(OCH_2)_3CMe$] with $CNBu^t$ in the presence of $Me_3NO$ yields the tetrasubstituted derivatives, $[Fe_3(CO)_8(CNBu^t)_4]$, $[Fe_3(CO)_8(CNBu^t)_3\{P(OMe)_3\}]$, $[Fe_3(CO)_8(CNBu^t)_3\{P(OCH_2)_3CMe\}]$, $[Fe_3(CO)_8(CNBu^t)_2\{P(OCH_2)_3CMe\}_2]$, $[Fe_3(CO)_8(CNBu^t)_2\{P(OCH_2)_3CMe\}\{P(OMe)_3\}]$ and $[Fe_3(CO)_8(CNBu^t)_2\{P(OMe)_3\}_2]$; the compounds were characterised by analysis, mass spectrometry, IR, and (in part) $^1H$ and $^{31}P$ NMR spectroscopy.**

Highly substituted derivatives of $[Ru_3(CO)_{12}]$ and $[Os_3(CO)_{12}]$ are well known, with crystal structures having been determined for $[Os_3(CO)_8\{P(OMe)_3\}_2(\mu\text{-dppm})]$,[1] $[Os_3(CO)_8\{P(OMe)_3\}_2(PPh_3)_2]$,[1] $[Ru_3(\mu\text{-}CO)_2(CO)_6\{PPh(OMe)_2\}_4]$,[2] $[Ru_3(CO)_8[\{(MeO)_2P\}_2NEt]_2]$,[3] $[Ru_3(CO)_8\{AsMe_2C{=}C(AsMe_2)CF_2CF_2\}_2]$,[4] $[Ru_3(CO)_8\{P(OPh)_3\}_4]$,[5] $[Ru_3(CO)_8\{P(OMe)_3\}_4]$,[5] $[Ru_3(\mu\text{-}CO)_3(CO)_5\{P(OEt)_3\}_4]$,[5] and $[Ru_3(CO)_{10}(dpam)]$.[6] In addition, hexasubstituted derivatives are known *i.e.* $[Ru_3(CO)_6(dppm)_3]$[7,8] and $[Os_3(CO)_6\{P(OMe)_3\}_6]$.[9]

In contrast, substitution of carbonyls in $[Fe_3(CO)_{12}]$ is only known as far as the tris derivatives, with crystal structures having been determined for $[Fe_3(CO)_9(PMe_2Ph)_3]$,[10] $[Fe_3(CO)_9\{P(OMe)_3\}_3]$,[11] and $[Fe_3(CO)_9\{P(OPr^i)_3\}_3]$.[11] $[Fe_3(CO)_{12}]$ readily fragments on substitution to give mainly monomeric compounds.[12] Recently it has been shown that substitution of $[Fe_3(CO)_{12}]$ proceeds smoothly when $Me_3NO$ is used as the reagent.[13] We have been using this procedure to synthesise a range of derivatives of $[Fe_3(CO)_{12}]$. When $[Fe_3(CO)_{10}\{P(OMe)_3\}_2]$ is reacted with $CNBu^t$ in $CH_2Cl_2$ in the presence of $Me_3NO$, in addition to the expected product, $[Fe_3(CNBu^t)(CO)_9\{P(OMe)_3\}_2]$, a second green band due to $[Fe_3(CNBu^t)_2(CO)_8\{P(OMe)_3\}_2]$ was observed on the silica gel column. The production of this second derivative was optimised by using *ca*. 10 mol of $CNBu^t$ and *ca*. 20 mol of $Me_3NO$ per mol of $[Fe_3(CO)_{10}\{P(OMe)_3\}_2]$ in $CH_2Cl_2$ and allowing the reaction to procede for 2–3 d at room temp. under nitrogen. Subsequent chromatography on silica gel using $CH_2Cl_2$ as eluent yielded the product, $[Fe_3(CNBu^t)_2(CO)_8\{P(OMe)_3\}_2]$ in 5% yield. The compound was characterised by $^1H$ and $^{31}P$ NMR and IR spectroscopy, mass spectrometry and elemental analysis.[14] Attempts to grow suitable crystals for X-ray diffraction have failed.

The same procedure was used to synthesise $[Fe_3(CNBu^t)_2(CO)_8\{P(OCH_2)_3CMe\}_2]$, $[Fe_3(CNBu^t)_2(CO)_8\{P(OMe)_3\}\{P(OCH_2)_3CMe\}]$, $[Fe_3(CNBu^t)_3(CO)_8\{P(OMe)_3\}]$, $[Fe_3(CNBu^t)_3(CO)_8\{P(OCH_2)_3CMe\}]$ and $[Fe_3(CNBu^t)_4(CO)_8]$ except in that an alumina column was used for $[Fe_3(CNBu^t)_3\{P(OMe)_3\}]$ and $[Fe_3(CNBu^t)_4(CO)_8]$. Yields are low varying between 5 and 15%, with the highest yield being obtained for $[Fe_3(CNBu^t)_3(CO)_8\{P(OCH_2)_3CMe\}]$. The compounds decompose quite readily in solution and this prevented the observation of $^{13}C$ NMR spectra. All the compounds were characterized using elemental analysis, IR spectroscopy and mass spectrometry.† In solution they slowly decompose to give significant concentrations of the monomeric derivatives. This coupled with the exchange between stereoisomers made it difficult to obtain reliable NMR spectra.





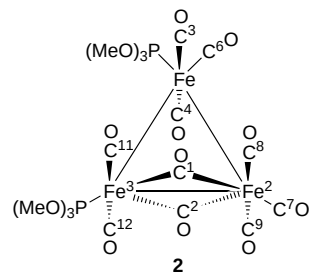


**Fig. 1** The 162 MHz $^{31}P$ NMR spectrum of $[Fe_3(CNBu^t)_2(CO)_8\{P(OMe)_3\}_2]$ in $[^2H_8]$toluene at 223 K. Note that the signals at $\delta$ 181 and 192 are impurities.

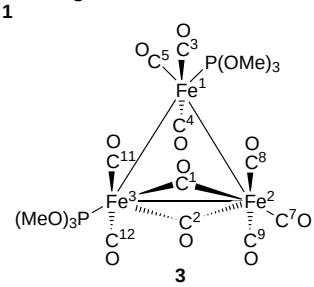
In general, the $^{31}P$ NMR spectra were the most informative. For example for $[Fe_3(CNBu^t)_2(CO)_8\{P(OMe)_3\}_2]$, which in solution exists as a mixture of at least four isomers, the $^{31}P$ NMR spectrum] in $[^2H_8]$toluene at room temp. is broad, but at 223 K has seven $^{31}P$ NMR signals at $\delta$ 165.7, 166.4 ($J$ 13 Hz), 167.7, 168.1, 172.3, 177.5 and 178.8 ($J$ 13 Hz) in significant intensities for $[Fe_3(CNBu^t)_2(CO)_8\{P(OMe)_3\}_2]$, Fig. 1. By using signal intensity and the coupling constant, these signals form three pairs and one singlet in the ratio 1.00 : 0.30 : 0.30 : 0.14, the pairs being $\delta$ 177.5 and 165.7, $\delta$ 178.8 and 166.4 and $\delta$ 168.1 and 167.7. It has been previously shown that $P(OMe)_3$ on the unbridged iron is at higher frequency than when on a bridged iron, and when the $P(OMe)_3$ ligands are in a linear arrangement, P–Fe–Fe–P, then a $J(^{31}P^{31}P)$ of *ca*. 6–25 Hz is observed.‡



It is known that the concerted bridge-opening bridge-closing mechanism is far too rapid to stop even at −100 °C when phosphorus substitution is only in positions 6 and/or 10, numbering as in **1**.[15] The introduction of a $CNBu^t$ does slow the

**1**

**2**

**3**

rate of the concerted bridge-opening bridge-closing mechanism sufficiently to cause substantial broadening at −100 °C in $[Fe_3(CNBu^t)(CO)_{11}]$ or $[Fe_3(CNBu^t)(CO)_{10}\{P(OMe)_3\}]$.[16] It is also known that the $CNBu^t$ ligand has a preference for an axial site on the unbridged iron, $Fe^1$, in so far as the crystal structures of $[Fe_3(CNBu^t)(CO)_{11}]$,[17] $[Fe_3(CNBu^t)_2(CO)_{10}]$[18] and $[Fe_3(CNBu^t)(CO)_{10}\{P(OMe)_3\}]$[16] have an isonitrile in this position. In the case of $[Fe_3(CNBu^t)_2(CO)_{10}]$, the second $CNBu^t$ is also on the unbridged iron, $Fe^1$, but in the equatorial position.

The $^{31}P$ NMR signals at $\delta$ 177.5 and 165.7 do not show $J(^{31}P^{31}P)$ and arise from an isomer with a bent phosphorus ligand arrangement as in **2**. The $^{31}P$ NMR signal at $\delta$ 172.3 arises from the concerted bridge-opening bridge-closing mechanism averaging the $P(OMe)_3$ ligands. This is consistent with the phosphorus ligands being arranged as in **3** and one $CNBu^t$ ligand being substituted into the ligand set 3, 5, 4, 9, 8 and the other $CNBu^t$ ligand being substituted into the ligand set 1, 12, 11, 2, 7. The third most intense set of signals at $\delta$ 166.4 and 178.8, $J(^{31}P^{31}P)$ 13 Hz, arises from **3** with both $CNBu^t$ ligands in one ligand set, probably, 3, 5, 4, 9, 8.

There is less information available to assign the structures of the other compounds.

We wish to thank the University of Sheffield for financial support.

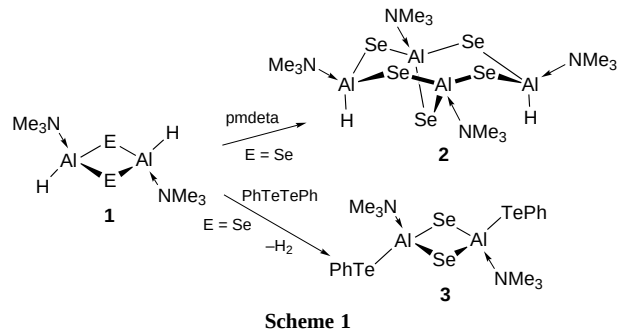
# Approaching a cluster of aluminium(III) selenide: $[Al_4Se_5(H)_2(NMe_3)_4]$

**Peter D. Godfrey,[a] Colin L. Raston,*[a] Brian W. Skelton,[b] Vicki-Anne Tolhurst[a] and Allan H. White[b]**



[a] *Department of Chemistry, Monash University, Clayton, Melbourne, Victoria 3168, Australia*
[b] *Department of Chemistry, University of Western Australia, Nedlands, WA 6907, Australia*

**The reaction of *trans*-[{$Me_3N(H)Al(\mu\text{-}Se)$}$_2$] with *N,N,N′,N″,N″*-pentamethyldiethylenetriamine (pmdeta) in toluene affords the tetranuclear, alane selenide cluster $[Al_4Se_5(H)_2(NMe_3)_4]$ (structurally authenticated and *ab initio* modelled), and with PhTeTePh yields a mixed chalcogenide *trans*-[{$Me_3N(PhTe)Al(\mu\text{-}Se)$}$_2$].**

We recently showed that elemental selenium or tellurium react under mild conditions with the trimethylamine adduct of alane, $[H_3AlNMe_3]$, in toluene affording the dimeric chalcogenidoalane, *trans*-[{$Me_3N(H)Al(\mu\text{-}E)$}$_2$] (E = Se, Te) **1**, Scheme 1, with the elimination of hydrogen.[1] This new class of compounds can be regarded as tertiary-amine-stabilised adducts of the simplest selenido- and tellurido-aluminium(III) species, *viz* [{$HAl(\mu\text{-}E)$}$_2$] (E = Se, Te) and should prove to have a rich chemistry. Instead of the adducts, base-free cubane structures are conceivable, [{$HAl(\mu_3\text{-}E)$}$_4$], noting that organometallic analogues have been prepared, [{$(\eta^5\text{-}C_5Me_5)Al(\mu_3\text{-}E)$}$_4$] (E = Se, Te)[2] and [{$Bu^tAl(\mu_3\text{-}S, Se or Te)$}$_4$.[3] For our system, such cubane type structures are computed to be less stable than the solvated dimers.

In developing the chemistry of the adducts we report reactions of *trans*-[{$Me_3N(H)Al(\mu\text{-}Se)$}$_2$] **1a** with (*i*) *N,N,N′,N″,N″*-pentamethyldiethylenetriamine (pmdeta) and (*ii*) PhTeTePh. Reaction (*i*) was an attempt to gain access to a stabilised Lewis-base-saturated monomeric H–Al=Se complex by chelation of the metal centre. This was deemed a synthetic target on theoretical grounds. Rather, an unprecedented tetranuclear cluster formed, $[Al_4Se_5(H)_2(NMe_3)_4]$ **2**, which approaches a stabilised cluster of aluminium(III) selenide. Reaction (*ii*) was successful in forming a mixed chalocogenide aluminium(III) species **3**, arising from metal hydride cleavage of the diorganoditelluride. This is related to the recently established facile cleavage of diorganoditellurides and diorganodiselenides by $[H_3AlNMe_3]$ affording $[(Me_3N)Al(ER)_3]$, (E = Se, Te, R = alkyl, aryl).[4]

Compounds **2** and **3** were prepared in toluene, Scheme 1.† While compound **2** is isolated in low yield, and crystallises over several weeks, its formation is reproducible. On mixing **1a** and pmdeta, a flocculant, insoluble, white precipitate was formed which is difficult to characterise: this product may be the ionic species $[\{(pmdeta)AlH_2\}^+]_2Se^{2-}$, and its formation would account for the change in Al : hydride : Se ratio from 1 : 1 : 1 in **1a** to 2 : 1 : 2.5 in **2**. It shows an IR band at 1789 $cm^{-1}$ *cf.* 1822 $cm^{-1}$ for $[(pmdeta)AlH_2]^+AlH_4^-$, a compound which has been structurally authenticated.[5] While the hydrides in **1** are resistant to further reaction with selenium or tellurium, reaction with a diorganoditelluride takes place, as demonstrated for **1a**, with elimination of hydrogen. Interestingly the integrity of the *trans*-isomer is maintained, whereas in the more complicated tetranuclear cluster this is lost with respect to the two residual hydrogens which are now in a *cis*-arrangement.

**Scheme 1**

Assignment of structure of the two compounds rests on X-ray diffraction studies.‡ Compound **2** crystallises as a toluene solvate with a single toluene and molecule of **2** as the asymmetric unit. The $Al_4Se_5$ metal core can be described as two six-membered rings, both in a boat conformation, sharing an $Al_2Se$ plane and the molecule approximates to $C_2$ symmetry, with *cis*-hydrido groups, Fig. 1. Indeed, departure from a higher potential $C_{2v}$ symmetry relates to puckering of the boat conformation of the two six-membered rings and angular distortion in $Al_3Se_4$ ring with angles subtended by Se(2,4) by two metal centres being more open at 98.6° (mean) relative to

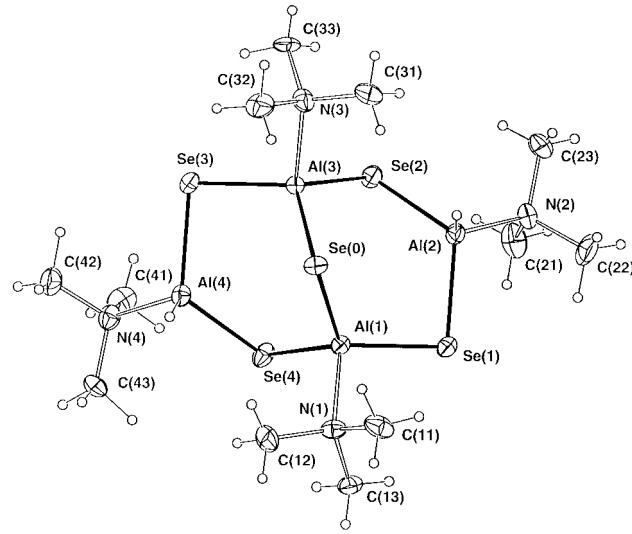


**Fig. 1** Projection of $[Al_4Se_5(H)_2(NMe_3)_4]$. **2** Selected distances (Å) and angles (°): Se(0)–Al(1,3) 2.361(4), 2.354(4), Se(1)–Al(1,2) 2.345(3), 2.358(4), Se(2)–Al(2,3) 2.356(4), 2.334(4), Se(3)–Al(3,4) 2.345(3), 2.360(5), Se(4)–Al(1,4) 2.332(4), 2.355(3), Al(1,2,3,4)–N(1,2,3,4) 2.05(1), 2.00(1), 2.05(1), 1.98(1); Al(1)–Se(0)–Al(3) 94.6(1), Al(1)–Se(1)–Al(2) 92.2(1), Al(2)–Se(2)–Al(3) 98.7(1), Al(3)–Se(3)–Al(4) 91.5(1), Al(1)–Se(4)–Al(4) 98.5(1), Se(0)–Al(1)–Se(1,4), N(1) 115.7(2), 113.2(1), 103.2(3), Se(1)–Al(1)–Se(4), N(1) 115.6(2), 102.2(3), Se(4)–Al(1)–N(1) 104.7(3), Se(1)–Al(2)–Se(2), N(2) 115.7(2), 101.8(4), Se(2)–Al(2)–N(2) 101.0(3), Se(0)–Al(3)–Se(2,3), N(3) 114.6(1), 114.5(2), 103.9(4), Se(2)–Al(3)–Se(3), N(3) 113.9(2), 104.7(3), Se(3)–Al(3)–N(3) 103.3(3), Se(3)–Al(4)–Se(4), N(4) 116.5(2), 104.2(4), Se(4)–Al(4)–N(4) 100.0(3). Computed values for the same molecule with $C_{2v}$ symmetry: Al(1)–N(1) 2.059, Al(2)–N(2) 2.086, Al(1)–Se(1,4) 2.431, Al(2)–Se(1,2) 2.445, Al(2)–H 1.600, Al(1)–Se(0) 2.437, Se(0)–Al(1)–N(1), Se(1,4) 103.49, 114.44, Se(1)–Al(1)–N(1), Se(4) 103.18, 115.78, N(1)–Al(1)–Se(4) 103.16, Se(1)–Al(2)–Se(2), N(2), H 119.33, 101.57, 115.27, Se(2)–Al(2)–N(2), H, 101.57, N(2)–Al(2)–H 98.90, Al(1)–Se(0)–Al(3) 99.75, Al(1)–Se(1)–Al(2) 111.99, Al(1)–Se(4)–Al(4) 111.99.

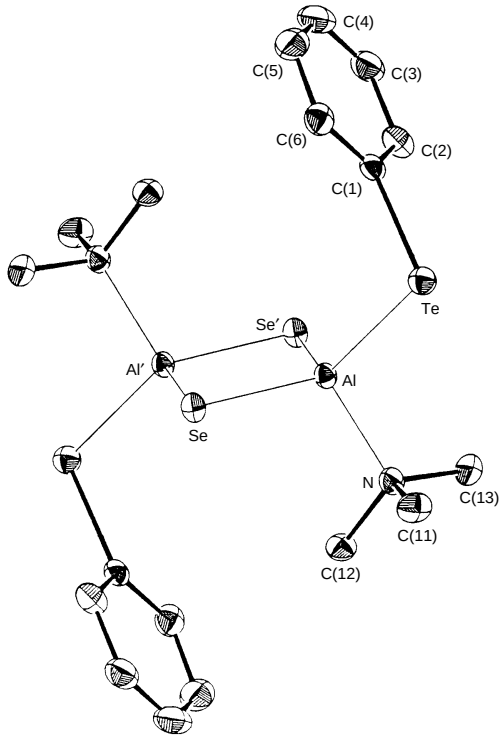

**Fig. 2** Projection of *trans*-[{$Me_3N$(PhTe)Al(μ-Se)}$_2$] **3**. Selected distances (Å) and angles (°): Te–Al, 2.610(2), Se–Al 2.359(2), Se–Al′ 2.347(2), Al–N 1.998(5); Al–Te–C(1), Al′ 94.6(1), 76.37(6), Te–Al–Se, N, Se′ 117.16(7), 102.1(1), 117.31(7), Se–Al–N, Se′ 107.2(2), 103.63(6), N–Al–Se′ 108.9(2)

those subtended by Se(1,3), 91.9° (mean). The corresponding angle at the unique selenium, Se(0), is intermediate at 94.6(1)°. All aluminium centres are four-coordinate. The bond distances around Al(1,3) which have the coordinated Lewis base $NMe_3$ are similar to those in [$(Me_3N)Al(SeEt)_3$], but the angles subtended by two seleniums are slightly more open at *ca*. 114.50, *cf*. 111.5(5), as are the Se–Al–N angles at *ca*. 113.4, *cf*. 87(1)°.[4] Similarly the bond distances around Al(2,4) are similar to those in *trans*-[{$Me_3N$(H)Al(μ-Se)}$_2$] (and **3**, see below) with the Se–Al–Se angles more open, at *ca*. 116.0°, *cf*. 103.10(7)°,[1] as expected for a larger ring system. Molecules of **3** are centrosymmetric, as the *trans*-isomer, Fig. 2. The $Al_2Se_2$ core is very similar to that in *trans*-[{$Me_3N$(H)Al(μ-Se)}$_2$].[1] The Te–Al distance at 2.610(2) Å is similar to that in [$(Me_3N)Al(TePh)_3$],[4] 2.589(2) Å.

An *ab initio* molecular-orbital calculation involving $C_{2v}$ structure optimisation at the RHF/LanL2DZ level was undertaken on **2** giving reasonable correlation of structural parameters with experimental values, except for the angular distortions associated with $C_2$ rather than $C_{2v}$ symmetry (Fig. 1).[6] Constraining the symmetry to $C_{2v}$ was necessary for computational convenience. In order to estimate the energy change on production *via* hydrogenation, a similar calculation was performed under $C_{2v}$ symmetry at the MP2/LanL2DZ level on the simpler analogous compound [$Al_4Se_5(H)_2(NH_3)_4$] and its hypothetical precursor [$Al_4Se_6(NH_3)_4$], the latter under $T_d$ symmetry as shown in Fig. 3. The MP2/LanL2DZ energies (in $E_h$) of the reactants [$Al_4Se_6(NH_3)_4$] (−287.918 974 1) and $H_2$ (−1.143 905 1) in combination with those of the products [$Al_4Se_5(H)_2(NH_3)_4$] (−279.906 603 9) and $H_2Se$ (−10.198 084 0) indicate that the formation of [$Al_4Se_5(H)_2(NH_3)_4$] *via* hydrogenation is exothermic by 654 kcal mol$^{-1}$ (1 cal = 4.184 J). Thus the analogous reverse reaction of converting **2** to [$Al_4Se_6(NMe_3)_4$] on treatment with $H_2Se$ is energetically unfavourable. However other sources of selenium, for example $Se(SiMe_3)_2$, may favour formation of [$Al_4Se_6(NMe_3)_4$], an area we are currently exploring.

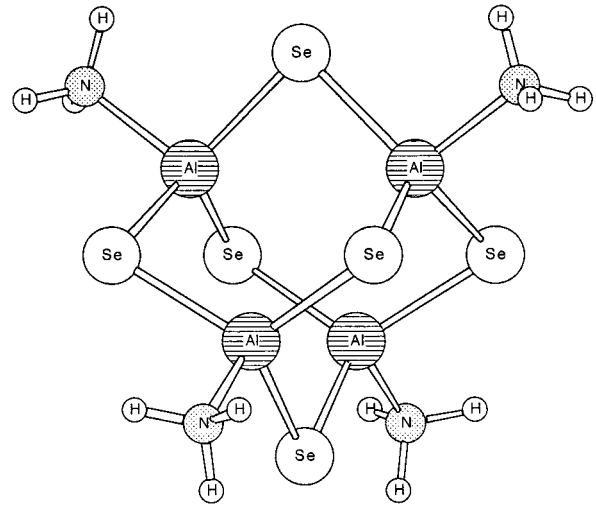

**Fig. 3** Computed structure of [$Al_4(\mu\text{-}Se)_6(Me_3N)_4$] with $T_d$ symmetry: Al–Se, N, 2.460, 2.059 Å; Se–Al–Se 116.16, Se–Al–N 101.46, Al–Se–Al 93.45°

We thank the Australian Research Council for support of this work.

# First structural characterization of an eight-coordinate cobalt(II) complex containing five-membered chelate rings: evidence for d-orbital σ-stabilization energy favoring eight- over six-coordination at cobalt(II) ions

**Welf O. Koch, Jens T. Kaiser and Hans-Jörg Krüger***

*Institut für Anorganische und Angewandte Chemie der Universität Hamburg, Martin-Luther-King-Platz 6, D-20146 Hamburg, Germany*

**For the first time, an eight-coordinate cobalt(II) complex is presented where only five-membered chelate rings are formed with the coordinated ligand; evidence is put forward that in addition to reasons of the tetraazamacrocyclic nature of the ligand 2,11-diaza-[3.3](2,6)pyridinophane (L), eight-coordination at cobalt(II) ions is, to some extent, favored with respect to six-coordination by the presence of d-orbital σ-stabilization energy as calculated by angular overlap methods.**

Structurally established eight-coordination at a cobalt ion is very rare and, to our knowledge, has only been reported for $[Co(NO_3)_4]^{2-}$ ions where the oxygen donor atoms assume a dodecahedral arrangement.[1] The existence of eight-coordinate cobalt(II) ions has also been implied to exist, without any structural proof, in another cobalt complex containing the ligand 1,8-naphthyridine.[2] Here we introduce the first structural characterization of an eight-coordinate cobalt(II) complex in which the ligand forms only five-membered instead of four-membered chelate rings with the metal ion and, further, we present evidence that eight-coordination at cobalt(II) ions is favored, to some extent, by d-orbital σ-stabilization energy as calculated by angular overlap methods.[3]

In a recent publication[4] we demonstrated that eight-coordinate iron-(II) and -(III) complexes can be obtained with the tetraazamacrocyclic ligand 2,11-diaza-[3.3](2,6)pyridinophane (L). In these complexes the metal ion is positioned in a sandwich-like fashion between the two ligand moieties. We showed that a distorted dodecahedral coordination geometry is achieved because of the *syn* boat–boat conformation of the two coordinated macrocyclic ligands.

The lilac cobalt(II) complex $[CoL_2]^{2+}$ was prepared by the addition of 1 equiv. of cobalt(II) perchlorate to a methanolic solution containing 2 equiv. of the tetraazamacrocyclic ligand. Upon recrystallization from acetonitrile–diethyl ether, the complex was isolated either directly as the perchlorate salt $[CoL_2][ClO_4]_2$ **1** or, after a preceding metathesis with sodium tetraphenylborate, as the tetraphenylborate salt $[CoL_2][BPh_4]_2 \cdot Et_2O$ **2**. Analogous procedures render the violet nickel(II) complexes $[NiL_2][ClO_4]_2 \cdot MeCN$ **3** and $[NiL_2][BPh_4]_2$ **4**.

The structure determinations† of both cobalt complexes unambiguously establish eight-coordination at the cobalt(II) ions. The coordination geometry around the cobalt(II) ion in **2** (Fig. 1) is best described as a distorted dodecahedron. Thus, the two diazapyridinophane ligands form a torsional angle of approximately 70° and there are substantial differences in lengths ( > 0.1 Å) observed between the two crystallographically distinct $Co–N_{py}$ and the two $Co–N_{amine}$ bonds, respectively. In contrast, in **1** (structure not shown) the cobalt ion is located in a nearly perfect dodecahedral coordination environment (torsional angle of 90°), providing the complex with $D_{2d}$ overall symmetry. The average $Co–N_{py}$ and $Co–N_{amine}$ bond lengths in **1** (which are approximately the same as the average bond lengths in **2**) are 2.308 ± 0.002 and 2.389 ± 0.005 Å, respectively; the average $N_{py}–Co–N_{py}$ and $N_{amine}–Co–N_{amine}$ angles, defined by the Co–N bonds to the same ligand moiety, are determined to be 72.96 and 132.61°, respectively. The magnetic moment of the solid cobalt(II) complex **2**, 4.45 $\mu_B$, is considerably lower than that of an octahedral cobalt(II) complex[5] but similar to that of cobalt(II) complexes with a tetrahedral[5] or a dodecahedral coordination geometry[2,6] around the metal ion. Because the magnetic moment scarcely changes upon dissolving the complex in dimethyl sulfoxide (4.41 $\mu_B$) and because eight-coordinate cobalt complexes are obtained in the solid state irrespective of the counter anions used in the preparation, it is difficult to imagine that the coordination number eight at the cobalt ion is just the result of some solid state effect and that it prevails only in the solid state. Thus, this study demonstrates that coordination number eight can be readily achieved with the 'relatively small', late first row transition metal ion cobalt in the moderately low +2 oxidation state. In the two previously investigated cobalt complexes where eight-coordination is observed or assumed, the ligands have rather small chelate bites forming four-membered chelate rings, whereby the interaction of the two donor atoms of a

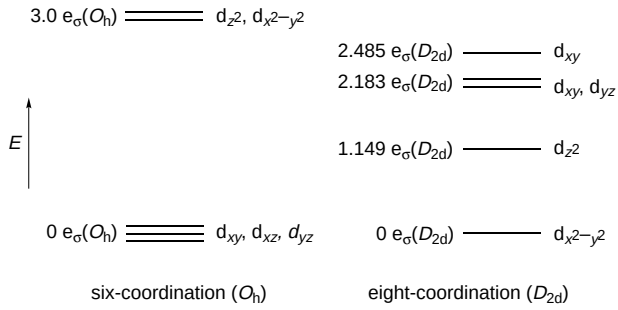

**Fig. 2** Energy diagrams for the d orbitals of a six-coordinate metal ion in an octahedral coordination geometry ($O_h$) and of an eight-coordinate metal ion in a dodecahedral coordination geometry ($D_{2d}$). The indicated energies of d orbitals are calculated by angular overlap methods[3] in units of $e_\sigma = \beta S_R^2$, assuming only σ-interactions between the metal ion and ligand donor atoms.

ligand with the metal ion is significantly favored by the spacial proximity of the donor atoms. In this study, for the first time, eight-coordination has been structurally established for a cobalt(II) ion where only five-membered chelate rings are present in the complex.

In contrast, the nickel(II) ion in **3**† is coordinated to all nitrogen donor atoms of one of the tetraazamacrocyclic ligands and to one each of the pyridine and amine nitrogen atoms of the second ligand (Fig. 1). Thus, the nickel ion assumes an octahedral coordination geometry which is also found in a preliminary structure determination of **4**.

Fig. 2 compares the energy levels obtained for an ideal octahedral and dodecahedral (using the angles within complex **1**) metal ion by angular overlap methods. With the assumption that π bonding can be neglected in these complexes, the dodecahedral site preference expressed as the difference in d-orbital σ-stabilization energies (calculated by angular overlap methods)[3] is: $8\ e_\sigma(D_{2d}) - 6\ e_\sigma(O_h)$ for high-spin $d^6$, $6.85\ e_\sigma(D_{2d}) - 6\ e_\sigma(O_h)$ for high-spin $d^7$ and $4.67\ e_\sigma(D_{2d}) - 6\ e_\sigma(O_h)$ for a $d^8$ metal ion. Considering that $|e_\sigma(D_{2d})|$ is smaller than $|e_\sigma(O_h)|$ owing to the larger M–N bond lengths in eight-coordinate complexes, eight- as well as six-coordination is possible for the cobalt(II) complex [depending on the relative magnitude of $e_\sigma(D_{2d})$ with respect to $e_\sigma(O_h)$], while only six-coordination is predicted to occur with nickel(II) ions according to angular overlap methods.‡ Clearly, eight coordination at the cobalt(II) as well as at the iron(II) ion[4] is favored by the distinct spacial properties of the tetraazamacrocyclic ligand L. However, in light of the finding that, in comparison with the cobalt(II) ion, the only slightly smaller nickel ion prefers octahedral over dodecahedral coordination geometry, evidence has been put forward that to some extent eight-coordination at iron(II) and cobalt(II) centres is stabilized with respect to six-coordination by electronic factors as illustrated by the d-orbital σ-stabilization energy calculated by angular overlap methods.

We are grateful to the Deutsche Forschungsgemeinschaft for financial support. We also thank Professor Dr O. Jarchow, Professor Dr U. Behrens and Dr J. Hanss for their assistance with the crystal structure determination of compound **1**.

‡ The calculation of the ligand field stabilization energies for dodecahedral and octahedral high-spin metal ions with $d^6$, $d^7$ and $d^8$ electron configurations shows that eight-coordination geometry is favored for a $d^6$ metal ion, while six-coordination is preferred by $d^8$ metal ions. For a $d^7$ metal ion, the difference in ligand field stabilization energy between both geometries is small, but favors octahedral coordination geometry.

# Single-molecule magnets: isomeric $[Mn_{12}O_{12}(O_2CC_6H_4Me\text{-}4)_{16}(H_2O)_4]$ complexes exhibiting different rates of resonant magnetization tunnelling

**Sheila M. J. Aubin,[a] Ziming Sun,[a] Ilia A. Guzei,[b] Arnold L. Rheingold,*[b] George Christou*[c] and David N. Hendrickson*[a]**

[a] *Department of Chemistry and Biochemistry-0358, University of California at San Diego, La Jolla, CA 92093-0358, USA*

**Two different isomeric forms of $[Mn_{12}O_{12}(O_2CC_6H_4Me\text{-}4)_{16}(H_2O)_4]$, differing in the positioning of $H_2O$ ligands, are structurally characterized and shown to have considerably different magnetization hysteresis loops.**

Single-molecule magnets have attracted considerable attention.[1–3] The presence of appreciable magnetic anisotropy in a big spin ground-state molecule leads to a potential-energy barrier for reversal of the direction of magnetization and an isolated molecule exhibits hysteresis in its magnetization *vs.* magnetic field response. The most thoroughly studied[4,5] single-molecule magnet $[Mn_{12}O_{12}(O_2CMe)_{16}(H_2O)_4]$ **1** has a magnetization that decays with a half-life of 2 months at 2.0 K after a magnetic field is removed. One of the most interesting aspects of complex **1** is that there are steps observed at regular intervals of magnetic field in the magnetization loop for oriented crystals. These steps have been attributed[6–8] to resonant magnetization tunnelling. We herein describe the preparation and X-ray structures of two new single-molecule magnets, $[Mn_{12}O_{12}(O_2CC_6H_4Me\text{-}4)_{16}(H_2O)_4]\cdot 3H_2O$ **2** and $[Mn_{12}O_{12}(O_2CC_6H_4Me\text{-}4)_{16}(H_2O)_4]\cdot HO_2CC_6H_4Me\text{-}4$ **3**, that differ in their space group and the positioning of their $H_2O$ ligands on the $Mn_{12}$ complexes.

The reaction of $Mn(ClO_4)_2$ (11 mmol) with $NBu^n{}_4[MnO_4]$ (4.3 mmol) and 4-methylbenzoic acid (140 mmol) in ethanol gives complexes **2** and **3**. When anhydrous ethanol is used complex **3** results, whereas a 20% $H_2O$–80% EtOH reaction medium yields the hydrate complex **2**. X-Ray quality crystals of **2** and **3** were grown from a $CH_2Cl_2$–hexanes mixture.

The structure† of complex **2** shows a $Mn_{12}$ complex with a $[Mn_{12}(\mu_3\text{-}O)_{12}]$ core, comprising a central $[Mn^{IV}{}_4O_4]^{8+}$ cubane held within a non-planar ring of eight $Mn^{III}$ ions by eight $\mu_3\text{-}O^{2-}$ ions. Peripheral ligation of complex **2** is provided by sixteen $\eta^2,\mu$-carboxylate groups and four $H_2O$ ligands. The eight $Mn^{III}$ ions fall into two groups of four $Mn^{III}$ ions. In group I each $Mn^{III}$ ion is bonded to a single $Mn^{IV}$ *via* two $\mu_3\text{-}O^{2-}$ bridges, while in group II each $Mn^{III}$ is bonded to two $Mn^{IV}$ ions *via* two $\mu_3\text{-}O^{2-}$ bridges. The four $H_2O$ ligands coordinate only to $Mn^{III}$ ions in group II. Complex **2** has two $H_2O$ ligands bonded to one $Mn^{III}$ ion and one $H_2O$ ligand on each of two other $Mn^{III}$ ions. The structure† of complex **3** shows that it is an isomer of the same $Mn_{12}$ complex. A drawing showing a superposition of the two $Mn_{12}$ complexes is shown in Fig. 1. It can be seen that the $Mn_{12}$ complexes in complexes **2** and **3** differ in the positioning of the four $H_2O$ ligands. Consequential rearrangements in the 4-methybenzoate ligands also occur.

Out-of-phase ac magnetic susceptibility ($\chi_M''$) signals are seen for both complexes **2** and **3**. Fig. 2 shows a plot for $\chi_M''$ *vs.* *T* for complex **3** (upper) and for hydrated complex **2** (lower) in the region 2–10 K, measured at frequencies of 50, 250 or 1000 Hz. Both samples of these two complexes exhibit two frequency-dependent $\chi_M''$ ac peaks, one in the region 2–4 K and the other in the region 4–7 K. However, complex **3** has predominantly a peak in the region 2–4 K, whereas hydrated complex **2** has predominantly a peak in the region 4–7 K. Several crystalline samples of $[Mn_{12}O_{12}(O_2CC_6H_4Me\text{-}4)_{16}(H_2O)_4\cdot xH_2O\cdot yHO_2CC_6H_4Me\text{-}4$ were prepared by varying the level of dryness of the EtOH reaction medium. As *x* and *y* varied, so did the intensity ratio of the two $\chi_M''$ peaks.

Fig. 3 shows magnetization hysteresis data obtained for oriented crystal samples of complexes **2** and **3**. A few small crystals of a given complex were suspended in eicosane at 40 °C, oriented in a 5.5 kG field and then the eicosane matrix was cooled to room temp. This gives a waxy cube with the crystals aligned with their easy axes of magnetization parallel. Steps are seen in the hysteresis loops for both complexes. The sample of complex **2** is first magnetically saturated in a +3.5 kG field. All of the complexes at 2.0 K will be in the $m_s = -10$ level of the $S = 10$ double-well potential. When the field is decreased to zero, each of the $m_s = -10, -9, -8, \cdots -1, 0$ levels on the right-hand side of the double well become equal in energy to the corresponding $m_s = 10, 9, 8, \cdots 1, 0$ level of the left-hand side. As the field is decreased from +3.5 kG to zero, there is the first step at zero field. The energy alignment leads to a resonant magnetization tunnelling. Individual molecules tunnel from one $m_s < 0$ level to an $m_s > 0$ level. If all molecules

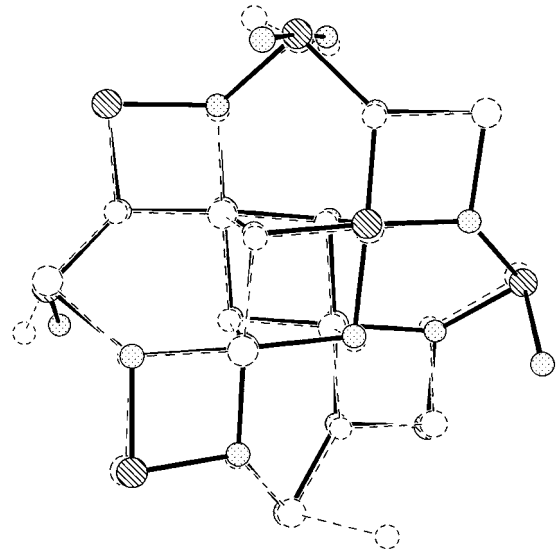

**Fig. 1** Drawing showing a superposition of the cores, without 4-methylbenzoate ligands, of the $[Mn_{12}O_{12}(O_2CC_6H_4Me\text{-}4)_{16}(H_2O)_4]$ molecules in complexes **2** (---) and **3** (—). The crosshatched and stippled spheres represent manganese and oxygen atoms, respectively, in the structure of **3**. The two isomers differ in the arrangements of four $H_2O$ ligands. Complex **2** has a 1,1,2 pattern of $H_2O$ ligand positions, where one $H_2O$ ligand is bonded to the Mn atom at the bottom of the drawing, one to the Mn atom at the left and two $H_2O$ ligands bonded to the 'top' Mn atom. Complex **3** has a 1,2,1 pattern of $H_2O$ ligands.

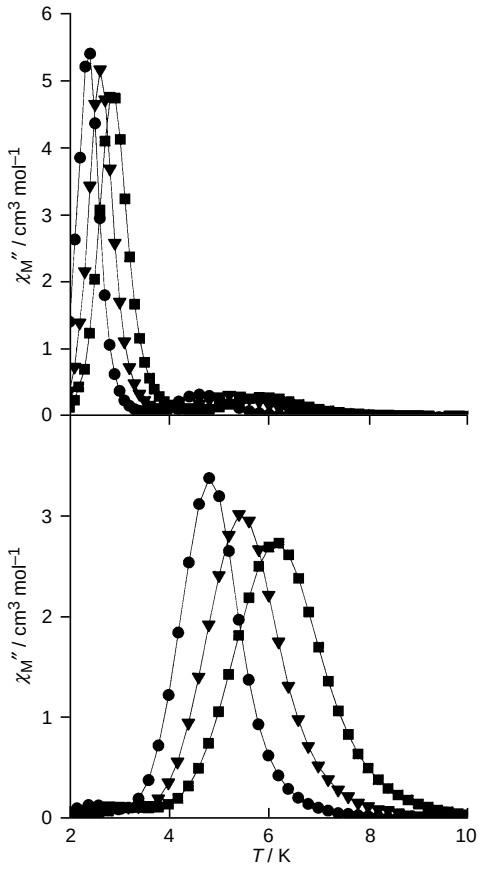

**Fig. 2** Plots of the out-of-phase ac magnetic susceptibility $\chi_M''$ *vs.* temperature for polycrystalline samples of the $Mn_{12}$ complexes **2** (lower) and **3** (upper). Data were collected with zero dc magnetic field and with an 1.0 G ac field oscillating at: (●) 50; (▼) 250 and (■) 1000 Hz.

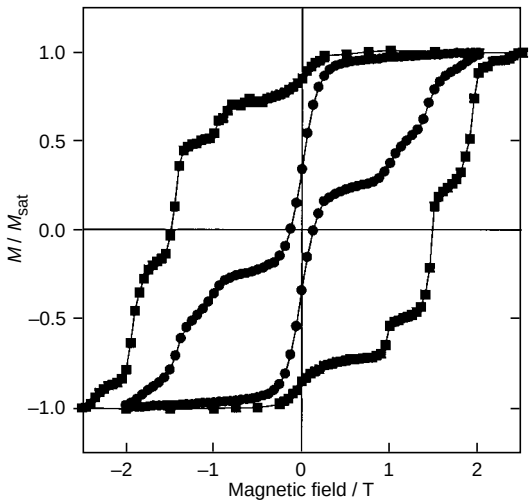

**Fig. 3** Magnetization hysteresis loops measured at 1.90 K for oriented crystals in eicosane matrix for complexes **2** (■) and **3** (●). The magnetization for each complex is plotted in units of the saturation magnetization $M_{sat}$ for that complex. The saturation magnetization values for complexes **2** and **3** are $1.20 \times 10^5$ and $1.05 \times 10^5$ cm$^3$ G mol$^{-1}$, respectively.

changed their direction of magnetization by thermal activation over the barrier, then the hysteresis loop would be a smooth function with no steps.

As can be seen in Fig. 3, it is of considerable interest to note there are appreciable differences in step heights between complexes **2** and **3**. The hysteresis loop of hydrated complex **2** is similar to that reported[6–8] for the acetate complex **1**. On the other hand, complex **3** shows a much steeper step at zero field than does complex **2**. Thus, complex **3** is exhibiting an appreciably faster rate of tunnelling of the magnetization than does complex **2**. This is the case in spite of the fact that complexes **2** and **3** have the same ligands and differ in their arrangements of four $H_2O$ ligands and space groups. The greater rate of tunnelling for complex **3** is consistent with the fact that this complex shows its $\chi_M''$ ac signal at a lower temperature than does hydrated complex **2**.

The origin of the faster rate of tunnelling for complex **3** than **2** is unclear. One possibility is that hydrated complex **2** has a $S = 10$ ground state as found for complex **1**, whereas complex **2** has a $S = 9$ ground state. The barrier height $\Delta$ in the double-well potential-energy diagram is equal to $\Delta = S^2|D|$, where $D$ gauges the axial zero-field splitting ($D\hat{S}_{z^2}$) in the ground state. The smaller thermal barrier ($\Delta$) for a $S = 9$ complex would also lead to larger tunnelling rates. A second possibility is that complexes **2** and **3** both have $S = 10$ ground states, but there are larger higher-order (quartic) zero-field interactions present for complex **3** and this leads to a faster tunnelling. Finally, the differences in rates between complexes **2** and **3** could be due to differences in rates of positioning a $Mn_{12}$ complex into the $m_s = -3$ level from which tunnelling occurs.

High-field EPR experiments are in progress to determine whether complexes **2** and **3** differ in their ground-state spins. Understanding the differences in hysteresis loops between complexes **2** and **3** should give insight into the unknown mechanism of magnetization tunnelling. This is essential if the potential application of single-molecule magnets to memory devices is to be realized.

# Development of a site-selective copper-ion-exchanging method for HZSM-5 by vapourization of a hexafluoroacetylacetonato–copper complex

**Yasushige Kuroda,*[a] Kazunori Yagi,[a] Yuzo Yoshikawa,[a] Ryotaro Kumashiro[b] and Mahiko Nagao[b]**

[a] *Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700, Japan*
[b] *Research Laboratory for Surface Science, Faculty of Science, Okayama University, Tsushima, Okayama 700, Japan*

**The deposition of copper ion into a single type of ion-exchange site in HZSM-5-type zeolite is successful using bis(1,1,1,5,5,5-hexafluoroacetylacetonato)copper(II) as a volatile complex, and the sample thus prepared gives a single IR absorption band at 2158 $cm^{-1}$ upon adsorption of CO, differing from a sample prepared by aqueous ion-exchange, which gives two bands at 2158 and 2151 $cm^{-1}$.**

Many applications of zeolites rely on their unique surface properties that are largely determined by the concentration, distribution and nature of exchanged ions, such as protons, alkali metal and transition metal ions. Among many kinds of zeolites, the copper-ion-exchanged ZSM-5-type zeolite (Cu-ZSM-5) has become one of the most promising materials for the catalytic decomposition reaction of $NO_x$ to $N_2$ and $O_2$.[1,2] This material has also a specific adsorption property for $N_2$ at room temperature; and hence it can be used as a catalyst for $N_2$ separation, fixation and activation.[3,4] From the viewpoints of the development of more effective catalysts, it is useful and important to obtain information on the nature of the active sites on Cu-ZSM-5 for $NO_x$ decomposition and specific $N_2$ adsorption. Thus far we have investigated the state of copper ion exchanged in mordenite-type zeolites by using CO as a probe molecule and have found that there are at least two main types of sites in this substance, giving IR bands at 2160 and 2150 $cm^{-1}$ when CO is adsorbed on each site.[5] This situation is consistent with the results obtained independently by Zecchina and coworkers[6] and by Iwamoto and Hoshino for the Cu-ZSM-5 system.[7] A great deal of effort has so far been made to analyze these exchanging sites. However, the understanding of the role of each site for $NO_x$ decomposition reaction and $N_2$ fixation is still far from being complete.[8,9] The presence of a number of different ion-exchanged sites leads to complications in such studies. The most pertinent approach is to prepare site-selectively copper-ion-exchanged ZSM-5.

In the present work, we succeeded in site-selective copper-ion deposition in this zeolite and the results obtained shed light on the analysis of active sites for $NO_x$ decomposition and $N_2$ adsorption.

Bis(1,1,1,5,5,5-hexafluoroacetylacetonato)copper(II), [Cu(hfac)$_2$] (Aldrich), was used as a vapourizing source in chemical vapour deposition (CVD).[10] For the measurement of IR spectra, the HZSM-5 sample (supplied from Tosoh Co.) was pressed into a pellet (5 mg) of 10 mm diameter, and it was initially treated at 300 K for 2 h under a reduced pressure of 1 mPa in the *in situ* cell. The [Cu(hfac)$_2$] complex was then vapourized onto this pellet at room temperature. The sample thus prepared was evacuated at 873 K under a reduced pressure of 1 mPa and then treated with CO at 300 K. The ion-exchanging operation of HZSM-5 with copper ions was also carried out in an aqueous solution in the same manner as described in the literature.[3]

Fig. 1 shows the transmission FTIR spectra for the HZSM-5 sample evacuated at 873 K (*a*) and for the HZSM-5 sample with modified surface by deposition of [Cu(hfac)$_2$] followed by evacuation at 873 K (*b*). The spectrum in Fig. 1(*a*) shows intense bands at 3746 and at *ca*. 3613 $cm^{-1}$, which are due to hydroxyl groups of free silanol and of the Brönsted acid site,

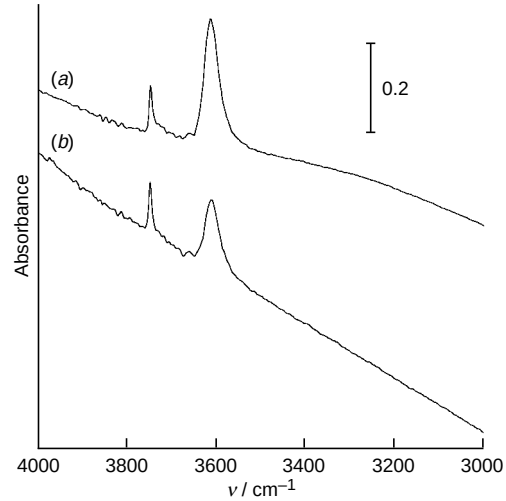

**Fig. 1** IR spectra of the HZSM-5 sample evacuated at 873 K (*a*) and for the surface-modified HZSM-5 sample with Cu(hfac)$_2$ and then subsequently evacuated at 873 K (*b*)

respectively. At first glance, the spectrum in Fig. 1(*b*) appears to be similar to the spectrum in Fig. 1(*a*). However, the relative intensity of the 3613 $cm^{-1}$ band to the 3746 $cm^{-1}$ band is lower for the surface-modified HZSM-5 sample, compared with that for the original HZSM-5 sample. These data suggest ion exchange of the proton on the Brönsted acid site with copper ion in the course of the evacuation process at higher temperatures.

Fig. 2 shows IR spectra for the sample prepared by deposition of [Cu(hfac)$_2$], as well as for a sample prepared by ion-exchange from aqueous solution. The spectra in Fig. 2(*b*) and (*d*) are those

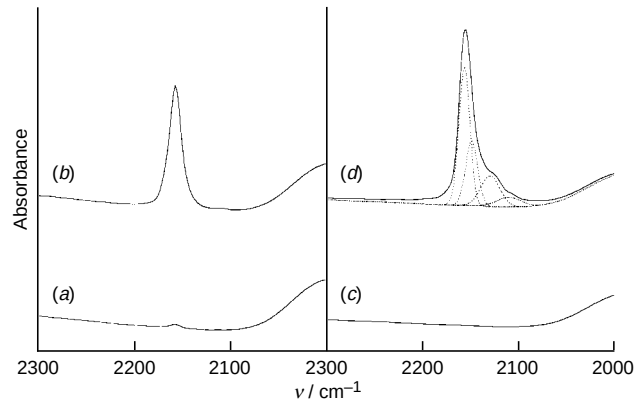

**Fig. 2** IR spectra for the Cu(hfac)$_2$-deposited HZSM-5 sample (*a*) and (*b*) and for the copper-ion-exchanged HZSM-5 sample (*c*) and (*d*). These samples were pretreated in the following manner: (*a*) and (*c*), evacuated at 873 K; (*b*) and (*d*), equilibrated with CO gas at 300 K under nearly zero pressure after evacuation at 873 K. The deconvolution (dotted line) curves for spectrum (*d*) are also depicted.

for samples equilibrated with CO under nearly zero pressure, *i.e.* the chemisorption region. The spectra for both samples evacuated at 873 K after CVD [Fig. 2(*a*)] or ion-exchange from aqueous solution [Fig. 2(*c*)] are also included for comparison. As can be seen from the Fig. 2(*a*) and (*c*), scarcely any band is discernible in the 873 K treated sample in the region shown. It is clearly seen that chemisorption of CO takes place on the sample prepared by the CVD method to give a single band at 2158 $cm^{-1}$ [Fig. 2(*b*)]. Chemisorption of CO also occurs for the sample prepared by ion-exchange from aqueous solution and the resultant CO species adsorbed give a broad IR band centred at *ca*. 2155 $cm^{-1}$ [Fig. 2(*d*)], which is slightly but obviously tailing to the lower wavenumber side. Based on the information accumulated so far,[11–14] it is generally agreed that an absorption band at *ca*. 2150 $cm^{-1}$ can be assigned to the C–O stretching mode of a CO species adsorbed on $Cu^{I}$; the copper complex was deposited on HZSM-5 by CVD and subsequent heat treatment reduced the $Cu^{II}$ to $Cu^{I}$. For the ion-exchanged sample, it is apparent that heat treatment *in vacuo* reduces $Cu^{II}$ to $Cu^{I}$, based on data described in previous papers.[3,5] A numerical deconvolution technique was applied to identify the bands in Fig. 2(*b*) and (*d*). For the CVD sample, only a single absorption band centred at 2158 $cm^{-1}$ is present, *i.e.* the copper ion-exchange occurred only at one type of site. For the sample prepared by ion-exchange from aqueous solution, the observed broad band at *ca*. 2155 $cm^{-1}$ is seen to be composed of two major components at 2158 and 2151 $cm^{-1}$. From the present experimental result, it is clear that for the sample prepared by ion-exchange from aqueous solution that both types of sites are occupied by copper ions. Recently, Zecchina and coworkers have reported, on the basis of EXAFS data, that two types of ion-exchanged sites exist on ZSM-5,[15] consistent with the above observations.

Taking the experimental data into consideration, it is also apparent that one of the two types of exchangeable sites in HZSM-5 is occupied selectively by copper ion in the sample prepared by CVD using $[Cu(hfac)_2]$, while in the sample prepared by ion-exchange from aqueous solution both types of sites are occupied by copper ion. This new ion-exchanging method (CVD) has potential to be utilized for the analysis of the active sites in the $NO_x$ decomposition reaction and also for the $N_2$ fixation reaction.

This work was supported by the Foundation from the Ministry of Education, Science, Sports and Culture of Japan (Nos. 08640750 and 09218242). We also thank Mr. T. Ozaki in the glassblowing workshop of Hiroshima University for technical assistance in making the *in situ* glass cell for IR measurements.

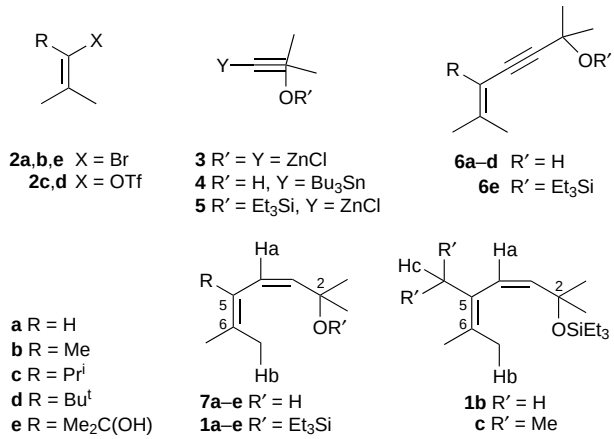
# Further demonstration of the higher reactivity of the vinyl hydrogen rather than the allyl hydrogen towards singlet oxygen



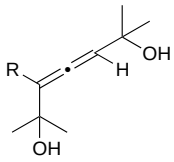
**Hajime Mori, Keiichi Ikoma and Shigeo Katsumura***

*School of Science, Kwansei Gakuin University, Uegahara 1-1-155, Nishinomiya 662, Japan*

**In a new linear twisted 1,3-diene, an anomalously high reactivity of the vinyl hydrogen rather than the allyl hydrogen towards singlet oxygen is observed.**

Previously, we reported the photosensitized oxygenation of significantly twisted *cis*-β-ionol derivatives, and found the vinyl hydrogen to be anomalously more reactive towards singlet oxygen than the allyl hydrogen in some significantly twisted compounds of *cis*-β-ionol derivatives. We proposed that this unusually high reactivity of the vinyl hydrogen in a significantly twisted 1,3-diene should be attributed to a large interaction between the σ* orbital of the vinyl hydrogen and the π orbital of another double bond.[1] Since only a few examples of significantly twisted 1,3-dienes are found in the literature,[2] although conjugated dienes are some of the most common systems in organic reactions as represented by pericyclic reactions, further investigation on the design, synthesis and photosensitized oxygenation of significantly twisted 1,3-dienes has been required. Here we report the photosensitized oxygenation of a newly designed linear twisted 1,3-diene, and describe a further demonstration of the unusually high reactivity of the vinyl hydrogen towards singlet oxygen.

The substrates **1a**–**e** were chosen for the photosensitized oxygenation because the substituent R on the olefin can be changed from hydrogen to methyl, isopropyl and *tert*-butyl, and when R is a bulky substituent the 1,3-diene structure would be twisted. Syntheses of these *cis*-1,3-diene derivatives were accomplished by palladium catalysed coupling of the appropriate vinyl halides or enol trifluoromethanesulfonates (triflates) with zinc or stannyl acetylides followed by partial hydrogenation and then protection of the tertiary hydroxy group. Thus, compounds **6a**,**b** were prepared from commercially available vinyl bromides **2a**,**b** by reaction with zinc acetylide **3** in the presence of tetrakis(triphenylphosphine)palladium (THF, 60 °C; **6a**, 80%; **6b**, 45% yield), respectively.[3] Compounds **6c**,**d** which have bulky substituents were synthesized by coupling of stannyl acetylide **4** with enol triflates **2c**,**d**,[4] which were prepared from the corresponding ketones[5] (LDA, *N*-phenyltrifluoromethanesulfonimide, THF), in the presence of the same palladium reagent (THF, room temp.; **6c**, 45%; **6d**, 52% yield).[6] Another enyne compound **6e** was also synthesized by coupling of vinyl bromide **2e**, prepared from methyl 3,3-dimethylacrylate ($Br_2$–$CH_2Cl_2$, DBU–THF, MeMgI–THF; 46% yield), with **5** under the same conditions as those of **2a**,**b** (**6e**, 84% yield). Partial reduction of the acetylene groups of **6a**–**e** to the corresponding *cis*-olefins by catalytic hydrogenation in hexane reflected the reactivity of their acetylene groups. Thus, **7a**,**b** were obtained with Lindlar catalyst in the presence of a catalytic amount of quinoline (**7a**, 47%; **7b**, 49% yield). In the absence of quinoline with Lindlar catalyst, **7c** was obtained (47% yield). Hydrogenation of **6d** with palladium on barium sulfate gave **7d** (60% yield) and of **6e** with palladium on charoal gave **1e** (MeOH, 90% yield). The *cis*-alcohols obtained were transformed into the corresponding triethylsilyl ethers **1a**–**d** in excellent yield ($Et_3SiCl$, DMAP, $Et_3N$, DMF).† The maximum absorption values in the electronic spectra of compounds **1b**–**e** were less than 210 nm, whereas that of **1a** was 238 nm. These data clearly show that **1b**–**e** are significantly twisted around the central single bond of the 1,3-diene. The most stable conformations of **1b**–**e** obtained by molecular mechanics calculations and molecular obrital calculations also support the significantly twisted structures.[1]§



The photosensitized oxygenation of **1a**–**e** was carried out in $CH_2Cl_2$ (1.0–2.0 mmol scale) by irradiation using a halogen lamp under an oxygen atmosphere in the presence of a catalytic amount of tetraphenylporphine and 1 equiv. of triphenylphosphine at 0 °C. The products were isolated by column chromatography and all of them were characterized by $^1H$, $^{13}C$ NMR and IR spectroscopy, and by elemental analysis or high resolution mass spectra for some compounds. The ene reaction of Ha and Hb gave allene **8** and isopropenyl compound **9**, respectively. In the case of **1b**,**c**, the ene reaction of Hc gave compounds **10b**,**c**, which might produce allene **11** by further oxygenation. The results of the photosensitized oxygenation are shown in Table 1. For compounds **1d**,**e**, allenes **8d**,**e** (mp 76–77 °C) were produced in 75 and 74% yield along with isopropenyl compounds **9d**,**e** in 8 and 9% yield, respectively. In these cases, the abstracted vinyl hydrogen Ha and allyl hydrogen Hb are located at the opposite sides of the C5–C6 double bond, and the vinyl hydrogens Ha were much more reactive than the allyl hydrogens Hb toward singlet oxygen.[7]¶

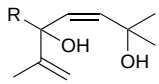


**Table 1** Ene reaction of acyclic twisted 1,3-dienes with singlet oxygen

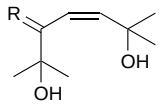
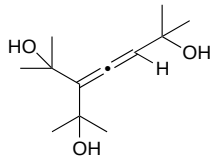
| | Yield (%) | | | |
|---|---|---|---|---|
| Substrate | **8**[a] | **9**[a] | **10**[a,b] | **11**[a,b] |
| **1a** | 29[b] | 45[b] | — | — |
| **1b** | 32[b] | 12[b] | 42 | — |
| **1c** | 38[b] | 27[b] | 8 | 17 |
| **1d** | 75[b] | 8[b] | — | — |
| **1e** | 74[c] | 9[c] | — | — |



[a] Isolated yield. [b] The yields are over three steps; silylation of the corresponding alcohol followed by photosensitized oxygenation and then desilylation. [c] The yields are over two steps; photosensitized oxygenation and desilylation.



**8a–e**

**9a–e**

**10b** R = $CH_2$
**10c** R = $Me_2C$

**11** (≡**8e**)

These results are compatible with those of the cyclic system reported previously. On the other hand, compound **1a** produced allene **8a** in 29% and isopropenyl compound **9a** in 45% yield, respectively. Photosensitized oxygenation of **1b** gave allene **8b** and allyl alcohol **10b** in 32 and 42% yield, respectively, along with isopropenyl compound **9b** in 12% yield. Since both the abstracted vinyl hydrogen Ha and the allyl hydrogen Hc in **1b** are located at the same side of the C5–C6 double bond, and the ene reactions of the Ha and the Hc with singlet oxygen gave the allene **8b** and the allyl alcohol **10b**, respectively, the relative yields of **8b** and **10b** obviously reflect the relative reactivity of the vinyl hydrogen and the allyl hydrogen. It is worth noting that the vinyl hydrogen shows comparable reactivity to the allyl hydrogen. Next, in the photooxygenation of **1c**, allene **8c**, isopropenyl compound **9c**, diene **10c** and trihydroxyallene **11**, which is identical to **8e**, were obtained in 38, 27, 8 and 17% yield, respectively. In this case, compound **11** must be produced from **10c**, giving a 25% yield of allyl hydrogen Hc abstracted products. It is noteworthy that the vinyl hydrogen Ha of **1c** was more reactive than the isopropyl hydrogen Hc, and that the sterically hindered hydrogen Hc in **1c** reacted with singlet oxygen to a similar extent as the allyl hydrogen Hb.

Unfortunately, we did not observe a clear relationship between the bulkiness of the C5 substituent and the twisting of the two double bonds, and hence between the extent of twisting and the yield of the oxygenated products. However, the evidence suggests that twisting and/or the C5 substituent have an effect on the reactivity of 1,3-dienes, since the relative proportions of C6 and C5 hydroxy products in the significantly twisted **1b**–**e** were the opposite to that of the conjugated **1a**, thus the proportions of C6 and C5 hydroxy products in **1b**–**e** were 63–75 *vs*. 27–8, while for **1a** the proportion was 29 *vs*. 45.

The results obtained here seem to support our proposal on the activation of the vinyl hydrogen based on σ*–π orbital interaction between the vinyl C–H bond and another double bond in significantly twisted 1,3-dienes.[1]

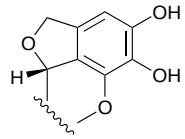
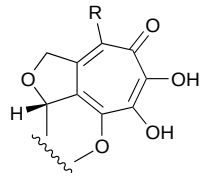
# Biosynthesis of Xenovulene A®: formation of a cyclopentenone *via* a unique ring expansion–ring contraction mechanism

**Mairi E. Raggatt,[a] Thomas J. Simpson*[a] and M. Inês Chicarelli-Robinson[b]**



[a] *School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS*
[b] *Natural Products Chemistry Department, Xenova Discovery Ltd, 545 Ipswich Road, Slough, Berkshire, UK SL1 4EQ*

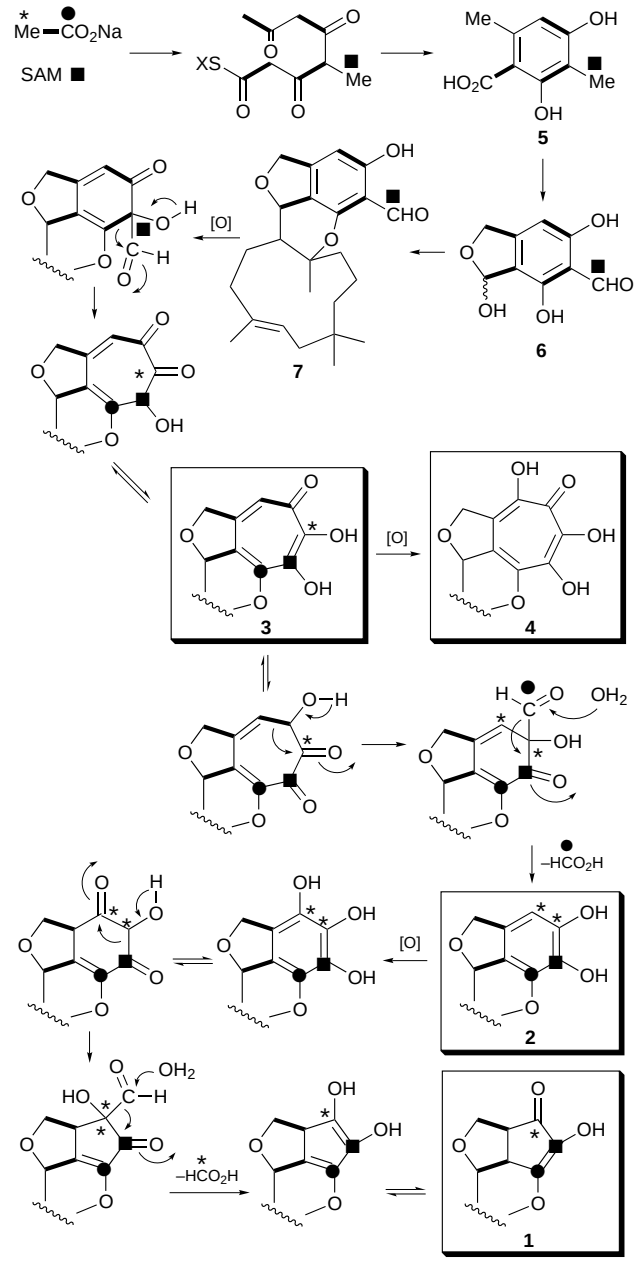
**Incorporation studies with $^{13}$C-labelled acetates and methionine in *Acremonium strictum* indicate that the cyclopentenone moiety in Xenovulene A® is formed *via* a unique pathway in which a C-methylated phenolic precursor undergoes ring expansion to a tropolone followed by two successive ring contractions resulting in incorporation of the C-methyl carbon into the five-membered ring.**



Xenovulene A® **1**, a novel inhibitor of benzodiazepine binding to the GABA-benzodiazepine receptor,[1] was isolated from cultures of *Acremonium strictum*.[2] The structure of **1** contains an unusual furocyclopentenone moiety fused to a humulene-derived 11-membered ring. A number of minor co-metabolites of **1** have been isolated[3] in which the cyclopentenone moiety is replaced by a trioxygenated benzene **2** or highly oxygenated tropolone rings, **3** and **4**. While fungal metabolites containing all of these types of rings are known, the presence of all three in a single family is unique.

**1**

**2**



**3** R = H
**4** R = OH

Recently, two very similar fungal metabolites, pycnidione[4] and eupenifeldin[5] were isolated. These both contain a similar fusion of a tropolone to humulene. The higher plant metabolite, lucidene, also contains a humulene ring fused to an *o*-hydrobenzyl moiety.[6] The fungal tropolone, stipitatonic acid is derived from 3-methylorsellinic acid **5** with incorporation of the methionine-derived 3-methyl group into the polyketide-derived aromatic ring.[7] In addition, the fungal cyclopentenone metabolites, terrein[8] and cryptosporiopsonol[9] have been shown to be derived by ring contraction of the aromatic ring of dihydroisocoumarin intermediates. Thus a plausible pathway to the Xenovulene metabolites **1**–**4** appeared to be *via* the polyketide-derived 3-methylorsellinic acid **5** (Scheme 1) which would be converted by standard biosynthetic modifications to the lactol **6**. This would react with the 6,7 double bond of humulene, either *via* a carbocation mediated addition or cycloaddition of the readily derived quinomethane to give the key tetracyclic intermediate **7**.

Ring expansion of the phenolic ring in **7** followed by hydroxylation would give the tropolones **3** and **4**, whereas oxidative decarboxylation of **7** would give **2**, ring contraction and decarboxylation of which would lead to Xenovulene A® **1**.

We now report incorporation studies with $^{13}$C-labelled acetates and methionine which render this branched pathway untenable and indicate a linear relationship among the metabolites.

The results of incorporations† of [1-$^{13}$C]-, [2-$^{13}$C]- and [1,2-$^{13}C_2$]-acetates and [*methyl*-$^{13}$C]methionine into Xenovulene A® are summarised in Fig. 1. Surprisingly, no intact acetate unit was present in the cyclopentenone ring and C-15 was not

**Scheme 1**

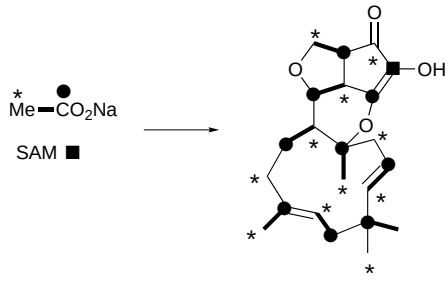


**Fig. 1**

derived from either the methyl or carboxy carbons of acetate. This was accounted for on feeding $^{13}$C-labelled methionine which gave an approximately 8% enrichment at C-15. To accommodate these results, the remarkable sequence outlined in Scheme 1 is proposed. Hydroxylation of **7** allows ring expansion *via* an α-ketol rearrangement to give **3** which, after further tautomeric adjustment, can ring contract and lose formic acid to form the trioxygenated benzenoid metabolite **2** with incorporation of the methionine-derived carbon into the aromatic ring. Further oxidation, α-ketol mediated ring contraction and loss of formate generates Xenovulene A® with the observed labelling pattern.

Work is in progress to obtain further information on the detailed mechanisms and the exact oxidation levels of the intermediates on the pathway. For example, analogous pathways in which the formyl group in **7** is at the hydroxymethyl or carboxy level can be proposed, but these necessitate more extensive reductive and oxidative adjustments to obtain the final structures. Overall, this represents a remarkable and unprecedented pathway in which a cyclopentenone is formed from a phenolic precursor *via* one ring expansion and two successive ring contractions.

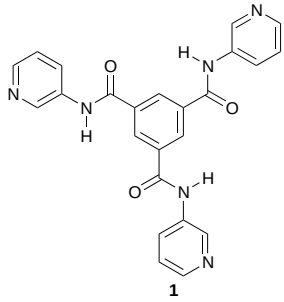
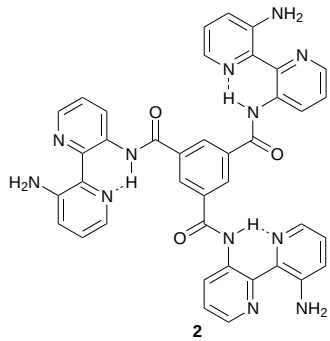
# Hydrogen-bonded porous solid derived from trimesic amide



**Anja R. A. Palmans,[a] Jef A. J. M. Vekemans,*[a] Huub Kooijman,[b] Anton L. Spek[b]† and E. W. Meijer[a]**

[a] *Laboratory of Organic Chemistry, University of Technology, PO Box 513, 5600MB Eindhoven, The Netherlands*
[b] *Bijvoet Center for Biomolecular Research, Crystal and Structural Chemistry, University of Utrecht, Padualaan 8, 3584 CH Utrecht, The Netherlands*



***N*,*N*′,*N*″-Tris(3-pyridyl)trimesic amide, 1, forms a unique *P*$\bar{3}$ symmetrical crystal containing pores with a mean diameter of 8.26 Å.**

Supramolecular assembly and crystal engineering are fruitful concepts to use in the design and development of structures with a desired shape. Recently these concepts evolved to be used in the construction of tubular superstructures[1] and porous solids.[2] Hydrogen bonding is one of the major tools which can be used to achieve the desired order.[3]

Here we report on the highly ordered infinite bilayer crystal structure of triamide **1**,‡ derived from trimesic acid (benzene-1,3,5-triacarboxylic acid) and 3-pyridylamine.§ In contrast to recently designed structures,[4] our result was entirely serendipitous. Structure **1** served just as a model for comparison with intramolecularly hydrogen-bonded structure **2**, a precursor for extended core discotic liquid crystals of enhanced thermal stability.[5]

**1**

**2**

The transparent, hexagon-shaped crystals of **1**, obtained upon crystallization from methanol, suggested hexagonal symmetry and prompted us to investigate a single crystal by X-ray diffraction. As indicated in Fig. 1 the asymmetric cell comprises only one third of a molecule while the unit cell is populated by two molecules.‡ Intermolecular hydrogen bonding between the pyridyl nitrogens and the amide NHs of adjacent molecules provides the basis for a macrocyclic organization in a rosette-like structure. A 30-membered macrocycle is formed with participation of six molecules and the 3-aminopyridyl units constitute the walls of a cavity with a mean diameter of 8.26 Å (Fig. 2).

The $C_3$-symmetry of the molecule then allows for the creation of an infinite two-dimensional honeycomb grid with repeating units at 13.87 Å in six directions and with a thickness of approximately 8.40 Å. According to Etter's[6] graph set analysis the nitrogen hydrogen bond donors and acceptors are involved in a $R_6^6(30)$ pattern. Closer inspection reveals the bilayer structure of an ensemble of molecules in one sheet (Fig. 3). The benzene units occupy alternating up and down positions. All the amide carbonyls point outwards, while the pyridyl units orientate their nitrogens inwards in the bilayer structure. This implies that although the crystal is achiral, the structure is a combination of trimesic units of *P*-helicity with units of *M*-helicity.

The infinite bilayer sheets themselves belong to a three dimensional super structure in which all the sheets are in fact repeating units placed exactly on top of each other. This results in the formation of a real porous structure with channels of

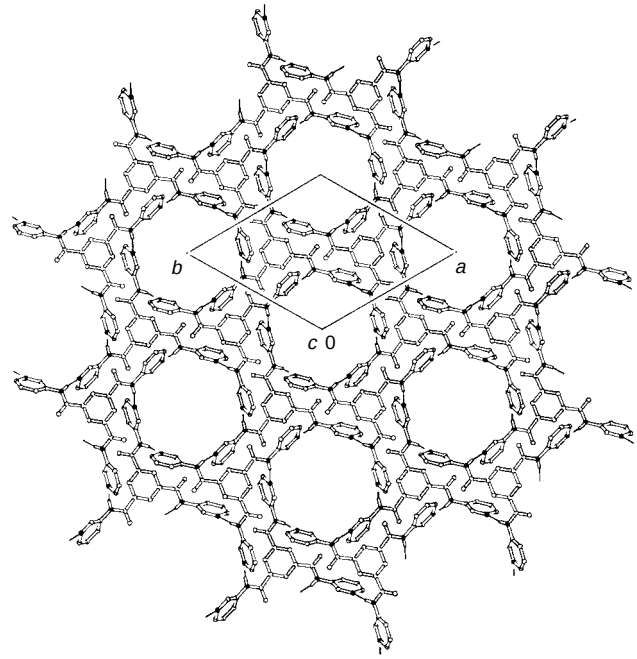


**Fig. 1** Infinite rosette structure of **1**

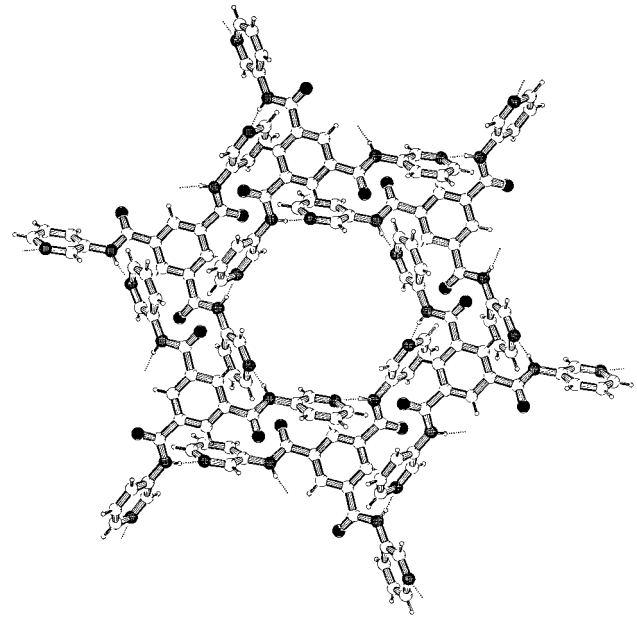

**Fig. 2** Cavity in **1** as a result of six-fold intermolecular hydrogen bonding

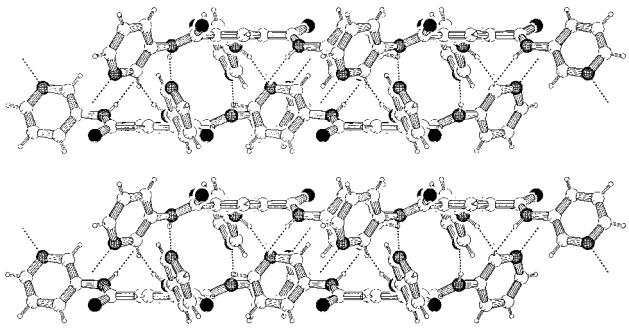

**Fig. 3** Superimposed bilayer structure of **1** creating channels

nanometer scale diameter and millimeter scale length. The formation of this 3D structure may rest simply on optimal packing. Alternatively it is rationalized by cooperative C–H··O interactions[7] (total length 3.39 Å) between each amide oxygen and a pyridyl C–H belonging to an adjacent bilayer.

Methanol is essential to guarantee the stability of the crystals, undoubtedly due to its role as a template and guest filling some of the void space in the interior of the channels, more specifically in the cavity surrounded by the six pyridyl units. The X-ray determination does not allow accurate localization of methanol in **1** but a molar ratio of 3 : 1 is estimated. According to the $^1$H NMR spectrum in [$^2H_6$]DMSO the molar content of methanol ranges from 1.5 to 3.0, depending on sample preparation. Elemental analysis of the crystals is irreproducible due to partial loss of methanol during analysis while analysis after removal of methanol at high temperature shows a deviation, presumably due to uptake of atmospheric (water) vapours. Upon heating between glass the crystals undergo, far below the melting point, a phase transition at 190 °C, suggesting loss of methanol. In air or in solvents like toluene the crystals become opaque and disintegrate. In pentane, by contrast, the crystals are stable.

To provide evidence for the accessibility of the channels for external molecules, a methanol–$CD_3OD$ exchange experiment was conducted¶ and the $^1$H NMR spectrum in [$^2H_6$]DMSO unambiguously demonstrates the complete disappearance of non-deuteriated methanol from the crystals. Analogous experiments have been conducted in other trimesic acid derivatives and in other tectonic molecules.[8] The calculated density of **1** without guests amounts to 1.0395 g cm$^{-3}$ and of **1**·**3** MeOH to 1.267 g cm$^{-3}$. This relatively low density contrasts with the higher density of many trimesic derivatives including the parent acid (1.449 g cm$^{-3}$).[9]

The presence of $C_3$-symmetry tends to induce void space in crystals, which Nature may compensate for by producing concatenated or interpenetrated structures or by incorporation of appropriate guest molecules. To our surprise, up to now no X-ray data are available on symmetrical secondary trimesic amides. In trimesic acid three-fold interpenetration of two-dimensional layers composed of three parallel molecules is observed,[9] unless guests like pyrene and ethanol are built in.[10] A pattern such as the one found in compound **1** is, to the best of our knowledge, unprecedented. It seems that in this particular molecule an acceptable compromise is found between void space, concatenation of molecules and inclusion of guests. The formation of a bilayer structure in compound **1** is reminiscent of the Piedfort units observed in other $C_3$-symmetric systems like 2,4,6-tris[4-(2-phenylpropan-2-yl)phenoxy]-1,3,5-triazine,[11] in which two π-stacked molecules are mutually rotating by 60° to resemble a spatially filled hexagonal system.

‡ *Crystal structure data* for **1**: $C_{24}H_{18}N_6O_3$, $M_r$ = 438.45, colourless, block-shaped crystal (0.3 × 0.5 × 0.5 mm), trigonal, space group $P\bar{3}$ (no. 147) with $a$ = 13.8762(10), $c$ = 8.4005(5) Å, $V$ = 1400.80(17) Å$^3$, $Z$ = 2, $D_c$ = 1.039 g cm$^{-3}$, $F$(000) = 456, $\mu$(Mo-Kα) = 0.7 cm$^{-1}$, 4819 reflections measured, 2135 independent, $R_{int}$ = 0.0288, 1.7° < $\theta$ < 27.5°, $\omega$ scan, $T$ = 150 K, Mo-Kα radiation, graphite monochromator, $\lambda$ = 0.71073 Å on an Enraf-Nonius CAD4 Turbo diffractometer on rotating mode. Data were corrected for Lp effects and for a linear instability of 1% of the reference reflections, but not for absorption. The structure was solved by automated direct methods (SHELXS96). Refinement on $F^2$ was carried out by full-matrix least-squares techniques (SHELXL96); no observance criterion was applied during refinement. Electron density in a disordered solvent area (the unit cell contains a channel parallel to the $c$-axis, through the origin, with a volume of 450 Å$^3$ and containing 111 electrons per $c$-translation period, suggesting the presence of approximately six molecules of methanol) was taken into account in the refinement *via* PLATON/SQUEEZE. Where relevant, data cited above are given without disordered solvent contribution. Positional parameters for hydrogen atoms were included in the refinement; initial values were obtained from a difference Fourier map. Refinement converged at a final $wR2$ value of 0.0973 $R1$ = 0.0376 [for 1727 reflections with $F_o > 4\,\sigma(F_o)$], $S$ = 1.071, for 118 parameters. A final difference Fourier showed no residual density outside −0.20 and 0.24 e Å$^{-3}$. CCDC 182/632.

§ *Synthesis* of **1**: Standard reaction of trimesic chloride (0.90 g, 3.39 mmol) with 3-pyridylamine (1.00 g, 10.6 mmol) in THF (20 ml) in the presence of triethylamine (1.6 ml, 1.13 g, 11.2 mmol) afforded a precipitate which after washing with water and diethyl ether and drying *in vacuo* gave **1** (1.18 g, 79%) as a white solid. Recrystallization from methanol (200 ml) afforded large, transparent hexagonal crystals, mp 287–289 °C; $\delta_H$([$^2H_6$]DMSO) 10.87 (s, NH), 9.01 (d, H-2′), 8.82 (s, H-2, 4, 6), 8.39 (dd, H-6′), 8.26 (ddd, H-4′), 7.47 (dd, H-5′), 4.15 (s, OH), 3.18 (s, $CH_3$); *m/z* (ES) (MeOH + $HCO_2H$) Calc. for $C_{24}H_{18}N_6O_3$ 438.142. Found: 439.1 (M + H)$^+$ and 219.9 (M + 2 H)$^{2+}$. Analysis (after exhaustive removal of methanol at 150 °C) Calc. C, 65.75; H, 4.14; N, 19.17. Found: C, 64.80; H, 4.17; N, 18.78%.

¶ Crystals of **1**·$(MeOH)_x$ were unloaded from exterior MeOH by repetitive immersion in pentane. Crystals were kept in $CD_3OD$ for four days. The crystals remained intact and were then filtered and washed with pentane. The $^1$H NMR spectrum in [$^2H_6$]DMSO indicated the complete replacement of MeOH by $CD_3OD$.

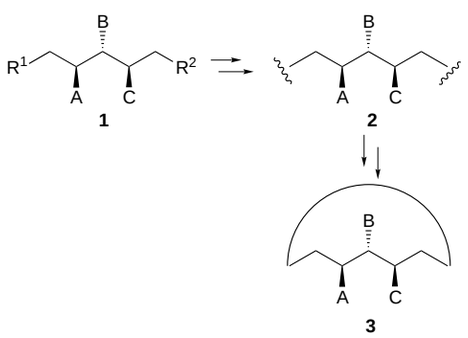
# Parlaying C–O chirality into C–C chirality: improving the cost/benefit ratio of carbohydrate templates

**J. Cristobal Lopez[a] and Bert Fraser-Reid*[b]**



[a] *Instituto de Quimica Organica General (CSIC) Juan de la Cierva 3, 28006 Madrid, Spain*

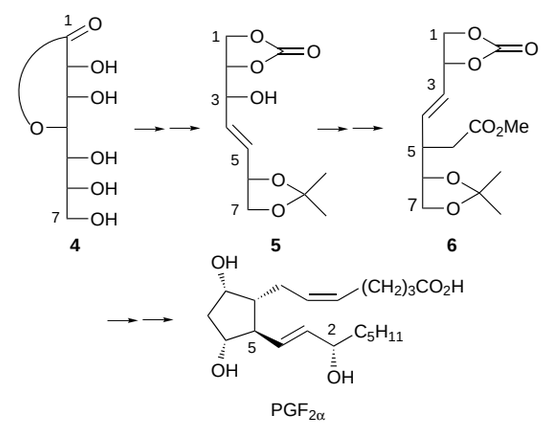
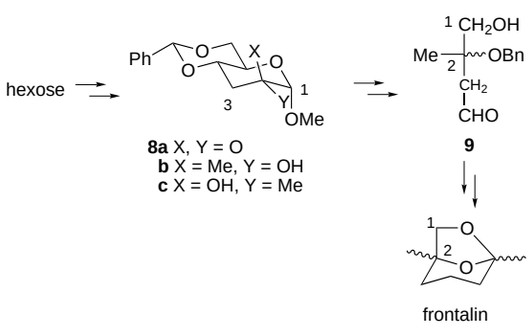
**Use of sugars as chirons for complex carbocyclic targets requires that C–O chirality be transmuted into C–C chirality. The cost/benefit ratio in such syntheses is one index of efficiency. For example, the process involving oxidation of a secondary alcohol followed by methylenation and hydrogenation gives, at best, a 1 : 1 ratio. The aim of lowering this ratio has been a feature of our synthetic studies, some of which are described in this article. Among other things, the studies show that the stereochemistry of pendant, off-template mixed acetals can direct the stereo- and regioselectivity choices (*e.g.* 5-*exo-trig versus* 6-*exo-trig*) in radical cyclization reactions.**

The term 'chirality transfer'[1] is generally used[2] in the context of the transformation profiled generically in Scheme 1, whereby a chiron[3] **1** is used to furnish a chiral fragment **2**, which is subsequently embedded in the target molecule **3**. The literature[4] is rich in examples of this basic strategy particularly with macrolide syntheses where the 'visual dialogue'[3] between the C–OH bonds of the starting sugar and the polyhydroxylic target is apt. In such examples chirality transfer refers to a prefabricated building block,[2] *e.g.* **2**, that is utilized convergently. However, the term may also refer to the process by which one type of asymmetry is transmuted into another, *e.g.* **4** → **5** or **5** → **6** (Scheme 2). The latter examples are abstracted from Stork's synthesis of prostaglandin $F_{2\alpha}$, notable for the fact that all of the sugar's C–OH bonds were utilized for some type of stereocontrol.[4] This study provided an excellent example of how to make optimum use of a sugar's many C–OH chiral centres.

Unfortunately this standard was not met in many syntheses that were to follow, as may be illustrated by the examples in Schemes 3 and 4, taken from the published work of one of the authors.[5,6]

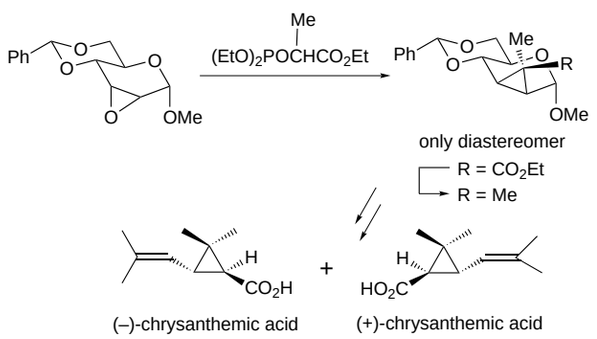


Thus in a synthesis of frontalin enantiomers (Scheme 3), ketone **8a** was used to give diastereoisomers **8b**, **c**, each of which was processed to furnish optically pure (*R*)- and (*S*)-**9**, which were then elaborated into (+)- and (−)-frontalin, respectively. In this exercise, the cost/benefit ratio is 4 : 1, based on the number of chiral centres lost and gained in going from the hexose to **9**.

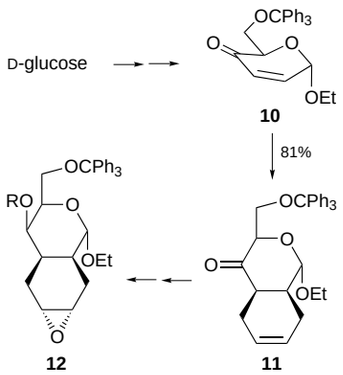


**Scheme 1**

This synthesis had merit in being enantiodivergent, as was also true for the chrysanthemic acid syntheses in Scheme 4; however, with the latter the cost/benefit ratio was improved to 2 : 1.



Ultimately, the case studies in Schemes 3 and 4 return to the challenge posed by Stork's prostaglandin synthesis (Scheme 2),

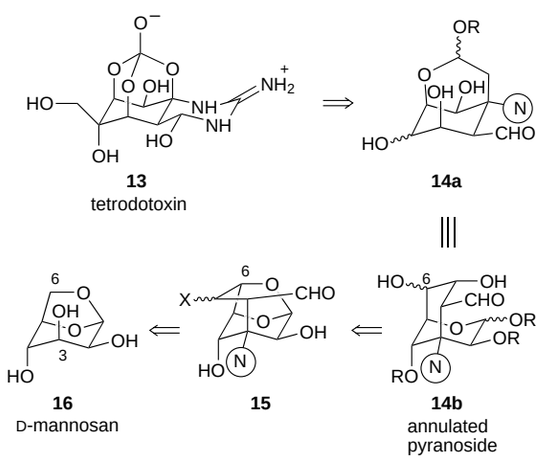


**Scheme 2**

**Scheme 3**

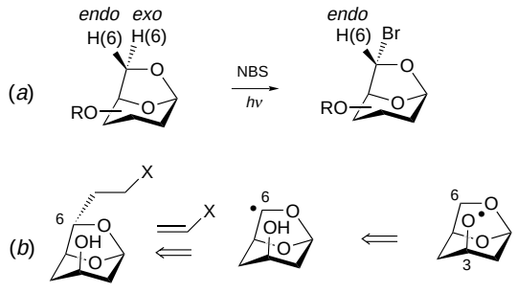
**Scheme 4**

**Scheme 5**



namely the problem of parlaying C–O into C–C stereochemistry.

*En route* to the well investigated α-enone **10**[7] (Scheme 5), three of the four chiral centres of D-glucose are 'destroyed', but because additions to **10** are facially selective, and the resulting adducts, *e.g.* **11**, are conformationally inflexible,[8] future transformations are highly diastereoselective.[9,10] As a result the cost/benefit ratio can sometimes be over compensated. In the case of **12**, for example, the ratio is 4 : 6 (ignoring the anomeric centre).



The indirect conversion of C–O into C–C chirality, as reported in Scheme 5, may be ascribed to the unique topographical features of enone **10**. However, with other substrates the prospect may not be as felicitous. In this article we give an account of some recent studies on the application of free radical methods for addressing the problem of C–O to C–C chirality transfer in connection with our program on converting carbohydrates into densely functionalized carbocycles.[11,12]

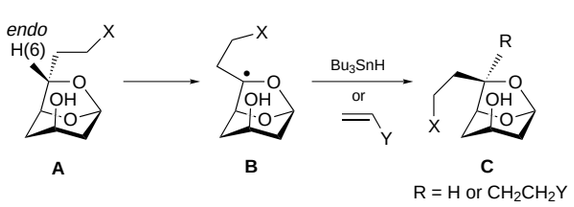
### C–O to C–C chirality transfer *via* serial 1,5-hydrogen transfer/intermolecular radical addition: the carbocyclic core of tetrodotoxin

Tetrodotoxin (TTX), **13**[13] occupies a unique place in natural products chemistry and efforts in our laboratory towards its synthesis employ the retrosynthetic plan summarized in Scheme 6.[14] The bicyclic entity **14a**, when displayed as in **14b**, emphasizes the relationship to an annulated pyranoside. Retron **15** indicates the need for a functionalized two-carbon bridge between C-3 and C-6 of an anhydropyranoside and further 'visual dialogue'[3] leads to commercially available D-mannosan **16** (1,6-anhydro-β-D-mannopyranose).

**Scheme 6**

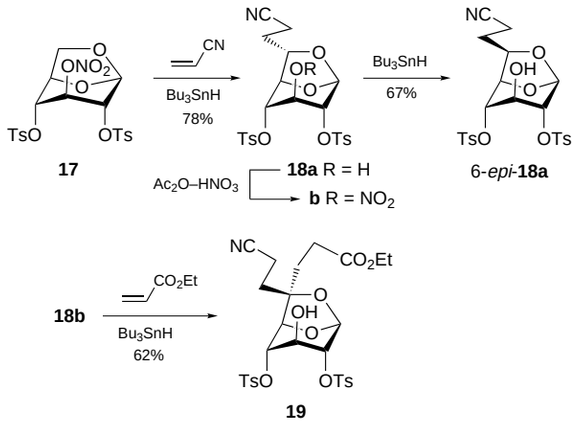
**Scheme 7**

Retron **15** requires a functionalized branch at C-6. This requirement is facilitated by the unusual $^1C_4$ conformation of 1,6-anhydro sugars which enables remarkably reactions as exemplified by the elegant site-, regio- and stereo-selective bromination described by Ferrier and Furneaux[15] [Scheme 7(*a*)]. Thus hydrogen abstraction and subsequent bromination both take place from the less hindered *exo* face of the dioxabicyclo[3.2.1]octane system.



Could these facile stereodirecting capabilities of 1,6-anhydro sugars be of service to us? As expressed retrosynthetically in Scheme 7, we could conceivably employ the enthalpy driven C–O → C–OH 1,5-hydrogen transfer process, which is the basis of the original Barton reaction for functionalizing a remote angular methyl group.[16] Thus an axial C(3)–O radical should generate a carbon-centred radical at C(6), which should trap an external alkene from the less hindered *exo* face[17] [Scheme 7(*b*)].

However, in the context of the TTX plan in Scheme 6, retron **15** requires the C(6)-substituent to be *endo* oriented. This requirement could be met by taking advantage of a highly remarkable facet of our strategy, *viz*. (i) that it is *endo*-H(6) which is transferred, and (ii) that the process is amenable to iteration. Therefore an alkyl substituent, stereoselectively introduced at C(6) (**A**, Scheme 8) still presents an *endo* H(6) for transfer leading to the planar π-radical (**B**, Scheme 8).



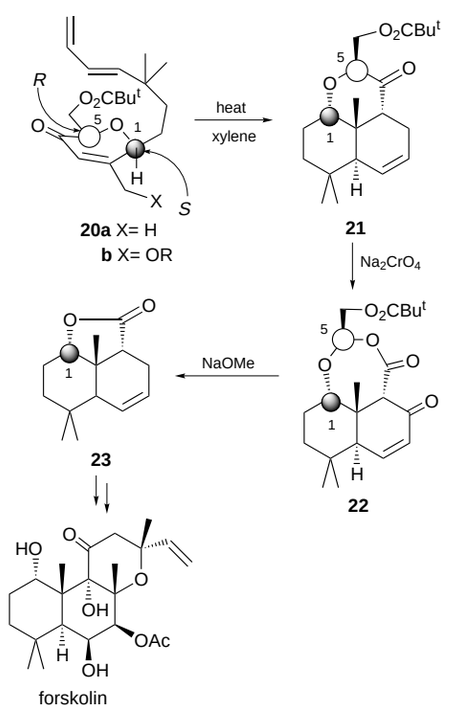
The latter radical could, in its turn, react from the *exo* face again with $Bu_3SnH$, *e.g.* **B** → **C** (R = H). Alternatively, we could take advantage of the nucleophilic character of the stabilized α-oxygenated radical[17] to foster reaction with electron-deficient alkenes. The method would then permit complete control in the creation of a secondary or tertiary branch at C-6, with either *R* or *S* orientation.

The design of this strategy was facilitated by studies in our laboratory which had shown that alkoxy radicals could be conveniently generated by reaction of nitrate esters with tri-*n*-butyltin hydride.[18] Accordingly, reaction of **17** with tri-*n*-butyltin hydride in the presence of acrylonitrile led to **18a**[19] (Scheme 9), and iteration of the process led to nitrate ester **18b** which on treatment with tri-*n*-butyltin hydride afforded 6-*epi*-**18a**.

On the other hand, a second branch at C-6 could be introduced stereoselectively by reaction of **18b** with tri-*n*-butyltin hydride in the presence of the appropriate radical trap, ethyl acrylate in the case of **19**.[19]

**Scheme 8**

**Scheme 9**



In this exercise the cost/benefit ratio is a highly rewarding 0 : 1 and it is noteworthy that the C(3)–OH is recovered unprotected after each operation.

### C–O to C–C chirality transfer *via* serial radical reactions on glycals: preliminary studies for the decalin portion of azadirachtin

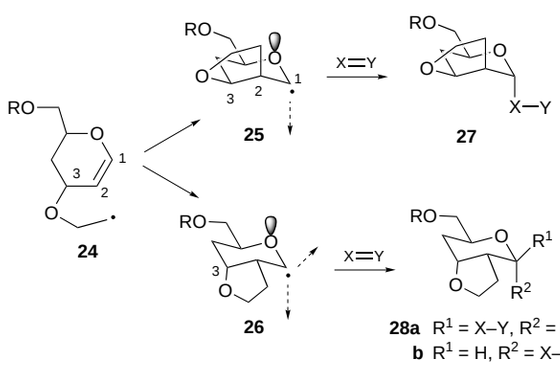
Carbohydrate based Diels–Alder strategies are specially useful in the preparation of carbocyclic natural products, and it is in that context that α-enones were investigated in our laboratories.[11] Thus intermolecular Diels–Alder reactions (see Scheme 5) led to an early synthesis of actinobolin.[20]

We have also reported a relay synthesis of forskolin which features an intramolecular Diels–Alder (IMDA) reaction as the key step, wherein the trienic enoce **20a** was used to furnish the *trans*-decalin precursor **21**[21](Scheme 10). Further functionalization employed simultaneous Baeyer–Villiger and allylic oxidations leading to **22**. Treatment of this acetal lactone with mild base provided **23**, which had served as a forskolin precursor in the laboratories of Ziegler[22] and Rúveda.[23]

However, the potential of this strategy was undermined by the many steps leading to **20a** from D-glucose. In particular,

**Scheme 10**

introduction of the vinyl methyl residue proved to be especially demanding. This challenge, together with cognizance that the C(10) alkyl residue of clerodane terpenoids, such as azadirachtin, is frequently oxygenated, compelled us to consider appropriately functionalized synthons such as **20b**.



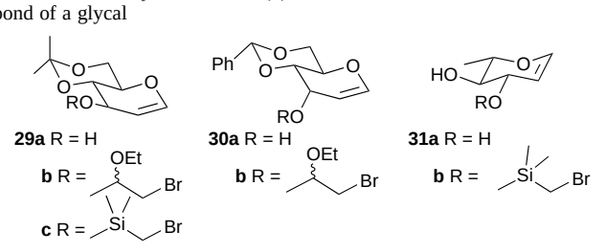
Our retrosynthetic analysis made use of the observation that, *en route* to decalin **23**, the chiral information at C(5) of enone **20a** was discarded (Scheme 10). The only essential chiral centre was therefore C(1). Thus either a D or an L sugar could be used as the starting material provided that the resulting stereogenic centre at C(1) would be *S*. This realization greatly simplified the synthetic planning because *S* chirality is found in β-D-*C*-glycosides as well as their α-L counterparts. The latter, in which the anomeric substituent is (normally) axially oriented, can be readily accessed through an anomeric radical.

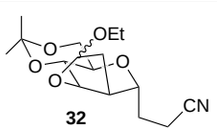
Besides this conceptual viability it was also of help to note that the functionalization of C(6) of the sugars was also irrelevant. Therefore L-rhamnal (a 6-deoxy L-sugar) could be used as the starting material, thus adding economical viability to the synthetic approach (compare: L-rhamnose, 1 kg = £280; L-glucose, 1 kg = £16 400).

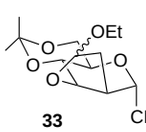
The need for a carbon branch at C(2) suggested that our recently developed strategy for serial radical reaction on glycals could be pressed into service (Scheme 11).[24] In this strategy, modelled after the Stork–Sher method,[25] serial radical reactions of C(3)-tethered glycals, *e.g.* **24**, leads to intermediate anomeric radicals *e.g.* **25** and **26**, which trap suitable reactants, *e.g.* X=Y, to afford *C*-glycosides *e.g.* **27** and **28**, respectively. We had also shown that the degree of stereocontrol depends on the interplay of 'shape selectivity'[25] (*vide infra*) and the radical anomeric effect.[26] When both are congruent, as in **25** → **27**, stereoselectivity is exquisite; however when both forces are in opposition, as in **26** → **28a,b**, lower preference in favour of 'shape selectivity' is observed.[24*a*]

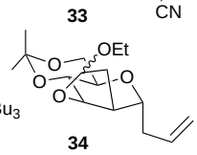
Selected examples illustrating the scope and viability of this procedure are shown in Table 1.[24*b*] The sequence takes place with complete stereoselectivity at the anomeric carbon for the formation of α-*C*-glycosides (entries 1–5, 7–9). However, the protocol is less exclusive in the case of β-*C*-glycosides since anomeric mixtures are obtained (see entry 6), Notably the procedure allows for introduction of one- or two-carbon branches at C(2), according to precedents from Stork and coworkers,[25] Nishiyama *et al.*[27] and Tamao *et al.*[28]

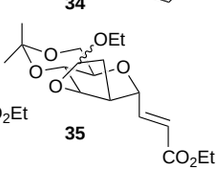
Implementation of the protocol for the decalin moiety (Scheme 12), takes advantage of the O(3) bond of **31** for installing carbon branches at C(1) and C(2). The latter stereocentre is 'destroyed' in going from **40** → **41**, but this event is inconsequential because it is the surviving stereogenic centre at C(1) that dictates stereoselectivity on the IMDA process, wherein three new chiral centres are created in **42b**.[29,30] The overall cost/benefit ratio in terms of C–O to C–C chirality transfer is 2 : 2 for the radical process, and increases to 3 : 4 if the IMDA process is included.

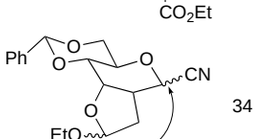


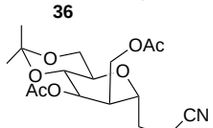


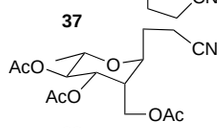


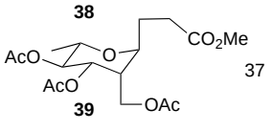






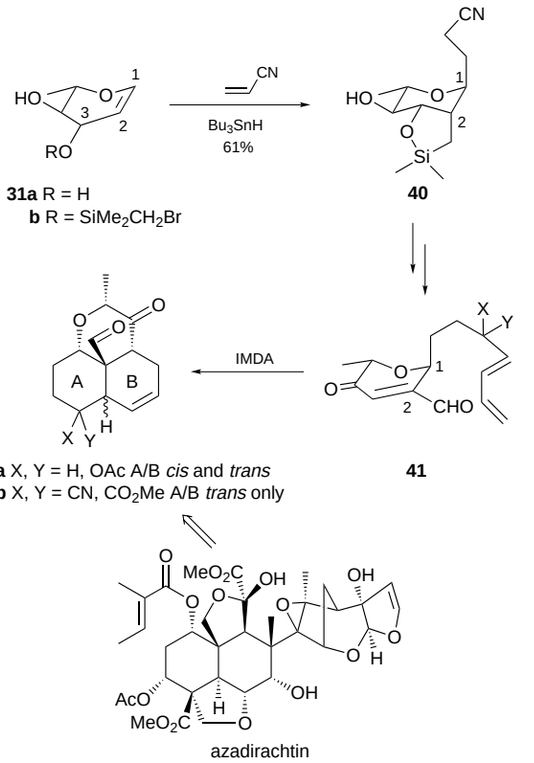






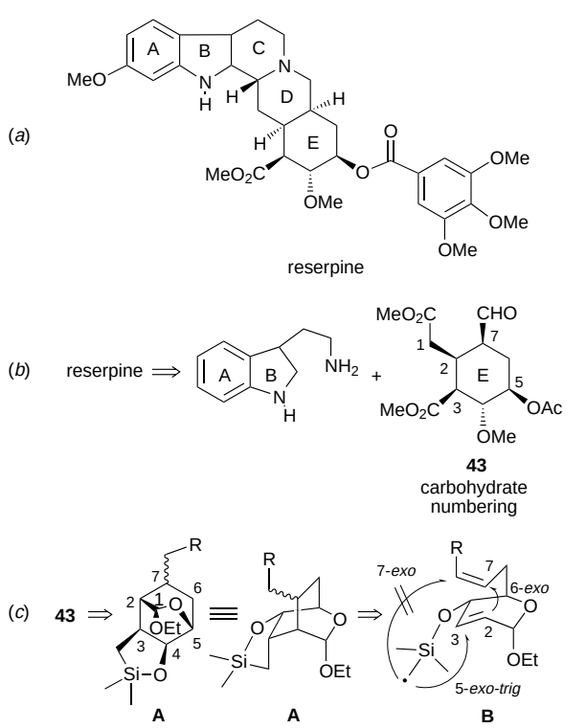
**Scheme 11**

## C–O to C–C chirality transfer *via* serial radical reactions on hex-2-enopyranosides: the cyclohexane fragment of reserpine



Reserpine, [Scheme 13(*a*)], a prominent member of the yohimbine family of indole alkaloids, possesses a pentacyclic skeleton which contains six chiral centres.[31] Woodward's landmark synthesis featured the richly functionalized E-ring intermediate **43** [Scheme 13(*b*)].[32] This densely functionalized cyclohexane which by itself accounts for five of the six chiral centres was especially appealing to us.

**Table 1** Radical cyclization of C(3) tethered radicals onto the $\Delta^{1,2}$ double bond of a glycal



| Entry | Substrate | Reaction conditions[a] | Radical trap | Product | Yield (%) |
|---|---|---|---|---|---|
| 1 | **29b** | A | CN |  **32** | 75 |
| 2 | **29b** | B | CN | **32** | 78 |
| 3 | **29b** | B | C=N–Bu$^t$ |  **33** | 76 |

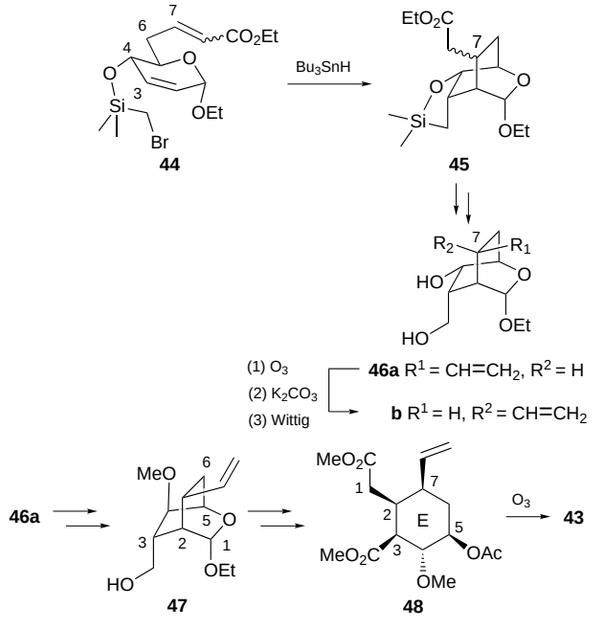
| 5 | **29b** | D | Bu$_3$Sn, CO$_2$Et |  **35** | 63 |
| 6 | **30b** | B | C=N–Bu$^t$ |  (5:1) β:α mixture **36** | 34 |
| 7 | **29c** | E | CN |  **37** | 61 |
| 8 | **31b** | E | CN |  **38** | 32 |
| 9 | **31b** | E | CO$_2$Me |  **39** | 37 |

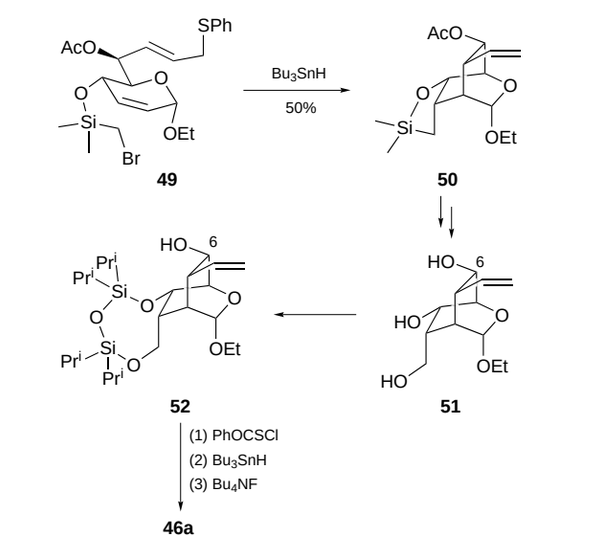
[a] For reaction conditions see ref. 24(*b*).



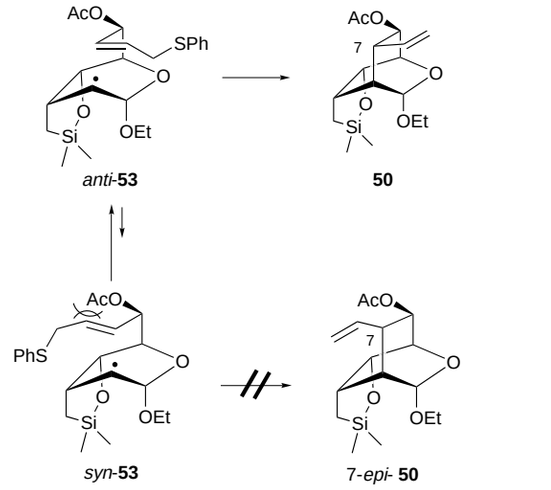
**Scheme 12**

Our strategy for this project was based on the correlation of a tricyclic cage **A**, with **43** [Scheme 13(*c*)].[33] Intermediate **A**, which already fulfills all functional and stereochemical requirements, could be accessed by serial radical cyclizations of a dienic pyranoside **B**. The latter contains two unsaturated sites, but the 5-*exo* mode should prevail over the 7-*exo* alternative, thereby presenting the resulting C(2) radical to C(7) for 6-*exo* cyclization. A C–O bond, this time at C(4), is once again key to

**Scheme 13**



Scheme 14



the plan, since it directs the stereochemical outcome in the formation of two [C(3), C(2)] of the three new stereogenic centres.

The strategy was first tested on pyranoside diene **44**[34] (Scheme 14), which furnished a mixture of caged compounds **45**. Oxidation of the silicon bridge in **45**, according to Tamao *et al.*,[28] gave a diol which was protected. Processing of the ethoxycarbonyl group into a vinyl moiety paved the way to epimers **46a,b**, which were readily separated. 'Unwanted' **46b** was transformed into **46a** (see Scheme 14), which could then be processed, *via* **47**, into **48**. Cyclohexane **48** is a masked precursor of Woodward's intermediate, in that the pendant vinyl residue at C(7) is retrosynthetically correlated with the aldehyde group of **43**.

Although the above mentioned strategy worked well, we were dissatisfied, because virtually no stereocontrol had been exerted over the C(7) vinyl residue. We therefore explored a parallel route in which a C–O bond at C(6) could be used to dictate the developing orientation at C(7).[35] Accordingly, radical cyclization of **49** (Scheme 15) led stereoselectively to **50** from which triol **51** was readily obtained. Selective protection

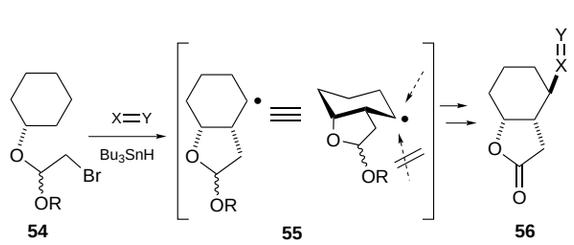
Scheme 15

Scheme 16

of the hydroxy groups paved the way for C(6) deoxygenation, furnishing **46a**.

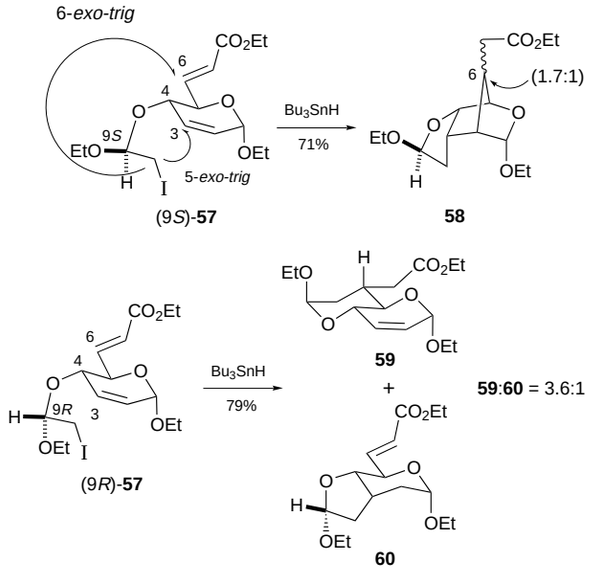
The stereochemical model, based on the release of 1,3-allylic strain[36] (*e.g.* **53** → **50**, Scheme 16), therefore worked well and represents an additional mode of C–O to C–C chirality transfer.

The overall result, in terms of C–O to C–C chirality transfer, is 2 : 2 for the first synthetic route, and it increases to 2 : 3 if the oxygenated substituent at C(6) is incorporated.



### C–O to C–C chirality transfer. Effects of the 'irrelevant' configuration at the anomeric centre of mixed haloacetals on the chemo- and stereo-selectivity of serial radical reactions.

Much of the chemistry utilized in the two preceding sections has relied on Stork's bicyclic radical **55**[25] (Scheme 17) which shows remarkable 'shape selectivity' in promoting reactions that occur *anti* to the fused five-membered ring. The latter, in turn, is formed by 5-*exo*-*trig* radical cyclization of haloacetals **54**. The configuration at the anomeric centre of these structures has always been considered as irrelevant,[25] a fact which is not surprising since the concept was developed in the context of the corresponding lactones **56**.

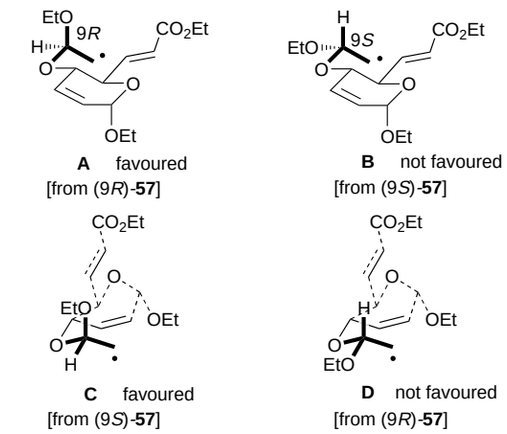


However, in the course of our exploratory studies,[37] we were intrigued by the suspicion that the configuration at the anomeric centre of the haloacetals was defining the stereoselectivity of the radical reaction. Accordingly, it was desirable to examine the reactions of diastereopure isomers.

The *R* and *S* haloacetals **57**[38] were chosen for this study because radical cyclization could take place at C(3) or at C(6). Interestingly, (9*S*)-**57** furnished exclusively tricyclic compounds **58** (Scheme 18), while (9*R*)-**57** gave rise to a mixture of regioisomeric bicyclic compounds **59** and **60**, with no evidence of a tricyclic product.

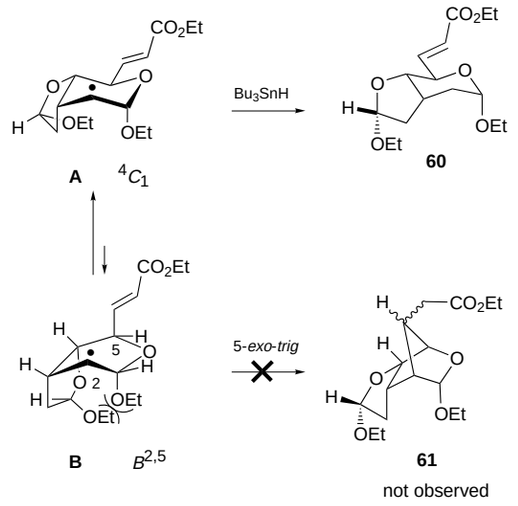
The opposite regioselectivity preferences observed for the epimers **57** may be rationalized by invoking intermediates, in which the ethoxy group enjoys an anomeric effect as in **A** and **C**, (Scheme 19). These gain precedence over those alternatives

Scheme 17



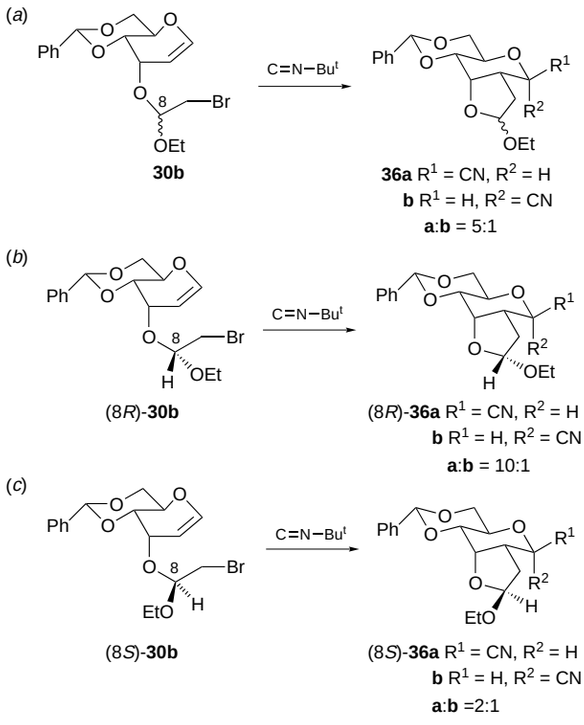
**Scheme 18**

where the ethoxy group occupies the more sterically advantageous pseudo-equatorial position, *e.g.* **B** and **C** (Scheme 19), as would be the case in the classical Beckwith–Schiesser model for 5-*exo-trig* ring closure of substituted hexenyl radicals.[39,40]

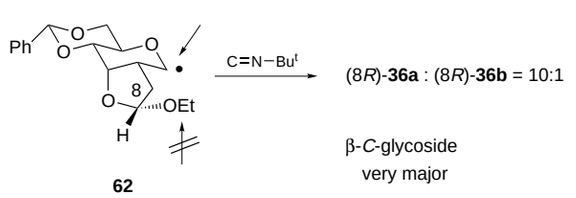


It is clear that in order for the second cyclization [C(2) to C(6)] to take place, the radical at C(2) must change conformation from a $^4C_1$ chair (**A**, Scheme 20), which enjoys an anomeric effect, to a $B^{2,5}$ boat (**B**, Scheme 20), which does not, and where all the substituents reside in pseudo-axial orientations. The fact that the double-cyclization product, **61**, is not obtained from (9*R*)-**57** [*cf.* (9*S*)-**57**, Scheme 18] may be associated with an additional destabilizing steric interaction between the two anomeric ethoxy groups in the required $B^{2,5}$ conformation as shown in Scheme 20.

In analysing the stereoelectronic factors depicted in Scheme 11, it was noted (see Table 1) that selectivity for the installation of an anomeric branch varied from complete (*i.e.* **25** → **27**) to selective (*ca.* 5–3 : 1) (*i.e.* **26** → **28a,b**).[24a] In light of the results in Schemes 18–20, it seemed wise to reexamine the reaction of **30b** (Scheme 21). In the presence of *tert*-butyl isocyanide,[24b] sequential cyclization–intermolecular radical trapping led to a *ca.* 5 : 1 mixture of epimeric cyanides **36a,b**, each one being itself a mixture of epimeric acetals.



It was therefore justifiable to study each isomer. Remarkably, each showed distinctly different behaviour (Scheme 21), for which Stork's carbocyclic series (Scheme 18) did not provide a precedent.[25] Obviously the radical anomeric effect is responsible for the high percentage of α-*C*-glycoside (8*S*)-**36b** obtained on the cyclization of (8*S*)-**30b**. On the other hand, in the cyclization of (8*R*)-**30b**, the presence of an *endo*-oriented ethoxy substituent efficiently shields the α-face and overrides the radical anomeric effect (see **62**, Scheme 22).



**Scheme 19**

**Scheme 20**

**Scheme 21**

**Scheme 22**

## Summary

We have presented a view on stereoselective radical transformations in which C–O bonds play a leading role on inducing C–C bond stereochemistry. One of the starting sugar's several C–O bonds has been used to induce C–C chirality for a variety of synthetic targets. Owing to their wealth of oxygen atoms, carbohydrates have been the substrates of choice for these transformations. However, from the last two examples it is clear that even 'imported' oxygen atoms can have a dramatic influence on newly formed C–C bonds.

## Acknowledgments

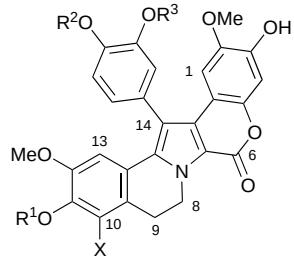
# Convergent total synthesis of lamellarin K†

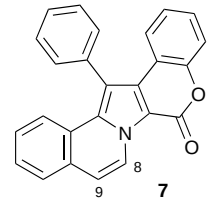
**Martin Banwell,*‡ Bernard Flynn* and David Hockless**



*Research School of Chemistry, Institute of Advanced Studies, The Australian National University, Canberra, ACT 0200, Australia*

**The azomethine ylide derived from dihydroisoquinolinium salt 24 undergoes an intramolecular [3 + 2] cycloaddition reaction to give pyrrole 25 which upon de-isopropylation affords the marine alkaloid lamellarin K 4.**

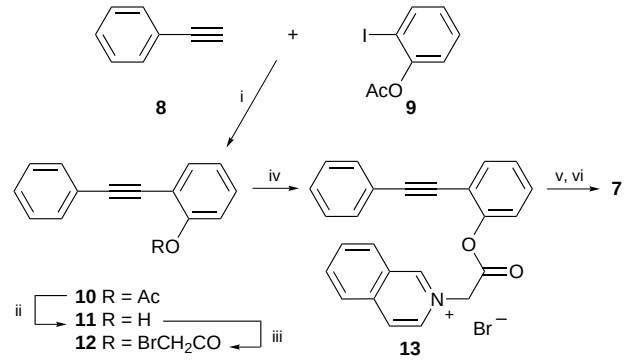
In 1985 Faulkner and his colleagues reported[1] the isolation of four members of a new class of marine natural product which they had obtained from a *Lamellaria* sp. of marine prosobranch mollusc collected in the waters off Palau. These compounds were called lamellarins A–D and through a combination of spectroscopic and X-ray crystallographic studies were shown to be highly oxygenated derivatives of 14-phenyl-6*H*-[1]benzopyrano[4′,3′ : 4,5]pyrrolo[2,1-*a*]isoquinolin-6-one or its 8,9-dihydro analogue. Thus, lamellarin D possesses structure **1** while congener C has structure **2**. Subsequently, Fenical[2] isolated further members of this type of compound (lamellarins E–H) from the Indian Ocean marine ascidian *Didemnum chartaceum*. More recently Bowden[3] reported obtaining lamellarins I–N from a Pacific ascidian *Didemnum* sp. collected off the north east coast of Australia, while Urban and Capon[4] have isolated lamellarin S from the same species.§ In 1997, Faulkner described[5] the isolation of nine new alkaloids of the lamellarin class, including the first examples of lamellarin sulfates, from an unidentified ascidian found in the Arabian Sea.



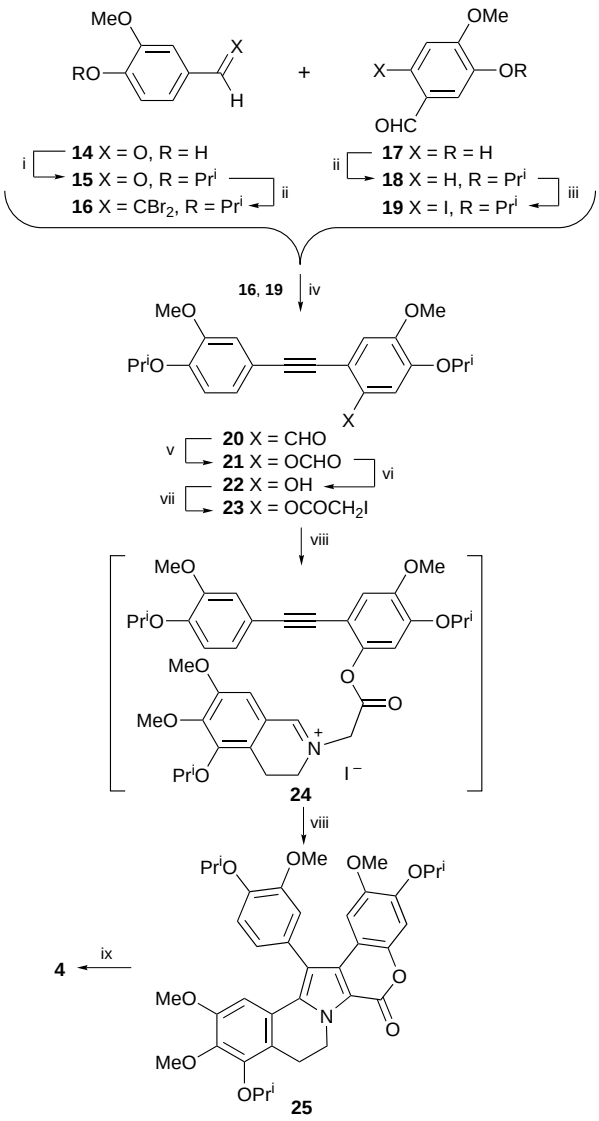
**1** $R^1$ = H, $R^2$ = Me
**6** $R^1$ = Me, $R^2$ = H

**2** X = OMe, $R^1$ = $R^3$ = Me, $R^2$= H
**3** X = OMe, $R^1$ = $R^2$ = $R^3$ = Me
**4** X = OH, $R^1$ = $R^3$ = Me, $R^2$ = H
**5** X = $R^1$ = $R^3$ = H, $R^2$ = Me

A number of the lamellarins exhibit highly interesting biological properties. For example, at concentrations of 19 μg $ml^{-1}$, compound **1** caused a 78% inhibition of cell division in a fertilised sea urchin assay while congener **2** caused 15% inhibition.[1] Lamellarins I **3**, K **4** and L **5** all showed comparable and significant cytotoxicity against P388 and A549 cell lines in culture ($IC_{50}$ ≈ 0.25 μg $ml^{-1}$ against each cell line).[3] Lamellarins K and L also exhibited moderate immunomodulatory activity (LcV : MLR 147 and 98, respectively).[3] In the NCl 60 cell-line panel, lamellarin N **6** showed some selectivity toward melanoma cell lines SK-MEL-5 ($LC_{50}$ 1.87 × $10^{-7}$ M) and UACC-62 ($LC_{50}$ 9.88 × $10^{-6}$ M).[5] Perhaps most significantly, very recent work at Pharma Mar S. A.[6] has raised the possibility that certain of the lamellarins, especially lamellarin K, may be highly effective in the treatment of multidrug resistant tumours.



Despite the intriguing biological properties and the unprecedented structures of lamellarins A–N and S–X (the parent frameworks are unknown) only two studies directed towards the total synthesis of these marine natural products appear to have been reported to date.§ Thus, very recently Steglich[7] described a biomimetic synthesis of lamellarin G trimethyl ether, while Ishibashi *et al*.[8] have completed total syntheses of lamellarins D and H. These reports prompt us to disclose a quite different and highly convergent method for the synthesis of the title compound **4** and the parent ring-system **7**.



**7**

The pivotal step in our approach to the lamellarin ring systems involves construction of the central pyrrole moiety *via* an intramolecular [3 + 2] cycloaddition of an isoquinoline-based azomethine ylide to a suitably tethered tolan,[9] a hitherto unproven process. The reaction sequence leading to the parent framework (Scheme 1) starts with Sonogashira cross-coupling[10] of phenylacetylene **8** and *o*-iodophenyl acetate **9**[11] to give, after hydrolysis of the initial coupling product **10**[11] (99%), *o*-hydroxytolan **11**.[11] This last compound was subjected to dicyclohexylcarbodiimide (DCC)-promoted coupling with α-bromoacetic acid and the resulting ester **12** (91% from **10**) treated with isoquinoline to give the isoquinolinium salt **13**. Compound **13** was immediately reacted with $Et_3N$ so as to generate the associated azomethine ylide which underwent intramolecular cycloaddition to the tethered triple bond upon heating. The resulting mixture of dihydropyrrole-type products thereby obtained was subjected to oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ). In this manner, the target compound **7** (92% from **12**, mp 313–315 °C) was obtained and its structure established by single-crystal X-ray analysis.‖

The highly convergent nature of the reaction sequence outlined here would suggest that this approach could be readily

**Scheme 1** *Reagents and conditions*: i, $Pd(PPh_3)_4$ (1 mol%), CuI (2 mol%), $Et_3N$, 18 °C, 4 h; ii, $K_2CO_3$ (1.5 equiv.), MeOH, 18 °C, 0.25 h; iii, $BrCH_2COBr$ (1 equiv.), DMAP (5 mol%), DCC (1.05 equiv.), $CH_2Cl_2$, 18 °C, 3 h; iv, isoquinoline (1 equiv.), THF, 18 °C, 6 h; v, $Et_3N$ (1 equiv), THF, 66 °C, 4 h; vi, DDQ (1 equiv.), $CH_2Cl_2$, 18 °C, then silica gel chromatography

**Scheme 2** *Reagents and conditions*: i, Pr$^i$Br (1.2 equiv.), $K_2CO_3$ (3.5 equiv.), DMF, 18 °C, 19 h; ii, $CBr_4$ (2 equiv.), Zn (2 equiv.), $PPh_3$ (2 equiv.), 0 to 18 °C, 22 h, then 0 °C, **15**, 18 °C, 1 h; iii, $AgOCOCF_3$ (1.1 equiv.), $I_2$ (1.1 equiv.), $CHCl_3$, reflux, 7 h; iv, **16**, Bu$^n$Li (2.05 equiv.), THF, −78 °C, 0.83 h then $ZnCl_2$ (1.1 equiv.), −78 to 18 °C, 1 h then **19** (0.95 equiv.), $Pd(PPh_3)_4$ (*ca*. 2 mol%), 18 °C, 4 h; v, MCPBA (1.5 equiv.), $KHCO_3$ (3 equiv.), $CH_2Cl_2$, 18 °C, 1 h; vi, $NH_3$ in MeOH (sat.), 18 °C, 1 h; vii, $ICH_2CO_2H$ (1.05 equiv.), DCC (1.05 equiv.), DMAP (5 mol%), $CH_2Cl_2$, 18 °C, 3 h; viii, 3,4-dihydro-6,7-dimethoxy-5-isopropoxyisoquinoline (1.1 equiv.), $ClCH_2CH_2Cl$, 18 °C, 7 h, then Hünig's base (1.0 equiv.), 83 °C, 32 h; ix, $AlCl_3$ (3.6 equiv.), $CH_2Cl_2$, 18 °C, 2 h

adapted to the preparation of lamellarins A–N and S–X as well as many analogues thereof. Certainly, compounds in the 8,9-dihydroseries would seem to be readily accessible as evidenced by our synthesis of lamellarin K **4** (Scheme 2). Thus, the isopropyl ether **15**[12] (100%), prepared from vanillin **14** under standard conditions,[13] was subjected to a Corey–Fuchs *gem*-dibromomethylenation reaction[14] thereby affording styrene **16** (100%, mp 36–38 °C). This latter compound was treated with Bu$^n$Li and the lithium acetylide so formed was *trans*-metallated using zinc(II) chloride. Palladium-mediated cross-coupling of the resulting alkynylzinc chloride with aryl iodide **19** (mp 75–76 °C) (obtained in 93% yield by iodination of the isopropyl ether **18**[15] of isovanillin **17** using $AgOCOCF_3$–$I_2$) then gave tolan **20** (84%, mp 121–122 °C) which was subjected to a Baeyer–Villiger reaction using MCPBA as oxidant. The resulting formate ester **21** was readily hydrolysed to the corresponding phenol **22** (92% from **20**, mp 130–131 °C). DCC-mediated condensation of this last compound with α-iodoacetic acid then provided ester **23** (97%, mp 127–128 °C) which was reacted with 3,4-dihydro-6,7-dimethoxy-5-isopropoxyisoquinoline (readily available by standard methods) to give salt **24**. This last compound was not isolated but immediately treated with Hünig's base. The resulting mixture was heated at reflux in 1,2-dichloroethane and in this manner cycloaddition (followed by *in situ* aromatisation) took place to give lamellarin K triisopropyl ether **25** (81% from **23**, mp 244–245 °C). Treatment of this last compound with 3.6 mol equiv. of $AlCl_3$ in $CH_2Cl_2$ at 18 °C resulted in three-fold de-isopropylation and formation of the target compound **4** (96%, mp 230–232 °C) which was identical, by $^1$H and $^{13}$C NMR spectroscopy, with an authentic sample.

We thank the Institute of Advanced Studies for financial support including the provision of a post-doctoral Research Fellowship to B. L. F. Associate Professor B. Bowden (James Cook University of North Queensland) is thanked for providing spectral data on lamellarin K.

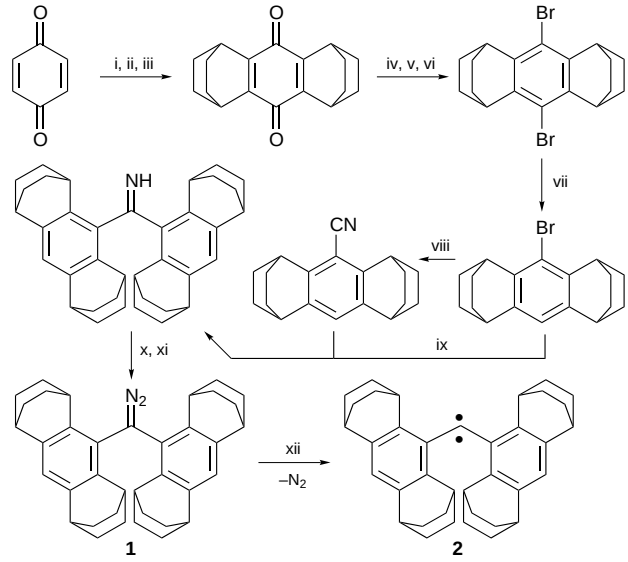
*Chemistry Department for Materials, Faculty of Engineering, Mie University, Tsu, Mie 514 Japan*



**Bicyclo[2.2.2]octyl groups are demonstrated to be very effective kinetic protectors for triplet carbenes.**

The stabilization of a triplet carbene[1] has emerged as a challenging target since the recent syntheses of stable singlet carbenes[2,3] upset the long-standing view that carbenes are not stable enough to be isolated in macroscopic scale at room temperature.[4] Steric protection is an ideal method for stabilizing the triplet since a protecting group when introduced near a carbene center not only blocks the carbene center from external reagents but also results in thermodynamic stabilization by increasing the carbene angle.[5–7] However, due to the voracious appetite of carbenes for electrons, which they can abstract even from very poor sources of electrons such as C–H bonds, this strategy encounters a limitation when alkyl groups are employed as protecting groups. For instance, dimesitylcarbene was shown to decay by undergoing dimerization and to have a half-life of 160 ms, some five orders of magnitude longer lived than triplet diphenylcarbene. However, when more methyl groups are introduced on the phenyl rings, the carbenic center is more effectively blocked from external reagents due to a buttressing effect, but it becomes more easily trapped by the *ortho* methyl groups, which are brought closer to the carbene center, to form benzocyclobutene: didurylcarbene ($t_{1/2}$ 410 ms) was twice as long-lived as dimesitylcarene, while decamethyldiphenylcarbene ($t_{1/2}$ 180 ms) decayed mainly unimolecularly by abstracting H from the *o*-methyl group and hence was shorter lived.[5a,d]

In this light, it is crucial to develop a protecting group which is sterically congesting but unreactive toward triplet carbenes. Bicycloalkyl groups are very attractive since bridgehead C–H bonds are less susceptible to hydrogen abstraction, although not entirely unsusceptible,[8] and thus the bridging chains will act as protectors. Thus, we generated diphenylcarbene protected by bicyclo[2.2.2]octyl groups and compared its reactivity with that of an open-chain 'counterpart', *i.e.* didurylcarbene (DDC).

The desired precursor diazomethane **1**† was prepared starting from a benzoquinone–cyclohexa-1,4-diene Diels–Alder reaction according to the reaction procedure as outlined in Scheme 1 and was obtained as a rather stable red solid with a mp of 183 °C (decomp.) after purification by gel permeation chromatography.

Irradiation of **1** in a 2-methyltetrahydrofuran (MTHF) glass at 77 K gave a fine structured EPR line shape characteristic of randomly oriented triplet molecules with a large *D* value attributable to a one-center nπ spin–spin interaction at the divalent carbon of diarylcarbene. The fine-structure constants were $|D|$ = 0.3951 cm$^{-1}$ and $|E|$ = 0.0106 cm$^{-1}$, showing unequivocally that the triplet signals are due to diphenylcarbene **2** generated from **1** as a result of $N_2$ elimination upon irradiation. The EPR signals were persistent at this low temperature but disappeared irreversibly when the matrix was thawed. Since the *E* value measures the difference of the magnetic dipole interaction along the *x* and *y* axes, it allows one to estimate the bond angle at the carbene center especially when weighted by *D*.[9] Comparison of the *E*/*D* value (0.0269) of **2** with that observed for DDC (*E*/*D* = 0.0279),[5c,d] an open chain 'counterpart' of **2**, indicates that carbenic center of **2** is slightly more sterically congested than that of DDC.

**Scheme 1** *Reagents and conditions*: i, cyclohexa-1,4-diene, 120 °C; ii, $H_2$–Pd/C; iii, $Br_2$; iv, $NH_2OH$; v, $SnCl_2$–$Br_2$; vi, $NaNO_2$–HBr and Cu, 20 °C; vii, Bu$^n$Li and $H_2O$; viii, CuCN; ix, Bu$^n$Li; x, $N_2O_4$; xi, $LiAlH_4$; xii, $h\nu$ ($\lambda$ > 300 nm)

Irradiation of **1** in MTHF glass at 77 K was then monitored by UV–VIS spectroscopy, which revealed the rapid appearance of new absorption bands at the expense of the original absorption due to **1**. As shown in Fig. 1, the new spectrum consists of two identifiable features, two intense UV bands with maxima at 318 and 333 nm and a weak and broad one with an apparent maximum around 483 nm. These features are usually present in the spectra of triplet diarylcarbenes in organic glasses at 77 K.[10] The glassy solution did not exhibit any changes for several hours when kept at 77 K. However, when it was allowed to warm to room temp. and then cooled to 77 K, the characteristic bands disappeared. On the basis of these observations, coupled with the EPR data, the absorption spectrum can be attributed to triplet carbene **2**.

Again essentially the same spectral features were noted in the case of DDC. However, in this case, as the matrix thawed and carbene absorption bands decreased, a new broad absorption at 375 nm appeared. This secondary intermediate was assigned to *o*-xylylene presumably formed by an intramolecular 1,4 H shift from an *o*-methyl group to the carbene center and leading to benzocyclobutene.[5a,d] The decay of the transient absorption of **2** was rather monotonous, no new band being detected even upon gradual warming, indicating that no intramolecular H abstraction occurs. This is in accord with the product analysis data.

Laser flash photolysis (LFP) of **1** in a degassed benzene solution at 20 °C with a 10 ns, 70–90 mJ, 308 nm pulse from a

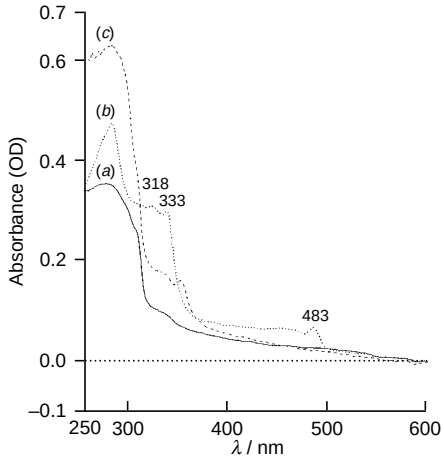


**Fig. 1** UV–VIS spectra obtained by irradiation of **1** in MTHF. (*a*) Spectrum of **1** in MTHF at 77 K. (*b*) Same sample after warming the matrix to room temperature and refreezing to 77 K. OD = optical density.

XeCl excimer laser produced a transient species showing a strong absorption around 320–330 nm and a weak absorption around 480 nm, which appeared coincident with the pulse (Fig. 2). On the basis of the low-temperature spectrum, we assign the transient product to triplet **2**. The inset in Fig. 2 shows the decay of **2**, which is found to be second order ($2k/\varepsilon l$ = 8.4 $s^{-1}$), suggesting that the carbene **2** decays mainly by undergoing dimerization. The approximate lifetime of **2** is estimated in the form of half-life, $t_{1/2}$, to be 1.5 ± 0.1 s.

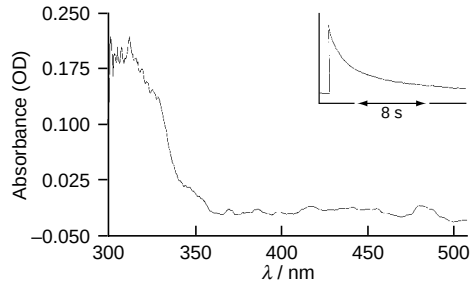

**Fig. 2** Absorption spectrum of the transient products formed during the irradiation of **1** in degassed benzene, recorded 50 μs after excitation. The inset shows the time course of the absorption at 480 nm (oscillogram traces).

The reactivities of **2** toward typical triplet quenchers, *i.e.* oxygen and cyclohexa-1,4-diene (CHD), were then investigated by using LFP. Thus, LFP of **1** on a degassed benzene solution in the presence of CHD generated a new signal attributable to the diarylmethyl radicals as the signals of **2** decayed, showing that triplet **2** abstracts H from the diene.[11] The rate constant ($k_{CHD}$) of H abstraction of **2** from CHD is determined from a plot of the apparent build-up rate constant of the radical *vs.* [CHD]. Similarly the rate constant ($k_{O_2}$) for the quenching of **2** by oxygen was determined from a plot of the observed pseudo-first-order growth rate of the carbonyl oxide[12] as a function of [$O_2$]. The data are summarized in Table 1 along with those obtained in the reaction of DDC.

**Table 1** Kinetic[a] and EPR data[b] for triplet diphenylcarbenes **1** and DDC

| Carbenes | $(2k/\varepsilon l)$/ $s^{-1}$ | $t_{1/2}$/s | $k_{CHD}$/ $M^{-1}$ $s^{-1}$ | $k_{O_2}$ $M^{-1}$ $s^{-1}$ | $D$/ $cm^{-1}$ | $E$/ $cm^{-1}$ |
|---|---|---|---|---|---|---|
| **2** | 8.4 | 1.5 | $3.6 \times 10^2$ | $2.3 \times 10^8$ | 0.3951 | 0.0106 |
| DDC | — | 0.41 | $3.4 \times 10$ | $7.1 \times 10^7$ | 0.3805 | 0.0106 |

[a] In benzene at 20 °C. [b] In MTHF at 77 K.

Thus, these observations clearly support our original idea that bicycloalkyl groups are not delivering hydrogens to triplet carbenic centers while they are acting as a fairly good kinetic protector for the carbene. In this way, the formation of a hydrocarbon triplet carbene having a half-life over a second under normal conditions, *i.e.* in degassed benzene solution at room temperature, was realized for the first time. It should be noted here that the reactivity of **2** toward typical triplet quenchers is somewhat higher than that of DDC, while the half-life of **2** in benzene is distinctly longer than that of DDC. Comparison of the optimized geometries between DDC and **2** obtained by the AM1/UHF method[13] reveals that there is slightly more space around carbene center in **2** compared to that in DDC, especially for a small particle such as hydrogen to attack, but that dimerization of the carbene center of **2** is obviously more severely retarded by the bulky rigid 'three-dimensional' bicyclic substituent compared to that of DDC which has more flexible methyl substituents.

The authors are grateful to the Ministry of Education, Science and Culture of Japan for support of this work.

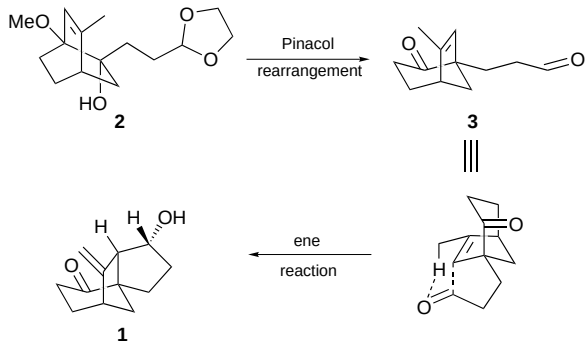
# Construction of the tricyclo[5.3.1.0$^{1,5}$]undecane system by a tandem pinacol rearrangement–ene strategy: a formal synthesis of (±)-perhydrohistrionicotoxin

**Deukjoon Kim,* Sung Woo Hong and Cheol Won Park**

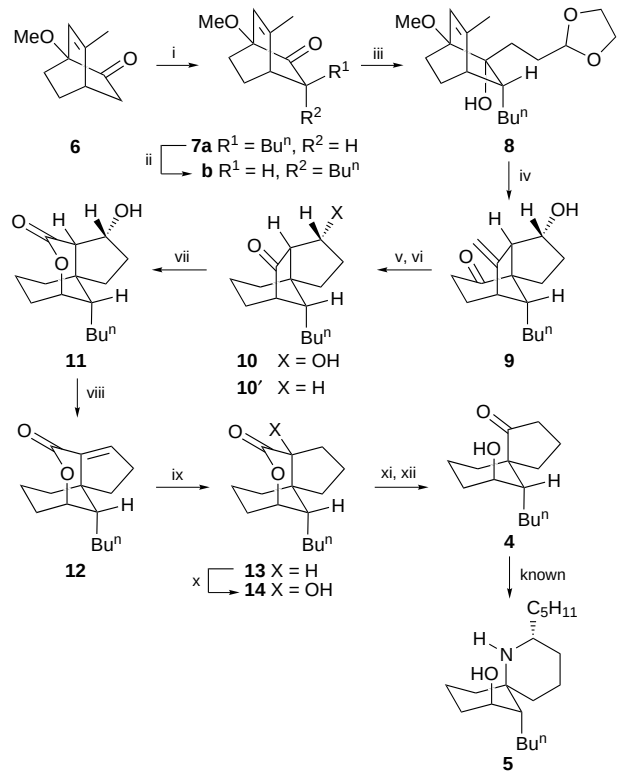
*College of Pharmacy, Seoul National University, San 56-1, Shinrim-Dong, Kwanak-Ku, Seoul 151-742, Korea*

**An advanced synthetic intermediate 4 for perhydrohistrionicotoxin 5 has been synthesized utilizing a novel tandem pinacol rearrangement–ene reaction as a key step.**



Construction of the tricyclo[5.3.1.0$^{1,5}$]undecane skeleton, which constitutes the carbon framework of natural products such as cedranes, has been a challenge to synthetic organic chemists and has led to the development of diverse and inspiring strategies.[1] We envisaged that highly functionalized tricyclo[5.3.1.0$^{1,5}$]undecane system **1** might be accessible by a novel tandem pinacol rearrangement–ene reaction on a Diels–Alder derived bicyclo[2.2.2]octene **2** *via* the intermediacy of bicyclo-[3.2.1]octene derivative **3** (Scheme 1).[2]

Reported herein is a stereoselective synthesis of an advanced intermediate **4**[3] for the synthesis of perhydrohistrionicotoxin **5**,[4] a hydrogenation product of a potent neurotoxin isolated from the Columbian frog *Dendrobates histrionicus*, which demonstrates the potential of our tandem pinacol rearrangement–ene protocol.



Alkylation of readily available ketone **6**[2a] by successive treatment with LDA and *n*-butyl iodide in THF containing HMPA produced a 75% yield of *exo* product **7a** (Scheme 2). Epimerization of *exo* isomer **7a** with methanolic NaOH produced a chromatographically separable 73 : 27 equilibrium mixture of *exo* and *endo* isomers **7a** and **7b** in a quantitative yield. Treatment of bicyclic ketone **7b**, secured in a large quantity by recycling of **7a**, with appropriate β-bromo ketal derived Grignard reagent under Barbier conditions[5] gave *endo* alcohol **8** in 92% yield stereospecifically. As we had planned, compound **8** underwent an efficient, novel, tandem pinacol rearrangement–ene reaction upon exposure to TsOH in refluxing acetone to afford tricyclic intermediate **9** and its epimeric alcohol in an 89 : 11 ratio (82% total yield).†

Next, we turned to the conversion of the key tricyclic intermediate **9** to our target compound **4** for a formal synthesis of perhydrohistrionicotoxin **5**. Removal of the keto function from **9** by Wolff–Kishner reduction,‡ followed by ozonolysis of the resulting alkene, produced hydroxy ketone **10** in 51% overall yield for the two steps. Regiospecific Baeyer–Villiger oxidation[6] of ketone **10** with MCPBA and subsequent elimination of the resulting β-hydroxy ester **11** gave α,β-unsaturated δ-lactone **12** (76% overall yield over two steps). Our originally projected synthetic plan for processing the key intermediate **4** by an ammonolysis–Hoffmann rearrangement protocol on **12** was thwarted by difficulties encountered in opening of the lactone. To circumvent these problems, catalytic hydrogenation of the alkene functionality in **12** and subsequent α-hydroxylation of the resulting lactone **13** *via* the method of Davis[7] yielded α-hydroxy lactone **14**. Finally, reductive opening of lactone **14** with $LiAlH_4$ to the corresponding diol, followed by oxidative cleavage with $NaIO_4$, delivered the desired keto alcohol **4** in 66% yield for the four steps from **12**.† $^1$H and $^{13}$C NMR spectral data of compound **4** were in good agreement with those of authentic samples kindly provided by Professors Ibuka and Smith.§

In summary, a formal synthesis of (±)-perhydrohistrionicotoxin **5** has been accomplished utilizing a novel tandem pinacol rearrangement–ene strategy and a regiospecific Baeyer–Villiger

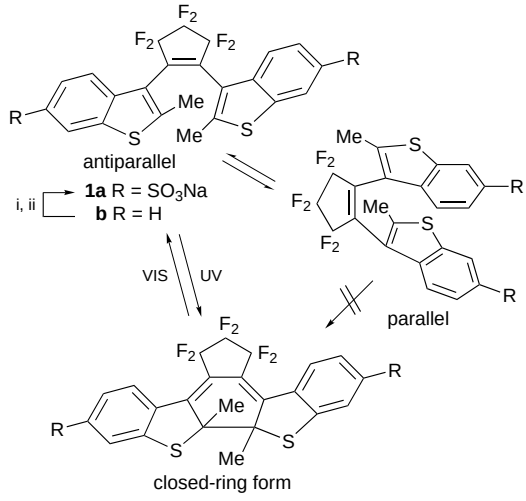
# Enhancement of the photocyclization quantum yield of 2,2′-dimethyl-3,3′-(perfluorocyclopentene-1,2-diyl)bis(benzo[*b*]-thiophene-6-sulfonate) by inclusion in a cyclodextrin cavity

**Michinori Takeshita,* Chang Nam Choi† and Masahiro Irie***

*Department of Chemistry and Biochemistry, Graduate School of Engineering, Kyushu University, Hakozaki 6-10-1, Fukuoka, 812-81, Japan*



**The photocyclization quantum yield of 2,2′-dimethyl-3,3′-(perfluorocyclopentene-1,2-diyl)bis(benzo[*b*]thiophene-6-sulfonate) is found to increase in aqueous solution after the addition of β- and γ-cyclodextrin, in which a photoreactive antiparallel conformation of diarylethene is favourably included.**

Photochromic reaction of diarylethenes are based on reversible photocyclization of hexatriene structures, as shown in Scheme 1.[1] The opened ring form of diarylethene has two conformations, parallel and antiparallel. The photocyclization can proceed only from the antiparallel conformation, while the parallel conformation is photochemically inactive.[2] The conformational change between the antiparallel and parallel conformations in solution limits the maximum cyclization quantum yield to 0.5.[3] If one can increase the ratio of antiparallel : parallel conformation, the cyclization quantum yield is expected to increase accordingly.

It is well known that cyclodextrins (CDs) have cavities whose sizes are dependent on the number of glucopyranose units, and can include various types of organic compounds by hydrophobic interactions in aqueous media.[4] Here we have attempted to control the ratio of the two conformations in an aqueous solution by including the 3,3′-(perfluorocyclopentene-1,2-diyl)bis(benzo[*b*]thiophene-6-sulfonate) in the CD cavities.

2,2′-Dimethyl-3,3′-(perfluorocyclopentene-1,2-diyl)bis-(benzo(*b*]thiophene-6-sulfonate)‡ **1a** was prepared by treatment of 2,2′-dimethyl-3,3′-(perfluorocyclopentene-1,2-diyl)bis(benzo[*b*]thiophen)[5] **1b** with chlorosulfonic acid in $CHCl_3$ and subsequent hydrolysis with 1% aqueous NaOH (Scheme 1).

Fig. 1(*a*) shows the $^1$H NMR spectrum of the methyl groups of the open-ring form of **1a** in $D_2O$ ($3.0 \times 10^{-3}$ mol dm$^{-3}$, 20 °C, 200 MHz). The methyl signals of each conformation are

**Scheme 1** *Reagent and conditions*: i, $ClSO_3H$, $CHCl_3$, room temp.; ii, 1% NaOH, 78%

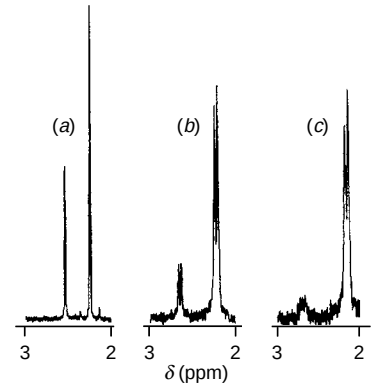


**Fig. 1** $^1$H NMR spectra of methyl protons in $D_2O$ ([**1**] = $3.0 \times 10^{-3}$ mol dm$^{-3}$); (*a*) **1a**, (*b*) **1a**–β-CD (1 : 5) and (*c*) **1a**–β-CD (1 : 10)

observed separately. This indicates that the conformational change takes place slowly relative to the NMR timescale ( < 56 Hz). The methyl protons at $\delta$ 2.27 (at higher magnetic field) are assigned to the antiparallel conformation.[2] Under the present conditions, the antiparallel conformation is favoured and the ratio of antiparallel : parallel was 64 : 36. This value shows that only 64% of **1a** is photoreactive. Upon addition of β- and γ-CD to this solution, the ratio of antiparallel : parallel conformations was increased, as shown in Fig. 2. When 10 equiv. of β-CD were added to the solution, the antiparallel conformation became dominant, as shown in Fig. 1(*c*). On the other hand, the addition of α-CD did not change the $^1$H NMR spectrum of **1a**. These results reveal that the cavity of β-CD is suitable for the antiparallel conformation of **1a**, whereas that of α-CD is too small to include **1a**. γ-CD is considered to have a small association constant with the diarylethene. The splitting of each

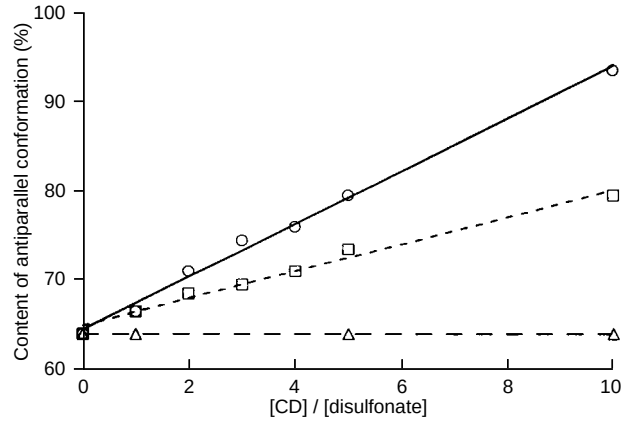

**Fig. 2** [CD]/[**1a**] *vs.* content of antiparallel conformation determined by $^1$H NMR spectroscopy ([**1a**] - $3.0 \times 10^{-3}$ mol dm$^{-3}$); (△) with α-CD, (○) with β-CD and (□) with γ-CD

**Table 1** Cyclization quantum yields of **1a** irradiated with 313 nm light in the presence of CD in aqueous solution[a]

| System | **1a** | **1a**–α-CD | **1a**–β-CD | **1a**–γ-CD |
|---|---|---|---|---|
| Quantum yield | 0.38 | 0.37 | 0.58 | 0.53 |

[a] [**1a**] = $4.0 \times 10^{-5}$ mol dm$^{-3}$; [CD] = $8.0 \times 10^{-3}$ mol dm$^{-3}$, 20 °C.

methyl proton of the both conformations of **1a** was observed in β-CD. The split suggests that the two methyl protons exist in different environments in the chiral CD cavity.

As described above, the diarylethene in the parallel conformation is not photoreactive. Therefore, the increase in the ratio of antiparallel : parallel conformations is expected to result in an increase in the cyclization quantum yield. Table 1 shows the cyclization quantum yields of **1a** irradiated with 313 nm light.[3,6]

As expected, the cyclization quantum yield of **1a** in the presence of a 200-fold excess of β-CD is *ca.* 1.5 times larger than that of **1a** in aqueous solution. NMR measurements indicated that almost all the diarylethene is in the antiparallel conformation in the presence of excess β-CD. The increase in the quantum yield is due to the increase in the proportion of molecules in the antiparallel conformation. On the other hand, no change was observed in either the $^1$H NMR spectrum or the quantum yield for cyclization of **1a** in the presence/absence of α-CD. The enhancement of quantum yield in the presence of β- and γ-CD is ascribed to the favourable antiparallel conformation of **1a** in the CD's cavities.

The authors are grateful to Professor S. Mataka and his coworkers at the Institute of Advanced Material Study, Kyushu University, for the measurement of mass spectra and elemental analyses. This work was partly supported by a Grant-in-Aid for Encouragement of Young Scientists (No. 09750956) from the Ministry of Education, Science and Culture, Japan.

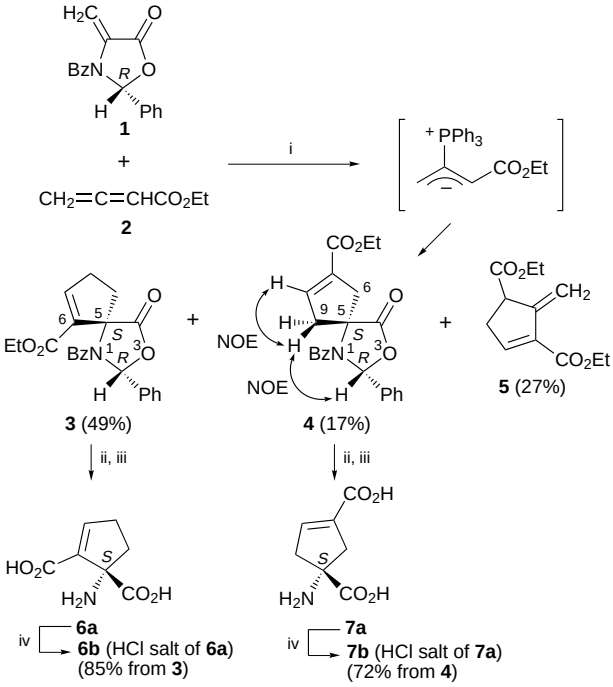
# Synthesis of novel conformationally restricted L-glutamate analogues



**Stephen G. Pyne,*[a] Karl Schafer,[a] Brian W. Skelton[b] and Allan H. White[b]**

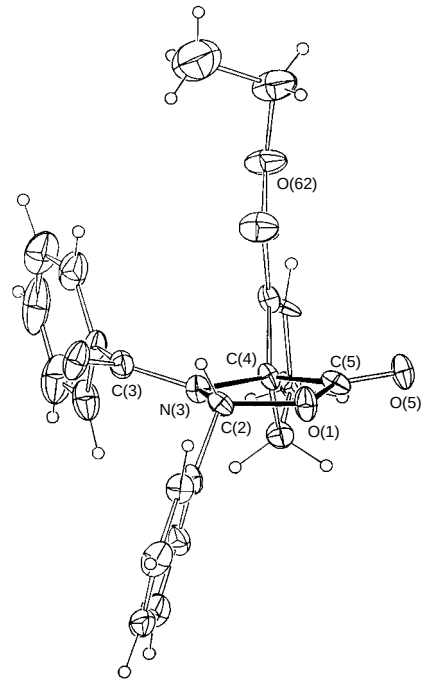
[a] *Department of Chemistry, University of Wollongong, Wollongong, New South Wales, 2522, Australia*
[b] *Department of Chemistry, University of Western Australia, Nedlands, Western Australia, 6907, Australia*

**The novel, optically active and conformationally restricted L-glutamate analogues 6, 7 and 11 have been prepared *via* the $PPh_3$ catalysed cycloaddition of the allenes 2 and 9 with the chiral oxazolidinone 1.**

L-Glutamate is an excitatory neurotransmitter in the mammalian central nervous system (CNS). This amino acid activates both the metabotropic and the ionotropic group of glutamate receptors. The latter group includes the *N*-methyl-D-aspartic acid (NMDA), α-amino-3-hydroxy-5-methylisoxazole-4-propionate and kainate receptor subclasses. These receptors form ligand-gated ion channels and mediate excitatory neurotransmission. The former receptor group are coupled to G-proteins and activate or inhibit intracellular signals. Elevated glutamate concentrations can lead to excitoxicity which has been implicated in the pathogenesis of neurological disorders, including epilepsy and chronic neurodegenerative diseases.[1,2] Excitatory amino acid transporters (EAATs) in the CNS maintain extracellular glutamate concentrations below excitotoxic levels.[3] Selective agonists and antagonists for glutamate receptor subtypes[1] and selective blockers for EAATs are invaluable tools in understanding neuronal biochemistry. Furthermore, such compounds allow an understanding of the structural features of these receptor subtypes and the future design of new therapeutics for the treatment of neurodegenerative diseases.[1] One such compound is the conformationally restricted glutamate analogue, (1*S*,3*R*)-1-aminocyclopentane-1,3-dicarboxylic acid (ACPDA), which selectively activates metabotropic glutamate receptors and differentiates them from the ionotropic type.[4] Here we describe a novel synthesis of some dehydro derivatives of ACPDA *via* the cycloaddition reactions of the chiral oxazolidinone **1**[5] and allenic esters **2** and **9** and report some preliminary results on the pharmacological activities of these compounds.

Treatment of a benzene solution of the oxazolidinone **1** (1 equiv.) and ethyl buta-2,3-dienoate **2**[6] (5 equiv.) with $PPh_3$[7] (0.1 equiv.) at room temperature for 5 h gave, after purification by column chromatography, the major cycloadduct **3**† (49%), the minor cycloadduct **4**† (17%) and the dimer **5**[7a] (27%) (Scheme 1). The diastereoisomeric ratio of **3** and **4** was estimated to be 77 : 23 from $^1$H NMR analysis of the crude reaction mixture. The stereochemistry of **3** was revealed by a single crystal X-ray structural analysis, as shown in Fig. 1.‡ This analysis showed that the major cycloadduct had the 5*S* stereochemistry at the newly created stereogenic centre, consistent with the known tendency of **1** in [3 + 2] cycloaddition reactions to give products that arise from attack of the three-atom component *anti* to the C(2) phenyl substituent.[8] The minor cycloadduct **4** was a regioisomer of **3** and also had the 5*S* stereochemistry as shown by NOESY experiments which revealed cross-peaks between the signal for H-2 and that for one H-9 proton, as indicated in structure **4** (Scheme 1). Interestingly, the regiochemistry of the major cycloadduct **3** was different to that of the major cycloadduct formed from the reaction of ethyl acrylate or methyl methacrylate with **2**–$PPh_3$.[7a] The enantiomeric purity of **3** was determined to be 88% from $^1$H NMR analysis of its

**Scheme 1** *Reagents and conditions*: i, $PPh_3$ (10 mol%); ii, 6 M HCl, reflux, 16 h; iii, ion-exchange; iv, HCl



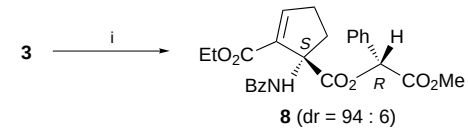


**Fig. 1** Projection of **3** through the heterocyclic ring plane (20% thermal ellipsoids are shown for C, N, O, H having arbitrary radii of 0.1 Å)

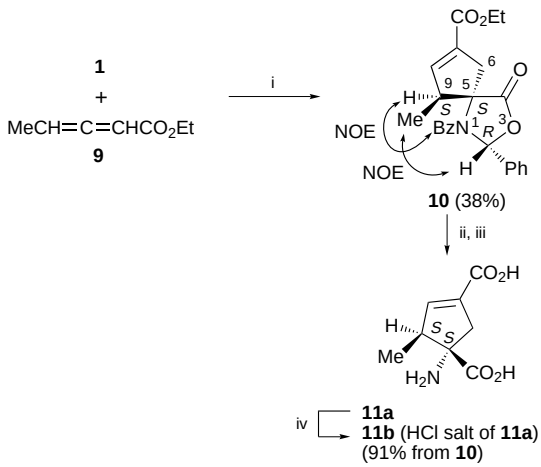
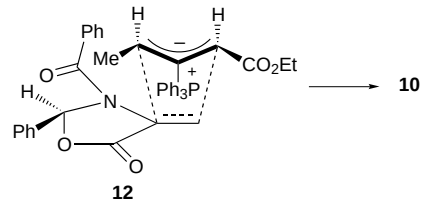


**Scheme 2** *Reagents and conditions*: i, (*R*)-methyl mandelate, $Et_3N$, $CH_2Cl_2$, 7 days, 63%

(*R*)-methyl mandelate derivative **8**, which was a 94 : 6 mixture of diastereoisomers [major: $\delta_H(CDCl_3)$ 5.99 (s), minor 5.98 (s)] (Scheme 2). Acid hydrolysis of **3** and **4** followed by purification *via* ion-exchange chromatography gave diastereoisomerically pure amino acids **6a** and **7a**, respectively, which were characterized as their respective hydrochloride salts, **6b**† and **7b**.† Amino acid **7a** has been reported recently, however this product was racemic and was obtained as a mixture of two isomers from which racemic **7a** could be obtained in 1.75% yield after selective crystallization.[9]



Treatment of a benzene solution of **1** and ethyl penta-2,3-dienoate **9**[6] (5 equiv.) with $PPh_3$ (0.1 equiv.) at room temperature for 5 h gave a single cycloadduct **10**† in 38% isolated yield after purification by column chromatography on silica gel. No other stereoisomer of **10** could be detected by $^1H$ NMR analysis of, or was isolated from, the crude reaction mixture. The 5*S*,9*S* stereochemistry of **10** was evident from NOESY experiments, which showed cross-peaks between H-2 and the C(9) methyl group and between H-9 and the *ortho* protons of the benzamido group, as shown in Scheme 3. Acid hydrolysis of **10** gave the amino acid **11a**, which was characterized as its hydrochloride salt **11b**.†

Thus the $PPh_3$ catalysed reactions of **2** and **9** with oxazolidinone **1** proceed in a different regiochemical sense. It is not clear if these reactions occur *via* a four step reaction sequence that involves initially a Michael addition reaction, then cyclization followed by proton transfer and then elimination of $PPh_3$,[7b] or *via* a three step mechanism *via* an initial 'concerted' 2,3-cycloaddition reaction.[7a] In the latter case, the transition state structure **12**, in which steric interactions between the substituents on the zwitterionic species formed between **9** and $PPh_3$ and the benzamido group on **1** are minimized, is consistent with the observed stereochemical outcome in **10** (Scheme 4). Attempts to obtain cycloadducts from the (2*S*)-*tert*-butyl analogue[5] of **1** and allene **2** gave only the dimer **5**.

In some preliminary studies, amino acids **6**, **7** and **11** showed no activity against NMDA-induced depolarizations in the rat neocortex at 500 μM concentrations.[10] Compound **11**, however, selectively blocks glutamate transport by EAAT2 expressed in

# Cubic lanthanide sulfido clusters: $Ln_8S_6(SPh)_{12}(thf)_8$ (Ln = Pr, Nd, Gd)

**Jonathan H. Melman, Thomas J. Emge and John G. Brennan***

*Department of Chemistry, Rutgers, the State University of New Jersey, Piscataway, NJ 08854-8087, USA*

**Lanthanide thiolates react with elemental sulfur to give $Ln_8S_6(SPh)_{12}(thf)_8$ clusters in high yield.**

Lanthanide thiolates [$Ln(SPh)_3$; Ln = Pr, Nd, Gd] react with elemental sulfur to give crystalline octametallic $Ln_8S_6(SPh)_{12}(thf)_8$ clusters in high yield.

Inorganic clusters are important synthetic targets because their unique physical properties provide insight into the relationships between molecular and solid state properties. Lanthanide (Ln)[1] clusters are scarcer than main group[2] or transition metal clusters,[3] primarily because no general synthetic approach to such materials has as yet been identified. The recent explosion of interest in determining the properties of Ln thiolates (SR), selenolates (SeR), and tellurolates (TeR) has in effect created a wide variety of potential starting materials for cluster syntheses.[1a,4] Relative to more conventional O, N, or C based anions, these singly charged, electropositive chalcogenolate ligands should be considerably more susceptible to displacement from Ln coordination spheres. Here we present an extremely general approach to the synthesis of lanthanide sulfido cluster materials: $Ln(SPh)_3$ reacts with elemental sulfur to form thiolate capped lanthanide sulfide clusters in 40–60% isolated yields.

Addition of sulfur to a suspension of $Ln(SPh)_3$ in thf results in the formation of a homogeneous solution that can be saturated by layering with hexane to give crystals of $Ln_8S_6(SPh)_{12}(thf)_8$ (Ln = Pr, Nd, Gd) [eqn. (1)].†

$$8\ Ln(SPh)_3 + 6\ S \rightarrow Ln_8S_6(SPh)_{12}(thf)_8 + 6\ PhSSPh \quad (1)$$

The compounds were characterized by conventional methods and the Gd derivative (**1**) was also characterized by low temperature single crystal X-ray diffraction.‡ Unit cell data for the Pr and Nd compounds indicated that all three clusters are isostructural. The clusters (Fig. 1) contain a cube of $Ln^{III}$ ions, with the six faces of the cube all capped with $S^{2-}$, and the 12 edges of the cube all spanned by μ-SPh. The cubic structure appears to be particularly stable: thus far, $Ln_8S_6(SPh)_{12}(thf)_8$ clusters§ have crystallized in three distinct phases which differ in the amount of lattice thf present, and the related selenido cluster $Sm_8Se_6(SePh)_{12}$ can be isolated in low yield from the thermal decomposition of $Sm(SePh)_2$.[1c] The isolation of a neutral cluster compound is an additional benefit of $Ln(SR)_3$ starting materials: whereas in $Ln(SeR)_3$ chemistry SeR abstraction by excess $Hg(SeR)_2$ is a complicating side reaction,[1c,5] in related thiolate work Ln–S bonds have yet to be cleaved by the addition of excess $M(ER)_2$ (M = Zn, Cd, Hg),[6] and so more rational syntheses are possible.

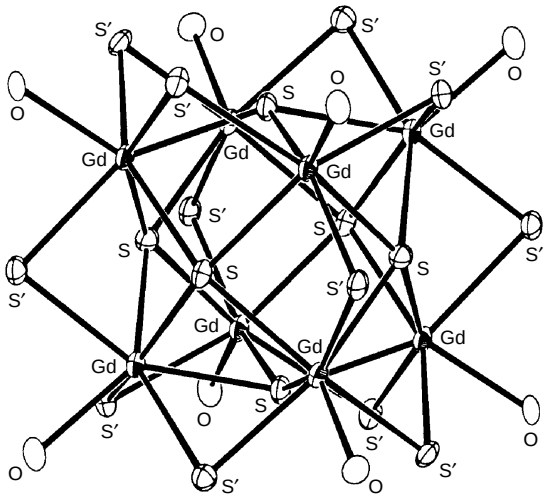

**Fig. 1** Molecular structure of $Gd_8S_6(SPh)_{12}(thf)_8$ **1**, with H and C atoms omitted for clarity. The unit cell contains two independent 'half' molecules that differ primarily in the orientation of the phenyl groups. The Gd–$S^{2-}$ bond lengths range from 2.746(4) to 2.835(4) Å and average 2.80 Å, while the Gd–S(Ph) (labeled S′) bond lengths range from 2.794(4) to 2.881(4) Å, and average 2.84 Å. Thermal ellipsoids are shown at the 50% probability level. The analogous Pr and Nd clusters are isostructural with the Gd cluster.

Thiolate displacement is clearly a general reaction that does not require a redox active metal. The reactivity can be understood in terms of 'hard', ionic metals preferentially binding harder, highly charged bases. The ability of $S^{2-}$ to bridge four metals must also contribute significantly to the stability of the final product. To date, only the middle of the Ln series (Pr–Tb) have yielded crystalline sulfido clusters from thf solution. The earlier (La, Ce) and later (Dy–Yb) lanthanides also react with elemental sulfur, as judged by the solubilization of $Ln(SPh)_3$, but these reactions precipitate microcrystalline materials from saturated thf solutions. Clusters of redox active Eu have also proven elusive. Solutions of europium(II) chalcogenoaltes in thf are colorless,[4f,g] and so the dark red solution color that results from the addition of S to a suspension of $Eu(SPh)_2$ in thf leads us to suggest that some form of $Eu^{III}$, with a visible S → Eu charge transfer absorption, is present in solution.

The facility with which lanthanide thiolates react with S–S bonds to form sulfido anions and PhSSPh at room temp. suggests the possibility that $Ln(SR)_3$ compounds may be valuable reagents for doping Ln into sulfide matrices.[7,8] Preliminary experiments indicate that reactions of $Ln(ER)_3$ (E = S, Se) with elemental Se procede similarly, and thus this is an extremely general synthetic route to lanthanide chalcogenide cluster compounds.

This work was supported by the National Science Foundation under Grant No. CHE-9628834.

† *Cluster synthesis*: under nitrogen, Ln (2.42 mmol), PhSSPh (0.791 g, 3.62 mmol), and Hg (0.06 g, 0.3 mmol) were combined in thf (35 ml). The lightly colored solution was stirred for 1 d. Elemental sulfur was added (0.058 g, 1.8 mmol, 0.75 equiv. to Ln), and after 3 d the solution [yellow green (Gd), blue (Nd), blue green (Pr)] was filtered to remove a trace of black solid, and the filtrate was layered with hexane. Colorless (Gd), light blue (Nd), or light green (Pr) crystals of $Ln_8S_6(SPh)_{12}(thf)_8 \cdot 2.9thf$ were collected (0.44–0.57 g, yields range from 42 to 57% with longer saturation times giving larger yields). The compounds do not melt but begin turning yellow between 165 °C (Pr) and 175 °C (Gd). Upon isolation, the crystals lose thf and become amorphous within hours. Elemental analyses are consistent with the structure (less lattice thf) if the compound is analyzed immediately after isolation [*e.g.* Calc. for $Pr_8S_6(SPh)_{12}(thf)_8$: C, 38.9; H, 3.90. Found: C, 37.1; H, 3.80%], but the materials continue to lose coordinated thf upon standing

at room temp. The IR and NMR spectra are essentially identical for all three compounds. $^1$H NMR ([$^2H_8$]thf) revealed only peaks due to displaced thf at $\delta$ 1.754(t) and 3.604(m). IR (KBr, Nujol): 3151w, 2923s, 2854s, 2724w, 2672w, 2199w, 2036w, 1947w, 1874w, 1813w, 1571m, 1461s, 1377s, 1305w, 1262w, 1169m, 1154m, 1113w, 1075m, 1022m, 973w, 917w, 863w, 803w, 736m, 724m, 691m, 662w, 481m cm$^{-1}$. Unit cell data (−120 °C): Pr; triclinic space group $P\bar{1}$, $a$ = 17.661(5), $b$ = 18.297(5), $c$ = 20.490(5) Å, $\alpha$ = 102.84(2), $\beta$ = 94.56(2), $\gamma$ = 94.17(2)°, $U$ = 6407(3) Å$^3$. Nd; triclinic space group $P\bar{1}$, $a$ = 17.632(4), $b$ = 18.236(3), $c$ = 20.441(2) Å, $\alpha$ = 102.92(1), $\beta$ = 94.65(2), $\gamma$ = 94.21(2)°; $U$ = 6357(2)Å$^3$.

‡ Complex **1** crystallizes in the triclinic space group $P\bar{1}$, with $a$ = 17.513(4), $b$ = 18.136(4), $c$ = 20.382(4) Å, $\alpha$ = 102.94(2), $\beta$ = 94.39(2)°, $\gamma$ = 93.72(2)°, $U$ = 6268(3)Å$^3$, $Z$ = 2, $D_c$ = 1.878 g cm$^{-3}$, (Mo-K$\alpha$ radiation at −120 °C). Full-matrix least-squares refinement [8486 observations with $I > 2\sigma(I)$] gave $R(F)$ = 0.054, $wR(F^2)$ = 0.115. CCDC 182/621.

§ The terbium complex crystallizes in the monoclinic space group $C2/c$, with $a$ = 26.706(8), $b$ = 20.751(5), $c$ = 46.95(1)Å, $\beta$ = 90.21(2)°, $U$ = 26 020(11) Å$^3$. The Sm compound crystallizes from thf–dme in the tetragonal space group $I4/m$, with $a$ = 18.256(6), $c$ = 21.478(7) Å, and $U$ = 7158(4) Å$^3$.

# Novel lamella hydrated sodium zinc arsenate with 4-connected two-dimensional nets

**Xianhui Bu, Thurman E. Gier and Galen D. Stucky**

*Chemistry Department, University of California, Santa Barbara, California 93106, USA*

**Hydrothermal synthesis and crystal structure of a lamellar hydrated sodium zinc arsenate with an unusual sheet structure are reported.**

Metal phosphates and arsenates are of interest for their chemical and physical properties and resulting applications as catalysts, non-linear optical materials, ion-exchangers *etc.*[1] Since the 1980s, many phosphate based zeolite analogs and novel structures have been synthesized.[2] This has further expanded the possible applications of metal phosphate based materials. Divalent metal phosphates and arsenates have the same total charge (+2 and +5) as that of zeolite aluminosilicates (+3 and +4). This has generated a lot of interest in synthesizing zeolite structural analogs in the $T^{2+}/T^{5+}$ system (T refers to a tetrahedral atom).[3] A number of zeolite structural analogs have been synthesized, including $Na_6(H_2O)_8(ZnPO_4)_6$ (sodalite), $(Na, TMA)_{96}M_{96}P_{96}O_{192}$ (M = Be, Zn; zeolite X), $Li_4M_4P_4O_{16}\cdot 4H_2O$ (M = Be, Zn; zeolite Li-ABW) and $Li_{24}Be_{24}P_{24}O_{96}\cdot 4H_2O$ (zeolite RHO).[4] Very recently, a large family of cobalt phosphate based zeolite structural analogs have been reported.[5,6]

The framework of a zeolite structure has the general composition of $AB_2$, where A is a 4-connected atom (tetrahedral atoms such as Al, Si, Zn, Be, P, As . . .) and B is any 2-connected atom (usually oxygen) which is shared between two tetrahedral atoms. The topology of zeolite structures is usually viewed based on the connectivity of tetrahedral atoms. Such a tetrahedral atom connectivity can be regarded mathematically as 4-connected 3D nets, which are constructed from 3-connected 2D sheets.[7] Thus, both 4-connected 3D nets and 3-connected 2D sheets are common among known structures. To our knowledge, however, there is no reported example of a structure in which tetrahedral atoms form 4-connected 2D sheets. In known structures, when lamellar structures are formed from tetrahedral atoms, there are always interruptions involved and the resulting structures, even if polymeric, are not completely 4-connected.[8]

Here, we report an unprecedented occurrence of 4-connected 2D sheets in a new hydrated sodium zinc arsenate. Owing to the formation of 4-connected sheets, no pendant oxygen atoms, hydroxyl groups or water molecules are present on the anionic sheet. Such a novel sheet structure could lead to interesting properties such as the ion-exchange characteristics.

The title compound was synthesized under hydrothermal conditions typically used in the synthesis of zeolites. To a polypropylene bottle was added 9.36 g of $Na_2HAsO_4\cdot 7H_2O$ (30 mmol), 0.8 g of NaOH pellets (20 mmol) and 25 ml of water. To the clear solution was then added 12.0 ml of a 2 M solution of $Zn(NO_3)_2$ (24 mmol) and the resulting gel was shaken thoroughly to give a thick white slurry. The slurry settled rapidly (pH = 6.5) and after standing overnight at 50 °C was recovered by standard filtration and drying techniques. Small crystals (6.282 g) were obtained at 99.4% yield. Thermal analysis showed that the material had a mass loss of 13.2% up to 210 °C with no further loss to 500 °C (calc. 13.7% for $NaZnAsO_4\cdot 2H_2O$). The residue at 500 °C was identical to the hexagonal product from the calcination of $Na_6(ZnAsO_4)_6\cdot 6H_2O$ (sodalite structure).[9]

The pH and temperature are critical to the formation of this phase. At higher pH, the sodalite phase appears and at lower pH an unidentified material appears. Even at pH = 6.5, heating to 100 °C for any period of time converts the title compound to the latter unidentified phase.

The crystal structure was solved using data collected on a Siemens SMART CDD diffractometer.† A full sphere of intensity data were collected with $\omega$ scans (width of 0.30 and exposure time of 30 s per frame). Final full-matrix refinements were against $F^2$ with anisotropic thermal parameters for non-hydrogen atoms. Hydrogen atoms were not included.

The asymmetric unit is $NaZnAsO_4\cdot 2H_2O$ with two unique sodium cations located at inversion centers. Tetrahedral atoms (Zn and As) are connected by oxygen atoms to form an infinite sheet (Fig. 1). Like zeolite structures, there is a strict alternation of $ZnO_4$ and $AsO_4$ tetrahedra which explains the Zn/As ratio of unity. The unique feature of the title arsenate is that all corners of Zn and As tetrahedra are shared with adjacent tetrahedra. This is unprecedented for a lamellar structure constructed from tetrahedral centers. The resulting sheet can thus be described as a 4-connected 2D net.

Both two unique sodium cations are octahedrally coordinated. Each sodium cation is coordinated to two oxygen atoms in the anion sheet and four water molecules. Corner-sharing sodium octahedra form an infinite sheet similar in structure to anionic sheets formed by $ZnO_4$ and $AsO_4$ (Fig. 2). These cationic sheets are formed from sodium and water molecules and are connected to the anionic sheets through Na–O bondings. Note that the anionic sheet is far from planar. A side view of alternating anionic and cationic sheets is shown in Fig. 3.

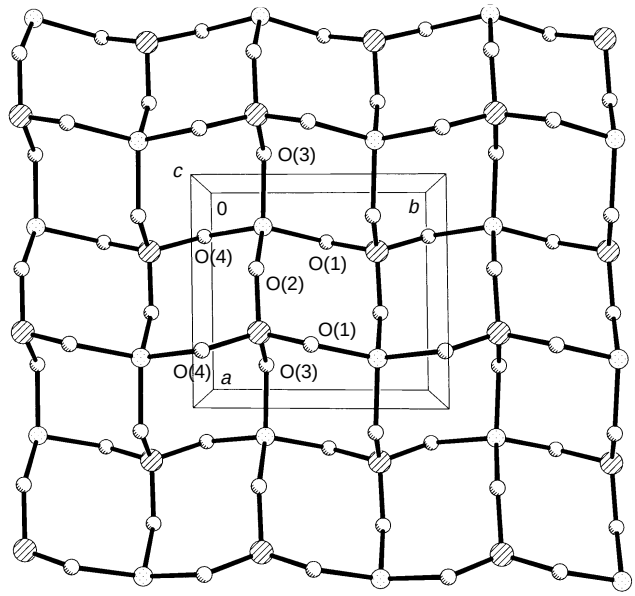

**Fig. 1** Projection down the *c*-axis showing the anionic sheet built from $ZnO_4$ and $AsO_4$ tetrahedra. There are four different 4-rings, all of which have a center of inversion.

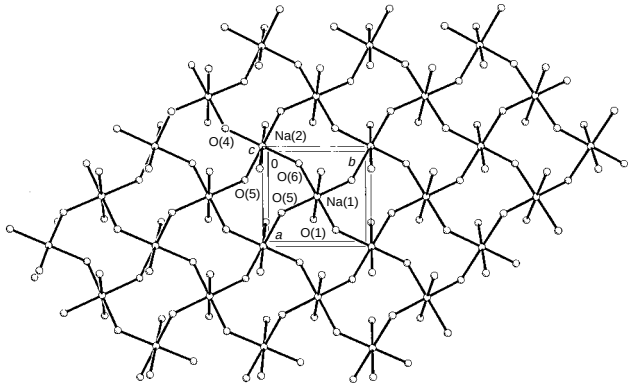

**Fig. 2** Projection down the *c*-axis showing the cationic sheet built from sodium octahedra. Two crystallographically unique sodium atoms are located at the unit cell origin and the face center which have inversion symmetry. Each ring contains four sodium cations and the center of each ring has inversion symmetry.

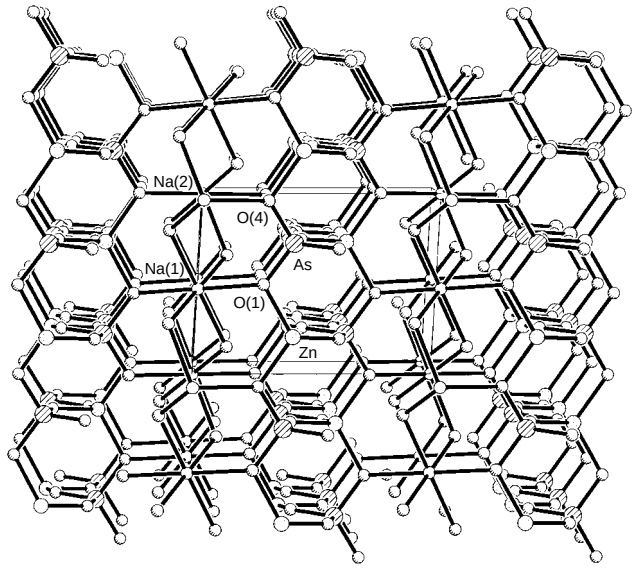

**Fig. 3** Side view (down the *a*-axis) of alternating anionic and cationic sheets

The circuit symbol, which enumerates the six distinct, smallest T-atom loop pathways[10] (including the central atom itself), can be written as ($4^4.6^2$) for all tetrahedral atoms. This type of tetrahedral atom configuration has never been previously known in either aluminosilicates or aluminophosphates. However, one chiral sodium zinc phosphate, $NaZnPO_4{\cdot}H_2O$, which has similar formula to the title compound, but monohydrated, has half of the zinc cations (a quarter of tetrahedral atom positions) in such a configuration.[11] Our arsenate represents an extreme case in which all tetrahedral atoms exist in the ($4^4.6^2$) configuration. The synthesis of the title compound suggests that there could be novel phases with framework topology intermediate between $NaZnPO_4{\cdot}H_2O$ and the title compound. This is an interesting possibility considering that $NaZnPO_4{\cdot}H_2O$ has a chiral symmetry and that chiral zeolites are very rare.[12]

Two other hydrated sodium zinc arsenates are known, both of which are tetrahedral framework structures. In $Na_6Zn_3(AsO_4)_4{\cdot}3H_2O$ which is a relatively dense phase, one corner of $AsO_4$ is terminated with a pendant As=O bond.[13] $Na_6(ZnAsO_4)_6{\cdot}8(H_2O)$ is a sodalite analog with a cage structure.[14] Compared to this sodalite structure, it is observed that the increased hydration transforms the structure from the 3D framework sodalite structure into a lamellar phase. We have synthesized and characterized phosphate analogs of these two hydrated sodium zinc arsenates,[4,15] but so far, the phosphate analog of the title compound has not been prepared.

It's of interest that both anionic and cationic sheets have the same grid pattern and that the two types of sheets strictly alternate. The interlayer interaction between two sheets is through Na–O bondings. It is clear that the translational periodicity in one type of sheet and the geometrical feature of the sheet structure can be imprinted onto the other type of sheet, which can in turn replicate the original sheet. The good match between the sodium sheet and the zinc arsenate sheet implies that it may be difficult for other tetrahedral atoms such as P, or other alkali metal cations to replace Zn, As or Na while maintaining the same type of structure. This may explain why the phosphate analog of the title compound has not been synthesized so far.

# Thermochemical alkane dehydrogenation catalyzed in solution without the use of a hydrogen acceptor

**Wei-wei Xu,[a] Glen P. Rosini,[a] Mukta Gupta,[b] Craig M. Jensen,*[b] William C. Kaska,[c] Karsten Krogh-Jespersen[a] and Alan S. Goldman*[a]**

**(PCP)$IrH_2$ [PCP = $\eta^3$-$C_6H_3(PBu^t_2)_2$-1,3] catalyzes the efficient (several hundred mol product/mol catalyst) dehydrogenation of alkanes under reflux to give the corresponding alkenes and dihydrogen.**

The development of effective systems for the functionalization of alkanes is one of the major goals in the field of homogeneous catalysis.[1] Conversion of alkanes to the corresponding alkenes is a particularly valuable functionalization reaction in view of the great versatility of alkenes as organic feedstock. Crabtree *et al.* first showed in 1979 that transition-metal phosphine complexes could effect stoichiometric dehydrogenation of alkanes;[2] this was later extended to catalytic dehydrogenation.[3,4] The high endothermicity of dehydrogenation was compensated for by either the use of a sacrificial hydrogen acceptor or by UV irradiation.[5]

Such systems were all plagued by ligand decomposition, however, and it was not until 1988 that the first 'high-turnover' ( > *ca.* 100 turnovers) dehydrogenation system was discovered: $Rh(PMe_3)_2(CO)Cl$ under UV irradiation.[6] This robust catalyst was later found to yield efficient thermochemical dehydrogenation through the use of sacrificial hydrogen acceptors and, surprisingly, added dihydrogen; unfortunately, the presence of $H_2$ atmosphere resulted in the hydrogenation of more than one mole sacrificial acceptor per mole dehydrogenated product.[7]

Most recently, the development of the first 'high-turnover' thermochemical catalysts not requiring $H_2$ atmosphere was reported: complexes of the 'pincer' ligand $\eta^3$-$C_6H_3(CH_2P$-$Bu^t_2)_2$-1,3 (PCP), including (PCP)$RhH_2$ or, more effectively, (PCP)$IrH_2$.[8]

The key to the effectiveness of the PCP-based catalysts appears to be their long-term stability at very high temperatures (*e.g.* 200 °C).[9] We considered that such temperatures are sufficiently high, in principle, to overcome the large positive enthalpy of dehydrogenation without the use of a sacrificial acceptor.†[10] This was indeed found to be the case and the remarkable stability of the catalyst is maintained under such conditions. Herein, we report the first example of efficient alkane dehydrogenation catalyzed homogeneously without the use of either light or a sacrificial hydrogen acceptor.

Refluxing a cyclooctane solution of (PCP)$RhH_2$ (10 mM) while passing a stream of argon above the condenser results in negligible rates of cyclooctene formation, ( < 2 mM after 24 h). As was found when sacrificial acceptors were used, the iridium analog is much more effective for 'acceptorless' dehydrogenation. Under similar conditions [2 mM (PCP)$IrH_2$], the initial rate of cyclooctene (COE) formation is 11 turnovers $h^{-1}$.‡

After 44 h, 104 turnovers are obtained; after 120 h, 190 turnovers are produced. These results may be compared with the most effective soluble 'acceptorless' dehydrogenation catalyst reported to date: $IrH_2(O_2CR)(PCy_3)_2$ (1.25 mM) was reported to yield 1.41 turnovers $h^{-1}$ COE, with a maximum of 28.5 turnovers obtained after 48 h.[11]

The high endothermicity of alkane dehydrogenation is obviously a key factor involved in the challenge of developing alkane dehydrogenation catalysts, particularly in developing an acceptorless dehydrogenation system. In this respect cyclooctane is anomalous, since its dehydrogenation enthalpy of 23.3 kcal $mol^{-1}$ contrasts with *ca.* 28–30 kcal $mol^{-1}$ required for the elimination of two secondary C–H bonds from more typical alkanes.[10] Extrapolation to typical alkanes, based on behavior observed with cyclooctane, is therefore, *a priori*, quite tenuous. We find, however, that the catalytic efficacy of (PCP)$IrH_2$ with other alkanes is at least comparable to that with cyclooctane and the higher reflux temperatures of less volatile solvents permit significantly greater rates. For example, in refluxing cyclodecane (201 °C), 170 and 360 turnovers cyclodecene are obtained after 4 and 24 h, respectively (*ca.* 3 : 1 *cis : trans*; 1.0 mM catalyst; see Fig. 1). This rapid dehydrogenation occurs in spite of the high dehydrogenation enthalpy of cyclodecane (30 and 33 kcal $mol^{-1}$ to form *cis*- and *trans*- cyclodecene, respectively).[10]

The decrease in the rate of alkene formation which invariably occurs with time is probably not due to inevitable decomposition of the catalyst but may be caused by build-up of alkene product. Accordingly, a fresh solution of catalyst in cyclooctane, to which had been added 10% COE, showed no increase in COE concentration upon reflux. The mechanism by which the alkene product inhibits the reaction remains to be determined.

Significant amounts of cyclooctane can also be dehydrogenated to give COE and molecular hydrogen in reactions carried out in a closed system under reduced pressure. In a typical experiment, a solution of cyclooctane (4.0 ml) and (PCP)$IrH_2$ (3 mg, 0.005 mmol) was sealed in a tube under 0.007 mbar of argon and fully immersed in a 200 °C oil bath. After 0.5 h, 10 turnovers of COE had been produced. The production of $H_2$ was confirmed by gas chromatographic analysis† of the vapor above

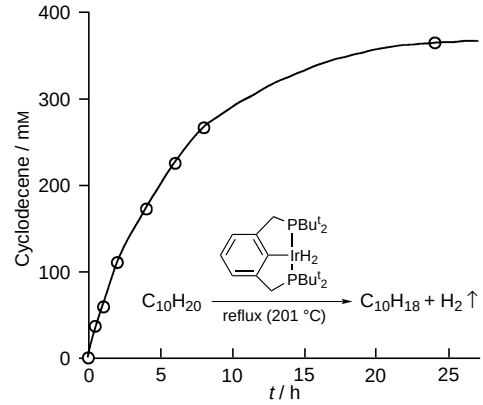

**Fig. 1** Cyclodecene formation (total, *ca.* 3 : 1 *cis*:*trans*) *vs.* time; (PCP)$IrH_2$ in refluxing cyclodecane (1.0 mM, 201 °C)

the reaction mixture. Increased levels of cyclooctane dehydrogenation were not observed in solutions which were heated for longer reaction times. However, additional dehydrogenation activity was achieved in solutions which had been heated to 200 °C for 0.5 h by removing the resulting $H_2$ by freeze–pump–thaw degassing. A total of 36 turnovers of COE were obtained in an experiment in which $H_2$ was removed four times through this procedure. These results demonstrate that under these conditions the catalysis is limited by equilibrium constraints rather than catalyst stability.

The PCP ligand clearly bears a close relationship (at least formally) to the ligand set in the putative catalytically active fragments $M(PR_3)_2Cl$ (M = Rh,[7] Ir[12]). In the case of the chloride complexes, rhodium has proven to be the more effective metal (for both transfer- and photo-dehydrogenation).[13] Thus the much greater efficacy of Ir *vs.* Rh in the case of the PCP complexes presents an issue which merits attention.

Although complexes $Rh(PR_3)_2ClH_2$ are classical dihydrides,[14] Milstein has reported the $T_1$ of $H_2Rh[\eta^3\text{-}HC(CH_2CH_2PBu^t_2)_2]$ to be 30–60 ms (−40 °C, 400 MHz)[15] strongly indicating the presence of a dihydrogen ligand. The closely related $(PCP)RhH_2$[16] is apparently also a dihydrogen complex: we find a $T_1$ value of 46 ms at 293 K (500 MHz)[17] and an H–D coupling constant of 33 Hz for (PCP)RhH(D).

We have previously reported that addition of $H_2$ to $Rh(PPr^i_3)_2Cl$ [to give $H_2Rh(PPr^i_3)_2Cl$] is highly exothermic ($\geqslant$ 33 kcal mol$^{-1}$).[18] The fact that $H_2$ addition to Rh(PCP) does not even cleave the H–H bond suggests that addition is much less favorable. Indeed, *ab initio* electronic structure calculations¶ yield remarkably different reaction energies for $H_2$ addition to the model fragments $Rh(PH_3)_2Cl$ and $Rh(PH_3)_2Ph$: −28.5 and −4.2 kcal mol$^{-1}$, respectively (producing dihydride and dihydrogen complexes, respectively, in accord with observation). In the case of Ir, the additions are much more exothermic though the difference between chloride and phenyl complexes is similar; respective values are $Ir(PH_3)_2Cl$: −54.1 kcal mol$^{-1}$ and $Ir(PH_3)_2Ph$: −23.0 kcal mol$^{-1}$.¶ These computational results strongly suggest a simple explanation for the very high catalytic activities of the $Rh(PR_3)_2Cl$ and Ir(PCP) fragments as compared with the 'converse' pair [*i.e.* Rh(PCP) and $Ir(PR_3)_2Cl$]. For Rh, the PCP complex adds $H_2$ too weakly. This implies not only that transfer of $H_2$ from alkane to rhodium is unfavorable, but it also suggests that C–H addition may be unfavorable, since $H_2$ normally adds much more favorably than C–H bonds. For Ir, $H_2$ addition to the chloride complex is highly exothermic; this may inhibit thermal loss of $H_2$ or even transfer of $H_2$ to a sacrificial acceptor. Thus, the similar affinities of the $Rh(PR_3)_2Cl$ and Ir(PCP) fragments for $H_2$ (*viz.*, −28.5 and −23.0 kcal mol$^{-1}$) may help explain their similarly high catalytic activities. In the case of the Rh complex, however, $H_2$ is needed to cleave the μ-Cl bridge and catalyst decomposition is observed at very high temperatures ($\gg$100 °C).[7] In the case of the Ir(PCP) unit, formation of analogous anion-bridged dimers is not possible and presumably the rigidity of the PCP ligand endows the complex with resistance to decomposition that is highly unusual for a transition-metal phosphine complex. Apparently, ligand stability and the appropriate (but unremarkable) energetics of oxidative addition to the Ir(PCP) fragment are the key factors resulting in the unprecedented ability to effect efficient alkane dehydrogenation without the use of light or a sacrificial acceptor.

† For example, if $\Delta G^{\neq}$ = 30.0 kcal mol (1 cal = 4.184 J), at 200 °C the catalytic turnover rate would be 500 h$^{-1}$. Since the dehydrogenation enthalpy of typical alkanes is on the order of 28–30 kcal mol$^{-1}$,[10] reasonable rates could be obtained (in principle) even if the favorable reaction entropy does not make any contribution in the transition state. Of course, a significant concentration of alkene can only be obtained by allowing hydrogen to escape, thereby permitting entropy to predominate over enthalpy.

‡ Addition of liquid Hg to the solution has no measurable effect on the rate of COE formation, indicating that the catalyst is not colloidal iridium: D. R. Anton and R. H. Crabtree, *Organometallics*, 1983, **2**, 855.

§ Density functional theory calculations including geometry optimization employing the B3LYP hybrid functional; effective small-core potentials and double-zeta basis sets on Rh and Ir (LANL2DZ model); all-electron basis sets for main group atoms: D95(d) for C, P and Cl, 6-311G(p) for dihydrogen and hydrides, and 3-21G for other H atoms. To model the PCP structure, the phenyl groups in the $M(PR_3)_2Ph$ complexes were held coplanar with the Ir and P atoms.

¶ Similarly, methane C–H addition to $Ir(PH_3)_2Cl$ is reported to be 29 kcal mol$^{-1}$ more exothermic than addition to $Ir(PH_3)_2H$ (−41.6 and −12.8 kcal mol$^{-1}$, respectively): T. R. Cundari, *J. Am. Chem. Soc.*, 1994, **116**, 340.

**A simple rapid solution-based method for forming the oxide layer at porous silicon is described which uses amphiphilic molecules to wet the hydrophobic porous structure.**

Porous silicon (PS) has received much interest in recent years owing to its remarkable luminescent properties allied with the possible compatibility of the material with existing semiconductor processing techniques.[1] However, it is well known that as-prepared PS exhibits weak and unstable photoluminescence (PL) as a consequence of the slow oxidation of the hydrogen-terminated silicon surface in air.[2] As a result, numerous post-formation treatments of PS have been reported which aim to stabilize the PL through the formation of a passivating oxide layer.[3] Some of these treatments involve mild oxidation by immersion of the PS in organic solvents prior to thermal oxidation but little explanation has been given as to the mechanism of this initial oxidation.

Here we report on a simple, rapid chemical procedure for the formation of the oxide layer at porous silicon using a dilute aqueous solution of the surfactant, hexadecyltrimethylammonium bromide. These findings are discussed in terms of the influence of the wetting properties of porous silicon on the mechanism of oxide formation. The consequences of this have significant implications for the recent efforts towards the development of covalent modifications of porous silicon surfaces.[4,5]

Porous silicon was formed by galvanostatic anodisation of a p- doped Si(100) wafer in a 50 : 50 solution of 48% aqueous HF and ethanol in a Teflon cell, with a current density of 19 mA $cm^{-2}$ for 4 min. The PS was then rinsed in de-ionised water (Millipore, 18 MΩ) to remove ethanol, immersed in 48% aqueous HF to ensure removal of any remaining oxide and finally rinsed in de-ionised water (20 s) and dried in a $N_2$ stream. An FTIR spectrum indicated that samples so prepared were hydrogen-terminated with little, or no oxide, present. These samples were then immersed in 1 mM aqueous solution† of hexadecyltrimethylammonium bromide (CTAB) and comparisons were made with samples treated with de- ionised water. Oxidation of the PS in de-ionised water and CTAB solution was followed using FTIR spectroscopy and Fig. 1 shows the spectra for a CTAB-treated sample. In each case the spectra show loss of intensity of $Si–H_x$ modes ($Si–H_x$ stretching modes around 2100 $cm^{-1}$ and the $SiH_2$ scissors mode at 910 $cm^{-1}$ ) and an increase in intensity of bands due to Si–O (1135, 1075, 878 $cm^{-1}$) and $O_xSi–H$ (2250, 2220 $cm^{-1}$).[6] The CTAB-treated PS also showed some evidence for adsorption of surfactant with bands observed in the C–H stretch region.

Oxidation in de-ionised water was very slow, taking place over a few days, whereas the reaction in CTAB solution was extremely rapid accompanied by visible gas evolution, assumed to be hydrogen on the basis of the expected reactions (1) and (2).[7]

$$Si–H + H_2O \rightarrow Si–OH + H_2 \quad (1)$$

$$Si–OH + H_2O \rightarrow SiO_2 + 3/2\ H_2 \quad (2)$$

Figs. 2 and 3 show plots of the integrated intensity of the Si–O modes and Si–H stretch modes *vs.* log (immersion time/min), respectively, and give clear evidence for a correlation between loss of Si–H and gain of Si–O modes. In addition to the significantly increased rate in CTAB solution it is also evident that almost twice as much oxidation occurs compared to water. Moreover, the total surface area of the CTAB-treated sample was 13% less than the control, as evidenced by the integrated intensity of the $Si–H_x$ stretch modes prior to oxidation. This

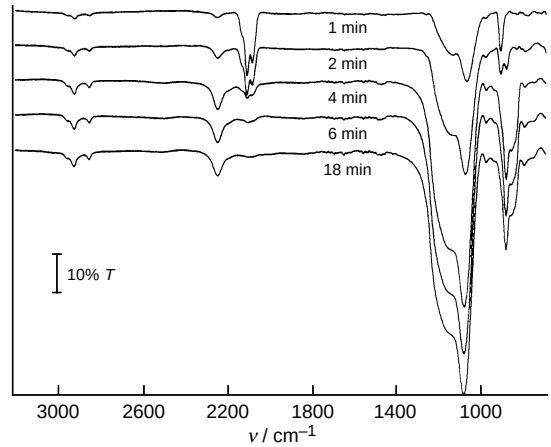

**Fig. 1** Transmission FTIR spectra for CTAB-treated porous silicon

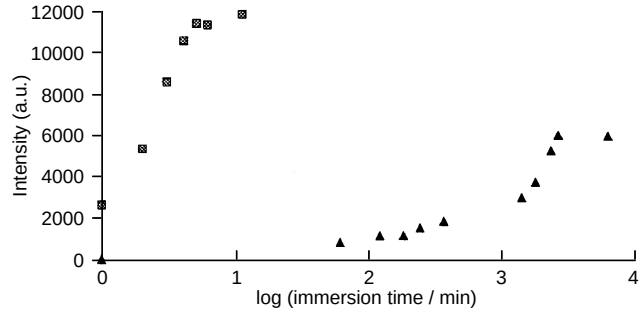

**Fig. 2** Plot of integrated intensity of the Si–O modes *vs.* log(immersion time/min) for water ( ▲ ) and CTAB-treated porous silicon (■)

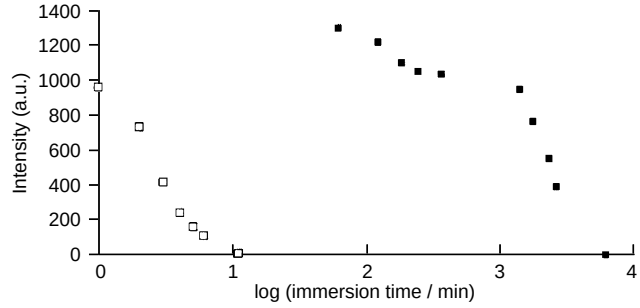

**Fig. 3** Plot of integrated intensity of the Si–H stretching mode *vs.* log(immersion time/min) for water (■) and CTAB-treated porous silicon (□)

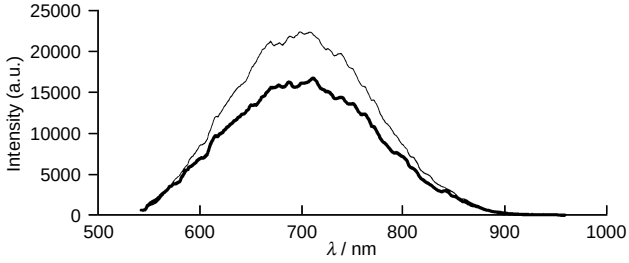

**Fig. 4** PL spectra of porous silicon before (—) and after treatment with CTAB (—)

shows that a greater percentage of the hydrogen-terminated surface is accessible to water molecules in the presence of CTAB.

PL spectra‡ of both as-prepared and CTAB-treated samples show a maximum at ~680 nm, typical of porous silicon (Fig. 4). Despite evidence from the IR spectra that no material is lost on CTAB-treatment, a small decrease in PL intensity is observed.§

The very significant enhancement of the oxidation by CTAB can be explained by considering the nature of the porous layer. Studies have shown that PS layers consist of silicon columns attached to the crystalline substrate with pore sizes in the nanometre range. The surface is highly hydrophobic with a large surface area (100–400 $m^2$ $cm^{-3}$).[1] The rapid oxidation observed in the CTAB-treated sample is explained as being due to a lowering of the surface tension ($\gamma$) of the liquid phase. Water can only oxidize the PS if it is in intimate contact with it. Immersion wetting of the PS is therefore a prerequisite to oxidation. Wetting will occur when:[8] $\gamma_{PS/air} > \gamma_{PS/H_2O} + \gamma_{H_2O/air}$.

Owing to the high surface tension of water ($\gamma_{H_2O/air}$ = 72.75 mN $m^{-1}$) and the hydrophobic nature of the PS surface, water does not spontaneously wet PS. The addition of CTAB lowers both $\gamma_{PS/H_2O}$ and $\gamma_{H_2O/air}$ thereby ensuring more complete wetting. Water molecules are therefore able to penetrate more effectively the porous structure leading to increased oxidation.

This finding has a considerable bearing on the post-preparation treatments and also for the more recent interest in the development of synthetic routes for the formation of molecular films at PS.[4,5] Specifically, the choice of solvent or reactant must take these effects into account. Most organic solvents have a significantly lower surface tension than water and may wet the PS surface more effectively on immersion.[9] Even nominally dry solvents will, if hygroscopic, absorb water from the surroundings thus enabling water, dissolved in the solvent, to penetrate, and oxidize, the PS.

Indeed, proof of this was demonstrated by immersion of PS in solvents under dry nitrogen using conventional Schlenk techniques to minimize contamination by water. Immersion in dry acetonitrile (distilled over $CaH_2$) for 30 min reveals considerable oxidation as observed by IR spectroscopy, equivalent to 4 h immersion in de-ionised water. Similar results were obtained with ethanol and ether, whereas no oxidation was observed with hexanes. The extent of oxidation is therefore clearly associated with the solvent's affinity for water.¶ These data reaffirm the acknowledged fact that under standard Schlenk line conditions adventitious water is present in sufficient quantity for oxidation to occur.[10]

These results suggest that the use of hygroscopic solvents in the chemical modification of PS is to be avoided if oxidation is undesirable. It is noteworthy that a recent report on the derivatization of PS using alcohols stresses the need for anhydrous conditions in the formation of alcohol-derived molecular films.[5]

In conclusion, the effect of organic molecules on the oxidation of hydrogen-terminated porous silicon is highly dependent on their hygroscopic nature and ability to lower the PS surface tension. This may be exploited for the rapid formation of an oxide layer. These findings are also relevant to chemists developing synthetic strategies for the covalent modification of PS.

† This concentration is close to the critical micelle concentration of CTAB ($9.2 \times 10^{-4}$ M) ensuring a minimum in surface tension for the liquid phase at minimum CTAB concentration.[11]

‡ Photoluminescence spectra were recorded using an EG&G Princeton Applied Research Peltier cooled photodiode array system (150 ms exposure time, 0.7 nm spectral resolution). Excitation was at 488 nm using a Spectra-Physics model 2010 argon ion laser and measured at room temp. (20–21 °C).

§ A recent review[1] has emphasised that the effect of oxidative treatments on PS luminescence intensity and peak wavelength varies between laboratories. Reports of both intensity decreases and increases and red or blue shifts have been made. A decrease in PL intensity on oxidation may be explained as due to the production of a strained $SiO_2$ layer containing defects which act as nonradiative recombination centres.[12]

**Water-insoluble porphyrins dissolve in aqueous solutions of amphiphilic polymers to give systems which mimic the action of peroxidase enzymes.**

Porphyrins hold an important position in oxidative mechanisms of metabolism, ranging from the oxygen-carrying capacity of haemoglobins to the oxidative reactions of cytochrome and peroxidase enzymes.[1] Mechanisms of reaction, in which an oxygen atom is transferred from a donor (*e.g.* $O_2$, $H_2O_2$, hydroperoxides, hypochlorites, iodates, iodosobenzene) to a substrate such as an alkene to form an epoxide or to an alkane or arene to form a hydroxy derivative, have been extensively examined, particularly for cytochrome P450 systems.[2] More recently, there has been considerable development of model cytochrome P450 enzyme systems as catalysts for oxidation.[3] Most research on peroxidases has been done with horse radish peroxidase[4] and sensitive tests have been developed to distinguish peroxidases from cytochromes P450.[5] However, relatively little research into peroxidase mimics has appeared and mostly has not distinguished between peroxidase and cytochrome P450 reaction mechanisms.[6] The present work describes a mimic for a peroxidase, which has intrinsic activity similar to that of horse radish peroxidase.

A variety of water-soluble iron or manganese porphyrins was prepared through sulfonation and metallation of 5,10,15,20-tetraarylporphyrins.[7] Other water-soluble metallo derivatives were prepared from 5,10,15,20-tetrakis(1-oxidopyridin-1-ium-4-yl)porphyrin[8] and from 5,10,15,20-tetrakis{4-[ω-hydroxypoly(ethoxy)ethoxy]phenyl}porphyrin.[8] As a quick test of the capacity of these water-soluble porphyrins for catalysing electron-transfer type oxidation with longevity of action, their ability to bleach a small range of red, orange and blue water-soluble dyes was examined, using $H_2O_2$ as the primary oxidant.[9] In all cases, 2–30% bleaching of the azo, anthraquinone and phthalocyanine dyes was observed but complete auto-oxidation and destruction of the porphyrin catalyst itself always occurred first and stopped the reaction. Indeed, with $H_2O_2$ alone and no added dye, the water-soluble manganese or iron 5,10,15,20-tetrakis(4-sulfophenyl)porphyrins were destroyed in 30 s and 2 min, respectively. Because cytochrome and peroxidase enzymes (albeit enveloped in a protein coat) can utilise $H_2O_2$ and porphyrin in an aqueous environment, it was decided to attempt to mimic the action of these proteins through use of synthetic porphyrins carried in amphiphilic water-soluble polymers. Two such examples of carriers used in the present work are poly(sodium styrene-4-sulfonate-*co*-2-vinylnaphthalene) (PSSS-VN) and poly(sodium styrene-4-sulfonate-*co*-2-vinylpyridine) (PSSS-VP).[10] It was found that porphyrins in PSSS-VN co-polymers formed systems that behaved like a typical peroxidase (horse radish peroxidase) and unlike P450 cytochromes.

Epoxidation of alkenes with $H_2O_2$ and P450 metalloporphyrin model catalysts is typically carried out under biphasic conditions.[11,12] Here, manganese(III) 5,10,15,20-tetraphenylporphyrin in aqueous PSSS-VN polymer with added imidazole effected the epoxidation of cyclooctene (48%), 1-methylcyclohexene (29%) and 2,3-dimethylbut-2-ene (7%) in $CH_2Cl_2$–aq. $H_2O_2$ but only very slowly and in the poor yields indicated. Significantly, the porphyrin survived these reactions with little auto-oxidation during 48 h. The percentage conversions are not only low but are in the reverse order of reactivity normally found for epoxidation of these alkenes with peroxy acids or cytochrome mimics, and indicate that the epoxidation was not the result of direct oxygen transfer from the metal centre of the porphyrin.

A number of substrates has been used to estimate peroxidase activity.[13] All of those tested in this work (phenols, amines, leuco dyes, ferrocyanide) gave positive responses with the PSSS-VN–porphyrin system, and were inactive in the presence of cyanide ion. Most of these substrates do not distinguish cytochrome P450 from peroxidase activity. The most definitive tests for peroxidase activity are generally considered to be colour reactions of guaiacol, mesidine and, particularly, the diammonium salt of 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS).[5] The PSSS-VN–porphyrin system showed significant activity in all of the above tests[13] but only the last three[5] were examined in kinetic detail to distinguish peroxidase specifically from cytochrome P450 activity. The graphs in Fig. 1 compare the rates of oxidation of ABTS with hydrogen peroxide alone and also in the presence of authentic horse radish peroxidase or manganese(III) 5,10,15,20-tetraphenylporphyrin in aqueous PSSS-VN polymer. The results have been normalised for the amounts of porphyrin in the

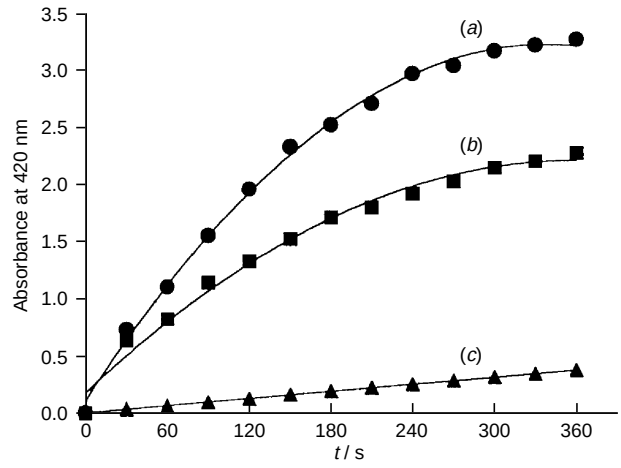

**Fig. 1** Graph showing the oxidation of ABTS by $H_2O_2$ in the presence of (*a*) horse radish peroxidase catalyst, (*b*) $Mn^{III}$ tetraphenylporphyrin–PSSS-VN polymer catalyst, and (*c*) no added catalyst. For (*a*), ABTS stock solution (0.2 ml) was mixed with $H_2O_2$ stock solution buffered to pH 8 (0.2 ml) and then horse radish peroxidase stock solution (2 ml) was added; the oxidation was monitored over a period of 6 min by the appearance and UV–VIS absorbance of a band at 405 nm due to the ABTS radical cation. After this time, the $H_2O_2$ had been used up. For (*b*), a similar solution was prepared and monitored but using a porphyrin–PSSS-VN stock solution in place of horse radish peroxidase. For (*c*), only $H_2O_2$ and ABTS solutions were mixed and monitored at 405 nm. For normalization purposes, the solutions were also monitored at 420 nm (porphyrin Soret band) so as to calculate the molar concentrations of porphyrin in the horse radish peroxidase and in the PSSS-VN system; the ABTS radical cation absorbance was divided by the molar concentration of porphyrin.

aqueous peroxidase and polymer solutions. Whilst horse radish peroxidase causes faster oxidation of ABTS, the biomimetic porphyrin–polymer system is 70% as fast; in the absence of either the authentic or artificial peroxidase, oxidation of ABTS with $H_2O_2$ is very slow. Similarly, the comparative effects of horse radish peroxidase and the PSS-VN–porphyrin system as catalysts in the $H_2O_2$ oxidation of guaiacol and mesidine showed that the authentic peroxidase and its mimic gave comparable rates of reaction and both exhibited a greatly increased rate compared with that for reaction with $H_2O_2$ alone. When the amphiphilic PSSS-VN polymer was replaced by the more hydrophilic PSSS-VP, the normally water-insoluble porphyrins dissolved as usual but the peroxidase-like activity was greatly reduced. It is notable that, in all these oxidations, the simple water-insoluble porphyrins such as manganese(III) 5,10,15,20-tetrakis(4-methoxyphenyl)porphyrin, when solubilised in water containing the amphiphilic polymer, were destroyed only very slowly as compared with the rapidity of auto-oxidation of similar water-soluble porphyrins in the absence of polymer. This stability suggests that the water-insoluble porphyrin molecules in the inner hydrophobic sphere of the PSSS-VN polymer must be isolated from each other so as to prevent mutual oxidation; the behaviour is characteristic of natural peroxidases.

The substrates to be oxidised (ABTS, guaiacol and mesidine) are soluble in water. For horse radish peroxidase, their approach to the metal centre in the porphyrin is prevented by the protein coat. For the PSSS-VN–porphyrin system it is probable that the porphyrin is not only held in the hydrophobic core of the PSSS-VN polymer in water but is isolated by intercalation between the many naphthalene residues in such a way that the oxidised metal centre is not open to approach by the substrate. Aggregation of polycyclic aromatic species through π–π interactions are well-known through UV effects[14] and it was found here that, in these PSSS-VN polymer–porphyrin systems, the Soret band near 420 nm is significantly broadened and reduced in height as compared with the free porphyrin.[8] Also, Mössbauer spectroscopy of the solid isolated by evaporation of water from a PSSS-VN polymer–iron porphyrin system revealed a small shift in the iron peak, suggesting electronic interaction of the porphyrin with surrounding groups.[8] Further, the substrates to be oxidised are water soluble and would not be expected to appear in the hydrophobic core of the polymer. Thus, for reaction to occur, an edge or edges of the porphyrin must be available for electron transfer reactions at the junction of the outer hydrophilic and inner hydrophobic surfaces of the polymer. If this is the case then the oxidation reactions catalysed by the PSSS-VN–porphyrin system would be closely similar to those typical of natural peroxidases and might be expected to have similar activity.

One difference between the natural enzymes and the PSSS-VN system lies in the absence of a formal apical ligand to the metal centre in the porphyrin in the latter. In horse radish peroxidase, this function is served by an imidazolyl nitrogen atom.[1b] In the PSSS-VN system at pH 8, the only apical ligand is likely to be $H_2O$ or $OH^-$. As catalytic activity in metalloporphyrins is influenced by the nature of such apical ligands, the activities of the horse radish peroxidase and the PSSS-VN–porphyrin mimic might not be expected to be identical. However, it has been demonstrated for oxidising systems with simple porphyrins as catalysts that the easily oxidised imidazole ligand can be profitably replaced by other ligands,[15a,b] including non-oxidisable inorganic varieties.[15a] It is encouraging that the rates of oxidation in the two systems are closely similar and that the porphyrin in the PSSS-VN polymer is not rapidly destroyed through auto-oxidation. In other work to be reported elsewhere, it is shown that a catalytic system, in which a porphyrin is covalently bonded between naphthalene residues in an analogue of PSSS-VN polymers, also behaves similarly and that even very simple sandwich molecules having a porphyrin covalently bonded between aromatic residues mimic the action of a peroxidase. It is concluded that porphyrins held in PSSS-VN amphiphilic polymers mimic peroxidase enzymic activity and do not behave like most other model porphyrin enzyme mimics, which resemble P450 cytochromes.

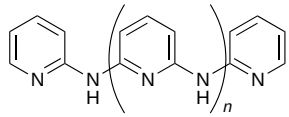
# New oligo-α-pyridylamino ligands and their metal complexes

**Ming-hwa Yang, Tzu-Wei Lin, Chin-Cheng Chou, Hsiao-Ching Lee, Hsiao-Chi Chang, Gene-Hsiang Lee, Man-kit Leung* and Shie-Ming Peng*†**

*Department of Chemistry, National Taiwan University, Taipei, Taiwan*

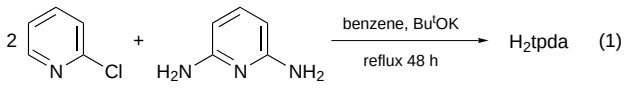


**Three novel oligo-α-pyridylamino ligands, tripyridyldiamine ($H_2$tpda), tetrapyridyltriamine ($H_3$teptra), pentapyridyltetramine ($H_4$peptea) are synthesized; the crystal structures of their metal complexes with the all-*anti* configuration of the chelating ligands are reported.**

Oligo-α-pyridines **I** exhibit an α-diimine functionality and chelating ability, they bind metal ions strongly and are used as building blocks for the self-assembly of metallosupramolecules.[1–3] We are interested in developing a new type of ligand which might bind oligonuclear metal ions chain; the oligo-α-pyridylamino ligands **II**.[4–6]

**I**

*n* = 0, bipyridine
*n* = 1, terpyridine
*n* = 2, quaterpyridine
*n* = 3, quinquepyridine
*n* = 4, sexipyridine



**II**

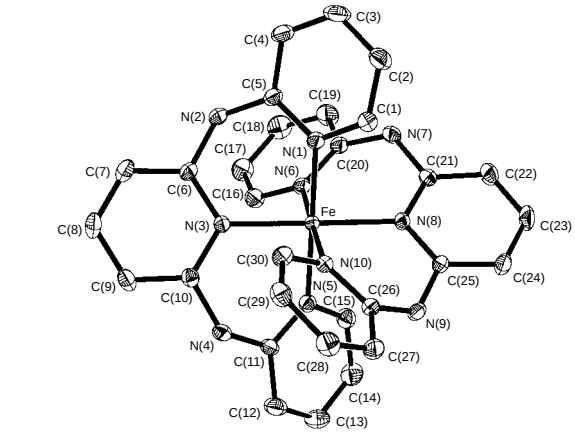
*n* = 0, dipyridylamine(Hdpa)
*n* = 1, tripyridyldiamine($H_2$tpda)
*n* = 2, tetrapyridyltriamine($H_3$teptra)
*n* = 3, pentapyridyltetramine($H_4$peptea)

Here, we report the synthesis of three novel oligo-α-pyridylamino ligands, tripyridyldiamine ($H_2$tpda), tetrapyridyltriamine ($H_3$teptra), and pentapyridyltetramine ($H_4$peptea). The crystal structure of their metal complexes with the all-*anti* conformation of the chelating ligands are presented.

The tripyridyldiamine ligand was synthesized by treating 2.2 equiv. of chloropyridine with 1 equiv. of 2,6-diaminopyridine under basic conditions [eqn. (1)]. The crude product was rinsed with water and recrystallized from propan-2-ol.[7] The iron complex of the ligand was synthesized by treating iron(II) chloride with 2 mol equiv. of $H_2$tpda in methanol [eqn. (2)]. The electronic spectrum (MeOH solution), shows maxima at 240 nm ($3.04 \times 10^4$ dm$^3$ mol$^{-1}$ cm$^{-1}$), 262 ($3.67 \times 10^4$), 278 ($3.81 \times 10^4$) and 334 ($3.72 \times 10^4$).

The molecular structure of $[Fe^{II}(H_2tpda)]^{2+}$ (Fig. 1)‡ reveals that the coordination geometry around $Fe^{II}$ is octahedral with two tridentate $H_2$tpda ligands arranged in a *mer*-configuration. The $H_2$tpda ligands coordinate to the iron(II) in an *anti–anti–anti–anti* conformation. The three pyridyl groups of the $H_2$tpda ligand are essentially planar and are twisted. The dihedral angle between each pair of neighboring pyridyl planes is 38°. The short Fe–N distances, ranging from 1.981(2) to 2.005(2) Å, are consistent with the low spin state of $Fe^{II}$.

The tetrapyridyltriamine ligand was synthesized by the palladium-catalyzed cross-coupling[8] of (6-bromo-2-pyridyl)(2′-pyridyl)amine and (6-amino-2-pyridyl)(2′-pyridyl)amine in the presence of catalyst [$Pd_2(dba)_3$, dppp, BuᵗOK, and 18-crown-6] in refluxing benzene [eqn. (3)]. The crude product was recrystallized from propan-2-ol. $H_3$teptra was characterized on the basis of $^1$H and $^{13}$C NMR spectroscopy, and mass spectrometry. $^1$H NMR in $(CD_3)_2SO$ clearly shows two singlets ($\delta$ 9.33, 9.07), four doublets ($\delta$ 8.19, 7.88, 7.72, 7.10) and three triplets ($\delta$ 7.62, 7.50, 6.84) which are consistent with the structural assignment.



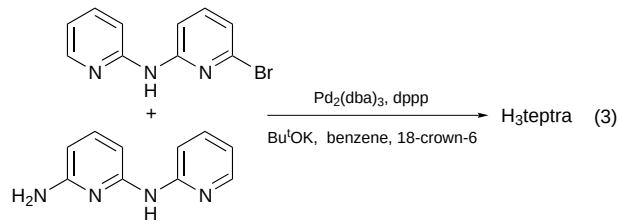


**Fig. 1** ORTEP view of $[Fe(H_2tpda)_2]^{2+}$. Selected bond lengths (Å) and angles (°): Fe–N 1.981(2)–2.005(2), av. 1.995; *cis*-N–Fe–N 88.68(9)–91.85(9), av. 90.0, N(1)–Fe–N(5) 179.2(1), N(3)–Fe–N(8), 179.2(1), N(6)–Fe–N(10), 178.6(1); dihedral angles between interpyridyl planes, Py(N1)–Py(N3), 40.8(1), Py(N3)–Py(N5), 34.4(1), Py(N6)–Py(N8), 40.2(1), Py(N8)–Py(N10), 37.6(1).

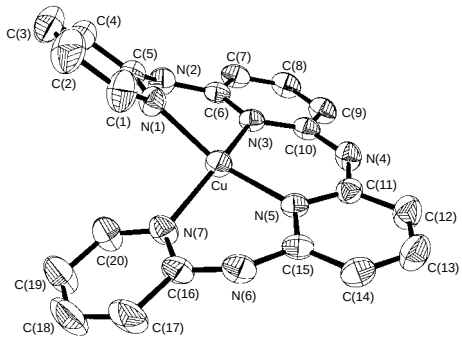
The $Cu^{II}$ complex of the ligand was synthesized by treating an equimolar amount of $Cu(ClO_4)_2$ and the $H_3$teptra in acetonitrile [eqn. (4)]. The electronic spectrum (MeCN solution), shows maxima at 239 nm ($2.70 \times 10^4$ dm$^3$ mol$^{-1}$ cm$^{-1}$), 270(sh) ($1.59 \times 10^4$), 328 ($3.77 \times 10^4$) and 368 ($9.71 \times 10^3$).

The molecular structure of $[Cu^{II}(H_3teptra)]^{2+}$ (Fig. 2)‡ reveals that the coordination geometry around $Cu^{II}$ is between planar and tetrahedral with the monohelical $H_3$teptra ligand having an all-*anti* comformation. The four pyridyl groups of the $H_3$teptra ligand are planar and the dihedral angle between each



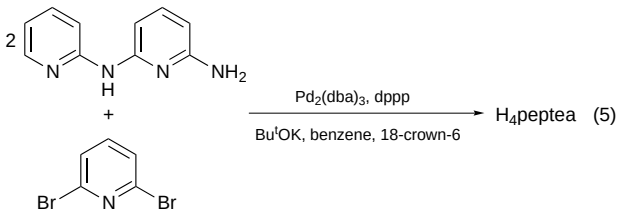


**Fig. 2** ORTEP view of $[Cu(H_3teptra)]^{2+}$. Selected bond lengths (Å) and angles (°): Cu–N 1.954(5)–1.982(5), av. 1.967; N(1)–Cu–N(3), 91.9(2), N(1)–Cu–N(5), 151.0(2), N(1)–Cu–N(7) 90.9(2), N(3)–Cu–N(5), 98.2(2) N(3)–Cu–N(7), 150.0(2), N(5)–Cu–N(7), 93.0(2); dihedral angles between interpyridyl planes, Py(N1)–Py(N3), 25.3(3), Py(N3)–Py(N5), 15.0(1), Py(N5)–Py(N7), 20.4(2).

pair of neighboring pyridyl planes is 25.3(3), 15.0(3), 20.4(3)°, respectively. The short Cu–N distances, ranging from 1.954(5) to 1.982(5) indicate a strong binding of the chelating ligand.

The synthesis of pentapyridyltetramine was similar to $H_3$teptra [eqn. (5)]. $H_4$peptea was characterized on the basis of its $^1$H and $^{13}$C NMR and mass spectrometry data. Although the $^1$H NMR spectrum of $H_4$peptea [in $(CD_3)_2SO$] only shows two singlets ($\delta$ 9.33, 9.06), five doublets ($\delta$ 8.19, 7.90, 7.28, 7.19, 7.08) and three triplets ($\delta$ 7.62, 7.50, 6.84), the intergrated area of the triplet at $\delta$ 7.50 is equivalent to that originating from three protons when compared to the area of the other triplet, indicating the existence of two independent triplets with an identical chemical shift at $\delta$ 7.50.

The $Cu^{II}$ complex of the ligand was synthesized by treating an equimolar solution of $Cu(ClO_4)_2$ and $H_4$peptea in acetonitrile and precipitated by adding diethyl ether [eqn. (6)]. The electronic spectrum (MeCN solution), shows maxima at 254 nm ($1.87 \times 10^4$ dm$^3$ mol$^{-1}$ cm$^{-1}$), 324 ($1.97 \times 10^4$), 344 ($1.65 \times 10^4$) and 378(sh) ($6.21 \times 10^3$).

The crystal structure of $[Cu^{II}(H_4peptea)]^{2+}$ (Fig. 3)‡ reveals that the coordination geometry around $Cu^{II}$ is trigonal bipyramidal with the monohelical $H_4$peptea ligand existing in an all-*anti* configuration. A crystallographic $C_2$ axis runs through the C(13)–N(5)–Cu chain. The three independent crystallographic pyridyl groups are planar and the dihedral angle between neighboring pyridine planes is *ca.* 21°.

In summary, the modified Buchwald's procedure[8] leads to the synthesis of new types of oligo-α-pyridylamino ligands. Their metal complexes were studied. The complexes demonstrate the chelating ability of the ligands. Attempts to isolate the metal complexes with different coordination modes of the ligands, *e.g.* the all-*syn* configuration of the ligands which bind metal ions in a chain are being undertaken.

We thank the National Science Council of the Republic of China for financial support.

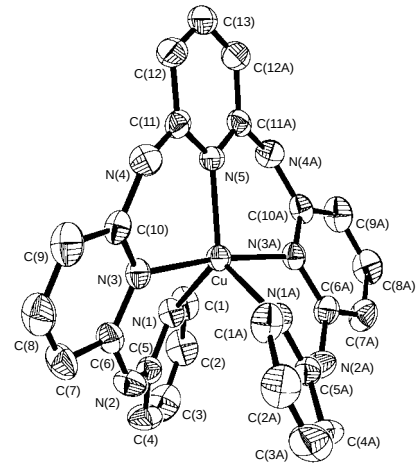

**Fig. 3** ORTEP view of $[Cu(H_4peptea)]^{2+}$. Selected bond length (Å) and angles (°): Cu–N(1) 2.102(5), Cu–N(3) 1.972(4), Cu–N(5) 2.017(6); N(1)–Cu–N(1A), 112.2(3), N(1)–Cu–N(3) 87.3(2), N(1)–Cu–N(3A), 88.4(2), N(1)–Cu–N(5), 123.9(1), N(3)–Cu–N(3A), 172.3(3), N(3)–Cu–N(5), 93.8(1); dihedral angles between interpyridyl planes, Py(N1)–Py(N3), 22.2(3), Py(N3)–Py(N5), 19.0(3).

# Mesoporous material containing framework tectosilicate by pore–wall recrystallization

**K. Richard Kloetstra, Herman van Bekkum and Jacobus C. Jansen**

*Laboratory of Organic Chemistry and Catalysis, Delft University of Technology, Julianalaan 136, 2628 BL Delft, The Netherlands*

**Partial recrystallization of the interporous aluminosilicate surface of MCM-41 and HMS by ion-exchanged tetrapropylammonium template results in a mesoporous material with surface-tectosilicate structures giving enhanced acidity and catalytic cracking activity.**

The development of the mesoporous molecular sieve MCM-41 by the workers of Mobil[1,2] has stimulated much research efforts in the field of acid[3,4] and base[5] catalysis. The strength of the acid sites of MCM-41 as well as of the related HMS material[6,7] is, however, rather weak compared to zeolites[8,9] owing to the amorphous character of the framework of both materials.[2,6–9] Here we report that upon increasing locally the crystallinity of the amorphous framework of MCM-41 and HMS, the acidity and catalytic activity improves substantially. The design of these catalysts is based on positioning tetrapropylammonium (TPA) cations at the interporous surface of MCM-41 and HMS which induces partial recrystallization of the pore wall *via* heterogeneous nucleation during thermal processing. Owing to short-range aluminosilicate–template interactions non-porous framework tectosilicate[10] is formed of the ZSM-5 precursor type.

Our approach to design a composite consisting of a mesoporous molecular sieve with interporous tectosilicate, denoted as porous nanocrystalline aluminosilicate (PNA) is based on the idea to recrystallize partially the amorphous framework of MCM-41 and HMS. By attachment of TPA cations, the template for ZSM-5,[11] onto the mesopore walls *via* an ion-exchange procedure a high dispersion of the TPA in the mesoporous material is achieved. This should result in a nucleation of ZSM-5 species and controlled conversion of MCM-41 and HMS. When the pre-positioning of TPA is omitted and a homogeneous aqueous mixture of TPAOH and MCM-41 is heated we observed that the MCM-41 is recrystallized overnight into aggregates of ZSM-5.[12] This process went even faster when purely siliceous MCM-41 was used, resulting in silicalite-1, which is however not useful in catalytic processes. Thus the need to pre-position TPA at the Al sites is a prerequisite to induce the recrystallization at the Al sites and suppress the diffusivity of TPA.

Considering partial recrystallization of MCM-41 and HMS, the ZSM-5 stoichiometry in the starting materials has to be optimized. It is well known that in as-synthesized ZSM-5 each TPA is surrounded by 24 tetrahedrally coordinated Si and/or Al atoms.[13] The Si/Al ratio (30) of the parent MCM-41 and HMS materials was chosen to be close to the above value. Here thirty one T-atoms (T = $SiO_4$ and/or $AlO_4^-$ tetrahedra) are neighbouring one TPA cation in TPA ion-exchanged MCM-41 (TPA-MCM-41). This ZSM-5 precursor-type situation is, according to Ostwald's rule of successive transformations,[10] expected to induce ZSM-5 crystallization Glycerol was selected as the solvent in the recrystallization, because it appeared to have unusual advantages in ZSM-5 synthesis. The high viscosity of glycerol will moderate zeolite growth and moreover glycerol can act as a stabilizing guest molecule.[14,15] It was proposed that various silicate structures are formed during aging due to the interaction of glycerol with silicate species.[15]

Calcined MCM-41 (1.0 g; Si/Al = 30; HNa-form)[5] was converted to TPA-MCM-41 by ion-exchange with a 50% excess of aqueous TPAOH ($2 \times 10^{-3}$ M solution) for 20 h, followed by washing and drying at 80 °C under vacuum. The Na/Al ratio decreased from 0.8 to 0.1 indicating a 90% substitution of $Na^+$ for TPA cations. TPA-MCM-41 with a tenfold excess mass of glycerol was loaded in a Teflon-lined autoclave and stirred for 2 h at room temp. and subsequently allowed to react at 120 °C statically for 24 h. Finally the material was collected by filtration, washed with demineralized water, dried at 100 °C and calcined at 500 °C for 5 h to remove the organics from the composite material (coded as PNA-1). Aluminosilicate HMS (Si/Al = 30; H-form)[16] was subjected to the same procedure resulting in the material PNA-2.

The substantial improvement of the catalytic activity, and thus the acidity, of the PNAs compared to the parent materials is demonstrated by the cracking of cumene (Table 1). The catalytic reactions were performed at 300 °C in a down-flow reactor (id = 7 mm) using 1 g of catalyst pellets (diameter 0.7–1.0 mm) and a $N_2$ flow of 25 ml $min^{-1}$ containing 14.4 μmol $min^{-1}$ of cumene. The parent MCM-41 and HMS materials in the $H^+$-form produce only benzene and propene with traces of α-methylstyrene. The enhanced cumene conversion over the PNAs is exclusively the result of a higher cracking activity.[17] The improved activity is therefore assigned to enhanced Brønsted acidity which is also reflected by the initial *n*-hexane cracking activity of the PNAs which is about four times higher than that of the MCM-41 and HMS materials. The PNAs showed no significant deactivation during 3 h on stream in the cumene reaction and showed similar activities after regeneration at high temperature indicating that the framework does not collapse and that the acid sites are still accessible. It may be mentioned that the cumene conversions over the four mesoporous aluminosilicates were not diffusion limited. This was, however, not the case for the cumene cracking over the microporous ZSM-5.

As shown in Fig. 1, the X-ray powder diffraction patterns of the parent MCM-41 and HMS materials and the corresponding PNAs do not differ significantly. The characteristic hexagonal features of MCM-41, which are reflected by the common $d_{100}$ diffraction peak and the 110, 200 and the much weaker 210 reflections in the 2θ range 4.0–7.0° are retained though with less

**Table 1** Conversion of cumene at 300 °C over PNAs and related parent materials

| Sample | Cumene conversion (%) at time on stream | |
|---|---|---|
| | 10 min | 3 h |
| MCM-41[a] | 14.7 | 13.6 |
| PNA-1 | 41.3 | 37.5 |
| HMS[a] | 24.8 | 26.8 |
| PNA-2 | 47.6 | 42.4 |
| ZSM-5[b] | 95.1 | 93.7 |

[a] MCM-41 and HMS in the $H^+$-form. [b] H-ZSM-5 with Si/Al = 78.

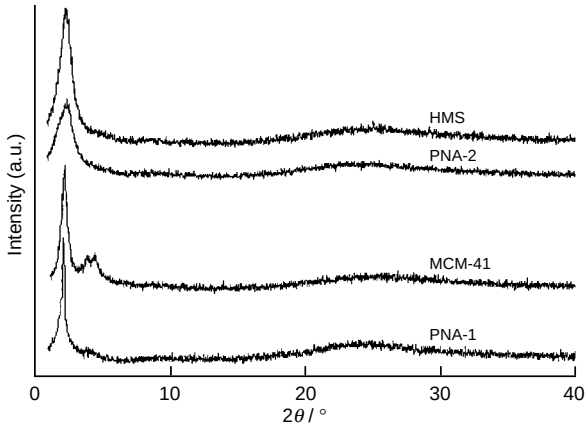

**Fig. 1** X-Ray powder diffraction patterns of the composite materials PNA-1 and PNA-2 together with the parent MCM-41 and HMS materials, respectively

intensity in PNA-1. The absence of high-order Bragg reflections in HMS, indicating small crystallite domains,[6,7] is also preserved in PNA-2. The intensity of the $d_{100}$ diffraction peak had decreased drastically when, instead of glycerol, water was used as the solvent. As indicated by the X-ray powder diffraction patterns the PNAs still possess mesoporous features and a large specific surface area measured by $N_2$ adsorption (1267 and 796 $m^2\ g^{-1}$ BET area and a pore size of 27 and 23 Å for HMS and PNA-2, respectively). TEM measurements showed that exclusively one solid phase was present.

FTIR spectroscopy reveals only for the PNA samples a distinct vibration at 550–560 $cm^{-1}$ (Fig. 2). Several researchers have assigned the 550 $cm^{-1}$ band to the asymmetric stretching mode of the five-membered ring present in ZSM-5 which should therefore be an indication of the presence of embryonal ZSM-5 structures.[18–22] The parent MCM-41 and HMS which have both an amorphous framework do not absorb at this wavenumber and therefore the 550 $cm^{-1}$ vibration is a good probe for detecting the degree of crystallinity of a siliceous MFI-type material even at this initial stage of ZSM-5 formation giving very small tectosilicate structures.[18,22]

Interestingly, $^{27}Al$ MAS NMR measurements show a transformation of strongly anisotropic Al into a quasi-isotropic tetrahedral environment going from HMS to PNA-2.

We conclude that thermally-treated TPA-MCM-41 and TPA-HMS recrystallize, assisted by glycerol, the amorphous aluminosilicate framework partly to such an extent that the framework Al environment is made more highly symmetric. Owing to the attachment of the TPA cations at the interporous framework in combination with the short TPA–aluminosilicate distance[23,24] the recrystallization process is forced to nucleate heterogeneously. The advantage of this process is the formation of embryonal ZSM-5 in a controlled way.

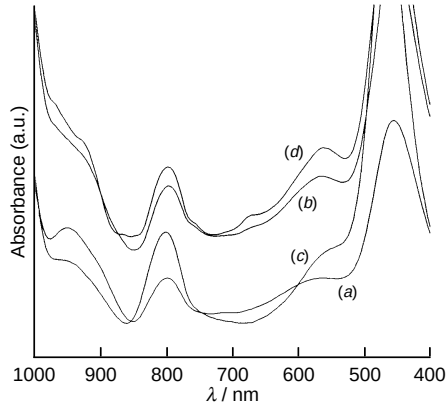

**Fig. 2** FTIR absorption spectra of MCM-41 (*a*), PNA-1 (*b*), HMS (*c*) and PNA-2 (*d*)

The importance of the TPA/T-atom ratio when partly recrystallizing MCM-41 and HMS materials is reflected by the production of only X-ray amorphous material when TPA/Al = 1 and Si/Al = 15 instead of 30. The higher amount of framework Al and therefore the increase of interattached TPA causes disturbance of the recrystallization of the framework. However, when the same mesoporous aluminosilicate is ion-exchanged at a TPA/Al ratio of 0.5 and subsequently thermally processed, the X-ray diffraction pattern was retained much better and an IR band at 550 $cm^{-1}$ was observed. The small size of the tectosilicate nanostructures makes detection of the 1220 $cm^{-1}$ band impossible.[22] Attempted preparation of PNA by interrupting the ZSM-5 crystallization using water as the medium appeared to be very difficult and not reproducible.[12]

In conclusion, the present approach to position the appropriate amount of template molecules inside a mesoporous aluminosilicate can lead to controlled partial reacrystallization and provide new interesting catalytic materials. Thus, upgrading of the catalytic properties of MCM-41 and related materials might lead to a more valuable component in commercial cracking catalysts used in oil refining of heavy feedstocks.[25]

**A new iron(III)–carbonato monomeric complex of *ortho*-phenylenebis(oxamato) (opba) 1 is synthesized, and spectroscopically and structurally characterized; it is a moderately efficient non-heme catalyst for the aerobic epoxidation of alkenes with co-oxidation of pivalaldehyde.**

There has been always a great interest in iron coordination chemistry owing to the relevant role that this transition metal ion plays in biology, particularly as the active metal center embedded in a large number of proteins involved in oxygen activation chemistry.[1] Now, this interest is directed towards mono- and di-nuclear non-heme iron proteins, owing to the surprisingly diverse functional properties exhibited by them.[2] Amido groups from asparagine or glutamine residues in the polypeptide backbone of some of these mononuclear iron proteins are frequently shown to coordinate to the iron metal center through their oxygen donor atom, like in lipid dioxygenase and isopenicillin *N*-synthase.[2a] Moreover, amido nitrogen coordination has been invoked in bleomycin, a natural iron-containing glycopeptide with antibiotic and antitumor properties of fundamental importance in medicine.[2a] That being so, it is evident that knowledge of the chemistry and reactivity properties of iron–amido complexes becomes particularly appropriate in order to understand the key steps of the enzymatic mechanism proposed for this class of non-heme iron proteins and antibiotics. Since the review of Sigel and Martin devoted to the coordinating properties of the amide bond with copper, nickel, cobalt and zinc metal ions,[3] a considerable effort has been made in the last fifteen years in order to detect iron ion interactions with the amide group.[4–6] Recently, we have initiated an investigation program to assess the possible use of bis-N-substituted oxamato ligands like *ortho*-phenylenebis-(oxamato) (opba) in the stabilization of unusual high oxidation state transition metal ions due to the high donor capacity of the deprotonated-amido group.[7] We report here on the synthesis and physical characterization,† and the crystal and molecular structure‡ of its corresponding oxamato iron(III) complex of formula $[NMe_4]_3[Fe(opba)(CO_3)]\cdot 5H_2O$ **1**, as well as its activity toward alkene epoxidation with dioxygen.

Complex **1** consists of mononuclear $[Fe(opba)(CO_3)]^{3-}$ complex anions (Fig. 1), tetramethylammonium cations and crystallization water molecules. The iron atom is bound to the two deprotonated amido nitrogens and two carboxylate oxygens of the opba ligand and to two oxygen atoms from the carbonate in a rhombically distorted octahedral coordination geometry. The carbonate chelating group is symmetrically bound to the metal (2.034, 2.045 Å for Fe–O) occupying two *cis* positions of the octahedron with a typical small bite angle [63.2° for O(7)–Fe–O(8)]. This imposes a non-planar conformation for the tetradentate opba ligand which is the only compatible with an octahedral environment at the metal ion. In fact, the opba ligand adopts a *cis*-β geometry with the N(1), N(2) and O(2) donor atoms occupying three meridional positions around iron. This situation contrasts to previous descriptions of mononuclear complexes with this ligand or its derivatives in which all four donor atoms form a plane (*trans* geometry).[7,8] The distortion from planarity of the opba ligand is accommodated by a disrotatory rotation of the C(3)–N(2) amide bond defined as the angle between the C(6)C(3)N(2) and C(3)N(2)C(4) mean planes [17 *cf.* 2° for the equivalent C(1)–N(1) amide bond], as previously observed in a related cobalt(III) diamido-*N*-dialkoxido complex.[9] This distortion is also reflected in the metal–ligand bond lengths, with a significant difference between the two Fe–O(carboxylate) bond distances of *ca.* 0.05 Å, the longer Fe–O(5) distance being *trans* to that of the carbonate ligand Fe–O(8) which is the longest bond of the octahedron. The Fe–N(amide) bond distances average 2.05 Å, a value very close to that observed in high-spin iron(III) complexes containing amido nitrogen bonds,[5] but significantly longer than those of the analogous intermediate[4b] or low-spin[6] iron(III)–amide bonds (1.93–1.96 Å).

In order to uncover the potential reactivity of this new iron(III) complex, we have examined its ability to catalyse the epoxidation of some representative disubstituted alkenes using dioxygen as oxidant in the presence of an aldehyde.[10] The

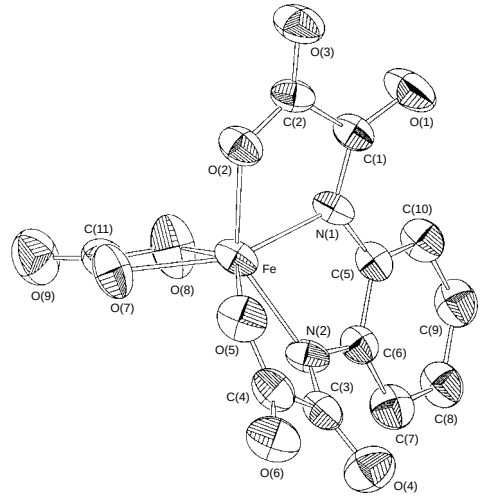

**Fig. 1** Perspective view of the anionic mononuclear unit of **1** with the atom numbering scheme (thermal ellipsoids are at the 30% probability level and hydrogen atoms have been omitted for clarity). Selected bond distances (Å) and angles (°) with standard deviations in parentheses: Fe–N(1) 2.048(5), Fe–N(2) 2.045(6), Fe–O(2) 1.986(4), Fe–O(5) 2.035(4), Fe–O(7) 2.034(5), Fe–O(8) 2.045(5); N(1)–Fe–N(2) 75.9(2), N(1)–Fe–O(2) 78.5(2), N(1)–Fe–O(5) 125.5(2), N(1)–Fe–O(7) 147.4(2), N(1)–Fe–O(8) 86.9(2), N(2)–Fe–O(2) 142.8(2), N(2)–Fe–O(5) 77.9(2), N(2)–Fe–O(7) 118.9(2), N(2)–Fe–O(8) 98.9(3), O(2)–Fe–O(5) 96.0(2), O(2)–Fe–O(7) 97.1(2), O(2)–Fe–O(8) 106.2(2), O(5)–Fe–O(7) 86.9(2), O(5)–Fe–O(8) 144.2(2), O(7)–Fe–O(8) 63.2(2).

**Table 1** Results for the epoxidation of alkenes by dioxygen and pivalaldehyde catalyzed by **1**[a]

| Entry | Alkene | *t*/h | Yield[b,c] (%) |
|---|---|---|---|
| 1 | *trans*-Stilbene | 3 | 95 |
| 2 | *cis*-Stilbene | 3[d] | 15 |
| 3 | Cyclohexene | 4 | 45 |
| 4 | 1,2-Dihydronaphthalene | 4 | 50 |
| 5 | 1,2-Dihydronaphthalene[e] | 4 | 80 |

[a] Reactions were carried out at room temperature by adding a fluorobenzene solution (0.2 ml) of the alkene (0.11 mmol) to a stirred mixture of the metal catalyst ($6.5 \times 10^{-3}$ mmol) and pivalaldehyde (0.33 mmol) in fluorobenzene (0.2 ml) under dioxygen atmosphere. The consumption of the alkene and the formation of the corresponding epoxide during the course of the reaction were monitored by TLC. The obtained epoxide and the unreacted alkene were separated by flash column chromatography on silica gel. [b] Yields refer to isolated and pure compounds (column chromatography on silica gel). All compounds exhibited spectral data consistent with their structures. [c] In the absence of catalyst some extension of epoxidation was observed. [d] With a reaction time of 24 h the final conversion was almost identical (*ca.* 20%). [e] In the presence of *N*-methylimidazole (0.11 mmol).

results are summarized in Table 1. Complex **1** catalyses the epoxidation of *trans*-stilbene by dioxygen plus pivalaldehyde in fluorobenzene solution with yields as high as 95% of the corresponding epoxide, *trans*-stilbene oxide, after 3 h (entry 1). By contrast, the percent conversion in the case of *cis*-stilbene is of only 15–20% even after a total reaction time of 24 h (entry 2), indicating that the catalytic epoxidation is greatly stereodependent. For both *cis*- and *trans*-stilbene, however, epoxides were the only oxidation products as confirmed by $^1$H NMR spectroscopy. As a matter of fact, no trace of the corresponding ketone or alcohol were detected for the epoxidation of cyclohexene which is typically regarded as a good substrate to check for competition of alkene epoxidation *vs*. allylic oxidation (entry 3). This observation suggests that typical free radical intermediates are not directly involved as potential epoxidizing agents. On the other hand, it is noteworthy that the amount of epoxide obtained with **1** increases in the presence of *N*-methylimidazole: for instance, almost a twofold yield enhancement was found for the epoxidation of 1,2-dihydronaphthalene, *i.e.* from 50 to 80% after 4 h (entries 4 and 5, respectively). Although it is premature to discuss the precise mechanism at the present stage, *N*-methylimidazole most likely acts as a monodentate donor ligand toward the iron(III) ion by replacement of the bidentate carbonate ligand, and thereby affording a vacant coordination site on the iron center for reaction with the potential oxidant. Furthermore, even if the exact role of the metal complex in the epoxidation of alkenes by dioxygen with co-oxidation of aldehydes is still unclear, recent studies by Valentine and coworkers[11] demonstrate that it coordinates to the acylperoxy radicals generated in the autoxidation of the aldehyde forming a metal-acylperoxo complex. That being so, iron(IV)–acylperoxo or iron(V)–oxo species derived by oxygen–oxygen bond cleavage of the acylperoxo group, seem to us the more probable candidates to play the role of active epoxidizing agents in our system. In this regard, it is interesting to note that Collins *et al*. have isolated stable iron(IV) complexes with amido-containing ligands which would be a model for the proposed catalytic entities in our oxidation system.[4a] Attempts to characterize these reactive intermediates species using other transition metal ions with more accessible high-valent oxidation states such as manganese are in progress in our laboratory.

† *Syntheses and selected data* for **1**: A solution of the diethyl ester derivative of opba (1.54 g, 5 mmol) in methanol (100 ml) was charged with a 25% methanol solution of $NMe_4OH$ (10 cm$^3$, 25 mmol) and the resulting mixture was stirred at 60 °C for 15 min in order to facilitate the hydrolysis of the ethyl ester groups. A methanolic solution (50 ml) of iron(III) perchlorate hydrate (1.77 g, 5 mmol) was then added dropwise *via* a dropping funnel under stirring. The resulting intensely red coloured solution was filtered to eliminate the white precipitate of $NMe_4ClO_4$, and reduced to a final volume of 10 ml on a rotatory evaporator. The concentrated solution was treated successively with diethyl ether and acetone to give a very hygroscopic product (solid or oil) which was recuperated with acetonitrile (300 ml). The suspension obtained was gently heated for 5 h with vigorous stirring and then filtered to eliminate the remainder of the solid particles. Upon standing at room temperature, a first crop of a side product appeared which was also filtered and separated from the mother-liquor. Slow evaporation of the filtered solution in air afforded, after 2 weeks, red needles of **1** in small amounts which were picked by hand, dried on filter paper and stored under vacuum owing to its hygroscopic character. The crystals so obtained were suitable for X-ray diffraction. Satisfactory elemental analyses were obtained (C, H, N, Fe). $\nu_{max}$/cm$^{-1}$ (KBr) 1660s (sh), 1635vs (br) and 1571s (CO) (opba ligand and $CO_3^{2-}$) and 950s (NC) from $NMe_4^+$. UV–VIS (MeCN) $\lambda_{max}$/nm [ε dm$^3$ mol$^{-1}$ cm$^{-1}$)] 221 ($4.0 \times 10^4$), 257 ($4.2 \times 10^4$), 264 (sh), 308 ($3.0 \times 10^4$), 408 ($2.7 \times 10^3$). Magnetic moment (room temp.): 5.9 $\mu_B$. EPR spectrum (X-band, powder sample, liquid-$N_2$ temperature): a strong feature at $g_{eff} = 4.3$ which typically arises in a completely rhombic system ($E/D = 1/3$) for $D > 0.23$ cm$^{-1}$.

‡ *X-Ray crystal structure analysis*: Enraf-Nonius CAD-4 diffractometer, Mo-Kα radiation, λ = 0.710 69 Å, graphite monochromator, 293 K. Lorentz and polarization effects but not absorption correction (μ = 9.26 cm$^{-1}$). Data collection, solution and refinement: ω-θ, standard Patterson methods with subsequent full-matrix least-squares method refinement. SHELX86, SHELX93.[12] $C_{23}H_{50}FeN_5O_{14}$, monoclinic, space group $P2_1/a$, $a$ = 11.441(2), $b$ = 17.496(2), $c$ = 17.047(2) Å, β = 104.52(2)°, $U$ = 3303(1) Å$^3$, $Z$ = 4, $D_c$ = 1.36 g cm$^{-3}$, $1 \leqslant \theta \leqslant 25°$, crystal size 0.15 × 0.10 × 0.05 mm. 4456 unique reflections with 3362 assumed as observed with $I \geqslant 2\sigma(I)$. The hydrogen atoms were located from a difference synthesis and refined with an overall isotropic thermal parameter. Refinement on $F^2$ of 390 variables with anisotropic thermal parameters for all non-hydrogen atoms gave $R$ = 0.079 and $R_w$ = 0.108 with $S$ = 1.8 (observed data). CCDC 182/628.

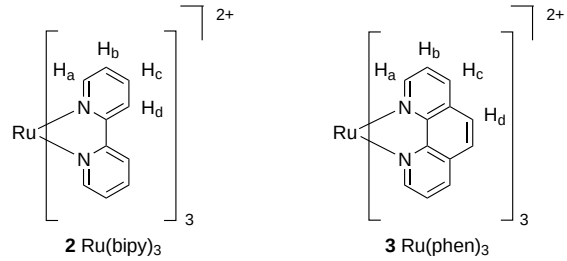
# Application of TRISPHAT anion as NMR chiral shift reagent

**Jérôme Lacour,* Catherine Ginglinger, France Favarger and Sonya Torche-Haldimann**



*Département de Chimie Organique, Université de Genève, quai Ernest Ansermet 30, CH-1211 Genève 4, Switzerland*

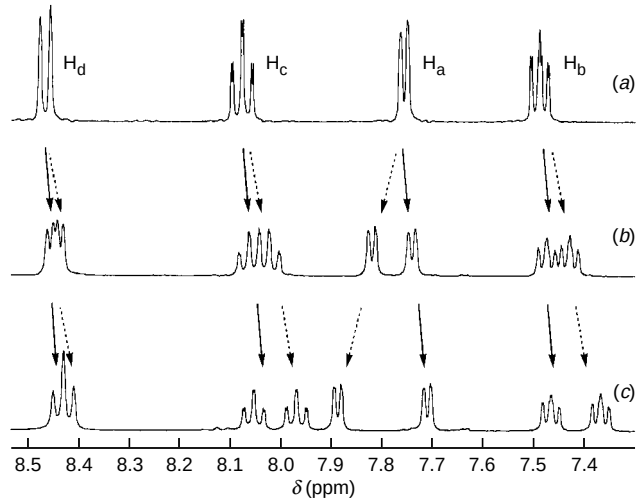
**TRISPHAT anion 1 is an efficient NMR chiral shift reagent for cationic tris(bisimine)ruthenium(II) complexes.**

Configurationally stable[1] tris(bisimine)ruthenium(II) complexes have been extensively studied in the fields of photochemistry, photophysics and as probes in DNA. Many applications require these compounds in an enantioenriched form and thus determination of their optical purity is a necessity.[2] Herein, we report the application of TRISPHAT anion **1** as a useful chiral NMR shift reagent[3] for two of these cationic complexes.

Recently, we have shown that chiral tris[tetrachlorobenzene-1,2-bis(olato)]phosphate anion **1** (or TRISPHAT) is configurationally stable in solution.[4] It was foreseen that **1** would be an interesting NMR chiral shift reagent† for chiral cationic compounds, and tris(bisimine) complexes of transition metals in particular. Addition of enantioenriched **1** to solutions of tris(bisimine)ruthenium(II) compounds would lead to the formation of diastereomeric ion pairs, which have, at least in principle, different chemical shifts. Furthermore, as cations and anion **1** possess the same $D_3$-symmetry, we thought that selective chiral discriminating interactions would likely occur, leading to a preferred association between the molecular propellers ($\Lambda^+ - \Lambda^-$ *vs.* $\Delta^+ - \Lambda^-$). As a result, enantiotopic protons, carbon atoms and other nuclei of the cationic complexes would be resolved. We decided to test this hypothesis with Ru(bipy)$_3$ **2** and Ru(phen)$_3$ **3** complexes using $Bu_3NH^+$–(*M*)-**1** salt [(+)-**1a**, 86% ee] as chiral shift reagent, which can be easily prepared as follows (Scheme 1). Addition of 0.5 equiv. of cinchonidine **4** to a solution of racemic tri-*n*-butylammonium salt [(±)-**1a**] in $CH_2Cl_2$ leads to the precipitation of a white solid **5** containing mainly cinchonidinium salts (72% de). Filtration and concentration of the mother liquor *in vacuo*, afford a white solid **6** containing the tri-*n*-butylammonium salt **1a** along with a minor amount of cinchonidinium salts. Recrystallisation of solid **6** in $CH_2Cl_2$–$CHCl_3$ affords, in the mother liquor, chemically and optically purified (+)-**1a** (86% ee).

Tris(bisimine)ruthenium(II) **2** and **3** were prepared as described by Broomhead and Young as dichloride salts (**2a**, **3a**).[5] Racemic Ru(phen)$_3$Cl$_2$ **3a** was resolved by recrystallization with (+)-antimonyl tartrate anion;[6] treatment of the tartrate or chloride salts with sodium perchlorate yielded the racemic or optically enriched [Ru(bipy)$_3$](ClO$_4$)$_2$·*x*H$_2$O (**2b**) and [Ru(phen)$_3$](ClO$_4$)$_2$·*x*H$_2$O (**3b**).‡

As foreseen, addition of 0.5–1.0 equiv. of (*M* or Λ)-TRISPHAT **1** to solutions of (±)-**2b** in $CD_2Cl_2$ (1–2 × $10^{-3}$ M), (±)-**3b** and (+)-**3b**[7] in 7–10% DMSO in $CD_2Cl_2$ (1–2 × $10^{-3}$ M)§ led to the resolution of the NMR spectra of the cations; we were able to distinguish between the two enantiomers and show that sample (+)-**3b** is optically pure. The resulting spectra at 400 MHz are shown in Figs. 1 and 2 and are compared to that of the same solutions in the absence of TRISPHAT. Upon addition of **1**, only the signals of one of the



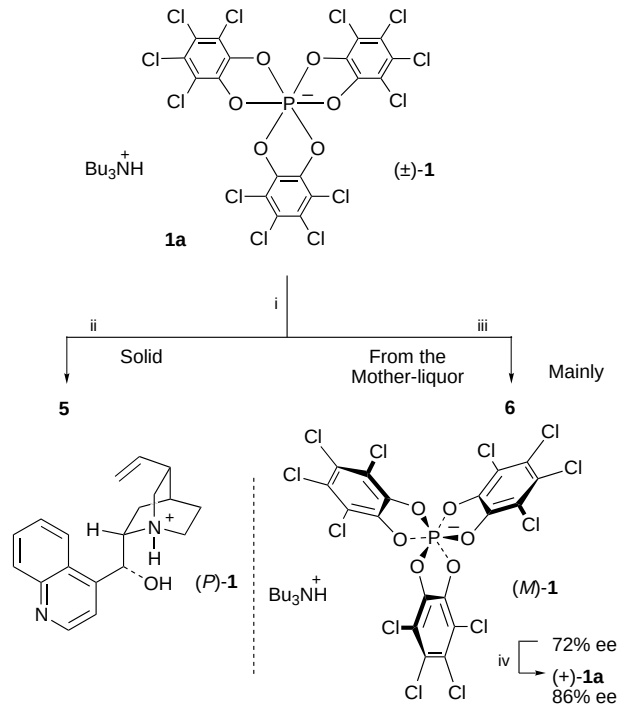


**Fig. 1** The $^1$H NMR spectra of racemic [Ru(bipy)$_3$(ClO$_4$)$_2$]·*x*H$_2$O **2** in the absence (*a*) and presence of (+)-**1a** [0.5 equiv. (*b*), 1.0 equiv. (*c*)]

**Scheme 1** *Reagents and conditions*: i, 0.5 equiv. of **4**, $CH_2Cl_2$, 20 °C, 6 h; ii, filtration, **5** (44%); iii, concentration of the mother liquor *in vacuo* (60 °C, $10^{-4}$ bar, 12 h), **6** (55%); iv, (+)-**1a** (86% ee) from the mother liquor after recrystallisation in $CH_2Cl_2$–$CHCl_3$

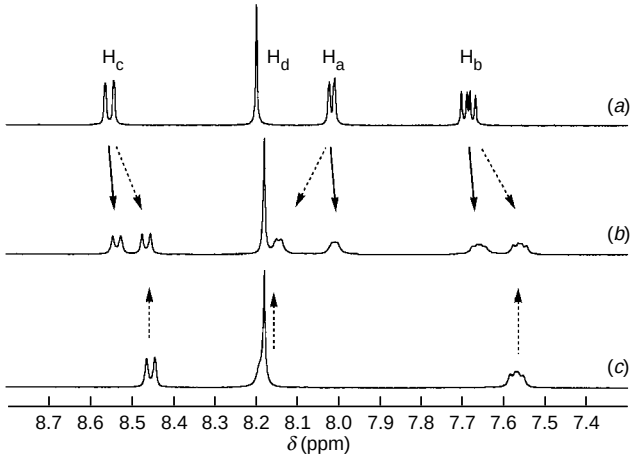

**Fig. 2** The $^1$H NMR spectra of $[Ru(phen)_3(ClO_4)_2]\cdot xH_2O$ **3** in the absence (*a*) and presence of 1.0 equiv. of (+)-**1a**: (±)-**3b** (*b*) and (+)-**3b** (*c*). Spectra (*a*), (*b*) and (*c*) were done in 10, 10 and 7% DMSO in $CD_2Cl_2$, respectively.

two enantiomers of **2** or **3** show strong shifts of its signals; observed chemical shifts ($\delta$), upfield or downfield shifts induced by the phosphate reagent ($\Delta\delta$), and the magnitude of the difference in chemical shifts of analogous protons of the two enantiomers of **2b** and **3b** upon addition of the shift reagent ($\Delta\Delta\delta$) are summarized in Tables 1 and 2 respectively.

As is shown in Tables 1 and 2, substantial differences between analogous $H_a$, $H_b$, $H_c$ protons of the enantiomers were found, while protons $H_d$ in **2**–**3b** remain essentially unchanged. Proton $H_a$, the closest from the $C_3$ axis, has the largest difference between the signals, and it is shifted downfield contrary to that of the others. We feel that the larger $\Delta\Delta\delta$ of $H_a$ and $H_b$ and smaller $\Delta\delta$ of $H_d$ are consistent with an ion-pairing model for anion induced shift, with cations and anions interacting most probably along their $C_3$ axes.

Finally, it is important to notice that the use of **1** as a NMR chiral shift reagent is not limited, in this case, by the presence of polar solvent such as DMSO or by non-coordinating ions.[2a,b]

In summary, by addition of chiral anion **1**, we have observed differences in the chemical shifts of enantiomers of cationic species. We have used this technique to confirm enantiomeric purity of a complex. We think that this technique will be quite general for chiral cationic species. The observation that only one enantiomer of the cation shows a strong shift upon addition of **1** is also important. Further studies are being conducted to determine if this effect is due to a preferred association of the two molecular propellers, the nature of the interaction and its effectiveness for chiral recognition processes.

**Table 1**

| Proton[a] | $\delta^b$ | | $\delta^c$ | | $\Delta\delta^c$ | $\Delta\Delta\delta^c$ |

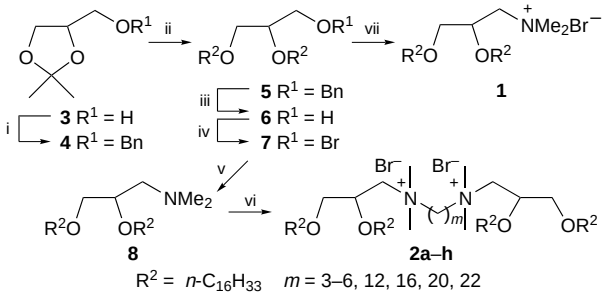
# Synthesis and vesicle formation from novel pseudoglyceryl dimeric lipids. Evidence of formation of widely different membrane organizations with exceptional thermotropic properties

**Santanu Bhattacharya,*† Soma De and Shaji K. George**



*Department of Organic Chemistry, Indian Institute of Science, Bangalore 560012, India*

**Eight new bis-cationic dimeric lipids 2a–h have been synthesized; TEM of their aqueous dispersions confirmed the vesicle formation and from the thermal, spectroscopic, DLS and XRD studies it has been revealed that they form three different kinds of membranous aggregate depending on the *m*-value.**

While the properties of vesicular membranes derived from a large number of 'monomeric' natural lipids[1] as well as their synthetic analogues[2] have been examined in great detail, there is no report in the literature that examines the properties of the membranes prepared from 'multimeric' lipids. This is despite the fact that several 'dimeric' and 'multimeric' lipid systems occur naturally and have important biological functions. Thus, cardiolipins (glycerol bridged dimeric phosphatidate lipids) constitute a class of complex phospholipids occurring mainly in the heart and skeletal muscles and show high metabolic activity.[3] Similarly, glycolipid A2 (composed of two phosphate headgroups and seven hydrophobic chains) serves as immunomodulator in mediating selective recognition of toxins, bacteria or viruses at the cell surfaces.[4]

Although dimeric (gemini) amphiphiles[5,6] that aggregate to form micelles are known, no analogous gemini form of lipids has been studied. Since cationic liposomes by themselves are receiving enormous current attention as effective non-viral gene transfection agents,[7] the resulting aggregates of dimeric lipids if cationic might be potentially useful. Along the lines of the above considerations, here we report the first synthesis of a family of bis-cationic, gemini lipids **2a**–**h** and their unusual membrane-forming properties on the basis of a combination of thermal, spectroscopic, dynamic light scattering (DLS), transmission electron microscopic (TEM) and reflection X-ray diffraction (XRD) methods supported by energy-minimization studies. To place the experimental data on these novel gemini membranes into appropriate perspective, we also include herein the related results from the vesicles of the corresponding 'monomeric' (control) lipid **1**.

Altogether eight new dimeric lipid systems **2a**–**h** were synthesized (Scheme 1). First the $CH_2OH$ group of the building block, 1,2-isopropylideneglycerol, **3** was protected in the form of a benzyl ether **4**. The isopropylidene group was then removed by treatment with HCl in aq. MeOH and the diol obtained upon preparative column chromatography over silica gel was alkylated with *n*-$C_{16}H_{33}Br$ (2.2 equiv.) to give **5** which upon hydrogenolysis afforded **6** in ~60% yield. Compound **6** was then converted to the corresponding bromide **7** by reaction with $PPh_3$–$CBr_4$; **7** was quaternized in the presence of $Me_3N$ in EtOH to give **1** in 80% yield. The bisquaternary systems **2a**–**h** were obtained from the corresponding dimethylamino derivative **8** upon refluxing with individual alkanediyl α,ω-dibromides in 60–75% yields.

**Scheme 1** *Reagents and conditions*: i, BnCl, KOH, $C_6H_6$, reflux, 87%; ii, aq. HCl–MeOH, reflux, 84%; *n*-$C_{16}H_{33}Br$, KOH, $C_6H_6$, reflux, 58%; iii, Pd–C/$H_2$, 60%; iv, $CBr_4$, $PPh_3$, $CH_2Cl_2$, 90%; v, $Me_2NH$–EtOH, heat, pressure tube, 95%; vi, $Br(CH_2)_mBr$, EtOH, reflux, 60–75% (exact yields depend on *m*); vii, $Me_3N$–EtOH, heat, pressure tube, 80%

Dispersion of lipids **1**, **2a**–**h** in water using probe or bath sonication afforded liposomes with a unimodal distribution of particle diameters as revealed by DLS (Table 1). Examination of DLS data on bath sonicated vesicles shows that vesicles from dimeric lipids were invariably larger. Within the vesicles among the dimeric lipid series, however, the hydrodynamic diameter variation as a function of *m*-value was very complex. The vesicular sizes were found to be the largest with lipids, **2**, of $m = 3$ and then decreased with increase in *m*-value up to $m = 12$ and then went up again with $m > 12$. Vesicle sizes were also found to strongly depend on the lipid concentration, thermal history and method of vesicle preparation. Thus while vortexing afforded mostly open lamellae and sonication gave small spherical, closed microstructures, reverse phase evaporation (REV) gave multilamellar vesicles (not shown).

**Table 1** The hydrodynamic diameters of vesicular aggregates, main phase-transition temperatures of vesicular **1**, **2a**–**h** and the unit-layer thicknesses of their corresponding self-supporting cast films

| Lipid (*m*-value) | DLS[a] size/nm | Main transition[b] (*T*/°C) | | Unit bilayer thickness/Å | |
|---|---|---|---|---|---|
| | | Microcal | Fluor. Pol. | Obs[c] | Calc.[d] |

| 22 | 52 | 66.3 | 53 | 30.8 | 49, 29[f] |

[a] Dynamic light scattering was examined with the vesicles prepared under identical conditions. All the vesicles ($1 \times 10^{-3}$ M) were prepared by bath sonication (Julabo USR3) for 10 min, at 70 °C and at 35 KHz. [b] Average deviation is ±0.5 °C for microcalorimetry; ±1.0 °C for fluorescence polarization method. [c] As obtained from reflection X-ray diffraction of cast films. [d] Lengths of two molecular layers of lipids as obtained from models. [e] Additional minor peaks at 66.1 and 71.6 °C were also observed. [f] Lengths of unit 'mono'layer-bilayer plans of lipids as obtained from models [g] Lengths of unit interdigitated and tilted bilayer plans of lipids as obtained from models.

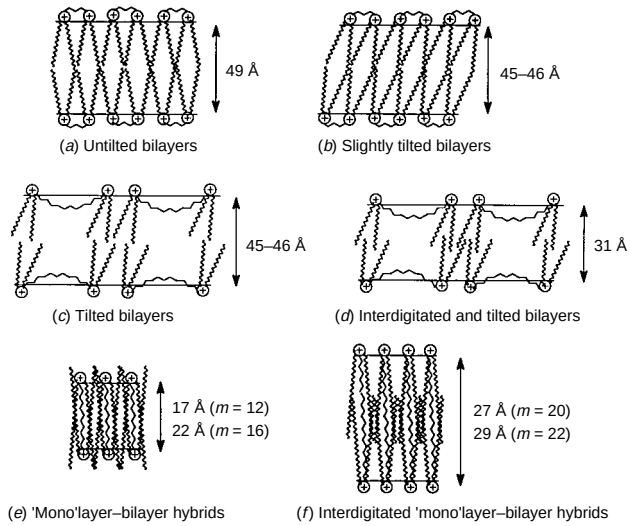

**Fig. 1** Schematic representation of possible bilayer forming motifs with gemini lipids as a function of *m*-value

The sonicated dispersions of different lipids (7 mM) were then converted to regular self-supporting films by casting on glass slides as described.[8] Reflection X-ray diffraction (Scintag XDS-2000) of these cast films gave the long spacings from individual lipid films as given in Table 1. Comparison of the corresponding molecular lengths of the gemini lipid units as determined from CPK models suggests the formation of slightly tilted bilayer arrangement [Fig. 1(*b*)] with **1** and with gemini lipids of *m*-values 3, 4, 5 and 6. But with **2e**, $m = 12$, the experimentally determined XRD data on the unit layer thicknesses cannot be explained by tilting alone suggesting the presence of additional interdigitations [Fig. 1(*d*)]. The alternative plan (*e*) is energetically unfavorable with the lipophilic chains protruding into the polar headgroup regions. To explain the reflection XRD data of **2g** and **2h**, we suggest a kind of monolayer–bilayer hybrid organization as shown in Fig. 1(*f*).

Independent examination of the thermotropic properties of the vesicles of **1** and **2a**–**h** by DSC, microcalorimetry and fluorescence methods showed that the changes in *m*-value in **2** profoundly influence their gel-to-liquid crystalline phase-transition temperatures (Table 1). Vortexing of 60 mM of either of **1** and **2a**–**h** in water afforded lameller gels which gave well-resolved, nearly reversible peaks as melting transitions ($T_m$) (Perkin Elmer DSC 7). Microcalorimetry (MC-2) of 1.0–2.5 mM sonicated vesicular specimens of either of the lipids reproduced the peaks due to $T_m$. Relative to **1**, there is a substantial increase in the gel-to-liquid crystalline transition temperature of the membranes derived from dimeric **2a**. In addition, unlike the membranes that are assembled from **1**, which show a sharp endothermic main transition at 45 °C, those made from **2a** exhibit a more complex melting pattern. For lipids with $m \geqslant 16$, the melting transition profiles appeared remarkably broadened (less cooperative), while for lipids with $m \leqslant 12$, the main transitions were quite sharp. Thus although the cooperativities of melting transitions with **2** ($m$ = 20–22) were severely reduced, alternative membrane organizational features allow broad but higher melting temperatures (see below). The latter could be a consequence of perturbation within the headgroup and/or direct interaction of the spacer chain with the hydrocarbon chain regions.

The fluorescence polarizations (*P*) due to the vesicle doped 1,6-diphenylhexa-1,3,5,-triene at various temperatures were then determined. The temperatures related to the break in *P vs. T* plot for the vesicles with $m$ = 0–16 were similar to the $T_m$ values obtained by calorimetric methods (Table 1). But the lipids with $m$ = 20 and 22 gave broader *P vs. T* variation, the mid-points of which were lower than the $T_m$ values obtained using microcalorimetry. Notably again the microviscosities (*ca.* 3.5–4.0 poise) of the vesicular aggregates of lipids with $m$ = 20–22 in their gel states were considerably lower than that of the lipids with lower *m*-values (*ca.* 10–11 poise) again suggesting gross differences in their suprastructural organizations.

Molecular mechanics calculation of the energy-minimized conformations of the dimeric lipids using DISCOVER (INSIGHT II) suggested that the packing in **2a** and **2b**, where $Me_2N^+$ headgroups are separated by three and four $CH_2$ units respectively, is much tighter than that in lipids with higher *m*-values. This should lead to a progressive decrease in $T_m$ as *m*-value increases from 3 to 10. As the *m*-value in lipid, **2**, reaches $\geqslant$12, this situation changes when the $(CH_2)_{12}$ connector in **2e** 'loops' into the vesicle interior to avoid 'undesirable' contacts with the bulk water. At $m$ = 16, the spacer chain should adopt an even more folded, wicket-like conformation further impairing the bilayer packing.‡ The greater extent of spacer chain looping into the membrane interior should disturb 'intra'-gemini lipid packing at $m$ = 16 even further [Fig. 1(*d*)]. This is consistent with the observation of lower $T_m$ value with vesicular **2f** than that with **2e**. As the *m*-value surpasses 16 in **2**, the suprastructural organizations in the membranes change again. This is because at $m \geqslant 20$, the length of spacer may now span as a 'monolayer' giving rise to 'mono'layer-bilayer hybrid type of suprastructures. Thus, strikingly, when *m*-value reaches $\geqslant$20, spacer chains probably hyperextend to produce (absolutely unrelated to the ones with lower *m*-values) 'monolayer' type organizations reminiscent of the assemblies seen in the bolaamphiphilic membranes [Fig. 1(*f*)].[9]

Since the freedom of motion of four independent hydrocarbon chains is critical to their properties at the membrane level, the present study clearly demonstrates that the interconnection of the 'monomeric' lipid by a polymethylene segment into a 'dimeric' lipid brings about ramifications far exceeding the seemingly trivial structural modification at the lipid level. These findings further emphasize the need for newer designs of synthetic lipid structures to expand the understanding of their behaviour upon membrane formation.

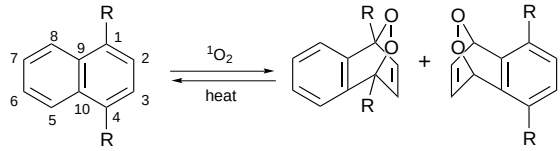
# First evidence of the formation of 5,8-endoperoxide from the oxidation of 1,4-disubstituted naphthalene by singlet oxygen



**Christel Pierlot and Jean-Marie Aubry***

*Equipe de Recherches sur les Radicaux Libres et l'Oxygène Singulet (URA CNRS 351) Faculté de Pharmacie, 3 rue du Professeur Laguesse BP 83 F59 006 Lille, France*

**Bulky water-soluble 1,4-disubstituted naphthalenes react with singlet oxygen giving the usual 1,4- and the unexpected 5,8-endoperoxides and showing that the regioselectivity of the [4 + 2] cycloaddition of singlet oxygen depends on the steric hindrance of the substrate.**

In contrast to anthracene and higher members of the acene series,[1] naphthalene does not react with singlet oxygen ($^1O_2$) to form the 1,4-endoperoxide.[2] However, the naphthalene 1,4-endoperoxide **2a** has been obtained indirectly in three steps from 1,6-imino[10]annulene.[3] When electron-donating substituents are introduced on the 1,4 positions of the naphthalene core, $^1O_2$ readily reacts leading regiospecifically to 1,4-endoperoxides.[4–6] 5,8-Endoperoxides have been solely observed when at least one additional methyl group was placed on the 6,7[7] or 8 positions[8,9] of the naphthalene core. In the course of our work on water-soluble carriers of $^1O_2$,[6,10] we have discovered that the photooxidation of the bulky non-ionic water-soluble 1,4-disubstituted naphthalene, *N*,*N*′,*N*″,*N*‴-tetrakis(2,3-dihydroxypropyl)2,2′-(naphthalene-1,4-diyldimethyl)bis(malonamide) **1b** (Scheme 1) leads to the simultaneous formation of the 1,4- and 5,8-endoperoxides (**2b** and **3b**). This example clearly shows that in addition to electronic effects, the steric hindrance of the substituents can modify the regioselectivity of the [4 + 2] cycloaddition of singlet oxygen on polycyclic aromatic hydrocarbons.

NMR and HPLC analysis of **1b**†‡ after dye-sensitized photooxygenation§ at −5 °C in $D_2O$–$CD_3OD$ (77 : 13) showed a 50% conversion in 2 h, and indicated that, beside the usual 1,4-endoperoxide **2b**, the unexpected 5,8-endoperoxide **3b** was also formed, with a time-independent ratio equal to 78 : 22 (Table 1). All spectra showed that the malonamide side chains remained unchanged during oxidation and the symmetry of each spectrum suggested that no other products of oxidation with lower symmetry, such as hydroperoxides, were formed.

**a** R = H
**b** R = $CH_2CH[CONHCH_2CH(OH)CH_2(OH)]_2$
**c** R = $CH_2CH_2CO_2Na$
**d** R = $CH_2CH(CO_2Na)_2$

**Scheme 1**

**Table 1** Product distribution after photooxidation of **1b**

| Solvent | *T*/°C | *t*/h | Conversion (%) | Regioselectivity **2b** : **3b** |
|---|---|---|---|---|
| $D_2O$–$CD_3OD$ (77 : 13) | −5 | 2 | 50 | 78 : 22 |
| $H_2O$–MeOH (77 : 13) | −5 | 2 | 3 | 100 : (< 1) |
| $D_2O$ | 25 | 1 | 26 | 69 : 31 |
| | 50 | 1 | 40 | (< 1) : 100 |
| $CD_3OD$ | 25 | 2 | 20 | 80 : 20 |

$^1$H and $^{13}$C NMR chemical shift assignments for **2b**¶ were in agreement with the spectral data of other 1,4-naphthalene endoperoxides such as **2c**.[10] The structure of the endoperoxide **3b**‖ was confirmed by comparison with **2b.** Thus, **3b** has four quaternary carbons in the aromatic region, in positions 1, 4, 9 and 10 (d, $J$ = 139.2 and 133.5 Hz) whereas **2b** has only two carbons of this type, C$^9$ and C$^{10}$ (d, $J$ = 142.2 Hz). Another telling difference was observed for the carbons supporting the peroxide bridge, which were the tertiary carbons C$^5$ and C$^8$ (d, $J$ = 75.7 Hz) for **3b** compared to the quaternary carbons C$^1$ and C$^4$ (d, $J$ = 83.4 Hz) for **2b**.

When the oxidation of **1b** was run over 2 h in $H_2O$–MeOH (77 : 13) instead of deuterated solvents, **2b** was formed with a 13 times lower yield (3% compared to 39%), and the concentration of **3b** became too small to be measurable. This lower yield was expected since the lifetime of $^1O_2$ is 15 times shorter in $H_2O$ than in $D_2O$. Chemical oxidation of **1b** by a chemical source of $^1O_2$ ($H_2O_2$–$MoO_4^{2-}$),[10] also led to the formation of **2b** and **3b**, confirming the involvement of singlet oxygen in the formation of both endoperoxides (Table 1).

Warming of the solutions of pure **2b** and **3b** obtained by semi-preparative HPLC indicated that both endoperoxides decompose giving the starting naphthalene **1b** and oxygen (Scheme 1) according to first order kinetics (Table 2). Comparison of the half-lives of decomposition ($t_{1/2}$) clearly showed the greater stability of **3b** since no significant decomposition occurred at 5 °C, and it was found to be ten times more stable than **2b** at 25 and 37 °C. On the contrary, **2b** was particularly thermolabile since its half-life at 37 °C ($t_{1/2}$ = 7 min) is three times shorter than that of other 1,4-endoperoxides such as **2c**. This phenomenon seems to be general, in fact we observed similar half-lives for other bulky 1,4-disubstituted endoperoxides such as **2d** ($t_{1/2}$ = 5 min at 37 °C). The poor stability of these 1,4-endoperoxides could result from the steric hindrance induced by the bulky substituents R in the 'butterfly' structure **2**, which would favour dissociation into the starting naphthalene derivative and oxygen.

$$\mathbf{1} + {}^1O_2 \xrightarrow{k_{r2}} \mathbf{2} \quad (1)$$

$$\mathbf{1} + {}^1O_2 \xrightarrow{k_{r3}} \mathbf{3} \quad (2)$$

**Table 2** Half-lives ($t_{1/2}$) of dissociation at 5, 25 and 37 °C for endoperoxides **2b**, **3b**, **2c** and **2d**, and rate constant ($k_r$) of their formation at −5 °C

| | $t_{1/2}$/min | | | $k_A/10^4$ M$^{-1}$ s$^{-1}$ |
|---|---|---|---|---|
| | 5 °C | 25 °C | 37 °C | ($D_2O$–$CD_3OD$ = 77 : 13) |
| **2b** | 540 | 30 | 7 | 3 |
| **3b** | stable | 300 | 70 | 1 |
| **2c** | stable | 113 | 23 | 142 |
| **2d** | 208 | 18 | 5 | 44 |

The rate constants, $k_{r2}$ [eqn. (1)] and $k_{r3}$ [eqn. (2)], for the chemical quenching of $^1O_2$ by **1b** were estimated by comparison with the well known $^1O_2$ acceptor **1c**[11] (Table 2). Thus, they were separately photooxidized in deuterated water at −5 °C under the same conditions. The kinetics of the disappearance of the starting materials indicated that **1b** ($k_{r2} + k_{r3} = 4 \times 10^4$ M$^{-1}$ s$^{-1}$) is about 13 times less reactive than **1c** ($k_r^{NDP} = 142 \times 10^4$ M$^{-1}$ s$^{-1}$). The constant regioselectivity observed at this temperature permits us to determine the contribution of each pathway: $k_{r2} = 3 \times 10^4$ M$^{-1}$ s$^{-1}$ and $k_{r3} = 1 \times 10^4$ M$^{-1}$ s$^{-1}$. The poor reactivity of **1b** towards $^1O_2$ could be explained by the electron-withdrawing effect of the amide function, which decreases the electronic density on the 1,4-positions of the naphthalene core, compared to the slight electron-donating effect of the sodium carboxylate functions of **1c**. However, since these groups are separated from the binding site by an ethylene linkage, it appears more likely that the difference of reactivity is mainly a consequence of the steric hindrance due to the side chains.[6]

To strengthen this hypothesis, we oxidized the tetra-(sodium carboxylate) **1d** which is more bulky than **1c**, but which exhibits a greater electronic density on the naphthalene ring due to the presence of four sodium carboxylate functions instead of two. Actually, the reactivity of **1d** towards $^1O_2$ is three times lower than that of **1c**. This result confirms the predominating contribution of steric hindrance over the electron-donating effects of the side chains of **1b** and **1d**.

It is noteworthy that the formation of the 5,8-endoperoxide **3b** is straightforward only when the oxidation of **1b** is carried out in deuterated water. Thus, in deuterated methanol, only 4% is obtained after 150 min at 25 °C (compared to 33% in deuterated water). This result seems astonishing if we refer to the lifetime of $^1O_2$, which is 3.5 times longer in $CD_3OD$ ($\tau_\Delta$ = 230 μs) than in $D_2O$ ($\tau_\Delta$ = 65 μs). In fact, contrary to a generally accepted principle, it was reported recently that the rate constants of singlet oxygen [4 + 2] cycloadditions ($k_r$) are strongly solvent-dependent. In particular, it was shown that highly structured solvents such as formamide and water considerably increase the reactivity of conjugated dienes and polycyclic aromatic derivatives.[2,12] Thus, the finding that **1b** exhibits a 15-fold higher rate constant in $D_2O$ than in $CH_3OD$ is just a further example of this accelerating effect.

Finally, it appears that the formation of the unusual 5,8-endoperoxide by reaction of $^1O_2$ with 1,4-disubstituted naphthalene is possible only when a number of stringent requirements are met: (i) substituents must be a little electron-donating to increase the electronic density of the whole naphthalene core; (ii) they must be very bulky to make difficult the approach of $^1O_2$ to the crowded ring and to impair the formation of the resulting butterfly structure; (iii) the peroxidation must be carried out in $D_2O$ in order to benefit from the rate-accelerating effect of water on the [4 + 2] cycloaddition of $^1O_2$ and from the enhancement of $^1O_2$ lifetime in deuterated solvents; (iv) a gentle warming of the reaction medium increases the ratio of 5,8- to 1,4-endoperoxides with oxidation time because of the greater thermolability of the 1,4-endoperoxide, which dissociates as it is forms whereas the 5,8-endoperoxide remains unchanged.

The authors are grateful to Dr A. Defoin for helpful discussions.

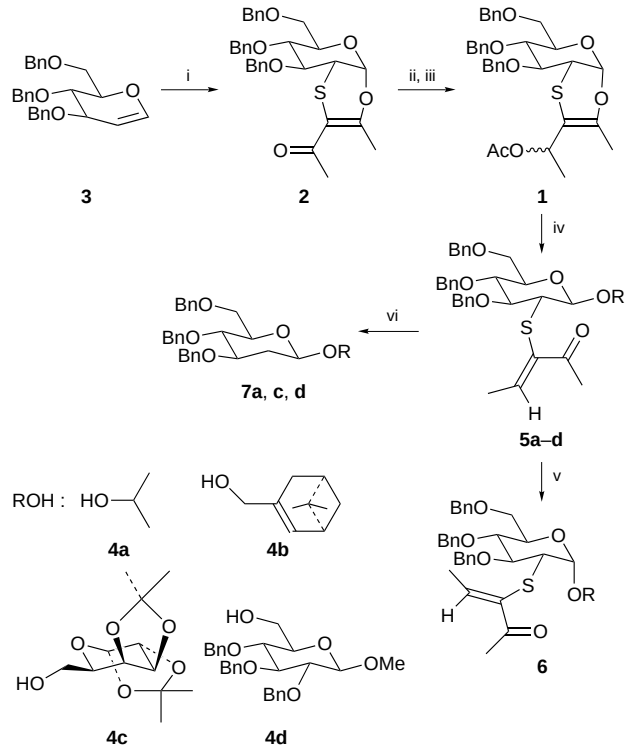
# Versatile intermediate for complete α/β stereocontrol in *O*-glycosidation reactions

**Giuseppe Capozzi,*† Francesca Mannocci, Stefano Menichetti, Cristina Nativi* and Serena Paoletti**



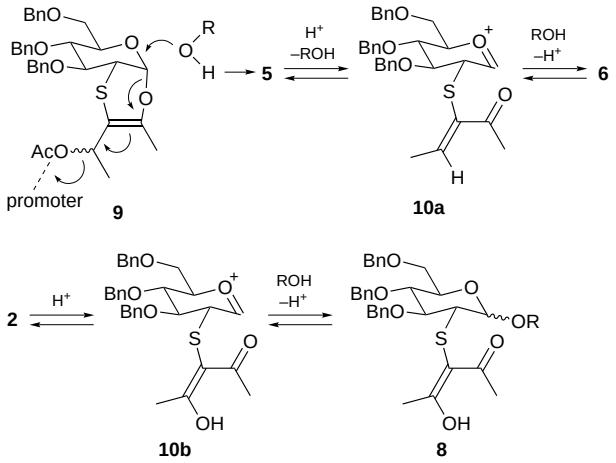
*Centro CNR 'Chimica e Struttura dei Composti Eterociclici', Dipartimento di Chimica Organica, Universita' di Firenze, via G. Capponi, 9 I-50121 Firenze, Italy*

**β-*O*-Glucosides 5, which can be completely converted to the α-anomers in the reaction medium, are obtained as single isomers by glycosidation of readily available donor 1 and are easily transformed into 2-deoxy-β-*O*-glucosides.**

Stereocontrol in *O*-glycosidation is a central matter in carbohydrate chemistry. A wide number of biologically important molecules originate from an aglycone and a saccharide by formation of a glycosidic linkage, moreover entire classes of polysaccharides are generated in nature by glycosidation of simpler carbohydrates.[1] A great effort has been devoted to optimise the glycosidation reaction as an indispensable transformation in organic chemistry. The crucial aspect has always been the achievement of a good level of stereocontrol on the formation of the glycosidic linkage, which usually leads to mixtures of α and β anomers. Efforts in this area have met with varying degrees of success.[2] While methods affording the α anomer with good selectivity are available, preparation of the pure β anomer is still a rare achievement. The problem is more serious for 2-deoxyglycosides, a class of derivatives of biological relevance, where the lack of assistance from proximal substituents and the low stability of precursors make the preparation of pure anomers, particularly the β anomer, a real challenge.[3] Our approach to the stereoselective synthesis of 2-deoxyglycosides was based on the exploitation of intermediates like **1**. We report here a synthetic protocol for *O*-glycosidation of tri-*O*-benzylglucal derivative **1** with complete stereocontrol of the glycosidic linkage, affording in a single reaction either α- or β-2-deoxyglucosides by simply controlling the experimental conditions. To the best of our knowledge, among the very few methods available, there is only one report of a selective preparation of β-2-deoxyglucosides that follows a similar approach.[4] The substantial improvement of the present protocol is the preparation of the β anomer as a pure isomer by using the readily available acetate **1** and the complete transformation of the β into the α anomer in the same reaction medium. The procedure is outlined in Scheme 1.

The oxathiine **1** is obtained from **2** which in turn is prepared in high yield as a single regioisomer by cycloaddition of tri-*O*-benzylglucal **3** with 2,4-dioxopentane-3-thione in a 95 : 5 α : β diastereomeric ratio.[5,6] Subsequent reduction of the carbonyl group to the alcohol and acetylation with acetic anhydride under standard conditions gave quantitatively the acetate **1**, which is further reacted without purification after removal under vacuum of pyridine and excess acetic anhydride. The glycosidic donor **1** is reacted in dry nitromethane at room temperature with the appropriate acceptor **4a**–**d** in the presence of a catalytic amount of methyl trifluoromethanesulfonate and quenching the reaction with pyridine.‡ Timing of quench is crucial for the success of β glycosidation. Quenching the reaction at the turning of the colour of the mixture from pale yellow to red affords the β glycosides **5** exclusively (reaction times and yields are given in Table 1). The stereochemistry of products is readily assigned by the chemical shift ($\delta$ 4.3–4.4) and coupling constants ($J_{1,2}$ 7.6–8.4 Hz) of the anomeric proton in the $^1$H NMR spectra.§ Chemically pure β-glycosides are obtained by flash column chromatography.

β-Glycosides **5** can be completely transformed into the α-anomers **6** by letting the product isomerise under the same reaction conditions; the isomerisation is presumably induced by acid catalysis. The aforementioned turning colour visually indicates the beginning of the isomerisation reaction, the time at which this occurs depends on the individual glycoside (from 0.5 h for **6a** to 1.5 h for **6d**¶). Thus, a single glycosidation reaction



**Scheme 1** *Reagents and conditions*: i, see ref. 5; ii, $LiAlH_4$ (0.5 equiv.), THF, 0 °C to room temp., 30 min, 92%; iii, $Ac_2O$, pyridine, room temp., 96%; iv, ROH (2 equiv.), MeOTf (0.2 equiv.), $MeNO_2$, room temp., v, MeOTf (0.2 equiv.), $MeNO_2$, room temp., 1 h, quantitative yield; vi, Raney-Ni, wet THF, 0 °C to room temp.

| 6 | **7c** | 30 | 65 |
| 7 | **7d** | 30 | 68 |

[a] Isolated yield.

**Scheme 2**

provides both anomers in pure form by careful control of the reaction time. Glycosidation of the parent ketone **2** under acid catalysis is more sluggish than that of the acetate **1**, invariably providing mixtures of the α and β anomers **8** (Scheme 2). Since β-glycosidation of **1** is totally stereoselective we take this evidence as an indication of a different reaction pathway followed by **1** and **2**. In the former case, owing to the higher reactivity of the acetate, the developing positive charge induced on **1** by the catalyst might be trapped by the acceptor *before* ring-opening of the oxathiine, as shown in **9**, allowing for a β-stereospecific glycosidic linkage formation. Subsequent α–β equilibration might proceed through an oxonium intermediate **10a** analogous to that leading to product mixture in the glycosidation of the ketone **10b**.

Deprotection of the thiosubstituted glycosides **5a,c,d,** to the corresponding 2-deoxyglycosides **7a,c,d**‖ is readily achieved by desulfurisation with Raney-nickel[4,7] (Scheme 1). Reaction times and yield are reported in Table 1.

In conclusion these preliminary results clearly indicate that the aceate **1** is a readily available and effective new donor for the synthesis of 2-deoxy-β-*O*-glycosides and that the described procedure might represent a competitive protocol for an efficient α–β stereocontrol in the glycosidation reaction.

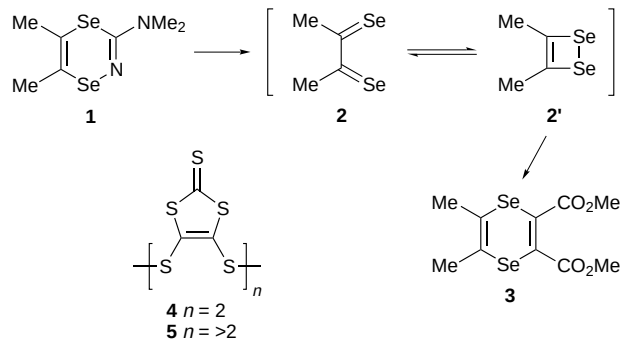
# 1,4-Diselenine synthesis by Diels–Alder reaction of a novel exocyclic 1,2-diselone: X-ray crystal structure of (5,6-dimethoxycarbonyl-1,4-diselenine-2,3-dithiolate)Ni(dppe) [dppe = 1,2-$(Ph_2P)_2C_2H_4$]

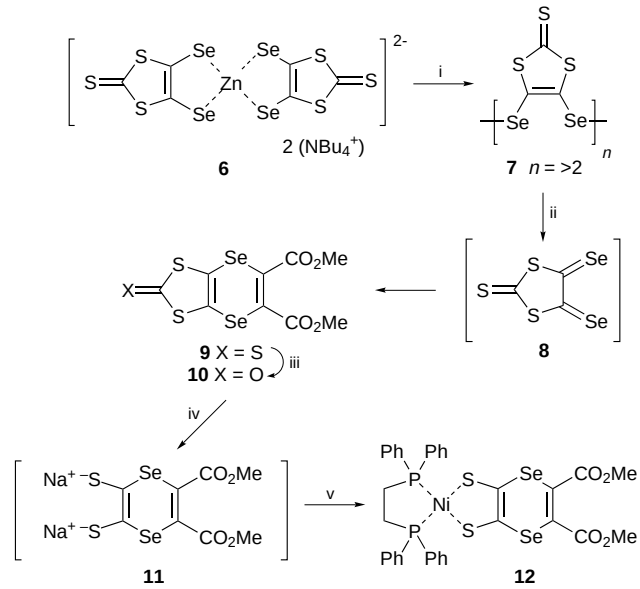


**Antony Chesney, Martin R. Bryce,* Andrei S. Batsanov and Judith A. K. Howard**

*Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE*

**The salt $(NBu_4)_2[Zn(dsit)_2]$ 6 has been converted into the polymer $(C_3S_3Se_2)_n$ 7 which is a source of the reactive 1,2-diselone 8, trapping of which with dimethyl acetylenedicarboxylate affords the 1,4-diselenine derivative 9, which is subsequently transformed into the 1,4-diselenine-2,3-dithiolate species 11, characterised by the X-ray crystal structure of a nickel complex 12.**

The synthesis of unusual organoselenium heterocycles, especially *via* cycloaddition chemistry of reactive N=Se[1] and C=Se[2] bonds, has recently attracted considerable attention. For example, the low-yielding synthesis of 1,4-diselenine derivative **3** from the unstable 1,4,2-diselenazine **1** was presumed to occur *via* the transient 1,2-diselone intermediate **2**, or the 1,2-diselenete tautomer **2′** (Scheme 1).[2c] We now report an entirely different approach to an exocyclic 1,2-diselone intermediate and its efficient trapping reaction to yield the highly-functionalised bicyclic 1,4-diselenine system **9** which is subsequently transformed into the nickel complex **12**.



1,4-Dithiine synthesis by reactions of either the dimer **4**[3] or the polymer **5**[4] of the $C_3S_5$ unit[4b,5] has been reported. We chose to investigate the selenium-containing salt $(NBu_4)_2[Zn(dsit)_2]$ (dsit = 1,3-dithiole-2-thione-4,5-diselenolate) **6**[6] as a novel precursor for 1,2-diselones. Zinc salt **6** was easily prepared on a multi-gram scale, according to the literature procedure employing the more reactive red form of selenium.[6a] Oxidation of **6** with $I_2$ in EtOH–acetone at −50 °C afforded a highly insoluble, air-stable† compound $(C_3S_3Se_2)_n$, assumed to be polymer **7**, in excellent yield. Treatment of **7** with $PBu_3$ in $CH_2Cl_2$ at 20 °C in the presence of excess dimethyl acetylenedicarboxylate (DMAD) afforded the bicyclic 1,4-diselenine derivative **9** in 57% yield, presumably *via* the intermediacy of the highly-reactive 1,2-diselone **8** (or a $PBu_3$ complex of **8**) (Scheme 2). The use of $PBu_3$ to depolymerise **7** was more successful than the usual method employed for the sulfur analogue $(C_3S_5)_n$ **5**, which is heated in a solvent such as benzene, toluene, dioxane or chlorobenzene.[4] The use of these conditions with **7** led to poor yields of adduct **9**, which was contaminated with a variety of unidentified components. 1,2-Diselones are extremely rare species.[2c] Electron diffraction experiments[7] clearly revealed that a cyclic 1,2-diselenete structure (*cf*. structure **2′**) is favoured over the acyclic diselone structure $F_3CC(Se)–C(Se)–CCF_3$. However, this is less likely to be the situation for intermediate **8**, which is the first exocyclic 1,2-diselone: the diselenete tautomer of **8** would be a very strained bicyclic system.

**Scheme 1**

Conversion of the thione functionality in **9** into the oxo derivative **10** proceeded almost quantitatively on reaction with mercuric acetate in a mixture of $CHCl_3$ and AcOH. Opening of the 1,3-dithiole ring of **10** was achieved by reaction with MeONa in anhydrous MeOH: the disodium salt of 5,6-dimethoxycarbonyl-1,4-diselenine-2,3-dithiolate **11** thereby formed reacted *in situ* with $NiCl_2$(dppe) [dppe = 1,2-$(Ph_2P)_2C_2H_4$] to afford the dark green dithiolene complex (5,6-dimethoxycarbonyl-1,4-diselenine-2,3-dithiolate)Ni(dppe) **12**. Complexation of 1,4-dithiine-2,3-dithiolate units with nickel species has been previously reported both by Rauchfuss[3] and Bereman[8] but, to the best of our knowledge, this is the first time the 1,4-diselenine-2,3-dithiolate system has been prepared. X-Ray analysis of crystals of complex **12**, grown from MeCN, unambiguously proved the structure of the complex (Fig. 1).‡

In complex **12**, the nickel atom adopts a square planar coordination, distorted by a slight (6.5°) tetrahedral twist. The

**Scheme 2** *Reagents and conditions*: i, $I_2$ (2.1 equiv.), EtOH–acetone, −50 to 20 °C, 2 h; ii, $PBu_3$ (1 equiv.), DMAD (2 equiv.), $CH_2Cl_2$, 20 °C; iii, $Hg(OAc)_2$, $CHCl_3$–AcOH (3 : 1 v/v), 20 °C, 12 h; iv, NaOMe, MeOH, 30 min; v, $NiCl_2$ (dppe)

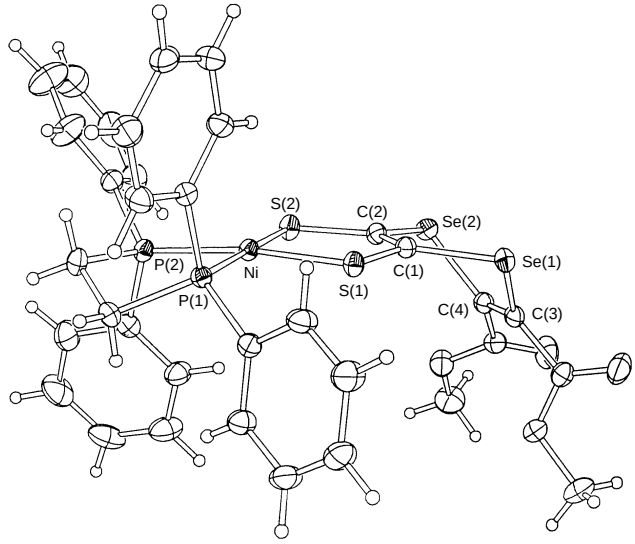


**Fig. 1** Molecular structure of **12**. Bond distances (Å): Ni–S(1) 2.168(1), Ni–S(2) 2.173(1), Ni–P(1) 2.175(1), Ni–P(2) 2.191(1), S(1)–C(1) 1.750(2), S(2)–C(2) 1.755(2), C(1)–Se(1) 1.917(2), C(2)–Se(2) 1.917(2), C(1)–C(2) 1.343(2), C(3)–Se(1) 1.918(2), C(4)–Se(2) 1.922(2), C(3)–C(4) 1.338(2).

Se(1)C(1)C(2)Se(2) moiety forms dihedral angles of 6.5° with the planar $NiS_2C_2$ ring and of 52.8° with the Se(1)C(3)C(4)Se(2) plane. The ester substituents at C(3) and C(4) are inclined to the latter plane by 48.5 and 55.3°, respectively.§ The folding of the diselenine ring in **12** is similar to that observed in [1,4]diselenino[2,3-*b*:5,6-*b′*]di[1]benzoselenole (54°) and 1,2,3,4,5,6,8,9,10,11,12,13-dodecahydrodicycloocta[1,4]diselenine[10] (49°), but larger than in nickel complexes with isoelectronic 2,3-dithiolato-1,4-dithiine ligands (28–43°).[3,11]

In summary, we have devised a short and expedient route to the 1,2-diselone **8** which has been converted to the 1,4-diselenine derivative **9** and hence the nickel complex **12**. This methodology affords a new and efficient approach to the synthesis of highly-functionalised derivatives of the rare 1,4-diselenine ring system. Further research into the Diels–Alder trapping of 1,2-diselone intermediate **8**, and the downstream organic and organometallic reactions of the products derived therefrom, will be reported in due course.

We are grateful to the EPSRC for funding this work and to the Leverhulme Trust for a scholarship (to A. S. B.) and the Royal Society for a Leverhulme Senior Research Fellowship (to J. A. K. H.).

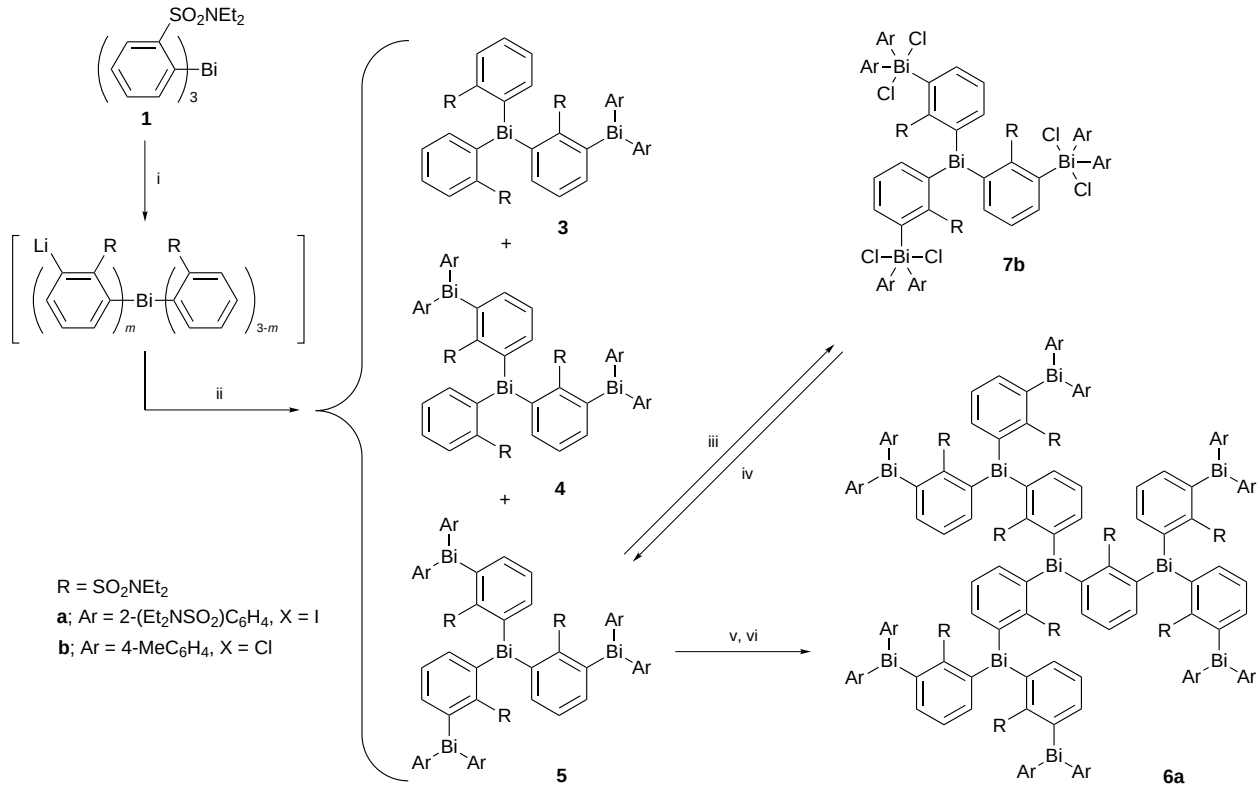
# First synthesis and properties of dendritic $Bi_n$-bismuthanes

**Hitomi Suzuki,* Haruto Kurata and Yoshihiro Matano**

*Department of Chemistry, Graduate School of Science, Kyoto University, Sakyo-ku, Kyoto 606-01, Japan*

**Directed tris-ortholithiation of tris[2-(diethylaminosulfonyl)phenyl]bismuthane 1 with *tert*-butyllithium followed by treatment with 3 equiv. of bis[2-(diethylaminosulfonyl)-phenyl]bismuth iodide 2a gives a symmetrically branched $Bi_4$-bismuthane 5a, which, on a similar treatment, is converted in a one-pot synthesis into a highly branched $Bi_{10}$-bismuthane 6a.**

Owing to excellent contrast density of bismuth toward X-rays of short wavelength, the synthesis of water-soluble non-ionic organobismuth compounds represents an interesting area of research in pursuit of iodine-free positive X-ray contrast agents. High bismuth content (m/m %) is a prerequisite for such a purpose and the incorporation of multiple bismuth atoms into a molecule is a straightforward approach to this. However, the literature to date contains no report of the synthesis of organobismuth compounds bearing more than two bismuth atoms in the molecule. Several tetraorganyldibismuthanes ($R_2BiBiR_2$) are known,[1] but they are quite sensitive to air and light and difficult to handle. During the course of our effort to synthesize polybismuth compounds, we came across a simple one-pot method for introducing three diarylbismuthyl units directly into the three aromatic rings of a triarylbismuthane and this methodology has now enabled us to gain easy access to highly branched aromatic polybismuth compounds. Herein we report the first synthesis of dendrimer-type aromatic polybismuth compounds bearing up to ten bismuth atoms in a single molecule,[2] utilizing the directed ortholithiation of triarylbismuthanes bearing a sulfonamide function at the *ortho* position of each aromatic ring.



Since the sulfonamide group is a good directing group in the ortholithiation of arenes,[3] tris[2-(diethylaminosulfonyl)-phenyl]bismuthane[4] **1** was chosen as the starting material for water-soluble neutral polybismuth compounds. This bismuthane was synthesized by the ortholithiation of *N*,*N*-diethylbenzenesulfonamide with butyllithium followed by treatment with 1/3 $BiCl_3$ in THF at −78 °C. Compound **1** contains acidic protons *ortho* to the sulfonyl group on the three aromatic rings, so it can be further lithiated in the presence of an excess of an alkyllithium. When compound **1** was lithiated with 1.1 equiv. of *tert*-butyllithium in THF at −78 °C for 1 h and then treated with 1 equiv. of bis[2-(diethylaminosulfonyl)phenyl]-bismuth iodide[5] **2a**, $Bi_2$-bismuthane **3a** and $Bi_3$-bismuthane **4a** were obtained in 37 and 18% yields, respectively, together with 25% of recovered starting material **1**, where $Bi_n$-bismuthane represents a bismuthane bearing *n* bismuth atoms in one molecule (Table 1, entry 1). When 3.3 equiv. of *tert*-butyllithium was used under appropriate conditions, a symmetrically branched $Bi_4$-bismuthane **5a** was obtained as the main product. The yields of these bismuthanes varied considerably depending on the temperatures employed; compound **5a** was obtained in moderate and good isolated yield when the reaction mixture was warmed to −20 and 0 °C before iodide **2a** was added (entries 3 and 4, respectively), whereas $Bi_4$-bismuthane **5a** was not formed at all when bismuthane **1** was reacted with *tert*-butyllithium followed by iodide **2a** at −78 °C (entry 2). These results suggest that the tris-ortholithiation of compound **1** was the crucial step for the formation of a dendrimer-type $Bi_4$-bismuthane **5a** and that it did not proceed to completion at −78 °C. An isomeric linear $Bi_4$-bismuthane was not formed under the conditions employed. When bis(4-methylphenyl)bismuth chloride[4] **2b** was used in place of iodide **2a**, tolyl-substituted analogues **3b**, **4b** and **5b** were obtained in 2, 6 and 11% isolated yields, respectively (entry 5). Three of four bismuth atoms in $Bi_4$-bismuthane **5b** readily underwent oxidative chlorination with an excess of sulfuryl chloride in $CH_2Cl_2$ at room temp. to give a hexachloride **7b** in 55% yield, in which the central bismuth atom is intact, while the outer three bismuth atoms are oxidized to $Bi^V$ (Scheme 1). The reduction of hexachloride **7b** with saturated aqueous $Na_2S_2O_3$ smoothly regenerated the original $Bi_4$-bismuthane **5b** in 92% yield. All $Bi_n$-bismuthanes **3a,b**, **4a,b** and **5a,b** and hexachloride **7b** obtained were characterized by NMR and MALDI-TOF mass spectroscopies as well as by elemental analyses.

$Bi_4$-bismuthane **5a** bears acidic protons at the positions *ortho* to the sulfonamide group in the six outer aromatic rings. This structural advantage enabled us to extend the present methodology further, making access possible to a highly branched dendrimer-type $Bi_{10}$-bismuthane **6a**. Thus, treatment of $Bi_4$-bismuthane **5a** with 6.6 equiv. of *tert*-butyllithium in THF at 0 °C for 1 h followed by the addition of 6 equiv. of iodide **2a** at −78 °C afforded a crude $Bi_{10}$-bismuthane **6a** in *ca.* 20% yield, accompanied by small amounts of $Bi_8$- and $Bi_9$-congeners. The $Bi_{10}$-dendrimer **6a**, isolated by gel permeation chromatography and further purified by column chromatography on silica gel, is a white powder which begins to decompose above 180 °C without melting. It is readily soluble in dichloromethane and chloroform, but insoluble in methanol and ethanol. Its MALDI-TOF mass spectrum showed a $(M + Na)^+$ peak at *m/z* 6558.1 (calc; 6561.9). In its $^{13}C$ NMR spectrum, three distinct sets of $^{13}C$ absorptions were observed for non-equivalent ethyl groups at $\delta$ 41.8, 40.3 and 40.0 for methylene carbons and at $\delta$ 14.1, 13.0 and 12.7 for methyl carbons, respectively. Simple NMR peak patterns observed suggest a high molecular symmetry in accord with the dendritic structure of bismuthane **6a**. In the sense of atomic mass of a key element involved, the dendrimer **6a** represents the heaviest example of dendrimers so far reported. Attempts to elucidate the molecular geometry of compound **5a** by X-ray analysis have so far met with failure owing to the rapid efflorescence of the specimen crystals in air.

**Table 1** Reaction of lithiated bismuthane **1** with halides **2**

| | | Conditions for step i | | Yield (%)[a] | | | |
|---|---|---|---|---|---|---|---|
| Entry | Halide | $Bu^tLi$ (equiv.) | *T*/°C | **1** | **3** | **4** | **5** |
| 1 | **2a** | 1.1 | −78 | 25 | 37 | 18 | 0 |
| 2 | **2a** | 3.3 | −78 | 9 | 7 | 31 | 0 |
| 3 | **2a** | 3.3 | −78 to −20 | 4 | 9 | 11 | 13 |

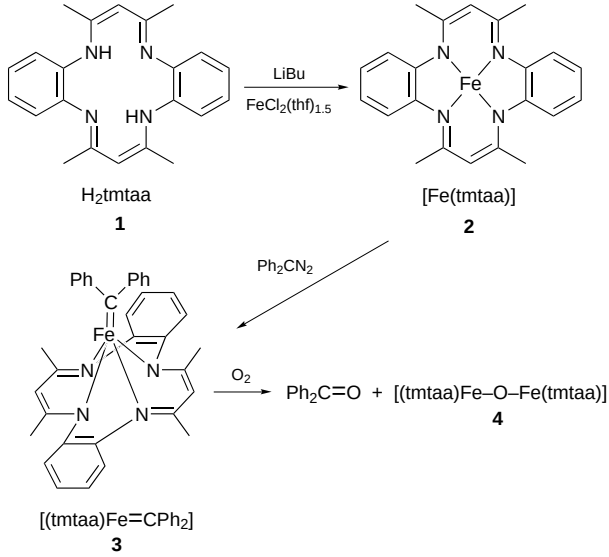
# Iron–carbene functionalities supported by a macrocyclic ligand: iron–carbon double bond stabilized by tetramethyldibenzotetraazaannulene

**Alain Klose,[a] Euro Solari,[a] Carlo Floriani,*[a] Nazzareno Re,[b] Angiola Chiesi-Villa[c] and Corrado Rizzoli[c]**



[a] *Institut de Chimie Minérale et Analytique, BCH, Université de Lausanne, CH-1015 Lausanne, Switzerland*
[b] *Dipartimento di Chimica, Università di Perugia, I-06100 Perugia, Italy*
[c] *Dipartimento di Chimica, Università di Parma, I-43100 Parma, Italy*

**We report an unprecedented entry to the chemistry of the iron–carbene functionality supported by an easily available macrocycle.**

The metal–carbene unit is a key functionality both in organometallic and organic chemistry.[1] It is usually bonded to conventional ancillary ligands, with a few remarkable exceptions in metal–porphyrin chemistry,[2–6] and particularly in the case of iron[2] and ruthenium.[2b,3,5] Despite of considerable effort in this field, owing to the relevance of metal–porphyrin carbene derivatives in chemistry and biology,[2,3] some facts are particularly surprising: (*i*) there is an absence of any modeling approach in macrocycle chemistry, *i.e.* the use of readily available macrocycles; (*ii*) the potential of the metal–carbene bonded to a macrocyclic structure is still to be explored; (*iii*) very few (three, at present) metal–porphyrin carbenes have been structurally characterized.[2a,6]

Here, we report a straightforward synthesis of iron–carbenes stabilized by the easily accessible tetramethyldibenzotetraazaannulene ligand ($H_2$tmtaa)[7] along with their structural characterization in solution and in the solid state. The availability of tetramethyldibenzotetraazaannulene encourages the use of [Fe(tmtaa)] for developing iron–carbene chemistry based on this and other macrocycles. The synthesis was performed by reacting **2**[8a] with the corresponding diazoalkane (Scheme 1).

The reaction of **2** with $Ph_2CN_2$ in THF at −30 °C, and then at room temperature, gave high yields of **3** as a green crystalline solid.† Complex **2** showed a very high thermal stability and resistance to hydrolysis. The reaction of **3** with dioxygen gave, almost quantitatively, benzophenone and the well known μ-oxo dimer **4**.[7a] The stability and the nature of the final compound

**Scheme 1**

derived from the reaction of **2** with diazoalkanes is strongly dependent on the substituents at the carbene carbon. In the case of $PhCHN_2$, the carbene derivative forms only at low temperature. It decomposes at room temperature leading to the starting material and *trans*-stilbene (81%) and *cis*-stilbene (19%), while in the presence of dioxygen it forms PhCHO and complex **4**. Owing to its diamagnetism, **3** has been readily characterized by $^1$H and $^{13}$C NMR spectroscopies and structural details have been revealed by X-ray analysis‡ (see Fig. 1). The coordination environment of iron is a distorted tetragonal pyramid, unlike iron–prophyrin[2a] or osmium–porphyrin[6b] examples, where the metal is always six-coordinate. The metal is displaced by 0.335(1) Å from the $N_4$ average plane. The Fe–C(23) vector is perpendicular to the $N_4$ core, the dihedral angle with the normal to the $N_4$ plane being 1.0(1)°. The carbene plane C(23)C(31)C(41) is almost parallel to the N(2)···N(4) vector, the torsion angles C(31)–C(23)–Fe–N(4) and C(41)–C(23)–Fe–N(2) being −15.5(3) and −15.2(3)°, respectively. The Fe–C(23) bond distance [1.794(3) Å] is particularly short compared to the only available iron–porphyrin [Fe=$CCl_2$ 1.83(3) Å][2a] or organometallic derivatives of iron, where it ranges from 1.978(3) to 1.85(3) Å.[9] The question whether the oxidation state of iron in **3** is +2 or +4 can be reasonably answered, in the absence of Mössbauer measurements, by considering the Fe distance from the $N_4$ plane. A correlation in tmtaa complexes has been established between the out of plane distance of the metal and its $d^n$ configuration.[7b] The value found in the present case [0.335(1) Å] is expected for low-spin $d^6$ five-coordinate iron(II), *e.g.* 0.29 Å in [Fe(tmtaa)(CO)].[8c] Much longer distances would be found for a $d^4$ configuration. The extended

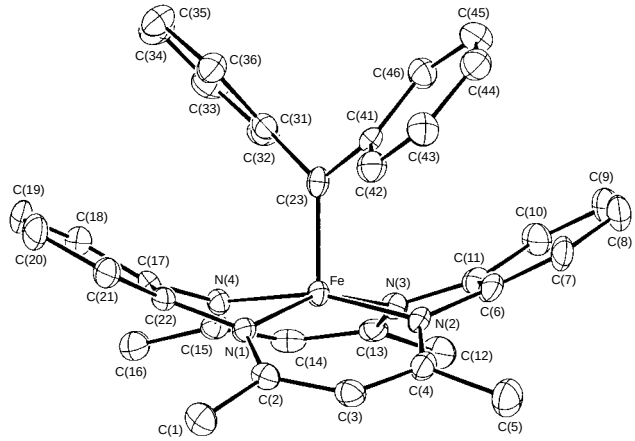


**Fig. 1** ORTEP drawing of complex **3** (50% probability ellipsoids. Selected interatomic distances (Å) and angles (°): Fe–N(1) 1.921(3), Fe–N(2) 1.926(2), Fe–N(3) 1.911(3), Fe–N(4) 1.920(2), Fe–C(23) 1.794(3), C(23)–C(31) 1.487(5), C(23)–C(41) 1.472(4); N(3)–Fe–N(4) 94.6(1), N(2)–Fe–N(4) 163.3(1), N(2)–Fe–N(3) 82.7(1), N(1)–Fe–N(4) 82.3(1), N(1)–Fe–N(3) 156.4(1), N(1)–Fe–N(2) 93.6(1), Fe–C(23)–C(41) 122.6(2), Fe–C(23)–C(31) 121.7(2), C(31)–C(23)–C(41) 115.7(3).

Hückel calculations further support the +2 oxidation state for iron in **3** and the use of carbene rather than alkylidene terminology for the present complexes. The tmtaa, which shows the usual saddle shape conformation,[7] has structural parameters quite close to those reported for the other iron complexes.[8]

† *Preparation* of **3**: To a cooled (−30 °C) THF solution (140 ml) of [Fe(tmtaa)]·thf[8a] (1.79 g, 3.80 mmol) was added dropwise a THF solution (40 ml) of diphenyldiazomethane (0.78 g, 4.0 mmol). When warmed to room temperature the solution became red. Nitrogen gas was slowly given off. After stirring for 2 d, the green solution was concentrated *in vacuo* (20 ml) and then hexane (15 ml) added. A green crystalline solid was obtained (1.70 g, 75%). Crystals suitable for X-ray analysis were grown in toluene (Found: C, 74.53; H, 5.77; N, 9.91. $C_{35}H_{32}FeN_4$ requires C, 74.47; H, 5.71; N, 9.92%). $^1$H NMR (200 MHz, $C_6D_6$, 25 °C): $\delta$ 6.88–6.76 (m, 8 H), 6.35–6.33 (m, 10 H), 5.13 (s, 2 H), 2.12 (s, 12 H). $^{13}$C NMR (100.6 MHz, $C_6D_6$, 25 °C): $\delta$ 313.2 (C carbene), 166.6, 157.9, 149.3, 127.1, 124.8, 120.9, 120.5, 119.7, 107.3, 67.8, 25.8, 23.2.

‡ *Crystal data* for **3**: $C_{35}H_{32}FeN_4\cdot C_7H_8$, $M$ = 656.7, triclinic, space group $P\bar{1}$, $a$ = 11.670(3), $b$ = 13.593(4), $c$ = 11.234(3) Å, $\alpha$ = 106.72(2), $\beta$ = 96.21(2), $\gamma$ = 77.62(2)°, $U$ = 1665.0(8) Å$^3$, $Z$ = 2, $D_c$ = 1.310 g cm$^{-3}$, $F(000)$ = 692, Mo-K$\alpha$ radiation ($\lambda$ = 0.710 9 Å), $\mu$(Mo-K$\alpha$) = 4.87 cm$^{-1}$: crystal dimensions 0.08 × 0.72 × 0.85 mm. The structure was solved by the heavy atom method and anisotropically refined for all the non-H atoms. All the hydrogen atoms were located from difference Fourier maps and introduced as fixed contributors in the last stage of refinement ($U_{iso}$ = 0.05 Å$^2$). For 4428 unique observed reflections [$I > 2\sigma(I)$] collected at $T$ = 133 K on a Rigaku AFC6S diffractometer ($5 < 2\theta < 50°$) and corrected for absorption the final $R$ is 0.059 ($wR_2$ = 0.163 for the 5293 reflections having $I > 0$ used in the refinement). All calculations were carried out on a QUANSAN Personal Computer equipped with an INTEL PENTIUM processor. CCDC 182/644.

# X-Ray crystal structure of (tetraphenylimidodiphosphinato)silver(I): an unexpected tetranuclear complex with two modes of coordination of silver

**Henri Rudler,[a] Bernard Denise,[a] José Ribeiro Gregorio[a] and Jacqueline Vaissermann[b]**

*[a] Laboratoire de Synthèse Organique et Organométallique, URA 408, and [b] Laboratoire de Chimie des Métaux de Transition, URA 419, Université Pierre et Marie Curie, T44-45, 4 place Jussieu 75252 Paris Cedex 5, France*

**Potassium tetraphenylimidodiphosphinate reacts with silver nitrate to give, upon recrystallization from ethanol, an unexpected tetranuclear complex $[Ag\{N(OPPh_2)_2\}]_4\cdot 2EtOH$, the structure of which is established by X-ray crystallography; preliminary results concerning its use as a catalyst for the aerobic co-oxidation of alkenes and aldehydes are described.**

The tetraphenylimidodiphosphinate ligand (TPIP), the 'inorganic' equivalent of β-diketonate ligands, has proven to lead to interesting complexes especially in the field of lanthanide NMR shift reagents.[1–4] Thus, $Pr(TPIP)_3$, owing to its high stability with respect to hydrolysis even in the presence of acids (in contrast to β-diketonates), can be used as a shift reagent for carboxylic acids and induces important simplification in their $^1H$ NMR spectra. Moreover, $Pr(TPIP)_3$ reacts instantaneously with carboxylates to lead to dinuclear complexes: in the case of acids containing a chiral centre, these complexes can be used to control the optical purity of the starting acids. Along the same lines, the use of $Gd(TPIP)_3$ as a relaxation agent for carboxylic acids has recently been outlined.[5] A common feature of all the complexes so far described is the mode of coordination of the TPIP ligand to the metal: as for β-diketonates, TPIP acts as a bidentate ligand.[4]

A second interesting feature of this ligand is its high stability towards oxidants: its preparation from the related phosphine can be carried out in concentrated hydrogen peroxide without noticeable decomposition. This observation and our ongoing efforts to develop new catalysts for the efficient, possibly asymmetric, epoxidation of alkenes, prompted us to carry out the systematic synthesis of various lanthanide and transition metal complexes containing this and related ligands for that purpose.[6] Among the latter, we were interested in silver complexes containing such ligands. Indeed, silver-based catalysts are used in the epoxidation of ethene;[7] however, complexes containing this metal have, to the best of our knowledge, not been tested in the aerobic aldehyde alkene co-oxidation system (Mukayama reaction).[8,9]

Moreover, since silver chelates have also found interesting applications in NMR spectroscopy of alkenes,[10,11] we decided to attempt the preparation of Ag(TPIP).

Here, we describe the synthesis and the unexpected X-ray structure of the new complex Ag(TPIP) and to provide preliminary results concerning its use as an oxidation catalyst.

When aqueous solutions of silver nitrate (0.170 g, 1 mmol; 10 ml $H_2O$) and of KTPIP (0.46 g, 1 mmol; 10 ml $H_2O$) were mixed a precipitate formed. Filtration of the solid followed by recrystallization from $CH_2Cl_2$–EtOH gave colorless crystals 0.34 g, 65% yield) which were stable in the air and in solution, and were suitable for X-ray analysis.† According to the NMR spectrum of the crystals,‡ half an equivalent of EtOH solvent was present in the product and elemental analysis confirmed this observation.

The molecular structure of Ag(TPIP) is shown in Fig. 1. The molecule is built up of four Ag(TPIP) units which are arranged pairwise and which contains two solvent molecules per formula unit. These molecular pairs reside on a crystallographically imposed centre of symmetry. From a formal point of view, two $Ag^+$ cations adopt the preferred[12,13] linear coordination by combination with two TPIP ligands giving $Ag(TPIP)_2^-$, with N(1)–Ag(1)–N(2) 172.0(1)°, so leaving three pendent P=O groups, the remaining P=O group being linked *via* a hydrogen bond to ethanol. Two $Ag^+$ cations share six P=O ligands and thus hold together the two $Ag(TPIP)_2$ anions. Moreover, these two anions are also coupled by a pair of Ag···Ag contacts (3.210 Å). The coordination of the two silver atoms to the six suitably oriented P=O groups occurs in such a way as to lead to a central planar $Ag_2O_2$ ring with O(3)–Ag(2)–O(3′) 91.1(2)°, the two oxygen atoms being dissymmetrically bonded to silver with Ag(2)–O(3) 2.269(2) and Ag(2)–O(3′) 2.654(2) Å. The coordination around silver is thus distorted tetrahedral with the oxygen atoms of the P=O groups as closest neighbours, the shortest bond occurring between silver and a terminal oxygen atom is Ag(2)–O(1) 2.195 Å.

The P=O bond lengths are comparable or slightly shorter (especially the P=O group linked to ethanol by its oxygen atom) than those found *e.g.* in $Pr(TPIP)_3$. By contrast, the P–N bonds are in general longer than those observed in $Pr(TPIP)_3$ (1.620 *vs.* 1.590 Å) thus confirming their single bond character.[14]

Direct comparison of this structure with that of the corresponding unstable silver β-diketonates[15,16] could unfortunately not be established since the latter structures are so far unknown.

Although a number of mononuclear complexes in which the silver cation is surrounded by four oxygen (or sulfur) atoms giving distorted tetrahedral environment are known,[17,18] as well

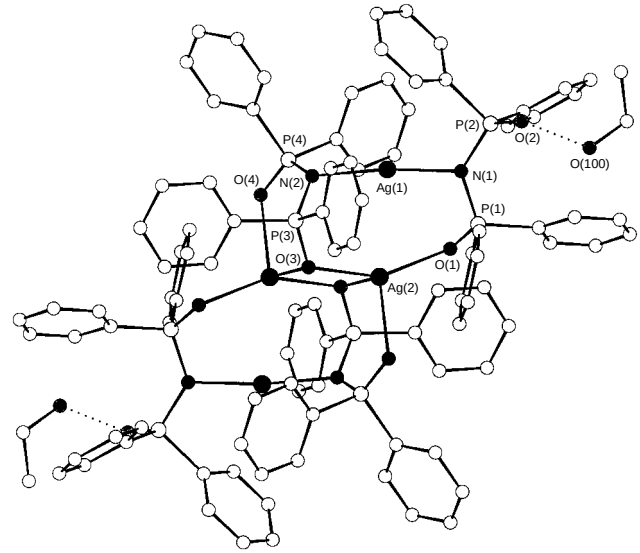

**Fig. 1** Molecular structure of $[Ag\{N(OPPh_2)_2\}]_4\cdot 2EtOH$ showing the atomic numbering scheme. Selected distances (Å) and angles (°): Ag(1)–N(1) 2.145(3), Ag(1)–N(2) 2.170(2), Ag(2)–O(1) 2.195(2), Ag(2)–O(3) 2.269(2), Ag(2)–O(3′) 2.654(2), Ag(2)–O(4′) 2.388(2); N(1)–Ag(1)–N(2) 172.0(2), O(3)–Ag(2)–O(3′) 90.84(8), P(1)–N(1)–P(2) 130.7(2), P(3)–N(2)–P(4) 124.6(2).

**Table 1** Epoxidation of various alkenes promoted by Ag(TPIP) in the presence of isobutyraldehyde and oxygen in dichloroethane

| Entry | Alkene (mmol) | *t*/h | Yield acid (%) | Yield epoxide (%) | Yield furan (%) | Yield pyran (%) |
|---|---|---|---|---|---|---|
| a | Cyclooctene (0.77) | 4 | 98 | 100 | | |
| b | Oct-1-ene (0.64) | 20 | 98 | 40 | | |
| c | Cholesteryl acetate (0.59) | 0.5 | 50 | 58[b] | | |
| | Cholesteryl acetate (0.59) | 2 | 80 | 100 | | |
| d | Linalool (0.57) | 3 | 70 | 26 | 30 | 4 |
| e | Linalool (0.57) | 21 | 99 | 5 | 85 | 10 |
| f | Linalool[c] (5.7) | 6 | 85 | 65 | 15 | |

[a] $P(O_2)$ = 1 atm, room temp.; aldehyde/alkene = 7; catalyst = 1 mol%. [b] α/β isomers: 32/68. [c] Linalool (1 ml), aldehyde (4 ml), catalyst (50 mg), dichloroethane (20 ml).

as an example of a trinuclear complex in which the silver atoms adopt both a linear and a tetrahedral coordination,[19] the central planar dinuclear structure with the two linear $Ag^-$ moieties found in the present complex is, to the best of our knowledge, unique.

Preliminary results of the catalytic properties of this complex in the oxidation of alkenes are promising. Many transition metals bearing various groups (usually β-diketonato ligands) are active in the aerobic co-oxidation of alkenes and aldehydes into epoxides and acids. However, one major problem is linked to the high rate of oxidation of the aldehyde to the acid: in such cases, the conversion of the alkenes into epoxides drops considerably, unless a large excess of aldehyde is used. We have now found that on the one hand that the lanthanide complexes (Pr, Eu, Dy) containing TPIP can be used for the epoxidation of alkenes: their activity are comparable to that of more classical complexes of Co and Mn.[6] On the other hand, as shown in Table 1, a series of alkenes gave, in the presence of Ag(TPIP), the corresponding epoxides (and their rearrangement products for linalool[20]) in yields and rates comparable to, or even higher than those observed for other metal TPIP complexes and also for the more classical metal β-diketonates (M = Mn, Co).[8,9,21,22] Although cyclooctene and cholesteryl acetate (entries a and c) are readily oxidized alkenes, the result achieved with Ag(TPIP) is striking since high rates and quantitative conversions into the epoxide are observed. However, and as for other catalysts, the results were rather sluggish for monosubstituted terminal alkenes (entry b). Finally, for linalool, the conditions could be varied in order to obtain either the epoxides or their rearrangement products[20] (entries d–f).

## Footnotes and References

† *X-Ray structure determination*: X-ray quality crystals were obtained by slow evaporation of $CH_2Cl_2$ from a solution of the silver complex in $CH_2Cl_2$–EtOH. Data were collected at room temperature on a Nonius CAD4 diffractometer. Empirical absorption correction using PSISCAN was applied. Anomalous dispersion terms and correction of secondary extinction were applied. The structure was solved by SHELXS[23] and refined by least-squares analysis using anisotropic thermal parameters for all non-hydrogen atoms. H atoms were located on a difference Fourier map, and their coordinates were refined as free atoms with an overall isotropic thermal parameter. 9260 reflections, with $F_o > 3\sigma(F_o)$ were used to solve and refine the structure to $R$ = 0.0338 and $R_w$ = 0.0324, 708 least-squares parameters. The programs used were CRYSTALS and CAMERON.[24,25]

# A novel method for large-scale synthesis of AgI nanoparticles

**Sihai Chen, Takashi Ida and Keisaku Kimura***

*Department of Material Science, Faculty of Science, Himeji Institute of Technology, Harima Science Garden City, Kamigori, Hyogo 678-12, Japan*

**Thiol-derivatised I–VII nanoparticles of AgI (7–16 nm) are prepared in large quantities by the reaction of silver nitrate with potassium iodide containing 1-thioglycerol in aqueous solution.**

Solid electrolytes with high ionic conductivity have drawn much attention because of the possibility for applications in solid-state battery and chemical sensing systems. Recently, we have found that the ionic conductivity of polycrystalline pellet of AgI increased significantly when the particle size is decreased from the bulk to 140 nm.[1,2] Following this finding the synthesis of large amounts of small AgI nanoparticles is strongly desirable. Several wet chemical methods such as the use of gelatin[3] or polymer,[4–7] control release of iodide ions from $CH_2I_2$[8,9] have been studied. However these methods were all applied to very diluted solutions ($< 10^{-3}$ M), and thus AgI can not be separated as a solid powder in large quantities. Here, we report the synthesis of a large amount of AgI nanoparticles using 1-thioglycerol (TG) as the size controller. This is the first extension of the use of thiolates in the synthesis of II–VI nanoparticles[10] to I–VII nanoparticles.

In order to grow AgI clusters with simultaneous attachment of a thiol monolayer on the particle surface, silver ions are injected in the iodide solution containing thiols maintaining $[Ag^+] = [I^-] + [TG]$. The size of the particles can be controlled by the $[I^-]/[TG]$ ratio. For a typical preparation with a $[I^-]/[TG]$ ratio of 9.0, 20 ml of a 0.2 M $AgNO_3$ solution was rapidly added into a solution containing 18 ml 0.2 M KI and 2 ml 0.2 M TG under vigorous stirring. After 20 min of reaction, the resulting turbid yellow solution was sealed into cellulose tubing (Type 24/32, pore size 2.4 nm, Visking company) and dialysized against flowing water for 24 h in the dark. The pH of the solution changed from 2.13 to 7.16. After freeze drying, 0.92 g of yellow powder which corresponds to a yield of 98% was obtained. Fig. 1 shows the electron micrograph (recorded with Hitachi 8100 instrument at 200 kV) of the AgI particles sampling from a 200 times diluted initial solution. The particles were spherical with a mean diameter of 16 nm but characterized by a wide size distribution (standard deviation of 9.4 nm, calculated from the digitalized image with a NIH software package). The morphology of these particles is different from that prepared by simply mixing $AgNO_3$ and KI in dilute solutions[4,5] which often shows the shape of regular triangles with rounded corners or irregular polygons. This difference indicates that thiolates can effectively inhibit the anisotropic growth of the special crystal plane of AgI nuclei, leading to the formation of small particles even in concentrated solutions.

Fig. 2 shows a typical electron diffraction pattern of the sample in Fig. 1. The strong diffraction spots indicate that the samples are polycrystalline, this is also confirmed by HRTEM image in the insert of Fig. 1. The measured lattice spacings calibrated with a standard gold film were 3.969 (100), 3.737 (002), 3.483 (101), 2.723 (102), 2.296 (110), 1.954 (112), 1.326 (300) and 1.249 Å (302) of β-AgI (wurtzite structure). Also, the spacings at 3.737 (111), 2.296 (220), 1.949 (311), 1.673 (400), 1.480 (331) and 1.249 Å (511) can be attributed to γ-AgI (zinc blende structure). The existence of only these two types of diffraction rings indicates that the particles are composed of only β- and γ-AgI.

X-Ray diffraction spectra of the solid powder (recorded with a Rigaku RINT/Dmax-2000 diffractometer) confirmed the above assignment (Fig. 3). All diffraction peaks show broadening compared to that of the bulk sample. The average particle size was 15 nm estimated from the Scherrer's equation. Further simulation of the XRD pattern with a Rietveld method, utilizing a program RIETAN-94 developed by Izumi[11] revealed that the

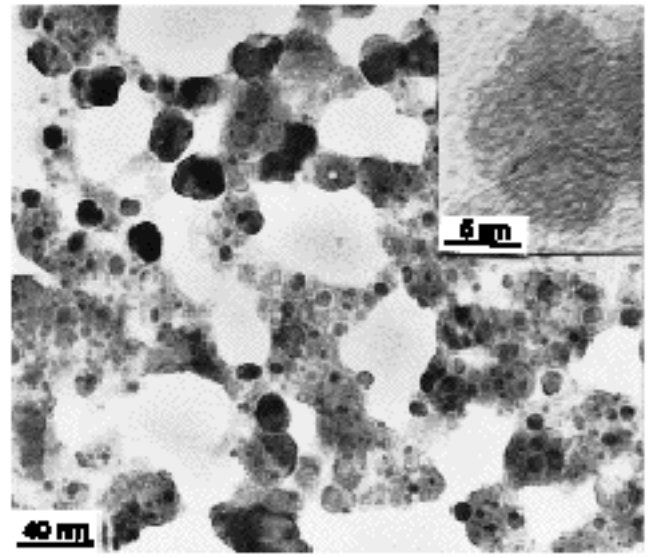

**Fig. 1** Transmission electron micrograph of AgI particles prepared with an initial $[I^-]/[TG]$ ratio of 9.0. The insert shows a high resolution TEM image of one particle.

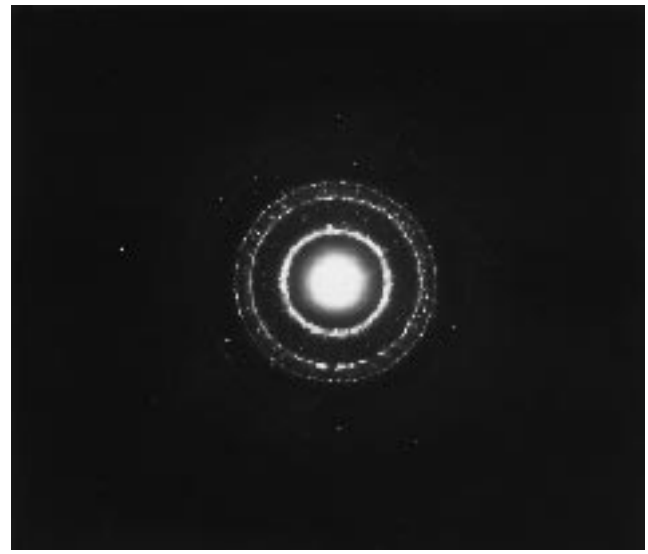

**Fig. 2** Electron diffraction pattern of the sample in Fig. 1

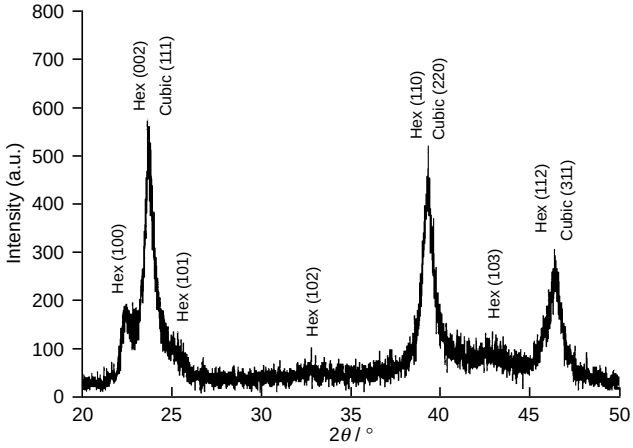

**Fig. 3** X-Ray diffraction pattern of the sample in Fig. 1

particles contain 36.5% of β- and 63.5% of γ-AgI. According to the theoretical dependence of X-ray diffraction peak intensity ratio, *R*, on the amounts of hexagonal and cubic AgI proposed by Berry (Fig. 1 in ref. 3, where *R* is the relative ratio of intensity of the center line of the diffraction triplet to the sum of intensities of the two outside lines, $[I(111)_{cubic} + I(002)_{hex}]/[I(100)_{hex} + I(101)_{hex}]$), a consistent result of 40.0% of β- and 60.0% of γ-AgI can be deduced.

The IR spectrum of the particles is similar with that of TG except for the absence of the S–H vibration peak at 2558 $cm^{-1}$. This phenomenon is also observed for other AgI particles prepared with lower $[I^-]/[TG]$ ratios, which contain more organics (up to 30.4%). Also, the resulting AgI solution is acidic (pH = 2.13). This shows that the following chemical reaction occurred (TG = R–SH):

$$R–SH + Ag^+ \text{ (surface)} \rightarrow R–SAg \text{ (surface)} + H^+ \qquad (1)$$

The thiolates are connected to the $Ag^+$ sites on the AgI particle surface *via* sulfur atoms, and act as the 'skin' of the AgI particles. Energy-dispersive X-ray microanalysis (Kevex system attached to Hitachi 8100) gave: Ag, 50.0; I, 45.2%. Thermogravimetry showed a 4.2% mass loss after heating the powder to 400 °C under a nitrogen atmosphere. If we assume that only the organics was lost after heat treatment (XRD confirmed that the residues were mainly AgI), about 88% of the organics were removed. After heating, the yellow powder turned black and bulk-like, with S still detected by EDX. This is reasonable owing to its strong interaction with silver ions. Upon decreasing the initial $[I^-]/[TG]$ ratio from 9.0 to 0.67, the size of the AgI particles decreased to *ca*. 7 nm as determined from XRD measurement, while the organic content increased to 30.4%.

We propose that this new method may find applications in large-scale synthesis of other I–VII nanoparticles such as AgBr or CuCl. Heat treatment may remove most of the organic layer. This suggests great potential in further increasing the electric conductivity of solid electrolytes by using nanometer sized AgI particles and futher work is under way.

This work was supported in part by Grant-in-Aids for Scientific Research on Basic Research (A: 09304068) and on Priority Areas (09215234), and a Grant-in-Aid for JSPS fellow from Ministry of Education, Science, Sports and Culture, Japan. One of us (S. C.) gratefully acknowledges a grant from the Japan Society for Promotion of Science for the postdoctoral fellowship.

# Direct synthesis of gold nanodispersions in sol–gel derived silicate sols, gels and films

**S. Bharathi and O. Lev***

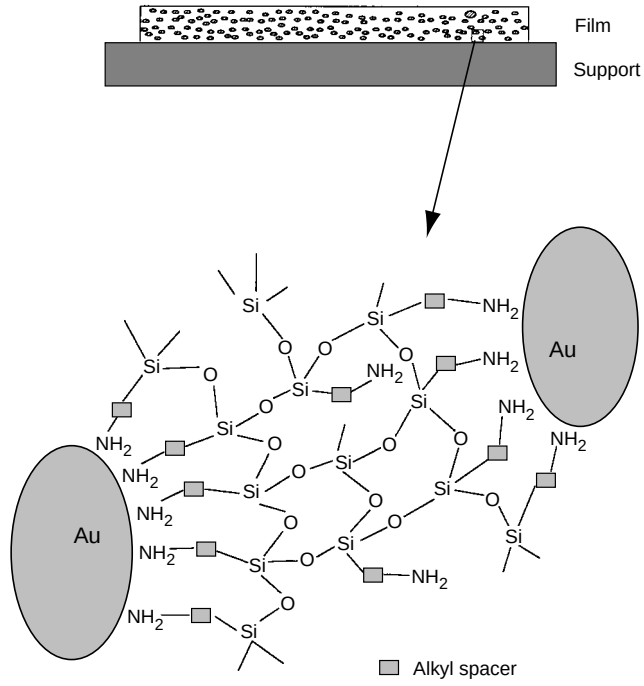
*Fredy and Nadine Herrmann School of Applied Sciences, The Hebrew University of Jerusalem, Jerusalem 91904, Israel*

**A simple method for the preparation of stable colloidal suspensions of gold nanoparticles in silicate sols, silicate based films and monoliths is presented; organically modified sol–gel monomers containing amine functional groups are used for the stabilisation of Au ions and the metal nanocrystalline sol.**

Several methods to produce metallic nanodispersions in aqueous and organic solvents have been recently reported.[1–4] In aqueous solutions colloids are stabilised by polymeric stabilisers [*e.g.* poly(vinyl pyrrolidine)][1] or buffer electrolytes such as *e.g.* citrate ions.[2] Long chain surfactants (*e.g.* quaternary ammonium compounds)[3] or specific ligands[4] are used to increase particle stability in organic solvents. In all these cases the removal of the stabilising agent causes immediate destabilisation of the sol. Encapsulation of metallic nanodispersions in sol–gel matrices is beset by additional complications. First, care should be taken to avoid aggregation or precipitation of the metal salts in the organic sol–gel precursors and additional means are required to prevent coalescence or precipitation of the metallic particles during sol–gel polymerisation. Two general schemes have been proposed for the encapsulation of metallic nanoparticles in sol–gel matrices. Silicate coated gold nanoparticles have been produced by preparing a gold sol by the citrate route and subsequent stabilisation by a 3-aminopropyltrimethoxysilane derived aminosilicate.[5] A second approach is based on sol–gel processing in inverse micelles.[6] Other methods to prepare highly dispersed metal particles in a porous support of silica or alumina were devised by hydrogen reduction or thermal decomposition of metal oxides or salts that were previously deposited on the support.[7] The method is simple to perform but gives a rather wide particle size distribution. Schubert and coworkers[8] developed a general methodology in which the metal ions are first attached to a silane monomer containing a chelating organofunctional group and then sol–gel polymerisation is initiated. The resulting gel is subsequently subjected to thermal oxidation giving a dispersion of metal oxide, which can then be reduced by treatment with hydrogen gas. Highly homogeneous monodispersions of nanocrystalline metals in sol–gel materials were produced by this method.

For practical reasons it is highly desirable that a single stabiliser should be employed for the stabilisation of the metal salt and the nanocrystalline sol. Additionally it is preferable that the sol will be stable for at least several weeks and that there should be no leaching of organic moieties or chelating agents from the supported catalysts. Sol–gel monomers containing amine functional chelating groups are very promising for this purpose. Alkylamines have been reported to form stable monolayers on bare gold substrates in the vapour phase[9] (although the stability of monolayers that were prepared from solvents was rather limited[10]). Furthermore, a recent report,[11] demonstrated that alkylamine can cap gold nanoparticles in a similar manner to that of thiols.[12]

Here, we use the precursors *N*-[3-(trimethoxysilyl)propyl]-ethylene diamine (EDAS) and aminopropyltrimethoxysilane (APS), which are capable of coordinating $AuCl_4^-$, stabilising the Au nanoparticles in the sol–gel solution, and becoming an integral and unleachable part of the supporting matrix after gelation. Gold colloid formation (*e.g.* by reduction with $NaBH_4$) can be initiated either before or after the polycondensation step. The preparation procedure involved the addition of the required amount of $HAuCl_4$ to EDAS or APS giving clear yellow solutions and subsequent sonication for 10 min. No phase separation or increased turbidity was noted, indicating a uniform dispersion of the gold salt in the silane precursor. The hydrolysis and condensation of the materials were then initiated by addition of a fixed quantity (3–5% by volume) of 0.1 M HCl and water (1–3% by volume) to the homogeneous solution. Formation of gold nanoparticles was achieved by subsequent dropwise addition of 0.4 M $NaBH_4$ solution (3–5% by volume) to the sol, causing an instantaneous purple coloration indicative of gold colloid formation.



The general reaction can be represented by eqns. (1) and (2)

$$(MeO)_3Si–X–NH_2 + HAuCl_4^- \rightarrow (MeO)_3Si–X–NH_3^+AuCl_4^- \quad (1)$$

$$(MeO)_3Si–X–NH_3^+AuCl_4^- \xrightarrow{NaBH_4} (MeO)_3Si–X–NH_2Au_m \quad (2)$$

where X is an alkyl spacer. Thus, the tetrachloroaurate anions are bound to silane precursors, which assures good homogenisation, and after reduction of $AuCl_4^-$ the amine groups attach to and stabilize the metal nanoparticles. A schematic illustration of the gold nanoparticles in the aminosilicate network is shown in Scheme 1.

Absorbance spectra of typical sols are shown in Fig. 1. A surface plasmon peak at *ca*. 500–540 nm, characteristic of a

**Scheme 1** Schematic illustration of Au naoparticles in a silicate matrix

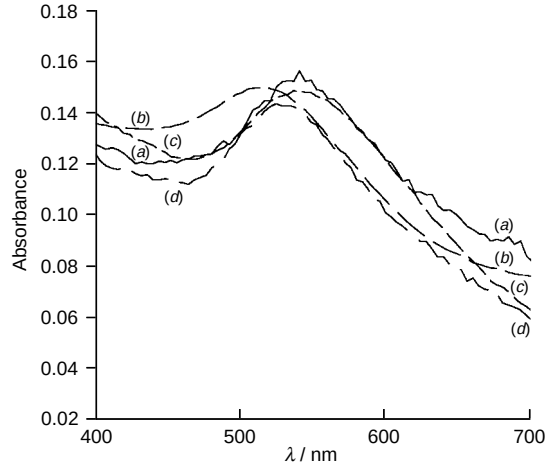


**Fig. 1** Visible spectra of different sols (*a*) EDAS : Au ratio 5 : 1 (*b*) EDAS : Au ratio 100 : 1, (*c*) the sol of (*a*) after a month and (*d*) thin film produced from sol (*a*)

gold sol, confirms the presence of Au nanoparticles. The surface plasmon absorbance of colloidal gold particles is affected by particle size as well as by the refractive index of the medium and thus it is impossible to determine the average particle size based on the optical characteristics alone.[13]

Gold sols were prepared with different EDAS : Au ratio, from < 1 : 1 to 100 : 1 in order to elucidate the sensitivity of particle size distribution to the gold loading. A stable gold sol was observed only for EDAS : Au ratio > 1. The absorbance spectra of the sols prepared using EDAS : Au = 5 : 1 and 100 : 1 are shown in Fig. 1(*a*) and (*b*). The absorbance maxima shifts from 540 to 514 nm as the Si : Au ratio is increased from 5 : 1 to 100 : 1. However, TEM investigations clearly showed that the particle size distribution was not affected by the Si : Au ratio, or by changing the aminosilane precursor. The small absorbance shift is probably caused by changes in the refractive index of the sol.[13] Fig. 1(*a*) and (*c*) show the absorbance spectra for a sol prepared with an Si : Au ratio of 5 : 1, taken 1 h after preparation and after a month. The time invariant spectra indicate good stability of the colloidal suspension. No visible aggregation of the particles took place over several months. Between the two silane precursors used, the EDAS–gold sols were stable for at least a few months as evidenced from the unchanged absorbance spectra. However gold sols prepared with APS were stable for only two weeks or so, after which slight deterioration of the sol homogeneity was observed. Attempts to prepare gold colloids using TEOS or methyltrimethoxysilane (MTMOS) without aminosilane precursors resulted in immediate aggregation of the gold particles during reduction with $NaBH_4$. This clearly establishes the role played by the aminosilanes in binding and dispersing the metal ions in addition to stabilising the Au nanoparticles.

The sol could be gelled to give monoliths of various shapes or films (1–10 μm thick) by dip or spin coating. A typical absorption spectrum of a thin silicate film containing a gold dispersion (prepared from a 5 : 1 EDAS : Au sol) is shown in Fig. 1(*d*). The resemblance of Fig. 1(*a*) and (*d*) indicates high stability of the dispersion which is maintained during sol–gel processing. Changes of sol–gel processing variables such as Si : HCl or Si : $H_2O$ ratio altered the rate of hydrolysis and gelation time but had no measurable influence on the particle size distribution of the resulting sol.

Transmission electron micrographs of the gold dispersed silica films were taken with a Philips electron microscope. A typical TEM image of gold nanoparticles prepared with EDAS : Au = 5 : 1 dispersed in a silicate network is shown in Fig. 2. It can be seen that the shape of the gold particles is mostly spherical with an average diameter of 5–6 nm. TEM images of particles obtained from the two aminosilane precursors were very similar. A few cylindrical (tubular) particles can also be seen which appear to be formed by coalescence of two or three particles.

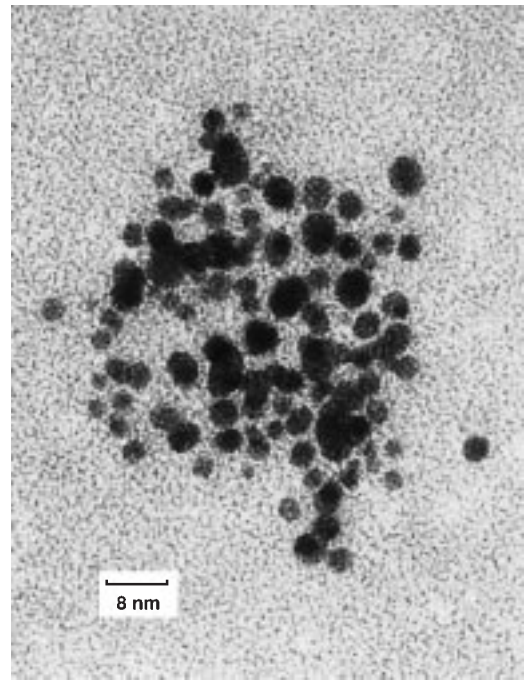

**Fig. 2** TEM image of Au nanoparticles with EDAS : Au ratio 5 : 1

In conclusion, it has been shown that Au nanoparticles can be stabilized in an organically modified silica sol, without the aid of any external stabilizing agent. Judicial selection of a suitable organo-functionalised sol–gel monomer can play a dual role of dispersing the metal salt precursors and stabilising the nanoparticles.

We thankfully acknowedge the financial help of MOS, Israel.

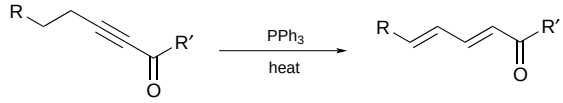
# A short synthesis of conjugated unsaturated amides and esters *via* triphenylphosphine-catalysed isomerisation of acetylenic pentafluorophenyl esters†

**Uli Kazmaier**

*Organisch-Chemisches Institut der Universität, Im Neuenheimer Feld 270, 69120 Heidelberg, Germany*

**Isomerisation of acetylenic pentafluorophenyl esters in the presence of phosphines gives rise to activated dienoic acids, which can be coupled directly with amines and alcohols in a simple one-pot procedure.**

Highly unsaturated carboxylic and fatty acids are very common in different types of natural products.[1] Many of these sometimes very complex compounds show interesting biological activities and are applied as antibiotics.[2] Unsaturated esters are found as side-chains of sugars,[3] such as the antifungal active papulacandins,[4] or as parts of macrocyclic lactones.[5] Unsaturated amides find application as insecticides,[6] and modified peptides[7] and cyclopeptides[8] are highly interesting from a pharmaceutical point of view.



Apart from eliminations[9] and Knoevenagel condensations,[10] Wittig and Horner–Emmons[11] reactions are used frequently for the synthesis of conjugated unsaturated carboxylic acids. Besides these well established approaches, organometallic transformations, such as cross coupling reactions[12] or metal-catalysed isomerisations of acetylenes to dienes,[13] are also becoming more and more important.

Recently we described a new isomerisation of acetylenic carbonyl compounds in the presence of triphenylphosphine.[14] Similar results were obtained by Guo and Lu.[15] While acetylenic ketones can easily be isomerised in the presence of 5–10% of $PPh_3$ at 80–100 °C (Scheme 1), the corresponding less reactive esters react only in the presence of weak acids (*e.g.* acetic acid). If the reaction is applied to activated enynes or diynes, conjugated trienes or tetraenes can be obtained as well.[16]

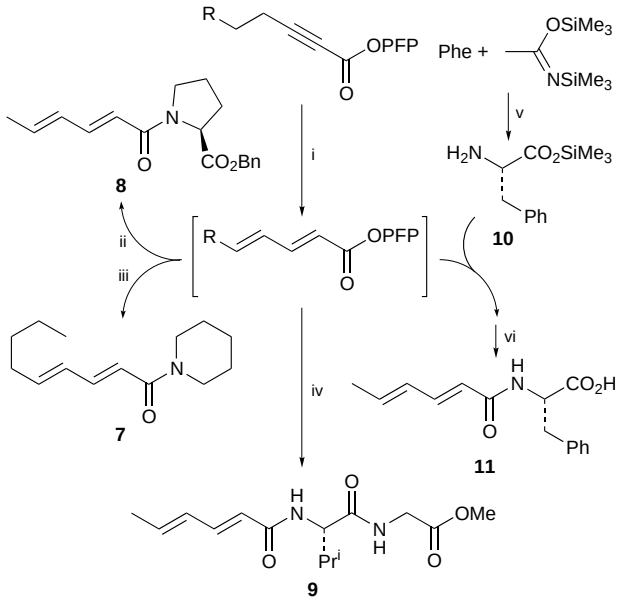
The reaction probably starts with a nucleophilic addition of the phosphine on the activated triple bond, followed by a set of proton transfer steps. Perhaps these steps are accelerated by weak acids. This mechanism seams reasonable, because several of the possible intermediates could be trapped and used for further reactions, *e.g.* Michael additions.[17]

This procedure gives easy and cheap access to these interesting compounds, although problems may arise during the isomerisation process with acid- or thermo-labile compounds. Acetylenic amides only react, if at all, under even more drastic conditions,[14] which may not be 'survived' by sensitive amides, like peptides.

For an application of this process to natural product synthesis it would be desirable to work under mild conditions and/or to combine the isomerisation of an activated acetylene with a successive esterification (or amide formation), probably in a one-pot procedure. This approach can be realized by using the corresponding acetylenic pentafluorophenol esters. These relatively stable esters are used frequently in peptide syntheses, especially for the syntheses of strained cyclic peptides.[18] The isomerisation of these esters proceeds under much milder conditions (Table 1), because of the strong electron-withdrawing effect of the fluorine atoms and the resulting activation of the triple bond.

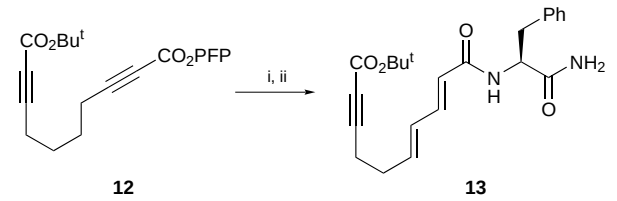
**Scheme 1**

Using 10 mol% of $PPh_3$ the isomerisation can be carried out at room temperature and under neutral conditions, which is important for the application of this procedure to sensitive substrates. Various acetylenic esters were investigated and, in general, the isomerisation was complete after stirring the reaction mixture overnight. The (*E*,*E*)-diene is formed almost exclusively (93–99%, as determined by NMR or GC analyses). If the esters tolerate higher temperatures, the amount of phosphine can be dramatically reduced, as shown with the last entries.‡ The higher temperatures are necessary for acceptable turnovers. From a synthetical point of view, it is convenient to carry out the isomerisation with 5% of phosphine at 50 °C, because under these conditions most reactions are complete after 4–5 h. The isomerisation only occurs in the presence of phosphines. No reaction was observed in the presence of tertiary amines, as determined by GC analysis, which is especially well-suited to monitoring the reaction progress. Obviously, the isomerisation proceeds directly from the acetylene to the conjugated diene. Allenic intermediates, as postulated in transition metal catalysed isomerisations,[13] could not be detected in any of the investigated examples.



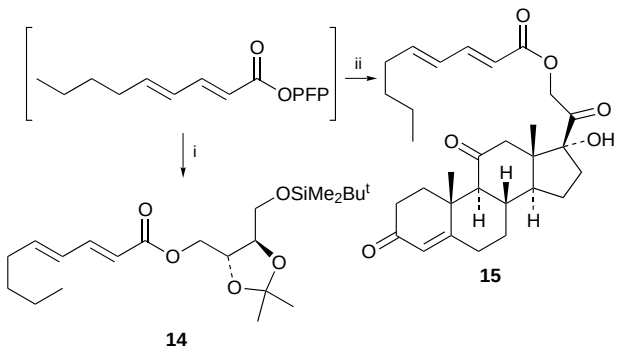
In general, the isomerisation proceeds in a very clean manner and without side reactions. Therefore the isomerised active esters can be coupled directly with nucleophiles in a one-pot procedure (Scheme 2).§ Thus conversion to the corresponding amides **7**, *e.g.* by reaction with amino acid esters **8** and peptides **9**, occurs at room temperature. To use this protocol in peptide syntheses, it would also be of interest to couple the dienoic acid to free amino acids, because the acylated amino acids obtained can be used directly for the next coupling step with further amino acids or peptides. This approach can be realized by heating the desired amino acid in toluene with bis(trimethylsilyl)acetamide (until the amino acid is completely dissolved) giving rise to the corresponding silyl ester **10**. The acylated amino acid **11** is obtained after acidic workup of the reaction mixture. The increased reactivity of the pentafluorophenol esters towards alkyl esters also allows their regioselective isomerisation and coupling, as illustrated with substrate **12** (Scheme 3).

**Table 1** $PPh_3$-catalysed isomerisations of **5**



| $PPh_3$ (%) | *T*/°C | *t*/h | Conversion (%) |
|---|---|---|---|
| 10 | 25 | 2 | 43 |
| 10 | 25 | 14 | 67 |
| 10 | 25 | 14 | 97 |
| 5 | 50 | 4 | quant. |
| 1 | 50 | 4 | 46 |
| 0.1 | 100 | 40 | 59 |

The reaction is almost independent of the solvent used. Alcohols, especially sterically hindered ones, do not react under the conditions of amide formation, and they can be used as solvents for amines which are not soluble in less polar solvents. Nevertheless, esterification is possible under transesterification conditions, as described by Seebach *et al.*[19] (Scheme 4). In the presence of LiBr and 1,4-diazabicyclo[2.2.2]octane (DABCO) or DBU, acylated polyols (*e.g.* **14**) and steroids (*e.g.* **15**) can be obtained. The formation of the corresponding Weinreb amides[20] also needs higher temperatures (80 °C) in comparison to the reaction of other amines.



Professor Dr G. Helmchen is thanked for his generous support of this work. Financial support by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged.

† Dedicated to Professor Huttner on the occasion of his 60th birthday.

‡ In these cases the reaction should be carried out under argon to avoid oxidation (deactivation) of the catalyst.

§ *General procedure* for the isomerisation/amide formation: 1 mmol each of alkynoic acid and pentafluorophenol were dissolved in 5 ml $CH_2Cl_2$ and, after addition of 0.1 mmol of DMAP, the solution was cooled to −20 °C. A solution of 1 mmol DCC in 1 ml $CH_2Cl_2$ was added and the mixture was allowed to warm to room temperature overnight. After filtration and evaporation of the solvent the residue was dissolved in 5 ml of toluene. After addition of 0.05 mmol of $PPh_3$ the solution was warmed to 50 °C for 5 h. After cooling to room temperature, 1–1.5 mmol of the corresponding amine were added and the mixture was stirred at room temperature overnight. The obtained crude product was purified by flash chromatography or crystallisation.

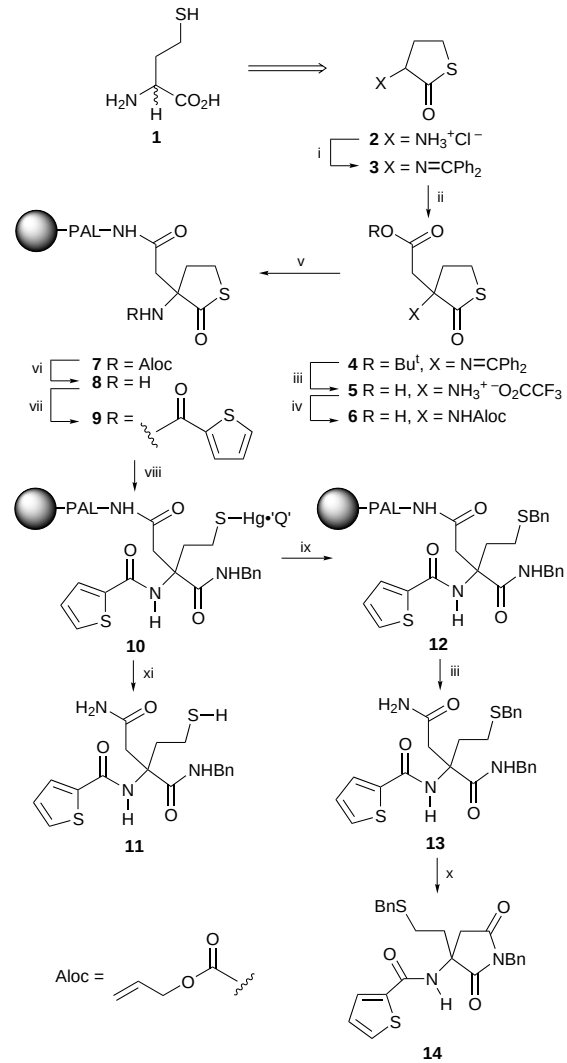
# Solid-phase synthesis of tri-functionalised, α-substituted carbamoylmethyl-homocysteine compounds, their release from the resin and subsequent intramolecular cyclisation to give novel 1,3,3-trisubstituted succinimides

**J. Alan Girdwood and Richard E. Shute***



*ZENECA Pharmaceuticals, Mereside, Alderley Park, Macclesfield, Cheshire, UK SK10 4TG*

**Attachment of DL-homocysteine thiolactone to polystyrene resin *via* the PAL-linker and an α-carbamoylmethyl group, followed by amino, carboxy and thiol derivatisation, including a novel Hg-assisted thiolactone ring-opening, and acidolytic cleavage from the solid-phase yields novel 1,3,3-trisubstituted succinimides *via* intramolecular cyclisation.**

Recently, the pharmaceutical industry has undertaken far-reaching changes in order to foreshorten the timelines of drug discovery and development. Within the former of these two processes, the technology of combinatorial chemistry has assumed an ever-increasing importance.[1] Fundamental to the recent development of this technique has been the use of solid-phase organic chemistry (SPOC).[2] Here we report: (i) attachment of the amino acid homocysteine (hCys) **1** to a polystyrene-based solid-support *via* the PAL-linker[3] and an acetate-derived spacer group attached to the α-carbon of the amino acid; (ii) on-resin derivatisation of the orthogonal carboxy, amino and thiol functionalities; (iii) release of target compounds from the resin; and (iv) an unexpected intramolecular cyclisation of the target compounds leading to novel 1,3,3-trisubstituted succinimide compounds. Derivatisation of the amino functionality was achieved by means of a novel heavy metal-assisted ring-opening of the thiolactone. The chemistry described has been optimised to take place under mild conditions, to be high yielding, to use diverse substituents or building blocks which are readily available, and to yield compounds of high purity. It is thus eminently amenable to the generation of a compound library suitable for general biological screening purposes.

With the proviso that we wished to preserve the three hCys functionality handles for on-resin derivatisation, we envisaged connection of DL-hCys thiolactone **2**, a cheap and readily available precursor to hCys, to the resin *via* an acidolytic amide linker group attached to the α-carbon (Scheme 1). Off-resin reaction of **2** with benzophenone imine yielded the stable Schiff's base **3**.† Deprotonation of the α-position by KOBu$^t$ was followed by alkylation with $BrCH_2CO_2Bu^t$ to give **4** in good yield. Treatment of **4** with dilute acid gave the thiolactone amino acid **5** which could be readily $N^{\alpha}$-protected by treatment with allyl chloroformate (Aloc-Cl) under Schotten–Baumann conditions to give the crystalline, protected template **6**. Complete attachment of **6** to PAL-polystyrene resin[3] to give **7** was achieved by means of standard coupling reagents and a two-fold excess of **6**. $Pd^0$-catalysed Aloc-deprotection of **7** was achieved within 2 h at room temp. as indicated by cessation of $CO_2$ evolution, to give **8**. Coupling of the model carboxylic acid thiophene-2-carboxylic acid to **8** was achieved using an excess of symmetrical anhydride and yielded **9**.§

Attempts to ring-open the thiolactone of **9** to give amide and free thiol by treatment with $BnNH_2$ in *N*-methylpyrrolidone at elevated temperatures over many hours were unsuccessful. This was indicated by our failure, not only to observe the loss of the diagnostic thiolactone carbonyl absorption peak at *ca*. 1700 $cm^{-1}$ in the FT-IR spectrum of resin **9** (data gathered on a mull of **9** in $CHCl_3$), but also, on cleavage and analysis by HPLC and mass spectrometry, to see any compound other than that based on starting material. Addition of catalysts such as DMAP or NaCN also failed to effect the desired reaction. Finally, on-resin ring-opening was achieved by means of a novel Hg-assisted reaction in the presence of $BnNH_2$ to yield **10**.¶ The exact nature of the resultant resin-bound thiolate species, –S–Hg–'Q', remains unclear. Acidolytic cleavage of **10** using TFA (aq.) and

**Scheme 1** *Reagents and conditions*: i, $Ph_2C{=}NH$, $CH_2Cl_2$, room temp., 91%; ii, KOBu$^t$, THF, $BrCH_2CO_2Bu^t$, room temp., 89%; iii, TFA (aq.), 90%; iv, $CH_2{=}CHCH_2O_2CCl$, dioxane, $Na_2CO_3$ (aq.), room temp., 75%; v, PAL-resin, $Pr^iN{=}C{=}NPr^i$, 1-hydroxybenzotriazole, DMF, room temp. vi, $Pd(PPh_3)_4$, $Bu^n{}_3SnH$, AcOH, $CH_2Cl_2$, room temp. vii, thiophene-2-carboxylic anhydride, DMF, pyridine, room temp.; viii, $BnNH_2$, $Hg(O_2CCF_3)_2$, THF, room temp.; ix, BnBr, THF, room temp.; x, prolonged treatment with TFA–$H_2O$ 9 : 1, room temp. or 1% conc. HCl in MeOH, room temp., 90%; xi, TFA, $Et_3SiH$ 99 : 1

examination of the product by HPLC and mass spectrometry yielded material that contained 2–3 distinct chemical species, none of which was readily characterisable. On the other hand, when TFA–$Et_3SiH$ was used instead of TFA (aq.), the free thiol, **11**, as characterised by HPLC and mass spectrometry, was produced in high yield and purity. Elemental analysis of resin **10** showed Hg and F to be present as well as the other expected elements, suggesting that 'Q' comprised a $CF_3CO_2^-$ counterion derived from $Hg(O_2CCF_3)_2$. However, closer analysis of the elemental composition revealed a F : S ratio significantly less than 3 : 1. This further implied that 'Q' was not wholly $CF_3CO_2^-$ anion, but rather suggested a mixture of $CF_3CO_2^-$ and a putative crosslinked –S–Hg–S– form with two neighbouring on-resin hCys thiolates joined through a mercuric ion. Such a mixture of on-resin species might explain the observation of a mixture of products on cleavage of **10** under non-reducing conditions.

The final stage in the on-resin synthesis was achieved by direct treatment of **10** with excess BnBr to give **12**.**

Treatment of **12** with TFA (aq.) for 1 h gave **13,**‖ the conformationally flexible hCys product that was our initial target, in over 60% overall yield and with a purity greater than 90% by HPLC. Somewhat unexpectedly however, if the acid treatment time was increased, we observed in the reversed-phase HPLC a later running impurity, which, under prolonged TFA (aq.) treatment, became the predominant, and most stable chemical species. HPLC and mass spectrometry indicated that this material was derived from **13** by loss of $NH_3$. Furthermore, treatment of chromatographically purified **13** with HCl in MeOH (aq.) rapidly gave **14**‖ in greater than 90% yield. This material was identical to the later running impurity observed on prolonged treatment of **13** with TFA (aq.).

Compound **14** arises *via* an intramolecular cyclisation analogous to the peptidyl 'aspartimide' reaction, a rearrangement which can, in Asx-Gly/Ser containing peptides, lead to unnatural β-linked isoAsx-Gly/Ser sequences.[5] This cyclisation has a number of major consequences for the chemistry as originally conceived. Firstly, it removes the primary carboxamide functionality, that vestige of the compound's link to the solid support, by tying it back to the rest of the molecule in a succinimide ring. Secondly, and perhaps of greater significance in the context of this chemistry being of utility for the generation of compound libraries, the cyclisation does not cause any of the introduced diversity substituents to be lost. The final product **14** still retains all the functionality attached to hCys as was required in the original design, only now displayed around a different, more constrained scaffold.

Finally, it is of note that substituted succinimides have a long and rich history in medicinal chemistry particularly as bioisosteres of hydantoins,[6] and also that the hydantoin ring system itself was not only one of the very earliest heterocycles to be exploited in combinatorial chemistry,[7] but continues to be of interest for the generation of diverse compound libraries.[8] In a similar fashion, 1,3,3-trisubstituted succinimide-based compound libraries†† derived, as we have shown, either from α-carbamoylmethylhomocysteine, or potentially from other α-carbamoylmethyl-substituted amino acids, should also be of utility in drug discovery programmes. Our further studies on compounds of this general type[10] will be reported in due course.

The authors acknowledge the contributions of Peter Robins, Rachel Stead, Dearg Brown, Brian Main, David Hollinshead, Brian Wright, Kath Barber and Eddie Clayton to this work.

† For a recent reference to the solution-phase chemistry of amino acid Schiff's bases of this type see ref. 4(*a*). For a recent reference to on-resin, amino acid Schiff's base chemistry see ref. 4(*b*).

§ In order to confirm the integrity and follow the progress of any particular reaction, acidolytic cleavage of a few milligrams of resin was performed at various times throughout the course of all reactions by treatment with TFA in the presence of either $Et_3SiH$ or $H_2O$ and the products examined by HPLC and mass spectrometry. Also, all intermediate resins were analysed by quantitative elemental analysis for changes in heavy atom percentages as a means of estimating on-resin chemical yields.

¶ Further investigation of the scope of this reaction indicated that $Hg(O_2CCF_3)_2$ (2–3 equiv.) in the presence of excess amine was required for efficient and high yielding reaction, and also that only primary aliphatic amines were effective.

‖ *Selected physical data* for: **13**: $\delta_H([^2H_6]DMSO)$: 2.30 (m, 4 H), 2.96 (ABq, 2 H), 3.62 (s, 2 H), 4.30 (d, 2 H), 6.86 (br, 1 H), 7.23 (m, 12 H), 7.16 (m, 1 H), 7.27 (m, 1 H), 8.28 (s, 1 H), 8.49 (br, 1 H); $\nu_{max}(CHCl_3)/cm^{-1}$ 1667, 1638 (C=O). For **14**: $\delta_H([^2H_6]DMSO)$ 2.10 (m, 2 H), 2.42 (m, 2 H), 2.93 (ABq, 2 H), 3.72 (s, 2 H), 4.59 (ABq, 2 H), 7.16 (m, 1 H), 7.29 (m, 10 H), 7.78 (m, 1 H), 7.92 (m, 1 H), 8.80 (s, 1 H); $\nu_{max}(CHCl_3)/cm^{-1}$ 1777, 1708, 1619 (C=O).

** Extensive washing of the resin at this stage with solvents (THF, $CH_2Cl_2$, MeOH and $Et_2O$) and with dithiothreitol in THF gave material which, under stringent elemental analysis conditions, showed no evidence of any residual mercury (not greater than 1 ppm).

†† During the course of our development work on this chemistry we used the following nine diversity reagents: AcOH, thiophene-2-carboxylic acid, 2-naphthyloxyacetic acid (≡'A'–$CO_2H$); $BnNH_2$, isoamylamine, methoxyethylamine (≡'B'–$NH_2$); bromophenacyl bromide, 4-methoxybenzyl chloride and 4-nitrobenzyl bromide (≡'C'–$CH_2Br$), in the parallel synthesis of a $3 \times 3 \times 3$, 27-membered combinatorial library of discrete, single compounds. HPLC chromatography, with UV and evaporative light scattering detection (ref. 9), as well as mass spectrometry analyses of the 27 final products indicated that in all cases the correct succinimide products, which are analogues of **14**, were formed in greater than 50% overall yield and in greater than 70% purity. (Analytical data for these 27 succinimide compounds are available from the authors.)

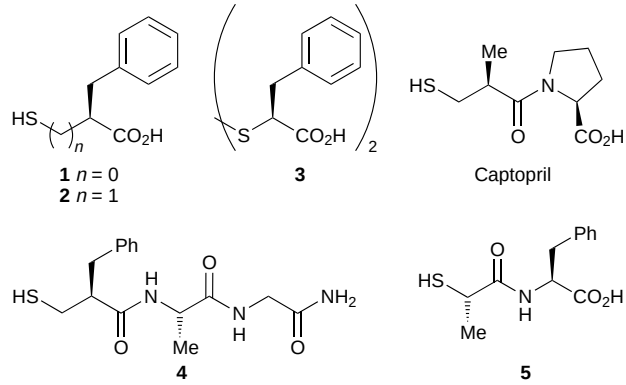
# Inhibition of carboxypeptidase A by (*S*)-2-mercapto-3-phenylpropanoic acid

**Christopher M. Lanthier, Gregory R. MacKinnon and Gary I. Dmitrienko***

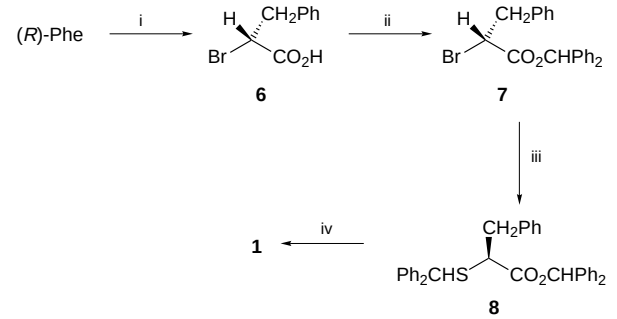
*Guelph-Waterloo Centre for Graduate Work in Chemistry, Waterloo Campus, Department of Chemistry, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1*



**(*S*)-2-Mercapto-3-phenylpropanoic acid is an effective competitive inhibitor of carboxypeptidase A, comparable in potency to (*S*)-3-mercapto-2-benzylpropanoic acid.**

Divalent metal ion-dependent proteolytic enzymes are involved in a wide variety of physiologically important processes and play a role in a number of disease states. It is widely recognized that selective inhibition of such enzymes is a viable strategy for therapeutic intervention. Notable successes have been reported in the development of very effective antihypertensive agents which function through inhibition of zinc-dependent angiotensin converting enzyme (ACE).[1] Intensive research efforts are underway aimed at developing related specific inhibitors for other zinc-dependent proteases such as neutral endopeptidase 24.11 and the matrix metalloproteases.[2,3] The ability to carry out rational design of inhibitors for such enzymes has been built upon detailed observations made in the development of specific inhibitors for the better characterized and understood zinc-dependent proteases such as carboxypeptidase A (CPA) and thermolysin.[4] Thus CPA has served as a valuable model system for the elucidation of guiding principles for the design of inhibition strategies for other less well understood but therapeutically important zinc-dependent proteases.

The now classical studies of the inhibition of CPA by benzylsuccinic acid[5] and by mercaptocarboxylic acid derivatives[6–8] played an important role in the definition of design criteria for the extremely successful commercial antihypertensive agents enaloprilat[9] and captopril.[10] The observation of the relative potencies of (±)-2-mercapto-3-phenylpropanoic acid **1** ($K_i$ = 1.2 μM)[7] and its homologue (*S*)-2-benzyl-3-mercaptopropanoic acid **2** ($K_i$ = 7.8 nM)[8] as competitive inhibitors of CPA has led to the conclusion that the insertion of a methylene group between the metal binding mercapto group and the α-carbon of an α-mercapto carboxylic acid derivative results in an optimal interaction between the active site and the mercapto, carboxylate and hydrophobic side chains of the inhibitor. The fact that inclusion of a similar methylene spacer between the mercapto group and the remainder of the structure of the ACE inhibitor captopril results in very high inhibitory potency ($K_i$ = 1.7 nM)[10] reinforced the belief that a spacing of approximately 4.1 Å between the sulfur atom and the carbonyl group carbon represents the ideal spatial relationship.



In the course of studies of the hydrolysis of thioesters by CPA we have prepared optically active 2-mercapto-3-phenylpropanoic acid **1** and have examined the kinetics of inhibition of CPA by this thiol. We report herein our observation that **1** is a much more effective inhibitor of the peptidase activity of CPA than previously believed, rivaling the potency of 3-mercapto-2-benzylpropanoic acid **2**, and point out the possible significance of this observation with respect to the rational design of specific zinc-binding inhibitors for metalloproteases.

The thiol **1** was synthesized *via* the route shown in Scheme 1. The known bromoacid **5**, prepared with retention of configuration by diazotization of (*R*)-phenylalanine in the presence of bromide, was converted to the benzhydryl ester **6** which was subjected to an $S_N2$ displacement with 1,1-diphenylmethanethiol as the nucleophile. Deprotection using trifluoroacetic acid–phenol yielded the free thioacid **1** (89% ee as measured by $^1$H NMR analysis of the Mosher's thioester[11] form of **1**.

Progress curves† for the CPA catalyzed hydrolysis of hippuryl-L-phenylalanine (HP)[12] in the presence of **1** were found to be biphasic with an initial low rate observed at short reaction times and a higher reaction rate at longer reaction times. That this phenomenon was associated with air oxidation of the thiol to the corresponding disulfide **3** was revealed by the fact that preincubation of solutions of **1** in air until no thiol could be detected using DTNB[13] assays prior to use in inhibition studies abolished the biphasic nature of the progress curves. The slopes of such progress curves were equal to those observed for the second phase of the biphasic curves observed in experiments employing solutions with equal concentrations of **1** which had not been preincubated in air. The inhibition by the disulfide **3**, which was isolated from such solutions and fully characterized, was found to be of the same order of magnitude as reported previously for the thiol **1** [$K_i$ = 3.6 ± 0.5 μM (competitive) for **3** *vs.* reported apparent $K_i$ of 1.2 μM (ref. 7) for racemic **1**].

Measurement of the true inhibitory potency of the thiol **1** required experimental conditions which inhibited the air oxidation process. This was eventually achieved by working with an argon atmosphere or, much more conveniently, by adding glutathione as an antioxidant. It was found that concentrations of glutathione as high as 0.1 mM could be tolerated without any observable influence on the rate of CPA

**Scheme 1** *Reagents and conditions*: i, NaBr, $NaNO_2$, $H_2SO_4$; ii, $Ph_2CN_2$, ether; iii, $Ph_2CHSH$, acetone; iv, $CF_3CO_2H$, $CH_2Cl_2$, PhOH

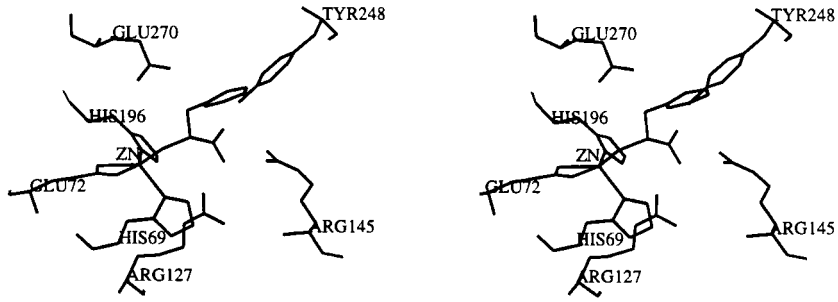


**Fig. 1** Stereoview of the predicted binding mode of **1** to the active site of CPA

catalyzed hydrolysis of HP. Inhibition of the CPA catalyzed hydrolysis of HP by **1** in the presence of glutathione was found to fit a competitive inhibition model as indicated in the Lineweaver–Burk plots.

Estimation of the potency of inhibition by **1** was complicated by the fact that the affinity of **1** for CPA was sufficiently high that inhibitor and enzyme depletion phenomena are significant and render invalid the normal assumptions associated with kinetic models of reversible inhibition. As a result, the graphical method of Dixon[14] which avoids such assumptions was employed to determine $K_i$ for inhibition of CPA catalyzed hydrolysis of HP to be 12.6 ± 1.0 nM. It thus appears likely that, in the earlier studies which concluded that the apparent $K_i$ for inhibition of peptidase activity by (±)-**1** was 1.2 μM (ref. 7), the inhibition observed resulted largely from the presence of the disulfide **3** rather than the thiol **1**.

The recognition that **1** ($K_i$ = 12.6 nM) is comparable in potency to **2** ($K_i$ = 7.8 nM)[8] raises interesting questions concerning the dimensions of the pharmacophore for selective zinc-binding inhibitors for $Zn^{2+}$-dependent proteases. It has been assumed previously that the apparent substantially higher inhibitory potency of **2** arose from the ability of the benzyl side chain of **2** to bind in the hydrophobic $S_{1'}$ pocket in the active site with the thiol sulfur atom interacting favorably with the $Zn^{2+}$ ion and the carboxylate group interacting with Arg-145. Docking of a model of **2** (not shown) in the active site of CPA‡ as defined by X-ray crystallographic coordinates suggests that such a hypothesis is reasonable and consistent with the active site interactions observed between the related thiol-type inhibitor **4** and the zinc-dependent endopeptidase thermolysin.[15] The apparent lower potency of the thiol inhibitor **1** has been assumed to result from an inability of the hydrophobic side chain, the thiol and the carboxylate group to simultaneously interact with the potential binding sites which are accessible to the same groups in the homologue **2**. A molecular modeling analysis of **1** docked in the active site of CPA confirms that the benzyl group in **1** has a diminished interaction with the hydrophobic pocket in the $S_{1'}$ subsite when the sulfhydryl sulfur atom is liganded to zinc and also reveals an interesting favorable interaction between the carboxylate of **1** and Arg-127 which might offset the loss of binding energy associated with the diminished hydrophobic interactions (Fig. 1). This model, although speculative, does suggest strategies for modification of the structure of 2-mercaptocarboxylic acid inhibitors to enhance inhibitor potency by increasing the interaction with the hydrophobic pocket which are now being pursued in this laboratory.

Although our observations clearly indicate the need for consideration of the stability of thiol type inhibitors in evaluation of inhibitory potency against zinc dependent proteases, it should be emphasized that some thiols are much better behaved than **1** and do not require the use of anaerobic conditions or radical scavengers in inhibition studies. For example the rates of air oxidation of the 3-mercaptocarboxylic acid **2** or the 2-mercaptocarboxamide **5**, which is a potent inhibitor of angiotensin converting enzyme,[16] are substantially lower than that observed for **1** such that no special precautions were found to be necessary in kinetic investigations with these compounds. Studies aimed at developing a mechanistic rationale for the susceptibility of 2-mercaptocarboxylates towards air oxidation are in progress.

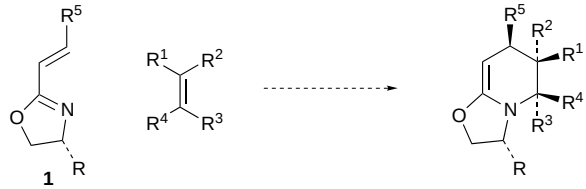
# Highly diastereoselective hetero-Diels–Alder reactions of alkenyldihydrooxazoles as an approach to novel pyrimidine derivatives

**Mark C. Elliott* and Elbertus Kruiswijk**

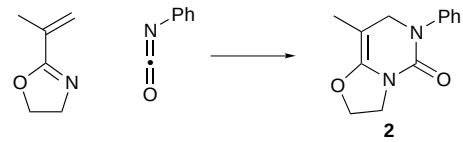
*Department of Chemistry, University of Wales Cardiff, PO Box 912, Cardiff, UK CF1 3TB*



**Chiral 2-alkenyldihydrooxazoles react with two equivalents of aryl and arylsulfonyl isocyanates to give chiral non-racemic dihydropyrimidone derivatives in high yield and with complete diastereocontrol.**

Despite the proven synthetic utility of the all-carbon Diels–Alder reaction,[1] the aza analogue has been much less investigated.[2,3] It offers the opportunity to prepare a wide range of biologically interesting piperidines in a single step with control over three stereogenic centres. We considered the possibility that alkenyldihydrooxazoles **1** could act as aza-dienes,[4] and since these compounds are readily available in enantiopure form from amino alcohols, an asymmetric aza-Diels–Alder reaction as shown schematically in Scheme 1 is an attractive possibility. To the best of our knowledge there is only one example of the use of alkenyldihydrooxazoles as aza-dienes. However, the reported infrared stretching absorption of the product (1760 $cm^{-1}$) seems inconsistent with the assigned structure **2** (Scheme 2).[5] Since neither the yield nor reaction conditions were reported, we felt it would be useful to investigate the reactions of alkenyldihydrooxazoles with isocyanates as a prelude to a broader study.[6,7]

To this end, dihydrooxazoles **3**–**6** were prepared as shown in Scheme 3 from readily available (*R*)-2-aminobutan-1-ol.



When **3** was heated in a sealed tube (150 °C, 1 h) with 2 equiv. of phenyl isocyanate, an essentially pure 2 : 1 adduct was obtained to which structure **8a** was assigned on the basis of spectroscopic data.†,‡ In fact, this reaction proceeds at room temp. (24 h), and at either temperature only a *single diastereoisomer was observed* (Scheme 4). Presumably this reaction proceeds *via* addition of a second molecule of phenyl isocyanate to compound **7**. The absence of any other products in the $^1H$ and $^{13}C$ NMR spectra of the crude reaction mixture conducted under a wide range of stoichiometries lead us to conclude that this process is faster than the hetero-Diels–Alder reaction. For a such a small chiral directing group this selectivity is particularly impressive.

The reactions of **3**–**5** with five different isocyanates gave similar results as shown in Table 1. In each case only a single

**Scheme 6** *Reagents and conditions*: i, 2 equiv. ArNCO, 150 °C, 24 h

diastereoisomer was observed in the $^1$H and $^{13}$C NMR spectra of the crude reaction mixture. The stereochemistry of **8c** and **10e** were determined by single crystal X-ray diffraction. All other compounds are assumed, on the basis of similar spectroscopic data, to have the same stereochemistry.

There has been much debate about the concerted nature, or lack thereof, in both normal[8] and hetero[9] Diels–Alder reactions. Given the highly polarised nature of the reacting partners, the initial interaction may be best represented as initial acylation of the dihydrooxazole nitrogen as shown in Scheme 5.[10] However, the present results do not rule out a concerted (although probably asynchronous) aza-Diels–Alder reaction.

The subsequent addition of the isocyanate may proceed either by a direct [2πs + 2πa] cycloaddition followed by cleavage of the β-lactam or by a stepwise enamine acylation.[11] In fact, when **6** was subjected to similar reaction conditions (2 equiv. phenyl isocyanate, 150 °C, 24 h) compound **12a** was obtained§ as a 1.7 : 1 mixture of diastereoisomers (Scheme 6). Similar reactions were observed with 4-bromophenyl and 4-methoxyphenyl isocyanates. No product could be isolated from the reaction with 4-nitrophenyl isocyanate, presumably due to the ease of hydrolysis of the corresponding β-lactam.

The structures of compounds **12** were assigned by analogy with compounds **8**–**10**, and are supported by extensive NOE studies. Unfortunately we have been unable to assign the stereochemistry of the major isomer. Furthermore, the quaternary carbon (a) in Scheme 6 is significantly deshielded ($^{13}$C resonance in **12**, 152.6 ppm), which could be explained by the contribution of a zwitterionic resonance form **13** to the overall structure (Fig. 1). The existence of **12** as a full zwitterion seems unlikely on the grounds of polarity. Rigorous purification of **12a**–**c** proved difficult due to the lability of these compounds. Chromatography over neutral alumina gave essentially pure compounds, although traces of the diaryl urea, derived from the isocyanate, could not be completely removed. To the best of our knowledge this work represents the first synthesis of the azeto[3′,2′ : 5,6]pyrimido[6,1-*b*]oxazole ring system. We are unable to consolidate our data with that of Seeliger *et al.*[5]

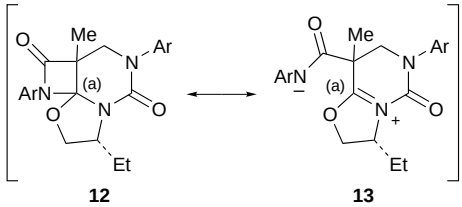

**Fig. 1**

This new variation on the Diels–Alder reaction has considerable potential in the provision of novel chiral nonracemic compounds. This is, as far as we are aware, only the second report of an asymmetric aza-Diels–Alder reaction of a chiral 1-azadiene.[3] Detailed experimental and computational studies are in progress to determine the mechanism and origin of stereoselectivity with a view to realising the potential of this reaction.

We thank the University of Wales, Cardiff for financial support of this research, Mrs A. Dams for microanalytical data and Mr R. Jenkins for mass spectrometric data. The X-ray crystallographic study of compounds **8c** and **10e** was carried out by Professor M. B. Hursthouse, Mr D. E. Hibbs and Mr D. S. Hughes of this department. Full details will be published elsewhere.

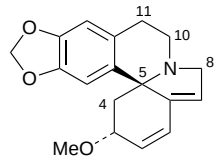
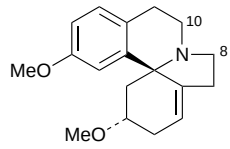
# (*S*)-Norreticuline is the precursor for the biosynthesis of *Erythrina* alkaloids

**Ulrich H. Maier and Meinhart H. Zenk***



*Lehrstuhl für Pharmazeutische Biologie, Universität München, Karlstrasse 29, D-80333 München, Germany*

**In contrast to previous assumptions, the isoquinoline alkaloid (*S*)-norreticuline is the biosynthetic precursor to *Erythrina* alkaloids and, furthermore, this precursor is asymmetrically incorporated into these spirocyclic alkaloids.**



*Erythrina*-type alkaloids[1] suggest an unusual biosynthesis. Barton and co-workers[2,3] made the important observation that these spirocyclic alkaloids are formed by skeletal rearrangement from benzylisoquinoline alkaloids. Extensive application experiments of potential precursors to *Erythrina crista-galli* (Fabaceae) plants previously showed that (*S*)-norprotosinomenine **1** was the precursor for the *Erythrina* skeleton of erythraline **2**, although the incorporation was only in the range of 0.25%.[3–5] This finding was supported by the reported successful incorporation of labelled **1** into the *Erythrina* alkaloid cocculidine **3** (up to 0.66%) using plants of the taxonomically remote *Cocculus laurifolius* (Menispermaceae).[6,7] Norprotosinomenine **1** is a natural product and was isolated from *Erythrina variegata* (formerly *lithosperma*) fruits together with alkaloids possessing the *Erythrina*-type skeleton.[8]

**1** $R^1$ = H, $R^2$ = Me, $R^3$ = OH, $R^4$ = Me, $R^5$ = H
**4** $R^1$ = Me, $R^2$ = H, $R^3$ = H, $R^4$ = H, $R^5$ = H
**5a** $R^1$ = Me, $R^2$ = H, $R^3$ = OH, $R^4$ = Me, $R^5$ = H
**5b** $R^1$ = Me, $R^2$ = H, $R^3$ = OH, $R^4$ = Me, $R^5$ = Me
**6** $R^1$ = Me, $R^2$ = H, $R^3$ = OMe, $R^4$ = H, $R^5$ = H
**7** $R^1$ = H, $R^2$ = Me, $R^3$ = OMe, $R^4$ = H, $R^5$ = H
**8** $R^1$ = H, $R^2$ = H, $R^3$ = H, $R^4$ = H, $R^5$ = H

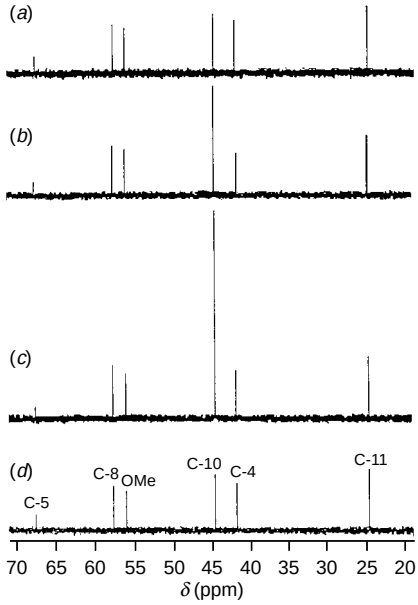
**2**

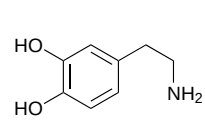
**3**

In the past, only 6-methoxy-7-hydroxytetrahydrobenzylisoquinoline alkaloids of the coclaurine **4** and reticuline **5b** type were recognized as biosynthetic precursors of a multitude of isoquinoline alkaloids occurring in plants such as aporphine-, benzophenanthridine-, bisbenzylisoquinoline-, morphinane-, pavine- and protoberberine-type alkaloids.[9] Norprotosinomenine **1** with a differing 6-hydroxy-7-methoxy substitution pattern is up to now the only biosynthetic exception to a phenol-coupled group of alkaloids and would require evolutionarily the development of a completely different and specific set of enzymes for the early steps of *Erythrina*-type alkaloid biosynthesis, since the enzymes of the coclaurine **4**–reticuline **5b** pathway are highly specific and do not accept alkaloidal substrates with the 6-hydroxy-7-methoxy pattern. This fact and the unusual carbon skeleton of the spirocyclic alkaloids prompted us to reinvestigate the structure of the precursors of *Erythrina* alkaloids.

Feeding experiments (cotton wick method)[3] with all four isomeric nortetrahydrobenzylisoquinoline alkaloids **1**, **5a**, **6** (nororientaline) and **7** (norisoorientaline), each tritium-labelled in the 6- or 7-methoxy group of ring A, were conducted using 4–5 month old plants, the same age as were used previously.[3] Erythraline **2**, the major alkaloid which is distributed in all parts of *E. crista-galli*, was isolated and found to be unlabelled ( < 0.0001%). Incubation of root, stem, leaf and flower tissue yielded the same result. Physiological transport experiments using $^3$H-labelled **4**–**7** showed that these potential precursor alkaloids were not transported at all in these plants. As a consequence, tissue slices (3–4 mm thick) were allowed to float on the aqueous tracer solution (0.5 μCi; 25 nmol) under constant shaking (150 strokes $min^{-1}$) for 24 h. Again, all vegetative tissue yielded no incorporation into erythraline **2**. However, fruit tissue showed considerable incorporation into erythraline **2** (11.8%) but only with (*S*)-norreticuline **5a** as precursor and not with **1**, **6**, **7**. All of the (*R*)-configurated potential precursors **1**, **5a**, **6**, **7** as well as their N-Me congeners were not incorporated. (*S*)-[6-O$C^3H_3$]Coclaurine **4**, however, was under these conditions incorporated to 11%. This clearly suggests that a coclaurine **4**–norreticuline **5a** pathway is operative in *Erythrina* alkaloid formation while the hitherto assumed norprotosinomenine **1** is not at all metabolized (confirmed by autoradiography of the fruit and other organ extracts). In spite of the high rate of incorporation of **4** and **5a** into the *Erythrina* alkaloids it could not be excluded that de- and re-methylation of potential precursors occurred under these feeding conditions as previously observed in other systems.[10]

To confirm specific incorporation and also to reinvestigate whether the later biosynthetic pathway to *e.g.* erythraline involves a symmetrical intermediate,[4,5] (*S*)-[1-$^{13}$C]-**1**,-**4**,-**5a**,-**6**,-**7** were synthesized by standard methods,[11] the correct position of the label was verified in each case by NMR analysis and the compounds applied at $10^{-4}$ M concentration to fruit slices (dry weight 18.2 g) as above. By isolation an average of 6 mg spectroscopically pure (UV, mass) erythraline **2** was obtained which was used for $^{13}$C NMR analysis of the enhanced signals (90.6 MHz, Bruker Aspect 3000) in $CDCl_3$. (*S*)-[1-$^{13}$C]Norprotosinomenine **1** yielded erythraline **2** that was unlabelled [Fig. 1(*a*)]. In contrast, (*S*)-[1-$^{13}$C]coclaurine **4** yielded **2** that was labelled at C-10 [Fig. 1(*b*), enrichment of 5.5% $^{13}$C, $^{13}$C atom excess calculated from mass spectral data]. (*S*)-[1-$^{13}$C]Norreticuline **5a** also labelled only C-10 of erythraline **2** [Fig. 1(*c*), enrichment of 9.3%]. If a symmetrical intermediate is occurring *en route* to the later steps to erythraline as postulated before,[4,5] $^{13}$C enrichment in the case of the **4** and **5a** feeding experiment would have occurred both at C-10 and C-8. Since at C-8 no enrichment is seen [Fig. 1(*b*), (*c*)], we have to conclude that *Erythrina* alkaloid biosynthesis does *not* involve a symmetrical intermediate of the diphenoquinone type. The previously observed labelling both of C-8 and C-10 of an *Erythrina*-type alkaloid after feeding [2-$^{14}$C]tyrosine[12] is easily explained. Norcoclaurine **8**, the precursor of coclaurine **4** and norreticuline **5a**, is formed from two different





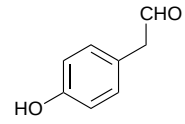


**Fig. 1** Proton-decoupled $^{13}C$ NMR partial spectrum of erythraline **2** (*a*) isolated after a feeding experiment with (*S*)-[1-$^{13}$C]norprotosinomenine **1**; (*b*) biosynthesized from (*S*)-[1-$^{13}$C]coclaurine **4**; (*c*) biosynthesized from (*S*)-[1-$^{13}$C]norreticuline **5a**; (*d*) unlabelled erythraline **2**

$C_6$–$C_2$ precursors analogous to all other 6,7-substituted isoquinoline alkaloids found in nature.[9,13,14] Tyrosine supplies both halves of the *Erythrina* alkaloids, while dopamine **9** is incorporated into the isoquinoline half of **4**, **5a**, **8** only. The benzyl part of these precursors is derived from 4-hydroxyphenylacetaldehyde **10** which in turn is also derived from tyrosine *via p*-hydroxyphenylpyruvate and subsequent decarboxylation to yield the aldehyde.[9] Thus the symmetrical labelling of an *Erythrina* alkaloid by [2-$^{14}$C]tyrosine in the reported experiment[12] is explained.

Finally, to probe the experiments reported on the incorporation of norprotosinomenine **1** into the *Erythrina*-type alkaloids in *Cocculus laurifolius*[6,7] we repeated these application experiments with the same plant. Again no incorporation of [1-$^{13}$C]-**1** into any of the *Cocculus* alkaloids was observed. **1** is, therefore, not a precursor to *Erythrina* alkaloids.

**9**

**10**

Future work on the biosynthesis of *Erythrina* alkaloids has to concentrate on the enzymes involved in (*S*)-norreticuline **5a** formation and on the later steps beyond precursor **5a** involving a non-symmetrical intermediate.

We thank Dr T. M. Kutchan for linguistic help in the preparation of this manuscript. This investigation was financially supported by SFB 369 of the Deutsche Forschungsgemeinschaft, Bonn, and by Fonds der Chemischen Industrie, Frankfurt/Main.

# Homobimetallic vanadium $d^1$–$d^1$ complexes: structure and magnetism

**Robert Choukroun,*[a] Bruno Donnadieu,[a] Isabelle Malfant,[a] Simone Haubrich,[a] Richard Frantz,[b] Christian Guerin[b] and Bernard Henner[b]**

[a] *Equipe Précurseurs Moléculaires et Matériaux, Laboratoire de Chimie de Coordination du CNRS, 205 Route de Narbonne, 31077, Toulouse Cedex, France*

[b] *Laboratoire des Précurseurs Organométalliques des Matériaux, UMR CNRS 44, CC007, Université de Montpellier 2, Place E. Bastaillon, F-34095 Montpellier Cedex 5, France*

**From $Me_3SiC{\equiv}C–C{\equiv}CSiMe_3$ and $Ph_2PC{\equiv}C–C{\equiv}CPPh_2$ diynes and vanadocene $VCp_2$, homobimetallic vanadium $d^1$–$d^1$ complexes are synthesized and characterized by X-ray crystal structures of $(Cp_2V)_2$(1-2η:3-4η-RC=C–C=CR), (R = $SiMe_3$ 1 $PPh_2$ 2); magnetic moments of both complexes from 300 to 2 K indicate an antiferromagnetic *J* exchange coupling of −10.5 and −59.8 $cm^{-1}$ for 1 and 2, respectively.**

Many interesting reactions of the highly reactive $MCp_2$ species have been reported[1] and the zirconocene $ZrCp_2$ is of particular interest.[2] Numerous research has been devoted to the formation of organic synthetic products and more recently as a synthon in the reactivity of the alkynyl C≡C bond. This interest arises from the favourable electronic and structural features of C≡CR ligands *via* σ or σ–π networks. They can be modulated by varying either or both substituents and the metal centers.[3] In particular, vanadocene $VCp_2$ was studied with different classes of unsaturated molecules and different metallacyclopropene structures were identified.[4] Since the vanadocene unit easily binds alkyne derivatives, the reactivity of diynes $Me_3SiC{\equiv}C–C{\equiv}CSiMe_3$ and $Ph_2PC{\equiv}C–C{\equiv}CPPh_2$ was investigated.[5] One might expect that two identical species possessing one unpaired electron connected by diynes with various R end-groups could produce different structural and magnetic situations.[6]

Treatment of 2 equiv. of $VCp_2$ with 1 equiv. of $Me_3SiC{\equiv}C–C{\equiv}CSiMe_3$ or $Ph_2PC{\equiv}C–C{\equiv}CPPh_2$ in pentane, resulted in a brown solution from which, *via* the oxidative addition of $VCp_2$ on the alkyne bonds, $(Cp_2V)_2$(1-2η:3-4η-$Me_3SiC$=C–C=$CSiMe_3$) **1** and $(Cp_2V)_2$(1-2η:3-4η-$Ph_2PC$=C–C=$CPPh_2$) **2** were isolated as crystals in yields of *ca*. 50 and 40%, respectively. Formulation of **1** and **2** as homobimetallic vanadium complexes was confirmed by X-ray crystallography (Figs. 1 and 2).† The bond distances and angles associated with the vanadium acetylene interaction indicate that the acetylene molecule is symmetrically attached to the vanadium atom *via* two σ-type V–C bonds of 2.14 Å (av.) and 2.10 Å (av.) for **1** and **2**, respectively. This produces a metallacyclopropene structure for the central $VC_2$ moiety, with an acute C–V–C angle of 35° (av.). The acetylene coordination is reflected by the average 0.08 Å increase of the C≡C distance and by the geometrical alterations which accompany the acetylene upon coordination. The C–C–R bond angles (R = $SiMe_3$, $PPh_2$) are reduced from 180° in a free acetylene to 140° (av.) in the vanadocene adducts.[4] The distance of the C–C bond for **1** [C(2)–C(3) 1.39 Å] and **2** [C(2)–C(2) 1.40 Å] indicates the presence of a partial double bond. The essential aspects of the structures though are the dihedral angle between both $VC_2$ units in the molecules which are 110.8° for **1** and 165.61° for **2**, which leads to vanadium–vanadium distances of 4.886(5) and 5.384(2) Å in **1** and **2**, respectively. The different orientation of the $Cp_2VC_2$ unit in **1** and **2** may be due to the steric effects of the substituents $SiMe_3$ and $PPh_2$ on the diynes. Another difference in the structural aspects of **1** and **2** is the butadiene skeleton. This is deformed for **1** [C(4) is above the plane defined by C(1)–C(2)–

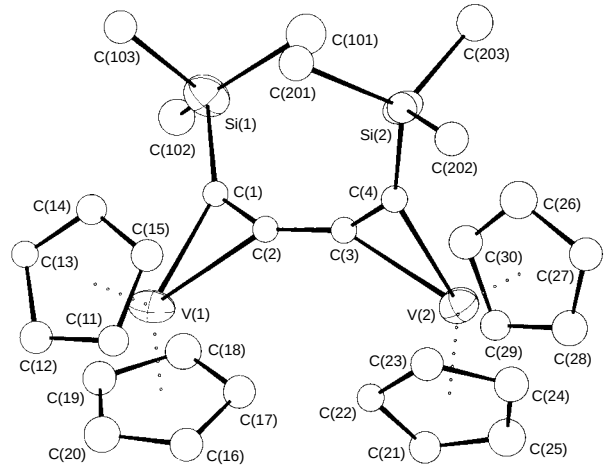

**Fig. 1** View of the molecular structure of **1** (bond lengths in Å, angles in °, hydrogen atoms omitted). V(1)–C(1) 2.14(2), V(1)–C(2) 2.15(2), V(2)–C(3) 2.16(2), V(2)–C(4) 2.13(2), C(1)–C(2) 1.25(3), C(2)–C(3) 1.39(2), C(3)–C(4) 1.28(3); C(1)–V(1)–C(2) 34.0(7), C(3)–V(2)–C(4) 34.7(8), Si(1)–C(1)–C(2) 139.8(20), Si(2)–C(4)–C(3) 140.2(20), C(1)–C(2)–C(3) 148.9(23), C(2)–C(3)–C(4) 149.1(23); V(1)···V(2) 4.886(5), V–Cp 1.977 (av.), Cp–V–Cp 138.4 (av.) [Cp are the centroids of the $C_5H_5$ rings C(11)–C(15), C(16)–C(20), C(21)–C(25), C(26)–C(30)].

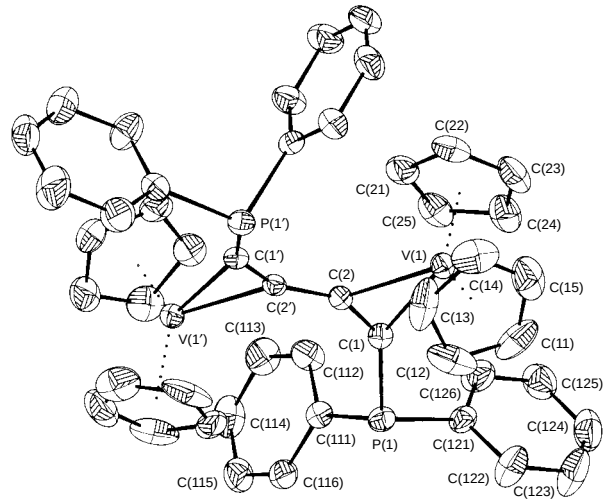

**Fig. 2** View of the molecular structure of **2** (bond lengths in Å, angles in °, hydrogen atoms omitted). V(1)–C(1) 2.092(5), V(1)–C(2) 2.116(4), C(1)–C(2) 1.283(6), C(2)–C(2′) 1.404(9); C(1)–V(1)–C(2) 35.5(2), P(1)–C(1)–C(2) 140.1(4), C(1)–C(2)–C(2′) 148.2 (6); V(1)···V(1′) 5.384(2), V(1)–Cp 1.968, V(1)–Cp′ 1.974, Cp–V(1)–Cp′ 137.57 [Cp, Cp′ are the centroids of the $C_5H_5$ rings C(1)–C(5), C(6)–C(10)].

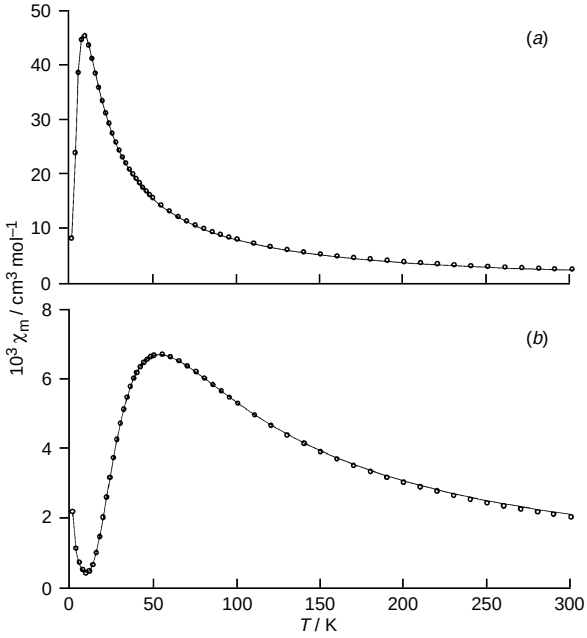

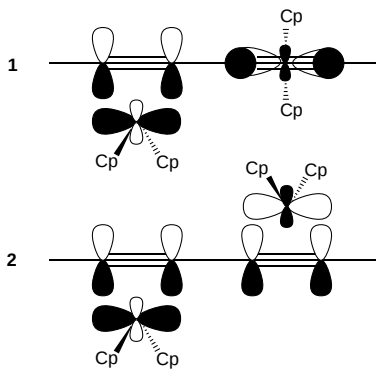

**Fig. 3** Temperature dependence of molar magnetic susceptibilities per vanadium (○) of (*a*) **1** and (*b*) **2** (the solid lines result from a least-squares theoretical fit)‡

C(3) by 0.63 Å] whereas all the carbon atoms are contained in a plane for **2**.

As a result of such situations, paramagnetic vanadium centers of $d^1$ electronic configuration could produce different magnetic behavior.[6,7] Variable-temperature magnetic susceptibility measurements have been carried out.‡ The effective magnetic moment $\mu_{eff}$ is 2.65 $\mu_B$ for **1** and 2.25 $\mu_B$ for **2** at 300 K. They decrease to reach 0.36 $\mu_B$ for **1** and 0.19 $\mu_B$ for **2** at 2 K. Fig. 3 show the plots of $\chi_m$, molar susceptibility per dimer, *vs.* temperature for **1** and **2**. The solid lines represent the good fit obtained to account for the observed dependence with an exchange interaction model. Fitting the data for **1** and **2** gives $J = -10.5$ and $-59.8$ cm$^{-1}$, respectively. The antiferromagnetic interaction for **2** is greater than that for **1** whereas the vanadium–vanadium distances show an opposite relation. In fact, the interaction is propagated by the carbon chain and a consideration of the bonding situation in the complex seems necessary. The orientation of the $Cp_2VC_2$ unit in the molecule suggests a favorable 'in-plane π type' geometry for complex **2**. This can be described as a linear combination of mainly p orbital character of the carbon of the diyne with the main contribution of the $d_{z^2}$ orbital of the HOMO in a $d^1$ type system.[4] This is disfavored in the complex **1** where the $Cp_2VC_2$ unit and their magnetic orbital contributions could be considered as orthogonal (Scheme 1).

In conclusion, our synthetic method is able to produce homobimetallic $d^1$ systems with organic substrates. Modification of the organic portion leads to different structure situations and varies the coupling propagated by extended bridges. We illustrate a strategy to potentially synthesize homobimetallic $d^1$ systems designed to produce differing metal–metal separations. The full extent of the interaction of metallocene $d^1$ $VCp_2$ with several unsaturated hydrocarbons is under investigation.

**Scheme 1**

† *Crystallographic data*: for **1**: $C_{30}H_{38}Si_2V_2$, $M$ = 557.70, triclinic, space group $P\bar{1}$, $a$ = 8.226(2), $b$ = 12.862(4), $c$ = 13.987(3) Å, $\alpha$ = 78.93(2), $\beta$ = 84.60(2), $\gamma$ = 82.05(2) °, $U$ = 1435.0 Å$^3$, $Z$ = 2, $D_c$ = 1.29 g cm$^{-3}$, $\mu$ = 7.28 cm$^{-1}$, $R(R_w)$ = 0.080(0.098), GOF = 1.5. For **2**: $C_{46}H_{40}P_2V_2$, $M$ = 780.34, orthorhombic, space group *Pbna*, $a$ = 12.940(2), $b$ = 16.757(2), $c$ = 17.638(2) Å, $U$ = 38.24.5 Å$^3$, $Z$ = 4, $D_c$ = 1.36 g cm$^{-3}$, $\mu$ = 5.87 cm$^{-1}$, $R(R_w)$ = 0.048(0.059), GOF = 0.85.

Data collection was performed at *ca.* 294 K on a IPDS STOE diffractometer using graphite monochromatized Mo-Kα radiation. The crystal of **1** is twinned and one of the two domains of the twin have been indexed; the integration was realized by using the program TWIN (STOE IPDS software), the overlapped reflections are automatically discarded by TWIN during the data reduction. The refinement of **1** was performed with the best data set containing once merging 60% of unique reflections. Computations were performed with the aid of CRYSTALS. The structure was solved by direct methods (SIR92[9]). All hydrogen atoms were found on difference Fourier maps but were introduced in the refinement as fixed contributors (C–H 0.96 Å) and recalculated after each cycle. For **2**, all non-hydrogen atoms were anisotropically refined; for **1**, only V and Si atoms were refined anisotropically owing to the low ratio of parameters to observations. CCDC 182/643.

‡ Magnetic susceptibilities were determined using a SQUID susceptometer within between 2 and 300 K. Using a Heisenberg Hamiltonian $H = -JS_AS_B$ with local spins $S_A = S_B = 1/2$, the magnetic interaction was estimated with a Bleaney–Bowers model for dimers[8] ($J$, $g$) including a percentage ($\rho$) of paramagnetic impurities. Parameters $J$, $g$ and $\rho$ were determined by least squares fitting. The average value of the $g$-factor was 2.12 for **1** and 1.95 for **2**. $\rho$ assumed as isolated $V^{IV}$ ions with the same molecular mass as the actual compounds **1** or **2**, so that the Curie constant $C$ was taken as $C = [N\beta^2/2k]g^2$, was found to be 0.018 for **1** and 0.006 for **2**.

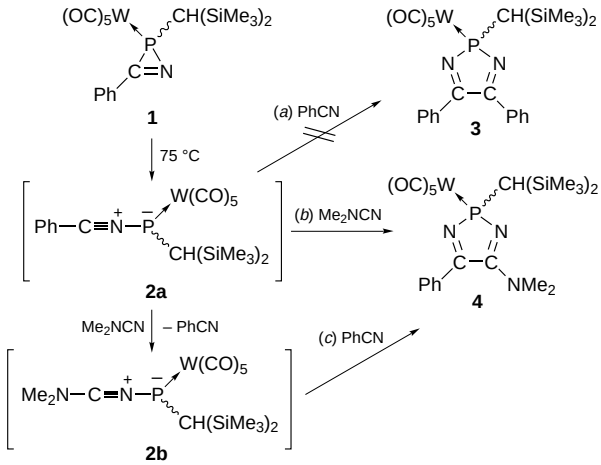
# Synthesis and structure of the first 2*H*-1,3,2-diazaphosphole complex

**Hendrik Wilkens, Jörg Jeske, Peter G. Jones and Rainer Streubel***

*Institut für Anorganische und Analytische Chemie der Technischen Universität Braunschweig, Postfach 3329, D-38023 Braunschweig, Germany*



**Thermal decomposition of the 2*H*-azaphosphirene tungsten complex 1 in benzonitrile and in the presence of dimethylcyanamide yields the 2*H*-1,3,2-diazaphosphole tungsten complex 4, containing a novel five-membered heterocyclic ligand; the overall reaction may be described as a 1,3-dipolar cycloaddition of an *in situ* generated nitrilium phosphane ylide complex to benzonitrile.**

Nitrilium ylides, like nitrile oxides,[1] sulfides[2] and nitrileimines,[1,3] are versatile building blocks in heterocyclic chemistry. Very recently, we obtained the first evidence of a nitrilium phosphane ylide complex as a reactive intermediate in the thermolysis of 2*H*-azaphosphirene tungsten complexes in the presence of dimethylacetylenedicarboxylate (DMAD) in toluene.[4] The formation of the 2*H*-1,2-azaphosphole tungsten complexes, which were obtained as by-products, was explained as a 1,3-dipolar cycloaddition of a nitrilium phosphane ylide complex to the trapping reagent.[4]

We now report the first synthesis of a 2*H*-1,3,2-diazaphosphole tungsten complex **4**, which has been obtained in good yield by thermal decomposition of the 2*H*-azaphosphirene tungsten complex **1** in benzonitrile and in the presence of 2 equiv. of dimethylcyanamide. Under these reaction conditions the 1,3-dipolar cycloaddition is stereoselective and the exclusive formation of this regioisomer was observed.

This reaction is interpreted as a further example of a 1,3-dipolar cycloaddition of the transiently formed nitrilium phosphane ylide tungsten complex **2b** to benzonitrile (Scheme 1, pathway (*c*)]. Pathways (*a*) and (*b*) seem less plausible, especially, if taken into account that under these reaction conditions the formation of the diphenyl-substituted 2*H*-1,3,2-diazaphosphole tungsten complex **3** was not observed [pathway (*a*)].

The composition of 2*H*-1,3,2-diazaphosphole tungsten complex **4** is confirmed by elemental analysis and mass spectrometry;† the structural formulation is based on the characteristic

**Scheme 1** *Reagents and conditions*: 1 mmol **1** was treated with 2 mmol dimethylcyanamide in benzonitrile at 75 °C for 1.5 h. Work-up by column chromatography at low temperature afforded **4** in good yield (67%, mp 90 °C).

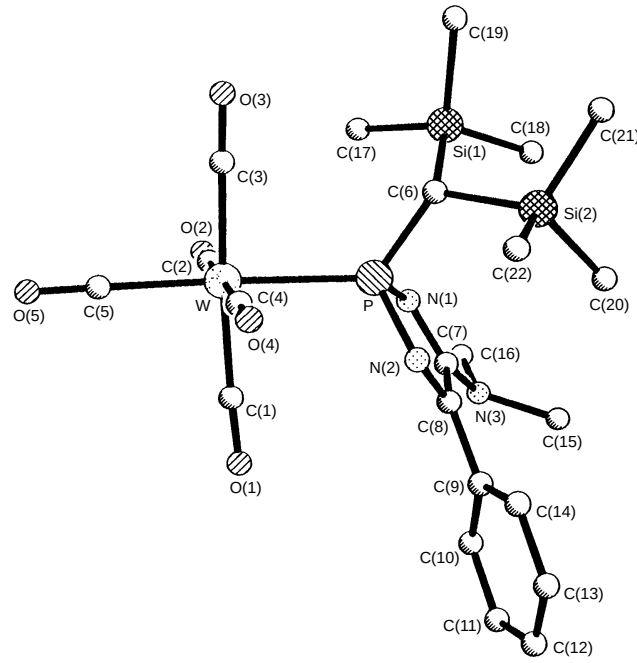


**Fig. 1** Molecular structure of complex **4** in the crystal. Radii are arbitrary. Selected bond lengths (Å) and angles (°): P–W 2.479(11), P–N(1) 1.705(3), P–N(2) 1.705(3), N(1)–C(7) 1.291(5), N(2)–C(8) 1.284(5), C(7)–C(8) 1.488(5); N(1)–P–N(2) 96.3(2), P–N(1)–C(7) 108.2(3), N(1)–C(7)–C(8) 114.0(3), N(2)–C(8)–C(7) 113.4(4), P–N(2)–C(8) 107.8(3).

NMR spectral data† in solution and was confirmed for the solid state by a X-ray crystal structure analysis.‡ In comparison to related 2*H*-1,2-azaphosphole tungsten complexes,[4] the 2*H*-1,3,2-diazaphosphole tungsten complex **4** displays a low-field shifted resonance signal of the phosphorus nucleus at $\delta$ 149.8 (*cf.* $\delta$ 102–105[4]) and a markedly increased phosphorus tungsten coupling constant of 257.1 Hz (*cf.* $^1J_{WP}$ 236–238 Hz[4]). The phosphorus–carbon coupling constants of the quaternary ring carbon atoms are 2–10 Hz, which are characteristically small for both five-membered heterocycles.

Remarkable features of the molecular structure of **4** and 2*H*-1,2-azaphosphole complexes[4] are the planar five-membered ring system and the localised double bonds; the latter being in contrast to the situation of aromatic heterocycles like 2*H*-1,2,3-diazaphospholes[5,6] and 2*H*-1,2,3-triazoles.[7] The coordination sphere of phosphorus is distorted tetrahedral and the phosphorus–tungsten bond length is 2.479(11) Å.

We are currently investigating the synthetic potential of nitrilium phosphane ylide complexes in 1,3-dipolar cycloaddition reactions.

This work was supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft.

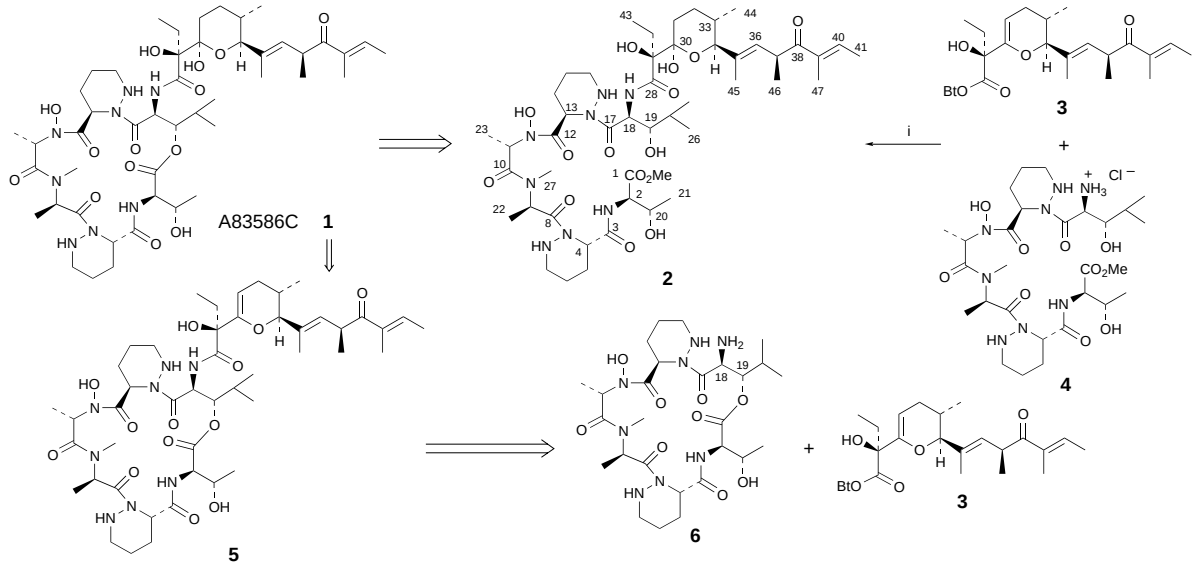
# Asymmetric total synthesis of antitumour antibiotic A83586C

**Karl J. Hale* and Jiaqiang Cai**

*Department of Chemistry, University College London, 20 Gordon Street, London, UK WC1H 0AJ*

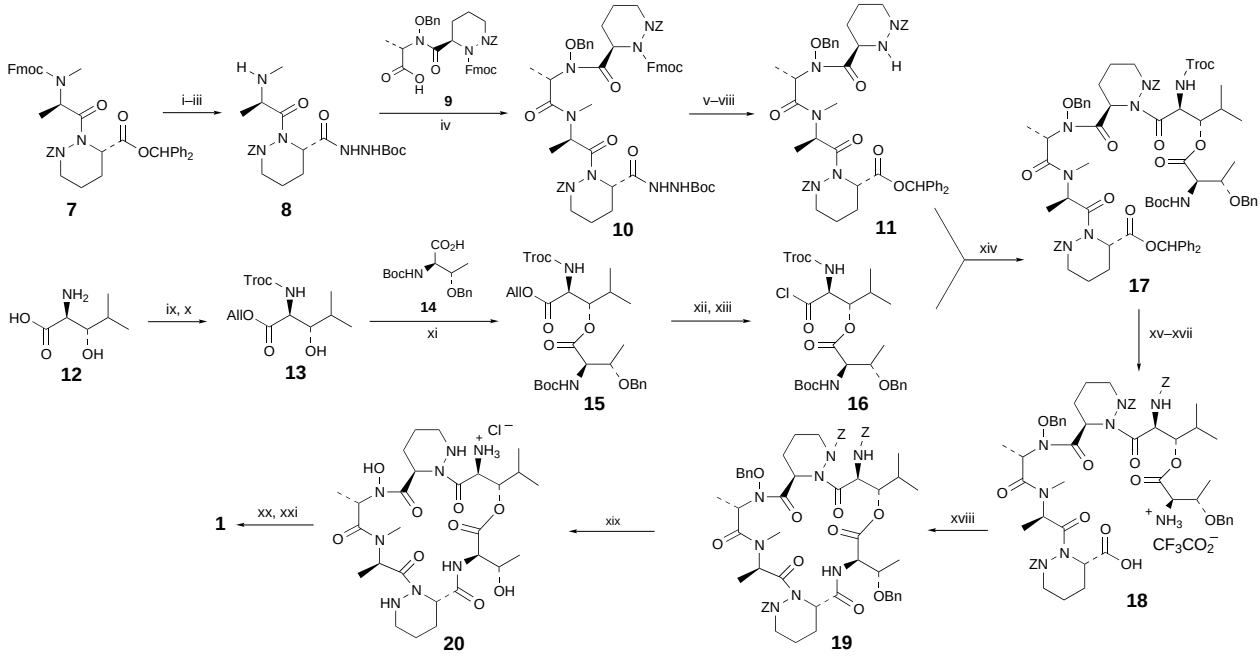
**The first asymmetric total synthesis of antitumour antibiotic A83586C has been accomplished.**

A83586C **1** is a highly ornate hexadepsipeptide isolated from the fermentation broths of *Streptomyces karnatakensis* by Smitka *et al.*[1] It shows pronounced antimicrobial activity *in vitro* against Gram-positive strains of bacteria, and can combat the growth of a CCRF-CEM human T-cell leukaemia line ($IC_{50}$ = 0.0135 μg $ml^{-1}$). From a synthetic standpoint, A83586C **1** presents a formidable challenge owing to its ominous expanse of diverse functionality, which looks set to overwhelm most protecting group endgames conceived for its total synthesis. In light of this, we thought it prudent to dispense with protecting groups for the final stages, and some time ago, we synthesised the C(1)–C(47) sequence **2** *via* a chemoselective union between **3** and **4** (Scheme 1).[2] Unfortunately, difficulties later arose not only in the macrolactonisation of **2**, but also its *seco*-acid. This led us to consider new ways of completing this synthetic venture. One plan that looked particularly worthwhile featured a coupling between **6** and **3** to obtain **5** and a subsequent glycal hydration at C(30) to produce **1**. We now report the first total synthesis of A83586C based on this strategy.



Initial attention focused on constructing **11** and **16** (Scheme 2). Tetrapeptide **11** was assembled in eight steps from known dipeptide **7**.[3] Our first manoeuvres replaced the $Ph_2CH$ ester[4] group in **7** with a Boc-NHNH group,[5] to prevent diketopiperazine formation occurring when the Fmoc group was removed with $Et_2NH$. Fortunately, this tactic worked very well, **8** being isolated uneventfully after Fmoc deprotection. Compound **8** coupled readily to acid **9**[3,6] in $CH_2Cl_2$ at 0 °C after sequential treatment with $Et_3N$ and bis(2-oxo-3-oxazolidinyl)phosphinic chloride (BOP-Cl);[7] **10** was obtained in 75% yield. The Boc group was cleaved from **10** with TFA, and the acyl hydrazine oxidised with *N*-bromosuccinimide (NBS) in aqueous THF.[8] Without further purification, the crude acid was esterified with $Ph_2CN_2$[4] and the Fmoc group excised to deliver **11**.

The synthesis of **16** was achieved from (2*S*,3*S*)-hydroxyleucine.[9] After Troc protection of the amino group,[6] a selective *O*-allylation was performed with $NaHCO_3$ and allyl bromide in DMF;[10] **13** was isolated in 92% yield. A range of coupling conditions were examined for establishing the O(19)–C(1) ester bond between **13** and **14**.[11] Success finally came using DCC and DMAP in $CH_2Cl_2$, but 5–10% epimerisation was always encountered at the α-carbon atom of the threonine unit. Notwithstanding this, **15** was usually prepared in 83–88% yield. The next two steps involved removal of the allyl ester group from **15** using palladium(0) catalysis,[12] and acid chloride formation with excess oxalyl chloride in benzene.



To our delight, [4 + 2]-fragment condensation between **11** and **16** was complete after 2 min when conducted in benzene at 60 °C in the presence of AgCN;[6] **17** was formed in yields of 73–86%.

Our next goal was to convert **17** into **18** and then macrolactamise at the (3*S*)-piperazic acid and D-threonine residues. The Troc group in **17** was substituted with a *Z* group by reacting **17** with excess zinc in acetic acid,[6] and acylating the crude amine with $BnO_2CCl$. TFA was then used to simultaneously deprotect the Boc and $Ph_2CH$ ester groups to give **18** in 78% overall yield for the three steps.

A significant number of peptide coupling reagents were evaluated for instigating the desired macrolactamisation of **18** to **19**, the majority of which performed poorly. Success was eventually attained with *O*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*′,*N*-tetramethyluronium hexafluorophosphate (HATU)[13] and *N*-ethylmorpholine (NEM) in $CH_2Cl_2$ under conditions of very

**Scheme 1** *Reagents and conditions*: i, $Et_3N$, $CH_2Cl_2$, −78 to 25 °C, $SiO_2$, 65%

**Scheme 2** *Reagents and conditions*: i, TFA–$CH_2Cl_2$ (10 : 1), PhOH (2 equiv.), 25 °C; ii, $BocNHNH_2$ (2 equiv.), DCC (2 equiv.), 1-hydroxybenzotriazole hydrate (HOBT) (2 equiv), THF (*ca.* 0.33 M), 0 to 25 °C, 93% (2 steps); iii, $Et_2NH$–MeCN (1 : 1) (*ca.* 0.55 M); iv, $CH_2Cl_2$ (*ca.* 0.15 M), add $Et_3N$ (2.3 equiv.) at −10 °C, stir 5 min, then add BOP-Cl (1.2 equiv.), warm to 0 °C, 4 h, 75% (2 steps); v, TFA–$CH_2Cl_2$ (1 : 1) (*ca.* 0.2 M), 0 °C; vi, NBS (2 equiv.), THF–$H_2O$ (1 : 1) (*ca.* 0.04 M), 0 to 25 °C; vii, $Ph_2CN_2$ (1.9 equiv.), $Me_2CO$ (*ca.* 0.16 M), 25 °C, 12 h, 68% (3 steps); viii, $Et_2NH$–MeCN (1 : 1) (*ca.* 0.24 M), 25 °C, 40 min; ix, Troc-Cl (1.05 equiv.), NaOH (2 equiv.), THF, $H_2O$, 25 °C, 90%; x, $NaHCO_3$ (4.3 equiv.), allyl bromide (6.2 equiv.), DMF (*ca.* 0.31 M), 25 °C, 92%; xi, DCC (1.2 equiv.), DMAP (1.25 equiv.), $CH_2Cl_2$ (*ca.* 0.322 M), 0 to 25 °C, 83–88%; xii, morpholine (6.5 equiv.), $(Ph_3P)_4Pd$ (5.9 mol%), THF (*ca.* 0.22 M), 0 to 25 °C, 59%; xiii, $(COCl)_2$ (20 equiv.), $C_6H_6$ (*ca.* 0.4 M), 25 °C, 2.5 h; xiv, AgCN (1.3 equiv.), $C_6H_6$ (*ca.* 0.12 M), 60 °C for 2 min, 73–86% (for viii, xiii, xiv); xv, Zn (70 equiv.), AcOH–$H_2O$ (10 : 1) (*ca.* 0.0685 M), 25 °C, 3 h; xvi, ZCl (3 equiv.), 10% aq. $NaHCO_3$, $CH_2Cl_2$, 25 °C, 2 h, 78% (2 steps); xvii, TFA–$CH_2Cl_2$ (2 : 1) (*ca.* 0.06 M), PhOH (2.2 equiv.), 0 °C, 1 h, 100%; xviii, HATU (10 equiv.), $CH_2Cl_2$ (500 ml), 0 °C, then slow addition of **18** (1.4 g) and NEM (13.5 equiv.) in $CH_2Cl_2$ (500 ml) over 3 h, then 0 °C, 2 h, then 25 °C, 30 h, 25%; xix, 10% Pd–C (= weight of **19** used), MeOH (*ca.* 0.01 M), HCl (1 equiv.), $H_2$ (1 atm.), 25 °C, 24 h; xx, **3** (1 equiv.), $CH_2Cl_2$ (*ca.* 0.03 M), −78 °C, add $Et_3N$ (9.3 equiv.), warm to 25 °C, stir 10 min, 31% (from **19**); xxi, $CDCl_3$ (wet), 72 h, 0 °C, 100%

high dilution. This produced **19** in a reproducible 25% yield after flash chromatography. Compound **19** was then deprotected by catalytic hydrogenolysis over palladium on carbon. We deliberately conducted this hydrogenation in methanolic HCl, so as to minimise the occurrence of O(19) to N(18) acyl rearrangement during this lengthy reaction. Without further purification, crude **20** was suspended in $CH_2Cl_2$ along with **3**.[2] After cooling to −78 °C, $Et_3N$ was added, and the reaction warmed to room temperature where it was stirred for 10 min. A rapid coupling ensued to deliver **5** in 31% yield after chromatographic purification. Upon standing in undried $CDCl_3$ (Aldrich) for 72 h, **5** readily hydrated to give A83586C in quantitative yield. The $^1H$ and $^{13}C$ NMR spectra of synthetic A83586C in $CDCl_3$ were identical in every respect with the spectra of authentic A83586C. In addition, synthetic A83586C also gave rise to an $(M + Na)^{+\cdot}$ ion at *m*/*z* 999.5360 in its high resolution FAB mass spectrum;† the calculated value for $C_{47}H_{76}N_8O_{14}Na$ is 999.5379.

We thank the EPSRC (Project Grant GR/J92590), Zeneca, Pfizer and Rhone-Poulenc Rorer for financial support. We thank Dr Tim Smitka of Eli Lilly for kindly supplying us with the original $^1H$ and $^{13}C$ NMR spectra of natural **1**. We are indebted to Dr Glyn Williams of Roche Products for obtaining the 500 MHz $^1H$ NMR spectrum of synthetic **1**, and to his colleague Dr B. K. Handa for urging us to try the HATU reagent. We thank the ULIRS MS Service for HRMS measurements.

† All new compounds reported in this synthetic route gave satisfactory 400 MHz $^1H$ and 100 MHz $^{13}C$ NMR and IR spectra, as well as HRMS and/or microanalyses within 0.4%.

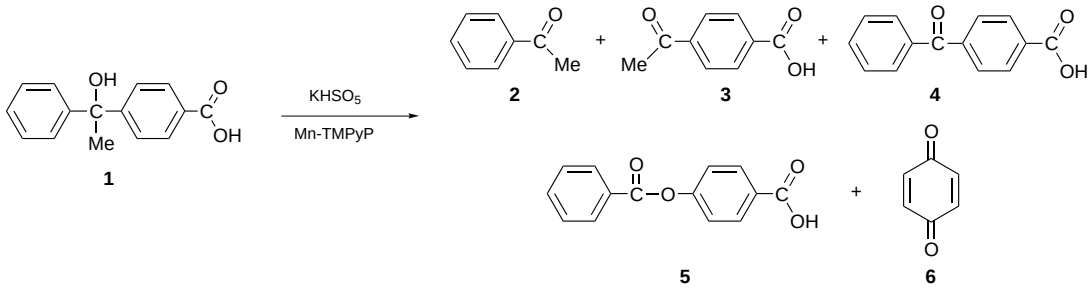
# Oxidation of tertiary diaryl alcohols catalyzed by a water-soluble metalloporphyrin: $C_{aliph}$–$C_{aliph}$ *versus* $C_{aliph}$–$C_{Ar}$ bond cleavage

**Karine Wietzerbin, Bernard Meunier*† and Jean Bernadou*‡**

*Laboratoire de Chimie de Coordination du CNRS, 205 route de Narbonne, 31077 Toulouse Cedex 4, France*

**In water and at room temperature, tertiary diaryl alcohols were easily cleaved by monopersulfate oxidation using a water-soluble metalloporphyrin catalyst to give mainly aryl methyl ketones and to a lower extent diaryl ketones, probably resulting from a β-fragmentation of the diarylethoxy radical $Ar_2MeC–O·$; a small amount of unexpected ester derivatives was also detected indicating at least one alternative pathway.**

As a part of our mechanistic studies on C–H bond oxidation catalyzed by water-soluble metalloporphyrins,[1–3] we wished to determine how the oxidation of some intermediate tertiary alcohols can give ketones through cleavage of a C–C bond. In addition, little is known about oxidative C–C bond cleavage by biomimetic catalysts, whereas this is a key step in the degradation of the lateral chain of cholesterol by cytochrome P-450.[4] Tertiary alcohols are usually resistant to oxidation and their oxidative conversion generally requires a sufficient intrinsic reactivity and the use of strong oxidants (*e.g.* concentrated $H_2O_2$ in sulfuric acid,[5] chromium(VI)[6] or cerium(IV)[7] reagents). We chose to develop this study on the two diarylmethyl alcohols 4-(1-hydroxy-1-phenylethyl)benzoic acid **1**§ and 1,1-diphenylethanol, using $KHSO_5$ as oxidant (hydrogen peroxide was also tested in similar conditions but proved to be inactive) and Mn-TMPyP¶ as catalyst. This water-soluble metalloporphyrin is well-known for its efficiency in epoxidation,[8] hydroxylation[2,3] or peroxidasic oxidation[9] reactions in aqueous media. The reaction products were identified by HPLC co-injection of authentic samples, and by NMR and GC–MS analyses of the product mixtures.



Among the compounds produced by the oxidation of **1**, two resulted from the loss of one of the two aromatic rings (**2**, **3**), two others from the loss of the methyl group (**4**, **5**) and the last one (**6**) was identified as benzoquinone (Scheme 1). Conversion and product yields are given in Table 1. More than 90% of the starting material was converted in 10 min at room temperature, with only 2% of catalyst (introduced in five consecutive additions). Such levels of conversion could not be obtained under similar conditions with cerium(IV) salts, which are well-known for their ability to oxidize some tertiary alcohols,[7] even in acetonitrile–water at reflux and/or raising the concentrations of substrate and oxidant by a factor of 100. The pool **2** + **3** + **4** + **5** represented about 50% yield (or 56% yield with respect to the starting material converted). Relative yields of ketones **2**, **3** and **4** show that cleavage of the $C_{aliph}$–$C_{Ar}$ bond (with release of a phenyl or a carboxyphenyl group) occurred more than 10 times faster than that of $C_{aliph}$–$C_{aliph}$ bond (with release of a methyl group). The relative scission of phenyl and 4-carboxyphenyl groups differed only by a factor of 2 (ratio **2**/**3** ≈ 2). Thus the relative rates of cleavage with formation of **2**, **3** and **4** were in the ratios 35 : 17.5 : 1.

These results are reminiscent of the oxidative cleavage of some tertiary alcohols by cerium(IV) salts in aqueous acetonitrile at reflux,[7] where *tert*-butyl, benzyl and allyl radicals were shown to be cleaved rapidly from the appropriate alcohol (the relative rates of formation of the *tert*-butyl : benzyl : allyl radicals were 20–63 : 4.4 : 1). In the present case, the formation of the ketones **2**–**4** suggests a mechanism involving the formation of a diarylethoxyl radical intermediate (Scheme 2) which is cleaved by β-fragmentation to give the three different ketones **2**, **3** and **4** and carboxyphenyl (route a), phenyl (route b) or methyl (route c) radicals. The diarylethoxyl radical could be formed from **1** in two steps by $e^-$ loss followed by $H^+$ abstraction, or directly by H· abstraction. Benzoquinone **6** might be an end-product deriving from one or both aryl radicals

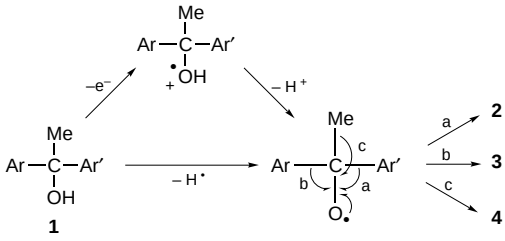


**Table 1** Yields of products obtained from oxidation of **1** catalyzed by Mn-TMPyP[a]

| Products | Yield (%)[b] | Selectivity (%)[c] |
|---|---|---|
| **2** | 27.9 ± 1.1 | 31.3 ± 0.7 |
| **3** | 14.0 ± 0.5 | 14.0 ± 0.4 |
| **4** | 0.8 ± 0.1 | 0.9 ± 0.1 |
| **5** | 7.7 ± 0.3 | 10.6 ± 0.3 |
| **6** | 9.2 ± 0.4 | 8.7 ± 0.2 |
| Conversion (%) | 90.5 ± 4.0 | |

[a] The reaction medium (1 ml of acetonitrile–water, 1 : 9) contained 66 mM phosphate buffer, pH 5 and 500 μM **1** (introduced as a 25 mM solution in acetonitrile) and 200 μM of *p*-diacetylbenzene as internal standard; [$KHSO_5$] was 10 mM, and [Mn-TMPyP] was 10 μM (introduced in five consecutive 2 nmol additions, every 2 min; the first addition initiated the reaction). The reaction was monitored by HPLC using a Nucleosil C18 10 μm column and 65 or 75% aqueous acetonitrile containing 0.1 M triethylammonium acetate as eluent (flow rate: 1 ml $min^{-1}$); the detection was performed at 240 nm and experimental errors were obtained from three independent experiments. [b] Yields were calculated after 10 min of reaction at room temperature. [c] Selectivity is defined as the ratio of product yield divided by substrate conversion.

**Scheme 1**

**Scheme 2** β-Fragmentation of a possible alkoxyl radical intermediate (Ar = phenyl and Ar′ = *p*-carboxyphenyl)

resulting from the β-scission (routes a, b), since we checked that phenol, benzoic acid and *p*-hydroxybenzoic acid, three putative evolution products of the released aryl radicals, could be quickly oxidized to **6** by the catalytic system. With this substrate, aryl (phenyl or carboxyphenyl) rather than methyl is lost, yielding acetophenone rather than benzophenone derivatives. This direction of cleavage differs from investigations on the decomposition of cumyloxyl radical[10,11] and from our recent results on oxidation of 4-(1-hydroxy-1-methylethyl)benzoic acid[3] where the loss of methyl is predominant. A plausible explanation of this special behaviour could be a combination of resonance stabilization of the resulting radicals (methyl less stable than aryl) and of the enhanced stability of acetophenone compared to acetone[10] or to benzophenone derivatives.

In the course of catalytic oxidation of **1**, the unexpected product **5** was detected. It was identified as benzoyloxybenzoic acid by MS and NMR analyses of a collected sample, and by comparison of its chromatographic behaviour with that of an authentic sample.§ Product **5** represented only about 8% yield when 10% acetonitrile was used in the reaction medium but this yield was increased up to 18% when the amount of acetonitrile was raised to 30%. At the same time, the yields of all other identified products were slightly lowered. Furthermore, the formation of **5** was dependent on oxygen concentration (yield of **5** was 1.5% under nitrogen and 7.5% under oxygen atmosphere, under experimental conditions slightly different from that of Table 1), while the formation of all the other products did not significantly depend on the atmospheric composition. It is also remarkable that the isomeric compound monophenyl terephthalate was not detected. A conceivable pathway to afford the ester **5** would be a Baeyer–Villiger oxidation of benzoylbenzoic acid (which is effectively produced in the reaction, product **4**) but this assumption can be discarded since, in a control experiment, we showed that benzoylbenzoic acid was stable under the catalytic oxidation conditions used. The results clearly demonstrate that pathway for formation of **5** is different from that of the other products **2**–**4** and **6** and, especially, that dioxygen probably plays a crucial role. The exact mechanism explaining the formation of this unexpected reaction product, which needs the cleavage of two C–C bonds, is presently unknown.

Similar experiments as with **1** were performed with 1,1-diphenylethanol. Here also, results show a high conversion of the substrate (more than 75%) and, while they are in qualitative agreement with the above data concerning the oxidation of **1** (oxidation products from 1,1-diphenylethanol were: acetophenone, benzophenone, *p*-benzoquinone and phenyl benzoate), the quantitative results differ significantly. Especially, the yield of phenyl benzoate was very low (about 1–2%), indicating that the carboxylic group present in **1** presumably plays a crucial role in orienting the reaction towards the ester **5**.

In summary, a highly efficient oxidative cleavage of a tertiary diaryl alcohol has been observed. Scission of the $C_{aliph}$–$C_{Ar}$ bond occurred preferentially compared to the $C_{aliph}$–$C_{Aliph}$ bond, yielding mainly acetophenone derivatives through a probable β-fragmentation mechanism. The presence of an ester derivative whose formation is oxygen dependent indicates that an alternative pathway is involved. An overall comprehensive mechanism of this oxidative cleavage reaction is presently under investigation using isotopic labelling experiments.

# Bifunctional catalytic membrane containing Brønsted acids and sites for enantioselective hydrogenation

**Diedrik Tas, Carla Thoelen, Ivo F. J. Vankelecom and Pierre A. Jacobs***

*Centre for Surface Chemistry and Catalysis, Faculty of Agricultural and Applied Biological Sciences, Katholieke Universiteit Leuven, Kardinaal Mercierlaan 92, 3001 Leuven, Belgium*

**The hydrogenation of methyl acetoacetate to give optically pure methyl 3-hydroxybutyrate is performed heterogeneously with high activity and enantioselectivity under mild reaction conditions due to the combination of Brønsted acid and Ru–binap sites in a polydimethylsiloxane membrane matrix.**

Binap based complexes are among the most versatile and selective catalysts used to produce chiral compounds.[1] Given their extremely high cost, immobilization of the catalyst is highly desirable to allow regeneration of the catalyst.

The first attempt at immobilization consisted of a triphasic approach in which the sulfonated form of the complex was dissolved in an ethylene glycol phase which adhered on one side to a support, with the other side in contact with an immiscible phase containing the substrate.[2] The system, however, is restricted in the choice of possible substrates and solvents. Recently, we reported a new, more versatile method to immobilize binap based complexes by simple occlusion in a polydimethylsiloxane (PDMS) membrane.[3]

The hydrogenation of β-keto esters, catalyzed by binap based complexes, is a very important class of enantioselective reaction. Unfortunately, it suffers from the need for high reaction temperatures ( > 60 °C) and high hydrogen pressures ( > 6 MPa).[4] In homogeneous reaction conditions, King *et al.* discovered that the addition of small amounts of strong inorganic acids allows the reaction to occur at 40 °C using reduced hydrogen pressures.[5] This, however, requires the separation of the acid from the products after reaction to keep the catalyst active and enantioselective.

In the present work, both a Ru–binap complex and toluene-*p*-sulfonic acid (PTSA) have been immobilized in a PDMS membrane *via* the same technique and used in the enantioselective hydrogenation of β-keto esters. This acidic chiral membrane shows substantially enhanced enantioselectivity and activity at room temperature, allowing catalyst separation and reuse after simple filtration.

Typically, binap–chloro(*p*-cymene)–ruthenium chloride was occluded in an elastomeric-type PDMS membrane together with PTSA. To do so, the PDMS membrane was synthesized in the presence of the binap complexes and the organic acid. A 20 vol% solution in chloroform of appropriate amounts of the prepolymer (RTV-615 A) and crosslinker (RTV-615 B) from General Electric was stirred in a 10 : 1 weight ratio together with an appropriate amount of PTSA (typically, 5 wt%) at room temp. for 1 h. The chiral complex (obtained from Aldrich) was then added (0.25 wt%), and the mixture was further stirred at room temp. for 1 h under a nitrogen atmosphere. After casting the mixture in a Petri dish, the solvent was allowed to evaporate for 18 h under nitrogen flux. The membrane was precured under vacuum at room temperature for 4 h, followed by curing under vacuum at 150 °C for 1 h. The catalyst membrane showed an average thickness of 0.2 mm, corresponding to a coverage of *ca.* 0.054 μmol $cm^{-2}$ for the Ru–binap complex. The complex and the acid are both wrapped in the elastomer network and retained by steric restrictions, in combination with van der Waals interactions between the occluded compounds and polymer chains.

Hydrogenation of methyl acetoacetate (MAA) (molar ratio MAA : Ru : solvent = 2500 : 1 : 25000) with the occluded Ru–binap complex was performed in a batch reactor at a pressure of 6 MPa at room temp. (RT), 40 or 60 °C.

An overview of the catalytic results obtained with the membrane occluded Ru–(*R*)-binap complex is given in Table 1. Entries 1–3 show that the Ru–binap PDMS membrane requires hydrogenation temperatures of at least 60 °C to exhibit reasonable activity and moderate enantioselectivity. Literature data show that the same is true for the homogeneous case.[4] Entries 4 and 5 show that strong organic acids like PTSA exert a comparable effect on catalyst activity as inorganic acids, allowing room temp. hydrogenation of methyl acetoacetate with high enantioselectivity. PTSA, added to the reaction mixture containing a Ru–binap membrane, activates the heterogeneous catalyst yielding good activity (entry 6). At the same time, a very significant increase in enantioselectivity from 61 to 93% is observed compared to the acid-free system at 60 °C (entry 3). However, this system still requires removal of PTSA from the reaction medium.

An acid/Ru–binap membrane, containing equal molar amounts of PTSA and Ru, shows a four-fold increase in activity at 40 °C while maintaining the high enantiomeric excess (entry 8) compared to the previous case (entry 6) in which PTSA was added to the reaction medium. The acid/Ru–binap membrane shows good activity and enantioselectivity at room temperature as well (entry 7). The ratio of PTSA to Ru–binap in the catalytic membrane was found to have a pronounced effect on the system's activity (Fig. 1). After an initial steep rise in activity resulting from an increase in concentration of the incorporated acid, an optimum activity is obtained at a molar ratio of $H^+$/Ru of about 10 (entry 9). The activity decrease at higher ratios is

**Table 1** Influence of PTSA addition to a Ru–binap PDMS membrane on the activity and enantioselectivity of the hydrogenation of methyl acetoacetate[a]

| Entry | Catalyst | PTSA | *T*/°C | TOF/$h^{-1}$[b] | Ee (%) |
|---|---|---|---|---|---|
| 1 | Ru–binap membrane | — | RT | — | — |
| 2 | Ru–binap membrane | — | 40 | — | — |
| 3 | Ru–binap membrane | — | 60 | 9.6 | 61 |
| 4 | Ru–binap homogeneous | 0.5[c] | RT | 8.2 | 97 |
| 5 | Ru–binap homogeneous | 0.5[c] | 40 | 59.2 | 96 |
| 6 | Ru–binap membrane | 0.5[c] | 40 | 1.8 | 93 |
| 7 | PTSA/Ru–binap membrane | 0.5[d] | RT | 3.7 | 79 |
| 8 | PTSA/Ru–binap membrane | 0.5[d] | 40 | 6.5 | 87 |
| 9 | PTSA/Ru–binap membrane | 2.0[d] | 40 | 41.6 | 92 |

[a] Reactions (4) and (5) (homogeneous), for reasons of solubility, were carried out in methanol, whereas the membrane reactions are carried out in ethylene glycol. [b] TOF = turnover frequency, calculated as turnover number per hour, is often referred to as turnover number (TON). [c] Amount of PTSA in the homogeneous reaction mixture (g per g Ru–binap). [d] Amount of PTSA incorporated in the PDMS membrane (g per g Ru–binap).

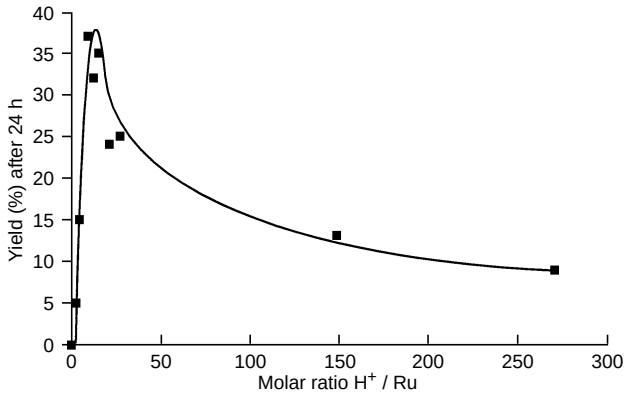

**Fig. 1** Influence of the amount of PTSA in PTSA/Ru–binap PDMS membranes, on the hydrogenation of methyl acetoacetate at 40 °C. The ee in all cases is 90 ± 3%.

probably due to a decreasing degree of crosslinking in the PDMS membrane when increasing amounts of acid are present. It seems that this results in moderate to severe leaching of the acid from the membrane, implying a decreasing concentration of incorporated acid and thus a drop in hydrogenation activity. Complex leaching is absent in all reported cases as measured by atomic absorbance spectrophotometry. The ruthenium content of the reaction mixture is lower than the detection limit of 0.16 ppm. Furthermore, after removing the membrane, the reaction mixture did not show any activity upon addition of fresh substrate. Up to the optimum point of activity, catalyst reuse after filtration is possible without loss of activity or enantioselectivity. These results clearly prove the heterogenity of the reported system.

In conclusion, a new highly active and enantioselective heterogeneous hydrogenation catalyst is presented, allowing room temp. hydrogenation of β-keto esters. The system consists of a Ru–binap complex, occluded in a PDMS membrane together with toluene-*p*-sulfonic acid activating the complex. The new catalyst has superior activity compared to its homogeneous equivalent. Moreover, reuse of the catalyst is possible after filtration.

# Dibenzotetrathiafulvalenes inserted with cycloalkanes and their tricyclic valence isomers: reversible C–C bond making/breaking upon electron transfer

**Takanori Suzuki,*[a]† Masahide Kondo,[b] Tatsuo Nakamura,[b] Takanori Fukushima[b] and Tsutomu Miyashi*[b]‡**

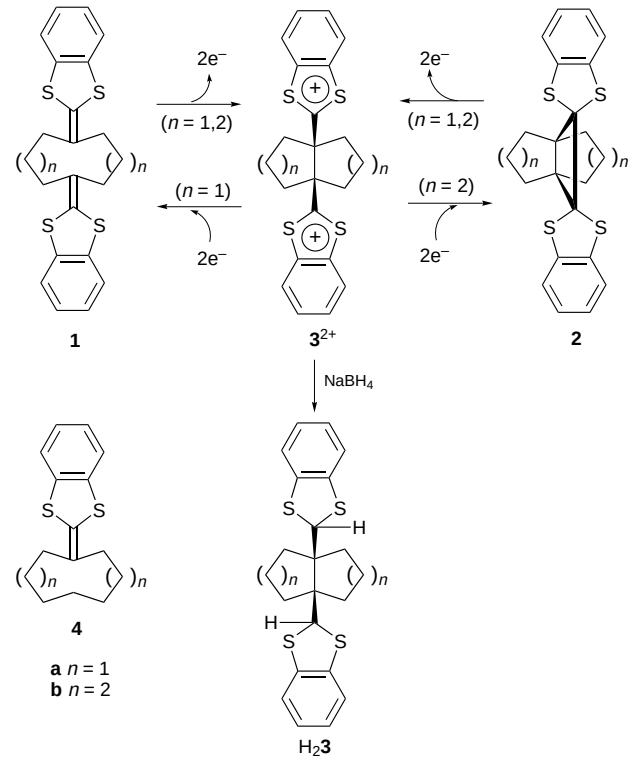
**The title TTF derivatives and their tricyclic valence isomers afford the same bicyclic dications upon two-electron oxidation, and the resulting dications regenerate either one or the other of the two isomers selectively upon reduction.**



Recently much attention has been focused on molecules whose geometry and properties can be controlled by external signals.[1] From this point of view redox systems that undergo drastic structural changes upon electron transfer (ET) are interesting[2] and might be applicable to the construction of electrochemical switches or molecular devices based on their optical response and bistability. A series of tetraalkylhydrazines[3] was the first group of organic compounds reported to show such a 'dynamic redox' property. Various bicyclic diamines[4] and a variety of dithioethers[5] can also be classified as dynamic redox systems which are further advantageous in regard to the bistability gained by forming a transannular N–N or S–S bond upon ionization. ET-induced transannular C–C bond formation has been well studied in terms of homoconjugation,[6] yet little has been reported on carbocyclic ring systems other than 1,3-dimethylenecyclobutanes. We have designed and prepared the dibenzo-TTF derivatives **1** inserted with cyclooctane or cyclodecane, and their dynamic redox properties are reported herein along with those of their tricyclic valence isomers **2**. It is worth noting that the same bicyclic dications $\mathbf{3}^{2+}$ were formed upon two-electron oxidation of **1** and **2** by C–C bond formation in the former and breaking in the latter. Furthermore, the resulting dication $\mathbf{3}^{2+}$ regenerated either **1** or **2** selectively depending on their ring size upon reduction (Scheme 1).

The Wittig–Horner reactions of the corresponding diketones or ketones with 2-methoxyphosphinyl-1,3-benzodithiole[7] afforded **1**§ and monofunctionalized derivatives **4**,§ respectively. Their oxidation potentials ($E^{OX}$) measured by cyclic voltammetry in $CH_2Cl_2$ are summarized in Table 1. The donating ability of **1** is much stronger than that of **4**, and even stronger than the fully conjugated dibenzo-TTF, indicating the presence of considerable interaction between the two chromophores in the cyclooctane skeleton.[8]

Upon oxidation with iodine **1a** afforded the dication salt $\mathbf{3a}^{2+}(I_3^-)_2$ in 86% yield, the structure of which was deduced from the $^{13}C$ NMR spectrum in $Me_2SO$ [**1a** $\delta$ 22.98, 35.58, 121.47, 122.30, 125.46, 126.37, 135.69; $\mathbf{3a}^{2+}(I_3^-)_2$ $\delta$ 25.03, 37.61, 70.33, 116.95, 121.89, 125.53, 134.60]. Formation of a transannular C–C bond was confirmed by X-ray analyses¶ of the salt [1.63(3) Å] as well as its dihydro derivative $H_2$**3a** [1.584(6) Å] obtained by the reaction of $\mathbf{3a}^{2+}$ with $NaBH_4$ in quantitative yield. The two benzodithiolium moieties in $\mathbf{3a}^{2+}$ are arranged in a face-to-face manner in close proximity (Fig. 1), which causes the very large upfield shift of $\delta_C$ for C-2 of benzodithiolium ($\delta$ 116.95) in $\mathbf{3a}^{2+}$ from the normal value ($\delta$ 182.4). This salt regenerated **1a** in quantitative yield upon reduction with $SmI_2$, indicating that **1a** and $\mathbf{3a}^{2+}$ constitute a reversible redox pair undergoing facile C–C bond formation upon ionization and its breaking in the reverse cycle.

For cyclodecane **1b**, dication salt $\mathbf{3b}^{2+}(I_5^-)_2$ which has a *cis*-decalin structure was formed in quantitative yield by reaction with iodine.‖ Although this low solubility salt decomposed easily when dissolved in $Me_2SO$, its stereochemistry and the formation of a transannular bond were confirmed by the X-ray analysis¶ of $H_2$**3b** obtained by the reaction of this salt with $NaBH_4$ in 90% yield. In contrast to the dication $\mathbf{3a}^{2+}$, this salt did not regenerate the starting diolefin **1b** upon reduction with $SmI_2$. The reduction product obtained in 92% yield was proven to be the tricyclic isomer **2b** as determined by X-ray analysis.¶

In order to investigate the involvement of such tricyclic isomers in the whole redox cycle, **2a**§ and **2b**§ were prepared by

**Scheme 1**

**Table 1** Oxidation potentials[a] and synthetic yields of new donors **1**, **2** and **4** (reference compound)

|---|---|---|---|---|
| Comp. | $E^{OX}$/V | Yield (%) | $E^{OX}$/V | Yield (%) |
| **1** | +0.55[b] | 37 | +0.69[c] | 13 |
| **2** | +1.03[b] | 71 | +0.95[c] | 98 |
| **4** | +1.03[d] | 91 | +1.13[d] | 61 |

[a] Anodic peak potentials ($E_{pa}$) *vs.* standard calomel electrode (SCE), 0.1 mol dm$^{-3}$ $Bu^n_4NBF_4$ in $CH_2Cl_2$, Pt electrode, scan rate 100 mV s$^{-1}$. Under the same conditions, $E_{pa}$ of dibenzo-TTF is +0.74 V and cathodic peak potential ($E_{pc}$) of 1,3-benzodithiolium is −0.13 V. [b] $E_{pc}$ = +0.36 V. [c] $E_{pc}$ = +0.14 V. [d] No cathodic peak was observed.

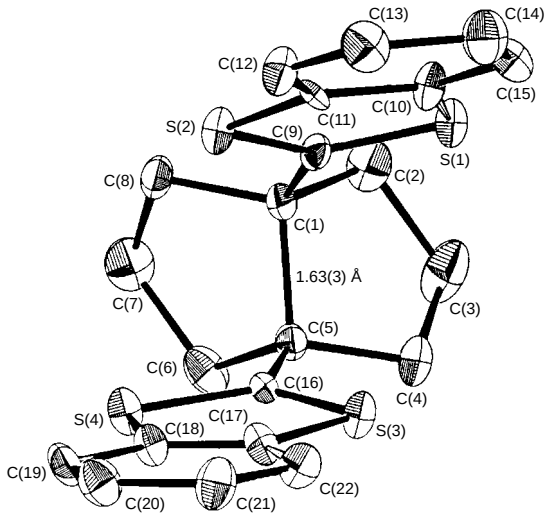

**Fig. 1** Molecular structure of the dication **3a**$^{2+}$ determined by X-ray analysis on its bis(triiodide) salt. The dihedral angle between 1,3-benzodithiolium moieties is 26°, and the torsion angle for C(9)–C(1)–C(5)–C(16) is 34°. Intramolecular contact between C(9)··C(16) is 2.80 Å.

the solid-state photoreaction of **1a** and *p*-$MeC_6H_4SO_3H$–catalyzed isomerization of **1b** in $CH_2Cl_2$, respectively, which are weaker electron donors than **1** (Table 1). Upon oxidation with iodine **2a** and **2b** afforded **3a**$^{2+}(I_3^-)_2$ and **3b**$^{2+}(I_5^-)_2$, in quantitative and 94% yield, respectively, thus making up the redox cycle shown in Scheme 1. These results indicate that **2b** and **3b**$^{2+}$ can be considered as a reversible dynamic redox pair, which is different from the previous case (**1a** and **3a**$^{2+}$) in the sense that the C–C bond breaking but not making occurs upon ionization. Although the reason of the divergent pathways for the dications **3a**$^{2+}$ and **3b**$^{2+}$ upon reduction is still unclear,** two different types of dynamic redox systems can be constructed by changing only the number of methylene units of the carbocyclic ring.††

CCDC 182/642.
‖ Specific formation of the *cis*-decalin skeleton may result from kinetic control because the *trans*-isomer has nearly the same heat of formation as **3b**$^{2+}$. It seems that a much larger structural change has to take place to form the *trans*-isomer although no information is available on the conformation of the starting material **1b**. The authors are grateful to one of the referees for pointing out such a possibility.
** One possible explanation is postulating an interaction between the p-orbital of benzodithiolium and the transannular σ bond in **3a**$^{2+}$, thus adding the contribution from the σ* orbital to its LUMO. See ref. 9.
†† Unlike **1a** and **1b**, cyclohexane-1,4-diylidenebis[2-(1,3-benzodithiole)] ($E_{pa}$ = +0.96 V) does not form a transannular C–C bond upon oxidation with iodine. The product is the salt of 2-(4′-iodobicyclo[2.2.1]heptan-1′-yl)-1,3-benzodithiolium having a spiro(1,3-benzodithiole) unit at C-7′.

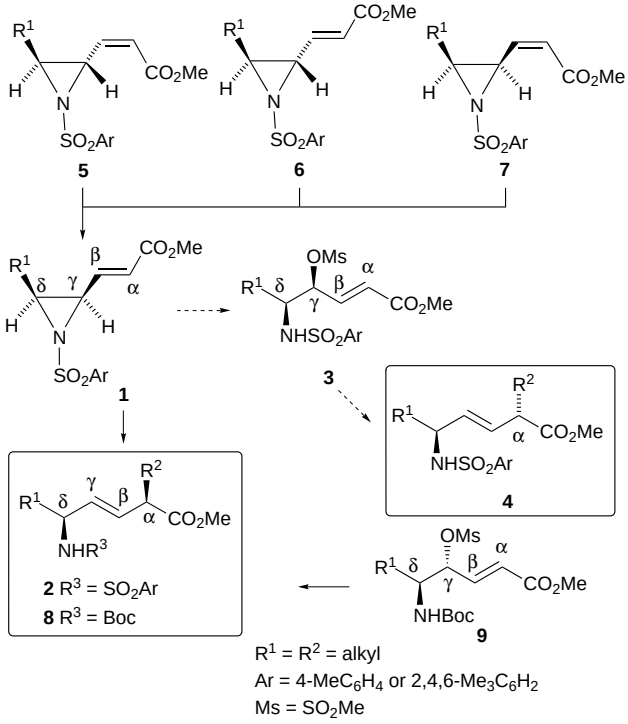
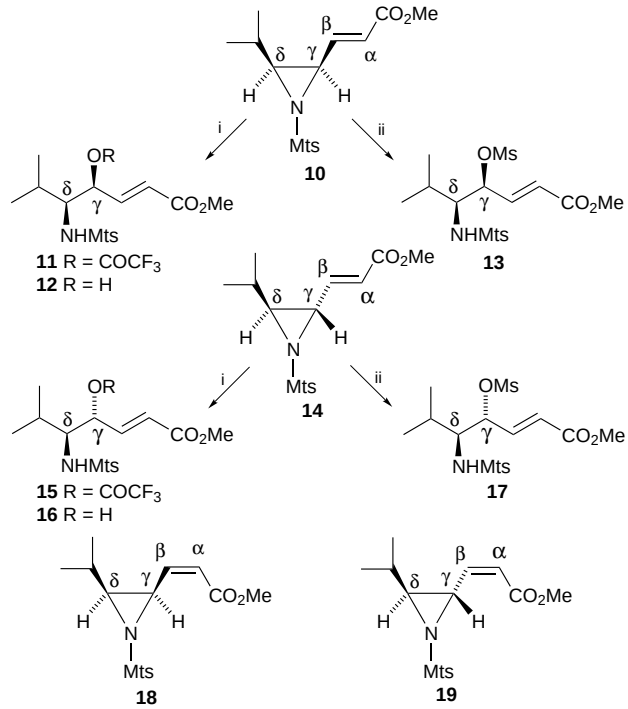
# Regiospecific ring-opening reactions of aziridines bearing an α,β-unsaturated ester group with trifluoroacetic acid or methanesulfonic acid: application to the stereoselective synthesis of (*E*)-alkene dipeptide isosteres

**Hirokazu Tamamura,* Masaki Yamashita, Hiroyuki Muramatsu, Hiroaki Ohno, Toshiro Ibuka, Akira Otaka and Nobutaka Fujii**



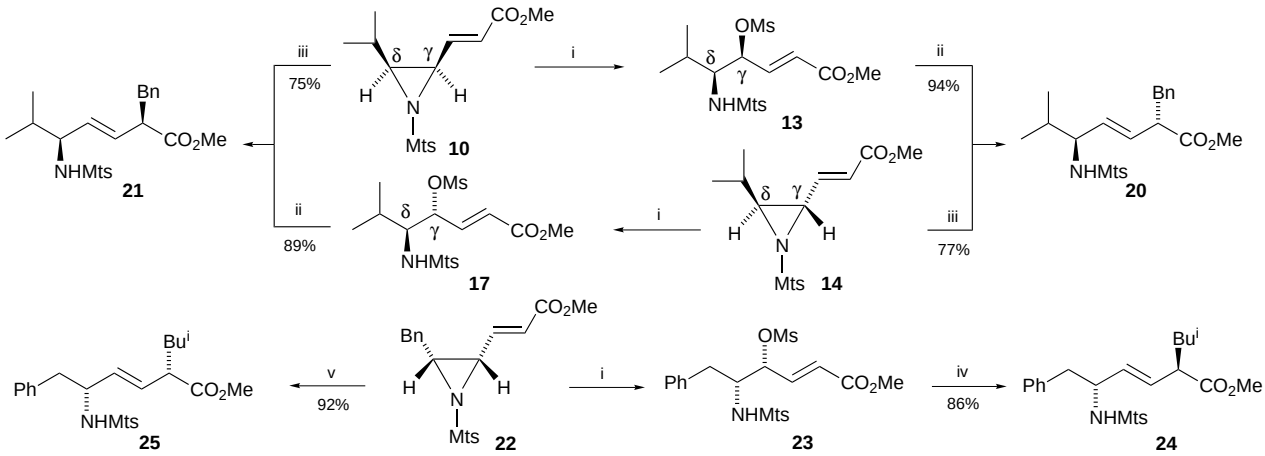
*Graduate School of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606-01, Japan*

**Reaction of *N*-(2,4,6-trimethylphenylsulfonyl)-γ,δ-*cis*- or -*trans*-γ,δ-epimino (*E*)-α,β-enoates with acids such as TFA or methanesulfonic acid (MSA) affords the stereo- and regioselective ring-opened products in high yields, and subsequent treatment of resulting δ-aminated γ-mesyloxy α,β-enoates with organocopper reagents yields diastereoisomerically pure (*E*)-alkene dipeptide isosteres.**



Among various dipeptide isosteres, use of (*E*)-alkene isosteres as backbone replacements of amide bonds in peptides has been well documented.[1] Recently we[2] and others[3] have reported that (*E*)-alkene isostere-containing peptides can exhibit potent biological activity. Because it has been reported that both the (*E*)-configuration and the stereochemistry at the α-position are important factors for biological activity, the stereocontrolled synthesis of both stereoisomers of types **2** and **4** from a single substrate of type **1** would be extremely valuable (Scheme 1). One advantage of such a strategy is that three other stereoisomeric enoates **5**, **6**, and **7** can be converted into the enoate **1** in synthetically acceptable yields merely by exposure to a palladium(0) catalyst (Scheme 1).[4] Previously we and others have developed two synthetic methods for the preparation of diastereomerically pure (*E*)-alkene dipeptide isosteres **2** and **8** by organocopper-mediated *anti*-$S_N2'$ reaction of β-aziridinyl α,β-enoate **1**[5] and δ-aminated γ-mesyloxy α,β-enoate **9**,[6] respectively.

Whereas ample precedent exists that various nucleophilic reagents,[7] including Lewis acids such as acetic acid,[8] TFA[9] and toluene-*p*-sulfonic acid in aqueous acetone,[10] attack simple *N*-unactivated or activated aziridines[11] at either of the two carbon atoms, yielding ring-opened products, the synthetically useful reactions involving γ,δ-epimino α,β-enoates of type **1** with TFA or methanesulfonic acid (MSA) have not previously been reported. Here we report the regio- and stereo-selective ring-opening reactions of aziridines and stereoselective synthesis of (*E*)-alkene dipeptide isosteres by treatment of the ring-opened products with organocopper reagents.



We initially examined ring-opening reactions using TFA. The required diastereoisomerically pure *N*-(2,4,6-trimethylphenylsulfonyl) (Mts)-protected aziridines bearing α,β-unsaturated esters were readily prepared according to reported methods.[4,5] Exposure of enoate **10** derived from L-valine to TFA at room temp. for 15 h afforded γ-trifluoroacetoxy α,β-enoate **11**, presumably *via* regioselective $S_N2$ ring-opening reaction at the γ-carbon position. Hydrolysis of **11** and silica gel flash chromatographic purification yielded the γ-hydroxy α,β-enoate **12** in 93% yield based on **10** (Scheme 2). In a similar manner, treatment of aziridine **10** with MSA (10 equiv.) in $CHCl_3$ at room temp. for 20 min gave exclusively γ-mesyloxy

**Scheme 1**

**Scheme 2** *Reagents*: i, TFA; ii, MSA

**Scheme 3** *Reagents*: i, MSA; ii, BnCu(CN)MgCl·$BF_3$; iii, BnCu(CN)MgCl·2LiCl; iv, Bu$^i$Cu(CN)MgCl·$BF_3$; v, Bu$^i$Cu(CN)MgCl·2LiCl

α,β-enoate **13** in essentially quantitative yield. It was found that the MSA-mediated ring-opening reaction proceeded much more faster than the reaction involving TFA. It is also noteworthy that, in both cases, ring-opened products generated by nucleophilic attack at the α- or δ-carbon positions could not be detected.

Regiochemical assignments for the trifluoroacetate **11** and the mesylate **13** were readily made by $^1$H NMR spectroscopy ($^1$H-$^1$H COSY). The γ,δ-*syn* stereochemistry of the *N*-protected amino alcohol **12** derived from **11** was confirmed by transformation of **12** into the original substrate **10** using the Mitsunobu conditions.[12] Since the mesylate **13** was prone to regenerate the original substrate **10** during silica gel flash chromatographic purification, the mesylate **13** could not be isolated.

Regioselective ring-opening of three other stereoisomeric enoates **14**, **18** and **19** with TFA or MSA was examined. Regioselective ring-opening was successfully carried out on the *trans*-(*E*)-isomer of the aziridine enoate **14** in a similar manner (the yield of **16** based on **14**: 78%). However, treatment of the *cis*-(*Z*)-enoate **18** and the *trans*-(*Z*)-enoate **19** with TFA or MSA gave complex product mixtures. This clearly demonstrates that a slight change in the structure of the substituents can significantly alter the reaction course. Since enoates **18** and **19** can be converted into the enoate **10** *via* Pd$^0$-catalysed reactions,[4] this ring-opening reaction has no significant problems associated with its practical use for the synthesis of (*E*)-alkene isosteres.

Next, treatment of the mesylate **13** with 4 equiv. of BnCu(CN)MgCl·$BF_3$ in THF at −78 °C for 30 min afforded the protected L,D-type (2*S*, 5*S*) dipeptide isostere Mts-L-Val-ψ[(*E*)-CH=CH]-D-Phe-OMe **20** in 94% yield based on **10** (diastereoselection > 99 : 1). This reaction occurred by an *anti*-$S_N2'$ reaction as shown in Scheme 3. In sharp contrast, an *anti*-$S_N2'$ reaction of the *cis*-(*E*)-enoate **10** with 4 equiv. of BnCu(CN)MgCl·2LiCl in THF at −78 °C for 30 min yielded the L,L-type (2*R*, 5*S*) isostere Mts-L-Val-ψ[(*E*)-CH=CH]-L-Phe-OMe **21** in 75% yield, as shown in Scheme 3. One important aspect of MSA-mediated ring-opening reactions is the inversion of configuration at the C-γ carbon *via* an $S_N2$ mechanism. Thus *cis*-(*E*)-enoates produce *syn*-(*E*)-mesylates, which are converted into L,D-type isosteres by organocopper reagents. On the other hand, *cis*-(*E*)-enoates themselves afford L,L-type isosteres with organocopper reagents. In a comparable study, the *trans*-(*E*)-enoate **14** was treated with MSA to yield the *anti*-(*E*)-mesylate **17**, which was converted with the organocopper reagent into the L,L-type isostere **21** in 89% yield based on **14**. In contrast, the organocopper-mediated reaction of the *trans*-(*E*)-enoate **14** afforded the L,D-type isostere **20** in 77% yield. As a result, two types of isosteres were stereoselectively synthesized from either *cis*- or *trans*-(*E*)-enoates. Likewise, the aziridine enoate **22** derived from D-phenylalanine produced the corresponding D,L-type isostere **24** and the D,D-type isostere **25** with the MSA–organocopper and the organocopper treatment, respectively.

In conclusion, regio- and stereo-selective ring-opening reactions of *N*-Mts-protected aziridines bearing an α,β-unsaturated ester by TFA or MSA have been found. These ring-opening reactions provide useful approaches for the stereoselective synthesis of both L,L-type (or D,D-type) and L,D-type (or D,L-type) (*E*)-alkene dipeptide isosteres from either γ,δ-*cis*- or -*trans*-γ,δ-epimino (*E*)-α,β-unsaturated esters. The authors are grateful to Dr Terrence R. Burke, Jr., NCI, NIH, for valuable discussions during the preparation of this manuscript.

# Chiral recognition ability of peptide-based molecular receptors

**Normand Voyer*† and Brigitte Guérin**

*Département de chimie, Université de Sherbrooke, Sherbrooke, Québec, Canada J1K 2R1*

**Peptidic receptors bearing a crown ether side chain show enantioselective recognition of aromatic carboxylate and ammonium species and could be useful in chiral separation technology.**

The development of novel molecular systems that allow cost efficient separation of enantiomers is an active area of research.[1] In addition to the conventional fractional crystallization of diastereoisomeric salts, several new approaches are being investigated in this area: membrane separation, enzymatic resolution and chiral chromatography.[2] Herein we report that peptide-based molecular receptors could be used in enantiomer separation systems since they exhibit chiral recognition towards aromatic ammonium and carboxylate species by using distant aromatic–aromatic and electrostatic interactions.

The flexible crown ether modified peptides **1**–**3** were designed to complex aromatic ammonium and carboxylate species *via* an induced-fit mechanism, as depicted schematically in Fig. 1.[3] Receptors **1**–**3** were synthesized by a solid-phase strategy on a polystyrene-based oxime resin.[3] They showed both efficient complexation of phenylalkylamines and binding processes provoked conformational changes of the peptidic backbone, from a β-sheet to highly dissymetric β-turn structure. These observations lead us to investigate their chiral recognition ability towards synthetically useful compounds.

The chiral recognition ability of **1**–**3** was studied by a conventional enantioselective transport experiment through a $CHCl_3$ membrane.[4] Briefly, for the ammonium species, an aqueous source phase (0.08 M HCl) containing the substrate (0.24 mmol) and $LiPF_6$ (0.6 mmol) was separated from the receiving phase (0.01 M HCl) by a $CHCl_3$ phase containing the chiral receptors (8 mM). For the carboxylate species, KCl was used in the source phase (0.08 M LiOH) instead of $LiPF_6$ and pure water replaced the 0.01 M HCl solution in the receiving phase. The *R* and the *S* enantiomers of the $K^+$ salts of *N*-benzyloxycarbonylalanine (*N*-Z-Ala-O$^-$K$^+$) **5** and *N*-benzoylphenylalanine (*N*-Bz-Phe-O$^-$K$^+$) **6**, and α-methylbenzylammonium (MBA) **7** were used as substrates. Attempts to use α-methylnaphthylammonium as substrate failed due to its ability to cross the organic layer without receptors. The results are reported in Tables 1 and 2 as first order transport rates and enantiomeric discrimination constants.

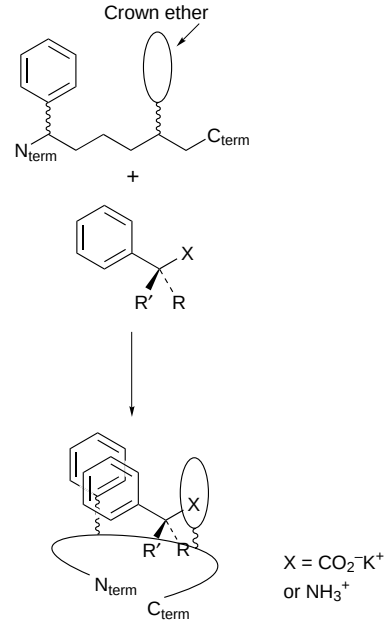

**Fig. 1** Working model for the chiral recognition ability of peptidic receptors **1**–**3** towards aromatic ammonium and carboxylate species. The binding of the guest by the cooperative action of the distant crown ether and benzyloxycarbonyl side chains induces conformational changes that lead to highly dissymetric complexes.

**Table 1** First order transport rates observed with peptidic receptors **1**–**3** and the crown ether **4** for the transport of substrates **5**–**7** across a $CHCl_3$ membrane[a]

| | | Rate/$10^5$ mol h$^{-1}$ | | | |
|---|---|---|---|---|---|
| | Substrates | **1** | **2** | **3** | **4** |
| **5** | (*S*)-Z-Ala-O$^-$K$^+$ | 6.16 | 4.73 | 1.40 | 10.3 |
| **5** | (*R*)-Z-Ala-O$^-$K$^+$ | 5.85 | 7.28 | 1.42 | 11.2 |
| **6** | (*S*)-Bz-Phe-O$^-$K$^+$ | 0.17 | 0.20 | 0.53 | 0.53 |
| **6** | (*R*)-Bz-Phe-O$^-$K$^+$ | 0.12 | 0.17 | 0.37 | 0.50 |
| **7** | (*R*)-(+)-MBA | 3.34 | 4.10 | 4.99 | 7.83 |
| **7** | (*S*)-(+)-MBA | 3.83 | 3.55 | 5.39 | 7.74 |

[a] Values reported are the average of three or more independent runs reproducible within ±5% performed at room temperature with a synchronized 6-position magnetic stirrer.

**Table 2** Enantiomeric discrimination constants (EDC = $k_S/k_R$) observed with peptidic receptors **1**–**3** and the crown ether **4** for the transport of substrates **5**–**7** across a $CHCl_3$ membrane

| | | EDC ($k_S/k_R$) | | | |
|---|---|---|---|---|---|
| | Substrate | **1** | **2** | **3** | **4** |
| **5** | (*S*/*R*)-Z-Ala-O$^-$K$^+$ | 1.05 | 0.65 | 0.99 | 0.92 |
| **6** | (*S*/*R*)-Bz-Phe-O$^-$K$^+$ | 1.42 | 1.18 | 1.43 | 1.06 |
| **7** | (*S*/*R*)-MBA | 1.15 | 0.89 | 1.08 | 0.99 |

One of the noteworthy features from the results is the enhanced enantioselectivity exhibited by the peptidic receptors as compared to their constituent crown ether amino acid **4** itself. This observation demonstrates the functional role of the peptidic frameworks in creating chiral clefts and the participation of aromatic–aromatic interactions in the complexation of the guests since the interplay of multiple binding sites is required for chiral recognition. Furthermore, no transport was observed in control experiments using the analogues of receptors **1**–**3** lacking the crown ring. Another point of importance is the different enantioselectivity demonstrated by peptidic receptor **2** compared to its positional analogues **1** and **3** in the cases of substrates **5** and **7**. Indeed, receptor **2** shows a preference for the *R* enantiomers whereas **1** and **3** transport the *S* enantiomers faster. It is worth considering a different complex structure between receptor **2** and the substrates. The peptidic receptors are known to exist in a β-sheet conformation in chlorinated solvents.[2] Under that conformation, the two binding side chains, the aromatic benzyloxycarbonyllysine and the crown ether, are on the same side of the peptidic framework for receptors **1** and **3**, but on opposite sides for their analogue **2** (Fig. 2). The different enantiomeric recognition ability of receptor **2** *versus* **1** and **3** is of importance since a subtle change in the spatial relationship of the binding elements (*i.e.* the relative position of the amino acids) allows the preparation of molecular systems selective for either enantiomer of a chiral compound of interest. The highest enantioselectivity was observed with receptors **1** and **3** and guest **5**, Bz-Phe-$O^-K^+$ [enantiomeric discrimination constant ($k_S/k_R$) = EDC = 1.42 and 1.43, respectively).

On the other hand, the three peptidic receptors transport the substrates at a slower rate than the monomeric crown analogue **4**. This could be due to the greater mobility and/or the faster decomplexation rate of the smaller and probably less stable crown complexes.

Even though several chiral receptors have been reported to achieve enantiomeric discrimination of carboxylate and ammonium compounds, the peptide-based molecular systems reported here have the advantages of being easily synthesized directly on polystyrene resin, the possibility of fine-tuning their enantioselectivity towards a desired enantiomer, and their suitability for optimization by combinatorial approach.[5] We are currently exploring the fundamental and practical aspects of peptidic receptors **1**–**3**.

The financial support of the NSERC of Canada, the Fonds FCAR du Québec, and the Université de Sherbrooke is gratefully acknowledged. B. G. thanks the NSERC of Canada for a postgraduate scholarship. The authors thank Dr Georges Dewynter (U. Montpellier-II, France) for critical reading of the manuscript.

# Interaction between poly(ethylene glycol) and human serum albumin

**David L. Cocke,* Hai-Jun Wang and Jinjiang Chen**

*Jack M. Gill Chair of Applied Chemistry and Chemical Engineering, Lamar University, Beaumont, TX 77710, USA*

**The thermodynamic nature of the interaction between polyethylene glycol and human serum albumin has been determined by affinity capillary electrophoresis.**

Poly(ethylene glycol) (PEG) is of extreme interest in biomaterials chemistry because of its very unusual and unique lack of interaction with biological matter.[1] Surface bound PEG is known to reduce protein adsorption and has become a very high interest research area.[2] Major efforts are in progress to immobilize PEG and PEG-like molecules at surfaces by chemical grafting[3–7] and numerous coating and physical bonding schemes.[8–16] In addition, it has found extreme interest for use in one of the most challenging problems in biomaterials chemistry involving blood contact interactions with biomaterials. In this case, the clotting factor fibrinogen is not absorbed, the complement system is not activated, platelets are not bound and viral particles are not bound to PEG coated surfaces.[17] PEG's resistance to protein adsorption has been attributed to a steric stabilization effect, unique solution properties and its molecular conformation in aqueous solution.[1] However, the interaction that does occur between the protein and PEG is being used to stabilize proteins in solution and causes a decrease in thermal stability,[18] which have been attributed to steric exclusion[19] and binding to the nonpolar regions of the protein molecule,[20] respectively. It has been proposed that competition between steric expulsion forces and van der Waals attraction between the protein and PEG control the protein adsorption process. Although numerous theories and models have been proposed, there remains no consensus. Bergström *et al.*[2] found that very little fibrinogen adsorption occurs on surfaces treated with PEG in the molecular weight range from 1500 to 19 000 but that significant adsorption occurs if the molecular weights of the polymers fall below 1500 with 100% adsorption for 250 molecular weight PEG polymers. One explanation given is that the PEGs reject the protein because of an unfavourable entropy (negative entropy) change associated with compression of the configurationally random heavily hydrated PEG chains by the protein adsorption. There is, however, considerable ordering of water around the PEG chain since two or three waters are closely associated with each ethylene oxide unit.[21,22] Protein interaction would release some of this water of solvation and produce a positive entropy change. Their model discusses the need for the negative entropy of compression to be compensated by the latter and speculate that the enthalpy for water loss would be enthalpically unfavourable. In addition, the positive free energy change for this process would have to be overcome by other interactions for sorption to take place. It is clear that more information on the interaction between PEG and proteins is badly needed.

In recent experiments, we have used affinity capillary electrophoresis (ACE) to examine the interaction between PEG and human serum albumin (HSA) and have determined data that is extremely relevant to thermodynamic models that discuss entropic and enthaplic favorable and unfavorable scenarios. The ACE binding experiments were performed at 30 kV at 25, 40 and 60 °C using an open-tubular arrangement on a Hewlett-Packard Model G1600A system with HP$^3$D chemstation software. The PEG concentrations were 0, 0.500, 1.00, 2.50, 3.00, 4.00 and 7.00 mg ml$^{-1}$. The pH was maintained at 7.00 by a sodium phosphate buffer and the samples consisted of 30.0 μM human serum albumin. The neutral marker *N*,*N*-dimethylformamide served as a metric for the electroosmotic flow. The ACE method for measuring interaction energies and entropies of proteins and substrates involves measuring the change in electrophoretic mobility $\Delta\mu_{R,L}$ of the protein complex in the presence of various concentrations of ligand ([L]) such as PEG (23). Here $\Delta\mu_{R,L}$ is given by eqn. (1), where $\mu_R$ is the mobility

$$\Delta\mu_{R,L} = \mu_{R,L} - \mu_R \quad (1)$$

of the protein receptor and $\mu_{R,L}$ is the mobility of the protein–ligand complex. Form these values, Scatchard analyses can be performed using eqn. (2), where $\Delta\mu_{R,L,max}$ is the mobility of

$$\Delta\mu_{R,L}[L] = K_b\Delta\mu_{R,L,max} - K_b\Delta\mu_{R,L} \quad (2)$$

the protein receptor when it is saturated with ligand. Plotting $\Delta\mu_{R,L}[L]$ *vs.* $\Delta\mu_{R,L}$ gives a straight line with slope $-K_b$ and intercept of $K_b\Delta\mu_{R,L,max}$ and thus produces equilibrium constants. The typical Scatchard plot is shown in Fig. 1 for 25 °C. Measurements and similar treatments at 40 and 60 °C produce equilibrium constants that can be used in a second law treatment derived from the van't Hoff equation ($\ln K = -\Delta H/8.3145T + \Delta S/8.3145$) and plot a $\ln[K]$ *vs.* $T^{-1}$ produces the enthalpy and entropy changes associated with the interactions. The second law plot is shown in Fig. 2. Here the enthalpy change was determined from the slope to be $\Delta H$ = 18.1 kJ mol$^{-1}$ and from the intercept, the entropy change was determined to be $\Delta S$ = 166 J mol$^{-1}$ K$^{-1}$. At room temperature, the free energy is calculated to be −31.4 kJ mol$^{-1}$.

These results show that the enthalpy of interaction is endothermic and that the interaction is entropically driven. This supports the conjecture that protein interaction would release some of the water of 'hydration' and produce a positive entropy change. The negative but small value of the free energy shows that the overall interaction is favorable but is not chemisorption or chemical binding but rather a process driven by other events. This information should help in formualting models of interaction between PEG and proteins and points to the fact that thermodynamic models must consider the entire system, protein, solvent and PEG.

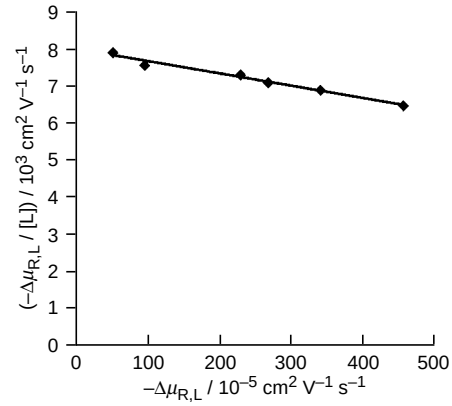

**Fig. 1** ACE-derived Scatchard plot for the interaction of the HSA with PEG at 25 °C

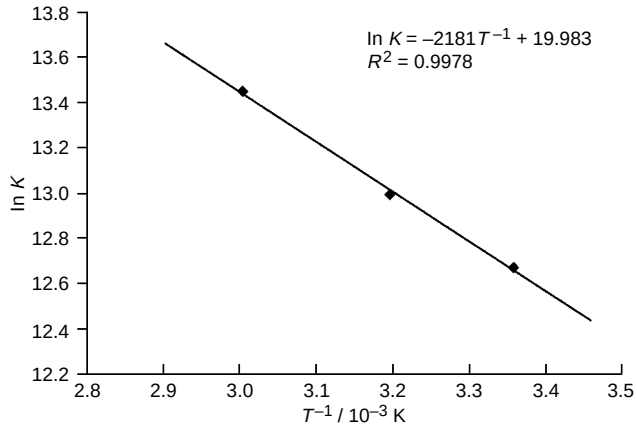

**Fig. 2** Second law plot of ln $K$ *vs.* $T$ with the equation for the line and the variance

The authors are grateful for the financial support of the Robert A. Welch Foundation (Houston, TX), the Texas Hazardous Waste Research Center (Gulf Coast Hazardous Substance Research Center) and the Texas Advanced Technology Program. We are particularly grateful to Dr Allan M. Ford for his insight concerning the importance of capillary electrophoresis and his support in obtaining the instrumentation. Special thanks go to Dr Jack M. Gill for his continuing support of the Gill Chair in Applied Chemistry and Chemical Engineering.

FEATURE ARTICLE

# The renewed challenge of antibacterial chemotherapy†

**Daniela Niccolai, Luca Tarsi and Russell J. Thomas**

*GlaxoWellcome S.p.A, Medicines Research Centre, Via A. Fleming 4, Verona, 37100 Italy*

**We are currently witnessing a dramatic and alarming increase in the incidence of bacterial infections resistant to most common antibiotics. In this article, we examine briefly the background to this situation, and the mechanisms both of antibacterial action and bacterial resistance. Following this introduction is a discussion of the evolution of the various antibacterial classes and of the current approaches being adopted to keep at bay the threat of a return to a pre-antibiotic era.**

Undoubtedly one of the greatest discoveries of modern times was that of penicillin by Sir Alexander Fleming in the 1920s.[1] Prior to the clinical introduction of penicillin in the 1940s bacteria were responsible for many of the world's most lethal diseases such as pneumonia, plague, gas gangrene, wound sepsis and tuberculosis, which has killed more people than any other disease. As a result of the work of Fleming and contemporaries such as Howard Florey and Ernst Chain, few people today consider bacterial infections as being as life threatening as viral infections, heart disease or tumours.

However today, we are approaching a medical crisis which, according to some experts, could see us return to the 'dark age' of the pre-antibiotic era.

There are several reasons for this rapid reversal of fortune in man's battle against infection. The pressures of natural selection are favourable in bacteria due to their rapid rate of multiplication. Thus a colony treated with a particular antibiotic may contain a small number of organisms which have developed a random mutation which renders it less susceptible to the antibiotic. Should these bacteria survive the treatment, for example when the patient fails to complete the prescribed course, they can then multiply, causing an infection less susceptible to the antibiotic class previously used. A second factor is the over-prescription of antibiotics common throughout the world. Many people suffering from viral infections are given, as a matter of routine, antibacterial agents. Similarly, huge quantities of antibiotics are used indiscriminately in meat and dairy farming and crop spraying at doses below those necessary to eradicate bacteria. This is an ideal medium for the selection of resistant strains. Another reason is the increase in the number of immunocompromised patients such as those taking anticancer drugs, immunosuppressants following organ transplants and AIDS patients. These people need to take extended antibacterial regimens as prophylaxis against infection. Pharmaceutical companies also believed for many years that antibacterial agents were no longer a high priority and shifted their resources into other, less well-covered therapeutic areas. Thus, when resistance to the available antibiotics first started to become a problem, there were few novel agents ready to replace them.

However, in the last few years, most of the major pharmaceutical companies have committed themselves to large research programmes aimed at both improving the potency of existing classes and, more notably at discovering novel approaches to antibacterial therapy.

Some of the more common bacterial pathogens and their associated disease states are summarised in Table 1.

Various resistance mechanisms are present in a wide variety of bacteria (Table 2), in many cases because of the transfer of resistance genes between different organisms. Resistant bacteria colonising hospital wards, operating theatres, equipment and even healthcare workers are now a major problem. Only a few years after the introduction of penicillin, *Staphylococcus aureus* strains became resistant due to the production of β-lactamase enzymes which hydrolysed the antibiotic before it had a chance to act.[2] Scientists countered this problem by developing β-lactamase stable agents such as methicillin, but again the bacteria fought back by altering the cell-wall target for β-lactams, the penicillin binding proteins (PBPs), to give methicillin resistant *Staphylococcus aureus* (MRSA). For the life-threatening infections caused by MRSA, the only viable treatment is vancomycin. As will be discussed later, some *Enterobacter* strains, in addition to being unaffected by all other classes of antibiotics, are also resistant to vancomycin (VRE). It has also been shown to be possible to create vancomycin resistant *S. aureus* mutants in the laboratory.[3] If and when this occurs in a hospital man will find himself, for the first time in

**Table 1** Common bacterial pathogens and their associated disease states

| Class | Associated diseases |
|---|---|
| **Gram-positive** | |

[a] UTI = Urinary tract infection.

half a century, unable to treat one of the most problematic pathogens of the pre-antibiotic age.

The rest of this short review is dedicated to an analysis of the various classes of antibiotics currently in either clinical use or undergoing clinical trials and consideration of the problems they face, before taking a look at possible approaches towards the next generation of antibacterial agents which will hopefully arise from the rapid advances in both biology and chemistry we are currently witnessing.

A qualitative impression of the amount of research being carried out on the various antibiotic classes can be gained by examining the number of patents issued each year. A schematic representation of a study of this kind is given in Fig. 1.[4]

## Penicillins

The revolution brought about by Fleming's discovery was based on a very simple β-lactam molecule, penicillin, which acts by irreversibly acylating proteins vital for the construction of the bacterial cell wall. These penicillin binding proteins (PBPs) have no mammalian counterpart, making the β-lactams one of the most selective drug classes known. The evolution of the β-lactam antibiotics has led to the development of several distinct structural classes (Fig. 2). As can be seen, the amount of novel research being carried out on penicillins (penams) is now very limited, and will therefore not be discussed here.[5]

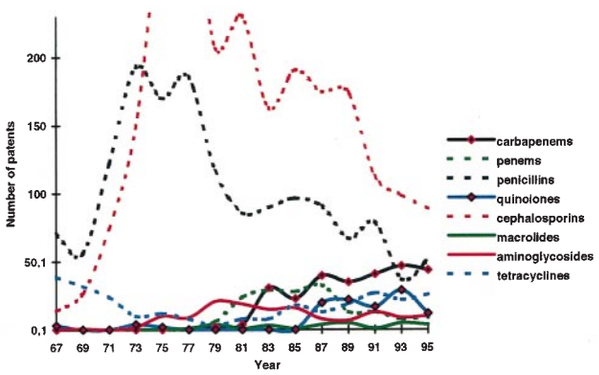

**Fig. 1** The changes in antibiotic research as shown by patent publications

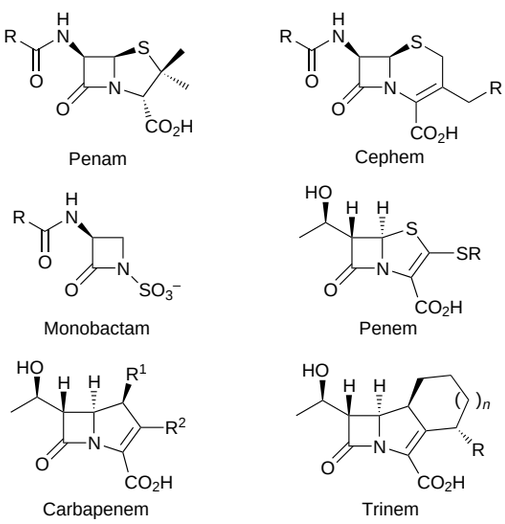
## Cephalosporins

A similar overall picture is apparent also for the cephalosporins (cephems), with increasing structural complexity, heavy patent coverage and the development of resistant strains leading to a reduction in research effort on this class.[6]

What research is still being done on cephalosporins is aimed at trying to obtain activity against specific pathogens. As a way of improving activity against the notoriously impermeable pathogen *Pseudomonas aeruginosa*, some compounds have been made with the aim of exploiting the tonB-dependent iron uptake mechanism by incorporating a catechol or catechol-like group.[7,8] No catechol-bearing β-lactam has yet completed clinical trials but the approach is nevertheless an interesting one.

In an attempt to regain activity against MRSA some cephalosporins bearing bulky aromatic substituted chains on the six-membered ring have been made.[9,10]



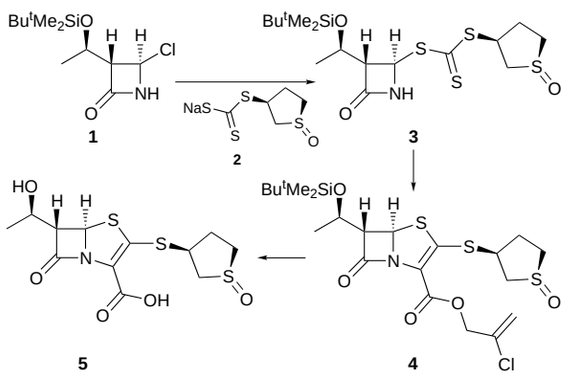


**Fig. 2** Structural classes of β-lactam antibiotics

**Table 2** Antimicrobial resistance by class

| Antimicrobial class | Mode of action | Baterial resistance mechanisms |
|---|---|---|
| β-Lactams | Cell wall biosynthesis inhibition | β-Lactamases<br>Altered PBP targets<br>Altered permeability |
| Glycopeptides | | |
| Fluoroquinolones | DNA gyrase A and topoisomerase IV inhibitors | Alteration of enzyme targets<br>Efflux pumps<br>Altered permeability |
| Aminoglycosides | Protein biosynthesis inhibitors | Enzymatic modification of antibiotic<br>Alteration of ribosome target |
| Chloramphenicol | | Enzymatic modification of antibiotic<br>Altered permeability |
| Macrolides | | Alteration of *23S* rRNA<br>Enzymatic modification of antibiotic |

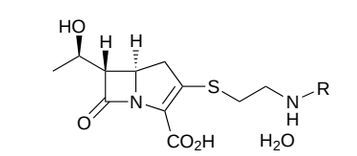
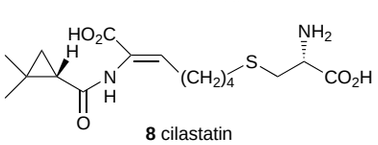
| Tetracyclines | | Efflux pumps<br>Aleration of ribosome target<br>Altered permeability<br>Enzymatic modification of antibiotic |
| Sulfonamides<br>Trimethoprim | Folic acid biosynthesis inhibitors | Altered permeability |

## Penems

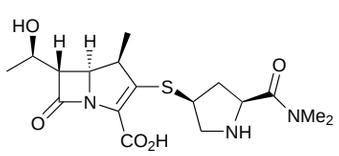


The penems are a purely synthetic class of β-lactam antibacterial agents.[11] It may be said, however, that considering the amount of extremely elegant research invested in the penem class, they have, from the clinical point of view, been decidedly disappointing. The main reasons for this are the difficulty of synthesis on a multi-tonne scale and the advent of the generally more potent carbapenem class. There is still however some interest in the penems, and there are currently a number of penems in clinical development including sulopenem **5** (Scheme 1). The key steps of the synthesis of compound **5** are the introduction of the thioxanthate substituent onto the transient azetinone generated from the 4-chloroazetidinone **1**. The resulting compound **3** is cyclised *via* an oxalimide route to the penem **4** which is then deprotected by standard methods to give sulopenem **5**.



**Scheme 1**

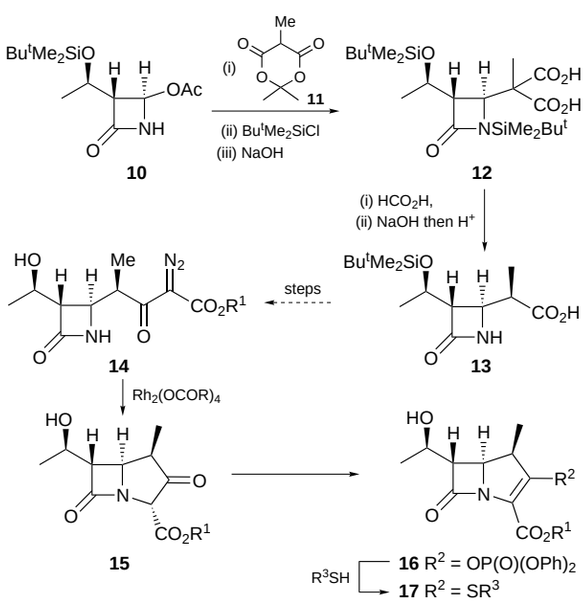
## Carbapenems



The first carbapenem, thienamicin **6**, was discovered as a natural product of *Streptomyces cattleya* in the late 1970s. Its formamidine derivative imipenem **7** was found to be much more chemically stable, and for a number of years has been an invaluable weapon against serious bacterial infection. Despite its chemical stability (due to the 6-hydroxyethyl side-chain it is also stable to all *conventional* β-lactamases), imipenem is rapidly inactivated in the kidney by mammalian dehydropeptidases (DHP) and is also nephrotoxic. This necessitates its co-administration with cilastatin **8**, which functions both as an inhibitor of DHP and reduces the renal accumulation of imipenem.[12]

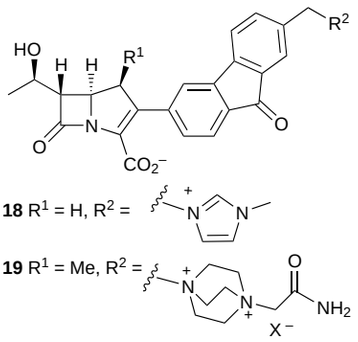
**6** R = H
**7** R = CH=NH

**8** cilastatin



**9** meropenem

Meropenem **9** has, by the introduction of a 1β-methyl substituent, eliminated the necessity of co-administration with cilastatin.[13] This, along with the fact that it is possible to inject the compound as a single large bolus dose prior to surgery (whereas imipenem must be administered more gradually, both to reduce the risk of seizures and to overcome its lower solubility), is considered to be the main advantage of meropenem over imipenem as, in terms of clinical relevance, their antibacterial spectra are both impressive.

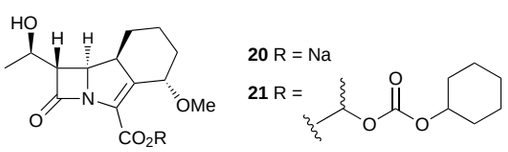


Although carbapenems have their origins as natural products, efficient, large-scale fermentation processes for key intermediates have yet to become commercially viable. Two key intermediates in the synthesis of 1β-methyl carbapenems are the 4-acetoxyazetidinone **10** and the propionic acid derivative **13**, in which all of the stereocentres in the final compounds are defined (Scheme 2).[14] While the need to explore novel syntheses of compound **10** (which is available commercially on a multi-tonne scale) is questionable, the control over the stereochemistry of the methyl group in **13** has led to many elegant approaches. One such route is shown in Scheme 2.[15] After alkylating the 4-acetoxyazetidinone **10** with the Meldrum's acid derivative **11**, *N*-silylation and saponification gave the diacid **12**, which was decarboxylated with catalytic formic acid to give the desired acid **13** in good yield and in a 94 : 6 ratio of β : α isomers. The transformation of acid **13** into a cyclised carbapenem system **17** is also outlined in Scheme 2.[16] Chain elongation to the diazo derivative **14** allowed an intramolecular rhodium octanoate-catalysed carbene insertion to the carbapenam keto ester **15** which was transformed into the enol phosphate **16**, an excellent substrate for a wide range of nucleophiles.

The current challenges in the discovery of novel carbapenems are largely based on broadening the spectrum even further, to include a wider range of problematic pathogens. As in the case of other β-lactams, carbapenems are largely ineffective against MRSA, as they have a low affinity for the PBP2' produced by these strains. The addition of a lipophilic group near the 'tail' of the molecule can increase affinity for PBP2', and workers at Merck have used this approach to synthesise anti-MRSA carbapenems such as L-695,256 **18** and its more soluble analogue L-742,728 **19**[17].

Resistance to carbapenems in *B. fragilis* and *P. aeruginosa* due to novel zinc-mediated metallo β-lactamases is starting to make an appearance, and will almost certainly increase in the coming years.[18] These enzymes are able to recognise the

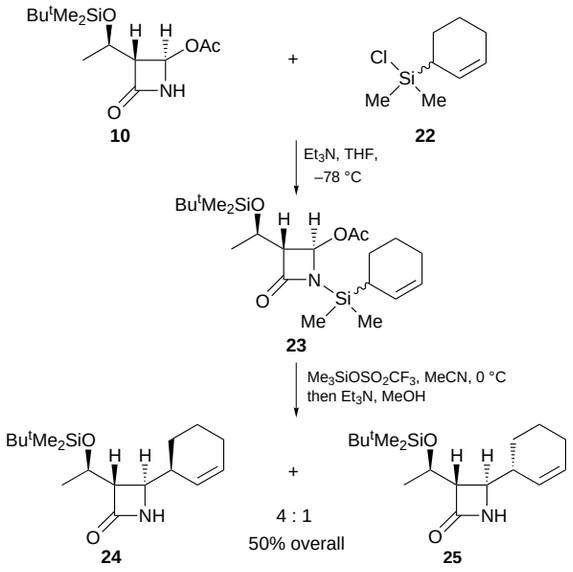
**Scheme 2**



hydroxyethyl side-chain which protects carbapenems from more traditional serine β-lactamases and in order to have stable compounds in the future it will be necessary to either modify the hydroxyethyl side chain (while trying to maintain the affinity for the PBPs) or design a new generation of metallo β-lactamase inhibitors.

A third mechanism of resistance exploited by *P. aeruginosa* is to suppress the synthesis of the D2 porin in the outer membrane through which imipenem and amino acids pass. However, it has been shown that meropenem maintains activity against these resistant strains, indicating that it has an alternative method of reaching its target.[19]

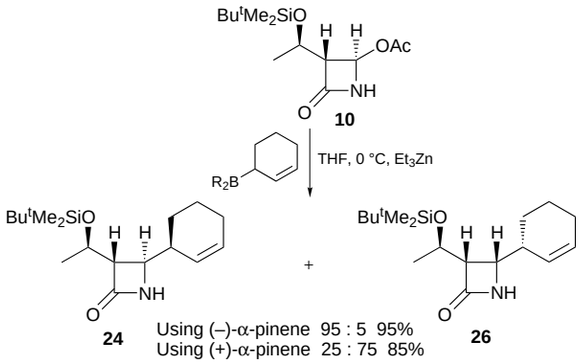
## Trinems



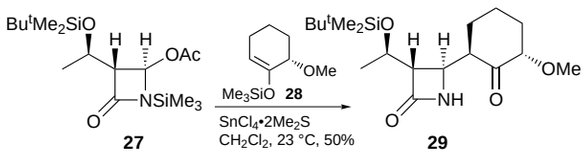
In the past few years there has been an increase in the exploration of novel β-lactam containing ring systems. Despite being structurally and synthetically interesting, many of the compounds generated in these programmes were unable, or unlikely, to exhibit significant antibacterial activity.[20] However, one both synthetically challenging and clinically relevant new class, the trinems, has emerged.[21]

Sanfetrinem **20**, the (4*S*)-methoxytrinem, and its orally bioavailable ester sanfetrinem cilexetil **21** are currently in Phase II clinical trials.[22] Its broad spectrum, which includes anaerobes and penicillin resistant *Streptococcus pneumoniae*, resistance to clinically relevant β-lactamases and stability to the renal dehydropeptidases which inactivate many penems and carbapenems, make it a promising agent for community acquired infections.

The challenge of the large-scale asymmetric synthesis of sanfetrinem has resulted in the recent publication of several quite different approaches. The original large-scale route to this compound, which was used successfully to produce the multikilogram quantity required for the Phase I study, suffered from a low overall yield and high number of steps.[21]

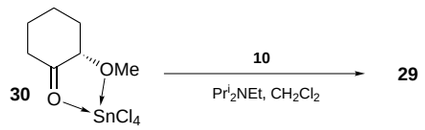


More recent approaches, however, have both reduced the number of steps and improved the overall yields to key intermediates. Two approaches to olefin **24** published recently involve an intramolecular Sakurai reaction with a cyclohexenylsilane[23] (Scheme 3), and dialkylcyclohexenylboranes[24] and appropriate Lewis acids (Scheme 4). An even more direct approach to sanfetrinem is *via* the direct condensation of (2*S*)-methoxycyclohexanone with the 4-acetoxazetidinone **10**. This has been achieved either *via* a Mukaiyama-like condensation (Scheme 5),[25] or more recently *via* zinc[26] or zirconium[27] enolates. A quite different approach to the key methoxy ketone **29** has also been published in a recent total synthesis of sanfetrinem.[28] With this method, the stereocontrol at the 6-position of the cyclohexanone ring is obtained by exploiting



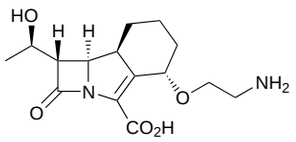
**Scheme 3**

the decarboxylation method originally applied to 1β–methyl carbapenems.[15] More recently still, a route to compound **29** using chelated tin(IV) enolates has been reported (Scheme 6).[29] In this method, optically active 2-methoxycyclohexanone is transformed into its stable tin(IV) chloride chelate **30**, which is then treated with a tertiary amine base, forming the corresponding enolate. This enolate then reacts with the 4-acetoxyazetidinone **10** and additional tin(IV) chloride to give the desired methoxy ketone **29**. This method, which was developed with the aid of low temperature NMR studies, has proved to give both high yields and stereocontrol and appears adaptable to a very large scale.

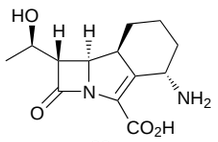


The promising biological activity obtained with sanfetrinem **20**, and the fact that this class presents a considerable synthetic

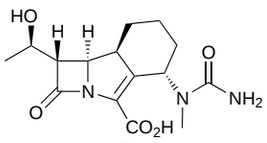
**Scheme 4**



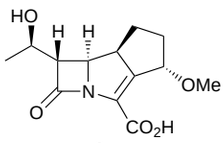
**Scheme 5**



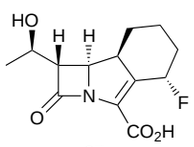
**Scheme 6**



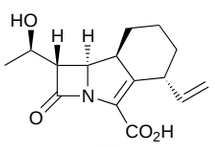
challenge, has encouraged research into other trinem molecules. Among the 4-alkoxy derivatives reported recently,[30] the 4-aminoalkoxy derivative **31** exhibited a promising biological



**31**



**32**



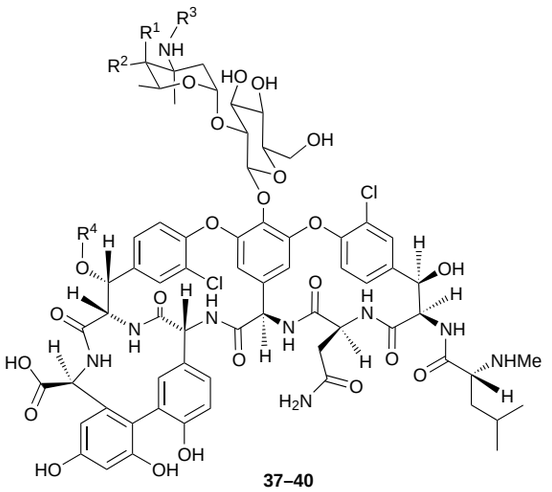
**33**

**34**

**35**

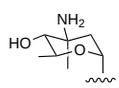
**36**

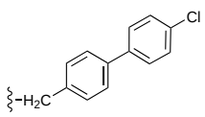
activity including *P. aeruginosa*. Other trinems reported recently include some 4-amino derivatives such as **32**,[31] 4-ureidotrinems including **33**,[32] the 5-membered ring analogue of sanfetrinem **34**,[33] stereo- and regio-isomers of sanfetrinem,[34] the highly unstable 4-fluorotrinem **35**[35] and a number of 4-alkenyl derivatives such as **36**.[36]

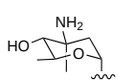


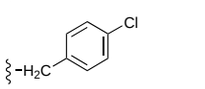
## Glycopeptides

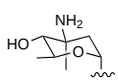
The glycopeptides are a family of antibiotics isolated from a variety of species including actinoplanes and streptomyces.[37] Vancomycin **37** and teicoplanin **41** are the most well-known members of this class and are used widely in the clinic as the drugs of choice in treating resistant Gram-positive species such as (MRSA), coagulase-negative staphylococci and multi-resistant enterococci.



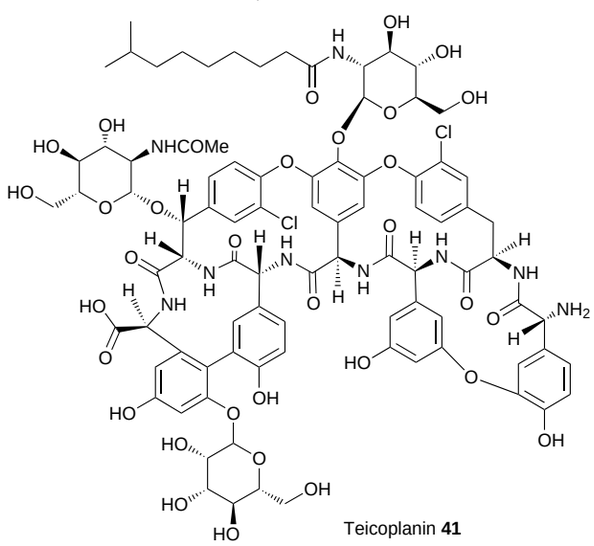








Five of the seven amino acids present are common to all glycopeptides, and their mode of action is to inhibit cell wall synthesis by interfering with a late stage in the assembly of the peptidoglycan. The conformation of the glycopeptides allows them to form a stable complex, by means of a hydrogen bond network, with the terminal dipeptide D-Ala-D-Ala of the peptidoglycan chain. This prevents both transglycosylation (chain elongation) and transpeptidation (cross-linking) with a consequent block of cell growth, subsequently leading to cell death. While the aglycone nucleus is responsible for the complexation of the D-Ala-D-Ala units, the sugar groups stabilise the complex (the modulation effect).

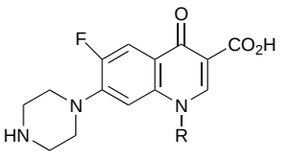


In recent years, a rapid increase in the incidence of infection and colonisation with vancomycin-resistant enterococci (VRE) has been reported from US hospitals, and the possibility of this resistance being transferred to *S. aureus* in the clinic is a cause for major concern. The mechanism of glycopeptide resistance in enterococci is well-understood and involves an alteration of the peptidoglycan precursor in which the terminal D-alanine is replaced with D-lactate, a change that reduces the ability of the antibiotic to bind to its target.[38]

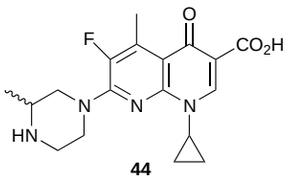
In order to overcome these resistance problems, new semisynthetic glycopeptides have been synthesised. Based on the observation that the introduction of lipophilic chains onto the amino sugar vancosamine of vancomycin enhanced activity against resistant enterococci, several derivatives were prepared *via* reductive alkylation of LY264826 **38**[39] (a derivative of vancomycin). Among these, the *p*-chlorophenylbenzyl derivative LY333328 **39**[40] was identified as the most potent compound against vancomycin resistant enterococci and has undergone preclinical studies. Recent studies on the prototype

**37–40**

| | $R^1$ | $R^2$ | $R^3$ | $R^4$ |
|---|---|---|---|---|
| vancomycin **37** | OH | H | H | H |
| LY264826 **38** | H | OH | H |  |
| LY333328 **39** | H | OH |  |  |
| LY191145 **40** | H | OH |  |  |

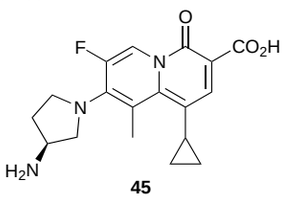


Teicoplanin **41**



*p*-chlorobenzyl derivative LY191145 **40**[41] have shown it to still have a poor affinity for D-Ala-D-Lac residues. However, the ability of LY191145 **40** to inhibit peptidoglycan biosynthesis may be explained in part by strong dimerization, allowing it to bind to two D-Ala-D-Lac units at the cell surface. Moreover, the hydrophobic side chain confers the ability to bind to bacterial membranes, anchoring the agent at the membrane-associated target site.[38]

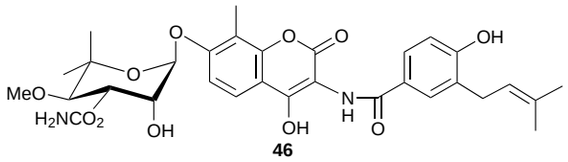
## Fluoroquinolones



The introduction, in the 1980s of fluoroquinolones such as norfloxacin **42** and ciprofloxacin **43** provided clinicians with a valuable weapon against infections.[42] These compounds are orally active, have a broad-spectrum and favourable pharmacokinetic and safety profiles.

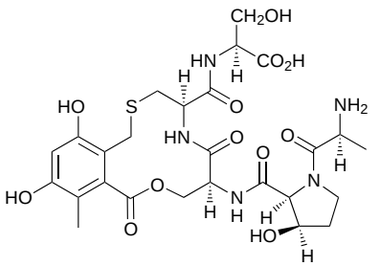
**42** R = Et
**43** R = cyclopropyl

**44**



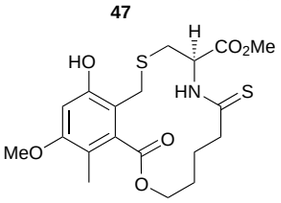
**45**

The primary mode of action of the quinolones is the inhibition of gyrase, a topoisomerase II responsible for the introduction of negative supercoils in bacterial DNA during its replication cycle.[43] Quinolones bind to the gyrase A subunit when it is complexed to the DNA, effectively blocking the supercoiling process. It has been shown that fluoroquinolones are also able to inhibit topoisomerase IV in several species including *S. pneumoniae*, *S. aureus* and *E. coli* and in some cases this may be the principal mode of antibacterial activity.[44]



The main challenge of current quinolone research is to improve Gram-positive and anaerobe potency.[45] Two compounds currently addressing these issues are grepafloxacin **44** and the structurally interesting 2-pyridone ABT-719.1 **45**.[46]

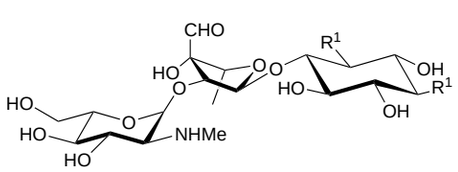
## Cyclothialidines



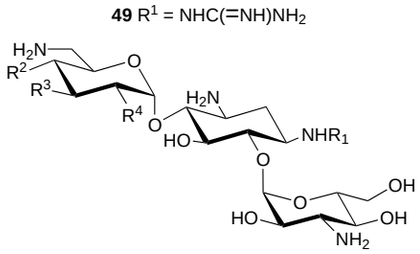
As mentioned previously, quinolones bind to the bacterial gyrase A subunit, thus blocking supercoiling. Gyrase is however a tetrameric protein comprised of two A and two B subunits. The B subunits have ATPase activity, necessary for the completion of the supercoiling cycle. When compared to the effort expended on quinolones, this target has, in the past, been largely overlooked. In the 1960s the coumarin antibiotics, such as novobiocin **46** were used clinically, although their toxicity and resistance development meant that they are now employed very rarely. Recently, however, scientists at both Hoffman-La Roche[47] and GlaxoWellcome discovered a new class of gyrase B inhibitors, the cyclothialidines. Despite having excellent activity against isolated gyrase B, cyclothialidine **47** has little or no activity against bacteria. More recently, scientists at Roche have been able to synthesise analogues, such as compound **48**, which act against a wide range of bacterial species. Several

**46**

**47**

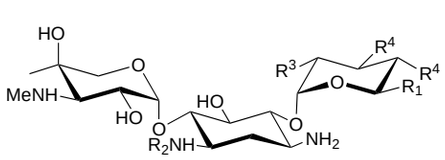


**48**

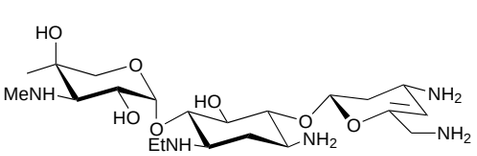


gyrase B protein subunit-inhibitor complexes have also been co-crystallised recently,[48] and it is hoped that the information gained from their X-ray crystal structures may aid the design and synthesis of novel gyrase B inhibitors.

## Aminoglycosides



The first aminoglycoside discovered, streptomycin **49** was isolated from *Streptomyces griseus* in 1944. Since then, around ten compounds have found a clinical application, including the natural products gentamicin **50** and tobramycin **52**, and the semisynthetic derivatives amikacin **53**, netilmicin **55** and dibekacin **54**. The aminglycosides are an extremely useful class of antibiotics, especially against serious Gram-negative bacterial infections,[49] and are frequently used in a synergistic combination with β-lactams. The amino groups present in these molecules are essential for biological activity, but may also be the cause of the nephrotoxicity associated with this class. The binding of the aminoglycoside to the ribosome causes misreading of a protein which is then incorporated into membranes, causing the formation of abnormal membrane channels and



**49** $R^1$ = NHC(=NH)$NH_2$

**52** $R^1 = R^3$ = H, $R^2$ = OH, $R^4 = NH_2$

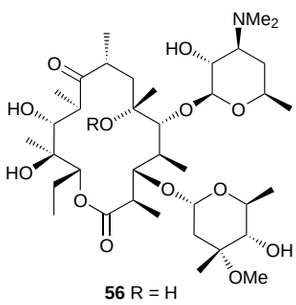
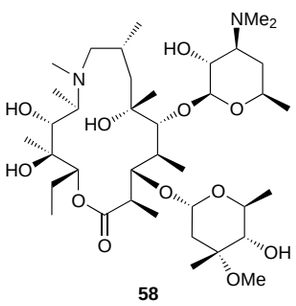
**54** $R^1 = R^2 = R^3$ = H, $R^4 = NH_2$

**50** $R^1$ = (*S*)-CH(Me)NHMe, $R^2$=$R^4$=H, $R^3$=$NH_2$
**51** $R^1$ = $CH_2NH_2$, $R^2$ = (*S*)-COCH(OH)$CH_2NH_2$, $R^3 = R^4$ = OH



**55**

altered permeability into the bacterial cell. This provokes an autocatalytic increase in aminoglycoside uptake, leading to rapid cell death.



Resistance to aminoglycosides can come about *via* a number of mechanisms. The most significant is the chemical modification of the antibiotic by intracellular enzymes. Low-level resistance may also occur as a result of altered permeability across the cell wall or mutations of the ribosome target. Recently a novel aminoglycoside, isepamicin **51**, has been described as being less susceptible to enzymatic inactivation.[50]

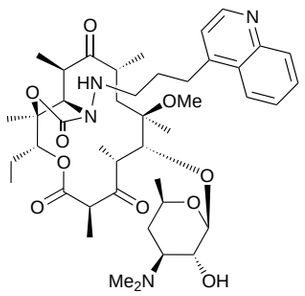
### Macrolides and ketolides

The first macrolide, the 14-membered ring compound erythromycin A **56**, isolated from *Streptomyces erythraeus*, was introduced to clinical use in the early 1950s. Displaying similar activity to penicillins against Gram-positive bacteria, erythromycin A has the advantage of also being active against bacteria having altered outer structures such as *Mycoplasma pneumoniae* and those such as *Legionella* and *Chlamydia* which survive within the host's cells.[51]

**56** R = H

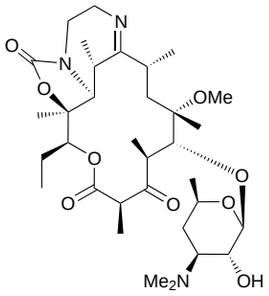
**58**

The macrolides act by inhibiting protein biosynthesis by blocking the peptidyl transferase centre of the *50S* subunit of the bacterial ribosome. Resistance to macrolides occurs either as a result of the enzymatic modification of the antibiotic or modification of targets (mutations of ribosomal proteins or rRNA genes).



Further research led to the development of semisynthetic macrolides such as dirithromycin, roxithromycin, clarithromycin **57** and azithromycin **58**. These derivatives overcome some of the drawbacks of older agents: poor oral bioavailability as a result of acid instability, gastrointestinal disturbances, poor tissue concentration and short half-life. Azithromycin **58**, a 15-membered azalide antibiotic, is synthesised by a stereospecific Beckmann rearrangement of (9*E*)-erythromycin A oxime, followed by the reduction and reductive *N*-methylation under Eschweiler–Clarke conditions.[52]

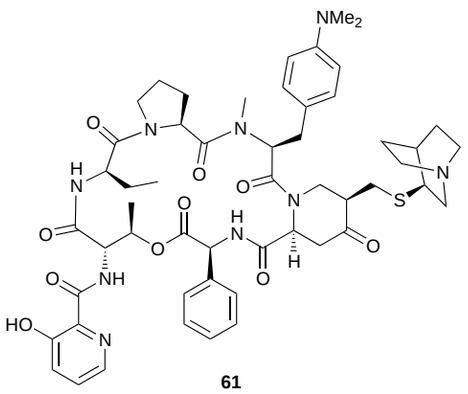
Recent research on 14-membered macrolides has led to the discovery of a new distinct class of these macrocyclic lactones, characterized by a 3-keto function instead of the cladinose moiety (hence the name ketolide), well-known for its lability in even weakly acidic media. Currently, the most promising ketolides appear to be RU-66647,[53] RU-64004[54] **59** and TE-802[55] **60**.



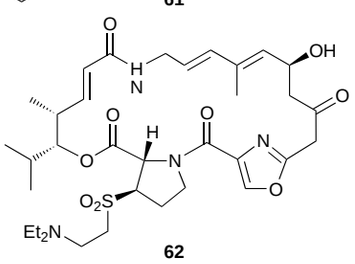
### Streptogramins

Macrolides have the same targets as the lincosamides and streptogramins, and these classes are frequently referred to as the MLS group. The streptogramins are a family of cyclic peptides produced by *Streptomyces* sp.[56] Each member of the class consists of at least two structurally different molecules, distinguished as being of either group A or group B agents. Group A molecules are polyunsaturated macrolactones, whereas group B compounds are cyclic hexadepsipeptides.

Quinupristin **61** and dalfopristin **62** are two injectable semisynthetic streptogramins currently in Phase III clinical trials. The compounds are used in synergistic combination



**59**



**60**

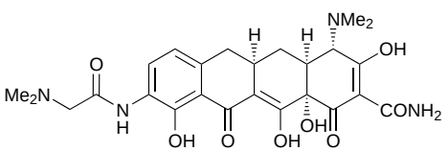
(RP59500, Synercid®) against Gram-positive bacteria, including multiresistant strains.

**61**

**62**

The synergy observed with the combination of quinopristin **61** and dalfopristin **62** can be explained in the remarkable way they bind to the peptidyl transferase domain of the *50S* ribosomal subunit. This synergy occurs because the attachment of a group A derivative such as dalfopristin **62** to the ribosome results in a conformational change, increasing the affinity for the group B compound quinopristin **61**. The resulting ternary complex is extremely stable and, unlike the bacteriostatic macrolides, streptogramins are bactericidal when used in combination.

More recent research into novel semisynthetic derivatives has allowed the discovery of an orally active streptogramin combination, RP106972, which is currently under investigation.[57]

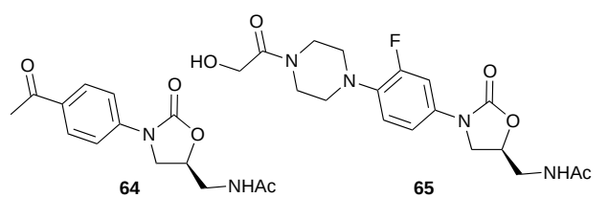


While resistance to single streptogramin components has been documented, it has been suggested that the quinupristin/dalfopristin combination should be less susceptible. However, according to a recent study reported at the 1996 Interscience Conference on Antimicrobial Agents and Chemotherapy (ICCAC) in New Orleans, resistance to the combination has already been seen in vancomycin resistant *Enterococcus faecium*.[58] Whether resistance to streptogramins will become a serious problem will only become apparent as their use in clinical situations becomes more widespread.

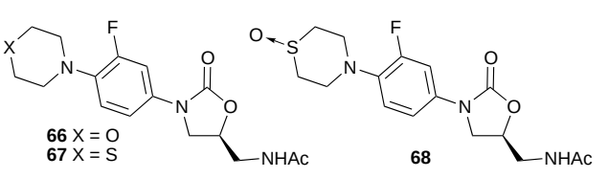
### Tetracyclines

Due to their broad spectrum, low toxicity, low incidence of side-effects and low cost, the tetracyclines were used intensively

both in clinical, agricultural and veterinary settings in the half century since their discovery.[59] The tetracyclines are bacteriostatic, and act by blocking the binding of aminoacyl-tRNA to the acceptor site on the *30S* ribosome.



Recently, structurally modified tetracyclines have overcome the severe resistance problems affecting this class. The so-called glycylcyclines maintain potent activity against resistant strains containing ribosomial protection factors (*tetM* and *tetO*) or efflux (*tetA-E*, *-L* and *-K*) determinants.[60] The most promising member of the class is CL 331,928 (DMG-DMDOT) **63** and research into modified tetracyclines is now the subject of new research programmes in several laboratories.

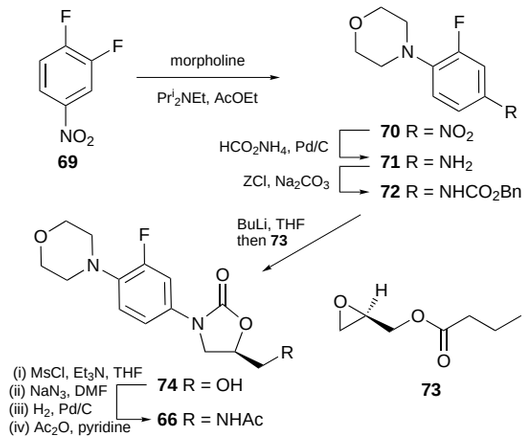


**63**

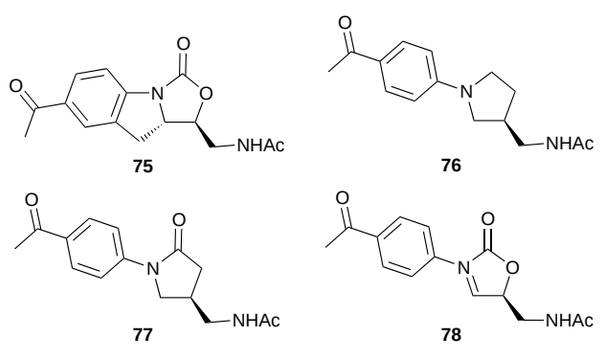
## Oxazolidinones

The last ten years have seen only one clinically significant novel class of antibiotics emerge from basic research, the oxazolidinones.[61] The pioneering work in this field was carried out at DuPont in the mid-1980s and culminated in the discovery of DUP 721 **64**. However, this molecule was found to exhibit

**64** **65**



**66** X = O
**67** X = S **68**



lethal toxicity in *in vivo* tests, and little further work was reported on this class until 1995, when Upjohn published a series of novel compounds. The toxicity problems encountered by DuPont and currently there are two oxazolidinones undergoing clinical trials, U-100592 **65** and U-100766 **66**.[62] Both compounds are active against Gram-positive bacteria, including resistant strains, and offer hope for the treatment of these extremely serious infections in the future. The oxazolidinones are believed to act by inhibiting an early step in bacterial protein synthesis. The versatile asymmetric synthesis of oxazolidinones, exemplified by U-100766 **66**, developed at Upjohn is shown in Scheme 7.

It has also been possible to extend the antibacterial spectrum of the class into mycobacterial species such as *M. tuberculosis* and *M. avium*, the latter being a life-threatening opportunistic infection of immunocompromised patients. Replacing the oxygen atom of the morpholine ring of U-100766 **66** with a sulfur atom gave the potent antimycobacterial oxazolidinone U100480 **67**. It is likely that the *in vivo* activity observed is due, at least in part, to its sulfoxide metabolite U-101603 **68**.

There have been other related but less well documented systems published in the last few years. While Upjohn has recently published *trans*-tricyclic systems such as **75**,[63] other groups have reported oxazolidinone ring-surrogate analogues. In one report, the inactive pyrrolidine **76** and pyrrolidinone **77** were contrasted with the active butenolide **78**.[64] This and related publications have prompted Brickner[62] to define a general structure–activity relationship, summarised in Fig. 3.

**Scheme 7**

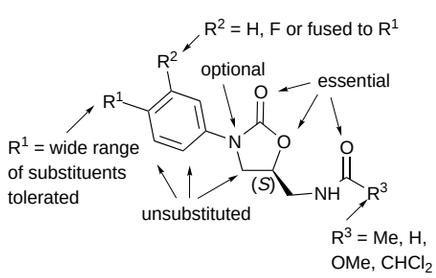
**75** **76**

**77** **78**

## The resurgence of tuberculosis

One of the reasons for the interest being shown in the oxazolidinones is their activity against mycobacterial species such as *M. tuberculosis.* Prior to the discovery of the aminoglycoside streptomycin **49** in 1944, there were no effective treatments for tuberculosis (TB). This breakthrough was the start of a new age of chemotherapy for what had been a major killer throughout the world. With the introduction of streptomycin and even more effective therapies, the incidence of tuberculosis, especially in the more developed countries, went into sharp decline, to the point that the disease was no longer perceived to be a serious threat to most people. In recent years, however, this complacent attitude to TB has been seriously challenged. In the majority of the developing countries the number of cases is increasing, and more people died of TB in 1995 than in any other year in history. Even in the industrialised states there is a growing anxiety at the number of new cases being reported. Currently more than one third of the world's population carries *M. tuberculosis*, and in developing countries the disease accounts for over 25% of all preventable deaths.

There are several reasons for this alarming situation. Poverty, resulting in overcrowding and poor hygiene, is undoubtedly a



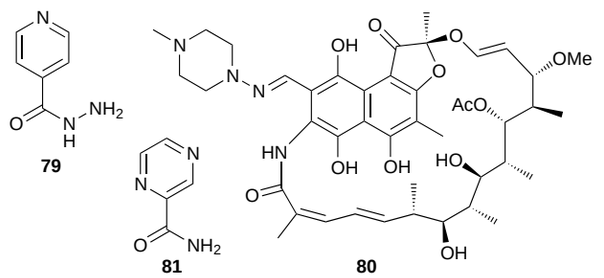


**Fig. 3** General structure–activity relationships

major factor in inner cities. The increase in the number of HIV seropositive people has also created a population less able to combat infection. In Asia, two-thirds of all TB cases are HIV-positive. A third reason is the increase in multidrug-resistant *M. tuberculosis* strains. A typical current therapeutic approach to TB may involve taking isoniazid **79**, rifampin **80** and pyrazinamide **81** for at least six months. As a result, non-

**79** **81** **80**

compliance, *i.e*. patients stopping therapy as soon as an improvement in the symptoms is felt, allows the remaining, more resistant bacteria to survive and spread.

Long-term benefits are unlikely to be gained by modifying existing antimycobacterial agents. The recent increase in research in this field will hopefully lead to the discovery of novel classes of compounds,[65] although the structures of these classes remain, as yet, unclear.

At present, studies are also being carried out to assess the efficacy of existing broad-spectrum antibacterials such as fluoroquinolones.[66] The possibility of using β-lactams in tuberculosis therapy has also been considered.[67] Although *M. tuberculosis* is naturally resistant to this class due to the production of intracellular β-lactamase, the use of elevated doses of newer, β-lactamase-stable agents such as carbapenems has been shown to work *in vitro*.

## Future approaches to antibacterial chemotherapy

The rapid emergence of multidrug resistant bacterial strains and the potential threat they pose to future generations means that the development of novel antibacterials is likely neither to be easy nor to offer a permanent solution to the problem.

Currently, there are two basic strategies for finding novel antibacterials. The first, which has been responsible for the discovery of most novel classes to date, is to screen natural product or corporate compound collections. This strategy provides a compound with demonstrable antibacterial activity, although it may take some time to discover the mode of action of the class, and working with a complex biological system such as a bacterial cell can make the generation of meaningful structure–activity relationships quite problematic, even before taking into account the inter-species diversity encountered.

The second strategy, which has become increasingly popular in recent years, is to identify the essential enzymes of the bacterial cell and to screen compounds as inhibitors of these systems. While this method allows a far greater control over the structure–activity relationship and in many cases facilitates the use of high-throughput screening technology, it involves taking at least one step back from the reality of bacterial infection in that it takes no account of how the compounds are able to permeate the bacterial cell to reach their target, or whether they are rapidly removed from the bacterial cell by efflux or enzymatic inactivation. At present, the number of targets is limited by our knowledge and understanding of gene and protein function. A significant improvement will be brought about by systematic elucidation of complete bacterial genomic sequences.[67] Genes and proteins found to be essential for bacterial cell survival are potential pharmaceutical targets.[68] Thus, using the current state-of-the-art technologies based around the high throughput screening of compound collections, high speed parallel synthesis and natural products will hopefully provide research groups with a number of novel lead classes for further optimisation. In some cases the further optimisation of the classes may be significantly helped by the availability of stuctural information on the target–inhibitor complexes provided by protein crystallography or high field protein NMR and mass spectroscopy.[69]

## Targeting bacterial virulence

An alternative approach currently being examined by several groups is that of modulating the virulence of bacteria.[70,71] For pathogenic bacteria to survive in the hostile environment of another organism they must first be able to attach themselves to host cells and then launch an assault whilst simultaneously debilitating the host immune system. To do this, bacteria produce products called virulence factors, which include attachment factors, toxins and lytic enzymes. Targeting these pathogenesis processes may give protection against a wide range of bacterial species, and result in an infection site-specific as opposed to microorganism specific therapy.

## Conclusions

Owing to the growing threat of infection due to multi-drug resistant bacteria we are already witnessing an increased effort not only aimed at finding more potent examples of existing agents but also, more encouragingly, a serious commitment to discover new classes of antibiotics. These new classes will hopefully evolve through the exploitation of the rapidly expanding number of known targets, the use of the latest techniques for combinatorial chemistry and high throughput screening, and by studying the processes used by the bacteria to establish infection.

## Acknowledgements

The authors thank Dr Daniele Donati, Dr Sergio Lociuro and Dr Tino Rossi for their support and suggestions, Dr Paul Wiedenau for proofreading and Dr Chiara Ghiron, both for discussions and help with the preparation of the manuscript.

**Daniela Niccolai was born in Sambuca Pistoiese in Italy in 1967, and received her Laurea in Industrial Chemistry from the University of Bologna in 1991. She studied for a further 18 months at the CNR institute in Bologna on antisense compounds, as antiviral and antitumour agents before joining GlaxoWellcome, Verona, where she has worked on both CNS and antibacterial projects in the Medicinal Chemistry Department.**

**Luca Tarsi was born in Cattolica in Italy in 1963, and received his Laurea in Chemistry, studying with Professor Diego Savoia in the University of Bologna. He joined Glaxo Wellcome, Verona, in 1993, where he has worked on antibacterial projects in the Medicinal Chemistry Department.**

**Russell J. Thomas was born in Swansea in 1966 and received his BSc from the University of Kent at Canterbury in 1987. Since completing his PhD at the University of Exeter with Professor Stanley M. Roberts he has worked in both the Medicinal Chemistry and Lead Discovery Departments of GlaxoWellcome, Verona. He is the co-author, with Chiara Ghiron, of *Exercises in Synthetic Organic Chemistry*, published in 1997 by Oxford University Press.**

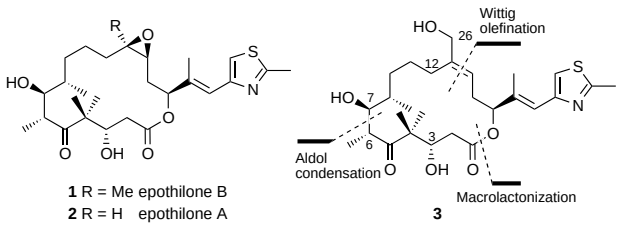
**A series of 26-substituted epothilones B (3, 22, 23a–n and 24a–h,j–l,o) have been constructed by total synthesis involving a selective Wittig olefination, an aldol reaction and a macrolactonization as key steps.**

The novel molecular structures and impressive antitumour properties of the epothilones[1] have captured the imagination of synthetic chemists, biologists[2,3] and clinicians. Isolated[1] from myxobacterium *Sorangium cellulosum*, these substances exhibit tubulin polymerization properties[2] similar to Taxol[4] and show potent cytotoxicity against Taxol-resistant tumour cells.[3] Research in this field has resulted in the total synthesis of the naturally occurring epothilones B **1**[5–7] and A **2**,[5,7–11] and a plethora of analogues.[5–17] Owing to the higher antitumour potency of the 12-methyl bearing epothilone B **2** as compared to epothilone A **1**, this substituent (the C26 methyl group) was considered a prime candidate for modification. An expedient entry into this series of compounds was sought. Here we report such a strategy which culminated in the total synthesis of 26-hydroxydesoxyepothilone B **3**, 26-hydroxyepothilone B **22** and a series of related analogues **23a**–**n** and **24a**–**h**,**j**–**l**,**o**.

The approach to the C26-modified epothilones B followed a similar path to that developed in these laboratories[5,7] for epothilone B **1**, and involved (i) stereoselective Wittig olefination, (ii) aldol condensation and (iii) macrolactonization (Fig. 1).

Protection of **4** (Scheme 1) as a trityl ($CPh_3$) ether furnished **5**† in 99%. Hydroboration of **5** led to **6** (94%), which was converted to **7** by the action of $PPh_3$, $I_2$ and imidazole (90%). Stereoselective alkylation of SAMP hydrazone **8**,[18] *via* its lithio derivative, with **7** led to **9**. The transformation of **9** to **10** proceeded under the influence of MMPP[7] (91%), and reduction of the latter with DIBAL-H provided aldehyde **11** (97%).



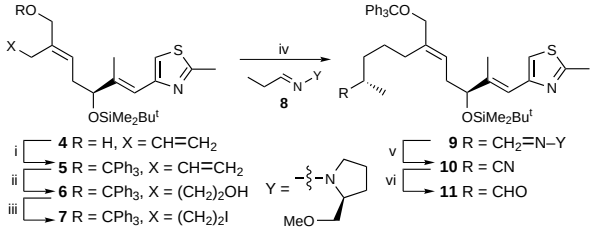


**Fig. 1** Structures of **1** and **2** and retrosynthetic analysis of **3**

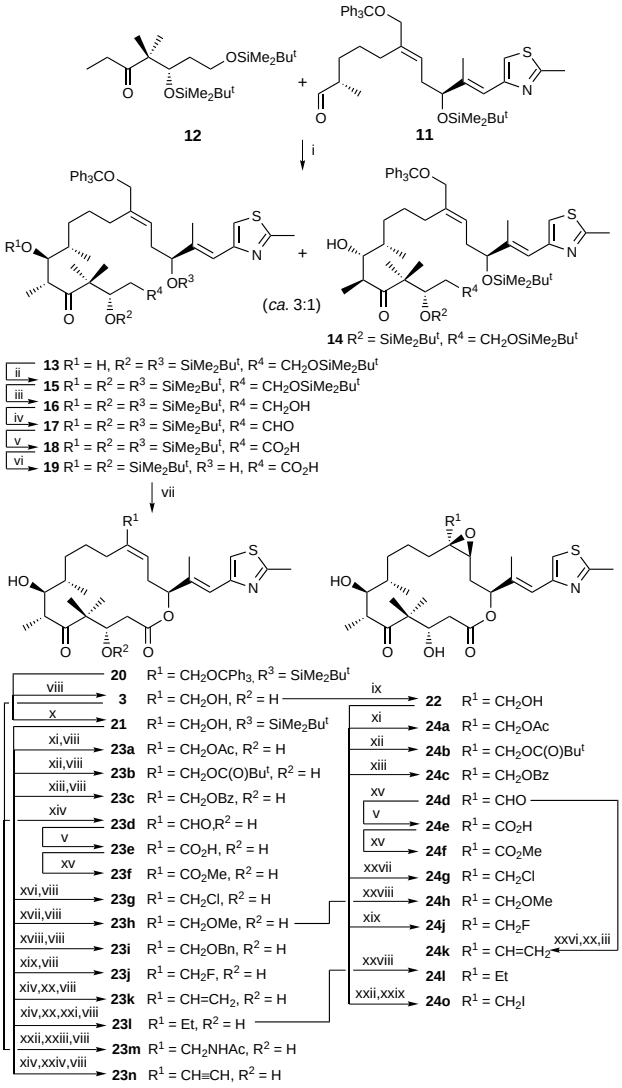
**Scheme 1** *Reagents and conditions*: i, $Ph_3CCl$, DMAP, DMF, 70 °C, 1 h; ii, 9-borabicyclo[3.3.1]nonane, THF, 0 °C, 2 h, then aq. NaOH (3 M), then 30% $H_2O_2$; iii, $I_2$, imidazole, $PPh_3$, $Et_2O$–MeCN (3 : 1), 0 °C, 0.5 h; iv, **8**, LDA, THF, 0 °C, 14 h, then **7**, THF, −100 → −20 °C, 10 h; v, monoperoxyphthalic acid (Mg salt) (MMPP), MeOH–phosphate buffer (pH 7) (1 : 1), 0 °C, 1 h; vi, DIBAL-H, toluene, −78 °C, 1 h



The coupling of the C1–C6 ketone fragment **12**[7,15] with **11** *via* a *syn*-selective aldol reaction (Scheme 2) furnished **13** along with its (6*S*,7*R*) diastereoisomer **14** (85% total yield, *ca.* 3 : 1). Chromatographic purification followed by silylation gave **15**. The use of buffered HF·pyridine in THF permitted selective desilylation of **15** giving **16** (74%), which was sequentially oxidized to **17**, and thence to carboxylic acid **18**. Selective desilylation at C15 was achieved by the use of $Bu_4NF$ in THF, providing **19** (89%). The latter compound was in turn subjected to the Yamaguchi macrolactonization forming **20** (75%). Exposure of **20** to HF·pyridine in THF promoted concomitant removal of both the silyl groups and the trityl moiety, leading to **3** (78%). Alternatively, treatment of **20** with camphorsulfonic acid in MeOH–$CH_2Cl_2$ resulted in the selective removal of the trityl group, giving **21** (70%). Sharpless asymmetric epoxidation of **3** then gave 26-hydroxyepothilone B **22** (76%).

The availability of **3**, **21** and **22** facilitated access to a number of 26-substituted epothilones. As indicated in Scheme 3, **21** was converted to **23a**–**c** by reaction with the corresponding acid anhydride or chloride under basic conditions followed by desilylation. $MnO_2$ oxidation of **3** proved highly efficient, providing α,β-unsaturated aldehyde **23d** (85%). Further oxidation of **23d** with $NaClO_2$ led to carboxylic acid **23e** (98%), which was converted to **23f** by treatment with $CH_2N_2$ (80%). Methylation and benzylation of **21** followed by desilylation afforded **23h** (58% overall) and **23i** (35% overall), respectively. Halogenation of **21** followed by desilylation led to chloride **23g** (73% overall) or fluoride **23j** (51% overall). Alternatively, treatment of **21** with $MnO_2$ and reaction of the resulting aldehyde with the anion derived from $Me_3SiCHN_2$ followed by

[a] Assays performed as in ref. 4. [b] Inhibition of human ovarian carcinoma cell growth. Assays performed as in ref. 7. Each $IC_{50}$ value shown is an average value obtained from three independent assays.

**Scheme 2** *Reagents and conditions*: i, LDA, THF, 0 °C, 15 min, then **12**, THF, −78 → −60 °C, 1 h, then **11**, THF, −78 °C; ii, $Bu^tMe_2SiOSO_2CF_3$, 2,6-lutidine, $CH_2Cl_2$, 0 °C, 2 h; iii, HF·pyridine, pyridine, THF, 0 → 25 °C, 4 h; iv, $(COCl)_2$, DMSO, $Et_3N$, $CH_2Cl_2$, −78 → 0 °C, 1.5 h; v, $NaClO_2$, $Me_2C$=CHMe, $NaH_2PO_4$, $Bu^tOH$–$H_2O$ (5 : 1), 25 °C, 2 h; vi, $Bu_4NF$, THF, 25 °C, 8 h; vii, 2,4,6-$Cl_3C_6H_2COCl$, $Et_3N$, THF, 0 °C, 1 h, then add to DMAP in toluene, 75 °C, 1 h; viii, 30% HF·pyridine (v/v), THF, 0 → 25 °C, 24 h; ix, (+)-diethyl L-tartrate, $Ti(OPr^i)_4$, $Bu^tOOH$, −30 °C, 2 h; x, camphorosulfonic acid, MeOH–$CH_2Cl_2$ (1 : 1), 0 → 25 °C, 3 h; xi, $Ac_2O$, DMAP, EtOAc, 0 °C, 0.5 h; xii, $Bu^tCOCl$, $Et_3N$, DMAP, $CH_2Cl_2$, 0 °C, 0.5 h; xiii, BzCl, $Et_3N$, DMAP, $CH_2Cl_2$, 0 °C, 0.5 h; xiv, $MnO_2$, $Et_2O$, 25 °C, 3 h; xv, $CH_2N_2$, $Et_2O$, 0 °C; xvi, $PPh_3$, $CCl_4$, 75 °C, 24 h; xvii, NaH, MeI, DMF, 0 °C, 1 h; xviii, NaH, BnBr, DMF, 0 → 25 °C, 1 h; xix, DAST, $CH_2Cl_2$, −78 → 25 °C, 1 h; xx, $Ph_3P^+CH_3Br^-$, $(Me_3Si)_2NLi$, THF, 0 °C; xxi, $H_2$, Lindlar catalyst, EtOAc, room temp., 15 min.; xxii, TsCl, $Et_3N$, DMAP, $CH_2Cl_2$, 0 °C, 1 h; xxiii, $NaN_3$, DMF, 25 °C, 10 h, then $PPh_3$, THF, 60 °C, 8 h, then $Ac_2O$, $CH_2Cl_2$, 10 min; xxiv, $Me_3SiCHN_2$, then $Bu^nLi$, THF, −78 → 0 °C, 1 h; xxv, TEMPO (0.008 M, $CH_2Cl_2$), NaOCl (0.035 M, 5% aq. $NaHCO_3$), aq. KBr (0.2 M), $CH_2Cl_2$, 0 °C, 0.5 h; xxvi, $Me_3SiCl$, $Et_3N$, $CH_2Cl_2$, 0 → 25 °C, 10 h; xxvii, $PPh_3$, MeCN–$CCl_4$ (1 : 3), 25 °C, 1 h; xxviii, methyl(trifluoromethyl)dioxirane, MeCN, 0 °C; xxix, NaI, acetone, 25 °C, 10 h

the usual desilylation conditions gave **23n** (68%). The aldehyde obtained from $MnO_2$ oxidation of **21** (90%) was also subjected to Wittig methylenation (85%) furnishing, after desilylation, alkene **23k** (85%). A similar sequence of reactions with this aldehyde (Wittig methylation and hydrogenation followed by desilylation) provided **23l**. Conversion of **3** to the corresponding tosylate, followed by displacement with $NaN_3$ in DMF and reduction with $PPh_3$, furnished the required primary amine. The latter was then exposed to $Ac_2O$ in $CH_2Cl_2$ providing the corresponding acetamide **23m** (39%, 4 steps). Similar chemistry was employed for the preparation of epothilones **24a–c, e–h** (Scheme 2). Compound **24d** was synthesized by selective oxidation of **22** with TEMPO–bleach (90%), and subsequent hydroxy protection, Wittig methylenation and deprotection allowed access to **24k** (49%, 3 steps). Iodide **24o** was prepared by selective tosylation of the primary hydroxy moiety of **22** and subsequent displacement with NaI (72%). Alternatively, treatment of **22** with DAST furnished fluoride **24j**. Reaction of **23h** and **23l** with methyl(trifluoromethyl)dioxirane provided, respectively, the epoxy methyl ether **24h** (20%) and the ethyl analogue **24l** (55%).

Table 1 shows the tubulin binding[5] and cytotoxicity properties of a selected number of the synthesized epothilones.

We thank Dr E. Hamel for a gift of purified tubulin and Dr P. Giannakakou for the cell lines. This work was supported by Novartis, the NIH, The Skaggs Institute for Chemical Biology, the CaP CURE Foundation, and the Fulbright Commission (M. R. V. F.).

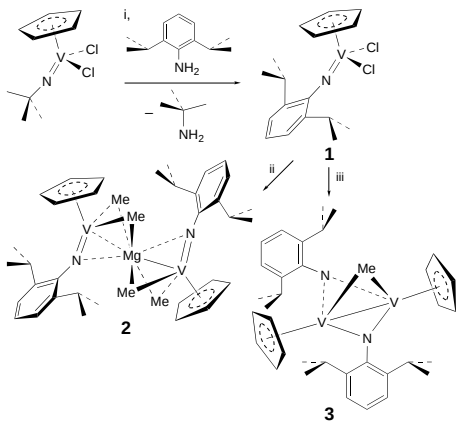
# Novel μ-methyl complexes of vanadium and their relevance to bimolecular deactivation of homogeneous imidovanadium polymerisation catalysts



**Michael C. W. Chan,[a] Jacqueline M. Cole,[b] Vernon C. Gibson*[a] and Judith A. K. Howard[b]**

[a] *Department of Chemistry, Imperial College, South Kensington, London, UK SW7 2AY*
[b] *Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE*

**Attempted dimethylation of [CpV(NC$_6$H$_3$Pr$^i_2$-2,6)]Cl$_2$ using Grignard reagents affords novel μ-methyl complexes arising by reductive dimerisation; the structure of one of these products, [CpV(NC$_6$H$_3$Pr$^i_2$-2,6)(μ-Me)$_2$]$_2$(μ-Mg) 2, reveals V–(μ-Me)–Mg, V–Mg, N–Mg and C–H···Mg interactions.**

There is presently much interest in the development of new-generation 'non-metallocene' catalysts for the polymerisation of α-alkenes. These include, for example, alkoxide,[1] thiolate,[2] amide,[3] imide,[4] tetradentate Schiff-base[5] and macrocyclic procatalysts.[6] In recent work we have been investigating the isolobal relationship between group 4 metallocenes and group 5 half-sandwich imido species[7] and have found that vanadium complexes of the type [CpV(NR)Cl$_2$] are particularly active amongst these group 5 metal pro-catalysts.[4a] Typically, they give high initial polymerisation activities but die over the course of a few minutes, a kinetic profile that is not uncommon in many homogeneous Ziegler-type polymerisation systems. In order to gain more insight into the deactivation process and to be able to control this behaviour, we set out to synthesise well defined cationic alkyl versions of these catalysts. Methyl derivatives were targeted since such species have proved to be suitable precursors in metallocene systems.[8] Here, we describe two highly unusual products arising from reactions of [CpV(NAr)Cl$_2$] (Ar = C$_6$H$_3$Me$_2$-2,6) **1** with methylmagnesium halides under differing conditions of solvent and Grignard reagent. The products are structurally exceptional and provide insight into the bimolecular deactivation process occurring in [CpV(NR)] polymerisation systems.†

The synthesis of the starting complex **1** has been described previously by Teuben and coworkers.[9] During the course of our studies, we have found that **1** and related imido complexes can also be prepared by an imido exchange route according to Scheme 1, a methodology that appears to be quite general.[10] Thus treatment of [CpV(NBu$^t$)Cl$_2$] with 2,6-diisopropylaniline in hot 1,2-dichloroethane affords [CpV(NAr)Cl$_2$] **1** in high yield.

**Scheme 1** *Reagents and conditions*: i, (CH$_2$Cl)$_2$, 75 °C, 10 d; ii, 2.5 MeMgBr, Et$_2$O, 12 h; iii, 3 MeMgCl in thf–Et$_2$O, 12 h

The paramagnetic magnesium-containing divanadium complex **2** was isolated from the reaction of **1** with excess MeMgBr in diethyl ether (Scheme 1). The molecular structure is shown in Fig. 1.‡ Complex **2** crystallises as a trimetallic V$_2$Mg cluster in the centrosymmetric space group $P2_1/c$, with the magnesium atom located at the centre of inversion. The structure consists of two methyl groups bridging between the vanadium atom of the [CpV(NAr)] fragment and the magnesium core. The V–Mg distance of 2.594(1) Å is similar to other proposed metal–Mg bonds[11,12] and therefore may be viewed as a direct V–Mg interaction. The N–Mg distance of 2.366(6) Å is within the range for a genuine bonding interaction,[13] although the V–N distance of 1.724(6) Å (1.60–1.68 Å in terminal imides,[14] 1.84–1.85 Å in bridging imides[3a,8,15]) and the V–N–C$_{ipso}$ angle of 160.6(5)° suggest that this interaction is weak and that the imido unit behaves more as a terminal ligand to the vanadium centre than a bridging group between V and Mg. The carbon atoms of the bridging methyl groups are located slightly closer to the vanadium [V–C$_{methyl}$ 2.200(7), 2.227(7) Å; Mg–C$_{methyl}$ 2.382(7), 2.408(7) Å] and the V–C$_{methyl}$ distances are longer than those reported for vanadium complexes with terminal alkyl groups (2.04–2.08 Å).[3,4,8,16] The two V–C$_{methyl}$–Mg angles are identical [68.4(2)°] and are typical for methyl groups bridging two metals.[11,16] The two highly distorted V–C–H angles (55, 77°) and the particularly short Mg–H separations (2.04, 2.35 Å) for H(18c) and H(19b) respectively,‡ indicate the presence of C–H···Mg agostic interactions [Fig. 1(*b*)]. The presence of the

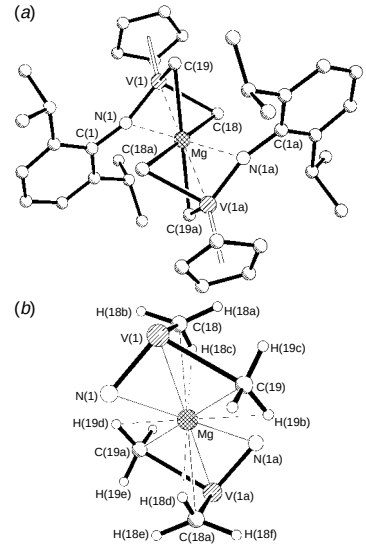


**Fig. 1** (*a*) The molecular structure of **2** with key atoms labelled. H atoms are omitted for clarity. Selected dimensions (Å and °): V(1)–N(1) 1.724(6), V(1)–C(18) 2.200(7), V(1)–C(19) 2.227(7), V(1)–Mg 2.594(1), Mg–N(1) 2.366(6), Mg–C(18) 2.408(7), Mg–C(19) 2.382(7); N(1)–V–C(18) 100.5, N(1)–V–C(19) 101.3(3), C(18)–V–V(19) 91.0(3), N(1)–V–Mg 62.7(2), C(18)–V–Mg 59.6(2), C(19)–V–Mg 58.6(2), V(1)–N(1)–C(1) 160.6(5), V(1)–C(18)–Mg 68.4(2), V(1)–C(19)–Mg 68.4(2); (*b*) view of the magnesium core showing the agostic C–H···Mg interactions.

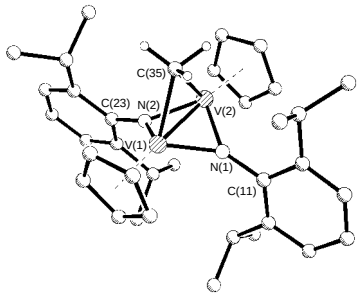

**Fig. 2** The molecular structure of **3** with key atoms labelled. H atoms are omitted for clarity. Selected dimensions (Å and °): V(1)–N(1) 1.867(3), V(1)–N(2) 1.882(3), V(2)–N(1) 1.896(3), V(2)–N(2) 1.894(3), V(1)–C(35) 2.215(4), V(2)–C(35) 2.310(4), V(1)–V(2) 2.324(1); V(1)–C(35)–V(2) 61.8(1), V(1)–N(1)–V(2) 76.3(1), V(1)–N(2)–V(2) 76.9(1), V(1)–N(1)–C(11) 143.8(2), V(2)–N(1)–C(11) 139.9(2), V(1)–N(2)–C(23) 142.4(2), V(2)–N(2)–C(23) 141.6(2).

magnesium core with its attendant weak ligand interactions (bonding distances 2.366–2.594 Å) appears to lend significant stability to this unusual product.

By contrast, in the presence of diethyl ether and tetrahydrofuran, **1** reacts with an excess of MeMgCl to afford the paramagnetic mono μ-methyl complex **3** (Scheme 1, Fig. 2). The crystal structure of **3**‡ consists of a single methyl and two arylimido groups bridging between two [CpV] units. The distances V(1)–C(35) [2.310(4) Å], V(2)–C(35) [2.215(4) Å] and the V(1)–C(35)–V(2) angle [61.8(1)°] are comparable with **2**. In this case, however, there are no close interactions of the bridging methyl C–H bonds with the adjacent metal centres. The V–N distances [av. 1.885(4) Å] are longer than for **2** owing to the decreased bond order resulting from the fact that the imido substituents are bridging. The V(1)–V(2) distance of 2.324(1) Å is within the range for a bonding interaction,[17] and the V–Cp(centroid) vectors are almost coaxial with the V–V bond. Finally, the bridging methyl and imides are arranged around the V–V axis such that C(35), N(1) and N(2) are approximately 120° to each other. We note that Teuben and coworkers have reported a related tolylimido complex, [CpV(μ-$NC_6H_4Me$-*p*)Me]$_2$, which contains bridging imido ligands and terminal methyl groups.[18]

Since dialkylation of a dihalide precursor is the prevalent route to a well defined cationic alkyl catalyst species, these observations provide an explanation for the rapid deactivation of [CpV(NR)] procatalysts and are likely to be of general relevance to other rapidly deactivating catalyst systems.

The EPSRC and the ILL are thanked for studentships to M. C. W. C. and J. M. C. respectively and BP Chemicals Ltd. is thanked for a CASE studnetship (to M. C. W. C.).

† Satisfactory elemental analyses have been obtained.

‡ *Crystal data*: **2**: $C_{19}H_{28}Mg_{0.5}NV$, $M_r$ = 333.52, orange-red irregular plate-shaped crystal (0.40 × 0.36 × 0.15 mm), monoclinic, space group, $P2_1/c$, $a$ = 10.220(2), $b$ = 9.909(2), $c$ = 18.658(3) Å, $\beta$ = 104.94(1)°, $U$ = 1825.6(6) Å$^3$, $Z$ = 4, $T$ = 150(2) K, $D_c$ = 1.213 g cm$^{-3}$, $F$(000) = 712, $\mu$ = 0.556 mm$^{-1}$. 2184 unique reflections ($2\theta$ < 45°) were measured on a Siemens P4 diffractometer with graphite monochromated Mo-Kα X-radiation ($\lambda$ = 0.710 73 Å); no absorption correction was made. Structure solved (by Patterson methods) and refined using SHELXL-93. 2179 reflections were used in the full-matrix least-squares refinement. Refinement of positional parameters for all non-H atoms and anisotropic thermal parameters for V (91 parameters) converged to $R_1[I > 2\sigma(I)]$ = 0.0602 and $wR_2[I > 2\sigma(I)]$ = 0.0912 [$w = 1/(\sigma^2F_0^2 + 0.0003P^2)$ where $P = (F_o^2 + 2F_c^2)/3$] with $S$ = 0.729. All bridging H atoms were found in the difference map but not refined. **3**: $C_{35}H_{47}N_2V_2{\cdot}0.5C_6H_{12}$, $M_r$ = 597.63, deep red diamond-shaped crystal (0.80 × 0.62 × 0.40 mm), monoclinic, space group, $P2_1/n$, $a$ = 9.924(2), $b$ = 21.653(4), $c$ = 16.235(3) Å, $\beta$ = 98.73°, $U$ = 3448(1) Å$^3$, $Z$ = 4, $T$ = 150(2) K, $D_c$ = 1.151 g cm$^{-3}$, $F$(000) = 1268, $\mu$ = 0.565 mm$^{-1}$. 4865 unique reflections ($2\theta$ < 46.5°) were measured on a Siemens SMART-CCD diffractometer with graphite monochromated Mo-Kα X-radiation ($\lambda$ = 0.710 73 Å); no absorption correction was made. Structure solved (by direct methods) and refined using SHELXL-93. 4857 reflections were used in the full-matrix least-squares refinement. Refinement of positional and anisotropic thermal parameters for all non-H atoms (364 parameters) converged to $R_1[I > 2\sigma(I)]$ = 0.0531 and $wR_2[I > 2\sigma(I)]$ = 0.1476 [$w = 1/(\sigma^2F_o^2 + 0.0650P^2 + 5.1588P)$] with $S$ = 1.208. Hexane solvent H atoms were not modelled. CCDC 182/609.

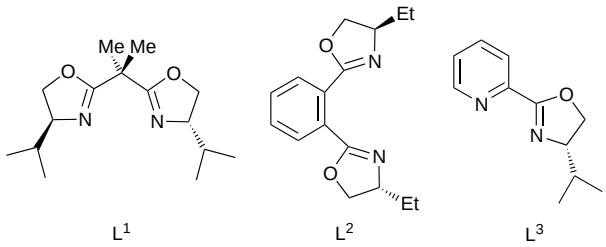
# Synthesis of chiral half-sandwich rhodium oxazoline complexes and their use as asymmetric Diels–Alder catalysts



**Adam J. Davenport, David L. Davies,* John Fawcett, Shaun A. Garratt, Latesh Lad and David R. Russell**

*Department of Chemistry, University of Leicester, Leicester, UK LE1 7RH*

**The reaction of $[(\eta\text{-}C_5Me_5)RhCl_2]_2$ with bidentate oxazoline containing ligands provides the cations $[(\eta\text{-}C_5Me_5)RhClL]^+$ 1–3, of which {1, L = 2,2′-isopropylidenebis[4-isopropyl-2-oxazoline] and 3, L = 4-isopropyl-2-(2-pyridyl)-1,3-oxazoline} are structurally characterised by X-ray diffraction; treatment of these with $AgSbF_6$ gives dications which are enantioselective catalysts for the asymmetric Diels–Alder reaction between methacrolein and cyclopentadiene.**

Half-sandwich complexes have been extensively used in stoichiometric and catalytic asymmetric synthesis and have therefore attracted much study.[1] Such complexes can be chiral at the ligand and/or the metal. To date much transition metal catalysed asymmetric synthesis has utilised phosphines as chiral ligands, however recently, N-donor ligands have attracted more attention.[2] Oxazolines, in particular, have found extensive use in asymmetric catalysis.[3] For example, bis-oxazolinylpropanes (*cf*. $L^1$) provide high enantioselectivity in copper catalysed cyclopropanation, aziridination and Diels–Alder reactions[4] whilst pyridyloxazolines (*cf*. $L^3$) have been used in rhodium catalysed asymmetric hydrosilylation of ketones.[5] However, the use of oxazoline ligands with half-sandwich complexes is much less well studied, being limited to two reports of arene ruthenium complexes.[6,7]

The complexes $[(\eta\text{-}C_5Me_5)RhClL]X$ (X = $PF_6$, $SbF_6$) (**1**–**3**; $L^{1–3}$) were prepared in good yield by refluxing the appropriate

ligand with $[(\eta\text{-}C_5Me_5)RhCl_2]_2$ in methanol in the presence of NaX.† In the case of the $C_2$ symmetric ligands $L^1$ and $L^2$, coordination of the ligands is readily apparent in the $^1H$ NMR spectrum since the $C_2$ symmetry is lost and only one isomer is possible. For complex **3** containing the unsymmetrical ligand $L^3$ two diastereomers are possible, however complexation is highly diastereostereoselective, only one diastereomer being observed by $^1H$ NMR.

The X-ray structures of **1** and **3** were carried out and the structures of the cations with selected bond distances and angles are shown in Figs. 1 and 2 respectively.‡ In each case the rhodium has a pseudo-octahedral geometry with the $\eta\text{-}C_5Me_5$ occupying three *fac* coordination sites. In **1** the Rh–N(1) bond length 2.117(6) Å is slightly shorter than the Rh–N(2) length 2.157(6) Å; possibly the isopropyl on C(12) interacts with the $\eta\text{-}C_5Me_5$ inhibiting a closer approach of N(2). The N(1)–Rh–N(2) chelate bite angle is 84.0(2)°. In **3** the ligand is coordinated such that the isopropyl substituent is on the same side as the chloride rather than the $\eta\text{-}C_5Me_5$ presumably to miminise unfavourable steric interactions. The Rh–N(1) (ox) bond length 2.109(4) is shorter than that of Rh–N(2) (py) 2.142(4) Å, whilst the chelate bite angle N(1)–Rh–N(2) is 76.0(2)° as found for a related arene ruthenium complex with the same ligand.[6] The use of L-valine in the ligand preparation means that the configuration at the chiral carbon is *S* and the structure shows that the rhodium is also *S* [based on the priority

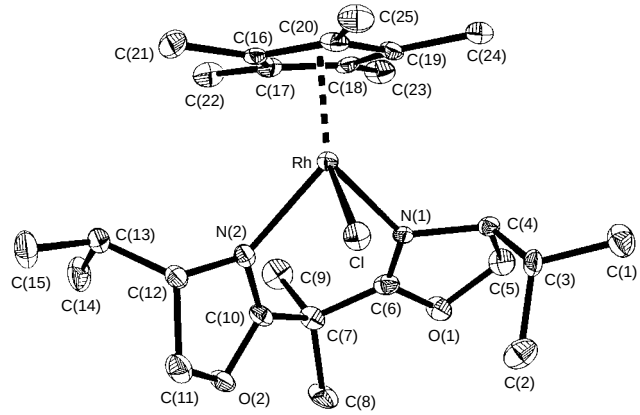


**Fig. 1** Molecular structure and atom numbering scheme for the cation of **1**. Selected bond distances (Å) and angles (°): Rh–N(1) 2.117(6), Rh–N(2) 2.157(6), Rh–Cl 2.406(2), N(2)–Ru–N(1) 84.0(2), N(1)–Rh–Cl 90.2(2), N(2)–Rh–Cl 82.1(2).

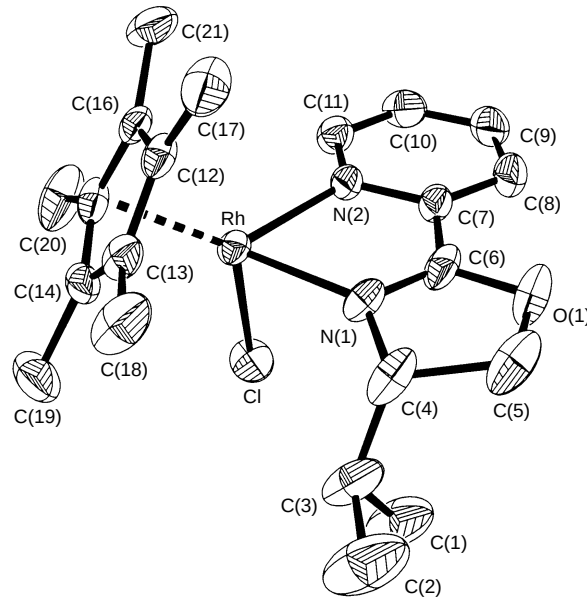

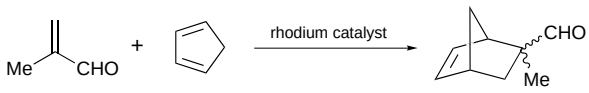

**Fig. 2** Molecular structure and atom numbering scheme for the cation of **3**. Selected bond distances (Å) and angles (°): Rh–N(1) 2.109(4), Rh–N(2) 2.142(4), Rh–Cl 2.407(1), N(2)–C(7) 1.345(6), C(7)–C(6) 1.456(8), C(6)–N(1) 1.260(6); N(2)–Rh–N(1) 76.0(2).

**Table 1** Enantioselective Diels–Alder reaction of methacrolein with cyclopentadiene in dichloromethane using catalysts prepared from $[(\eta\text{-}C_5Me_5)RhCl(L)]^+$

| Entry | Catalyst (mol%) | *T*/°C | *t*/h | Yield (%) | Isomer ratio (*exo*:*endo*) | Ee[a] (%) |
|---|---|---|---|---|---|---|
| 1 | **1**(5) | room temp. | 24 | 62 | 94:6 | 29 |
| 2 | **2**(5) | room temp. | 48 | 10 | 90:10 | 2 |
| 3 | **3**(1) | room temp. | 24 | 45 | 94:6 | 52 |
| 4 | **3**(2) | room temp. | 24 | 57 | 94:6 | 53 |
| 5 | **3**(2) | 0 | 72 | 81 | 95:5 | 68 |

[a] Enantiomeric excess of the major *exo* product.

arene > Cl > N (ox) > N (py)].[8] The observation of an NOE effect between the NCH and $\eta\text{-}C_5Me_5$ suggests that this geometry is retained in solution.

Asymmetric catalysis of Diels–Alder reactions mostly with Ti, Al, B or Ln complexes has been reported previously.[9] However, such catalysts are often extremely sensitive to water and may form dimers or oligomers in solution. As a result, characterisation of the actual catalytic species and understanding the mechanism of catalysis and selectivity are particularly difficult. Many of these drawbacks may be overcome with half-sandwich late transition metal Lewis acids. For example, cyclopentadienyl–rhodium[10] and –iron[11] complexes with chiral phosphorus ligands are catalysts for asymmetric Diels–Alder reactions and a related ruthenium complex is a catalyst for the hetero Diels–Alder reaction.[12]

The chloride in **1**–**3** is readily removed with $AgSbF_6$ to form dications. Solutions of these dications in $CH_2Cl_2$ have been tested as catalysts for the Diels–Alder reaction between methacrolein and cyclopentadiene and the results are shown in Table 1.§ The dication derived from **1** is a reasonable catalyst but gives only modest enantioselectivity (Entry 1) whilst that from **2** shows little or no activity and no enantioselectivity (Entry 2). However, the dication from **3** is a reasonable catalyst even at fairly low catalyst ratio (1 mol%) showing good *exo*:*endo* selectivity with moderate enantioselectivity (Entry 3). Increasing the catalyst ratio gives an increased yield but no increase in ee (Entry 4). However, carrying out the reaction at lower temperature leads to an increase in ee (Entry 5). The absolute configuration of the major *exo* product using **3** as catalyst is consistent with the isopropyl shielding the *Si* face of the coordinated methacrolein leading to attack of cyclopentadiene at the *Re* face as shown in Fig. 3. Coordination of the methacrolein with *Si* face exposed is disfavoured due to steric interactions of the alkene with the $\eta\text{-}C_5Me_5$. The reasons for the difference in catalytic activity of complexes **1**–**3** are not yet clear, though similar reactivity patterns are observed for related arene ruthenium complexes with the same ligands.[6,13]

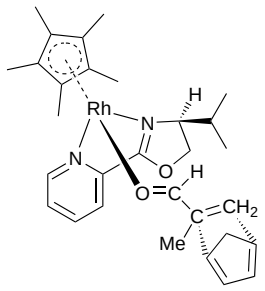

**Fig. 3** Model of the transition state

We thank the University of Leicester for a studentship (SAG) and Johnson Matthey for a loan of $RhCl_3$.

† *Selected spectroscopic data* for **2**: $^1$H NMR (250 MHz, $CDCl_3$, 20 °C, $SiMe_4$). $\delta$ 0.77 (t, 3 H, *J* 7 Hz, $CH_2$*Me*), 0.96 (t, 3 H, *J* 7 Hz, $CH_2$*Me*), 1.29 (s, 15 H, $C_5Me_5$), 1.60 (m, 2H, C*H*$_2$Me), 1.95 (m, 1 H, C*H*H′Me), 2.30 (m, 1 H, CHH′Me), 4.12 (tt, 1 H, *J* 5, 8.5 Hz, NCH), 4.6 (m, 5 H, 3 ×OCH + 2 × NCH), 7.84 (m, 2 H, aryl), 8.04 (m, 1 H, aryl), 8.16 (m, 1 H, aryl). Satisfactory elemental analysis (C, H, N) obtained for **1**–**3**.

‡ *Crystal data*: for **1**: $C_{25}H_{41}ClF_6N_2O_2RhSb$, $M$ = 775.71, orthorhombic, space group $P2_12_12_1$, $a$ = 13.335(2), $b$ = 13.496(2), $c$ = 17.740(3) Å, $U$ = 3192.7(9) Å$^3$, $Z$ = 4, $D_c$ = 1.614 g cm$^{-3}$, $\mu$ = 1.505 mm$^{-1}$, $F$(000) = 1552, graphite-monochromated Mo-K$\alpha$ radiation ($\lambda$ = 0.710 73 Å). Data collected on a Siemens P4 diffractometer at 190 K. 4829 reflections collected with 2.75 < $\theta$ < 26.99°, 4619 unique ($R_{int}$ = 0.0173). A $\psi$-scan absorption correction was applied. The structure was solved by Patterson methods and refined using full-matrix least squares on $F^2$ (SHELXL96).[14] Anisotropic displacement parameters used for all non-hydrogen atoms, hydrogens included in calculated positions (C–H 0.96 Å), with isotropic displacement parameters set to 1.2 $U_{eq}$(C). The $SbF_6^-$ anion was found to be disordered, this was modelled with each fluorine atom given equal site occupancy between two different sites. Final $R_1$ = 0.0743, $wR_2$ = 0.0784 (all data); Flack parameter, −0.06(3).

For **3**: $C_{21}H_{29}ClF_6N_2OPRh$, $M$ = 608.79, tetragonal, space group $P4_32_12$, $a$ = 12.844(5), $c$ = 30.542(13) Å, $U$ = 5038(3) Å$^3$, $Z$ = 8, $D_c$ = 1.605 g cm$^{-3}$, $\mu$ = 0.908 mm$^{-1}$, $F$(000) = 2464, graphite-monochromated Mo-K$\alpha$ radiation ($\lambda$ = 0.710 73 Å). Data collected as above. 7418 Reflections collected with 2.55 < $\theta$ < 27.09°, 5507 unique ($R_{int}$ = 0.0256). The structure was solved by Patterson methods and refined using full-matrix least squares on $F^2$ (SHELXL96).[14] One of the two anions (on special positions) exhibits positional disorder and the F atoms were each assigned fractional occupancy factors. All non-hydrogen atoms were refined anisotropically, hydrogen atoms were generated in their idealised positions (C–H 0.96 Å) and allowed to ride on their respective parent carbon atoms with isotropic displacement parameters set to 1.2 $U_{eq}$(C). Final $R_1$ = 0.0731, $wR_2$ = 0.0801 (all data); Flack parameter, −0.03(4). CCDC 182/648.

§ The catalysis was carried out as described in ref. 6.

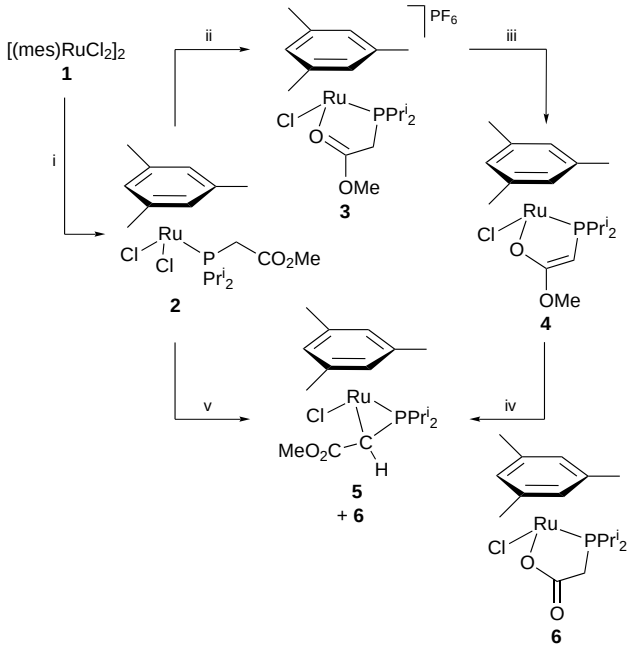
# Phosphinomethanide *versus* phosphinoenolate: thermodynamical preference for a three- instead of a five-membered chelate ring

**Gerhard Henig, Michael Schulz and Helmut Werner***

*Institut für Anorganische Chemie der Universität Würzburg, Am Hubland, D-97074 Würzburg, Germany*

**The phosphinoenolate complex 4, which is prepared stepwise from $[(mes)RuCl_2]_2$ 1 *via* the neutral and cationic compounds 2 and 3 as isolated intermediates, rearranges slowly in benzene to the thermodynamically more stable phosphinomethanide isomer 5; the presence of a three-membered RuCP ring in the latter is confirmed by X-ray crystallography.**



Following the development of the Shell Higher Olefin Process (SHOP),[1] the chemistry of phosphinoenolate metal complexes has become a focus of general interest.[2] While it has been shown by numerous examples that both β-phosphinoketones and β-phosphinoesters are easily converted to ligands of general composition $R_2PCH{=}C(R)O^-$ in the coordination sphere of transition metals,[3] we discovered more recently that from functional phosphines such as $Pr^i_2PCH_2CO_2R$ (R = Me, Et) phosphinomethanide units $Pr^i_2PCHCO_2R^-$ can also be generated.[4] However, it was not known which of the isomeric forms $Pr^i_2PCH{=}C(OR)O^-$ and $Pr^i_2PCHCO_2R^-$, the first forming a five-membered and the second a three-membered chelate ring, is more stable in a particular metal–ligand environment and whether the two types of ligands can be transformed into each other.

The half-sandwich-type complex **2**, which by analogy to previous work[5] was prepared from **1** and $Pr^i_2PCH_2CO_2Me$, reacts with an equimolar amount of $AgPF_6$ in $CH_2Cl_2$ to give the chelate compound **3** (Scheme 1) in almost quantitative yield.† The IR spectrum of the orange–red, nearly air-stable solid displays a C=O stretching frequency at 1618 $cm^{-1}$ (in $CH_2Cl_2$), which is lower by about 110 $cm^{-1}$ if compared with the frequency of $Pr^i_2PCH_2CO_2Me$.[6] This supports the assumption that the functional phosphine is coordinated *via* phosphorus and oxygen to the metal.

Treatment of the $PF_6^-$ salt **3** with $KOBu^t$ in THF led to a rapid change of colour from deep red to bright red and gave, after recrystallization from $CH_2Cl_2$–hexane (1 : 3), the phosphinoenolate complex **4** in 78% yield. The most characteristic features of the NMR spectroscopic data of **4** are the signal at $\delta$ 3.19 [*J*(PH) 3.7 Hz] for the vinylic proton and the two resonances at $\delta$ 180.5 ($CO_2$) and 44.5 (=CH) for the carbon atoms of the chelate ring, which display a strong P–C coupling of 28.6 and 70.6 Hz, respectively.

While phosphinoenolate complexes, such as those used for the oligomerization and polymerization of alkenes,[1,7] seem to be quite stable, compound **4** is thermally labile and slowly rearranges in benzene at room temp. to isomer **5**. After 3 d the reaction is complete. There is, to the best of our knowledge, no precedence for this type of isomerisation process which is probably driven by the conversion of the C=C double into a C–C single bond and the re-formation of the intact $CO_2Me$ unit. The IR spectrum of **5** (in KBr) displays a C=O stretch at 1661 $cm^{-1}$, the $^1H$ NMR spectrum a doublet at $\delta$ 2.71 [*J*(PH) 3.1 Hz] for the C*H*$CO_2Me$ proton and the $^{13}C$ NMR spectrum a singlet at $\delta$ 10.0 for the carbon atom of the RuPC three-membered ring.

The X-ray crystal structure analysis of **5** (Fig. 1) confirmed the structural proposal outlined in Scheme 1.‡ The ruthenium is coordinated by the mesitylene ring, one chloride and the P,C-

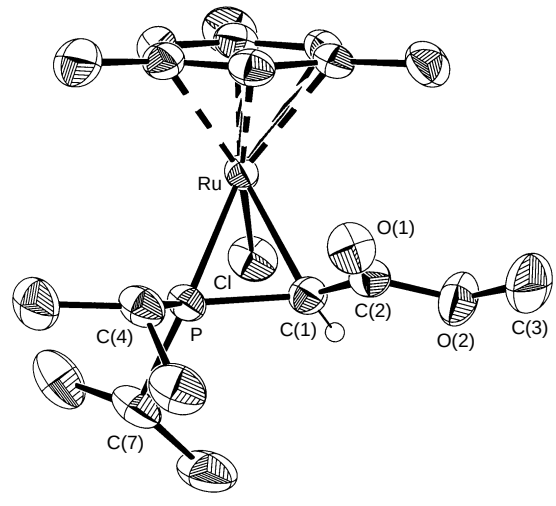

**Fig. 1** Molecular structure (ORTEP drawing) of **5**. Selected bond distances (Å) and angles (°): Ru–P 2.269(1), Ru–Cl 2.410(1), Ru–C(1) 2.201(2), P–C(1) 1.761(2), P–C(4) 1.832(2), P–C(7) 1.847(2), C(1)–C(2) 1.455(3), C(2)–O(1) 1.208(3), C(2)–O(2) 1.363(3); P–Ru–Cl 88.97(3), P–Ru–C(1) 46.37(6), C(1)–Ru–Cl 84.97(6), Ru–P–C(1) 64.77(7), Ru–C(1)–P 68.86(7), P–C(1)–C(2) 125.5(2), Ru–C(1)–C(2) 116.5(1), C(1)–C(2)–O(1) 128.6(2), C(1)–C(2)–O(2) 110.0(2), O(1)–C(2)–O(2) 121.3(2).

bonded phosphinomethanide ligand, the $CO_2Me$ substituent of which is pointing away from the Ru–Cl axis. The bond angles of the three-membered ring are comparable to those found in the osmium analogue of **5**[4] and in various [$L_nM\{\kappa^2$(P,C)-$Ph_2PCH_2\}$] complexes.[8] The distance P–C(1) is shorter by *ca*. 0.08 Å than the distances P–C(4) and P–C(7) indicating a substantial double-bond character of the phosphorus–carbon bond in the RuCP unit.

The phosphinomethanide and not the isomeric phosphinoenolate compound is also formed, although as the minor component, on treatment of **2** with $Al_2O_3$/NaH in THF (Scheme 1). The main product of this reaction is the phosphinocarboxylate complex **6**, which has been characterized by elemental analysis and spectroscopic techniques. Both the IR and $^1$H NMR data are similar to those of [(mes)RuCl{$\kappa^2$(P,O)-$Ph_2PCH_2C(O)O$}], obtained by acid hydrolysis of [(mes)-$RuCl_2(Ph_2PCH_2CO_2Bu^t)$] (mes = $C_6H_3Me_3$-1,3,5).[9] We note that in contrast to **2**, the related osmium compound [(mes)-$OsCl_2(Pr^i_2PCH_2CO_2Me)$] reacts with $Al_2O_3$/NaH in THF to give the corresponding phosphinomethanide complex [(mes)-OsCl{$\kappa^2$(P,O)-$Pr^i_2PCHCO_2Me$}] almost quantitatively.[4]

In conclusion, the present work has shown that, in connection with [(mes)RuCl] as a building block, a three-membered chelate ring of a phosphinomethanide complex is thermodynamically more stable than a five-membered ring of the phosphinoenolate metal isomer. At present, we are investigating whether an analogous isomerisation (as that of **4** to **5**) also occurs if the CH fragment of the $RuOC_2P$ five-membered ring is replaced, *e.g.* by a CC(O)NHR unit which is formed by insertion of an isocyanate into the C–H bond.[2a]

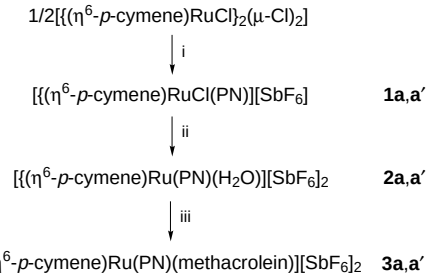
*[c] Departamento de Química Inorgánica, Escuela Universitaria de Ingeniería Técnica Industrial, Instituto de Ciencia de Materiales de Aragón, C.S.I.C.-Universidad de Zaragoza, 50009 Zaragoza, Spain*

**On the basis of spectroscopic and structural studies a full catalytic cycle is proposed for the Diels–Alder reaction between methacrolein and cyclopentadiene when the new chiral aquo-complexes ($R_{Ru}$, $S_{Ru}$)-[($\eta^6$-*p*-cymene)Ru(PN)($H_2O$)][$SbF_6$]$_2$ {PN = (3a*S*, 8a*R*)-2-(2-diphenylphosphinophenyl)-3a,8a-dihydroindane[1,2-d]oxazole} are used as catalysts.**



The Diels–Alder reaction is one of the most important reactions owing to its synthetic relevance and to its mechanistic implications.[1] For these reasons, considerable efforts have been devoted to the development of its enantioselective versions.[2] Among them the use of chiral transition-metal Lewis acids is one of the most recent and versatile variants.[3] It is commonly assumed that for activated alkenes, such as acroleins, the catalytic activity implies an $\eta^1$-coordination mode through the oxygen atom followed by subsequent attack of the diene.

**I**

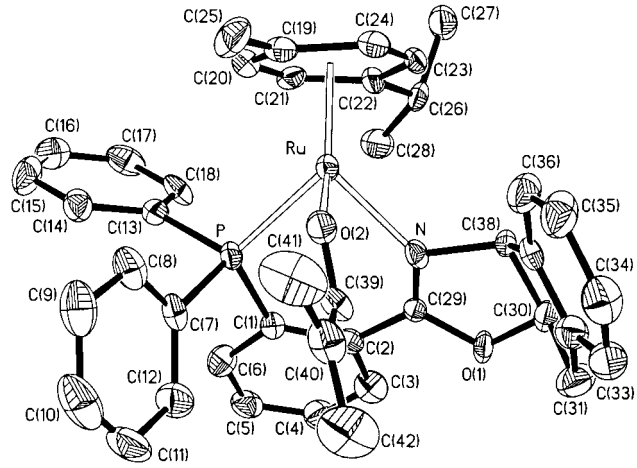
However, studies supporting this assumption in transition metal catalyzed enantioselective Diels–Alder reactions are very scarce.[4] Following our studies on transition metal complexes with chiral metal centres,[5] we report here spectroscopic and crystallographic evidence that supports the aforementioned path for the Diels–Alder reaction between methacrolein and cyclopentadiene (HCp) catalyzed by the new aquo-complexes ($R_{Ru}$, $S_{Ru}$)-[($\eta^6$-*p*-cymene)Ru(PN)($H_2O$)][$SbF_6$]$_2$, including the X-ray crystal structure determination of the Lewis acid–dienophile adduct ($S_{Ru}$)-[($\eta^6$-*p*-cymene)Ru(PN)(methacrolein)][$SbF_6$]$_2$. The new enantiopure phosphinoxazoline ligand **I**, prepared from (1*S*,2*R*)-1-aminoindan-2-ol according to the Williams' procedure,[6] was used as a chiral auxiliary. The methacrolein complex was prepared following the sequence of reactions depicted in Scheme 1. Complexes **1** were prepared as a 70 : 30 mixture of epimers at ruthenium in essentially quantitative chemical yield. Enantiopure **1a** and **1a′** can be obtained by fractional crystallization from methanol and $CH_2Cl_2$–$Et_2O$, respectively.† NOE difference spectra support an *S* configuration at ruthenium[7] for **1a**.‡

The aquo-complexes **2** were obtained as a mixture of epimers at the metal.† The water molecule proceeds from the solvents. The epimeric composition is independent from the composition of the starting chloride compound **1**, but it depends on the solvent. $^1$H NMR spectra of aliquots of the same solid sample reveal 65 : 35 and 82 : 18 epimeric ratios in $(CD_3)_2CO$ and $CD_2Cl_2$, respectively. ROESY experiments indicated that the configuration at the metal for the major diastereomer is *S*.§

**Scheme 1** *Reagents*: i, PN, $NaSbF_6$, MeOH; ii, $AgSbF_6$, $CH_2Cl_2$–acetone (95 : 5, v/v); iii, methacrolein (excess)

At room temp., dichloromethane solutions of **2** catalyse rapidly the Diels–Alder reaction of methacrolein with HCp (91% conversion in 20 min), the system operating with low loading (5% mol), good *exo* : *endo* selectivity (92 : 8) and moderate enantioselectivity {46% in the *exo* adduct (1*R*,2*S*,4*R*)-2-methylbicyclo[2.2.1]hept-5-ene-2-carbaldehyde}.¶

In order to probe the mechanism of the Diels–Alder catalysis, **2** was combined separately with HCp and methacrolein (**2**: methacrolein or HCp, 1 : 20 molar ratio). While no interaction with HCp was detected by either $^1$H or $^{31}$P NMR, immediate adduct formation with methacrolein occurred to give **3** in 73% chemical yield as a 90 : 10 mixture of epimers at the metal† along with 27% of unreacted **2**. From the NMR solution single-crystals of complex **3** were obtained. An X-ray difraction study‖



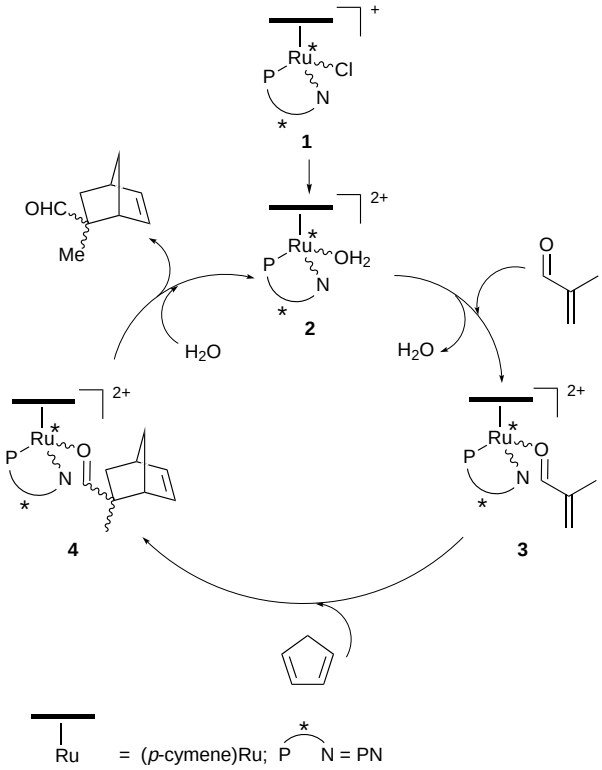


**Fig. 1** Molecular representation of ($S_{Ru}$)-**3**. Selected bond distances (Å) and angles (°): Ru–P 2.327(2), Ru—N 2.106(6), Ru–O(2) 2.110(5), O(2)–C(39) 1.219(8), C(39)–C(40) 1.448(11), C(40)–C(41) 1.475(13), C(40)–C(42) 1.329(13); P–Ru–N 89.0(2), P–Ru–O(2) 89.7(2), N–Ru–O(2) 85.7(2), Ru–O(2)–C(39) 131.2(5), O(2)–C(39)–C(40) 123.1(7), C(39)–C(40)–C(41) 118.3(8), C(39)–C(40)–C(42) 116.0(8), C(41)–C(40)–C(42) 125.7(8).

**Scheme 2**

showed an $\eta^1$-coordination mode through the oxygen atom for the methacrolein ligand which adopts an *S-trans* configuration. The methacrolein fragment maintains its planar structure upon coordination [O(2)–C(39)–C(40)–C(42) torsion angle −178.8(8)°], with the metal atom slightly out of this plane by 0.024(6) Å. The absolute configuration at the metal centre results to be *S*.[7] (Fig. 1).

Subsequent addition at 183 K of HCp to $CH_2Cl_2$ solutions of **3**, prepared as above, (**2** : methacrolein : HCp, 1 : 20 : 40 molar ratio) produced the appearance in the $^{31}P$ NMR spectrum of a new broad peak centred at $\delta$ 32.9 at the expense of the major epimer of **3**, the minor one and the aquo-complexes **2** retaining their relative intensities. At this temperature the Diels–Alder reaction was not observed and we assume that the new resonance would be due to one of several of the possible metal–complex diastereoisomers **4** in which the Diels–Alder adduct is still coordinated to the metal. On warming to 253 K the reaction starts and the sole species observed during the catalytic process are the aquo-complexes **2**. When the catalysis has been completed compounds **2** remain and, as expected, addition of methacrolein regenerates compounds **3** restarting the catalytic cycle.

In conclusion, the catalytic cycle depicted in Scheme 2 is proposed on the basis of spectroscopic data and of the X-ray molecular structure of the complex ($S_{Ru}$)-[($\eta^6$-*p*-cymene)Ru-(PN)(methacrolein)][$SbF_6$]$_2$. Further work in this area is in progress in order to optimise the catalytic conditions and to obtain information on the origin of the enantioselectivity.

For **3a′** (minor diastereomer): $^{31}P\{^1H\}$ NMR (121.4 MHz, $CD_2Cl_2$, −90 °C, $H_3PO_4$) $\delta$ 39.2 s.

‡ The X-ray crystal structure determination of **1a** confirm the assigned configuration: D. Carmona and F. J. Lahoz, unpublished work.

§ The priority orders for the chloride (**1**) and aquo-compounds (**2**) are *p*-cymene > Cl > P > N and *p*-cymene > P > O > N, respectively. Note that, comparing **1** to **2**, if the configuration at the metal is the same its descriptor changes and *vice versa*.

¶ *Catalytic Diels–Alder reaction*: a solution of the catalyst (0.025 mmol) in 2 ml of dry $CH_2Cl_2$ was prepared under argon. The dienophile (0.5 mmol in 2 ml of $CH_2Cl_2$) and freshly distilled cyclopentadiene (3 mmol in 2 ml of $CH_2Cl_2$) were added consecutively by syringe. The resulting solution was stirred until the dienophile was consumed (GC). Yields and *exo* : *endo* ratios were determined by GC analysis. The reaction mixture was concentrated and filtered through silica gel ($CH_2Cl_2$–hexane as eluent) before the determination of the enantiomeric purity. Ee values were determined by $^1H$ NMR spectroscopy in the presence of the chiral shift reagent Eu(hfc)$_3$. The configuration of the major adduct was assigned by comparing the sign of $[\alpha]_D$ with that in the literature.[9]

‖ *Crystal data* for ($S_{Ru}$)-**3**: $C_{42}H_{42}F_{12}NO_2PRuSB_2$, $M$ = 1196.32, orthorhombic, space group $P2_12_12_1$, $a$ = 11.3401(8), $b$ = 18.2209(12), $c$ = 20.7142(13) Å (by least-squares refinement of the setting angles for 92 reflections within $\theta$ = 12.5–19.5°), $U$ = 4280(1) Å$^3$, $Z$ = 4, $D_c$ = 1.857 g cm$^{-3}$, $T$ = 200.0(2)K, $\mu$ = 1.73 mm$^{-1}$, $F$(000) = 2344, orange irregular block (0.69 × 0.48 × 0.38 mm). Data were collected on a Siemens P4 diffractometer with graphite-monochromated Mo-K$\alpha$ radiation ($\lambda$ = 0.710 73 Å) within a 2$\theta$ range 4–50°. 8444 reflections collected, 7508 unique. Absorption correction applied according to $\psi$-scan method. The structure was solved by direct methods (SHELXS-86)[8] and refined by full-matrix least squares on $F^2$ using all unique data. Anisotropic displacement parameters used for all atoms except for the disordered $SbF_6^-$ groups. Hydrogens included in calculated (methyl groups) or found positions (all the remaining H atoms). Final $R_1$ = 0.0636; $wR_2$ = 0.0950 (SHELXL-93, all data) for 570 parameters. CCDC 182/640.

# Asymmetric dihydroxylation with silica-anchored alkaloids

**Carsten Bolm,* Astrid Maischak and Arne Gerlach**

*Institut für Organische Chemie, RWTH Aachen, Professor-Pirlet-Strasse 1, D-52056 Aachen, Germany*

**Diols with excellent enantiomeric excesses are obtained from unfunctionalised alkenes in high yields by osmium-catalysed dihydroxylations using silica-bound pyrimidine and pyrazinopyridazine ligands.**

The Sharpless asymmetric dihydroxylation (AD) is an efficient catalytic method for the enantioselective oxidation of unfunctionalised alkenes.[1] Since its discovery in 1988[2] the catalyst system has been continuously optimised,[3] so that now almost any alkene can be transformed to the corresponding diol with high enantioselectivity. In order to ease the recovery of the ligands after the catalysis, the use of various polymer-supported cinchona alkaloids has been studied.[4–7] Most of the insoluble ligands are easily handled but suffer from disadvantages, such as longer reaction times and lower enantioselectivity. Recently, we[6] and others[7] introduced soluble polymer-supported alkaloids with MeO-PEG tethers which gave catalysts with similar reactivity and enantioselectivity as those reported for the original Sharpless system. Ligand recovery was easily accomplished by addition of ethereal solvents to the reaction mixture followed by filtration of the precipitated alkaloid. In our approach,[6] the MeO-PEG attachment was designed such that negative steric interactions between the polymer backbone and the alkaloid moiety were minimised. We now report on the anchoring of this type of specifically modified cinchona alkaloid on insoluble inorganic carriers based on silica. In contrast to organic polymers, this kind of heterogeneous support offers a variety of possible applications due to its mechanical and thermal stability.

The polysiloxane-anchored bis(9-*O*-dihydroquinidinyl)pyrazinopyridazine **1** and bis(9-*O*-dihydroquinidinyl)pyrimidine **2** were synthesised from the corresponding phenols ($R^1$, $R^2$ = H)[6] and commercial functionalised silica† using standard acylation or nucleophilic substitution reactions.

The catalysed asymmetric dihydroxylations of representative alkenes were performed under standard reaction conditions in $Bu^tOH$–$H_2O$ (1 : 1) using $K_3[Fe(CN)_6]$–$K_2CO_3$ as oxidant, 0.5–1 mol% of $K_2OsO_2(OH)_4$ and 2 mol% of immobilised ligand. Mechanical stirring was applied in order to avoid silica deterioration. The most significant results are summarised in Table 1.

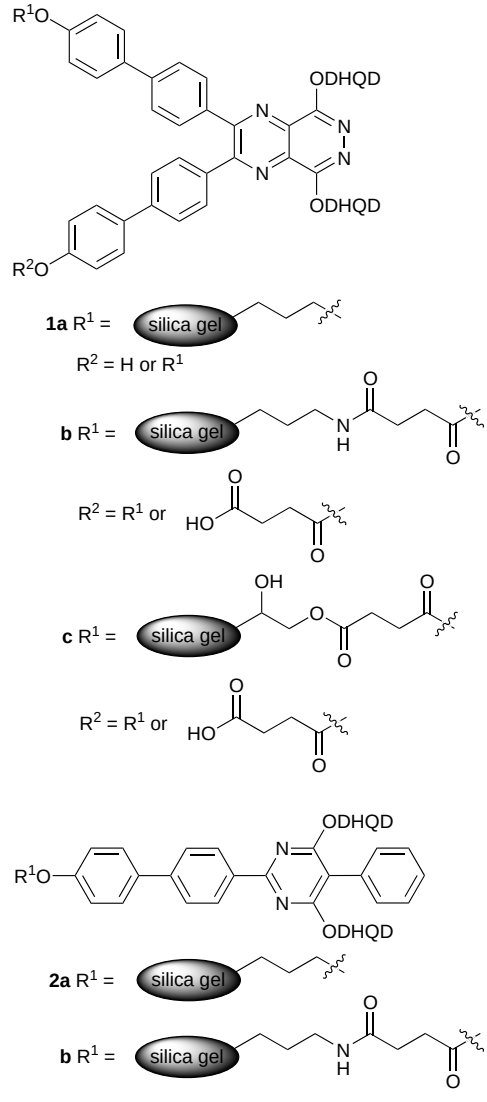

**Table 1** Enantioselectivities in the AD of various alkenes[a]

| Entry | Alkene | Ligand | Yield (%) | Ee (%)[b] | Configuration |
|---|---|---|---|---|---|
| 1 | *trans*-PhCH=CHPh | **1a** | 77 | 99 (99) | (*R*,*R*) |
| 2 | PhCH=$CH_2$ | **1a** | 93 | 98 (99) | (*R*) |
| 3 | PhCH=$CH_2$ | **1b** | 93 | 90 | (*R*) |
| 4 | PhCH=$CH_2$ | **1c** | 92 | 97 | (*R*) |
| 5 | $C_8H_{17}CH=CH_2$ | **2a** | 51 | 84 (89) | (*R*) |
| 6 | $C_8H_{17}CH=CH_2$ | **2b** | 53 | 61 | (*R*) |
| 7 | $Bu^tCH=CH_2$ | **2b** | 62 | 70 (92) | (*R*) |

[a] AD experiments as per typical protocol (see text). [b] Determined either by comparison of the specific rotation with the authentic samples or by HPLC using a chiral stationary phase [refs. 3(*a*), 4(*f*), 6]. The ee values of products which were obtained from catalyses with non-polymer supported DHQD ligands [ref. 3(*b*)] are given in parentheses.

In the AD of styrene and stilbene, exceedingly high enantioselectivities were achieved with heterogeneous silica-anchored ligands **1a** and **1c** having ether and ester linkers, respectively. A slightly lower asymmetric induction was observed when amido linked **1b** was applied (Table 1, entry 3). Presumably, residual amino groups on the silica surface or the amido linker itself have a negative influence, giving diols with reduced enantiomeric excess. Support of this hypothesis was gained in AD experiments performed with alkaloid-free amino functionalized silica gel. The rapid formation of racemic diol revealed the high catalytic activity of the support.

Under homogeneous conditions pyrimidine ligands are most suitable for the enantioselective dihydroxylation of aliphatic, terminal alkenes. Therefore, AD reactions of dec-1-ene were performed with silica-supported pyrimidines **2a** and **2b** (Table 1, entries 5 and 6). Catalyses with both ligands afforded the

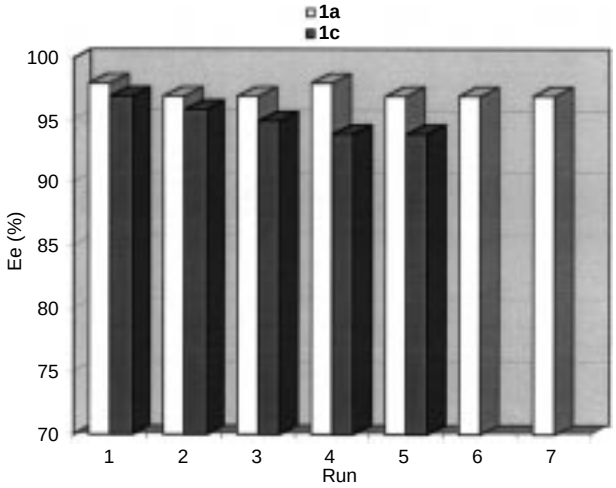

**Fig. 1** Enantioselectivities in consecutive AD reactions of styrene using silica-supported alkaloids **1a** and **1c**

corresponding diols in moderate yield with enantiomeric excesses of 84 and 61%, respectively. The former value compares well to the one obtained with the original homogeneous Sharpless system (89% ee).

In order to examine the stability of the catalyst and the possibility of ligand recovery, **1a** and **1c** were used in consecutive AD reactions of styrene. As shown in Fig. 1, silica-supported alkaloid **1a** was used seven times without significant loss of enantioselectivity. The enantiomeric excess of the diol stayed in the range of 97–98%, and the chemical yields were excellent. In contrast, in AD reactions with silica-attached **1c** the efficiency of the catalysis decreased with each run. Presumably, parts of the alkaloid were lost in each recycling process due to a minor ester hydrolysis under the basic reaction conditions. In order to ensure the presence of sufficient amounts of osmium in the reaction mixture, 0.5–1 mol% of $K_2OsO_2(OH)_4$ was added before each run in the experiments described above. Without this addition, a considerable decrease in activity was observed, indicating metal leaching during catalyst recovery. For example, in consecutive AD reactions of styrene in the presence of **1a** *without* the addition of osmium, the diol yield dropped from 93% in the first run to 50 and 34% yield in the second and third run, respectively. Even under these very unfavourable conditions, and despite the metal loss, the catalysis still benefits from the phenomenon of 'ligand acceleration'[8] and gives the products with high enantiomeric excess (run 1: 98% ee; run 2: 98% ee; run 3: 95% ee).

The results of this investigation can be summarised as follows. (i) The enantioselectivities in these heterogeneous AD reactions are excellent, and diols with up to 99% ee are formed. (ii) The new silica-bound alkaloids can be quantitatively recovered by simple filtration. (iii) Recycled ligands give catalysts which perform several times without loss of activity and enantioselectivity. (iv) Consecutive use of the immobilised ligands in AD reactions is possible but requires the addition of small quantities of osmium after each run. If no metal is added the enantioselectivity remains high but the catalyst activity is reduced.

This research was supported in part by grants from the BMBF and the Fonds der Chemischen Industrie.

# Synthesis of polyfunctionalized thiophenes and enediynes *via* ring-opening reactions of 3-lithiated thieno[2,3-*b*](and [3,2-*b*])thiophenes, 3,4-dilithiated thieno[2,3-*b*]thiophenes and 3,6-dilithiated thieno[3,2-*b*]thiophenes

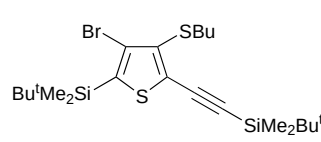
**Lance S. Fuller,[a] Brian Iddon MP*[b]† and Kevin A. Smith[b]**

[a] *Synthetic Chemicals Ltd., Four Ashes, Nr. Wolverhampton, UK WV10 7BP*
[b] *Chemical Sciences Division, Science Research Institute, University of Salford, Salford, UK M5 4WT*

**Solutions of the title lithiated thienothiophenes were synthesized from 2,5-disubstituted 3,4-dibromothieno[2,3-*b*]thiophenes or 3,6-dibromothieno[3,2-*b*]thiophenes *via* Br → Li exchange with 1.0 or 2.0 equiv. of BuLi (THF, −78 °C), respectively, and gave either polyfunctionalized thiophenes or polyfunctionalized enediynes (by a novel tandem ring-opening process in these cases) on being allowed to warm up to ambient temperature.**

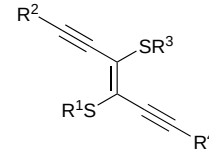
Previously we have reported that ethereal ($Et_2O$ or THF) solutions of benzo[*b*]thiophen-3-yllithium[1–3] and its derivatives[2–4] (prepared from the corresponding 3-bromobenzo[*b*]-thiophene *via* Br → Li exchange with BuLi at −78 °C) undergo a ring-opening process, **1** → **2** (Scheme 1), as the solutions

**1** **2**



**Scheme 1**

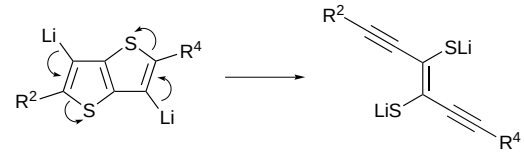
are warmed up to give the lithium salt of an *o*-mercaptophenylacetylene, which can react further, *e.g.* by *S*-butylation with the bromobutane produced in the initial Br → Li exchange reaction or through metallation at the terminal alkyne position. Selenophen-3-yllithium[5–9] and 3-thienyllithium[2,6–12] behave similarly and yield enynes. We now report novel tandem ring-opening processes of 3,4-dilithiated thieno[2,3-*b*]thiophenes and 3,6-dilithiated thieno[3,2-*b*]thiophenes which afford novel enediynes. This work was prompted by intense current interest in enediynes as precursors to more complex molecular architectures.[13]



First we treated 2,3,5,6-tetrabromothieno[3,2-*b*]thiophene[14,15] successively with 2.0 equiv. of BuLi (THF, ambient temperature) and $Bu^tMe_2SiCl$, then the resulting solution of 3,6-dibromo-2,5-bis(*tert*-butyldimethylsilyl)thieno[3,2-*b*]thiophene[14] was cooled to −78 °C and a further 1.0 equiv. of BuLi was added. The resulting mixture was allowed to warm up slowly to ambient temperature, then it was quenched by addition of 20% aq. $NH_4Cl$. Following a standard work-up procedure (extraction of the crude product with $Et_2O$ and flash chromatography on silica with light petroleum as eluent) we obtained 3-bromo-2-*tert*-butyldimethylsilyl-5-*tert*-butyldimethylsilylethynyl-4-butylsulfanylthiophene **3** (70% yield) as a yellow oil.‡ Other 2,5-disubstituted 3,6-dilithiothieno[3,2-*b*]-thiophenes[14] can be prepared and converted similarly into polyfunctionalized thiophenes analogous to compound **3**.

When thiophene **3** was treated successively with 1.0 equiv. of BuLi (THF, 0 °C) and MeI, it gave the enediyne **4** (89% yield) as a yellow oil, thus demonstrating that each thiolate anion, as it is generated in this two-stage process, can be captured by a different alkylating reagent.

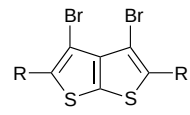
Both ring-opening processes can be carried out in tandem. Thus, we converted 2,3,5,6-tetrabromothieno[3,2-*b*]thiophene



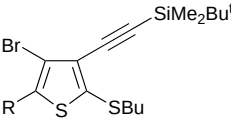
**3**

**4** $R^1$ = Me, $R^2$ = $R^4$ = $SiMe_2Bu^t$, $R^3$ = Bu
**5** $R^1$ = $R^3$ = Bu, $R^2$ = $R^4$ = $SiMe_2Bu^t$
**6** $R^1$ = $R^3$ = Bu, $R^2$ = $R^4$ = H

into 3,6-dibromo-2,5-bis(*tert*-butyldimethylsilyl)thieno[3,2-*b*]-thiophene[14] *in situ*, as described before, then added a further 2.0 equiv. of BuLi (THF, 0 °C) prior to allowing the reaction mixture to warm up slowly to ambient temperature which, after work-up in the standard way, gave the enediyne **5** (70% yield) as a yellow oil. The extremely unstable enediyne **6** (73.5% yield) was prepared by removal of the $Bu^tMe_2Si$ groups from compound **5** *via* treatment with $Bu_4NF$ in THF. Starting from 2,3,5,6-tetrabromothieno[3,2-*b*]thiophene we have prepared a number of other enediynes using this strategy. Essentially the thienothiophene ring is a template to which a variety of functional groups can be attached prior to the tandem ring-opening process **7** → **8** (Scheme 2), *e.g. via* Br → Li exchange

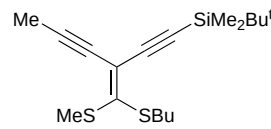


**7** **8**



**Scheme 2**

techniques, by $Pd^0$-catalysed coupling reactions or through further modification of initial products such as by Wittig reactions of aldehydes.



When 2,3,4,5-tetrabromothieno[2,3-*b*]thiophene[16] was treated successively with 3.4 equiv. of BuLi (THF, −65 °C) and 4.8 equiv. of $Me_3SiCl$, it gave 3,4-dibromo-2,5-bis(trimethylsilyl)thieno[2,3-*b*]thiophene **9** (51% yield) as a solid which decomposed when heated to 125 °C in a capillary tube. A similar attempt (2.6 equiv. BuLi, THF, but at 0 °C instead of

**9** R = $SiMe_3$
**10** R = $SiMe_2Bu^t$

**11** R = $SiMe_2Bu^t$
**12** R = H

**13**

−65 °C; 2.4 equiv. of $Bu^tMe_2SiCl$) to synthesize 3,6-dibromo-2,5-bis(*tert*-butyldimethylsilyl)thieno[2,3-*b*]thiophene **10** gave this compound (mp 112–114 °C) in only 23% yield together with 3-bromo-2-*tert*-butyldimethylsilyl-4-*tert*-butyldimethylsilylethynyl-5-butylsulfanylthiophene **11** (33%), a pale yellow solid with mp 35–37 °C, and 4-bromo-3-*tert*-butyldimethylsilylethynyl-2-butylsulfanylthiophene **12** (18%) as a pale yellow oil (formed by loss of the 2-$Bu^tMe_2Si$ group from compound **11**).

When treated successively with 2.0 equiv. of BuLi (THF, 0 °C) and an excess of MeI, the bromothiophene **11** was converted into 2-*tert*-butyldimethylsilylethynyl-1-butylsulfanyl-1-methylsulfanylpent-1-en-3-yne **13** (87% yield) as a yellow oil. In this reaction not only does the MeI capture the generated thiolate anion but it also displaces a $Bu^tMe_2Si$ group.

We thank the EPSRC (CASE award to K. A. S.) and Synthetic Chemicals Ltd. for financial support, Mrs Ruth Howard for recording mass spectra and Dr M. A. Stuckey for recording the 300 MHz $^1$H NMR spectra.

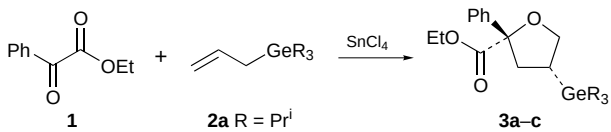
# Lewis acid mediated [3 + 2] cycloaddition of allylgermane: stereoselective synthesis of germyl substituted tetrahydrofurans

**Takahiko Akiyama* and Megumi Suzuki**

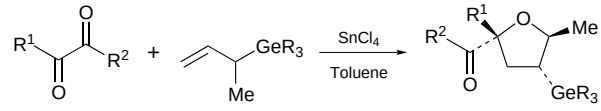


*Department of Chemistry, Faculty of Science, Gakushuin University, 1-5-1, Mejiro, Toshima, Tokyo 171, Japan*

**Tin(IV) chloride mediated [3 + 2] cycloaddition of allylgermanes to α-dicarbonyl compounds proceeds highly stereoselectively to give tetrahydrofurans in good yields.**

Cycloadditions are one of the most useful methods for the stereoselective construction of ring compounds. Numerous cycloadditions have been developed and have been effectively employed in the total synthesis of natural products.[1] Recently Lewis acid promoted [3 + 2] and [2 + 2] cycloadditions of allylsilane with α,β-unsaturated carbonyl compounds and ketones have been extensively studied.[2] For example, allylsilanes bearing bulky silyl substituents work as 1,3-dipole equivalents and both five-membered carbocycles[3] and heterocycles[4,5] have been constructed stereoselectively. Furthermore, allylsilanes have been found to act as 1,2-dipole equivalents depending on the reaction conditions to form four-membered carbocycles[6] and heterocycles stereoselectively.[7] We have recently reported that the Lewis acid promoted [3 + 2] cycloaddition of allylsilanes bearing sterically demanding silyl substituents to α-keto esters proceeded smoothly to afford tetrahydrofurans stereoselectively.[4] Furthermore the Lewis acid mediated cycloaddition of allylstannanes has been studied.[8] In striking contrast, the Lewis acid promoted cycloaddition of allylgermane has not been reported.[9] In connection with our interest in cycloaddition in allylsilane chemistry, we studied the cycloaddition of allylgermane. Reported here is the first [3 + 2] cycloaddition of allylgermane.

First, allyltriisopropylgermane **2a** was treated with an α-keto ester in the presence of a Lewis acid. After screening Lewis acids, we found that the use of tin(IV) chloride in toluene led to the formation of a cycloadduct **3a** as a single stereoisomer in 48% yield (Scheme 1).† Other conventional Lewis acids did not give the cycloadduct. Use of an allylgermane bearing a bulky germyl substituent is mandatory for the formation of the cycloadduct in good yield. Allylgermanes with less sterically demanding germyl substituents such as **2b** and **2c** decreased the yields of the tetrahydrofurans **3b** and **3c** to 17 and 7% yields respectively. In these cases, the normal allylation product was obtained predominantly.‡



Furthermore, introduction of a methyl group at the α-germyl position improved the yield of the tetrahydrofurans significantly and the results are shown in Table 1. Treatment of **1** with allylgermane **4** and tin(IV) chloride in toluene at −78 °C for 40 min gave rise to the cycloadduct in 53% yield (entry 1). Ethyl pyruvate and an α-diketone also afforded the cycloadducts in good yields (entries 2 and 3). The reason why use of **4** inceased

**1** **2a** R = Pr$^i$, **b** R = Ph, **c** R = Et **3a–c**

**Scheme 1**

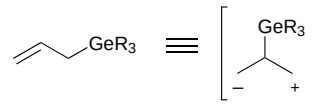


**Table 1** Results of the cycloaddition

**4** **5**

| Entry | R$^1$ | R$^2$ | Conditions | Product | Yield (%) |
|---|---|---|---|---|---|
| 1 | Ph | OEt | −78 °C, 40 min | **5a** | 53 |
| 2 | Me | OEt | −40 °C, 11 min | **5b** | 62 |
| 3 | Me | Me | −40 °C, 12 min | **5c** | 72 |

the yield of the adduct is accounted for as follows: the α-germyl methyl group stabilizes the β-germyl carbocation thus facilitating the germyl migration to produce cycloadducts in better yields than with **2b**.

The present cycloadditions exhibited excellent levels of diastereoselection, producing the tetrahydrofurans with diastereoisomeric excesses (des) reaching > 96% as determined by $^1$H and $^{13}$C NMR spectroscopy. The relative stereochemistry of **3a** and **5a** was unambiguously determined by a multiple NOE study. The stereochemistries of other tetrahydrofurans were estimated by analogy.

In conclusion, we have developed a novel method for the stereoselective formation of germyl substituted tetrahydrofurans by a tin(IV) chloride promoted [3 + 2] cycloaddition of allylgermane to α-keto esters. The utility of allylgermanes bearing sterically demanding germyl substituents as 1,3-dipole equivalents has been demonstrated for the first time.

† Compound **3a** (R = Pr$^i$) was prepared as follows: in a two-necked round bottomed flask, a mixture of **1** (41.5 mg, 0.23 mmol) and **2a** (67.2 mg, 0.28 mmol) in dry toluene (3.2 ml) was stirred at −20 °C. To this mixture tin(IV) chloride (30 μl, 0.26 mmol) was added dropwise and the stirring was continued at the same temperature for 5 min. The reaction was quenched by the addition of 1 M aqueous HCl. The aqueous layer was extracted with ethyl acetate and the combined organic layers were washed with brine, dried over anhydrous $Na_2SO_4$ and concentrated to dryness. Purification of the crude mixture by preparative TLC ($SiO_2$, hexane–ethyl acetate, 7 : 1, v/v) gave **3a** (47.2 mg) in 48% yield.

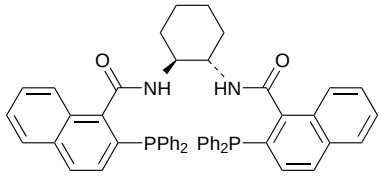
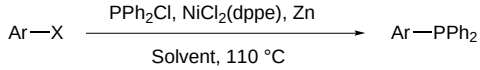
**Nickel-catalysed cross-coupling of aryl sulfonates and aryl halides with chlorodiphenylphosphine and a reductant directly affords tertiary phosphines, which have application in a wide variety of asymmetric catalysis.**



Tertiary phosphines are extremely useful ancillary ligands in homogeneous catalysis, especially as chiral ligands in asymmetric homogeneous catalysis as exemplified by **1**–**3**.[1–8] The preparations of tertiary phosphines can be divided into four major categories: Friedel–Crafts reactions,[9,10] the reaction of halophosphines with organometallic reagents[11,12] and the reaction of phosphides[13–15] or diarylphosphine compounds[16–18] in the presence of a transition metal catalyst with aryl halides or sulfonate esters. All of the methods have drawbacks ranging from limitations due to incompatabilities with other functional groups, the necessity for a separate step to reduce the phosphine oxide, to the use of pyrophoric reagents. We report here a convenient and direct route to tertiary phosphines by transition metal cross-coupling reaction that eliminates these problems.

**1**

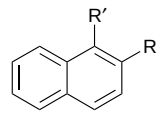


**2**

**3**

We have determined that tertiary phosphines can be prepared from aryl trifluoromethanesulfonates by nickel-catalysed cross-coupling with $Ph_2PCl$ in the presence of zinc in DMF at 110 °C (Scheme 1). $Ph_2PCl$ has the advantage that it is not pyrophoric, inexpensive and readily available for large scale usage. For example, 2-diphenylphosphinonaphthalene **5** is prepared from **4** *via* nickel-catalysed cross-coupling with $Ph_2PCl$ in 89% yield.† The zinc plays a dual role in the reaction. It reduces $Ni^{II}$ to $Ni^0$ as well as providing $Ph_2PZnCl$ for transmetallation.

This methodology appears to be quite general for the preparation of other tertiary phosphines (Table 1). The nickel-catalysed cross-coupling procedure successfully produces phosphines in good yields directly from aromatic sulfonates, aromatic halogens, benzylic bromides and vinyl bromides and iodides. Also, the cross-coupling can occur with aromatic



**Scheme 1**

**22**
(Tf = $CF_3SO_2$)

Trifluoromethanesulfonate substrates give higher yields compared to the corresponding bromide substrate due to hydrodehalogenation side reaction. Double cross-coupling of the *S*-isomer of the bis(trifluoromethanesulfonate) **22** can be achieved to form *S*-BINAP **1** without any racemisation of the axial chirality.‡

This methodology is a convenient procedure to prepare a wide variety of tertiary phosphines. The use of a cheap phosphorus reagent coupled with the tolerance of the reaction to a wide variety of functional groups as well as direct access to phosphorus(III) products makes this a useful, versatile approach to phosphorus ligands.

† *Typical reaction procedure*: to a solution of **4** (10.6 g, 40 mmol), $NiCl_2$(dppe) [dppe = ethylenebis(diphenylphosphine)] (0.315 g, 0.60 mmol) and $Ph_2PCl$ (8.85 g, 40 mmol) in anhydrous DMF (25 ml) was added Zn (4.10 g, 63 mmol) portionwise at 5–10 °C. The mixture was heated to 100–110 °C and monitored by GC. The reaction mixture was cooled to 80 °C, filtered and rinsed with a minimal amount of DMF. The combined filtrate was cooled to 5 °C and the product crystallised overnight. The solids were filtered, rinsed with MeOH and dried at room temp. under vacuum to give 11.21 g (89%) of **5** as an off-white solid. Satisfactory $^1H$ and $^{31}P$ NMR and mass spectral data were obtained on all the products.

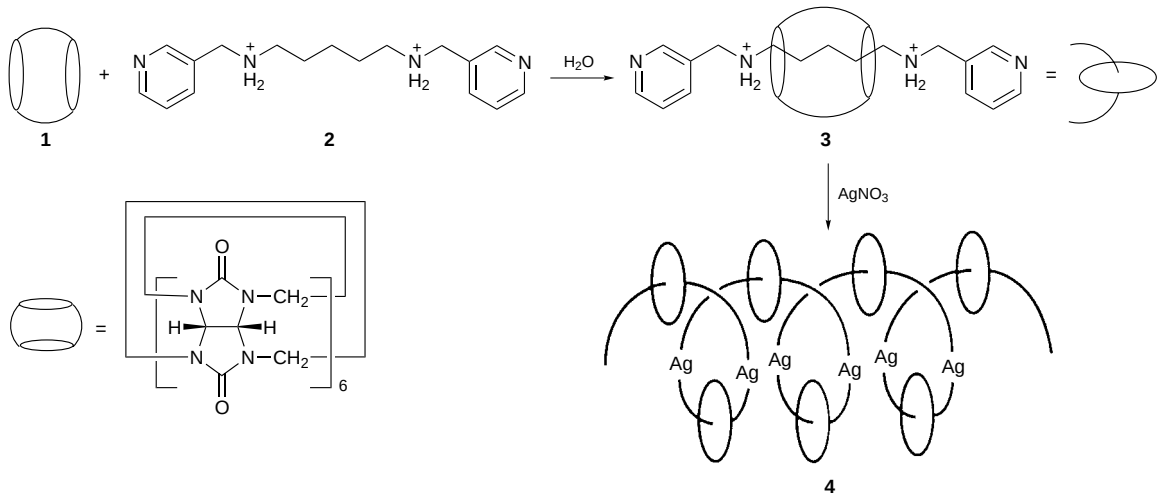
# Helical polyrotaxane: cucurbituril 'beads' threaded onto a helical one-dimensional coordination polymer

**Dongmok Whang, Jungseok Heo, Chang-Ahn Kim and Kimoon Kim***

*Department of Chemistry and Center for Biofunctional Molecules, Pohang University of Science and Technology (POSTECH) San 31 Hyojadong, Pohang 790-784, South Korea*

**Formation of a pseudorotaxane by threading a cucurbituril 'bead' with a *N*,*N*′-bis(3-pyridylmethyl)-1,4-diaminopentane 'string' followed by reaction of the pseudorotaxane with $AgNO_3$ yields a polyrotaxane, the X-ray crystal structure of which reveals the 'beads' threaded onto a helical one-dimensional coordination polymer.**



Polyrotaxanes[1] in which a number of cyclic molecular 'beads' are threaded onto a linear 'string' have received considerable attention in recent years due not only to their structures and properties but also to their potential applications as new materials.[1c] We have recently reported[2] a simple one-step approach to construct 1D and 2D polyrotaxane coordination polymers in the solid state. It involves formation of a pseudorotaxane first by threading a molecular 'bead' with a 'string' which has suitable functional groups at both ends and then formation of a polyrotaxane coordination polymer by allowing the end functional groups of the pseudorotaxane to coordinate to metal centers (Scheme 1). In this approach a

**Scheme 1**

judicious choice of metal ion is important to achieve the desired solid state structure. Under the same or similar conditions, for instance, $Mn^{2+}$, $Cu^{2+}$ and $Ag^{+}$ result in totally different structures; they are a simple rotaxane, a 1D polyrotaxane and a 2D polyrotaxane, respectively.[2] Counter-anions also play an important role in determining the solid state structure: for example, silver nitrate leads to a 2D polyrotaxane whereas silver tosylate yields a 1D polyrotaxane.[2b] A unique and interesting twist in this approach to construction of polyrotaxanes results from changing the 'string' from *N*,*N*′-bis(4-pyridylmethyl)-1,4-diaminobutane, used previously in this procedure,[2] to *N*,*N*′-bis(3-pyridylmethyl)-1,5-diaminopentane. Herein we report the first example of helical polyrotaxanes in which cyclic beads are threaded on helical one-dimensional coordination polymers.

The formation of the pseudorotaxane **3**, by threading cucurbituril **1**[3] with *N*,*N*′-bis(3-pyridylmethyl)-1,5-diaminopentane dihydronitrate **2**, followed by the reaction of **3** with $AgNO_3$ yielded **4** (Scheme 2).† The X-ray crystal structure‡ of **4** reveals a 1D polyrotaxane in which cucurbituril 'beads' are threaded on a 1D coordination polymer with a formula of $–[Ag–pyCH_2NH_2(CH_2)_5NH_2CH_2py–]_n^{3n+}$. The asymmetric unit consists of a Ag ion, a pseudorotaxane **3**, one of the pyridine units of which is coordinated to the silver ion, and three nitrate ions to balance the charge (Fig. 1). Most interestingly, the coordination polymer has a helical structure extended along the *b* axis with a pitch of 17.9 Å which is the same as the *b* axis length (Fig. 2). There are equal amounts of right- and left-handed helices in the crystal (it is a racemic mixture). In each helix, two 'supermolecules' of **3** and two silver ions constitute one turn. Each silver ion is coordinated by two 'supermolecule' **3** in a linear fashion: Ag–N(25) 2.133(8), Ag–N(28) 2.138(7) Å, N(25)–Ag–N(28) 177.9(3)°. A cucurbituril 'bead' is held tightly at the middle of each repeating unit by strong hydrogen bonds between the protonated amine nitrogen atoms of the 'string' **2** and the oxygen atoms of cucurbituril: N(26)···O(1) 2.914(10) Å, N(26)···O(2) 3.082(10) Å, N(26)···O(6) 2.893(10) Å, N(27)···O(8) 2.793(9) Å, N(27)···O(9) 2.754(9) Å, N(27)···O(10) 3.089(9) Å. It is interesting to note that N(26) is displaced from the six-oxygen plane of the portal by only 0.037(7) Å, but from the other amine nitrogen N(27) by 0.721(8) Å. Moreover, the 3-pyridyl unit attached to N(26) make a dihedral angle of 61° with the six-oxygen plane whereas that connected to N(27) is nearly parallel to the portal plane

**Scheme 2**

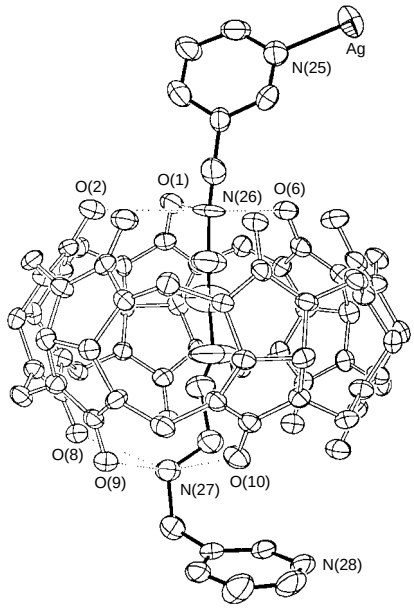


**Fig. 1** Asymmetric unit of the crystal structure of **4**. Counter-ions ($NO_3^-$) and water molecules in the lattice are omitted for clarity.

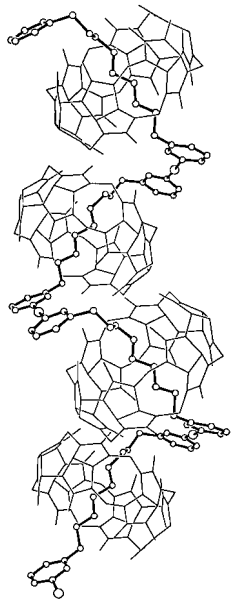

**Fig. 2** Structure of **4** showing cucurbituril 'beads' threaded onto a helical 1D coordination polymer

(angle 9°). The parallel conformation of the 3-pyridyl unit makes the polymer chain change its direction sharply, which eventually leads to a helical structure (Fig. 3).

In conclusion, we present here an unprecedented helical 1D polyrotaxane in which cyclic 'beads' are threaded onto a helical

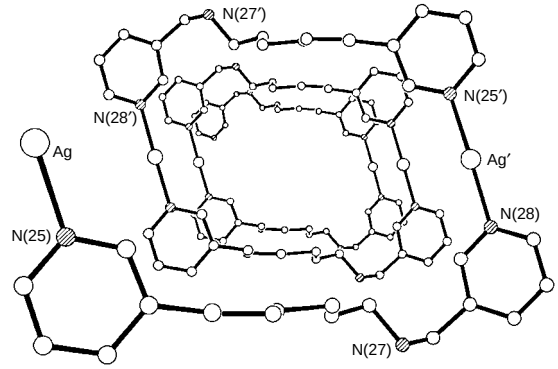

**Fig. 3** The helical 1D coordination polymer threading cucurbituril 'beads' (omitted) in **4**. The pitch of the helix is 17.9 Å. Bond distances (Å) and angle (°) around the silver ion: Ag–N(25) 2.133(8), Ag–N(28) 2.138(7), N(25)–Ag–N(28) 177.9(3).

coordination polymer. It still remains to be determined how one enantiomer, either right- or left-handed polyrotaxane helices can be enantioselectively constructed. Such chiral helical polyrotaxanes may have interesting applications.

# Isolation and comprehensive solid state characterization of $Cl_3Al–O–PCl_3$

**Neil Burford,*[a] Andrew D. Phillips,[a] Robert W. Schurko,[a] Roderick E. Wasylishen[a] and John F. Richardson[b]**

[a] *Department of Chemistry, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J3*
[b] *Department of Chemistry, University of Louisville, Louisville, Kentucky 40292, USA*

**The crystal structure of $Cl_3Al–O–PCl_3$ contains covalent molecular units with an essentially linear Al–O–P axis, and a similar solution structure is indicated by NMR spectroscopy.**

Binary mixtures of $AlCl_3$ and $OPCl_3$ have been under examination for nearly 150 years,[1] and the existence of various formulae has been envisaged. Conductivity measurements[2,3] and radiochlorine exchange studies[4] imply the formation of ionic systems of the type $[OPCl_2][AlCl_4]$[2,4] and $[Cl_2Al(OPCl_3)_2][AlCl_4]$.[3] The more complex salts $[Al(OPCl_3)_4][AlCl_4]_3$[5] and $[Al(OPCl_3)_6][AlCl_4]_3$[5,6] are postulated on the basis of Raman[5] and NMR[6] spectroscopic data. Most reports propose the covalent formulae, $Cl_3AlOPCl_3$,[7–16] $(Cl_3Al)_2OPCl_3$,[9,11] $Cl_3Al(OPCl_3)_2$,[9,13,17] or $(Cl_3Al)_2(OPCl_3)_3$,[7,15] on the basis of melting points,[17] thermal analysis,[16] vapour pressure measurements,[9,10] vibrational spectroscopy,[11,12,13] mass spectrometry,[14] NMR spectroscopy[5,7] or X-ray powder diffraction.[15] Nevertheless, definitive structural assignment for any of these is not yet available.

We now report the isolation and comprehensive solid state characterization of $Cl_3AlOPCl_3$, which can be crystallized from $CH_2Cl_2$ solution.† The melting point of the crystals (183–185 °C) corresponds to the well established dystectic for a 1 : 1 stoichiometry (186.5 °C,[17] 188 °C[8]). The crystal structure reveals $Cl_3AlOPCl_3$ as covalent molecular units without significant intermolecular interactions. As illustrated in Fig. 1, the plane defined by Cl(3), Al, O, P and Cl(1) lies on a crystallographic mirror plane so that the chlorine atoms adopt an eclipsed orientation. The Cl–Al and Cl–P bond lengths are typical of four-coordinate aluminium and phosphorus, respectively. Although the Al–O bond length is consistent with those in compounds containing $C_3AlO$ units,[18] it is significantly longer than observed for $Cl_3AlOPPh_3$ [1.733(4) Å].[19]

The similarity of the solution and solid state $^{31}P$ and $^{27}Al$ NMR chemical shifts implies retention of the covalent structure in solution. Although the Raman spectroscopic features (band intensities, assignments and interpretations) described in the literature are somewhat varied, the five most intense bands for the crystalline material correspond with five of the six strong bands reported for the 1 : 1 binary mixture (591, 452, 350, 210, 168, 118 $cm^{-1}$),[5] which has therefore previously been incorrectly assigned the ionic formula $[Al(OPCl_3)_4][AlCl_4]_3$.

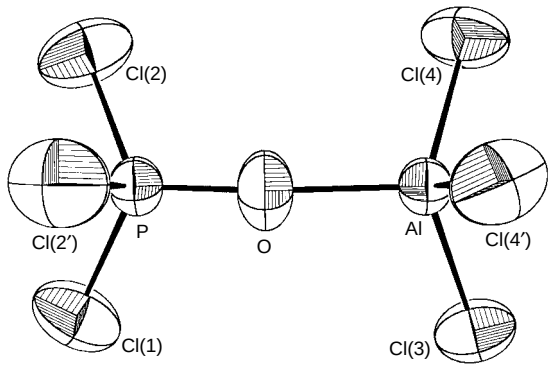

**Fig. 1** ORTEP view of $Cl_3AlOPCl_3$. Selected bond lengths (Å) and angles (°): Al–O 1.780(4), Al–Cl(3) 2.093(2), Al–Cl(4) 2.103(2), P–Cl(1) 1.929(2), P–Cl(2) 1.929(1), O–P 1.436(3); Al–O–P 176.0(4), O–Al–Cl(3) 106.9(2), O–Al–Cl(4) 106.18(9), Cl(3)–Al–Cl(4) 112.78(5), Cl(4)–Al–Cl(4′) 111.47(5), Cl(1)–P–Cl(2) 108.07(7), Cl(2)–P–Cl(2′) 107.71(8), O–P–Cl(1) 110.9(2), O–P–Cl(2) 111.0(1).

The most striking feature in the solid state structure of $Cl_3AlOPCl_3$ is the large Al–O–P angle [176.0(4)°], which is consistent with the near $C_{3v}$ symmetry assigned for a species in the melt on the basis of Raman spectra,[5] and with the structure assigned to $Br_3AlOPBr_3$ on the basis of single crystal NQR and NMR spectroscopy,[20] but is surprising when compared with the bent structure of $F_5AsOPCl_3$ [As–O–P 136.6(4)°].[21] While there are numerous examples of compounds containing a linear oxygen centre, most involve a transition metal.[22] Those between p block elements $\{(C_{10}H_8NO)_2Al–O–Al(NOC_{10}H_8)_2$,[23] $Ph_3Si–O–SiPh_3$,[24] $[(Me_2N)_3P–O–P(NMe_2)_3]^{2+}$,[25] $Ph(OMe)C–O–AlMe(BHT)_2$[26] and $X_3E–O–PPh_3$ ($X_3E$ = $Cl_3Al$, $Br_3Al$, $Cl_3Ga$)[19]$\}$ maybe imposed by substituent steric strain, but such interactions are insignificant in the title compound, as the intramolecular Cl(Al)···Cl(P) distances [Cl(1)···Cl(3) 4.645(2), Cl(2)···Cl(4) 4.428(2) Å] are substantially greater than the sum of the van der Waals' radii for chlorine (3.6 Å).[27] Moreover, the Al–P separation [3.213(2) Å] is greater than that between the silicon centres in the non-linear (Si–O–Si, 146°) isoelectronic molecule $Cl_3Si–O–SiCl_3$ (3.13 Å,[28] also the close contact limit for silicon centres).[29] $Cl_3AlOPCl_3$ is a useful and simple example of a non-VSEPR structure, although novelties or exceptions to the VSEPR model[30] were recognized at the outset (*e.g.* $H_3SiOSiH_3$[31] and $Cl_5RuORuCl_5$),[32] and internuclear repulsions may play a role in the determination of molecular geometry.[29]

$Cl_3AlOPCl_3$ is best viewed as one of an extensive series of phosphoryl coordination complexes which exhibit a range of angles (134–180°) at the dicoordinate oxygen centre,[22,33] although the widest angle previously reported for complexes of $OPCl_3$ is 164.1(4)°.[34] The O–P bond in $Cl_3AlOPCl_3$ is typical, in that it is essentially unchanged from that reported for the gas phase structure of the free ligand $OPCl_3$ [1.449(5) Å].[35] Therefore, we envisage the coordinative interaction to involve a purely non-bonding electron pair on oxygen, and invoke a similar model to that proposed for coordination complexes containing organo-carbonyl ligands, the M–O–C bond angle of which has a shallow energy minimum and is readily distorted by a number of factors.[36]

The observations and conclusions presented here have important structural implications for other $OPCl_3$ complexes, including the recently reported $Cl_3FeOPCl_3$.[37]

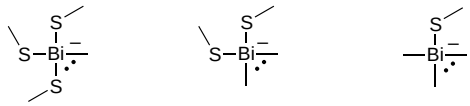
# Ammoniumthiolatobismuth halides: a new thiolate bonding environment for $Bi^{III}$ as an alternative to metathesis and chelation

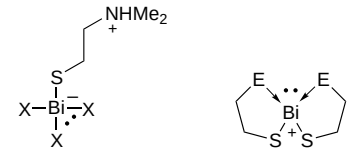
**Glen G. Briand, Neil Burford* and T. Stanley Cameron**



*Department of Chemistry, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J3*

**Synthesis, isolation and characterization of the first monothiolatobismuth complexes are contrary to the prominent thiophilicity, the tendency towards maximum metathesis and the extensive chelation chemistry of bismuth.**

The coordination chemistry of the heavier p block elements is diverse due primarily to the potential for both covalent and coordinative bonding, the access of coordination numbers up to nine, and facile ligand exchange in solution. Despite the rapid developments in the chemistry of bismuth resulting from demonstrated bioactivity[1] and the need for viable synthetic approaches to new materials,[2] systematic assessments of coordinative environments for bismuth still require the identification, characterization and classification of numerous structural possibilities. Thiobismuth derivatives are perhaps the most extensively studied series of bismuth compounds owing to their high thermal and reactive stability, and include complexes of thiolato,[3,4] dithiocarboxylato derivatives,[5] thione[6] and thioether[7] ligands. Numerous examples of multithiolato compounds (**1** and **2**) have been structurally characterized, but monothiolato complexes of type **3** have only been postulated on the basis of spectroscopic data.[8]



**1a** **2a** **3a**

**1b** **2b** **3b**

Here we describe the isolation and characterization† of ammoniumthiolatobismuth halides **4**, which are formed in high yield independent of stoichiometry in the reactions of $HSC_2H_4NMe_2HX$ with either $Bi(NO_3)_3$ or $BiX_3$ (X = Cl **a**, Br **b**). An X-ray crystallographic study of **4a** (Fig. 1) confirms the empirical formula and the pendant ammoniumethanethiolato moiety. The one-dimensional spirocyclic polymeric array, typical of bismuth halides,[4,9] is due to association of the bismuth centres by alternating chlorine and sulfur coordinative bridges, imposing a near octahedral, six-coordinate environment for bismuth. The two Bi–$Cl_{terminal}$ bonds [2.615(4), 2.636(3) Å] are predictably shorter than the Bi–$Cl_{bridging}$ bonds [2.776(4), 3.001(4) Å], and the Bi–S bond [2.669(3) Å] which is *trans* to the Bi–$Cl_{bridging}$ bonds is significantly shorter than that which is *trans* to the Bi–$Cl_{terminal}$ [2.927(3) Å] bond. These comparisons can be interpreted in terms of the bismuth centre engaging four covalent bonds (three to chlorine and one to sulfur) and two bridging coordinative bonds (one to chlorine and one to sulfur), which presumably dissociate on solvation to give the monomer in solution.

Although observation of a monothiolatobismuth environment of type **3b** in derivatives of **4** is contrary to the prominent thiophilicity of bismuth and the tendency towards maximum metathesis (which gives bonding environments **1** and **2**),[4,10–12] the quantitative halogenation of bismuth in the reaction of $Bi(NO_3)_3$ with $HSC_2H_4NMe_2HX$ implies that derivatives of **4** are thermodynamically favoured. In addition, formation of **4** contrasts the extensive chelation chemistry of bismuth, and specifically the reaction of aminoethanethiol (the conjugate base of $HSC_2H_4NH_3X$) with $Bi(NO_3)_3$ in acetic acid, which gives **5a** $(NO_3)\cdot H_2O$ as the result of a double metathesis.[12] We conclude that the thiophilicity of $Bi^{3+}$ is greater than that of $BiX_3$ (X = Cl, Br), and the higher basicity of the halide ligands restricts thiolation. Interestingly, $Bi(NO_3)_3$ and $BiX_3$ react with mercaptoethanol ($HSCH_2CH_2OH$) to give **5b** by virtue of bisthiolation,[10,11] implying that the higher protic basicity of the amine inhibits the chelation which is observed for the hydroxythiolate.

**4a** X = Cl
**b** X = Br

**5a** E = $NH_2$
**b** E = OH

Derivatives of **4**, as the first examples of bonding type **3b**, represent a fundamental missing link in the developing chemistry of bismuth, and their thermodynamically favoured formation bodes well for efficient and systematic assessment of a potentially extensive new direction, including anions of the type $[X_3BiSR]^-$, which we are currently examining.

We thank the Natural Sciences and Engineering Research Council of Canada for funding, the Atlantic Region Magnetic Resonance Centre and the Dalhousie Mass Spectrometry Centre for the use of instrumentation.

# Synthesis and redox properties of MCM-48 containing copper and zinc

**Martin Hartmann,* Sandrine Racouchot and Christian Bischof**

*Institute of Chemical Technology I, University of Stuttgart, D-70550 Stuttgart, Germany*

**MCM-48 materials, synthesized for the first time in the presence of copper and zinc salts, show remarkable redox properties in contrast to materials prepared by ion-exchange or impregnation.**

Since their rediscovery (as we learned recently[1] these materials were discovered more than 25 years ago) by researchers of the Mobil Oil Company in 1992[2,3] ordered mesoporous materials (denoted as M41S) have initiated intensive research resulting in an overwhelming number of publications. However, most studies have dealt with the hexagonal form, MCM-41.[4,5] MCM-48, the cubic member (space group $Ia\bar{3}d$) of the M41S family was investigated only in a limited number of studies.[6–9] The third member of the M41S family, MCM-50, is an unstable lamellar phase.[2,3]

The incorporation of transition metal ions into micro- or meso-porous molecular sieves is of considerable interest for catalytic applications. For MCM-48 to be useful with respect to catalytic applications, metal ions have to be incorporated into the amorphous walls. Attempts on the incorporation of Al, Mn, V, Ti and Cr have been reported so far.[11–14] Temperature programmed reduction (TPR) is a useful tool for collecting information on the redox properties of transition metal ions in zeolites and other porous supports.

The present work describes the first redox-type MCM-48 material containing copper and zinc introduced during the synthesis of the material. Temperature programmed reduction experiments of the calcined material show the availability of copper for redox reactions.

The MCM-48 materials were synthesized using cetyltrimethylammonium bromide (CTAB), tetraethylorthosilicate (TEOS) and NaOH. A gel with a molar composition of 0.61 CTAB : 1 $SiO_2$ : 0.25 $Na_2O$ : 61 $H_2O$ was prepared and different amounts of $Cu(MeCO_2)_2 \cdot H_2O$ and $ZnSO_4 \cdot 2H_2O$ were added. The resultant gel was loaded into autoclaves and heated to 373 K for 72 h. After synthesis the materials were recovered by filtration, washed with water and ethanol and finally calcined in flowing nitrogen up to 200 °C and in flowing air up to 540 °C for 18 h. For comparison, copper containing MCM-48 samples have been prepared by ion-exchange and impregnation, using standard procedures. The resulting materials were characterized by powder X-ray diffraction (XRD), atomic absorption spectroscopy, nitrogen adsorption and desorption (at 77 K) and temperature programmed reduction (TPR). The TPR measurements were performed in an Altamira AM1 instrument with a flow of 10 vol.% $H_2$ in Ar. A heating rate of 3 K $min^{-1}$ was chosen to enhance resolution and avoid 'hot spots'. Prior to the first reduction experiment, the samples were activated in a helium flow containing 10 vol.% $O_2$ up to a maximum temperature of 400 °C at a rate of 5 K $min^{-1}$.

The powder X-ray diffraction patterns of the calcined CuMCM-48, CuZnMCM-48 and ZnMCM-48 materials are presented in Fig. 1 and correspond well with those reported for pure siliceous MCM-48. XRD studies reveal that MCM-48 materials can be synthesized in the presence of copper and zinc salts. While the addition of copper acetate to the synthesis gel up a ratio $n_{Si}/n_{Cu} = 15$ has no influence on the quality of the XRD pattern, the ZnMCM-48 materials show XRD patterns with somewhat lower intensity. Assuming cubic symmetry, the unit cell size of the calcined materials was calculated to be 9.36 nm for CuMCM-48, 9.31 nm for CuZnMCM-48 and 8.45 nm for ZnMCM-48 (Table 1).

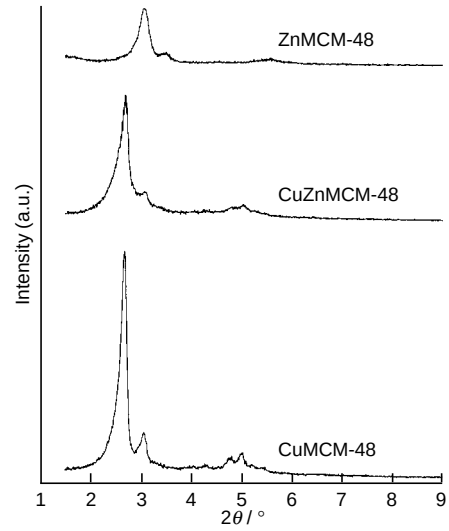

**Fig. 1** X-Ray diffraction pattern of as-synthesized CuMCM-48, CuZnMCM-48 and ZnMCM-48

The $N_2$ isotherms (Fig. 2) show no hysteresis in all samples under investigation. The surface area of the transition metal ion containing materials is reduced in comparison to the pure siliceous material. The surface areas and pore diameters were calculated from the nitrogen adsorption–desorption isotherms using BET and BJH analysis. The results of these calculations and the chemical analysis are collected in Table 1. The molar silicon/metal ratios of the starting gel were $n_{Si}/n_{Me} = 80$ leading to a reduced ratio in the calcined materials.

In agreement with the XRD powder pattern the nitrogen adsorption is largely reduced in ZnMCM-48 with $n_{Si}/n_{Zn} = 80$, while copper introduction does not affect the adsorption capacity. Similar findings were reported on AlMCM-41 materials,[15] showing that the mechanism of copper and zinc introduction might be significantly different. While co-precipitation of $Cu(OH)_2$ or complexation of $Cu^{2+}$ by the surfactant under the basic conditions of the synthesis prevent encapsulation of copper into the amorphous walls, Zn can be expected to be in the walls of MCM-48 as claimed in the Mobil patent.[16] The copper species can be removed by washing of the as-

**Table 1** Properties of the samples under investigation

| Sample | $n_{Si}/n_{(Cu+Zn)}$ | $n_{Cu}/n_{Zn}$ | $a_0$/nm | $A_{BET}$/ $m^2\ g^{-1}$ | $d_p$[a]/nm |
|---|---|---|---|---|---|
| MCM-48 | — | — | 8.33 | 1400 | 2.4 |
| CuMCM-48 | 35.8 | — | 9.36 | 1136 | 2.3 |
| CuZnMCM-48 | 48.5 | 1.4 | 9.31 | 1059 | 2.3 |
| ZnMCM-48 | 53.2 | — | 8.45 | 925 | 1.9 |

[a] The pore diameters were calculated from the desorption branch of the adsorption isotherm using the BJH model.

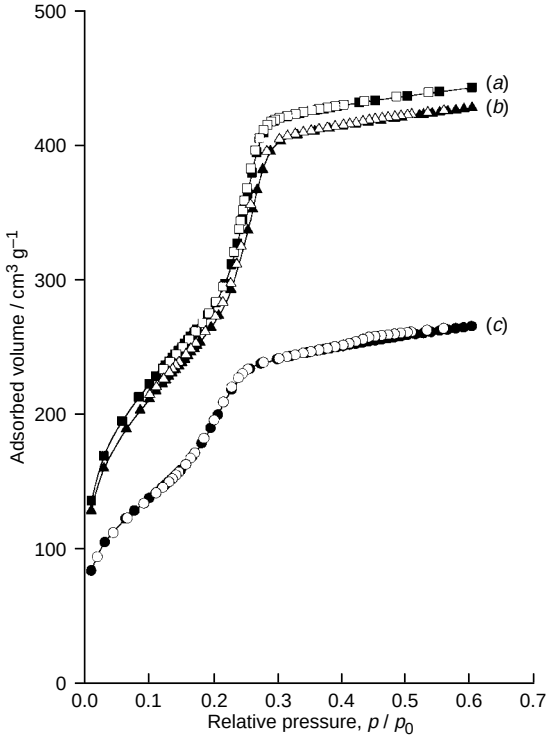

**Fig. 2** Nitrogen adsorption (closed symbols) and desorption (open symbols) at 77.3 K of (*a*) CuMCM-48, (*b*) CuZnMCM-48 and (*c*) ZnMCM-48

synthesized samples with 0.1 M HCl solution at 80 °C and are therefore most likely located within the channels. Complexation of copper by the surfactant has been established by EPR spectroscopy.[17]

The TPR profiles of CuMCM-48 and CuZnMCM-48 are displayed in Fig. 3. The sharp maximum of hydrogen consumption at 164 °C is accompanied by a shoulder at 184 °C (CuMCM-48). Temperatures in this range can be associated with the reduction of finely dispersed CuO to copper metal in the channels of MCM-48. The copper oxide is formed during calcination and/or sample pretreatment along with a color change from blue to brown. After the TPR experiment the sample exhibits a gray–red color, which is typical for copper metal clusters. The structural integrity of the sample has been checked by XRD and $N_2$ adsorption. The complete reduction of CuO dispersed on MCM-48 can be achieved at a substantial lower temperature than on $\gamma$-$Al_2O_3$ (210 °C)[18] or $SiO_2$ (350 °C).[19] Copper impregnated (Fig. 3) or ion-exchanged MCM-48

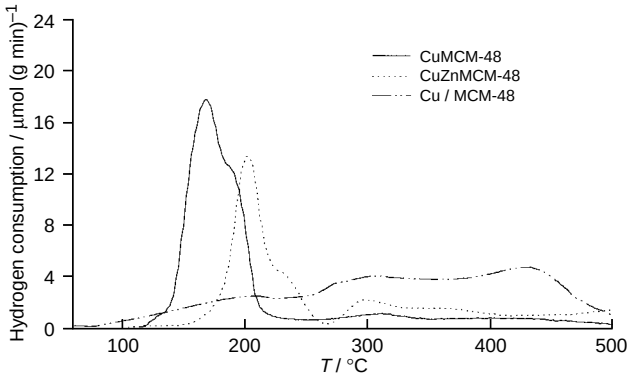

**Fig. 3** TPR profiles of CuMCM-48, CuZnMCM-48 and Cu/MCM-48

(not shown) do not exhibit a sharp signal in this temperature range. The reduction of CuO diluted with $SiO_2$ can be observed at 220 °C.

CuZnMCM-48 exhibits a somewhat different TPR profile. In comparison with the TPR profile of CuMCM-48 the reduction occurs at a significantly higher temperature (197 °C), but the halfwidth of the peak and the degree of reduction are remarkably reduced. The delay in copper reduction owing to the presence of zinc has been well observed in zeolites and CuO/ZnO catalysts.[20] The synergistic effect of zinc in reduction of copper is exploited for the commercial methanol catalyst (CuO/ZnO/$Al_2O_3$)[21] and has been shown for the first time to be effective in the M41S class of materials, with copper and zinc introduced *via* synthesis. The low reduction temperatures in the MCM-48 materials compared to silica might be associated with the size of the copper oxide particles. Smaller CuO particles are expected to be reduced at lower temperatures. This finding is further substantiated by an increase in reduction temperature with repeated redox cycles leading to agglomeration of smaller particles.[22]

Financial support by Deutsche Forschungsgemeinschaft (DFG) and Fonds der Chemischen Industrie is gratefully acknowledged. We are also grateful to Prof. J. Weitkamp for continuous support.

# Determination of localised corrosion mechanisms using a scanning vibrating reference electrode technique

**D. A. Worsley, H. N. McMurray and A. Belghazi**

*Department of Materials Engineering, University of Wales Swansea, Singleton Park, Swansea, UK SA2 8PP*

**A scanning electrochemical technique is used to show the influence of differential aeration on the kinetics and mechanism of corrosion reactions occurring at the exposed edge of galvanised sheet steels overcoated with organic layers of dissimilar thickness.**

Mass produced organic coated galvanised sheet steel is of increasing importance in the construction industry. Metallic corrosion at exposed cut edges is a potential failure mechanism[1] which must be assessed when evaluating the performance of new coating technologies. Conventional methods for evaluating cut edge performance are empirical and rely on the measurement of coating delamination rates under accelerated corrosion conditions. This is often time consuming and gives little mechanistic information. Various conventional electrochemical techniques, most notably electrical impedance spectroscopy,[2–4] have been used to study the corrosion of organic coated metals. However, none of these techniques possess the spatial resolution necessary to investigate properly the highly localised electrochemical reactions occurring at the cut edge, where dissimilar metal surfaces are closely approximated. The scanning vibrating reference electrode technique (SVRET) enables the quantitative mapping of localised ionic current fluxes by the measurement of potential gradients in solution, and has been successfully used to investigate both galvanic[5–10] and pitting[11,12] corrosion. Here we describe the use of SVRET to elucidate the kinetics and mechanism of cut edge corrosion in a model series of laboratory prepared organic coated galvanised steel samples.

SVRET measurements are carried out in aqueous electrolyte and employ a vibrating microtip electrode which is mechanically scanned at a small fixed distance from the corroding surface. It has been shown[5] that the ac voltage signal detected by the vibrating electrode is proportional to the potential gradient ($F$) parallel to the direction of vibration which is in turn proportional to the current density component in that direction. Thus for a point current source ($i$) in a medium of conductivity $\kappa$, the value of $F$ at any distance $x$, $y$ and $z$ from the source is given by:

$$F = \frac{iz}{2\pi\kappa(x^2 + y^2 + z^2)^{1.5}} \quad (1)$$

The apparatus used in this study comprised a 125 μm diameter platinum microdisc electrode vibrated normal to the scanned surface with a frequency of 140 Hz and amplitude of *ca*. 25 μm. The vibration frequency was set by a lock-in amplifier (EG & G model 5110) which also served to detect the SVRET signal. The vibrating electrode was positioned using a motorised, computer controlled, micromanipulator platform. All measurements were carried out in 0.86 M aqueous NaCl at 25 °C. The apparatus was calibrated using a known current density and was shown to exhibit an excellent linear response in the range 0.05–125 A m$^{-2}$ at the scan height of 125 μm.

Laboratory prepared model samples were prepared from 1 mm thick sheet steel (composition: Fe 99%), which had been hot-dip coated in a molten zinc bath containing *ca*. 0.2 mass% Al to produce a 20 μm coating of practically pure zinc (composition Zn 99.85%, Al 0.15%) with minimal formation of iron–zinc intermetallic phases.[13] The galvanised samples were pre-treated with chromic acid to aid polymer adhesion before being overcoated on both sides with a 5 μm thickness of a heat cured epoxy based polymer (Beckers PVC primer supplied by Beckers Paints Ltd). This was performed on a continuous coil coating line with the organic coating applied using rollers. A 140 μm laminate coating, consisting of PVC, was then applied to one or both sides of the sheet to produce asymmetrically and symmetrically coated samples. The coated samples were cut into 2 × 1 cm coupons and all but one cut edge masked using epoxy adhesive. The exposed cut edge was carefully polished flat using fine emery paper (down to 1200 grade). The polished coupons were immersed in a shallow electrolyte bath which was in contact with room air. The concentration of dissolved oxygen (in bulk solution) was therefore assumed to be approximately constant at 2 × 10$^{-5}$ mol dm$^{-3}$.[14] The exposed cut edge was positioned uppermost and horizontal, and scanned repeatedly with the vibrating probe moving in a plane 125 μm above the exposed metal surface. The results of this type of experiment are illustrated in Fig. 1(*a*)–(*c*) which show isocurrent contour maps of ionic current density in the plane of scan. Areas of positive current, associated with anodic activity at the metal surface, are shown as light and areas of negative current, associated with cathodic activity, are shown as dark. Free corrosion potentials of −0.65 and −1.05 V *vs*. SCE were measured in 0.86 M aqueous NaCl for mild steel and zinc respectively and it is therefore to be expected that zinc coating will cathodically protect steel at the cut edge. On this basis it is assumed that the predominant electrochemical reactions occurring under the experimental conditions are the anodic dissolution of zinc [eqn. (2)] and the cathodic reduction of oxygen at the steel surface [eqn. (3)].

$$Zn = Zn^{2+} + 2e \quad (2)$$

$$O_2 + 2H_2O + 4e = 4OH^- \quad (3)$$

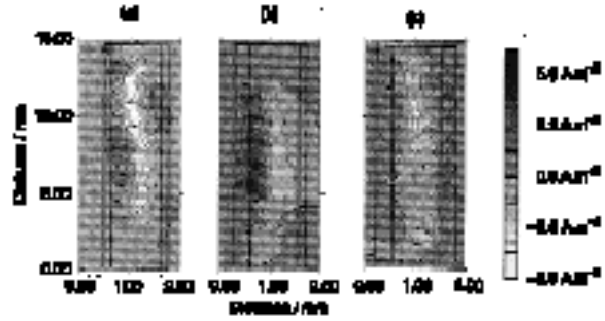

**Fig. 1** Isocurrent contour plots showing the anodic (light) and cathodic (dark) current density distributions over (*a*) a corroding cut edge with 5 μm epoxy primer both sides, (*b*) an identical sample with a 140 μm PVC coating applied to one side and (*c*) an identical sample with a 140 μm PVC coating applied to both sides. The sample position is shown together with schematic representations of the relative coating thicknesses applied to each side of the sample.

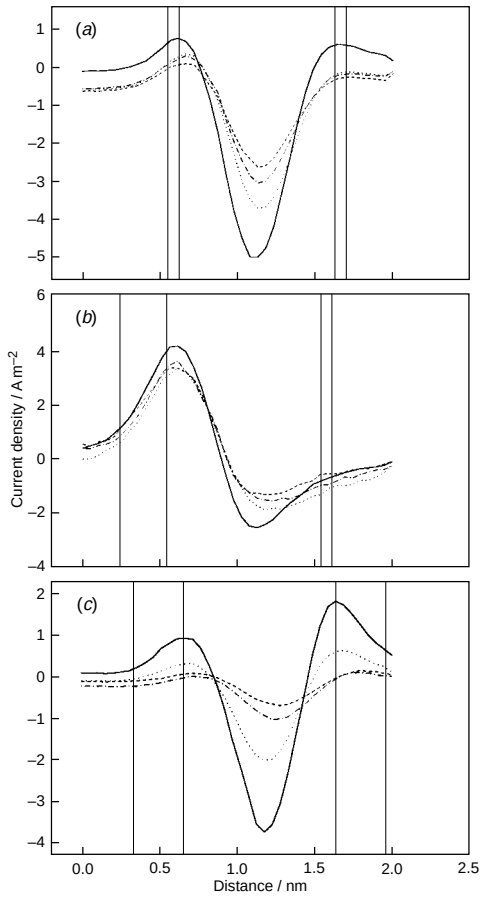

**Fig. 2** Normal component of current density distribution in plane of the scan across the thickness of the cut edge for successive scans over a 6 h period for (*a*) 5 μm epoxy primer both sides, (*b*) an identical sample with a 140 μm PVC coating applied to one side and (*c*) an identical sample with a 140 μm PVC coating applied to both sides after 0 h (—), 2 h (···), 4 h (–·–·–) and 6 h (---) immersion in 5% NaCl. The sample position is shown together with schematic representations of the relative coating thicknesses applied to each side of the sample.

Fig. 1 shows the differences in localised corrosion behaviour exhibited by cut edge samples prepared with symmetric and asymmetric thickness of organic coating. Symmetrically coated samples [Fig. 1(*a*) and (*c*)] show the anticipated symmetrical pattern of electrochemical activity with the cathodic steel surface bounded on either side by strips of anodic zinc. However, asymmetrically coated samples show a marked displacement of cathodic activity to the side where the organic coating is thinner, with a corresponding concentration of anodic activity on the more thickly overcoated zinc layer. This finding is perhaps more clearly illustrated in Fig. 2 in which current density data from individual, hourly repeated, area scans have been summed along the length of the cut edge so as to derive a series of current profiles representing the average current distribution across the thickness of the edge as a function of time. It may be seen from Fig. 2 that, in addition to any instantaneous differences in current distribution, current values decay markedly with time for symmetrical organic coatings, whereas for the asymmetric coating currents are substantially undiminished after 6 h.

The sharp difference in current distribution observed between the asymmetrically and symmetrically coated cut edge samples is probably due to the establishment of a differential aeration cell in the asymmetric case [illustrated in Fig. 1(*b*) and Fig. 2(*b*)]. Differential aeration arises for two reasons. Firstly, the thinner organic coating presents a smaller geometrical obstacle to oxygen diffusing or convecting through the electrolyte to the exposed metal surface. Secondly, the oxygen permeability of a coating will be inversely proportional to the coating thickness.[15] Higher steady state oxygen concentrations at the solution contacting zinc surface lying on the side of the thinner coating favour local cathodic activity through reaction (3).

In recent work[16] it has been shown that the cathodic reduction of oxygen, and hydrolytic processes catalysed by the $OH^-$ ions so produced, are key reactions in promoting the disbondment of organic polymer coatings. This implies that the extent of cathodic activity occurring immediately proximate to the polymer–metal interface will be the most significant factor determining rates of coating disbondment. The rapid decay of currents observed for the symmetrically coated samples may therefore be ascribed to blockage of the originally exposed metal surface by corrosion products with little or no fresh metal surface becoming available due to disbondment of the organic coating. Two basic chloride corrosion products [$6Zn(OH)_2{\cdot}ZnCl_2$ and $4Zn(OH)_2{\cdot}ZnCl_2$] have been identified for zinc corroding in NaCl solutions exceeding 0.1 M.[17] The much slower decay of currents observed for the asymmetrically coated samples may be ascribed to the continuous exposure of fresh metal surface through cathodic disbondment of the thinner organic coating as a result of intense cathodic activity immediately proximate to the zinc–polymer interface. Indeed, visible degradation of the thinner coating was observed in similar samples exposed to 5% NaCl for extended periods with *ca*. 500 μm delamination in 170 h.

The results obtained from the model system also indicate that differential aeration can be an important factor in the mechanism of cut edge corrosion in quiescent solutions of bulk electrolyte.

We thank British Steel Strip Products, Port Talbot and the EPSRC for funding this research under the Materials for Better Construction Initiative.

**The synthesis of a novel layered sodium titanosilicate, $Na_3(Na,H)Ti_2O_2[Si_2O_6]_2.H_2O$ (AM-4), and the solution of its crystal structure by *ab initio* methods are reported.**

Mixed framework minerals and synthetic compounds with structures built from common polyhedral units (octahedra and tetrahedra sharing all oxygens with at least two other neighbouring polyhedra) are of great interest, particularly with respect to host–guest chemistry, structural diversity, ion-exchange and adsorption properties, and shape selective catalysis. The large class of titanium silicates encompasses more than 70 minerals, mainly with mixed cation frameworks. During the last decade ynthetic inorganic and materials chemists have attempted to prepare titanium silicates by using high-temperature solid state ceramic and hydrothermal methods. Recently, we have reported the synthesis of analogues of minerals nenadkevichite,[1] umbite, narsarsukite[2] and penkvilksite.[3,4] We have also solved the structures of the important microporous material ETS-10,[5] as well as rhombohedrally distorted $Na_4[Ti_4O_4(SiO_4)_3]_6\cdot H_2O$.[6] Here, we wish to report the synthesis and structure determination of a novel titanium silicate layered compound, monoclinic $Na_3(Na,H)Ti_2O_2[Si_2O_6]_2\cdot 2H_2O$.

In a typical AM-4 synthesis, an alkaline solution was prepared by mixing 27.04 g sodium silicate solution (27% m/m $SiO_2$, 8% m/m $Na_2O$, Merck), 14.76 g NaOH (EKA Nobel) and 38.46 g $H_2O$. To this 40.30 g of $TiCl_3$ (15% m/m solution of $TiCl_3$ in 10% m/m HCl, Merck) were added and stirred thoroughly. The gel, with a composition 5.6 $Na_2O$ : 3.1 $SiO_2$ : 1 $TiO_2$ : 123 $H_2O$, was autoclaved at 230 °C under autogeneous pressure for 4 d. The Teflon-lined autoclaves were then quenched in cold water. The crystals, obtained in 80% yield, were filtered off, washed at room temp. with distilled water and dried overnight at 100 °C.

Thermogravimetry (TGA-50 Shimadzu analyzer) gives a total mass loss between 20 and 500 °C of *ca.* 7.4%. The crystal morphology and elemental analysis of crystals were studied on a JEOL JSM-6400 (SEM) and JEOL 2000FX (TEM). The sample studied has an Na : Ti : Si composition ratio of *ca.* 2 : 1 : 2. Diffraction data were collected with a Siemens D500 powder diffractometer using Co-K$\alpha$ X-radiation (1.799 Å). Intensity data for *h, k, l* were collected by the step counting method (step 0.01° and time 30 s) in the range 2$\theta$ 5–100°. X-Ray diffraction pattern autoindexing was performed with the PROSZKI package[7] from the well resolved first 40 lines with an absolute error of 0.02 (2$\theta$) on peak positions. A monoclinic cell swas indicated by the DICVOL[8] and POWDER[9] indexing programs with high figures of merit. Since different programs employing various indexing strategies yielded the same results, the unit cell parameters obtained were taken as correct and were refined with a non-peak weighting scheme by APPELMAN[10] which yielded $a$ = 5.19(3), $b$ = 8.59(5), $c$ = 29.35(5) Å and $\beta$ = 89.40(2)°. The space group $A2/a$ (no. 15) was unambiguously determined from systematic absences: $k + l = 2n$ ($hkl$) and $h + l = 2n$ ($h0l$). Peak intensities were altered by changing the method of sample preparation indicating the occurrence of preferred orientation effects. Scanning electron microscopic observations of crystal morphology showed that the crystalline material consists of 10–15 μm platelet single crystals likely to produce orientation effects. In order to reduce preferred orientation effects the side-loading technique was used. The program EXTRA[11] was used to extract structure factor amplitudes of 439 reflections occurring in the 2$\theta$ interval measured by the LeBail method.[12] At this stage, the following refined unit cell parameters were obtained: $a$ = 5.187, $b$ = 8.582, $c$ = 29.239 Å and $\beta$ = 89.49°.

In the absence of heavy atoms, the crystal structure was solved by direct methods using the program SIRPOW optimised for powder data.[13] Structure factors of 254 (excluding the first and several other high-angle overlappings) reflections were used. The solution of the crystal structure was performed in absence of reliable data on the chemical composition of the compound, its density and unit cell contents. This resulted in the

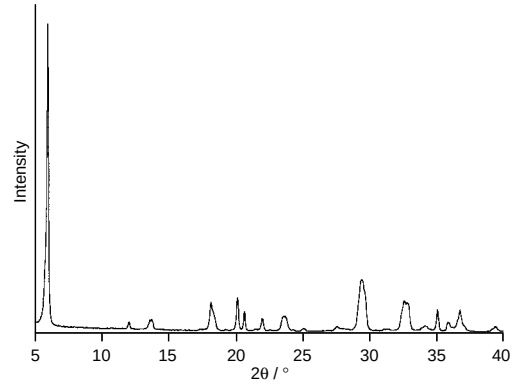

**Fig. 1** X-Ray diffraction pattern of AM-4 recorded with Cu-K$\alpha$ radiation (this was not the data used for structure refinement which was recorded with Co-K$\alpha$ radiation)

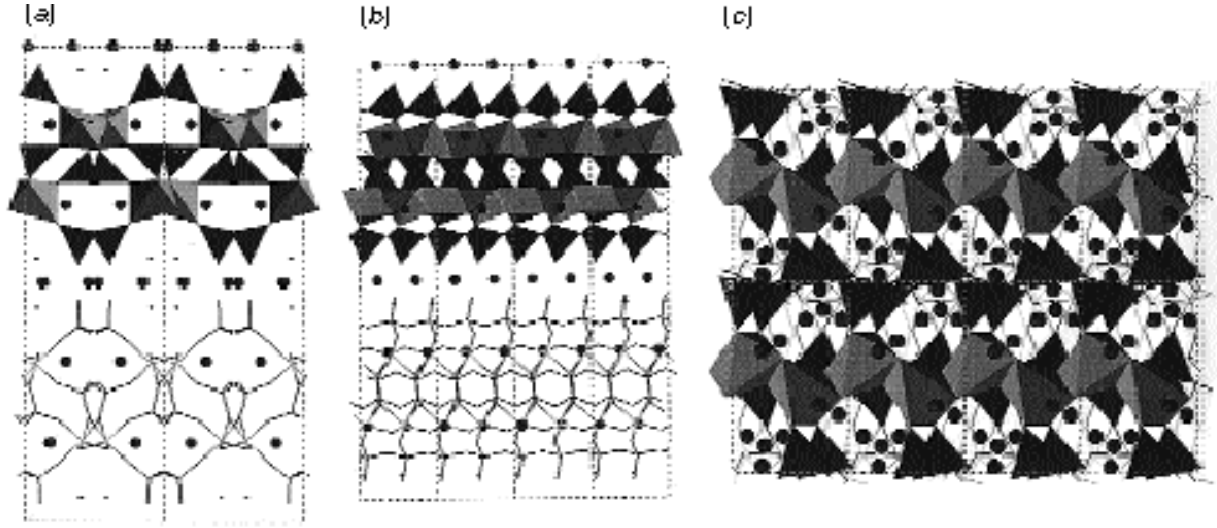

**Fig. 2** Structure of AM-4: (*a*) viewed down [100] showing the small cages containing sodium cations within the titanosilicate layers and further sodium cations between the layers; (*b*) viewed down [010]; (*c*) viewed down [001] showing chains of edge-sharing $TiO_6$ octahedra connected by chains of corner-sharing $SiO_4$ tetrahedra

need to vary the unit cell contents and the default settings of SIRPOW. Most atoms were located simultaneously, however, relabelling of atoms was necessary coupled with bond distance and bond angle changes. This procedure was alternated with least-squares refinement.

The coordinates of atoms obtained from direct methods were used in the Rietveld refinement of the structure by GSAS and are given in Table 1.[14] The final profile analysis refinement was carried out in the range $2\theta$ 13–70° and involved the following parameters: structural, 42 atomic coordinates, 14 isotropic temperature factors; profile, one scale factor, three halfwidth, three cell parameters, one peak asymmetry parameter; global parameters, one zero point, six coefficients of polynomial background. Because of instability of the peak shape coefficients several soft constraints to some of the bond distances were applied. The final results of the refinement fit correspond to a satisfactory model of the crystal structure, [$R(F^2$ = 4.5%] and profile factors ($R_p$ = 6.8%, $wR_p$ = 9.4%) indicators: space group *A*2/*a* (no. 15), *a* = 5.2012(8), *b* = 8.573(2), *c* = 29.300(6) Å, $\beta$ = 89.26(1)°, *U* = 1306.4(4) Å$^3$, *Z* = 4, $D_c$ = 2.74 g cm$^{-3}$, atoms in the asymmetric unit 14, relative mass of cell 2224.38. The experimental X-ray diffraction pattern for AM-4 is shown in Fig. 1.

The crystal structure of AM-4 is built from $TiO_6$ octahedra and $SiO_4$ tetrahedra which form layers perpendicular to [001]. Each layer consists of a five-tier sandwich of $Si_T : Ti_O : Si_T : Ti_O$-$Si_T$ (O = octahedral, T = tetrahedral) and this can be seen in Figs. 2(*a*) and (*b*). Between the layers are $Na^+$ cations and water molecules. Sodium cations also exist in small cages within the layers.

The major features of the structure are zigzag chains of edge-sharing $TiO_6$ octahedra running along [100] which are connected together by corner sharing pyroxene type $SiO_4$ tetrahedra, Fig. 2(*c*). Within the titanate chains the Ti···Ti cation repulsion is manifested in a shifting of the Ti by *ca.* 0.1 Å from the centre of the octahedron away from the shared edge. Consequently, Ti–O distances in the Ti octahedra vary widely, ranging from 1.841 Å in the oversaturated Ti–O(5) bond to 2.138 Å in the undersaturated Ti–O(7) bond. Such distortions from the average value of 1.969 Å have been observed in many so-called 'shared structures' and it produces a shortening of the shared edge O(5)···O(7) to 2.387 Å and an elongation of the opposite edge. Similar octahedral distortions take place in the structure of mineral vinogradovite.[15] The two one-dimensional and independent pyroxene-type [$Si_2O_6$] chains are also present in the structure of vinogradovite. The Si(1)–O(non-bridging) bonds are shorter than the Si(1)–O(bridging) bonds, and the O(2)–Si(1)–O(7) angle, with its two non-bridging oxygen atoms, is much larger (122.7°) than other angles.

In conclusion, we report the successful synthesis and structural determination of a novel layered titanosilicate, AM-4, which may have applications in heterogeneous catalysis, adsorption, molecular sieving and cation exchange. Work is in progress to determine whether such layered materials can be pillared in a similar manner to smectite clays.

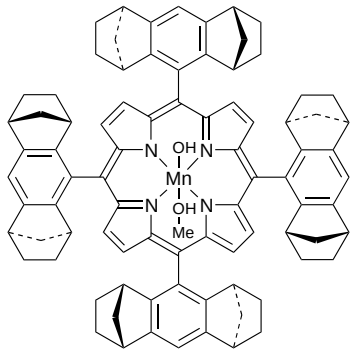
# Catalytic and asymmetric aziridination of alkenes catalysed by a chiral manganese porphyrin complex



**Tat-Shing Lai,[a] Hoi-Lun Kwong,[b] Chi-Ming Che*[a] and Shie-Ming Peng[c]**

[a] *Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong, PR China*

[c] *Department of Chemistry, National Taiwan University, Taipei, Taiwan*

**A $D_4$-manganese(III) porphyrin is utilized to catalyze aziridination of styrene-type substrates with enantiomeric excess ranging from 43 to 68%; evidence for a $Mn^{IV}$ reactive intermediate in the catalysis was obtained from spectroscopic studies and organic product analysis.**

Metalloporphyrins have potential applications in asymmetric organic syntheses.[1] When compared to metal Schiff-base complexes, they can offer more robust catalysts[2] that can lead to high product turnover numbers and facilitate the detection and/or isolation of highly reactive intermediates in the catalyses.[3,4] Here, we report the evidence of a $Mn^{IV}$ reactive intermediate in a chiral manganese $D_4$-porphyrin-catalyzed nitrene transfer reaction. This reaction also features the first example of chiral porphyrin catalysts for asymmetric alkene aziridination with moderate enantioselectivities.

The chiral manganese(III)porphyrin catalyst Mn(P*)(MeOH)(OH) [$H_2$P* = 5,10,15,20-tetrakis(1,2,3,4,5,6,7,8-octahydro-1,4 : 5,8-dimethanoanthracen-9-yl)porphyrin] **1** used in this work was prepared by the method of Halterman and Jan.[5] Upon recrystallization of **1** from MeCN–MeOH–$CH_2Cl_2$ (1 : 10 : 2 v/v) red crystals of [Mn(P*)(MeOH)(OH)]·MeCN·MeOH·3$H_2O$ were obtained. Its structure was determined by X-ray crystal analysis† and a perspective view of the molecule is shown in Fig. 1.

**1**

With this bulky porphyrin ligand, a new manganese species which is capable of catalyzing nitrene transfer to alkenes is detected immediately after mixing stoichiometric amount of **1** and PhINTs in $CH_2Cl_2$ at room temp. This species has an apparent room temp. half-life of *ca.* 30 min in $CH_2Cl_2$ and is proposed to be a $Mn^{IV}$–PhINTs adduct (Scheme 1). The $Mn^{IV}$ formulation is based on the following reasons: its UV–VIS absorption spectrum (Fig. 2) with a Soret band at 433 nm, is similar to $Mn^{IV}$ porphyrin complexes reported previously;[6] its EPR spectrum shown in Fig. 3 is consistent with a high-spin octahedral $d^3$ ion.[6] It reacts rapidly with alkenes such as styrene to regenerate the starting complex **1** with the concomitant formation of aziridine in good yield and in moderate enantioselectivity ( > 70% yield and 50% ee for styrene) (Scheme 1). The UV–VIS spectral changes of its reaction with styrene are shown in Fig. 2. With excess styrene, the reaction follows pseudo-first-order kinetics (monitored at 480 nm) and the observed rate law is: rate = $k_2$[$Mn^{IV}$][styrene] with the second order rate constant being 2.0 × $10^{-3}$ $dm^3$ $mol^{-1}$ $s^{-1}$. Attempts were made to isolate this $Mn^{IV}$–PhINTs species in solid form by removal of the solvent at low temperature. A brown solid was obtained and its IR spectrum showed bands at 1340 and 1159 $cm^{-1}$ assigned to the tosyl moiety. However, this species slowly converted to

**1** and some unidentifiable substance in solution at room temperature.

The aziridination and amination of alkenes can be rendered catalytic and enantioselective by addition of PhINTs. The results are listed in Table 1. Enantioselectivity was moderate, ranging from 40 to 68% depending on both the position and the electronic demand of the substituents, with the best result obtained with *o*-bromostyrene. At a catalyst : PhINTs : alkene ratio of 1 : 200 : 4000, the chemical yields based on the amount of PhINTs used were moderate and note that the turnover numbers were good, usually around 100. With another portion of PhINTs added, the turnover number increased from 130 to *ca*. 292 in the case of styrene (Entries 2 and 3). At a catalyst : PhINTs : alkene ratio of 1 : 600 : 4000, a turnover number of 480 and aziridine at comparable ee were obtained (Entry 4). These turnover numbers are relatively high when compared with that of the reported chiral Mn–salen catalysts.[7] For alkenes that did not possess allylic hydrogen atom (Entries 1–11), aziridine was the only product. However, for alkenes that have allylic hydrogen (Entries 12 and 13), allylic amination became the major product with only minimal aziridination occurred. This result is intriguing since only a few methods for allylic amination are known.[8] From the yields and turnover numbers, the present findings feature one of the best results for catalytic allylic amination of alkenes. The absolute configuration of the aziridine obtained was *R*.

# Absence of chiral discrimination in the interaction of tris(diphenylphenanthroline)ruthenium(II) with DNA

**Hye-Kyung Kim, Per Lincoln, Bengt Nordén and Eimer Tuite***

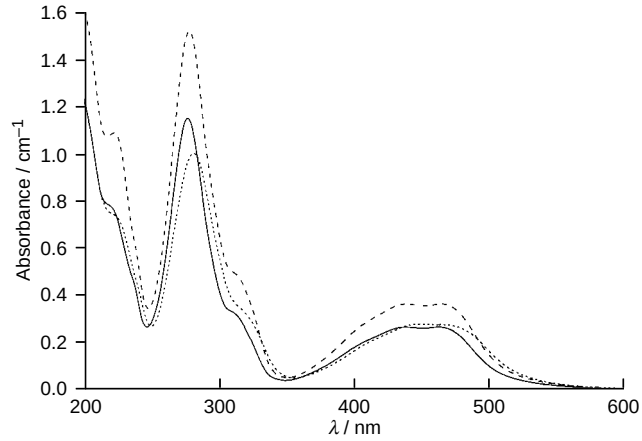
*Department of Physical Chemistry, Chalmers University of Technology, S-412 96 Göteborg, Sweden*

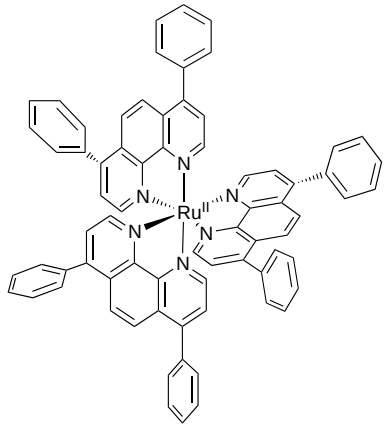
**Δ- and Λ-$[Ru(dpphen)_3]^{2+}$ (dpphen = 4,7-diphenyl-1,10-phenanthroline) bind non-intercalatively to B-form DNA and, unlike other octahedral metal complexes, show insignificant enantioselectivity in their interaction.**

Octahedral tris-diimine metal complexes possess two enantiomers having right (Δ)- and left (Λ)-handed propeller forms which might be intuitively anticipated to interact favourably with hosts having the same helical chirality, *e.g.* the right (B)- and left (Z)-handed forms of DNA, respectively. Indeed, most of these complexes have been found to interact to some degree stereoselectively with DNA.[1,2] The most dramatic reported example of such behaviour is that of $[Ru(dpphen)_3]^{2+}$, (dpphen = 4,7-diphenyl-1,10-phenanthroline) for which it has been claimed that the Δ-enantiomer interacts specifically with B-form DNA and the Λ-enantiomer specifically with Z-form DNA.[3–5] It was also suggested that this compound might bind to DNA by intercalation, perhaps with a single phenyl ring of one ligand threading through the helix to lie in the opposite grove.[6] However, the hydrophobicity and limited solubility of the salts of this complex which have been examined ($Cl^-$, $ClO_4^-$, $PF_6^-$) necessitated the addition of an organic solvent (10% $Me_2SO$ in the cited studies) which could potentially have perturbed the DNA structure and influenced the findings.

In order to study the interaction of $[Ru(dpphen)_3]^{2+}$ with DNA in purely aqueous medium, we have prepared the diacetate salt of the complex, which is more soluble than those previously examined.† The experiments have been carried out in acetate buffer which minimizes precipitation problems and allows spectroscopic measurements in aqueous solution.

Interaction with DNA is demonstrated by changes in the absorption spectrum of the complex when calf thymus (CT) DNA is present [Fig. 1]. The MLCT (metal-to-ligand charge transfer) band in the visible region experiences a red-shift, a change of band shape and hyperchromism, and the changes are of equal magnitude for both enantiomers. This contrasts with the behaviour of related metal complexes such as the externally binding $[Ru(bpy)_3]^{2+}$,[6] the non-intercalating $[Ru(phen)_3]^{2+}$,[7,8]





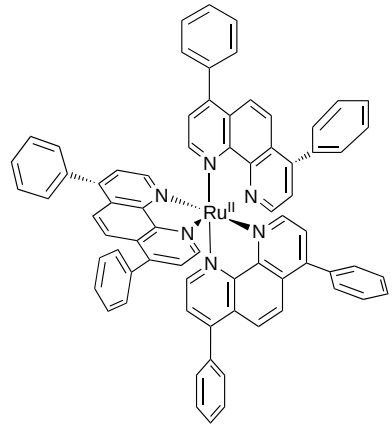


**Fig. 1** Absorption spectra of Δ-$[Ru(dpphen)_3]^{2+}$ (10 μM) in 5 mM sodium acetate buffer (pH 6.0) (—) and 50% ethanol (---) and, after subtraction of the DNA spectrum, in the presence of CT DNA (500 μM) (···). Identical changes were observed for Λ-$[Ru(dpphen)_3]^{2+}$.

and the intercalating $[Ru(phen)_2(dppz)]^{2+}$:[9] in these cases, the red-shifts in the MLCT band in the presence of DNA are accompanied by hypochromism. In order to further investigate the cause of the unusual spectral changes for $[Ru(dpphen)_3]^{2+}$, which are suggestive of a de-aggregation process, the effect of adding ethanol to an aqueous solution of the complex was examined.‡ In 50% ethanol [Fig. 1], *ca.* 33% hyperchromism, without substantial red-shifts or changes of band-shape, was observed over the entire spectrum for each enantiomer which likely results from de-aggregation of the hydrophobic metal complex, since addition of the same quantity of ethanol to a solution of the much less hydrophobic $[Ru(phen)_3]^{2+}$ (dichloride salt in the same buffer) has only a very slight hyperchromic effect (*ca.* 5%, data not shown). In the presence of DNA, it is likely that the observed spectral changes result from a combination of hyperchromism due to de-aggregation, and a

Λ-$[Ru(dpphen)_3]^{2+}$

Δ-$[Ru(dpphen)_3]^{2+}$

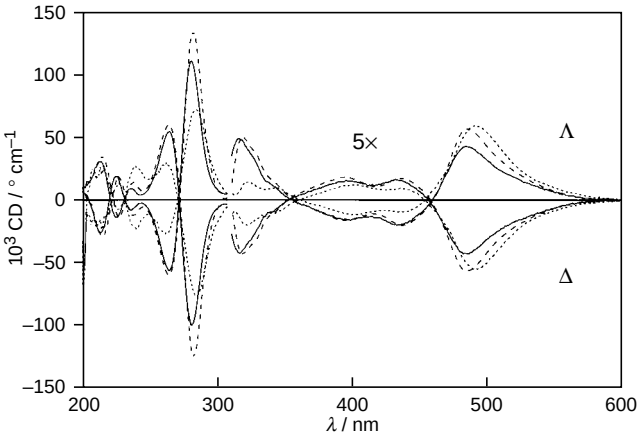

**Fig. 2** CD spectra of $[Ru(dpphen)_3]^{2+}$ enantiomers (10 μM) in 5 mM sodium acetate buffer (pH 6.0) (—) and 50% ethanol (---) and, after subtraction of the DNA spectrum, in the presence of CT DNA (500 μM) (···)

red-shift, altered band shape and hypochromism owing to the interaction with the nucleic acid (features which are quite marked in the UV region after subtraction of the DNA spectrum, assuming the latter is unaltered). The similarity of the absorption changes for Δ- and Λ-$[Ru(dpphen)_3]^{2+}$ indicates similar binding modes and affinities for both enantiomers.

In order to probe for enantioselectivity in the interaction of $[Ru(dpphen)_3]^{2+}$ with B-DNA, the circular dichroism (CD) of the complex was measured in the absence and presence of CT DNA. The Δ- and Λ-enantiomers have intrinsic CD spectra which are mirror images of each other. In the presence of DNA [Fig. 2], almost identical CD changes of equal magnitude but opposite sign were observed for the two enantiomers both in the VIS and, after subtraction of the DNA spectrum, in the UV. The CD changes due to addition of ethanol [Fig. 2] are not identical to the changes caused by DNA, so DNA binding does induce CD in addition to changes that accompany de-aggregation. Although changes of CD indicate interaction of the complex with DNA, it is not possible to interpret these changes in absolute structural terms. However, for other related metal complexes the interaction with DNA generally produces CD changes that are non-symmetric,[8,9] even for the external binder $[Ru(bpy)_3]^{2+}$. Hence, the CD spectroscopy indicates that both enantiomers interact in a similar manner with B-form DNA. This conclusion was supported by dialysis experiments of the racemate *vs*. CT DNA in which no enantioselectivity could be detected.

Linear dichroism (LD) spectroscopy has proven to be an excellent discriminator between different modes of binding of small molecules to DNA through comparison of the average orientation of the DNA bases with that of known transition moments in the molecule.[10] When $[Ru(dpphen)_3]^{2+}$ (25 μM) is added to a concentrated solution of CT DNA (500 μM), the linear dichroism observed for the metal complex in the visible region is extremely small (for Λ at *ca*. 420 nm, $LD^r$ = +0.023 normalized to perfect orientation), even by comparison with the non-intercalating $[Ru(bpy)_3]^{2+}$ complex (for Λ at *ca*. 420 nm, $LD^r$ = +0.261). This suggests that although $[Ru(dpphen)_3]^{2+}$ interacts with DNA, the orientation of the bound complex is very random which is not consistent with an intercalative geometry of the bound ligand. There is, however, a notable decrease of LD magnitude in the DNA band in the presence of $[Ru(dpphen)_3]^{2+}$ which indicates that the metal complex has a sufficiently intimate interaction with DNA to decrease its orientation.§ The DNA orientation in the presence of either Δ- or Λ-$[Ru(dpphen)_3]^{2+}$ is about 60% that of free DNA. This is a further indication of the similarity of binding of Δ- and Λ-$[Ru(dpphen)_3]^{2+}$ to B-DNA. Other metal complexes have also been found to influence DNA orientation[8,9,12] but unlike $[Ru(dpphen)_3]^{2+}$ the enantiomers usually have significantly different effects: for $[Ru(phen)_3]^{2+}$ which binds enantioselectively under similar conditions, the Δ-enantiomer causes a 50% reduction in orientation while the Λ-enantiomer affects orientation only slightly.[8]

Our conclusions are that $[Ru(dpphen)_3]^{2+}$ is an extremely hydrophobic molecule of low solubility that neither intercalates nor binds stereoselectively to B-form DNA.

This research was supported by the Carl Trygger and Wenner-Gren Foundations (E. T.), and the Swedish Natural Science Research Council (NFR) and the EU Biomed4 programme (B. N.). E. T. is grateful to the EU TMR programme for a postdoctoral fellowship.

† Resolution of racemic $[Ru(dpphen)_3]^{2+}$ was accomplished by repetitive recrystallization of its arsenyl salt from ethanol–water [arsenyltartrate of L-(+)-tartaric acid gave the Δ-enantiomer and D-(−) gave Λ]. The complex was converted to its acetate salt by dissolution of the arsenyltartrate salt in hot acetic acid and subsequent precipitation with saturated aqueous sodium acetate. The enantiomeric purities were estimated to be > 95%.

‡ At concentrations < *ca*. 20 μM there was no precipitation of $[Ru(dpphen)_3]^{2+}$. Light-scattering experiments did not indicate the formation of large aggregates (detection limit *ca*. 40 nm) and no residual absorbance was observed above 600 nm which provided a qualitative indication of light scattering for concentrations above 50 μM.

§ The $LD^r$ of added methylene blue[11] at low binding ratio was used as an internal orientation reference.[9,12]

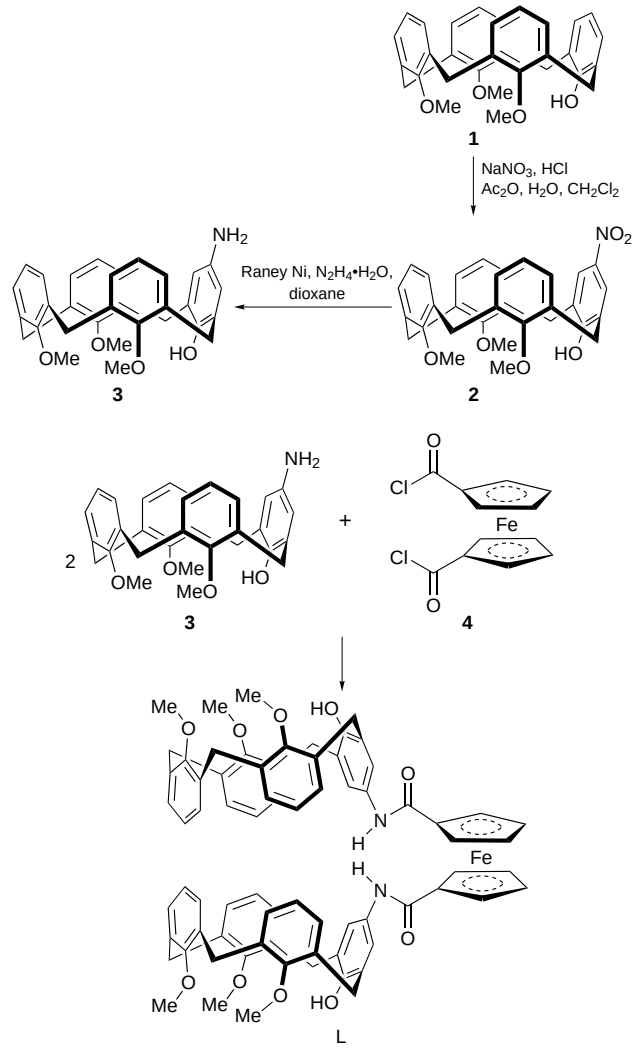
# Solvent dependent anion selectivity exhibited by neutral ferrocenoyl receptors

**Paul D. Beer* and Matthew Shade**



*Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford, UK OX1 3QR*

**The nature of the solvent medium dramatically alters the anion recognition properties of a new bis(calix[4]arene) ferrocenoyl receptor L by influencing both the magnitude of stability constants and the anion binding selectivity trend the receptor displays.**

The recognition of anionic guest species of biochemical, medical and environmental importance by positively charged or neutral abiotic receptor molecules is an area of ever increasing research activity.[1] Although a wide range of solvents and solvent mixtures have been used in anion binding studies relatively little attention has been paid as to how the nature of the solvent affects the stability of anion–receptor complexes[2] and perhaps more importantly the anion selectivities of the receptors. We report here a preliminary investigation into the complexation of a number of anions in a range of solvents by a new neutral, amide functionalised ferrocenoyl bis(calix[4]arene) receptor[3] and demonstrate the novel finding that the solvent medium alone can dramatically influence the anion selectivity preference of a particular neutral amide containing receptor.

The trimethoxy lower-rim substituted calix[4]arene compound **1**[4] was treated with sodium nitrate and hydrochloric acid to produce the nitro derivative **2** in 80% yield. Using Raney nickel and hydrazine hydrate, **2** was reduced to the amine **3** and immediately condensed with 1,1′-bis(chlorocarbonyl) ferrocene **4**[5] to afford the new ferrocenoyl-bis(calix[4]arene) L as an orange solid in 82% yield (Scheme 1).

The anion coordination properties of L were investigated by $^1$H NMR anion titration experiments in $CD_2Cl_2$, $CD_3CN$ and $(CD_3)_2CO$ solutions with tetrabutylammonium chloride, benzoate and acetate salts. Significant downfield perturbations of the receptor's amide, cyclopentadienyl and upper-rim calix aromatic protons *ortho* to the amide groups were observed in all solvents suggesting anion binding is taking place at the bis(calix[4]arene)–ferrocenoyl upper-rim vicinity of the receptor. Stability constants were calculated from the resulting titration curves using EQNMR[6] and these values are presented in Table 1, and, for comparison purposes, Table 2 displays stability constant data for the non-calix[4]arene receptor **5**. It is immediately apparent from both Tables that the solvent exerts a very great effect on the complex equilibrium between the receptor and anionic guest with the magnitude of stability constant varying by over two orders of magnitude in some cases. A comparison of the data shows that there is no obvious relationship between complex stability and bulk solvent properties such as relative permittivity ($\varepsilon$) and dipole moment ($\mu$). It is noteworthy however, that there is a correlation between the stability constant values and the Gutmann acceptor number (AN) of the solvent,[7] which gives a quantitative measure of the solvent's hydrogen-bond donor ability. Both Tables show that as AN decreases, the stability constant values increase. A solvent with a greater AN acts as a more effective hydrogen-bond donor so solvates anions to a greater extent and competes with the receptor for binding of the anion. What is of real significance is the observation that the anion selectivity preferences of both receptors change as the solvent AN decreases. L exhibits the solvent dependent selectivity trends ($CD_2Cl_2$) $PhCO_2^-$ > $Cl^-$ > $MeCO_2^-$; ($CD_3CN$) $PhCO_2^-$ > $MeCO_2^-$ > $Cl^-$; [$(CD_3)_2CO$] $MeCO_2^-$ > $Cl^-$ > $PhCO_2^-$ while **5** shows ($CD_2Cl_2$) $PhCO_2^-$ ≈ $MeCO_2^-$ > $Cl^-$;

$[(CD_3)_2CO]$ $MeCO_2^-$ > $PhCO_2^-$ > $Cl^-$. These selectivity sequences may be rationalised in terms of relative anion solvation. As the hydrogen-bond donor ability of the solvent (AN) decreases the smaller, harder anions, acetate and chloride, become bound preferentially over the larger, charge diffuse benzoate. In the same manner that chloride and acetate are more heavily solvated in even very weakly protic solvents, in aprotic solvents they bind more strongly to the only protic source present, the ferrocene diamide receptor. As Tables 1 and 2 illustrate it can be concluded that the more heavily solvated anions are affected by changes in solvent to a greater extent than those which are less heavily solvated.

Interestingly with respect to receptor structure the introduction of the bis(calix[4]arene) cavity serves to amplify the solvent dependent anion stability constant values and selectivity effects. It can be seen from Tables 1 and 2 that the increases in stability constants (as AN decreases) for the bis(calix[4]arene) receptor are significantly larger than those for the non-calix[4]arene analogue **5**.

In conclusion the preliminary results presented here show that the nature of the solvent used in the study of anion binding by neutral hydrogen-bond donor receptors can determine both the magnitudes of stability constants and the anion binding selectivity. The selectivity of the receptors is best described in terms of the competition between the solvent and the receptor for the binding and solvation of the anions. The effect of the receptor's structure can be more clearly discerned when comparisons between stability constants and selectivities in different solvents are made and a suitable model compound is used.

We thank EPSRC for use of the mass spectrometry service at University College Swansea.

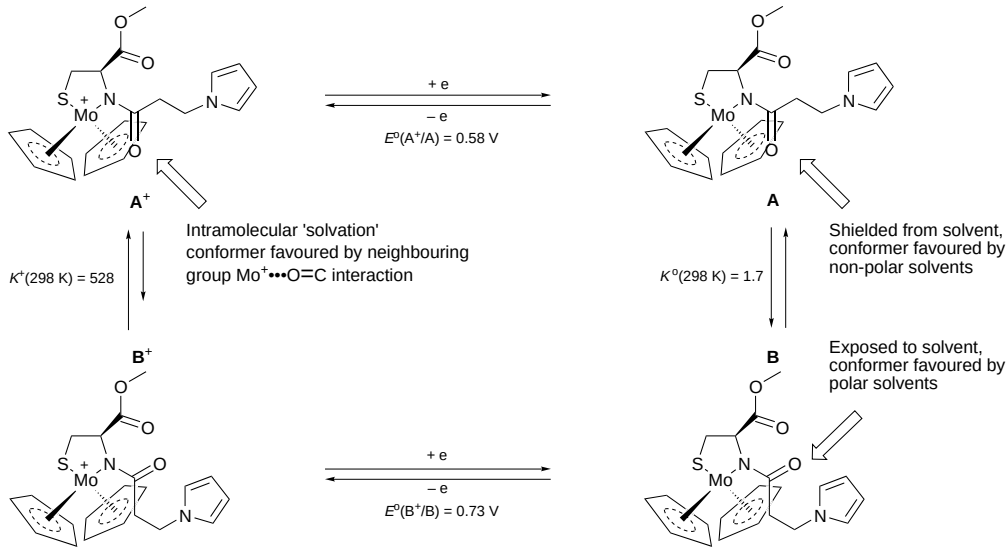
# Ligand rotamers and redox isomerism: metallo-pseudo-prolines

**Marcus C. Durrant,[a] Shirley A. Fairhurst,[a] David L. Hughes,[a] Saad K. Ibrahim,[a] Mario Passos,[a,b] Arlete Queiros[b] and Christopher J. Pickett*[a]**

[a] *The Nitrogen Fixation Laboratory, John Innes Centre, Norwich Research Park, Colney, Norwich, UK NR4 7UH*
[b] *Departamento de Química, Escola de Ciências, Universidade do Mino, Campus de Gualtar, 4700 Braga, Portugal*

**A ligand rotation which orientates the oxygen atom of an amide group towards or away from a neighbouring metal centre provides rotamers A and B with *E*° potentials which differ by 150 mV; oxidation of the metal centre of B switches the system from a state in which there is a small difference in the relative populations of the rotamers to one in which the *cis*-amide conformation greatly predominates; this new metallocycle system can be viewed as a pseudo-proline with redox sensitive rotameric properties.**



Redox-linked isomerism involving, for example, *cis–trans* rearrangement of ligands about a transition metal centre is a well established and much studied phenomenon, particularly for 17-/18-electron systems: well resolved redox processes for each isomer pair can sometimes be observed and the energetics and dynamics of interconversion of the geometric forms established.[1,2] Processes involving an essentially fixed geometric disposition of coordinating atoms about a transition metal centre and the isomerisation of a ligand rarely lead to discretely observable isomer redox processes[3] either because activation energy barriers are small and hence dynamics of isomer interconversion are fast, or because through-bond/through-space perturbations of the metal redox energetics in the two isomeric forms are weak or closely similar.

Herein we describe an exceptional system in which both the activation energy barrier for the interconversion of ligand states is sufficiently large, and electronic effects on the energetics of the redox chemistry sufficiently distinguished, to allow electrochemica observation of discrete redox isomers and their interconversion at and below ambient temperature, as set out in Scheme 1.

*N*-(3-Pyrrole-1-yl)propanoyl-L-cysteine methyl ester[4] ($H_2L$) reacts with $[Mo(\eta\text{-}C_5H_5)_2Cl_2]$ in EtOH–$NEt_3$ to give $[Mo(\eta\text{-}C_5H_5)_2L]$ which was isolated as an orange–brown crystalline material in 75% yield. $^1$H NMR [$CD_3CN$, $CD_2Cl_2$ or $(CD_3)_2NCDO$] spectroscopy of the product shows two distinct sets of resonances in each solvent, indicative of the presence of two isomeric forms of the complex. $^1$H NMR ($CD_2Cl_2$) exchange spectroscopy (EXSY) shows that the isomers interconvert. Cyclic voltammetry {MeCN, DMF or $CH_2Cl_2$–0.2 M $[NBu_4][BF_4]$; vitreous carbon} confirms the presence of two isomeric forms of $[Mo(\eta\text{-}C_5H_5)_2L]$ (**A** and **B**) each of which undergoes reversible one-electron oxidation at *E*° potentials separated by *ca.* 150 mV, Fig. 1. On the cyclic voltammetric timescale the isomer pairs **A**/**B** and $\mathbf{A}^+/\mathbf{B}^+$ are interrelated by dynamic square-scheme equilibria[2] (Scheme 1).

Cyclic voltammograms were recorded in the DMF electrolyte over a range of temperatures and scan rates and thermodynamic and kinetic parameters obtained by digital simulation of the current–potential data (Digisim 2.0).† The equilibrium constant, $K°(298\ K) = 1.7 \pm 0.1$ for the conversion of **A** to **B** estimated from the electrochemical analysis in the DMF electrolyte is concordant with that independently determined by integration of the cyclopentadienyl and methyl $^1$H NMR [$(CD_3)_2NCDO$] resonances.

X-Ray structural analysis of a crystalline sample of $[Mo(\eta\text{-}C_5H_5)_2L]$, from intensity measurements of poor quality, shows two independent molecules which are distinct conformers of the same rotamer.[5] In both molecules the Mo is chelated by cysteinyl S and amide N atoms which form part of a five-membered metallocycle ring, the amide carbonyl group is essentially co-planar with the metallocycle and its oxygen atom is deployed *trans* to the metal atom. The principal difference between the two molecules is the arrangement of the pendant $CH_2CH_2(NC_4H_4)$ group. In solution, $^1$H NMR [$CD_3CN$, $CD_2Cl_2$ or $(CD_3)_2NCDO$] data are consistent with free rotation

**Scheme 1**

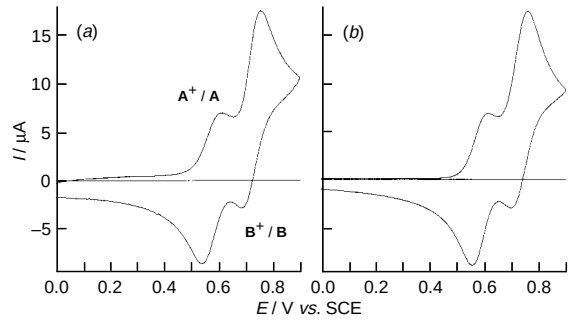


**Fig. 1** Experimental (*a*) and simulated (*b*) cyclic voltammograms for $[Mo(\eta\text{-}C_5H_5)_2L]$. Experimental data recorded in DMF–0.2 M $[NBu_4][BF_4]$ at a vitreous carbon working electrode of area 0.0707 $cm^2$; scan rate 100 mV $s^{-1}$, *T* 273 K; total concentration of $[Mo(\eta\text{-}C_5H_5)_2L]$ 2.3 mM.

about the C–C and C–N bonds in the $CH_2CH_2(NC_4H_4)$ group; evidently the difference in the solid state structures does not bear on the solution isomerism.

Molecular mechanics calculations[6] (ChemX, MM2) based on the two crystallographic structures also preclude the geometric arrangement of the pendant $CH_2CH_2(NC_4H_4)$ group as the origin of the solution isomerism. The activation energy calculated for the interconversion of the two crystallographic forms is $\Delta H^{\ddagger}_{calc.} < 5$ kcal $mol^{-1}$ (1 cal = 4.184 J) whereas the enthalpy of activation determined experimentally for the conversion of **A** to **B** in the DMF electrolyte is $\Delta H^{\ddagger}_{exp.} = 20.1$ kcal $mol^{-1}$. An activation energy barrier of this latter magnitude is more typically associated with processes involving restricted rotation about C–N amide bonds, *e.g.* DMF, 19.6 kcal $mol^{-1}$. MM2 calculations for the conversion of **A** to **B** through *cis–trans* amide bond isomerisation, as shown in Scheme 1, gives $\Delta H^{\ddagger}_{calc} = 24.7$ kcal $mol^{-1}$ which is in good agreement with the experimental data.

Further support for the *cis–trans* amide bond isomerisation process was obtained by nuclear Overhauser effect (NOE) difference spectroscopy. Irradiation of the β methylene protons of rotamer **A** in $CD_2Cl_2$ showed NOE enhancement of the γ-H resonance of the chiral centre but no enhancement of the cyclopentadienyl ring proton resonances, Fig. 2. Conversely, irradiation of the β methylene protons of rotamer **B** in $CD_3CN$ showed NOE enhancement of the cyclopentadienyl ring proton resonances but absence of NOE enhancement of the γ-H resonance, Fig. 2. This is consistent with the assignment of **A** and **B** as the *cis* and *trans*-amide isomers, respectively; the mean β-H–γ-H distances in the calculated structures are 2.3 and 4.5 Å for **A** and **B**, respectively.

The *cis–trans* amide bond isomerisation provides a rationale for other properties of the system. In the *cis* conformation the oxygen atom of the carbonyl is deployed towards the molybdenum atom (**A** calc. Mo···O distance, 3.23 Å) and through space interaction could contribute towards the stabilisation of the positive charge on the oxidised metal centre. The observation that *E*° (*cis*-rotamer $\mathbf{A}^+/\mathbf{A}$) is negative of *E*° (*trans*-rotamer $\mathbf{B}^+/\mathbf{B}$) is consistent with this (**B** calc. Mo···O distance, 4.3 Å). Stabilisation of $\mathbf{A}^+$ by what might be considered as intramolecular solvation by the amide oxygen explains why $\mathbf{A}^+$ is the thermodynamically favoured cation. The equilibrium constant for the conversion of $\mathbf{B}^+$ to $\mathbf{A}^+$ estimated from the electrochemical data is $K^+$ (298 K) ($CH_2Cl_2$) = 528, Scheme 1.

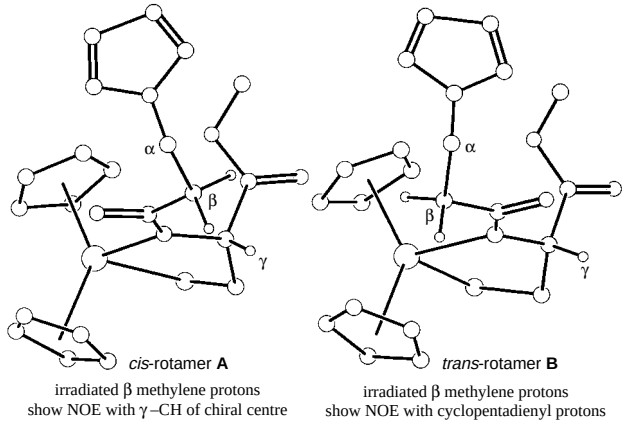

**Fig. 2**

The equilibrium between **A** and **B** is markedly solvent dependent: in polar solvents such as MeCN or DMF the *trans*-amide rotameter **B** is the more stable species, in the less polar solvent $CH_2Cl_2$ (or $CHCl_3$) the converse is true, for example, *K*° (298 K) ($CH_2Cl_2$) = 0.5 for the conversion of **A** to **B**. In the *trans* configuration, the amide oxgyen of **B** is exposed on the surface of the molecule whereas in the *cis* configuration of **A** it is shielded by the cyclopentadienyl rings. Thus polar interactions of the amide carbonyl group presumably stabilise **B** with respect to **A**. Consistent with this, IR spectroscopy in MeCN shows two distinct amide C=O bands with that for the major isomer **B** at a significantly lower energy (1562 $cm^{-1}$) than that for **A** (1582 $cm^{-1}$).

In conclusion, a ligand rotational isomerism which places the oxygen atom of an amide group close to or distant from a neighbouring metal centre can lead to redox isomers with substantially different *E*° potentials. In addition, it is evident that oxidation of the metal centre switches the system from a state in which there is a small difference in the relative thermodynamic stabilities of the isomers to one in which the *cis*-amide rotamer greatly predominates.

In a wider context, we note that the kinetics and energetics associated with *cis–trans* amide bond isomerism in prolines and in pseudo-prolines with ring heteroatoms is receiving considerable attention because of the importance of the rotamers in protein folding and recognition processes.[7] The metallocycle system described herein can be viewed as a pseudo-proline with redox-sensitive rotameric properties. Cyclopentadienyl ring substitution, N- or C-terminus modification, and/or changing the metal offer the prospect of refining the energetics and dynamics of the system. Notably, simply replacing the pyrrole group by a phenyl ring gives an analogous redox isomer system but with *K*° (298 K) (DMF) now close to unity.

We gratefully acknowledge the support of 'Comissao INVOTAN' for providing travel and subsistence funds for M. P. to work in the Nitrogen Fixation Laboratory and the BBSRC both for funding the research and for providing an equipment grant EQP05815.

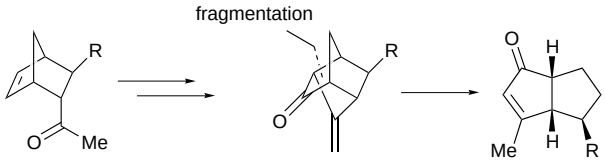
# Synthesis of the naturally occurring [3.3.3]propellane (±)-modhephene featuring a photocycloaddition–reductive fragmentation diquinane construction

**Curt A. Dvorak and Viresh H. Rawal†**

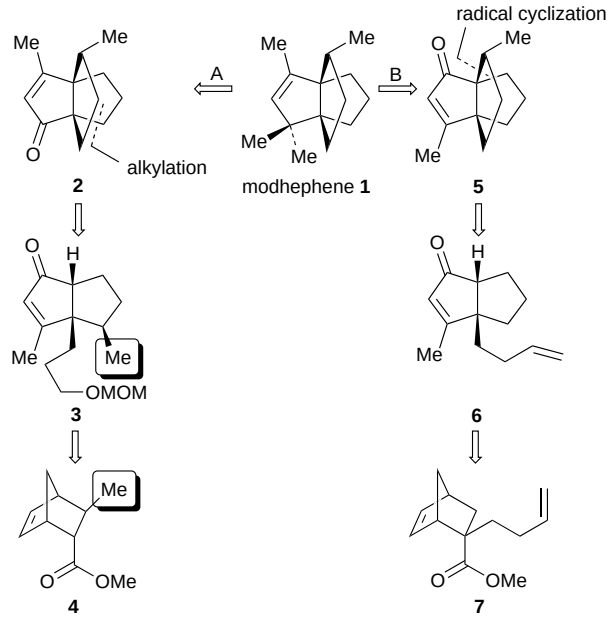
*Department of Chemistry, The University of Chicago, Chicago, IL 60637 and Department of Chemistry, The Ohio State University, Columbus, OH 43210, USA*

**Modhephene has been synthesized in 11 steps and 21% overall yield from cyclopentadiene, by a stereoselective route that features a photocycloaddition–fragmentation sequence for the construction of the diquinane core.**



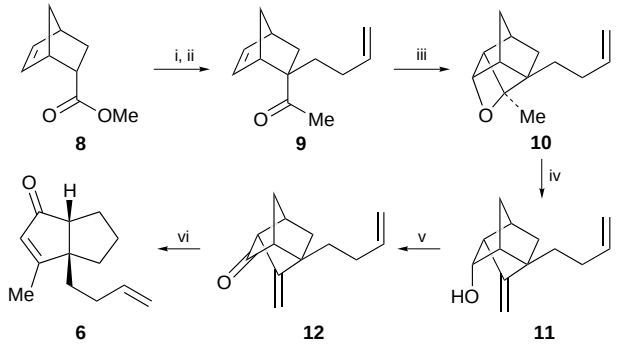
The fascinating realm of the polyquinane sesquiterpenes, recently reviewed,[1] has stimulated the development of new methodologies for the construction of fused five-membered rings. Previously we reported a route to di- and tri-quinanes that takes advantage of the connectivity gained when acylnorbornyl derivatives, obtained *via* the Diels–Alder reaction, are subjected to the Paterno–Büchi reaction (Scheme 1).[2] This expeditious assembly of a [3.3.0]bicyclic array is well suited for the synthesis of many members of the polyquinane class of natural products. We have completed concise, high-yielding syntheses of natural products having linear[2d] and angular triquinane[2b,e] frameworks using the photocycloaddition–fragmentation sequence. We report here a concise synthesis of naturally occurring propellane, modhephene **1**,[3] further extending the utility of our general strategy.

The propellane skeleton, the three contiguous quaternary centers, and the angular methyl group combine to make modhephene an attractive synthetic challenge, one taken on by several research groups.[4] We have examined two routes to modhephene, outlined retrosynthetically in Scheme 2. Appealing at first was a route that took advantage of enone **3**, a late-stage intermediate in our isocomene synthesis, wherein the methyl group stereochemistry was controlled through a Diels–Alder reaction.[2b,e] While it was possible to form the third ring by an alkylative cyclization of the terminal iodide derived from **3**,[5] the resulting enone **2** could not be converted to modhephene.[2h,l] An alternate route to the propellane framework of modhephene hinged on formation of the ring containing the angular methyl group, potentially by a radical cyclization.[6] The requisite diquinane precursor **6** was expected to be readily available through the photocycloaddition–reductive fragmentation sequence.

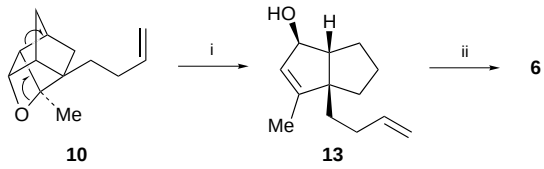


Diquinane **6** was prepared in high overall yield as described in Scheme 3. Norbornene **8**, obtained from cyclopentadiene and methyl acrylate ($H_2O$, room temp., 100%), was alkylated selectively on the *exo* face with 4-bromobut-1-ene using LDA in THF with 1,3-dimethyl-3,4,5,6-tetrahydropyrimidin-2(1*H*)-one (DMPU). The resulting ester **7** was converted into methyl ketone **9** by a one-pot modification of Corey's procedure,[7] affording the Paterno–Büchi precursor in 94% yield for the two steps. Irradiation of ketone **9** with Corex-filtered light provided oxetane **10** (89%), which possesses the connectivity required for a diquinane. Initially a three step sequence was used to convert oxetane **10** to a diquinane. Treatment of **10** with $Pr^i_2NMgI$ gave alcohol **11**, which on oxidation with pyridinium dichromate (PDC) gave keto alkene **12** in good overall yield. Reductive fragmentation of **12** afforded the expected diquinane, **6**, in 80% yield.

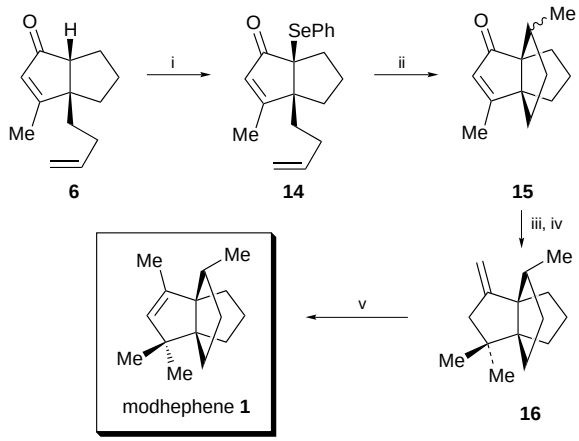
The hidden diquinane unit was also liberated by a novel, direct fragmentation of the strained oxetane precursor, which shortened the sequence by one step (Scheme 4). Treatment of oxetane **10** with LDBB (2.0 equiv.), the radical anion of 4,4′-di-*tert*-butylbiphenyl, in the presence of $Et_3Al$ (2.1 equiv.)[8] promoted the simultaneous scission of the oxetane C–O bond and the back-bond of the norbornane skeleton, affording diquinane moiety **13** in 86% yield.[9] The resulting allylic alcohol was then oxidized to enone **6** under standard conditions.



In preparation for closure of the final propellane ring, a suitable radical precursor was introduced α to the carbonyl group of **6** (Scheme 5). Selenation of the kinetic enolate of **6** afforded the desired phenyl selenide in 61% yield, provided inverse quenching conditions were employed. The bridgehead radical derived from **14** was expected to undergo 5-*exo*-*trig* cyclization onto the butenyl side-chain, concurrently setting the angular methyl group stereochemistry.[4m] Subjection of selenide **14** to standard radical conditions gave an excellent yield of the propellane (95%), albeit with a disappointing 2 : 1 ratio of inseparable diastereomers. This ratio was increased to a useful 6 : 1 level (69%) by carrying out the cyclization in toluene at −78 °C using $Et_3B$–air to initiate the radical chain.[10]



**Scheme 1**



**Scheme 2**

**Scheme 3** *Reagents and conditions*: i, LDA, THF, DMPU, 4-bromobut-1-ene; ii, $MeS(O)CH_2Li$, THF; Zn, aq. NaOH, $PhCH_3$ (94% overall); iii, *hν*, PhH, corex filters (89%); iv, $Pr^i_2NMgI$ (2.6 equiv.) in THF (1.0 M), room temp., 1.5 days (87%); v, PDC (2.9 equiv.), DMF, room temp., 1 day (91%); vi, LDBB (3 equiv.) in THF (0.1 M), −78 °C (80%)

**Scheme 4** *Reagents and conditions:* i, LDBB, THF, $Et_3Al$, −78 °C, 4 h, warm to room temp., 12 h (86%); ii PDC, DMF, room temp., 16 h (91%)

**Scheme 5** *Reagents and conditions*: i, LDA, THF, −78 °C to room temp.; PhSeCl, −78 °C, inverse quench (61%); ii, $Bu_3SnH$, AIBN, PhH, reflux (2:1, 95%) (6:1 at −78 °C); iii, $Me_2CuLiCN$, THF, $Et_2O{\cdot}BF_3$; iv, $Ph_3P{=}CH_2$, THF (85% overall), MPLC separation; v, TsOH (cat.), $CH_2Cl_2$, 3 h (~100%)

The final two carbons were appended as previously described. Introduction of the geminal dimethyl unit to the hindered enone **15** requires a Lewis acid to assist the 1,4-addition of the higher order cuprate.[4b,l] Wittig olefination of the keto group with triphenylphosphonium methylide[4d] put in place the final carbon. The major diastereomer from the radical cyclization was separated at this stage by MPLC and then treated with a catalytic amount of TsOH, which isomerized the double bond to the endocyclic position, affording modhephene **1**. The minor diastereomer was similarly converted to epimodhephene.

The modhephene synthesis described here was accomplished in 11 steps from cyclopentadiene, with an overall yield of 21%, the highest to date. The synthesis illustrates the direct fragmentation of the cage-like oxetane **10** to diquinane **13** as well as the stereocontrolled formation of the propellane skeleton.

# Conformational preferences of $R^1R^2C{=}O{\cdot}H_2BF$ complexes

**Mark D. Mackey and Jonathan M. Goodman***

*University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW*

**Molecular orbital calculations have quantified both the C–H hydrogen bond and the anomeric effect in $R^1R^2C{=}O{\cdot}H_2BF$ complexes.**

It has recently been shown[1] that a hydrogen bond from a formyl C–H hydrogen to fluorine or oxygen is an important conformational restriction.[2] This is consistent with our calculations on $R^1R^2C{=}O{\cdot}H_2BF$ complexes, which prefer conformations with the fluoride eclipsing the carbonyl double bond (Fig. 1). We had suggested that this conformational preference may be due to a generalised anomeric effect,[3] which led to the interaction between fluorine and the adjacent group. The crystallographic results suggest that a formyl C–H to fluorine hydrogen bond is the controlling interaction. This can be used to explain the selectivity in many reactions. Here we report new *ab initio* calculations which allow us to investigate the relative importance of these two effects.

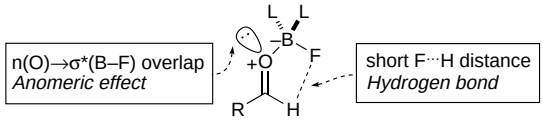

**Fig. 1** Carbonyl $H_2BF$ complexes: anomeric effect and hydrogen bond

The orientation of the coordinating Lewis acid will be affected by an anomeric effect (reinforced by a dipole–dipole interaction between the C=O and B–F bonds which we include in the anomeric effect for this analysis), a hydrogen bond and steric effects. It is not easy to separate these effects, because they will be combined in all molecules. The effect of changing from fluoride to chloride to bromide can be calculated. However, this may be expected to diminish both the anomeric effect (because the π–σ* energy match will be adversely effected) and also any H–halide interaction, because the orbital overlap will become less. This will not, therefore, help to distinguish these two effects.

We have already reported that the barrier for rotation around the O–B bond of formaldehyde complexed with $H_2BF$ (Fig. 2, structure 1) is 14 kJ mol$^{-1}$ at the MP2/6-31G*//3-21G level, using CADPAC.[4] We have now repeated this calculation at the MP2/6-31G**//MP2/6-31G** level and obtained a very similar figure (15 kJ mol$^{-1}$). In this complex, steric effects between the formyl hydrogen and the Lewis acid are likely to be small, so this should represent the sum of the anomeric effect and the hydrogen bond strength. In order to try and separate these effects, we performed calculations on the ketene complex **2** and the propynal complex **3**, reasoning that both these complexes should not have a hydrogen bond, but would show the anomeric effect. The results are summarised in Table 1.

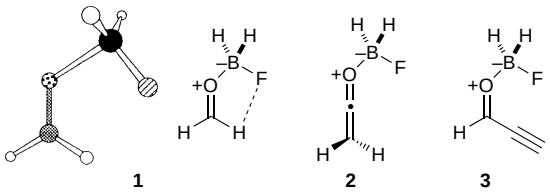

**Fig. 2** Complexes with and without hydrogen bonds

**Table 1** Results of calculations at the MP2/6-31G**//MP2/6-31G** level

| Molecule | Barrier to rotation about O–B kJ mol$^{-1}$ | H–F distance for lowest energy structure/Å | Strength of complexation/ kJ mol$^{-1}$ [a] | C=O–B–F torsion angle for lowest energy structure (°) |
|---|---|---|---|---|
| **1** | 15 | 2.20 | 48 | 0 |
| **2** | 1.4[b] | — | 15 | 0 |
| **3** | 6 | — | 34 | 0 |
| **4** | 13 | 2.04 | 54 | 60 |
| **5** | —[c] | 2.26, 2.34 | 50 | 14 |

[a] No correction for BSSE or zero-point energy was made. [b] MP2/6-31G**//3-21G level. [c] Not determined because of the size of the system.

The ketene complex **2** shows only weak association with the Lewis acid. The barrier to rotation is less than 2 kJ mol$^{-1}$, but the O–B bond is 2 Å long. We may take this as a minimum value for the magnitude of the anomeric effect, which is likely to be larger in molecules, such as **1**, for which the O–B bond is shorter.

The propynal complex **3** shows much stronger complexation. The barrier to rotation around the O–B bond is now 6 kJ mol$^{-1}$, which is a typical magnitude for an anomeric effect.[5] There is likely to be some steric repulsion between the triple bond and the fluorine, which suggests that this value may be slightly too low. However, if we accept the value of 6 kJ mol$^{-1}$ for the anomeric effect, we are left with 9 kJ mol$^{-1}$ to attribute to the hydrogen bonding interaction, for complex **1**. We may conclude, therefore, that both effects are important, but the hydrogen bonding interaction is probably larger.

Our calculations also suggested that there may be hydrogen bonding interactions to hydrogens further from the carbonyl group (Fig. 3). The barrier to rotation for the acetone complex **4** is 19 kJ mol$^{-1}$ (RHF/3-21G level). If we assume that the anomeric effect has a similar magnitude to the formaldehyde case, this gives a value of 13 kJ mol$^{-1}$ for the hydrogen bond. At a higher level of theory (MP2/6-31G**//MP2/6-31G**) the geometry of the global minimum structure changes. Instead of a C=O–B–F dihedral angle of about 0° (as found at the RHF/3-21G level and illustrated in Fig. 3), the preferred geometry has a dihedral angle of about 60°. The barrier to rotation falls to 14 kJ mol$^{-1}$. If, following Allinger,[6] we assume that the anomeric effect falls off as the square of the consine of the C=O–B–F angle, then the anomeric contribution at 60° rotation is about 1.5 kJ mol$^{-1}$. We may, therefore, suggest a strength of about 12

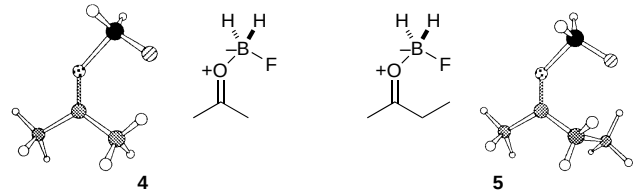

**Fig. 3** Acetone and butanone complexes (RHF/3-21G geometries)

kJ mol$^{-1}$ for the F–H hydrogen bond to the methyl group of acetone, which is similar to that estimated at the lower level of theory. This is stronger than the hydrogen bond for the formyl C–H, presumably because the geometry is better. The F–H distance in the formaldehyde complex is 2.20 Å, compared with 2.04 Å for the acetone complex. For comparison, the sum of the van der Waals radii for hydrogen and fluorine is 2.55 Å. The C–H–F angle is 100° for formaldehyde, and a more favourable 130° for acetone.

The structure of the (*Z*)-butanone complex **5**, in which the Lewis acid is complexed to the side of the ethyl group, appears to show hydrogen bonds both to the methylene adjacent to the carbonyl and also to the remote methyl group. Such an interaction is unusual, as the C–H bond is not activated by an adjacent group.[7] The geometries obtained at the low and high levels of theory are rather similar. If the energy is monitored as the O=C–C–C dihedral angle is rotated, there is a sudden change as the hydrogen bond to the methyl group breaks. This energy jump is about 4 kJ mol$^{-1}$ at the MP2/6-31G** level. The complexation energy is similar for complexation on the methyl side and the ethyl side of the ketone (there is a preference for complexation on the methyl side at the RHF/3-21G level, which diminishes at higher levels of theory), and so the energy of the interaction with the methylene hydrogen must be at about 8 kJ mol$^{-1}$, to balance the overall energy. In fact, the strength of the hydrogen bond is likely to be greater than this, because this figure does not take adverse steric effects into account.

A summary of the different effects controlling the preferred conformations of the Lewis acid complexes is given in Table 2. This should help with the further analysis of the many systems for which these effects are important.[8]

In conclusion, hydrogen bonds and anomeric effects are both important in determining the preferred conformations of carbonyl–Lewis acid complexes of this type. These calculations have allowed us to approximately quantify these effects, and this should be a useful guide in designing systems which take advantage of this interaction.

**Table 2** Quantification of anomeric and hydrogen bonding effects

| Parameter | | Energy/kJ mol$^{-1}$ |
|---|---|---|
| Anomeric effect: | (for eclipsing geometries) | 6 |
| Hydrogen bonds: | Formyl C–H | 9 |
| | α-Methyl C–H | 12 |
| | β-Methyl C–H | 4 |
| | α-Methylene C–H | 8 |

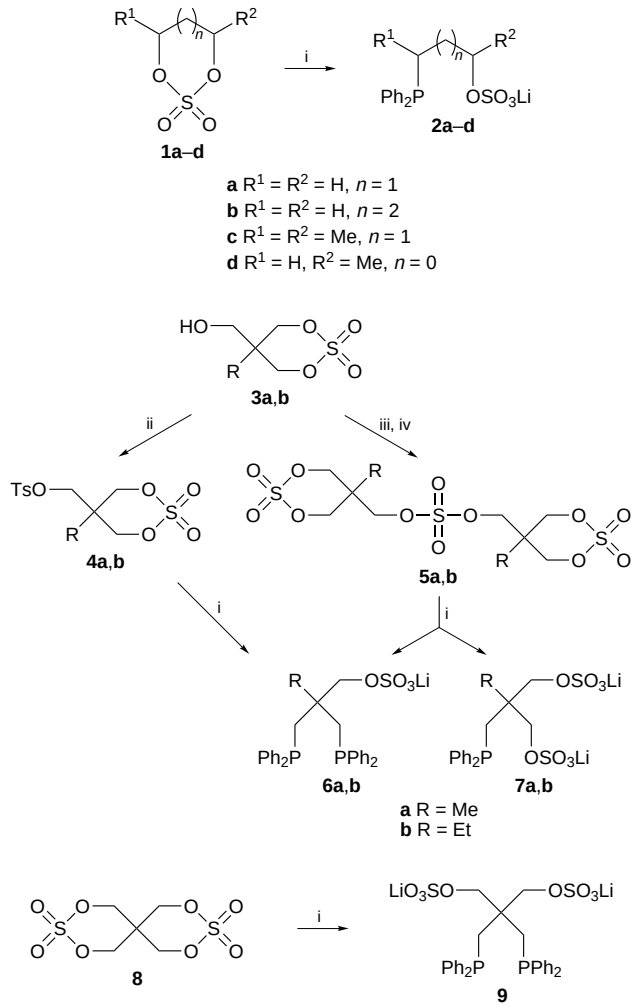
# A new route for the synthesis of amphiphilic and water-soluble ligands: mono- and di-tertiary phosphines having an alkylene sulfate chain

**Henrik Gulyás, Péter Árva and József Bakos***

*Department of Organic Chemistry, University of Veszprém, H-8201 Veszprém, PO Box 158, Hungary*

**Cyclic sulfates react with $LiPPh_2$ to form a series of new amphiphilic or water-soluble ligands: monotertiary phosphines with one or two alkylene sulfate chains and ditertiary phosphines with one or two hydrophilic tails attached to bridgehead carbon atom; the application of zwitterionic $Rh^I$ complexes $(sulfatephos)_2Rh(cod)$ and (sulfatediphos)Rh(cod) in liquid biphasic catalysis has been demonstrated for the hydroformylation of styrene and oct-1-ene.**

Much effort has been directed toward the synthesis of new catalytic species, with some recent focus on water-soluble catalysts.[1] Transition metal complexes can easily be rendered water-soluble by incorporating polar substituents,[2] *e.g.* $SO_3Na$, $CO_2Na$, OH, $PMe_3^+$, $NMe_3^+$, $PO(ONa)_2$ and polyethers. We reasoned that a new route to amphiphilic or water-soluble phosphine ligands would be of particular interest because (i) a wide range of starting compounds (*e.g.* diol, triol, tetraol) is available, (ii) the synthesis is simple and (iii) it might be possible to access a series of amphiphilic or water-soluble phosphines. To the best of our knowledge, only a very few examples of ligands with amphiphilic properties have been reported,[3] and the 'sulfated' phosphines reported here are the first examples of this kind.



The mono- and bi-dentate phosphines were synthesized *via* the reaction of cyclic sulfates[4] with lithium diphenylphosphide. The water-solubility of these phosphines is provided by the sulfate group. Cyclic sulfates were obtained by a simple one-pot reaction from the corresponding diols, triols or tetraol following the procedure developed for 1,2-cyclic sulfates by Gao and Sharpless.[5] This involves the treatment of diols with $SOCl_2$ followed by ruthenium-catalysed oxidation.

The synthesis of the ligands is outlined in Scheme 1. A homologous series of monotertiary phosphines of the type $Ph_2PCH(R^1)(CH_2)_nCH(R^2)OSO_3Li$ ($n$ = 1,2, $R^1$ = $R^2$ = H; $n$ = 1, $R^1$ = $R^2$ = Me; $n$ = 0, $R^1$ = H, $R^2$ = Me) has been prepared. Nucleophilic attack occurred with complete inversion at the stereogenic centre of the electrophilic cyclic sulfate (**1c**) and with complete regioselectivity (**1d**).

The new ligands are monotertiary phosphine ligands (sulfatephos) with one (**2**) or two alkylene sulfate chains (**7**) or ditertiary phosphine ligands (sulfate-dppp) with one (**6**) or two hydrophilic tails (**9**) attached to the bridgehead carbon atom. A general procedure for the conversion of cyclic sulfates to amphiphilic or water-soluble phosphines was developed (Table 1). Our approach combines the introduction of the $PPh_2$ moiety and the formation of the charged β-, γ- or ω-sulfate functionality. Note that the anionic nature of the sulfate moiety, which is still a leaving group, renders it kinetically less reactive than the cyclic sulfate. Although β-substituted ethyl sulfates are subjected to hydrolyse slowly in water[6] or rapidly by using a catalytic amount of sulfuric acid,[5] the lithium salts of the sulfates in Table 1 proved to be stable in neutral or slightly basic aqueous solution. For example, when an aqueous solution of **9** was heated at 80 °C for 1 h, no appreciable decomposition or hydrolysis was detected.

The double 'sulfation' of triols (**5**) or the 'sulfation' of triols followed by tosylation (**4**) suggests a variety of useful transformations of these forgotten electrophiles. From a synthetic point of view, noteworthy applications of our methodology are those involving the mixed acyclic-bicyclic sulfate esters **5**; they lead to ditertiary phosphines **6** with very poor water-solubility and water-soluble monotertiary phosphines **7** in one reaction. In addition, **6** can also be obtained from **4**.

Compound **9** forms a complex when reacted in a 2 : 1 ratio with $[Rh(COD)Cl]_2$ in MeOH or EtOAc–$H_2O$. $^{31}P$ NMR spectroscopic data of this complex are characteristic of a cationic complex [$\delta$ 13.9 ($J_{RhP}$ 141 Hz) in $CD_3OD$ or in $D_2O$)] and do not significantly differ from those derived from dppp.[7] The MS FAB$^+$ spectrum displays a $[M + Li]^+$ peak at 855 and the MS FAB$^-$ spectrum displays a $M^-$ peak at 848. A zwitterionic structure for the complex $[Rh(COD)((Ph_2PCH_2)_2C(CH_2OSO_3Li)(CH_2OSO_3))]$ is suggested in which one of the $OSO_3^-$ groups of the ligand acts as the counterion for rhodium.

| **5b** | 41 | 95–98 | **6b** | 79 | −26.2[e] | 33.3[e] |
| | | | **7b** | 65 | −28.4[d] | 36.8[d] |
| **8** | 17 | 279 | **9** | 73 | −28.9[d] | 35.4[d] |

[a] Reactions were performed by the addition of sulfate to the solution of $LiPPh_2$ in THF at 0 to −5 °C. [b] Isolated but not optimized yields. [c] Phosphine oxide was obtained at room temperature by oxidation of the phospine with $H_2O_2$ in water or in a mixture of water and MeOH. [d] $^{31}P\{^1H\}$ NMR ($D_2O$). [e] $^{31}P\{^1H\}$ NMR ($CDCl_3$).

A preliminary investigation of the potential of **2c** and **9** in liquid biphasic catalysis has been carried out. Oct-1-ene is hydroformylated in a $H_2O$–PhMe or $H_2O$–oct-1-ene biphasic system in the presence of $[Rh(COD)Cl]_2$ associated with **2c** (35 bar of CO, 35 bar of $H_2$, 60 °C, 1 : 300 Rh to substrate ratio, 6 h, 100% conversion). In both cases, the reaction gives nonanal (54%), branched aldehydes (44%) [2-methyloctanal (38%) and 2-ethylheptanal (6%)] and isomerized octenes (2%). Most importantly, the catalytically active rhodiumcarbonyl–surfactant-phosphine complex is quantitatively recovered by simple extraction with water of the organic phase, which contains the product; the aqueous phase could be reused with a slight loss of catalytic activity. When styrene was hydroformylated in a $H_2O$–PhMe biphasic system, complete chemoselectivity for aldehydes and a high regioselectivity (up to 91%) for branched aldehydes were achieved in 3 h. Although the (1*R*,3*S*)-1-methyl-3-(diphenylphosphino)butyl lithium sulfate salt is chiral, no optical induction has been observed.

When the hydroformylation of styrene was performed with the highly water-soluble ligand **9**, complete chemoselectivity for aldehyde and an 81% regioselectivity for branched aldehydes was achieved. After reaction the organic phase was colourless, and the rhodium is located in the aqueous phase, which could be reused with a slight loss of catalytic activity. When the residue derived from the hydrocarbon layer was analysed by $^{31}P$ NMR spectroscopy, no appreciable amount of phosphorus was detected.

In conclusion we have introduced a new class of amphiphilic and water-soluble mono- and di-tertiary phosphines with considerable promise for the modification of liquid biphasic catalysis. The simplicity of the procedure and the rich achiral and chiral pool of diols, triols and tetraols should give synthetic chemists many ideas for the synthesis of achiral and even chiral water-soluble phosphines. With the homologous series of ligands, we are uniquely situated to vary the water-solubility imposed by the number of the sulfate groups and $PPh_2$ moieties without significantly varying the electronic nature of the metal centres in a corresponding series of complexes.

Financial support from the Hungarian National Science Foundation (OTKA-T016269) and the Ministry of Culture and Education (FKFP-0803/1997) is gratefully acknowledged. We are grateful to Mr Béla Édes for skillful assistance in the catalytic experiments.

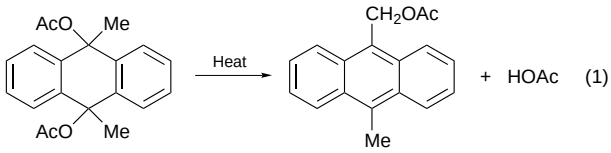
# 9-Alkylanthracene radical cations. An alternate route to apparent products of deprotonation

**J. M. Tanko* and Yonghui Wang**



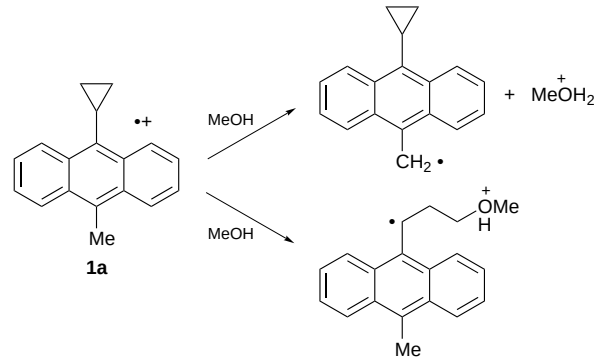
*Department of Chemistry, Virginia Polytechnic Institute and State University, Blacksburg, VA 24061-0212, USA*

**Side-chain oxidation products formed in the oxidation of 9-alkylanthracenes in MeOH–MeCN do not arise from radical cation deprotonation.**

The removal of an electron from a hydrocarbon dramatically increases its acidity. For example, the p$K_a$ of toluene drops from 41 to *ca.* −13 with the removal of a single electron. Consequently, there is a great deal of interest in the thermodynamic and kinetic acidity of radical cations.[1–4]

For an alkylaromatic radical cation, there are two competing pathways for reaction with a base (B:); side chain deprotonation (yielding a benzyl radical), and/or nucleophilic addition to the aromatic ring.[5–8] For alkylbenzenes, the side-chain deprotonation predominates. The effect of structure (of either the alkylbenzene or the base) on the rate of deprotonation has been extensively studied, and the deprotonation is believed to proceed *via* an early (reactant-like) transition state. Rate constants were successfully correlated to the Brønsted equation, with $\alpha \approx 0.25$–$0.30$.[4,9] The rate constant for deprotonation of $PhCH_3^{\bullet+}$ ($H_2O$ as base) is approximately $1.0 \times 10^7$ M$^{-1}$ s$^{-1}$.[6]

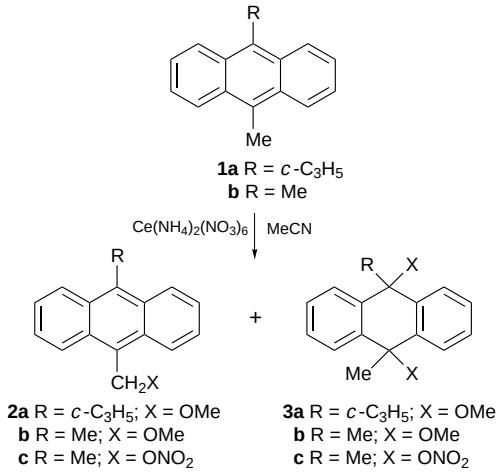
In the case of 9-alkylanthracenes, the situation is more complicated. Thermodynamically, these radical cations are quite acidic (9-methylanthracene is estimated to have a p$K_a$ of *ca.* −6.4),[2] however the literature is somewhat contradictory in terms of the extent to which these radical cations undergo deprotonation. In 1970, Parker reported that radical cations generated from 9-alkyl- and 9,10-dialkyl-anthracenes lead mainly to products derived from nucleophilic addition of solvent (water, alcohol, acetic acid, *etc*.) to the aromatic ring.[10] Moreover, when HOAc was the solvent and at elevated temperatures, the initially formed addition products were observed to eliminate HOAc and rearrange to yield a 'side-chain oxidation' product [eqn. (1)].[10] Similarly, Camaioni and



(1)

co-workers also found that a significant fraction of 'side-chain oxidation' products were derived from HOAc-addition products.[7,11] Others have generally ascribed the side-chain oxidation products as arising exclusively from deprotonation of a radical cation.[12,13]

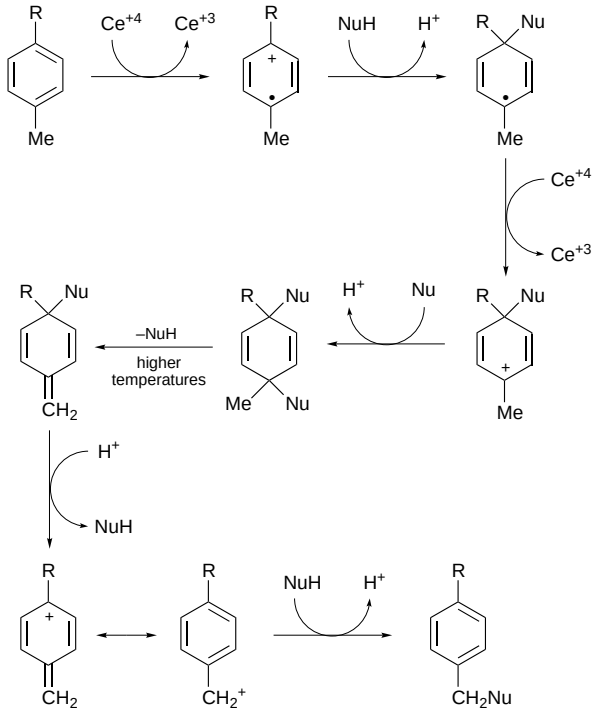
We became interested in this problem as the result of a continuing study of the chemistry of radical cations derived from cyclopropylarenes.[14] Initially, using the radical cation generated from 9-cyclopropyl-10-methylanthracene **1a**, we had hoped to use the deprotonation reaction in an intramolecular competition to clock the rate of methanol-induced cyclopropane ring opening (Scheme 1).



Treatment of **1a** with 1.9 equiv. of ceric ammonium nitrate in MeCN–MeOH at 45 °C led to side-chain oxidation product **2a** and ring-oxidation product **3a** (Scheme 2) in 37 and 57% yield, respectively. However, when the reaction was conducted at 0 °C, **3a** was formed in 91% yield, and no **2a** was detected (mass

**Scheme 1**

balances > 95%). This dramatic effect of temperature on the product ratio suggested that **2a** was *not* arising from the direct deprotonation of a radical cation.



In order to test this hypothesis, 9,10-dimethylanthracene **1b** (Scheme 2) was treated with 1.9 equiv. of $Ce^{IV}$ under a variety of conditions (Table 1), and essentially the same results were obtained: at 0 °C, only ring-oxidation product **3b** was found; at 45 °C approximately equal amounts of **2b** and **3b** were formed. In order to determine whether **2b** was formed from **3b**, the following control experiment was run: **1b** was allowed to react

**Scheme 2**

**Table 1** Products arising from treatment of 9,10-dimethylanthracene with $Ce^{IV}$ under various conditions

| Reaction conditions | **2b** (%) | **3b** (%) |
|---|---|---|
| 0 °C; 30 min | 0.0 | 98.3 |
| 45 °C; 30 min | 40.8 | 53.0 |
| 0 °C; 30 min *then* 45 °C; 30 min | 0.0<br>43.0 | 94.3<br>49.0 |

**Scheme 3** Note: To conserve space, only the central ring of the 9,10-disubstituted anthracene is shown

with $Ce^{IV}$ at 0 °C for 30 min, and the reaction mixture was divided into two portions. The first portion was subject to work-up, and analyzed by $^1H$ NMR spectroscopy. The only product detected was **3b**. The second portion, which was warmed to 45 °C for 30 min and subsequently subject to the same work-up, was found to contain **2b** and **3b** in approximately the same ratio as when **1b** was reacted with $Ce^{IV}$ at 45 °C.

The conversion **3b** → **2b** is apparently favored by higher reaction temperatures, and requires the presence of a Lewis acid. (**3b** is stable at 50 °C indefinitely. However, in the presence of a small amount of $H^+$, **3b** is quantitatively converted into **2b** within 15 min.)

In the absence of MeOH, oxidation of **1b** at 0 °C, followed by work-up, leads exclusively to side-chain oxidation product **2c**. However, the failure to isolate **3c** is likely because of its instability. Indeed, when the reaction was conducted in $CD_3CN$ and analyzed by $^1H$ NMR *prior* to work-up, we found no resonances attributable to either **1b** or **2c**. We tentatively assign the observed resonances to **3c**. After work-up of the NMR sample, **2c** was the only observed product (85% yield). The presumed mechanism for these reactions is summarized in Scheme 3.

These results demonstrate that deprotonation (base = MeOH or $NO_3^-$) of 9-alkylanthracene radical cations is slow† relative to nucleophilic addition to the aromatic ring, and that little of the observed side-chain oxidation product can be attributed to deprotonation of the radical cation. The observed side-chain oxidation products actually arise from further reaction of the nucleophillic addition product. Conversion of this initially formed adduct to the side-chain oxidation product is facile in the presence of a Lewis acid and at higher reaction temperatures. Consequently, it is dangerous to draw mechanistic inferences pertaining to the deprotonation of 9-alkylanthracene radical cations based upon product analyses.‡

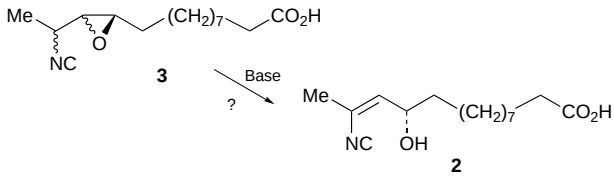
# On the synthesis of vinyl isonitriles

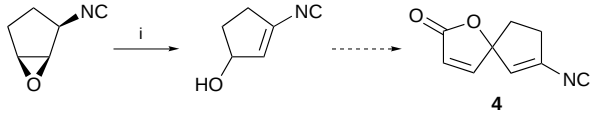
**Jack E. Baldwin, Deqi Chen and Andrew T. Russell**



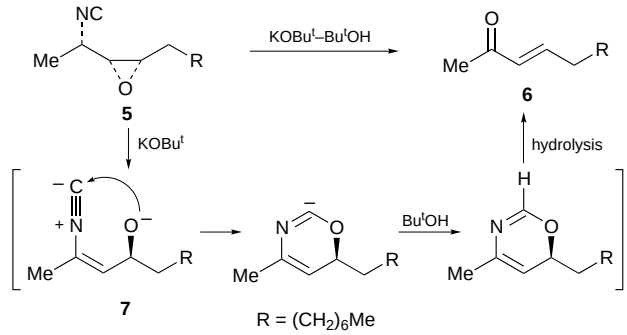
*The Dyson Perrins Laboratory, South Parks Road, Oxford, UK OX1 3QY*

**A reversal of the stereochemistry of base mediated isomerisation of some isonitrile epoxides to hydroxy-vinyl isonitriles on changing from lithium diisopropylamide to lithium bis(trimethylsilyl)amide is reported and applied to a synthesis of racemic desepoxyaerocyanidin.**

As part of our studies on the synthesis of the epoxy isonitrile antibiotic aerocyanidin **1**[1] we required access to vinyl isonitrile **2**.[2] We considered that base mediated isomerisation of an epoxide of general structure **3** could provide a stereocontrolled access to these systems (Scheme 1). During these studies we noted a pronounced dependence of the stereochemical outcome of the isomerisation on the choice of base.

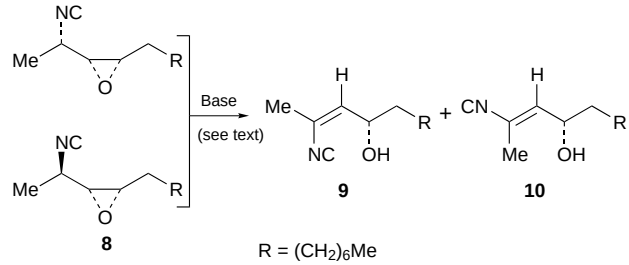


Aerocyanidin **1**

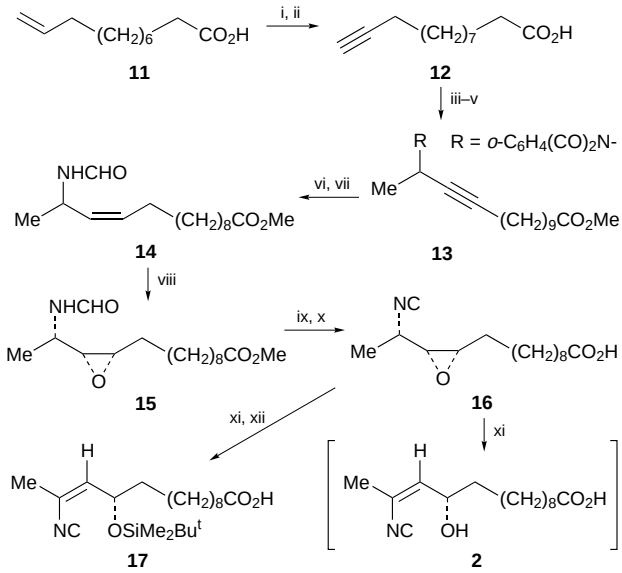


**Scheme 1**

Following our successful application of this approach to the synthesis of the spirocyclic isonitrile **4**, in which a proton *anti* to the epoxide was removed (Scheme 2),[3] we treated isonitrile epoxide **5** with Bu$^t$OK in Bu$^t$OH but obtained only the α,β-unsaturated ketone **6**. This presumably arises by rearrangement of the initially formed oxyanion **7** as proposed in Scheme 3. This result reflects observations made by Schöllkopf *et al.* regarding the stability of γ-hydroxy isonitriles in saturated acyclic systems.[4] They observed that under basic protic conditions cyclisation to the corresponding 5,6-dihydro-4*H*-1,3-oxazine occurs whereas under basic aprotic conditions the starting material was recovered. Thus we turned to the use of strong bases in an aprotic solvent system. In this context it has been shown that epoxides can be isomerised to allylic alcohols with lithium amide bases *via* a *syn*-elimination process and a cyclic six-membered transition state has been postulated to account for this.[5] Treatment of **8** with LDA in THF at −20 °C gave a 2 : 1 mixture of **9** : **10** with **9** presumably arising *via* a *syn*-β-elimination (Scheme 4).† In an attempt to optimise the selectivity of this process we exchanged the LDA for lithium bis(trimethylsilyl)amide and observed a reversal of stereoselectivity with a **9** : **10** ratio of 1 : 7. To take advantage of this enhanced selectivity we returned to diastereoisomer **5** and found



**Scheme 2** *Reagents and conditions*: i, KOBu$^t$, THF, −78 °C, 56%



**Scheme 3**

it to rearrange with a 12 : 1 (**9** : **10**) selectivity and 96% yield. We speculated that this isomerisation proceeded through an *anti*-elimination *via* an open transition state and found that the relative rate of the *anti*-elimination could be increased by the addition of a small quantity of 12-crown-4 which resulted in an increase in selectivity for **9** to 20 : 1. Consistent with this is the observation that while LDA causes rearrangement of **5** with a 1 : 7 (**9** : **10**) ratio addition of 12-crown-4 depresses the ratio to 2 : 3.[6]

With this result in hand we undertook the synthesis of **2** (Scheme 5). Arndt–Eistert homologation of commercially available **11** afforded after bromination and elimination alkyne acid **12** in 66% overall yield. The dilithium anion of **12** was quenched with acetaldehyde and after conversion to the methyl ester introduction of the required amino group was effected under Mitsunobo conditions to give **13** (47% from **12**).[7] Hydrogenation over a Lindlar catalyst afforded the corresponding *Z*-alkene which, after deprotection of the phthalimide with methylamine, was smoothly formylated with acetic formic anhydride in 60% yield for the three steps. Taking advantage of the allylic strain in the *Z*-vinylformamide **14** we used MCPBA to affect a directed epoxidation to yield **15** as a single stereoisomer (79%).[8] Dehydration with trifluoromethanesulfonic anhydride[9] afforded the corresponding isonitrile epoxide (83%) which was saponified with $Ba(OH)_2$ (87%) to afford **16** for the key isomerisation reaction. Treatment of **16** with lithium bis(trimethylsilyl)amide at −15 °C in the presence of a small quantity 12-crown-4 afforded **2** which proved to be an unstable compound decomposing slowly to an α,β-unsaturated ketone corresponding to **6**. Therefore the lithium alkoxide of **2** was protected *in situ* as a *tert*-butyldimethylsilyl ether **17** (57%)

**Scheme 4**

**Scheme 5** *Reagents and conditions*: i, $(COCl)_2$, DMF, $CH_2Cl_2$; ii, (a) $CH_2N_2$, $Et_2O$, $Et_3N$ then $Ag_2O$, $Na_2S_2O_5$, dioxane, $H_2O$; (b) $Br_2$, $Et_2O$ then Na, liq. $NH_3$, 66% overall; iii, $Bu^nLi$, THF, −20 °C then MeCHO, THF, −5 °C, 58%; iv, $CH_2N_2$, $Et_2O$, 0 °C, 100%; v, phthalimide, $Ph_3P$, DEAD, THF, 16 h, 81%; vi, $H_2$, Lindlar's catalyst, quinoline, hexane, EtOAc, 24 h, 90%; vii, $MeNH_2$ (40% aq.) $CH_2Cl_2$, 16 h then AcOCHO, $CH_2Cl_2$, 67% (two steps); viii, MCPBA, $CH_2Cl_2$, 79%; ix, $Tf_2O$, $Pr^i_2NEt$, $CH_2Cl_2$, −78 °C, 83%; x, $Ba(OH)_2$, MeOH then citric acid, 87%; xi, LHMDS, THF, −15 °C; xii, TBSOTf, 57% (for two steps)

to permit full characterisation. The geometry of the double bond was supported by NOE spectroscopy, a 6% enhancement in the intensity of the vinylic proton resonance on irradiation of the vinyl methyl resonance being observed.

In summary we have noted a reversal of the stereochemistry of base mediated isomerisation of a series of isonitrile epoxides to allylic alcohols on switching from LDA to lithium bis-(trimethylsilyl)amide. Using this observation we have prepared racemic desepoxyaerocyanidin **2**.

† Given the established acidity of protons adjacent to isonitriles[10] we cannot preclude the possibility that the isomerisation goes, at least in part, *via* an $E_1cb$ mechanism. In circumstances where a substantial portion of the product derived from this mechanism the differences in stereochemical outcome between the diastereoisomers would require that ring opening of the epoxide is faster than bond rotation.

# A new approach to peptide synthesis

**Christopher J. Moody,[a,b] Leigh Ferris,[b] David Haigh[c] and Elizabeth Swann[a]**

[a] *Department of Chemistry, University of Exeter, Stocker Road, Exeter, Devon, UK EX4 4QD*

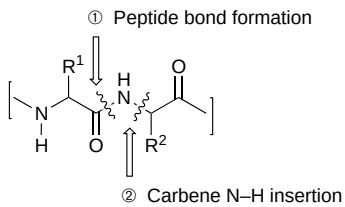
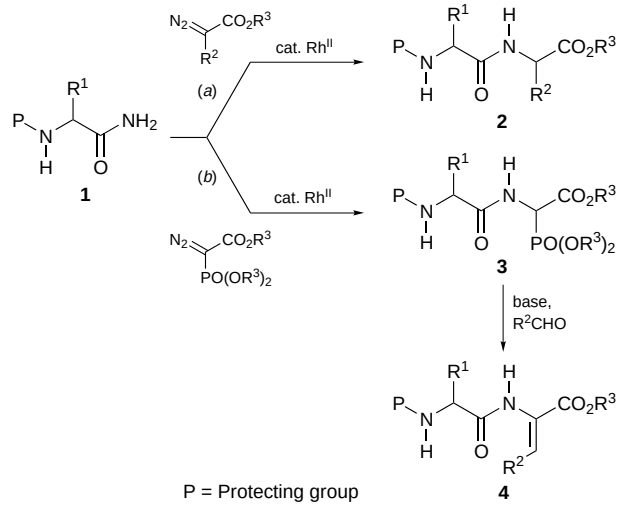
**A new approach to the synthesis of dipeptides is described based on the formation of the NHCHR[1]CONH–CHR[2]CO bond by carbenoid N–H insertion, rather than the formation of the peptide bond itself.**

Peptides and proteins play a central role in all living organisms, and hence the synthesis of such compounds has emerged as a subject in its own right.[1] In fact peptide synthesis is so highly developed that chemists rarely, if ever, consider any approach other than the formation of the amide bond (Fig. 1, disconnection 1). We now report a new approach to peptide synthesis which involves for formation of the CONH–CHRCO bond by a metal carbene N–H insertion reaction (Fig. 1, disconnection 2), and its application in the synthesis of dipeptides of dehydro amino acids, including the protected dehydro dipeptide component of the tunichrome Mm-2.

The N–H insertion reactions of metallocarbenoids, first described in 1952,[2] have found use in synthesis particularly in the construction of bicyclic β-lactams.[3] We have recently described the application of such N–H insertion reactions in the preparation of α-amino acids, α-aminophosphonates and phosphonoglycines,[4,5] and therefore were attracted by the possibility of using carbenoid N–H insertions in a synthesis of dipeptides which, unusually, does not rely on formation of the peptide bond itself. Two approaches starting from readily available *N*-protected amino acid amides **1** were considered (Scheme 1). Firstly, the use of diazo esters which would lead directly to dipeptides **2** [Scheme 1(*a*)]. There is one reported example of this approach which resulted in the synthesis of Z-Phe-α,α,α-trifluoroAla-OMe **2** (P = Z, $R^1$ = Bn, $R^2$ = $CF_3$, $R^3$ = Me) from methyl 2-diazo-3,3,3-trifluoropropionate,[6] and we have used both methyl 2-diazo-2-phenylacetate and methyl 2-diazo 3-oxobutanoate to give dipeptides **2** ($R^2$ = Ph and Ac respectively).[7,8] In the latter case the dipeptides **2** ($R^2$ = Ac) were cyclodehydrated to give oxazoles.[8,9] The second approach, which is reported herein, involves the rhodium(II)-catalysed reaction of diazophosphonoacetate to give phosphonates **3**, Wadsworth–Emmons reaction of which leads to the dehydro dipeptide **4** [Scheme 1(*b*)].

The key N–H insertion reaction was carried out by treating a mixture of the *N*-protected amino acid amide **5** and triethyl diazophosphonoacetate with a catalytic amount of rhodium(II) acetate in toluene, and resulted in the formation of the phosphonates **6** in good yield (Scheme 2, Table 1). The N–H insertion reaction was completely regioselective, in that no competing insertion into the carbamate N–H bond was





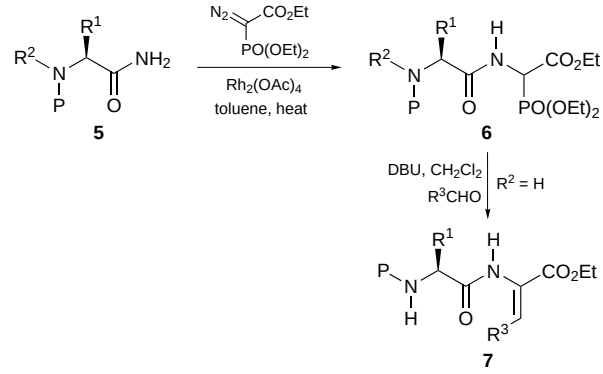


**Fig. 1**

**Scheme 1**

observed. Although related phosphonates have been prepared previously by synthesis of the corresponding α-aminophosphonate followed by peptide coupling,[10] the simplicity of this new method gives it some advantages. Wadsworth–Emmons reaction of the phosphonates **6** with a range of aldehydes using DBU as base[11] gave the corresponding dehydro dipeptides **7** in good yield (Scheme 2, Table 2). In each case a

**Scheme 2**

$^a$ Ar = *N*-Boc-indol-3-yl.

**Scheme 3**

single diastereoisomer was formed which on the basis of literature precedent was assigned the *Z*-configuration.

Finally, the new approach to dipeptides was applied to the synthesis of the dehydro dipeptide fragment of Mm-2 **8** ($Ar^1$ = $Ar^2$ = 3,4-dihydroxyphenyl), a blood pigment of the tunicate *Molgula manhattensis*.[12] Although this compound has been synthesised previously,[12] the projected disconnection (Scheme 3) to the protected dehydro dipeptide **9** ($Ar^2$ = 3,4-dibenzyloxyphenyl) differs from the published strategy. The phosphonate **10**, prepared from *N*-Boc-leucinamide and trimethyl phosphonoacetate in exactly the same way as its triethyl analogue **6e**, reacted readily with 3,4-dibenzyloxybenzaldehyde to give the required dipeptide **11** ($Ar^2$ = 3,4-dibenzyloxyphenyl) as a single *Z*-diasteromer. Hydrolysis of ester **11** gave the required acid **9** in 95% yield (Scheme 3).

In summary, we have shown that carbenoid N–H insertion reactions can be applied in a new approach to peptides which does not involve the formation of the peptide bond itself; such an approach may offer advantages in some cases.

We thank Loughborough University and SmithKline Beecham Pharmaceuticals for their support.

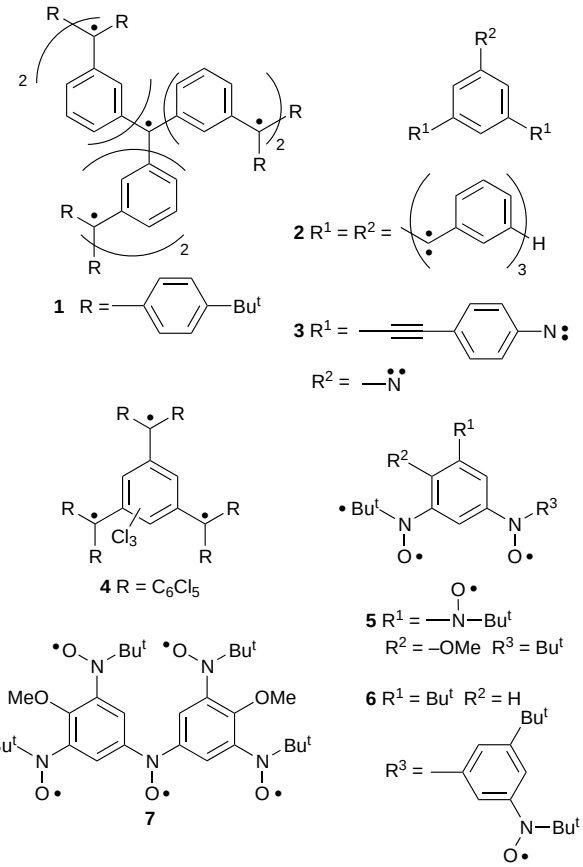
# Molecular structure and magnetic properties of *N*,*N*-bis{4-methoxy-3,5-bis(*N*-*tert*-butyl-*N*-oxyamino)phenyl}aminoxyl. An approach to a stable and high-spin pentaradical

**Junpei Fujita,[a] Yoshihisa Matsuoka,[a] Kenji Matsuo,[a] Masakazu Tanaka,[a] Takeyuki Akita,[a] Noboru Koga*[a] and Hizu Iwamura*[b]**



[a] *Faculty of Pharmaceutical Sciences, Kyushu University, Fukuoka 812-82, Japan*
[b] *Institute for Fundamental Research of Organic Chemistry, Kyushu University, Fukuoka 812-81, Japan*

**A stable pentaradical, *N*,*N*-bis{4-methoxy-3,5-bis(*N*-*tert*-butyl-*N*-oxyamino)phenyl)}aminoxyl, is prepared and its ground state determined to be a sextet ($S$ = 5/2) by SQUID magnetization measurements of the pentaradical diluted in poly(vinyl chloride) matrix.**

Poly(triarylmethyl) radical **1** ($S$ = 7/2),[1] nonacarbene **2** ($S$ = 9),[2] and trinitrene **3** ($S$ = 3)[3] are some of the highest-spin organic molecules rivalling high-spin $3d^5$ $Mn^{II}$, $Fe^{III}$ and $4f^7$ $Gd^{III}$ ions. However, these organic open-shell species are kinetically unstable and can be kept only in solid solution at cryogenic temperature under exclusion of air. Stable counterparts that can be bottled in the neat state under air are limited to perchlorinated triradical **4** ($S$ = 3/2).[4] Knowing that the methoxy group, while weakening the ferromagnetic coupling, increases the kinetic stability of **5**,[5] and that **6**[6] is a reasonably stable quartet, we designed pentakis(aminoxyl) radical **7** as a stable, high-spin, and high-spin-density pentaradical.

Pentaradical **7** was prepared in a manner similar to the procedure[6] for triradical **6** by using bis(hydroxyamino) derivatives protected with *tert*-butyldimethylsilyl groups in place of protected monohydroxylamines. A solution of 1-bromo-4-methoxy-3,5-bis[*N*-*tert*-butyl-*N*-(*tert*-butyldimethylsiloxy)-amino]benzene in THF was lithiated with *n*-butyllithium and coupled with 0.5 mol equiv. of pentyl nitrite to give monoradical **7a**† (7.7%) whose EPR spectrum ($\nu_0$ = 9.509 GHz) in benzene showed a hyperfine structure consisting of a triplet of quintets ($a_N$ = 10 G, $a_H$ = 1.85 G). Monoradical *N*,*N*-bis[4-methoxy-3,5-bis(*N*-*tert*-butyl{*N*-*tert*-butyldimethylsiloxy}-amino)phenyl]aminoxyl **7a** was deprotected in the presence of $NBu^n_4F$ followed by oxidation with silver oxide in ether and purification by column chromatography (silica gel/*n*-hexane–diethyl ether). Recrystallization from ether gave indefinitely stable pentaradical **7** as red needles.‡ It is somewhat unstable in dilute benzene and THF solution; a decrease of the EPR signal intensity by 5% was observed after 24 h under ambient conditions. Pentaradical **7** crystallizes in the monoclinic space group $P2_1/n$ (no. 14) with four molecules in the unit cell. An ORTEP drawing and stick model for the molecular and crystal structure of **7** are shown in Fig. 1(*a*) and (*b*), respectively.‡

The crystal was found to contain 0.5 of a molecule of diethyl ether per molecule of **7** and it is situated near the radical unit $S_{A1}$. The molecular structure of **7** has no symmetry axis and two sets of aminoxyl radicals $S_A$ and $S_B$ have *syn* and *anti*§ conformations, respectively, with respect to the benzene ring. The dihedral angles of the central *N*,*N*-diarylaminoxyl radical $S_C$ with the two aryl rings are 23.7 and 32.9° and those of $S_A$ and two $S_B$ with the benzene rings are relatively large [60–76°; Fig. 1(*a*)]. The average distances among the three aminoxyl radical moieties within a molecule are in the range 4.96–5.74 Å to construct a two-triangular five-spin system. As indicated in Fig. 1(*b*), there are two intermolecular short distances i and ii between the radical centers which should be responsible for the appearance of a strong intermolecular antiferromagnetic interaction at low temperature;[8] two molecules make a head-to-tail dimer structure with a separation of 3.35 Å and the resulting dimers align at a distance of 3.69 Å to form a chain structure along the *b* axis.

The X-band EPR spectrum of pentaradical **7** in toluene solution at room temp. showed one broad signal with $\Delta H_{PP}$ = 20 G at $g$ = 2.0064. In the corresponding spectrum ($\nu_0$ = 9.410 GHz) of **7** in frozen solution at 6.5 K, five signals (318.8, 327.2, 335.3, 343.4, and 351.8 mT) were observed in addition to the signal ($g$ = 4.019) due to a $\Delta m_S$ = 2 transition. The spectrum was simulated as a sextet with $S$ = 5/2 to afford $g$ = 2.0062 and zero-field splitting parameters $|D/hc|$ = 0.0039 and $|E/hc|$ = 0.0013 $cm^{-1}$.¶ As the temperature was increased from 12 to 100 K, the intensity of the signal at $g$ = 2 decreased in accordance with the Curie law, suggesting that the sextet was a ground state.

The magnetic susceptibility of a crystalline sample of pentaradical **7** was measured on a SQUID magnetometer/susceptometer in the temperature range 2–350 K at a constant field of 200 mT. The $\chi_{mol}T$ value at 350 K is 2.09 emu K $mol^{-1}$

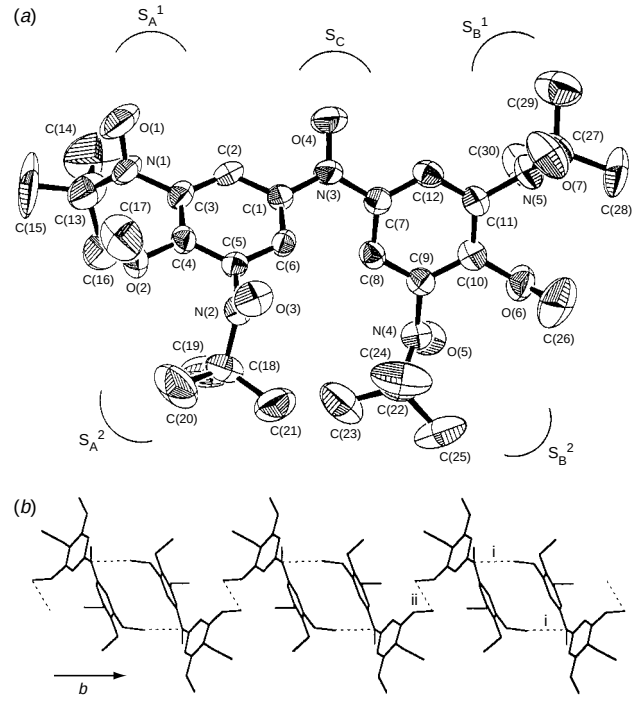


**Fig. 1** Molecular and crystal structure of pentaradical **7**: (*a*) ORTEP drawing with thermal ellipsoid plot at the 30% probability level. The diethyl ether molecule of crystallization is omitted for clarity; torsion angles between the benzene ring and the radical N–O bond are 75.8°, −62.9, −63.1 and 60.3° for $S_A^1$[O(1)N(1)C(3)C(2)], $S_A^2$[O(3)N(2)C(5)C(6)], $S_B^1$[O(7)N(5)C(11)C(12)] and $S_B^2$[O(5)N(4)C(9)C(10)], respectively. The average distances between the two nitrogens and two oxygens are 5.53, 5.56 and 4.96 Å for $r(S_{A1}S_{A2})$, $r(S_{A1}S_C)$ and $r(S_{A2}S_C)$ and 5.57, 5.74 and 5.04 Å for $r(S_{B1}S_{B2})$, $r(S_{B1}S_C)$ and $r(S_{B2}S_C)$, respectively, and (*b*) a stick model of crystal structure; Bu$^t$ groups are omitted for clarity. Broken lines indicate short contacts (Å) between the atoms of the radical centers; (i) 3.35 and (ii) 3.60.

which is slightly greater than 1.88 emu K mol$^{-1}$ calculated as a spin only value for five isolated radical centers. As the temperature was decreased from 350 K, $\chi_{mol}T$ values increased gradually and reached a maximum of 2.22 emu K mol$^{-1}$ at 120 K and then decreased sharply. The maximum value is considerably smaller than theoretical 4.38 emu K mol$^{-1}$ for $S$ = 5/2 and suggests that intermolecular antiferromagnetic interaction takes place predominantly below 120 K, as expected from the X-ray crystal structure of **7**.

In order to exclude the contribution of the intermolecular antiferromagnetic interaction at low temperature, a sample of **7** doped in poly(vinyl chloride) (PVC) matrix was prepared and employed for a SQUID measurement. The field dependence of a PVC film‖ containing 2% **7** was investigated at 2, 4, and 6 K and the $M/M_S$ *vs.* $H/T$ plot is shown in Fig. 2 together with a theoretical curve obtained on the basis of the Brillouin function** for $S$ = 5/2. The theoretical curve fitted the experimental data reasonably well indicating that the five aminoxyl radicals interact ferromagnetically to produce a sextet state.

In summary, stable pentaradical **7** was successfully prepared and its molecular structure was revealed by X-ray structure analysis. Its magnetic properties revealed that ferromagnetic interactions occur predominantly among the five spins within a molecule to produce a sextet ground state. However, the exchange coupling parameters ($J$) among them could not be estimated quantitatively from a $\chi_{mol}T$–$T$ plot since the intermolecular antiferromagnetic interaction among the pentaradical

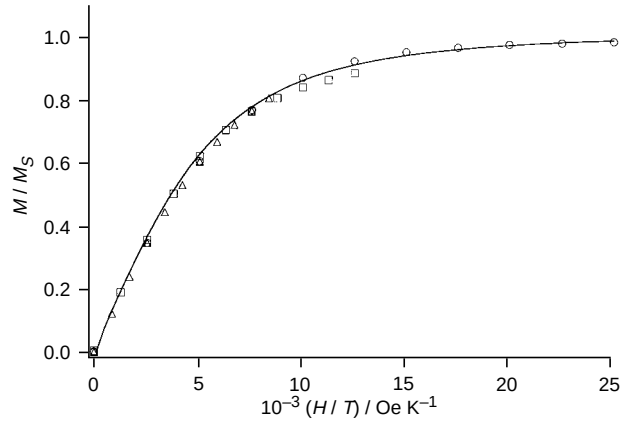

**Fig. 2** Field dependence of the magnetization at 2 (○), 4 (□), and 6 K (△) as expressed by $M/M_S$ *vs.* $H/T$ plots for pentaradical **7**. The solid curves are theoretical ones for $S$ = 5/2 as described in text.

molecules at low temperature caused by short intermolecular contacts between radical centers in the crystalline state was very strong.

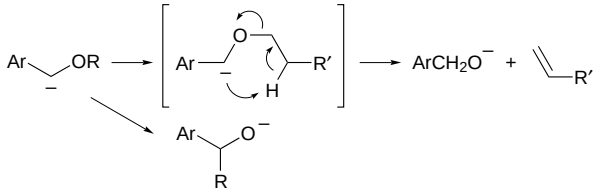
# Base-induced cyclization of 1-benzyloxy-2,2,4,4-tetramethylpentan-3-ones: intramolecular nucleophilic addition of an anion of a benzyl ether to the carbonyl moiety without the Wittig rearrangement or protophilic decomposition

**Masakatsu Matsumoto,* Nobuko Watanabe, Akio Ishikawa and Hiroyuki Murakami**

*Department of Materials Science, Kanagawa University, Tsuchiya, Hiratsuka, Kanagawa 259-12, Japan*

**Alkyl benzyl ethers bearing a carbonyl moiety in the alkyl chain (1) cyclize effectively, without the Wittig rearrangement or protophilic decomposition, to give hydroxytetrahydrofurans (*trans*-2) on treatment with Bu$^t$OK in DMSO at room temperature, whereas LDA–THF induces the cyclization of 1 to afford predominantly the stereoisomer *cis*-2.**

The α-carbanion of an alkyl benzyl ether is unstable and undergoes protophilic cleavage (elimination)[1,2] or Wittig rearrangement[3–5] even at low temperature (Scheme 1), so that little is known of its nucleophilic addition or substitution reactions, although extensive studies have been made on the rearrangement and the decomposition.[6] We report here that (i) the α-carbanion of an alkyl benzyl ether is able to add effectively to a carbonyl moiety in the alkyl chain *via* intramolecular nucleophilic addition without Wittig rearrangement or protophilic decomposition, and (ii) the addition is sterically controlled by the base–solvent system used.



When benzyl ether **1a** (1.1 g, 4.0 mmol) was treated with Bu$^t$OK (8.0 mmol) in DMSO (12 ml) under $N_2$ at room temperature for 4 h, **1a** was exclusively transformed into tetrahydrofuran *trans*-**2a** (91%), which was isolated as a colourless oil in 88% yield after chromatographic purification ($SiO_2$) (Table 1, entry 1). The structure of *trans*-**2a** was determined by $^1$H NMR, NOESY, IR and mass spectral analysis.† A combination of base and solvent, *e.g.* Bu$^t$OK–THF or MeONa–DMSO, was ineffective for the cyclization of **1a**. On the other hand, after treatment of **1a** with LDA–THF at room temperature for 2 h, the cyclization took place smoothly to afford a stereoisomer *cis*-**2a** as colourless crystals (mp 83.0–83.5 °C) together with a small amount of *trans*-**2a** (*cis* : *trans* = 82 : 18) (94%) (entry 2). When the cyclization was carried out at 0 °C, the stereoselectivity was somewhat improved (*cis* : *trans* = 91 : 9) (entry 3). The reaction of **1a** with LDA–THF proceeded sluggishly at −78 °C. The other benzyl ethers **1b**–**d** also underwent base-induced cyclization to afford the corresponding tetrahydrofurans **2b**–**d** with similar stereoselectivities, as shown in Table 1. It is noteworthy that even benzyl ether **1c** bearing an electron-donating substituent at the *para*-position underwent cyclization in LDA–THF, even though Bu$^t$OK–DMSO was ineffective (entries 6 and 7).

The present results showed that (i) an alkyl benzyl ether is probably stable enough to undergo nucleophilic reaction without Wittig rearrangement or decomposition, so long as an electrophile such as a carbonyl moiety exists in a favourable situation, and (ii) the stereoselectivity of cyclization is tightly controlled by the base–solvent system used. The stereoselectivity can probably be rationalized as follows: for the Bu$^t$OK–DMSO system, a naked anion of **1** attacks the carbonyl *via* transition state **T-1**, in which interaction between the aryl and *tert*-butyl groups is minimized, thus giving the sterically less congested isomer *trans*-**2** (Scheme 2). On the other hand, in the

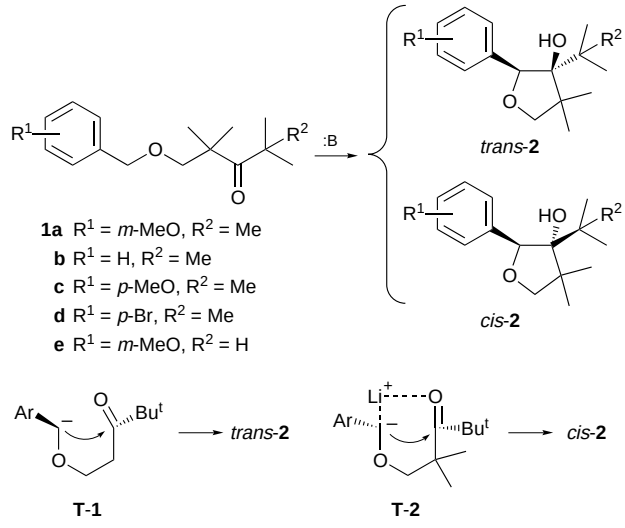


**Table 1** Base-induced cyclization of alkyl benzyl ethers **1**

| Entry | | System[a] | *t*/h[b] | Conversion (%)[c] | Ratio *trans* : *cis*[d] |
|---|---|---|---|---|---|

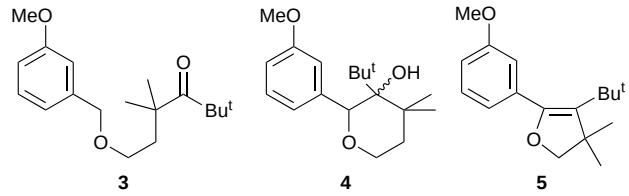
| 5 | **1b** | B | 2 | 99 | **2b** 9 : 91 |
| 6 | **1c** | A | 4 | 0 | — — |
| 7 | **1c** | B | 5[f] | 86 | **2c** 12 : 88 |
| 8 | **1d** | A | 4 | 99 | **2d** 100 : 0 |
| 9 | **1d** | B | 2 | 96 | **2d** 10 : 90 |
| 10 | **1e** | A | 4 | 72 | **2e** 93 : 7 |
| 11 | **1e** | B | 5[f] | 63[g] | **2e** 13 : 87 |

[a] A: **1** (4.0 mmol), Bu$^t$OK (8.0 mmol), DMSO (12 ml). B: **1** (4.0 mmol), LDA (8.0 mmol), THF (12 ml). [b] Carried out at room temp. unless stated otherwise. [c] No product other than **2** was observed, unless stated otherwide. [d] Determined *via* $^1$H NMR analysis of the crude product. [e] Reaction performed at 0 °C. [f] Reaction performed at −78 °C for 2 h and then at room temp. for 3 h. [g] *trans*-**2e** (5.5%), *cis*-**2e** (31%) and **1e** (37%) recovered after chromatography.



**Scheme 1**

**Scheme 2**

LDA–THF system a lithium ion might coordinate the carbonyl oxygen and the benzyl α-carbanion in transition state **T-2** to afford *cis*-**2** predominantly, even though the repulsive interaction between the aryl and *tert*-butyl moieties is thermodynamically unfavourable. This rationalization is consistent with the effect of temperature on the stereoselectivity in the cyclization of **1a** using LDA–THF. It is noteworthy that 18-crown-6 promoted the *trans*-selective cyclization of **1a** with Bu$^t$OK in THF to give *trans*-**2a** exclusively (room temp. for 4.5 h; 87%).

Since the substrate **1** lacks a β-hydrogen on the alkyl chain, it is not susceptible to protophilic decomposition to form a terminal alkene (Scheme 1), but it should undergo [1,2]-Wittig rearrangement. Thus, we examined the reaction of benzyl ether **3** as a representative ether bearing β-hydrogens on the alkyl chain. Treatment of **3** with LDA in THF (−78 °C to room

**3** **4** **5**

temp.) gave the expected cyclization product **4** in high yield,‡ while the use of Bu$^t$OK–DMSO induced almost no reaction. Thus, intramolecular nucleophilic addition of the α-carbanion of an alkyl benzyl ether to the carbonyl of the alkyl site takes place effectively even if it bears β-hydrogens. In addition, we should note that benzyl ether **1e** bearing an isobutyryl moiety also gave the corresponding cyclization product **2e** on treatment with a base even though **1e** possesses an acidic proton adjacent to the carbonyl moiety (entries 10 and 11).

Both isomeric hydroxytetrahydrofurans *trans*- and *cis*-**2a** were easily dehydrated to give dihydrofuran **5**, which is a key intermediate for the synthesis of a dioxetane used as a highly efficient chemiluminescent substrate[7]§ in high yield upon treatment with $SOCl_2$ and pyridine at room temperature. The other furans **2** obtained here were similarly dehydrated to give the corresponding dihydrofurans.

The present results show that the α-carbanion of an alkyl benzyl ether such as **1** or **3** undergoes nucleophilic addition to a carbonyl moiety existing in the same molecule without Wittig rearrangement or protophilic decomposition. Furthermore, the present cyclization should form a facile entry to sterically crowded cyclic enol ethers.

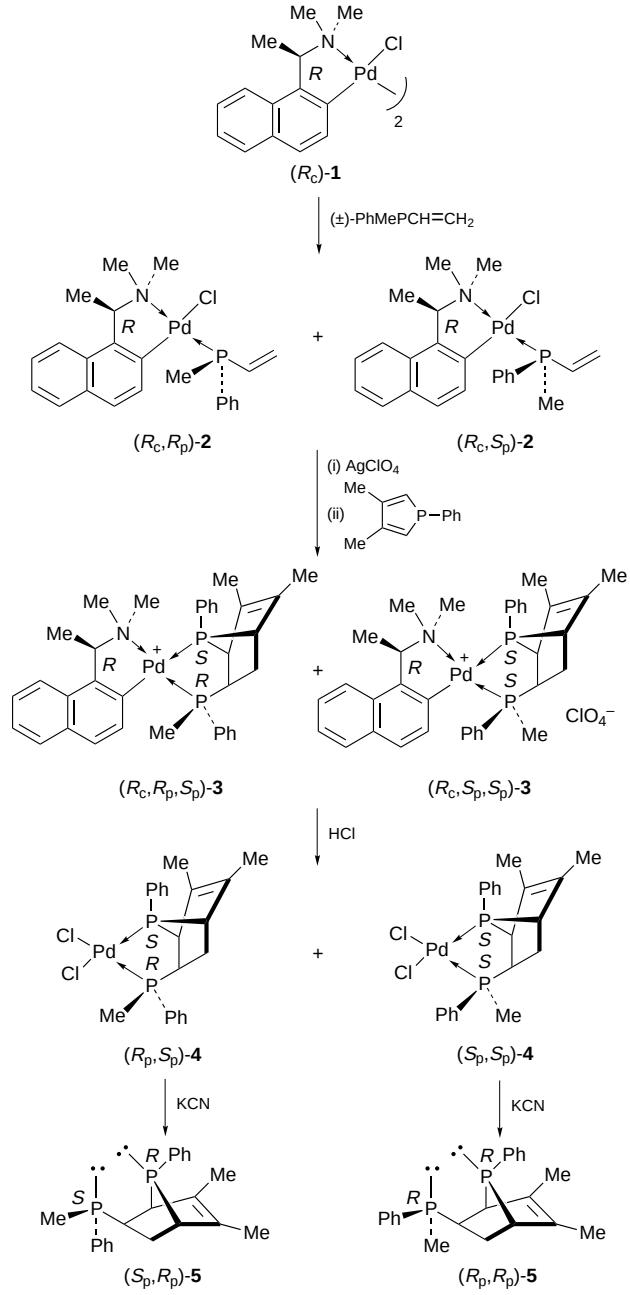
# Asymmetric synthesis of two diastereomeric P-chiral diphosphine ligands containing a pair of dissimilar asymmetric phosphorus donor atoms



**Anming Liu, K. F. Mok and Pak-Hing Leung***

*Department of Chemistry, National University of Singapore, Kent Ridge 119260, Singapore*

**Two diastereoisomeric P-chiral diphosphine ligands, each containing a pair of dissimilar phosphorus donor atoms, have been prepared efficiently in their optically pure forms from a chiral organopalladium complex-promoted asymmetric Diels–Alder reaction between 1-phenyl-3,4-dimethylphosphole and methylphenylvinylphosphine.**

Enantiomerically pure P-chiral diphosphines are critically important as chiral auxiliaries in asymmetric catalysis.[1] To date, these chiral ligands are readily available from asymmetric synthesis[2] or from classic optical resolution.[1,3] However, no asymmetric synthesis of diphosphines containing a pair of dissimilar asymmetric phosphorus donor atoms have been reported hitherto. The sole example of optical resolution of a related ligand, 1-(methylphenylarsino)-2-(methylphenylphosphino)benzene, required the somewhat difficult separation of the (*R**,*R**) and (*R**,*S**) diastereoisomers prior to the individual resolution of the two racemic diastereoisomers.[3] We believe that the development of a more efficient asymmetric synthesis to all possible diastereoisomers of dissimilar P-chiral diphosphines may present a unique opportunity to probe in detail the subtle stereochemical interactions between diphosphine auxiliaries and the incoming reaction substrates in the important field of homogeneous asymmetric catalysis. We now delineate the first asymmetric synthesis of two diastereoisomeric P-chiral diphosphines without the prerequisite diastereoisomer separation which can be rather tedious.

As illustrated in Scheme 1, the racemic form of methylphenylvinylphosphine split the chlorine bridges in ($R_c$)-**1** regiospecifically[4] to give a pair of diastereoisomeric complexes ($R_c$,$R_p$)- and ($R_c$,$S_p$)-**2**. The neutral complexes could not be separated by fractional crystallization and were crystallized quantitatively as a 1 : 1 diastereoisomeric mixture from $CH_2Cl_2$–$Et_2O$. The 202 MHz $^{31}P$ NMR spectrum of the crystallized product in $CDCl_3$ exhibited two sharp singlets of equal intensity at $\delta$ 17.1 and 17.2. Treatment of this diastereoisomeric chloro complex mixture with silver perchlorate gave the corresponding perchlorato analogues.[5] These reactive intermediates were not isolated and were treated directly with stoichiometric quantities of 1-phenyl-3,4-dimethylphosphole in $CH_2Cl_2$ at room temperature for 4 h. Thus a 1 : 1 mixture of the diastereoisomeric complexes ($R_c$,$R_p$,$S_p$)-**3** and ($R_c$,$S_p$,$S_p$)-**3** was formed quantitively. The $^{31}P$ NMR spectrum of the crude reaction mixture in $CDCl_3$ exhibited only four doublets of identical coupling constants (41.9 Hz) and similar intensities. Two of these doublets were recorded at $\delta$ 116.2 and 116.7. These typical low-field $^{31}P$ NMR chemical shifts are consistent with the formation of two stereochemically distinct bridgehead phosphorus atoms with the *exo-syn* stereochemistry in the two diastereoisomers. The other two non-bridgehead phosphorus atoms exhibited doublet resonances at $\delta$ 38.4 and 44.2. The diastereoisomeric template complexes, however, could not be induced to crystallize. Treatment of the complex mixture with conc. HCl removed the naphthylamine auxiliary chemoselectively to give the dichloro complexes ($R_p$,$S_p$)-**4** and ($S_p$,$S_p$)-**4**. These diastereoisomeric complexes exhibited very different solubilities in organic solvents. Hence, upon crystallization from $CH_2Cl_2$–$Et_2O$, the less soluble ($S_p$,$S_p$) isomer was obtained as pale yellow prisms (90%), mp > 230 °C (decomp.), $[\alpha]_D$ +11.2 (*c* 0.5, $CH_2Cl_2$). The more soluble ($R_p$,$S_p$) isomer was subsequently obtained from $CHCl_3$–$Et_2O$ as beige prisms (70%), mp > 230 °C (decomp.), $[\alpha]_D$ +97.6 (*c* 0.5, $CH_2Cl_2$). The molecular structure and the absolute stereochemistry of both diastereoisomers were determined by X-ray structural analyses (Figs. 1 and 2).† The studies reveal that the absolute

**Scheme 1**

Selected bond lengths (Å) and angles (°); Pd–P(1) 2.238(1), Pd–P(2) 2.219(1), Pd–Cl(1) 2.359(1), Pd–Cl(2) 2.365(1), P(1)–C(1) 1.836(3), P(1)–C(9) 1.815(3), P(1)–C(15) 1.809(3), P(2)–C(2) 1.847(3), P(2)–C(5) 1.850(3), P(2)–C(21) 1.804(3), C(1)–C(6) 1.570(4), C(3)–C(4) 1.341(5), P(1)–Pd–P(2) 83.0(1), P(1)–Pd–Cl(1) 170.4(1), P(1)–Pd–Cl(2) 90.1(1), P(2)–Pd–Cl(1) 91.6(1), P(2)–Pd–Cl(2) 172.8(1), Cl(1)–Pd–Cl(2) 95.5(1), C(2)–P(2)–C(5) 81.6(1).

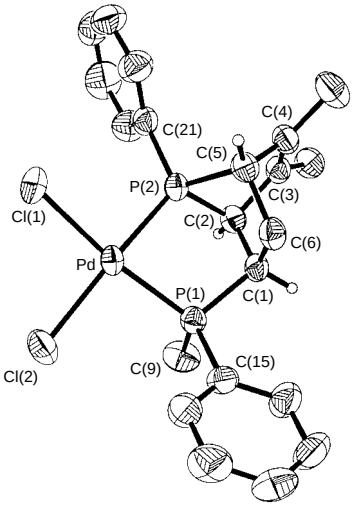


**Fig. 2** Molecular structure and absolute stereochemistry of ($S_p$,$S_p$)-**4**. Selected bond lengths (Å) and angles (°); Pd–P(1) 2.246(1), Pd–P(2) 2.223(1), Pd–Cl(1) 2.351(1), Pd–Cl(2) 2.380(1), P(1)–C(1) 1.825(3), P(1)–C(9) 1.801(3), P(1)–C(15) 1.806(3), P(2)–C(2) 1.833(3), P(2)–C(5) 1.837(3), P(2)–C(21) 1.801(3), C(1)–C(6) 1.561(4), C(3)–C(4) 1.325(4), P(1)–Pd–P(2) 82.8(1), P(1)–Pd–Cl(1) 172.7(1), P(1)–Pd–Cl(2) 93.0(1), P(2)–Pd–Cl(1) 90.4(1), P(2)–Pd–Cl(2) 170.4(1), Cl(1)–Pd–Cl(2) 94.1(1), C(2)–P(2)–C(5) 82.1(1).

configurations at P(2), C(1), C(2) and C(5) in both molecules are *S*, *R*, *S* and *S*, respectively, and the two isomers are diastereoisomeric at P(1) only.

Treatment of a $CH_2Cl_2$ solution of ($S_p$,$S_p$)-**4** with aqueous cyanide liberated the optically pure diphosphine ($R_p$,$R_p$)-**5** quantitatively as an air-sensitive oil with $[\alpha]_D$ −22.6 (*c* 0.5, $CH_2Cl_2$). The $^{31}$P NMR spectrum of the free diphosphine in $CDCl_3$ exhibited a pair of doublets at $\delta$ 91.2 and −22.6 ($J_{PP}$ 70.2 Hz). The low field $^{31}$P resonance indicates that the *exo–syn* stereochemistry is retained. It is noteworthy that the apparent inversion of configuration that takes place at both phosphorus stereogenic centres during the liberation reaction is merely a consequence of the Cahn–Ingold–Prelog (CIP) rules.[6] The optical purity of ($R_p$,$R_p$)-**5** was further confirmed by the quantitative repreparation of ($R_c$,$S_p$,$S_p$)-**3** from the liberated ligand and ($R_c$)-**1**: the 202 MHz $^{31}$P NMR spectrum of the crude product exhibited a pair of doublets at $\delta$ 116.7 and 38.4 only. Similarly, free diphosphine ($S_p$,$R_p$)-**5** was liberated from ($R_p$,$S_p$)-**4** as an air-sensitive oil with $[\alpha]_D$ +42.4 (*c* 0.5, $CH_2Cl_2$). The $^{31}$P NMR spectrum of ($S_p$,$R_p$)-**5** in $CDCl_3$ exhibited the two doublet resonances at $\delta$ 91.4 and −22.8 ($J_{PP}$ 66.6 Hz).

Finally, it should be noted that the enantiomeric forms of ($R_p$,$R_p$)- and ($S_p$,$R_p$)-**5** can be prepared similarly from methylphenylvinylphosphine and 1-phenyl-3,4-dimethylphosphole using ($S_c$)-**1** as the chiral reaction promoter. Investigations on the catalytic properties of transition metal complexes containing these optically active diastereoisomeric diphosphines are currently in progress.

We are grateful to the National University of Singapore for support of this research (Grant No. RP960675) and research scholarships to A. M. L.

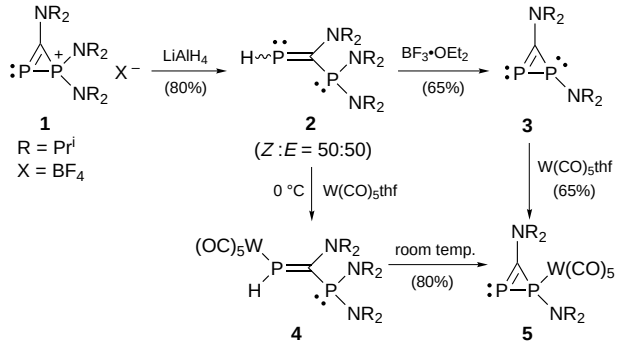
# New routes to free and coordinated 1*H*-diphosphirenes

**Didier Bourissou, Yves Canac, Maria Isabel Collado, Antoine Baceiredo and Guy Bertrand***

*Laboratoire de Chimie de Coordination du CNRS, 205 route de Narbonne, 31077 Toulouse Cédex 04, France*

**Diphosphirenium salt 1 reacts with $LiAlH_4$ leading to *P*-hydrophosphaalkene 2, which on treatment with a catalytic amount of $BF_3{\cdot}OEt_2$ affords 1*H*-diphosphirene 3, while with a stoichiometric amount of $W(CO)_5$(thf), complex 4 is obtained.**

Among the smallest dinitrogen- and diphosphorus-containing unsaturated heterocycles **A**–**D**, only the chemistry of 3*H*-diazirines **A** has been extensively explored.[1] So far, no 3*H*-diphosphirenes **B** have been observed,[2] and only one 1*H*-diazirine **C**[3] has been spectroscopically characterized. The only known free 1*H*-diphosphirene **D** was isolated as long ago as 1989 by Niecke *et al.*,[4a] although two complexes featuring heterocycle **D** as an $\eta^1$-ligand have been prepared more recently.[4b,c] The lack of simple synthetic methods for the preparation of heterocycles **D** has undoubtedly hampered the development of their chemistry. Indeed, all the known examples have been obtained by addition of free[4a] or coordinated phosphinidenes[4b,c] to phosphaalkynes. Here we report new synthetic routes to free and coordinated heterocycles **D** which are reminiscent of the Neber synthesis of 2*H*-azirines[5] and the Graham synthesis of 3-halogeno-3*H*-diazirines.[6]



**A** **B** **C** **D**

We have already shown that ring opening reactions occur when the readily available diphosphirenium salt **1**[7a,b] is treated with nucleophiles.[7c,d] In a similar way, addition of one equivalent of lithium aluminium hydride to a thf solution of **1** afforded the corresponding *P*-hydrophosphaalkene **2** as a 50 : 50 mixture (according to NMR spectroscopy) of *Z* and *E* isomers in 80% total yield.†

The similarity between compound **2** and the Neber and especially the Graham amidine precursors is obvious. However, instead of using a base to induce the 1,3-elimination reaction, a thf solution of **2** was treated with a catalytic amount (5%) of $BF_3{\cdot}OEt_2$ at room temperature. After work up, the 1*H*-diphosphirene **3** was obtained as a light yellow oil in 65% yield. The spectroscopic data† for **3** compared well with those reported for the other known 1*H*-diphosphirene.[4a]

The corresponding coordinated 1*H*-diphosphirene **5** can be obtained by treatment of **3** with $W(CO)_5$(thf);[8] from **2**, the two step process gave access to complex **5** in 42% yield. Interestingly, addition of one equivalent of $W(CO)_5$(thf) to phosphaalkene **2** directly afforded **5** which was isolated after workup in 80% yield. Monitoring the reaction by $^{31}$P NMR spectroscopy at 0 °C showed the primary formation of complex **4** as a single isomer in an *E* configuration,[9] where the metal is $\eta^1$-bonded to the $\sigma^2$-phosphorus atom [$^{31}$P NMR: −71.0 (s, $^1J_{PH}$ 267.4, $^1J_{PW}$ 129.4 Hz, P–H), +66.5 (s, P–$NR_2$)]. The transformation of **4** into **5** involved both the elimination of diisopropylamine and the migration of the metal fragment. The former process is probably induced by a catalytic amount of $W(CO)_5$(thf) which acts as a Lewis acid. The metal shift is governed by the higher thermodynamic stability of **5** compared to the isomeric complex featuring the metal fragment at the $\sigma^2$-phosphorus atom.

**Scheme 1**

These new synthetic routes can be used on multi-gram scales readily allowing for the development of the chemistry of 1*H*-diphosphirenes, as shown by the recent preparation of a diphosphirenylium salt complex[8] and a diphosphirenyl radical dimer.[10]

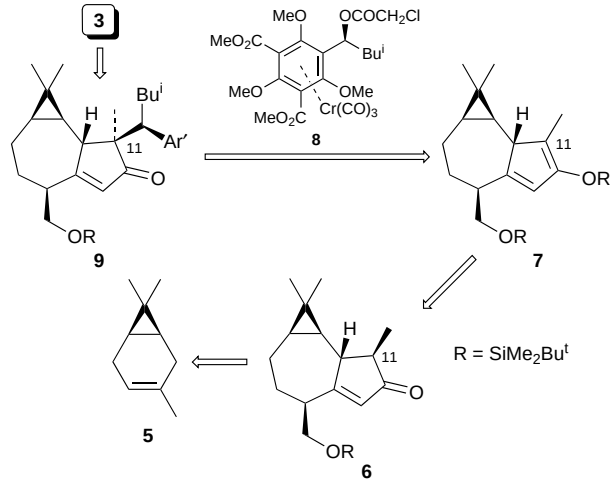
# First stereoselective total synthesis of macrocarpal C: structure elucidation of macrocarpal G

**Tetsuaki Tanaka,[a] Hidenori Mikamiyama,[a] Kimiya Maeda,[a] Toshimasa Ishida,[b] Yasuko In[b] and Chuzo Iwata*[a]**

[a] *Faculty of Pharmaceutical Sciences, Osaka University, 1-6 Yamadaoka, Suita, Osaka 565, Japan*
[b] *Osaka University of Pharmaceutical Sciences, 4-20-1 Nasahara, Takatsuki, Osaka 569-11, Japan*

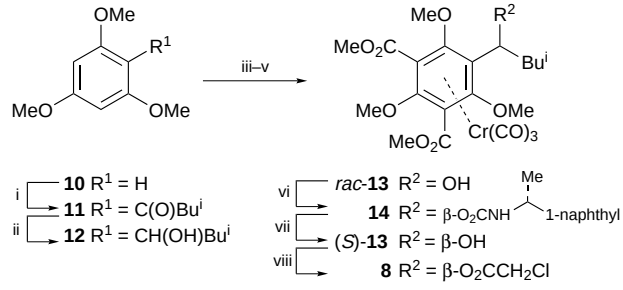
**The first stereoselective total synthesis of macrocarpal C is achieved *via* a coupling reaction of a silyl dienol ether with a novel hexasubstituted benzene chromium tricarbonyl complex as an optically active benzyl cation equivalent, thereby clarifying the identity of macrocarpal C and G.**



Macrocarpals[1,2] are structurally characterized by fusion of isopentylphloroglucinol dialdehyde to various sesquiterpene skeletons and are known to exhibit various interesting biological activities, such as antibacterial activity,[2a,c,e,g] inhibitory activity of HIV reverse transcriptase,[2b] aldose reductase[2d,e] and glucosyl transferase.[2e,g] Since the original isolation of macrocarpal A **1** from *Eucalyptus macrocarpa* in 1990,[2a] a number of macrocarpals have been isolated from *Eucalyptus* species.[2b–g] Complete structures have been elucidated for macrocarpals A (**1**), B (**2**) and C (**3**) using X-ray diffraction studies and spectral and chemical investigations, and the absolute stereochemistries of **1** and **3** have been determined by a modified Mosher's method.[2b] Macrocarpal G **4**,[2c] however, has been assigned the same planar structure as **3**,† and quite a few macrocarpals have not been designated relative stereochemistries. In this communication, we report the first and highly stereoselective total synthesis of macrocarpal C **3**, thereby clarifying its identity with respect to macrocarpal G **4**.

Macrocarpal A **1** (β-Ar) Macrocarpal C **3** Macrocarpal G **4**
Macrocarpal B **2** (α-Ar)

Ar = 2,4,6-trihydroxy-3,5-diformylphenyl



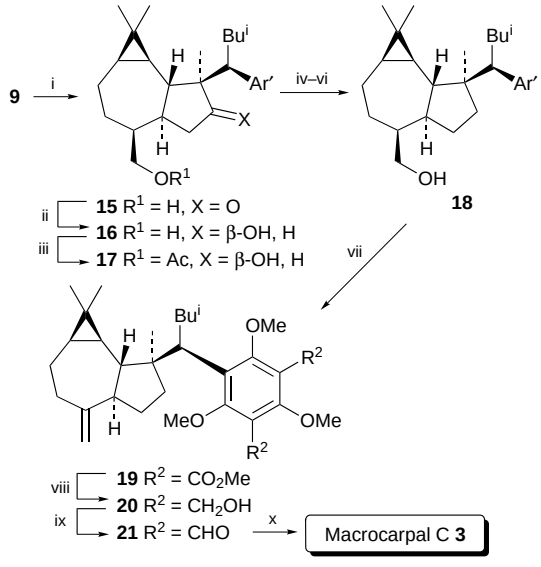
As illustrated in the retrosynthetic analysis of macrocarpal C **3** (Scheme 1), our synthetic approach began from the previously reported tricyclic enone **6**,[3] which we prepared from the commercially available and inexpensive (+)-3-carene **5**. The coupling reaction of the sesquiterpene moiety **6** with the isopentylphloroglucinol dialdehyde part is a crucial step requiring high stereoselectivity at both the benzylic and C11 positions. To this end, we planned the Lewis acid mediated coupling reaction of silyldienol ether **7** with a novel hexasubstituted benzene chromium tricarbonyl complex **8** as an optically active benzyl cation equivalent. Our previous studies suggested that an electrophile would be introduced stereoselectively at the C11 position from the less hindered β-side of **7**.[3] In connection with stereochemical control at the benzylic position, it is known that, with some nucleophiles, $S_N1$-type carbon–carbon bond formation *via* the $Cr(CO)_3$-stabilized carbonium ion proceeds with stereochemical retention at the benzylic position.[4] Hence, the desired coupling product **9**,

**Scheme 1**

which possesses the requisite functionalities and desired stereochemistry for the subsequent manipulations toward macrocarpal C **3**, would be obtained selectively after complexation.

Scheme 2 outlines the synthesis of the chiral chromium complex **8** starting from commercially available 1,3,5-trimethoxybenzene **10**. Friedel–Crafts acylation of **10** with isovaleryl chloride, followed by LAH reduction led to alcohol **12** *via* ketone **11**. After complexation of **12** with $Cr(CO)_6$, stepwise introduction of two methoxycarbonyl groups *via* direct nuclear lithiation[5] to the aromatic ring furnished diester *rac*-**13**. The resolution of this racemic benzyl alcohol was then examined. Diastereomeric carbamates derived from the CuCl assisted[6]

**Scheme 2** *Reagents and conditions*: i, isovaleryl chloride, $AlCl_3$, $CH_2Cl_2$, 0 °C, 81%; ii, LAH, $Et_2O$, 0 °C, 91%; iii, $Cr(CO)_6$, $Bu^n_2O$–1,4-dioxane–*n*-heptane (5 : 5 : 1), 120 °C, 43% (92% based on conversion); iv, $Bu^nLi$, TMEDA, THF, −78 °C, then $CO_2$, −78 °C, then $TMSCHN_2$, $C_6H_6$–MeOH (4 : 1); v, LDA, TMEDA, THF, −50 °C, then $CO_2$, −78 °C, then $TMSCHN_2$, $C_6H_6$–MeOH (4 : 1), 75% overall; vi, (*R*)-(−)-1-(1-naphthyl)ethyl isocyanate, CuCl, DMF, 99%, then separation; vii, $BF_3{\cdot}Et_2O$, wet MeCN, 0 °C, 81%; viii, $(ClCH_2CO)_2O$, pyridine, $CH_2Cl_2$, 0 °C, 92%



**Scheme 3** *Reagents and conditions*: i, Bu$^t$Me$_2$SiOTf, Et$_3$N, Et$_2$O–CH$_2$Cl$_2$ (1 : 1), 98%; ii, **8**, ZnCl$_2$, CH$_2$Cl$_2$; iii, CAN, MeOH, 0 °C, 61% from **8**

reaction of *rac*-**13** with (*R*)-(−)-1-(1-naphthyl)ethyl isocyanate[7] were separated by simple chromatography on silica gel. Hydrolysis of the polar carbamate **14** was achieved by treatment with $BF_3{\cdot}Et_2O$ in hydrous MeCN to provide the alcohol (*S*)-**13**, $[\alpha]_D^{26}$ −21.9 ( > 98% ee) without racemization.‡ Finally, (*S*)-**13** was converted to the chloroacetate **8**, which was expected to have the required reactivity.[8]

With the desired chiral complex **8** as an aromatic side-chain unit in hand, we subjected **8** to the coupling reaction (Scheme 3). For this purpose, the enone **6** was converted to the *tert*-butyldimethylsilyl dienol ether **7**. A 1.5-fold excess of this intermediate was then coupled with the chiral complex **8** in the presence of ZnCl$_2$[9] to afford **9** stereoselectively§ after decomplexation with ceric ammonium nitrate (CAN).

Since the stereoselective route to the promising precursor of macrocarpal C **9** had already been developed, we further pursued the total synthesis (Scheme 4). Catalytic hydrogenation of the enone **9** afforded desilylated ketone **15** with the desired stereochemistry.[3] NaBH$_4$ reduction of **15** followed by acetylation of the primary hydroxy group led to monoacetate **17**¶ *via* diol **16**. The application of modified Grieco's protocol[10] allowed dehydration of the C10 secondary hydroxy group of **17**. Deacetylation of the resulting product followed by catalytic hydrogenation afforded alcohol **18**, which was subjected to dehydration again, furnishing *exo*-olefin **19**. DIBAL-H reduction of diester **19** followed by oxidation afforded trimethyl macrocarpal C **21** *via* diol **20**. Finally, the cleavage of all three methyl ethers was fully achieved by our original method (10 equiv. of 4-MeC$_6$H$_4$SLi, 50 equiv. of HMPA, toluene, reflux)‖ to furnish macrocarpal C **3**, which was identical to a natural authentic sample ($^1$H and $^{13}$C NMR).** Moreover, the synthetic sample was found to be identical to natural macrocarpal G **4**.††

**Scheme 4** *Reagents and conditions*: i, $H_2$ (5 atm), 10% Pd–C, MeOH, 88%; ii, NaBH$_4$, MeOH, 96%; iii, Ac$_2$O, DMAP, CH$_2$Cl$_2$, 100%; iv, 2-NO$_2$C$_6$H$_4$SeCN, Bu$^n_3$P, THF, sealed tube, 75 °C, then 30% aq. $H_2O_2$ 0 °C; v, NaOMe, MeOH, 64% from **17**; vi, $H_2$ (5 atm), 10% Pd–C, MeOH, 100%; vii, 2-NO$_2$C$_6$H$_4$SeCN, Bu$^n_3$P, THF, 50 °C, then 30% aq. $H_2O_2$, 0 °C, 77%; viii, DIBAL-H, toluene, −78 °C, 100%; ix, Pr$^n_4$NRuO$_4$, 4-methylmorpholine *N*-oxide, molecular sieves 4 Å, MeCN, 87%; x, 4-MeC$_6$H$_4$SLi, HMPA, toluene, reflux, 58%

We thank Professor Mugio Nishizawa (Tokushima Bunri University) for provision of natural macrocarpal C **3** and copies of its spectra. We also thank Professor Seiichi Homma (Ochanomizu University) for copies of the spectra for natural macrocarpal G **4**. This research was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, Sports and Culture of Japan (No. 08672425).

## Footnotes and References

* E-mail: iwata@phs.osaka-u.ac.jp

† The $^1$H and $^{13}$C NMR spectra of macrocarpals C **3** and G **4** were measured in different solvents, which made comparison difficult. In ref. 1, however, it has been considered that these were diastereomers due to the difference between their physicochemical properties.

‡ Enantiomeric purity was determined by $^1$H NMR analysis of Mosher ester derivatives.[11] Absolute stereochemistry was assigned by Mosher's method.[12]

§ A small amount (2%) of the benzylic epimer of **9** was obtained, but neither the C11 epimer nor the regioisomer was isolated.

¶ The structural assignment of **17** was confirmed by X-ray crystallographic analysis of its C10 carbonylimidazolide derivative **22**. *Crystal data* for **22**: $C_{39}H_{54}N_2O_{11}$, $M$ = 726.86, orthorhombic, space group $P2_12_12_1$, $a$ = 16.723(2), $b$ = 19.979(2), $c$ = 11.547(2) Å, $V$ = 3858.0(9) Å$^3$, $Z$ = 4, $D_c$ = 1.251 g cm$^{-3}$, $\mu$(Cu-K$\alpha$) = 7.13 cm$^{-1}$, $F$(000) = 1560, $T$ = 293 K. The structure was solved by direct methods and refined by full-matrix least-squares to $R$ = 0.052 and $R_w$ = 0.067 using 2185 reflections with $F_o > 3\sigma(F_o)$. CCDC 182/601.

‖ A preliminary study suggested that only bis-demethylation would occur by the use of sodium salt (4-MeC$_6$H$_4$SNa), as previously reported.[13]

** Synthetic **3** displayed $^1$H and $^{13}$C NMR spectra that were indistinguishable from those of the natural isolate and showed the following optical properties: $[\alpha]_D^{25}$ −22.1 (*c* 0.150, EtOH). A small rotation, $[\alpha]_D^{24}$ −3.0 (*c* 0.92, EtOH), was originally reported for **3** that had been isolated from *E. globulus*.[2b] This rotation, however, is believed to be erroneous due to contamination of the natural sample (M. Nishizawa, personal communication, April 15, 1997).

†† Synthetic **3** exhibited spectroscopic data ($^1$H, $^{13}$C, IR) identical to those for natural macrocarpal G **4**. The rotation for synthetic **3**, $[\alpha]_D^{25}$ −24.7 (*c* 0.135, MeOH), corresponded closely to the rotation reported for **4**, $[\alpha]_D$ −27.1 (*c* 0.59, MeOH).[2c]

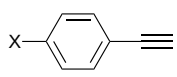
# ≡CH··π *versus* ≡CH···Halogen interactions—the crystal structures of the 4-halogenoethynylbenzenes

**Hans-Christoph Weiss,[a] Roland Boese,*[a] Heather L. Smith[b] and Michael M. Haley[b]**



[a] *Institut für Anorganische Chemie, Universität Essen, Universitätsstrasse 3-5, D-45117 Essen, Germany*
[b] *Department of Chemistry, University of Oregon, Eugene, Oregon 97403, USA*

**The crystal structures of the 4-halogenoethynylbenzenes are quite similar and exhibit ≡CH···π interactions, whereas the structure of 4-fluoroethynylbenzene has very interesting and rare intermolecular ≡CH···F contacts.**

The X-ray crystal structures of 1,4-dihalogenobenzenes (α-form of 1,4-dichlorobenzene) are, for the most part, isomorphous;[1–6] notable exceptions are the structures of 1,4-diiodobenzene[7] and those which contain fluorine.[8] For mixed 1,4-dihalogenobenzenes a disorder was found such that the positions of the ring carbon atoms are almost fixed, but the sites of the halogens are crystallographically equivalent.[1,9] The packing motif typically found in 1,4-dihalogenobenzenes is a zigzag pattern of intermolecular X···X interactions.

Fluorine containing compounds, however, crystallize differently.[8] Fluorine often plays a special role in that it is expected not to exhibit intermolecular F···F contacts. We recently reported the crystal structures of a series of ethynylated benzenes in which ≡CH··π interactions predominated.[10] Combining both moieties (halogen and ethynyl group) in a single benzene derivative might lead to a deeper insight into the intermolecular interactions of the ethynyl group.

Accordingly we present the crystal structures of the 4-X-ethynylbenzenes (with X = F **4**, Cl **1**, Br **2** and I **3**).† The

**1** X = Cl
**2** X = Br
**3** X = I
**4** X = F

X-ray structures of compounds **1**, **2** and **3** are isomorphous. The cell dimensions are quite similar and remarkably also comparable to those of the 1,4-dihalogenobenzenes. The packing motif of **1** is easy to surmise: the molecules form a layer structure in the *bc* plane similar to that observed in the α-form of 1,4-dichlorobenzene,[2–4] in 1,4-dibromobenzene,[5] and also in 1,4-diethynylbenzene.[10,11] The molecules are tilted by 32.7° out of this plane (Fig. 1) and are held together by attractive ≡CH··π and Cl··Cl contacts, both of which dominate the packing. This geometry of T-shaped ≡CH··π hydrogen bridges is known from other alkynes,[12] as well as the zigzag pattern of the terminal chlorine atoms (*e.g.* in the α-form of 1,4-dichlorobenzene[2–4]). The ≡CH··π contacts to the center of the triple bond are quite short whereas the intermolecular Cl··Cl distances are relatively long (Table 1) but still have a significant attractive character.

Molecules **2** and **3** are disordered in the same manner as the mixed 1,4-dihalogenobenzenes: the center of inversion is in the center of the disordered ring system. This means that if the disorder is resolved 50% of the 1- and 4-positions of the benzene ring are occupied by the halogen atom and 50% by the ethynyl group (Fig. 2). Nevertheless, the packing motifs are the same as in **1** or in the 1,4-dihalogenobenzenes with the same zigzag pattern at the two ends of the molecules. For bromide **2**, two different positions of the ring system could be found and refined. The intermolecular interactions that determine the crystal packing are ≡CH··π and X···X. Hydrogen bridges between the ethynyl hydrogen atom to bromine or iodine might exist if statistical disorder is assumed; however, this is not very likely because the resulting ≡CH···X distances are much shorter than the sums of the van der Waals radii ($d_{H\cdots Br}$ = 243.9, $\Sigma_{vdW}$ = 299; $d_{H\cdots I}$ = 238.9, $\Sigma_{vdW}$ = 314 pm[13]). This indicates that the disorder is not statistical; instead there exists a disorder in which ordered domains or layers within the lattice are statistically distributed in the crystal.

**Table 1** Selected intermolecular geometric parameters of compounds **1–3**[a]

| Comp. | *d*(X–X)/pm | ∠(C–X···X)(°) | *d*(≡CH··M)/pm | ∠(≡CH··M)(°) |
|---|---|---|---|---|
| **1** | 379.0 | 92.5 | 357.9 | 171.9 |
| **2** | 386.7 | 96.1 | 266.9 | 173.6 |
| **3** | 394.9 | 97.0 | 255.7 | 174.9 |

[a] M represents the center of the triple bond, X the halogen atoms. The positions of the hydrogen atoms were normalized to a C–H distance of 108 pm.

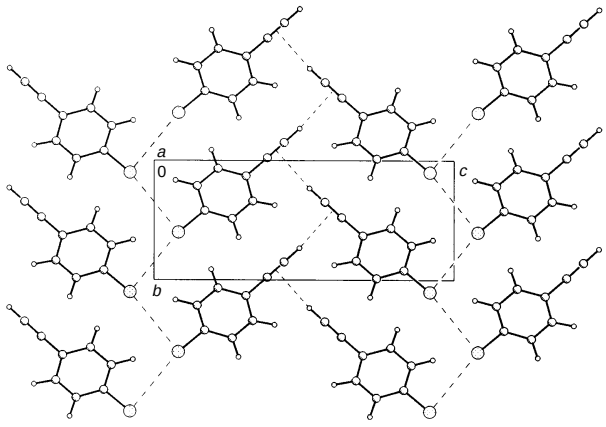


**Fig. 1** View along *a*-axis of the crystal structure of **1**

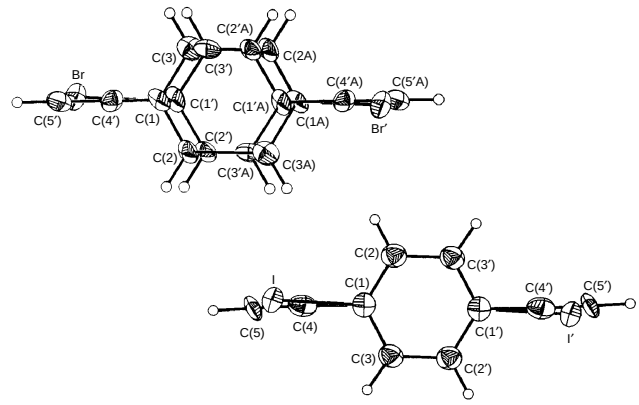

**Fig. 2** The type of disorder of **2** and **3**

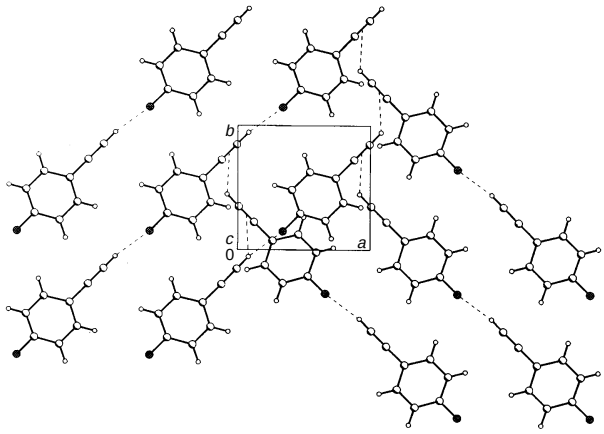

**Fig. 3** The two interactions which dominate the packing in the structure of **4**

In contrast to the other systems, the packing of fluoride **4** is totally different, as is shown in Fig. 3. Two attractive forces dominate the arrangement. In both cases the ethynyl hydrogen atoms serve as hydrogen bridge donors. One acceptor is the triple bond, but this contact does not possess an ideal geometry: The ≡CH··π distance is comparatively long (307.6 pm) and the angle ≡C–H··π is rather small (129.4°). The other attractive contact is much more interesting: a hydrogen bond to covalently bound organic fluorine is very much disputed.[14,15] The ≡CH··F distance in **4** is 226.4 pm and thus is significantly shorter than the sum of the van der Waals radii (254 pm[13]). The ≡CH··F angle of 140.4° supports the assumption that a ≡CH··F hydrogen bridge exists, at least if the carbon atom is sp-hybridized. This is also sustained by the fact, that the packing of **4** is totally different compared to 4-halogenoethynylbenzenes **1**–**3**. Therefore we must conclude that the predominant interactions in **4** consist of ≡CH··F hydrogen bridges.

We gratefully acknowledge the DFG, the Fonds der Chemischen Industrie and the NSF for financial support of this work.

# Macropolyhedral boron-containing cluster chemistry. Triple cluster fusion and the molecular structure of $[(PMe_3)_2IrB_{26}H_{24}Ir(CO)(PMe_3)_2]$. A 28-vertex metallaborane cluster with a polyboron core†

**Jonathan Bould,[a,b] John D. Kennedy,*[a] Lawrence Barton[b] and Nigam P. Rath[b]**

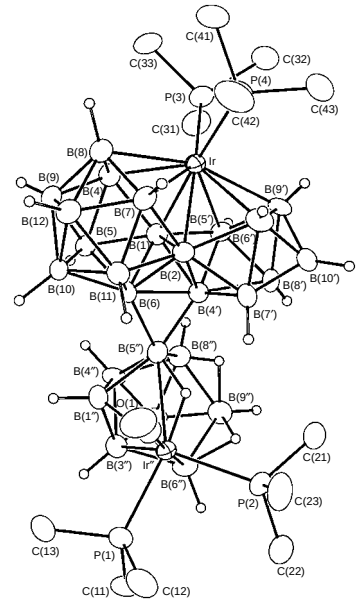
[a] *The School of Chemistry of the University of Leeds, Leeds, UK LS2 9JT*
[b] *The Department of Chemistry of the University of Missouri St. Louis, St. Louis, Missouri 63121, USA*

**$[(PMe_3)_2IrB_{26}H_{24}Ir(CO)(PMe_3)_2]$, from the thermolysis of $[(CO)(PMe_3)_2HIrB_8H_{12}]$ in molten $B_{10}H_{14}$, is a triple-cluster species that consists of *closo* twelve-vertex $\{IrB_{11}\}$ and *closo* ten-vertex $\{IrB_9\}$ units fused by (*a*) a common $\{IrB_2\}$ triangular face and (*b*) by an adjacent 'wedge' interboron linkage that also binds a *nido* nine-vertex $\{IrB_8\}$ subcluster; the resulting $\{Ir_2B_{26}\}$ cluster has a novel five-boron core.**

The extension of contiguous polyhedral boron-containing cluster chemistry beyond the constraints of single clusters of up to fourteen vertices is engendered by cluster fusion to generate so-called macropolyhedral species. Several compounds of up to about twenty vertices have been synthesized by the fusion of two clusters, but triple fusion to generate larger macropolyhedral assemblies has so far proved elusive. The *arachno* nine-vertex system appears to be particularly suitable for cluster-fusion chemistry, for example in the synthesis of $B_{18}H_{22}$ and its derivatives,[1] and in macropolyhedral platinaborane,[2] thiaborane,[3] and iridaborane formation.[4] These processes all appear to occur *via* reactive nine-vertex intermediates. We surmised that, if these intermediates are generated in the presence of suitable substrates of intermediate reactivity, then the possibility of mixed or multiple fusion to generate larger macropolyhedral assemblies arises. In this regard the *arachno*/*nido* $\{IrB_8\}$ system has interesting reactivity,[5] and we have recently reported preliminary results on the autofusion of the *arachno* nine-vertex compound $[(CO)(PMe_3)_2HIrB_8H_{12}]$ to give double-cluster $[(CO)(PMe_3)_2IrB_{16}H_{14}Ir(CO)(PMe_3)_2]$[4] and the mixed cluster fusion of molten *nido*-$B_{10}H_{14}$ with $[(CO)(PMe_3)_2HIrB_8H_{12}]$ to give double-cluster $[(PMe_3)_2(CO)IrB_{17}H_{20}]$ **1**.[6] We now report preliminary findings on the principle of multiple cluster fusion, as manifested in the isolation and characterization of a triple-cluster species of formulation $[(PMe_3)_2HIrB_{26}H_{24}(CO)(PMe_3)_2]$ **2** from the latter molten $B_{10}H_{14}$ system.

The sample of compound **2** was prepared by reaction of $[(CO)(PMe_3)_2HIrB_8H_{12}]$ (25 mg, 610 μmol) with $B_{10}H_{14}$ (134 mg; 1100 mmol; mp *ca*. 99 °C) under $N_2$ at 134 °C for 25 min. The excess of molten $B_{10}H_{14}$ was used to engender solubility of $[(CO)(PMe_3)_2HIrB_8H_{12}]$ and also to minimise the double-cluster autofusion[4] that would give $[(CO)(PMe_3)_2IrB_{16}H_{14}Ir(CO)(PMe_3)_2]$. The excess $B_{10}H_{14}$ was then removed by vacuum sublimation (bath *ca*. 80 °C). Extraction with $CH_2Cl_2$, filtration through silica gel, followed by repeated TLC (95 : 5 $CH_2Cl_2$–MeCN) on silica gel G revealed many coloured products, and ultimately gave an orange band [$R_F$ 0.7 using $CH_2Cl_2$–hexane (1 : 1)] as a predominant component. HPLC separation (silica, Lichrosorb Si60 7 μm; 260 × 16 mm column; rapid initial gradient 25% $CH_2Cl_2$ in hexane to 100% $CH_2Cl_2$, flow rate 4 ml $min^{-1}$) gave one impure major component of $R_T$ *ca*. 32 min, and several minor components, of which one has been identified as [7,7-$(PMe_3)_2$-7-(CO)-*syn*-7-$IrB_{17}H_{20}$] **1** ($R_T$ *ca*. 30 min).[6] Repeated fractional crystallisation of the principal component of the mixture with $R_T$ *ca*. 32 min gave a small sample ( < *ca*. 500 μg) of orange–yellow crystals of a $CH_2Cl_2$ solvate of $[(PMe_3)_2IrB_{26}H_{24}Ir(CO)(PMe_3)_2]$ **2** (Fig. 1). They were identified by single crystal X-ray diffraction analysis‡ and NMR spectroscopy.§ Although the very small quantities and complex nature of the compound have precluded chemical shift assignments by homonuclear $^1H$ or $^{11}B$ NMR COSY techniques, the NMR data on the bulk material are otherwise consistent with the structure of Fig. 1. Separation of the many reaction products is difficult; NMR spectroscopy suggests the presence of a number of other large iridaborane cluster compounds.

Structurally the compound is seen to be based on the conceptual fusion, with a common $\{IrB_2\}$ triangular face, of a *closo* twelve-vertex $\{IrB_{11}\}$ unit **IA** and a *closo* ten-vertex $\{IrB_9\}$ unit **IB**. The clusters are additionally linked by an interboron 'wedge' linkage that is also involved in multicentre bonding to the third subcluster, a *nido* nine-vertex $\{IrB_8\}$ unit **IC**. This latter linkage is reminiscent of the intercluster linkages in the simpler macropolyhedrals $B_{14}H_{22}$ and $B_{15}H_{23}$.[9] Mechanistically, *arachno* $[(CO)(PMe_3)_2HIrB_8H_{12}]$ will readily dehydrogenate to give *nido* $[(CO)(PMe_3)_2IrB_8H_{11}]$ under the



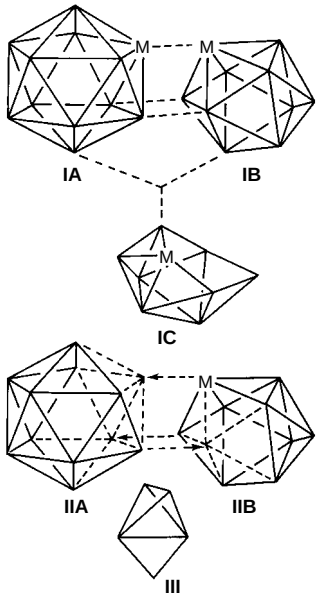


**Fig. 1** Representation of the crystallographically determined molecular structure of $[(PMe_3)_2IrB_{26}H_{24}Ir(CO)(PMe_3)_2]$ with non-hydrogen atoms as thermal ellipsoids of 50% probability, and with the methyl hydrogen atoms omitted for clarity. Selected interatomic distances (Å): to Ir: B(1) 2.149(8), B(2) 2.248(8), B(4) 2.296(9), B(7) 2.330(9), B(8) 2.329(9), B(5′) 2.416(8), B(6′) 2.273(10), B(9′) 2.351(9); to Ir″: B(1″) 2.161(8), B(3″) 2.263(9), B(5″) 2.533(8), B(6″) 2.287(9). Selected interboron distances: to B(6): B(1) 1.786(11), B(2) 1.874(12), B(5) 1.814(12), B(10) 1.776(11), B(11) 1.797(12), B(4′) 1.822(11), B(5″) 1.854(12); to B(7′): B(4′) 1.848(12), B(8′) 1.859(12), B(6′) 1.832(12), B(10′) 1.688(12), B(2) 1.803(12). Angles (°) between interatomic vectors at B(2) are in the ranges 53.4(4)–69.0(4), 98.9(4)–113.8(8), 121.4(5)–124.8(7) and 143.7(6)–155.4(7).

reaction conditions.[4,10] A *nido* {$IrB_8$} unit **IIB** will supply two vertices to the *nido* decaboranyl skeleton **IIA** to generate the {$IrB_{11}$} unit **IA**, with a reciprocal supply of one vertex to the *nido* unit **IIB** to generate the {$IrB_9$} unit **IB**. The fusion mechanism is thereby seen to be the successive addition of two *nido*-type {$IrB_8$} units **IC** and **IIB** to the *nido*-decaboranyl substrate **IIA**. Although a very minor product of a reaction system that yields several complex iridaboranes, a simple stoichiometry can be written as in eqn. (1).

$$2[(CO)(PMe_3)_2HIrB_8H_{12}] + B_{10}H_{14} \rightarrow [(PMe_3)_2IrB_{26}H_{24}Ir(CO)(PMe_3)_2] + CO + 8H_2 \quad (1)$$

Compound **2** has several noteworthy features. (*a*) It nicely demonstrates the principle of triple cluster fusion and (*b*) with 28 vertices it one of the biggest contiguous boron-cluster compounds yet synthesized. (*c*) There are two vertices, one boron and one iridium, that have the high cluster connectivity number eight. The iridium atom has the high overall coordination number ten. If multicentre bonding of boron is limited to participation in two- and three-centre bonding only, eight-connectivity represents the maximum for boron with its four valence orbitals. (*d*) The {$IrB_8$} subcluster still retains *nido* nine-vertex character, and is therefore in principle available for further cluster incorporation, either for increased condensation within the 28-vertex system, or for fusion with a further substrate to generate quadruple cluster character. (*e*) At the region of conjunction of the three subclusters there is a central five-boron unit **III** without *exo* substituents.

This last feature suggests new types of families of large borane-based species based on globular structures that have condensed inner borons-only cores surrounded by outer spheres based on boron hydride cluster features, as distinct from the rope-like structures envisaged by extension of classical two-borons-in-common macropolyhedral fusion modes.[11] The known species $B_{20}H_{16}$, with a four-boron core,[12] is a simpler example of this. At the other extreme, a boron ball surrounded by a boron–hydride skin could be envisaged. In principle a continuum of behaviour between the ropes and the globules is available. These globular-core configurations for large borane clusters contrast to (hypothetical) hollow fullerene-based boron structures upon which speculation has recently centred.[13] Metal cluster compounds can be regarded as domains of metal lattice with peripheral valencies occupied by ligands, and hydrocarbons can be regarded as based on fragments of diamond or graphite with peripheral valencies bound to hydrogen. In this context it may be noted that there is a tetrahedral {$B_4$} unit in β-rhombohedral boron itself,[14] at the point of fusion of three icosahedral units with a common vertex.

We thank the Johnson-Matthey Company for a loan of $IrCl_3 \cdot 3H_2O$, the National Science Foundation (USA) and the EPSRC (UK) for the financial support of this work, and the NSF for a grant to purchase the X-ray diffractometer used.

**A novel tetranuclear iron(III) complex, [{$Fe_2$(tren)$_2$($\mu$-O)}$_2$($\mu_4$-$PO_4$)][$ClO_4$]$_5$·2.5$H_2O$ 1 [tren = tris(2-aminoethyl)-amine], is synthesized; X-ray crystal structure analysis reveals that 1 contains a tetranuclear cation in which the iron atoms are linked by a $\mu_4$-$PO_4^{3-}$ bridge, which is a hydrolytic product from 4-nitrophenyl phosphate.**

The important and diversified roles of iron in biology have long been recognized and intensively studied. Non-heme iron proteins, besides iron–heme and iron–sulfur proteins, have attracted intensive attention in recent years.[1] This class of iron proteins contain either mono- or oxo-bridged binuclear or polynuclear iron cores, such as those found in hemerythrin, ribonucleotide reductase, purple acid phosphatase and ferritin.[1] Therefore, tremendous efforts have been devoted to the synthesis and characterization of binuclear and polynuclear iron model complexes to facilitate the understanding of structure and function of nonheme iron proteins. Hitherto, at least two tetranuclear iron(III) complexes were found to occur in nature.[2] Almost all of the synthetic tetranuclear iron(III) compounds can be envisaged as dimers of dimers, at least in terms of their molecular architecture.[3–9] These complexes can be further classified into three structure types: the first is termed 'butterfly' with a $[Fe_4(\mu_3\text{-}O)_2]^{8+}$ core[3] or $[Fe_4(\mu_3\text{-}OR)_2]^{10+}$ (R = H, Me) cores;[4,5] the second contains a distorted adamantane-like $[Fe_4(\mu\text{-}X)_2(\mu\text{-}OH)_2(\mu\text{-}O)_2]^{4+}$ (X = hydroxo, alkoxo or phenoxo) cores;[6] and the third can be viewed as consisting of two well separated $Fe_2(\mu\text{-}X)(\mu\text{-carboxylato})_n$ (X = O, OH, alkoxo; $n$ = 1, 2) cores,[7–9] which are linked through two non-interacting hydrocarbon tethers,[7] two oxo[8] or two alkoxy[9] bridges. Another interesting tetranuclear iron(III) system contains a 'metallocrown' core which consists of an $(Fe–N–O)_3$ ring capped by another iron(III).[10]

In our effort to synthesize model complexes for purple acid phosphatase which catalyzes the hydrolysis of certain phosphate esters under acidic conditions,[1] a novel tetranuclear iron(III) complex, [{$Fe_2$(tren)$_2$($\mu$-O)}$_2$($\mu_4$-$PO_4$)][$ClO_4$]$_5$·2.5$H_2O$ **1** was produced. The most interesting aspect of **1** is that the bridging $PO_4^{3-}$ group was a hydrolytic product of a phosphate monoester which was used as a precursor together with an iron(III) polyamine complex in our synthetic reaction. This suggests that the iron(III) polyamine actually expedites the hydrolytic cleavage of the ester bond in the phosphate monoester, a process likely involving a two- or poly-metal mechanism. To the best of our knowledge, this is the first example of a tetranuclear iron(III) complex in which the four iron(III) are linked with a $\mu_4$-$PO_4^{3-}$ bridge. Here we report the synthesis and structural characterization of the novel compound **1**.

When 4-nitrophenyl phosphate was treated with a methanol solution of $Fe^{III}$ and tren, a green solid was readily formed. The tetranuclear iron(III) complex **1** was isolated by filtration.† Its structure was determined by single crystal X-ray analysis.‡ Two other products were also obtained when the filtrate was evaporated in air. One is yellow and spectral analysis shows that it is 4-nitrophenol which is another hydrolytic product from 4-nitrophenyl phosphate. The second product is red and is insoluble in common organic solvents. Its IR and Raman spectra show that it may be a mononuclear iron(III) complex containing tren and 4-nitrophenyl phosphate ligands, but no $ClO_4^-$ anion.

The cation structure in complex **1** is shown in Fig. 1. Four iron centers, each chelated by a tetradentate tren ligand, are connected pairwise by two μ-oxo and further consolidated by a tetradentate phosphate. The complex can thus be viewed as consisting of two (tren)Fe–O–Fe(tren) units with a central tetradentate $PO_4^{3-}$ group bridging all four irons. The two 'dimers' are structurally similar but crystallographically independent. The Fe–O(oxo) distances and Fe–O–Fe angles fall in the normal range.[1a] However, the bond lengths of Fe(3)–O(6) [1.813(6) Å] and Fe(4)–O(6) [1.822(6) Å] are slightly longer than those of Fe(1)–O(5) [1.805(6) Å] and Fe(2)–O(5) [1.785(6) Å], the angle Fe(3)–O(6)–Fe(4) [129.4(3)°] is smaller than that of Fe(1)–O(5)–Fe(2) [134.2(3)°], and the distance of Fe(3)···Fe(4) (3.286 Å) is slightly shorter than that of Fe(1)···Fe(2) (3.307 Å). This can be elucidated by the formation of a hydrogen bond between the bridging O(6) and a neighboring water molecule [O(6)···O(1w) 2.743 Å]. The presence of this hydrogen bond confers a partial hydroxo character to O(6) and results in elongation of the Fe–O(6) bond

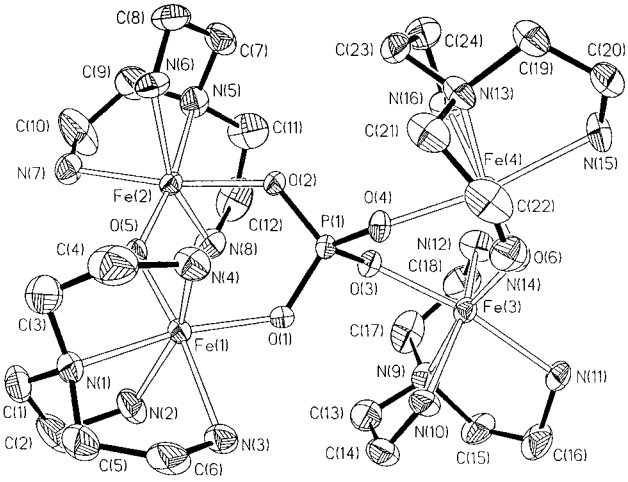

**Fig. 1** Structure of the tetranuclear iron cation in **1**. Selected interatomic distances (Å) and angles (°): Fe(1)···Fe(2) 3.307, Fe(3)···Fe(4) 3.286, Fe(1)···Fe(3) 5.768, Fe(1)···Fe(4) 5.942, Fe(2)···Fe(3) 6.014, Fe(2)···Fe(4) 6.013, Fe(1)–O(1) 1.955(6), Fe(1)–O(5) 1.805(6), Fe(1)–N(1) 2.204(8), Fe(1)–N(2) 2.180(9), Fe(1)–N(3) 2.223(8), Fe(1)–N(4) 2.195(8), Fe(2)–O(2) 2.008(6), Fe(2)–O(5) 1.785(6), Fe(2)–N(5) 2.237(8), Fe(2)–N(6) 2.163(8), Fe(2)–N(7) 2.177(8), Fe(2)–N(8) 2.216(8), Fe(3)–O(3) 2.005(6), Fe(3)–O(6) 1.813(6), Fe(3)–N(9) 2.225(8), Fe(3)–N(10) 2.185(8), Fe(3)–N(11) 2.196(8), Fe(3)–N(12) 2.182(9), Fe(4)–O(4) 1.984(6), Fe(4)–O(6) 1.822(6), Fe(4)–N(13) 2.231(8), Fe(4)–N(14) 2.172(8), Fe(4)–N(15) 2.197(8), Fe(4)–N(16) 2.186(8); Fe(1)–O(5)–Fe(2) 134.2(3), Fe(3)–O(6)–Fe(4) 129.4(3), Fe(1)–O(1)–P(1) 131.5(3), Fe(2)–O(2)–P(1) 129.9(4), Fe(3)–O(3)–P(1) 126.1(3), Fe(4)–O(4)–O(4) 130.7(3).

distances, narrowing of the Fe(3)–O(6)–Fe(4) angle, and shortening of the Fe(3)···Fe(4) distance. Furthermore, there is a small but significant structural *trans* influence exerted by the oxo-bridges on each of the four iron atoms in complex **1**. The four P–O lengths (av. 1.533 Å) and P–O–P angles (av. 109.8°) are almost equivalent within experimental error, indicating the trianionic charge of the $PO_4^{3-}$ is equally distributed over the four oxygen atoms of the phosphate. The phosphate can therefore be viewed as an ideal tetrahedron. All of the lattice water molecules are found to be involved in hydrogen bonds either to perchlorate [O(2w)···O(18) 2.841, O(2w)···O(21) 2.930, O(3w)···O(25) 2.426 Å] or toμ-oxo [O(6)···O(1w) 2.743 Å].

The UV–VIS spectrum of **1** in acetonitrile exhibits rich features in the 400–500 nm region similar to those of other tetranuclear iron(III) compounds.[7] It displays three strong absorption bands at *ca*. 213, 237 and 320 nm, which are readily assigned to the intraligand transitions. The weak band at *ca*. 693 nm is due to a ligand field transition. The IR spectrum of **1** shows two strong peaks at *ca*. 1145 and 978 $cm^{-1}$ which are characteristic of $PO_4^{3-}$ stretch vibrations. The peak at 778 $cm^{-1}$ can be assigned to the asymmetric Fe–O–Fe stretch vibration, comparable with that found in other oxo-bridged iron(III) compounds.[3b,6a,b,7a,b,8] The symmetric stretch vibration of the Fe–O–Fe unit is Raman active and was found at 464 $cm^{-1}$ in the Raman spectrum of **1**.

Although quite a few tetranuclear iron(III) complexes have been synthesized, almost all of them are bridged by carboxylate ligands. Hence **1** provides the first example of a tetranuclear iron(III) complex linked by a tetradentate phosphate. The most interesting observation in this reaction is that the phosphate monoester undergoes hydrolysis in the presence of the iron(III) polyamine complex, and the intermediate $PO_4^{3-}$ anion functions in the $\mu_4$-mode to generate tetranuclear iron complex **1**. This may involve either a two- or poly-metal mechanism in the hydrolysis reaction. Complex **1** also provides a good model for the hydrolysis of phosphate ester *in vivo* by purple acid phosphatase. Study of the detailed mechanism of the hydrolysis of phosphate mono-, di- and tri-esters by iron polyamine complexes is in progress.

† *Preparation of* **1**: to a red solution of methanol (10 ml) containing $Fe(ClO_4)_3 \cdot 9H_2O$ (0.492 g, 1 mmol) was added tren (0.15 g, 1.03 mmol) dissolved in methanol (10 ml) with stirring at room temp. After stirring for 20 min, to the brown solution was added $Na_2(O_2NC_6H_4OPO_3) \cdot 6H_2O$ (0.19 g, 0.51 mmol), the solution turned graminaceous in a few minutes, followed by precipitation of the complex as a green powder. The mixture was further stirred for 4 h and filtered. The green solid was dissolved in MeCN (5 ml) and filtered, and dark-green crystals were obtained by diffusing ethyl acetate into the acetonitrile solution. Anal. Found: C, 19.21; H, 5.40; N, 14.95. Calc. for $C_{24}H_{77}Cl_5Fe_4N_{16}O_{28.5}P$: C, 19.49; H, 5.21; N, 15.16%. UV–VIS spectrum (MeCN): $\lambda_{max}$ = 213 nm ($\varepsilon = 4.5 \times 10^4$ $dm^3$ $mol^{-1}$ $cm^{-1}$), 237 ($4.7 \times 10^4$), 320 ($3.4 \times 10^4$), 362 (sh), 415 (sh), 448 (712), 490 (540), 693 (br, 120). IR data ($\nu$/$cm^{-1}$, KBr pellet): 1145s ($\nu_{P-O}$), 1113–1088s ($\nu_{Cl-O}$ + $\nu_{P-O}$), 978s ($\nu_{P-O}$), 778m ($\nu_{Fe-O-Fe}$) 627s ($\nu_{Cl-O}$). Raman shift ($cm^{-1}$): 1026 ($\nu_{P-O}$), 941 ($\nu_{Cl-O}$), 627 ($\nu_{Cl-O}$), 464 ($\nu_{Fe-O-Fe}$).

‡ *Crystal data* for **1**: $C_{24}H_{77}Cl_5Fe_4N_{16}O_{28.5}P$, $M$ = 1477.64, monoclinic, space group $P2_1/c$ (no. 14), $a$ = 11.749(3), $b$ = 17.357(2), $c$ = 28.271(4) Å, $\beta$ = 97.41(1)°, $U$ = 5721.9(4) Å$^3$, $Z$ = 4, $D_c$ = 1.715 g $cm^{-3}$, $\mu$ = 1.351 $mm^{-1}$; 7873 independent reflections were collected, of which 7870 were used in the $F^2$ refinement; $R$ = 0.071 [5347 observed reflections with $I > 2\sigma(I)$]. The intensities were collected at 293 K on a Siemens P4 diffractometer using Mo-K$\alpha$ radiation ($\lambda$ = 0.710 73 Å). The crystal structure was solved by direct methods. Two of the five independent perchlorate groups exhibit two-fold orientational disorder. All non-hydrogen atoms were refined anisotropically by full-matrix least squares. Hydrogen atoms were placed in calculated positions with C–H 0.96 Å, assigned fixed isotropic thermal parameters and allowed to ride on their respective parent atoms. All computations were carried out on a PC-486 using the SHELXTL-PC program package. CCDC 182/659.

# Rigorous mathematical approaches to strategic bonds and synthetic analysis based on conceptually simple new complexity indices

**Steven H. Bertz*[a] and Toby J. Sommer[b]**

[a] *Complexity Study Center, 88 E. Main Street, Suite 220, Mendham, NJ 07945, USA*
[b] *Sphinx Pharmaceuticals, A Division of Eli Lilly and Company, Cambridge, MA 02139, USA*

**The enumeration of all possible subgraphs of the molecular graph is the basis for new complexity indices $N_S$ (number of kinds of subgraphs) and $N_T$ (total number of subgraphs) that are useful for synthetic analysis, *e.g.* the determination of topological strategic bonds.**

The first bonds to be broken in the retrosynthetic direction (*i.e.* the last formed in the synthetic direction) have been termed 'strategic bonds' by Corey *et al.*[1] Topological strategic bond identifies one selected on the basis of purely mathematical techniques,[2] and heuristic strategic bond on the basis of current methodology.[3] (Note that it is possible for a bond to be both.) The methods introduced here to calculate the topological strategic bonds are based on the enumeration of all possible subgraphs of a molecular graph $G$.[4] Topological approaches such as graph theory[5] are of interest, as they focus on the fundamental connectivity relationships inherent in a target structure. Setting these in place lies at the heart of synthetic strategy, as emphasized by Hendrickson.[6]

The number of kinds of subgraphs $N_S(G)$ and the total number of subgraphs $N_T(G)$ are new graph invariants,† which are useful indices of the complexity of $G$.[7,8] The relationship between graphs and subgraphs is analogous to that between structures and substructures, which chemists grasp intuitively. For simplicity, only connected skeletal ('hydrogen-suppressed'[5b]) graphs are considered. Then, the molecular graph of methane is a point, ethane is two points connected by a line (the path of length 1), and propane is the path of length 2.[9,10] The molecular graph of 2-methylpropane (2-Me-propane) has 3 'propane' subgraphs in addition to 3 'ethane' and 4 'methane' subgraphs. The graph itself is counted as a subgraph to preserve mathematical rigor.[5]‡ Consequently, $N_T$(2-Me-propane) = 11 and $N_S$(2-Me-propane) = 4.

It is easy to verify that the total number of subgraphs increases monotonically with chain length, branching and cyclization (homologous series), the major criteria of a complexity index.[11,12] Multiple bonds are included by considering multigraphs, *e.g.* ethyne has 1 'ethyne' {●≡●} and 3 'ethene' {●=●} subgraphs in addition to 3 'ethane' and 2 'methane.' Heteroatoms are included in a natural way by finding all possible (labelled) subgraphs of the corresponding labelled molecular graph: propan-2-ol has 1 'propan-2-ol' {(●–)$_2$●–○}, 2 'ethanol' {●–●–○}, 1 'propane' {●–●–●}, 1 'methanol' {●–○}, 2 'ethane' {●–●}, 1 'water' {○} and 3 'methane' {●} subgraphs. Thus, $N_T$(propan-2-ol) = 11, the same as '2-Me-propane' (above). However, 'propan-2-ol' has more kinds of subgraphs; thus, $N_S$(propan-2-ol) = 7, whereas $N_S$(2-Me-propane) = 4. For connectivity $N_T$ is a robust measure, and for the overall complexity $N_S$ is a simple and useful index. When applied to substructures, the latter is also useful in the measurement of molecular diversity.[13]

Fig. 1 illustrates the 1-bond (**2**–**5**), 2-bond (**6**–**15**) and selected 3-bond (**16**–**17**) disconnections for the fused 6-membered ring system **1**,§ which has long been a paramount synthetic problem. The ordered pair $N_S$, $N_T$ is given in parentheses for each structure. Based on $N_T(G)$, the order of increasing complexity in the 1-bond case is **5** < **4** < **3** < **2**, and in the 2-bond case it is **9**, **15** < **8** < **14** < **12** < **7** < **13** < **6** < **11** < **10**. Where the target is dissected into more than one piece, $N_T(G)$ is calculated for each and summed. Of all the possible 2-bond disconnections that break one bond in each ring, only the best one (**13**) is shown here, and it is not very effective.

In the 1-bond case the largest simplification involves breaking the fusion bond (**1**⇒**5**). This disconnection was eliminated from the heuristic bondset by LHASA rule 4: 'to avoid the formation of rings having greater than seven members during antithetic [retrosynthetic] bond cleavage, any bond common to a pair of bridged or fused primary rings whose envelope is eight-membered or larger cannot be considered strategic.'[1] Progress in eight-membered ring synthesis renders this rule archaic,[14] and also rule 1: 'because of the relative ease of formation of common-sized rings, a strategic bond must be in a four-, five-, six-, or seven-membered 'primary' ring.'[1]

If we restrict the problem to annulation of a 6-ring onto a pre-existing bond, then the greatest retrosynthetic simplification is **1**⇒**4**, which corresponds to the ring closure step of the Robinson Annulation. This is consistent with LHASA rule 2A: 'a strategic bond must be directly attached to another ring (*exo* to another ring). . .'.[1] This is one of the most important rules, and it has a purely topological basis. In contrast, the exception is completely heuristic, *viz*. rule 2B: 'due to the paucity of ring closure methods in which bonds are formed to pre-existing three-membered rings, strategic bonds may not be *exo* to rings of that size.'[1] Rule 2B may change with more research, rule 2A

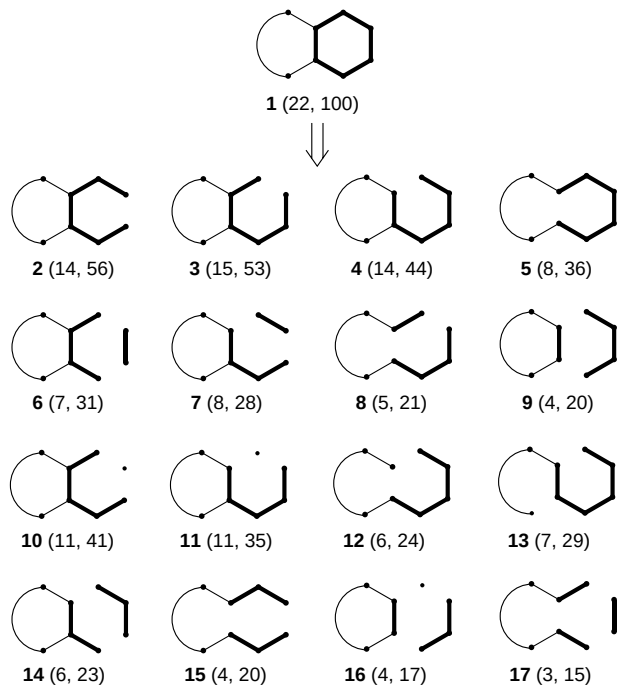

**Fig. 1** 1-bond (**2**–**5**), 2-bond (**6**–**15**), and selected 3-bond (**16**, **17**) disconnections of the fused six-membered ring system **1**; ($N_S$, $N_T$) is given below each structure

will not. Breaking the adjacent ('*exo*') bond minimizes the degrees of the points (valences of the atoms), which is also the basis for rule 3: '. . . strategic bonds should be in the ring (or rings) which exhibits the greatest degree of bridging.'[1]

Of the 2-bond 'Diels–Alder disconnections' resulting in daughters **6**–**9**, the one that affords two pieces of the same complexity (**1**⇒**9**)§ gives the greatest simplification, which is in harmony with the heuristic principle of convergence.[15] It is interesting to note that this 2-bond disconnection is also the overall disconnection for the Robinson Annulation. Furthermore, to minimize the total complexity of the synthetic route by maximizing the symmetry in the synthesis graph (reflexivity),[16] the two pieces should be identical if possible.

Particularly noteworthy is the impressive simplification provided by the 'bis-allyl disconnections' (*e.g.* **1**⇒**14**, **15**), which are comparable to the best Diels–Alder disconnections. This is clearly a reaction that would be worth developing.[17]¶ The 2-bond disconnections that produce an isolated 'methane' (*e.g.* **1**⇒**10**, **11**) are the least efficient of this class. (Synthetic equivalents include $CCl_2$, CN, CO, *etc*.) However, if the 1-carbon fragment is part of a process that forms other bonds as well, the overall result can be very efficient (next paragraph).

The most dramatic simplifications calculated here involve 3-bond disconnections. A particularly interesting 3-bond process is **1**⇒**16**. It corresponds to the Dötz–Wulff reaction, in which the 1-carbon (CO) and 3-carbon units derive from a metal–carbene complex and the 2-carbon unit comes from an alkyne.[18] Disconnection **1**⇒**17** is realized in the cobalt-mediated alkyne trimerization developed by Vollhardt and coworkers.[19] This reaction renders obsolete LHASA rule 5: 'Bonds within aromatic rings are not considered to have potential strategic character.'[1]

An example of the use of $N_S$ in synthetic analysis is provided by disconnections involving heteroatoms. The values of $N_S$ for pentan-1-ol, butyl methyl ether, and ethyl propyl ether are 11, 13, and 12, respectively. These molecules may be considered to be the daughters from the 1-bond disconnections of oxacyclohexane ($N_S$ = 18) at the C–O α-bond, the adjacent C–C β-bond, and the remote C–C γ-bond, respectively. These disconnections have $-\Delta N_S$(α-bond) = 7, $-\Delta N_S$(β-bond) = 5, and $-\Delta N_S$(γ-bond) = 6. ($\Delta N_S$ is the retrosynthetic change in complexity, daughter minus target; $-\Delta N_S$ is the change in complexity in the synthetic direction.) The greatest simplification involves breaking the C–O bond. This is consistent with the LHASA C-heterobond procedure: 'to the set of strategic bonds determined by application of rules 1–6 above is added the collection of bonds in the cyclic network between carbon and O, N and S. . .'.[1] Moreover, $N_S$ also identifies **1**⇒**5** as the most efficient 1-bond and **1**⇒**9**, **15** as the most efficient 2-bond disconnections.

The daughter structures are all subgraphs of the target *T*, as are all the second generation daughters obtained by considering the first generation to be new targets *T*′. Consequently, by generating all possible subgraphs of *T*, we also generate all possible retrosynthetic intermediates and thereby all possible direct synthetic routes. Actual intermediates are usually synthetic equivalents of these retrosynthetic ones and typically contain more atoms, making them more complex. The various routes can then be evaluated by using the principle of minimization of excess complexity[20] or the related principle of maximization of target-relevant complexity.[14]

While our new approach is conceptually simple, for large problems it is important to have a simpler index that parallels $N_T(G)$, and the number of pairs of adjacent bonds $\eta$ ('propane' subgraphs) does this well. Only one pair of structures (**12**, **14**) is ordered differently by $N_T(G)$ and $\eta$, which confirms the validity of our previous work on synthetic analysis.[2,8,11,20] (There are more degeneracies in the simpler index.) The number of spanning trees has also been proposed to be the 'complexity' of a planar graph,[21] but it is not useful for graphs without rings. A 'middle way' might be to count all paths[10] or walks.[22] Moreover, paths, walks or $N_T(G)$ include long-range 'interactions', which can be critically important, as emphasized by Lehn in his $MI_2$ approach to complexity.[23]

In conclusion, the total number of subgraphs $N_T(G)$ is a robust measure of connectivity ('topological complexity'), and the number of kinds of subgraphs $N_S(G)$ is a simple measure of the overall complexity of a molecular graph *G*. These new indices are useful for understanding strategic bond disconnections. Some of them correspond to powerful known reactions, while others suggest new reactions that would efficiently increase molecular complexity. The fact that we can derive certain of the 'heuristic' rules for strategic bonds mathematically establishes that they have a purely topological basis and suggests that topology may be the 'unseen hand' of synthesis. The other rules are revealed to be principally a function of the state of the art, for which our approach provides objective benchmarks.‖

We thank V. Shcherbukhin (Astra Hässle) and W. F. Wright (AT&T) for interesting discussions and useful references.

† Invariants are independent of isomorphism, *i.e.* how the graph is drawn.[5]

‡ By including the graph *G* as a subgraph of itself, $N_T(G)$ is given by simple formulas, *e.g.* $N_T(K_{1,n}) = 2^n + n$ for the star graphs and $N_T(P_{n-1}) = n(n + 1)/2$ for the *n*-alkanes.

§ Strictly speaking, the new 6-ring is annulated onto the middle bond of butane, as the arcs are not included in the subgraphs. Functionality need not be included at the strategic level; *cf*. the antepenultimate paragraph for tactical considerations.

¶ An intramolecular example has been reported;[17] however, it does not increase complexity significantly, as it is not a construction reaction.[6]

# Synthesis and structural characterisation of tripodal titanium silsesquioxane complexes: a new class of highly active catalysts for liquid phase alkene epoxidation

**Mark Crocker,*[a] Ruud H. M. Herold[a] and A. Guy Orpen[b]**

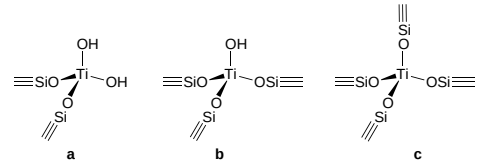
[a] *Shell Research and Technology Centre Amsterdam, Postbus 38000, 1030 BN Amsterdam, The Netherlands*
[b] *School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS*

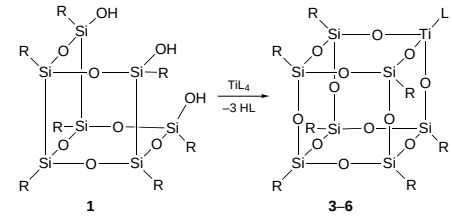
**Titanium silsesquioxane complexes [Ti(L)($R_7Si_7O_{12}$)], possessing tripodal geometry, represent models for heterogeneous titanosilicate catalysts; the new complexes are exceptionally active and selective catalysts for liquid phase alkene epoxidation reactions.**

The remarkable catalytic properties of titanosilicates such as titanium silicalite-1 (TS-1) have generated considerable scientific interest, particularly with regard to the nature of the active titanium species present. It is now generally accepted that a four-coordinate lattice titanium site is the catalytically active species in these materials.[1] Furthermore, recent studies point toward the involvement of titanium sites possessing tripodal geometry, representing so-called open lattice sites,[2,3] although the presence of closed lattice sites ('tetrapodal' sites) and bipodal sites has also been inferred (see Fig. 1).[1,2] With this in mind we have prepared soluble analogues of these different titanium species based on incompletely condensed silsesquioxane precursors and have studied the catalytic properties of the resulting complexes.[4] Recently we became aware of related studies aimed at modelling heterogeneous titanium-based epoxidation catalysts, which also employ silsesquioxane derivatives;[5,6] prompted by these reports we now describe our own findings.

Incompletely condensed silsesquioxanes have recently attracted interest as models for the silica surface.[7,8] Elegant work by Feher and coworkers has revealed that the molecular structure of **1** (see Scheme 1) shares many structural similarities with β-cristobalite (111) and β-tridymite (0001). Although the exact nature of the silica surface is a matter of great controversy, the occurrence of cristobalite- and tridymite-like surface structures has been frequently postulated on the basis of both experimental and theoretical studies. On this basis, we have prepared titanium complexes of **1** in which the silsesquioxane ligand functions as a model for the siliceous surface in a tripodal titanium site. Similarly, the monosilylated form of **1**, disilanol species **2** (Scheme 2) has been used to model the siliceous surface in bipodal and tetrapodal titanium sites.

Reaction of **1** with homoleptic titanium(IV) complexes $TiL_4$ (L = $CH_2Ph$, $NMe_2$, $OSiMe_3$, $OPr^i$) occurs with protonolysis, affording in each case a product with the empirical formula [TiL{(c-$C_6H_{11})_7Si_7O_{12}$}] (Scheme 1) on the basis of elemental analysis and solution $^1H$ NMR data. $^{29}Si$ NMR spectra of the products are particularly informative, the observation in each case of three resonances for the silsesquioxane Si atoms in a 3 : 1 : 3 ratio being consistent with the $C_{3v}$ symmetry expected





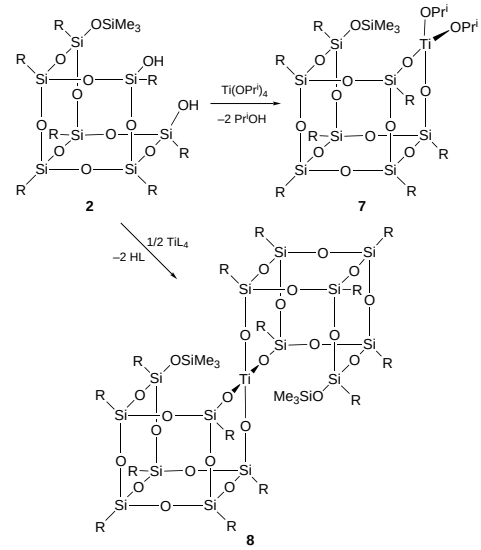


**Fig. 1** Possible framework titanium sites in titanosilicates: (*a*) bipodal site, (*b*) tripodal (open lattice) site, (*c*) tetrapodal (closed lattice) site

**Scheme 1** Synthesis of compounds **3**–**6**: L = $CH_2Ph$ **3**, $NMe_2$ **4**, $OSiMe_3$ **5**, $OPr^i$ **6**; R = cyclohexyl

for a tripodal TiL(silsesquioxane) species. In the case of **6**, $^{29}Si$ NMR data indicate the presence of a second species containing five distinct silicon environments (with relative ratios 2 : 2 : 1 : 1 : 1), corresponding to the dimer [Ti{(c-$C_8H_{11})_7Si_7O_{12}$}(μ-$OPr^i$)]$_2$ recently reported by Maschmeyer *et al.*[7] Freshly prepared solutions of **6** were found to contain exclusively the monomer, while at longer equilibration times a monomer : dimer ratio of *ca.* 5 : 2 was observed in $C_6D_6$.

The monomeric nature of **5** was confirmed by the results of a single crystal X-ray diffraction study (see Fig. 2). The crystal structure of **5** consists of isolated molecules separated by normal van der Waals contacts. Molecules of **5** lie in crystallographic special positions of $\bar{3}$ site symmetry and are consequently disordered; only one of the two centrosymmetrically related images of the disordered molecule is shown. The molecular structure of **5** consists of a pseudo-tetrahedral titanium(IV) centre coordinated by the tridentate silsesquioxane ligand and siloxy ($OSiMe_3$) ligand such that the complex has exact $C_3$ symmetry [disregarding the cyclohexyl substituent at Si(1′), the silicon opposite titanium]. As a consequence of the disorder the details of the apparent molecular geometry must be treated with scepticism. However, the gross geometry of **5** in the

**Scheme 2** Synthesis of **7** and **8** (L = $CH_2Ph$, R = cyclohexyl)

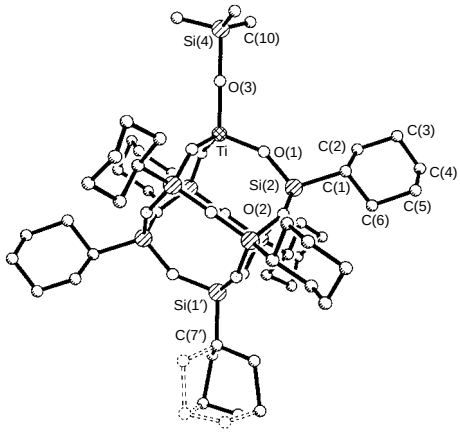

**Fig. 2** Molecular structure of **5** showing atom labelling scheme. All hydrogen atoms have been omitted for clarity. Only one of the two centrosymmetrically related images of the disordered molecule is shown. Selected distances (Å) and angles (°): Ti–O(1) 1.658(6), Ti–O(3) 1.84(2), Si(2)–O(1) 1.625(6), Si(2)–O(2) 1.641(6), O(3)–Si(4) 1.79(2); O(1′)–Ti–O(1) 107.4(2), O(1)–Ti–O(3) 111.4(2), O(1)–Si(2)–O(2) 108.0(3), Si(2)–O(1)–Ti 151.0(4), Si(4)–O(3)–Ti 180.0.

solid state is clearly established, and by inference so is the structure of the monomer form of the isopropoxy analogue **6**, which also crystallises in space group $R\bar{3}$ with similar cell dimensions to **5**, and has molecules lying at the same special positions as **5**. For **6** the disorder is less well resolved and refinement less satisfactory.

The reaction of disilanol **2** with [Ti(OPr$^i$)$_4$] was examined as a possible route to a model bipodal titanium site. Addition of a diethyl ether solution of **2** to the titanium complex resulted in a smooth reaction and the subsequent isolation of [Ti(OPr$^i$)$_2${(c-$C_6H_{11})_7Si_7O_{11}(OSiMe_3)$}] **7** as the sole product (Scheme 2). $^1$H NMR data are consistent with the presence of two inequivalent isopropoxy groups in **7**, while the observation of the five signals in the $^{29}$Si NMR spectrum corresponding to the silsesquioxane $Si_7O_{11}$ core indicates that, as for the free ligand, a plane of symmetry runs through the silsesquioxane ligand, with the alkoxide ligands lying in the plane.

The reaction of 2 equiv. of silsesquioxane **2** with [Ti(CH$_2$Ph)$_4$] was chosen as a convenient means of preparing a model for the closed lattice site. In aprotic solvents a rapid reaction occurs with the formation of a colourless solution, from which bis(silsesquioxane) complex **8** can be isolated in quantitative yield (Scheme 2).

$^1$H and $^{29}$Si NMR spectroscopy reveal the presence of only one type of –OSiMe$_3$ group in **8**, suggesting equivalence of the {(c-$C_6H_{11})_7Si_7O_{11}(OSiMe_3)$} ligands. The presence of molecular $C_2$ symmetry in **8** is confirmed by the results of X-ray crystallography.[9] Consistent with tetrahedral coordination of the Ti$^{IV}$ centre, seven resonances are observed in the $^{29}$Si NMR spectrum for the framework silsesquioxane Si atoms, indicating that the local mirror symmetry of the silsesquioxane ligands is not retained at titanium.

The epoxidation of oct-1-ene with Bu$^t$OOH (TBHP) was chosen as a convenient test of the epoxidation activity of complexes **3**–**8**. At the alkene/TBHP molar ratio of *ca.* 20 employed, pseudo-first order kinetics are observed corresponding to the rate equation:

$$\mathrm{d[epoxide]}/\mathrm{d}t = k_1[\mathrm{TBHP}]$$

(where $k_1 = k_2[\mathrm{Ti}] = k_3[\mathrm{Ti}][\mathrm{alkene}]$)

At high TBHP conversions (generally > 80%), some deviation from first order kinetics is observed, corresponding to a decrease in the reaction rate. This can be attributed to the fact that the reaction is autoretarded by the *tert*-butanol co-product, a phenomenon observed previously for epoxidation catalysts.[10]

The calculated second order rate constants for TBHP conversion ($k_2 = k_1/[\mathrm{Ti}]$) for complexes **3**–**8** are shown in Table 1. Most striking is the finding that the measured values of $k_2$ for the tripodal complexes **3**–**6** are *ca.* one order of magnitude greater than for **7** and **8**, while the former complexes also show superior selectivity. Complexes **3**–**6** are also considerably more active under these test conditions than titanosilicate catalysts such as Ti-MCM-41,[11] when compared on the basis of $k_2$ values. Our conclusion is that the (most) active site in these materials, as far as epoxidation catalysis is concerned, corresponds to the tripodal, open-lattice type of titanium site. The comparatively low epoxidation activity of Ti-MCM-41 can be ascribed to the fact that only a small fraction of the titanium sites in the material are exposed at the surface and possess the correct coordination environment.

**Table 1** Epoxidation of oct-1-ene with TBHP catalysed by titanium silsesquioxane complexes[a]

| Catalyst | $10^2\ k_2$/ dm$^3$ mol$^{-1}$ s$^{-1}$ | Selectivity to epoxide[b] (%) |
|---|---|---|
| **3** | 123 | 95 |
| **4** | 63 | 99 |
| **5** | 97 | 97 |
| **6** | 149 | 93 |
| **7** | 9.3 | 75 |
| **8** | 4.7 | 83 |
| Ti-MCM-41[c] | 2.6 | 94 |

[a] Conditions: $T$ = 80 °C, Ti = 0.2 mmol, TBHP = 30 mmol, oct-1-ene (75 g) as solvent. [b] Selectivity = (mol 1,2-epoxyoctane formed/mol TBHP consumed) × 100; selectivities were determined at 90% TBHP consumption. Data quoted are derived from at least two runs. [c] Ti content = 1.43 mass%.
