† *Crystal data* for $[Sm\{Ni(pro)_2\}_6][ClO_4]_3\cdot 6CH_3OH$: purple, tetrahedron, $C_{66}H_{120}Cl_3N_{12}Ni_6O_{42}Sm$, $M_w$ = 2363.05, cubic, space group *F*23 (no. 196), $a$ = 21.335(2) Å, $U$ = 9710(1) Å$^3$, $D_m$ = 1.64 g cm$^{-3}$, $D_c$ = 1.62 g cm$^{-3}$, $Z$ = 4. Based on the systematic absences (*hkl*: $h + k$, $k + l$, $h + l \neq 2n$), packing considerations, a statistical analysis of the intensity distribution, and the successful solution and refinement of the structure, the space group was determined. Since the absolute configuration of L-Hpro was known, the structure analysis was based on this configuration. A crystal having approximate dimensions of 0.40 × 0.30 × 0.40 mm was mounted in a glass capillary. All measurements were made on a Rigaku AFC5R diffractometer using the ω–2θ scan technique to a maximum 2θ value of 60°, with graphite monochromated Mo-Kα (λ = 0.710 69 Å) radiation at 20 °C. Scans of (1.55 + 0.30 tan θ)° were made at a speed of 16.0° min$^{-1}$ (in ω). Of the 2048 reflections which were collected, 1296 were unique ($R_{int}$ = 0.053); equivalent reflections were merged. The linear absorption coefficient, μ, was 19.1 cm$^{-1}$. An empirical absorption correction based on azimuthal scans of several reflections was applied. This resulted in transmission factors ranging from 0.8920 to 0.9963. The data were corrected for Lorentz and polarization effects. A correction for secondary extinction was applied (coefficient = 1.53190 × 10$^{-7}$). The structure was solved by heavy-atom Patterson methods and expanded using Fourier techniques. The non-hydrogen atoms were anisotropically refined. The final cycle of full-matrix least-squares refinement was based on 769 observed reflections [$I > 3.0\sigma(I)$] and 121 variable parameters and converged at $R$ = 0.033 and $R_w$ = 0.039. At the final stage of refinement, the difference Fourier map showed minimum and maximum peaks between −0.26 and +0.22 e Å$^{-3}$. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/398.

‡ 5 mmol dm$^{-3}$ $[Sm\{Ni(pro)_2\}_6]^{3+}$ in 0.1 mol dm$^{-3}$ tetraethylammonium perchlorate–acetonitrile solution at a glassy carbon disk electrode (scan rate = 200 mV s$^{-1}$).

# A new approach to identifying substrate binding sites on isolated FeMo-cofactor of nitrogenase

**Karin L. C. Grönberg, Carol A. Gormal, Barry E. Smith and Richard A. Henderson***

*Nitrogen Fixation Laboratory, John Innes Centre, Norwich Research Park, Colney, Norwich, UK NR4 7UH*

**A kinetic method is described which is capable of detecting the binding of molecules and ions such as $CN^-$, $N_3^-$, $Bu^tNC$, imidazole and $H^+$ to the isolated FeMo-cofactor of nitrogenase, and indicates where on the cofactor these species bind.**

The Mo-based nitrogenase converts dinitrogen to ammonia by a sequence of electron- and proton-transfer reactions, and a variety of other small, unsaturated molecules are similarly transformed. There is strong evidence that these substrates are converted into products at a $MoFe_7S$(homocitrate) cluster: the FeMo-cofactor[1,2] (Fig. 2) which can be extracted into *N*-methylformamide (NMF), free from the polypeptide. Fundamental to the understanding of nitrogenase is identification of where these substrates bind on this cluster.[3] Herein, we report the novel approach of using kinetics to detect the binding of a variety of molecules (including some of the substrates of nitrogenase) on extracted cofactor. This approach also indicates where on the cluster this binding occurs.

The principle reaction used in our approach is a simple substitution reaction. Extracted cofactor[4] in the $S = 3/2$ state reacts with one $PhS^-$/FeMo-co.† It is likely that this reaction occurs at tetrahedral Fe and involves displacement of NMF by $PhS^-$. When studied on a stopped-flow spectrophotometer, this substitution is associated with an exponential absorbance increase ($\lambda$ = 400–500 nm), and the rate of the reaction is independent of $[PhS^-]$, with $k_1^{NMF} = 50 \pm 5\ s^{-1}$. These observations are consistent with a mechanism involving rate-limiting dissociation of NMF.

Binding other molecules (L) anywhere on the cluster will perturb the overall electron distribution and would be expected to affect the lability of the Fe–NMF bond. The magnitude of this labilisation gives information about where L binds relative to the site of $PhS^-$ substitution: a large perturbation would be expected from binding close to (or at) the tetrahedral Fe, whereas a small perturbation is expected from binding close to (or at) the remote Mo.[4]

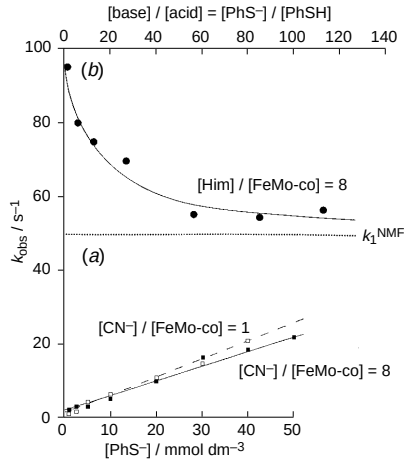

**Fig. 1** (*a*) Effect of $[PhS^-]$ on the rate of the reaction with $CN^-$ and FeMo-cofactor and (*b*) effect of $[PhS^-]_f/[PhSH]_f[PhSH]_f$ ($[PhS^-]_0$ = 0–50 mmol $dm^{-3}$) on the rate of the reaction of $PhS^-$ with imidazole and FeMo-cofactor. The value of $k_1^{NMF}$ is shown as a dotted line at $k_{obs} = 50\ s^{-1}$.

The addition of L = $C_2H_2$ or CO to the cofactor has no effect on the rate of the reaction with $PhS^-$, and it must be concluded that these molecules do not bind to the cofactor in the $S = 3/2$ state. However, for all other species studied (L = $N_3^-$, $Bu^tNC$, $CN^-$, imidazole or $H^+$) perturbations to the rate are observed.

Addition of $CN^-$ to the cofactor ($[CN^-]/[FeMo\text{-}co] = 1.0$) affects the reaction with $PhS^-$ in two ways (Fig. 1). First, the substitution reaction is slower ($k_1^{NMF}/k_1^{CN} = 62.5$). Secondly, the rate law contains two terms: one exhibits a first-order dependence on $[PhS^-]$ the other is independent of $PhS^-$. These observations are consistent with $CN^-$ being bound to tetrahedral Fe and displacement by $PhS^-$ occurring *via* the associative ($k_2^{CN}$) and dissociative ($k_1^{CN}$) pathways shown in Fig. 2.

The addition of excess $CN^-$ ($[CN^-]/[FeMo\text{-}co] \geqslant 2$) leads to further perturbations of the rate: $k_1^{CN}$ is increased by a factor of 1.7, whilst $k_2^{CN}$ is decreased by a factor of 1.2. These small effects are consistent with: (*a*) binding of an additional $CN^-$ remote from the tetrahedral Fe (probably at Mo); (*b*) the presence of this cyanide being transmitted through the cluster. Our interpretation that $CN^-$ binds at both the tetrahedral Fe and the Mo is consistent with EPR studies[5] (which indicate that cofactor can bind more than one $CN^-$) and EXAFS studies[6] (which indicate that when $[CN^-]/[FeMo\text{-}co] = 4$, cyanide is bound to Mo). Of all the molecules studied here, $CN^-$ is the only one which shows binding to more than one site.

The rate of $PhS^-$ substitution is only slightly perturbed on addition of L = $N_3^-$ or $Bu^tNC$ to cofactor (Table 1) which is consistent with these species binding at the Mo end. $N_3^-$ accelerates and $Bu^tNC$ inhibits the rate of reaction with $PhS^-$, presumably as a consequence of the relative electron-releasing and -withdrawing properties of these coordinated molecules.

In the protein, Mo is bound to the polypeptide by the imidazole group of His-442. Consistent with this, our kinetic approach indicates that imidazole binds at the Mo end of extracted cofactor since in the presence of this molecule the rate of the $PhS^-$ substitution reaction is only slightly perturbed. Interestingly, at

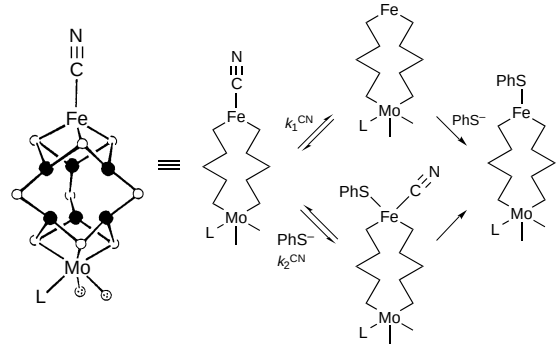

**Fig. 2** ● = three-coordinate Fe, ☉ = O (from homocitrate ligand), ○ = S. Proposed pathways for the reaction between FeMo-cofactor (only skeleton shown for clarity) and $PhS^-$ in the presence of $CN^-$. Rate law: $-d[\text{FeMo-co}]/dt = \{k_1^{CN} + k_2^{CN}[PhS^-]\}[\text{FeMo-co}]$; when $[CN^-]/[\text{FeMo-co}] = 1$, L = NMF, $k_1^{CN} = 0.8\ s^{-1}$, $k_2^{CN} = 5.1 \times 10^2\ dm^3\ mol^{-1}\ s^{-1}$; when $[CN^-]/[\text{FeMo-co}] \geqslant 2$, L = CN, $k_1^{CN} = 1.35\ s^{-1}$, $k_2^{CN} = 4.3 \times 10^2\ dm^3\ mol^{-1}\ s^{-1}$.

**Table 1** Indicated substrate binding sites on FeMo-cofactor in $S = 3/2$ state[a]

| Substrate (L) | $k_1^{NMF}/k_1^{L}$ | Binding site | Spectroscopic information |
|---|---|---|---|
| CO | 1.0 | No binding | No change in $^{19}F$ NMR spectrum of *p*-$CF_3C_6H_4S$–FeMo-co in the presence of CO.[8] |
| $C_2H_2$ | 1.0 | No binding | |
| $CN^-$ | | | |
| $[CN^-]/[FeMo\text{-}co] = 1$ | 62.5 | Fe | Large changes in EPR spectrum.[5] |
| $[CN^-]/[FeMo\text{-}co] \geqslant 2$ | 37 | Mo | EXAFS shows $CN^-$ bound to Mo when $[CN^-]/[Mo] = 4$.[6] |
| | | | $CN^-$ affects relaxation time of *p*-$CF_3C_6H_4S$–FeMo-co.[8] |
| | | | Stoichiometry experiments using EPR indicates more than one $CN^-$ can bind to FeMo-co.[5] |
| $N_3^-$ | 0.83 | Mo | EPR spectrum of FeMo-co[9] sharpens in presence of $N_3^-$. |
| $Bu^tNC$ | 1.21 | Mo | MeNC affects relaxation time of *p*-$CF_3C_6H_4S$–FeMo-co.[8] |
| Him | 0.52 | Mo | EPR spectrum of FeMo-co[9] sharpens in the presence of Him. |
| $H^+$ | 0.16 | S | Both EPR spectrum and electrochemistry indicated |

[a] After several weeks storage of FeMo-co in an anaerobic box the experimental value of $k_1^{NMF}$ gradually increased although activity of FeMo-co is retained. This we attribute to an increase in the concentration of protons in solution due to dithionite decomposition. $k_1^{L}$ is the rate constant when the substrate L is present, and $k_1^{NMF}$ is the rate constant in the absence of L, determined on the same day.

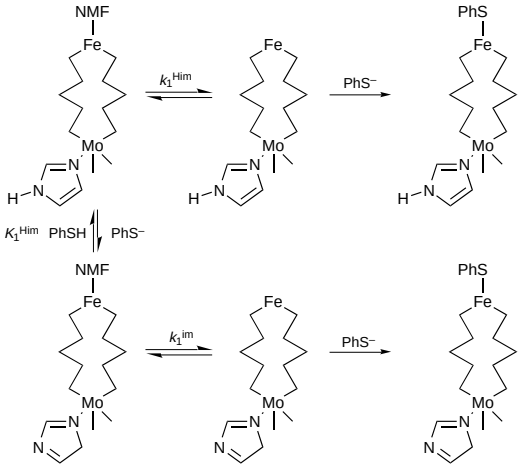

**Fig. 3** Proposed pathways for the reaction between FeMo-cofactor (only skeleton shown) and $PhS^-$ in the presence of imidazole. Rate law:

$$\frac{-d[\text{FeMo-co}]}{dt} = \frac{\{k_1^{Him} + k_1^{im}K^{Him}[PhS^-]_f/[PhSH]_f\}[\text{FeMo-co}]}{1 + K_1^{Him}[PhS^-]_f/[PhSH]_f}$$

where $k_1^{Him} = 95\ s^{-1}$, $k_1^{im} = 50\ s^{-1}$ and $K_1^{Him} = 8 \times 10^{-2}$. The subscript 'f' denotes the concentration of 'free' reactant, having made allowance for the protolytic reaction between uncoordinated imidazole and $PhS^-$: $ImH + PhS^- \rightleftharpoons Im^- + PhSH$. If $[PhS^-]_0 > [Him]_0$ and this reaction goes to completion, (where subscript 0 denotes total concentration of the reagent) $[PhS^-]_f = [PhS^-]_0 - [Him]_0$ and $[PhSH]_f = [Him]_0$.

low $[PhS^-]$ the reaction is accelerated ($k_1^{NMF}/k_1^{Him} = 0.52$), whilst at higher concentrations of $PhS^-$ the acceleration is less marked (Fig. 1). This behaviour is consistent with $PhS^-$ acting not only as a nucleophile to cofactor, but also as a base which can deprotonate imidazole and that the rate of the substitution reaction with $PhS^-$ is sensitive to the state of protonation of the coordinated imidazole. The proposed mechanism is shown in Fig. 3.

Studies on a variety of synthetic Fe/S-based clusters have shown that invariably protons bind to μ-S atoms and increase the substitution reactivity of the cluster.[7] FeMo-cofactor exhibits analogous behaviour with the rate of the $PhS^-$ substitution being faster in the presence of $[NHEt_3]BPh_4$ ($k_1^{NMF}/k_1^{H} = 0.16$).‡ This large acceleration in rate makes it likely that protonation is at a μ-S close to the tetrahedral Fe.[7]

Table 1 shows that the results of our kinetic studies are consistent with earlier studies on binding of molecules at extracted FeMo-cofactor. However, our kinetic approach is more versatile since it circumvents the problem of poor spectroscopic response associated with binding of molecules to cofactor.

This study indicates that various nitrogenase substrates can exhibit a marked selectivity for different sites on cofactor and that there are at least three sites at which substrates can bind. (*i*) The Mo (or a site at this end of the cluster) at which all anionic and neutral substrates bind, (*ii*) tetrahedral Fe at which cyanide prefers to bind, and (*iii*) μ-S where protons bind.

We acknowledge the BBSRC for supporting this work and John Innes Foundation for a studentship to K. L. C. G.

## Footnotes

† FeMo-cofactor from wild type *Klebsiella pneumoniae* M5al was extracted into an NMF solution containing sodium dithionite and sodium phosphate buffer, pH 8, using a modification of the method of P. A. McLean, D. A .Wink, S. K. Chapman, A. B. Hickman, D. M. McKillop and W. H. Orme-Johnson. (*Biochemistry*, 1989, **28**, 9402). In NMF solution, the cluster-protein ligands His-442 and Cys-275 are most likely replaced by solvent molecules. In the kinetic experiments, cofactor was diluted to *ca.* $1 \times 10^{-4}$ mol $dm^{-3}$ in NMF and reacted with $[NEt_4]SPh$ (0–50 mmol $dm^{-3}$). In studies with $L = CN^-$, $N_3^-$, $Bu^tNC$, CO, $C_2H_2$ and imidazole, the substrate was added to a solution of FeMo-cofactor (gases added by syringe), such that (for instance) $[L]/[FeMo\text{-}co] = 8$.

‡ The kinetics of this reaction exhibit a dependence on the ratio, $[NHEt_3^+]_f/[NEt_3]_f$:

$$\frac{-d[\text{FeMo-co}]}{dt} = \frac{\{k_1^{H}K^{H}[NHEt_3^+]_f/[NEt_3]_f\}[\text{FeMo-co}]}{1 + K^{H}[NHEt_3^+]_f/NEt_3]_f}$$

The concentration of 'free' reactants, has made allowance for the protolytic equilibrium: $[NHEt_3]^+ + PhS^- \rightleftharpoons NEt_3 + PhSH$.

Since this reaction goes to completion when $[NHEt_3{}^+]_0 > [PhS^-]_0$, $[NHEt^{3+}]_f = [NHEt_3^+]_0 - [PhS^-]_0$ and $[NEt_3]_f = [PhS^-]_0$.

These kinetics describe a mechanism involving rapid protonation of the cofactor ($K^H = 5.6 \times 10^{-2}$), followed by rate-limiting dissociation of the Fe–NMF bond ($k_1^H = 312\ s^{-1}$).

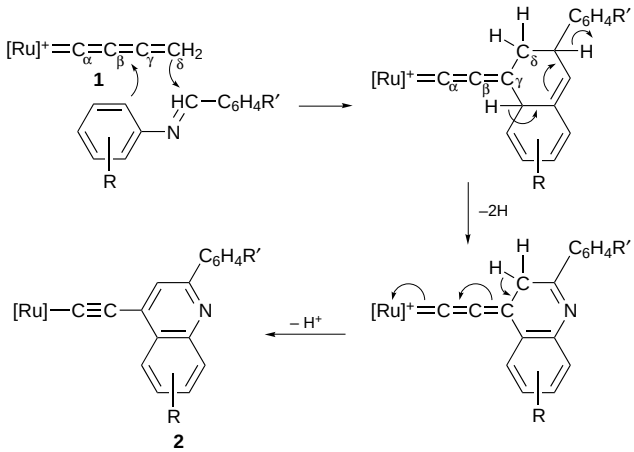
# Cycloaddition of aromatic imines to a ruthenium butatrienylidene complex: synthesis of 4-ethynylquinoline and 1-azabuta-1,3-diene complexes

**Michael I. Bruce,*[a] Peter Hinterding,[a] Mingzhe Ke,[a] Paul J. Low,[a] Brian W. Skelton[b] and Allan H. White[b]**



[a] *Department of Chemistry, University of Adelaide, Adelaide, South Australia 5005, Australia*
[b] *Department of Chemistry, University of Western Australia, Nedlands, Western Australia 6907, Australia*

**Reactions of aromatic imines with the putative butatrienylidene–ruthenium cation $[Ru(C{=}C{=}C{=}CH_2)(PPh_3)_2(\eta\text{-}C_5H_5)]^+$ gives complexes containing either 4-ethynylquinoline or 1-azabuta-1,3-diene ligands; the molecular structures of $[Ru(C{\equiv}CC_9H_4MeN)(PPh_3)_2(\eta\text{-}C_5H_5)]$ and $[Ru\{C{\equiv}CC(CH{=}CHPh){=}N(C_6H_4NO_2\text{-}3)\}(PPh_3)_2(\eta\text{-}C_5H_5)]$ are reported.**

We have recently described the formation of an intermediate cationic complex from the reaction between buta-1,3-diyne and $[Ru(thf)(PPh_3)_2(\eta\text{-}C_5H_5)]^+$ which, from its method of formation and subsequent reactions, is proposed to be the butatrienylidene cation $[Ru(C{=}C{=}C{=}CH_2)(PPh_3)_2(\eta\text{-}C_5H_5)]^+$ **1**.[1] We showed that its reactivity is characterised by nucleophilic attack at $C_\gamma$, as predicted by theoretical studies.[2]

The availability of **1**, in which the outer carbons of the four-carbon unsaturated ligand are not sterically protected by the bulky $PPh_3$ ligands as are atoms $C_\alpha$ and $C_\beta$, encouraged us to study its chemistry in more detail. In particular, we were interested in the possibility of cycloaddition to the unsaturated $C_4$ chain through reactions which might involve successive electro- and nucleo-philic attack on a suitable substrate. We chose to examine first *N*-benzylideneaniline and were pleased to discover that the sought-after reaction occurred readily and in high yield.

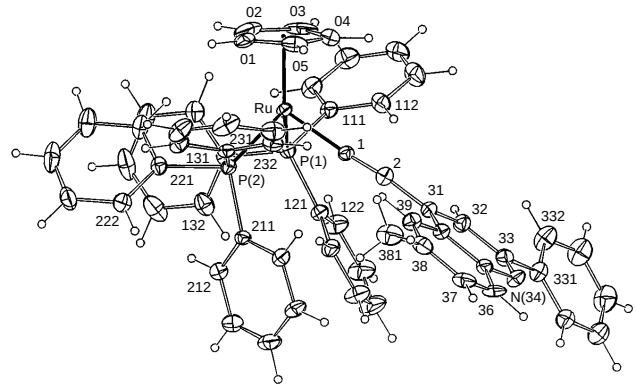
Thus, addition of *N*-benzylideneaniline (2 equiv.) to a solution of **1** in thf at −50 °C resulted in an immediate colour change to orange–red. Work up by preparative thin layer chromatography (TLC) afforded the yellow complex **2a** (Scheme 1), which was initially characterised as a 1 : 1 adduct by mass spectrometry.† The reaction can be extended to other imines containing substituted C-bonded aryl groups and/or electron-donating substituents on the N-bonded aryl group. The X-ray determined structure of **2b**, obtained from **1** and $PhCH{=}NC_6H_4Me$-4, is shown in Fig. 1 and important bond parameters are collected in the caption. A conventional $Ru(PPh_3)_2(\eta\text{-}C_5H_5)$ fragment is attached by an Ru–C σ bond to an acetylenic ligand of which the other substituent is a 4-quinolinyl group. Structural characteristics of this ligand are not exceptional and further discussion will be deferred until the full report. Similar tricyclic heterocycles are obtained with naphthylimines.

**Scheme 1** R = H, 4-Me, 4-OMe; R′ = H, 3- or 4-$NO_2$ [Ru] = $Ru(PPh_3)_2(\eta\text{-}C_5H_5)$

A remarkable property of complexes **2** is their extreme sensitivity towards protonation, traces of water being sufficient to form to deep claret coloured cations, $[Ru(C{\equiv}CC_9H_4RNH)(PPh_3)_2(\eta\text{-}C_5H_5)]^+$ **3**,† also characterised by an X-ray study for R = H, full details of which will be reported elsewhere.‡ N-Methylation can be achieved using methyl triflate. Complexes **2** and **3** form a readily reversible base–acid system, but in contrast with the well known acetylide–vinylidene systems,[3] there is no evidence for protonation occurring at the acetylide β-carbon.

A likely pathway for this reaction is (*i*) attack of $C_\delta$ of cation **1** on the electron-deficient carbon of the imine, (*ii*) electrophilic attack of $C_\gamma$ on the N-bonded aryl group (Scheme 1). The resulting dihydroquinoline is dehydrogenated to form **2** by a second molecule of imine which is thereby reduced to the corresponding benzylamine, which has been isolated and characterised. Consequently, optimum yields are obtained from reactions between **1** and 2 equiv. of imine.

The presence of electron-withdrawing substituents on the N-bonded aryl group results a different reaction course being followed. Thus, the reaction between **1** and $PhCH{=}N(C_6H_4NO_2\text{-}3)$ gives **4** (Scheme 2)† which was also fully characterised by a single-crystal X-ray study.‡ A molecule of **4** is shown in Fig. 2 and significant bond parameters are included in the caption. Again an $Ru(PPh_3)_2(\eta\text{-}C_5H_5)$-substituted alkynyl fragment is present, now attached to a 1-azabuta-1,3-diene ligand through C(3). No cyclisation involving either aryl group is found in this case, nor does any dehydrogenation take place. Similar complexes have been obtained from



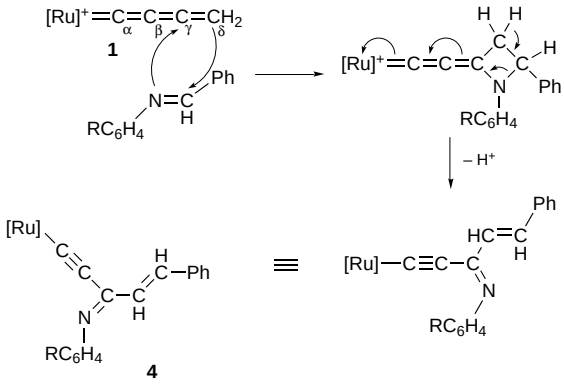


**Fig. 1** Plot of a molecule of $[Ru(C{\equiv}CC_9H_4MeN)(PPh_3)_2(\eta\text{-}C_5H_5)]$ **2b** showing the atom numbering scheme; carbon atoms are designated by number only. In both Figures, non-hydrogen atoms are shown as 20% thermal ellipsoids; hydrogen atoms have arbitrary radii of 0.1 Å. Significant bond parameters: Ru–P(1) 2.308(2), Ru–P(2) 2.300(2), Ru–C(1) 1.997(7), C(1)–C(2) 1.19(1), C(2)–C(31) 1.42(1) Å; Ru–C(1)–C(2) 175.6(7), C(1)–C(2)–C(31) 170.2(8)°.

reactions between **1** and PhCH=N($C_6H_4$R-4) (R = $NO_2$, $CO_2$Et) and PhCH=N(1-$C_{10}H_7$).

In this variant, we propose that a formal [2 + 2] cycloaddition of the $C_\gamma$=$C_\delta$ double bond in **1** to the N=CH of the imine occurs, possibly by attack of the imine N atom on $C_\gamma$ rather than the aryl carbon, after initial $C_\delta$–C(imine) bond formation as in (*i*) above. There is little precedent for this reaction, although it resembles the [2 + 2] cycloadditions of tetracyanoethene (tcne) to transition-metal σ acetylide complexes.[4] In the present case, we do not observe any deep coloured intermediates, but nevertheless, it is unlikely that a concerted addition occurs (which would contravene the Woodward–Hoffmann rules). The initial four-membered $C_3N$ ring formed in such a reaction could undergo ring cleavage (also found with the alkyne–tcne cycloadducts) to give the observed products (Scheme 2).

**Scheme 2** R = $NO_2$-3 or -4, $CO_2$Et-4; [Ru] = Ru($PPh_3$)$_2$(η-$C_5H_5$)

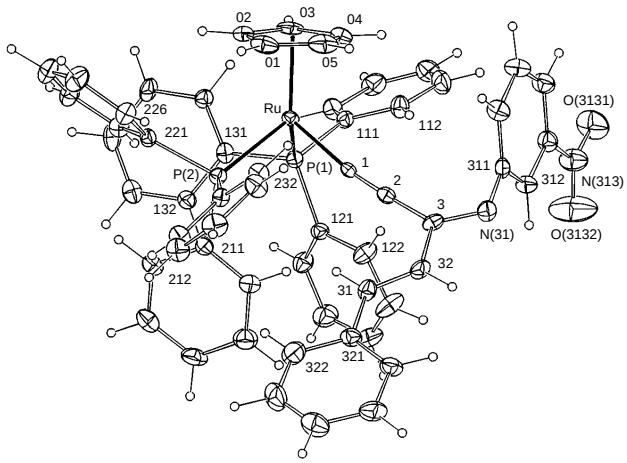

**Fig. 2** Plot of a molecule of [Ru{C≡CC(CH=CHPh)=N($C_6H_4NO_2$-3)}($PPh_3$)$_2$(η-$C_5H_5$)] **4** showing the atom numbering scheme. Significant bond parameters: Ru–P(1) 2.319(2), Ru–P(2) 2.293(2), Ru–C(101) 1.978(8), C(1)–C(2) 1.22(1), C(2)–C(3) 1.43(1), C(3)–C(32) 1.48(1), C(3)–N(31) 1.280(9), C(31)–C(32) 1.32(1) Å; Ru–C(1)–C(2) 171.2(6), C(1)–C(2)–C(3) 176.9(6)°.

Preliminary studies show that other 1,3-dynyl complexes undergo similar reactions. Further discussion of these interesting transformations will be given in the full report.

We thank the Australian Research Council for support of this work and the Deutsche Forschunsgemeinschaft for a Fellowship (P. H); P. J. L. held an Australian Postgraduate Award.

**A covalently linked 2D $Cu^{II}$ compound, $[Cu(O_2CCF_3)_2(3\text{-}pyOH)_2]_n$ 1 (3-pyOH = 3-hydroxypyridine), when dissolved in thf, undergoes conversion to a hydrogen-bond linked 2D $Cu^{II}$ compound, $[Cu(O_2CCF_3)_2(3\text{-}pyOH)_2(thf)_2]$ 2, which upon heating or standing at 23 °C for a few hours is converted back to compound 1 by losing the coordinated thf molecule; weak ferromagnetic interactions between $Cu^{II}$ centres dominate in both compounds.**

There has been an increasing interest in metal complexes containing paramagnetic metal ions and exhibiting extended structures because of their potential applications in molecular magnetic materials.[1] One commonly used strategy in building metal complexes with extended structures is to employ appropriate bridging ligands which are capable of binding to several metal centres through direct bond formation and promoting magnetic interactions as well. The drawback of this strategy is that the complexes tend to have a poor solubility in common solvents which makes them difficult to characterize and fabricate. In contrast, compounds which have hydrogen-bond linked extended structures usually have a good solubility in common solvents. The shortcoming of hydrogen-bonded systems is that the magnetic interactions between the metal centres are usually weak and sometimes the compound undergoes irreversible dissociation when dissolved.[2,3] It is conceivable that if one can use both covalent and hydrogen bonds in building the extended structures, the compounds may have the desired magnetic properties and solubility. In fact, such a strategy has been adapted either by serendipity or by design in a number of magnetic metal complexes where the extended structures are dictated by both covalent and hydrogen bonds.[3,4] We have been interested in building extended structures by using bifunctional ligands (ligands that are capable of forming both metal–ligand bonds and hydrogen bonds).[4] We report herein an unusual structural interconversion, facilitated by the bifunctional ligand, 3-hydroxypyridine (3-pyOH), between a novel $Cu^{II}$ complex $[Cu(O_2CCF_3)_2(3\text{-}pyOH)_2]_n$ **1**, exhibiting a two-dimensional covalently linked extended structure and weak ferromagnetic exchange, and a hydrogen-bonded 2D $Cu^{II}$ complex[4] $[Cu(O_2CCF_3)_2(3\text{-}pyOH)_2(thf)_2]_n$ **2**.

Compound **1** was obtained from the reaction of $Cu(OMe)_2$ with 2 equiv. of trifluoroacetic acid and 3-hydroxypyridine in either 1,4-dioxane or MeCN as a royal blue crystalline solid. The molecular structure of **1** (Fig. 1), established by single-crystal X-ray diffraction analysis,† has an inversion centre. The 3-pyOH ligand acts as a bridging ligand to two $Cu^{II}$ *via* the nitrogen and the oxygen atoms. The $Cu^{II}$ centre in **1** is an elongated octahedron with two nitrogen atoms of the 3-pyOH ligands and two oxygen atoms of the trifluoroacetate ligands occupying the basal positions and two oxygen atoms of the 3-pyOH ligands from the neighbouring molecules occupying the axial positions. The H(5) atom of the 3-pyOH ligand forms a hydrogen bond with the non-coordinated oxygen atom of the trifluoroacetate ligand [O(1′)···O(3) 2.65(2) Å]. As a consequence of the 3-pyOH bridge, compound **1** has an extended 2D sheet structure as shown in Fig. 2. Each mononuclear $Cu^{II}$ unit in the 2D sheet is linked to four other identical mononuclear $Cu^{II}$ units by four 3-pyOH ligands, related by inversion centres with a Cu···Cu separation of 7.27 Å. The two pyridyl rings from two neighbouring mononuclear units are partially stacked with

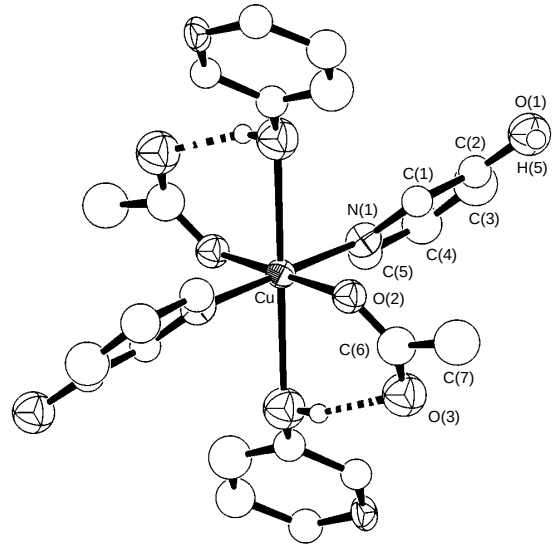

**Fig. 1** An ORTEP diagram showing the mononuclear unit of **1** with 50% ellipsoids and labelling scheme. The fluorine atoms are omitted for clarity. Important bond distances (Å) and angles (°): Cu–O(1′) 2.63(1), Cu–O(2) 1.95(1), Cu–N(1) 1.99(1); N(1)–Cu–O(2) 89.9(5), N(1)–Cu–O(1′) 85.1(4), N(1′)–Cu–O(1′) 94.9(4).

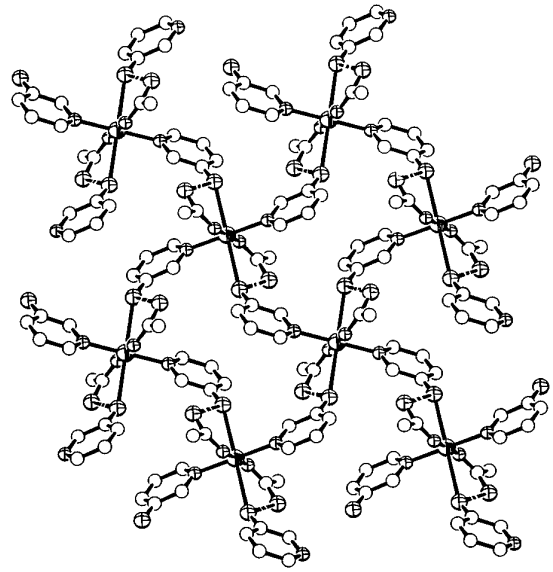

**Fig. 2** A diagram showing the two-dimensional structure of **1** projected down the *a* axis. The fluorine atoms are omitted for clarity.

the shortest atomic separation distance being 3.67 Å. The 2D sheets of **1** stack along the *a* axis with the interlayer Cu···Cu distance being 8.99 Å.

Compound **1** is closely related to $[Cu(O_2CCF_3)_2(3\text{-pyOH})_2(thf)_2]_n$ **2** where the axial positions are occupied by two thf ligands and the mononuclear $Cu^{II}$ units are linked together to form a 2D sheet through intermolecular hydrogen bonds between 3-pyOH and trifluoroacetate ligands (Fig. 3). The separation distance[4] between two neighbouring $Cu^{II}$ ions in the 2D sheet of **2** is 8.04 Å, much longer than that in **1**. Compound **1** is insoluble in solvents such as $CH_2Cl_2$ and MeCN, but very soluble in thf. Upon dissolving in thf, the hydroxy groups at the axial positions in **1** are replaced by two thf molecules and compound **1** is converted to compound **2**. Upon heating or standing at 23 °C for a few hours, compound **2** is converted back to compound **1** in the solid state, accompanied by the loss of thf, as confirmed by X-ray powder diffraction, TGA and DSC analyses. The thf ligand in **2** is replaced by the hydroxy group of the 3-pyOH ligand from a neighbouring $Cu^{II}$ centre in the 2D sheet. The bifunctionality of the 3-pyOH ligand clearly facilitated the conversion process. In **2**, the hydroxy group of the 3-pyOH ligand forms a hydrogen bond only to link the mononuclear units together while in **1** it forms a new weak Cu–O bond, retaining the hydrogen bond, to link the mononuclear units together. It is conceivable that such a structural interconversion is common occurrence among complexes where the metal centres are bound by weak donor ligands and bifunctional ligands. However, to our knowledge, the reversible interconversion between a covalently bonded and a hydrogen-bonded inorganic 2D structure, as observed in **1** and **2**, has not been reported previously. We believe that this interconversion process is important because it provides a mechanism for switching between a soluble and an insoluble phase.

Interestingly, despite the dramatic bonding difference between **1** and **2**, both compounds display similar magnetic properties. For example, the EPR spectrum of the powder sample of **1** at 77 K has a broad signal with $g_\perp = 2.077$ and $g_\parallel = 2.223$, consistent with the elongated octahedral geometry,[5] and a weak half-field transition band at $g = 4.240$, indicative of the presence of magnetic exchange between the $Cu^{II}$ centres.[5] The EPR spectrum of the powder sample of **2** at 77 K resembles that of **1** with $g_\perp = 2.080$ and $g_\parallel = 2.221$ and a weak half-field transition peak at $g = 4.200$. The nature of magnetic exchange in **1** and **2** was established by magnetization and magnetic susceptibility measurements. The effective magnetic moment of **1** increases steadily with the decrease of temperature in the range of 2–10 K, suggesting the presence of ferromagnetic exchange.[6] The magnetization of **1** at 2 K increases rapidly with increasing field strength and reaches 6105 emu G $mol^{-1}$ (1.095 $\mu_B$) at 55 kG, in good agreement with the theoretical magnetization saturation $M_s = 5950$ emu G $mol^{-1}$ (1.065 $\mu_B$) for an $S = 1/2$ and $g_{av} = 2.13$ system.[6] The magnetization curve at 2 K is above the curve of Brillouin function[6] for an $S = 1/2$ and $g_{av} = 2.13$ system, consistent with the presence of weak ferromagnetic interactions. Because all the mononuclear $Cu^{II}$ units in the 2D sheet of **1** are identical and related to each other by inveresion centres, the ferromagnetic interaction is likely to be two dimensional. The low temperature susceptibility data $\chi_m$ and $\chi_m T$ (2 K–10 K) were fitted successfully by using a 2D, spin = 1/2 Heisenberg model,[7] yielding $g = 2.137$ and $J = 0.020(2)$ $cm^{-1}$ from the $\chi_m T$ data and $g = 2.138$ and $J = 0.018(2)$ $cm^{-1}$ from the $\chi_m$ data, supporting the presence of weak 2D ferromagnetic exchange. Preliminary data indicated that **2** is also a weak ferromagnetic interaction dominated system, as evidenced by the positive intercept ($\theta = 1.25$ K) on the *T* axis obtained by the extrapolation of the $C/\chi_M$ data of **2** (5 K–280 K). We have not been able to obtain data below 5 K for **2** due to its poor stability under high vacuum.

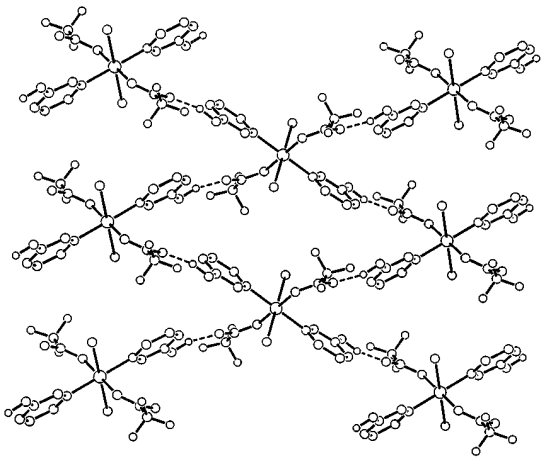

**Fig. 3** A diagram showing the two-dimensional structure of **2**. The carbon of thf were omitted for clarity.

The 3-pyOH ligand in **1** binds to a $d_{z^2}$ and a $d_{x^2-y^2}$ orbitals located at two $Cu^{II}$ centres, respectively, thus makes the interaction of the two $d_{x^2-y^2}$ magnetic orbitals *via* a σ pathway impossible. Therefore, if the σ orbital interaction dictates the spin exchange, one can predict that the magnetic interaction within the 2D sheet of **1** would be either paramagnetic or ferromagnetic.[1,6,8] The π orbitals of the 3-pyOH ligand are essentially orthogonal to the $d_{x^2-y^2}$ orbital. Consequently, the π superexchange pathway, which may yield antiferromagnetic exchange, also becomes impossible. We therefore believe that the weak ferromagnetic exchange observed in **1** is likely caused by orbital orthogonality imposed by the geometric constraint of the 3-pyOH ligand. Dipole–dipole interactions may also contribute since the magnitude of the spin interaction in **1** is very small.

We thank the NSERC (Canada) for financial support and Professor C. V. Stager for use of the magnetometer.

# Experimental study of hydrogen bonding by mutual diffusion

**Nong Chen and T. C. Chan***

*Department of Applied Biology and Chemical Technology, The Hong Kong Polytechnic University, Hung Hom, Kowloon, Hong Kong*

**The use of diffusion data to determine the relative strength of hydrogen bonding and the number of solvent molecules associated with a pseudo-planar solute is demonstrated; the solvation numbers are found to be approximately equal for solutes containing the same polar group in ethanol at 298.2 K.**

Hydrogen bonding is one of the most common and important molecular phenomena which has received intense attention from the earliest days of the subject. Although experimental and theoretical publications on hydrogen bonding abound,[1] however, our knowledge of this phenomenon in liquids is still in its relative infancy. In particular, the nature and consequences of solute–solvent interactions involving hydrogen bonding in very dilute solutions are not well known. This may be due largely to the fact that hydrogen bonding in very dilute solutions is difficult to study by current experimental methods. Nonetheless, the lack of such information may hinder further understanding of the behaviour of many drugs and biological molecules.

Previously, we have found[2] that a linear relationship exists between the reciprocal of the limiting mutual diffusion coefficients ($1/D_{12}$) and the molecular volume ($V$) of non-associated solutes with similar shape. In a preliminary report,[3] we have recently shown evidence of the effect of strong solute–solvent interactions on diffusion and also that the effect can be quantified. This has prompted us to measure more diffusion data, with the primary aim to understand the transport properties of associated molecules. Also, we believe that diffusion measurements can be alternatively designed to probe information about hydrogen bonding. Here, we report the limiting mutual diffusion coefficients of aromatic solutes containing one polar functional group capable of hydrogen bonding in ethanol at 298.2 K. All solutes studied are pseudo-planar in shape. The purpose of this work is to demonstrate how hydrogen bonding in dilute solution can be studied by diffusion data.

Mutual diffusion coefficients at trace concentrations were measured by the Taylor dispersion method, known also as the chromatographic peak-broadening technique. The apparatus and procedures used in the experiment were the same as those described before.[2,3] In this work, the solvent ethanol (99.9%+, E. Merck) was filtered before use with 20 μm stainless-steel HPLC solvent filter. The solute mesitylene (98%, Riedel-de Haen) was purified by fractional distillation; aniline (99.5%+, Aldrich), *p*-chloroaniline (99%+, Fluka), *p*-toluidine (99.9%, Aldrich), 4-chloro-2-methylaniline (99%, Aldrich), 1-naphthylamine (99%+, E. Merck), phenol (99.5%, E. Merck), *p*-chlorophenol (99.5%+, BDH), *p*-cresol (99%+, Fluka), 1-naphthol (99%+, Aldrich), 2-naphthol (99%, Aldrich), biphenyl-2-ol (99%+, E. Merck), anisole (99%+, E. Merck), *p*-chloroanisole (98%+, Fluka), *p*-methylanisole (99%+, E. Merck), 2-methoxynaphthalane (99%, Aldrich), acetophenone (99%, Aldrich), propiophenone (99%+, E. Merck), and 2-acetylnaphthalene (99%+, E. Merck) were used as received. All data were measured at 298.15 ± 0.02 K.

The limiting mutual diffusion coefficients as determined by the Taylor dispersion method are summarized in Table 1. These values are the averages resulting from three or more diffusion measurements. The uncertainty listed is the average absolute error. The reproducibility of data here is consistent with those reported in our previous works using the same technique.[2–5] Also shown in the table are values of the van der Waals volume of the solute monomers, which are calculated from group increments given in the literature.[6–9] When $1/D_{12}$ was plotted against $V$ of the non-associated pseudo-planar solutes, a linear relationship was obtained. The linear regression line is shown in Fig. 1. Also presented in this figure are values for other solutes given in Table 1. Except for aromatic ethers, all $1/D_{12}$ data of these solutes deviate positively from the 'non-associated' line. The deviations indicate that the diffusivities of the solutes are retarded by the volume increase due to hydrogen bonding with the solvent molecules. In this study, the increase in solute size cannot be attributed to solute–solute interaction because the solutions are very dilute and the solvent ethanol is polar. In fact, experimental evidence has already shown that aniline molecules are not even self-associated in non-polar *n*-tetradecane.[3] It is

[a] van der Waals volumes are averages from refs. 6–9. [b] From ref. 2. [c] From ref. 3.

interesting that linear relationships also exist between $1/D_{12}$ and $V$ of all pseudo-planar solutes containing the same polar group. The regression lines for phenols, aromatic amines and phenones are shown also in Fig. 1. Remarkably, the slopes for all straight lines in the figure are nearly the same. From Fig. 1, it can be seen that aromatic ethers behave practically as non-associated solutes, and that the strengths of polar groups associated with the solvent through hydrogen bonding decrease in the sequence –OH > $–NH_2$ > –C(O)–.

The increase in size of a polar solute after association can be evaluated from the deviation of its $1/D_{12}$ value from the 'non-associated' line at the same monomeric solute volume in Fig. 1. This is equivalent to the increase in the van der Waals volume that produces such amount of $1/D_{12}$ deviation on the 'non-associated' line. That the linear regression lines of solutes containing –OH, $–NH_2$ and —C(O)– groups are nearly parallel with those of the non-associated solutes indicates that the increased sizes are approximately equal for all solutes containing the same polar group. The average number of ethanol molecules associated with a solute can be determined subsequently from the solute volume increased and the van der Waals volume of the ethanol monomer. The solvation numbers thus calculated for phenols, aromatic amines and phenones are given in Table 2. From this table, it is clear that all phenols on average diffuse together with *ca*. 2.5 ethanol molecules and all aromatic amines with *ca*. one. Phenones are nonetheless only weakly associated with ethanol. The fact that there is little association between phenones (also aromatic ethers) and ethanol is not surprising as the solutes have to compete with other ethanol molecules for forming hydrogen bonds with the solvent. Due to steric hindrance and lack of a proton contribution to form hydrogen bonds, phenones and aromatic ethers are expected to be less competitive in this respect. It should be noted that ethanol is self-associated with an association number of 2.8 in the liquid state at 298.2 K.[10,11] Although solvation numbers can also be calculated[12] from the well known Stokes–Einstein equation, however, the applicability of this equation is not valid for non-spherical solute molecules and for solute molecules small in size compared to the solvent molecules.[13–16] The effects of shape on mutual diffusion have been shown[2] to be as large as 26% in the case of *n*-tetradecane as solvent at 298.2 K.

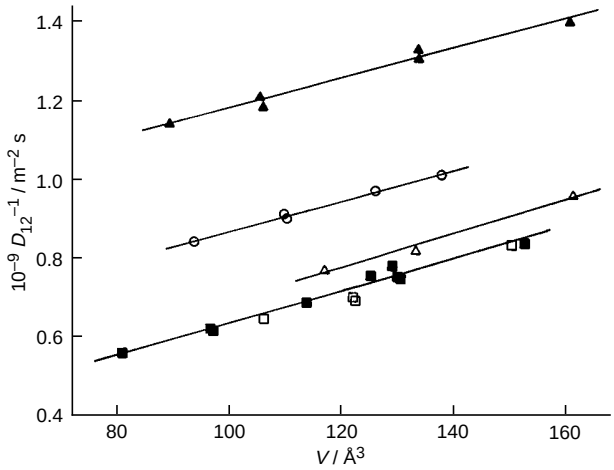

**Fig. 1** Variation of $1/D_{12}$ with molecular volume of solutes diffusing in ethanol at 298.2 K: (■) non-associated solutes, (□) aromatic ethers, (△) phenones, (○) aromatic amines and ( ▲ ) phenols

**Table 2** Solvation numbers (*n*) for solutes in ethanol

| | *n* |
|---|---|
| Phenols | |
| Phenol | 2.6 ± 0.2 |
| *p*-Chlorophenol | 2.6 ± 0.2 |
| *p*-Cresol | 2.5 ± 0.2 |
| 1-Naphthol | 2.5 ± 0.2 |
| 2-Naphthol | 2.6 ± 0.2 |
| Biphenyl-2-ol | 2.4 ± 0.2 |
| Aromatic amines | |
| Aniline | 1.1 ± 0.1 |
| *p*-Chloroaniline | 1.1 ± 0.1 |
| *p*-Toluidine | 1.1 ± 0.1 |
| 4-Chloro-2-methylaniline | 1.1 ± 0.1 |
| 1-Naphthylamine | 1.0 ± 0.1 |
| Phenones | |
| Acetophenone | 0.3 ± 0.1 |
| Propiophenone | 0.2 ± 0.1 |
| 2-Acetylnaphthalene | 0.3 ± 0.1 |

It is interesting that the diffusion coefficients of *p*-chloroaniline (*p*-$ClC_6H_4NH_2$) and *p*-toluidine (*p*-$MeC_6H_4NH_2$) are approximately equal. These two solutes are of similar size and shape. The close resemblance in size between a chloride group and a methyl group has already been discussed.[17] The two solutes are nevertheless different in molecular mass by 19%. Similar results are observed for *p*-chlorophenol (*p*-$ClC_6H_4OH$) and *p*-cresol (*p*-$MeC_6H_4OH$) as well as for *p*-chloroanisole (*p*-$ClC_6H_4OMe$) and *p*-methylanisole (*p*-$MeC_6H_4OMe$). The present data thus further indicate that solvation numbers are insensitive to the mass as well as the size of the monomeric solutes but dependent only on the type of polar group attached.

The authors wish to thank M. L. Chan and K. W. Fong for their technical assistance. This work was supported partially by the Hong Kong Polytechnic University under Grant 350/410, and partially by the Hong Kong Research Grants Council under Grant HKP 88/94P.

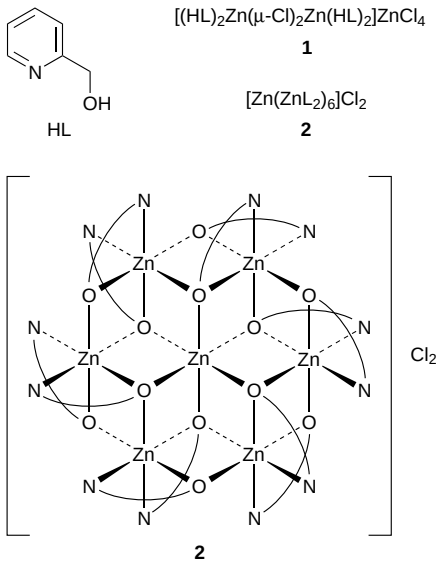
# Oligonuclear zinc complexes of 2-pyridylmethanol

**Markus Tesmer, Bodo Müller and Heinrich Vahrenkamp***

*Institut für Anorganische und Analytische Chemie der Universität Freiburg, Albertstr. 21, D-79104 Freiburg, Germany*

**The title ligand HL leads to the zinc complexes $[(HL)_2Zn(\mu\text{-}Cl)_2Zn(HL)_2]ZnCl_4$ 1 and $[Zn(ZnL_2)_6]Cl_2$ 2; the ligand arrangement and core structure of 2 make the self-assembly of this complex understandable and show its topological relation to the cadmium iodide structure.**



Metal alkoxides, specifically those of zinc, are oligomeric or polymeric,[1] and it is actually difficult to obtain simple mononuclear zinc alkoxide complexes like $[Zn(OR)_2L_2]$ or $[Zn(OR)L_3]$.[2] Such complexes seem attractive either as precursors of new ZnO-containing materials[3] or as models of the enzyme–substrate combination in horse-liver alcohol dehydrogenase (ADH).[4] We therefore tried to obtain such species in a more stable form by making use of the chelate effect, combining the L and OR functions in one ligand molecule. Our ligand of choice was 2-pyridylmethanol whose alkoxide anion can form a five-membered chelate ring. We found that chelation takes place when the ligand is combined with zinc and chloride. The resulting complexes, however, had the unexpected compositions $Zn_3(HL)_4Cl_6$ and $Zn_7L_{12}Cl_2$,† which were found by X-ray analysis to belong to compounds **1** and **2**.‡

Compound **1** resulted from $ZnCl_2$ and HL in diethyl ether. Its strong tendency of formation under these circumstances is obvious from the fact that the reactions were quantitative with respect to HL for stoichiometric ratios ranging from 3 : 4 to 3 : 2. Complex **1** is soluble only in strong donor solvents, and crystals were obtained by diffusion of hexane into a thf solution. Their structure determination (see Fig. 1) revealed the ionic nature of **1** containing the centrosymmetrical dinuclear dications comprised of two $(HL)_2ZnCl$ units. Being a five-membered chelate ring ligand, HL favours octahedral coordination of zinc, as it does for copper in the only other structurally characterized HL complex of a transition metal, $[Cu(HL)_2(salicylate)_2]$.[5]

As $ZnCl_2$–HL combinations, either with or without additional base, did not lead to pyridylmethanolato complexes, a non-polar approach to them was attempted by reacting $Zn[N(SiMe_3)_2]_2$ with HL. In hydrocarbon solvents this produced a precipitate of approximate composition $ZnL_2$. Attempts to purify this by crystallization from strong donor solvents failed, and surprisingly it reacted with $CHCl_3$ or $CH_2Cl_2$ incorporating chlorine with formation of **2** which is soluble in these solvents from which it crystallizes upon diffusion of hexane into the solution. Subsequently it was found that **2** results directly from $Zn[N(SiMe_3)_2]_2$ and HL in $CH_2Cl_2$. At the moment we can only speculate on the course of this reaction which seems to take part of its driving force from the ideal geometry of the resulting $Zn_7L_{12}$ cation (see below).

The formula drawing of **2** in which the chelate ligands are indicated only symbolically indicates the highly symmetrical nature of the complex dication comprised of a central $ZnO_6$ unit surrounded in a disk-like fashion by six $ZnO_4N_2$ units. This is the first such heptametal arrangement for zinc, and it bears no relation to the double cubane arrangement in $[Zn_7Me_6(OMe)_8]$.[6] Its stability and preferred formation become understandable when viewing a space filling model of it, Fig. 2. The six aromatic rings on each side of the $Zn_7O_{12}N_{12}$ scaffold are stacked in triples of pairs such that they perfectly encapsulate the polar inner structure of the cation. The hydrophobic exterior of the cation offers no point of attachment for the chloride anions or the solvating dichloromethane molecules, and it is the reason for the good solubility of **2**. We can think of no other chelate ligand arrangement or core structure of a $Zn_xL_y$ complex derived from 2-pyridylmethanol that would lead to such a perfect match. Thus the cations of **2** are an illustrative example of self-assembly.

When looking at the inorganic core of **2** alone (Fig. 3), another general feature of this complex becomes visible. To a good approximation the O and N atoms form two layers of a close packed array, and of the octahedral interstices in this array one half are filled with zinc ions. Thus the cations of **2** represent fragments of the cadmium iodide or brucite structure inside an organic ligand environment. In this respect **2** is a topological equivalent of the $Fe_{17}$ and $Fe_{19}$ complexes of the tetradentate

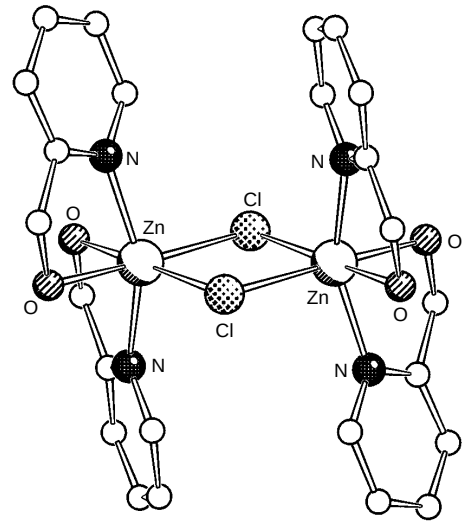


**Fig. 1** Atomic arrangements (bond lengths in Å) in the dication of **1**: Zn–O 2.214(3), 2.217(3); Zn–N 2.075(4), 2.083(3); Zn–Cl 2.409(2), 2.459(2) Å

HEIDI ligand.[8] In both cases the same assembly principle, *i.e.* matching of the ligands' and the core's spatial requirements, is operative.

One would assume that complexes like **2** should exist for pyridylmethanolato complexes of other transition metals. But while the oligonucleating ability of this ligand is well documented,§ we found no other complex like **2** and no other complex with a $M_7X_{24}$ core like in **2** in the literature.

While Fig. 3 points to the materials aspect of these complexes, the aspect of modelling zinc-coordinated intermediates of ADH-catalysed alcohol oxidation lies in the bonding type of the 2-pyridylmethyl-derived ligands. Complex **1** corresponds to the zinc-bound alcohol, **2** to the zinc-bound alkoxide, and the complex $[Zn_2Cl_4(2\text{-pyridylcarbaldehyde})_2]\cdot H_2O$ previously reported by us[9] represents aldehyde coordination by the same type of chelating ligand. Although all three species are zinc chloride compounds as well, their compositions and structures differ so much that a comparative discussion must await the further development of the zinc complex chemistry of these ligands.

This work was supported by the Deutsche Forschungsgemeinschaft.

# Common factors in the mode of action of vancomycin group antibiotics active against resistant bacteria

**Gary J. Sharman and Dudley H. Williams***

*Cambridge Centre for Molecular Recognition, University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW*

**It is shown that a semisynthetic glycopeptide, with activity against vancomycin resistant bacteria, possesses (as do other glycopeptides active in this way) features which promote its dimerisation and membrane anchoring.**

Vancomycin resistance is a growing problem in the treatment of bacterial infection.[1–5] It arises as a result of a modification of the bacterial cell wall in which the C-terminal D-alanine of cell-wall peptides, to which the antibiotic normally binds, is replaced by D-lactate.[6–8] This results in a repulsive interaction between ligand and antibiotic, and consequently a large decrease in affinity for cell-wall peptides. However, a number of semi-synthetic glycopeptides have recently been developed which show remarkable activity against vancomycin-resistant bacteria.[9] In recent work,[10] we have provided evidence that one such antibiotic, biphenylchloroeremomycin (BCE) or LY307599, developed by researchers at Eli Lilly & Co. in Indianapolis, owes its activity against vancomycin-resistant bacteria to its ability to dimerise and anchor to bacterial cell membranes. We have demonstrated that these two locating devices, which we have previously identified as being important in the mode of action of glycopeptides,[11,12] act cooperatively together to greatly increase the low, intrinsic free solution binding of ligands terminating in D-lactate. We now show that a second semisynthetic glycopeptide (MDL 63246) with activity against vancomycin-resistant bacteria, developed independently by researchers at Lepetit, also appears to share the same locating devices.

MDL 63246 (Fig. 1) is prepared semisynthetically from the antibiotic A40926,[13,14] a relative of the clinically important teicoplanin.[15] Teicoplanin (Fig. 1) shows no evidence of

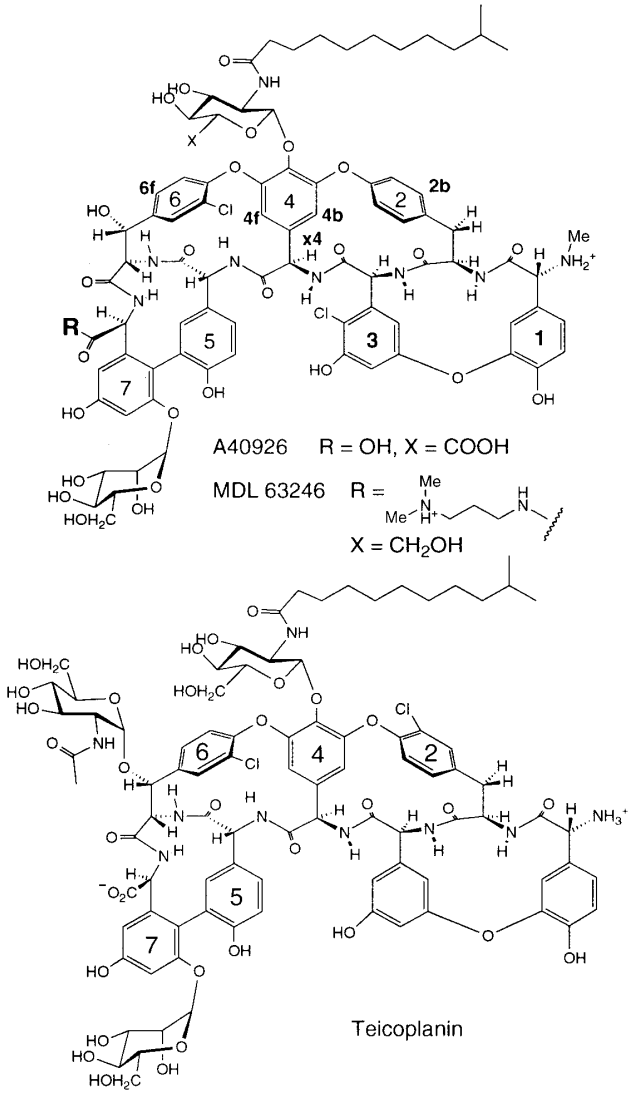

**Fig. 1** Structure of the glycopeptide antibiotics teicoplanin, A40926 and MDL 63246

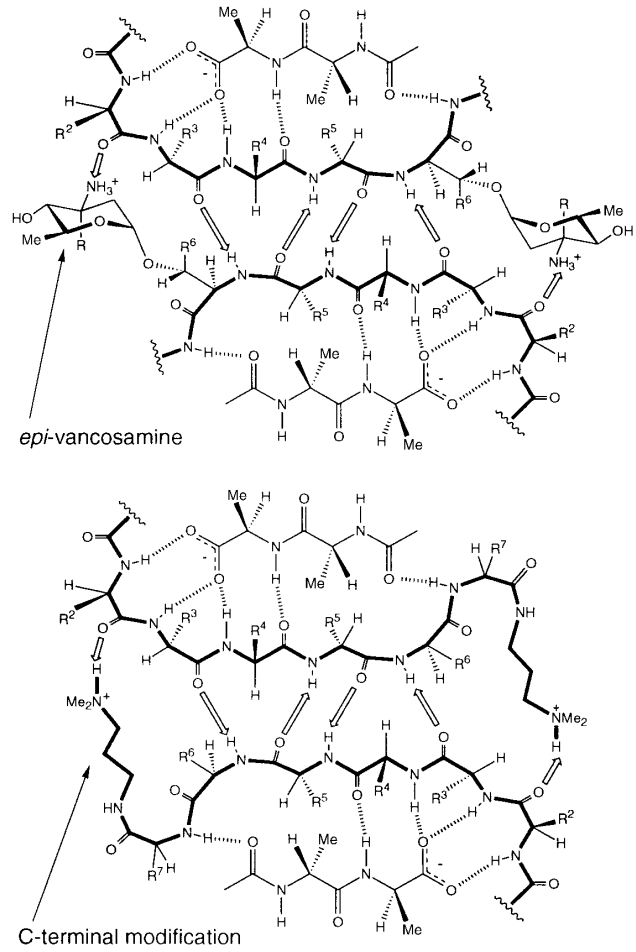

**Fig. 2** Structure of the dimer interface of MDL 63246 and eremomycin, showing how the C-terminal diamine of the former can fulfil a similar role to the *epi*-vancosamine sugar of the latter

dimerisation, but it does possess a membrane anchoring $C_{11}$ chain attached *via* the ring 4 sugar,[16] a feature shared by A40926. However, there are a number of structural differences between A40926 and teicoplanin. A40926 has a ring 3 chlorine, lacks a ring 2 chlorine, and perhaps most importantly in the present context, lacks the acetylated ring 6 sugar found in teicoplanin. The acetylated ring 6 sugar is thought to be the main factor which prevents teicoplanin from dimerising, as it would lead to an unfavourable steric interaction in the dimer structure. It was thus hypothesised that A40926 might dimerise to a limited extent. The structures of the dimers formed by several members of the vancomycin group have been determined by X-ray crystallography[17,18] and two dimensional NMR spectroscopy.[19,20] The use of a CPK model revealed that the diamine present on the C-terminus of MDL 63246 could stabilise such a dimer structure in a similar manner to the *epi*-vancosamine sugar of the antibiotic eremomycin, which increases the dimerisation constant by a factor of *ca*. 100.[21] This increase is due, at least in part, to the formation of a hydrogen bond between the ammonium ion of the *epi*-vancosamine with an amide carbonyl on the other side of the dimer. It further promotes dimerisation in complexes with cell-wall analogues due to an extended salt bridge, mediated through this amide between ammonium ion on one side of the dimer and carboxylate of the cell-wall peptide in the binding pocket of the other side of the dimer (Fig. 2).[19] Thus it was hypothesised that MDL 63246 might dimerise, and that its activity could be explained on the basis of the combined effect of dimerisation and membrane anchoring, exactly as for BCE.

To test this hypothesis, evidence was sought that MDL 63246 did indeed dimerise. When glycopeptide antibiotics dimerise, many $^1$H NMR resonances change their chemical shift in a characteristic way and these shifts are thus indicative of dimerisation. The α-proton of residue 4 (x4) is particularly useful in this respect, as it shifts from *ca*. δ 5.5 in monomer to *ca*. δ 6.5 in dimer. Hence, where the process of dimerisation is in fast exchange, the chemical shift of x4 increases as the antibiotic concentration and proportion of dimer increase.[21] As x4 moves through a region of the spectrum which is relatively uncluttered by other peaks, it serves as an excellent probe for dimerisation. A 3 mM sample of the parent compound A40926 was thus prepared with the ligand di-*N*-Ac-Lys-D-Ala-D-Ala. The $^1$H NMR spectrum was assigned from DQF-COSY, NOESY and TOCSY spectra. The chemical shift of x4 was δ 5.61. On dilution to 0.5 mM, x4 did shift upfield, but only very slightly (< 0.05 ppm), suggesting very weak dimerisation. However, for MDL 63246, a 3 mM solution gave an x4 shift of δ 6.12, changing to δ 5.84 at 0.5 mM. This concentration dependent x4 chemical shift strongly suggested that dimerisation was taking place. A plot of x4 chemical shift versus antibiotic concentration was therefore used to calculate the dimerisation constant by fitting the curve to the expression for dimerisation using a least squares algorithm. Such a plot yielded a dimerisation constant, $K_{dim}$, of 600 dm$^3$ mol$^{-1}$ for MDL 63246 (Fig. 3).

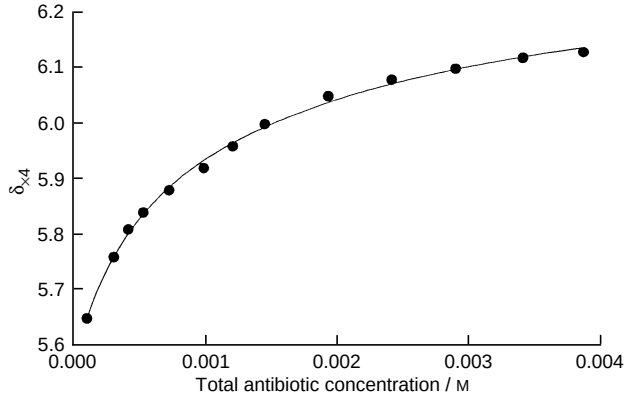

**Fig. 3** Plot of x4 chemical shift against total MDL 63246 concentration. This curve yields a dimerisation constant of 600 ± 100 dm$^3$ mol$^{-1}$.

The dimer structure was investigated further by two dimensional NMR spectroscopy. DQF-COSY, TOCSY and NOESY experiments were used to assign the structure and study its conformation. Several NOE enhancements were observed which were inconsistent with the covalent structure of the antibiotic, but which were indicative of a dimer. These included NOEs between x4 and 6f, an aromatic proton on residue 6 of the antibiotic, and between 6f and 4b (Fig. 1). An NOE enhancement was also observed between 2b and the *N*-methyl groups of the C-terminal diamine, suggesting the diamine was in a position where it could hydrogen bond to the amide between residues 2 and 3, and participate in an extended salt bridge in the presence of cell wall peptides (Fig. 2).

The second example of an antibiotic which dimerises and possesses a membrane anchor, and which exhibits enhanced activity, lends further support to the hypothesis that these two locating devices act cooperatively to enhance binding at the surface of the bacteria. In the case of MDL 63246, it may be possible to improve activity further by modifications which improve dimerisation. This could be achieved in a number of ways, such as optimisation of the C-terminal diamine, through changes in length or removal of rotors. Use of a different base antibiotic, such as teicoplanin with the ring 6 sugar removed, could also improve dimerisation; this antibiotic possesses a ring 2 chlorine, a feature known to enhance dimerisation.[21]

We would like to thank Gruppo Lepetit, Gerenzano, Italy, for kindly supplying samples of MDL 63246 and A40926 and Dr E. Selva (Gruppo Lepetit) for helpful comments. We also thank the EPSRC for financial support.

# Unrolling the hydrogen bond properties of C–H···O interactions†

**Thomas Steiner**

*Institut für Kristallographie, Freie Universität Berlin, Takustrasse 6, D-14195 Berlin, Germany*

**It has long been known that C–H groups may form weak hydrogen bonds. The characteristics of these interactions, however, have been explored systematically only recently. Currently, a qualitative understanding is being replaced by quantitative insight into the general properties and functions of weak hydrogen bonds like C–H···O. The current state is reviewed here, with a focus on results obtained by crystal correlation studies.**

## Introduction

The idea that C–H groups may be involved in attractive electrostatic interactions of appreciable strength is usually attributed to Glasstone:[1] in 1937, he explained the formation and the physical properties of liquid complexes like 1 : 1 chloroform–acetone by dimer association, as shown in Fig. 1.

Vibrational spectroscopists soon classified this interaction as a C–H··O 'hydrogen bond', with similar properties to O–H··O or N–H··O hydrogen bonds but lower bond energy. In the following 50 years, however, progress in the field was slow and in some periods even stagnant. Despite conclusive spectroscopic[2] and crystallographic[3] evidence for the structural importance of C–H··O interactions, they were widely neglected or their existence even denied.[4]

Only recently, a wave of interest in weak hydrogen bonding emerged in the different fields of structural chemistry[5] and biology.[6] It is now well documented that C–H··O interactions (and other types of weak hydrogen bonds) are important as secondary interactions, and in many instances even play dominant roles in determining crystal packing[7] and molecular conformation,[8] in molecular recognition processes,[9] in the stabilisation of inclusion complexes[10] and in the stability and possibly even in the activity of biological macromolecules.[11] Most of these studies have concentrated on the *function*, not the *nature*, of weak hydrogen bonds.

The analyses of individual systems were paralleled by detailed investigations on the general characteristics of C–H··O interactions. It turned out that the 'crystal correlation' technique is particularly fruitful in this context. This statistical method is essentially based on comparative analysis of large amounts of published structural data,[12] and can reveal geometrical characteristics and structural preferences that cannot be shown from individual crystal structures alone. In particular, if the studied characteristics are soft, as is normally the case for effects from weak interactions, crystal correlation is often the only suitable access to the problem. The most frequently used source of structural data is the Cambridge Structural Database[13] (CSD), where currently over 160 000 organic and organometallic crystal structures are archived, which offers powerful data retrieval and analysis software. Recent statistical studies on C–H··O interactions will be briefly reviewed here. It will be necessary to point at the limitations of our models (which are narrower than is often assumed), and *caveat* to simplified views must be stated.

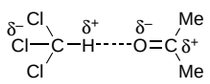

**Fig. 1** Chloroform–acetone dimer

## Some fundamentals

In 1963, Allerhand and Schleyer[14] qualitatively concluded from vibrational spectroscopic experiments that the ability of a C–H group to donate hydrogen bonds depends on the C hybridisation, as C($sp^1$)–H > C($sp^2$)-H > C($sp^3$)–H, and increases with the number of adjacent electron-withdrawing groups. The enhancement of the C–H donor strength by neighbouring electronegative groups is often called 'activation' of C–H. This effect can make even C($sp^3$)–H a relatively strong hydrogen bond donor; examples are $CHCl_3$ and $CH(NO_2)_3$. Particularly strong donors are obtained if C($sp^1$)–H is further activated by neighbouring electronegative atoms, such as in N≡C–H.

Hydrogen bonds in general are composed of different types of interactions.[6] As for all intermolecular interactions, there is a non-directional 'van der Waals' contribution, which is weakly bonding at long distances (by dispersion forces) and strongly non-bonding at short distances (by exchange repulsion). At their optimal geometry, van der Waals interactions contribute some tenths of a kcal $mol^{-1}$ to the hydrogen bond energy. An electrostatic component (dipole–dipole, dipole–charge, *etc.*) is directional and bonding at all distances. It reduces with increasing distance and with reducing dipole moments or charges involved. For donors like O–H or N–H, the electrostatic component is the dominant one in a hydrogen bond (several kcal $mol^{-1}$). This is also true for strongly polarized C–H groups (up to 2 kcal $mol^{-1}$, see below), whereas for weakly polarized C–H groups the electrostatic component is of similar magnitude to the van der Waals contribution. Only for the strongest types of hydrogen bonds does a charge-transfer component become important;[6] it does not play a relevant role for weak C–H··O interactions. The above circumstances carry eminent implications. (i) Electrostatic forces vary smoothly with varying geometry, and diminish only slowly with increasing distance; this leads to a pronounced softness of the hydrogen bond geometry. C–H··O interactions can be easily stretched, compressed and bent from optimal geometry. (ii) The bonding situation is strongly dependent on the donor and acceptor polarisations; therefore, weak hydrogen bonds involving polarizable groups can be critically influenced by their surroundings. (iii) With falling C–H polarisation, the directional electrostatic component is reduced, whereas the isotropic van der Waals component is unaffected; the net interaction therefore loses directionality. (iv) Upon compression, the van der Waals contribution becomes repulsive and might even result in a positive (*i.e.* non-bonding) net energy; this will be more important the smaller the electrostatic component is.

In C–H··O bonds, the net charge on carbon may be negative; this is the classical hydrogen bonding situation ($C^{\delta-}$–$H^{\delta+}$··$O^{\delta-}$). Carbon may also carry a positive partial charge ($C^{\delta+}$–$H^{\delta+}$··$O^{\delta-}$); this also results in electrostatic attraction between donor and acceptor (with different directionality characteristics). The typical partial charges involved are roughly 0 to +0.2 *e* units on H, and depend strongly on the particular system under study.

The bond energies of C–H··O interactions have been much debated. The energies are small and difficult to determine experimentally,[2] so that our knowledge is mainly based on computations. Earlier theoretical studies have been very inconsistent, but modern quantum chemical calculations seem to provide realistic energy estimations, at least for simple molecular systems *in vacuo* (*i.e.* isolated dimers or oligomers). Currently, there is consensus that C–H··O energies are typically $\leqslant 2$ kcal mol$^{-1}$ and gradually fade away with increasing H··O separation (compare 'normal' non-ionic O–H··O hydrogen bonds: *ca*. 3–8 kcal mol$^{-1}$).[6] Gavezotti called this a 'continuum from zero to a moderately strong interaction'.[15] Only for the most acidic C–H donors, and for interactions with partly or dominant ionic character, are energies > 2 kcal mol$^{-1}$ reported. As examples, bond energies for some C–H··O bonded dimers *in vacuo* as obtained by recent *ab initio* molecular orbital calculations[16,17] are given in Table 1 (for computational details, see Table legend). According to these computations, a C≡C–H··$OH_2$ interaction can be regarded as a 'proper' hydrogen bond with an energy of *ca*. 2.2 kcal mol$^{-1}$.[16] For the very weakly polarized donor $CH_4$, on the contrary, equilibrium bond energies are calculated to be 0.5–0.6 kcal mol$^{-1}$, which are dominated by a two-thirds van der Waals contribution.[17] It must be stressed that the above data are valid only for the particular situation they were calculated for: hydrogen bonds are strongly influenced by their surroundings, such as by the solvent and by other hydrogen bonds, so that interaction strengths in the liquid or solid state will in the general case deviate from the values in Table 1.

## Hydrogen bond distances

The shortest bonding C–H··O contacts observed in crystal structures have donor–acceptor separations for C··O of *ca*. 3.0 Å and for H··O of *ca*. 2.0 Å. Such short contacts occur only with acidic C–H donors such as those shown in Fig. 2; recent examples with $CH(NO_2)_3$ and Si–C≡C–H are shown in Fig. 3.[18] Even for acidic C–H, however, H··O contacts of *ca*. 2.0 Å are not the normal case; more typical are H··O distances in the range 2.1–2.3 Å.

If H··O separations in crystals are statistically characterized, different behaviour is observed for chemically different C–H types. For the strongest C–H donors, such as C≡C–H and $CHCl_3$, the frequency distributions of H··O interactions have a well defined maximum, probably corresponding to an optimal value, and fall off for longer distances (Fig. 4). This is a characteristic that is also observed for 'conventional' hydrogen bonds like O–H··O.[6] For weaker donors, the maximum is shifted to longer distances and becomes less pronounced, and for the weakest C–H donor species, there is no maximum and the number of contacts increases with increasing distance. Two realistic examples of such distributions are shown in Fig. 5 (the distance cutoff of these distributions will be discussed below). The observations for weak C–H donors are not straightforward to interpret, because one might expect to see a maximum (though a weak one) for these too. One of the probable determinants of the distributions is that, in competition with other intermolecular forces, hydrogen bonds from the less acidic C–H donors will more frequently be the loosers and be pushed out of optimal geometry than those from the more acidic ones.

Crystallographers are often tempted to associate hydrogen bond distances with hydrogen bond strengths. It is stressed that this is misleading, and that the shorter contact is not necessarily the stronger hydrogen bond, nor that a given contact is 'not a hydrogen bond' just because it is beyond a certain distance

**Table 1** Examples for calculated[a] hydrogen bond energies in C–H··O bonded dimers *in vacuo*. These values need *not* be valid for condensed state arrangements.

| System | Energy/ kcal mol$^{-1}$ | Reference |
|---|---|---|
| H–C≡C–H··O=$CH_2$ | −1.15 | 16 |
| H–C≡C–H··$OH_2$ | −2.19 | 16 |
| N≡C–H··$OH_2$ | −3.79 | 16 |
| $CH_4$··$OH_2$ | −0.59 | 17(*a*) |
| $CH_4$··$OH_2$ | −0.53 | 17(*b*) |
| $NH_2$–$CH_3$··$OH_2$ | −0.61 | 17(*b*) |
| $NH_3^+$–$CH_3$··$OH_2$ | −9.3 | 17(*b*) |

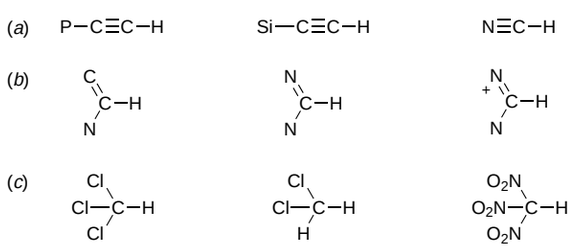

**Fig. 2** C–H groups that can donate short C–H··O hydrogen bonds with H··O around and below 2.1 Å. Examples are given for (*a*) C(sp$^1$)–H, (*b*) C(sp$^2$)–H and (*c*) C(sp$^3$)–H. The examples given for C(sp$^2$)–H are of particular importance for structural biology, because they occur in constituents of nucleic acids and of proteins.

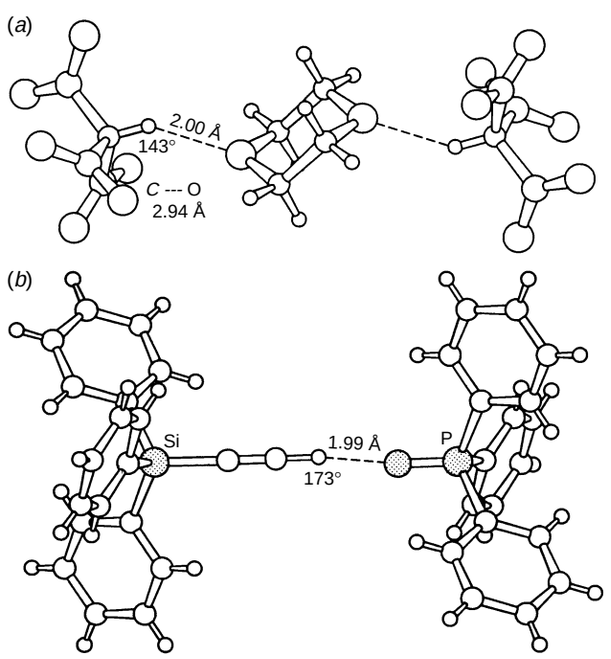

**Fig. 3** The short end of C–H··O hydrogen bonding: the crystalline adducts (*a*) trinitromethane–dioxane [ref. 18(*a*)] and (*b*) triphenylsilylacetylene–triphenylphosphine oxide [ref. 18(*b*)]. Numerical data is given for normalised hydrogen positions (C–H = 1.09 Å).

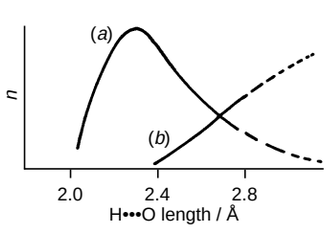

**Fig. 4** H··O Frequency distribution for (*a*) strong donors and (*b*) weak donors

limit. Attempts to obtain reliable bond length–bond energy correlations remained unsuccessful (the same is true for conventional hydrogen bonds). Still, it will be shown below that the *mean* H··O distances of large data samples of related hydrogen bonds carry relevant chemical information on donor and acceptor nature.

*Influence of donor acidity and acceptor basicity*

Certain 'strong' or 'activated' C–H donors form on average shorter contacts to oxygen than the less activated species. Quantification of this effect was achieved by Desiraju in a series of crystal correlation studies.[20–22] For chloroalkyl compounds, he demonstrated that the mean donor–acceptor separation of hydrogen bonds follows the sequence $Cl_3CH$ < $Cl_2CCH$ < $ClC_2CH$ < $C_3CH$, with mean C··O separations of 3.32, 3.40, 3.46 and 3.59 Å, respectively.[20] Similarly, alkynes form shorter contacts to oxygen than alkenes.[21] In an important generalisation, a direct correlation between average C··O separations and carbon acidity (in $Me_2SO$) could be shown (Fig. 6).[22] This correlation, however, is fairly sharp only for sterically unhindered donors, whereas for sterically hindered C–H groups, the average C··O separations are elongated compared to the values expected from Fig. 6. C–H acidity and therefore donor strengths can also be increased by steric strain on carbon, as was recently shown by Allen *et al.* for C–H in cyclopropane and related three-membered rings.[5d]

An effect of acceptor polarity on mean donor–acceptor separations was shown in a database analysis of small solvent molecules in varying crystal environments (Table 2).[19] In Table 2, the effect from donor polarisation shows up in the columns: with increasing C–H polarisation, the mean H··O separations reduce from 2.62 Å (for the Me groups of acetone) to 2.22 Å (for chloroform). This is a reduction of 0.4 Å. Note the fine gradation in the strengths of the weak methyl donors, which increase as N≡C–Me > O=S(Me)$_2$ > O=C(Me)$_2$, reflecting the different degrees of 'activation'. The effect from acceptor polarity (or basicity) is weaker, but can still be clearly seen in the rows: the variation in H··O separations between the strongest acceptor, C=O, and the weakest, C–O–C, is about 0.1 Å.

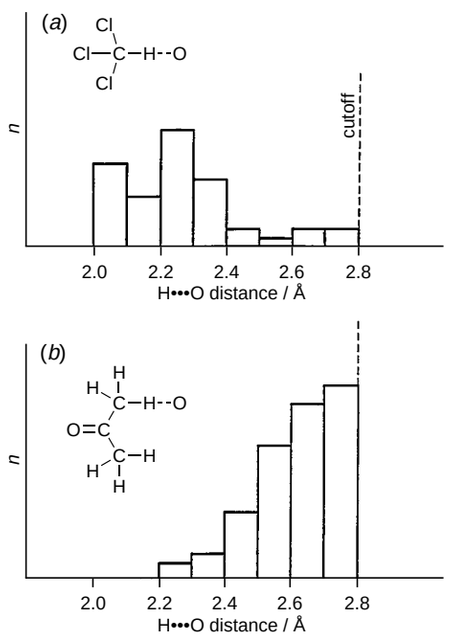

**Fig. 5** Two examples for realistic H··O frequency distributions in crystals for (*a*) chloroform donors, and (*b*) acetone donors; drawn using the data analysed in ref. 19

## Directionality

*Donor directionality of short C–H···O contacts*

Hydrogen bonds in general are directional interactions with a preference for linear geometry. For C–H··O interactions, this

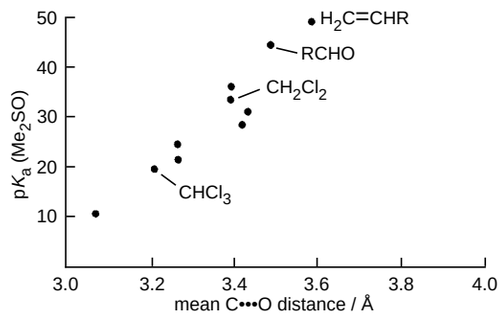

**Fig. 6** Correlation of mean C··O distance with the C–H acidity. Adapted from Pedireddi and Desiraju (ref. 22). Only data for sterically unhindered donors is shown. Each of the data points represents the mean value of broad distributions such as those in Fig. 5.

**Table 2** Mean C··O and H··O separations (Å) for C–H··O hydrogen bonds from small solvent molecules to various acceptor types (with H··O < 2.8 Å, for normalized H-positions)[a] (from ref. 19).

| | Acceptor | | | | | |
|---|---|---|---|---|---|---|

[a] Standard errors of the mean values given in parentheses, number of examples ($n_{CH}$) given in square brackets. Data for acceptors with $n_{CH}$ < 3 are not given individually, but included in the column for 'all O'. [b] Molecular residue.

property was first shown by Taylor and Kennard, who analysed the geometry of very short C–H··O contacts (H··O < 2.4 Å) in organic neutron crystal structures.[23] For these short contacts, the frequency distribution of C–H··O angles ψ is shown in Fig. 7(*a*): most frequent are slightly bent arrangements with angles in the interval ψ = 150–160°, whereas heavily bent contacts do not occur. To interpret this distribution properly, one must consider that the solid angle covered by an angular interval Δψ is smaller for linear than for bent angles (see inset of Fig. 7); if the distribution is weighted by 1/sin ψ, the more relevant figure to the right is obtained ('cone correction' as introduced by Kroon and Kanters[24]). This figure shows that linear contacts are preferred, as must be expected for electrostatic dipole interactions. For comparison, Fig. 7(*b*) also shows corresponding histograms for O–H··O hydrogen bonds in carbohydrates, which possess essentially the same characteristics, with an only slightly more pronounced preference for linearity.

*Donor directionality: the general case*

Fig. 7 demonstrates that C–H··O interactions are in principle directional. Due to the weakness of the interaction, however, the C–H··O hydrogen bond can be easily bent, so that directionality is blurred if steric hindrance or competition with other hydrogen bonding groups comes into play. This can be clearly observed for C–H··O contacts in carbohydrates, where O–H··O hydrogen bonds are the dominant intermolecular interaction forming a frame in which the weaker interactions have to adjust. Fig. 8 shows a scatterplot of ψ against H··O bond lengths for intermolecular C–H··O contacts in carbohydrate neutron crystal structures.[25] Most of the donors are of the type shown in Fig. 9, *i.e.* 'activated' C($sp^3$)–H groups. Despite the competitive situation, numerous C–H··O interactions with H··O separations down to about 2.25 Å are formed. The shortest of the contacts show the same preference for approximate linearity as those in Fig. 7, but with increasing distance the directionality rapidly becomes softer. From about H··O = 2.7 Å on, all angles ψ occur. The quasi-isotropic behaviour at longer distances should not be regarded as a sign of a lack of directionality; it is merely a consequence of competition with stronger forces.

Not every near-neighbour arrangement involving C–H and O is necessarily a hydrogen bond, and in a plot like Fig. 8 it is not generally possible to spot which of the data represent significant bonding interactions, which do not, and which are borderline cases. One of the circumstances causing this uncertainty is the occurrence of simultaneous contacts to atoms other than oxygen, in particular the ubiquitous repulsive H··H contacts. This problem can be illustrated[27] as shown for water acceptors in Fig. 10. A realistic example with a clearly repulsive and an 'uncertain' arrangement is shown in Fig. 11. The real problem is the uncertain cases, which are very difficult to interpret in individual crystal structures, and to filter them out from a given statistical data sample.

A problem that has as yet not been tackled seriously is the directionality behaviour of the weakest C–H donor types such as methyl groups. For these, contributions from dispersion forces are similar or even larger than the electrostatic contribution,[17] so that C–H··O interactions might become almost isotropic.

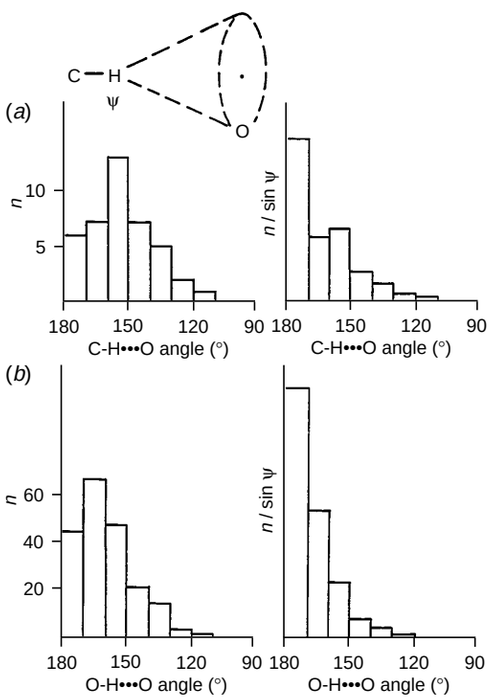

**Fig. 7** Frequency distribution of X–H··O angles (ψ) in crystal structures: (*a*) 41 intermolecular C–H··O contacts with H··O < 2.4 Å in organic neutron crystal structures (ref. 23); (*b*) 196 O–H··O hydrogen bonds in carbohydrate X-ray crystal structures (ref. 24). The inset illustrates the 'cone correction' (ref. 24) (weighting by 1/sin ψ) that relates the left and the right histograms. The idea to show C–H··O and O–H··O histograms in one figure was adapted from a lecture of J. Kroon (Utrecht, Sept. 5, 1995).

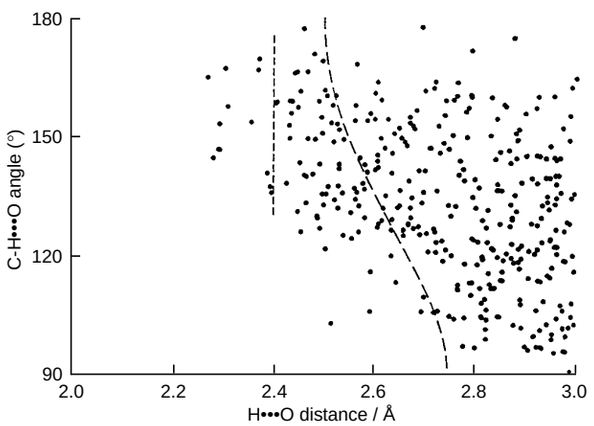

**Fig. 8** Scatterplot of the C–H··O angle against the H··O distance in intermolecular C–H··O contacts in carbohydrate neutron crystal structures. Drawn using data analysed in ref. 25. The straight dashed line at H··O = 2.4 Å shows the arbitrary distance cutoff used in ref. 23 (compare Fig. 7). The curved dashed line represents the H··O van der Waals separation based on a spherical oxygen atom and a non-spherical hydrogen atom (ref. 26). The conventional assumption of the van der Waals separation would be a vertical line at H··O = 2.6 or 2.7 Å.

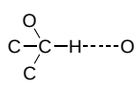

**Fig. 9** Typical C–H donor in carbohydrates

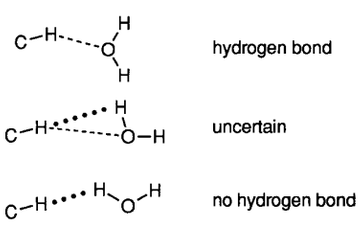

**Fig. 10** Possible geometries of C–H to water contacts

*Acceptor directionality*

The acceptors of hydrogen bonds exhibit complex but weak directionality behaviour that depends on their chemical nature. For carbonyl acceptors, X–H vectors tend to point at the oxygen 'lone-pair lobes' which are in the carbonyl plane, in theory forming angles of 120° with the C=O bond.[29] For ether, hydroxy and water acceptors, hydrogen bonds are weakly clustered in the bisecting plane of $R^1$–O–$R^2$.[30]

In the context of C–H··O hydrogen bonding, acceptor directionality has as yet only been discussed for C=O acceptors. Following initial indications,[23,31] the subject was studied in more detail in a crystal correlation study of acidic and sterically unhindered C–H donors which are not in competitive situations ($CHCl_3$, $CH_2Cl_2$, C≡C–H).[32] If the approach of C–H to O=C is characterized by the angle α (H··O=C) and the torsion angle ω (H··O=C–Y), the polar scatterplot shown in Fig. 12 is obtained. The histogram shows the distribution of angles ω and indicates a preference for in-plane contacts (ω ≈ 0). The acceptor directionality that becomes apparent from Fig. 12 is very soft, but significant.

## Notes on cutoff criteria

Formerly, it was common practice among crystallographers to define hydrogen bonds as X–H··Y contacts shorter than the H··Y or the X···Y van der Waals separation. It has been repeatedly pointed out that this concept is faulty:[6] there is no experimental or theoretical evidence that at a certain critical distance, the interaction is switched from 'hydrogen bond' to 'van der Waals' type. The electrostatic component of the hydrogen bond also operates beyond van der Waals separation. This is reflected in the appearance of Fig. 8, which lacks any discontinuities. The straight dashed line shows the conservative

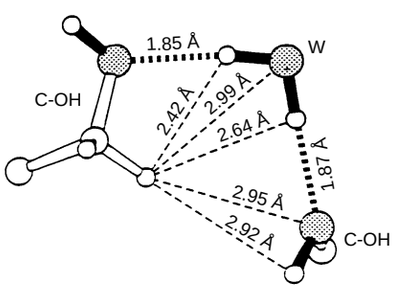

**Fig. 11** An example of long C–H··O contacts associated with repulsive H··H contacts. The C–H···water contact is presumably repulsive, and the net interaction of the C–H··OH contact is uncertain. In other geometries, such long C–H··O contacts can be assessed as weakly bonding in nature [adapted from ref. 25, using neutron diffraction data of β-cyclodextrin–11.6 $H_2O$ at 120 K (ref. 28)].

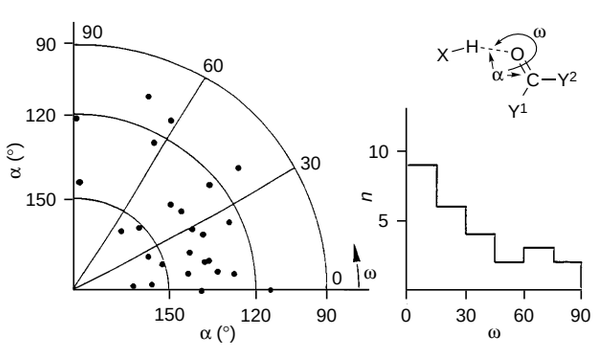

**Fig. 12** Approach of acidic and sterically unhindered C–H donors to C=O acceptors (26 data points) (ref. 32). Geometrical definitions are shown in the inset. The data are indicative of soft but significant acceptor directionality.

2.4 Å van der Waals cutoff used by Taylor and Kennard,[23] and the curved dashed line represents an alternative van der Waals cutoff[25] based on a possibly non-spherical H-atom.[27] Both divide the distribution as arbitrarily as any other cutoff would do.

In many instances, computational practice requires the use of cutoff definitions. A compromise must then be found between the desire not to omit too many attractive long-distance interactions, and not to include too many dubious (Fig. 10) or insignificant 'hydrogen bonds'. The first desire calls for a distance cutoff so long that maxima in distance distributions (if existing, Fig. 4) are included; this requires values > 2.6 Å. Since dubious arrangements, such as those shown in Fig. 10, occur mainly with long H··O separations > 2.8 Å,[27] the author has repeatedly used this value as a pragmatic cutoff distance in crystal correlation studies. In samples containing fewer dubious arrangements, longer cutoff values, such as 3.0 or 3.2 Å, can be justified. In any case, cutoff criteria are coarse instruments and should be avoided whenever possible.

## Effect on covalent geometries

Hydrogen bonding has consequences for the covalent bonding of the involved groups. In an interaction $R^1$–X–H··Y–$R^2$, the X–H and Y–$R^2$ bonds are weakened, resulting in bond lengthening and lowering of the stretching frequencies, and the $R^1$–X bond is strengthened and thereby shortened. These effects are very pronounced for O–H··O hydrogen bonds.[33] For the C–H··O interactions, analogous effects should be expected to occur on a smaller scale. In infrared absorption spectra, weakening of C–H and Y–R can in many instances be clearly observed,[2,34] but the extent to which the weakening reflects in the covalent geometry has been only poorly investigated. As a first such effect, slight lengthening of the C–H bond was shown from neutron diffraction data of amino acid $C_\alpha$–H bonds.[35*a*] The reported lengthening, of *ca*. 0.01 Å for contacts with H··O of *ca*. 2.3 Å, corresponds to a weakening of the C–H bond by roughly 0.03 valence units (for bond length–bond valence relations in general, see ref. 36).

In an individual neutron crystal structure, slight lengthening of an acetylenic C–H bond in a short C≡C–H··O interaction (H··O = 2.07 Å) was reported only recently.[35*b*]

## Cooperativity

Hydrogen bonds possess the important property of *cooperativity*; in arrays of *n* interconnected hydrogen bonds, the total bond energy is larger than the sum of *n* isolated hydrogen bonds ('*non-additivity*'). There are two different mechanisms that can produce this effect: functional groups which may act as hydrogen bond donor and acceptor simultaneously often form chains of the type $O^{\delta-}$–$H^{\delta+}$··$O^{\delta-}$–$H^{\delta+}$··$O^{\delta-}$. In these chains, due to mutual polarisation of the involved groups, the individual hydrogen bonds enhance each other's strengths by around 20%.[6] A different mechanism is charge flow in suitably polarizable π-bond systems ('*resonance assisted hydrogen bonds*'.[37])

Based on structural and electrostatic analogies, such effects can be postulated to occur also with weak hydrogen bond types. Of particular interest is the C≡C–H residue, which can donate C–H··Y and accept X–H··π hydrogen bonds simultaneously.[38–40] Three patterns that are topologically equivalent are shown in Fig. 13, and one may expect that they also have analogous cooperativity properties (of course, of different strengths).

(*a*) O–H------O–H------O

(*b*) C–H------O–H------O

(*c*) X–H----C≡C–H----O

**Fig. 13** Three topologically equivalent hydrogen bond patterns

Unfortunately, direct experimental evidence for energy enhancement is difficult to obtain. For arrangements like the one in Fig. 13(*c*), however, spectroscopic evidence for cooperativity has been supplied.[38a] The crystalline sex steroid mestranol contains cooperative and non-cooperative C≡C–H···O hydrogen bonds, which can be directly compared spectroscopically.[38b] More complex patterns have also been observed, such as the cycles shown in Fig. 14, for which non-additivity has been claimed.[40]

A well known example for conventional 'resonance assisted hydrogen bonding' is the carboxylic acid dimer shown in Fig. 15(*a*), and an analogous C–H··O pattern is shown in Fig. 15(*b*). It is supposed that this pattern is stronger than just the sum of two C–H··O=C hydrogen bonds. However, the mere structural analogy is not a proof for significant cooperativity effects in Fig. 15(*b*), so that further investigations are required.

A pattern with C–H··N bonding that is immediately suggestive of cooperativity is the infinite chains in crystalline HCN[41] (Fig. 16). Liquid HCN is composed of finite chains of this kind. In a recent *ab initio* quantum chemical study of $(HCN)_n$ chains, it was in fact calculated that the H··N distances and the C–H stretching frequencies reduce with increasing system size, whereas the C–H bond lengths increase. Even at the octamer stage, saturation of the effect had not yet completely been reached.[42]

Quantum chemical calculations have also been performed on the infinite molecular chains in crystalline *N*,*N*-dimethylnitroamine (Fig. 17). For these, using semiempirical molecular orbital calculations, Sharma and Desiraju estimated an energy enhancement of around 20%; the effect reaches saturation at about the pentamer stage.[43]

## Thermal vibrations

Hydrogen bonding reduces the thermal vibrations of the engaged residues. For C–H··O interactions, this effect was first shown for terminal alkynes.[44] The acetylenes are good probes in this context, because they are among the most acidic C–H donors and, at the same time, they enjoy pronounced vibrational freedom. The situation is sketched in Fig. 18.

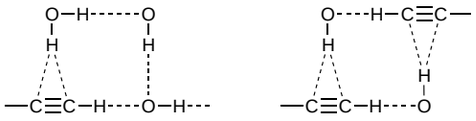

**Fig. 14** Two cooperative hydrogen bond cycles involving C–H···O interactions

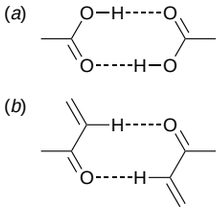

**Fig. 15** Resonance assisted hydrogen bonding

**Fig. 16** The infinite hydrogen bonded chains in crystalline HCN

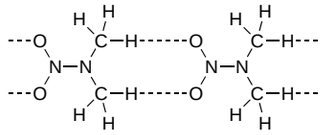

**Fig. 17** The infinite molecular chains of crystalline *N*,*N*-dimethylnitroamine

A free C≡C–H moiety can vibrate strongly, normally with the vibration amplitude largest for the terminal C-atom [Fig. 18(*a*)]. In a C≡C–H··X hydrogen bond, the alkynyl orientation is more restricted [Fig. 18(*b*)]. The vibration behaviour can be described semi-quantitatively by the ratio of isotropic displacement parameters $U(C2)/U(C1)$, which is significantly larger than 1 for the situation in Fig. 18(*a*), and close to 1.0 for that in Fig. 18(*b*). This ratio was correlated with the H··X separation for 51 C≡C–H groups in 42 crystal structures (X = O, N, π-acceptors), and the obtained correlation clearly shows the anticipated effect (Fig. 19):[44] on average, the *U* ratio continuously reduces with shortening H··X distance, indicating a reduction of the thermal vibration. It is of relevance that this effect is not only observed for the shortest hydrogen bonds, but also for relatively long contacts with H··X in the range 2.6–2.8 Å, reflecting the long-range nature of the interaction.

The complementary effect on the acceptor side was shown by Braga *et al.* for an organometallic compound[31] (Fig. 20). For metal-coordinated carbonyl groups, the ratio $U(O)/U(C)$ was reported to be larger for free M–CO [Fig. 20(*a*)] than for CO accepting M–CO··H–C interactions [Fig. 20(*b*)], indicating reduction of the acceptor vibration due to C–H··O hydrogen bonding.

## C–H···O replacing stronger hydrogen bonds

In many crystal structures, C–H··O interactions are observed as bystanders or subalterns to more dominant systems of stronger interactions. This can easily lead to the view that C–H··O interactions, although in principle of hydrogen bond type, are too weak to have similar functions in structure formation and

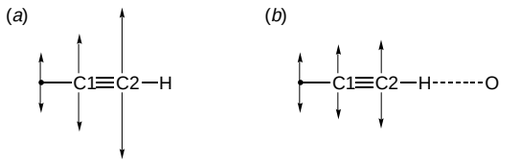

**Fig. 18** Thermal vibrations of the (*a*) unbonded and (*b*) C–H··O bonded C≡C–H moiety

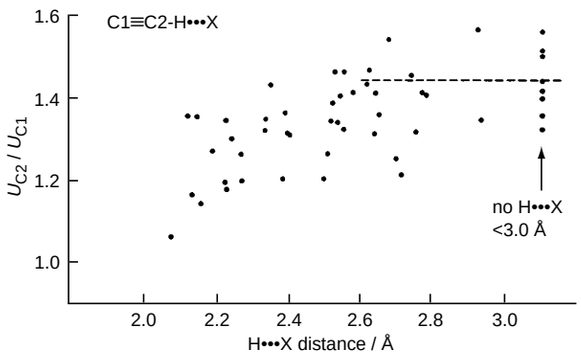

**Fig. 19** Correlation of the quantity $U(C2)/U(C1)$ with the H··X distance in C1≡C2–H··X hydrogen bonds (X = O, N, π-bonds), for normalized hydrogen positions. The horizontal line shows the mean value for C≡C–H groups with no H··X contact shorter than 2.8 Å (adapted from ref. 44).

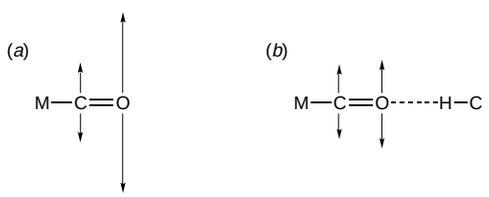

**Fig. 20** Thermal vibrations for the (*a*) unbonded and (*b*) M–C=O··H bonded M–CO moiety

stabilisation as the stronger O/N–H··O hydrogen bonds. However, this is not true in all cases (in many, though, it is), and opposite observations have also been made. The author first encountered this problem when studying the coordination of water molecules in various environments,[27,45,46] mainly from highly accurate neutron diffraction data. It became apparent that water molecules frequently accept C–H··$O_W$ interaction, which have the major function of 'filling up' the preferred two-fold acceptor functionality, if stronger O–H or N–H donors are not suitably available (Fig. 21). The coordination geometries of the arrangements shown are completely analogous. There is no doubt that these C–H··$O_W$ interactions are formed only as a last resort if stronger hydrogen bonds are lacking, but if they form, C–H donors actually take the role and function of O–H or N–H.

Several examples have been published where, in isomorphous crystal structures, an N/O–H··O hydrogen bond in one structure is isofunctionally replaced by a C–H··O interaction in the other. The classical examples are the isomorphous complexes urea–barbital and acetamide–barbital[47] (Fig. 22). Other examples are the isomorphous inclusion complexes of β-cyclodextrin with diethanolamine and with pentane-1,5-diol, where a clearly structure-stabilizing N–H··O bond is substituted by a C–H··O interaction of the same function,[48] and the replacement of an N–H··$Cl^-$ by a C–H··$Cl^-$ interaction in isomorphous adenosine derivatives.[49] In all these cases, both interactions have the same function in structure stabilisation, *i.e.* in these instances, the C–H··O interactions do in fact play the role of a stronger hydrogen bond.

## Outlook

The process of characterizing the hydrogen bond properties of C–H··O interactions is slow and troublesome, and far from being finished. Some of these properties are already well documented, whereas others appear vague and indistinct (making parts of the review unsatisfactory to write). Important points that are as yet only poorly understood are the long-distance properties of weak hydrogen bonds, cooperativity effects, non-additivity properties in general, the competition properties with other intermolecular forces, the roles of very weakly polarized groups like Me, the C–H groups of organic ions ($N^+$–C–H of various types, $P^+Ph_4$ *etc.*), the behaviour upon compression by other crystal forces or by intramolecular strain ('*forced contacts*') and the gradual transition from directional to isotropic interactions.

Relevant effects that cannot be studied by crystallographic methods are (for example) bond energies, thermodynamic properties in general and the influence of solvent. A large volume of quantum chemical calculations is required to obtain a broad picture of interaction energies under various conditions. This should include studies on non-additivity phenomena.

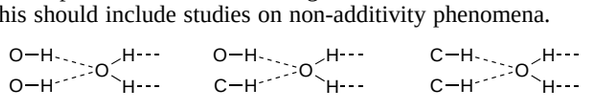

**Fig. 21** Analogous coordination geometries for two different forms of hydrogen bond

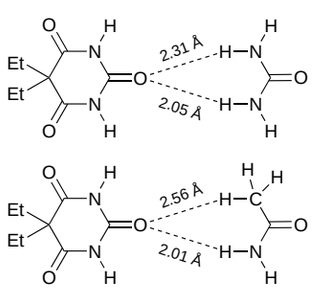

**Fig. 22** Isomorphous complexes of (*a*) urea–barbital and (*b*) acetamide–barbital

This review has concentrated on the special case of the weak hydrogen bonds formed between C–H donors and oxygen acceptors. Related directional interactions between other weak donor–acceptor combinations are also studied extensively, in particular with the important π-acceptors (see ref. 50 and literature cited therein). Also these interactions play important roles in structural chemistry and biology, and deserve further investigation.

# Tagging in combinatorial chemistry: the use of coloured and fluorescent beads

**Bryan J. Egner,[a] Sunil Rana,[a] Helen Smith,[a] Nathalie Bouloc,[a] Jeremy G. Frey,[a] William S. Brocklesby[b] and Mark Bradley*[a]**

[a] *Department of Chemistry, University of Southampton, Southampton, UK SO17 1BJ*
[b] *Department of Physics and Optoelectronics Research Centre, University of Southampton, Southampton, UK SO17 1BJ*

**Fluorescent confocal microscopy is a practical and very sensitive (fmol bead$^{-1}$) and non-destructive tagging technique for use in combinatorial chemistry.**

The power of solid phase and combinatorial chemistry is now being widely utilised by the major pharmaceutical players in the generation or optimisation of lead compounds in the drug discovery process.[1] Library generation can take place in a number of ways, perhaps the most powerful being the solid phase split and mix strategy such that each distinct 'bead' of the support contains only a single compound.[2] Screening from single beads requires means of compound identification and has led to the use of tagging, perhaps the most elegant approach being the arylcarbene system of Still.[3]

An addition to the area of tagging/decoding would be the use of the absorption or fluorescence spectrum of the resin bead. The simplest approach would be to covalently dye the beads and inspect under a microscope. The use of confocal fluorescence microscopy and complete spectrum analysis would enhance the sensitivity and potential of the system and enable the use of a number of fluorescent dyes which together with spectrum deconvolution would provide a very sensitive dye coding system.

In the first study a number of commercially available dyes† were covalently coupled by amide bond formation to TentaGel-S-$NH_2$ beads (130 μm) and a small peptide library (448 compounds $X_3X_2X_1$-linker-β-Ala-β-Ala-resin was prepared.[2] A selection of beads from the library were Edman sequenced and confirmed that the first residue ($X_1$) of the library was consistent with the colour of the single bead. The fluorescent microscope allowed ambiguities to be resolved, *e.g.* between pyrene and unlabelled TentaGel beads which were very similar by transmittance [Figs. 1(*a*)–(*c*)].

The fluorescence technique was extended by the use of a confocal microscope laser system.‡ The use of a single excitation line restricted the range of fluorescent dyes that could conveniently be used in these initial studies, however it was sufficient for initial proof of principle studies.

*Single dyes*–TentaGel beads (130 μm) were labelled with fluoroscein (0.01%) and erythrosin (0.02%).§ The beads were swollen in water, placed on a microscope slide with a cover slip and analysed under a confocal microscope‡ to give the spectra shown in Fig. 2. The spectra were clearly defined, relatively sharp and with distinguishable maxima. The degree of dye loading was varied by several orders of magnitude to give the spectra shown in Fig. 3. This showed the expected decrease in intensity with decreasing nominal bead loading and that as calculated increasing the bead loading above 0.1% did not give a uniform increase in relative fluorescence due to dye saturation. Fig. 3 shows loadings at 1 in $10^5$ and demonstrates that even at this level of tagging the fluorescent signals are clearly observable, corresponding to approximately 3–4 femtomoles bead$^{-1}$. Labelling down to 1 in $10^6$ (300–400 attomoles bead$^{-1}$) has also been demonstrated to be possible, although in this case the limits were determined by the amount of background fluorescence and Raman scattering from the bead

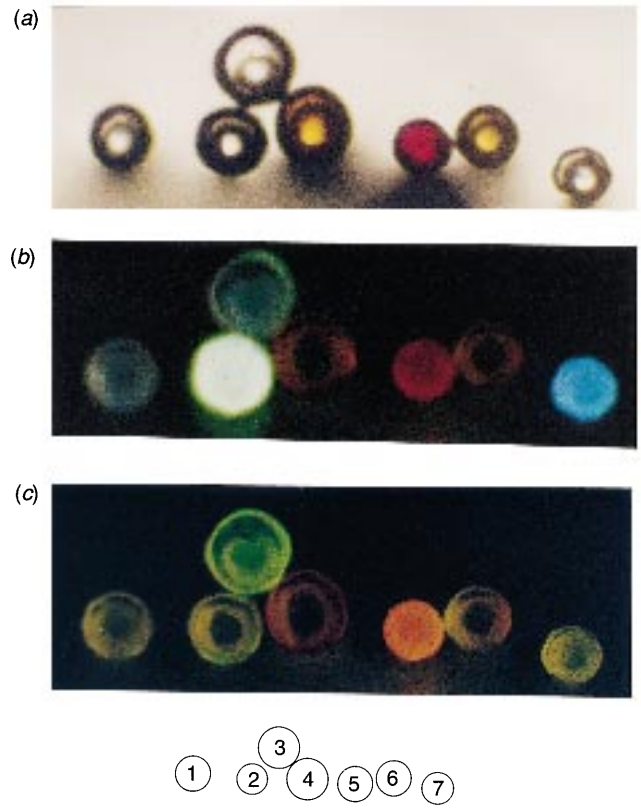

**Fig. 1** Tagged beads under differing observation conditions 1 = unlabelled bead, 2 = dansyl, 3 = fluorescein, 4 = methyl red, 5 = erythrosin, 6 = mordant orange, 7 = pyrene. (*a*) Transmittance. (*b*) Fluorescence (excitation 340–380 nm, suppression filter 425 nm). (*c*) Fluorescence (excitation 420–490 nm, suppression filter 515 nm).

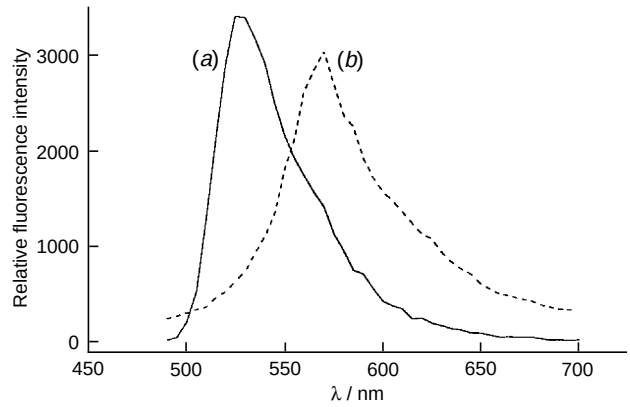

**Fig. 2** Fluorescence spectra obtained from single tagged TentaGel beads. (*a*) 0.01% Fluorescein. (*b*) 0.02% Erythrosin.

itself. The number of molecules excited in this case is approximately 20 000. The intensity of fluorescence between beads of the same loading was also relatively uniform.¶

*Multiple dyes*–The potential problems associated with using several dyes in a tagging system is one of internal quenching by either energy transfer or reabsorption by the dyes. However, we reasoned that, due to the unusual environment created within a bead such quenching phenomena might be reduced in nature due to site isolation, especially at low substitution levels. Initial studies using beads with approximately equimolar numbers of dye labelled sites (0.01%) gave spectra which showed quenching was taking place but that it was not complete. The experiments were repeated keeping one dye at a fixed level within the beads and varying the ratio of the other. The spectra are shown in Fig. 4.

We have in this initial study used two very similar dyes with strongly overlapping absorbance and emission spectra and clearly this is a worse-case scenario. It does however suggest that, by using several different dyes with varying absorbance/emission spectra and by varying the dye loadings (by orders of magnitude), a viable tagging method can be produced.

The simplicity of using dyed beads to allow initial position identification has been demonstrated. If spectra are known for the various starting beads then the initial reaction component of the library when added to the bead is therefore known. The technique is non-destructive, thus allowing full subsequent analysis by other techniques, very sensitive, with detection levels easily down to femtomoles of material/bead and with a linear response to tagging levels. Although limited in this report, it will be simple to expand these studies by the use of a greater range of dyes with reduced reactivity. The use of coloured and fluorescent beads has the potential, we believe, to simplify the identification of library members for single bead screening applications.

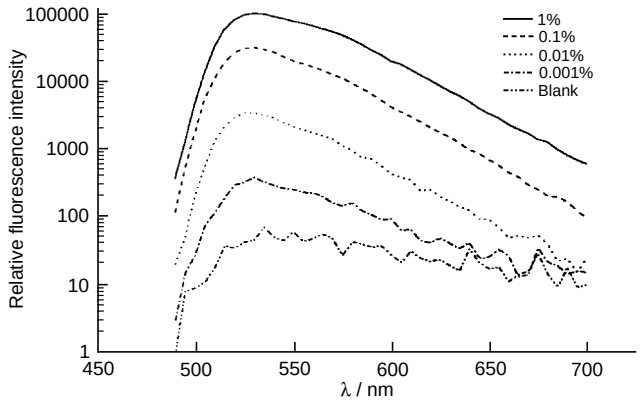

**Fig. 3** Fluorescence linearity with loading. Relative fluorescence intensity against wavelength at varying tagging levels.

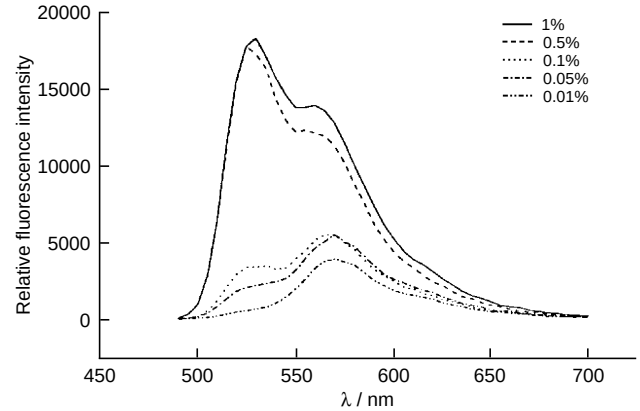

**Fig. 4** Dye combinations. Fixed erythrosin level (0.02%) with varying levels of fluorescein (1, 0.5, 0.1, 0.05 and 0.01%).

## Footnotes

† The dyes utilised in this study and the corresponding first amino acid in the library were pyrene butanoic acid (Val), methyl red (Ala), erythrosin B (Gln), dansyl chloride (Ser), fluorescein isothiocyanate, mordant orange (Asp) and succinylated disperse red (Leu), unlabelled beads (Lys). The following Fmoc amino acids were used in library generation: [$X_1$ = Ala, Asp(Bu$^t$), Gln, Leu, Lys(Boc), Ser(Bu$^t$), Val], [$X_2$ = Ala, Gly, Leu, Lys(Boc), Ser(Bu$^t$), Phe, Pro, Val], [$X_3$ = Asp(Bu$^t$), Gly, Leu, Lys(Boc), His(Trt), Ser(Bu$^t$), Phe, Val]. Four erythrosin labelled beads gave the amino acid sequences LAQ, HPQ(2) and GKQ, two pyrene labelled beads gave the sequences GPV and GFV, two methyl red labelled beads gave the sequences LPA and VQA and a mordant orange labelled bead gave the sequence GFD. TentaGel beads had a loading of *ca.* 300–400 pmoles bead$^{-1}$ as determined by Edman sequencing.

‡ Fluorescence was excited using a focused $Ar^+$ ion laser beam with a wavelength of 476 nm and a power of approximately 4 μW. The approximate spot radius was 0.5 μm, giving a laser intensity of *ca.* $5 \times 10^6$ W m$^{-2}$. This was well below the saturation intensity of the dye (approximately $10^9$ W m$^{-2}$) so all fluorescence should be linear in laser intensity. The area of the laser spot on the bead was *ca.* $8 \times 10^{-13}$ m$^2$. The illuminated region of the bead can be approximated as a cylinder with a cross-section equal to the laser spot size and a length equal to the bead diameter. The illuminated volume, $1 \times 10^{-16}$ m$^3$, is thus only 1 part in 11 000 of the total bead volume. Assuming the available binding sites ($400 \times 10^{-12}$ moles bead$^{-1}$) are evenly distributed throughout the bead, then there will be $2 \times 10^{10}$ binding sites within the illuminated volume and an effective concentration of 0.33 M if all the sites are filled. Taking into account the dye absorption coefficient, the path length through the bead and the effective concentration, the Beer–Lambert Law absorption by the bead will be $I = I_0e^{-a}$, with $a = 370$. If only a fraction, $f$ (filling factor), of the sites are loaded the absorption produced by the dyed bead is $I = I_0e^{-af}$. For occupancies above $f = 10^{-2}$ (*i.e.* > 1%) the bead will be optically thick and the exponential will depart significantly from a linear relationship between dye loading and fluorescent intensity—the addition of more dye will not significantly increase the fluorescence observed because all the available light is already being absorbed by the dye and so the addition of more dye produces no more fluorescence. The light was dispersed with a scanning triple monochromator and detected with a photomultiplier.

§ The beads were labelled by treatment with varying equivalents of FITC. The nominal % bead loading is the maximum number of sites which could be labelled under the reaction conditions. Beads were labelled with erythrosin using DIC and HOBt in DMF. Relative loadings for erythrosin were derived by comparison of the relative fluorescent intensities with FITC labelled beads and the extinction coefficients of the two dyes.

¶ The average fluorescent intensity of 12 beads (± S.D) at the nominal bead loading 1%, 123 000 ± 15 000; 0.1%, 27 400 ± 8000; 0.01%, 2950 ± 610; 0.001%, 271 ± 70.

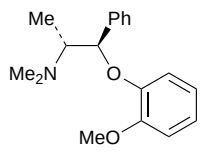
# Enantioselective [2,3] sigmatropic rearrangement mediated by a butyllithium–chiral ligand complex

**Shino Manabe*†**



*Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113, Japan*

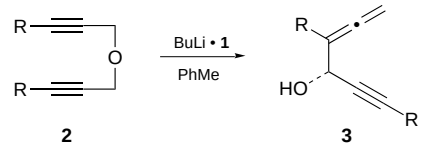
**The first enantioselective [2,3] sigmatropic rearrangement of acyclic diprop-2-ynyl ethers and alkenyl benzyl ethers is achieved by a BuLi–chiral ligand complex.**

The [2,3] sigmatropic rearrangement has been studied with regard to its stereochemical course in view of its synthetic application to the preparation of highly functionalized derivatives.[1] Asymmetric [2,3] sigmatropic rearrangement involving chiral auxiliaries has been investigated by Nakai and co-workers and Enders and co-workers in order to achieve high diasteroselectivity.[2] However, the enantioselective version of this reaction has remained one of the unsolved problems in the field of synthetic organic chemistry. Marshall and Lebreton reported the first example of this reaction, in which a 13-membered cyclic ether afforded the prop-2-ynylic alcohol in 70% ee by the use of a chiral lithium amide.[3] But it has also been reported that the same lithium amide was not effective for acyclic substrates.[3,4] Fujimoto and Nakai demonstrated an enantioselective reaction for acyclic substrates *via* a boron ester enolate.[5] Gladysz and co-workers reported the enantioselective [2,3] sigmatropic rearrangement of sulfur ylides using a chiral rhenium complex.[6] However, no examples of an enantioselective reaction of acyclic substrates involving an $sp^3$ carbanion, which are the most typical substrates in this rearrangement, have been demonstrated so far. We report herein the first example of an enantioselective [2,3] sigmatropic rearrangement of acyclic ethers involving an $sp^3$ carbanion.[7]

Recently, this reaction was reported to proceed with complete inversion of configuration at the carbanion carbon centre to give the newly generated chiral centre.[8] On the other hand, Hoppe *et al.* and Beak and co-workers have shown that asymmetric deprotonations can be effected with $Bu^sLi$–(−)-sparteine complex to give a chiral dipole-stabilized carbanion which reacts with electrofiles to give enantiomerically enriched products.[9] So it is expected that an enantioselective [2,3] sigmatropic rearrangement could be possible if a chiral carbanion can be generated by use of a BuLi–chiral ligand complex. We have found that a complex of butyllithium with a chiral ligand **1**[10]‡§ exerts a pronounced effect on this rearrangement.

Initially acyclic diprop-2-ynyl ethers **2** were studied as they have simple and symmetrical structures. The first attempt at enantioselective [2,3] sigmatropic rearrangement of **2a** mediated by a complex of BuLi–(−)-sparteine was unsuccessful. Although (−)-sparteine is known as a good chiral ligand in many reactions, **3a** was obtained in only 23% yield and 9% ee. As a result the chiral amino ether **1** was designed, and was found to work as a good chiral ligand for BuLi in this reaction.¶ Some representative results are summarized in Table 1.‖

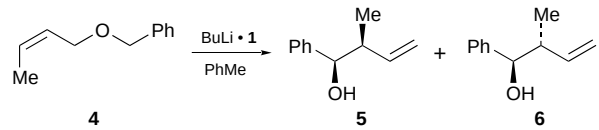
**1**



This chiral amino ether **1**–BuLi complex is effective not only for diprop-2-ynyl ether **2** but also for *cis*-but-2-enyl benzyl ether **4** (Scheme 1). The reaction gives *syn* alcohol **5** and *anti* alcohol **6** in a ratio of 9 : 1 in 50% yield.[11] The ee of *syn* alcohol **5** was 64% and the ee of *anti* alcohol **6** was 80%. Relative stereochemistries were determined by $^1H$ NMR coupling constants,[12] and the ee and absolute configuration of the *syn* alcohol were determined by $^1H$ NMR after conversion to the corresponding (*R*)-MTPA ester.[13]** The ee of *anti* alcohol **6** was determined directly by chiral HPLC [DAICEL CHIRALCEL OJ, hexanes–$Pr^iOH$ (50 : 1), 0.75 $cm^3$ $min^{-1}$, λ = 254 nm].

Interestingly, the ee was sensitive to the substitution pattern of the alkene. For instance, when *trans*-but-2-enyl benzyl ether is used, the reaction gives **5** and **6** in the ratio 65 : 35 in 48% yield. The ee of the *syn* alcohol **5** decreased to 16%, and the ee of the *anti* alcohol **6** also decreased to 12%. In the case of 3-methylbut-2-enyl benzyl ether **7** (Scheme 2), the desired product **8** was obtained in 68% yield and in 40% ee.††

In summary, the chiral ligand **1**–BuLi complex is effective for the enantioselective [2,3] sigmatropic rearrangement of acyclic ethers involving an $sp^3$ carbanion.



The author would like to thank Professor Kenji Koga for helpful discussions.

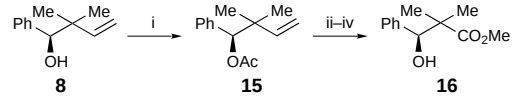
† Present address: The Institute of Physical and Chemical Research (RIKEN), Hirosawa, Wako-shi, Saitama 351-01 Japan.
‡ All new compounds gave satisfactory spectroscopic data.
§ Compound **1** was prepared from (1*R*, 2*R*)-(−)-norpseudoephedrine in two steps: (i) HCHO, $HCO_2H$ (100%); (ii) guaiacol, DEAD, $PPh_3$, THF (25%). $^1$H NMR (270 MHz, [$^2H_6$]benzene): δ 7.4–6.6 (9 H, m), 5.15 (1 H, d, *J* = 6.6 Hz), 3.43 (3 H, s), 3.13 (1 H, dd, *J* = 6.6, 6.9 Hz), 2.40 (6 H, s); mp 57 °C; $[\alpha]_D^{24}$ −79 (*c* 2.3, $CHCl_3$). Mitsunobu reaction proceeded, with net retention of configuration, *via* the azirizinium ion. The relative configuration was determined by X-ray analysis. The kind assistance of Dr Makoto Nakajima (Pharmaceutical Sciences, Hokkaido University) with the X-ray analysis is gratefully acknowledged.
¶ Typical procedure: To a solution of chiral ligand **1** (315 mg, 1.10 mmol) in toluene (16 cm$^3$), BuLi (0.63 cm$^3$, 1.67 M hexane solution, 1.05 mmol) was added dropwise at −78 °C under Ar atmosphere. After 5 min diprop-2-ynyl ether **2a** (290 mg, 1.0 mmol) in toluene (1 cm$^3$) was added dropwise to the resulting pale yellow solution *via* a cannula. The flask was rinsed with toluene (1 cm$^3$). The whole mixture was stirred at −78 °C for 5 h. The reaction was quenched with 1 M HCl (20 cm$^3$), and the aqueous layer was extracted with ethyl acetate (30 cm$^3$ × 3). The organic layer was washed with 1 M HCl (20 cm$^3$), saturated aqueous $NaHCO_3$ (20 cm$^3$) and brine (20 cm$^{-3}$). After drying the mixture over $Na_2SO_4$, the mixture was concentrated. The residue was then purified by silica gel column chromatography, and hydroxy allene **3a** (145 mg, 50%) was obtained as a colourless oil.
‖ *Spectroscopic data* for **3a**: $^1$H NMR: δ 4.95 (1 H, d, *J* = 3.0 Hz), 4.93 (1 H, d, *J* = 3.0 Hz), 4.82 (1 H, dd, *J* = 1.9, 1.9 Hz), 2.23 (1 H, dt, *J* = 1.9, 7.0 Hz), 2.22 (1 H, dt, *J* = 1.9, 7.0 Hz), 2.1–2.0 (2 H, m), 1.68 (1 H, brs), 1.6–1.1 (20 H, m), 0.89 (6 H, t, *J* = 6.3 Hz); $^{13}$C NMR: δ 204.37, 106.33, 86.38, 79.43, 79.03, 63.25, 31.81, 31.72, 29.27, 29.11, 28.77, 28.54, 27.68, 27.53, 22.59, 18.71, 14.04; $\nu_{max}$/cm$^{-1}$ 3400, 3000–2850, 2210, 1950, 850; *m/z* 290 ($M^+$), 289 ($M^+ - 1$); $[\alpha]_D^{24}$ + 18 (*c* 0.95, $CHCl_3$). For **3a**, **3b** and **3c**, ees were determined by HPLC analysis [DAICEL CHIRALCEL OD-H, hexanes–Pr$^i$OH (300 : 1), λ = 254 nm] of the corresponding *p*-nitrobenzoates. For **3c**, the ee was determined by chiral HPLC analysis [DAICEL CHIRALCEL OD-H, hexanes–Pr$^i$OH (300 : 1), λ = 254 nm] of the corresponding 3,5-dinitrobenzoates. For **3d**, the ee was determined by HPLC analysis [DAICEL CHIRALCEL OD-H, hexanes–Pr$^i$OH (300 : 1), λ = 254 nm]. Compound **3a** could be converted to ketone **10** in four steps, as shown in Scheme 3.



**Scheme 3** *Reagents and conditions*: i, $MeOCH_2Cl$, Pr$^i_2$NEt, $CH_2Cl_2$, 70%; ii, $OsO_4$, pyridine, PhH, 50%; iii, $H_2$, $Pd(OH)_2$–C, MeOH; iv, $NaBH_4$, MeOH; v, $NaIO_4$, acetone, water, 30% (3 steps)

The absolute configuration of **3a** was determined by comparison of the optical rotation of **10**, which was derived from commercially available (*R*)-glycidol **11**, as shown in Scheme 4.

For **3b**–**d**, the absolute stereochemistries were assumed to be of the same orientation as for **3a** according to the $^1$H NMR spectra of the corresponding (*R*)-*O*-methylmandelates. See J. A. Marshall and X. Xang, *J. Org. Chem.*, 1990, **55**, 2995.
** The absolute stereochemistry of the minor compound **12** was not determined.
†† Compound **8** was converted to **16** in four steps as shown in Scheme 5. The ee and the absolute configuration of compound **8** [$[\alpha]_D^{24}$ +22 (c = 0.84, $CHCl_3$)] were determined by optical rotation of compound **16**. The ee and absolute configuration of **16** are known: M. Gette, J. Capillon and J. P. Gette, *Tetrahedron*, 1973, **29**, 3659.

**Scheme 4** *Reagents and conditions*: i, Bu$^t$Me$_2$SiCl, Et$_3$N, DMAP, $CH_2Cl_2$, quant.; ii, octylmagnesium bromide, CuI, THF, 66%; iii, $MeOCH_2Cl$, Pr$^i_2$NEt, $CH_2Cl_2$, quant.; iv, $Bu_4NF$, THF, 82%; v, Jones' reagent, acetone; vi, MeNH(OMe)·HCl, Diethyl cyanophosphonate, Et$_3$N, DMF, 76% (2 steps); vii, heptylmagnesium bromide, THF, 97%

**Scheme 5** *Reagents and conditions*: i, $Ac_2O$, Et$_3$N, DMAP, $CH_2Cl_2$, 91%, ii, $O_3$, MeOH; iii, $H_2O_2$, aq. NaOH; iv, $CH_2N_2$, Et$_2$O, 30% (3 steps)

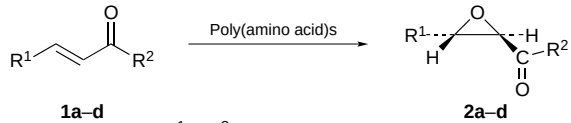
# Asymmetric epoxidation of enones employing polymeric α-amino acids in non-aqueous media



**Paul A. Bentley,[a] Sophie Bergeron,[a] Michael W. Cappi,[a] David E. Hibbs,[b] Michael B. Hursthouse,[b] Thomas C. Nugent,[a] Rosalino Pulido,[a] Stanley M. Roberts*[a] and L. Eduardo Wu[a]**

[b] *School of Chemistry and Applied Chemistry, University of Wales, Cardiff, PO Box 912, Cardiff, UK CF1 3TB*

**Urea–hydrogen peroxide complex in an organic solvent and in the presence of DBU and poly-(L)-leucine causes rapid asymmetric epoxidation of the enones 1a, b and d.**

Poly(amino acid)s are cheap surrogates of enzymes for promoting some stereoselective organic reactions.[1] For example, Banfi *et al.* have described a method for the asymmetric epoxidation of chalcones using these polymeric catalysts; thus the enone **1a** was transformed into the chiral epoxy ketone **2a** (Scheme 1 and Table 1, entry 1).[2] The reaction involved a triphasic system comprising alkaline aqueous hydrogen peroxide, an organic solvent and the insoluble polymer. Subsequently the asymmetric epoxidation has been shown to be a reliable, robust reaction and the range of enones undergoing oxidation has been extended considerably; for example the dienone **1b** affords the unsaturated epoxy ketone **2b** in good yield and excellent enantiomeric excess (Table 1, entry 2).[3]

Nevertheless, several limitations to the protocol became evident. First, reaction times were often unacceptably long (≥3 days; Table 1, entry 2) and all of these reactions required continuous addition of oxidant and base. The use of aqueous sodium hydroxide caused slow degradation of the poly(amino acid) and precluded the epoxidation of compounds possessing alkali-sensitive functionality. Secondly, the polymer, prepared as an amorphous solid, required swelling (to form a gel) through contact with aqueous organic solvent for a period of 6 h. Thirdly, compounds of the type $R^1CH{=}CHCOC\mathit{H}R^2R^3$ or $R^1COCH{=}CHC\mathit{H}R^2R^3$, *i.e.* with 'active' hydrogen atoms, were oxidized slowly [often with poor selectivity (Table 1, entry 3)], or not at all (Table 1, entry 4).[4]

**1a–d** **2a–d**

**a** $R^1 = R^2$ = Ph
**b** $R^1$ = CH=CHPh, $R^2$ = 2-naphthyl
**c** $R^1$ = Ph, $R^2 = Pr^i$
**d** $R^1$ = Ph, $R^2$ = Me

**Scheme 1**

We have now found a satisfactory solution to many of these problems by conducting the asymmetric epoxidation in a two-phase non-aqueous system made up of oxidant, a non-nucelophilic base, immobilised poly(amino acid)[5] and an organic solvent.

Thus chalcone **1** (0.24 mmol) was added to dry THF (0.8 $cm^3$), immobilised poly-(L)-leucine[5] (PLL) (100 mg), urea–hydrogen peroxide complex (UHP)[6] (1.2 equiv.) and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (1.2 equiv.). The ensuing reaction was complete in 30 min and provided the epoxyketone **2a** in high yield and excellent optical purity after column chromatography (Table 1, entry 5). Use of immobilised poly-(D)-leucine (PDL) gave rise to the enantiomeric epoxy ketone *ent*-**2a** (Table 1, entry 6). The use of more solvent (2.0 $cm^3$) resulted in a slower reaction (96% conversion after 1 h) but no diminution in the optical purity of the product (96% ee). For these reactions the work-up procedure is very straightforward; the insoluble polymer is simply filtered off and, indeed, may be recycled (at least six times) without reduction in the rate of the epoxidation, the yield or the optical purity of the product.

Preliminary investigations also showed that changes could be made to the nature of the solvent, the base and the oxidant. Thus, repeating the non-aqueous Juliá oxidation of chalcone **1a** in 1,2-dimethoxyethane, *tert*-butyl methyl ether and ethyl acetate

**Table 1** Asymmetric epoxidation of some α,β-unsaturated ketones using oxidant and poly(amino acid) catalyst

[a] PLL: poly-(L)-leucine; PLA: poly-(L)-alanine; PDL = poly-(D)-leucine.

gave results which were almost identical to those obtained using THF. Polar aprotic solvents such as dimethyl sulfoxide and dimethylformamide gave equally good results but dichloromethane, acetonitrile and toluene were less satisfactory, giving rise to longer reaction times and/or less enantioselective reactions.

While DBU can be replaced with 1,5-diazabicyclo-[4.3.0]non-5-ene (DBN), Hunig's base (*N*,*N*-diisopropylethylamine) is much less effective (Table 1, entries 7 and 8); triethylamine gave no reaction. 1,4-Diazabicyclo[2.2.2]octane–peroxide complex (DABCO–$1.5H_2O_2$)[7] may be used as the oxidant (Table 1, entry 9) but, in contrast, 90% hydrogen peroxide gave rise to a slower reaction and a product that was less optically pure (Table 1, entry 10).

It is very significant that α,β-unsaturated ketones, which required long reaction times when employing the Juliá triphasic conditions, were transformed quickly, with great selectivity, in the new biphasic system (Table 1, entry 11). Furthermore, styryl methyl ketone **1d** was oxidized to the epoxy ketone **2d** over 4 h in moderate yield and optical purity (Table 1, entry 12; *cf*. entry 4). Hence it seems that the new reaction conditions will broaden the range of epoxy ketones that can be prepared using this methodology.

In a parallel research programme we are investigating the further reactions of the chiral epoxy ketones available from the Juliá methodology. For example, we have shown that the epoxy ketone **2a** is alkylated diastereoselectively using methyllithium or butyllithium and $CeI_3$,[8] giving rise to compounds **3a** and **3b** as the major products which were separated from the minor isomers **4a** and **4b** by chromatography (Scheme 2). The structural identity of compound **3b** was elucidated by X-ray crystallography (Fig. 1).† This methodology gives rise to epoxides formally derived from allylic tertiary alcohols, compounds not readily obtainable in optically active form using the Sharpless technology.[9]

**Scheme 2** *Reagents and conditions*: i, MeLi or BuLi, $CeI_3$, THF, −70 °C

† *Crystal data* for $C_{19}H_{22}O_2$, $M$ = 282.37, monoclinic, space group $P2_1$, $a$ = 10.753(2), $b$ = 5.6320(10), $c$ = 13.403(2) Å, β = 104.930(4)° (by least-squares refinement of the setting angles for 250 reflections within θ = 1.96–24.98°), $V$ = 784.3(2) Å$^3$, $Z$ = 2, $D_c$ = 1.196 g cm$^{-3}$, $T$ = 150 K, μ(Mo-Kα) = 0.76 cm$^{-1}$, $F$(000) = 304, crystal size = 0.5 × 0.6 × 0.5 mm.

Data were collected on a FAST TV Area detector diffractometer following previously described methods (ref. 10). From the ranges scanned, 3383 data were recorded ($1.96 < \theta < 24.98°$; index ranges: $-11 < h <$, $-4 < k < 6$, $-14 < l < 14$) and merged to give 2170 unique [$R$(int) = 0.0653].

The structure was solved *via* direct methods (ref. 11) and refined on $F_o^2$ by full-matrix least-squares (ref. 12) using all unique data corrected for Lorentz and polarisation factors. All non-hydrogen atoms were anisotropic. The hydrogen atoms were inserted in idealised positions with $U_{iso}$ set at 1.5 times the $U_{eq}$ of the parent. The weighting scheme used was $w = 1/[\sigma^2(F_o)^2 + (0.0137P)^2]$, where $P = [\max(F_o)^2 + 2(F_c)^2]/3$; this gave satisfactory agreement analyses. Final $R_1$ (on $F$) and $wR_2$ (on $F_o^2$) values were 0.0544 and 0.0647 for all 2170 data and 192 parameters. The corresponding $R$ values were 0.0355 and 0.0615 for 1498 data with $I > 2\sigma(I)$. Sources of scattering factors as in ref. 12. The numbering of the atoms is shown in Fig. 1.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. # Crystal and molecular structure of a ketocarboxylatocopper(II) intermediate in the oxygenation of a copper(I) flavonolate complex

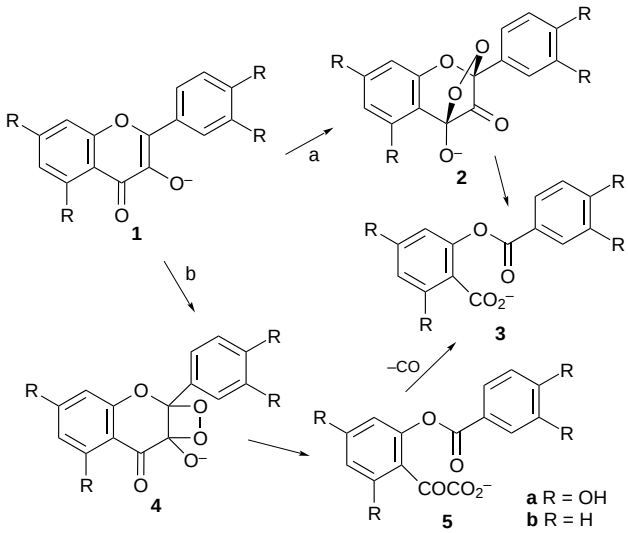
**István Lippai,[a] Gábor Speier,*[a] Gottfried Huttner[b] and László Zsolnai[b]**

[a] *Department of Organic Chemistry, University of Veszprém, 8201 Veszprém, Hungary*
[b] *Ruprecht-Karls Universität, Anorganisch-Chemisches Institut, 69120 Heidelberg, Germany*

**Flavonol reacts with metallic copper in the presence of 2,2′-bipyridine to give dihydrogen and a mixture of compounds with the stoichiometric composition [$Cu^{I}$(bpy)(fla)] from which on standing only [$Cu^{I}(bpy)_2]_2[Cu^{I}(fla)_3$] can be isolated; oxygenation of the solution of the mixture results in the ketocarboxylatocopper(II) complex [$Cu^{II}$(bpy)(fla)(2-$HOC_6H_4COCO_2$)], which hints at a copper-mediated oxidative cleavage of the pyranone ring in the flavonolate ligand *via* a 1,2-dioxethane intermediate by $^3O_2$.**

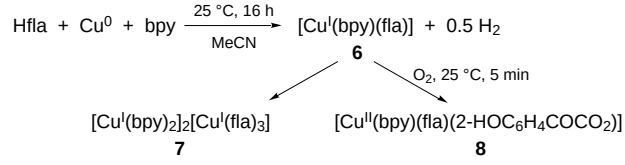
Quercetin **1a** (3′,4′,5,7-tetrahydroxyflavonol) is metabolized in fungi to a depside (phenolic carboxylic acid ester) and carbon monoxide by quercetin 2,3-dioxygenase.[1] It is a Cu-containing dioxygenase and the coordination of **1a** to copper(II) at its active site was assumed as the key intermediate.[2] Flavonol **1b** forms stable complexes with copper(I)[3] and copper(II),[4] and simple copper complexes have been used in model reactions.[5] For the oxidative cleavage reaction of the heterocycle pathways *via* an endoperoxide (route a) and 1,2-dioxethane (route b) have been proposed (Scheme 1).[6]

Our aim was to prepare neutral mixed-ligand copper(I) flavonolate complexes and to investigate their oxygenation reaction in order to find possible chemical pathways of the enzymatic reaction. Equimolar amounts of flavonol **1b** (flaH) react with 2,2′-bipyridine (bpy) and metallic copper in acetonitrile at room temperature to yield a mixture of compounds with the stoichiometric composition of [$Cu^{I}$(fla)(bpy)] **6** according to Scheme 2. The compounds in the mixture are believed to be [$Cu^{I}$(fla)(bpy)] and anionic copper(I) species such as [$Cu^{I}(fla)_2]^-$, and [$Cu^{I}(fla)_3]_2^-$ with [$Cu^{I}(bpy)_2]^+$ counter cations from which on standing of the solution at room temperature only [$Cu^{I}(bpy)_2]_2[Cu^{I}(fla)_3$] **7** as red crystals are obtained. **7** consists of two cationic tetrahedral copper(I) ions each with two bpy ligands and a counter anion containing octahedral copper(I) with three flavonolate ligands. The structure of **7** was based on an X-ray structure determination, however the one N atom of bpy and one of the flavonolate ligands are heavily disordered, and thus full details are not provided. In this unique six-coordinated copper(I) species the average Cu–O distances are 2.069 Å (3 O–H) and 2.151 Å (4 C=O) and the average Cu–N bond length is 2.029 Å.



The oxygenation of the acetonitrile solution of the mixture **6** at room temperature and atmospheric dioxygen pressure proceeds very rapidly (few minutes) and green crystals of **8** are obtained in 11% yield (Scheme 2). Complex **8** shows bands in the UV–VIS region at 421 nm (log (ε/dm$^3$ mol$^{-1}$ cm$^{-1}$) 4.15), 311 (4.26), 258 (4.39) and 615 (1.73) nm and IR absorptions at 1605 cm$^{-1}$ [ν(CO)] and 3005 cm$^{-1}$ [ν(OH)]. It is paramagnetic with $\mu_{eff}$ = 1.83 $\mu_B$ and EPR parameters in acetonitrile are $g$ = 2.123 and $A_{Cu}$ = 77.18 G.

The crystal structure of [$Cu^{II}$(bpy)(fla)(2-$HOC_6H_4COCO_2$)]† is shown in Fig. 1.



The complex has a square pyramidal geometry. Two oxygen atoms of the chelating flavonolate ligand and two nitrogen atoms of bpy occupy basal positions while the carboxylate oxygen atom of the ketocarboxylato ligand occupies the apical position. The copper–nitrogen bond distances [Cu–N(1) 1.982(7), Cu–N(2) 1.968(6) Å] do not differ much from those in [$Cu^{II}$(fla)(bpy)]$ClO_4$ [1.961(4), 1.978(4) Å] but are much shorter than those in [$Cu^{II}$(fla)(tmeda)(MeCN)]$ClO_4$ [2.023 (6), 2.024(7) Å].[7] The ketocarboxylate ligand is monodentate with a C–O bond distance of 2.231(5) Å. The plane of the keto group is perpendicular to the carboxylato group and lies in the plane of the 2-hydroxyphenyl moiety and forms through hydrogen-bonding with the OH group a stable six-membered ring. This may also contribute to the stability of its structure compared to that in bis(thienyl-2)-2-glyoxylatocopper(II), and its dihydrated complex, where both the keto and carboxylato groups are bonded to the copper with average Cu–O distances of 2.077 Å.[8]

The copper–oxygen bond distances [Cu–O(5) 2.190(9), Cu–O(6) 1.760(11) Å] with the flavonolate ligand involving the 4-CO and 3-OH groups are very different from those found for [Cu(fla)$(PPh_3)_2$][3] [Cu–O(2) 2.051(4); Cu–O(3) 2.167(5) Å] and for [Cu$(fla)_2$][4] [Cu–O(2) 1.901(2); Cu–O(3) 1.944(3) Å].

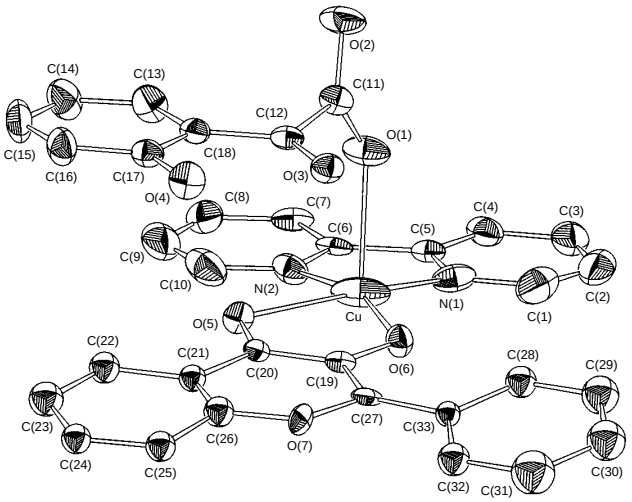
Complex [$Cu^{II}$(bpy)(fla)(2-$HOC_6H_4COCO_2$)] is probably formed according to Scheme 3. The coordinated flavonolate ligand **1b** in **6** rapidly takes up triplet dioxygen to yield a 1,2-dioxethane species **9**, which breaks down to the *O*-benzoyl-2-hydroxyphenylglyoxylatocopper species **10**. This reacts then

**Scheme 1**

**Scheme 2**

probably with further flavonol, and hydrolysis of the ester group leads to 2-hydroxyphenylglyoxylato copper(II) complex **8**. The ketocarboxylato copper(II) complex **8** is surprisingly stable towards decarbonylation. At 80 °C in acetonitrile no decarbonylation occurs over 7 h. At 150 °C in dmf carbon monoxide and salicylic acid are formed due to decarbonylation as established by GCMS.

The formation of a ketocarboxylatocopper complex **8** in the oxygenation of a copper flavonolate may suggest that the oxidative cleavage reaction of the coordinated flavonolate ligand could proceed *via* a 1,2-dioxethane intermediate **9** which upon the usual decomposition and hydrolysis of the ester linkage leads to the ketocarboxylato complex **8**. The easiness of the oxygenation allows the reasoning that this route (route b) for the scission reaction may be favoured over the route a as shown in Scheme 1. Singlet oxygen in its [2 + 2] reaction with flavonol



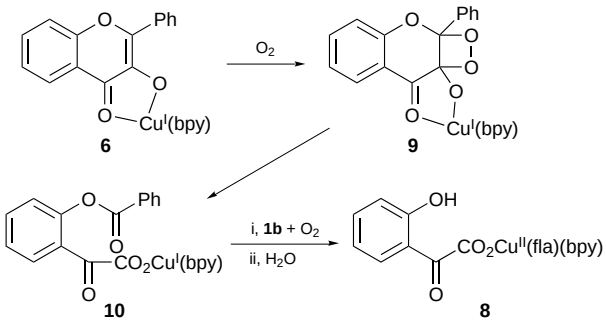


**Fig. 1** The structure of [Cu$^{II}$(bpy)(fla)(2-HOC$_6$H$_4$COCO$_2$)]. Relevant bond distances (Å) and bond angles (°): Cu–N(1) 1.982(7), Cu–N(2) 1.969(6), Cu–O(1) 2.231(5), Cu–O(5) 2.190(9), Cu–O(6) 1.760(11), C(19)–O(6) 1.350(11), C(20)–O(5) 1.286(2), C(19)–C(20) 1.369(14), C(19)–C(27) 1.437(2); O(5)–Cu–O(6) 81.4(4), O(6)–Cu–N(1) 110.5(4), N(1)–Cu–N(2) 81.5(2), N(2)–Cu–O(5) 84.4(3), Cu–O(5)–C(20) 105.8(9), Cu–O(6)–C(19) 116.8(7), O(5)–C(20)–C(19) 117.1(12), O(6)–C(19)–C(20) 118.7(9), O(6)–C(19)–C(27) 120.5(9).

**Scheme 3**

was found to proceed according to this reaction pathway. $^3O_2$ in the presence of copper ions seems to afford similar reactions and is unique in this type of reactions. Kinetic, photochemical (testing of chemiluminescence), and decarbonylation reactions are being carried out to shed light on the mechanism of this reaction route of quercetinase mimicking C–C bond cleavage.

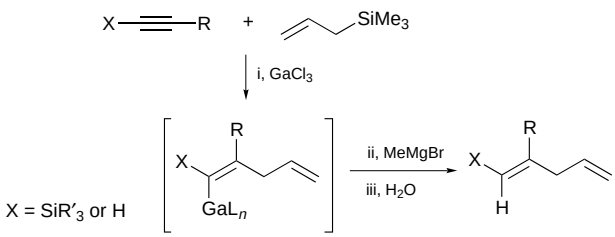
# Allylgallation reaction of carbon–carbon triple bonds with allylsilanes and $GaCl_3$



**Masahiko Yamaguchi,*† Takayuki Sotokawa and Masahiro Hirama**

*Department of Chemistry, Graduate School of Science, Tohoku University, Aoba, Sendai 980-77, Japan*

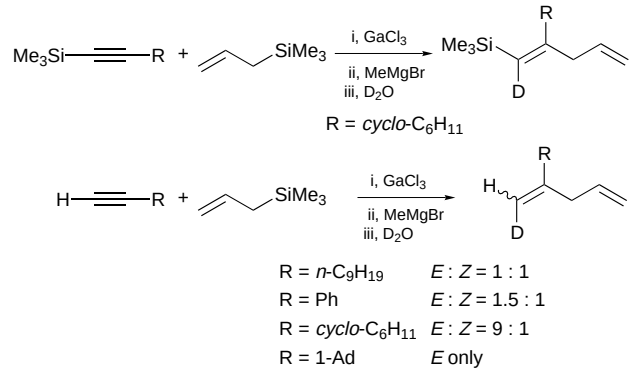
**Treatment of alkynes with allyltrimethylsilanes in the presence of $GaCl_3$ gives 1,4-dienes *via* allylgallation.**

Allylmetallation reactions of carbon–carbon triple bonds are known for organometallic compounds of magnesium, boron, aluminium, indium, zinc, titanium, zirconium and tantalum.[1] Metal-induced allylation reactions with allyltrimethylsilanes were also recently reported.[2] During our studies on the chemistry of novel organogallium compounds.[3,4] allylgallation reaction of silylalkynes or alk-1-ynes was found to take place upon treatment with allylsilanes and $GaCl_3$.

A mixture of an alkynyltrimethylsilane and allyltrimethylsilane in methylcyclohexane was treated with $GaCl_3$ at room temp. for 30 min. Then methylmagnesium bromide was added at −78 °C and 1-trimethylsilyl-2-substituted-1,4-diene was obtained after aqueous workup (Scheme 1 and Table 1). Although silylalkynes undergo self-dimerization in the presence of $GaCl_3$,[3] the cross-coupling reaction with allysilane is more rapid. C–C bond formation occurs regioselectively at the β-carbon atom of silylalkynes, and the (*E*)-relation between the silyl and allyl groups was determined by NOE. Primary and secondary aliphatic alkynes, and aromatic alkynes reacted smoothly. A tertiary aliphatic alkyne, however, was inert to the reaction. Triethylsilylethyne also reacted at the β-carbon atom giving a 1-silylpenta-1,4-diene with (*E*)-configuration (*J* 18.6 Hz). Since reaction of triethylsilylalkynes and allyltrimethylsilane gave 1-triethylsilylpenta-1,4-dienes and not trimethylsilyl derivatives, the silyl groups in the products are derived from silylalkynes. The allylation took place with alk-1-ynes as well as silylalkynes giving 2-substituted-1,4-dienes. Aliphatic and aromatic alk-1-ynes including a tertiary alkyl derivative could be allylated. The reaction was also carried out in other non-coordinating solvents such as benzene, chlorobenzene and dichloromethane. Some examples are shown in Table 1 in which chlorobenzene gave better results than methylcyclohexane because of the higher solubility of the substrates. Disubstituted alkynes, diphenylacetylenes and oct-4-yne, gave rise to oligomerization, and allylation products could not be detected.

**Scheme 1**

**Table 1** Allylgallation reactions of silylacetylenes and alk-1-ynes



| X | R | Yield (%) |
|---|---|---|
| $SiMe_3$ | *n*-$C_5H_{11}$ | 81[a] |
| | *n*-$C_9H_{19}$ | 79[a] |

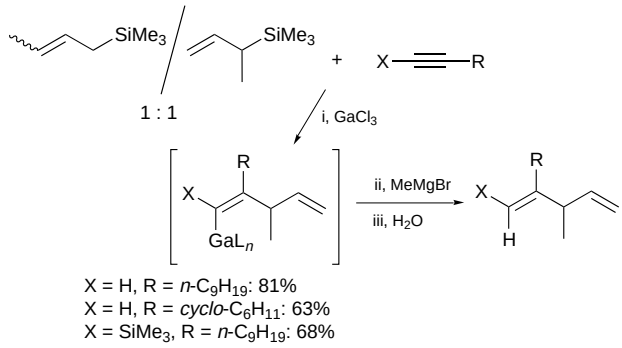
| | Ph | 56 |
| | *p*-$MeOC_6H_4$ | 45[c] |

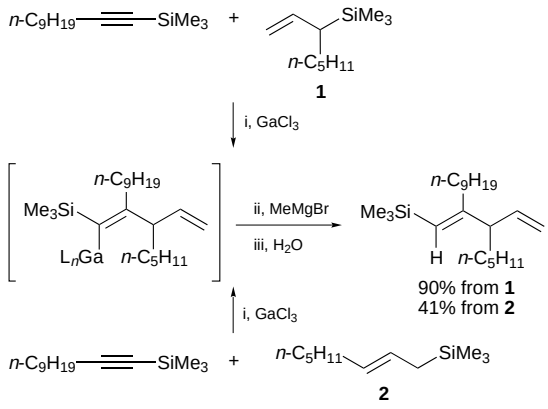
[a] (*E*)-Configuration was determined by NOE. [b] 4 mol equiv. of allylsilane was used, and yield of diallylated product is shown. [c] Reaction was conducted in chlorobenzene.

Deuteriation experiments indicated the formation of vinylgallium intermediates (Scheme 2). Thus, the present allylation takes place *via* allylgallation with carbon–carbon triple bonds. The organometal treatment before the aqueous workup is essential to attain satisfactory yields, which probably is required for the effective protonation of the vinylgallium intermediates.[4] While the allylgallation of silylalkynes gave *cis*-addition products, mixtures of isomers were obtained from alk-1-ynes depending on the substituents. *cis*-Addition took place predominantly with secondary and a tertiary alk-1-ynes, while comparable amounts of *trans* isomers formed for primary and aryl derivatives. The stereochemistries appear to reflect the relative thermodynamic stability of *E*- and *Z*-vinylgallium intermediates.

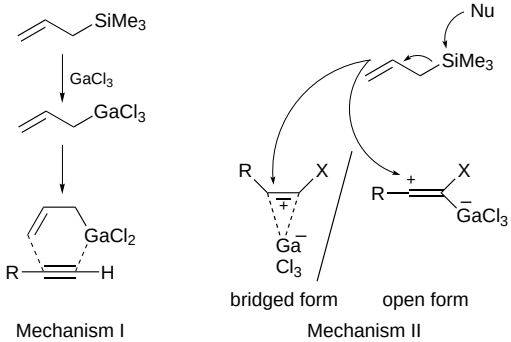


Substituted allylsilanes added to alkynes at the more hindered site irrespective of the structure of the starting organosilicon compounds. A 1 : 1 mixture of but-2-enylsilane and but-3-en-2-ylsilane[5] gave 3-methyl-1,4-diene exclusively (Scheme 3). Both oct-1-en-3-ylsilane **1** and oct-2-ene-1-ylsilane **2**[6] reacted similarly (Scheme 4).

Two mechanisms (I or II) are conceivable for the allylgallation reaction: (I) formation of an allylgallium intermediate by the transmetallation of allylsilane with $GaCl_3$ followed by the



**Scheme 2**



addition to a carbon–carbon triple bond or (II) attack of allylsilane to alkyne activated by $GaCl_3$, the structure of which can be either open or bridged (Scheme 5). Our recent studies showed both examples of the carbogallation reaction. The dimerization reaction of silylalkynes with $GaCl_3$ may involve an alkynylgallium intermediate formed by the transmetallation reaction (mechanism I).[3] In the aromatic β-silylvinylation reaction, attack of aromatic hydrocarbons to $GaCl_3$-activated silylethyne is a probable pathway (mechanism II).[4] The regioselectivity of substituted allylsilanes can be a probe to discriminate between the two mechanisms in the present system. Isomeric allylsilanes would give the same products *via* mechanism I provided that the allyl transposition of the allylgallium intermediate is rapid enough. Mechanism II would involve an $S_E2'$ pathway *via* allyl transposition of allylsilanes; C–C bond formation taking place at the γ-carbon atom of the silicon group. The reactions of substituted allylsilanes are consistent with mechanism I (Scheme 4). The lower yield in the reaction of **2** compared to **1** may be due to the inefficiency of such

**Scheme 3**

**Scheme 4**

**Scheme 5** Possible mechanisms of the allylgallation reaction

allylmetallations,[1,2] however, was not observed in some reactions of alk-1-ynes; primary and aromatic alk-1-ynes gave mixtures of *cis*- and *trans*-addition products (Scheme 2). We tentatively ascribed this to the isomerization of the initially formed *cis*-adducts to the thermodynamic equilibrium.

Allylmetallation reactions of other group 13 elements except for gallium are known. It is now known that allylgallation takes place with both silylalkynes and alk-1-ynes. Treatment of alk-1-ynes with allylsilane and a catalytic amount of $AlCl_3$ or $EtAlCl_2$ was recently reported to give the allylsilylation product. Jung proposed a mechanism involving allylation of silicon-stabilized vinyl cations,[2a] while Yamamoto proposed allylalumination related to our mechanism II (Scheme 5).[2b] In spite of the use of a similar allylating reagent system, allylsilane and a Lewis acid of the group 13 element, different mechanisms are proposed in these reactions and for our reaction. Determination of the precise mechanisms will be subject of future work.

This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science, and Culture, Japan (No. 07554065 and 08404050). Generous gifts of silicon reagents from Shin-Etsu Chemicals Co., LTD. are also gratefully acknowledged.

‡ *Typical experimental procedure*: under an argon atmosphere, a 1.0 M solution of $GaCl_3$ in methylcyclohexane (1 ml, 1.0 mmol) was added dropwise over 10 min to a mixture of 1-trimethylsilyl-2-cyclohexylacetylene (0.18 g, 1.0 mmol) and allyltrimethylsilane (0.23 g, 2.0 mmol) in methylcyclohexane (10 ml) at room temp. After stirring for 30 min, the mixture was cooled to −78 °C, and 0.92 M methylmagnesium bromide in thf (6.4 ml, 6.0 mmol) was added dropwise. The cooling bath was removed, and stirring was continued for 1 h at room temp. Water was then added, and organic materials were extracted twice with hexane. The combined extracts were washed with saturated aqueous $NH_4Cl$ and brine, dried over $Na_2SO_4$, and concentrated. Flash column chromatography on silica gel (hexane) gave (*E*)-1-trimethylsilyl-2-cyclohexylpenta-1,4-diene (0.17 g, 77%).

**The first example of a spin-crossover iron(II) compound with a large negative third-order polarizability, associated with an instantaneous electronic response, is reported; magnetic measurements show that this compound, *cis*-bis(thiocyanato)bis[*N*-(2-pyridylmethylene)aminobiphenyl]iron(II), characterized by X-ray structural data is in the high-spin form at room temperature.**

As future generations of optoelectronic devices for telecommunications and information storage, optical switching and signal processing will rely upon the development of materials with large non-linear optical (NLO) responses,[1] many studies have been carried out in this field over the last two decades.[1–9] Organic derivatives received much attention in view of their efficiency and fast NLO response times and their tailorability towards the chemical structure for a given NLO process.[1–5] Nevertheless, in the last years, investigations of metallo-organic compounds brought in many new variables and gave a new dimension to the area.[2,6–9] For instance, compared to organic molecules, metal complexes offer a larger variety of structures, such as diversity of metals, oxidation states and various arrangements of the ligands around the metal. Furthermore, some of these complexes may behave as molecular bistables between low-spin (LS) and high-spin (HS) states.[11–13] The vast majority of studies involving coordination compounds have been dedicated to quadratic optical non-linearities, while third-order responses have scarcely been investigated.[6–9] Here, we present the first example of an iron(II) derivative presenting a large negative third-order polarizability together with a cross-over between LS and HS states. Negative third-order non-linearities are uncommon, and have the property to induce a self-defocusing effect, which can be applied to eliminate the non-linear optical auto-optical annihilation of a potential all-optical device.[3] Additionally, the few negative third-order polarizabilities that have been measured[3,7–9] are relatively large in absolute magnitude compared to molecules with positive $\gamma$.[4,5] We report here a new iron(II) spin-crossover compound with a large negative polarizability at room temperature, where it is in its high-spin state.

*cis*-Bis(thiocyanato)bis[*N*-(2-pyridylmethylene)aminobiphenyl]iron(II), $[FeL_2(NCS)_2]$,† was prepared in anhydrous methanol by mixing *N*-(2-pyridylmethylene)aminobiphenyl‡ and $Fe(NCS)_2$. The ligand was synthesized from 2-pyridinecarbaldehyde and 4-aminobiphenyl. Single crystals of $[FeL_2(NCS)_2]$ were obtained by slow diffusion in methanol, using a H double-tube glass.

Fig. 1 shows the magnetic susceptibility measurements, performed first from 280 K by decreasing and then by increasing temperatures. The $\chi_M T$ ($\chi_M$ = molar magnetic susceptibility, $T$ = temperature) product decreases slightly from 3.68 $cm^3$ K $mol^{-1}$ at 280 K to 2.89 at 222 K, then drops suddenly around $T_c$ *ca.* 202 K down to 0.46 at 177 K, and reaches the lower limit of 0.02 in the vicinity of 120 K. The curve $\chi_m T$ *vs.* $T$, obtained in the warming up mode, is similar, with a thermal hysteresis of *ca.* 4 K. The magnetic measurements demonstrate that the iron compound exhibits a complete spin transition between high-spin ($S$ = 2) and low-spin ($S$ = 0) states.

The molecular structure§ of this compound in the high-spin state is shown in Fig. 2. The iron atom is located on a twofold axis and the two NCS groups have a *cis* conformation. The Fe–N($CS^-$) distances [Fe–N(2) 2.041(8) Å] are shorter than the Fe–

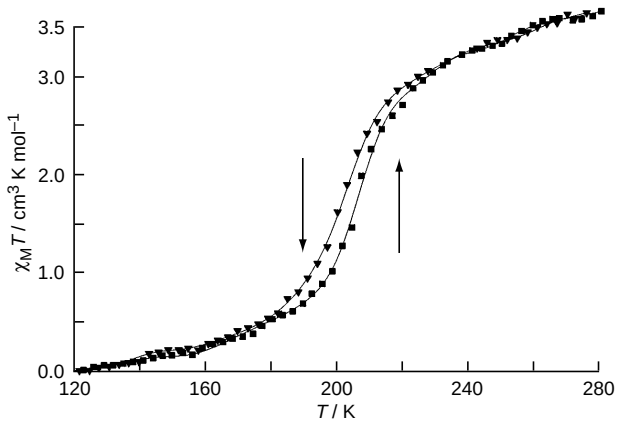

**Fig. 1** Magnetic properties of $[FeL_2(NCS)_2]$ at decreasing (▼▼▼) and increasing (■■■) temperatures

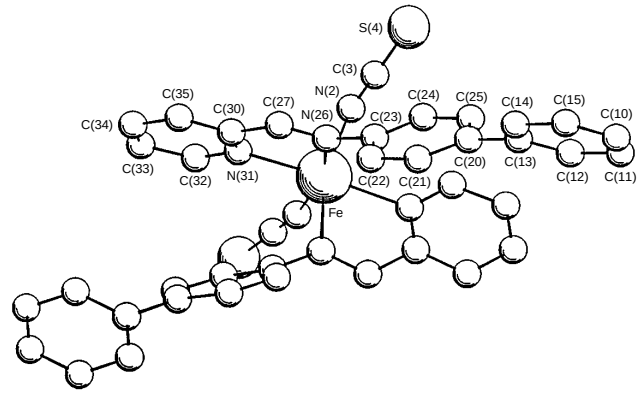

**Fig. 2** Perspective view of $[FeL_2(NCS)_2]$ including the numbering of non-hydrogen atoms. Hydrogen atoms were omitted for clarity. Fe–N bond lengths are consistent with high-spin $Fe^{II}$ and close to those reported for $[Fe(phen)_2(NCS)_2]$.[11] It can also be noticed that the $NCS^-$ groups are linear [N(2)–C(3)–S(4) 179.7°], whereas the Fe–N–C(S) linkages are bent (167.0°), as previously reported for $[Fe(phen)_2(NCS)_2]$ (179.4, 167.0°).[11]

N (organic ligand) distances [Fe–N(26) 2.250(8) Å, Fe–N(31) 2.228(8) Å], which leads to a pronounced distorsion of the $FeN_6$ octahedron. This is also illustrated by the N–Fe–N angles: N(26)–Fe–N(31) 74.4(3)°, N(31)–Fe–N(2) 90.3(3)° and N(26)–Fe–N(2) 96.0°.

The third-order non-linear optical susceptibility ($\gamma$) recorded by optical Kerr effect¶ at room temperature for $[FeL_2(NCS)_2]$ dissolved in acetonitrile is presented in Fig. 3 and compared to the response for pure acetonitrile. From this figure we can clearly conclude that (*i*) the $\gamma$ susceptibility of $[FeL_2(NCS)_2]$ is negative. This has been also observed for (cyclopentadienyl)-bis(phosphine)ruthenium σ-nitroarylacetylides ($\gamma = -210$ to $450 \times 10^{-36}$ esu),[7] metallotriazolohemiporphyrazines (with $Fe^{2+}$, $\gamma = -3100 \times 10^{-36}$ esu)[8] and metallophthalocyanines (with $Co^{2+}$, $\gamma = -32\,800 \times 10^{-36}$ esu);[9] (*ii*) the magnitude of the signal, recorded for the weak concentration of molecules largely overcomes the Kerr signal due to the acetonitrile solvent. Taking into account the molecular concentration, we obtain $\gamma = -130\,000 \times 10^{-36}$ esu (*vs.* $1 \times 10^{-36}$ esu for acetonitrile); (*iii*) the time response allows us to assign the Kerr signal to the electronic contribution exclusively. It is important to notice that no slower processes, such as reorientation mechanisms (picosecond timescale), are observed for $[FeL_2(NCS)_2]$, where the $\gamma$ signal at longer times is maily due to acetonitrile. It can be also noticed that the comparison between the signal recorded for $[FeL_2(NCS)_2]$ ($\gamma = -130\,000 \times 10^{-36}$ esu) and the ligand (L, $\gamma = 1500 \times 10^{-36}$ esu) in acetonitrile shows clearly that the negative magnitude is induced by the metal ion.

We noticed a very weak absorption of the sample around 800 nm, which may bring about a resonant contribution to the $\gamma$ susceptibility. In order to address this problem, we have recorded $\gamma$ as a function of the laser wavelengths. The data recorded for $[FeL_2(NCS)_2]$, dissolved in butyronitrile are presented in Fig. 4. The decrease of the negative signal intensity at shorter wavelength can be attributed to an increase of a positive component, due to the resonant contribution. This is further confirmed, if we compare the signal recorded for $[FeL_2(NCS)_2]$ in acetonitrile ($-130\,000 \times 10^{-36}$ esu at $\lambda = 800$ nm) and in butyronitrile ($-49\,000 \times 10^{-36}$ esu at $\lambda = 804$ nm), where the maxima of the UV–VIS spectra is bathochromically shifted; *i.e.* $\lambda$(acetonitrile) = 577 nm and $\lambda$(butyronitrile) = 620 nm, respectively.

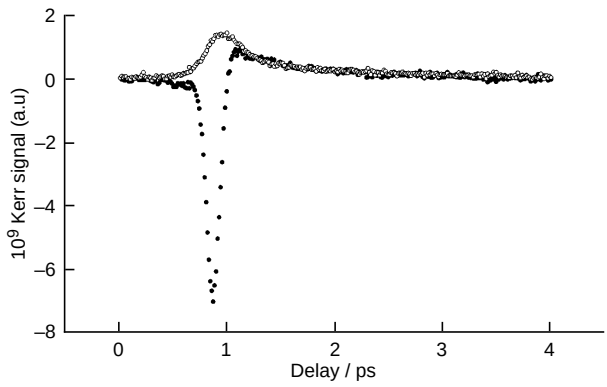

**Fig. 3** Third-order molecular optical non-linearities for acetonitrile (○○○) and $[FeL_2(NCS)_2]$ (●●●) in the HS state dissolved in acetonitrile ($c = 7.85 \times 10^{-4}$ mol dm$^{-3}$)

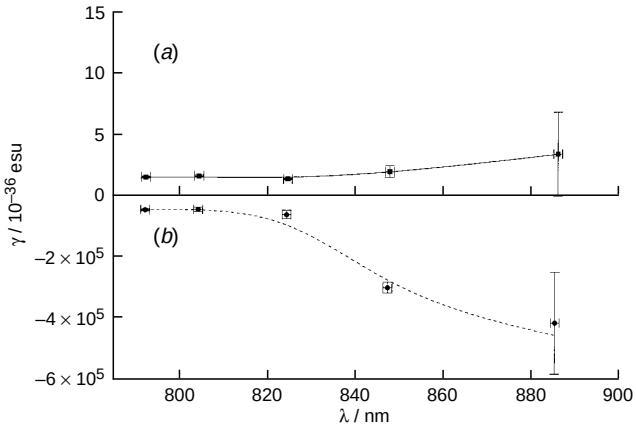

**Fig. 4** Third-order molecular optical non-linearities as a function of wavelength for (*a*) butyronitrile (—) and (*b*) $[FeL_2(NCS)_2]$ (---) dissolved in butyronitrile ($c = 10^{-4}$ mol dm$^{-3}$)

NLO measurements of this compound, with a low-spin state configuration, are in progress to further probe the role of the metal centre.

§ *Crystal data* for $C_{38}H_{28}FeN_6S_2$: $M$ = 688, orthorhombic, space group *Pccn* ($Z$ = 4), $a$ = 12.949(7), $b$ = 15.183(2), $c$ = 17.609(5) Å; $U$ = 3462(2) Å$^3$; $D_c$ = 1.33; μ = 4.921 mm$^{-1}$. Measurements were made with a Nonius CAD-4 diffractometer; Cu-Kα radiation (1.5418 Å); crystal shape: black plate, 0.125 × 0.35 × 0.50 mm; the unit-cell parameters came from 25 reflections; Bragg angle $\theta < 65°$; empirical absorption correction $0.822 < T < 1.000$; scan type ω–θ; 3331 measured reflections, 1109 observed [$I > 3\sigma(I)$]; structural determination with MITHRIL and structural refinement with SHELX76; 215 parameters; $R$ = 0.045; $R_w$ = 0.035; $w = 1.985/[\sigma^2(F)]$; $(\Delta/\sigma)_{max}$ = 0.2; $\Delta\rho_{max,min}$: 0.20, −0.15 e Å$^{-3}$. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/374.

¶ Third-order optical non-linearities $\chi^3$ ($-3\omega;\omega,\omega,\omega$) were performed at 800 nm using a CW mode-locked Ti : sapphire laser working at 76 MHz. The molecular $\gamma$ (esu unit) has been deduced from $\chi^3$ ($-3\omega;\omega,\omega,\omega$) by $\gamma = \chi^3/(LN\eta_a)$, where $\eta_a$ is the Avogadro number, $L$ the local field correction and $N$ is the concentration. All results are referenced to $\chi^3$ ($-3\omega;\omega,\omega,\omega$) of SF59 ($6.5 \times 10^{-21}$ m$^2$ V$^2$ = $4.6 \times 10^{-13}$ esu), which leads to $\gamma_{CS_2} = 4.32 \times 10^{-34}$ esu.

# Synthesis and isolation of an all-carbon tetraanion; a discrete $C_{60}^{4-}$ fulleride salt

**Yongping Sun and Christopher A. Reed***

*Department of Chemistry, University of Southern California, Los Angeles, CA 90089-0744, USA*

**The highly reduced, all-carbon tetraanion, $C_{60}^{4-}$, earlier identified as a discrete ion in solution by electrochemical and spectroscopic methods, can be synthesized and isolated as an analytically pure, sodium cryptand salt.**

There is considerable current experimental and theoretical interest in the high negative charge states attainable in small aromatic molecules.[1] The first isolable tetraanion of a π hydrocarbon (rubrene, $C_{42}H_{28}$) has recently been reported[2] and the all-carbon π frameworks of fullerenes present further interesting targets for the study of anionic charge buildup.

The electron accepting ability of $C_{60}$ is its most characteristic chemical property and the maximal extent of charge buildup is an intriguing phase-dependent question. In the gas phase, two electrons can bind to give the rare example of a stable dianion.[3] In the solid state, the heavier alkali- or alkaline-earth cations can interstitially stabilize negative valencies at least as large as 8 in the so-called superfullerides.[4] Intercalated lithium stabilizes the $C_{60}^{12-}$ state, presumably with some degree of covalency.[5] In solution, the highest $C_{60}^{n-}$ fullerides known are $n = 6$ on the electrochemical timescale[6] and $n = 5$ for low-temperature spectroscopic identification.[7] In synthetic chemistry, discrete fulleride salts have only been isolated up to $n = 3$.[8,9] We now report the successful synthesis and isolation of a discrete salt of the highly reduced tetraanion, $C_{60}^{4-}$ ion.

The nature of the $C_{60}^{4-}$ ion is of interest for a number of reasons. For alkali-metal intercalated $C_{60}$, it is not well understood why $A_4C_{60}$ salts are insulating while $A_3C_{60}$ salts are metallic and superconducting.[10] A detailed knowledge of the electronic structure of the discrete repeating units, namely $C_{60}^{4-}$ and $C_{60}^{3-}$, may be instructive. With its $t_{1u}^4$ configuration, $C_{60}^{4-}$ is the electron–hole equivalent of the $C_{60}^{2-}$ ion, whose electronic structure is controversial.[11,12] Mirrored properties would be interesting. The question of a singlet *vs*. a triplet ground state for $C_{60}^{4-}$ is particularly intriguing because unexpectedly, neither $C_{60}^{2-}$ nor $C_{60}^{3-}$ obeys Hund's rule.[9,11] For $C_{60}^{3-}$, it is presently unknown whether there is a relationship between Cooper pairs of superconducting electrons and the unanticipated tendency of localized spins on $C_{60}^{n-}$ fullerides to attain minimum multiplicity.

The synthesis of an analytically pure salt of $C_{60}^{4-}$ was achieved in an inert-atmosphere glovebox by stirring a suspension of $C_{60}$ (20.0 mg, 0.0278 mmol) in tetrahydrofuran (thf) (35 ml) with a piece of freshly cut sodium in the presence of 4.2 equiv. of cryptand 222 (44.0 mg, 0.117 mmol).† The reaction proceeds *via* successive reductions with $[Na(crypt)^+]_4[C_{60}^{4-}]$ precipitating as a dark brown, microcrystalline solid. The product was filtered off, the ball of excess sodium removed as completely as possible with tongs, and the product washed with thf and dried under vacuum (90%). Anal. calc. for $C_{132}H_{144}N_8Na_4O_{24}$: C, 68.38; H, 6.26; N, 4.83; Na, 3.97. Found: C, 67.69, 66.80; H, 6.16, 6.17; N, 4.88, 5.25; Na, 5.25%. Integration of the NOE-suppressed $^{13}C$ NMR signals (15 s pulse delay) of the cryptand (δ 67.9, 66.9, 52.1) *vs*. fulleride (see below) gives the expected 4 : 1 ratio of cation to anion. The product is exceedingly air sensitive, oxidizing initially to $C_{60}^{3-}$ as the major product. It dissolves without immediate decomposition in scrupulously dried, deoxygenated dimethyl sulfoxide. Electrochemical estimates[13] of the $pK_a$ of the conjugate acid, $C_{60}H^{3-}$ ($pK_a = 37$), suggest that $C_{60}^{4-}$ is a sufficiently powerful base to remove a proton from $Me_2SO$ ($pK_a = 31$). That this does not occur within a day or so indicates either that this reaction is very slow or that the $pK_a$ estimate is incorrect for electrolyte-free solvent. Traces of protonic solvents (*e.g.*, water) in the $Me_2SO$ cause immediate oxidation to $C_{60}^{3-}$, presumably *via* fullerene hydrocarbon formation. Attempted cation metathesis reactions with $NBu_4Cl$ and with $[N(PPh_3)_2]Cl$ both led to oxidation to $C_{60}^{3-}$, presumably due to acidity of the α-methylene protons in $NBu_4^+$ and redox instability[14] of $[N(PPh_3)_2]^+$, respectively.

The fingerprint region for the absorption spectrum of fullerides is in the near-IR region and corresponds to $t_{1u}$–$t_{1g}$ transitions of *ca*. 1 eV.[7,15] The VIS–NIR spectrum of $[Na(crypt)^+]_4[C_{60}^{4-}]$ in $Me_2SO$ is shown in Fig. 1. The absence of a band at 780 nm indicates the absence of $C_{60}^{3-}$. Maxima at 730 and 1195 nm are consistent with those reported for electrochemically generated $C_{60}^{4-}$ in benzonitrile (728, 1209 nm)[15] and rubidium-reduced $C_{60}^{4-}$ in liquid ammonia (715, 1175 nm).[7]‡

We have recently shown that for $n = 1$, 2 and 3, the $C_{60}^{n-}$ fullerides have broad, downfield-shifted resonances in their solution $^{13}C$ NMR spectra, the result of paramagnetism.[11,17] The same is true for $C_{60}^{4-}$, indicating that it too has significant paramagnetism at room temperature. The spectrum in $(CD_3)_2SO$ is shown in Fig. 2. The chemical shift of δ 185 is essentially the same as that of $C_{60}^-$ (δ 186) and $C_{60}^{2-}$ (δ 184) but different from that of $C_{60}^{3-}$ (δ 197). An integrity check on the NMR sample was run after measurement and, within the limits of VIS–NIR detection (*ca*. 5%), it indicated no decay to $C_{60}^{3-}$ ($\lambda_{max} = 780$ nm). Interestingly, the chemical shift of the discrete $C_{60}^{4-}$ ion (δ 185) is not very different from that in solid-state $K_4C_{60}$ (δ 180) and $Rb_4C_{60}$ (δ 182).[18] The interpretation of $^{13}C$ chemical shifts in fullerides is complex, but to a first approximation, the *ca*. 40 ppm downfield shift can be equated with an average spin density of about one unpaired electron per buckyball. This suggests that like $C_{60}^{2-}$, the singlet ($S = 0$) and triplet ($S = 1$) states are close in energy. Fast intersystem crossing and/or electron transfer would average the signal to that approximating an $S = 1/2$ system. Efforts to quantify the singlet–triplet splitting for $C_{60}^{4-}$ and $C_{60}^{2-}$ by NMR methods

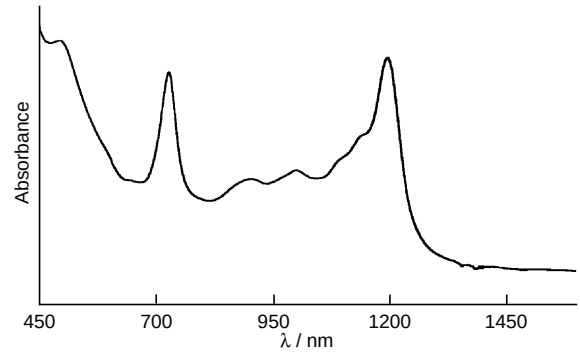

**Fig. 1** VIS–NIR spectrum of $C_{60}^{4-}$ in $Me_2SO$

are ongoing. The present results are in qualitative agreement with those on $Rb_4C_{60}$ where a localized singlet ground state is proposed with a close-lying triplet a few hundred $cm^{-1}$ higher in energy.[19]

EPR spectroscopy has been widely used to investigate the spin states of fullerides but interpretations have been bedeviled by problems of sensitivity to impurities, the difficulty of quantifying overlapping signals with widely differing line-widths, aggregation uncertainties in frozen solution, *etc.*[11,12] Preliminary results on $C_{60}^{4-}$ salts fare no better. Fig. 3 shows the low-temperature EPR spectrum of $C_{60}^{4-}$ in frozen $Me_2SO$ solution. Comparison to the spectrum of $C_{60}^{3-}$ under identical conditions of cation and solvent (also shown in Fig. 3) indicates the presence of $C_{60}^{3-}$ in the $C_{60}^{4-}$ sample even though this is undetectable by NIR. The additional, sharper signals are potentially ascribable to $C_{60}^{4-}$, but it would be premature to make such an assignment in view of the difficulties[11,12] associated with assigning the spectrum of $C_{60}^{2-}$, of which $C_{60}^{4-}$ is the electron–hole equivalent. Since these signals appear to have integrated intensities that are less than the trace $C_{60}^{3-}$ signal, the simplest interpretation is that $C_{60}^{4-}$ is EPR silent at 4 K because of a singlet ground state.§ However, a close-lying, thermally accessible triplet state is indicated by the paramagnetically shifted $^{13}C$ NMR signal seen at room temperature.

In summary, despite its exceedingly strong reducing nature (−2.35 V *vs*. ferrocene),[6] the discrete $C_{60}^{4-}$ ion can be isolated with an 'innocent' cation. This opens the way to deeper studies of its electronic and molecular structure and to studies of its chemical reactivity, particularly with electrophiles.[20]

We are grateful to Robert D. Bolskar for assistance and to the National Institutes of Health (USA) for support (GM 23851).

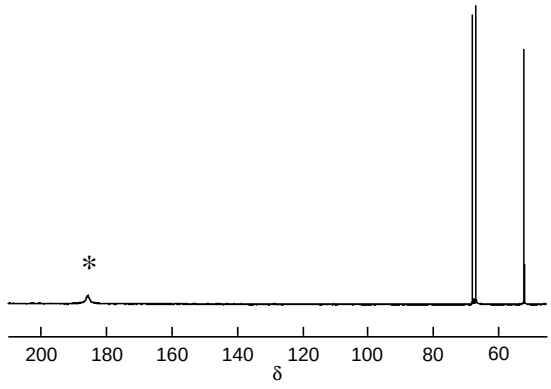

**Fig. 2** $^{13}C$ NMR spectrum of $C_{60}^{4-}$ in $(CD_3)_2SO$ (34196 scans, 125.8 MHz) Peak marked * at δ 185 is from $C_{60}^{4-}$; the others are from Na(cryptand 222)$^+$

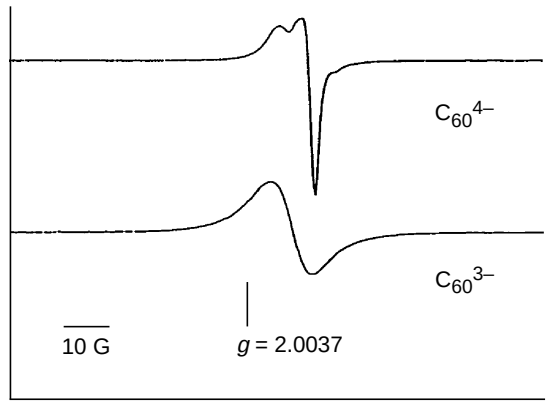

**Fig. 3** EPR spectra of $C_{60}^{4-}$ and $C_{60}^{3-}$ in frozen $Me_2SO$ solution at 5 K

## Footnotes

† Cryptand 222 is a commercially available alternative to a crown ether for chelation of sodium ions (Aldrich 29, 111-0).

‡ A third report on the NIR of $C_{60}^{4-}$ with a single $\lambda_{max}$ at 934 nm is inconsistent with the present work and with refs. 7 and 15.[16]

§ $C_{60}^{4-}$ has been reported by Baumgarten *et al.*[16] to be diamagnetic because no EPR signal was found. However, since their NIR spectrum[16] is inconsistent with literature reports[7,15] and the present work, it is possible that their $C_{60}^{4-}$ product, if formed, was completely insoluble under the conditions used.

# ITQ-4: a new large pore microporous polymorph of silica

**Miguel A. Camblor,* Avelino Corma and Luis A. Villaescusa**

*Instituto de Tecnología Química, UPV-CSIC, Avda. Los Naranjos s/n, 46071 Valencia, Spain*

**A new silica polymorph of zeolitic nature with large pores, a large void volume and essentially no connectivity defects, is prepared by direct hydrothermal synthesis in a fluoride medium.**

An infinity of different hypothetical topologies can be built based on $TO_4$ tetrahedra sharing all their vertices to yield (4;2) three-dimensional nets,[1] and more than a hundred are actually known to occur as silica, aluminosilicate and aluminophosphate materials.[2] Among the pure silica materials the number of actual topologies is relatively small: several dense phases and clathrasils and only a limited number of microporous phases are known. It is notable that, until very recently, only two pure silica polymorphs having 12 membered ring (12MR) large pore structures, ZSM-12[3] and SSZ-24,[4] have been obtained by direct synthesis. This is despite recent calorimetric measurements[5] and theoretical calculations[6] which showed that the enthalpy of formation of microporous or dense pure silica phases relative to that of quartz is very small (below 15 kJ per mol of $SiO_2$). This result suggests there should be little energetic limitation to the synthesis of pure silica phases of ever decreasing framework density and thus is in contrast with the seeming difficulty to synthesize such phases. Obviously, it is not possible to directly extend these results to the template-mediated synthesis of pure silica phases, since what is actually synthesized is the composite silica framework/templating species. However, it has been suggested that the formation of pure silica phases is geometrically and kinetically, rather than energetically, controlled,[5] implying it is a matter of finding the right templating effect and the right chemical path. We reported recently the first synthesis of a true pure silica polymorph† with a three-dimensional zeolitic channel system of large pores (12MR), which beautifully exemplifies the above statement. In this case, the long-sought pure silica zeolite β spontaneously nucleates and grows free of connectivity defects under hydrothermal conditions, in the presence of both tetraethylammonium cations and $F^-$ anions.[7] Pure silica β is the $SiO_2$ polymorph with the lowest framework density ever reported by direct synthesis. Rather than on the templating ability of tetraethylammonium, the success of this synthesis relied on the use of fluoride anions at near neutral pH in a dense system ($H_2O/SiO_2$ *ca.* 7).[8] The use of $F^-$ anions for the synthesis of defect-free pure silica phases was first established by Flanigen and Patton[9] and subsequently developed by others.[10] The results we present here show how this methodology may be extended, revealing its successful application to the synthesis of another new, large pore microporous pure $SiO_2$ phase containing a large void volume. The synthesis of an increasing number of new microporous pure silica phases using this strategy can be anticipated, with the limits of the method with respect to pore size and void volume still to be established.

The synthesis of the new phase (denoted as ITQ-4, for Instituto de Tecnología Química-4)[11] in its pure $SiO_2$ form free of connectivity defects was achieved by using *N*-benzylquinuclidinium employing conditions similar to those previously described for pure silica zeolite β.[7] In a typical synthesis 24.59 g of tetraethylorthosilicate were added to 42.46 g of a $1.4 \times 10^{-3}$ mol $g^{-1}$ solution of *N*-benzylquinuclidinium hydroxide, and the mixture was stirred for 8 h at room temp. allowing evaporation of the ethanol produced. Then, after adding 10.12 g of water lost during the evaporation and 2.46 g of 48 mass% HF and stirring, the mixture was transferred to PTFE lined stainless steel 60 ml autoclaves, which were heated at 150 °C under tumbling (60 rpm) for 12.5 days. The resulting mixture (pH = 8.2) was then filtered and washed with deionized water. A white highly crystalline solid was obtained (15 g solid/100 g of initial reaction mixture, *i.e. ca.* 90% of the silica was recovered in the solid) having a characteristic powder X-ray diffraction (XRD) pattern shown in Fig. 1(*a*). This pattern was indexed as monoclinic with unit-cell dimensions of $a$ = 18.599(1), $b$ = 13.401(9), $c$ = 7.701(2) Å and β = 101.39(1)°. Chemical analysis reveals, within experimental error, that the sample contains no Al, and further suggests the organic cation to still be intact within the zeolitic channels [Anal. Found: C, 14.83; H, 1.91; N, 1.25. $(C_{14}H_{20}NF)_{2.16}Si_{32}O_{64}$ requires C, 15.12; H, 1.81; N, 1.26%]. Thermogravimetric and difference thermal analyses show no mass loss below 100 °C, indicating the presence of very little or no occluded water, while in the temperature range 200–750 °C there are two overlapping mass loss steps of roughly equal size which amount to about 20% mass, attributable to the oxidation of the template. The experimental chemical composition of $(C_{14}H_{20}NF)_{2.16}Si_{32}O_{64}$ has been calculated for a unit cell containing 32 $SiO_2$ units (the number of Si atoms per unit cell was derived from the measured void volume fraction and the unit-cell volume). The volume of two template molecules {*ca.* 310 $Å^3$ per molecule, assuming free rotation of both the quinuclidinium and benzene moieties around the N–$C^9$ and $C^9$–$C^{10}$ bonds, respectively, of the *N*-benzyl-1-azoniumbicyclo[2,2,2]octane} per unit cell is in very good agreement with the void volume derived by $N_2$ adsorption [670 $Å^3$ (u.c.)$^{-1}$, see below], suggesting that there is a close packing of the organics within the silica framework and that essentially all the void volume accessible to $N_2$ in the calcined sample is occupied by the *N*-benzylquinuclidinium in the as-made sample. This

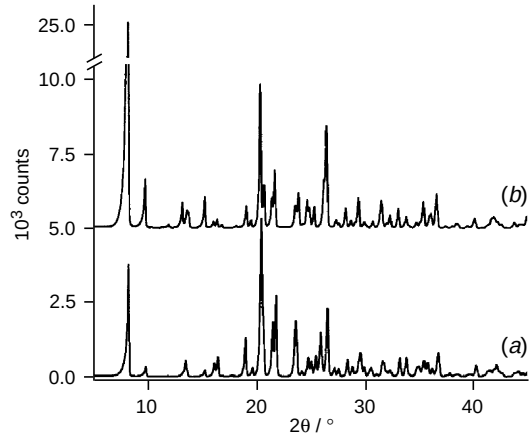

**Fig. 1** Powder X-ray diffractograms of (*a*) as prepared ITQ-4 and (*b*) ITQ-4 after calcination at 580 °C for 3 h. The changes to the pattern after calcination are related to a change in the unit-cell dimensions of the de-templated solid. Philips PW1820 diffractometer, Cu-Kα radiation, 0.020° 2θ step size and 0.500 s count time.

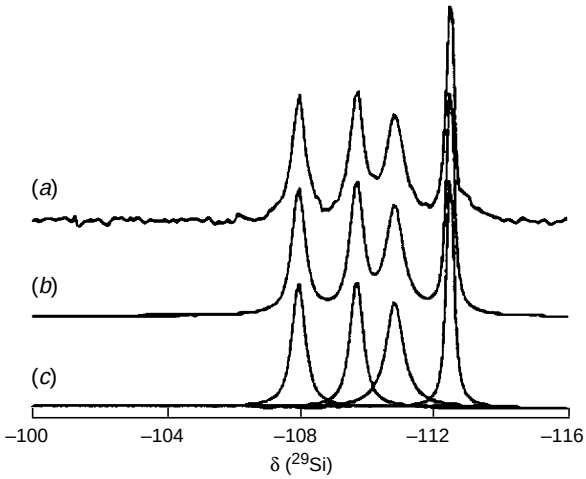

**Fig. 2** $^{29}$Si MAS NMR spectra of calcined ITQ-4, distinctly showing four resolved Si(4Si) crystallographic sites in the structure of the new pure $SiO_2$ polymorph: experimental (*a*), simulated (*b*) and deconvoluted components (*c*). Spectrum recorded on a Varian VXR400 SWB at 5 kHz spinning rate, 60 s recycle delay, 79.4586 MHz, 3π/8 rad, 3 μs pulse length, 264 scans.

implies that the void volume accessible to $N_2$ consists only of rather large cages or channels.

After calcination at 580 °C for 3 h the solid is freed of the organic material with retention of its crystallinity [Fig. 1(*b*)] and symmetry (as deduced from the laboratory XRD data, which were fully indexed with the same symmetry for the as-made and calcined materials). There are however significant changes in peak positions due to changes in the unit-cell parameters [*a* = 18.619(20), *b* = 13.478(9), *c* = 7.625(16) Å, β = 101.947(16)°]. Upon calcination, the unit cell shrinks in the *c* crystallographic direction, while it expands in the *a* and *b* directions, the overall result being a contraction of its volume by a factor of 0.5% (1880.66 and 1871.88 Å$^3$ for the as-made and calcined samples, respectively). Typically, zeolite frameworks expand upon removal of the organic molecules by calcination, while the effect observed here suggests a tight fit of the template within the zeolitic void volume, with the framework relaxing in the calcined form. No loss of crystallinity was observed after heating ITQ-4 to at least 1273 K. The high thermal stability of this phase is attributed to its pure silica nature and to the absence of Si–O–Si connectivity defects (see below). After calcination, the microporous nature of ITQ-4 was probed by its $N_2$ adsorption isotherm at 77 K, from which the following adsorption values were derived: microporous volume 0.21 cm$^3$ g$^{-1}$, micropore area 415 m$^2$ g$^{-1}$, BET surface area 433 m$^2$ g$^{-1}$. By adsorption of Ar at 87.3 K and using the Horvath–Kawazoe formalism a pore size of 6.2 Å was calculated suggesting ITQ-4 is a large 12MR pore material.

The true $SiO_2$ nature of ITQ-4 (*i.e.* a 4-connected three-dimensional net of $SiO_4$ tetrahedra with no Si–O–Si connectivity defects and no Al) is evidenced by $^{29}$Si MAS NMR spectroscopy of calcined pure silica ITQ-4 (Fig. 2). First, and within the limits of detection of this technique, no signals are detected in the region below δ 105, showing the absence of Si(3Si, 1OH) or Si(3Si, 1Al) species. Secondly, the spectrum shows a very high resolution of tetrahedral Si(4Si) sites, directly attributable to the crystallographically distinct Si environments in the structure. Such a high resolution is generally only observed in cases where there is essentially complete absence of Si–OH and Si–O–Al species. In Table 1 a list of the intensities and positions of the four deconvoluted components of the spectrum is given, together with the average Si–O–Si angles calculated using the relationship of Thomas *et al.*[12] for every resolved Si site. The rather small Si–O–Si average angle for

**Table 1** Results of the deconvolution of the $^{29}$Si MAS NMR spectrum of pure $SiO_2$ ITQ-4

| Signal (δ) | Relative intensity | Average Si–O–Si angle[12] |
|---|---|---|
| −107.97 | 23.8 | 142.5 |
| −109.71 | 23.9 | 145.5 |
| −110.86 | 27.6 | 147.5 |
| −112.52 | 24.8 | 150.3 |

every Si site in ITQ-4 (142–150°) is remarkable, the average value (146.5°) being *ca.* 5–10° smaller than the usual T–O–T angles typically found in pure silica zeolites (around 150–155°).

Finally, we note that in view of its characteristic XRD pattern, ITQ-4 appears to be related, being probably isomorphous, to a recently described zeolite of unknown structure, SSZ-42,[13] for which no report exists in the literature. The information contained in its original patent suggests this material is a large pore one. Very interestingly, SSZ-42, for which the template employed here can also be used, can not be synthesized in the absence of B atoms in the conditions reported in the patent ($OH^-$ media). Thus, the synthesis reported here, when viewed together with that already reported for pure $SiO_2$ β,[7] exemplifies how the appropriate synthesis method can help circumvent the apparent difficulty of synthesizing very open pure silica polymorphs, and corroborates the conclusion drawn by other authors concerning the small energetic limitations to the synthesis of large pore pure silica phases.[5]

The authors acknowledge the Spanish DGICYT (MAT 94-0359-C02-01) for financial support and Dr P. Barrett for helpful comments and discussions.

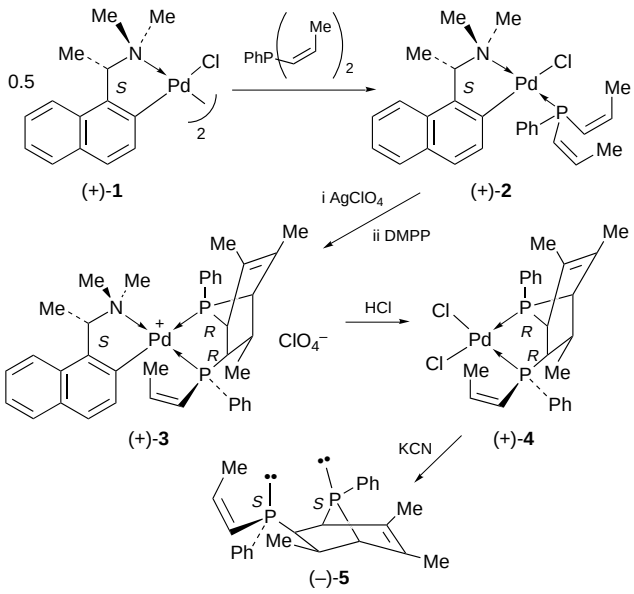
# Asymmetric synthesis of a rigid diphosphine ligand containing two phosphorus and four carbon stereogenic centres by means of a chiral palladium complex promoted Diels–Alder reaction

**Pak-Hing Leung,*[a] S. Selvaratnam,[a] C. R. Cheng,[a] K. F. Mok,[a] Nicholas H. Rees[b] and William McFarlane[b]**



[a] *Department of Chemistry, National University of Singapore, Kent Ridge, Singapore 0511*
[b] *Department of Chemistry, University of Newcastle Upon Tyne, Newcastle Upon Tyne, UK NE1 7RU*

**An optically pure diphosphine ligand containing two phosphorus and four carbon stereogenic centres is prepared efficiently by a chiral organopalladium complex promoted asymmetric Diels–Alder reaction between phenyldi[(*Z*)-prop-1-enyl]phosphine and 1-phenyl-3,4-dimethylphosphole.**

Despite the critical importance of chiral phosphines in asymmetric catalysis,[1] only a few P-chiral phosphines have been obtained by means of asymmetric synthesis.[2] The majority of this class of chiral auxiliaries were prepared by optical resolutions which involved the somewhat technically tedious separation of diastereomers. Here we present a simple and highly stereoselective synthesis of a rigid diphosphine that contains two phosphorus and four carbon stereogenic centres.

As illustrated in Scheme 1, the monodentate phenyldi[(*Z*)-prop-1-enyl]phosphine was coordinated regiospecifically[3] to the chloro-bridged dimer (+)-**1** to give the monomeric compound (+)-**2** as pale yellow prisms, $[\alpha]_D$ +99.1 (*c* 1.1, $CH_2Cl_2$).† Upon coordination, the prochiral dienophile is activated and is capable of reacting with an adjacent coordinated cyclic diene, 1-phenyl-3,4-dimethylphosphole (DMPP).[4] Thus, chloro abstraction from (+)-**2** in $CH_2Cl_2$ using silver perchlorate followed by treatment with DMPP at room temp. for 6 h gave the corresponding [4 + 2] cycloaddition product (+)-**3** as colourless prisms in 70% isolated yield, mp 151–153°C (decomp.), $[\alpha]_D$ +10.9 (*c* 2.0, $CH_2Cl_2$). X-Ray analysis of (+)-**3** confirmed that the desired diphosphine coordination complex had formed (Fig. 1) and established the absolute stereochemistries of the six chiral centres created: *R* at P(13), P(20), C(14), C(17) and *S* at C(18), C(19).‡ In $CDCl_3$, the two-dimensional ROESY NMR spectrum[5] of the complex indicated that the new bidentate and the (*S*)-naphthylamine auxiliary interact stereochemically (Fig. 2). For example, Me(23) at the P–vinylic function shows an NOE contact with the protruding aromatic proton at C(2) (signal G). Similarly, the phenyl group at the bridgehead phosphorus shows proximity to both neighbouring N–Me groups (signals H and I). More dramatically, long-range interactions such as Me(24)···Me(27) (signal J) and Me(24)···Me(29) (signal K) are clearly seen in the spectrum. In the solid state, the C(24)···C(27) and C(24···C(29) distances are 4.54 and 4.73 Å, respectively. These interchelate NOE interactions confirm that the new chiral diphosphine is sensitive to the stereochemical environment of the palladium coordination sphere.

The (*S*)-naphthylamine auxiliary can be chemoselectively removed from (+)-**3** by treatment with conc. HCl to give the dichlor species (+)-**4** as stable pale yellow prisms in 85% isolated yield, mp 249–250°C (decomp.), $[\alpha]_D$ +44.5 (*c* 1.1, $Me_2SO$). The free diphosphine can be liberated quantitively from (+)-**4** by treating a dichloromethane solution of the dichloro complex with aqueous cyanide for 10 min. The

**Scheme 1**

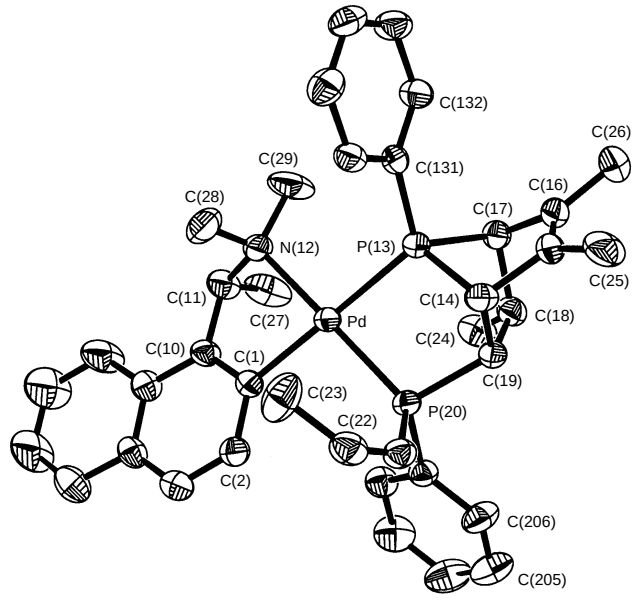


**Fig. 1** ORTEP drawing of the cation in (+)-**3** showing the six new chiral centres formed in the Diels–Alder reaction. Selected bond lengths (Å) and angles (°): Pd–C(1) 2.051(5), Pd–N(12) 2.129(4), Pd–P(13) 2.351(1), Pd–P(20) 2.256(2), P(13)–C(14) 1.853(5), P(13)–C(17) 1.843(5), C(15)–C(16) 1.323(7), P(20)–C(19) 1.852(5), P(20)–C(21) 1.806(5), C(21)–C(22) 1.312(7), C(14)–P(13)–C(17) 81.2(2), C(14)–C(19)–P(20) 105.0(3), C(19)–C(18)–C(24) 118.1(5), C(18)–C(19)–P(20) 115.3(3).

optically active diphosphine was obtained as a highly air-sensitive viscous colourless oil with $[\alpha]_D$ −53.9 (*c* 1.3, $CH_2Cl_2$). The $^{31}P$ NMR spectrum of free (−)-**5** in $CDCl_3$ exhibited a pair of doublets at δ 85.7 and 39.6 ($J_{PP}$ 51.3 Hz). The low-field signal confirms that the *exo–syn* stereochemistry is retained.[4] It is noteworthy that the apparent inversion of configuration that takes place at both phosphorus stereogenic centres when the diphosphine is liberated from the metal is merely a consequence of the Cahn–Ingold–Prelog (CIP) sequence rules.[6]

Investigations on the catalytic properties of transition-metal complexes containing this rigid optically active diphosphine are currently in progress.

We acknowledge the financial support for this project from the National University of Singapore (Grant RP 920606), research scholarships to S. S. and C. R. C. and UK EPSRC for NMR equipment.

***meso*-Tetrakis(3-sulfonatomesityl)porphyrinato]chromium(III) [$Cr^{III}$(tsmp)] in aqueous solution can undergo electrochemical reduction to form a stable radical anion and oxidation to generate very stable radical cations $Cr^{III}$(tsmp$^{\cdot+}$) and O=$Cr^{IV}$(tsmp$^{\cdot+}$), which reacts with alkenes to produce enones at room temperature.**

Cytochrome P-450 is a monooxygenase which acts as a mediator for oxygen transfer reactions in biological systems. Metalloporphyrins have been intensively used as catalysts in mimicking cytochrome P-450.[1–3] Formation of a high-valent oxo–metal complex is essential for such catalytic reactions, and can be generated by reacting metalloporphyrins with chemical oxidants such as $ClO^-$,[4] $H_2O_2$,[5] alkyl peroxides,[6] percarboxylic acid,[7] iodosylbenzene,[8] $KHSO_5$,[9] or nitrogen oxides.[10] Also, electrochemical methods have been developed in aqueous[11] and non-aqueous[12] solutions.

We have synthesized water-soluble [*meso*-tetrakis(3-sulfonatomesityl)porphyrinato]chromium(III) [$Cr^{III}$(tsmp)] and found that the *ortho*-methyl groups in the tetramesitylporphyrin provided good steric protection for the *meso*-carbons upon radical cation or anion formation. The steric hindrance also prevents the formation of the μ-oxo dimer[13] in aqueous solutions. $Cr^{III}$(tsmp) exhibits two p$K_a$ values at 8.5 and 11.6, respectively, according to spectrophotometric titration and can be compared with the p$K_{a1}$ and p$K_{a2}$ values for [*meso*-tetrakis(4-sulfonatophenyl)porphyrinato]chromium(III) [$Cr^{III}$(tspp)] of 7.63 and 11.45, respectively.[14]

In pH 0.0–3.0 buffer solutions, $Cr^{III}$(tsmp)$(H_2O)_2$ undergoes a one-electron oxidation at a formal potential of 0.875 V (*vs.* Ag/AgCl), which is invariant in this pH range. $\lambda_{max}$ of the Soret band shifts from 448 to 424 nm and the molar absorption decreases dramatically. A broad band in the region 600–800 nm indicates cation radical formation in the porphine ring. An isosbestic point is observed clearly at 434 nm which shows only two components are present in equilibrium. The number of electrons transferred ($n$) and formal potential were determined from the literature procedure[15] to be 1.0 and +0.875 V, respectively. On the other hand, oxidation of $Cr^{III}$(tspp) leads to decomposition and the absorption spectrum becomes featureless. The instability of $Cr^{III}$(tspp) to oxidation is consistent with ring oxidation.[16]

In pH 3.2 buffer solution, two distinct one-electron transfer steps could be observed spectroelectrochemically and both oxidation products are very stable. The first oxidation follows the same pattern as that at pH 0.0–pH 3.0 and thus is ring-centred [Fig. 1(*a*)]. In the second step, $\lambda_{max}$ of the Soret band shifts from 424 to 406 nm with similar absorbance [Fig. 1(*b*)].

In pH 3.5–5.5 buffer solutions, the first oxidation potential is invariant while the second one shifts cathodically with increase in pH. The two oxidation potentials become closer and finally merge. In pH 6.0–8.0 buffer solutions, the two one-electron oxidations merge into a two-electron step (Fig. 2). The final absorption spectra are identical for both pH ranges. The number of electrons transferred ($n$) and the slope of formal potential were determined to be 2.0 and −56 mV/pH, respectively. Hence, according to the Nernst equation,[17] the oxidation step involves transfer of two protons upon two-electron oxidation.

Spectroelectrochemical studies show that O=Cr-$(H_2O)$(tsmp$^{\cdot+}$) is also very stable and can be reversibly reduced in 6.0 ⩽ pH ⩽ 8.0 buffer solution. This oxochromium(IV) porphyrin radical cation is apparently more stable than its iron counterpart.[11b]

Fig. 3 shows thin-layer spectra of $5 \times 10^{-5}$ M $Cr^{III}$-$(H_2O)_2$(tsmp) and 0.05 M cyclopent-2-en-1-acetic acid in pH 7.0 buffer solution at $E_{appl}$ = 0.73 V, which should correspond to a

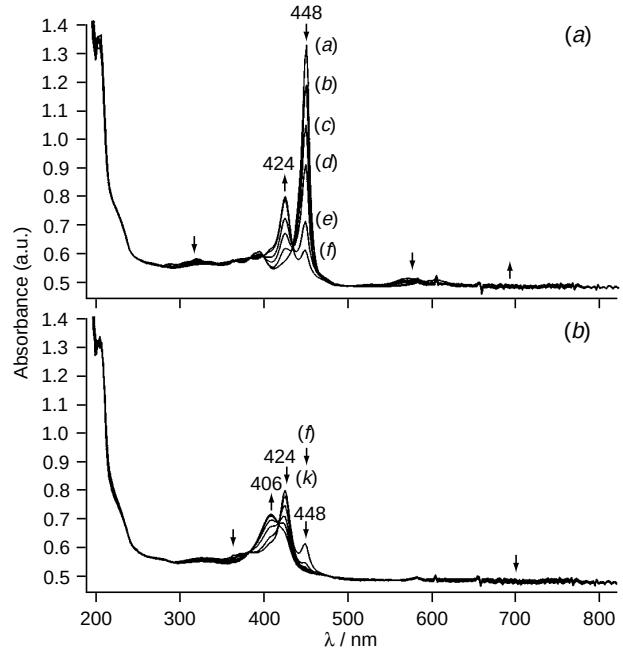

**Fig. 1** Thin-layer spectra of $5 \times 10^{-5}$ M Cr(tsmp) at different oxidation potentials in pH 3.2 buffer solution. $E_{appl}$ = (*a*) 0.50 (*b*) 0.83 (*c*) 0.85 (*d*) 0.87 (*e*) 0.91 (*f*) 0.95 (*g*) 1.01 (*h*) 1.07 (*i*) 1.09 (*j*) 1.11 (*k*) 1.15 V.

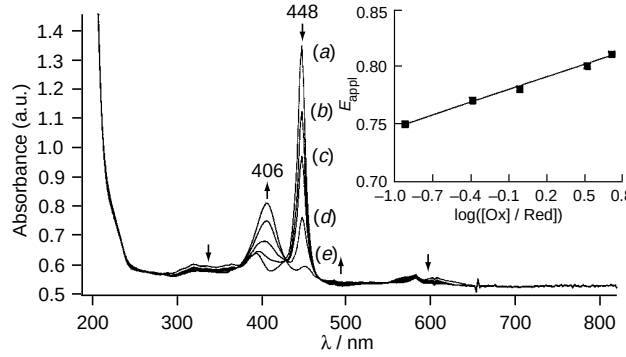

**Fig. 2** Thin-layer spectra of $5 \times 10^{-5}$ M Cr(tsmp) at different oxidation potentials in pH 6.0 buffer solution. $E_{appl}$ = (*a*) 0.50 (*b*) 0.77 (*c*) 0.78 (*d*) 0.80 (*e*) 0.89 V. Inset: plot of $E_{appl}$ *vs.* log ([Ox]/[Red]) for Cr(tsmp).

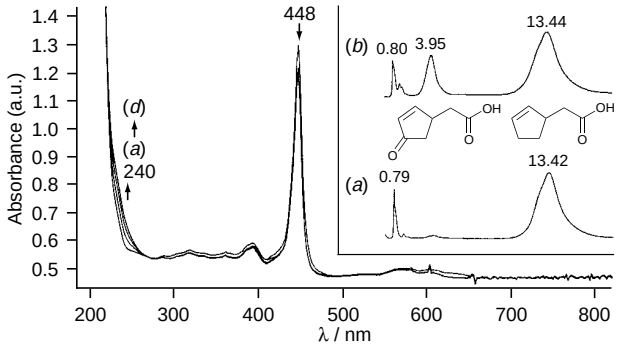
1 : 1 mixture of $Cr^{III}(H_2O)_2$(tsmp) and O=$Cr^{IV}$(tsmp$^{\cdot+}$). However, the absorption band of the latter at 406 nm is not seen. Rather, the absorption band of $Cr^{III}(H_2O)_2$(tsmp) decreases slightly. In the 240 nm region, an absorbance corresponding to enone formation[11] increases gradually. Bulk electrolysis of $5 \times 10^{-5}$ M $Cr^{III}(H_2O)_2$(tsmp) and 0.05 M cyclopent-2-en-1-acetic acid was conducted at $E_{appl}$ = 0.73 V in pH 7.0 buffer solution. Ion chromatography of the reaction mixture showed that the peak of cyclopent-2-en-1-acetic acid was reduced and a peak corresponding to cyclopent-2-en-4-one-1-acetic acid was observed (Fig. 3). The turnover rate is *ca*. 0.5 turnovers min$^{-1}$ based on the spectroelectrochemical results. Purging the solution with $N_2$ during electrolysis led to significantly less enone.

Electrocatalysis at $E_{appl}$ = 0.99 V in pH 3.6 buffer solution can also produce cyclopent-2-en-4-one-1-acetic acid but the turnover rate is slower, *ca*. 1/4 that at pH 7.0. To the best of our knowledge, this is the first reported oxochromium(IV) porphyrin radical cation reaction with alkenes in aqueous solutions at room temp.† The 424 nm band of $Cr^{III}(H_2O)_2$(tsmp$^{\cdot+}$) is still observed in the pH 3.6 solution while at pH 7.0 O=$Cr^{IV}(H_2O)$(tsmp$^{\cdot+}$) is reduced to $Cr^{III}(H_2O)_2$(tsmp). Reaction pathways are thus proposed in Scheme 1.[11]

We also observed spectroelectrochemically[15] that $Cr^{III}(H_2O)_2$(tsmp) can undergo stable and reversible one-electron reduction in pH 9.0 buffer solution. The Soret band shifts from 440 to 420 nm and the intensity drops to about 1/3. A broad band is observed in 600–800 nm region. The absorption spectrum indicates the formation of a radical anion, which is consistent with reported results by radiolysis.[20] It suggests that $Cr^{III}$, which has the surplus of an extra positive charge by subtracting the dianion of the porphyrin coordination, stabilizes the extra electron on the porphine ring. The stabilization effect does not occur with $Zn^{II}$(tsmp).[11*b*]



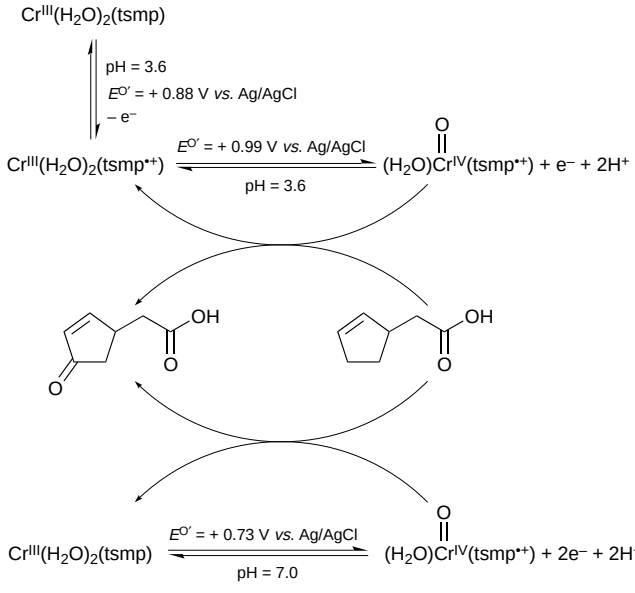


**Fig. 3** Thin-layer spectra of $5 \times 10^{-5}$ M Cr(tsmp) at different oxidation potentials in pH 7.0 buffer solution containing 0.05 M cyclopent-2-en-1-acetic acid. $E_{appl}$ = (*a*) 0.19 V (*b*) 0.73 V for 20 min. (*c*) 0.73 V for 30 min. (*d*) 0.73 V for 40 min. Inset: ion chromatograph of the mixture. (*a*) before electrolysis (*b*) after electrolysis at $E_{appl}$ = 0.73 V for 80 min.

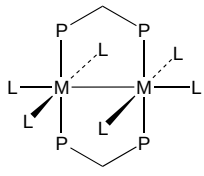
# Stable boat and chair isomers of dimetal complexes containing the $[M_2(\mu\text{-dppm})_2]$ unit (M = Re; dppm = $Ph_2PCH_2PPh_2$)

**Wengan Wu, Phillip E. Fanwick and Richard A. Walton***

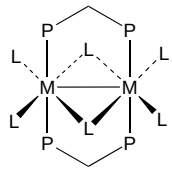
*Department of Chemistry, Purdue University, West Lafayette, IN 47907-1393, USA*

**Reactions of the triply bonded complexes $[Re_2Br_3(\mu\text{-dppm})_2(CO)(CNR)]Y$ (dppm = $Ph_2PCH_2PPh_2$; R = 2,6-dimethylphenyl; Y = $O_3SCF_3$, $PF_6$) with RNC afford edge-sharing bioctahedral complexes of the type $[Re_2(\mu\text{-Br})_2(\mu\text{-dppm})_2Br(CO)(CNR)_2]Y$, which are shown to contain Re–Re single bonds and exist in novel isomeric forms with boat and chair conformations for the $Re_2(\mu\text{-dppm})_2$ unit.**



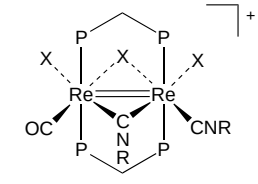
In the course of studies aimed at delineating the factors which determine the stabilities of various structural isomers of dimetal complexes of types **A** and **B** (P–P represents a bridging bidentate phosphine), and the mechanisms of the isomer conversions, we have encountered a new class of isomers which have relevance to the structural chemistry of open bioctahedra (**A**) and edge-sharing bioctahedra (**B**), as well as other classes of complexes which contain a $M_2(\mu\text{-dppm})_2$ unit (dppm = $Ph_2PCH_2PPh_2$).[1–3]

The mixed carbonyl–isocyanide complexes of the type $[Re_2X_3(\mu\text{-dppm})_2(CO)(CNR)_2]Y$ (X = Cl, Br; R = 2,6-dimethylphenyl; Y = $O_3SCF_3$, $PF_6$) have been identified in at least five different structural forms, with metal–metal bond orders ranging from 3 to 0 (Scheme 1).[4–10] In some instances, isomerizations have been observed to occur at elevated temperatures (*i.e.* **1** → **2** and **3** → **4**).[4–6,9] Previously, the X-ray structural characterizations of salts of **1**–**5** have shown that the $Re_2(\mu\text{-dppm})_2$ unit (two fused five-membered rings in the cases of **1**, **2**, **3** and **5** and an eight-membered ring for **4**) exists in a stable boat conformation. Further characterizations of the bromo complex **5** have now established that preparative samples of the $O_3SCF_3$ and $PF_6$ salts consist of a mixture of two isomers with the same basic structure as that depicted in Scheme 1, but which differ in possessing either a boat (**5a**) or chair (**5b**) conformation for the $Re_2(\mu\text{-dppm})_2$ unit.



The reactions of the unsymmetrical, coordinatively unsaturated dirhenium(II) complexes $[Re_2Br_3(\mu\text{-dppm})_2(CO)(CNR)]Y$ (Y = $O_3SCF_3$, $PF_6$)[8,10] with 1 equiv. of RNC in $CH_2Cl_2$ or acetone afford mixtures which contain the salts of the isomeric pair (**5a**)Y and (**5b**)Y as the major product [yield 40–70%, product ratio (**5a**)Y : (**5b**)Y *ca.* 5 : 95).† The spectroscopic and electrochemical properties of diamagnetic (**5a**)Y and (**5b**)Y are very similar,[8] and do not readily permit a distinction to be made between the structures of the components of the mixture. However, an X-ray structure determination on a crystal of (**5a**)$PF_6$ has shown[8] the structure to be that of the isomer with the boat conformation [the Re–Re distance is 3.0456(8) Å]. Although we have been unable to obtain single crystals of the major isomers (**5b**)$O_3SCF_3$ and (**5b**)$PF_6$ directly from the preparative reaction mixtures which are of a quality suitable for an X-ray structure determination, we have done so by an alternative procedure.

Treatment of (**5b**)$O_3SCF_3$ with $[Co(\eta^5\text{-}C_5H_5)_2]$ in $CH_2Cl_2$ affords the paramagnetic, one-electron reduced product $[Re_2Br_3(\mu\text{-dppm})_2(CO)(CNR)_2]$ **6** in high yield. The addition of $[Fe(\eta^5\text{-}C_5H_5)_2]PF_6$ to a $CH_2Cl_2$ solution of **6** re-oxidizes it quantitatively to (**5b**)$PF_6$.‡ The structural identities of **6** and (**5b**)$PF_6$ have been established by X-ray crystallography which shows that both possess a chair conformation for the $Re_2(\mu\text{-dppm})_2$ unit.§ An ORTEP representation of the structure of **6** is shown in Fig. 1; the structure of the dirhenium cation present in (**5b**)$PF_6$ is essentially the same, with the exception of the parameters associated with the $Re_2(\mu\text{-Br})_2$ unit (see caption for Fig. 1). The Re–Re bond distances in the structures of (**5b**)$PF_6$ and **6** are 3.028(2) and 3.8023(10) Å, respectively; the former is essentially identical to the Re–Re distance in (**5a**)$PF_6$.[8] These distances, along with the magnetic properties of (**5b**)$PF_6$ and **6**, are consistent with the presence of Re–Re bonds of order one and zero, respectively. Accordingly, the one-electron reduction of (**5b**)$O_3SCF_3$ leads to a species $[(RNC)_2Re(\mu\text{-Br})_2(\mu\text{-dppm})_2ReBr(CO)]$ **6** which can best be considered formally as a charge separated $Re^{I}$–$Re^{II}$ species (18e–17e) rather than one containing a Re–Re bond of order 0.5.



The properties of (**5b**)$PF_6$ as prepared by the ferrocenium oxidation of **6** are identical to samples which are present in previously reported[8] mixtures of (**5a**)$PF_6$ and (**5b**)$PF_6$. Accordingly, the reduction of (**5b**)$O_3SCF_3$ to **6**, and the oxidation of **6** to (**5b**)$PF_6$ occur with preservation of a chair conformation. The

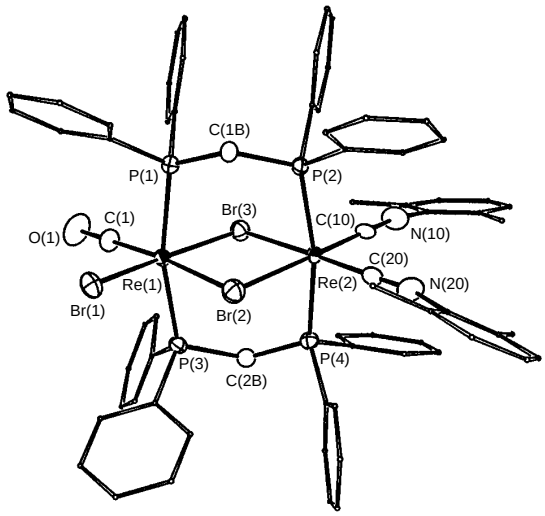

**Fig. 1** ORTEP representation of the structure of the dirhenium complex $[Re_2Br_3(\mu\text{-dppm})_2(CO)(CNR)_2]$ in crystals of **6**·$CH_2Cl_2$, showing the chair conformation for the $Re_2(\mu\text{-dppm})_2$ unit. Thermal ellipsoids are drawn at the 50% probability level except for the phenyl group atoms of the dppm ligands and the xylyl groups of the RNC ligands which are circles of arbitrary radius. Selected bond distances (Å) and bond angles (°): Re(1)···Re(2) 3.8023(10), Re(1)–C(1) 1.838(14), Re(1)–Br(1) 2.509(2), Re(1)–Br(2) 2.6184(11), Re(1)–Br(3) 2.5813(9), Re(1)–P(1) 2.444(2), Re(1)–P(3) 2.451(2), Re(2)–C(10) 1.929(7), Re(2)–C(20) 1.931(7), Re(2)–Br(2) 2.6289(9), Re(2)–Br(3) 2.6560(11), Re(2)–P(2) 2.407(2), Re(2)–P(4) 2.387(2); P(1)–Re(1)–P(3) 166.02(5), C(1)–Re(1)–Br(1) 91.9(4), C(1)–Re(1)–Br(3) 97.7(4), Br(1)–Re(1)–Br(2) 82.81(4), Br(3)–Re(1)–Br(2) 87.75(3), P(4)–Re(2)–P(2) 168.58(5), C(10)–Re(2)–C(20) 90.1(3), C(20)–Re(2)–Br(2) 94.7(2), C(10)–Re(2)–Br(3) 89.1(2), Br(2)–Re(2)–Br(3) 85.99(3), Re(1)–Br(2)– Re(2) 92.87(3), Re(1)–Br(3)–Re(2) 93.09(3). Note: the structure of the dirhenium cation present in the structure of (**5b**)$PF_6$·$2CH_2Cl_2$ is very similar to that of **6**, with the exception of the presence of a Re–Re single bond [3.028(2) Å]. This leads primarily to differences in the parameters for the $Re_2(\mu\text{-Br})_2$ unit between these two structures. The bond distances in the structure of the cation **5b** which correspond to Re(1)–Br(2), Re(1)–Br(3), Re(2)–Br(2), Re(2)–Br(3) in the structure of **6** are 2.556(2), 2.553(2), 2.599(3), and 2.604(3) Å, respectively, while the angles (°) which correspond to Re(1)–Br(2)–Re(2) and Br(2)–Re(1)–Br(3) are 71.95(9) and 109.50(9)°, respectively.

large increase in Re–Re distance which accompanies the reduction of the salts (**5b**)Y to **6** (*ca*. 0.78 Å), would be expected to reduce the ring strain in the $Re_2(\mu\text{-dppm})_2$ unit and allow conversion to the most stable ring conformation. Since no conformation change occurs, we can conclude that the chair conformation, as is already present in (**5b**)Y, is more stable than the boat conformation in (**5a**)Y. This is supported by the observation that solutions of (**5a**)$PF_6$ in dichloromethane convert slowly to the more thermodynamically stable isomer (**5b**)$PF_6$ (96 h at 25 °C, 24 h at reflux) in essentially quantitative yield.

Further studies are underway to examine the scope of this chemistry as it relates to other $M_2(\mu\text{-dppm})_2$ complexes, and the redox behaviour of the less stable boat conformer **5a**, which is typically obtained in much lower yield than **5b**.

† An alternative method for the synthesis of mixtures of (**5a**)Y and (**5b**)Y is the reaction of the triply bonded, neutral complex $[Re_2Br_4(\mu\text{-dppm})_2(CO)(CNR)]$ with a mixture of TlY (1 equiv.) and RNC (2 equiv.).

‡ *Synthesis*: **6**: a sample of (**5b**)$O_3SCF_3$ (120 mg, 0.0659 mmol) was mixed with $[Co(\eta^5\text{-}C_5H_5)_2]$ (12.5 mg, 0.0661 mmol) in $CH_2Cl_2$ (15 ml) at 25 °C. The reaction mixture, which changed from red–brown to green within 5 min, was stirred for 30 min, filtered, and the volume of the filtrate reduced to 2 ml. An equal volume of $Et_2O$ was added to induce precipitation of yellow $[Co(\eta^5\text{-}C_5H_5)_2]O_3SCF_3$, which was filtered off and the filtrate stripped to dryness. The green residue (**6**) was washed with $Et_2O$ (3×5 ml) and dried; yield 94 mg (85%). Anal. Calc. for $C_{69}H_{62}Br_3N_2OP_4Re_2$: C, 49.59; H, 3.73; N, 1.68. Found: C, 49.21; H, 3.65; N, 1.48%. Recrystallization from $CH_2Cl_2$–$C_2H_5CO_2Me$ afforded X-ray quality crystals. IR spectrum (Nujol mull): ν(CN) 2050(sh), 2012s and 1919s, (br) $cm^{-1}$; ν(CO) 1858vs $cm^{-1}$. Cyclic voltammogram (0.1 M $Bu^n_4NPF_6$–$CH_2Cl_2$, Pt-bead electrode, ν = 200 mV $s^{-1}$, potentials *vs*. Ag/AgCl): $E_{\frac{1}{2}}^{ox3}$ = +1.43 V, $E_{\frac{1}{2}}^{ox2}$ = +0.65 V, $E_{\frac{1}{2}}^{ox1}$ = +0.10 V, $E_{\frac{1}{2}}^{red}$ = −0.83 V. Magnetic moment: $\mu_{eff}$ ≈ 1.4 $\mu_B$ (Evans method, $CDCl_3$).

(**5b**)$PF_6$: a mixture of **6** (42.0 mg, 0.0251 mmol) and $[Fe(\eta^5\text{-}C_5H_5)_2]PF_6$ (9.0 mg, 0.027 mmol) in 10 ml of $CH_2Cl_2$ was stirred at 25 °C. A change from green to red–brown occurred within a few min. After a period of 1 h the reaction solution was reduced in volume to *ca*. 1 ml, and 15 ml of $Et_2O$ added to induce precipitation of (**5b**)$PF_6$, which was filtered off and washed with $Et_2O$ (3 × 5 ml); yield 41.5 mg (91%). Recrystallization from $CH_2Cl_2$–$Pr^i_2O$ afforded X-ray quality crystals. The properties of (**5b**)$PF_6$ were identical to those of samples obtained previously[8] as mixtures with (**5a**)$PF_6$.

§ *Crystal data*: **6**·$CH_2Cl_2$ at 203 K: space group $P\bar{1}$ with $a$ = 13.330(4), $b$ = 16.226(3), $c$ = 16.327(6) Å, α = 99.29(2), β = 90.66(3), γ = 91.59(2)°, $Z$ = 2, $D_c$ = 1.674 g $cm^{-3}$. An empirical absorption correction was applied (μ = 5.434 $mm^{-1}$). Structure solved using the Enraf-Nonius structure determination package (MolEN) and refined through the use of SHELXL-93. Hydrogen atoms included but not refined. A cut-off $F_o^2 > 2\sigma(F_o)^2$ used for *R*-factor calculations to give $R(F_o)$ = 0.040, $R_w(F_o^2)$ = 0.112, and GOF = 1.099. Disorder between the terminal CO and Br ligands associated with Re(1); a disorder model involving fractional CO and Br occupancies for each site was refined satisfactorily to 0.707(6) CO/0.293(6) Br for one site and 0.293(6)CO/ 0.707(6)Br for the other.

(**5b**)$PF_6$·$2CH_2Cl_2$ at 203 K: space group $P\bar{1}$ with $a$ = 13.800(5), $b$ = 16.927(8), $c$ = 17.556(5) Å, α = 87.05(7), β = 77.56(6), γ = 69.67(7)°, $Z$ = 2, $D_c$ = 1.757 g $cm^{-3}$. An empirical absorption correction was applied (μ = 5.153 $mm^{-1}$). All other procedures as for the structure of **6**·$CH_2Cl_2$; the final residuals were $R(F_o)$ = 0.065, $R_w(F_o^2)$ = 0.185, and GOF = 1.021. Disorder between the terminal CO and Br ligands modeled satisfactorily as 0.50/0.50 for both sites. Full structural details for **6**·$CH_2Cl_2$ and (**5b**)$PF_6$·$2CH_2Cl_2$ will be published later.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. # Unusual conversions of a zwitterionic polyfused triazine with electron-deficient dienophiles

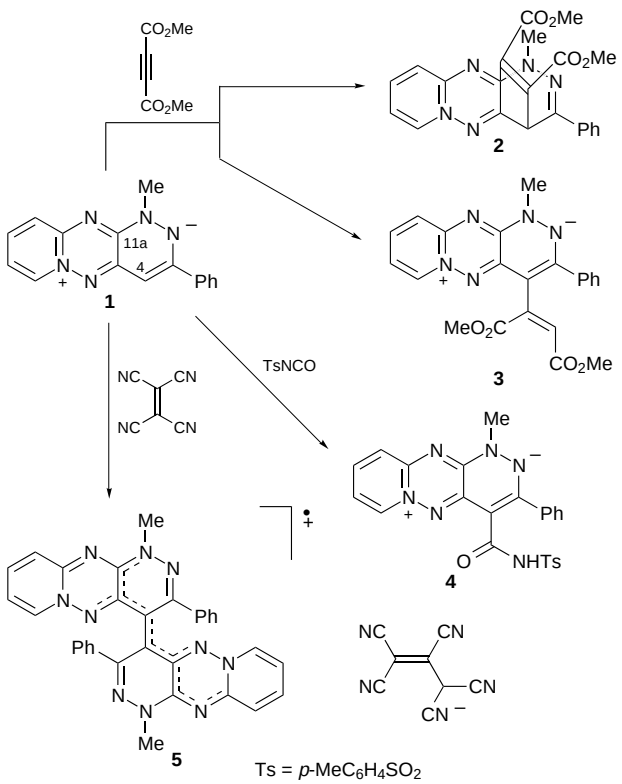
**Zsuzsanna Riedl,[a] György Hajós,*[a] András Messmer,[a] Antal Rockenbauer,[a] László Korecz,[a] Gert Kollenz,[b] Walter M. F. Fabian,[b] Karl Peters[c] and Eva-Maria Peters[c]**



[a] *Central Research Institute for Chemistry, Hungarian Academy of Sciences, PO Box 17, H-1525, Budapest, Hungary*
[b] *Karl Franzens University, Department of Organic Chemistry, Heinrichstr. 28, A-8010 Graz, Austria*
[c] *Max-Planck-Institut for Solid Material Research, D-70569, Germany*

**Investigation of reactions of the zwitterionic polycycle 1 with electron-deficient dienophiles revealed that Michael addition products 3** and **4, selective cycloadducts 2 and, in a special case, a stable dimeric radical cation 5 are formed.**

As a result of our investigations on ring transformation reactions[1] with furo[2,3-*e*]pyrido[1,2-*b*][1,2,4]triazinium salts[2] we synthesized some new zwitterionic polyazaheterocycles (*e.g.* the 1,3-disubstituted pyrido[1,2-*b*]pyridazino[3,4-*e*]-[1,2,4]triazine derivative **1**), the reactivity of which towards dienophiles, because of their highly dipolar character seemed of particular interest. We decided to investigate the reactivity of the new derivative **1** with three different dienophiles (*i.e.* dimethyl acetylenedicarboxylate, toluene-*p*-sulfonyl isocyanate and tetracyanoethylene) (Scheme 1).

We found that zwitterion **1**, when treated with dimethyl acetylenedicarboxylate at room temperature in $CH_2Cl_2$ for 24 h, afforded a mixture of two components (1 : 1), which were separated by chromatography (silica, chloroform–methanol, 25 : 1). Structure elucidation of the more polar component (a pale yellow spot by TLC) by $^1$H NMR spectroscopy revealed the formation of the bridged [3 + 2]-cycloadduct **2**,†‡ whereas the less polar product (a brown–red spot) was proved *via* an X-ray analysis (Fig. 1) to be the Michael adduct **3**.†§ The X-ray data confirmed the *Z* configuration at the exocyclic double bond, as well as a strong predominance of the mesomeric form outlined on Scheme 1. The selective formation of cycloadduct **2** seemed to be in agreement with the results of the FMO analysis of this compound: positions 4 and 11a had the highest $c_{LUMO}$ values (0.6 and 0.54, respectively). Formation of Michael addition products was again experienced when **1** was reacted with toluene-*p*-sulfonyl isocyanate, thus exclusively affording compound **4**.¶

An unexpected result was obtained from the reaction of tricycle **1** with tetracyanoethylene. A blue crystalline compound was obtained, which could not be analysed by NMR spectroscopy. An X-ray investigation (Fig. 2) revealed the structure of compound **5** containing a highly delocalized radical cation, as established by EPR spectroscopy.‖ The central 'formal' C=C bond is the longest [C(1)–C(21) = 145.9 pm] of all the C–C bonds present in **5**.** The two tricyclic fused triazine units are highly twisted [torsion angle C(2)–C(1)–

**Scheme 1**

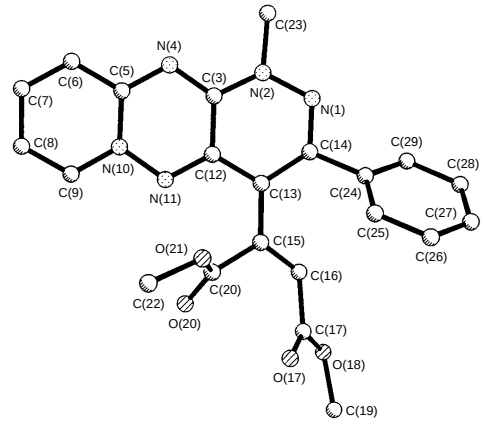


**Fig. 1** Stereoview of **3**

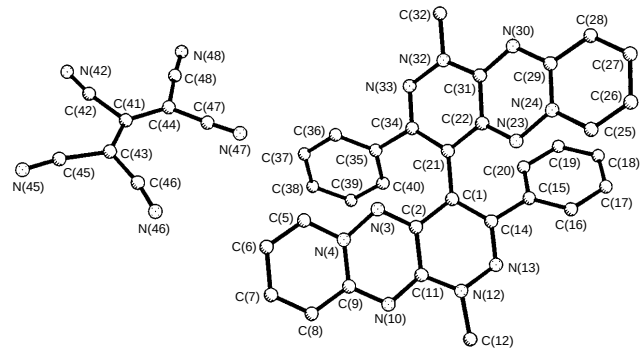

**Fig. 2** Stereoview of **5**

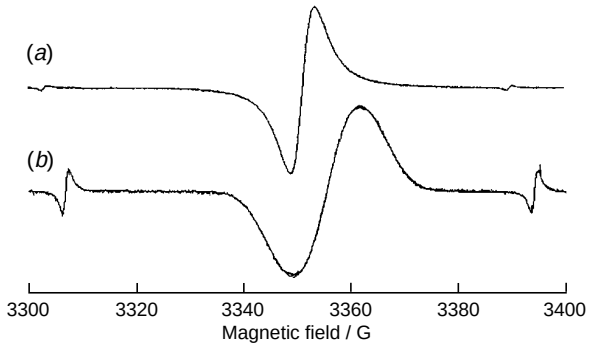

**Fig. 3** Calculated and experimentally found EPR spectra of **5** in (*a*) the solid and (*b*) the solution states

C(21)–C(22) = 131.3°] and arranged in an *anti* conformation. Formation of this unusual product can be rationalized by the primary attack of the reagent at position 4, followed by an oxidative coupling to the dimer radical cation which is stabilized by the pentacyanopropenide anion.[3,4] These anions are usually obtained either from dimerization of tetracyanoethylene under basic conditions[5] or through base-catalysed addition of malononitrile to tetracyanoethylene.[6]

The EPR spectrum of **5** (Fig. 3) showed one broad singlet, and dilution and degassing did not produce any hyperfine structure. Computer fitting of the line profile (Fig. 3) gave a perfect fit if proton splittings are removed from the AM1 calculations,[7] while the *K* proportionality constant for nitrogen is adjusted ($K_N$ = 2340) in the hyperfine coupling *versus* spin density relation $A_N = K_\rho$). The largest nitrogen coupling (2.6 G) is reasonable for the dimer cation radical when compared to the largest nitrogen coupling (7.1 G) in the monomeric cation radical of isoalloxanine,[8] and the observed *g* factor (2.0037) is also typical for cation radicals.[9] No EPR signal for an anion radical (*g* = 2.0026, well resolved hyperfine structure[10]) was detected.

## Footnotes

† All new compounds gave spectroscopic and analytical data in accordance with their assigned structures.

‡ *Selected spectroscopic data* for **2**: Pale Yellow Crystals, mp 218–20 °C; $^1$H NMR (400 MHz, $CDCl_3$): δ 7.62 (1 H, d, H-7), 7.75, 7.35–7.30 (5 H, m, Ph), 7.25 (1 H, t, H-9), 7.06 (1 H, d, H-10), 6.52 (1 H, t, H-8), 4.84 (1 H, s, H-4), 3.83, 3.80 (6 H, s, $CO_2$Me), 3.27 (3 H, s, Me).

§ *Selected spectroscopic data* for **3**: Brown–red crystals, mp 198–202 °C; $^1$H NMR (400 MHz, $CDCl_3$— δ 7.32 (1 H, d, H-7), 7.30 (5 H, m, Ph), 7.05 (1 H, t, H-9), 7.02 (1 H, t, H-8), 6.30 (1 H, d, H-10), 5.83 (1 H, s, H-2′), 3.58, 3.42 (6 H, s, COMe), 3.13 (3 H, s, Me).

*X-Ray crystallographic analysis* of **3**. The brown–red crystal was grown by slow evaporation of an acetonitrile solution of **3**. The crystal was monoclinic, space group *C*2/*c*, with cell dimensions *a* = 1917.5(7), *b* = 838.6(3), *c* = 2561.1(9) pm and *V* = 4051(2) × $10^6$ pm$^3$. *Z* = 8 molecules ($C_{22}H_{18}N_5O_4$, $M_w$ = 417.43) in the unit cell ($D_c$ = 1.369 g cm$^{-3}$). Intensity data were measured for 6448 reflections (4651 unique) on a Siemens R3m/V diffractometer using a crystal with dimensions 0.4 × 1.3 × 0.25 mm (Mo-Kα radiation, graphite monochromator, Wyckoff-scan, θ range = 1.75–27.5°, linear absorbtion coefficient = 0.09 mm$^{-1}$, absorbtion correction: Ψ-scan). The structure was solved by direct phase determination and refined by full-matrix-least square analysis using Siemens SHELXTL PLUS (Micro VAX II); all hydrogen positions of riding model had fixed isotropic *U*. The data-to-parameter ratio was 12.83, *R*, $R_w$ = 0.054, 0.049; weighting scheme $w = 1/\sigma^2(F)$. The largest difference peak and hole in the last map were 0.32 and 0.21 e Å 4$^{-3}$, respectively.

¶ *Selected spectroscopic data* for **4**: Brown–red crystals, mp 228–230 °C (DMF); IR (KBr) ν/cm$^{-1}$ 3180, 3040, 2920, 1660, 1620, 1590, 1560, 1530.

‖ *Selected spectroscopic data* for **5**: Blue crystals, mp 240–42 °C; IR ν(KBr)/cm$^{-1}$ 2196, 1627, 1561, 1508.

** *X-Ray crystallographic analysis* of **5**: The dark blue crystal was triclinic, space group $P\bar{1}$, with cell dimensions *a* = 1299.7(2), *b* = 1349.7(2), *c* = 1078.0(2) pm, α = 92.31(1), β = 95.88(1), γ = 99.70(1)° and *V* = 1850.9(5) × $10^6$ pm$^3$. *Z* = 2 molecules ($C_{32}H_{24}N_{10}$ + $C_8N_5$, $M_w$ = 376.38) in the unit cell ($D_c$ = 1.282 g/cm$^{-3}$). Intensity data were measured for 8485 reflections (8485 unique) on a Siemens R3m/V diffractometer using a crystal with dimensions 0.5 × 0.7 × 0.15 mm (Mo-Kα radiation, graphite moinochromator, Wyckoff-scan, θ range 1.75–27.5°, linear absorbtion coefficient = 0.08 mm$^{-1}$, absorbtion correction: Ψ-scan). The structure was solved by direct phase determination and refined by full-matrix least-squares analysis using Siemens SHELXTL PLUS (MicroVAX II); all hydrogen positions of riding model had fixed isotropic *U*. The data-to-parameter ratio was 12.14, *R*, $R_w$ = 0.076, 0.069, respectively; weighting scheme $w = 1/\sigma^2(F)$. The largest difference peak and hole in the last map were 1.01 and 0.46 e Å$^{-3}$, respectively. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. # Poly(ethylene glycol) (PEG) as a reagent support: the preparation and utility of a PEG–triarylphosphine conjugate in liquid-phase organic synthesis (LPOS)

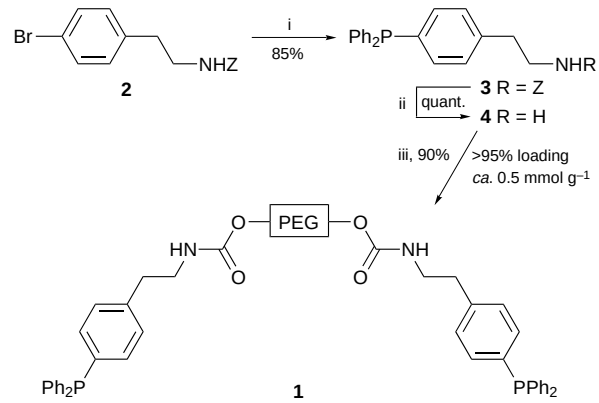
**Paul Wentworth Jr., Anthony M. Vandersteen and Kim D. Janda***

*Department of Chemistry, The Scripps Research Institute and the Skaggs Institute for Chemical Biology, 10550 N. Torrey Pines Rd., La Jolla CA92037, USA*

**The preparation and application in the Staudinger and Mitsunobu reactions of a liquid-phase, poly(ethylene glycol)-arylphosphine conjugate 1 is described.**

The development of both soluble and insoluble functionalized polymers is currently of tremendous interest in the fields of combinatorial chemistry, peptide synthesis and nucleic acid synthesis.[1] The conversion of reactions in solution to either soluble or insoluble polymer-supported chemical methodologies, with the benefits of ease of product isolation, minimization of side-reactions and the ability to use an excess of reagents to drive a reaction to completion, is an on-going challenge.



Because of problems associated with the use of insoluble polymeric reagents and substrates under heterogeneous conditions, such as lowered reactivities, extended reaction times, diffusion-limited reactivity and reagent leaching,[2] soluble-matrices such as poly(ethylene glycol) (PEG),[3] fluorous supports,[4] linear polystyrenes[5] and polyethylene[6] are receiving increasing attention for combinatorial synthesis[7] and as supports for heterogeneous catalysts.[8] Previous work from our group has demonstrated the preparation and utility of PEG derivatives for liquid-phase combinatorial synthesis (LPCS),[7] peptidomimetic synthesis[9] and as ligand supports for the Sharpless dihydroxylation reaction.[10]

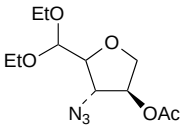
We now report an extension of liquid-phase synthesis into the field of reagent supports.[11] In our latest effort, we have conjugated $PPh_3$ to $PEG_{3400}$ and studied its utility in the Staudinger and Mitsunobu reactions. There are a number of reports highlighting the utility of $PPh_3$ bound to solid polymeric supports, such as polystyrene and copolymers of styrene and divinylbenzene, in the Wittig reaction[12] and for azide reduction.[13] An important component of this work is a comparison between the liquid- and solid-phase reagent approaches.

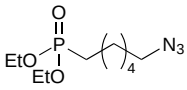
For any successful polymer-supported strategy optimal loading is essential, therefore two important considerations biased our choice of a suitable matrix. First, the PEG polymer was chosen to have two free hydroxy groups per polymer strand. Second, we chose the PEG polymer with the lowest molecular weight possible which did not suffer from changes in its physical properties after attachment of the triphenylphosphine moiety. $PEG_{3400}$ was found to satisfy both of these requirements. Two synthetic strategies were developed for the preparation of the PEG-triarylphosphine conjugates. In the first, $PEG_{3400}$ was reacted with an excess of *p*-bromophenyl isocyanate in dichloromethane, to generate a carbamate linked *p*-bromophenyl PEG derivative in greater than 95% yield. The loading was almost quantitative as judged by the $^1H$ NMR resonance of the PEG methylene protons $\alpha$ to the carbamate linkage. The diphenylphosphine group was incorporated by a modification of the method of Relles and Schluentz.[14] A stirred suspension of the carbamate PEG derivative in THF was reacted with lithium diphenylphosphide under reflux for 16 h. $^1H$ NMR Spectral analysis showed that this reaction was accompanied by significant decomposition of the PEG support, determined by the appearance of multiple methylene signals outside the methylene envelope ($\delta_H$ 3.2–3.8) of the PEG polymer, reducing the yield of reagent to < 70%. No attempt was made to further characterize the PEG decomposition products, rather in a second approach, the substituted triarylphosphine derivative was synthesized separately from the polymer and incorporated in the final step (Scheme 1). Benzyloxycarbonyl (Z) protected *p*-bromophenethylamine **2** was reacted with potassium diphenylphosphide in degassed THF under reflux for 8 h. After silica gel chromatography, the triarylphosphine derivative **3** was obtained in 85% yield. Following a quantitative deprotection of the Z group of **3** by catalytic hydrogenation (Pd–C), amine **4** reacted smoothly with the bis-*p*-nitrophenyl carbonate of $PEG_{3400}$ (Shearwater Polymers Inc.) in degassed $CH_2Cl_2$ at room temp. for 2 h. Repeated precipitation of the reaction mixture from diethyl ether gave the PEG–phosphine reagent **1** in 90% yield, with no accompanying decomposition of the polymer. The oxidation state and purity of the phosphine reagent were confirmed by $^{31}P$ NMR spectroscopy ($\delta_P$ $CDCl_3$ −5.8) with no detectable arylphosphine oxide ($\delta_P$ $CDCl_3$ 28.4) being formed during the conjugation reaction. Polymer loading, measured by both $^1H$ NMR spectroscopy and by following the formation of *p*-nitrophenol during the course of reaction, was excellent (> 95%, 0.5 mmol of phosphine per gram of polymer).

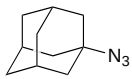
One of the many chemoselective procedures available for the reduction of azides is the Staudinger reaction.[15] A recent report has shown that $PPh_3$ linked to polystyrene beads can perform the Staudinger reaction for a number of azides.[13] However, no precedence exists for a soluble polymer supported approach for this reaction. By using the soluble support **1** a range of alkyl and aryl azides were smoothly converted into their respective amines at room temperature. The reaction times were all faster than with an insoluble $PPh_3$ reagent and in one case no reduction was observed with the polystyrene-supported phosphine highlighting the improved utility of this liquid-phase methodology (Table 1).

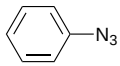
The Mitsunobu[16] reaction is a commonly used procedure, with wide-ranging application throughout organic chemistry. It

**Scheme 1** *Reagents and conditions*: i, $KPPh_2$ (6.0 equiv.), THF, reflux, 24 h; ii, 10% Pd–C, $H_2$ (30 psi), $CH_2Cl_2$, room temp. 2 h; iii, $PEG_{3400}$–$PNP_2$, 2 h $CH_2Cl_2$, room temp.









can be complicated by side-product formation with the result that isolation of the products is usually accompanied by chromatography. In an attempt to address such problems for combinatorial library synthesis, an insoluble polymer-supported approach to Mitsunobu ether formation has been reported.[17] However, in this example, the alcohol substrate was linked to the support and the reagent, $PPh_3$, was in solution, so the reaction was still heterogeneous in nature.

By utilising our liquid-phase approach, reaction of PEG–phosphine **1** with phenol and each of the alcohols outlined in Table 2, in the presence of diethylazodicarboxylate (DEAD), gave etherification under ambient conditions. Precipitation of the oxidized PEG–phosphine conjugate **1** from diethyl ether allowed isolation of the product, aryl alkyl ethers, in analytically pure form, without the need for silica gel chromatography. As found for the preceding Staudinger reduction, reaction times were shorter with the soluble reagent than for the heterogeneous reaction. In addition benzyl alcohol gave no ether product when treated with the solid phase reagent.

In summary, we have shown that a soluble PEG–phosphine reagent can be readily prepared and utilised in the liquid-phase Staudinger and Mitsunobu reactions. Product isolation is routine and the reactions are high yielding. The use of this novel liquid-phase reagent in LPOS offers considerable advantages over solution-based methodologies because the side-product is removed by simple filtration after precipitation of the spent reagent, so no chromatography is necessary. Furthermore, an excess of the reagent can be used without subsequent problems during purification. By comparison with the heterogeneous reaction, product yields are equivalent but reaction times are shorter and the reagent proved much more versatile, reacting with all the substrates tested. This work has highlighted a novel soluble polymer-supported reagent approach to LPOS and offers a new addition to polymer-bound phosphorane chemistries. Perhaps one of the most exciting features of this reagent is its generality, with potential application to many other phosphine-based methodologies such as the Wittig olefination and bromination of alcohols. More generally, for most reactions that are accompanied by unwanted side-products, this procedure may offer a routine solution to the problems encountered during product purifications. Finally this soluble polymer-supported reagent methodology should be compatible with high-throughput organic synthesis and automation technology.

This work supported in part by the R. W. Johnson Pharmaceutical Research Institute and the Skaggs Institute for Chemical Biology.

**Table 1** Comparative Staudinger reactions using **1** and polystyrene–$PPh_3$ with azides

| | **1** | | Polystyrene–$PPh_3$ | |
|---|---|---|---|---|
| Azide | Yield (%) | *t*/h[a,b] | Yield (%) | *t*/h[b,c] |
|  | 95 | 2 | – | No reaction |
|  | 98 | 1.5 | 82 | 8 |
|  | 91 | 4.5 | 95 | 11 |
|  | 90 | 3 | 94 | 3.5 |

[a] In a typical reaction the azide (1 mmol) and $PEG_{3400}$–$PPh_3$ conjugate (1.1 mmol) were dissolved in $CH_2Cl_2$ (5 ml), water was then added (1.1 equiv.) and the reaction mixture was stirred at room temp. On completion, the reaction mixture was concentrated to half its volume and poured onto cold diethyl ether. The spent PEG reagent was filtered under aspirator pressure using a frit and the mother liquor was evaporated to dryness to give the amines in analytically pure form. [b] The reaction was considered complete when no starting azide was detected by TLC. [c] In a typical reaction the conditions were the same as above with the exception that **1** was replaced by a polystyrene–$PPh_3$ resin (1.1 mmol) (Aldrich Chem. Co.). The work-up involved filtration of the resin followed by evaporation of the filtrate.

**Table 2** Alkyl aryl ethers prepared[a] with either **1** or polystyrene–$PPh_3$

| | **1** | | Polystyrene–$PPh_3$ | |
|---|---|---|---|---|
| Alcohol | Yield (%) | *t*/h[b] | Yield (%) | *t*/h[c] |
| Butan-1-ol | 85 | 3 | 87 | 8 |
| Isopropanol | 88 | 5 | 94 | 7 |
| Allyl alcohol | 87 | 2 | 82 | 5 |
| Benzyl alcohol | 75 | 10 | — | No reaction |

[a] In a typical reaction, phenol (1 mmol) was added to **1** or polystyrene–$PPh_3$ (1.5 mmol) in $CH_2Cl_2$ (3 ml) and stirred for 20 min. Then the listed alcohol (1 mmol) and DEAD (1.1 mmol) were added and the reaction stirred at room temp. [b] On completion, the reaction mixture was concentrated to half volume and the urea side-product filtered. The reaction mixture was then poured onto diethyl ether. The used PEG reagent was filtered and the mother liquor concentrated to give the pure ether products. [c] The workup procedure involved filtration of the resin and concentration to allow removal of the hydrazine side-product. The pure ether products were isolated by evaporation of the $CH_2Cl_2$.

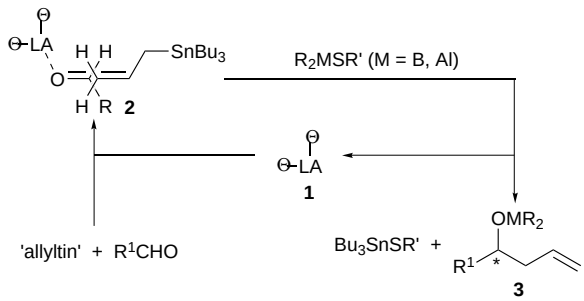
# Bifunctional molecular accelerator for catalytic asymmetric allylation: $R_2MSR'$ (M = B, Al) as a useful synergetic reagent



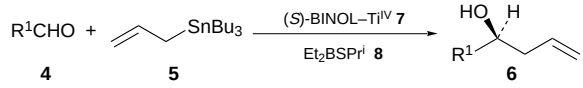
**Chan-Mo Yu,* Ha-Soon Choi, Won-Hyuk Jung, Hyuk-Jun Kim and Jaewook Shin**

*Department of Chemistry, Sung Kyun Kwan University, Suwon 440-746, Korea*

**Dramatic acceleration of the catalytic process of asymmetric allylation of achiral aldehydes is observed by the utilization of the bifunctional synergetic reagents $R_2MSR'$ (M = B, Al).**

Chiral homoallyl alcohols are very useful intermediates for the enantioselective synthesis of complex chiral substances.[1] The exceptional power of the allyl transfer reaction to aldehydes in forming optically active homoallylic alcohols has been enhanced by newly developed enantioselective versions, especially chiral Lewis acid-catalysed addition of the allyl transfer reagent to a carbonyl functionality.[2] The development of synthetic methods for achieving absolute stereoselection by the utilization of chiral catalysts increasingly requires precise control of the reaction pathway based on mechanistic behaviour and the rational design of new reagents and processes.[3] The geometrical possibilities offered by chemical transformation together with the predictable power of mechanistic behaviour can allow the design of new catalytic systems. Recently, we demonstrated the utilization of the molecular accelerator $Me_3SiSPr^i$, designed on the basis of mechanistic speculation, for catalytic asymmetric allylation that resulted in not only a significant increase in the reaction rate but also a reduced dosage of chiral catalyst.[4] Described herein is an extension of the molecular accelerating strategy aimed at finding new reagents and realizing useful and practical asymmetric syntheses. This research led to the discovery of the remarkable synergetic reagent $R_2M–SR'$ (M = B, Al), which expedites the catalytic process of asymmetric allylation with high levels of enantioselectivity. In the present research, two major advances have been made in the enantioselective synthesis of homoallylic alcohols: (i) this system exhibited a dramatic increase in catalytic ability; (ii) alkylthioborane has advantages over alkylthiosilane in terms of efficacy, stereoselectivity and applicability to other systems.

Our rationale for the introduction of a molecular accelerator into the catalytic system was based on speculation illustrated in Scheme 1. In order to increase catalytic ability, regeneration of chiral catalyst **1** as a consequence of dissociation of product **3** from the reaction complex must be achieved. We reasoned that if a bifunctional synergetic reagent, *i.e.* $R_2MSR'$(M = B, Al), could control the catalytic allylation process *via* the Sn–S (enhancement of Sn–C bond breaking) and M–O (dissociation of product **3**) bond forming steps to reinforce regeneration of catalyst **1**, practical and efficient catalytic asymmetric allylation might be realized in a predictable fashion. The key to this prediction is the strong Sn–S and M–O bonds relative to the weaker M–S bond.



**Scheme 1**

The starting point of this present research was the availability of $R_2BSR'$; alkylthioboranes are readily prepared in quantity, easily purified by distillation and stable to storage.[5] Several alkylthioboranes ($R_2BSR'$: R = Et, Bu; R′ = Et, $Pr^i$, Bu, $Bu^t$, Ph) were prepared and examined for their abilities as synergetic reagents in the allylation of hydrocinnamaldehyde with allyltributylstannane in the presence of (*S*)-BINOL–$Ti^{IV}$ complex **7** (10 mol%).† Preliminary investigations indicated that efficient allylation was realized with $Et_2BSPr^i$ at −20 °C for 5 h (93% isolated yield; 97% ee); this result is superior to the control system (−20 °C for 70 h, 78% isolated yield with 94% ee). Upon optimisation, the catalytic allyl transfer reaction was conducted by dropwise addition of $Et_2BSPr^i$ (**8**, 1.2 equiv.) in $CH_2Cl_2$ at −20 °C to the mixture of **4** ($R^1$ = $CH_2CH_2Ph$, 1.0 equiv.) and **5** (1.3 equiv.) in the presence of chiral catalyst **7** (10 mol%) and 4 Å molecular sieves. After 5 h at −20 °C, the resulting reaction mixture was treated with aqueous $NaHCO_3$. After work up, the final purification of the homoallyl alcohol can be effected by silica gel chromatography.

This discovery prompted us to carry out more experiments with reduced amounts of chiral catalyst. Indeed, we were delighted to find that the same reaction proceeds with 1 mol%

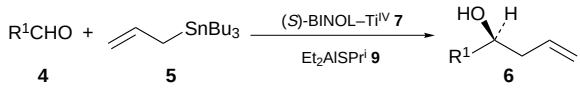
[a] All reactions were run at −20 °C in $CH_2Cl_2$. [b] Absolute configurations were determined by direct comparison with specific rotations of known alcohols. [c] BINOL–$Ti(OPr^i)_4$ = 2:1 ratio. [d] Chromatographed yields. [e] Enantiomeric exess was determined using chiral shift reagent [Eu(hfc)$_3$] and by preparation of (+)-MTPA ester derivatives, analysis by $^1$H NMR spectroscopy and comparison with authentic samples.

(*S*)-BINOL–$Ti^{IV}$ complex to give a 77% isolated yield with 93% ee. Additional experiments with various aldehydes were carried out and representative results are summarized in Table 1. The reactions are generally complete after 5–8 h at −20 °C. We observed that better enantioselectivities and chemical yields were obtained with less hindered aldehydes compared to the more substituted cyclohexanecarbaldehyde.



Although the role of $Et_2BSPr^i$ in accelerating the allyl transfer reaction must be a consequence of the dissociation of the product from reaction complex with regeneration of chiral catalyst, the exact mechanism has not been rigorously elucidated, and may involve concerted or stepwise participation.[6]

We next turned our attention to examining the feasibility of this system using a alkylthioalane.[7] Several catalytic allylations of aldehydes employing $R_2AlSR'$ were conducted under identical conditions to those described above, and the use of $Et_2AlSPr^i$ **9** proved to be most effective. Representative results are listed in Table 2. It is worthy of note that the catalyst–$Et_2AlSPr^i$ system affords high enantioselectivities and chemical yields with 10 mol% of catalyst after 5 h, while with reduced amount of catalyst, especially less than 5 mol%, sharply reduced levels of asymmetric induction are observed.‡

In conclusion, an efficient method for the catalytic enantioselective addition of allyltributylstannane to aldehyde is described which employs a molecular accelerator, $R_2MSR'$, and 1–2 mol% of BINOL–$Ti^{IV}$, furnishing homoallylic alcohol in good yield with useful levels of enantioselectivity. We believe that this approach to increasing catalytic ability by the use of synergetic reagents could be widely applicable, not only in the field of asymmetric carbonyl addition, but also in other related reactions.

## Footnotes

† For the allylation reaction described herein, optimal enantioselectivity are observed with 2 : 1 BINOL–$Ti(OPr^i)_4$ in the presence of activated 4 Å molecular sieves.

‡ According to the results of control experiments under identical condition except for the use of catalyst, $Et_2BSPr^i$ did not catalyse allyl transfer, while $Et_2AlSPr^i$ turned out to be a very weak promoter. We did not observe any transmetallation reactions between Sn and B or Al.

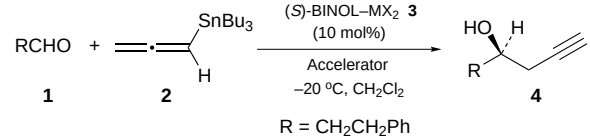
# Catalytic asymmetric prop-2-ynylation involving the use of the bifunctional synergetic reagent $Et_2BSPr^i$

**Chan-Mo Yu,* Sook-Kyung Yoon, Ha-Soon Choi and Kwangwoo Baek**

*Department of Chemistry, Sung Kyun Kwan University, Suwon 440-746, Korea*



**Efficient catalytic asymmetric prop-2-ynylation of achiral aldehydes with allenyltributylstannane promoted by a BINOL–$Ti^{IV}$ complex (10 mol%) is achieved with high enantioselectivity by the use of $Et_2BSPr^i$.**

We report here a useful catalytic method for the enantioselective synthesis of but-3-yn-1-ols from the reaction of an allenyltin reagent with achiral aldehydes promoted by a chiral Lewis acid together with a synergetic reagent. Among the fundamental asymmetric reactions, allylic transfer from chiral reagents to a carbonyl functionality, forming enantiomeric rich homoallylic alcohols, attracts considerable attention from the synthetic community since the resulting products serve as chiral building blocks for multi-step syntheses.[1] In spite of the structural versatility of the prop-2-ynylic system, there have been few reports in this area compared with the allylic system, mainly due to a lack of reactivity and regiochemical problems.[2] While a couple of chiral allenyl reagents employing chiral auxiliaries have been developed to realize a highly enantio- and regio-selective synthesis of but-3-yn-1-ols,[3] catalytic chiral Lewis acids have been introduced in the reaction of aldehydes with allenylstannane.[4] Nonethless, the method for catalytic asymmetric prop-2-ynylation employing chiral Lewis acids is not ideal, mainly due to poor catalytic ability (50–100 mol%) and long reaction times (72–100 h). The method described herein is successful with a variety of aldehydes in the presence of a catalyst employing a bifunctional synergetic reagent and affords products of high enantiomeric purity. The process utilizes a readily available alkylthioborane as a synergetic reagent.

Our initial studies began with hydrocinnamaldehyde **1** and allenyltributylstannane **2**.[5] Treatment of **1** with **2** in the presence of (*S*)-BINOL–$Ti^{IV}$ (10 mol%) in $CH_2Cl_2$ at −20 °C for 24 h afforded only a barely detectable amount of adduct **4**. We subsequently observed that synergetic reagents, which were previously utilized for catalytic asymmetric allylation,[6] can also be employed for catalytic asymmetric prop-2-ynylation. After surveying series of alkylthioboranes and alkylthiosilanes, several key points emerged: (i) $Et_2BSPr^i$ was generally superior to other reagents, including $Me_3SiSPr^i$; (ii) a 1 : 1 mixture of the BINOL–$Ti(OPr^i)_4$† or BINOL–$Zr(OPr^i)_4$‡ complexes proved to be the most effective catalyst; (iii) the new systems exhibited a dramatic acceleration of the reaction rate as well as significantly increasing catalytic ability in comparison with the non-accelerator system;[4] (iv) optimal chemical yields and enantioselectivities were observed with the use of $CH_2Cl_2$ as a solvent compared to other solvents such as toluene, diethyl ether or propionitrile. Selected results for the preliminary studies are summarised in Table 1. Especial encouraging were entries 2 and 5; therefore, chiral catalysts BINOL–$Ti^{IV}$ and –$Zr^{IV}$ with $Et_2BSPr^i$ were chosen for systematic studies because they exhibited high level of enanatioselectivity with reasonable chemical yields.

The prop-2-ynylation reaction was performed according to the following procedure: all reactions were carried out in the presence of 4 Å molecular sieves to remove any trace of water. To a solution of **1** (R = $CH_2CH_2Ph$, 1 equiv.) and **2** (1.3 equiv. in the presence of (*S*)-BINOL–$Ti^{IV}$ **5** (10 mol%) at −20 °C was added dropwise $Et_2BSPr^i$ (1.2 equiv.) in $CH_2Cl_2$. After 9 h at −20 °C, the reaction mixture was quenched by the addition of saturated aqueous $NaHCO_3$. Work up and silica gel chromatography ($SiO_2$, deactivated with 1% of $Et_3N$ in hexane; eluent, hexane–EtOAc) afforded the alcohol **4** (R = $CH_2CH_2Ph$) in 86% isolated yield and 94% ee. Using these optimal conditions, a range of experiments on the catalytic asymmetric prop-2-ynylation of aldehydes was carried out. From Table 2 it can be seen that asymmetric prop-2-ynylations were conducted on a variety of aldehydes under identical conditions to furnish alcohols **4** with excellent enantioselectivities. Reaction times and chemical yields, as indicated in Table 2, were dependent on the steric environment of the substrates. It is worthy of note that the reaction also produced trace amounts of isomeric allenyl alcohol ( < 2%) according to analysis of the $^1H$ NMR spectra of the crude products. A reduced dosage of chiral catalyst **5**

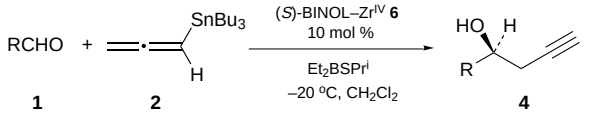
| 7 | Ph | 10 | 15 | 52 | 92 |



[a] All reactions were run at −20 °C. [b] Absolute configurations were verified by comparison of specific rotation sign with authentic and/or literature values. [c] Yields refer to isolated and purified products. [d] Enantiomeric excess values were determined by preparation of (+)-MTPA ester derivatives, analysis by $^1H$ NMR spectroscopy (C*H*OR) and comparison with authentic and racemic samples.

resulted in diminished chemical yields, longer reaction times and poorer stereoselectivites.

Catalytic asymmetric prop-2-ynylation promoted by the (*S*)-BINOL– $Zr^{IV}$ ‡ complex was also investigated under similar conditions to those described above. Most of the isolated major alcohols were contaminated with a trace of the isomeric allenyl alcohol ( < 3%), but in the case of cyclohexanecarbaldehyde the product ratio proved to be 93 : 7 as judged by $^1$H NMR spectroscopic analysis of the crude products. The data summarised in Table 3 allow the following points to be stated: (i) as expected, the process using the molecular accelerator is effective in terms of reaction time as well as chemical yield; (ii) in general, the $Zr^{IV}$ complex provides modest to excellent enantioselectivities, which are somewhat lower than those of the $Ti^{IV}$ complex; (iii) the enantioselectivities correlate with the degree of steric hindrance in the substrates.

The work disclosed here is innovative mainly because of the reinforcement of catalytic ability outlined, especially with the less reactive allenylstannane.[8] However, further extension of the understanding of this chemistry is required in the following areas: (i) the exact mechanism by which $Et_2BSPr^i$ accelerates the catalytic process,which involves dissociation of the product from the reaction complex and regeneration of the chiral catalyst; (ii) the origin of isomeric allenyl alcohols is also unclear, and may involve equilibration between allenyl- and prop-2-ynyl-tin reagents or α- and γ-orientation to tin in the transition state.

**Table 3** Catalytic prop-2-ynylation promoted by the BINOL-$Zr^{IV}$ complex

**1** **2** **4**

| Entry | R | *t*/h | Yield (%) | Ee (%) |
|---|---|---|---|---|
| 1 | $PhCH_2CH_2$ | 9 | 72 | 92 |
| 2 | $C_6H_{11}$ | 9 | 71 | 87 |
| 3 | c-$C_6H_{11}$ | 15 | 67 | 68 |
| 4 | $Me_2CHCH_2$ | 15 | 65 | 91 |
| 5 | Ph | 15 | 44 | 71 |

[a] All conditions were identical with those of Table 2.

In conclusion, the enantioselective prop-2-ynylation of achiral aldehydes, a process of clear synthetic potential, has been advanced to a new level of practicality and stereoselectivity as a result of the utilization of a molecular accelerator to increase catalytic ability and reactivity. Studies are in progress to extend this chemistry to more highly functionalised tin reagents, including racemic allenylstannanes for kinetic resolutions. We believe that further studies will provide a better understanding of this chemical phenomenon.

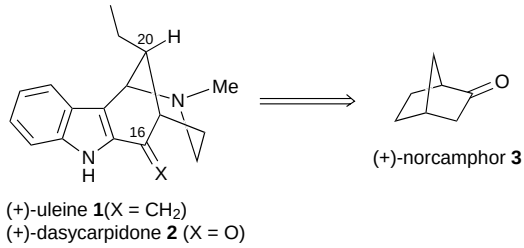
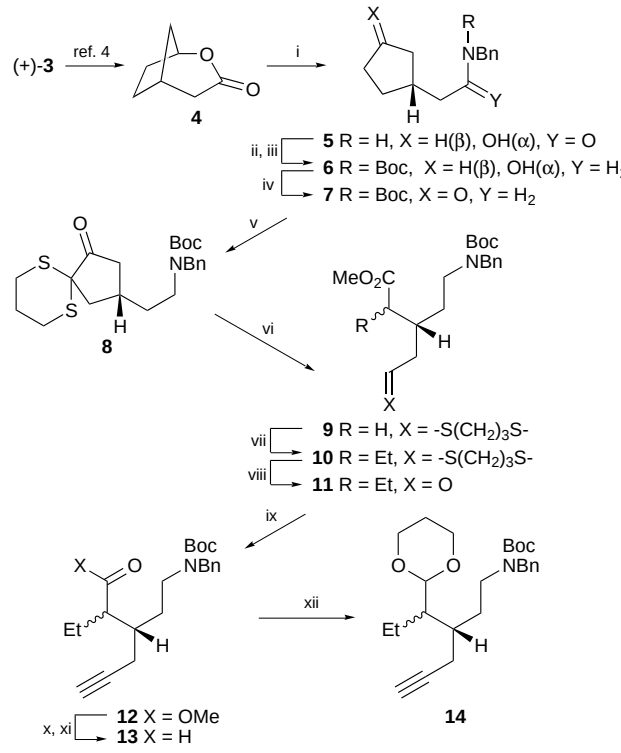
# First enantiocontrolled syntheses of (+)-uleine and (+)-dasycarpidone

**Masanori Saito, Mitsuhiro Kawamura, Kou Hiroya and Kunio Ogasawara***



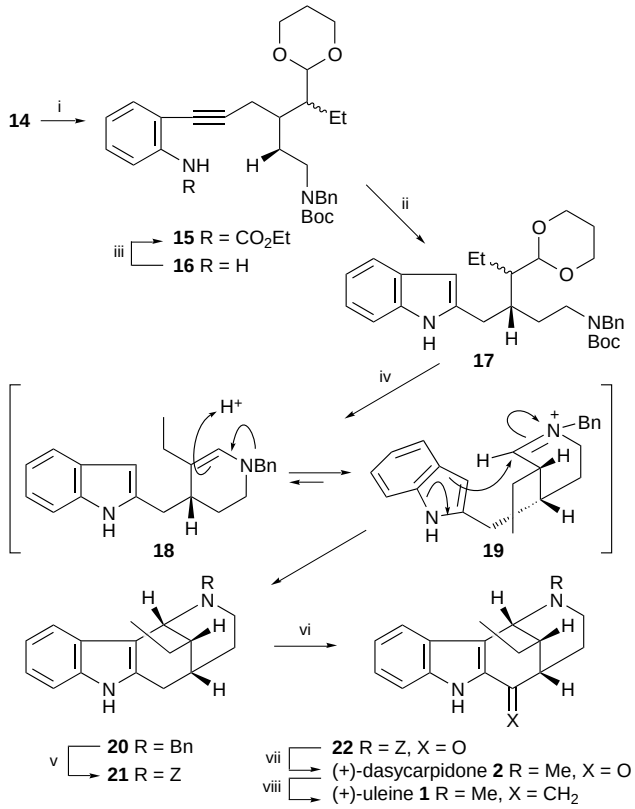
*Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980-77, Japan*

**Stereocontrolled syntheses of (+)-uleine and (+)-dasycarpidone are achieved for the first time in an enantiocontrolled way starting from (+)-norcamphor.**



Although a number of racemic syntheses of the uleine type indole alkaloids have been reported,[1] no enantiocontrolled synthesis has been disclosed to date. We report here the first stereo- and enantio-controlled construction of the representatives of this group, (+)-uleine **1** and (+)-dasycarpidone **2**, using (+)-norcamphor **3** as starting material (Scheme 1).[2]

(+)-Norcamphor **3**† was first transformed into the δ-lactone **4**[3a] which was then condensed with benzylamine to give the amide alcohol **5**,‡ mp 94–95 °C, $[\alpha]_D^{33}$ −1.95 (*c* 0.55, $CHCl_3$), in 75% yield. Hydride reduction of **5** followed by *N*-carbamoylation of the resulting amine yielded the carbamate **6**, $[\alpha]_D^{27}$ −0.76 (*c* 1.0, $CHCl_3$), which was oxidized to give the cyclopentanone **7**, $[\alpha]_D^{30}$ +58.0 (*c* 0.9, $CHCl_3$), in 90% overall yield. Transformation of **7** into the α-diketone monothioketal[3,4] **8**, mp 72–74 °C, $[\alpha]_D^{29}$ −43.5 (*c* 0.742, $CHCl_3$), followed by alkaline cleavage[3–5] yielded the acyclic methyl ester **9**, $[\alpha]_D^{31}$ +43.1 (*c* 0.3, $CHCl_3$), in 59% overall yield after treatment of the resulting acid with diazomethane. Exposure of **9** to iodoethane in the presence of sodium hexamethyldisilazide in THF containing HMPA at −78 °C afforded the α-ethyl ester **10** in 73% yield as an inseparable epimeric mixture with recovery of 14% of the starting material. The dithiane group of **10** was hydrolysed to give the aldehyde **11** in 92% yield which was treated with dimethyl 1-diazo-2-oxopropylphosphonate[6] in the presence of potassium carbonate to furnish the terminal acetylene **12** in 90% yield. Compound **12** was then converted into the 1,3-dioxane **14** in 72% overall yield *via* the aldehyde **13** by sequential reduction, oxidation and acetalization[7] (Scheme 2).



To construct the indole framework,[8,9] the acetylene **14** was first coupled with ethyl (2-iodophenyl)carbamate in the presence of dichlorobis(triphenylphosphine)palladium(II) [$PdCl_2(PPh_3)_2$] and copper(I) iodide in triethylamine[10] to give the arylacetylene **15** in 86% yield. Cyclization was then carried out by treating **15** with sodium ethoxide in ethanol[8,9] at reflux to furnish the indole **17** in 64% yield accompanied by 31% of the de-*N*-acylated product **16** which, after separation, was treated with ethyl chlorocarbonate in pyridine to recover the carbamate **15** in 81% yield. The indole **17**, on reflux with TFA, afforded stereoselectively the tetracyclic amine **20**, $[\alpha]_D^{29}$ −155.3 (*c* 0.7, $CHCl_3$), in 54% yield accompanied by the readily separable 20-epimer (4%) by spontaneous deacetalization, decarbamoylation and stereoselective cyclization. The observed stereoselectivity may be rationalised by intervention of the enamine intermediate **18** which allowed epimerization of the C-20 stereogenic centre and stereoselective generation of the iminium intermediate **19** followed by its stereoselective cyclization[2a,b,d] under the conditions. Since the amine **20** was found to be unstable under the oxidation conditions, it was first transformed into the carbamate **21**, $[\alpha]_D^{28}$ +89.4 (*c* 0.4, $CHCl_3$), in 74% overall yield by sequential catalytic debenzylation and carbamoylation.[2d] The resulting carbamate **21** was then treated with pyridinium dichromate (PDC) on Celite in the presence of *tert*-butyl hydroperoxide (TBHP)[11] in benzene to afford the 16-ketone **22**, $[\alpha]_D^{28}$ +231.8 (*c* 0.2, $CHCl_3$), in 54% yield. Concurrent *N*-deprotection and *N*-methylation of **22** under the reductive conditions[2d] in the presence of 37% formalin afforded (+)-dasycarpidone **2**, $[\alpha]_D^{30}$ +63.1 (*c* 0.7, $CHCl_3$) [natural: $[\alpha]_D^{26}$ +64.7 (*c* 1.02, $CHCl_3$)],[12] in 83% yield. By following the established procedure,[2a,b] (+)-dasycarpidone **2** obtained was transformed into (+)-uleine **1**, $[\alpha]_D^{27}$ +18.2 (*c* 0.3, $CHCl_3$) [natural: $[\alpha]_D^{25}$ +16.5 (*c* 0.91, $CHCl_3$);[12] $[\alpha]_D^{27}$ +20 (*c* 0.94, $CHCl_3$)[13]], in 71% overall yield on treatment with methyl-

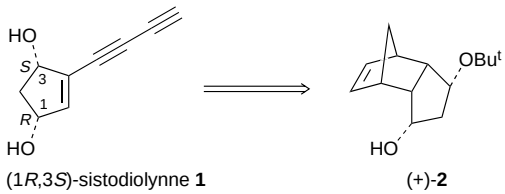
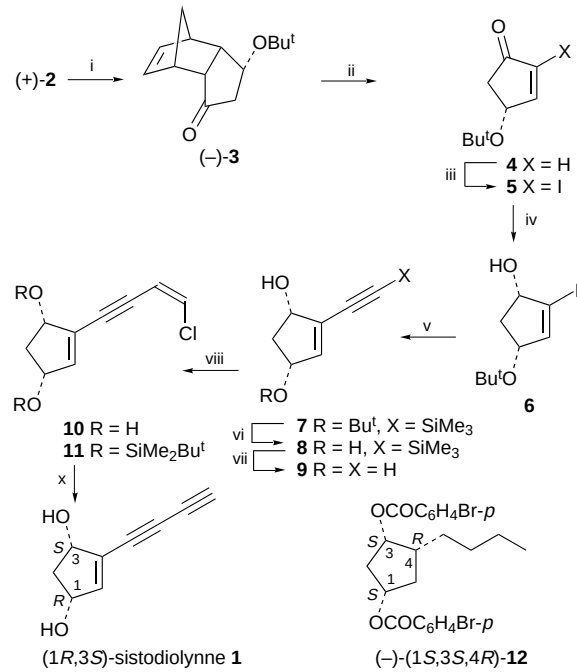
# Enantiocontrolled construction of sistodiolynne, an unusual polyketide from the wood-decay fungus *Sistrema raduloides*

**Tsutomu Sugahara and Kunio Ogasawara***



*Pharmaceutical Institute, Tohoku University, Aobayama, Sendai 980-77, Japan*

**Sistodiolynne, an unusual polyketide isolated from the wood decay fungus *Sistorema raduloides*, has been constructed stereoselectively from a chiral cyclopentenol building block to verify the proposed structure.**



Sistodiolynne [(1*R*,3*S*)-4-butadiynylcyclopent-4-ene-1,3-diol] **1** is a metabolite of the wood rot decay fungus *Sistorema raduloides* (P. Karst) Donk which was recovered from indoor air of a museum in San Juan, Puerto Rico.[1] The compound **1** proved to be extremely air-sensitive and only stable in solution. It has been shown by labelling experiments that it arises from five acetate units with loss of a methyl carbon from one of the acetate units during the biosynthesis. Its structure was determined by spectroscopic methods, mainly, NMR, and the absolute configuration was proposed by circular dichroism of the di(4-bromobenzoate) of the perhydro derivative of the natural product. In relation to our recent synthesis of chiral cyclopentenone building blocks,[2,3] we were interested in converting our chiral cyclopentenol block **2** into sistodiolynne **1** so as to establish an enantiocontrolled synthesis and to confirm the proposed structure. Here we report the first construction of sistodiolynne **1** and the all-*cis* di(4-bromobenzoate) (−)-**12** of the perhydro derivative of **1**, which verified the proposed structure for the natural product (Scheme 1).

The optically pure tricyclic alcohol[2] (+)-**2**, $[\alpha]_D^{28}$ +75.4 (*c* 1.2, $CHCl_3$), mp 95 °C, obtained by lipase-mediated kinetic resolution,[2] was first transformed into the (*R*)-cyclopentenone[2,4] **4**, $[\alpha]_D^{28}$ +53.2 (*c* 0.9, MeOH), in 72% overall yield *via* the tricyclic ketone (−)-**3**, $[\alpha]_D^{26}$ −186.6 (*c* 1.0, $CHCl_3$), by sequential oxidation and thermolysis (Scheme 2). Although optically active **4** may be obtained more directly from the cyclopentenol precursor by a similar lipase-mediated resolution[2] or from racemic **4** by chemical resolution,[4] the present procedure seemed more appropriate with respect to the optical purity of the product. Exposure of **4** to iodine in the presence of pyridine[5] gave the air sensitive α-iodo enone **5**, which was immediately reduced with sodium borohydride–cerium(III) chloride[6] to give stereoselectively *cis*-4-*tert*-butoxy-2-iodocyclopent-2-enol†‡ **6**, $[\alpha]_D^{28}$ +41.0 (*c* 0.9, $CHCl_3$), mp 90–92.5 °C, as a single product in 92% overall yield from **4**. The stereochemistry of **6** was determined by a NOE experiment on the benzoate of **6**, which exhibited significant interaction between the C(1) ($\delta_H$ 5.70) and C(4) ($\delta_H$ 4.54) protons. Moreover, the stereochemistry of **6** was confirmed unambiguously by converting it into *cis*-4-*tert*-butoxycyclopent-2-enol[2] in 80% yield on exposure to *tert*-butyllithium followed by acetic acid in tetrahydrofuran (THF) at −78 °C. A cross-coupling reaction[7,8] between **6** and trimethylsilylacetylene proceeded without difficulty using dichlorobis(triphenylphosphine)palladium(II) $[PdCl_2(PPh_3)_2]$[9] as catalyst in the presence of copper(I) iodide in triethylamine to give the enyne **7**, $[\alpha]_D^{28}$ +70.2 (*c* 1.4, $CHCl_3$), in 96% yield. To remove the two different protecting groups, **7** was sequentially exposed to titanium(IV) chloride[2,10] and tetrabutylammonium fluoride to give *cis*-1-ethynylcyclopent-1-ene-3,5-diol **9**, $[\alpha]_D^{25}$ −40.8 (*c* 0.5, $CHCl_3$), in 70% overall yield *via* **8**.

Very fortunately, a mild two-step construction of a 1,3-diyne functionality from a terminal acetylene exists.[11] To apply this procedure, **9** was first coupled with *cis*-1,2-dichloroethylene in the presence of tetrakis(triphenylphosphine)palladium(0)[12] in butylamine to give the dienynediol **10**, accompanied by a trace of inseparable phenylphosphine impurities, which was isolated in the pure state as the di(*tert*-butyldimethylsilyl) ether **11**, $[\alpha]_D^{27}$ −43.8 (*c* 0.3, $CHCl_3$), by treating the mixture with *tert*-butyldimethylsilyl chloride in the presence of imidazole. The overall yield of **11** from **9** was 71%. Exposure of **11** to tetrabutylammonium fluoride (5 equiv.) in THF at room temperature[11] for 10 h furnished sistodiolynne **1** as a highly unstable oil by concurrent desilylation and dehydrochlorination. Although the product generated could not be isolated in a pure

state as it polymerised even in a solution during purification as described,[1] its $^1$H NMR spectrum measured directly [in $(CD_3)_2CO$] was identical to that of the natural product.[1]

On the other hand, **11** was hydrogenated under medium-pressure conditions in the presence of palladized carbon to convert it into the mixture containing the stable perhydro derivative of the natural product **1** as the major product. The major product isolates as the di(4-bromobenzoate) **12**, after desilylation and 4-bromobenzoylation, had a circular dichroism (CD) spectrum, showing the first Cotton effect (negative) at 251 nm and the second (positive) at 234 nm, which was identical to that reported for **12** having the 1*S*,3*S*,4*R* configuration (negative at 251 nm and positive at 231 nm) originated from the natural product **1**. This indicated the stereochemistry of sistodiolynne **1** to be 1*R*,3*S* as proposed.

In summary, we could not isolate sistodiolynne **1** in a pure form owing to its intrinsic instability, however, the present synthesis verified the correctness of the proposed structure of the natural product made by spectroscopic methods.

# Characterisation of two different mixed-valence states in a strongly interacting dimolybdenum complex

**Andrzej Wlodarczyk,* Garry A. Doyle, John P. Maher, Jon A. McCleverty* and Michael D. Ward**

*School of Chemistry, University of Bristol, Cantock's Close, Bristol, UK BS8 1TS*

**The pyrazine-bridged bimetallic complex [{Mo(NO)[HB(dmpz)$_3$]Br}$_2$(μ-pz)]$^z$ [HB(dmpz)$_3$ = tris(3,5-dimethylpyrazolyl)borate] exists within a five-membered electron-transfer chain where $z$ = −2, −1, 0, +1 and +2; the mixed-valence species with $z$ = −1 is delocalised on the EPR and IR spectroscopic timescales whereas that with $z$ = +1 is valence-trapped.**

The most celebrated dimetallic mixed-valence compound is the so-called Creutz–Taube ion, [{Ru(NH$_3$)$_5$}$_2$(μ-pz)]$^{5+}$, derived by coupling two Ru$^{II}$ pentammine fragments by pyrazine followed by one-electron oxidation of the product.[1] It is now generally accepted that this ion exhibits class III mixed-valence behaviour, namely that the unpaired electron is delocalised over the metal ions and the bridging ligand.[2] Many other examples of such mixed-valence species have been described, showing a wide range of behaviour from fully delocalised to valence-trapped.[2] The majority of these species are usually assembled by coupling diamagnetic monometallic fragments using bridging ligands of varying lengths, geometries and delocalisation. In all but a few cases, these precursors are oxidised in a one-electron process to generate the mixed-valence ion, although two types of molybdenum complex, [{Mo(CO)$_3$(PR$_3$)}$_2$(1,4-pz)]$^-$ (ref. 3) and [{Mo(NO)[HB(dmpz)$_3$]X}$_2${C$_6$H$_4$(NH)$_2$-1,4}]$^-$ (X = Cl, Br, I),[4] are generated by reduction of the diamagnetic precursors, the former being described as a radical anionic ligand stabilised by metal carbonyl fragments,† whereas the latter is fully delocalised on the EPR timescale.

For a number of years we have been studying a series of binuclear molybdenum nitrosyls containing bridging dipyridine ligands. These complexes contain two metal-based redox centres whose interaction, determined electrochemically, is mediated significantly by the bridging ligand.[5] Furthermore, these compounds are paramagnetic (one unpaired electron on each metal atom), the unpaired spins being coupled either ferro- or antiferro-magnetically depending on bridging ligand geometry, and their EPR spectra reveal spin–spin correlation over remarkably long distances.[6] Our preceding work on molybdenum nitrosyl complexes of 4,4′-dipyridyl and its analogues, [{Mo(NO)[HB(dmpz)$_3$]Cl}$_2$(NC$_5$H$_4$EC$_5$H$_4$N)] [E = nothing, (CH=CH)$_n$, (C$_6$H$_4$)$_n$] has shown that the metal–metal interactions gradually diminish with increasing length of E. Conversely we expected that a dimetallic species containing 1,4-pyrazine as bridge should reveal very substantial electrochemical and magnetic interactions, at least twice as large as those in the Creutz–Taube ion ($\Delta E_p$, the separation between the redox potentials, is *ca*. 390 mV).

Our early attempts to make species of the type [{Mo(NO)[HB(dmpz)$_3$]X}$_2$(1,4-pz)] (X = Cl or I) were partially successful, revealing unexpectedly rich electrochemical behaviour,[7] although the species were difficult to purify and also appeared to decompose readily. However, we have now obtained pure samples of the bromo complex, [{Mo(NO)[HB(dmpz)$_3$]Br}$_2$(1,4-pz)].‡ In contrast to the behaviour of [{Ru(NH$_3$)$_5$}$_2$(1,4-pz)]$^{5+}$ in aqueous media, this species exhibits two reversible one-electron reductions (established coulometrically) as well as two reversible one-electron oxidations. The former occur at −0.95 and −2.39 V in dichloromethane *vs*. the ferrocene–ferrocenium couple, and the latter at +1.08 and +1.18 V, respectively. The separation between the reduction potentials, a measure of the coulombic interaction between the two redox centres, is 1440 mV, the largest we have so far detected and amongst the largest known, equivalent to a comproportionation constant $K_c = 2.2 \times 10^{24}$. For the first time we have also detected a separation between the oxidation processes in this class of dimetallic, *viz*. 100 mV ($K_c$ = 49). That interaction between the reduction processes is so much larger than that between the oxidations implies that the added electrons in the reduced form are substantially delocalised over the bridge whereas the unpaired electron in the oxidised form is not. Thus [{Mo(NO)[HB(dmpz)$_3$]Br}$_2$(1,4-pz)]$^z$ exists within a five-membered electron-transfer chain ($z$ = −2, −1, 0 +1 and +2), reminiscent of dithiolene complexes,[8] in which the formal valence-electron configuration of the two metals may be represented as {18 : 18}$^{2-}$, {18 : 17}$^-$, {17 : 17}, {17 : 16}$^+$ and {16 : 16}$^{2+}$.

The green isovalent parent species ($z$ = 0; {17 : 17}) is EPR 'silent' in contrast to related bipyridyl species [{Mo(NO)-[HB{dmpz)$_3$]Cl}$_2$(NC$_5$H$_4$EC$_5$H$_4$N)].[5,6] We expect that the unpaired spins in this species will be quite strongly coupled antiferromagnetically, as we have observed in analogues,[6] and in such circumstances EPR signals are not observed.§ The deep blue reduced monoanion ({18 : 17}$^-$), generated by cobaltocene reduction, exhibits an EPR spectrum composed of the superimposition of one, six and eleven line multiplets derived by a single electron coupling equally to both metal nuclei ($^{95}$Mo, $^{97}$Mo $I$ = 5/2; *ca*. 25% abundance in total),¶ with $g$ = 1.979, $A_{Mo}$ = 2.9 mT. The IR spectrum of the neutral precursor exhibits a single NO stretching frequency at 1626 cm$^{-1}$ (in $CH_2Cl_2$) which, on reduction, moves to 1585 cm$^{-1}$, but remains a single peak. Our spectral data are consistent with class III, fully delocalised mixed-valence behaviour for the {18 : 17}$^-$ monoanion on both the EPR and the IR timescale, implying that the electron exchange rate is $10^{13}$ s$^{-1}$ or faster. Our previously reported mixed-valence molybdenum complexes [{Mo(NO)[HB(dmpz)$_3$]X}$_2${C$_6$H$_4$(NH)$_2$-1,4}]$^-$ are delocalised on the EPR timescale,[4] but localised according to their IR spectra (two $\nu_{NO}$) indicating that the electron exchange rate lies between $10^8$ and $10^{13}$ s$^{-1}$. Such behaviour is very rare although it has been detected in binuclear iron carbonyls and rhenium nitrosyls.[9]

Further electrochemical reduction to generate the dianion, {18 : 18}$^{2-}$, which we predict should be diamagnetic, is difficult because of the proximity of the reduction process to the decomposition of the electrolysis medium, but by monitoring the EPR spectrum of the monoanion while reduction was occurring, we observed that the intensity of the signal decreased significantly without qualitative change in its appearance, *i.e*. consistent with the formation of diamagnetic material.

Oxidation of the neutral precursor by controlled potential electrolysis in dichloromethane at +1.05 V, afforded a brown solution of [{Mo(NO)[HB(dmpz)$_3$]Br}$_2$(1,4-pz)]$^+$ ({17 : 16}$^+$), the EPR spectrum of which was difficult to obtain due to decomposition but appeared unlike that of the monoanion described above and contained sextet signals with $A_{Mo}$ *ca*. 5.0 mT. However, the isoelectronic chloride,

$[\{Mo(NO)[HB(dmpz)_3]Cl\}_2(1,4\text{-pz})]^+$ (generated similarly), was more stable, exhibiting an EPR spectrum with $g$ = 1,979 and $A_{Mo}$ = 4.8 mT, having a one and six line superimposed pattern,¶ which shows that the unpaired electron is coupled with only one Mo atom. The IR spectrum of the bromo monocation exhibited two NO stretching frequencies, at 1720 and 1606 $cm^{-1}$ (the chloro species was similar, $\nu_{NO}$ = 1717, 1608 $cm^{-1}$). The fully oxidised brown dication $[\{Mo(NO)[HB(dmpz)_3]Br\}_2(1,4\text{-pz})]^{2+}$ ($\{16:16\}^{2+}$) was prepared by oxidation of the neutral parent by acetylferrocenium ion. It was EPR 'silent' and therefore probably diamagnetic, and exhibited only one $\nu_{NO}$ (1703 $cm^{-1}$). On the basis of these spectral data we conclude that the partially oxidised monocations $[\{Mo(NO)[HB(dmpz)_3]X\}_2(1,4\text{-pz})]^+$ (X = Cl, Br) are valence-trapped.

While the isovalent $[\{Mo(NO)[HB(dmpz)_3]Br\}_2(1,4\text{-pz})]$ ($\{17:17\}$) behaves in a way reminiscent of its ruthenium analogue, it exhibits more extensive electron-transfer capability. This is partly a function of solvent, base electrolyte, *etc.*, and the original Creutz–Taube ion was characterised electrochemically in aqueous media which has a more limited voltage window. Nevertheless, the dinuclear molybdenbum nitrosyl described here is one of the very few compounds in which mixed-valence behaviour is generated by oxidation and reduction and it is unique in giving rise, reversibly, to two different classes of mixed-valence states without significant structural modification. The electrochemical data nicely complement the EPR spectral results, since the character of the mixed-valence states is related to the comproportionation constants for the mixed-valence species, a large value of $K_c$ implying substantial delocalisation while a small $K_c$ implies significantly less interaction.

We are grateful to the EPSRC for the support of this work, and to the Politechnika Krakowska for leave of absence for A. W.

† This system cannot be defined as a genuine mixed-valence species, since the metal-based orbitals are formally occupied (each metal centre has 18 valence electrons prior to reduction) and the LUMO must be predominantly bridging ligand based.

‡ Both $[\{Mo(NO)[HB(dmpz)_3]Br\}_2(1,4\text{-pz})]$ and $[Mo(NO)\{HB(dmpz)_3\}Br(1,4\text{-pz})]$ are prepared by refluxing $[Mo(NO)\{HB(dmpz)_3\}Br_2]$ with pyrazine in toluene containing triethylamine and are separated chromatographically on silica gel using dichloromethane–thf as eluent. FABMS: 1087 ($M^+$). (Found C, 38.1; H, 4.4; N, 20.4. $C_{22}H_{52}B_2Br_2Mo_2N_{16}O_2$ requires C, 37.6; H, 4.5; N, 20.6%). Cyclic voltammetry in $CH_2Cl_2$, using Pt bead electrode, ferrocene as reference, $[NBu^n_4]PF_6$ as base electrolyte, scan rate 50 and 100 mV $s^{-1}$.

§ Preliminary magnetic susceptibility measurements in the range 80–300 K show that $[\{Mo(NO)[HB(dmpz)_3]Cl\}_2(1,4\text{-pz})]$ exhibits antiferromagnetic behaviour ($J$ *ca.* −180 $cm^{-1}$) consistent with our recently reported findings regarding the sign and magnitude of $J$ (ref. 6).

¶ $^{95}Mo$ and $^{97}Mo$ have $I$ = 5/2, a relative overall abundance of *ca.* 25% and similar nuclear magnetic moments. For an electron coupled to one Mo atom, the signal consists of a singlet (*ca.* 75% of Mo nuclei, $I$ = 0) and a sextet (*ca.* 25% of Mo nuclei, $I$ = 5/2). For an electron coupled to two Mo atoms, the signal appears as a singlet ($I$ = 0, $I$ = 0), 1 : 1 : 1 : 1 : 1 : 1 sextet ($I$ = 5/2, $I$ = 0), and 1 : 2 : 3 : 4 : 5 : 6 : 5 : 4 : 3 : 2 : 1 11-fold multiplet ($I$ = 5/2, $I$ = 5/2) nuclear spin combinations. From previous data, we expect $A_{Mo}$ to be 4.5–5.0 mT for one electron coupled to one Mo centre and 2.4–2.5 mT for one coupled to two Mo centres (refs. 4, 5).

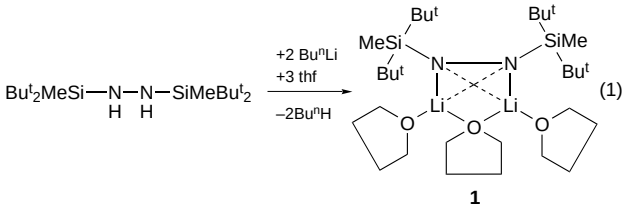
# Oxidation of monomeric *N*,*N*′-dilithium *N*,*N*′-bis(di-*tert*-butylmethylsilyl)hydrazide to the diazene

**Henning Witte-Abel, Uwe Klingebiel* and Mathias Noltemeyer**



*Institut für Anorganische Chemie der Universität, Tammannstr. 4, D-37077 Göttingen, Germany*

**The reaction between the bis(silyl)hydrazine RNHNHR and butyllithium in thf affords the first monomeric dilithium bis(silyl)hydrazide RNLiNLiR·3thf 1 (R = SiBu$^t_2$Me) and the crystal structure of 1 is presented; the thermally stable bis(silyl)diazene RN=NR 2 (R = SiBu$^t_2$Me) is formed in the reaction between 1 and $Br_2$.**

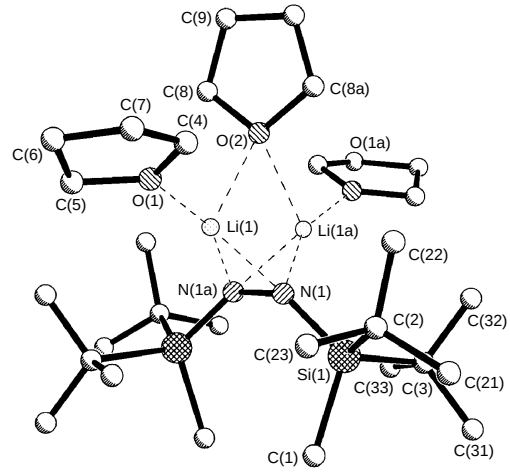
The syntheses of the first silyl hydrazines were described by Aylett[1] and Wannagat and Liehr[2] in the 1950s. They developed essentially two methods of preparation;[3] the reaction of halogenosilanes (X = Cl, Br, I) with (*a*) hydrazines and (*b*) lithium hydrazides. Especially lithium derivatives of silyl hydrazines showed a large variety in substitution and oxidation reactions. In 1964 Bailey and West discovered the migration of silyl groups from one nitrogen atom to the other and opened up a new era in organometallic chemistry.[4,5] In 1968 Wiberg *et al*. prepared the first bis(silyl)diazene, $Me_3SiN{=}NSiMe_3$ in the reaction of lithium tris(trimethylsilyl)hydrazide with tosylazide, a very reactive, thermally unstable compound.[6,7]

In spite of the successful use of the lithium hydrazides in preparative chemistry, the first crystal structure analyses were carried out only about 30 years later.[3,8] Since then, the crystal structures of seven hydrazides, all of which are only silyl substituted, have been published. The results were often unexpected. Hexameric, tetrameric and dimeric hydrazides have been described.[3,8–12] The lithium ions in these oligomers are differently 'side-on' and 'end-on' coordinated to the N–N unit. The degree of oligomerisation decreases with increasing bulkiness of the silyl substituents. We present the first crystal structure analysis of a monomeric dilithium derivative of an *N*,*N*′-bis(silyl)hydrazine and its oxidation to the bis(silyl)-diazene.

Dilithiated *N*,*N*′-bis(di-*tert*-butylmethylsilyl)hydrazine **1** is formed in the reaction of the bis(silyl)hydrazine with 2 equiv. of *n*-butyllithium in thf [eqn. (1)].†‡

The crystal structure of **1**§ which is depicted in Fig. 1 consists of well separated monomers. The lithium ions are 'side-on' coordinated to the N–N bond. They are *cis*-positioned to the hydrazine unit. The coordination sphere of the lithium ions is saturated with three thf molecules. One thf molecule bridges two lithium cations. In this case, Li–O contacts [Li(1)–O(2) 219.3 pm] are longer (19 pm) than the other [Li(1)–O(1) 200.0 pm]. The Li–N distances differ by about 10 pm [Li(1)–N(1a) 196.1; Li(1)– N(1) 185.7 pm]. The structural analysis confirms the *ab initio* calculations,[13] according to which lithium cations in hydrazides can be coordinated equally by both N atoms of the hydrazine.

Silyl derivatives of diazenes can be prepared with different oxidation methods of lithium hydrazides.[7] We used as oxidation



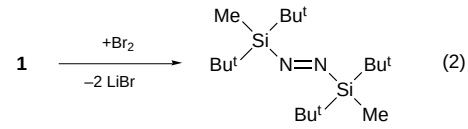


**Fig. 1** Molecular structure of **1**; selected bond lengths (pm) and angles (°): Si(1)–N(1) 168.2(4), Si(1)–C(1) 189.4(6), Si(1)–C(2) 192.6(5), Si(1)–C(3) 194.1(5), N(1)–N(1a) 153.1(6), N(1)–Li(1) 185.7(8), N(1)–Li(1a) 196.1(9), Li(1)–N(1a) 196.1(9), Li(1)–O(1) 200.0(9), Li(1)–O(2) 219.3(9); N(1a)–N(1)–Si(1) 131.7(2), N(1a)–N(1)–Li(1) 70.0(3), N(1a)–N(1)–Li(1a) 62.8(3), Si(1)–N(1)–Li(1a) 121.6(3), Li(1)–N(1)–Li(1a) 80.8(5), N(1)–Li(1)–N(1a) 47.2(3), N(1)–Li(1)–O(1) 139.2(5), N(1a)–Li(1)–O(1) 158.2(5), N(1)–Li(1)–O(2) 101.4(4), N(1a)–Li(1)–O(2) 98.1(4), O(1)–Li(1)–O(2) 99.7(4), Li(1)–O(2)–Li(1a) 68.7(4); atoms labelled a are related to unlabelled equivalents by the symmetry operation $-x + 1, y, -z + \frac{1}{2}$

reagent of **1** elemental bromine in thf and isolated the diazene **2** in about 50% yield [eqn. (2)].

Compound **2** is light green and thermostable in contrast to other known bis(silyl)diazenes,[7] which are thermally unstable, slowly decomposing above −35 °C and extremely air sensitive (inflammable in oxygen). **2** can be distilled at 90 °C (0.01 mbar) without decomposition and handled in the presence of air. Only one X-ray structural determination has been carried out of a bis(silyl)diazene, the bis(trimethylsilyl)diazene by Veith and Bärnighausen,[14] which shows that the diazene is *trans*-configurated with a planar SiNNSi framework. NMR measurements of **2** prove that it is only obtained as one stereoisomer.

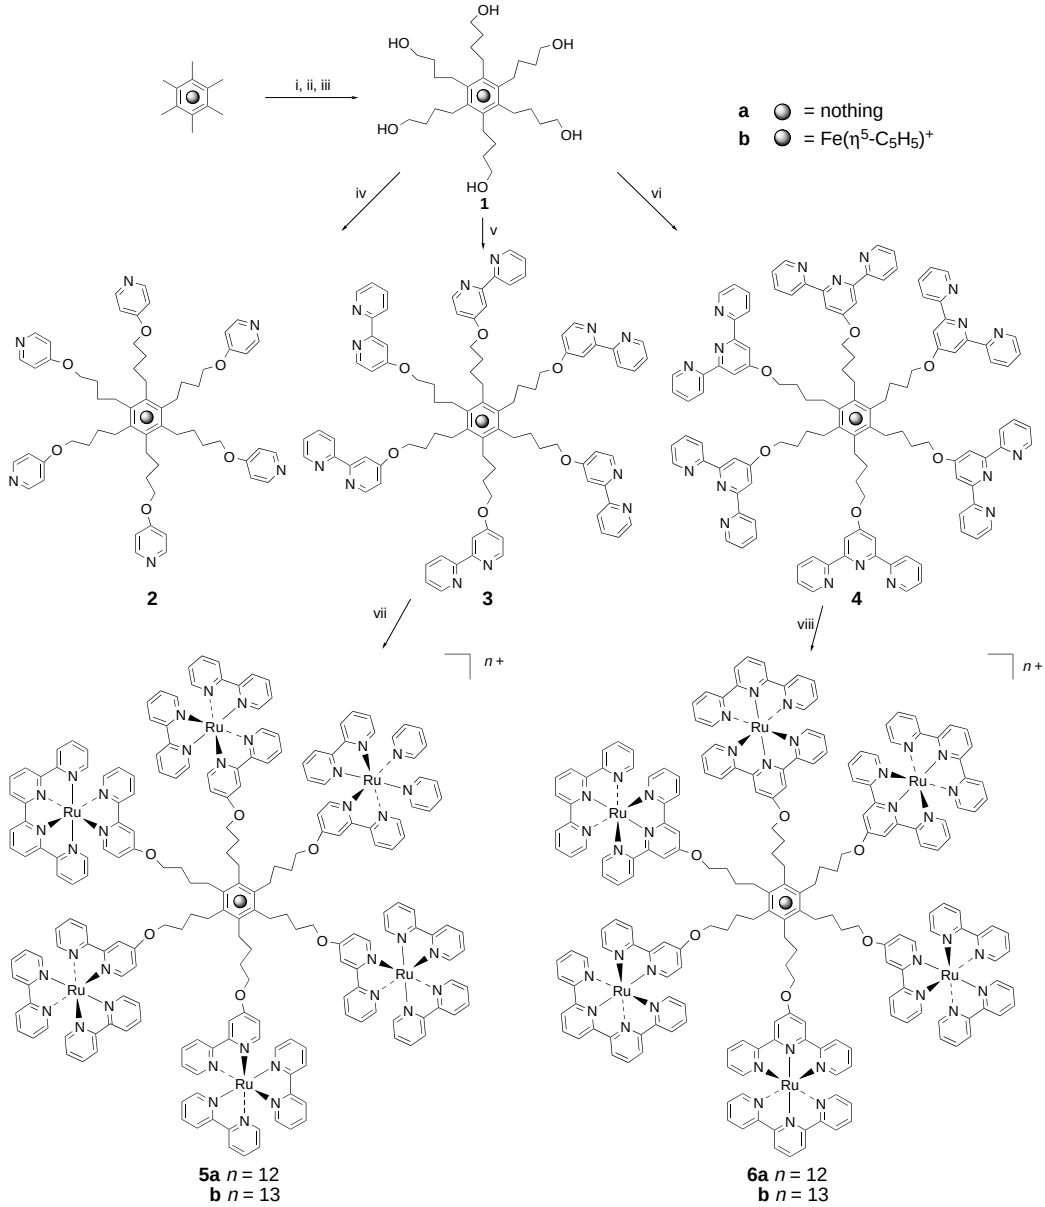
# $Fe(\eta^5\text{-}C_5H_5)^+$ initiated construction of hexaruthenium–polypyridine complexes



**Valérie Marvaud and Didier Astruc**

*Laboratoire de Chimie Organique et Organométallique, URA CNRS No 35, Université Bordeaux I, 33405 Talence Cédex, France*

**Aromatic stars containing hexa-pyridine, -bipyridine and -terpyridine branches are synthesised with or without the central $Fe(\eta^5\text{-}C_5H_5)^+$ group and coordinated to ruthenium(II) polypyridine moities to construct hexa- and hepta-nuclear hexa-bipyridine and -terpyridine complexes.**

Oligopyridines have recently fascinated the supramolecular chemistry community[1] as powerful building blocks for the construction of inorganic helicates,[2,3] antennas,[4] metallo-stars[5] and metallo-dendrimers[6] containing photoactive redox sites.[1,4,7] In this context, and given our interest in redox-active metallodendrimers for molecular recognition and electronics and polyelectronic redox catalysis,[8] we have synthesized 'inorganometallic' hexaruthenium(II) bipyridine and terpyridine complexes which we are now reporting for the first time.

Our standard route which involves the hexa-alkylation of $[Fe^{II}(\eta^5\text{-}C_5H_5)(\eta^6\text{-}C_6Me_6)]PF_6$ using iodoalkyl derivatives under basic conditions is very successful, for instance to

**Scheme 1** Synthesis of the hexaruthenium and heptametallic complexes; *Reagents and conditions*: i, Bu$^t$OK, allylbromide, thf; ii, if decomplexation is required: $h\nu_{vis}$, $PPh_3$, MeCN; iii, $BH_3$·thf, methylbut-2-ene, thf; then $H_2O_2$, $OH^-$; iv, KOH, $Me_2SO$, 4-bromopyridine, 30 °C; v, KOH, $Me_2SO$, 4-chloro-2,2′-bipyridine, 30 °C; vi, KOH, $Me_2SO$, 4′-chloro-2,2′:6′2″-terpyridine, 30 °C; vii, $[Ru(bipy)_2Cl_2]$, ethanol, 80 °C, $NH_4PF_6$; viii, $[Ru(terpy)Cl_3]$, *N*-ethylmorpholine, methanol, 80 °C, $NH_4PF_6$

synthesize hexaferrocene stars.[9] However, all attempts to obtain the hexapyridine compound by direct alkylation of $[Fe^{II}(\eta^5\text{-}C_5H_5)_2(\eta^6\text{-}C_6Me_6)]PF_6$ with 4-iodoalkyl-4′-methyl-2,2′-bipyridine in the presence of KOH and dimethoxyethane (dme) failed, apparently due to dehydrohalogenation or/and partial decomplexation of the $[Fe(\eta^5\text{-}C_5H_5)(\eta^6\text{-}C_6Me_6)]^+$ complex in the presence of 2,2′-bipyridine. A new synthetic strategy was therefore required, the principle of which consisted of synthesizing the hexol before coupling the 4-chloro-2,2′-bipyridine derivative by alkoxy dehalogenation.[10] Using this approach, we also synthesized the hexapyridine and hexaterpyridine compounds which were successfully hexaruthenated.

Perallylation of $[Fe^{II}(\eta^5\text{-}C_5H_5)(\eta^6\text{-}C_6Me_6)]PF_6$ eventually followed by visible photolysis, regiospecific hydroboration and oxidation using $H_2O_2$ under basic conditions yields the hexol **1a** and the corresponding iron complex **1b**, as already known,[9b] Scheme 1. The reaction of these two products, **1a** and **1b**, with bromo- or chloro-pyridyl compounds (4-bromopyridine, 4-chloro-2,2′-bipyridine and 4′-chloro-2,2′:6′,2″-terpyridine) in $Me_2SO$ in the presence of KOH gave the associated hexasubstituted products, soluble in organic solvents and fully characterised by NMR ($^1H$, $^{13}C$, COSY spectroscopy) and mass spectra ($FAB^+$). The analytical and spectroscopic data for hexapyridine **2a**, hexabipyridine **3a**, hexaterpyridine **5a**, $[Fe(\eta^5\text{-}C_5H_5)(\text{hexapyridine})]PF_6$ **2b** and $[Fe(\eta^5\text{-}C_5H_5)(\text{hexaterpyridine})]PF_6$ **5b**† show the expected structures. The reaction of **1b** with 4-chloro-2,2′-bipyridine was disappointing, the expected $Fe(\eta^5\text{-}C_5H_5)$ complex of the hexabipyridine **3b** was never cleanly obtained. This is probably due to a partial decomplexation of the $[Fe(\eta^5\text{-}C_5H_5)(\eta^6\text{-}C_6Me_6)]^+$ complex, as mentioned above. Interestingly, this decomplexation is limited with the terpyridine derivatives, the difference with the bipyridine case being explained by steric effects. The ruthenation of **3a**, **4a** and **4b** was carried out using standard procedures with $[Ru(bipy)_2Cl_2]$ and $[Ru(terpy)Cl_3]$ as starting materials. The products **5a** and **6a** were then obtained and fully characterized by NMR ($^1H$, $^{13}C$, COSY spectroscopy) and mass spectra (MALDI-TOF and electrospray, ES).

The MALDI-TOF spectra show peaks at *m/z* 5510.7 and 5499.1 which are assigned to (**5a** − $PF_6$) and (**6a** − $PF_6$); these results were confirmed by the ES spectra. Further evidence for the presence of the terminal $[Ru(bipy)_3]^{2+}$ moieties is given by electrochemical measurements where the set of $Ru^{II}$–$Ru^{III}$ redox systems gives a single and reversible anodic wave at +0.82 and +0.79 V (*vs.* Fc–$Fc^+$) respectively. For compound **6b**, partial decomplexation of the iron core is indicated by the ES data.

We have shown that a new synthetic route for metallo-stars is open *via* a combination of organometallic, organic and inorganic chemistry. We are currently carrying out further studies on the construction of higher generations of functionalised dendrimers containing ruthenium polypyridine complexes at the periphery.

We thank J. Guittard, J.-C. Blais, E. Leize and A. Van Dorsselaer for the mass spectroscopic studies.

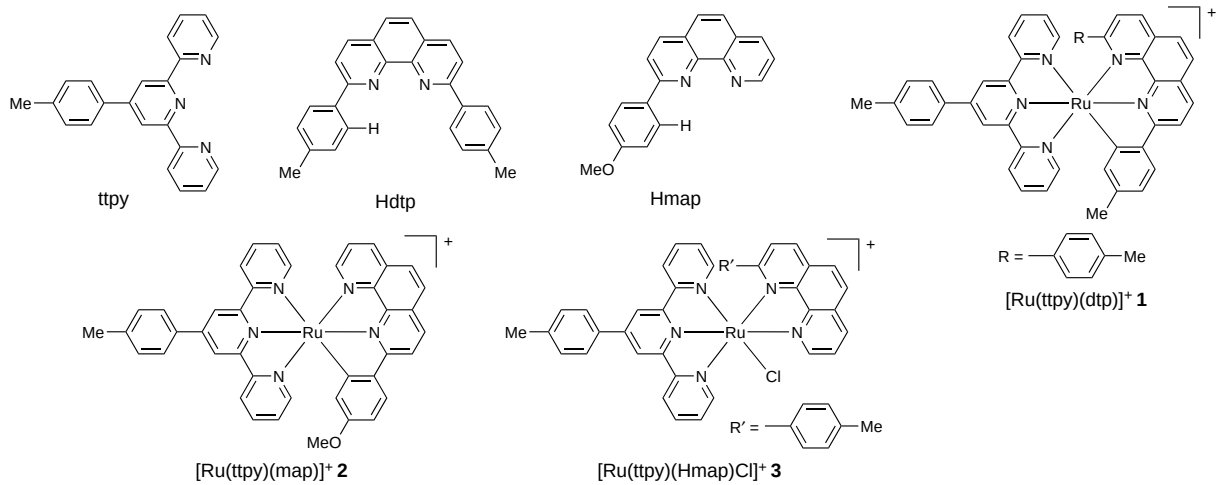
**Two cyclometallated ruthenium(II) complexes incorporating mono- or di-substituted phenanthroline moieties are synthesized and characterized by single-crystal X-ray diffraction; the complex with a sterically hindered ligand displays a long-lived MLCT excited state.**

Transition-metal complexes exhibiting luminescence from metal-to-ligand charge transfer (MLCT) excited states have been the subject of numerous studies.[1] In this field, the $d^6$ polypyridyl complexes of $Ru^{II}$,[2] $Os^{II}$[3,4] and $Re^{I}$[5] form the major class of such compounds. Recently, cyclometallated complexes[6,7] of $d^6$ and $d^8$ transition-metal ions have also shown interesting photophysical properties. Since ruthenium terpyridine type complexes are particularly suitable to build up multicomponent systems,[8] the search for compounds of this type displaying long-lived MLCT excited states at room temperature remains a stimulating challenge. Here, we describe the synthesis, crystal structures and photophysical properties of two luminescent cyclometallated ruthenium complexes. Interestingly, the photophysical properties of the compounds can be strongly modified by introducing small structural changes in the cyclometallating ligand.



In the presently reported complexes, 4′-tolyl-2,2′:6′,6″-terpyridine (ttpy) affords NNN coordination. It is associated with the 1,10-phenanthroline ligand bearing different aromatic substituents in the 2 and 9 positions and leading to NNC coordination. The aromatic sustituents are two tolyl groups for Hdtp[9] and a *p*-anisyl group for Hmap[10] (Scheme 1).

The deep purple complexes $[Ru(ttpy)(dtp)]^+$ **1** and $[Ru(ttpy)(map)]^+$ **2** were prepared by the reaction of $[Ru(ttpy)Cl_3]$ with the phenanthroline ligand Hdtp or Hmap in refluxing acetic acid in the presence of one drop of *N*-ethylmorpholine. Considering that both cyclometallated (NNC) and the non-cyclometallated (NN) products could be obtained with Hmap, it is not surprising, in view of previous results[11] that Hdtp leads exclusively to the formation of the cyclometallated (NNC) compound. Satisfactory analytical data have been obtained for these complexes. Single crystals of **1** and **2** were obtained by slow diffusion of benzene into an acetonitrile solution of each compound. The structures of **1** and **2** were determined by single-crystal X-ray diffraction† and the ORTEP diagrams are shown in Fig. 1 and 2.

By comparing the X-ray structures of **1** and **2**, it is clear that the ruthenium(II) coordination polyhedra are very similar, except for one particular Ru–N distance. In fact, the bond between the metal and the nitrogen atom *ortho* to the linkage point of the tolyl group borne by the phenanthroline nucleus is *ca*. 0.06 Å longer in **1** than in the unsubstituted compound **2**. This difference probably reflects the steric effect of the aromatic group in the vicinity of the Ru coordination sphere, which is also in agreement with the close proximity between the tolyl group and the central pyridine ring of the ttpy chelate. This stacking situation is likely to result in donor–acceptor interactions involving the tolyl group (donor) and the Ru-bonded central pyridine (acceptor). This would explain the very different photophysical behaviour of **1** as compared to **2**.

The electrochemical and spectroscopic data for **1** and **2** are collected in Table 1.

It is of note that whereas **2** is practically not luminescent in acetonitrile at room temperature, **1** luminesces and displays a

**Scheme 1**

relatively long-lived excited state ($\tau$ = 95 ns). In fact, **1** seems to be one of the longest-lived[12] terpy-type ruthenium(II) complexes.

Clearly, the electronic properties of both compounds **1** and **2** seem to be almost identical (Table 1). The remarkable effect of the tolyl group onto the MLCT excited state lifetime of **1** could be related to the steric protection of the metal and strong rigidifying of the molecular edifice *via* $\pi$–$\pi$ interaction with the ttpy ligand of the complex.

This work has been supported by the CNRS (France) and by CNR (Italy). We thank Patrice Staub for his technical assistance.

† *Crystal data*: **1**, purple crystals from benzene–acetonitrile. $2(C_{48}H_{36}F_6N_5PRu)\cdot CH_3CN$, $M$ = 1898.8, monoclinic, space group $P2_1/n$; $a$ = 21.196(6), $b$ = 17.212(5), $c$ = 11.312(3) Å, $\beta$ = 95.40(2), $U$ = 4103(3) Å$^3$, $Z$ = 2, $D_c$ = 1.537 g cm$^{-3}$, $\mu$ = 41.337 cm$^{-1}$. Measurements: Philips PW1100/16, $\theta$–2$\theta$ flying step-scans, Cu-K$\alpha$ graphite-monochromated radiation ($\lambda$ = 1.5418 Å), $T$ = 173 K. 5396 reflections ($\theta$ = 3–54°), of which 4334 unique with $I > 3\sigma(I)$ were used for structure solution (direct methods) and refinement (full-matrix least squares); $R$ = 0.081, $R_w$ = 0.143. The C(20)–C(26) tolyl moiety adopts two orientations (50/50); for one of them a MeCN solvent molecule is present. Atoms C(25)–C(26) in both orientations were introduced as fixed contributors with isotropic temperature factors allowed to vary during refinement. All other non-hydrogen atoms were refined anisotropically. The hydrogen atoms were calculated and fixed in idealized positions [$d$(C–H) = 0.95 Å, $B$(H) = 1.3 $B_{equiv}$ for the carbon to which it was attached] with the exception of C(20)–C(26) tolyl and $CH_3CN$ protons not introduced. **2**, dark blue crystals from benzene–acetonitrile. $C_{41}H_{30}F_6N_5OPRu$, $M$ = 854.8; monoclinic, space group $P2_1/n$; $a$ = 12.535(3), $b$ = 16.512(4), $c$ = 18.334(5) Å, $\beta$ = 107.86(2), $U$ = 3611(3) Å$^3$, $Z$ = 4, $D_c$ = 1.572 g cm$^{-3}$, $\mu$ = 5.387 cm$^{-1}$. Measurements: Nonius MACH3, $\theta$–2$\theta$ scans, Mo-K$\alpha$ graphite-monochromated radiation ($\lambda$ = 0.7107 Å), $T$ = 283 K. 8376 reflections ($\theta$ = 2–26°), of which 3664 unique with $I > 3\sigma(I)$ were used for structure solution (direct methods) and refinement (full-matrix least squares); $R$ = 0.056, $R_w$ = 0.076. The fluorine atoms of the $PF_6^-$ anion are disordered over two positions (50/50) and where assigned isotropic temperature factors. All other non-hydrogen atoms were refined anisotropically and treated as above. For all computations, the Nonius MolEN/Vax package was used.[13]

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/389.

# Activation of $CO_2$ by laser-ablated group 6 metal atoms

**Philip F. Souter and Lester Andrews***

*Department of Chemistry, University of Virginia, Charlottesville, Virginia 22901, USA*

**The primary reaction products of laser-ablated group 6 atoms with $CO_2$ prove to be the insertion products OMCO and $O_2M(CO)_2$ (M = Cr, Mo, W) which are isolated in argon matrices and identified by the effects of isotopic substitution on their IR spectra.**

Carbon dioxide is a naturally abundant carbon source that has been implicated as a contributor to the predicted global warming often referred to as the 'greenhouse effect'. The interaction between $CO_2$ and transition-metal centres is receiving increased attention[1–4] as the possibilities of recycling $CO_2$ generated in industrial emissions[5] and also of replacing petroleum with $CO_2$ as the starting material for the synthesis of fine chemicals[6] both represent exciting and important goals. Previous studies of the interaction of metal atoms with $CO_2$ in low-temperature matrices focussed on the interaction of Li,[7] Cs[8] and Al[9] with $CO_2$. Additionally the interaction of several of the first-row transition metals, including Cr, with $CO_2$ has been investigated both experimentally in solid $CO_2$[10] and theoretically.[11] In this laboratory, the reactions of B, U, Ti and Be with $CO_2$ have been investigated and all four were found to insert into $CO_2$ to give OMCO (M = B, U, Ti, Be) as the primary reaction product.[12–15] Much attention has been devoted to the organometallic chemistry of $CO_2$ and a comprehensive review has recently been published.[4] The main problem with the chemistry of $CO_2$ lies in its inherent thermodynamic stability and methods of 'activating' $CO_2$ are consequently actively being sought. We have studied the reactions between laser-ablated group 6 metal atoms and $CO_2$–Ar mixtures and have trapped the reaction products, including OMCO and $O_2M(CO)_2$, in argon matrices and identified them by the effects of isotopic substitution.

The technique used for matrix investigation of the reactions of pulsed laser-ablated metal atoms has been detailed previously.[12–16] FTIR spectra were recorded on a Nicolet 550 at 0.5 $cm^{-1}$ resolution. Typically mixtures of between 0.5 and 2%

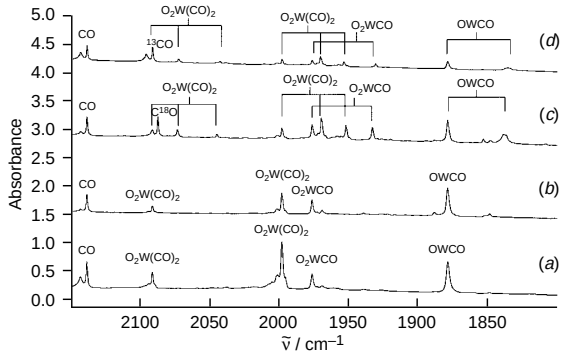

**Fig. 1** IR spectra in the region 2150–1800 $cm^{-1}$ for samples from the reactions of W atoms with $CO_2$ mixtures in argon during condensation at 6–7 K; (*a*) 2% $CO_2$, (*b*) 0.5% $CO_2$, (*c*) 0.5% $C^{16}O_2$–$C^{16}O^{18}O$–$C^{18}O_2$ and (*d*) 0.5% $^{12}CO_2$–$^{13}CO_2$ after annealing to 20 K followed by broad-band UV photolysis and further annealing to 30 K

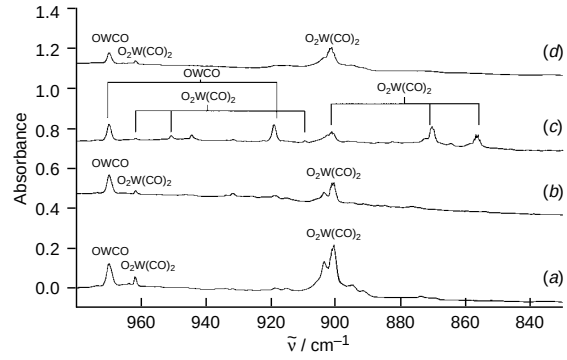

**Fig. 2** IR spectra in the region 980–830 $cm^{-1}$ for samples from the reactions of W atoms with $CO_2$ mixtures in argon during condensation at 6–7 K; (*a*) 2% $CO_2$, (*b*) 0.5% $CO_2$, (*c*) 0.5% $C^{16}O_2$–$C^{16}O^{18}O$–$C^{18}O_2$ and (*d*) 0.5% $^{12}CO_2$–$^{13}CO_2$ after annealing to 20 K followed by broad-band UV photolysis and further annealing to 30 K

**Table 1** Observed IR absorptions ($cm^{-1}$) of the dominant products in the reaction of laser-ablated group 6 atoms with $CO_2$ trapped in an Ar matrix at *ca.* 6–7 K

[a] Refers to $^{52}$Cr. [b] Refers to $^{98}$Mo. [c] Antisymmetric M–O stretch. [d] Symmetric stretch.

$CO_2$ in Ar were deposited at a rate of *ca.* 3 mmol $h^{-1}$ for 1–2 h onto a CsI window held at 6–7 K while the metals were ablated using 35–50 mJ $pulse^{-1}$ of the YAG 1064 nm fundamental.

Figs. 1 and 2 show the effects of isotopic substitution upon the IR spectra of matrix-isolated deposits containing the products from the reaction of W with $CO_2$ in Ar. The frequencies of the observed bands from the reactions of $CO_2$ with Cr, Mo and W and their proposed assignments are presented in Table 1.

OMCO: the dominant product from the reactions of group 6 metal atoms with 0.5% $CO_2$–Ar mixtures is the direct insertion product OMCO. Full details are given in Table 1 for all three metals which behave in an analogous fashion. In the case of tungsten, absorptions at 1879.0 and 969.6 $cm^{-1}$ correspond to the CO and WO stretching fundamentals of the OWCO molecule. In experiments run with $^{13}CO_2$ and $C^{18}O_2$, these bands shift to 1837.0 and 969.6 $cm^{-1}$ and 1838.8 and 918.9 $cm^{-1}$, respectively, confirming that this molecule contains a CO and a WO group, based upon comparison of observed isotopic frequency ratios with calculated harmonic diatomic ratios. Experiments run with $^{12}CO_2$–$^{13}CO_2$, $C^{16}O_2$–$C^{18}O_2$ and $C^{16}O_2$–$C^{16}O^{18}O$–$C^{18}O_2$ all revealed isotopic doublets in the CO stretching region and the latter two revealed doublets in the WO stretching region. This isotopic pattern confirms the presence of exactly one CO group and exactly one WO group allowing definitive spectral assignment of these bands to the OWCO molecule. For both Cr and Mo isotopic splittings due to the natural abundances of the metal isotopes were observed for the MO stretching fundamental and the observed statistical distribution confirmed the presence of exactly one metal atom. These findings are in contrast to a previous study of the reaction of thermally generated chromium atoms with neat $CO_2$ in which there was no evidence for the insertion reaction.[10]†

$O_2M(CO)_2$: the other main product from these reactions proved to arise from the insertion of the metal atoms into two $CO_2$ molecules. As might be anticipated, by raising the concentration of $CO_2$ from 0.5 to 2% the relative yield of $O_2M(CO)_2$ to OMCO increases. In the CO stretching region for all three metals, the symmetric and antisymmetric CO stretching fundamentals were both observed. In the case of the reaction of W with $CO_2$, the bands at 2091.1 and 1998.2 $cm^{-1}$ can be assigned to the symmetric and antisymmetric CO stretching modes of $O_2W(CO)_2$ while the bands at 961.6 and 901.1 $cm^{-1}$ can be assigned to the symmetric and antisymmetric WO stretching modes of the $O_2W(CO)_2$ molecule. Reaction with $^{13}CO_2$ gave bands at 2042.9, 1953.6, 961.6 and 901.1 $cm^{-1}$, whereas reaction with $C^{18}O_2$ gave bands at 2045.1, 1952.1, 909.4 and 856.1 $cm^{-1}$. Reaction with either $C^{16}O_2$–$C^{18}O_2$ or $C^{16}O_2$–$C^{16}O^{18}O$–$C^{18}O_2$ gave rise to 1 : 2 : 1 triplets for all four bands. This is indicative of the presence of precisely two equivalent CO groups and two equivalent oxygen atoms and confirms that the two oxygens and CO groups bound to the tungsten must come from two different $CO_2$ molecules. Reaction with a $^{12}CO_2$–$^{13}CO_2$ mixture revealed a 1 : 2 : 1 isotopic triplet for both CO stretching fundamentals further confirming the presence of two equivalent CO groups. In the cases of both Cr and Mo, the presence of exactly one metal atom is clearly demonstrated by the statistical distribution of the metal isotopic pattern for the M–O antisymmetric stretching fundamental. There have been numerous previous studies involving the photolysis of $M(CO)_6$ with $O_2$[18–21] and bands in these spectra were assigned to the $O_2M(CO)_2$ molecules. The CO stretching region in these experiments was extremely congested but the bands that are observed here for $O_2Mo(CO)_2$ and $O_2W(CO)_2$ are essentially the same as those observed by Almond *et al.* for their species 'C' which was assigned to $O_2M(CO)_x$, not those observed for their species 'D' which was assigned to $O_2M(CO)_2$.[20] Our results for $O_2Cr(CO)_2$ do however confirm the previous correct identification of this molecule.[18,20]

Other bands: the previously characterised metal monoxides, MO,[21–23] were observed although this represents the first reported isolation of CrO (846.5 $cm^{-1}$) in a matrix. In the case of the reaction with tungsten, a bridged species $OW(\mu\text{-}CO)_2WO$, the dimer of OWCO, is formed. Only the antisymmetric CO stretching mode is observed in a region typical for bridging CO groups. The observed band at 1713.4 $cm^{-1}$ from the reaction of W with $CO_2$ shifts to 1674.5 $cm^{-1}$ on reaction of W with $^{13}CO_2$ and 1675.9 $cm^{-1}$ on reaction of W with $C^{18}O_2$. It shows a 1 : 2 : 1 triplet at 1713.4, 1692.8 and 1675.9 $cm^{-1}$ upon reaction with either $C^{16}O_2$–$C^{18}O_2$ or $C^{16}O_2$– $C^{16}O^{18}O$–$C^{18}O_2$, and a 1 : 2 : 1 triplet at 1713.4, 1691.9 and 1674.5 $cm^{-1}$ upon reaction with a $^{12}CO_2$–$^{13}CO_2$ mixture, indicating two equivalent CO groups. The product is not observed in reactions involving CO and its yield is suppressed by using higher concentrations (2%) of $CO_2$, presumably due to further reaction of OWCO with $CO_2$. The lack of an analagous product for Cr or Mo probably reflects the greater strength of the metal–metal bonding, present in such a complex, of tungsten. DFT calculations confirm the presence of metal–metal bonding in this molecule. Other products observed include the molecules $O_2MCO$, $OCr(CO)_2$ and the $CO_2$ complex $Cr(\eta^1\text{-}OCO)$ and these results will be discussed in a full paper.

## Footnotes

* E-mail: lsa@virginia.edu

† The band observed in ref. 10 at 960 $cm^{-1}$, tentatively assigned to a $CO_2$ reaction product, occurs at almost the same energy as the antisymmetric stretch of $CrO_2$, an almost inevitable impurity in a reaction involving thermally generated Cr atoms. With no isotopic data and no associated carbonyl stretches this band is most likely due to $CrO_2$ in a $CO_2$ matrix.

# *In situ* EPR studies of electron transfer across a polarised liquid/liquid interface

**Robert A. W. Dryfe, Richard D. Webster, Barry A. Coles and Richard G. Compton***

*Physical and Theoretical Chemistry Laboratory, Oxford University, South Parks Road, Oxford, UK OX1 3QZ*

**The design and operation of the first ever *in situ* EPR cell for studying charge-transfer processes accompanying polarisation of the liquid/liquid interface is presented as well as EPR absorption data obtained from the reduction of TCNQ (to $TCNQ^{\cdot -}$) and the oxidation of TTF (to $TTF^{\cdot +}$) by the ferro–ferri-cyanide redox couple at the water/1,2-dichloroethane interface.**

The liquid/liquid interface has attracted increasing attention, both from a theoretical and experimental standpoint, due to its potential relevance to fields as diverse as analytical chemistry, hydrometallurgy and membrane science.[1] Imposition of an external potential difference across this interface has allowed charge-transfer processes to be studied voltammetrically, but interpretations are frequently plagued by controversy because of the difficulty in conclusively identifying the participating species and, crucially, resolving ion- and electron-transfer processes from one another.[2] The latter is of particular interest as it involves bimolecular electron exchange which can be controlled through the potential difference imposed on the water/organic interface. Spectroscopic experiments, including EPR spectroscopy,[3,4] have been used successfully to clarify processes at the metal/electrolyte and semiconductor/electrolyte interfaces. To date spectroscopic reports of liquid/liquid processes have been confined to UV–VIS absorption and emission spectroscopy,[5,6] whereas *in situ* EPR spectroscopy is an ideal way to detect and identify paramagnetic participants, which has not been hitherto applied.

The cell used to perform the interfacial polarisation-EPR experiments is shown in Fig. 1 and is essentially a conventional silica flat cell[7] modified so that a counter and reference electrode can be inserted into either end. The cell was assembled by first filling the higher density solvent through the capillary at the base of the cell [Fig. 1(*f*)] using silicone tubing and a syringe, so that the solvent reached the midpoint of the flat portion of the cell [Fig. 1(*a*)], and then sealing the silicone tubing with a Hoffman clamp. The upper, less dense phase, was then introduced into the cell from the top using a Pasteur pipette. Using this filling method a liquid/liquid interface could be generated and maintained in the mid-portion of the flat part of the cell.

The EPR cell has two counter electrodes of coiled 0.5 mm diameter platinum wire located outside the thin layer section [Fig. 1(*b*) and (*d*)]. The two reference electrodes are 0.5 mm diameter silver wires, flattened at one end to a thickness which enabled their insertion into the flat part of the cell [Fig. 1(*c*) and (*e*)]. Both silver pseudo-reference electrodes were positioned to within 5 mm of the liquid/liquid interface. To obtain optimal control of the potential difference applied between the liquid phases, the portions of the reference electrodes outside the flat part of the cell were jacketed in Teflon tubing [Fig. 1(*h*)] and sealed with silicone rubber so that they were only in contact with the solutions inside the flat part of the cell. The inherent high resistivity of a flat cell combined with low relative permittivity solvents (*e.g.* 1,2-dichloroethane, DCE) can be partially overcome using this arrangement, and reasonable linear sweep voltammetry can be obtained using a four-electrode (two counter and two reference electrodes) potentiostat.

The use of the cell shown in Fig. 1 enabled EPR spectra to be obtained for both the interfacial reduction of TCNQ and

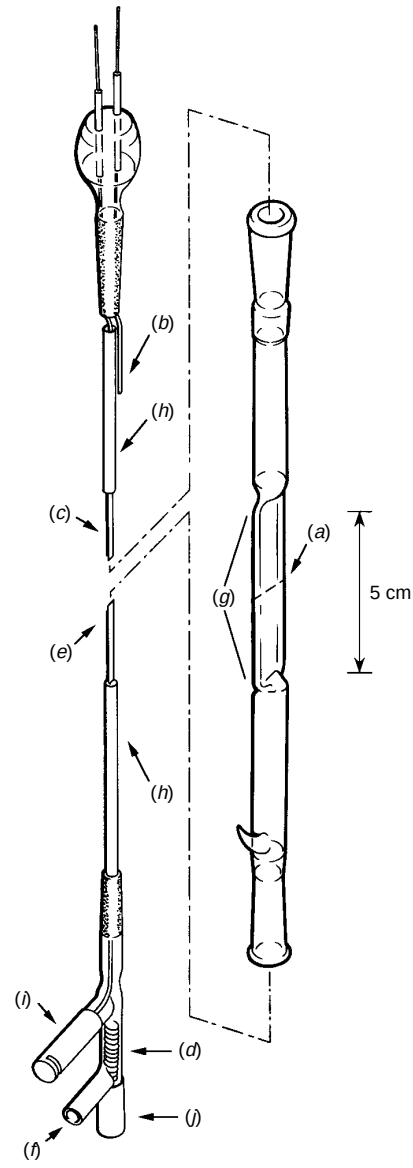

**Fig. 1** Silica cell for performing liquid/liquid electrochemical-EPR experiments: (*a*) interface between two immiscible liquids, (*b*) platinum wire counter electrode 1, (*c*) silver wire reference electrode 1, (*d*) platinum wire counter electrode 2, (*e*) silver wire reference electrode 2, (*f*) capillary to fill lower portion of cell, (*g*) thin layer portion of cell, (*h*) Teflon/silicone rubber sleeves surrounding lower portions of reference electrodes, (*i*) electrical contact to reference electrode 2 and (*j*) electrical contact to counter electrode 2

oxidation of TTF (dissolved in DCE) by the aqueous phase ferri–ferro-cyanide couple, following application of a potential difference directly to the liquid/liquid interface. The TCNQ–ferrocyanide system has been previously investigated using both external polarisation with a four-electrode potentiostat and the scanning electrochemical microscope, both techniques indicating that the charge-transfer process observed at the liquid/liquid interface is due to heterogeneous reduction of TCNQ by the aqueous couple[8,9] [eqn. (1)].

$$\mathrm{TCNQ(DCE) + Fe(CN)_6^{4-}(aq) \rightleftharpoons TCNQ^{\cdot-}(DCE) + Fe(CN)_6^{3-}(aq)} \quad (1)$$

A similar mechanism can be written for the oxidation of TTF [eqn. (2)], where in each case an appropriate potential difference (oxidising or reducing), relative to the two reference electrodes used, can be imposed across the water/DCE interface to drive the reaction in either the forward or reverse direction.

$$\mathrm{TTF(DCE) + Fe(CN)_6^{3-}(aq) \rightleftharpoons TTF^{\cdot+}(DCE) + Fe(CN)_6^{4-}(aq)} \quad (2)$$

The presence of the organic radicals, and hence the occurrence of an electron-transfer process, was verified using EPR spectroscopy. The EPR spectra obtained for $TCNQ^{\cdot-}$ and $TTF^{\cdot+}$ in DCE at room temperature consisted of single broad lines with peak-to-peak line widths of 5.2 and 3.0 G, respectively. It is unlikely that the line broadening observed is due to the $TCNQ^{\cdot-}$ and $TTF^{\cdot+}$ radicals interacting with the iron complexes in the aqueous phase as broad EPR spectra were also obtained from $TCNQ^{\cdot-}$ and $TTF^{\cdot+}$ radicals which had been generated electrochemically in the appropriate single-phase three-electrode cell[7] using DCE and the same supporting electrolyte, bis(triphenylphosphoranylidene)ammonium tetrakis(4-chlorophenyl)borate ($BTPPA^+TCPB^-$). The broadening of the EPR spectra is probably caused by the strong ion pairs formed between the product radicals and the organic phase electrolyte cation ($BTPPA^+$) or anion ($TCPB^-$) respectively, undergoing fast electron exchange with neutral TCNQ or TTF.[10]

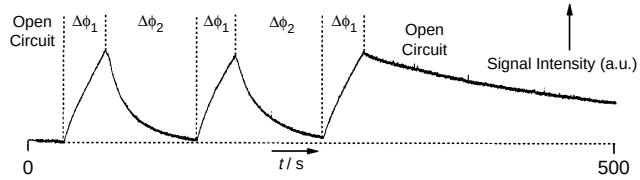

**Fig. 2** Time-sweep first derivative EPR spectrum of $TTF^{\cdot+}$ recorded at constant magnetic field using a liquid/liquid electrochemical-EPR cell. The organic phase (DCE) contained 5 mM TTF and 36 mM $BTPPA^+$ $TCPB^-$. The aqueous phase contained 25 mM $K_4[Fe(CN)_6]$, 25 mM $K_3[Fe(CN)_6]$ and 0.1 M $Li_2SO_4$. EPR sweep time = 500 s, sweep width = 0 G, modulation amplitude = 2.0 G and time constant = $10 \times 10^{-2}$ ms. $\Delta\phi_1$ = oxidising potential, $\Delta\phi_2$ = reducing potential. The potential difference imposed to induce oxidation of the TTF was +0.7 V, whilst this process was reversed using a potential difference of −0.1 V (*vs.* the Ag pseudo-reference electrodes used). See text for further details.

An EPR time-sweep experiment for the oxidation of TTF, where the magnetic field was held at a constant value corresponding to the maximum absorption, is shown in Fig. 2. The time-sweep EPR experiments were performed by applying a potential difference, between the silver pseudo-reference electrodes located in each liquid phase, which was sufficient to cause an electron to be transferred across the water/DCE interface from TTF to $[Fe(CN)_6]^{3-}$. The resulting increase in $TTF^{\cdot+}$ in the organic phase caused an increase in signal intensity of the absorption spectrum (Fig. 2), which displayed a square-root temporal dependence as expected for a potential-step occurring under conditions of one-dimensional diffusion.[11] Jumping to a potential difference sufficiently negative to drive the back reaction immediately caused a decrease in the intensity of the absorption signal (also Fig. 2) due to $TTF^{\cdot+}$ being reduced back to neutral TTF. The time-sweep EPR data obtained for the reduction of TCNQ was very similar to that reported for the oxidation of TTF. The spectrum in Fig. 2 also shows that when the potentiostat is open-circuited after generating $TTF^{\cdot+}$ the signal intensity decreases with time. $TTF^{\cdot+}$ is stable in DCE, therefore, the decay in signal intensity can be attributed to the radical diffusing away from the most sensitive part of the EPR cavity since the sensitivity shows a cosine squared dependence on distance, its maximum lying at the cavity centre.[3] Steps are currently in progress to enable accurate kinetic measurements to be made using this cell.

R. A. W. D. and R. D. W. gratefully acknowledge the Royal Commission for the Exhibition of 1851 and the Ramsay Memorial Fellowships Trust respectively for post-doctoral fellowships. We thank Mr J. Freeman for assistance with figures.

# Synthesis and structural characterisation of two- and three-dimensional fluorinated indium phosphates

**Hongbin Du,[a] Jiesheng Chen,[a] Wenqin Pang,*[a] Jihong Yu[a,b] and Ian D. Williams*[b]**

[a] *Key Laboratory of Inorganic Hydrothermal Synthesis, Department of Chemistry, Jilin University, Changchun, China*
[b] *Department of Chemistry, Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong*

**Hydrothermal synthesis of two new fluorinated indium phosphates [$InPO_4F$(Hen)] and [$In_5P_4F_3O_{16}(en)_3(OH_2)_2$] is carried out in the system $In_2O_3$–$P_2O_5$–en–HF–$H_2O$ (en = ethylenediamine); these have two- and three-dimensional inorganic frameworks respectively, with the latter having ten-membered ring channels spanned by coordinated en; the fluorides bridge exclusively between indium ions and may be linear or bent.**

The synthesis of new classes of inorganic microporous solids, with different architectures and pore chemistry to classical zeolite-related materials, remains an active area.[1–3] Extensive use of organic amines as structure directing agents promotes microporous solid formation, with frequent inclusion of the amine in the microporous channel. Using this approach, a rich chemistry has already been established for group 13 phosphates of Al[4–6] and Ga[7–10] and work is now emerging on the indium phosphate family. Previously three indium phosphates templated by organic amines have been reported, [$H_2$en]-[$In(HPO_4)_2$][11] [$In_8(HPO_4)_{14}(H_2O)_6](H_2O)_5(H_3O)(N_2C_3H_5)_3$[12] and [$C_5H_5NH$][$In(HPO_4)(H_2PO_4)_2$].[13]

The presence of fluoride as a mineraliser in hydrothermal synthesis frequently has a pronounced effect on the microporous phases produced[14] and may even result in the incorporation of fluoride into the inorganic framework, as observed for certain alumino-[15] and gallo-phosphates.[16] We report herein the synthesis and structure of two fluorinated indium phosphates, [$InPO_4F$(Hen)] **1** and [$In_5P_4F_3O_{16}(H_2O)_2(en)_3$] **2**, using ethylenediamine (en) as the organic structure directing agent in a fluoride-containing system.

Compounds **1** and **2** were synthesized hydrothermally. An aqueous mixture of indium hydroxide, 85% (m/m) phosphoric acid, ethylenediamine and 40% (m/m) hydrofluoric acid with the gel molar composition 1.0 $In(OH)_3$ : 1.0 $H_3PO_4$ : 1.0 en : 2.0 HF : 80 $H_2O$ was heated at 180 °C for 20 days under autogeneous pressure in a Teflon-lined stainless-steel autoclave. The resulting crystalline products were filtered off, washed thoroughly with water and dried at room temp. Microscopic examination revealed two phases, predominantly compound **1** which formed tablets of maximum dimension 150 μm, together with a small amount (*ca*. 10%) of a second phase, compound **2**, as small rectangular blocks of maximum dimension 60 μm. X-Ray photoelectron spectroscopy on the product mixture indicated the presence of In, P and stoichiometric amounts of fluorine. Energy dispersive X-ray analysis on selected single crystals of the two compounds confirmed the presence of these elements in both phases. Their structures were then determined by single-crystal X-ray diffraction.†

[$InPO_4F$(Hen)] **1** is a two-dimensional network with monoprotonated ethylenediamine groups $(Hen)^+$ pendant to $InPO_4F$ layers through coordination of one amino group to the indium. A view perpendicular to the layer is shown in Fig. 1. The two-dimensional sheet has chains of corner-shared indium octahedra which are linked to other chains by phosphate bridges forming $In_4P_2$ six-membered rings. The corner-sharing of the In octahedra is due to fluoride ions which bridge symmetrically in a bent manner between the In atoms [In–F 2.121, 2.129(5) Å, In–F–In 133.2(2)°]. Although crystallographically it is difficult to distinguish μ-F from μ-OH, this bridging position is the only chemically reasonable location for the fluorine which must be present in this compound. The phosphate groups point alternately above and below the layer and have three oxygen atoms forming In–O–P bridges and one terminal P–$O^-$ functionality. This is hydrogen bonded to three pendant ammonium $NH_3R^+$ chains of the adjacent layer, which serves to organise the overall packing of the structure.

Compound **2**, has a three-dimensional open framework with a 5 : 4 In : P ratio. Its structure is complex featuring ten-membered rings ($In_6P_4$) which are spanned by en bridges between opposite indium atoms (Fig. 2). In addition en acts as a simple chelate to one indium centre. Once more, the fluorides are assigned to bridging environments between In atoms but may be linear or bent. The bent bridges have similar geometry to those found for **1** [bent In–F 2.136, 2.135(5) Å, In–F–In 125.9(2)°]. The linear bridges are also assigned to be fluoride, rather than oxide, on the basis of charge balance. Linear In–F–In linkages are well established, and occur in several condensed phases including [InOF].[17] The shorter In–F bond [linear In–F 2.068(1) Å] found for the linear case, is expected due to involvement of the fluoride lone pairs in π bonding and the smaller radius of sp hybridised fluorine. All phosphate oxygen atoms form In–O–P bridges and the coordination environments of the indium atoms are completed by aqua ligands [In–O 2.295(9) Å].†

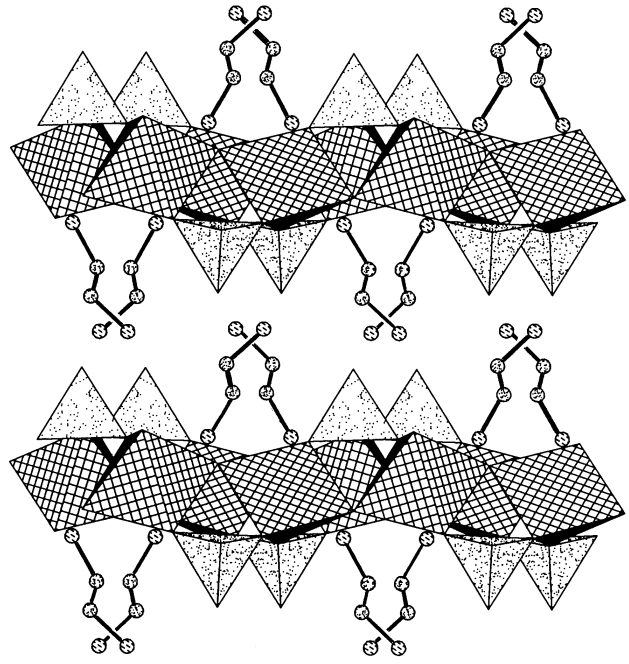

**Fig. 1** Projection of **1** along the *c*-axis showing a side view of the sheets with pendant [Hen] groups

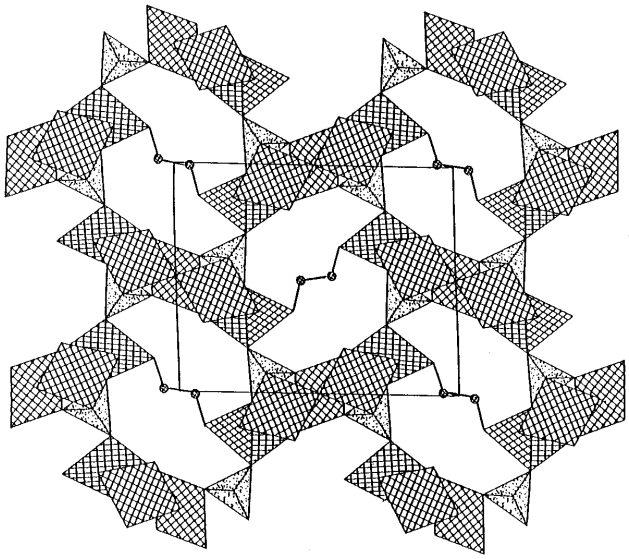

**Fig. 2** Polyhedral representation of **2** projected down [001]

Whilst use of stoichiometric levels of fluoride in these syntheses can result in $F^-$ incorporation, the use of lesser amounts can still promote crystallisation of indium phosphate phases not containing fluoride itself.[18] For example, in the same system for the synthesis of **1** and **2**, the use of 0.2 mol equiv. HF results in two other phases:[19] a two-dimensional layer compound $0.5[H_2en][InPO_4(OH)]$ (*ca.* 80%) and a chiral three-dimensional phase $[H_3O][InPO_4(OH)]$ (3%), which is isostructural with $Rb[InPO_4(OH)]$.[20]

The In/P ratios in **1** and **2** are unity or indium rich, in contrast to the previously reported indium phosphates containing template counterions, which are phosphorus rich.[11–13] Fluoride bridges and coordinated ethylenediamine groups exclusively occupy the surplus coordination sites of the octahedral indium atoms. This means that fewer phosphate groups are required than for constructing solely In–O–P linked systems, or that fewer oxygens need be in relatively unfavourable three-coordinate environments compared to $InPO_4$ itself. In conclusion, we believe more diverse stuctural types will continue to be found for mixed octahedral–tetrahedral framework materials and that use of fluoride may be a useful synthetic strategy to assist in their formation.

# First X-ray crystal structure of a lanthanide(III) monoporphyrinic complex using non-planar porphyrin rings

**Georgios A. Spyroulias,[a] Alexis Despotopoulos,[a] Catherine P. Raptopoulou,[b] Aris Terzis[b] and Athanassios G. Coutsolelos*[a]**

[a] *Laboratory of Bioinorganic Coordination Chemistry, Department of Chemistry, School of Science, University of Crete, PO Box 1470, 714 09-Heraklion, Crete, Greece*

[b] *Institute of Materials Science, N.C.S.R. 'Demokritos', 15310-Aghia Paraskevi, Athens, Greece*

**Twenty-three years after the first synthesis of lanthanide(III) porphyrins the X-ray crystal structure of [$Tb^{III}$(β-$Cl_8$tpp)($O_2$CMe)($Me_2SO_2$] is reported; the synthetic route to four halogenated porphyrins $H_2$(β-$X_n$tpp) (X = Cl or Br, *n* = 4 or 8) is described and compared with the corresponding [$Tb^{III}$(β-$X_n$tpp)($O_2$CMe)]; the highly distorted structure of the $Tb^{III}$ complex is compared with similar perhalogenated porphyrinic complexes; the X-ray structure of the brominated free base is also reported.**

Since the first reported synthesis of lanthanide monoporphyrinates in 1974,[1a] several studies on these systems have appeared in the literature.[1,2] Here, we report on the first X-ray structure of a lanthanide monoporphyrinate, [$Tb^{III}$(β-$Cl_8$tpp)($O_2$CMe)-($Me_2SO$)$_2$], and the structure of the inherently non-planar free base $H_2$(β-$Br_8$tpp). The synthesis of the [$Tb^{III}$(β-$X_n$tpp)($O_2$CMe)] and $H_2$(β-$X_n$tpp) derivatives, is also described (X = Cl or Br, *n* = 4 or 8). This new family of lanthanide(III) monoporphyrinates is promising both for the synthesis of novel homo- and hetero-leptic bisporphyrinates, formally analogous to the photosynthetic reaction centre special pair,[3] and for their photochemical[1b] and magnetic properties.[1d]

According to a previously reported chlorination procedure,[4] stirring an *o*-dichlorobenzene solution of [$Ni^{II}$(tpp)] (1 equiv.) at 150 °C for 2–3 h with 4.2 or 12 equiv. of bromo (or chloro) succinimide affords [2,7,12,17-*tetra*- or 2,3,7,8,12,13,17,18-octahalogeno-5,10,15,20-tetraphenylporphyrinato]nickel(II) respectively.†‡ The chromatographically pure ($Al_2O_3$/$CH_2Cl_2$) nickel(II) derivatives were then demetallated in concentrated $H_2SO_4$ (95%). The analytically pure free bases were obtained after extraction with $CH_2Cl_2$–$H_2O$, drying over $MgSO_4$, and chromatography (once or twice) on $Al_2O_3$/$CH_2Cl_2$.§ Reaction of tris(pentane-2,4-dionato)terbium(III) (15 equiv.) with $H_2$(β-$X_n$tpp) (1 equiv.) in refluxing 1,2,4-trichlorobenzene (tcb),[5] for 3 h affords the corresponding terbium monoporphyrinate complexes.¶‖ The terbium(III) complexes were purified by column chromatography on $Al_2O_3$ using, in order, toluene (elimination of tcb), $CH_2Cl_2$ (the unreacted free base is separated), MeOH–dmf (3 : 1 v/v) (part of the desired derivative) and $Me_2SO$ (the major quantity of the desired complex) as eluents. The last two fractions were collected, evaporated to dryness, and the solid residue was recrystallized by slow evaporation in a saturated toluene solution.

The ORTEP diagram of the complex [$Tb^{III}$(β-$Cl_8$tpp)($O_2$C-Me)($Me_2SO$)$_2$] shown in Fig. 1,** sheds light on the molecular structure of lanthanide monoporphyrinates. The coordination sphere of terbium consists of the four nitrogen atoms of the substituted porphyrin, the oxygen atoms of a bidentate acetate and the oxygen atoms of two $Me_2SO$ solvent molecules. The coordination geometry of the terbium(III) ion is square antiprismatic, the average dihedral angle between a pair of N–Tb–N and O–Tb–O planes being 46.74°. The mean Tb–N and Tb–O bond distances are 2.427 and 2.445 Å, respectively. The terbium(III) ion lies 1.282 and 1.469 Å out of the mean $N_4$ and mean $O_4$ plane, respectively, while the $N_4$ and $O_4$ mean planes manifest a dihedral tilt angle of 1.71°. Scheidt and Lee[6] have shown that the mean absolute perpendicular displacements of the β-carbons from the porphyrin mean plane ($C_\beta$) increase with decreasing dihedral angles between the phenyl rings and porphyrin core in saddled [M(tpp)]$^{n+}$ derivatives. The porphyrin ring of the $Tb^{III}$ complex also manifests a marked saddle distortion with a mean absolute perpendicular displacement for the β-carbons from the $N_4$ mean plane of 0.89 Å. Relative to [$Fe^{III}$(β-$Cl_8$tmp)Cl] ($C_\beta$ = 0.87 Å),[7] [Zn(β-$Cl_8$tfp)] ($C_\beta$ = 0.79 Å),[8a] and [Ru(β-$Cl_8$tfp)] ($C_\beta$ = 0.48 Å),[8b] this magnitude of distortion is the largest yet observed for a β-halogeno metalloporphyrin. The displacement of the individual chlorine atoms from the $N_4$ mean plane is in the range 1.03–2.18 Å, which is considerably larger than that found in [Zn(β-$Cl_8$tfp)] (1.17–1.48 Å)[8a] and [Ru(β-$Cl_8$tfp)] (0.68–1.11 Å).[8b] Finally, as in the following structure of the free base, rotation of the phenyl rings with respect to the porphyrin mean plane minimizes unfavourable steric interactions with the flanking chloride substituents. The dihedral angles formed between the phenyl rings and the $N_4$ mean plane are: 49.03° [C(21)–C(26)], 49.36° [C(27)–C(32)], 49.38° [C(33)–C(38)] and 49.74° [C(39)–C(44)].

The saddle distortion of $H_2$(β-$Br_8$tpp) is particularly severe (Fig. 2). Thus, the $C_\beta$ are canted well above the $N_4$ mean plane ($C_\beta$ = 1.263 Å) relative to that observed in the related species

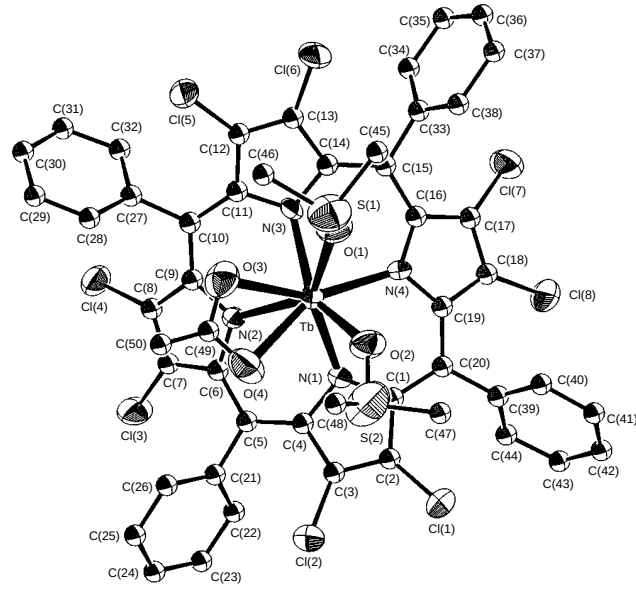

**Fig. 1** ORTEP diagram of [$Tb^{III}$(β-$Cl_8$tpp)($O_2$CMe)($Me_2SO$)$_2$]. All carbon atoms are shown isotropic for clarity, and heteroatoms are anisotropic with 30% probability thermal ellipsoids.

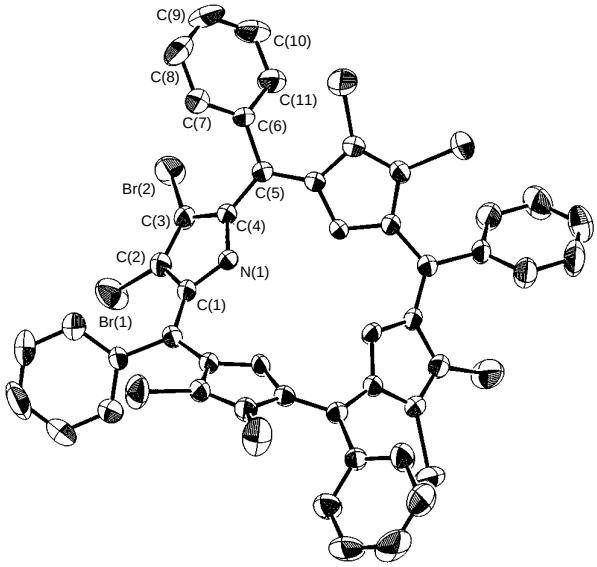

**Fig. 2** ORTEP diagram of $H_2$(β-$Br_8$tpp)·2dmf labelling the crystallographically independent atoms with 50% probability thermal elliposids

$H_2$(β-$Br_8$tfpp) ($C_\beta$ = 0.903 Å)[7] and $H_2$(β-$Br_8$tmp) ($C_\beta$ = 0.95 Å).[7,8b] The pronounced non-planarity of $H_2$(β-$Br_8$tpp) is also reflected by the large average perpendicular displacement of the *meso* carbons ($C_m$ = 0.317 Å) from the $N_4$ mean plane relative to that observed for $H_2$(β-$Br_8$tmp) ($C_m$ = 0.30 Å),[7,8b] and $H_2$(β-$Br_8$tfpp)[8a] ($C_m$ = 0.091 Å). The marked saddle distortion of $H_2$(β-$Br_8$tpp), and hence tipping of the pyrrole rings, results in particularly acute dihedral angles for the phenyl rings relative to the $N_4$ mean plane (29.7°). The pyrrole rings themselves are alternately canted above and below the $N_4$ mean plane with an average value of 44.6°.

The role played by non-planar porphyrin ligands in the coordination chemistry of rare-earth elements, and the unusual spectroscopic properties (UV–VIS, NMR data and electrochemical potentials) of their mono- or bis-porphyrinate complexes are two intriguing questions currently under investigation in our laboratory.

This research was supported by the Greek General Secretariat of Research and Technology through Grant A/A No. 1946 (1995) and by the General Secretariat of Athletic (OPAP). We are grateful to Dr O. Q. Munro for helpful discussions during the preparation of the manuscript. Mrs A. Athanassion is gratefully acknowledged for financial support to C. P. R.

## Footnotes

† This lack of regiospecificity is justified by the predominant absence of localized double-bond character in the metalloporphyrin (see also ref. 4) which results in the introduction of one halogen atom in each pyrrolic/pyrrolenic ring; H. J. Callot, *Tetrahedron Lett.*, 1973, **50**, 4987.

‡ A detailed description of the synthesis, purification and the complete spectroscopic data of the nickel(II) β-tetra- and β-octa-halogenated tpp complexes as well as the X-ray study of [Ni(β-$Br_8$tpp)] will be published elsewhere, work in progress.

§ UV–VIS data in $CH_2Cl_2$, 20 °C, $\lambda_{max}$/nm, [log(ε/dm$^3$ mol$^{-1}$ cm$^{-1}$) in parentheses]: $H_2$(β-$Cl_4$tpp), 426 (5.44), 523 (4.35), 599 (3.56), 667 (3.54); $H_2$(β-$Cl_8$tpp), 453 (5.38), 551 (4.04), 601 (4.03), 719 (3.85); $H_2$(β-$Br_4$tpp), 430 (5.40), 527 (4.29), 598 (3.51), 673 (3.49); $H_2$(β-$Br_8$tpp), 469 (5.31), 569 (4.02), 625 (4.14), 745 (3.88). All complexes gave satisfactory elemental analysis data.

¶ The pyrolysis of $Tb^{III}(acac)_3$ during the course of this high temperature synthesis provides a reasonable explanation for the unexpected presence of the acetate ligand on the coordination sphere of terbium. For all the investigated complexes characteristic IR bands were observed at the regions 1440–1446 and 1490–1496 cm$^{-1}$, representative of the bidentate coordination of the $O_2$CMe ligand (see also: K. Nakamoto, in *Infrared and Raman Spectra of Inorganic and Coordination Compounds*, Wiley, 3rd edn., 1978).

‖ UV–VIS data in $CH_2Cl_2$, 20 °C, $\lambda_{max}$/nm, [log(ε/dm$^3$ mol$^{-1}$ cm$^{-1}$) in parentheses]: [$Tb^{III}$(β-$Cl_4$tpp)($O_2$CMe)], 432 (5.25), 563 (4.20), 596 (3.76); [$Tb^{III}$(β-$Cl_8$tpp)($O_2$CMe)], 460 (4.77), 553 (3.69), 598 (3.85), 652 (3.89); [$Tb^{III}$(β-$Br_4$tpp)($O_2$CMe)], 432 (5.20), 569 (4.15), 596 (3.64); [$Tb^{III}$(β-$Br_8$tpp)($O_2$CMe)], 474 (4.65), 552 (3.48), 612 (3.42), 669 (3.50). All complexes gave satisfactory elemental analysis data.

** *Crystal data*: [$Tb^{III}$(β-$Cl_8$tpp)($MeCO_2$)($Me_2SO$)$_2$], $C_{72}H_{63}Cl_8N_4O_5S_2Tb$, $M$ = 1570.91; monoclinic, space group $P2_1/c$; $a$ = 19.775(5), $b$ = 13.516(3), $c$ = 30.015(6) Å, β = 108.409(7)°, $U$ = 7612(3) Å$^3$, $Z$ = 4, $D_c$ ($D_m$) = 1.371 (1.36) g cm$^{-3}$, $T$ = 298 K. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. # Resin type can have important effects on solid phase asymmetric alkylation reactions

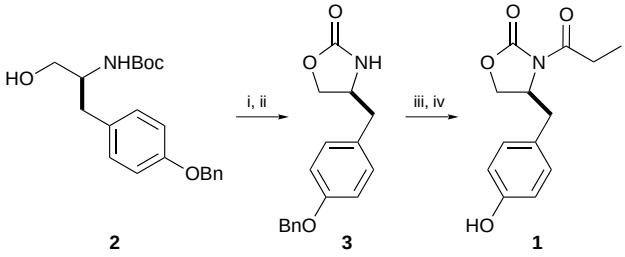
**Kevin Burgess* and Dongyeol Lim**

*Department of Chemistry, Texas A & M University, College Station, TX 77843-3255, USA*



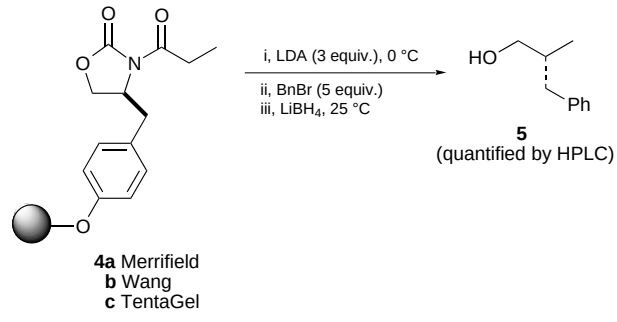
**A new *N*-propionylated oxazolidinone 1 is prepared; asymmetric alkylations of this auxiliary proceed with varying yields and enantioselectivities when supported on Merrifield, Wang and TentaGel R PHB resins.**

Techniques for solid phase organic syntheses[1] are pivotal for the development of combinatorial methods and other approaches to high throughput syntheses.[2–4] Asymmetric reactions on a solid phase have not been widely explored so far, yet they have potential advantages for some applications.[5] Supported chiral auxiliaries, for instance, can be recovered by filtration, and could potentially be recycled.

Two issues that need to be addressed for syntheses and applications of supported chiral auxiliaries are, first, how the auxiliary will be linked to the solid phase and, second, which solid phase will be used. At least two approaches to these problems have been reported. Leznoff initiated this area of research in studies wherein chiral amines were *O*-linked to Merrifield resin; condensations of these supported amines with cyclohexanone gave imines which were then deprotonated and *C*-methylated with high stereoselectivities.[6] More recently, Kurth and co-workers have attached pyrrolidine-based auxiliaries to Merrifield resin and used them in allylation/iodolactonization sequences.[7–9] Neither of these studies, however, embraced auxiliaries that are widely used in contemporary organic syntheses, and some of the supports that are now favoured for solid phase reactions. Here we describe an oxazolidinone **1** that can be conveniently linked to polymeric materials, and demonstrate that the choice of resin is important with respect to applications of the supported-auxiliary.

Synthesis of the oxazolidinone **1** began with commercially available Boc-Tyr(Bn) which was easily reduced to the corresponding alcohol **2** ($Pr^iOCOCl$, $NEt_3$, THF, then $NaBH_4$, $H_2O$). Removal of the *N*-protecting group and reaction with phosgene gave oxazolidinone **3** (Scheme 1). This material was then *N*-propionylated and subjected to hydrogenolysis to give the desired auxiliary **1**.

One of the attractive features of oxazolidinone **1** is that the phenolic hydroxy group is available for attachment to polymers. For Merrifield's resin this was accomplished *via* nucleophilic displacement of the benzylic chloride (3 equiv. of **1**, $Bu^tOK$, catalytic 18-crown-6/$Bu_4NI$, DMF, 75 °C, 3.5 d).[9] However, for the Wang and TentaGel resins Mitsunobu couplings[10] were used (3 equiv. of **1**, $EtO_2CNNCO_2Et$, $PPh_3$, 20 h).[11–13] Loadings of the auxiliary on the resins were difficult to determine accurately; after some experimentation, the following method was developed. The functionalized resins were reacted with lithium benzyloxide, and the benzyl propionate produced was quantified using HPLC and NMR. On the basis of these measurements it was calculated that approximately 30% of the available reactive sites on the Merrifield resin were coupled with the auxiliary under the conditions described above. For the Wang and TentaGel resins the corresponding loadings were 56 and 60% respectively.

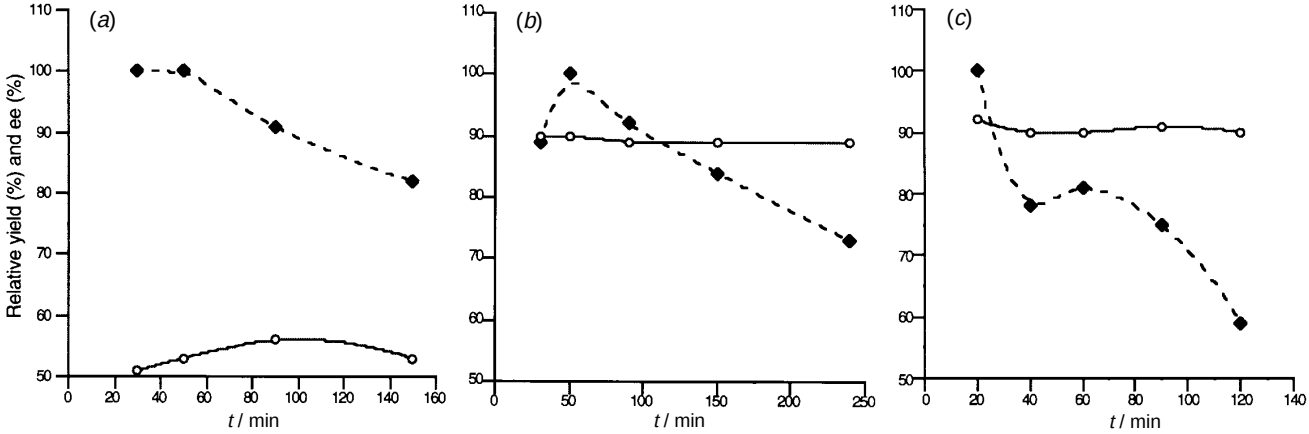


**Scheme 1** *Reagents and conditions*: i, HCl, $Et_2O$–EtOAc, 25 °C, 15 h (93%); ii, $COCl_2$, KOH–$K_2CO_3$ (aq), MePh, 0–25 °C, 12 h (98%); iii, $(EtCO)_2O$, LiCl, $NEt_3$, THF, −78–25 °C, 18 h (93%); iv, $H_2$, cat. Pd–C, MeOH–EtOAc, 25 °C, 12 h (96%)

Deprotonation of the supported oxazolidinones **4** with LDA in THF then reaction with benzyl bromide was chosen as a model transformation. These reactions were followed by IR (KBr disc). With Wang resin for instance, the supported oxazolidinones **4** had carbonyl stretches at 1704 and 1785 $cm^{-1}$. Benzylation of this material shifted the IR bands to 1701 and 1778 $cm^{-1}$. Hydrolytic cleavage of the benzylated propionate produced resin with a single carbonyl stretch at 1743 $cm^{-1}$, corresponding to the supported auxiliary. IR spectra of similar, but unsupported, auxiliaries have carbonyl stretches at *ca*. 1752 $cm^{-1}$.

A series of preliminary reactions showed the number of equivalents of base and the reaction times had a significant effect on the enantiomeric excess. It was also observed that reactions on the TentaGel resin were faster than on the Merrifield and Wang supports. Consequently, a series of experiments were performed in which 3 equiv. of LDA were added to the heterogeneous auxiliary at 0 °C. For the Merrifield and Wang resins, benzyl bromide was added after 30 min, allowed to react at 0 °C for 30 min, then for a systematically varied time at 25 °C. For the TentaGel based system, benzyl bromide was added after 20 min, and allowed to react for various times at 0 °C. The results of these studies are summarized in Fig. 1.

Fig. 1 shows that the yield of alcohol **5** reaches a maximum in the initial stages of the reaction, then decreases. For the TentaGel resin, the maximum yield is observed at short reaction times and decreases more precipitously as the reaction time is extended than for either the Merrifield or the Wang resins. Throughout, the HPLC traces of the material cleaved from the support show only one UV active product, hence the reduction in the yield is not due to formation of supported impurities with UV chromophores. Decreased yields could, however, be due to



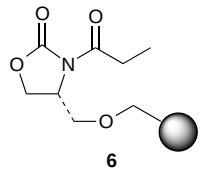


**Fig. 1** Percent yield (relative to the maximum for that reaction (◆) and enantiomeric excess (○) profiles for benzylation of the supported auxiliary **4** on (*a*) Merrifield, (*b*) Wang and (*c*) Tentagel R PHB resins. For conditions, see text.

**Table 1** Asymmetric alkylation reactions of the Wang-supported oxazolidinone **4b**

| | Reaction conditions | | | | |
|---|---|---|---|---|---|
| Alkylating agent | Equiv. LDA | Time/h at 0 °C | Time/h at 25 °C | Yield[a] (%) | Ee[b] (%) |
| BnBr | 3 | 0.5 | 0.33 | 66 | 90 |
| BnBr | 2 | 1.0 | 12 | 39 | 86 |
| $CH_2CHCH_2Br$ | 3 | 0.5 | 0.33 | 25 | 81[c] |
| $CH_2CHCH_2Br$ | 2 | 2.0 | 15 | — | 88 |
| $BnOCH_2Cl$ | 3 | 0.5 | 0.33 | 12 | 71[d] |
| $BnOCH_2Cl$ | 2 | 2.5 | 14 | 20 | 76[d] |

[a] For the alkylation and cleavage steps combined, determined by analytical HPLC using phenylpropanol as an internal standard. Authentic racemic products were prepared by solution phase syntheses and identified by $^1H$ and $^{13}C$ NMR spectroscopy. [b] Determined by analytical HPLC using a ChiralCel OD column. [c] Yields and ees were determined by using a chiral GC column prepared 'in house'. [d] Errors were relatively high because HPLC resolution of the enantiomers on a ChiralCel OD did not give baseline separation.

**6**

loss of the propionyl group from the oxazolidinone prior to cleavage.[14] Consistent with this, the IR stretch for the supported amide at 1701 $cm^{-1}$ diminishes with reaction time. Throughout, the measured enantiomeric excesses of the product **5** vary by ±3%; this fluctuation is probably within experimental error. However, in other experiments it was observed that after longer reaction times the enantiomeric excess of the product decreases measurably.

Overall, the data in Fig. 1 indicate that in terms of yield, enantiomeric excess and preservation of yield after extended reaction times, Wang resin is the preferred support. It is also cheaper than TentaGel resin, and has a higher loading capacity. Several more reactions were therefore performed using Wang resin and the results are summarized in Table 1. Yields and enantiomeric excesses obtained for benzyl bromide were superior to those obtained with other electrophiles. However, the results for these other electrophiles probably could be improved *via* optimization studies of the type carried out for the benzylation reactions.

After this work was complete, but before these studies were submitted for publication, other researchers reported the preparation of an oxazolidinone **6**, supported on Merrifield resin.[15] One alkylation reaction of this material was described (2 equiv. LDA, THF, 0 °C, then 2 equiv. BnBr; deprotonation and alkylation time unspecified), and that benzylation product (isolated as the acid) had an enantiomeric excess of 96%. We would have anticipated that the structural differences between auxiliaries **6** and **4** would be such that the tyrosine derivative **4** would give higher diastereoselectivities. In fact, **4** on Merrifield resin in our study gave stereoselectivities that are markedly inferior to those reported for **6** on the same resin, a result that we find surprising.

Overall, we conclude that optimization of these solid phase alkylation reactions is more difficult than for the corresponding solution phase reactions; the support has a marked effect and different resins may be most suitable for different oxazolidinones and electrophiles. Generally, solid phase reactions are more difficult to study than transformations in solution because they are more difficult to monitor. In addition, this work shows that resin type can be a significant variable that can further complicate the process of optimization.

We thank Dr Aroonsiri Shitangkoon for help with the chiral chromatography. Financial support for this research was obtained from The National Institutes of Health and The Robert A. Welch Foundation, and K. B. thanks the NIH for a Research Career Development Award and the Alfred P. Sloan Foundation for a fellowship. NMR facilities were provided by the NSF *via* the chemical instrumentation programme.

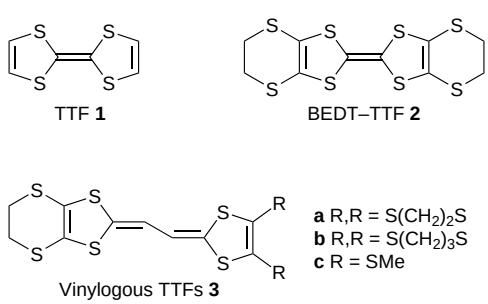
# New vinylogous tetrathiafulvalene π-electron donors with lower oxidation potentials

**Lianhe Yu* and Daoben Zhu**

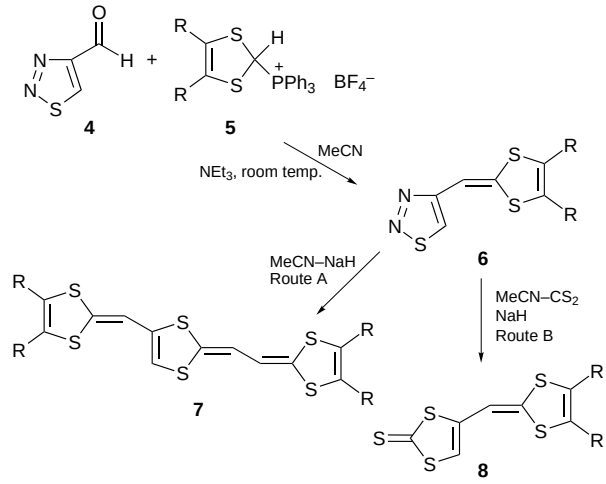


*Laboratory of Organic Solids, Institute of Chemistry, Chinese Academy of Sciences, Beijing 100080, PR China*

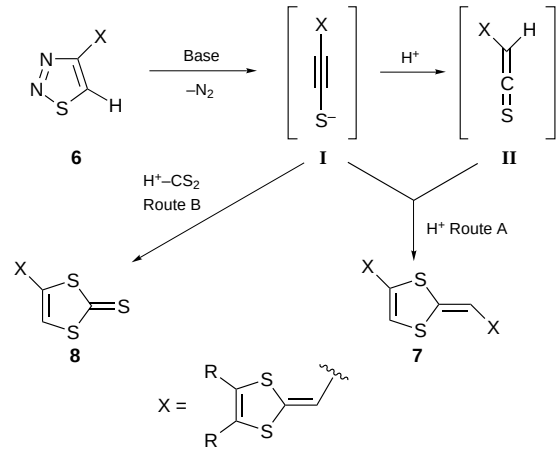
**The efficient synthesis of three new vinylogous TTF and three new 1,3-dithiole-2-thione derivatives is described; cyclic voltammetry establishes that the new donors have significantly lower solution oxidation potentials than BEDT–TTF.**

Among the organic donors, much work has been done on the tetrathiafulvalenes (TTF) **1** in the race for new organic conductors and/or superconductors.[1] Modification of the basic TTF framework leading to new functionalized π-donors has been intensively studied,[2] notably, bis(ethylenedithiol)tetrathiafulvalene (BEDT–TTF) **2** has produced organic superconductors with $T_c$ values as high as 12.8 K.[3] The synthesis of new π-donors related to TTF is central to the understanding of the solid-state properties of this fascinating class of materials. In particular, derivatives with lower oxidation potentials than the parent compounds TTF and BEDT–TTF are prime targets, an interesting type of such derivatives involves insertion of a conjugated spacer between two 1,3-dithiole rings, *i.e.* the so-called vinylogous TTF **3**.[4] The synthesis of such extended TTFs reported in the literature is mainly based on the Wittig–Horner reaction of a (1,3-dithiol-2-yl)phosphonium salt with an appropriate aldehyde.[4] Herein we report an alternative route to the new vinylogous **7** as well as new 1,3-dithiole-2-thiones **8** *via* base catalysed ring opening of 4-(1,4-dithiafulven-6-yl)-1,2,3-thiadiazole; this route seems to have been overlooked as an entry into the preparation of such vinylogous derivatives.[5]

The synthesis of the new donors is outlined in Scheme 1. The key starting material, 4-formyl-1,2,3-thiadiazole **4**, was prepared by the Hurd–Mori reaction,[6] while the (1,3-dithiol-2-yl)phosphonium salts **5** were synthesized by a well-established four-step reaction[7] from the corresponding readily available 1,3-dithiole-2-thiones.[8]



Equimolar amounts of **4** and **5** were condensed in dry acetonitrile in the presence of triethylamine at room temperature under nitrogen, which afforded **6** in 80–85% yield. Treatment of **6** with base (NaH 80% mineral dispersion) in neat acetonitrile at ambient temperature under nitrogen gave the corresponding novel vinylogous TTF derivatives **7a**–**c** in 40–70% yield after purification (route A).† However, when carbon disulfide was added, the NaH catalysed ring opening of **6** afforded new 1,3-dithiole-2-thione **8** in 70–85% yield (route B).‡ Compounds **8** are important synthetic building blocks for the construction of new types of (1,4-dithiafulven-6-yl)-substituted TTF derivatives. The target molecules **7a** and **7b** are very insoluble in organic solvents, nevertheless, the solubility of **7** can be improved by changing the R group, and indeed, **7c** (R = SMe) is very soluble in organic solvents such as $CH_2Cl_2$, $CHCl_3$, THF, MeCN. Molecular ion peaks of all new donors could not be obtained using EI, CI or FAB mass spectra, however, the field desorption mass spectra of **7** were successfully recorded.



The mechanism of the base catalysed ring opening of 4-substituted 1,2,3-thiadiazole is briefly outlined in Scheme 2.[9]

Base catalysed decomposition of **6** afforded alkyne **I** and subsequently **II**. It is proposed that 1,3-addition of **I** to the thioketene **II** affords **7**,[9a] however, when $CS_2$ is added, 1,3-addition of **I** to $CS_2$ affords **8** in a similar manner.

The electrochemical properties of **7** were investigated by cyclic voltammetry. All new vinylogous derivatives **7a**–**c**

**Scheme 1** Synthesis of novel vinylogous TTF and 1,3-dithiole-2-thione derivatives

**Scheme 2** Mechanism for the formation of **7** and **8**

undergo two reversible, single-electron oxidations, *e.g*. Fig. 1 shows the cyclic voltammogram of compound **7b** recorded at 50 mV $s^{-1}$. Very similar results were obtained for the other donors. In order to compare the $E_1^{1/2}$ and $E_2^{1/2}$ values of **7** with those of the related vinylogous **3**, we have also synthesized the known donors **3a**–**c** according to the method described in the literature.[4] Table 1 shows the redox potentials of **7** along with TTF **1**, BEDT–TTF **2** and **3**.

From Table 1, two important consequences of enlarging the conjugated π-system are observed: (i), both the first and second oxidation potentials of **7** are lower in comparison with **1**, **2** and **3**, obviously demonstrating that **7** is a more efficient electron donor than BEDT–TTF as expected from the calculated ionization potentials, and (ii) the difference between the two redox waves $\Delta E^{1/2}$ is reduced in the vinylogues derivatives, evidence of reduced intramolecular Coulombic repulsion in the dication state, suggesting that there is scope for obtaining molecular conductors or magnets based upon entirely new π-electron donors.

As expected from these results, all new donors **7** behave as good precursors for organic metals, and thus further experiments are underway to prepare charge transfer complexes based on the novel donors.

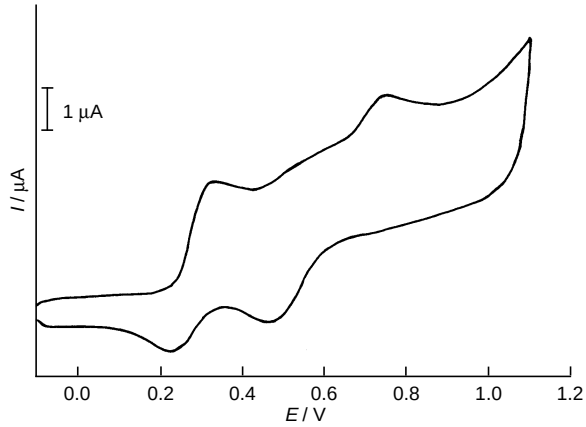


**Fig. 1** Cyclic voltammogram of **7b** range from 0.0 to 1.2 V

**Table 1** Cyclic voltammetric data for donors **1**, **2**, **3** and **7**[a]

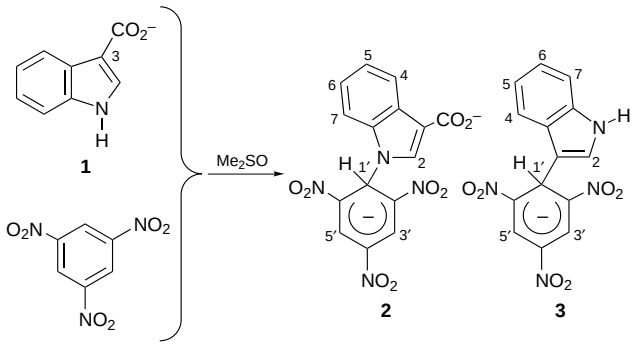
# The first isolation of a π-complex precursor in Meisenheimer complex formation

**Patricia Sepulcri, Régis Goumont, Jean-Claude Hallé, Erwin Buncel*† and François Terrier***

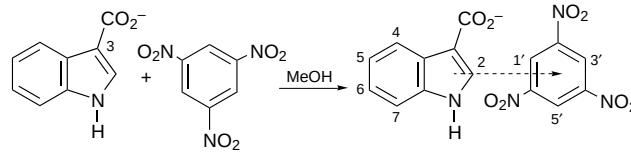
*Laboratoire SIRCOB, EP CNRS 102, Bâtiment Lavoisier, Université de Versailles, 45, Avenue des Etats-Unis, 78035 Versailles Cedex 05, France*

**Treatment of 1,3,5-trinitrobenzene with indole-3-carboxylate ion in methanol affords an isolable π-complex which is the precursor of the N- and C-adducts expected from the interaction.**



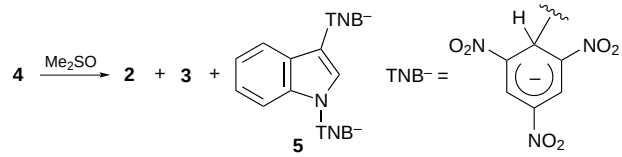
While the intermediacy of anionic σ-complexes in nucleophilic aromatic substitution is now well established,[1–5] the role of charge-transfer (CT) or π-complexes in such processes remains controversial.[6–10] A variety of experimental methods have provided evidence for the formation of CT or π-complexes in the interaction of electron-deficient aromatics (acceptors) and bases/nucleophiles (donors), but it is uncertain whether these species are formed in competing processes, concurrently, or whether they are present as intermediates on the $S_NAr$ reaction pathways. In a series of papers by Bunton and co-workers evidence has shown that π-complexes *and* charge-transfer (electron-transfer) complexes are formed prior to the anionic covalent σ-complex adducts, enroute to $S_NAr$ displacement, and are also intermediates in H/D exchange.[11–15] However, to our knowledge there has been no report so far of the actual isolation of CT or π-complexes in $S_NAr$ or σ-complex formation processes with a simple (classical) nitroaromatic compound such as 1,3,5-trinitrobenzene.[16] In this report we present evidence for the first instance of this kind.

The reaction of 1,3,5-trinitrobenzene (TNB) with indole-3-carboxylate (**1** as $Na^+$ salt) in $Me_2SO$, as followed by NMR spectroscopy, gives rise to the TNB N-adduct **2** concurrently with the TNB C-adduct **3** formed through decarboxylation (Scheme 1). These adducts could readily be characterized by $^1H$ and $^{13}C$ NMR spectroscopy (Table 1).[2,3]



However, when carried out in methanol the reaction takes a different course. This reaction gives rise to an adduct which can be isolated from the solution as the sodium salt and which we formulate as the π-complex **4** (Scheme 2). The adduct can be simply prepared by mixing 0.2 M methanolic solutions of TNB and indole 3-carboxylate ($Na^+$ salt) and evaporating to dryness.

This brown solid has been characterized as follows. The UV–VIS spectrum contains new bands (not present in TNB or **1**) of low intensity characteristic of π- or CT complexes[17] at 385, 413, 474 and 500 nm. Especially noteworthy in the $^1H$ NMR spectrum (Table 1) is the substantial shift to high field of the protons relative to the parent nitro-aromatic ($\Delta\delta$ = 0.50 ppm).[18] ESI mass spectroscopy experiments show the expected peak corresponding to the molecular ion of **4** (*m/z* 373). Also, CAD (collision activated dissociation) of this molecular ion shows the required daughter peaks, *i.e.* the indolecarboxylate (*m/z* 160) and TNB, actually (TNB − H)$^-$, (*m/z* 212) portions.



Interestingly, when **4** is placed in $Me_2SO$, it rapidly gives rise to the TNB N-adduct **2**, the TNB C-adduct **3** formed upon

decarboxylation, and the N–C diadduct **5** (Scheme 3). The mono-adduct **3** and the diadduct **5** were obtained previously from the direct reaction of TNB with indolide ion under more basic experimental conditions.[19]

While indole itself has been known to form a molecular complex with TNB,[20] the use in the present work of the indole-3-carboxylate ion (**1**) has allowed solubilization in methanol and, equally importantly, has increased charge density of the indole nucleus, thus stabilizing the π-complex.

Further work towards definitive characterization of π-complexes in these systems will be concerned with X-ray structure determination, kinetic studies, and structural variation of the indole moiety with the view of modulating the stability of these complexes.

Grants in aid of this research from CNRS (France) and NSERCC (Canada) are gratefully acknowledged.

# Unusual alkylidene ligands: synthesis and structure of the cyclopentadienylidene complex $[(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2(=C_5H_4)]$

**Paula M. Briggs,[a] Victor G. Young, Jr.[b] and David E. Wigley*[a]**

[a] *Carl S. Marvel Laboratories of Chemistry, Department of Chemistry, University of Arizona, Tucson, Arizona 85721, USA*
[b] *X-Ray Crystallographic Laboratory, Department of Chemistry, University of Minnesota, Minneapolis, Minnesota 55455, USA*

**The unique alkylidene complex $[(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2(=C_5H_4)]$ 2 is prepared in low yield from the reaction of $[(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2Cl_2]$ 1 with 2 equiv. of MeLi and is fully characterised including an X-ray structural determination.**

Transition-metal cyclopentadienyl complexes are situated at the heart of modern organometallic chemistry.[1] Of the known bonding modes of $C_5H_5$ and its analogues, the $\eta^5:\eta^1\text{-}C_5H_4$ structure that bridges two metal centres is well established and has played a role in the development of transition-metal metallocene chemistry.[2] We wish to report a new bonding mode of the $C_5H_4$ ligand that is ostensibly formed upon decomplexing the $\eta^5$ portion of a bridging $\eta^5:\eta^1\text{-}C_5H_4$ moiety, *viz.* the $\eta^1\text{-}C_5H_4$ alkylidene, or cyclopentadienylidene, ligand in the mononuclear complex $[(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2(=C_5H_4)]$.

Upon reacting a thf solution of $[Ta(NEt_2)_2Cl_3(OEt_2)]$[3] with 1 equiv. of $NaC_5H_5$, a red solution is obtained from which yellow–orange crystals of $[(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2Cl_2]$ **1** can be isolated in high yield (Scheme 1).† When $[(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2Cl_2]$ **1** is reacted with 2 equiv. of MeLi (−35 °C, toluene–$Et_2O$), the reaction quickly develops an orange colour and is accompanied by the evolution of a gas that is shown to be $CH_4$ by GCMS analysis (Scheme 1). After work-up of the oil obtained from this reaction, orange crystals of compound **2** may be obtained in low yield. In addition to resonances assigned to the $C_5H_5$ and $NEt_2$ ligands, the $^1$H NMR data for **2** {[$^2H_8$]thf} reveal two multiplets at δ 6.68 ($CH^\alpha$) and 5.49 ($CH^\beta$) that integrate to two protons each and its $^{13}$C NMR spectrum ($C_6D_6$) reveals three $^{13}$C resonances at δ 235.7, 124.5 and 113.6. On the basis of these NMR data, including HETCOR and NOE spectra, and an X-ray crystallographic study (*vide infra*), **2** is formulated as the terminal alkylidene, or cyclopentadienylidene, complex $[(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2(=C_5H_4)]$ (Scheme 1).

Although the orange–brown oil obtained from the $[(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2Cl_2]$ + 2MeLi reaction contains multiple products (including paramagnetic species), $[(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2(=C_5H_4)]$ **2** is the only product that we could isolate from the reaction mixture and then in only *ca.* 15% yield based on $C_5H_5$ (7.5% based upon tantalum). This low yield is not improved by changes in the reaction time, temperature, solvent, or the work-up procedure, nor can $[(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2(=C_5H_4)]$ **2** be prepared in greater yield by other synthetic methods.

$$[Ta(NEt_2)_2Cl_3(OEt_2)] + NaC_5H_5 \xrightarrow{thf} [(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2Cl_2] + NaCl$$

$$[(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2Cl_2] + 2MeLi \xrightarrow[-35\ °C,\ -CH_4]{toluene\text{–}Et_2O} [(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2(=C_5H_4)] + \text{other products}$$

15%

**Scheme 1**

The molecular structure of $[(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2(=C_5H_4)]$ **2** was determined by X-ray crystallography and is presented in Fig. 1.‡ The overall geometry can be described as a three-legged piano stool containing a terminal alkylidene ligand, as indicated by the short Ta–C(1) distance of 2.037(4) Å, which is well within the range expected for $d^0$ Ta=C double bonds.[4] The $C_5H_4$ ligand is planar and is clearly π localised as the diene, as indicated by the alternating C–C bond lengths around the ring. The plane of the $C_5H_4$ alkylidene ligand is slightly tilted from perpendicular with respect to the $\eta^5\text{-}C_5H_5$ plane (dihedral angle 74.8°) and the $NEt_2$ ligands are considerably tilted such that the Ta–N(3)–C(31)–C(33) plane is 54.9° and Ta–N(4)–C(41)–C(43) is 142.2° from the $\eta^5\text{-}C_5H_5$ plane. Such an arrangement places the two $TaNC_2$ planes nearly perpendicular (92.9°) to each other. Finally, the short Ta–N bonds of *ca.* 1.97 Å indicate significant $N(p_\pi)$–$Ta(d_\pi)$ electron donation from the amido ligand.[5]

Related structures containing $C_5H_4$ ligands have been described, for example the $\eta^5:\eta^1\text{-}C_5H_4$ ligand is well established in complexes such as $[(\eta^5\text{-}C_5H_5)(\eta^5:\eta^1\text{-}C_5H_4)NbH]_2$,[6] $[(\eta^5\text{-}C_5H_5)(\eta^5:\eta^1\text{-}C_5H_4)WH]_2$,[7] $[(\eta^5\text{-}C_5H_5)(\eta^5:\eta^1\text{-}C_5H_4)Mo]_2$[8] and $[(\eta^5\text{-}C_5H_5)(\eta^5:\eta^1\text{-}C_5H_4)Ti(PMe_3)]_2$.[9] If the *ipso* carbon (only) of the $\eta^5$ portion of an $\eta^5:\eta^1\text{-}C_5H_4$ ligand is decomplexed, an $\eta^4:\eta^1\text{-}C_5H_4$ ligand is generated, an example of which is seen in $[(\eta^5\text{-}C_5H_5)Co(\eta^4:\eta^1\text{-}C_5H_4)Co(\eta^5\text{-}C_5H_5)(PMe_3)]$,[10] and if the *ipso* carbon of an $\eta^1\text{-}C_5H_4$ ligand bridges two metals, a $\mu(\eta^1)\text{-}C_5H_4$ complex results as in Wilkinson's $[\{Re(=NBu^t)_2(\eta^1\text{-}C_5H_5)\}_2\{\mu(\eta^1)\text{-}C_5H_4\}(\mu\text{-}O)]$.[11] Finally, we note that Herrmann and coworkers have generated transient $[(\eta^5\text{-}C_5H_5)Mn(CO)_2(=C_5H_5)]$ from the reaction of

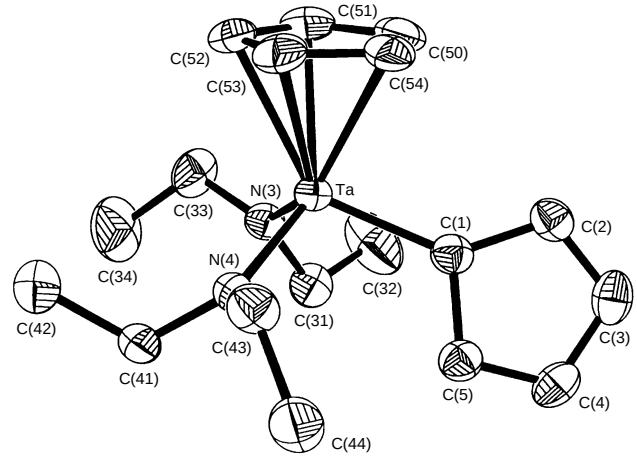

**Fig. 1** Molecular structure of $[(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2(=C_5H_4)]$ **2** with atoms drawn as 50% ellipsoids. Selected bond distances (Å) and angles (°): Ta–C(1) 2.037(4), Ta–N(3) 1.969(3), Ta–N(4) 1.966(3), C(1)–C(5) 1.455(5), C(1)–C(2) 1.451(5), C(2)–C(3) 1.367(5), C(3)–C(4) 1.426(6), C(4)–C(5) 1.369(5); N(3)–Ta–N(4) 100.59(12), N(3)–Ta–C(1) 105.47(13), N(4)–Ta–C(1) 101.30(13), Ta–C(1)–C(2) 136.1(3), Ta–C(1)–C(5) 118.4(3), C(1)–C(2)–C(3) 109.4(3), C(2)–C(3)–C(4) 108.8(3), C(3)–C(4)–C(5) 108.1(3), C(4)–C(5)–C(1) 109.5(3).

$[(\eta^5\text{-}C_5H_5)Mn(CO)_2(thf)]$ with $N_2C_5H_4$,[12] but this complex rapidly dimerises by a [2 + 2] cycloaddition of the cyclopentadienylidene ligands to afford $[(\eta^5\text{-}C_5H_5)(CO)_2\text{-}Mn(=C_5H_4C_5H_4=)Mn(CO)_2(\eta^5\text{-}C_5H_5)]$.

The formation of $[(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2(=C_5H_4)]$ **2** appears to involve both an intermolecular cyclopentadienyl transfer reaction and a C–H activation process of some type. Initial experiments have shown that $[(\eta^5\text{-}C_5H_5)Ta(NEt_2)_2Cl_2]$ **1** reacts with 2 equiv. of $CD_3Li$ to afford $CD_3H$ gas, but no $CH_4$. Further mechanistic experiments are in progress.

# Fluxional processes in organotransition-metal $C_{60}$ complexes

**Malcolm L. H. Green* and Adam H. H. Stephens**

*Inorganic Chemistry Laboratory, South Parks Road, Oxford, UK OX1 3QR*

**Variable-temperature and EXSY $^{13}$C NMR studies on [M(NO)(PPh$_3$)$_2$($\eta^2$-C$_{60}$)] (M = Co, Rh), [Ru(NO)(PPh$_3$)$_2$($\eta^2$-C$_{60}$)H] and [Rh(CO)(PPh$_3$)$_2$($\eta^2$-C$_{60}$)H] show the presence of C$_{60}$–metal moiety rotation and migration processes and the data allow extensive assignment of δ(C$_{60}$) $^{13}$C NMR resonances.**

The dynamical behaviour of organotransition-metal fullerene complexes has been little investigated. The only reported examples are fullerene–metal bond axis rotation for [M(CO)$_4$($\eta^2$-C$_{60}$)] (M = Fe, Ru) and [Fe(CO)$_4$($\eta^2$-C$_{70}$)][1,2] and metal moiety migration for [Pd(PR$_3$)$_2$($\eta^2$-C$_{60}$)] [R$_3$ = Me$_2$Ph, MePh$_2$, (OMe)$_3$] from preliminary variable-temperature $^{13}$C NMR studies.[3,4] Similar behaviour has been implicated for [C$_{60}${Ir(CO)(PEt$_3$)$_2$Cl}$_2$],[5] [C$_{60}${Pt(PEt$_3$)$_2$}$_6$],[6] [{Ru(η-C$_5$Me$_5$)(MeCN)$_2$}$_3$(C$_{60}$)]$^{3+}$[O$_3$SCF$_3^-$]$_3$[7] and [C$_{70}${Ir(CO)(PPh$_3$)$_2$Cl}$_2$.[8]

Here we report variable-temperature and two-dimensional EXSY $^{13}$C NMR spectroscopic studies of [M(NO)(PPh$_3$)$_2$(η$^2$-C$_{60}$)] (M = Co **1**, Rh **2**), [Ru(NO)(PPh$_3$)$_2$($\eta^2$-C$_{60}$)H] **3** and [Rh(CO)(PPh$_3$)$_2$(η$^2$-C$_{60}$)H] **4** which have allowed us to identify for the first time several fluxional processes. The $^1$H and $^{31}$P{$^1$H} NMR spectra remained unchanged between −90 and 50 °C, as expected. The new complexes were prepared by substitution of PPh$_3$ by C$_{60}$ from the relevant precursor.

At low temperatures the $^{13}$C NMR spectra of **1**–**4**, allowing for the commonly occurring accidental degeneracy of resonances, were consistent with a complex possessing $C_s$ symmetry (Table 1). Thus the structures are very similar to those previously determined for **4**[9] and the related complex of **3**, [Ru(NO)(PPh$_3$)$_2$($\eta^2$-C$_{60}$)Cl].[2]

On warming **2**, as illustrated in Fig. 1, the number and intensity of δ(C$_{60}$) $^{13}$C NMR signals changed to a 17 line $C_{2v}$ symmetry pattern (allowance again being made for isochronous resonances). Such changes are indicative of the onset of free rotation about the metal–fullerene bond. Observation of coupling for the C(1) (δ 83) carbon atoms and partially resolved coupling for C(2) (δ 160; see Fig. 2 for numbering scheme) carbon atoms to the $^{103}$Rh and $^{31}$P nuclei shows that the rotation is non-dissociative. The $^{13}$C{$^1$H} NMR spectra of **1** and **3** showed broadly similar features although signal coalescence occurred at different temperatures consistent with changes in the extent of π-back donation [$\Delta G^{\ddagger}$ *ca*. 9, 10 and 14 kcal mol$^{-1}$ for **1** at −60 °C, **2** at −50 °C and **3** at 0 °C, respectively (1 cal = 4.184 J)].

Further warming of samples of **1**, **2** and **4** resulted in all δ(C$_{60}$) resonances collapsing to a single broad peak at δ *ca*. 145 indicating that the metal moiety is migrating over the whole fullerene surface as all the carbon atoms have become chemically equivalent ($I_h$ symmetry). This migration was investigated using two-dimensional $^{13}$C EXSY NMR and, for the first time for a fullerene compound, it was possible to unambiguously assign it as a [1,3]-shift mechanism.

The two-dimensional $^{13}$C EXSY NMR ($\tau_{mix}$ = 0.5) spectrum of **1** (Fig. 2) reveals the expected number and nature of correlations for a [1,3] shift. For example, most signals, including C(2) and C(3), have four correlations (corresponding

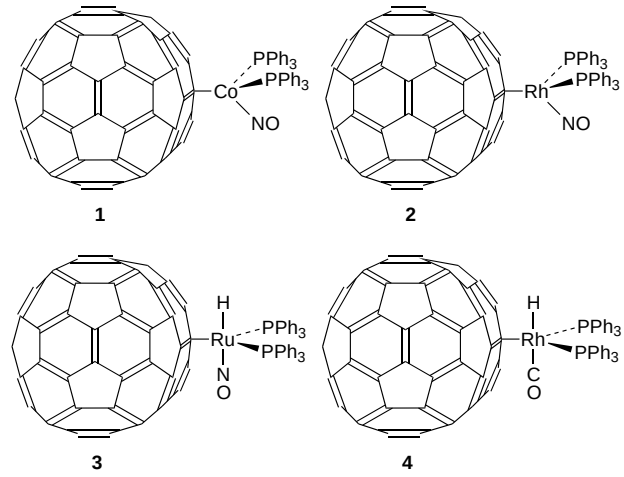

**Table 1** Summary of the δ(C$_{60}$) $^{13}$C NMR (125 MHz) intensity information for **1, 2, 3** and **4** and for model monoadducts with $C_s$, $C_{2v}$ and $I_h$ symmetry[a]

| Complex | *T*/°C | No. of peaks (intensity) | *T*/°C | No. of peaks (intensity) | *T*/°C | No. of peaks |
|---|---|---|---|---|---|---|
| **1** | −90 | 11(br)[b] | −10 | 4(2) + 11(4)<br>1(8) | 50 | 1(v br)[b,c] |
| **2** | −90 | 4(1) + 15(2)<br>1(4) + 1(6)<br>2(8) | −40 | 3(2) + 10(4)<br>1(6) + 1(8) | 25 | 1(v br)[b] |
| **3** | −90 | 2(1) + 13(2)<br>2(4) + 2(5)<br>1(6) + 1(8) | 50 | 4(2) + 11(4)<br>1(8) | | |
| **4** | −90 | 2(1) + 19(2)<br>2(3) + 2(4)<br>1(6) | | | 25 | 1(v br)[b,c] |
| $C_s$ | | 4(1) + 28(2) | | | | |
| $C_{2v}$ | | | | 4(2) + 13(4) | | |
| $I_h$ | | | | | | 1(60) |

[a] It is assumed that fullerene $T_1$ relaxation times do not vary significantly within a molecule. [b] Signals too weak and broad to be accurately integrated. [c] Recorded at 75 MHz.

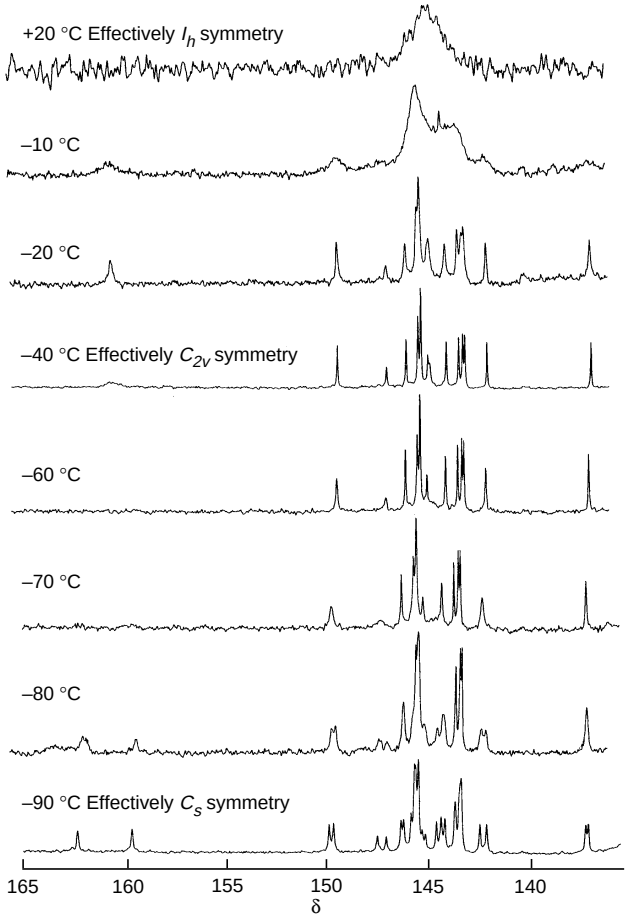

**Fig. 1** The $^{13}C\{^1H\}$ NMR (125 MHz, −90 to 25 °C, $C_4D_8O$) spectrum of **2** in the fullerene $sp^2$ region

to metal migration to the four adjacent C=C bonds). Also, C(1) showed only two correlations [to C(2) and C(3)] again indicating that only one type of migration, namely a [1,3] shift, is occurring. Owing to resonance overlap only 16 lines are clearly observable, although the total intensity is consistent with the presence of 60 fullerene carbon atoms. Tracing the unique set of correlations additionally allows assignment of most of the $\delta(C_{60})$ resonances† and out of approximately 400 fullerene compounds characterised by $^{13}C$ NMR spectroscopy this is only the second example. Interestingly, the assignment order has many similarities with that previously determined for $[(C_{60})OsO_4(4\text{-}Bu^tC_5H_4N)_2]$ using two-dimensional NMR INADEQUATE spectroscopy on an expensive isotopically enriched sample.[10] In consonance with both these studies and by observation of scalar couplings, a useful generality for fullerene assignments becomes apparent: For all 6,6-closed fullerene organic or organometallic adducts the lowest field signal(s) ($\delta > ca.$ 150) are due to the C(2) atoms and one, two or four resonances are present for a $C_{2v}$, $C_s$ or $C_1$ symmetry complex.

So far, we have not been able to unambiguously assign the mechanism to a dissociative (more likely) or an intramolecular $\eta^4$-$C_{60}$ process.

In summary, we have described the dynamical $^{13}C$ NMR properties of the compounds **1**–**4**. These studies have shown that the compounds collectively undergo rotation about the metal–fullerene bond axis and migration of the metal fragment over the surface of $C_{60}$. In each case the symmetry of the complexes is different and results in a significantly different $^{13}C$ NMR spectrum.

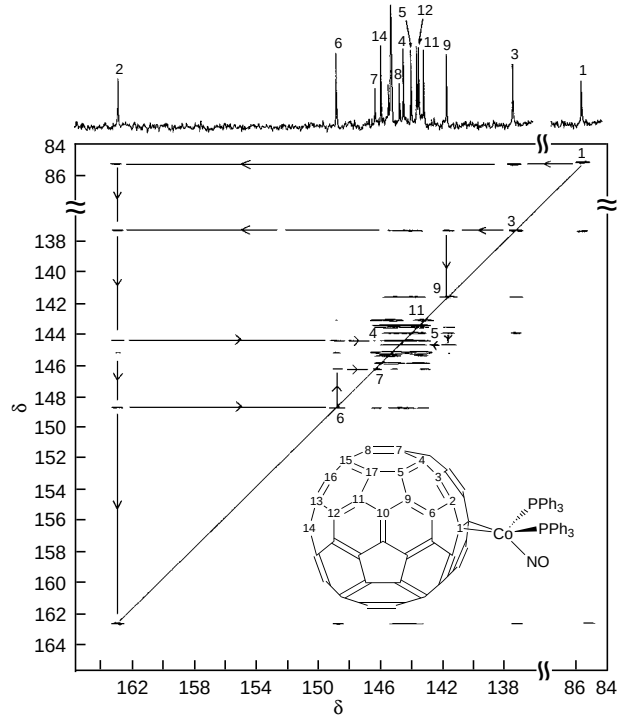

**Fig. 2** $^{13}C$–$^{13}C$ NMR (125 MHz, 5 °C, $C_4D_8O$) EXSY spectrum of **1** ($\tau_{mix}$ = 0.5 s)

We would like to thank Drs Mark Wormwald and Tim Claridge for help with the variable-temperature studies, Richard Douthwaite for supplying samples of $[Rh(CO)(PPh_3)_2(\eta^2\text{-}C_{60})H]$, and Lincoln College, Oxford for a JRF to A. H. H. S.

# Epoxidation of unsaturated fatty esters over large-pore Ti-containing molecular sieves as catalysts: important role of the hydrophobic–hydrophilic properties of the molecular sieve

**M. A. Camblor, A. Corma,* P. Esteve, A. Martínez and S. Valencia**

*Instituto de Tecnología Química, CSIC-UPV, Avda de los Naranjos s/n, 46071 Valencia, Spain*

**Ti-β and Ti-MCM-41 catalysts are able to epoxidize methyl oleate using hydrogen peroxide or *tert*-butyl hydroperoxide as oxygen donors with high conversions and epoxide selectivities.**

Epoxidized fatty acids and their derivatives are useful commercial chemicals used, *e.g.* as stabilizers in halogen-containing polymers, as additives in lubricants, in the manufacture of cosmetics and pharmaceuticals, fungicidal and algicidal solutions, and in wood treatment.[1–5] In existing industrial processes the epoxide is produced by reacting the unsaturated compound with a peracid either preformed[6] or synthesized *in situ*[7] with an organic acid, usually acetic or formic acid, and hydrogen peroxide. Using this procedure, the yields to epoxide are relativelly low as a consequence of the low $H_2O_2$ selectivities. Thus, it would be interesting to replace the processes based on peracids by a more desirable catalytic one.[8–12]

Recently, it has been shown that the incorporation of Ti into the framework of zeolites produce oxidation catalysts with unique shape-selective properties.[13] Large-pore Ti-β zeolite[14] and the mesoporous material Ti-MCM-41,[15] when properly prepared, are active for the selective oxidation of bulky substrates that can not diffuse inside the Ti-silicalite channels.[16–17] Because of their oxidation properties and the advantages related to the use of solid catalysts in industrial processes, Ti-β and Ti-MCM-41 could open new possibilities in the field of fatty acids and esters if they could selectively epoxidize the double bound, forming stable epoxides.

Here we report a new and interesting application of large-pore zeolites containing Ti in the framework such as the selective epoxidation of unsaturated fatty acids using organic and inorganic peroxides. We will show that the hydrophobic–hydrophilic properties of the zeolite play an important role when, as in this case, the organic reactant has two moieties with different polarities and an aqueous solution of $H_2O_2$ is used as oxidant.

Hydrophilic Ti-β samples were prepared as follows: samples 1 and 2 were synthesized by diluting tetraethylammonium hydroxide (TEAOH) (35%, Aldrich, Na < 1 ppm, K < 47 ppm) with the required amount of water to which tetraethylorthotitanate (TEOTi, Alfa) and tetraethylorthosilicate (TEOS, Merck) were added at room temperature with stirring. Finally, a solution of aluminium nitrate (Merck) was also added. Sample 4 was prepared by the hydrolysis of TEOS in an aqueous solution of TEAOH and $H_2O_2$ (35%, Fluka) under stirring. TEOTi was added and the mixture was left under stirring to allow the evaporation of the ethanol produced. Finally, dealuminated zeolite-β seeds were added under stirring (4 g of solid per 100 g of total $SiO_2$ in the reaction mixture). Sample 3 was synthesized in the same way but using non-dealuminated zeolite-β seeds which determined the total Al content of the reaction mixture.

A hydrophobic Ti-β sample (sample 5) was prepared as follows: TEOS was hydrolysed in an aqueous solution containing TEAOH and $H_2O_2$ followed by the hydrolysis of TEOTi and allowing evaporation of ethanol and water to the resultant clear solution, water lost in the evaporation and the appropriate amount of HF (48%) were added.

The chemical composition of the gels are listed in Table 1. After crystallization at 413 K and rotation at 60 rpm, the solids were separated, washed until pH = 9, dried at 353 K and calcined at 853 K.

A Ti-MCM-41 sample was synthesised as follows: an aqueous solution of tetramethylammonium silicate (25% TMAOH, 10% $SiO_2$, Aldrich) was added to an aqueous solution containing 29.0% hexadecyltrimethylammonium bromide (CTAB, Merck). When the solution was homogenized, amorphous silica (Aerosil 200, Degussa) and titanium isopropoxide (Alfa) were added. The molar chemical composition of the synthesis mixture was: $SiO_2$ : 0.15 CTAB : 24.3 $H_2O$ : 0.26 TMAOH : 0.016 $TiO_2$. The gel was heated at 413 K under static conditions. After filtering, the solid was washed, dried and calcined at 813 K for 1 h in a flow of $N_2$, followed by 6 h in air. The Ti content of the final solid was 2.5 mass% expressed as $TiO_2$.

Reactions were carried out batchwise in a 5 ml round-bottomed flask with continuous stirring. The flask contained the catalyst (30 mg), the substrate (1 mmol of methyl oleate), the solvent, when used (2 ml), and the peroxide (0.25 mmol). Products were analysed by capillary gas chromatography (25 m, 5% methylphenylsilicone) and their identification was established by GCMS. Unreacted peroxide was determined by iodometric titration.

Table 2 shows the results obtained in the epoxidation of methyl oleate with hydrogen peroxide on Ti-β and Ti-MCM-41 catalysts. As can be seen, higher conversions and $H_2O_2$

**Table 1** Chemical composition of Ti-β samples

| | Gel synthesis | | | | | | Solid | |

[a] Reaction conditions as in Table 2. Methanol used as solvent.

selectivities were obtained on Ti-β. It has been reported[18] that polar solvents, such as methanol or acetonitrile, enhance the activity of hydrophilic materials as epoxidation catalysts. However, the higher hydrophility of Ti-MCM-41, as compared to Ti-β, has a detrimental effect because it decreases the adsorption of the organic substrate and, consequently, it favours $H_2O_2$ decomposition.[17]

The epoxide is practically the only product obtained in acetonitrile with both catalysts while the epoxide selectivities are lower in methanol. In the case of Ti-β, the Al atoms present in the zeolite framework generate surface acid groups which catalyse the ring opening of the epoxide by addition of a protic molecule. When decreasing the zeolite acidity, *i.e.* decreasing the Al content in the catalyst, the epoxide selectivity increases (Table 3). This increase is even larger when the hydrophobic Ti-β, sample 5, is used. When there are no Al atoms in the catalyst framework (Al-free Ti-β and Ti-MCM-41), opening of the oxirane ring still occurs. This means that there are sites other than those associated with the Al framework which are able to catalyse the side reaction. These acid sites have been assigned to peroxo or hydroperoxo species formed by the interaction of hydrogen peroxide with Ti atoms in the zeolite.[19,20] The selectivity to the epoxide is significantly improved (*ca.* 90%) when the Al-free Ti-β sample is washed with an aqueous solution containing $Na^+$ cations (Table 3), although the activity of the catalyst slightly decreased.

As the presence of water inhibits the catalytic activity of Ti-MCM-41, the epoxidation of methyl oleate was also carried out using *tert*-butyl hydroperoxide (TBHP) as oxygen donor (Table 4). In this case, no solvent is needed to perform the epoxidation, with corresponding savings in reactor volume and separation costs. Under such reactions conditions Ti-MCM-41 was a highly effective catalyst with high conversions and selectivities to the epoxide and TBHP (*ca.* 91 and 99%, respectively). Ti-β is also able to epoxidize methyl oleate using TBHP as oxidant. Although the reaction rate is slower with respect to $H_2O_2$ due to steric restrictions to the formation of the transition state, the epoxide and TBHP selectivities are > 80%.

**Table 4** Epoxidation of methyl oleate with TBHP over Ti-β and Ti-MCM-41 catalysts[a]

| Catalyst | Oleate conv. (% of max.) | Epoxide selectivity (%) | TBHP conv. (%) | TBHP selectivity (%) |
|---|---|---|---|---|
| Ti-β[b] | 49.3 | 97.4 | 51.9 | 95.0 |
| Ti-MCM-41 | 64.6 | 91.1 | 65.3 | 98.9 |

[a] *Reaction conditions*: 296 mg methyl oleate, 112 mg TBHP (80% in *tert*-butyl peroxide), 30 mg catalyst. 70 °C, 8 h. [b] Sample 5.

In conclusion, hydrophobic Ti-β/$H_2O_2$ and Ti-MCM-41/TBHP have been demonstrated to be effective catalytic systems to prepare epoxidized fatty esters with high conversions and selectivities to epoxide.

# Biosynthesis of fluoroacetate and 4-fluorothreonine by *Streptomyces cattleya*. Glycine and pyruvate as precursors

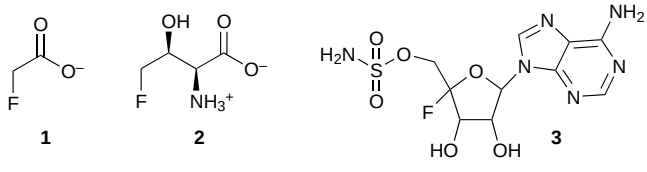
**John T. G. Hamilton,[a] Muhammad R. Amin,[b] David B. Harper*[a] and David O'Hagan*[b]†**

[a] *Microbial Biochemistry Section, Department of Food Science, The Queen's University of Belfast, Newforge Lane, Belfast, UK BT9 SPX*

[b] *University of Durham, Department of Chemistry, Science Laboratories, South Road, Durham, UK DH1 3LE*

**Using $^{19}F$ NMR spectroscopy, $^{13}C$-labelled glycines and pyruvates are shown to be incorporated at high levels into fluoroacetate and 4-fluorothreonine by resting cells of *Streptomyces cattleya*; the labelling patterns illustrate a conversion of glycine *via* serine to pyruvate, where the C-2 and C-3 carbon atoms of pyruvate contribute both carbon atoms of fluoroacetate and C-3 and C-4 of 4-fluorothreonine respectively.**

Fluorinated natural products are rare in nature.[1,2] The most ubiquitous of this class of natural product is fluoroacetate **1**, which is found in a wide variety of plant species in both arid and tropical regions around the world.[1,3] Only two bacterial strains, both actinomycetes, have been identified with the ability to biosynthesise organofluorine compounds. Fluoroacetate **1** and 4-fluorothreonine **2** are coproduced by *Streptomyces cattleya*[4] when grown in the presence of a source of fluoride and suspensions of resting cells of the organism provide an attractive system in which to explore the biosynthesis of these fluorinated metabolites.[5,6] Nucleocidin **3** was isolated[7] from *Streptomyces calvus* in 1957, although a correct structure for the molecule was not advanced until 1969.[8] Unfortunately more recent attempts to produce the antibiotic in culture have failed.[9] Here we report a study using $^{19}F$ NMR spectroscopy of the incorporation of [1-$^{13}C$]-, [2-$^{13}C$]-, [1,2-$^{13}C_2$]-glycine and [1-$^{13}C$]-, [2-$^{13}C$]-, [3-$^{13}C$]-pyruvate into both fluoroacetate **1** and 4-fluorothreonine **3** by *S. cattleya*. In each case the labelled precursors were incubated at a final concentration of 10 mM with resting cell suspensions and incorporation of $^{13}C$ label into the fluorometabolites was examined using GC–MS and $^{19}F$ NMR spectroscopy after 48 h.



The results of the GC–MS study, which are reported elsewhere,[10] revealed several striking features. A low level of incorporation of $^{13}C$ label (< 4%) from [1-$^{13}C$]glycine into fluoroacetate **1** contrasted with a very high level of incorporation (40%) from [2-$^{13}C$]glycine. Furthermore the labelling patterns in fluoroacetate from [2-$^{13}C$]- and [1,2-$^{13}C_2$]-glycine were practically identical, indicating that the high proportion (80% of total $^{13}C$ incorporation) of double incorporation observed in the [1,2-$^{13}C_2$]glycine experiment is not due to the incorporation of glycine as an intact two carbon unit but rather that the C-2 of glycine is recombined during the biosynthesis of fluoroacetate.

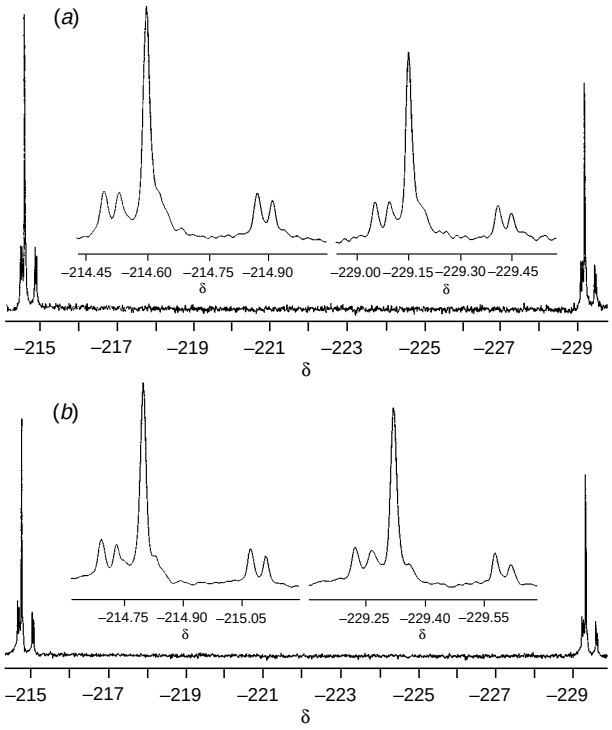
It was not possible to assess from the GC–MS data the precise extent of recombination of C-2 of glycine into C-3 and C-4 of 4-fluorothreonine and so the degree of analogy between the labelling pattern in C-3 and C-4 of 4-fluorothreonine and the C-1 and C-2 of fluoroacetate could not be ascertained. The uncertainty was resolved by $^{19}F\{^1H\}$ NMR spectroscopy. A direct comparison of the incorporation of isotope into C-1 and C-2 of fluoroacetate with that into C-3 and C-4 of 4-fluorothreonine was made by $^{19}F\{^1H\}$ NMR spectroscopy after concentration of the supernatant at the end of each experiment. Proton decoupling was advantageous in simplifying the complexity of the $^{19}F$ NMR signals at −214.6 ppm for fluoroacetate and −229.15 ppm for 4-fluorothreonine, revealing coupling patterns which indicate intact $^{19}F$-$^{13}C$-$^{13}C$, $^{19}F$-$^{13}C$-$^{12}C$ and $^{19}F$-$^{12}C$-$^{13}C$ combinations ($^1J_{^{19}F\text{-}^{13}C}$ = 165 Hz, $^2J_{^{19}F\text{-}^{13}C}$ = 18 Hz) in the resultant metabolites. The signals for each of the two fluorinated metabolites obtained by $^{19}F\{^1H\}$ NMR spectroscopy always possessed a similar multiplicity indicating that $^{13}C$ incorporations in terms of magnitude and regiochemistry into C-1 and C-2 of fluoroacetate mirror those into C-3 and C-4 of 4-fluorothreonine. The most obvious interpretation of this observation is that both sets of carbons have an identical biosynthetic origin and that there is a single fluorinating enzyme operating in *S. cattleya*. Our previous studies[5,6] have ruled out a direct interconversion of one of the metabolites to the other, so we are forced to the conclusion that each fluorometabolite arises by metabolism of a (presently unknown) common fluorinated intermediate.

The $^{19}F\{^1H\}$ NMR spectrum resulting from incubation of [2-$^{13}C$]glycine with resting cells is shown in Fig. 1. This spectrum has identical features to that obtained after incubation with [1,2-$^{13}C_2$]glycine which is entirely consistent with the GC–MS data and confirms that only C-2 of glycine is contributing $^{13}C$ label to the fluorinated metabolites. The similarity in the patterns of the $^{19}F$ NMR signals of the resultant fluoroacetate and 4-fluorothreonine is striking. In each case the parent (unlabelled) signal (singlet) has a predominant doublet of doublets ($^1J_{^{19}F\text{-}^{13}C}$ = 160 Hz, $^2J_{^{19}F\text{-}^{13}C}$ = 18 Hz, α + β-shift = 0.09 ppm) associated with it due to populations of **1** and **2** (*ca*. 40%) with an intact $^{19}F$-$^{13}C$-$^{13}C$ combination. There is also a doublet ($^1J_{^{19}F\text{-}^{13}C}$ = 165 Hz, α-shift = 0.07 ppm) due to populations (*ca*. 5%) with an intact $^{19}F$-$^{13}C$-$^{12}C$ combination. This is apparent as a small increase in the intensity of the left hand arms of the predominant doublet of doublets. Finally the right hand arm of a doublet (18 Hz, β-shift = 0.02) can be seen at the base of the unlabelled peaks for **1** and **3** due to populations (*ca*. 7%) with an intact $^{19}F$-$^{12}C$-$^{13}C$ combination.

The high level of recombination of C-2 of glycine in both fluorometabolites and very low incorporation of C-1 is most readily explained if glycine is converted to serine or a metabolite of serine such as pyruvate (Scheme 1). In bacteria[11] glycine is cleaved and C-2 is processed *via* $N^5$, $N^{10}$-methylene-tetrahydrofolate by serine hydroxymethyltransferase and condensed with another molecule of glycine to generate serine. Further metabolism of serine by serine dehydratase generates pyruvate.

In order to explore this putative relationship further the incorporation of $^{13}C$-labelled pyruvates into fluorometabolites by resting cell suspensions of *S. cattleya* was examined by GC–MS and $^{19}F\{^1H\}$ NMR spectroscopy. The results of the GC–MS study are reported elsewhere and indicate that C-2 and C-3 of

**1** **2** **3**



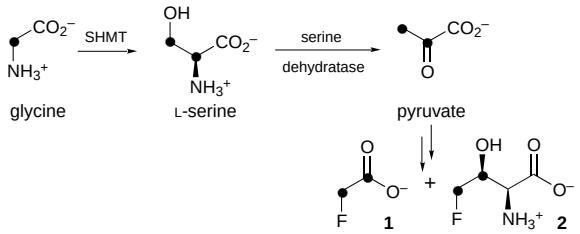


**Fig. 1** $^{19}F\{^{1}H\}$ NMR spectrum of fluoroacetate **1** (−214.60 ppm) and 4-fluorothreonine **2** (−229.15 ppm) in the supernatant after incubation of resting cells of *S. cattleya* for 48 h with (*a*) [2-$^{13}$C]-glycine and (*b*) [1,2-$^{13}C_2$]glycine. The insets show expansions of each signal.

**Scheme 1** Proposed pathway accounting for the labelling of the fluorometabolites by [2-$^{13}$C]glycine and $^{13}$C-labelled pyruvates

pyruvate are probably incorporated as a unit into fluoroacetate.[10] The supernatants from these experiments were analysed by $^{19}F\{^{1}H\}$ NMR spectroscopy to assess the extent of the similarity in the pattern of incorporation into the two metabolites. As with the experiments conducted with labelled glycines, the signals obtained from each of the fluorometabolites by $^{19}F\{^{1}H\}$ NMR spectroscopy always possessed a similar multiplicity indicating that $^{13}$C incorporation into C-1 and C-2 of fluoroacetate paralleled exactly that into C-3 and C-4 of 4-fluorothreonine.

Fig. 2 shows the $^{19}F\{^{1}H\}$ NMR spectrum obtained following incubation of [3-$^{13}$C]pyruvate with resting cell suspensions. It is clear that each of the signals assigned to fluorometabolites **1** (−214.8 ppm) and **2** (−229.3 ppm) has satellites ($^{1}J_{^{13}C\text{-}^{19}F}$ = 165 Hz) associated with it. These correspond to a population (*ca*. 30%) of molecules in each case which possess an intact $^{19}$F-$^{13}$C-$^{12}$C combination. No other labelled populations are apparent. Therefore we can conclude that C-3 of pyruvate has regiospecifically labelled the fluoromethyl groups of **1** and **2**. Similarly the resultant spectrum (not shown) from the [2-$^{13}$C]pyruvate feeding experiment had satellites associated with each fluorometabolite resonance, indicative of a two bond coupling between F and $^{13}$C ($^{1}J_{^{13}C\text{-}^{19}F}$ = 18 Hz). Thus C-2 of pyruvate has regiospecifically labelled C-1 of fluoroacetate and C-3 of 4-fluorothreonine (*ca*. 40%). Thus C-2 and C-3 of pyruvate contribute C-1 and C-2 of fluoroacetate and C-3 and C-4 of fluorothreonine as summarized in Scheme 1.

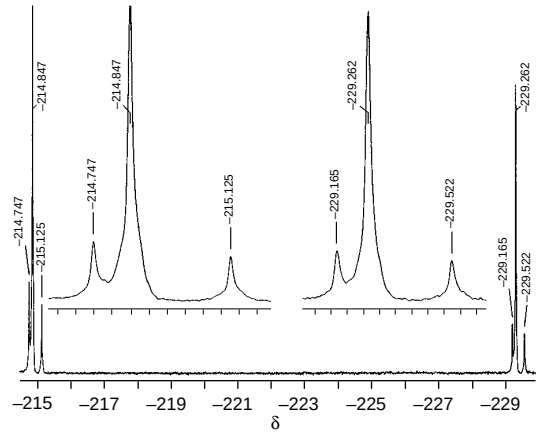

**Fig. 2** $^{19}F\{^{1}H\}$ NMR spectrum of fluoroacetate **1** (−214.8 ppm) and 4-fluorothreonine **2** (−229.3 ppm) in the supernatant after incubation of resting cells of *S. cattleya* for 48 h with [3-$^{13}$C]pyruvate. The insets show expansions of each signal

Although these results show clearly that pyruvate is a highly effective precursor of the fluorometabolites in resting cells of *S. cattleya*, it cannot be concluded that pyruvate, or a closely related metabolite such as β-hydroxypyruvate,[12] is the substrate for fluorination. Studies using stable and radiolabelled precursors[6,12] have shown that glycerol is a good precursor in fluoroacetate biosynthesis. The fluorination substrate must therefore be situated between pyruvate and glycerol on the glycolytic pathway. The very high incorporations observed into the fluorometabolites from labelled pyruvate may owe more to the tight channelling of intermediates in this pathway than the proximity of pyruvate to the carbon substrate for fluorination. The stereochemical processing of glycerol prior its incorporation into the fluorometabolites **1** and **2** is consistent with this hypothesis.[13]

We thank BNFL, Company Research Laboratory (CRL), Springfields, for financial support, Mr Ian H. MacKeag of the University of Durham for recording $^{19}F\{^{1}H\}$ NMR spectra and Dr Roy Bowden, BNFL Fluorochemicals and Dr Harry Eccles, BNFL CRL, for their close interest in this project.

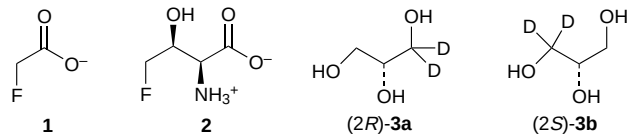
# Biosynthesis of fluoroacetate and 4-fluorothreonine by *Streptomyces cattleya*. The stereochemical processing of glycerol

**Jens Nieschalk,[a] John T. G. Hamilton,[b] Cormac D. Murphy,[b] David B. Harper*[b] and David O'Hagan*[a]†**

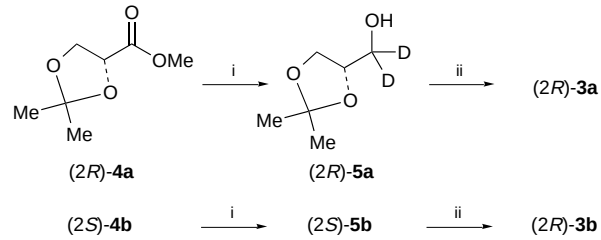
[a] *University of Durham, Department of Chemistry, Science Laboratories, South Road, Durham, UK DH1 3LE*
[b] *Microbial Biochemistry Section, Department of Food Science, The Queen's University of Belfast, Newforge Lane, Belfast, UK BT9 5PX*



**When both (2*R*)-[1-$^2H_2$]- and (2*S*)-[1-$^2H_2$]-glycerol are incubated with resting cell suspensions of *S. cattleya*, only the 2*R*-enantiomer labels the fluoromethyl groups of fluoroacetate and 4-fluorothreonine, with retention of both deuterium atoms, placing metabolic and mechanistic limitations on the process of biological fluorination.**

*Streptomyces cattleya* is one of very few biological systems which have been identified with the capability of biosynthesising organofluorine natural products.[1] We are currently investigating[2–5] the pathways by which fluorometabolite biosynthesis is achieved in *S. cattleya* and have shown[4] the efficient incorporations of glycine and pyruvate into fluoroacetate **1** and 4-fluorothreonine **2** by resting cell suspensions of *S. cattleya*.

The incorporations are consistent with the conversion of glycine to serine and then serine to pyruvate,[4,5] and the labelling patterns indicate that C-2 and C-3 of pyruvate contribute C-1 and C-2 of fluoroacetate **1** and C-3 and C-4 of 4-fluorothreonine **2** respectively. Tamura *et al*.[6] have shown that [2-$^{13}$C]glycerol is efficiently incorporated into fluoroacetate **1** by cell suspensions of *S. cattleya*, the isotope becoming regiochemically located at C-1 of fluoroacetate. Together these findings suggest that, prior to incorporation into the fluorometabolites, pyruvate and glycerol enter a common pathway and the glycolytic pathway emerges as the most obvious candidate.



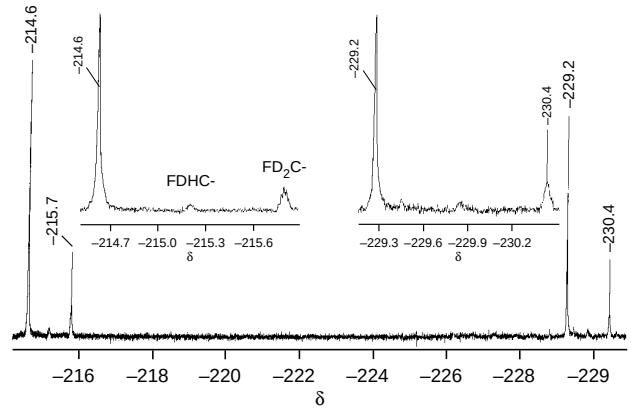
To shed further light on the role of glycerol we have investigated the stereochemical processing of glycerol during fluorometabolite biosynthesis in *S. cattleya*. Only two of the three carbon atoms of glycerol can contribute the carbons of fluoroacetate **1** and C-3 and C-4 of 4-fluorothreonine **2**, thus one of the prochiral hydroxymethyl groups of glycerol is cleaved during the biosynthetic process. In order to probe the cryptic stereochemistry of glycerol metabolism in *S. cattleya*, both (2*R*)-[1-$^2H_2$]- **3a** and (2*S*)-[1-$^2H_2$]-glycerol **3b** were prepared such that the prochiral hydroxymethyl groups of glycerol were independently labelled.

Isotopically enriched [1-$^2H_2$]glycerols **3a** and **3b** were synthesised as shown in Scheme 1 following a previously reported[7] protocol. This involved $LiAlD_4$ reduction of either (*R*)- or (*S*)-methyl 2,2-dimethyl-1,3-dioxolane-4-carboxylate, **4a** or **4b** {$[\alpha]_D$ −9.9 (neat) lit.,[8] −10.1 (neat)} respectively, to generate the corresponding alcohols **5a** and **5b** {$[\alpha]_D$ −12.2 (neat), lit.,[7] −14.9 (neat)}. Deprotection using aqueous mineral acid generated the desired glycerols **3a** and **3b**‡ in good overall yield as summarised in Scheme 1. The enantiomeric glycerols **3a** and **3b** were administered in separate experiments to resting cell suspension cultures[5] of *S. cattleya* at a final concentration of 7.5 mM. The level of isotope incorporation into the resultant fluoroacetate **1** was determined by GC–MS analysis[5] after 48 h in each case. The data indicated that deuterium had only become incorporated into fluoroacetate **1** from (2*R*)-[1-$^2H_2$]glycerol **3a** ($M$ + 2 = 28%, $M$ + 1 = 5%). No significant incorporation of isotope from (2*S*)-[1-$^2H_2$]glycerol **3b** was apparent.

This conclusion was confirmed by $^{19}F\{^1H\}$ NMR analysis of the supernatants from each experiment. The presence of a deuterium atom geminal to fluorine is readily diagnosed by an induced shift to lower frequency in the $^{19}F$ NMR spectrum.[9] The effect is additive and each deuterium atom induces a shift of *ca*. 0.6 ppm in magnitude. The resultant $^{19}F\{^1H\}$ NMR spectrum from the (2*R*)-[1-$^2H_2$]glycerol **3a** feeding experiment is shown in Fig. 1.

Proton decoupling simplifies the $^{19}F$ NMR signals of the two fluorometabolites and allows a more accurate assessment of the level of incorporation. The signals of both fluoroacetate **1** (−214.6 ppm) and 4-fluorothreonine **2** (−229.2 ppm) have an associated signal shifted to higher frequency, by 1.2 ppm. This

**Scheme 1** *Reagents and conditions*: i, $LiAlH_4$, $Et_2O$, 30 min., 77%; ii, HCl (2%), 2 h, room temp., 100%



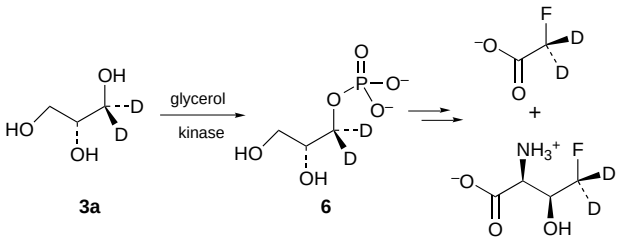


**Fig. 1** $^{19}F\{^1H\}$ NMR spectrum of fluoroacetate **1** (−214.6 ppm) and 4-fluorothreonine **2** (−229.2 ppm) formed on incubation of resting cell suspensions of *S. cattleya* with (2*R*)-[1-$^2H_2$]glycerol **3a**. Insets show expansions of the relevant regions of the spectrum. Both signals have deuterium-induced upfield shifted (1.2 ppm) signals associated with the incorporation of geminal di-deuterium labelled fluoromethyl groups ($FD_2C$). A shifted (0.6 ppm) signal of lower intensity indicates a population of molecules containing a single deuterium atom on the fluoromethyl groups (FDHC).

is assigned in each case to that population (*ca*. 28%) of molecules containing two deuterium atoms on the fluoromethyl group ($FD_2C$). There is also a minor signal in each case shifted to higher frequency by 0.6 ppm which corresponds to a smaller population (< 5%) of molecules carrying a single deuterium atom on the fluoromethyl group (FDHC). It should be noted that the levels and patterns of deuterium incorporation into fluoroacetate **1** and 4-fluorothreonine **2** are very similar, reinforcing the conclusion[4,5] that the fluoromethyl groups in the metabolites have a common origin and that there is consequently a single fluorinating enzyme in *S. cattleya*.

Only (2*R*)-[1-$^2H_2$]glycerol **3a** was incorporated into the fluorinated metabolites and therefore only the *pro-R* hydroxymethyl carbon of glycerol contributes C-2 of fluoroacetate **1** and C-4 of 4-fluorothreonine **2**. The *pro-S* hydroxymethyl group of glycerol must be cleaved and lost during fluorometabolite biosynthesis. The nature of this stereochemical processing allows certain conclusions to be drawn about the pathway leading to the substrate for fluorination. Glycerol is phosphorylated by glycerol kinase at its *pro-R* hydroxymethyl group to generate *sn*-glycerol-3-phosphate **6**, prior to its entry into the glycolytic pathway, as illustrated in Scheme 2.

Whilst these experiments do not reveal the substrate for the fluorination enzyme they do indicate that the carbon atom of glycerol which becomes activated by phosphorylation *in vivo* is also that one which is fluorinated downstream. Also the predominantly labelled populations in each of the fluorinated metabolites retained both deuterium atoms from (2*R*)-[1-$^2H_2$]glycerol **3a**, thus we can conclude that no obligatory oxidation is required at this carbon centre prior to fluorination.

The retention of both deuteriums is consistent with two minimal mechanistic hypotheses. The fluorination event may involve nucleophilic substitution by fluoride at the original phosphorylated (or enzymatically activated) carbon atom of *sn*-glycerol-3-phosphate **6** or of a metabolite derived from **6** on the glycolytic pathway to pyruvate. Alternatively fluoride may be introduced by an elimination–addition process on a glycolytic intermediate. This latter hypothesis intuitively appears less likely; however it is not ruled out by the labelling pattern observed. These results provide the first, albeit tentative, mechanistic insight into the process of biological fluorination based on empirical observation.

**Scheme 2** Observed incorporation (28%) of **3a** into fluoroacetate and 4-fluorothreonine in *S. cattleya*

We acknowledge BNFL Company Research Laboratory (CRL), Springfields, and the EC for financial support. We also thank Mr Ian H. McKeag of the University of Durham for recording $^{19}F\{^1H\}$ NMR spectra and Dr Roy Bowden, BNFL Fluorochemicals and Dr Harry Eccles, BNFL CRL for their close interest in this project.

## Footnotes

# Synthesis of a new solid acid: silica pillared lanthanum niobate with a supergallery

**Can-xiong Guo, Wen-hua Hou, Ming Guo, Qi-jie Yan* and Yi Chen**

*Department of Chemistry, Nanjing University, Nanjing 210093, China*

**Stepwise intercalations of *n*-decylamine and oligosiloxanes followed by calcination at 823 K in air results in a thermostable supergallery layered lanthanum niobate; the new material shows an interlayer free spacing of 17.4 Å along with a high Brunauer–Emmett–Teller surface area of 251 $m^2\ g^{-1}$; the acidity of the new pillared material is markedly enhanced with respect to the original lanthanum niobate.**

As an approach to obtain thermally stable porous materials, various inorganic oxo-cations have been intercalated into layered solids such as smectite clays and phosphates.[1,2] Calcination of these cation-intercalated materials formed inorganic pillared solids with different characteristics.[3] Metal oxides based on octahedral framework structures but possessing lamellar structures showed unusual properties in applications for separations, sorption and conduction[4] as well as photocatalysis.[5] However, the non-swelling nature of these layered metal oxides prevents the facile ion exchange of large oxo-cations so that only a few papers concerning pillared metal oxides have been published so far.[6] Among these lamellar oxides, lanthanum niobate (lanthanum niobium oxide, $HLaNb_2O_7$) whose layers are only built of corner-sharing octahedra to form thick perovskite slabs is found to show stronger Brønsted acidity than $HTiNbO_5$ and similar layered oxides.[7] Its photocatalytic activity is also notable.[5] Unfortunately, it loses almost all of its acidity upon heat treatment at 773 K due to the removal of interlayer water.[8]

In most of the reported lamellar solids pillared by inorganic pillars such as aluminium Keggin ions and tetrameric zirconium cations, the gallery heights are comparable to the van der Waals thickness of the host layers.[3,9] Pillared materials in which the gallery height is substantially larger than (twice or more) the thickness of the host layer have scarcely been obtained by pillaring with inorganic pillars to date.[10,11] Silica also is one of the most commonly used pillars. The lateral spacing of silica pillared materials may easily be varied based upon the preparation conditions.[11–13] The use of organosiloxanes as the source of silica enables facile intercalation of the pillar precursur and pore formation upon calcination of the organic groups.[11,12]

On the basis of progress concerning the pillared layered oxides materials made in the laboratory,[6,15,16] we report here the first synthesis of a new type of solid acid material: a silica pillared lanthanum niobate with a supergallery. The new material showed a supergallery of 17.4 Å accompanied by a Brunauer–Emmett–Teller (BET) surface area as high as 251 $m^2\ g^{-1}$. Additionally, the acidity of the new pillared material was markedly enhanced with respect to the original lanthanum niobate and hence its activity might be expected to be comparable to that of strong solid acid hydrated niobium oxide, $Nb_2O_5{\cdot}nH_2O$ for the dehydration of $Pr^iOH$.

The starting material, $KLaNb_2O_7$, was prepared by a solid-state reaction of a mixture of $K_2CO_3$, $La_2O_3$ and $Nb_2O_5$ in molar ratios of 1.25 : 1.0 : 2.0 at 1373 K overnight. The proton exchange reaction was carried out at 333 K in a solution of $HNO_3$ (6 mol $dm^{-3}$) for 3 d (solution changed daily). *n*-Hexylamine was intercalated by stirring lanthanum niobate powder with a *n*-hexylamine solution (50% v/v, EtOH) at 333 K for 36 h. After the separation of *n*-hexylamine-intercalated $HLaNb_2O_7$ by centrifugation, the solid (2 g, dried at 333 K) was treated with *n*-decylamine (100 $cm^3$, 50% v/v, EtOH) at 348 K for 2 weeks. Oligosiloxane-intercalated $HLaNb_2O_7$ was prepared by refluxing the *n*-decylammonium-intercalated lanthanum niobate with an aqueous solution of $H_2NC_3H_6Si(OEt)_3$ (20% v/v, 200 $cm^3$) for 4 days with stirring. The solid was then separated by centrifugation followed by drying at 363 K. The calcination of the above solid in air at 823 K resulted in the novel silica-pillared material with a supergallery.

The obtained $HLaNb_2O_7$ showed an X-ray diffraction (XRD) pattern [Fig. 1(*a*)] coincident with that reported in the literature.[7] The intercalation of *n*-hexylamine gave rise to a material with an expanded interlayer distance of *ca*. 26 Å shown by the (001) reflection at $2\theta = 3.4°$ where the peak positions other than (00*l*) reflections remain unchanged. Further substitution by *n*-decylammonium led to a layered material with (001) reflection at $2\theta = 2.45°$, which indicates the formation of an even larger basal spacing of *ca*. 36 Å. The interlayer gallery height occupied by *n*-decylammonium ions is *ca*. 28.4 Å by subtraction of the host layer thickness of 7.6 Å.[7] The oligosiloxane cation-intercalated $HLaNb_2O_7$ showed a (001) reflection at an even lower $2\theta$ value of 1.9°, corresponding to an interlayer distance of *ca*. 46 Å. After calcination at 823 K, the inorganic silica pillared material showed an interlayer distance of *ca*. 25.0 Å as suggested by the (001) reflection at $2\theta = 3.5°$ [Fig. 1(*b*)]. This indicates a 'supergallery' of *ca*. 17.4 Å which is substantially larger than the host layer thickness. A significant increase in gallery height is achieved compared to that of non-pillared $HLaNb_2O_7$ where the basal spacing is only *ca*. 10.8 Å. The layered structure of the new supergallery pillared material is thermally very stable and its structure was retained upon heat treatment at 973 K with only a slightly decreased interlayer distance of *ca*. 24.2 Å as shown by its (001) reflection at $2\theta = 3.6°$.

The porosity of $HLaNb_2O_7$ is greatly increased by pillaring with silica. The BET surface area of the new pillared material reaches 251 $m^2\ g^{-1}$ most of which arises from micropores (micropore area = 197 $m^2\ g^{-1}$). The original $HLaNb_2O_7$ is

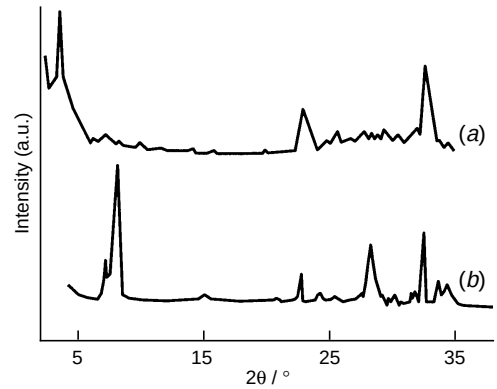

**Fig. 1** X-Ray diffraction (XRD) patterns of (*a*) $HLaNb_2O_7$ (dried at 333 K) and (*b*) silica-pillared $HLaNb_2O_7$

actually a non-porous solid with a surface area of only *ca*. 5 $m^2\ g^{-1}$. Considering the fact that the gallery height resulting from pillaring reaches 17.4 Å, a new type of nanoporous material[9] is thought to be formed by pillaring with silica. The new material shows an adsorption–desorption isotherm with a hysteresis loop (Fig. 2) upon $N_2$ adsorption at 77 K. The obtained hysteresis loop may be classified as type H4 or H3 (by IUPAC classification) suggesting the existence of narrow slit-like pores associated with aggregates of plate-like particles where the type I character of the adsorption isotherm indicates the microporosity predominated in the new material.[18] It is also in good agreement with the micropore area measurement.

The possibility of using this material for acid catalysed reactions was investigated by the probe reaction of $Pr^iOH$ decomposition at 573 K which showed complete conversion of the reactant to dehydration products, illustrating the strong acidic property of the new material. In comparison, non-pillared $HLaNb_2O_7$ pretreated at 573 K showed only 32% conversion under the same reaction conditions. A significant enhancement of acidity is achieved by pillaring the lanthanum niobium oxide with silica. The new pillared material showed catalytic activities as high as that of the strong solid acid niobic acid under the same conditions.

To conclude, silica pillared $HLaNb_2O_7$ is a thermostable porous layered solid acid material containing a supergallery. The new material is expected to show shape selective effects for catalytic reactions in which larger molecules can be used. The high thermal stability of the new pillared material also enables its application at some critical conditions either as an acid catalyst or as a catalyst support. Further systematic characterization of this new material and investigations on its shape selectivity in catalysis as well as other fields are actively being undertaken.

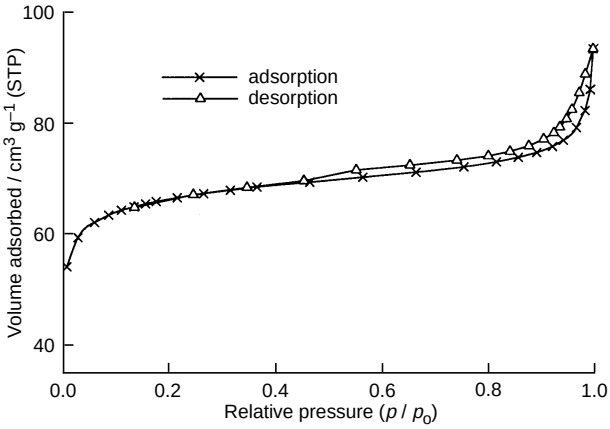

**Fig. 2** Adsorption–desorption isotherm of $N_2$ at 77 K on silica-pillared $HLaNb_2O_7$

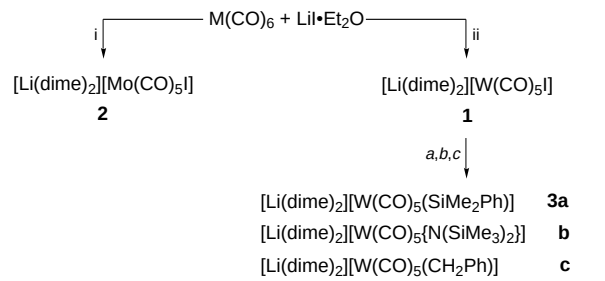
# $[Li(dime)_2][W(CO)_5I]$ as a novel synthon for the preparation of silyl, amino and organyl derivatives of pentacarbonyl tungsten (dime = diethylene glycol dimethyl ether)



**W. Palitzsch, U. Böhme* and G. Roewer**

*Institut für Anorganische Chemie der TU Bergakademie Freiberg, Leipziger Str. 29, D-09596 Freiberg, Germany*

**The one-pot reactions of $M(CO)_6$ with dime in the presence of $LiI{\cdot}Et_2O$ give $[Li(dime)_2][M(CO)_5I]$ (M = W 1, Mo 2); the reaction of 1 with $LiSiMe_2Ph$, $LiN(SiMe_3)_2$ and $PhCH_2MgCl$ affords the novel complexes $[Li(dime)_2][W(CO)_5R]$ [R = $SiMe_2Ph$ 3a, $N(SiMe_3)_2$ 3b, $CH_2Ph$ 3c].**

Pentacarbonyl (alkyl- and aryl-alkoxycarbene) group 6 metal complexes have attracted much interest as useful reagents for organic synthesis.[1,2] The production of water-soluble catalysts is an area of considerable current interest.[3] The role of ionic metal complexes as active species in homogeneous catalysed reactions is well documented.[4,5] A simple chemical procedure for the synthesis of anionic monosubstituted derivatives of transition-metal carbonyls should be highly interesting, especially to generate coordinatively unsaturated species with potential applications in catalysis. The design of simple synthetic routes for these compounds is therefore very important.

Compounds containing the $[M(CO)_5X]^-$ ion (M = Mo,W; X = Br) have been synthesized *via* difficult routes.[6] We found a very simple way to generate such complexes. The one-pot reaction of $W(CO)_6$ with dime in presence of $LiI{\cdot}Et_2O$ leads to the hitherto unknown $[Li(dime)_2][W(CO)_5I]$ **1** (Scheme 1).

**Scheme 1** *Reagents and conditions*: i, M = Mo, dime, 80 °C, −CO, $-Et_2O$, 70%; ii, M = W, dime, 80 °C, −CO, $-Et_2O$, 80%; *a*, $LiSiMe_2Ph$, dme, 0 °C, −LiI, 64%; *b*, $LiN(SiMe_3)_2$, THF, 0 °C, −LiI, 84%; *c*, $CH_2PhMgCl$, $Et_2O$, 0 °C, −MgClI, 77%

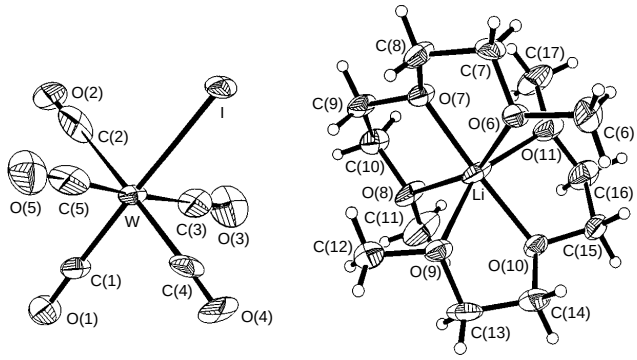


**Fig. 1** Crystal structure of **1**. Selected bond distances (Å) and angles (°): W–I 2.871(2), W–C(1) 1.97(2), W–C(2),C(3),C(4),C(5) 2.04(2)–2.10(2); I–W–C(1) 178.7(3), I–W–C(2),C(3),C(4),C(5) 86.7(4)–91.2(4); Li–O 2.00(2)–2.22(2).

The X-ray crystal structure analysis of **1** reveals the molecular structure shown in Fig. 1.‡ The structure was solved and refined in space group $P2_1/c$. The lithium atom is coordinated by two molecules of dime with a distorted octahedral coordination geometry. The $[W(CO)_5I]^-$ anion has nearly $C_{4v}$ symmetry with a W–I bond length of 2.871 Å.

First experimental studies showed a surprising stability of **1** during dissolving tests in protic solvents. We could observe only very slow decomposition in the air. The same synthetic route was applied to the synthesis of $[Li(dime)_2][Mo(CO)_5I]$ **2**.†

The $[W(CO)_5I]^-$ anion represents an interesting building block. It is very easy to substitute the iodine retaining the $d^6$ character of tungsten. We used the $[W(CO)_5I]^-$ anion as a starting tungsten complex for reactions with different nucleophilic reagents to substitute the iodine. For example, complex **1** reacts with $LiSiMe_2Ph$ to give compound **3a**, and with a lithium amide (*b*) to give compound **3b**.§ Treatment of **1** with a Grignard reagent (*c*) produces complex **3c** (Scheme 1).§ All new compounds were isolated and purified by extraction with pentane and subsequent recrystallization with dichloromethane.

Further studies to extend the scope of these reactions to molybdenum carbonylates and to other nucleophilic reagents, as well as studies on the reactivity of the obtained products are under way.

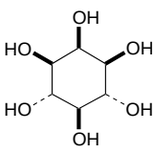
# Synthesis of acyclic and heterocyclic natural products utilizing cyclitols as novel chiral building blocks

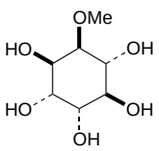
**Noritaka Chida† and Seiichiro Ogawa**

*Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223, Japan*



**The synthesis of biologically important natural products which contain acyclic or heterocyclic structures, starting from cyclitols, is described. Stereoselective functionalization and subsequent regioselective ring cleavage of cyclitol derivatives provides precursors for the synthesis of a wide variety of natural products. The successful synthesis of acyclic and heterocyclic natural products reveals the usefulness and importance of cyclitols as novel chiral building blocks.**

## Introduction



The synthesis of natural products possessing biological activity and interesting structures in an enantiomerically pure form is a highly important area of modern organic and medicinal chemistry. To construct the asymmetric centres in the target molecule, compounds with established asymmetric centres, such as naturally occurring amino acids,[1] terpenes[2] and carbohydrates, are frequently employed as the starting material (chiral building block).[3] Among them, carbohydrates, especially aldohexoses such as D-glucose, have been widely used due to their ready availability and versatility.[4] Cyclitols (polyhydroxycycloalkanes), which are classified as a type of carbohydrate, occur widely in nature.[5] *myo*-Inositol **1**, known as a constituent of a secondary messenger in cells which stimulates the release of calcium from storage sites, is easily obtained from corn-steep liquors and commercially available at relatively low price.‡ While *myo*-inositol is a meso compound, L-quebrachitol [1L-(−)-2-*O*-methyl-*chiro*-inositol] **2**, isolated in large quantities from the serum of the rubber tree,[6]§ is an optically active cyclitol possessing a methyl ether function. In spite of their abundance in nature and ready availability, cyclitols have not been utilized widely as starting materials for the synthesis of natural products other than cyclitol derivatives. Given that regioselective cleavage of their cyclohexane ring is possible, cyclitols are expected to be versatile starting materials for the synthesis of acyclic or heterocyclic natural products. In this article, the synthesis of several acyclic and heterocyclic natural products starting from cyclitols (*myo*-inositol and L-quebrachitol), based on tactics involving stereoselective functionalization followed by regioselective ring cleavage of the cyclitol ring, are described.

## Regioselective ring cleavage of the cyclohexane ring in cyclitols

A major advantage in using cyclitol as a starting material compared with aldohexoses is that there are no synthetic limitations imposed by the presence of a hemiacetal functionality. The cyclic structure as well as the established protection-deprotection methods of polyhydroxy groups[5] in cyclitols allowed us to introduce many kinds of functional groups stereoselectively on the cyclohexane ring. If one could cleave the cyclohexane ring in functionalized cyclitol derivatives at any chosen position, the array of chiral centres from the cyclitol derivatives, which are sometimes difficult to obtain from convensional sugars such as D-glucose, D-galactose, D-mannitol and so on, could be transferred to the target molecule. To cleave the cyclohexane ring in cyclitols, oxidative glycol cleavage would be anticipated to be an effective and reliable method. However, difficulty is sometimes encountered in distinguishing between the two newly formed formyl carbons. On the other hand, Baeyer–Villiger reaction of polyhydroxycyclohexanone derivatives possessing oxygen and other functionalities at the α-carbons is an attractive method to cleave the cyclohexane ring, since the terminal carbons of the product usually have different oxidative states. Early studies on the Baeyer–Villiger reaction of polyhydroxycyclohexanones derived from *myo*-inositol by Fukami *et al.*[7] revealed that the reaction proceeded in a highly regioselective manner, and suggested that the substituent on the α-carbon should be an important factor for influencing the regioselectivity. To clarify the governing factor controlling the regioselectivity, a series of unsymmetrical polyhydroxycyclohexanone derivatives were synthesized from *myo*-inositol and L-quebrachitol, and subjected to Baeyer–Villiger reaction.[8] Some results are shown in Scheme 1. This study showed that the migratory ability of substituted carbons adjacent to the carbonyl in the polyhydroxycyclohexanone system are strongly affected by the nature of substituents on the α-carbon; the migratory aptitudes are: a carbon possessing benzyloxy > methoxy > cyclic ketaloxy ≫ acyloxy ≈ methyl > hydrogen. These results suggested that n-electron density on the oxygen atom attached to the adjacent carbon to the carbonyl is of significance, implying that an n–σ*≠ interaction (Cieplak postulate[9]) might account for the observed regioselectivity. Thus it should now be possible to design polyhydroxycyclohexanone derivatives which undergo regioselective Baeyer–Villiger reaction.

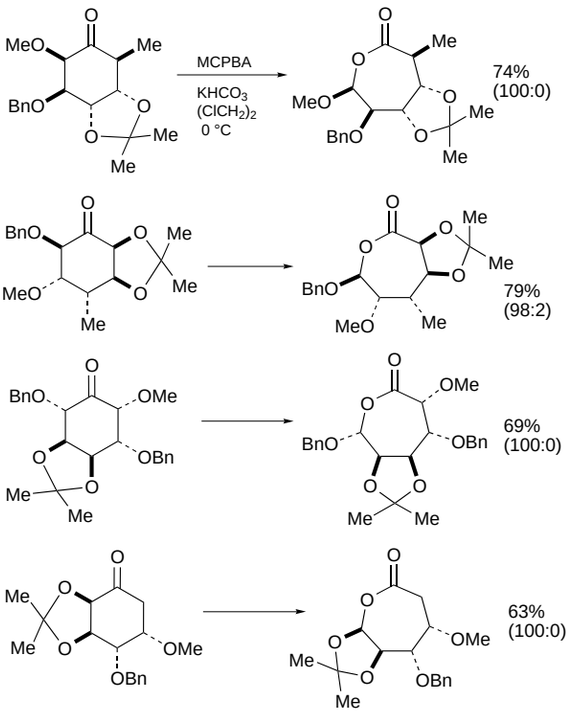
*myo*-inositol **1**

L-quebrachitol **2**

## Synthesis of natural products starting from *myo*-inositol

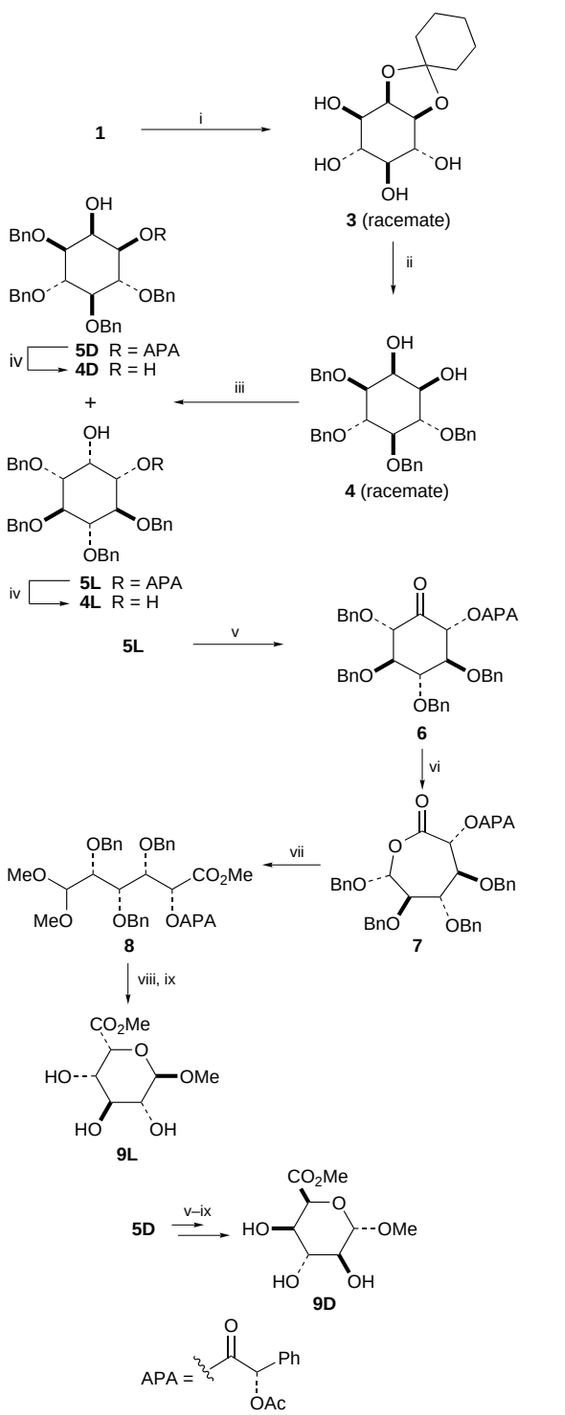
### *Iduronic acid derivative and nojirimycin*

Since *myo*-inositol **1** is a *meso* compound, chemical transformation usually provides *meso* or racemic products. Therefore it is necessary to perform an asymmetric reaction[10] or optical resolution[11] to prepare optically pure *myo*-inositol derivatives. Cyclic ketal formation of **1** gave racemic **3**[12] in high yield (Scheme 2). After *O*-benzylation, diol **4** was obtained by acidic hydrolysis. When diol **4** was reacted with an equimolar amount of (*S*)-(+)-α-(acetoxy)phenylacetic acid in the presence of 1,3-dicyclohexylcarbodiimide (DCC) and 4-dimethylaminopyridine (DMAP) at −15 °C, formation of a pair of diastereoisomers (**5D** and **5L**) was observed. These compounds are easily separated by silica gel chromatography or recrystallization to



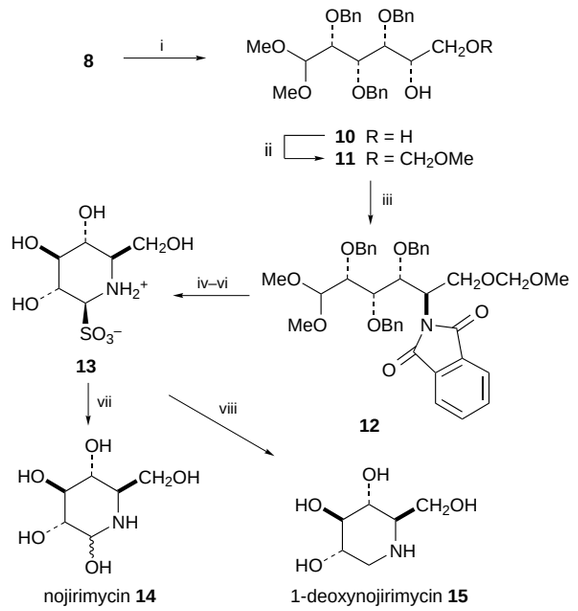
provide **5D** and **5L** in 36 and 35% isolated yields, respectively. Removal of the (*S*)-(+)-α-(acetoxy)phenylacetyl group from **5D** afforded **4D**, and from **5L** gave **4L**, both in quantitative yield. The absolute configurations of **4D** and **4L** were confirmed by comparison of their $[\alpha]_D$ values with literature ones,[11a] and the optical purities of **4D** and **4L** were estimated to be > 98% ee, respectively, by HPLC analyses using a chiral column (chiralcel OD).

Oxidation of **5L** afforded ketone **6**, whose Baeyer–Villiger reaction with MCPBA proceeded in a highly regioselective manner and provided the 7-membered acetal lactone **7**. Treatment of **7** with MeOH and $HC(OMe)_3$ in the presence of toluene-*p*-sulfonic acid (TsOH) caused the lactone ring to open, providing acyclic product **8** after methyl ester formation. This compound was transformed into L-iduronic acid derivative **9L**.[13] Similar treatment of **5D** provided the enantiomer **9D**.[13]



The acyclic sugar derivative **8** is a versatile intermediate for the synthesis of natural products possessing polyhydroxy functionality. DIBAL-H reduction of **8** gave diol **10** (Scheme 3), whose primary hydroxy group was selectively protected to afford **11**. Introduction of an amino functionality by Mitsunobu reaction provided **12**. Compound **12** was effectively converted into (+)-nojirimycin bisulfite adduct **13**.[14] (+)-Nojirimycin **14**[14] and (+)-1-deoxynojirimycin **15**[14b] were easily obtained from the adduct **13**.

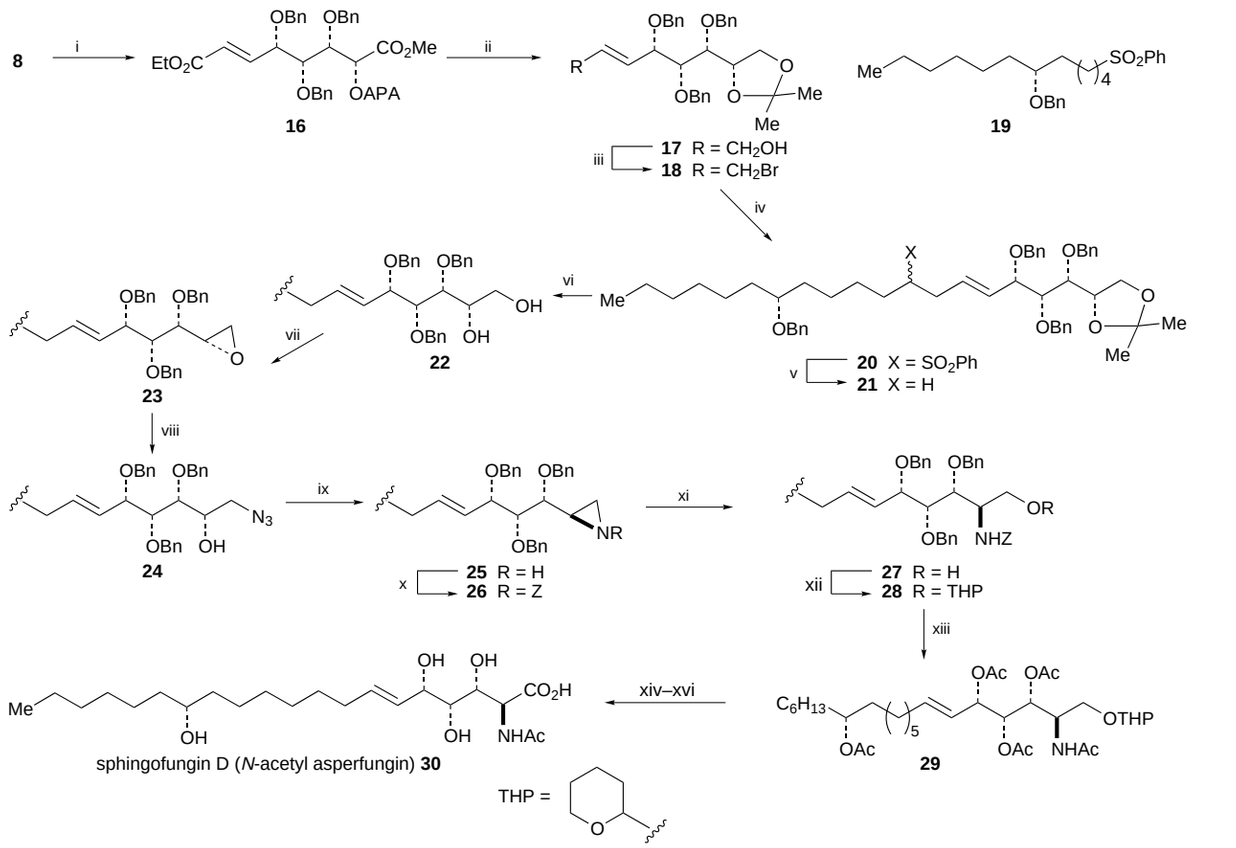
*Sphingofungin D*



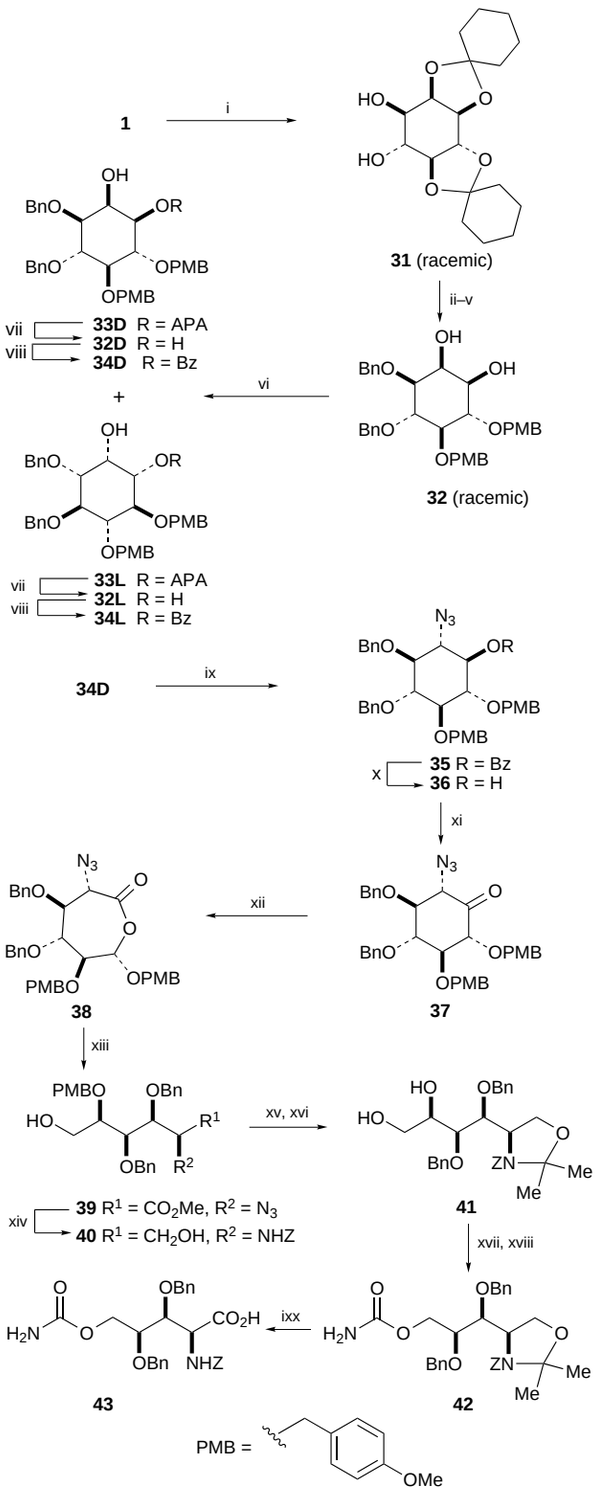
Compound **8** was also employed for the total synthesis of the novel antifungal agent sphingofungin D (*N*-acetyl asperfungin) (Scheme 4).[15] Acidic hydrolysis of the dimethyl acetal group in **8** afforded the corresponding acyclic *aldehydo*-sugar, whose Wittig reaction with $Ph_3P{=}CHCO_2Et$ provided *E*-alkene **16**. This was transformed into allyl bromide **18** in three steps. Reaction of **18** with sulfone **19**, which was synthesized from the coupling product of commercially available (*R*)-epoxyoctane and 4-[(tetrahydropyran-2-yl)oxy]butylmagnesium chloride in four steps, followed by desulfonization afforded the $C_{20}$ backbone **21** of sphingofungins. Removal of the acetonide group provided diol **22**. Although introduction of an amino functionality at the C-2 position in **22** by intermolecular $S_N2$ reaction was difficult, it was found that intramolecular nitrogen delivery worked well for this substrate. Thus, Mitsunobu reaction of **22** afforded epoxide **23**, which was transformed into primary azide **24**. Treatment of **24** with $Ph_3P$ followed by reaction with ZCl generated inverted aziridine **26**, whose

**Scheme 1** Partial decomposition of the products during silica gel chromatography was observed. The ratios of the major product and its regioisomer were determined by 270 MHz $^1$H NMR analysis of the products before isolation.

**Scheme 2** *Reagents and conditions*: i, cyclohexanone, TsOH, $C_6H_6$; ii, NaH, BnCl, DMF; iii, (*S*)-(+)-(AcO)CHPh$CO_2$H, DCC, DMAP, $CH_2Cl_2$, −15 °C; iv, MeONa, MeOH; v, $CrO_3$ in dil. $H_2SO_4$, $Me_2CO$, 0 °C; vi, MCPBA, $KHCO_3$, $(ClCH_2)_2$, 0 °C; vii, TsOH, $HC(OMe)_3$, MeOH, 80 °C, then $CH_2N_2$, $CH_2Cl_2$; viii, 3% methanolic HCl, reflux; ix, $H_2$, 20% $Pd(OH)_2$ on carbon, EtOH.



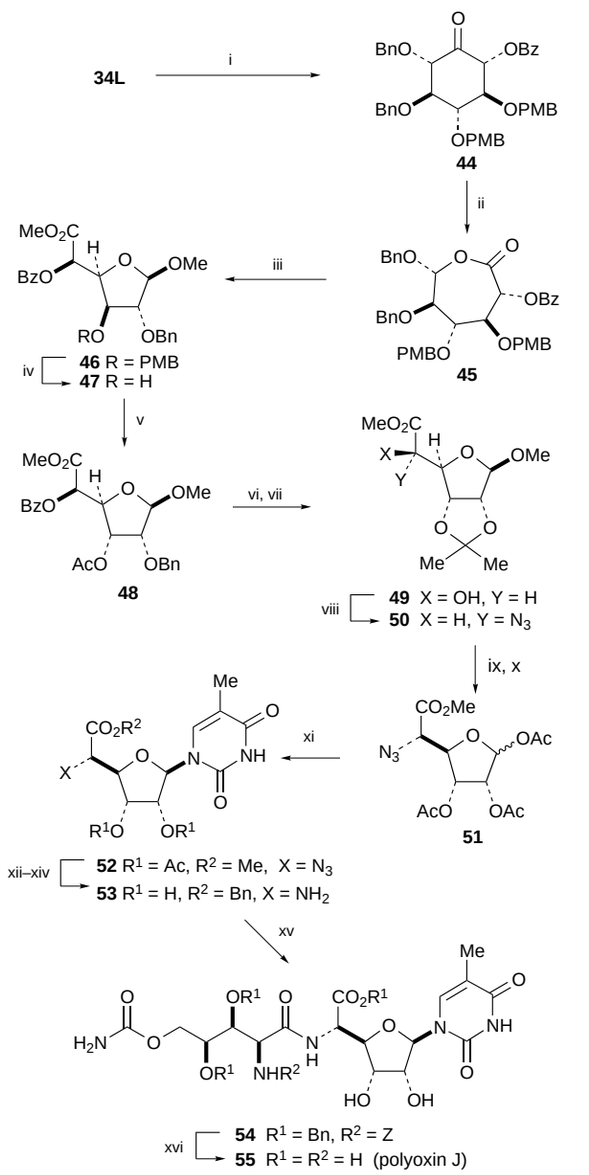
**Scheme 3** *Reagents and conditions*: i, $LiAlH_4$, THF, 0 °C; ii, $MeOCH_2Cl$, $Pr^i_2NEt$, $CH_2Cl_2$, 0 °C; iii, phthalimide, $Ph_3P$, diethyl azodicarboxylate (DEAD), THF, room temp.; iv, $H_2NNH_2{\cdot}H_2O$, MeOH, reflux, then $Boc_2O$, $Et_3N$, $CH_2Cl_2$; v, $H_2$, 20% $Pd(OH)_2$ on carbon, EtOH; vi, $SO_2$(gas), $H_2O$, 40 °C; vii, Dowex 1 X2 resin ($OH^-$ form), $H_2O$; viii, $H_2$, Raney-Ni (W-4), $Ba(OH)_2$, $H_2O$.



aziridine ring was cleaved with KOAc to provide **27** after hydrolysis of the *O*-acetyl function. The primary hydroxy group was protected as a tetrahydropyran-2-yl (THP) ether to afford **28**. Treatment of **28** with Li–$NH_3$ gave **29** after *N*,*O*-acetylation. Removal of the *O*-THP group and subsequent oxidation, followed by de-*O*-acetylation afforded sphingofungin D **30**. This total synthesis confirmed the proposed C-2–C-5 stereochemistry, and assigned the undetermined absolute configuration at C-14 in sphigofungins to be *R*.[15]

*Polyoxin J*

The antifungal antibiotic polyoxin J **55** consists of two fragments, amino acid portion **43** and nucleic acid portion **53**. These two key fragments were synthesized from a pair of optically resolved *myo*-inositol derivatives (**32D** and **32L**), respectively.[16] The known racemic diol **31**,[12] prepared from **1** in one step was converted into another racemic diol **32** (Scheme 5). Optical resolution of **32** using (*S*)-(+)-α-(acetoxy)phenylacetic acid afforded **33D** and **33L**, which are easily separated by silica gel chromatography. Basic methanolysis of **33D** and **33L** provided optically active diols **32D** and **32L**, respectively. Synthesis of the amino acid moiety in polyoxin J employed **32D**, which was converted into **34D**. After introduction of an azide group in an $S_N2$ fashion, ketone **37** was subjected to Baeyer–Villiger reaction to provide lactone **38** as the sole product. Basic opening of the lactone ring followed by reduction gave acyclic product **39**. Further reduction of the ester and azide functions and subsequent protection of the amino group afforded diol **40**. *N*,*O*-Acetalization and removal of the *para*-methoxybenzyl (PMB) group gave **41**, and subsequent



**Scheme 4** *Reagents and conditions*: i, AcOH–$H_2O$ (4:1), 80 °C, then $Ph_3P{=}CHCO_2Et$, $CH_2Cl_2$, room temp.; ii, DIBAL-H, $CH_2Cl_2$, 0 °C, then $Me_2CO$, camphorsulfonic acid (CSA), 0 °C; iii, $Ph_3P$, $CBr_4$, $CH_2Cl_2$, room temp.; iv, BuLi, **19**, THF–HMPA (10 : 1), −78 °C; v, Na–Hg (6%), $Na_2HPO_4$, THF–MeOH (1 : 1), room temp.; vi, CSA, MeOH, room temp.; vii, $Ph_3P$, DEAD, PhMe, reflux; viii, $NaN_3$, DMF–$H_2O$ (9 : 1), 100 °C; ix, $Ph_3P$, toluene, 50 °C, 30 min, then reflux; x, ZCl, $Et_3N$, $CH_2Cl_2$; xi, AcONa, 15-crown-5, DMF, 100 °C, then $K_2CO_3$, MeOH, room temp.; xii, 3,4-dihydro-2*H*-pyran, pyridinium toluene-*p*-sulfonate (PPTS), $CH_2Cl_2$, room temp.; xiii, Na, THF–liq. $NH_3$ (1 : 1), −78 °C, then $Ac_2O$, pyridine, room temp.; xiv, PPTS, EtOH, 50 °C; xv, $CrO_3$ in dil. $H_2SO_4$, acetone, 0 °C; xvi, LiOH, THF–$H_2O$ (2 : 1), room temp.

**Scheme 5** *Reagents and conditions*: i, 1,1-dimethoxycyclohexane, TsOH, DMF; ii, NaH, BnBr, DMF; iii, TsOH, EtOH, room temp.; iv, NaH, 4-$MeOC_6H_4CH_2Cl$, DMF; v, AcOH–$H_2O$ (4 : 1), 80 °C; vi, (*S*)-(+)-(AcO)CHPh$CO_2H$, DCC, DMAP, $CH_2Cl_2$, −15 °C; vii, MeONa, MeOH, 0 °C; viii, BzCl, DMAP, pyridine, room temp.; ix, $MeSO_2Cl$, pyridine, 50 °C, then $NaN_3$, DMF, 80 °C; x, MeONa, MeOH; xi, dimethyl sulfoxide, DCC, $CF_3CO_2H$, pyridine, $C_6H_6$, room temp.; xii, MCPBA, $KHCO_3$, $(ClCH_2)_2$, 0 °C; xiii, $NaBH_4$, MeONa, MeOH, 0 °C; xiv, $LiAlH_4$, $Et_2O$, then ZCl, $NaHCO_3$, THF–$H_2O$; xv, 2,2-dimethoxypropane, TsOH, DMF, then $Ac_2O$, pyridine; xvi, 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ), $CH_2Cl_2$–$H_2O$, then MeONa, MeOH; xvii, $Pb(OAc)_4$, $C_6H_6$, room temp., then $NaBH_4$, MeOH; xviii, 4-nitrophenyl chloroformate, then $NH_3$–MeOH, $CH_2Cl_2$; ixx, TsOH, MeOH, room temp., then $CrO_3$ in dil. $H_2SO_4$, $Me_2CO$, 0 °C.

glycol cleavage followed by carbamoylation gave **42**. This was transformed into amino acid moiety **43**.

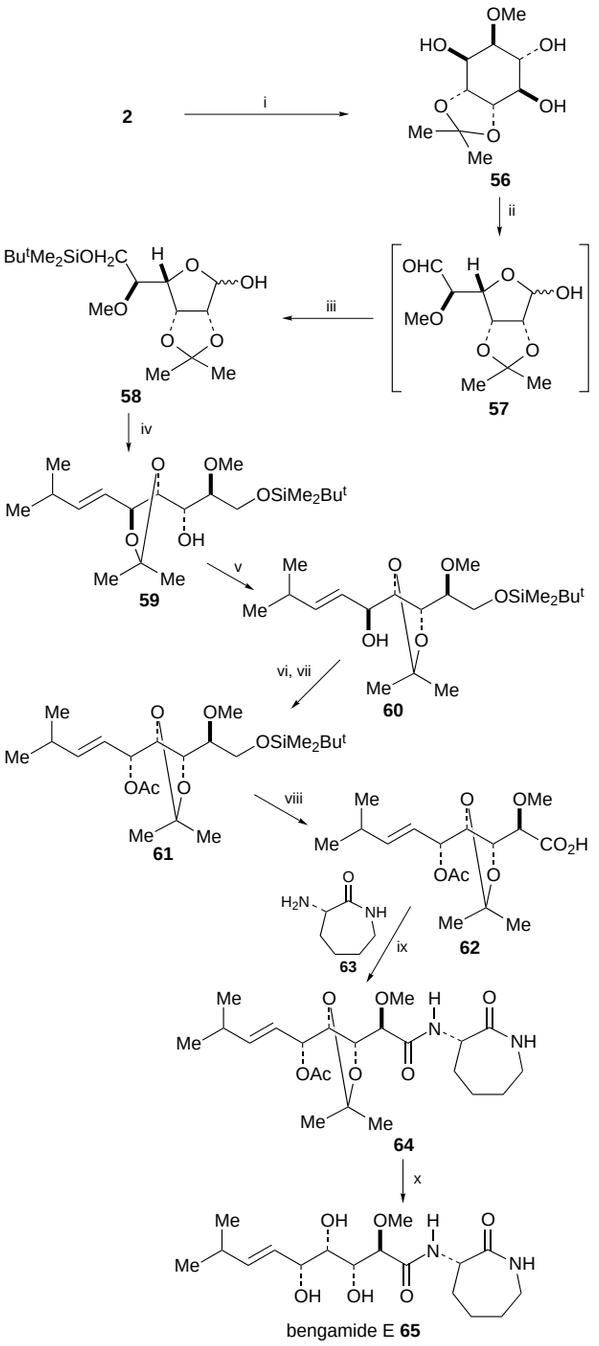
On the other hand, preparation of the nucleoside portion started from the enantiomeric diol **32L** (Scheme 6). Baeyer–Villiger reaction of the ketone **44** derived from **32L** in two steps afforded the acetal lactone **45** as the sole product. Acidic methanolysis of **45** followed by methyl ester formation provided furanoside **46** as the major product. Interestingly, the PMB group at C-3 in **45** was removed under the acidic reaction conditions. Inversion of the C-3 hydroxy group in **46** and subsequent exchange of the protecting groups gave **49**, into

**Scheme 6** *Reagents and conditions*: i, pyridinium dichromate, molecular sieves 4A, $CH_2Cl_2$; ii, MCPBA, $KHCO_3$, $(ClCH_2)_2$, 0 °C; iii, TsOH, $HC(OMe)_3$, MeOH, room temp., then MeI, $NaHCO_3$, DMF; iv, DDQ, $CH_2Cl_2$–$H_2O$; v, $(CF_3SO_2)_2O$, pyridine, $CH_2Cl_2$, 0 °C, then AcOK, DMF, 5 °C; vi, MeONa, MeOH then $H_2$, $Pd(OH)_2$, EtOH; vii, 2,2-dimethoxypropane, TsOH, DMF, room temp.; viii, $(CF_3SO_2)_2O$, pyridine, $CH_2Cl_2$ then $NaN_3$, DMF, room temp.; ix, Dowex 50W X8 ($H^+$ form), MeOH, room temp., then $Ac_2O$, pyridine; x, $Ac_2O$, $H_2SO_4$, $CH_2Cl_2$–AcOH; xi, 5-methyl-2,4-bis(trimethylsilyloxy)pyrimidine, $Me_3SiOSO_2CF_3$, $CH_2Cl_2$, room temp.; xii, $H_2$, 5% Pd–$BaSO_4$, dioxane–$H_2O$, then $Ba(OH)_2$, dioxane–$H_2O$, room temp.; xiii, $Boc_2O$, $K_2CO_3$, dioxane–$H_2O$, then BnBr, $NaHCO_3$, DMF, room temp.; xiv, $CF_3CO_2H$, EtOAc, 0 °C; xv, **43**, $(EtO)_2P(O)CN$, $Et_3N$, DMF, room temp.; xvi, $H_2$, 10% Pd–C, MeOH–$H_2O$.

which was introduced an azide function with inversion of configuration to provide **50**. Acetolysis of **50** gave **51**, which was condensed with 5-methyl-2,4-bis(trimethylsilyloxy)pyrimidine under Vorbruggen conditions to afford **52**. This was transformed into the benzyl ester of the nucleoside portion **53** of polyoxin J in four steps. Coupling of **43** with **53** using the Shioiri procedure gave **54**, deprotection of which provided polyoxin J **55**.[16]

## Synthesis of natural products starting from L-quebrachitol

### *Bengamide A, B and E*



L-Quebrachitol **2** is optically active and has a convenient configuration for the selective protection of hydroxy groups. Compounds derived from **2** by cleavage of the cyclohexane ring are expected to be versatile and useful chiral building blocks for the synthesis of a variety of natural products. A short synthesis of L-mannitol from **2** reported by Angyal and Hoskinson[17] in 1963 revealed the effectiveness of this approach. We applied this approach to the total synthesis of the bengamides,[18,19] which are novel amino acid derivatives with anti-infectious disease activity isolated from marine organisms.

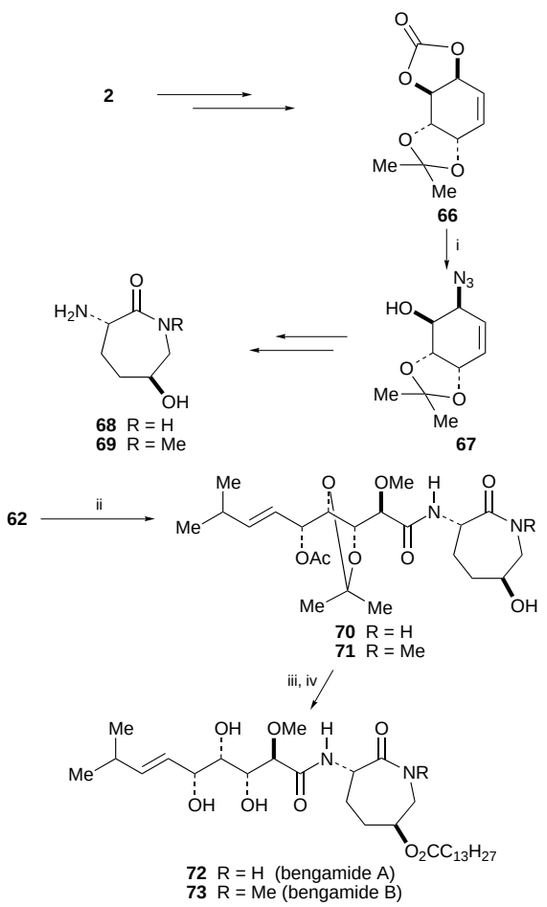
Periodate oxidation of mono-*O*-isopropylidene derivative **56**[20] of L-quebrachitol gave dialdofuranose derivative **57** (Scheme 7). Spontaneous furanose ring formation allowed us to distinguish the two formyl carbons generated by the oxidation. Treatment of **57** with $NaBH_4$ followed by silyl ether formation provided furanose **58**, which was subjected to Wittig olefination to give *E*-alkene **59** as the major product. In this reaction, the combination of base (BuLi) and solvent (benzene) was found to be essential for the selective formation of the *E*-alkene. Mild acid treatment of **59** caused the migration of acetonide group and the partial removal of the $SiMe_2Bu^t$ group. After resilylation, the C-5 hydroxy group in **60** was inverted by an oxidation-reduction procedure followed by *O*-acetylation to give **61**. Oxidation of the primary hydroxy group gave carboxylic acid **62**, which was condensed with cyclo-L-lysine **63** under the conditions of Shioiri to afford **64**. Deprotection of **64** provided bengamide E **65**. This first total synthesis fully confirmed the proposed structure of bengamide E.[18]

The novel hydroxylated caprolactams **68** and **69** found in bengamide A and B, respectively, were initially synthesized from L-glutamic acid[19*a*] in non-stereoselective manner, and later from L-quebrachitol stereoselectively using Pd-catalysed regio- and stereo-selective azidation of conduritol derivative **66** as the key reaction[19*b*] (Scheme 8). Similar condensation of the caprolactams **68** and **69** with **62** gave **70** and **71**, respectively. Selective acylation of **70** and **71** with myristic acid, (tetradecanoic acid), followed by deprotection, furnished the total synthesis of bengamide A **72**[19*a*] and B **73**.[19*b*]

### *Oudemansin X*

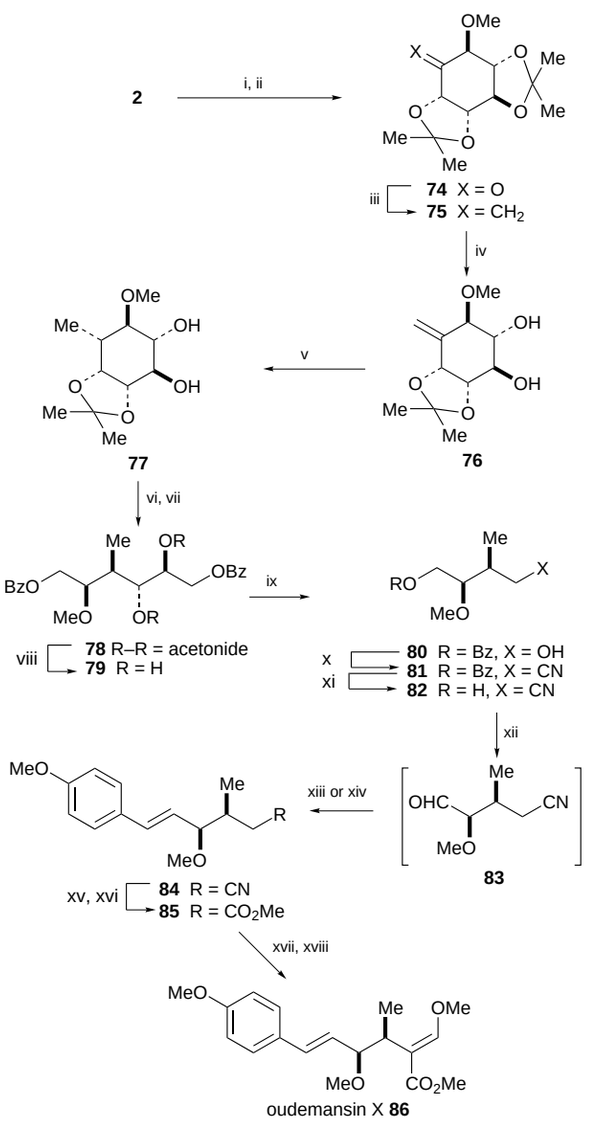
If one can introduce carbon substituents into cyclitol rings stereoselectively, the usefulness of cyclitols as chiral building blocks would be further extended. We pursued this idea, which culminated in the total synthesis of the novel antifungal antibiotic oudemansin X **86** (Scheme 9).[21] Peterson olefination of ketone **74**[20] derived from **2** in two steps, gave *exo*-alkene **75**. Removal of the *trans*-*O*-isopropylidene group gave **76**, whose hydrogenation afforded **77** exclusively. The bicyclic structure in **76** completely controlled the reaction face. Periodate oxidation of **77**, followed by reduction and benzoylation, provided **78**, which was converted into another diol **79**. Glycol cleavage of **79** followed by $NaBH_4$ treatment gave four-carbon unit **80**. After one-carbon homologation by introduction of a cyano group, the benzoyl group was deprotected and the resulting alcohol was oxidized to give aldehyde **83**. Wittig olefination and subsequent isomerization of the double bond, or Takai reaction (formation of *E*-vinyl iodide) followed by Pd-catalysed cross-coupling reaction of **83**, provided the β-styryl compound **84**. The nitrile group in **84** was converted into a methoxycarbonyl group to give **85**, whose lithium ester enolate was trapped with methyl formate; *O*-methylation with dimethyl sulfate completed the first total synthesis of oudemansin X **85**.[21]

**Scheme 7** *Reagents and conditions*: i, 2,2-dimethoxypropane, TsOH, DMF; ii, $NaIO_4$, $Me_2CO$–$H_2O$ (5:1), 0 °C; iii, $NaBH_4$, MeOH, 0 °C, then $Bu^tMe_2SiCl$, $Et_3N$, DMAP, $CH_2Cl_2$, room temp.; iv, $Me_2CHCH_2P^+Ph_3Br^-$, BuLi, $C_6H_6$, room temp.; v, TsOH (5 mol%), MeCN, 0 °C then $Bu^tMe_2SiCl$, $Et_3N$, DMAP, $CH_2Cl_2$; vi, $MnO_2$, $CH_2Cl_2$, room temp., then $Zn(BH)_4$, $Et_2O$–PhMe, −78–0 °C; vii, $Ac_2O$, pyridine, room temp.; viii, $Bu_4NF$, AcOH, THF, then $CrO_3$ in dil. $H_2SO_4$, $Me_2CO$, 0 °C; ix, **63**, $(EtO)_2P(O)CN$, $Et_3N$, DMF; x, MeONa, MeOH, then $CF_3CO_2H$–THF–$H_2O$.



## Other related work

As discussed above, cyclitols, by their regioselective ring cleavage, have now become useful chiral building blocks for the preparation of acyclic and heterocyclic natural products. Successful implementation of this strategy by our group has given: D- and L-galactose derivatives,[6b] L-mannose, L-talo and L-guluronate derivatives,[22] (−)-isoavenaciolide,[23] (−)-ethisolide,[23b] (+)-galactostatin,[24] (+)-1-deoxygalactostatin,[24] restricticin[25] (from L-quebrachitol) and lincosamine[26] (from *myo*-inositol).



Since L-quebrachitol is an optically active polyhydroxy cyclohexane derivative, transformation of L-quebrachitol into natural or unnatural products having polyfunctional cyclohexane structures is also important work. Such approaches include syntheses of: aminocyclitols by Ogawa and co-workers,[27] carba-sugar derivatives by Paulsen *et al.*[28] (−)-ovalicine by Bath *et al.*[29] cyclophellitol by Akiyama and co-workers,[30] inositol phosphate derivatives by Kozikowski and co-workers,[31] Akiyama and co-workers[32] and Potter and co-workers,[33] and simmondsin by Chida and co-workers.[34] Utilization of L-quebrachitol as a chiral auxiliary in asymmetric synthesis is reported by Akiyama and co-workers.[35] Other applications of L-quebrachitol in the preparation of bioactive compounds are found in the recent excellent review by Kiddle.[36]

## Conclusions

We have shown that cyclitols are versatile chiral building blocks in natural product synthesis. The cyclic structure of cyclitols allowed us to introduce a variety of functionalities regio- and stereo-selectively on the cyclohexane ring. By subsequent cleavage of the cyclohexane ring at a chosen position, cyclitols serve as useful precursors for acyclic and heterocyclic natural products. The regioselective Baeyer–Villiger reaction can be used for the successful implementation of such approaches. As *myo*-inositol and L-quebrachitol are readily available in large quantities from plants, they are expected to be used widely as a chiral building block for the synthesis of structurally complex natural or non-natural products, and are also expected to be employed as raw materials for the preparation of non-carbohydrate products in the chemical industry.

**Scheme 8** *Reagents and conditions*: i, $NaN_3$, $Pd(PPh_3)_4$ (3 mol%), THF–$H_2O$ (5 : 1), room temp.; ii, **68** or **69**, $(EtO)_2P(O)CN$, $Et_3N$, DMF; iii, MeONa, MeOH, then $C_{13}H_{27}CO_2H$, 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride, DMAP, $CH_2Cl_2$–THF, −50 to −15 °C; iv, MeONa, MeOH, then $CF_3CO_2H$–THF–$H_2O$.

**Scheme 9** *Reagents and conditions*: i, 2,2-dimethoxypropane, TsOH, DMF; ii, $RuO_2$, $NaIO_4$, $CHCl_3$, room temp.; iii, $Me_3SiCH_2MgCl$, THF, then KH, THF, room temp.; iv, TsOH, MeOH, 0 °C; v, $H_2$, Raney-Ni (W-4), EtOH, room temp.; vi, $NaIO_4$, $NaHCO_3$, $Me_2CO$–$H_2O$, 0 °C, then $NaBH_4$, MeOH, 0 °C; vii, BzCl, pyridine, viii, AcOH–$H_2O$ (4 : 1), 70 °C; ix, $NaIO_4$, $NaHCO_3$, $Me_2CO$–$H_2O$, 0 °C then $NaBH_4$, MeOH, 0 °C; x, $MeSO_2Cl$, pyridine, then NaCN, DMF, 50 °C; xi, MeONa, MeOH, 0 °C; xii, pyridinium chlorochromate, $CH_2Cl_2$; xiii, $Ph_3P^+CH_2C_6H_4(p\text{-OMe})Cl^-$, BuLi, THF, 0 °C then PhSH, AlBN, $C_6H_6$, reflux; xiv, $CHI_3$, $CrCl_2$, DMF–THF, room temp., then $(p\text{-OMe})C_6H_4MgBr$, $Pd(PPh_3)_4$ (5 mol%), $C_6H_6$, room temp.; xv, DIBAL-H, $CH_2Cl_2$, acidic (aq. $H_2SO_4$) work up; xvi, $NaClO_2$, $NH_2SO_3H$, $NaH_2PO_4$, Bu$^t$OH–$H_2O$, room temp., then $CH_2N_2$, $Et_2O$–$CH_2Cl_2$; xvii, $(Me_3Si)_2NLi$, THF, −78 to −40 °C, then $HCO_2Me$; xviii, $(MeO)_2SO_2$, $K_2CO_3$, $Me_2CO$, room temp.

**Acknowledgement**

We thank Yokohama Rubber Co. Ltd. (Tokyo, Japan), for a generous gift of L-quebrachitol. We also thank Yamakawa Chemical Industry Co. Ltd. (Tokyo), for donation of (*S*)-(+)-α-(acetoxy)phenylacetic acid. Financial support from the Japan Science Society, Ministry of Education, Science and Culture of Japan, and the Moritani Scholarship Foundation is gratefully acknowledged.

**Noritaka Chida was born in Sendai, Japan, in 1956. He received his PhD in 1983 from Tohoku University under the supervision of Professor Akira Yoshikoshi. From 1983 to 1986 he worked for Mercian Co. Ltd. as a researcher in the chemistry division. In 1986, he joined the Department of Applied Chemistry, Keio University, where he is now Associate Professor. In 1987–1988 he held a postdoctoral position with Professor Amos B. Smith, III, at the University of Pennsylvania. His research interests include the total synthesis of biologically important and structurally interesting natural products, and the development of novel and efficient chemical reactions.**

**Seiichiro Ogawa is now working on the synthesis of biologically active sugar mimics composed by cyclitols and carba-sugars. After obtaining his PhD in 1967 from Keio University, he joined the Faculty of Engineering, Keio University, and is currently Professor of Chemistry. He attended the University of Illinois as a postdoctoral researcher in 1967, and, seven years later he received the Alexander von Humboldt Fellowship and worked at Technische Hochschule, Darmstadt.**

# Organic electroluminescent devices with Langmuir–Blodgett films of an amphiphilic complex with an 8-hydroxyquinoline as an emitter

**Jianming Ouyang,*[a] Ling Li,[b] Zihou Tai,[b] Zuhong Lu[c] and Guangming Wang[c]**

[a] *Department of Chemistry, Jinan University, Guangzhou, 510632, P.R. China*
[b] *State Key Laboratory of Coordination Chemistry, Coordination Chemistry Institute, Nanjing University, Nanjing, 210093, P.R. China*
[c] *National Laboratory of Molecular and Bioelectronics, Southeast University, Nanjing, 210096, P.R. China*

**Electroluminescent (EL) devices with a single layer structure [indium-tin-oxide/emitting layer (Langmuir–Blodgett films)/Al] are synthesised using an intensely fluorescent amphiphilic complex, bis(*N*-hexadecyl-8-hydroxyquinoline-2-carboxamide)lanthanum [La(HQ)$_2$(H$_2$O)$_4$Cl] as the emitter material; green–yellow electroluminescence is observed with a low drive voltage (9 V).**

Organic electroluminescent (EL) devices have recently received much attention because they can potentially produce emissions of all colours from blue to red in accordance with the wide selection of organic emitting materials, and because of their possible applications as large-area light-emitting displays,[1–7] which are difficult to achieve using inorganic light-emitting cells.

Thin aromatic hydrocarbon films that fluoresce could have practical significance as large area electroluminescent panels if ultra-thin high quality aromatic hydrocarbons films can be constructed.[8,9] Tang *et al.*[1,2] found that the 8-hydroxyquinoline-aluminium (Alq$_3$) complex can be used as an emitting element in EL devices. As an emitting material, Alq$_3$ has excellent properties such as highly stable film formation, high carrier transport and good heat resistance. In the EL diode Tang *et al.* designed, high external quantum efficiency, luminous efficiency and brightness are achievable at a driving voltage below 10 V. Hamada *et al.*[6] have developed other organic EL devices with 8-hydroxyquinoline–metal complexes, such as Znq$_2$, Beq$_2$, Mgq$_2$, Zn(mq)$_2$, Be(mq)$_2$ and Al(prq)$_3$ (mq and prq are 2-methyl-8-hydroxyquinoline and 7-propyl-8-hydroxyquinoline, respectively), as the emitter. The emissions of these devices are green or blue and they have a luminance of more than 3000 cd m$^{-2}$. For example, the EL device with Znq$_2$ has a luminance of 16 200 cd m$^{-2}$, higher than the luminance of Alq$_3$ (15 800 cd m$^{-2}$). There is no report of Langmuir–Blodgett (LB) films of 8-hydroxyquinoline complexes being used as an emitting layer. LB film techniques make it possible to prepare organic functional ultra-thin films with a controlled thickness at a molecular size and well-defined molecular orientation,[10,11] and the long chain 8-hydroxyquinoline complexes have strong fluorescence at room temperature.[12,13] Therefore, if these amphiphilic 8-hydroxyquinoline derivatives complexes can be incorporated in LB films, these films will be of higher quality than the general vacuum deposited films and may have potential applications in molecular electronic devices.[12]

The synthesis of the amphiphilic ligand, *N*-hexadecyl-8-hydroxyquinoline-2-carboxamide (HHQ) and its lanthanum complex, La(HQ)$_2$(H$_2$O)$_4$Cl, which has high fluorescence efficiency,[12] were carried out by a previously reported method.[12,14] The molecular structure of La(HQ)$_2$(H$_2$O)$_4$Cl is shown in Fig. 1. The EL device has a single layer structure: ITO/emitting layer (9- or 19-layer LB films)/Al, as shown in Fig. 1. The substrate is an indium-tin-oxide (ITO) coated glass with a sheet resistance of about 20 Ω/□, and it was cleaned by the known standard procedure.[15] The LB films of the La(HQ)$_2$(H$_2$O)$_4$Cl amphiphilic complex (the emitting layer) were prepared by a conventional LB technique. The amphiphilic complex was spread from a chloroform solution on a subphase of Millipore-filtered water. The transfer was performed at 0.025 N m$^{-1}$ with a dipping speed of 3 mm min$^{-1}$. After the various LB films were made aluminium to a thickness of 300 nm was deposited at 10$^{-5}$ Torr onto the LB film surface as the top electrode with a deposition rate of 1.0 nm s$^{-1}$. The emitting area was 2 × 3 mm$^2$. The luminance of the EL devices was measured with a luminance meter. All measurements were carried out at room temperature in air under DC bias conditions.

Fig. 2 shows the relationship of current density and voltage of the EL devices with 9- and 19-layer LB films. The shapes of the curves are strongly dependent on the thickness of the LB films of La(HQ)$_2$(H$_2$O)$_4$Cl (luminance layer). The driving voltage increases with increasing LB film layer. The driving voltage for

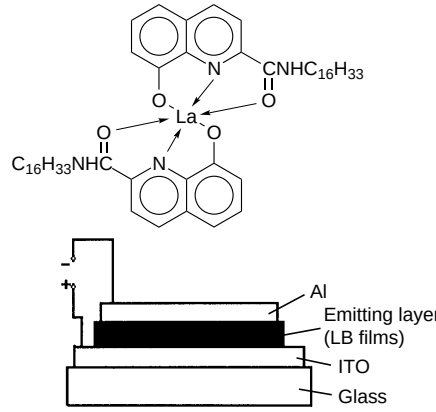

**Fig. 1** Configuration of the EL cells and the molecular structure of the material used in this study

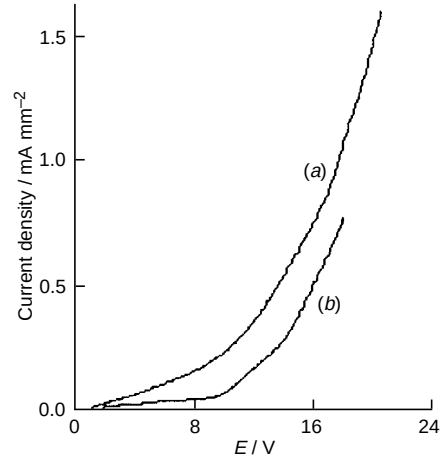

**Fig. 2** The relationship of current density and voltage of the EL cell with the emitter of the La(HQ)$_2$(H$_2$O)$_4$Cl LB films: (*a*) 9-layer, (*b*) 19-layer

the cell with 19-layer LB films was 9 V. At a given voltage, the current density for the EL cell with a thinner LB film emitter is higher than that for the thicker one. The curves can be fitted to an injection-limited model where the electron current is limited by electron emission from the cathode into the $La(HQ)_2(H_2O)_4Cl$ LB film layer.

The luminance–current density characteristics of the EL cell with the emitter of the 19-layer $La(HQ)_2(H_2O)_4Cl$ LB films are shown in Fig. 3. Green–yellow emission with a luminance of about 330 pw was achieved which was enhanced with the injection current elevation in the region of 0.1–1.00 mA $mm^{-2}$.

Comparison of the EL emission spectrum of the cell with the PL spectrum of 19-layer $La(HQ)_2(H_2O)_4Cl$ LB films[12] showed that the spectrum does not change greatly. The PL and EL peak wavelengths and the half values of these two spectra are 520, 515 and 170, 200 nm, respectively. The EL emission spectrum is independent of the driving voltage and current. This result indicated that the radiative recombination of injected electrons and holes takes place in the $La(HQ)_2(H_2O)_4Cl$ LB films.[1]

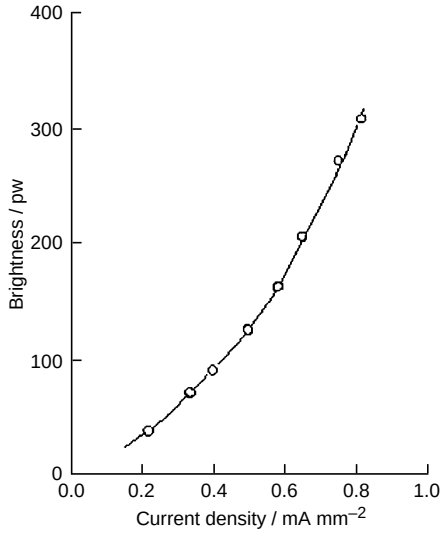

**Fig. 3** The relationship of brightness and current density of the EL cell with the emitter of the 19-layer $La(HQ)_2(H_2O)_4Cl$ LB film

This research was supported by a grant from the National Natural Science Foundation of China.

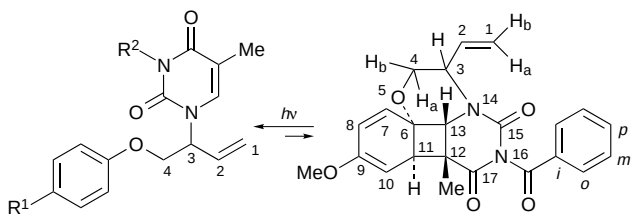
# Fully selective intramolecular *ortho* photocycloaddition of 4-(4-methoxyphenoxy)-3-($N^3$-benzoylthymin-1-yl)but-1-ene: an unprecedented benzene–thymine photocycloaddition



**Wim Saeyens,[a] Roger Busson,[b] Johan Van der Eycken,[c] Piet Herdewijn[a] and Denis De Keukeleire*[a]†**

[a] *Universiteit Gent, Faculty of Pharmaceutical Sciences, Harelbekestraat 72, B-9000 Gent, Belgium*
[b] *Katholieke Universiteit Leuven, Rega Institute, Minderbroedersstraat 10, B-3000 Leuven, Belgium*

**On irradiation of 4-(4-methoxyphenoxy)-3-($N^3$-benzoylthymin-1-yl)but-1-ene 1 at 254 nm in THF a single photoadduct 2 is formed as a result of chemo-, regio- and stereo-selective intramolecular *ortho* photocycloaddition of the thymine double bond to the 1,2-positions of the phenyl ring.**

Covalent modification of DNA may occur by photochemical activation of complexes between intercalating drugs and DNA, and between proteins and DNA. 4-(4-Methoxyphenoxy)-3-($N^3$-benzoylthymin-1-yl)but-1-ene **1** can be considered as a model structure to study this cross-linking reaction. Compound **1** represents an arene–alkene bichromophore separated by a tether of three atoms. Intra- as well as inter-molecular photocycloadditions in such compounds are well documented.[1] Both *ortho* and *meta* photocycloadditions of the alkene to the arene have been observed, while the preferred reaction mode depends on subtle stereoelectronic effects. It was shown that the presence of a methoxy group in an *ortho* position favours attack of the alkene at the 1,2-positions.[2] On the other hand, 4-phenoxybut-1-enes undergo mainly 2,6-*meta* photocycloaddition.[2] Furthermore, introduction of a group allylic to the alkene has a major influence on the reaction outcome.[3] We were interested in examining the photocycloaddition of 4-(4-methoxyphenoxy)-3-($N^3$-benzoylthymin-1-yl)but-1-ene **1**, in which these features are combined. Moreover, this compound allowed us to study the competition between the alkene and the 5,6-double bond of the thymine ring in the photocycloaddition reaction. Additionally, we investigated the photoreactivity of compounds **3**–**5** as analogues of **1**.

Trichromophore **1**‡ was synthesized by reaction of 4-methoxyphenol with butadiene monoxide in $Me_2SO$ in the presence of KOH,§ followed by coupling of the resulting 3-hydroxy-4-(4-methoxyphenoxy)but-1-ene (57%) with $N^3$-benzoylthymine under Mitsunobu conditions (40%).[4] Irradiation of **1** in THF (50 mg in 20 ml, 254 nm, 20 min) yielded a single photoproduct **2** (23%) in addition to unchanged starting material. Increasing the reaction time (up to 90 min) did not appreciably change the ratio of **1** to **2** before formation of degradation products started. Photoadduct **2** was isolated by preparative HPLC on silica using ethyl acetate–hexane (3:7) as eluent. Irradiation (1 h) of **2** under conditions identical to those used for **1** afforded a mixture of **1** and **2** in approximately the same ratio as observed for the forward reaction.

**1** $R^1$ = OMe; $R^2$ = Bz
**3** $R^1$ = H; $R^2$ = Bz
**4** $R^1$ = OMe, $R^2$ = H
**5** $R^1$ = H; $R^2$ = H

**2**

The structure of **2**‡ (arbitrary numbering) was fully elucidated by $^1$H and $^{13}$C NMR. Analysis of the $^{13}$C NMR data clearly revealed eight instead of four signals for aliphatic carbons, in addition to the five benzoyl peaks and eight other $sp^2$-carbon signals. From a DEPT spectrum the presence of an intact vinyl group was inferred (a methylene $sp^2$-carbon at δ 118.71 and a methine $sp^2$-carbon at δ 131.64), together with two carbonyls (δ 169.38 and 150.51), an oxygenated non-protonated carbon (δ 155.48) and three methine $sp^2$-carbons at δ 129.35, 124.90 and 87.81. The two typical C-5 and C-6 thymine $sp^2$-resonances were absent. Apparently, chemoselective *ortho*-photocycloaddition of the thymine double bond at the 1,2-positions of the phenyl group had taken place leaving the vinyl group unaltered. Although [2 + 2] photocycloadducts of thymine and its derivatives are well known,[5] the type of arene–alkene photocycloaddition observed in this study is to our knowledge unprecedented.

The structure‡ of this photocycloadduct was further confirmed by a complete analysis of the $^1$H NMR spectrum *via* COSY and HETCOR experiments. The stereochemical relationships were derived from NOE experiments. The *cis* configuration of the methyl group and the methine proton (H-13), originally being H-6 of thymine, was established, as well as the *trans* relationship between the methyl group and the methine proton (H-11) originally at the *ortho* position of the alkoxy chain. Obviously, the rings annelated to the cyclobutane moiety are in the *cis–anti–cis* configuration. The [2 + 2] photocycloaddition is indeed expected to occur in the *cis* mode,[6] while the steric requirements are accomodated by the less constrained *anti* configuration. The stereochemistry at the remaining chiral centre (C-3) can be deduced on account of the conformational features of the 1-aza-4-oxacyclohexane ring. The proton is in a pseudo-axial position (*S*-configuration in structure **2**) as ascertained by the magnitude of the coupling constants with the vicinal H-4 protons (9.4 and 8.0 Hz) and by the observation of a NOE enhancement between H-3 and H-4b and not with H-4a. The existence of a NOE between the *ortho* hydrogen of the benzoyl group and H-11, and between the methyl group and H-8 and H-10, supports the stereochemical assignment.

The exclusive formation of photocycloadduct **2** can be rationalized in terms of the control elements present in **1**. The *ortho* photocycloaddition is accounted for by the presence of the *para*-methoxy group, which should exhibit similar electronic behaviour to an *ortho*-methoxy group.[2] A similar preference for the *ortho* reaction was also noted for 3-acetoxy-4-(4-methylphenoxy)but-1-ene.[7] On the other hand, the more pronounced polarization of the thymine double bond in comparison with the vinyl group would preferably lead to *ortho* addition, as this reaction mode predominates when the ionization potentials of the reacting entities differ to a certain extent.[8] Dimerization

usually encountered in thymine derivatives is prevented by carrying out the reaction in dilute medium and also by the efficiency of the intramolecular photocycloaddition.

Interestingly, independent irradiation of $N^3$-benzoylthymine and 4-phenoxy-3-($N^3$-benzoylthymin-1-yl)but-1-ene **3**, under the same conditions as described, resulted in complete substrate consumption yielding mainly polar constituents, in which loss of the benzoyl group was evident from the NMR data. Analogous thymine-unprotected compounds, such as 4-(4-methoxyphenoxy)-3-(thymin-1-yl)but-1-ene **4** and 4-phenoxy-3-(thymin-1-yl)but-1-ene **5**, proved to be light-stable, even after prolonged irradiation (24 h). It is, therefore, deduced that the presence of both the *para*-methoxy and the $N^3$-benzoyl groups is required in order to direct the intramolecular arene–alkene photocycloaddition thereby showing the sensitivity of this reaction to subtle and unexpected substituent effects. The *para*-methoxy group apparently creates suitable electronic conditions for *ortho* addition, while it remains to be clarified whether the benzoyl group activates or the secondary amide inhibits photocycloaddition.

In most instances, the *ortho* adducts, resulting from intramolecular arene–alkene photocycloaddition, suffer from further reactions depending on the varying stabilities of the particular compounds formed in the cascade. The bicyclo[4.2.0]octa-2,4-diene unit, present in such *ortho* photoadducts, normally rearranges on heating into a cyclooctatriene, which subsequently gives a mixture of [2 + 2] photocycloadducts. Only occasionally have primary *ortho* photoadducts been isolated as stable compounds, as was found on irradiation of pentafluorophenylprop-2-enyl ether,[9] 2-methyl-6-(4-fluorophenyl)-hex-2-ene[10] and 1-(2-methoxybenzyloxy)-3-methylbut-2-ene.[11] In the present case, after heating **2** in refluxing THF for several hours we were not able to detect cyclooctatriene-like structures, nor was there any evidence for a Diels–Alder-type reaction between the alkene and the cyclohexa-1,3-diene units present in **2**.

In conclusion, we have observed the intriguing photoreactivity of trichromophore **1** since a single, stable *ortho* photoadduct **2** arose under full chemo-, regio- and stereo-selective control. This unprecedented reaction may imply potential cross coupling of pyrimidine bases in nucleic acids with aromatic amino acids in proteins or with intercalating drugs by virtue of a [2 + 2] photocycloaddition, thereby inducing DNA alterations which may interfere with biological function. Hitherto, it was known that amino acids could photochemically add across the double bond of pyrimidine bases,[12] but results obtained for the present model system may shed light on yet different photochemical nucleic acids–protein and/or nucleic acids–drug interactions.

§ Cleavage of epoxides usually requires attack by reactive nucleophiles as described by Posner and Rogers (*J. Am. Chem. Soc.*, 1977, **99**, 8208). We were able to effect the reaction using 4-methoxyphenolate in $Me_2SO$ (57%). In the absence of the activating *para*-methoxy group the yield is significantly decreased (20%).

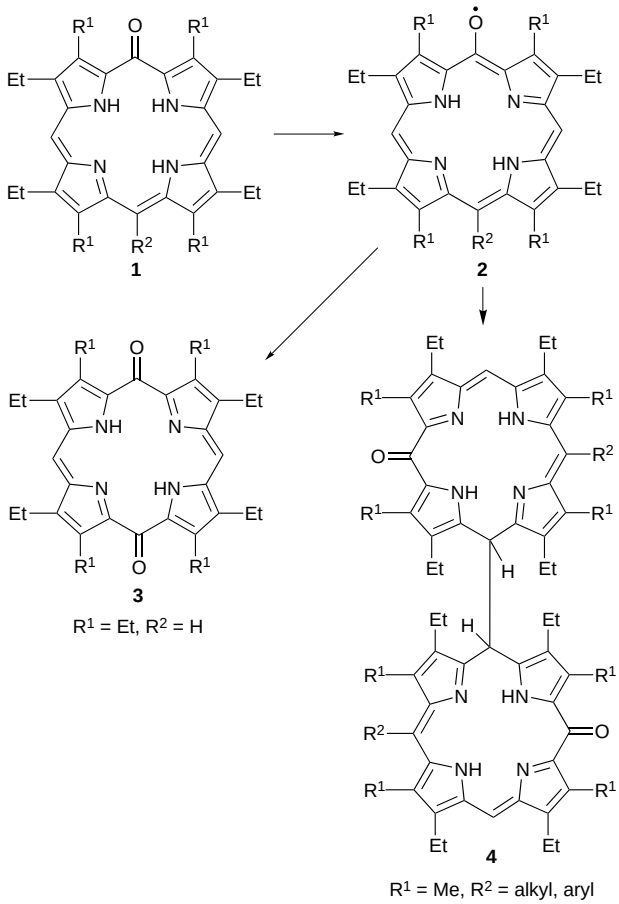
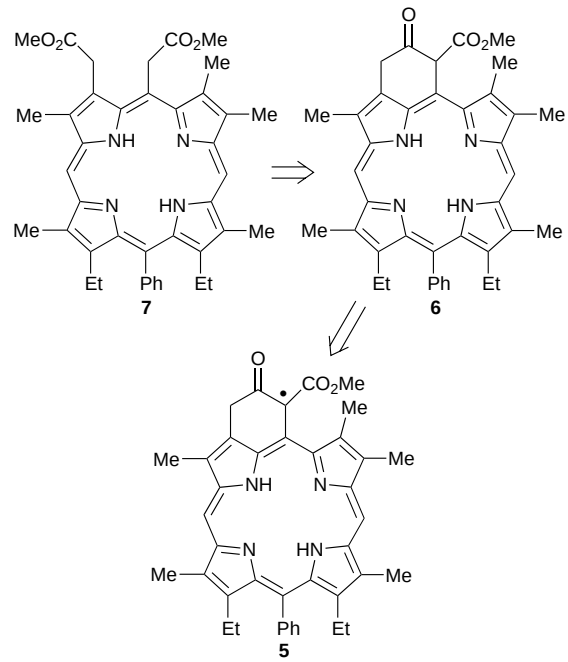
# New chemistry of porphyrin β-ketoesters: synthesis of a novel covalently-linked dimer

**Robert T. Holmes, Jack J. Lin, Richard G. Khoury, Colin P. Jones and Kevin M. Smith*†**



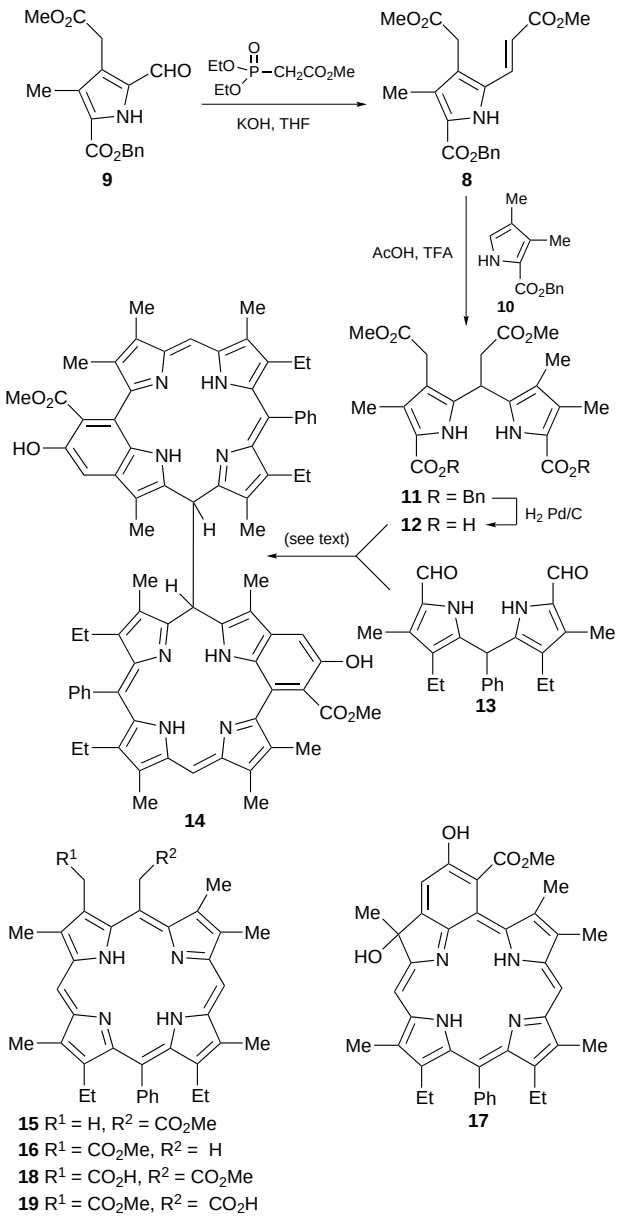
*Department of Chemistry, University of California, Davis, CA 95616, USA*

**Porphyrinyl β-ketoesters dimerize to afford novel bistetrapyrrole systems by way of a radical process; the X-ray structure of one such bistetrapyrrole 14 is reported.**



Oxophlorins **1** can be readily oxidized by dioxygen to form π-stabilized radicals **2**,[1] oxo derivatives **3**,[2] or covalently linked dimers **4**,[3] by mechanisms similar to those established in phenolic chemistry (Scheme 1).[4] An example of a very stable (sterically encumbered) oxophlorin π-radical was recently reported,[5] and although porphyrins can readily undergo one-electron oxidation (to give π-cation radicals) these transient species usually decompose to the parent porphyrin.[6] Based on knowledge of phenolic chemistry and its analogies with oxophlorin chemistry,[7] one might anticipate that any porphyrin system which could efficiently form a radical at a *meso*-benzylic atom (*e.g*. the carbonyl oxygen in oxophlorins, or a *meso*-benzylic methylene carbon) should undergo chemistry similar to that of oxophlorins (*e.g*. carbon–carbon dimerization, reaction with dioxygen). Literature precedent suggests[8] that benzylic porphyrin radicals (*e.g*. **5**) should, in principle, be accessible through porphyrins (*e.g*. **6**) suitably substituted with β-ketoester substituents (Scheme 2).

The precursor **7** of **6** was synthesized using established pyrrole chemistry; it was initially anticipated that Dieckmann cyclization of **7** would give **6**. The Michael acceptor pyrrole **8** was obtained from the formylpyrrole **9** by way of a Horner–Wadsworth–Emmons reaction (Scheme 3). Treatment of **8** with the 2-unsubstituted pyrrole **10** in refluxing acetic acid containing TFA gave the unsymmetrical dihydrodipyrrin **11**,[9] which upon catalytic bisdebenzylation gave **12**. MacDonald ('2 + 2') condensation between **13**[10] and the unsymmetrical dihydrodipyrrin dicarboxylic acid **12** in the presence of acid and zinc acetate, followed by removal of zinc with acid and then a basic work-up, did not yield the expected porphyrin **7**. Instead, a green compound was isolated ($\lambda_{max}$ 424, 606 nm). $^1$H NMR spectroscopy indicated a non-conjugated macrocycle had been formed [δ 12.67, 11.51 (each s, 1 H, NH)]. X-Ray crystallographic analysis‡ (Fig. 1) confirmed the structure of the compound to be the novel 10, 10′-bismacrocycle **14**. The linking 10,10′ carbon–carbon bond length is 1.58 Å. Along with dimer **14**, porphyrins **15** and **16** and the hydroxy-substituted chlorin **17** [$\lambda_{max}$ 424, 606 nm; δ 11.50, 8.93 (each br s, 1 H, OH)] were isolated. The structural assignment of **17** is based on spectroscopic similarities between **17** and the analogue in the 15-unsubstituted series, for which an X-ray crystal structure (not shown) has been obtained.



It was possible to isolate the target dimethyl ester porphyrin **7** in good yield by purifying the crude reaction mixture on neutral alumina instead of silica gel. Based on observations of the reactivity of **7** it became clear that the β-ketoester function

**Scheme 1**

**Scheme 2**

**Scheme 3**

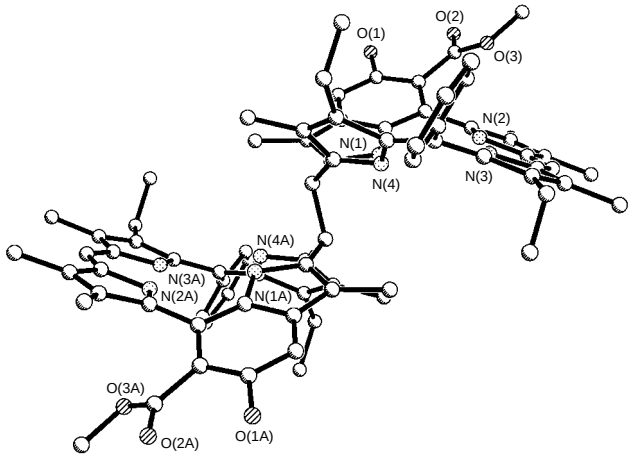


**Fig. 1** Molecular structure of dimer **14**

was not being formed by way of a base-catalysed Dieckmann process upon **7**. Subsequently, non-basic methods were developed to permit the controlled synthesis of covalent dimer **14** (by way of **6**), and the side products, simply by adsorbing porphyrin **7** on silica gel under $CH_2Cl_2$ for 14 h. Presumably, water present on the silica gel makes it possible for small amounts of the bis(methoxycarbonylmethyl)porphyrin **7** to hydrolyse and form monocarboxylic acid by-products such as **18** and **19**. At this point, decarboxylation would form porphyrin **15** (or **16**, depending upon which ester has been hydrolysed) or it could follow a mechanism to form the corresponding 'anhydro' derivative. The so-called anhydro-reaction[12,13] proceeds reversibly by way of an acid catalysed equilibrium which, in this case, would be driven by formation of the β-ketoester moiety on the periphery of the porphyrin **6** *via* attack by the methylene adjacent to the remaining ester in **18** upon a putative acylium species formed from its acetic acid substituent.

‡ *Crystal data* for **14**. Crystals were grown from $CH_2Cl_2$–cyclohexane. A parallelepiped single crystal was selected with dimensions 0.18 × 0.13 × 0.05 mm. The unit cell was triclinic $P\bar{1}$ with cell dimensions $a$ = 11.208(2), $b$ = 12.474(3), $c$ = 14.368(3) Å, $\alpha$ = 78.35(3), $\beta$ = 76.86(3), $\gamma$ = 83.98(3)°, $V$ = 1912.2(7) Å$^3$, and $Z$ = 2 (FW = 748.7). X-ray diffraction data were collected on a Siemens $P2_1$ diffractometer with a fine-focus sealed tube [$\lambda$(Cu-K$\alpha$) = 1.54178 Å] at 130(2) K in $\theta$–2$\theta$ scan mode to $2\theta_{max}$ = 112°. Of 5278 reflections measured ($\pm h,\pm k,\pm l$) 3283 were independent and 1932 had $I > 2\sigma$ ($R_{int}$ = 0.039). The structure was solved by direct methods and refined (based on $F^2$ using all independent data) by full-matrix least-squares methods (Siemens SHELXTL V. 5.02); number of parameters = 441. Hydrogen atom positions were located by their idealized geometry and refined using a riding model. An absorption correction was applied using XABS2.[11] Final $R$ factors were $R1$ = 0.083 (based on observed data) and $wR2$ = 0.1998 (based on all data). Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Center (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/406.

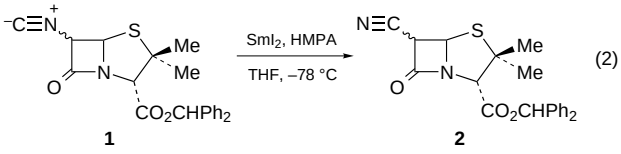
# Isonitrile–nitrile rearrangement promoted by samarium(II) iodide

**Han-Young Kang,*[a] Ae Nim Pae,[b] Yong Seo Cho,[b] Hun Yeong Koh*[b] and Bong Young Chung*[c]**

[a] *Department of Chemistry, Chungbuk National University, Cheongju 361-763, Korea*
[b] *Department of Applied Science, Korea Institute of Science and Technology, PO Box 131, Cheongryang, Seoul 130-650, Korea*
[c] *Department of Chemistry, Korea University, Seoul 136-701, Korea*

**A samarium(II) iodide-promoted rearrangement of isonitriles to nitriles, which requires an α-alkoxycarbonyl group at the carbon atom bearing the isonitrile group, occurs under very mild conditions and contrasts with the thermal version of the rearrangement, which usually requires high temperature.**

The isonitrile–nitrile rearrangement, which has been known for about ninety years, proceeds thermally with retention of stereochemistry at the migrating carbon [eqn. (1)].[1–3] This



(1)

implies that the bond-forming and -breaking steps occur simultaneously and that there is little development of charge in the transition state. This rearrangement occurs at high temperature (250–280 °C) and is believed to take place *via* a radical intermediate. When the migrating carbon atom contains delocalizing groups such as alkoxycarbonyl or phenyl, then rearrangement also takes place but with low retention of configuration.[4] This reaction has also been the focus of theoretical investigation.[5]

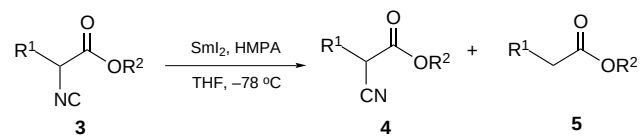
Samarium(II) iodide is a useful tool for synthetic organic chemists since it is known for promoting various organic transformations.[6] Among the useful reactions of this reagent, reductive cleavage of α-heteroatom-substituted carbonyl substrates, involving deoxygenation of the functionality containing heteroatoms such as oxygen, sulfur and halogen, has been one of the most utilized.[7] However, in the case of functional groups containing a nitrogen atom, reductive cleavage has rarely been studied despite the importance of the transformation. The first systematic study of the reductive cleavage of aziridines adjacent to a carbonyl group has recently been reported.[8]

During the course of investigations on reactions promoted by samarium(II) iodide we had an opportunity to study the reaction of penicillanate **1** in the presence of this powerful single electron-transferring agent [eqn. (2)].

(2)

We anticipated a reduced product. However, to our surprise, a nitrile **2** was obtained in 70% yield (contained 5% of the reduced product). The diastereoisomers of **1** were separated,† and each was treated under the same reaction conditions. Both diastereoisomers (α-NC and β-NC) provided approximately the same ratio of **2** (α-CN : β-CN = 1 : 1.5), which indicated that the stereoselection induced by the migrating NC group and/or the β-lactam nucleus is low.

In order to investigate the generality and limitations of this isonitrile–nitrile rearrangement, various carboxylic acid derivatives with an α-isonitrile group were prepared. Synthesis of the substrates was easily achieved in a straightforward manner starting from the corresponding α-amino acids.‡



The results of the isonitrile–nitrile rearrangement promoted by samarium(II) iodide are summarized in Table 1. The rearrangement proceeds under very mild conditions in contrast to the thermal version, in which a temperature of up to 300 °C is required. The samarium(II) iodide-promoted isonitrile–nitrile rearrangement tolerates various types of functionality as shown in Table 1. Yields are variable, and usually formation of the corresponding reduced products **5** is also observed.

Decyanation of α-cyanocarboxylic esters promoted by samarium(II) iodide was reported by us.[9] Conversion of nitriles **4** to the reduced products **5** is precluded since this process in the presence of samarium(II) iodide requires higher temperature (room temperature). Therefore, the reduced products **5** are believed to be formed directly from the isonitrile substrate and not *via* the rearranged compounds, nitriles **4**. Under our conditions ($SmI_2$, THF–HMPA, −78 °C) the rearranged products **4** are usually formed predominantly. The substrate **3d**, having an isocyano group at the benzylic position, produced only the corresponding reduced product **5d**. Importantly, the isonitrile substrate has to be activated by an alkoxycarbonyl group for successful rearrangement. In the case of **3e** only the isonitrile group attached to the carbon α to the carbonyl group was isomerized, as expected.

Generally, 1.2–1.5 equiv. of samarium(II) iodide are sufficient for the rearrangement. However, in some cases, 2.5 equiv. were employed to complete the reaction. It is also appropriate to note that this process, which provides α-cyanocarboxylates and the corresponding reduced (deaminated) products, can be understood as an efficient method for deamination of α-amino acid derivatives, since the isonitriles prepared were made from the corresponding α-amino acids and at higher temperature α-cyanocarboxylates are known to undergo decyanation in the presence of samarium(II) iodide.[9]

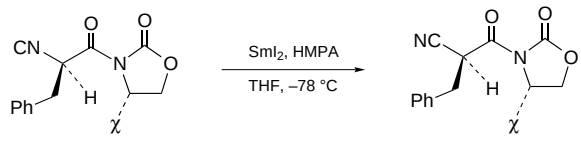
From the view-point of the synthetic potential of this rearrangement, we investigated the possibility of utilization of the reaction for asymmetric synthesis (Table 2). We prepared

**Table 1** Isonitrile–nitrile rearrangement promoted by samarium(II) iodide

| Isonitrile | $R^1$ | $R^2$ | $SmI_2$ (equiv.) | Product (% yield) 4 | 5 |
|---|---|---|---|---|---|
| **3a** | H | PMB[a] | 1.2 | **4a** (50) | **5a** (11) |
| **3b** | $(CH_3)_2CHCH_2$ | PMB[a] | 1.2 | **4b** (50) | **5b** (10) |
| **3c** | Bn | Me | 1.0 | **4c** (57) | **5c** (12) |
| **3d** | Ph | Me | 2.5 | **4d** (0) | **5d** (46) |
| **3e** | $CN(CH_2)_4$ | PMB[a] | 2.5 | **4e** (50) | **5e** (20) |
| **3f** | $PMBO_2CCH_2$ | PMB[a] | 1.8 | **4f** (40) | **5f** (11) |

[a] PMB = *p*-methoxybenzyl.

the substrates shown in Table 2 having chiral oxazolidinone auxiliaries.§



The efficiency of the differentiation of the diastereotopic faces by Evans' chiral auxiliaries (**3g** and **3h**) was first tested. Both cases show reasonable diastereoselectivities. Hoping to enhance the effectiveness of shielding to achieve a better de, a recently reported chiral auxilary (χ = $CHPh_2$; **3i** in Table 2) was also introduced.[10] However, in this case, no further increase in de was observed. Although only limited cases were tested, the results from Table 2 indicate that diastereoselectivity might be achieved if an appropriate chiral environment can be maintained. However, the systems considered here are not effective enough to obtain the desired level of diastereoselectivity. The reason could be either that the stereocentres responsible for the stereoselection are located far away from the carbon bearing the isocyano group or that the isocyano and cyano groups are linear, and thus are unable to provide efficient shielding of one diastereotopic face compared with the other.¶

Ito and co-workers have reported their investigation of the reaction of samarium(II) iodide with an isonitrile group.[11] In their cases, samarium(II) iodide promotes α-addition reactions of isonitriles. In our cases it is, however, probably reasonable to conclude that the reaction starts with an electron-transfer to the carbonyl group since no reaction was observed with a substrate without an α-alkoxycarbonyl group. The next step would involve breaking the bond between the migrating carbon atom and the nitrogen atom of the isocyano group, although the exact nature of the intermediate is not clear at the moment. At this stage, when benzylic stabilization is possible, return of the removed isonitrile moiety is not allowed and this results in exclusive formation of the reduced product. Otherwise the removed isonitrile moiety returns, with rearrangement, to the migrating carbon atom or, if this process cannot compete, the carbon atom previously bearing the isocyano group is captured by a hydrogen atom.

In conclusion, the samarium(II) iodide-promoted rearrangement of isonitriles to nitriles has been discovered and investigated. This rearrangement occurs under very mild conditions, in contrast to the thermal version of this rearrangement, which usually requires high temperature. This rearrangement should be included in the list of useful organic transformations promoted by samarium(II) iodide.

We are grateful to the Korea Ministry of Science and Technology and the Organic Chemistry Research Center (sponsored by the Korea Science and Engineering Foundation) for generous financial support.

**Table 2** Rearrangement of substrates with chiral auxiliaries

**3** **4**

| Isonitrile | χ | $SmI_2$ (equiv.) | Product (% yield) | De (%) |
|---|---|---|---|---|
| **3g** | $CH(CH_3)_2$ | 1.2 | **4g** (60) | 65 |
| **3h** | $CH_2Ph$ | 1.2 | **4h** (55) | 68 |
| **3i** | $CHPh_2$ | 1.2 | **4i** (48) | 68 |

## Footnotes

† Lichrosorb Si60 Semi-prep column, hexane–ethyl acetate = 3 : 1.

‡ The required isonitrile substrates were prepared by one of the following routes from the corresponding α-amino acids. Method A: i, $SOCl_2$, MeOH; ii, $HCO_2H$, $Ac_2O$, pyridine; iii, triphosgene, $Et_3N$, $CH_2Cl_2$, −78 °C. Method B: i, $HCO_2H$, $Ac_2O$; ii, *p*-Methoxybenzyl chloride, $K_2CO_3$, DMF; iii, triphosgene, $Et_3N$, $CH_2Cl_2$, −78 °C.

§ The purity of the substrates in Table 2 was checked by NMR spectroscopy. The isonitriles **3g**–**i** were all pure single diastereoisomers. For compounds **3g**–**i** the absolute stereochemistry of the carbon atom bearing the isonitrile group is, however, not clear at this point since epimerization could take place during the synthesis from the corresponding amino acids under the reaction conditions described in ref. 10. In all cases in Table 2, formation of the reduced products (corresponding to **5**) was not observed.

¶ The de values could be affected by epimerization during purification.

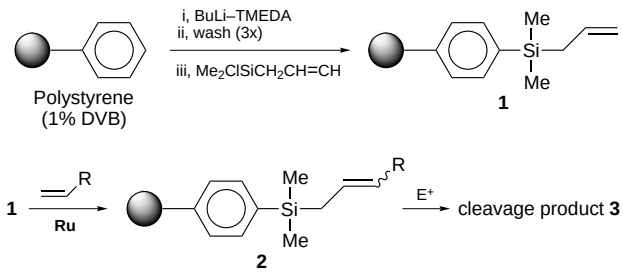
# Ruthenium-catalysed cross metathesis binding of functionalized olefins to polystyrene resin *via* a novel allylsilyl linker suitable for electrophilic cleavage

**Matthias Schuster, Norbert Lucas and S. Blechert*†**



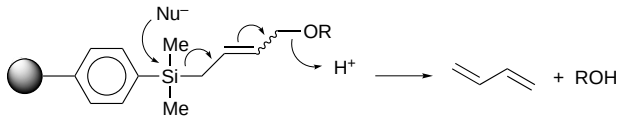
*Institut für Organische Chemie, Sekr. C3, Technische Universität Berlin, Straße des 17. Juni 135, D-10623, Germany*

**1% Divinylbenzene-crosslinked allyldimethylsilyl polystyrene 1 undergoes highly efficient ruthenium-catalysed cross-metathesis with functionalized terminal olefins and allows electrophilic cleavage of the resulting functionalized allylsilane.**

During the last decade, olefin metathesis has emerged as a powerful synthetic tool for the formation of C=C double bonds.[1] Most recently, it has been demonstrated that highly selective cross-coupling[2] between functionalized terminal olefins can be performed under catalysis of well defined metathesis catalysts.[3] In the advent of combinatorial chemistry there is an increasing demand for innovative chemistry on solid supports including novel linker concepts. Cross metathesis involving polymer-supported olefins should enable the binding of target molecules *via* the highly stable C=C double bond in a catalytic manner. In an initial report[4] we described the catalytic immobilisation of several small nonpolar molecules to a modified trityl polystyrene resin using Grubbs' ruthenium initiator[3] $Cl_2(PCy_3)_2$-Ru=CHPh **Ru** (Cy = cyclohexyl). Cross metathesis products were characterized after cleavage from the acid-labile trityl linker.

Here we present allyldimethylsilyl polystyrene **1**, which upon ruthenium-catalysed cross metathesis with terminal olefins yields immobilized products **2** (Scheme 1). Products **2** can be subject to electrophilic attack[5] resulting in C–Si cleavage and, thus, the formation of soluble products **3**. Cleavage can be performed either as protodesilylation or in combination with an additional synthetic step, when electrophiles other than $H^+$ are employed.

Polystyrene **1** closely resembles soluble allyltrimethylsilane, which was found to be an excellent cross metathesis partner by us and others.[2] The synthesis of **1** by treatment of polystyrene (1% DVB-crosslinked) (DVB = divinylbenzene) with BuLi–TMEDA and subsequently with allyldimethylsilyl chloride is based on the observation[6] that under these conditions metallation occurs in the *para*-position of the phenyl ring, exclusively.‡ The silicon content of **1** was determined by Inductive Coupled Plasma-Optical Emission Spectroscopy (ICP-OES) of sodium tertaborate melt samples. We found that removal of excess BuLi–TMEDA by repeated washing of the lithiated polymer ensures high loading capacities and significantly decreases the amount of the electrophile required. The resin employed throughout this study had a silicon content of 1.3 mmol $g^{-1}$. Cross metathesis was performed in refluxing dichloromethane using 0.05 mmol of **Ru** and 1.0–2.0 mmol of terminal olefin per gram of resin.§ Loadings of cross metathesis



**Scheme 1** Synthesis of, **Ru**-catalysed cross-metathesis with, and electrophilic cleavage from polystyrene-supported allylsilane **1**

**Table 1** Results of the electrophilic cleavage of metathetically obtained polystyrene-supported allylsilanes **2**

| Metathesis product **2** | Cleavage product **3**[2] |
|---|---|
| R = | |
| **2a**[b] | **3a**[d] (0.5 mmol $g^{-1}$) |
| **2b**[b] | **3b**[d] (0.43 mmol $g^{-1}$) |
| **2c**[c] | **3c**[d] (0.34 mmol $g^{-1}$) |
| **2d**[c] | **3d**[d] (0.41 mmol $g^{-1}$) |
| **2e**[c] | **3e**[d] (0.59 mmol $g^{-1}$) |
| **2f**[c] | **3f**[e] (0.38 mmol $g^{-1}$) |
| **2g**[c] | **3g**[d] (<0.1 mmol $g^{-1}$) |
| **2a**[b] | **3h**[f] (0.50 mmol $g^{-1}$) |

[a] Isolated yield of cleavage product **3** per gram of **2** given in parentheses. [b] Methathesis conditions: 300 mg **1**; 0.6 mmol terminal olefin; 0.015 mmol **Ru**; 5 ml $CH_2Cl_2$ (reflux); 18 h. [c] Metathesis conditions: 300 mg **1**; 0.3 mmol terminal olefin; 0.015 mmol **Ru**; 5 ml $CH_2Cl_2$ (reflux); 18 h. [d] Cleavage conditions: 3% TFA in $CH_2Cl_2$, 18 h. [e] Cleavage conditions: 1.5% TFA in $CH_2Cl_2$, 24 h. [f] To 500 mg of **2a** in 20 ml $CH_2Cl_2$ was added 1.3 mmol 1,1-diethoxypropane and 1.3 mmol $TiCl_4$ at −78 °C. After 22 h aqueous work-up ($NaHCO_3$) and flash chromatography of the $CH_2Cl_2$ phase gave the product.

**Scheme 2** Proposed mechanism for the protodesilylation of allysilanes **2** with oxygen in the allyl position

immobilisation products **2** were calculated from the amount of soluble cleavage products **3**, liberated from **2** by protodesilylation with TFA (3% in $CH_2Cl_2$).

As shown in Table 1, protodesilylation of **2a** furnished the homologized product **3a**;¶ 0.5 mmol was released per gram of **2a**. This modification level indicates a highly effective metathesis reaction. A diester function does not affect the immobilisation reaction as demonstrated by the synthesis of **2b** with 0.43 mmol $g^{-1}$. Protodesilylation yields the expected product **3b**. A major goal of this study was to demonstrate that polyfunctional molecules of biological interest such as glycosides and amino acid derivatives can also be effectively coupled to **1**. Indeed **2c** was formed with a capacity of 0.34 mmol $g^{-1}$. Protodesilylation to **3c** proceeded with complete retention of the acetal, thus underlining the exceptionally mild cleavage conditions. However, cleavage of **2d** under identical conditions furnished tetra-*O*-acetyl glucose **3d** instead of the expected homoallyl glycoside. Possibly, deglycosylation of **2b** proceeds through a modified protodesilylation mechanism as shown in Scheme 2.

The same cleavage pattern should be obsered when allyl esters are used in the metathesis reaction. Indeed, cleavage of **2e** and **2f** furnished the respective free carboxylic acids **3e** and **3f**. This special type of allyl ester is even more acid sensitive than the Boc group, which remains intact when the cleavage reaction is performed using 1.5% TFA for 24 h. The scope of this unexpected cleavage reaction remains to be investigated. In contrast to isoleucin allyl ester derivatives the metathetical immobilisation of the protected *C*-allylglycinol was less successful, as demonstrated by the amount of **3g** that could be released from **2g**. Eventually, we wished to demonstrate the utility of solid phase-bound allylsilanes **2** as starting materials for C–C bond formation. To give a first example of the addition of a carbon electrophile to a polymer-supported allylsilane, a mixture of **2a** and 1,1-diethoxyethane was treated with $TiCl_4$. The yield of product **3h** proved comparable to the yield of the corresponding protodesilylation product **3a**.

In conclusion, we have presented a novel polystyrene resin containing an allylsilyl linker moiety. The linker enables both binding of functionalized olefins by catalytic cross metathesis and cleavage under exceptionally mild acidic conditions. The linker allows the cleavage to be performed under formation of an additional C–C bond. A cyclisation–cleavage strategy employing intramolecular electrophilic attack is currently being developed.

‡ Synthesis of **1**: 8 g of polystyrene (1% DVB) was suspended in 12 ml of cyclohexane, 12 ml (80 mmol) TMEDA and 48 ml (1.6 M in hexane, 77 mmol) BuLi were added and the suspension was gently shaken for 3 d at ambient temperature under exclusion of moisture and air. The supernatant was removed through a septum and replaced by 30 ml cyclohexane. This procedure was repeated twice, before 12 ml (80 mmol) allyldimethylsilyl chloride was added under shaking. After 1 h the reaction was quenched with 40 ml methanol, the resin was quickly filtered off, washed repeatedly with methanol, dichloromethane and MeOBu$^t$ and dried under vacuum.

§ Synthesis of **2b**: to 300 mg of **1** in 5 ml absolute dichloromethane was added 120 mg (0.6 mmol) of **2a** and 12 mg (0.015 mmol) of **Ru**. The resulting suspension was refluxed under argon atmosphere (glove box) for 18 h. The resin was filtered off and washed with 20 volumes each of DMF, chloromethane, methanol and diethyl ether. Residual diethyl ether was removed under high vacuum.

¶ After acidic cleavage homoallyldimethylsilanol was isolated as a minor byproduct. Its formation can be rationalized by the following reaction sequence:

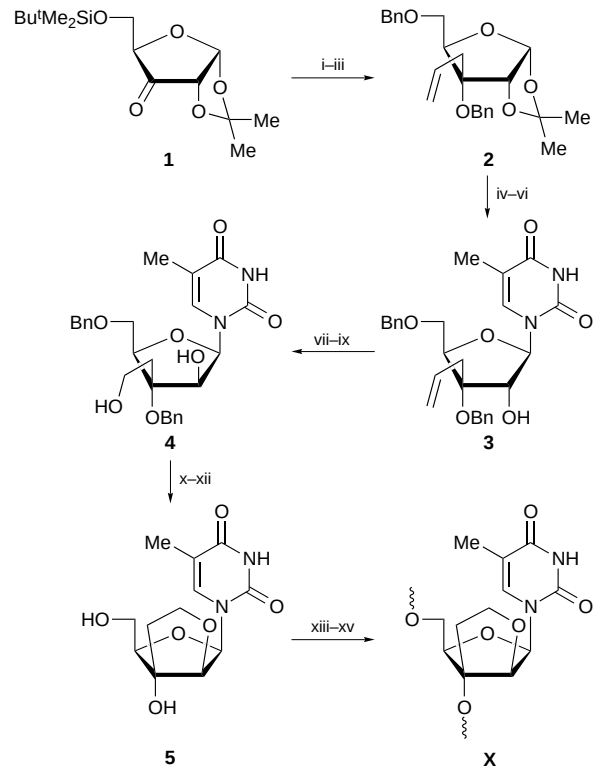
# A novel class of conformationally restricted oligonucleotide analogues: synthesis of 2′,3′-bridged monomers and RNA-selective hybridisation

**Poul Nielsen,[a] Henrik M. Pfundheller[a] and Jesper Wengel[b]*†**

[a] *Department of Chemistry, Odense University, 5230 Odense M, Denmark*
[b] *Department of Chemistry, University of Copenhagen, Universitetsparken 5, 2100 Copenhagen, Denmark*



**A novel 2′,3′-bicyclic nucleoside 5 has been synthesised and incorporated into oligonucleotide analogues resulting in strong and selective binding to an RNA complement.**

Research towards modified oligonucleotides able to hybridise with ssRNA (antisense or ribozyme approach) as a novel class of therapeutic agents currently attracts much attention.[1] The potential of enhancing duplex stability using conformationally restricted oligonucleotide analogues has been investigated, as recently described in a review by Herdewijn.[2] Bicyclo nucleosides with an additional 3′,5′-ethylene bridge,[3] bicyclic carbocyclic nucleosides with a 1′,6′- or 4′,6′-methano bridge,[4] 2′,3′-riboacetal dimers,[5] 3′,6′-anhydrogluco-2′,5′-formacetal trimers[6] and conformationally restricted 1,5-anhydro-2,3-dideoxy-D-*arabino*-hexitol nucleosides[7] have been synthesised and incorporated into oligodeoxynucleotides in order to obtain an entropic advantage through the rigidity of the structures, thereby increasing duplex stability. Here we report on the synthesis and the promising melting results for 2′,3′-bridged bicyclic pentofuranose oligonucleotides. This work was stimulated by molecular modelling studies indicating the possibility of a preferential 3′-*endo* conformation of the monomers as required for RNA-selective binding.

The bicyclic nucleoside **5** was synthesised in twelve steps from the known ulose **1**[8] in an overall yield of 10% using a strategy (see Scheme 1) where the additional alkyl chain was introduced before, and the cyclisation accomplished after, the nucleoside coupling step.‡ Whereas Grignard additions on 3′-keto nucleosides afforded *xylo*-configured isomers as major products,[9] the presence of the 1,2-*O*-isopropylidene group in ulose **1** directs the addition of Grignard reagents to proceed from the β-face of the furanose. Thus, the first step was a stereoselective Grignard addition of an allyl group at the 3-*C*-position generating, after desilylation and concomitant benzylation, the furanoside **2** with the preferred *ribo* configuration in 59% yield. An allyl group was preferred to a vinyl group as this Grignard addition was more successful in our hands. The required inversion of the configuration at the 2-carbon could most conveniently be performed, using an anhydro-approach,[10] after the nucleoside coupling step. Using standard methods, furanose **2** was deprotected and acetylated, whereafter the 2′-*O*-unprotected nucleoside **3** was obtained in 79% yield (from **2**) using the silyl Hilbert–Johnson/Birkofer method as modified by Vorbrüggen and co-workers[11] followed by deacetylation. Mesylation and treatment with aqueous base gave a 2-*O*,2′-*O*-anhydro intermediate which was directly hydrolysed affording an *arabino*-configured nucleoside. The double bond was oxidatively cleaved and 3′-*C*-hydroxyethyl nucleoside **4** was obtained in 32% yield (from **3**) after reduction. Selective tosylation of the primary hydroxy group, cyclisation using strong base and debenzylation afforded the nucleoside **5** in 68% yield (from **4**).§ The new bicyclic nucleoside **5** was incorporated into oligonucleotides as monomer **X** (see Scheme 1) after 4,4′-dimethoxytrityl(DMT)-protection of the 5′-hydroxy group and conversion to the corresponding phosphoramidite building block.

Six modified oligonucleotides were synthesised[12] and evaluated towards both complementary single-stranded DNA and RNA.¶ As seen from Table 1, incorporation of one to four modified bicyclic nucleotides **X** into a 14-mer destabilises duplexes with the DNA complement $dA_{14}$ by 2–3 °C per modification, irrespective of **X** being incorporated in a row or alternating with unmodified nucleotides. Analogously, a lowering of the melting temperature by approximately 3 °C per modification was observed for duplexes with the RNA complement $rA_{14}$ when incorporating monomer **X** once or several times alternating with unmodified nucleotides.

More encouraging results were obtained towards the RNA complement when incorporating the bicyclic nucleoside **X** in a row of four (5′-$T_5\mathbf{X}_4T_5$-3′), as a minor increase in melting temperature compared to the unmodified control was observed. Following this trend, an increase in the melting temperature of

12.5 °C was observed for the duplex between the (almost) fully modified oligonucleotide 5′-$\mathbf{X}_{13}$T-3′ and complementary RNA. These results indicate that these new 2′,3′-bicyclo oligonucleotides ('2′,3′-BcNAs') form a duplex structure with complementary RNA which is thermally significantly more stable than the corresponding unmodified DNA–RNA duplex. The structure of the duplex 2′,3′-BcNA–RNA is probably different from that of wild type DNA–RNA as indicated by the destabilising effect of one or two bicyclic nucleosides in an otherwise unmodified DNA strand. The shapes of the circular dichroism spectra, known to be diagnostic of a particular duplex structure, recorded for $T_{14}$ : $rA_{14}$ and $\mathbf{X}_{13}$T : $rA_{14}$ are, however, similar. It is thus clear that conclusions about the structural basis for the observed increase in thermal stability must await results from other sequences and from extensive molecular modelling and NMR studies.

Degradation by nucleases signifies a serious limitation to *in vivo* application of both natural and many modified oligonucleotides. We have therefore evaluated the novel 2′,3′-BcNA ($\mathbf{X}_{13}$T) against snake venom phosphodiesterase (a 3′-exonuclease) using a method described earlier.[13] Whereas the unmodified control ($T_{14}$) is fully degraded within 10 min, $\mathbf{X}_{13}$T (or $\mathbf{X}_{13}$) remains intact for the 60 min monitored. Thus, although other nucleases need to be evaluated, this result suggests that 2′,3′-BcNAs may be effectively protected against nucleolytic degradation.

In conclusion, a new bicyclic thymidine analogue **5** has been synthesised and used as a monomer to construct a novel class of conformationally restricted 2′,3′-bicyclo oligonucleotides ('2′,3′-BcNAs'). Melting experiments revealed excellent thermal stability of a 2′,3′-BcNA–RNA duplex, which, together with the observed stability towards 3′-*exo* nucleolytic degradation, suggests 2′,3′-BcNAs to be interesting candidates as antisense molecules.

**Table 1** Melting experiments of modified oligonucleotides[a]

| | Complimentary ssDNA ($dA_{14}$) | | Complimentary ssRNA ($rA_{14}$) | |
|---|---|---|---|---|
| Oligonucleotide | $T_m$/°C | $\Delta T_m$/°C | $T_m$/°C | $\Delta T_m$/°C |

‡ Full characterisation of all intermediates will be published as part of a forthcoming publication.

§ The structure of nucleoside **5** was verified from MS, $^1$H NMR, $^{13}$C NMR, $^1$H–$^1$H COSY and NOE experiments. *Selected data* for **5**: $^1$H NMR (250 MHz; [$^2H_6$]DMSO): δ 11.3 (1 H, br s, NH), 7.36 (1 H, d, *J* 1.1, 6-H), 5.80 (1 H, d, *J* 4.3, 1′-H), 5.61 (1 H, s, OH), 4.86 (1 H, m, 5′-Ha), 3.89 (1 H, d, *J* 4.2, 2′-H), 3.85 (1 H, m, 2″-H), 3.83–3.64 (3 H, m, 4′-H, 5′-Hb, 2″-H), 2.14 (1 H, m, 1″-H), 1.81 (1 H, m, 1″-H), 1.78 (3 H, d, *J* 1.0, Me); $^{13}$C NMR (62.9 MHz; $CD_3OD$): δ 166.7 (C-4), 152.2 (C-2), 139.7 (C-6), 110.1 (C-5), 89.4, 89.1, 85.5, 85.2 (C-1′, C-2′, C-3′, C-4′), 71.4 (C-2″), 61.6 (C-5′), 37.0 (C-1″), 12.7 (Me) (Found: C, 47.4; H, 5.7; N, 9.0; $C_{12}H_{16}N_2O_6\cdot H_2O$ requires C, 47.7; H, 6.0; N, 9.3%). Mutual NOE contacts between H-1′ and H-2′ and between H-1′ and H-4′, as well as the lack of contacts between H-5′ and H-1′ or H-2′ and between H-2′ and H-6, confirm the assigned β-*arabino* configuration.

¶ The oligonucleotides were synthesised on a Pharmacia Gene Assembler in 0.2 μmol scale using commercial 2-cyanoethyl phosphoramidites (2 min coupling time, *ca*. 99% stepwise yield) and the amidite derived from nucleoside **5** (2 × 12 min coupling time, *ca*. 95% stepwise yield). Purification of 5′-*O*-DMT-ON oligonucleotides was accomplished using disposable reversed-phase chromatography cartridges (Cruachem Inc.), which includes 5′-*O*-detritylation. The composition of the oligonucleotides were verified by MALDI-MS and the purity by capillary gel electrophoresis. Minor peaks (< 5%) originating from $\mathbf{X}_{10}$T, $\mathbf{X}_{11}$T and $\mathbf{X}_{12}$T were detected when running $\mathbf{X}_{13}$T.

**The new tritopic ligand L contains three 2,2′:6′,2″-terpyridine (tpy) metal-binding domains and reacts with iron(II) salts to form a species of stoichiometry $[Fe_3L_2]^{6+}$ which adopts a doubly looped (bow tie) structure.**

Ligands containing multiple oligopyridine or 1,10-phenanthroline metal-binding domains are widely used in the metal-directed assembly of topologically and structurally novel supramolecules such as multiple helices, knots, boxes, grids and catenanes.[1] The majority of systems investigated to date have rigid or short flexible spacers between the metal-binding domains in order to limit the possibilities in conformational space. Here, we discuss the effect of introducing long flexible spacers.

Our target was molecule L which contains three 2,2′:6′,2″-terpyridine (tpy) metal-binding domains separated by a $O(CH_2)_{10}O$ spacer. This was prepared in two steps from 5,5″-dinitro-2,2′:6′,2″-terpyridine **1**[2] in 38% overall yield (Scheme 1). The reaction of **1** with an excess of decane-1,10-diol in $Me_2SO$ in the presence of KOH gave **2** as a white solid in 50% yield.‡ Subsequent reaction of **1** with 2 equiv. of 4′-chloro-2,2′:6′,2″-terpyridine[3] under the same reaction conditions gave L as a white crystalline solid‡ in 75% isolated yield. The free ligand L is highly symmetrical and the $^1H$ NMR spectrum clearly shows that rings A and C are equivalent, as are rings D and F, and rings E and G.

Ligand L contains three terdentate metal-binding domains and is expected to interact with six-coordinate metal centres. Whilst polymeric structures might be expected from an uncontrolled assembly process, the coding within the metal and ligand might be sufficient to lead to $M_3L_2$ species in which the 18 donors of two ligands are satisfied by three six-coordinate centres. A number of discrete $M_3L_2$ molecular species might be expected, including non-cyclic helical, catenated or looped structures (Fig. 1). Surprisingly, the reaction of L with 3 equiv. of $FeCl_2·4H_2O$ in $MeOH–CHCl_3$ gave a single purple product which was obtained as the $PF_6^-$ salt in 77% yield after recrystallisation from $MeCN–thf–H_2O$.

The stoichiometry $[Fe_3L_2][PF_6]_6$ was confirmed by microanalysis and the FAB mass spectrum exhibited peaks at *m/z* 2972 $\{Fe_3–L_2(PF_6)_5\}$ and 2827 $\{Fe_3L_2(PF_6)_4\}$. The doubly looped structure is easily distinguished from double helical and

**Scheme 1** *Reagents*: i, KOH, $HO(CH_2)_{10}OH$, $Me_2SO$; ii, 4′-chloro-2,2′;6′,2″-terpyridine, KOH, $Me_2SO$

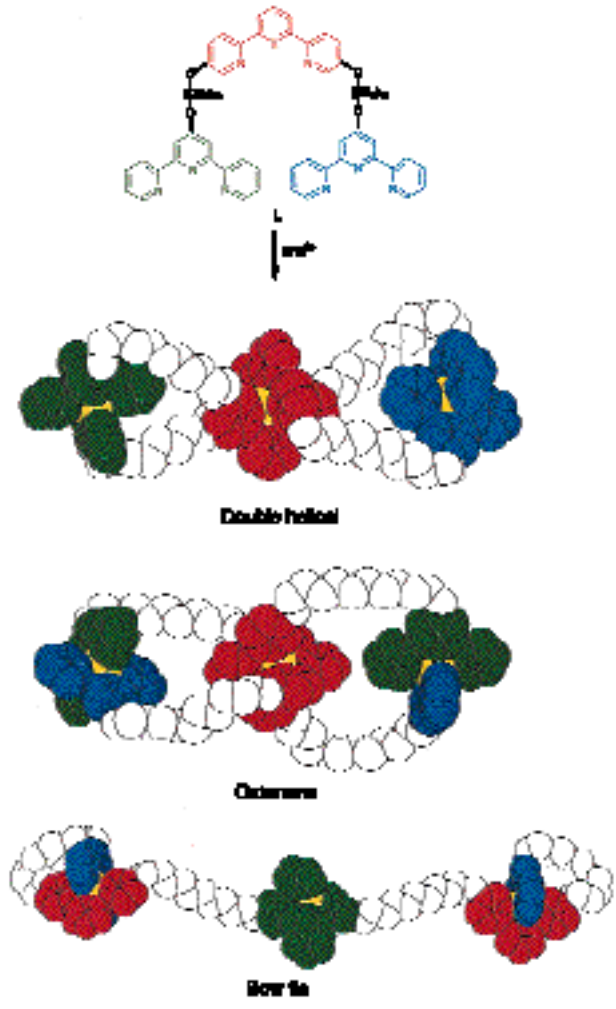

**Fig. 1** Possible consequences of the formation of 3:2 complexes with L

catenated structures on the basis of molecular symmetry. In the catenane and the double helix the two 4′-substituted tpy rings (green and blue) of each ligand are equivalent. This means that rings D and F are equivalent, as are rings E and G. Furthermore, the central (red) 5,5″-disubstituted tpy unit is symmetrical with rings A and C being equivalent. In contrast, the bow tie (double looped) structure is unique with the green and blue ligands being non-equivalent and rings A and C of the central red tpy unit also being non-equivalent. The 500 MHz $^1$H NMR spectrum of a $CD_3CN$ solution of $[Fe_3L_2][PF_6]_6$ is shown in Fig. 2 together with the assignments that follow from a COSY experiment and from comparison with model compounds. The simplest feature of note is the observation of two equal intensity signals for $H^{6A}$ and $H^{6C}$. This asymmetry of the central tpy unit is only possible in the doubly looped structure. The remaining assignments fully confirm the asymmetry that is only compatible with the looped structure.

The non-equivalence of the iron(II) centres is also seen in the differential pulse voltammogram of an acetonitrile solution of $[Fe_3L_2][PF_6]_6$ which exhibits a two-electron iron(II)/(III) process at +0.64 V (terminal metal centres) and a single electron process at +0.75 V corresponding to the central iron centre (all potentials quoted against internal ferrocene–ferrocenium couple). These potentials correspond well to the model compounds $[FeL^1{}_2][PF_6]_2$ ($L^1$ = 4′-ethoxy-2,2′:6′,2″-terpyridine, +0.60 V) and $[FeL^2{}_2][PF_6]_2$ [$L^2$ = 5,5″-bis(*n*-$C_{10}H_{21}O$)-2,2′:6′,2″-terpyridine, +0.73 V].

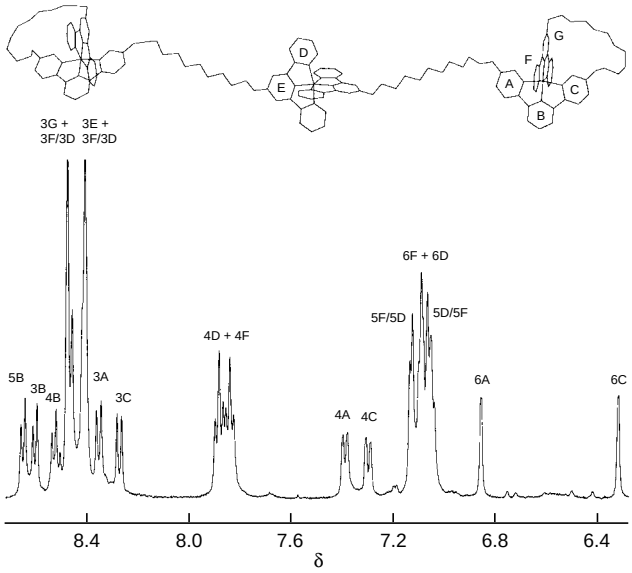

**Fig. 2** The aromatic region of the 500 MHz $^1$H NMR spectrum of a $CD_3CN$ solution of the looped complex $[Fe_3L_2][PF_6]_6$ showing the assignments

In conclusion, we have shown that the tritopic ligand L forms a doubly looped structure upon coordination to iron(II). Although singly looped structures have been described previously[4] we believe this to be the first example of such a five-component assembly of a doubly looped system. We are currently investigating the effects of varying the chain length and the metal centres.

We should like to thank the Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung (Grant numbers: 21-37325.93 and 20-043359.95), the University of Basel and Ciba-Geigy for support.

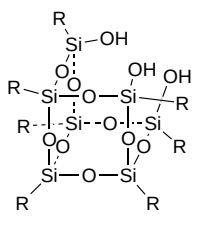
# Synthesis and structural characterization of a remarkably stable, anionic, incompletely condensed silsesquioxane framework

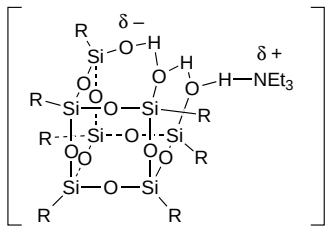
**Frank J. Feher,* Shawn H. Phillips and Joseph W. Ziller**

*Department of Chemistry, University of California, Irvine, CA 92697-2025, USA*



**The reaction of $[(C_6H_{11})_7Si_7O_9(OH)_3]$ 1 (2 equiv.) with $[(C_6H_{11})_7Si_7O_9(OTl)_3]$ 3 affords a conproportionation product that reacts with $[PPh_4]Cl$, $[PBu^n_4]Cl$ and $[NBu^n_4]Br$ to produce the corresponding salts of $[(C_6H_{11})_7Si_7O_{10}(OH)_2]^-$ 5 (*i.e.* the monoanion derived from deprotonation of 1); a single-crystal X-ray diffraction study of the $[(NBu^n_4)]^+$ salt of 5 indicates that the molecules exist as isolated ion pairs with strong intramolecular hydrogen bonding; implications of this result for the chemistry of silica are discussed.**

Silicates hold a unique place among major industrial raw materials because their constituent elements, mainly silicon and oxygen, together comprise nearly 80% of the atoms available on the earth's surface.[1] The inexhaustible supply of silicates, coupled with their impressive versatility, has led to thousands of applications and stimulated an intense interest in both the chemistry and physical properties of silicates.[2]

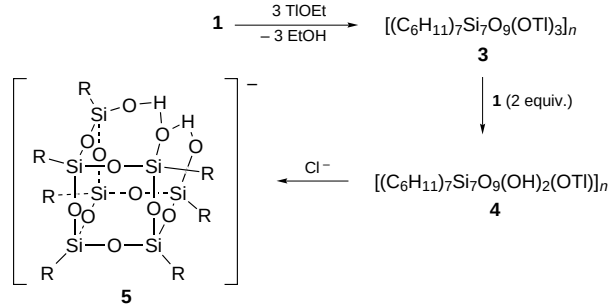


Numerous approaches have been explored for gaining molecular-level insights into the complex surface chemistry of siliceous materials, but detailed structural characterization and mechanistic studies on surface complexes are still inherently difficult. In order to assist and guide the study of silica and silica-supported catalysts, we[3] and others[4] have been exploring the chemistry of soluble siloxanes and silsesquioxanes,[5] as well as their metal-containing derivatives.[6] A large fraction of our work has focused on silsesquioxanes and metallasilsesquioxanes derived from trisilanol **1**, which can be conveniently prepared from $(C_6H_{11})SiCl_3$.[3a,7]

The chemistry of **1** is similar in many respects to the chemistry of other silanols,[6b] but there are a number of notable differences. For example, **1** is monosilylated with remarkable selectivity upon reaction with $Me_3SiCl$ in $NEt_3$–thf.[3b] Similarly, the reaction of **1** with an excess of $SbMe_5$ quickly produces a monofunctionalized product which only slowly reacts further with additional $SbMe_5$.[3e] Mechanistic studies relating to these and other observations strongly suggested that the unique reactivity of **1** was a consequence of increased acidity caused by hydrogen bonding between the three siloxy groups. In the case of silylation reactions, the intermediacy of ion pairs (*e.g.* **2**) was strongly implicated.[3b]

Here, we report the synthesis, spectroscopic characterization, and X-ray crystal structure of a remarkably stable anion that is formally derived from the deprotonation of **1**. In stark contrast to anions derived from simple alcohols and silanols, the monoanion of **1** does not react with phosphonium ions;[3d] it is also stable with respect to cyclocondensation. The implications of this result for the chemistry of silica surfaces will be discussed.

**1** R = $C_6H_{11}$



**2**

The reaction of **1** with thallium(I) ethoxide (Tl/SiOH = 1) affords an excellent yield of $[(C_6H_{11})_7Si_7O_9(OTl)_3]_n$ **3**,[8] which upon addition to a solution of **1** (2 equiv.) in $C_6D_6$ immediately produces a new complex which exhibits three methine (SiCH) resonances (3 : 3 : 1) in the room-temperature $^{13}C$ NMR spectrum; the most downfield resonance is exchange-broadened. On the basis of our previous work with Tl-substituted silsesquioxanes,[8] this data is most consistent with a $C_s$-symmetric conproportionation product (*e.g.* **4**) which undergoes facile exchange of one $Tl^I$ and two protons H between three siloxy groups on a $C_3$-symmetric $[R_7Si_7O_{12}]^{3-}$ framework.†

The addition of $[PPh_4]Cl$, $[PBu^n_4]Cl$ or $[NBu^n_4]Br$ to a solution of **4** in toluene immediately precipitates thallium halide to afford a quantitative NMR yield of a single silsesquioxane framework, which is spectroscopically indistinguishable from the product formed upon reaction of **1** with $Ph_3PCH_2$.[3d] $^1H$, $^{13}C$, $^{29}Si$ and $^{31}P$ NMR spectra of the products obtained from the reaction of **4** with $[PPh_4]Cl$ and $[PBu^n_4]Cl$ indicate the formation of a common silsesquioxane framework with free $[PPh_4]^+$ and $[PBu^n_4]^+$ as the only P-containing species in solution.‡ The NMR data provide no basis for distinguishing between a monomeric anionic silsesquioxane framework (*e.g.* **5**) and more complex oligomeric structures that are often adopted by silanols and incompletely condensed silsesquioxanes,[9] so a single-crystal X-ray diffraction study was performed to examine the nuclearity and extent of hydrogen bonding.§

Well formed crystals of the $[NBu^n_4]^+$ salt of **5** were obtained from toluene–hexane (2 : 1) at −35 °C. As illustrated in Fig. 1, the molecule crystallizes as isolated ion-pairs with strong intramolecular hydrogen bonding. The Si/O framework is remarkably symmetric and is nearly superimposable with a fully condensed $R_8Si_8O_{12}$ framework.[5,10] The O(1)···O(3) and O(2)···O(3) distances (2.576 and 2.569 Å) are shorter than O···O separations observed for most neutral, hydrogen-bonded silanols,[9] but they are well within the range observed for other hydrogen-bonded oxygen atoms.[11] Hydrogen atoms from the two siloxy groups, H(1) and H(2), were located and refined. In both cases, the atoms are involved in grossly unsymmetrical, nearly linear, hydrogen-bonding interactions with one short (0.88–0.89 Å) O–H bond and one long (1.68–1.70 Å) O···H bond. Similarly unsymmetrical hydrogen bonds are not uncommon when short O–H–O bonds do not straddle a symmetry element.[11] The structure represented by **5** nicely describes the overall hydrogen-bonding arrangement.

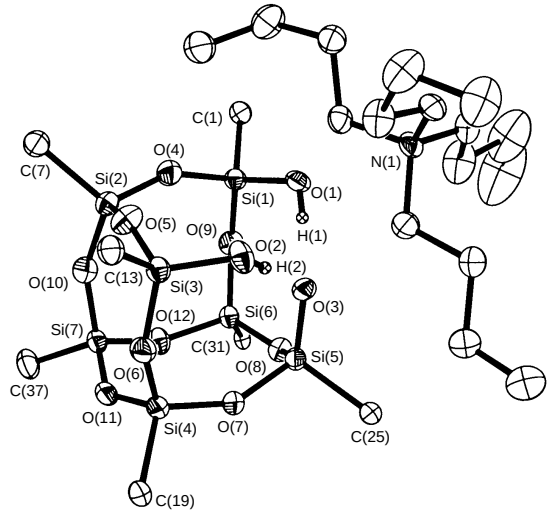


**Fig. 1** ORTEP plot of $[NBu^n_4]$ **5**. For clarity, thermal ellipsoids have been plotted at 50% probability and only C attached to Si are shown for cyclohexyl groups. Selected distances (Å) and angles (°): Si(1)–O(1) 1.618(3), Si(1)–O(4) 1.630(3), Si(3)–O(2) 1.606(4), Si(3)–O(5) 1.627(3), Si(5)–O(3) 1.588(3), Si(5)–O(7) 1.645(3), Si(1)–O(9) 1.637(3), Si(2)–O(4) 1.616(3), Si(3)–O(6) 1.624(3), Si(4)–O(7) 1.614(3), Si(5)–O(8) 1.651(3), Si(6)–O(9) 1.608(3), Si–C (av.) 1.862(5), N–C (av.) 1.521(6), Si(1)–O(1)–H(1) 113.8, Si(3)–O(2)–H(2) 114.2, O(1)–Si(1)–O(4) 110.9(2), O(1)–Si(1)O(9) 110.7(2), O(2)–Si(3)–O(5) 111.0(2), O(2)–Si(3)–O(6) 110.4(2), O(3)–Si(5)–O(7) 112.3(2), O(3)–Si(5)–O(8) 111.7(2), Si(2)–O(4)–Si(1) 152.5(2), Si(2)–O(5)–Si(3) 153.6(2), Si(4)–O(6)–Si(3) 146.7(2), Si(4)–O(7)–Si(5) 149.8(2), Si(6)–O(8)–Si(5) 138.7(2), Si(6)–O(9)–Si(1) 147.5(2), Si(7)–O(10)–Si(2) 153.4(2), Si(7)–O(11)–Si(4) 138.6(2), Si(7)–O(12)–Si(6) 149.7(2), O–Si–C (av.) 109.1(2), C–N–C (av.) 109.5(4), C–C–N (av.) 115.2(5).

The unexpected stability of **5** has a number of important implications for the chemistry of silica surfaces. Our results demonstrate that extensive hydrogen bonding can stabilize anions derived from multiply hydrogen-bonded silanols. In the case of **5**, the anion is so stable that it does not coordinate to a phosphonium ion, even in a hydrocarbon solvent. Because conjugate acids of stable anions are generally more acidic that conjugate acids of less stable anions, the acidity of silica surfaces sites possessing multiply hydrogen-bonded siloxy groups must be greater than the acidity of isolated SiOH groups. Although somewhat controversial, this conclusion is completely consistent with recent work by Drago[12] and Morrow,[13] which implicates the existence of a significant subset of hydrogen-bonded siloxy groups which is both more acidic and more reactive toward $SbMe_5$ than isolated siloxyl groups.

It is interesting to consider whether surfaces sites analogous to **5** could be detected on silica because similar arrangements should be both accessible and stable. Detailed examination of IR spectra might provide an answer, but the OH stretching frequency for the $[NBu^n_4]^+$ salt of **5** (3563 $cm^{-1}$ in thf) appears within the range assigned to vicinally hydrogen-bonded disilanols. It might, however, be possible to detect the hydrogen-bonded protons (δ *ca*. 11–12) by using solid-state NMR techniques.[14] We are currently exploring this possibility, as well as the rich reaction chemistry of **5**.

This work was supported by the National Science Foundation (USA).

† $[(C_6H_{11})_7Si_7O_9(OH)_2(OTl)]$ **4**: $(C_6H_{11})_7Si_7O_9(OH)_3$ **1**[3a] (30 mg, 0.031 mmol) and $(C_6H_{11})_7Si_7O_9(OTl)_3$ **3**[8] (24 mg, 0.015 mmol) were dissolved in $C_6D_6$ (*ca*. 0.5 ml). Examination of the NMR spectra ($^1H$ and $^{13}C$) revealed the formation of a single silsesquioxane product. Although this product cannot be isolated in pure form, it reacts with a variety of halide salts to afford stable salts of **5**.

‡ $[NBu^n_4]^+$, $[PBu^n_4]^+$, and $[PPh_4]^+$ salts of $[(C_6H_{11})_7Si_7O_{10}(OH)_2]^-$ **5**: in a typical reaction, 1 mol. equiv. of $[NBu^n_4]Br$, $[PBu^n_4]Cl$ or $[PPh_4]Cl$ was added to a solution of **4** prepared from **1** (339 mg, 0.348 mmol) and **3** (276 mg, 0.174 mmol) in toluene (10 ml); in all cases, a white precipitate formed immediately. The solution was stirred for 8 h and then filtered to remove Tl halide. The $[NBu^n_4]^+$ salt of **5** was obtained in 83% yield as large rectangular crystals from hexane–toluene (−35 °C). The $[PBu^n_4]^+$ and $[PPh_4]^+$ salts were obtained as white microcrystalline precipitates in 71 and 59% yields by crystallization (−35 °C) from toluene–hexane and toluene–acetonitrile, respectively.

§ *Crystallographic data*: for $[NBu^n_4]$**5**: $C_{58}H_{115}NO_{12}Si_7$, $M$ = 1215.14, monoclinic, space group $P2_1/c$, $a$ = 15.329(4), $b$ = 18.943(6), $c$ = 24.109(7) Å, $U$ = 6838.6(35) Å$^3$, Z = 4. Intensities were measured at 158 K with Mo-Kα radiation (λ = 0.71073 Å) and corrected for Lorentz and polarization effects. The mean intensity of three standard reflections decreased by < 1% during the experiment. The structure was solved by direct methods; final refinements were carried out with anisotropic thermal parameters for all non-H atoms: 9506 unique reflections collected; 711 parameters refined; $R_1$ = 0.0548, $wR_2$ = 0.1165 for 9502 reflections with I > 2σ($I$). Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/412.

# Solution structures and exchange phenomena of the new alkene polymerization initiators (η-$C_5Me_5$)TiMe(E)(μ-Me)B($C_6F_5$)$_3$ (E = $C_6F_5$, $OC_6F_5$) and [(η-$C_5Me_5$)Ti($OC_6F_5$)$_2$][BMe($C_6F_5$)$_3$]

**Tracey L. Tremblay, Sean W. Ewart, Mark J. Sarsfield and Michael C. Baird***

*Department of Chemistry, Queen's University, Kingston, Ontario, Canada K7L 3N6*

**The solution structures and dynamics of the new alkene polymerization initiators (η-$C_5Me_5$)TiMe($C_6F_5$)(μ-Me)B($C_5F_5$)$_3$ 2, (η-$C_5Me_5$)TiMe($OC_6F_5$)(μ-Me)B($C_6F_5$)$_3$ 3 and [(η-$C_5Me_5$)Ti($OC_6F_5$)$_2$][BMe($C_5F_5$)$_3$] 4 are compared and contrasted with those of the known initiator (η-$C_5Me_5$)-TiMe$_2$(μ-Me)B($C_6F_5$)$_3$ 1; compound 2 undergoes neither spontaneous ion-pair dissociation to the solvent separated [(η-$C_5Me_5$)TiMe($C_6F_5$)]$^+$ and [BMe($C_6F_5$)$_3$]$^-$ nor borane dissociation to its precursors (η-$C_5Me_5$)TiMe$_2$($C_6F_5$) and B($C_6F_5$)$_3$; in contrast, 3 is more labile and does undergo ion-pair dissociation, while 4 exists in solution as the separated ion species in equilibrium with its precursors, (η-$C_5Me_5$)TiMe($OC_6F_5$)$_2$ and B($C_6F_5$)$_3$.**

There is currently considerable interest in the utilization of group 4 metal complexes of the types [(Cp′)$_2$MMe]$^+$X$^-$ and [(Cp′)MMe$_2$]$^+$X$^-$ (Cp′ = substituted cyclopentadienyl; M = Ti, Zr, Hf; X$^-$ = poorly coordinating anion) as initiators for alkene polymerization.[1–3] Since most of the more active molecular alkene polymerization initiators are cationic rather than neutral,[1–3] one might anticipate that increasing the Lewis acidity of the metal atoms by incorporation of more electron-withdrawing ligands would result in even hgher activities. However, binding of X$^-$ to the cationic species [(Cp′)$_2$MMe]$^+$ and [(Cp′)MMe$_2$]$^+$ may also be enhanced by increasing the Lewis acidity,[4] resulting in inhibition of monomer coordination, while the relative rates of initiation, propagation, termination and chain transfer are affected unpredictably by ligand substitution.[1,5] The result is that electron-withdrawing ligands sometimes result in both decreased catalytic activity and reduced polymer molecular masses.[5]

Although detailed studies of ion-pairing phenomena and their effects on catalytic activities of some metallocene systems [(Cp′)$_2$MMe]$^+$X$^-$ are available,[4] relatively little is known as yet of the behaviour of monocyclopentadienyl systems [(Cp′)MMe$_2$]$^+$X$^-$. Interestingly, it has been shown that the zwitterionic compound (η-$C_5Me_5$)TiMe$_2$(μ-Me)B($C_6F_5$)$_3$ **1** (Fig. 1, E = Me), formed by treating (η-$C_5Me_5$)TiMe$_3$ with B($C_6F_5$)$_3$ [eqn. (1)],[3] undergoes facile displacement of borate anion,

(η-$C_5Me_5$)TiMe$_2$E + B($C_6F_5$)$_3$ ⇌ (η-$C_5Me_5$)TiMeE(μ-Me)B($C_6F_5$)$_3$ (1)

E = Me **1**, $C_6F_5$ **2**, $OC_6F_5$ **3**

[BMe($C_6F_5$)$_3$]$^-$, on reaction with other ligands.[3] Furthermore, magnetization transfer experiments have demonstrated a low degree of reversible borate dissociation from **1** at 223 K [eqn. (2); E = Me][3] but no exchange between terminal and bridging methyl groups was detected, *i.e.* the borane in **1** does not 'hop' from one methyl to another [reverse of eqn. (2)],

(η-$C_5Me_5$)TiMeE(μ-Me)B($C_6F_5$)$_3$ ⇌ [(η-$C_5Me_5$)TiMeE]$^+$[BMe($C_6F_5$)$_3$]$^-$ (2)

as occurs in some metallocene systems.[4a–d]

In order to better understand the effects of ligand electronic properties on catalytic activities of this class of compounds, we have extended our investigation to the methyl-bridged chiral compounds (η-$C_5Me_5$)TiMe($C_6F_5$)(μ-Me)B($C_6F_5$)$_3$ **2** and (η-$C_5Me_5$)TiMe($OC_6F_5$)(μ-Me)B($C_6F_5$)$_3$ **3**, and to the achiral, apparently ionic compound [(η-$C_5Me_5$)Ti($OC_6F_5$)$_2$][BMe($C_6F_5$)$_3$] **4**. The new zwitterionic complexes **2** and **3**, in which one of the methyl ligands of **1** has been replaced by the more electronegative ligands $C_6F_5$ and $OC_6F_5$, formed cleanly on treatment of solutions of (η-$C_5Me_5$)TiMe$_2$($C_6F_5$)† and (η-$C_5Me_5$)TiMe$_2$($OC_6F_5$)† with 1 equiv. each of the borane B($C_6F_5$)$_3$ in $CD_2Cl_2$ at 195 K [eqn. (1)]. These complexes decompose above 283 K and could not be isolated, but have been fully characterized by $^1$H, $^{13}$C and $^{19}$F NMR spectroscopic studies ($CD_2Cl_2$, 223–283 K).†

The $^1$H, $^{19}$F and $^{13}$C{$^1$H} NMR spectra† of **2** and **3** are all consistent with structures as in Fig. 1, sharp terminal Ti–Me and broadened μ-MeB resonances being especially characteristic of the zwitterionic structures proposed.[3] Interestingly, however, the $^1$H NMR spectrum of **2** at 223 K exhibits a doublet Ti–Me resonance because of long-range coupling with one of the *o*-fluorine atoms of the Ti–$C_6F_5$ ligand ($J_{HF}$ 3.1 Hz), while the $^{19}$F spectrum of **2** at 223 K exhibits five equal intensity resonances attributable to the Ti–$C_6F_5$ group, On warming, the pairs of *o*- and *m*-$^{19}$F resonances broaden and coalesce at *ca.* 293 and 273 K, respectively, although the *p*-fluorine resonance and all of the borate fluorine resonances remain well resolved in the temperature range 223–283 K. These observations require that both rotation about the Ti–$C_6F_5$ bond and inversion at the chiral metal (involving ion-pair dissociation–recombination[4a–d]) be slow on the NMR timescale at 223 K, while consideration of the coalescence temperatures suggests an approximate $\Delta G^{\ddagger}$ of 50.6 ± 2.1 kJ mol$^{-1}$ for the exchange process(es).[7] This would represent a lower limit for both processes, and is to be compared with *ca.* 58 ± 19 kJ mol$^{-1}$ for ion-pair dissociation–reorganization processes of similar zirconocene and hafnocene complexes.[4a–d]

Consistent with this interpretation and in contrast to **1**,[3] attempted magnetization transfer experiments provided no evidence in the $^1$H NMR spectrum of **2** for dissociation of the borate anion [BMe($C_6F_5$)$_3$]$^-$; thus the (μ-Me)B($C_6F_5$) moiety is relatively strongly bound to the titanium centre in **2**. In contrast, irradiation of the μ-Me resonance of **3** did result in magnetization transfer and appearance of a weak free borate resonance, indicating an equilibrium between solvent separated ion pairs and the methyl bridged species, as with **1**.[3] With neither **2** nor **3**

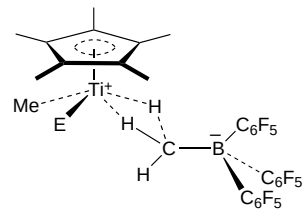

**Fig. 1** Proposed structure for **1** (E = Me), **2** (E = $C_6F_5$) and **3** (E = $OC_6F_5$)

was there evidence from spin-transfer experiments for Ti–Me/B–Me exchange, as occurs in zirconocene systems.[4a–d]

Compounds **1**,[3] **2** and **3** all behave as ethene and propene polymerization catalysts under strictly anhydrous conditions in toluene. While the polyethylene formed is generally too insoluble for even high-temperature GPC measurements, the molecular masses of the polypropylene formed at 195 K decrease in the order **2** ($M_w = 2.3 \times 10^6$, $M_w/M_n = 1.7$) > **3** ($M_w = 2.0 \times 10^6$, $M_w/M_n = 1.7$) > **1** ($M_w = 0.3 \times 10^6$, $M_w/M_n = 1.3$). The low dispersities observed are consistent with single site catalysts in all cases,[1] but the most Lewis acidic catalyst gives the highest molecular mass polymer, just the opposite to apparent trends in metallocene systems.[5] On the other hand, the yields of polymers obtained with **2** and **3** are about 30% lower than those obtained with **1**, consistent with stronger borate coordination to the more Lewis acidic catalytic sites. Thus combination of the types of Lewis acidic complexes described here with counter anions which, perhaps for steric reasons,[8] coordinate less weakly than $[BMe(C_6F_5)_3]^-$, may well lead to alkene polymerization catalysts of high activity.

The solution behaviour observed for **4** was most unexpected. The methyl abstraction reaction of (η-$C_5Me_5$)$TiMe(OC_6F_5)_2$ with 1 equiv. of $B(C_6F_5)_3$ in $CD_2Cl_2$ was monitored by $^1H$ and $^{19}F$ NMR spectroscopy in the temperature range 223–298 K, and it was found that the $^1H$ and $^{19}F$ spectra at 223 K exhibited resonances attributable only to the solvent separated species of **4**, $[(\eta\text{-}C_5Me_5)Ti(OC_6F_5)_2]^+$ and $[BMe(C_6F_5)_3]^-$; none were attributable to coordinated borate as in **1**–**3**. Remarkably, warming the NMR solution of **4** resulted in the reversible reappearance of the resonances of the neutral precursor (η-$C_5Me_5$)$TiMe(OC_6F_5)_2$, and at 263 K there was a substantial amount of both species present. Spin saturation transfer and variable-temperature experiments showed them to be in equilibrium, with $\Delta H = -1.25 \pm 0.1$ kJ mol$^{-1}$, $\Delta S = -46 \pm 4$ J K$^{-1}$ mol$^{-1}$ for conversion to the non-ionic species. The ability of **4** to engage in Ti–Me/B–Me exchange stands in contrast to **1**–**3** and even to methylzirconocene systems,[4a–d] for which variable-temperature NMR studies imply similar exchange but not the major shift in equilibrium noted here. Since $[(\eta\text{-}C_5Me_5)Ti(OC_6F_5)_2]^+$ is expected to be a relatively strong Lewis acid, its unusual disinclination to bind the borate anion must be attributed to steric hindrance by the three bulky ligands on the titanium hindering close approach of the borate anion. In **4**, moreover, it appears that the strong but sterically hindered Lewis acid $[(\eta\text{-}C_5Me_5)Ti(OC_6F_5)_2]^+$ effectively competes with $B(C_6F_5)_3$ for possession of the methyl group, presumably *via* a transient methyl bridged species although none was detected in the spin saturation experiments. An alternative structure for **4** such as $\{[(\eta\text{-}C_5H_5)Ti(OC_6F_5)(\mu\text{-}OC_6F_5)]_2\}^{2+}$ seems unlikely since (*a*) the pentafluorophenoxy groups are equivalent in the $^{19}F$ NMR spectrum and (*b*) **3** clearly does not contain such a μ-$OC_6F_5$ group.

**A polymer electrolyte film made of lithium perchlorate dissolved in a mix of high molecular mass poly(ethylene oxide) (PEO) and shorter PEO–azobenzene diblocks, shows a reversible 70% conductivity increase under UV light irradiation at room temperature.**

Only few published works have dealt with light-induced reversible ionic conductivity changes in polymer films.[1–3] In most cases the studied effect arises from a single molecular mechanism. For instance, photoactivated reversible cation complexation is obtained for some spiropyrans[1] or crowned malachite greens.[2] Indeed a 5% reversible increase from $5.3 \times 10^{-6}$ S cm$^{-1}$ at 30 °C, was observed when a polymethacrylate bearing both methoxylated benzospiropyrans and short polyether chains and dissolving zinc chloride, was irradiated by UV light.[1] Fluctuations of very low ionic conductivity, about $10^{-10}$ S cm$^{-1}$, were also described for a crowned malachite green dissolved in a PEO matrix containing a sodium salt and submitted to pulsed UV light.[2] A similar effect for conductivities lying around $10^{-8}$ S cm$^{-1}$ at 80 °C, was also obtained with polyester composite films containing crowned azobenzenes and a lithium salt.[3] In this latter case however the azobenzene based molecules exhibited liquid-crystalline behaviour and the conductivity increase was related to a transition from the nematic phase to the isotropic liquid one.[3] Indeed *cis–trans* photoisomerism of azobenzenes is well known and the birefringent nematic phase of some linear *trans*-azobenzenes can be erased by UV light when the bent *cis* form thus produced disrupts the liquid-crystal order. This effect has been used for image storage in either nematic polymer films[4] or ferroelectric smectic layers.[5] For the present work, we used the azobenzene photoisomerism in a different way allowing efficient light monitoring of ionic conductivity of polymer electrolyte films at levels as high as about $10^{-4}$ S cm$^{-1}$.

The chemical method for coupling short monomethylated PEO chains ($M_w$ = 750) with alkylated azobenzene (Scheme 1)† was adapted from literature data.[6] 1-(4-Hydroxyphenyl) 2-(4-hexylphenyl)diazene **1** (AZOH),[6] exhibited several endothermic transitions at 33, 40, 53 and 77 °C on differential scanning calorimetry (DSC) recordings, the intensity of which increased in the same order as the transition temperatures. Several liquid-crystal phases appeared up to the isotropic liquid. For AZOH–PEO **2**, the DSC trace showed a unique melting point at 25 °C near that of the starting methylated PEO (30 °C). When lithium perchlorate was added, the endothermic melting peak became very weak at 36 °C and a glass transition became clearer at −33 °C. Self-supporting polymer electrolyte films were thus prepared by dissolving AZOH–PEO **2** and lithium perchlorate in commercial PEO ($M_w = 5 \times 10^6$) at an O/Li ratio of 12. The glass transition of this polymer electrolyte was at *ca.* −33 °C and the melting point at 36 °C suggesting that both crystalline and amorphous phases were present in the material. This point is of importance since ionic conduction of polymer films is restricted to their amorphous phase.[7]

The effect of UV-light laser irradiation (363 nm) in the conductivity of the films is clearly observable in the impedance spectra showed in Fig. 1. A *ca.* 70% increase of the conductivity arose under UV light. No detectable effect was obtained in identical conditions but for an electrolyte film which did not contain compound **2**. Increasing the light intensity from 0 up to 50 mW cm$^{-2}$ enhanced the conductivity growth according to a logarithmic law. A saturation effect was then observed for light power values above 70 mW cm$^{-2}$, as expected for an absorption phenomenon. Switching off the UV-light source restored reversibly the initial conducting state within a few minutes (Figs. 1 and 2). As shown in Fig. 3, the magnitude of the light-induced conductivity increase was roughly the same throughout the explored temperature range up to 50 °C. At higher temperatures the light effect tended to disappear.

The photoactivation mechanism of the ionic conductivity in our polymer films appears to be complex. The disorder resulting from the light-induced *trans–cis* structural change of the azobenzene moieties and also possibly from erasing long-range ordering of interacting *trans* azobenzene groups, obviously increased the free volume in the material. However the linear

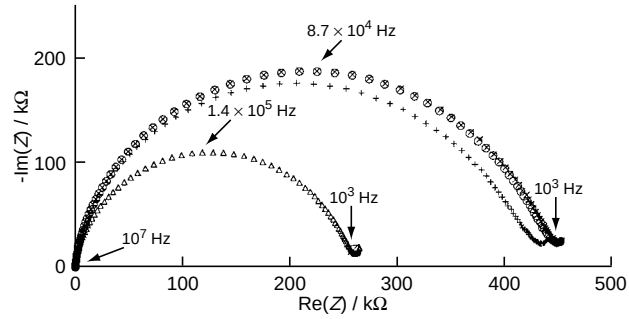

**Fig. 1** Nyquist plots of the complex impedances obtained at 20 °C for a polymer film made of PEO ($M_w$ 5 × 10$^6$) 50%, AZOH–PEO **2** 50% and $LiClO_4$ (O/Li = 12): (*a*) before UV irradiation (○), (*b*) under UV irradiation (363 nm, 75 mW cm$^{-2}$ (△), (*c*) 5 min after switching off the UV light (+), (*d*) 10 min after switching off the UV light (×). The conductivity cells were made of 410 μm thick polymer films sandwiched between two ITO-covered glass pieces.

part of the Arrhenius plots in Fig. 3 suggests an activated mechanism for the ionic conduction. Therefore an increase of the number of mobile charges in the photoactivated state, arising from a disorder induced ion-pair separation, could be put forward. Closer scrutiny of the 'semi-circles' in Fig. 1, reveals that they in fact include two dielectric relaxations with a different sensitivity to the UV irradiation. The latter could correspond either to a two-phase system or to different conduction mechanisms. One should also take into account that the *cis–trans* thermal back isomerism was probably not a time-limiting step for our system, as suggested by the symmetrical time variation of the conductivity after switching off or on the light irradiation (Fig. 2).

In conclusion, the possibility of efficient optical control of quite good conductivities for polymer electrolytes is demonstrated. Various technical applications could be envisioned, especially for systems using polymer electrolyte films. Further experiments are presently under way to investigate the mechanism of the optical transition and to obtain even larger effects.

We are indebted to Michel Armand (presently at the University of Montreal, Canada) for having favoured this work.

# A highly reactive functional model for catechol 1,2-dioxygenase: reactivity studies of iron(III) catecholate complexes of bis[(2-pyridyl)methyl][(1-methylimidazol-2-yl)methyl]amine

**Mark Duda, Matthias Pascaly and Bernt Krebs***

*Anorganisch-Chemisches Institut der Westfälischen Wilhelms-Universität, Wilhelm-Klemm-Str. 8, D-48149 Münster, Germany*

**The system consisting of an iron(III) salt and bis[(2-pyridyl)-methyl][(1-methylimidazol-2-yl)methyl]amine (bpia) in methanol reacts with various catechols with insertion of dioxygen; in the case of 3,5-di-*tert*-butylcatechol the efficient catalytic activity of the system is shown.**

Intradiol dioxygenases are non-haem iron enzymes and take part in biological mechanisms for metabolising aromatic compounds.[1] The enzymes catalyse the intradiol cleavage of catechols to *cis,cis*-muconic acids. Spectroscopic investigations indicate that the active site iron remains in the iron(III) oxidation state during the whole catalytic cycle. A variety of studies have tried to understand the mechanism in its enzymatic and model chemistry aspects and a number of functional models have been synthesised with various ligand systems.[2–4] Especially tetradentate ligands (L) have shown a great ability to influence the physical properties of the metal complexes and therefore the dioxygenase activity as the ligand sets are varied. Que and coworkers have found a correlation between the Lewis acidity of the iron centre in a series of iron(III) complexes of tripodal ligands, the product yield, and the reactivity.[2] According to these investigations a substrate activation rather than oxygen activation mechanism has been proposed. In this mechanism the substrate loses both of its protons upon coordination to the iron centre followed by partial oxidation of the catecholate due to ligand-to-metal charge transfer, resulting in a substrate with semiquinone character. The attack of $O_2$ on the activated substrate yields a transient alkylperoxy radical which combines with the equally short-lived iron(II) centre to generate an alkylperoxoiron(III) species. The peroxy adduct decomposes by a Criegee-type rearrangement to muconic anhydride. In most cases 3,5-di-*tert*-butylcatechol (dbc) has been used as a substrate in functional investigations, but little work has been devoted to the oxygenation of other catechols.[3]

We have prepared iron(III) catecholate complexes *in situ* under an argon atmosphere with bis[(2-pyridyl)methyl][(1-methylimidazol-2-yl)methyl]amine (bpia)[5] as a tetradentate ligand and a series of catechols (dbc, 4-mc, 4-bc, cat, tcc).† Their UV–VIS spectra in methanol solution are dominated by two moderately intense absorption bands. These bands are assigned as catcholate-to-$Fe^{III}$ charge-transfer transitions similar to those observed in the spectra of other iron catecholate complexes with tripodal ligands,[6] suggesting that a complex of the form [Fe(bpia)(catecholate)]$^+$ has been prepared. The positions of the lower energy band are dependent on the nature of the catecholate, with the LMCT bands observed to shift to lower energies by varying the substituents on the catecholate from electron-withdrawing to -donating (Table 1). The complexes have been isolated, and with tetrachlorocatecholate (tcc) as substrate we have obtained crystals to solve the structure of [Fe(bpia)(tcc)]$ClO_4$.[7] The crystal structure exhibits an asymmetrical chelated tetrachlorocatecholate ligand (Fig. 1). The Fe–O bond *trans* to the aliphatic N [Fe–O(1) 1.919(3) Å] is about 0.03 Å shorter than the corresponding bond *trans* to the heterocyclic N [Fe–O(2) 1.948(3) Å]. The difference in bond lengths is due to a *trans* effect where the catecholate oxygen with the shorter bond is in the *trans* position to the much weaker amine ligand.

All catecholate complexes of Table 1 react with dioxygen to yield products due to the oxidative cleavage of the catechol ring.‡ The immediate product appears to be the *cis,cis*-muconic anhydride, although only in the case of 3,5-di-*tert*-butylcatechol was this cleavage product isolated as 3,5-di-*tert*-butyl-1-oxacyclohepta-3,5-diene-2,7-dione. With 4-bc, 4-mc, and cat furanones derived from nucleophilic attack on one carbonyl of the anhydride, followed by cyclisation, were identified.

The kinetics of the reaction with dioxygen was followed by monitoring the disappearance of the lower energy charge-transfer band (Fig. 2). The reactions all exhibit pseudo-first-order kinetics under conditions where dioxygen is in excess after complex formation. The pseudo-first-order rate constants show a dependence on the nature of the substrate. The rates of the reactions increase in the order tcc $\ll$ cat < 4-bc $\approx$ 4-mc < dbc (Table 1). While [Fe(bpia)(tcc)]$^+$ is rather stable against dioxygen attack, the reaction rate of the [Fe(bpia)(dbc)]$^+$ complex with $O_2$ is rather high. This order of activity correlates with the energy of the lower energy LMCT band of the complexes: electron-donating substituents on the catechol result in a higher dioxygenase reactivity.

Accordingly the reactivity grows with increasing Lewis acidity of the iron centre within the series of [Fe(bpia)(catechol-

**Table 1** Properties of the [Fe(bpia)(catecholate)]$^+$ complexes

| Catechol | $\lambda_{max}$/nm | $k^a$/dm$^3$ mol$^{-1}$ s$^{-1}$ |
|---|---|---|
| dbc | 558, 865 | 4.3 |
| 4-mc | 515, 842 | 2.6 |
| 4-bc | 519, 836 | 2.3 |
| cat | 510, 800 | 0.083 |
| tcc | 528, 729 | $> 10^{-5}$ |

[a] Reactions run in methanol under air, 25 °C, $c = 5 \times 10^{-4}$ mol dm$^{-3}$, 2 equiv. of piperidine as base, $k = k_{obs}/[O_2]$.

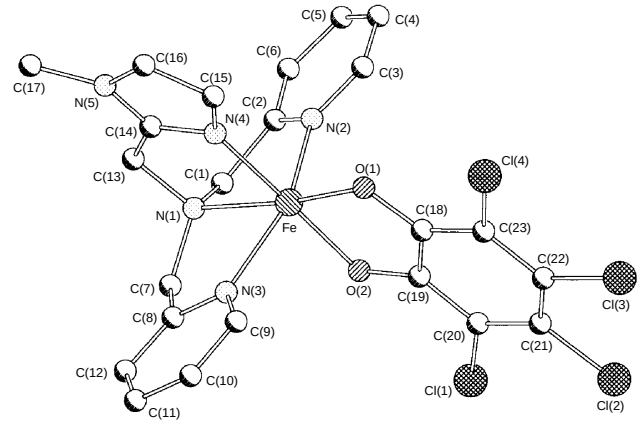

**Fig. 1** Structure of [Fe(bpia(tcc)]$^+$

ate)]$^+$ complexes. Our observation supports the substrate activation mechanism proposed by Que.[2]

The system consisting of $Fe(ClO_4)_3 \cdot 9H_2O$ and bpia in acetonitrile catalyses the oxidation of dbc to *cis,cis*-muconic anhydride rapidly and efficiently. In the presence of 10% of the catalyst 90% of the desired cleavage product is obtained. We have isolated 3,5-di-*tert*-butyl-*o*-benzoquinone (dbq) as a by-product in small amounts. By reducing the amount of the iron catalyst the yield of dbq increases, but even with 1% $[Fe(bpia)(MeCN)_2]^{3+}$ nearly 80% of the catechol reacts with dioxygen in 12 h to 3,5-di-*tert*-butyl-1-oxacyclohepta-3,5-diene-2,7-dione. With turnover numbers up to 80 this iron(III) complex is the most effective catalyst for the oxidative cleavage of catechols reported yet.

Progress of the reaction can be followed by $^1$H NMR spectroscopy (Fig. 3). The signals of the free substrate (δ 6.82, 1.36, 1.24) disappear along with the appearance of signals of the muconic anhydride (δ 6.57, 6.16, 1.25, 1.14) and of the by-product, 3,5-di-*tert*-butyl-*o*-benzoquinone (δ 7.01, 6.14, 1.23, 1.19). The width of the signals is due to the formation of the paramagnetic $[Fe(bpia)(dbc)]^+$ complex in solution during the reaction. At the end of the reaction the signals become sharp indicating a μ-oxo-bridged dinuclear iron(III) complex with antiferromagnetic coupling in solution.

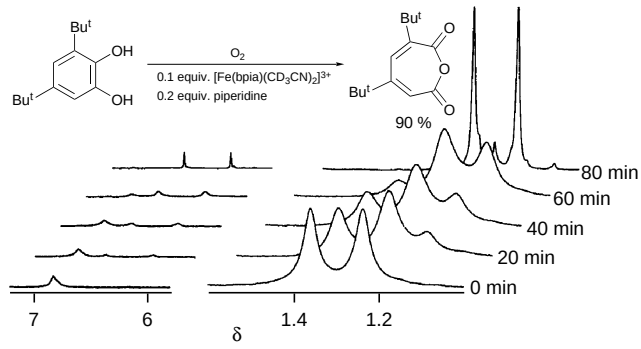

**Fig. 3** Catalytic oxidation of 3,5-di-*tert*-butylcatechol monitored by $^1$H NMR spectroscopy

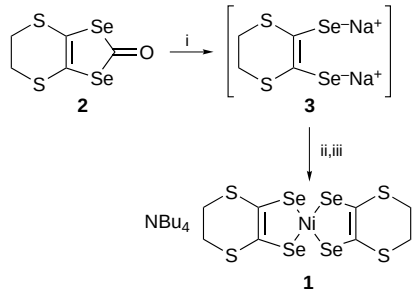
# Synthesis, structure and physical properties of the new selenium containing metal complex $NBu_4[Ni(ddds)_2]$ (ddds = 5,6-dihydro-1,4-dithiin-2,3-diselenolate)

**Hideki Fujiwara,* Emiko Arai and Hayao Kobayashi***

*Institute for Molecular Science, Myodaiji, Okazaki 444, Japan*



**The synthesis, structure and physical properties of the new selenium containing metal complex $NBu_4[Ni(ddds)_2]$ (ddds = 5,6-dihydro-1,4-dithiin-2,3-diselenolate) are described.**

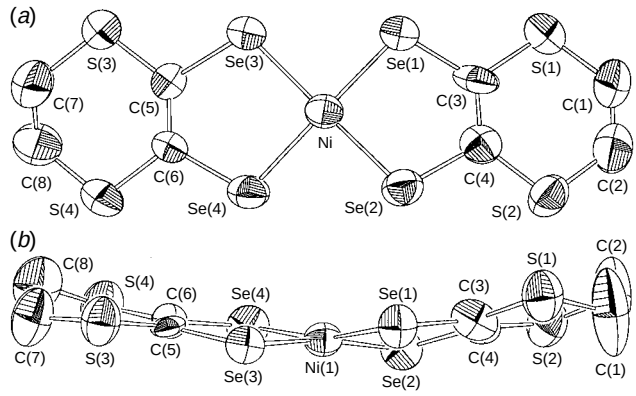
In the past two decades development of new organic conductors has undergone rapid progress. Among them, conductors based on bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF) have played a key and major role in the search for new organic superconductors.[1] On the other hand bis(dithiolene) metal complexes are also of great interest because they show a variety of crystal structures and conducting properties upon variation of central metal atoms and counter ions. However conducting salts of bis(dithiolene) metal complexes show a tendency to form one-dimensional structures and become insulating at low temperatures although some superconductors have been discovered from $[M(dmit)_2]$ complexes (dmit = 4,5-disulfanyl-1,3-dithiole-2-thione).[2] Recently, it has been reported that the radical cation salts of $[M(dddt)_2]$ complexes (M = Ni, Pd; dddt = 5,6-dihydro-1,4-dithiin-2,3-dithiolate) produce various highly conducting salts metallic down to low temperatures.[3] $[M(dddt)_2]$ complexes were first synthesized about ten years ago[4] and have structures remarkably similar to that of the BEDT-TTF molecule. In this context, development of selenium analogues of $[M(dddt)_2]$ has attracted our interest because the selenium substitution of inner sulfur atoms is expected to increase the transverse interaction and to stabilize the metallic state at low temperature. This strong stabilization of the metallic state has been shown in BETS [bis(ethylenedithio)tetraselenafulvalene], the selenium analogue of BEDT-TTF, from which new organic superconductors have been recently discovered.[5] Here, we report on the synthesis, structure and physical properties of the new selenium containing metal complex $NBu_4[Ni(ddds)_2]$ **1**.

$NBu_4[Ni(ddds)_2]$ was synthesized as shown in Scheme 1. Ketone **2**[6] was hydrolysed with 20% sodium ethoxide in dry thf at 0 °C to generate the corresponding diselenolate **3**, which was treated successively with an ethanol solution of nickel dichloride hexahydrate and tetrabutylammonium bromide to crystallize the tetrabutylammonium nickel complex. The resultant precipitate was collected and washed with methanol and recrystallized from acetone–isopropyl alcohol to afford dark green and air-stable platelike crystals in 84% yield.†

The crystal structure‡ of the present complex is different from each of reported structures of $NBu_4[Ni(dddt)_2]$.[4c,d] In the unit cell there is one crystallographically independent tetrabutylammonium cation and a $[Ni(ddds)_2]$ anion. The molecular structure of the $[Ni(ddds)_2]$ anion is shown in Fig. 1. The nickel is coordinated by the four selenium atoms of the ligands in a slightly distorted square planar geometry with a dihedral angle of 15.7° between two five-membered rings. Each of the two chelating ligands is almost planar except for the ethylene bridge. The mean Ni–Se distance in the present anion [2.267(3) Å] is longer than that of the corresponding $[Ni(dddt)_2]$ anion [2.132(9) Å][4c] and the difference between these values (*ca*. 0.14 Å) is almost equal to that between the atomic covalent radii of sulfur and selenium. The intramolecular Se···Se lengths [Se(1)···Se(2) 3.268(3), Se(3)···Se(4) 3.267(3) Å] are longer than that of inner sulfur atoms of $[Ni(dddt)_2]^-$ [3.068(3) Å][4a] and are closer to the S···S lengths [S(1)···S(2) 3.451(8), S(3)···S(4) 3.461(7) Å]. This result suggests that the expanse of electron clouds of chalcogen atoms is nearly uniform in the transverse direction over the whole anion, in contrast to the case of $[Ni(dddt)_2]^-$, and therefore more effective two-dimensional intermolecular interaction is expected in its conducting solids. Fig. 2 shows the *bc*-projection for $NBu_4[Ni(ddds)_2]$ from which it is seen that there is no stacking or columnar structure of the anions and each anion is surrounded by counter tetrabutylammonium cations.

Electrochemical properties were investigated by cyclic voltammetry. $NBu_4[Ni(ddds)_2]$ shows two pairs of reversible

**Scheme 1** *Reagents and conditions*: i, 20% NaOEt (4 equiv.), thf, 0 °C, 2 h; ii, $NiCl_2 \cdot 6H_2O$ (0.5 equiv.) in EtOH, 0 °C, 2 h; iii, $NBu_4Br$ (0.5 equiv.) in EtOH, 0 °C, 1 h



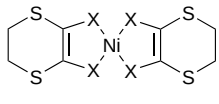


**Fig. 1** Structure of the anion moiety of $NBu_4[Ni(ddds)_2]$: (*a*) projection to the molecular plane and (*b*) side view

X=Se; $[Ni(ddds)_2]^-$ **1**

redox waves, which correspond to the two redox processes leading the dianion to the neutral state, and one irreversible redox wave. The redox potentials of **1** and its related nickel dithiolene complexes are listed in Table 1. The first and second redox potentials are at −0.60 and +0.16 V, respectively, and are about 0.1 V higher than those of the sulfur derivative $NBu_4[Ni(dddt)_2]$ (−0.71 and +0.03 V) under identical conditions, suggesting that selenium lowers the electron-donating ability of **1**. On the other hand **1** shows an oxidation wave corresponding to the neutral to cationic state, although it is irreversible, suggesting the possibility of formation of radical cation salts of $[Ni(ddds)_2]$ similar to the case found for $[Ni(dddt)_2]$.

The room-temperature magnetic susceptibility of **1** was measured using a SQUID magnetometer at 1 T. Complex **1** is paramagnetic with $\mu_{eff}$ = 1.77 $\mu_B$ corresponding to one unpaired electron per molecular formula (calculated $\mu_{eff}$ = 1.73 $\mu_B$ for a one unpaired electron system) as a consequence of the crystal structure in which each anion is efficiently separated from others by bulky tetrabutylammonium cations, so preventing interaction.

Synthesis of $[M(ddds)_2]^-$ complexes with other central metal atoms and preparation of their neutral species and conducting salts are now in progress.

# Large tunnels in the hydrothermally synthesized open-framework iron phosphate $[H_3N(CH_2)_3NH_3]_2[Fe_4(OH)_3(HPO_4)_2(PO_4)_3]\cdot xH_2O$

**Kwang-Hwa Lii* and Yuh-Feng Huang**

*Institute of Chemistry, Academia Sinica, Taipei, Taiwan*

**The synthesis and characterization of a microporous iron phosphate is described; the structure consists of infinite chains of iron–oxygen octahedra linked by phosphate groups to generate large tunnels containing 20-ring windows in which water molecules and the charge-compensating organic cations reside.**

A large number of molybdenum and vanadium phosphates with open-framework structures have been synthesized under mild hydrothermal conditions using organic amines as structure-directing agents.[1,2] These microporous materials are of interest because of their rich structural chemistry and potential applications as molecular sieves, ion-exchange materials and catalysts. Since we had synthesized a large number of ternary iron phosphates and arsenates with a variety of complex crystal structures by a high-temperature, high-pressure hydrothermal method,[3] the possibility of preparing three-dimensional frameworks containing large voids filled with cationic organic templates seemed reasonable. Recently, an organically templated iron phosphate $[H_3NCH_2CH_2NH_3]_{0.5}[Fe(OH)PO_4]$ was reported.[4,5] It is isotypic with the layered gallophosphate $[H_3NCH_2CH_2NH_3]_{0.5}[Ga(OH)PO_4]$ obtained in ethylene glycol.[6] We have also synthesized a 1,4-diazabicyclo[2.2.2]octane encapsulating iron phosphate, $[HN(CH_2CH_2)_3NH][Fe_8(HPO_4)_{12}(PO_4)_2(H_2O)_6]$.[7] It adopts a pillared layer structure and its framework is closely related to that of an imidazole encapsulating indium phosphate.[8] To our knowledge, these are the only two examples of organically templated iron phosphates in the literature. Here we describe the synthesis and structural characterization of a 1,3-diaminopropane encapsulating iron phosphate, $[H_3N(CH_2)_3NH_3]_2[Fe_4(OH)_3(HPO_4)_2(PO_4)_3]\cdot xH_2O$ **1**. Its framework structure is unique and contains two-dimensional arrays of large tunnels in which water molecules and the charge-compensating organic cations are located.

Hydrothermal treatment of $FeCl_3\cdot 6H_2O$ (1.5 mmol), $H_3PO_4$ (7.5 mmol), $H_2N(CH_2)_3NH_2$ (7.5 mmol), and water (10 ml) for 3 days at 180 °C yielded a yellow crystalline product. A yellow crystal was used to determine its structure by single-crystal X-ray diffraction.† The material is single phase as judged by comparison of the powder X-ray diffraction of the bulk product to the pattern simulated from the coordinates derived from the single-crystal study. Thermal gravimetric analysis showed mass loss in multiple steps over the temperature range 25–800 °C of 36.73%. Based on powder X-ray diffraction, the final decomposition product at 800 °C is a mixture of $FePO_4$ and $Fe_4(P_2O_7)_3$.[9] The observed total mass loss reflects the presence of lattice water molecules and agrees well with that calculated for the loss of 2 $H_2N(CH_2)_3NH_2$, 9 $H_2O$ of crystallization and 4.5 $H_2O$ from the decomposition of framework (36.7%), as indicated by eqn. (1).

$$[H_3N(CH_2)_3NH_3]_2[Fe_4(OH)_3(HPO_4)_2(PO_4)_3]\cdot 9H_2O \rightarrow 2\ FePO_4 + 0.5\ Fe_4(P_2O_7)_3 + 13.5\ H_2O \quad (1)$$

Samples of **1** appeared to lose water over time if stored in a desiccator. Only four lattice water oxygen sites could be located from the single-crystal X-ray diffraction study. The room-temperature Mössbauer spectrum is a doublet and does not show different Fe components as indicated from the crystal structure. The spectral parameters are δ (isomer shift) = 0.393 mm $s^{-1}$ (relative to iron foil at 300 K), $\Delta E_Q$ (quadrupole splitting) = 0.604 mm $s^{-1}$, and Γ (full width at half-height) = 0.36, 0.35 mm $s^{-1}$. The isomer shift is consistent with those for iron(III) phosphates.[10]

The structure of **1** consists of a three-dimensional covalently bonded framework built up from $FeO_6$ octahedra and phosphate tetrahedra. The fundamental building unit is an octahedral tetramer, which is shown in Fig. 1. The unit involves an edge-sharing $Fe(2)_2O_{10}$ dimer which further links at the shared corners to two $Fe(1)O_6$ octahedra forming a $Fe_4O_{20}$ tetramer. A topologically identical cluster exists in the iron phosphate mineral leucophosphite, $K_2[Fe_4(OH)_2(H_2O)_2(PO_4)_4]\cdot 2H_2O$.[11] The tetramer in **1** possesses $\bar{1}$ symmetry located at the midpoint of the shared edge. $Fe(2)O_6$ is more distorted than $Fe(1)O_6$ because of edge-sharing. The $\mu_3$- and μ-oxo atoms, O(11) and O(12), which coordinate to Fe atoms only, are the hydroxo oxygens. The H atoms are not involved in hydrogen bonding. Each tetramer is joined by corner-sharing, *via* –O(12)–Fe(1)–O(12)– bonds, to two other tetramers forming orthogonal, but non-intersecting infinite chains parallel to the <100> directions. One may regard the infinite chain as a column. In a unit cell, there are four layers of columns with *z* values equal to 0, 1/4, 1/2 and 3/4, respectively. Each column lies in an *a*-glide plane and columns in adjacent layers are $4_1$-screw axis related. The columns are interlinked by phosphate tetrahedra generating large tunnels running parallel to <100>, in which the diprotonated 1,3-diaminopropane and water molecules reside (Fig. 2). The amine molecules are well ordered, which can be attributed to the formation of extensive hydrogen bonds. Within tunnels are 20-ring windows formed by the edges of ten iron-oxygen octahedra and ten phosphate tetrahedra in an alternating manner. The P(1)–O(4)H groups project into the tunnels at a nearest O(4)···O(4) distance of 7.35 Å. The long side of the ring has a free dimension (minimum O···O distance less one O diameter of 2.6 Å) of 10.4 Å. The framework also contains open

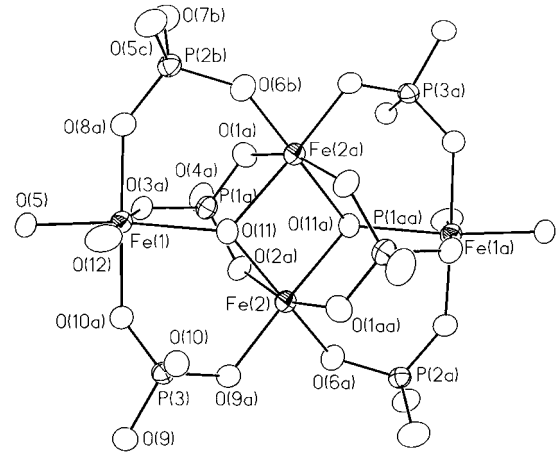

**Fig. 1** The tetranuclear iron cluster in compound **1**: thermal ellipsoids are shown at 60% probability

windows delimited by four infinite chains, through which they connect orthogonal, non-intersecting tunnels. The presence of large open windows is also reflected in the very low framework metal atom density. For **1**, there are 10.5 M atoms (M = Fe, P) per 1000 Å$^3$ compared with the value of 12.7 atoms per 1000 Å$^3$ for the very open faujasite (M = Si),[12] 12.1 atoms per 1000 Å$^3$ (M = Fe, P) for the phosphate mineral cacoxenite which contains enormous channels,[13] and 9.3 atoms per 1000 Å$^3$ for $[HN(CH_2CH_2)_3NH]K_{1.35}[V_5O_9(PO_4)_2]\cdot xH_2O$ (M = V, P) which is among the lowest framework density materials known.[2]

In summary, the synthesis and structure of an iron phosphate, $[H_3N(CH_2)_3NH_3]_2[Fe_4(OH)_3(HPO_4)_2(PO_4)_3]\cdot xH_2O$ is reported. The incorporation of $H_3N(CH_2)_3NH_3$ cations extends the iron phosphate framework into a large pore size range. The structures are very sensitive not only to the nature of the templates incorporated but also to reaction conditions. When 1,4-diazabicyclo[2.2.2]octane is used instead of diaminopropane, a different compound with a composition of $[HN(CH_2CH_2)_3NH]_3[Fe_8(HPO_4)_{12}(PO_4)_2(H_2O)_6]$ with a pillared layer structure is formed.[7] Other hydrothermally prepared iron phosphates with microporous structures have been prepared and will be reported elsewhere.

† *Crystal data* for $[H_3N(CH_2)_3NH_3]_2[Fe_4(OH)_3(HPO_4)_2(PO_4)_3]\cdot xH_2O$: tetragonal, space group $I4_1/a$; $a$ = 15.4017(3), $c$ = 28.9421(4) Å, $U$ = 6840.1(8) Å$^3$, $Z$ = 8, $M_r$ = 903.58, $D_c$ = 1.755 g cm$^{-3}$, μ(Mo-Kα) = 19.8 cm$^{-1}$, λ = 0.710 73 Å, graphite monochromator, crystal dimensions: 0.18 × 0.12 × 0.12 mm. The crystal was mounted on a Siemens Smart-CCD diffractometer equipped with a normal focus, 3 kW sealed tube X-ray source. Intensity data were collected in 1200 frames with increasing ω (width of 0.30° per frame). Of the 4115 unique reflections collected ($2\theta_{max}$ = 57.5°), 2939 reflections were considered observed [$I > 3.0\sigma(I)$] after Lorentz polarization and semiempirical absorption corrections using the SHELXTL-PC program package ($T_{min,max}$ = 0.725, 0.761).[14] The structure was solved by direct methods: the Fe and P atoms were first located and the C, N, and O atoms were found in the final difference Fourier map. The H atoms were not located. Bond-valence calculations[15] indicated that both Fe atoms were trivalent, O(4), O(7), O(11) and O(12) had valence sums of 1.26, 1.15, 1.02 and 1.11, respectively, and all other oxygen atoms had values between 1.71 and 1.92. O(4), O(11) and O(12) are hydroxo oxygens. The valence sum of O(7) is satisfied by forming hydrogen bonds [O(7)···N(1) = 3.06, O(7)···O(4) 2.58 Å]. Four lattice water sites were located in the structural tunnels. Each site is partially occupied. Refinement (212 variables) was performed by full-matrix least-squares analysis, with isotropic thermal parameters for water oxygens and anisotropic thermal parameters for all other atoms. $(\Delta\rho)_{max,min}$ = 1.17, −0.80 e Å$^{-3}$. The reliability factors converged to $R(F)$ = 0.052, $R_w(F)$ = 0.058 and GOF = 1.78. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/424.

# Photoreduction of carbon dioxide with hydrogen over $ZrO_2$

**Yoshiumi Kohno,* Tsunehiro Tanaka, Takuzo Funabiki and Satohiro Yoshida**

*Department of Molecular Engineering, Graduate School of Engineering, Kyoto University, Sakyo-ku, Kyoto 606-01, Japan*

**Among many transition-metal oxides, zirconium oxide is found to be active for photocatalytic reduction of carbon dioxide to carbon monoxide with hydrogen in the gas phase.**

From the viewpoint of environmental problems, catalytic reduction of carbon dioxide to more valuable compounds has been investigated extensively.[1–3] However, this reaction often requires severe conditions of high pressure and/or high temperature. In contrast, by photoirradiation, photocatalytic reduction of carbon dioxide with hydrogen may occur even under mild conditions.

As a photocatalyst for such types of reactions, noble metal/titanium oxide systems are the most well known and have been extensively investigated so far.[4–6] Zirconium oxide has rarely been reported to be active; however, Sayama *et al*. recently reported that zirconium oxide showed excellent photocatalytic activity for the decomposition of liquid water and photoreduction of aqueous carbonate.[7,8] They also reported that metal loading inactivated zirconium oxide, in contrast to the case of titanium oxide. In the present study, we report that zirconium oxide without metal loading is active for photocatalytic reduction of gaseous carbon dioxide with hydrogen under mild conditions of low pressure and room temperature. The wide band-gap of $ZrO_2$ (5.0 eV) permits the photoreduction of carbon dioxide with hydrogen.

Zirconium oxide used in this study was prepared from an aqueous solution of zirconium oxychloride by precipitation with 25 mass% $NH_3$(aq). The precipitate obtained was washed with distilled water followed by filtration until the filtrate was negative towards $AgNO_3$. The sample was dried at 373 K overnight, grounded to powder, and calcined at 773 K for 5 h in a dry air stream. The XRD pattern indicated that the resulting powder was zirconium oxide in a mixture of monoclinic and tetragonal phases. Other metal oxides were commercially available ones and they were calcined at 773 K for 5 h prior to use. Before reactions, the oxides were heated at 673 K for 30 min in the air and evacuated for 30 min at the same temperature, followed by treatment with 8 kPa $O_2$ for 75 min and evacuation for 30 min at 673 K.

The photocatalytic reaction was carried out in a closed static system connected to a vacuum line. A 500 W ultrahigh-pressure mercury lamp (Ushio Denki USH-500) was used as the light source. A metal oxide sample (0.3 g) was spread on the flat bottom of a quartz reactor and subjected to illumination from the bottom. A mixture of $CO_2$ (150 μmol) and $H_2$ (50 μmol) was admitted to the reactor, and the total pressure in the reactor was *ca*. 25 kPa. After the irradiation, the gases were analysed by an on-line TCD gas chromatograph (Shimadzu GC-8A) using argon as a carrier gas, which can detect $H_2$, $CH_4$ and CO. Temperature programmed desorption (TPD) experiments were carried out for zirconium oxide, and the desorbed gases were detected by a quadrupole-type mass spectrometer (ULVAC Massmate-100). To avoid the interference of nitrogen at the signal $m/z$ = 28, $^{13}C$ labelled CO or $CO_2$ was used.

Activity for photoreduction of $CO_2$ was investigated using $TiO_2$, $ZrO_2$, $V_2O_5$, $Nb_2O_5$, $Ta_2O_5$, $WO_3$ and ZnO. Among these, only $ZrO_2$ was found to be active, and other metal oxides showed no activity for this reaction at all. With $ZrO_2$, 1.0 μmol of CO was detected after 6 h photoirradiation, and no other reduced product was detected by an FID gas chromatograph (which can detect gaseous hydrocarbons and oxygenates) and a mass spectrometer, as well as the on-line TCD gas chromatograph. $ZrO_2$ is stable under photoirradiation and no appreciable difference was found in Zr $L_{III}$ edge XANES spectra of $ZrO_2$ before and after photoreaction. When the reaction was carried out in the dark, no CO was detected, although $CO_2$ is known to be adsorbed on the surface of $ZrO_2$. This indicates that photoirradiation is essential for this reaction. When the short wavelength region of the irradiated light was cut off by a series of filters which permits light with wavelength $\lambda > 370$, 330, 310 and 290 nm, the amount of evolved CO after 6 h photoirradiation changed from 1.0 μmol to 0, 0, 0.1 and 0.4 μmol, respectively. From these results, it can be concluded that the light with wavelength < 300 nm was required to enable this reaction to proceed.

Without introduction of $CO_2$ no trace of CO was detected after UV irradiation. When $^{13}CO_2$ was used instead of $^{12}CO_2$, only $^{13}CO$ was detected. These results show that CO was produced from the $CO_2$ admitted to the system.

Fig. 1 shows the time dependence of the amount of CO formed and $H_2$ consumed. The rate of CO formation mildly decreased from 8 to *ca*. 40 h irradiation. On the other hand, the consumption rate of $H_2$ was very fast at the beginning, and then slowed. The amount of consumed $H_2$ was larger than the amount of evolved CO at all times. This suggests that $H_2$ may be adsorbed onto the catalyst surface in a dissociated form[9] or incorporated into other compounds containing carbon atom(s). We then tried to decompose any adsorbed species by heating the catalyst sample after photoirradiation. More CO evolution was observed, while the amount of desorbed $H_2$ was small. After 6 h of photoirradiation, 1.0 μmol of CO was detected (as mentioned above), and when the catalyst sample was heated at 673 K for 20 min after 2 min evacuation, 3.3 μmol of CO was evolved. When the photoirradiation time was extended to 40.5 h, 3.2 μmol of CO was formed, and by heating the catalyst, 5.8 μmol of CO was evolved. This observation shows that

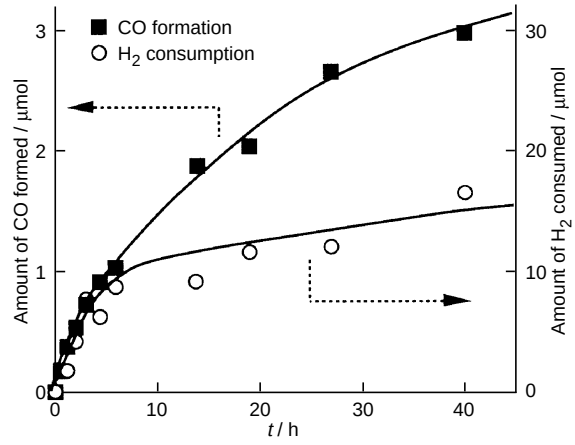

**Fig. 1** Time dependence of CO formation and $H_2$ consumption over $ZrO_2$ under irradiation; initial amounts of $CO_2$ and $H_2$ were 150 μmol and 50 μmol, respectively

photoirradiation of the catalyst surface produces some material decomposed into CO by heat. The most intriguing question at this stage is whether this CO source is photoadsorbed CO or arising from surface intermediates.

To elucidate this, TPD experiments were carried out. Samples of CO adsorbed $ZrO_2$ under photoirradiation and $ZrO_2$ used as the photocatalyst for $CO_2$ reduction were investigated. The CO TPD profiles are shown in Fig. 2. A single peak was observed for both samples in the range from 500–700 K, but the temperatures of the maxima are different. Photoadsorbed CO was desorbed at *ca*. 630 K, while the CO desorption maximum from the surface of the catalyst after photoreaction was observed at *ca*. 610 K. This result firmly suggests that the surface species differ for the two samples. In other words, surface intermediates may exist on the catalyst surface under irradiation, and the reaction is expected to proceed *via* intermediates to yield CO. Future studies will clarify the reaction mechanism through detection and identification of these intermediates.

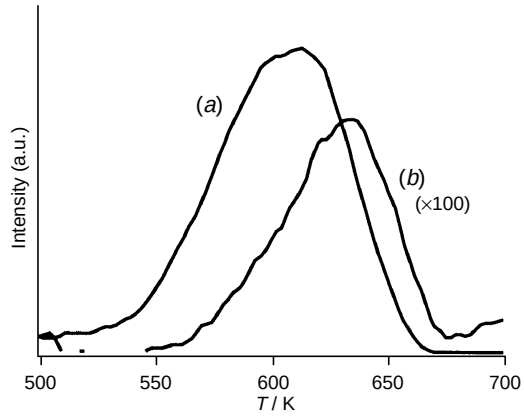

**Fig. 2** TPD profiles for (*a*) CO desorbed from the catalyst surface after photoreaction and (*b*) CO simply photoadsorbed on $ZrO_2$; the intensity of profile (*b*) is multiplied by 100

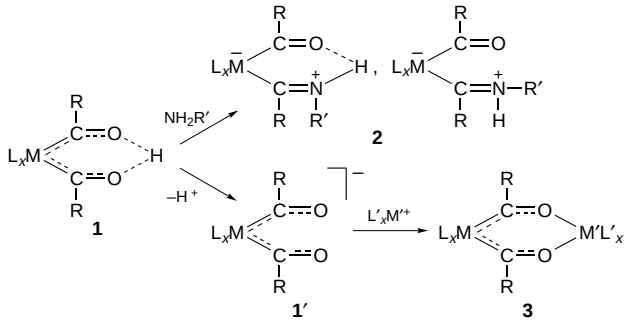
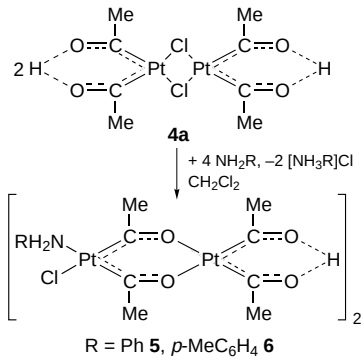
# Synthesis and structures of platina-β-diketonato complexes of platina-β-diketones; organometallic analogues of platinum blue complexes



**Dirk Steinborn,* Michael Gerisch, Frank W. Heinemann and Clemens Bruhn**

*Institut für Anorganische Chemie, Martin-Luther-Universität Halle-Wittenberg, Kurt-Mothes-Str. 2, D-06120 Halle, Germany*



**The platina-β-diketone $[Pt_2(\mu\text{-}Cl)_2\{(COMe)_2H\}_2]$ 4a reacts with aniline or *p*-toluidine to give the first platina-β-diketonato complexes of platina-β-diketones $[\{(NH_2R)ClPt(\mu\text{-}COMe)_2Pt[(COMe)_2H]\}_2]$ (R = Ph 5, *p*-$MeC_6H_4$ 6), whose X-ray crystal structures reveal the formation of head-to-head dimers with zigzag $Pt_4$ chains analogous to platinum blue complexes.**

Metalla-β-diketones **1** are organometallic analogues of the enol tautomers of 1,3-diketones where the methine group is replaced formally by the $L_xM$ moiety.[1] It is known that complexes **1** react with primary amines $NH_2R'$ to give the corresponding metalla-β-ketoimines **2**.[1,2] The deprotonated complexes **1′** are capable of forming metal complexes of metalla-β-diketonates **3** with two bridging acyl ligands,[1,3] Scheme 1. Previously we described the synthesis of $[Pt_2(\mu\text{-}Cl)_2\{(COR)_2H\}_2]$ (R = Me **4a**, Et **4b**) being the first platina-β-diketones and, indeed, the first dinuclear metalla-β-diketones.[4] Here, we report the reactions of **4a** with aromatic amines to give, unexpectedly, platina-β-diketonato complexes of platina-β-diketones which were revealed to be of the platinum blue structural type.

The platina-β-diketone **4a** reacts with aniline and *p*-toluidine in a molar ratio 1 : 2.1 in dichloromethane as solvent to give the dimeric bis(acyl)-bridged platinum complexes **5** and **6** in high yield (73 and 68%, respectively), Scheme 2.† Intermediates in these reactions might include the monomeric complexes $[PtCl\{(COMe)_2H\}(NH_2R)]$ (R = Ph, *p*-$MeC_6H_4$), of which half is deprotonated with substitution of the chloro ligand to give **5** and **6**, respectively. An indication of this is the formation of $[NMe_4][Cl_2Pt(\mu\text{-}COMe)_2Pt\{(COMe)_2H\}]$[5] in the reaction of **4a** with $[NMe_4]OH$.

**Scheme 1**

**Scheme 2**

Compounds **5** and **6** crystallize from dichloromethane as well shaped, yellow and red, air-sensitive crystals of $[\{(NH_2R)ClPt(\mu\text{-}COMe)_2Pt[(COMe)_2H]\}_2]\cdot x CH_2Cl_2$ (R = Ph, *p*-$MeC_6H_4$; $x$ = 2), respectively, which lose 1 mol of $CH_2Cl_2$ upon drying *in vacuo* ($x$ = 1).‡ They melt with decomposition at 90–91 °C (**5**·$CH_2Cl_2$) and 92–93 °C (**6**·$CH_2Cl_2$). Solutions of **5** and **6** are quite unstable at room temperature. Complex **6** is monomeric in chloroform solution (found: 692.1 g $mol^{-1}$; calc. for $[\{NH_2(p\text{-}MeC_6H_4)\}ClPt(\mu\text{-}COMe)_2Pt\{(COMe)_2H\}]$ 706.0 g $mol^{-1}$). The C–O stretching vibrations for the bridging acyl ligands appear at lower wavenumbers (1514s, 1535vs $cm^{-1}$) than those in **4a** (1548 $cm^{-1}$) which is in agreement with the series: acyl {*e.g.* ν(C–O) 1639 $cm^{-1}$ in *trans*-[PtCl(COMe)$(PPh_3)_2$][6]} > β-diketone (**4a**) > μ-COMe (**5**, **6**). As expected, all four methyl groups of the organo ligands in **6** are chemically inequivalent in the $^1H$ NMR spectrum. In **5** two methyl groups are isochronous by chance.

The identities of **5** and **6** were confirmed by X-ray structure determinations.§ The molecular structures are shown in Figs. 1 and 2, with selected bond lengths and angles. They reveal the presence of head-to-head dimers in the solid state with a crystallographically imposed inversion centre ($C_i$). Both structures are very similar apart from the orientations of the amine ligands {torsion angle C(5)–N–Pt(1)–Pt(2) 105.9° [18.0°]}.¶

The coordination of Pt(1) [Cl, N, C(1), C(2)] and Pt(2) [C(3), C(4), O(1), O(2)] is square planar. These coordination planes are inclined at an angle of 95.7(6) [103.6(4)°]. Thus, the six-membered rings [Pt(1), C(1), O(1), Pt(2), C(2), O(2)] exhibit boat conformations with Pt(1)···Pt(2) distances of 3.284(1) [3.160(1) Å]. There are no significant differences between the four Pt–C {$d$(Pt–C) = 1.89(3)–1.98(2) [1.93(2)–2.00(2) Å]}

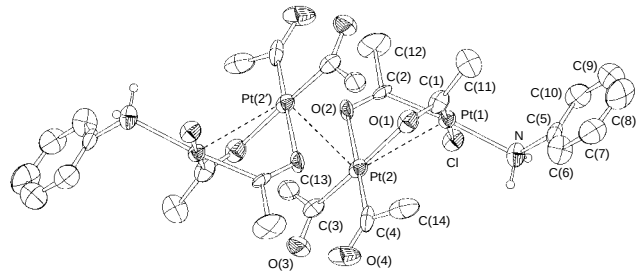


**Fig. 1** Molecular structure in the solid state with atomic labelling scheme for **5**; thermal ellipsoids are drawn at the 30% probability level, H-atoms are omitted for clarity. Selected distances (Å) and angles (°): Pt(1)–Pt(2) 3.284(1), Pt(2)–Pt(2′) 3.186(2), Pt(1)–C(1) 1.95(2), Pt(1)–C(2) 1.98(2), Pt(1)–Cl 2.409(6), Pt(1)–N 2.18(2), Pt(2)–O(1) 2.15(2), Pt(2)–O(2) 2.18(2), Pt(2)–C(3) 1.89(3), Pt(2)–C(4) 1.97(3), C(1)–O(1) 1.25(3), C(2)–O(2) 1.21(3), C(3)–O(3) 1.24(3), C(4)–O(4) 1.22(4), O(3)–O(4) 2.28(4); Cl–Pt(1)–N 84.0(5), Cl–Pt(1)–C(2) 93.6(7), N–Pt(1)–C(1) 98.5(9), C(1)–Pt(1)–C(2) 84(1), O(1)–Pt(2)–O(2) 85.0(7), C(3)–Pt(2)–C(4) 89(1), O(1)–Pt(2)–C(4) 94(1), O(2)–Pt(2)–C(3) 92(1), Pt(1)–Pt(2)–Pt(2′) 119.80(5).

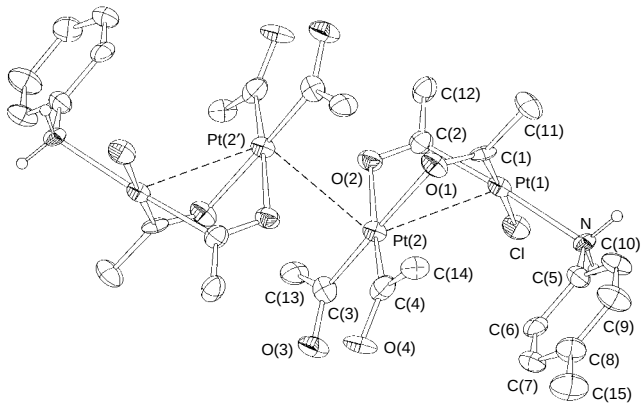

**Fig. 2** Molecular structure in the solid state with atomic labelling scheme for **6** with details as in Fig. 1. Selected distances (Å) and angles (°): Pt(1)–Pt(2) 3.160(1), Pt(2)–Pt(2′) 3.152(2), Pt(1)–C(1) 1.95(2), Pt(1)–C(2) 2.00(2), Pt(1)–Cl 2.390(4), Pt(1)–N 2.23(1), Pt(2)–O(1) 2.15(1), Pt(2)–O(2) 2.18(1), Pt(2)–C(3) 1.93(2), Pt(2)–C(4) 1.95(2), C(1)–O(1) 1.24(2), C(2)–O(2) 1.24(2), C(3)–O(3) 1.30(2), C(4)–O(4) 1.29(2), O(3)–O(4) 2.37(2); Cl–Pt(1)–N 86.0(3), Cl–Pt(1)–C(2) 91.9(5), N–Pt(1)–C(1) 95.8(6), C(1)–Pt(1)–C(2) 86.2(7), O(1)–Pt(2)–O(2) 84.6(4), C(3)–Pt(2)–C(4) 93.8(8), O(1)–Pt(2)–C(4) 89.5(7), O(2)–Pt(2)–C(3) 92.2(6), Pt(1)–Pt(2)–Pt(2′) 127.52(3)°.

and C–O bonds {*d*(C–O) = 1.21(3)–1.25(3) [1.24(2)–1.30(2) Å]} nor significant differences to those in **4a** [*d*(Pt–C) = 1.95(1) Å, *d*(C–O) = 1.23(1), 1.26(1) Å]. The O–H–O bridge in the remaining platina-β-diketone unit {*d*[O(3)···O(4)] = 2.28(4) [2.38(2) Å]} is comparable to that in **4a** [*d*(O···O) = 2.37(1) Å].

The most noticable structure feature of **5** and **6** is the zigzag chain of the $Pt_4$ unit with an angle between the Pt(1)–Pt(2) and Pt(2)–Pt(2′) vectors of 119.80(5) [127.52(3)°]. As expected for a $Pt^{II}$–$Pt^{II}$ ($d^8$–$d^8$) interaction,[7] the distance Pt(2)–Pt(2′) {3.186(2) [3.152(2) Å]} is rather long but comparable with those in $Pt^{II}$ complexes with columnar structures (3.09–3.60 Å)[8] and with those of amidate-bridged tetranuclear platinum complexes (platinum blue complexes[9]) with platinum in the +2.0 average oxidation state (3.13–3.24 Å).[10]

Besides **5** and **6**, the platinum blue complexes are the only ones with chain-like $Pt_4$ units. But there are important differences in the structures: in **5** and **6**, the Pt–Pt distances in the ligand bridging units {*d*[Pt(1)–Pt(2)] = 3.284(1) [3.160(1) Å]} are longer than those between the dinuclear units {*d*[Pt(2)–Pt(2′)] = 3.186(2) [3.152(2) Å]}. In the platinum blue complexes, the amidate-bridged Pt–Pt distances are the shortest ones (2.88–3.03 Å). Furthermore, the tilt angles between the platinum coordination planes in the ligand bridging units are between 30 and 40° in platinum blue complexes but 95.7(6)° in **5** and 103.6(4)° in **6**. Correspondingly, the Pt–Pt–Pt zigzag angles are greater by *ca*. 35–40° in platinum blue complexes than in **5** and **6**. Summarizing, the platina-β-diketonate complexes of platina-β-diketones **5** and **6** can be regarded as organometallic analogues of platinum blue complexes.

We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support and the companies Merck (Darmstadt) and Degussa (Hanau) for loans of chemicals.

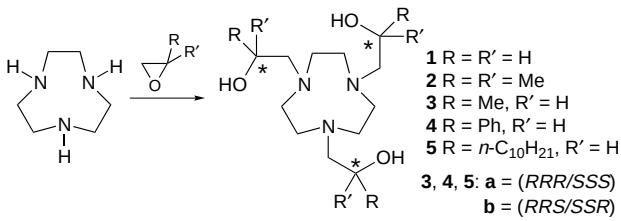
# Discrimination between magnesium(II) and calcium(II) by 1,4,7-tris(2-hydroxyalkyl)-1,4,7-triazacyclononane ligands



**Jurriaan Huskens[a] and A. Dean Sherry*[a,b]**

[a] *University of Texas at Dallas, Department of Chemistry, PO Box 830688, Richardson, Texas 75083-0688, USA*
[b] *University of Texas Southwestern Medical Center, Department of Radiology, the Rogers Magnetic Resonance Center, 5801 Forest Park Road, Dallas, Texas 75235-9085, USA*

**The title ligands and their possible diastereomeric forms show large selectivity differences for complexation of $Mg^{II}$ and $Ca^{II}$ which are related to the twist angle of the plane of coordinating hydroxy groups relative to the plane of macrocyclic ring nitrogens.**

Although calcium(II) and magnesium(II) both play vital roles in many biological processes, it is quite problematic to differentiate 'ionic' or weakly bound *vs*. tightly bound $Mg^{II}$ in a biological sample due to interference from ubiquitous $Ca^{II}$. Very few ligands have been reported that show a high enough selectivity for $Mg^{II}$ over $Ca^{II}$ to overcome this problem. This is especially evident in the development of ion-specific electrode methods for $Mg^{II}$ where the current technology requires a substantial correction for both $Ca^{II}$ and pH.[1] We recently described several 1,4,7-triazacyclononane derivatives containing methylene phosphinate ester, methylene phosphinate, or mixed acetate side-arms that showed a selectivity for $Mg^{II}$ over $Ca^{II}$ of, in some cases, more than two orders of magnitude.[2,3] Although the small cyclononane ring usually guarantees a higher Mg/Ca selectivity ($K_{sel} = K_{MgL}/K_{CaL}$) over most other ligand systems,[4] there are significant selectivity differences between known 1,4,7-triazacyclononane derivatives with different side-arm coordinating groups. For example, nota [1,4,7-triazacyclononane-1,4,7-tris(acetic acid)] has a $K_{sel}$ of 5.9[5] while notmp [1,4,7-triazacyclononane-1,4,7-tris(methylene methylphosphinate)] has a $K_{sel}$ of 170.[3] While investigating these selectivity differences in more detail, we discovered that the Mg/Ca binding selectivity of several trisubstituted 2-hydroxyalkyl derivatives of 1,4,7-triazacyclononane varied by three orders of magnitude and learned that stereochemistry of neighbouring side-chain groups defined the metal-ion selectivity. Although the ligands reported here did not bind significant amounts of $Mg^{II}$ or $Ca^{II}$ in aqueous solution, the dramatic selectivity of these systems for binding of $Mg^{II}$ in acetonitrile may serve as guide to developing better ion-specific membrane electrode systems.

All ligands were prepared by the reaction of 1,4,7-triazacyclononane with an excess of the corresponding epoxide (Scheme 1), as described before for **1**.[6] If R ≠ R′, two diastereomers of each derivative were formed when racemic epoxide was used. The ratio between the (*RRR*/*SSS*) (**a**) and the (*RRS*/*SSR*) (**b**) forms of **3**, **4** and **5** was in all cases 1 : 3, as statistically expected. Optically pure **3a** and **4a** were prepared from the corresponding chiral (*S*)-epoxides.

**Scheme 1**

The magnesium(II) and calcium(II) complexes of these ligands were studied by $^{13}C$ NMR spectroscopy (125 MHz) at room temp. using $CD_3CN$ as the solvent. The metal-to-ligand ratios were varied from 0–1.5 by the addition of magnesium(II) or calcium(II) perchlorate. In all cases, a 1 : 1 complex, in slow exchange with the free ligand, was formed completely upon addition of a stoichiometric amount of metal perchlorate. For **1** and **2**, single resonances were observed for all ring carbons and for all equivalent nuclei from the side-chains, while for **3a** and **4a** the ring carbons showed two resonances upon metal complexation. In the diastereomeric mixtures of **3**, **4** and **5**, eight equally intense ring carbon resonances could be detected for both MgL and CaL: two arise from the symmetrical (*RRR*/*SSS*)-isomer, while six belong to the unsymmetrical (*RRS*/*SSR*)-isomer. Analogously, the resonances of the side-chain nuclei appear as four equally intense lines.† Identification of the diastereomers of **3** and **4** was accomplished by comparison with the spectra of optically pure **3a** and **4a**, while for **5** the spectra were compared to the data obtained for **3**.

The Mg/Ca selectivities of the ligands were determined by $^{13}C$ NMR on samples with both $Mg^{II}$ and $Ca^{II}$ in excess. For a sample containing **3a** : **3b** : Mg : Ca = 1 : 3 : 6 : 6, the $^{13}C$ NMR spectrum (Fig. 1) showed that both $Mg^{II}$ and $Ca^{II}$ formed complexes with **3b** ($K_{sel}$ = 0.25), while **3a** only bound $Mg^{II}$. Selectivity experiments with pure **3a** indicated that $K_{sel}$ = 590 for this ligand. This led to the conclusion that the orientation of a single methyl group in these ligands results in a Mg/Ca selectivity difference of more than three orders of magnitude. Only **3a**, **4a** and **5a** exhibit good to excellent Mg/Ca selectivities (Table 1), while **1**, **2**, **3b**, **4b** and **5b** barely discriminate between $Mg^{II}$ and $Ca^{II}$.

To further investigate these large selectivity differences, we used molecular-mechanics calculations‡ to find the optimal

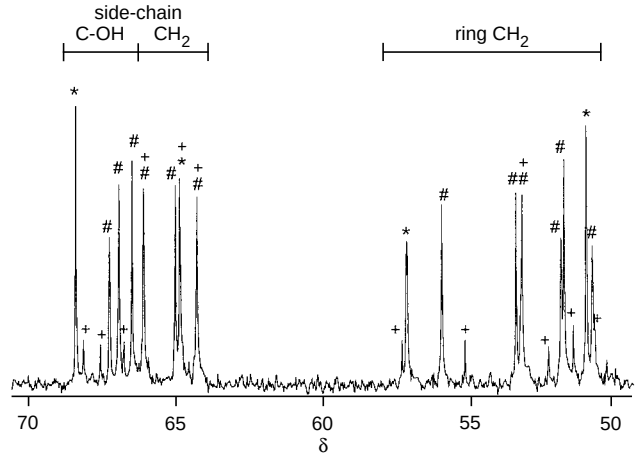


**Fig. 1** $^{13}C$ NMR spectrum of a sample with **3a** : **3b** : Mg : Ca = 1 : 3 : 6 : 6; * Mg(**3a**); + Mg(**3b**); # Ca(**3b**) (methyl resonances not shown)

structures of the magnesium(II) and calcium(II) complexes of **1**, **2**, **3a** and **3b**. Local energy minima were observed for structures in which the side-chains adopted one of three possible coordination modes (Fig. 2). The methyl groups in all optimized structures of **3a** and **3b** were pointing out from the centre, causing all side-chains to be in the same orientation for **3a**, while for **3b** two different side-chain orientations were present in each optimized structure. Table 1 shows the coordination mode of the lowest energy state of all magnesium(II) and calcium(II) complexes of **1**, **2** and **3**. Only for **3a**, the magnesium(II) complex had a different structure (AAA) than the calcium(II) complex (BBB).

The coordination modes AAA, BBB and CCC give rise to different 'twist angles', α, *i.e.* the rotation of the plane of coordinating oxygen atoms compared to the plane of ring nitrogens (Fig. 2). Since the carbon atoms of the macrocyclic ring are positioned alternately above and below the plane of ring nitrogens, these compounds contain an inherent twist of the plane of the side-chain carbon atoms directly connected to the ring nitrogens. Here, we define a positive α as a twist of the plane of coordinating oxygens in the same direction as the plane of side-chain carbons relative to the ring nitrogens. The twist α was large and positive for the AAA configuration, smaller (but positive) for BBB, and negative for CCC.§ Molecular mechanics showed that, for the magnesium(II) complexes, the large α (AAA) is only favoured when there is a driving force on the side-chains to put a residual R-group away from the centre and if any resulting steric hindrance between two side-chains is absent. As a result, Mg(**1**) adopted the BBB conformation because there is no driving force, while Mg(**2**) and Mg(**3b**) did not adopt AAA or AAB due to resulting steric hindrance between methyl groups of neighbouring side-chains. Only for Mg(**3a**) [and for Mg(**4a**) and Mg(**5a**)] were all factors optimal for adopting the AAA conformation. The large twist (AAA) makes the cavity for the metal ion quite small, so that this conformation is not optimal for the larger $Ca^{II}$ ion, which always preferred the BBB (or ABB) structure.

In conclusion, we have found that triazacyclononane derivatives that are able to accommodate $Mg^{II}$ in a small, tight cavity (large α) form complexes with structures (AAA), different from those of $Ca^{II}$ (BBB). This appears to be the origin of the large Mg/Ca selectivity seen for these ligands. Similar conformational changes that depend on the size of the metal ion have been observed in crystal structures of a few transition-metal complexes, *e.g.* the zinc(II) complex of **3a** adopted the BBB conformation,[7] while the smaller cations $Co^{III}$ and $Cr^{III}$ preferred the AAA structure.[8] For nota, the nickel(II) and nickel(III) and chromium(III) complexes adopted the BBB conformation, while the larger $Cu^{II}$ and $Fe^{III}$ preferred CCC.[9] The present study is the first, however, to relate this phenomenon to a (large) difference in metal ion selectivity. A more elaborate study involving acetate, phosphonate ester, and phosphinate side-chains will be published elsewhere.

This research was supported in part by grants from the Robert A. Welch Foundation (AT-584) and the NIH Biotechnology Research Program (P41-RR02584).

**Table 1** Selectivities, $K_{sel}$ (= $K_{MgL}/K_{CaL}$),[a] of the macrocyclic ligands (Scheme 1) as obtained from $^{13}C$ NMR competition experiments, and the preferred side-chain coordination modes (Fig. 2) as obtained from MMX calculations

| | | Mode | |
|---|---|---|---|
| Ligand L | $K_{sel}$ | MgL | CaL |
| **1** | 0.18 | BBB | BBB |
| **2** | 3.0 | BBB[b] | BBB |
| **3a** | 590 | AAA | BBB |
| **3b** | 0.25 | ABB | ABB |
| **4a** | 16 | | |
| **4b** | 0.06 | | |
| **5a** | 60[c] | | |
| **5b** | 0.28 | | |

[a] ±5%. [b] CCC has only slightly higher energy. [c] Lower limit; observed only for a mixture of **5a** and **b**.

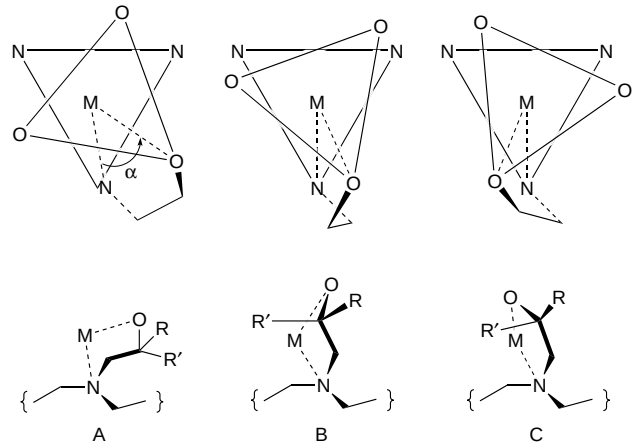

**Fig. 2** Schematic front and top views of the possible coordination modes of the side-chains of the metal complexes of **1**, **2** and **3** for which energy minima were observed by molecular-mechanics calculations, and the resulting twist angles, α, of the plane of coordinating oxygens relative to the plane of macrocyclic ring nitrogens

## Footnotes

* E-mail: sherry@utdallas.edu

† In **5**, only the first two carbon nuclei of R (= $n$-$C_{10}H_{21}$) were thus resolved.

‡ The geometries of the magnesium(II) and calcium(II) complexes of **1**, **2** and **3** were optimized using the built-in MMX forcefield of Hyperchem 4.5 on a 486DX, 66 MHz PC. Side-chains were positioned roughly into modes A, B or C (Fig. 2) before optimization, and the position of the OH protons in **1**, **2** and **3**, and of the methyl groups in **3** was varied systematically for observation of the local minima.

§ Trigonal prism: α = 0; octahedron: α = 60°. Twist angles observed for the magnesium(II) complexes were approximately +40, +10 and −30° for AAA, BBB, and CCC, respectively, while for the calcium(II) complexes these were +25, +5 and −20°.

# Synthesis, derivatization, and structural characterization of $[Mn(CNC_6H_3Me_2\text{-}2,6)_5]^-$, a five-coordinate isonitrilate complex containing $Mn^{-I}$

**Tracy L. Utz, Patricia A. Leach, Steven J. Geib and N. John Cooper***

*Department of Chemistry and Materials Research Center, University of Pittsburgh, Pittsburgh, Pennsylvania 15260, USA*

**Naphthalenide reduction of $[Mn(CNC_6H_3Me_2\text{-}2,6)_5Cl]$ forms solutions of trigonal-bipyramidal $[Mn(CNC_6H_3Me_2\text{-}2,6)_5]^-$, as established by an X-ray diffraction study of a $[K(18\text{-}C\text{-}6)(dme)]^+$ salt and derivatization with $SnClPh_3$ to give $[Mn(CNC_6H_3Me_2\text{-}2,6)_5(SnPh_3)]$.**

Our recent syntheses of the first isonitrilates (homoleptic isonitrile complexes of metals in negative oxidation states) generated complexes of $Co^{-I}$ $\{[Co(CNC_6H_3Me_2\text{-}2,6)_4]^-\}$[1] and of $Ru^{-II}$ $\{[Ru(CNC_6H_3Me_2\text{-}2,6)_4]^{2-}$ and $[Ru(CNBu^t)_4]^{2-}\}$.[2] The existence of these complexes established that isonitrilates could be prepared with several different metals, with metals in oxidation states as low as −II, and with both alkyl and aryl substituents on the ligands. It remained unclear, however, whether isonitrilates could be prepared in geometries other than tetrahedral; the cobalt(−I) and ruthenium(−II) complexes are all four coordinate, and a tetrahedral geometry has been established crystallographically[1] for $[Co(CNC_6H_3Me_2\text{-}2,6)_4]^-$ and is consistent with IR data in the ruthenium(−II) case,[2] as would be anticipated on the basis of the $d^{10}$ configurations of the metals and by analogy with the isoelectronic carbonylmetalates $[Co(CO)_4]^-$[3] and $[Fe(CO)_4]^{2-}$.[4] Structurally characterized homoleptic carbonylmetalates are known in five[5,6] and six coordinate[7,8] geometries, but the established propensity of isonitrile ligands to couple in higher coordinate environments[9] left open whether isonitrilates would be accessible in similar geometries despite the close analogies between isonitriles and CO.[10] We have now examined the synthesis of five coordinate manganese(−I) isonitrilates, and we wish to report the synthesis of the trigonal-bipyramidal isonitrilate $[Mn(CNC_6H_3Me_2\text{-}2,6)_5]^-$ **1**$^-$ and its structural characterization as a $[K(18\text{-crown-}6)(dme)]^+$ salt (dme = dimethoxyethane), together with evidence that **1**$^-$ can react as a metal centred nucleophile with simple electrophiles (Scheme 1).

**Scheme 1** *Reagents and conditions*: i, $CNC_6H_3Me_2$-2,6; ii, 2 K(Naph); iii, 18-C-6, dme; iv, $SnClPh_3$

We recently reported that cobalt(−I) isonitrilates can be prepared by naphthalenide reduction of any of a range of cobalt(0), cobalt(I) and cobalt(II) precursors which contain an adequate number of isonitrile ligands,[1] and this led us to approach the synthesis of $[Mn(CNC_6H_3Me_2\text{-}2,6)_5]^-$ by reduction of $[Mn(CNC_6H_3Me\text{-}2,6)_5Cl]$ **2**.[11] Dropwise addition of 2 equiv. of a 0.4 M potassium naphthalenide [K(Naph)] solution[12] to an orange thf solution of **2** at −78 °C gave a blood-red solution. The sharp $\nu_{CN}$ bands of **2** at 2062s and 2008(sh) $cm^{-1}$ were replaced by two broad $\nu_{CN}$ absorptions at 1920s and 1710m $cm^{-1}$ indicating complete consumption of **2** and formation of a more reduced isonitrile complex. These solutions are extremely air sensitive, changing from blood red to cherry red in seconds, and are also thermally unstable, undergoing a similar colour change in a few days at room temperature.

Initial attempts to isolate the reduction product were unsuccessful, but it was readily established that this solution is an effective source of $[Mn(CNC_6H_3Me_2\text{-}2,6)_5]^-$ by addition of $SnClPh_3$ (1 equiv. in thf) at −78 °C. The solution became clear and yellow in colour, and IR spectra indicated complete consumption of the anion and formation of a new species with higher energy $\nu_{CN}$ bands at 2135m, 2064(sh) and 1998s $cm^{-1}$. The solvent was removed under reduced pressure and the product was purified by slow diffusive mixing of a pentane layer into a concentrated toluene solution to give crystals of $[Mn(CNC_6H_3Me_2\text{-}2,6)_5(SnPh_3)]$ **3**† in 88% yield.

Isolation of a crystalline salt of $[Mn(CNC_6H_3Me_2\text{-}2,6)_5]^-$ from the reduction of $[Mn(CNC_6H_3Me_2\text{-}2,6)_5Cl]$ required that samples be maintained at or below −30 °C, and began with filtration of a freshly prepared solution through a bed of Celite 545 into a flask containing 1 equiv. of neat 18-crown-6 (18-C-6). After 1 h the solvent was removed under reduced pressure and the mixture was washed with pentane to give a red–brown solid from which red–black crystals of [K(18-C-6]**1**† could be obtained in 53% yield by crystallization from a saturated dme solution following addition of a layer of pentane. This material does not entirely redissolve in dme; this behaviour is reminiscent of that of alkali-metal salts of $[M(CO)_5]^{2-}$ (M = Cr, Mo, W) in the solid state at room temperature.[6]

Crystals suitable for X-ray diffraction studies were grown from a freshly prepared sample of [K(18-C-6)]**1** by dissolving it in a minimal volume of dme and cooling the unfiltered solution to −30 °C overnight. A low-temperature diffraction study‡ established that these crystals contain [K(18-C-6)(dme)]**1**, a dme solvate of [K(18-C-6)]**1**, but this material is not stable in the solid state at room temperature and crystals do not diffract well if stored for more than few days.

In this salt of **1**$^-$ the bis-chelate dme and the 18-C-6 ligand are both coordinated to the $K^+$ counter ion, effectively blocking $K^+$– Mn$^-$ contact ion pairing in the solid state, and allowing the $[Mn(CNC_6H_3Me_2\text{-}2,6)_5]^-$ anion (Fig. 1) to adopt a geometry close to the trigonal bipyramid anticipated by analogy with the established structures of five coordinate carbonylmetalates[5,6] and of the isoelectronic $d^8$ homoleptic isonitrile complex $[Fe(CNBu^t)_5]$.[13] The C(1) and C(5) isonitriles are in the axial positions, but there are some irregularities in the coordination

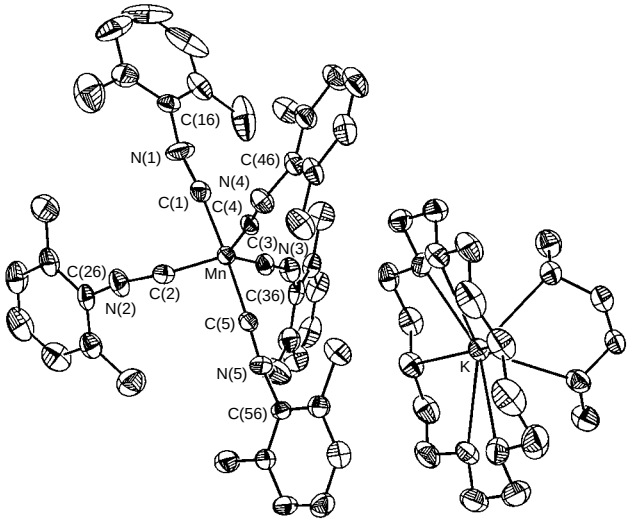

**Fig. 1** Molecular structure of [K(18-C-6)(dme)][Mn($CNC_6H_3Me_2$-2,6)$_5$] ([K(18-C-6)(dme)]**1**; 35% probability ellipsoids; hydrogen atoms omitted for clarity). Selected bond lengths (Å) and angles (°): Mn–C(1) 1.847(6), Mn–C(2) 1.724(6), Mn–C(3) 1.837(6), Mn–C(4) 1.806(6), Mn–C(5) 1.869(6), C(1)–N(1) 1.195(7), C(2)–N(2) 1.185(7), C(3)–N(3) 1.225(7), C(4)–N(4) 1.219(7), C(5)–N(5) 1.184(6) Å; C(1)–Mn–C(5) 174.4(3), C(2)–Mn–C(4) 123.7(3), C(2)–Mn–C(3) 111.9(3), C(3)–Mn–C(4) 124.3(2), C(1)–Mn–C(2) 82.9(3), C(1)–Mn–C(3) 98.1(3), C(1)–Mn–C(4) 85.3(2), C(2)–Mn–C(5) 94.2(2), C(3)–Mn–C(5) 87.4(2), C(4)–Mn–C(5) 92.4(2), C(1)–N(1)–C(16) 163.2(7), C(2)–N(2)–C(26) 143.3(6), C(3)–N(3)–C(36) 149.2(6), C(4)–N(4)–C(46) 149.2(5), C(5)–N(5)–C(56) 163.4(6)°.

sphere. The C(2) isonitrile in particular has Mn–C and C≡N bonds which are 0.097 Å ($>15\sigma$) and 0.04 Å ($>5\sigma$) shorter, respectively, than the average C≡N bonds in the other two equatorial isonitriles; we ascribe this shortening to distortions induced by van der Waals interactions between neighbouring [Mn($CNC_6H_3Me_2$-2,6)$_5$]$^-$ ions, consistent with the 2.95 and 2.72 Å distances between the hydrogen atoms on the *para* carbon and one *meta* carbon of the C(2) isonitrile and the aryl plane of the C(3) isonitrile ligand. It is interesting that the axial isonitriles are less bent at nitrogen (both 163°) than the equatorial isonitriles (av. 147°, range 143–149°); a similar pattern in metric parameters for [Fe($CNBu^t$)$_5$] was ascribed to more effective back bonding from the low-valent Fe(0) metal centre to the equatorial isonitrile ligands.[13]

Our results establish that isonitrilates can be prepared in five coordinate environments, and that a $d^8$ example adopts a trigonal bipyramidal geometry. The successful synthesis of [Mn($CNC_6H_3Me_2$-2,6)$_5$]$^-$ represents a significant addition to the small number of complexes accepted to contain manganese in the −I oxidation state,[14] and its derivatization with $SnClPh_3$ also suggests that **1**$^-$ may prove a valuable intermediate which will allow access to an isonitrile chemistry of Mn comparable to the carbonyl chemistry of Mn accessible from the isoelectronic carbonylmetalate [Mn(CO)$_5$]$^-$.[15]

# New methoxy-substituted 9-phenylxanthen-9-ylamine linkers for the solid phase synthesis of protected peptide amides

**Mark Meisenbach,† Hartmut Echner and Wolfgang Voelter***

*Physiologisch-chemisches Institut, Abteilung für Physikalische Biochemie, Universität Tübingen, Hoppe-Seyler-Str. 4, D-72076 Tübingen, Germany*

**New methoxy-substituted 9-phenylxanthen-9-ylamine linkers are described for the solid phase synthesis of peptide amides *via* the Fmoc strategy; depending on the cleavage conditions, the peptide amides can be cleaved rapidly and in high purity in their protected or deprotected forms.**

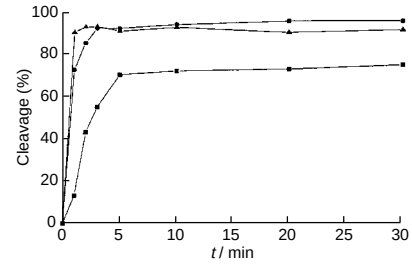
Efficient stepwise solid-phase syntheses of C-terminal peptide amides yielding products of high purity are of interest for several reasons: (i) a considerable number of hormones, including secretin, calcitonin, oxytocin, thyroliberin and luliberin, bear a C-terminal acid amide function, (ii) several peptidyl amides, such as indolicin or protegrins, have potent antimicrobial activities, (iii) changing the C-terminal carboxy function of a biologically active peptide into a peptidyl or peptidyl N-alkyl amide often leads to analogues with more favourable or prolonged activity, and (iv) fully protected, but N-terminally free, peptide amides are needed for the assembly of longer chains.[1]

Highly acid-labile linkers are desirable, especially for the synthesis of peptide fragments in the protected form *via* the efficient Fmoc–Bu$^t$ SPPS strategy, as they allow the cleavage of peptide amides under very mild conditions. The xanthenylamine linker (XAL) system has been described as a useful handle for the synthesis of peptide amides,[2,3] but the conditions (30 min with 1% TFA–$CH_2Cl_2$ v/v)[1] used for their cleavage from the resin also cause, for example, loss of the trityl protection group from His, and it is therefore not suitable for the preparation of side chain-protected peptide segments with *e.g.* His(Trt)-containing peptide amides.[4] The rapid acidolysis (50% TFA, < 5 min) of the 9-phenylxanthen-9-yl (Pixyl) protection group for the carboxy amide function of asparagine and glutamine recently developed in our laboratory[5] prompted us to increase the acid lability of XAL by introducing methoxy-substituted phenyl residues in position 9.

The starting material, 3-hydroxyxanthen-9-one **1**, was synthesized in good yield *via* a three-step procedure from *o*-chlorobenzoic acid and *m*-methoxyphenol.[6,7] Treatment of **1** with sodium methoxide and chloromethylated polystyrene in *N*,*N*-dimethylacetamide (DMA) yielded resin **2**, free of chloride. The resulting xanthenol resins **3a** and **3b** were prepared from **2** *via* a Grignard reaction using the corresponding bromo reagents in THF. The disappearance of the CO band in the IR spectrum at 1645 cm$^{-1}$ indicated that the reaction had gone to completion. Both resins, **3a** and **3b**, were converted with AcCl in toluene into the chloro forms, and then by treatment with ammonia in $CH_2Cl_2$ into the amino compounds **4a** and **4b** (Scheme 1).‡

As a test case, Fmoc-Gly-OH was coupled to the resin using DCC (3 equiv., 2 h) and the remaining amino groups were capped with $Ac_2O$–Pr$^i_2$EtN (1 : 1) in $CH_2Cl_2$ for 20 min. To determine the extent of functionalization of the resin, the Fmoc-group was cleaved with 25% piperidine–DMF and the solution of the 9-fluorenylmethyl piperidine adduct was measured by UV spectroscopy at $\lambda$ = 290 nm. The loading determined was 0.52 and 0.58 mmol Fmoc-Gly g$^{-1}$ resin for **5a** and **5b**, respectively. Other Fmoc amino acids were attached to the resins and the degree of resin loading was found to be satisfactory, even with highly sterically hindered amino acids such as Fmoc-Val-OH ( > 0.43 mmol g$^{-1}$) and Fmoc-Asn(Trt)-OH ( > 0.35 mmol g$^{-1}$).

Kinetic studies were performed to compare the cleavage times of Fmoc amino acids from the resins **5a** and **5b** with those



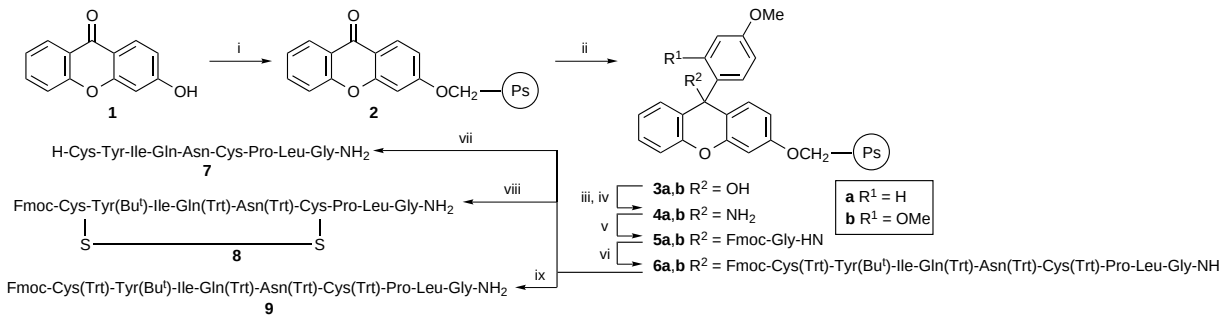


**Fig. 1** Cleavage kinetics of Fmoc-Gly-$NH_2$ from ( ▲ ) **5b**, (●) **5a** and (■) 9-aminoxanthen-3-yloxymethyl polystyrene resin (XAL)

(for **a**) or 1-bromo-2,4-dimethoxybenzene (10 equiv.) (for **b**), THF, 12 h, reflux; iii, AcCl (20 equiv.) PhMe, 40 °C, 1 h; iv, 50% $NH_3$ in $CH_2Cl_2$, −45 °C to room temp., 1 h; v, Fmoc-Gly-OH, DCC, $CH_2Cl_2$; vi, standard Fmoc–Bu$^t$ solid phase procedures (see footnote ‖); vii, 10% TFA–$CH_2Cl_2$, 15 min, TFA–thioanisole–ethanedithiol–$H_2O$–PhOH (10 : 0.5 : 0.5 : 0.5 : 0.5, v/v/v/v/w), TFA, 2 h, room temp.; viii, $I_2$ (10 equiv.) in 0.5% TFA–$CH_2Cl_2$ (v/v), 3–5 min; ix, 1% TFA–$CH_2Cl_2$ (v/v), 3–10 min

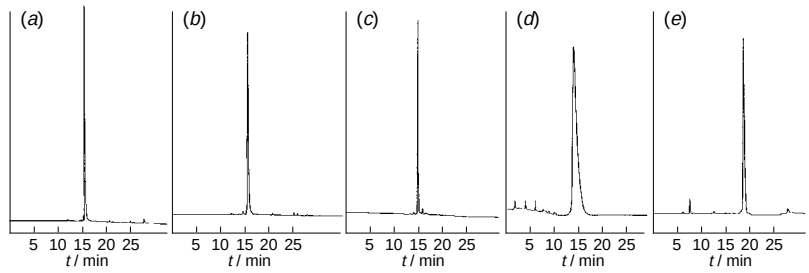

**Fig. 2** Reversed-phase high performance liquid chromatograms of synthetic oxytocin: (*a*) deprotected crude product **7** cleaved from **6a**; (*b*) deprotected crude product **7** cleaved from **6b**; (*c*) oxidized unprotected crude product cleaved from **6b**; (*d*) protected crude product **9** cleaved from **6b**; (*e*) protected oxidized crude product **8** cleaved from **6b**. Column: Nucleosil 5 μm $C_{18}$ 4.6 × 250 mm. Eluents: [for (*a*)–(*c*)] A = $H_2O$–TFA (1000 : 0.25), B = MeCN–$H_2O$–TFA (600 : 400 : 0.2); [for (*d*) and (*e*)] A = $H_2O$–TFA (1000 : 0.25), B = MeCN–TFA (1000 : 0.2). Gradients (A : B): [for (*a*)–(*c*)] 0–1 min (95 : 5), 1–31 min (95 : 5 to 5 : 95); [for (*d*)] 0–1 min (20 : 80), 1–11 min (20 : 80 to 0 : 100), 11–30 min (0 : 100); [for (*e*)] 0–1 min (40 : 60), 1–16 min (40 : 60 to 0 : 100), 16–30 min (0 : 100). Flow rate: 1 ml $min^{-1}$. Detection: λ = 214 nm. Concentration: 1 mg $ml^{-1}$.

from the 9-aminoxanthen-3-yloxymethyl polystyrene support (Novabiochem). The Fmoc-Gly-resins were treated with 1% TFA in $CH_2Cl_2$ and aliquots (*ca*. 5 mg) were periodically withdrawn from the reaction vessel to determine the degree of cleavage *via* UV spectroscopy,§ demonstrating the expected much higher acid lability of the new linkers compared to the commercially available XAL (Fig. 1).

The practicability of the new linker system is illustrated by the efficient synthesis of our model peptide oxytocin [Fmoc-Cys(Trt)-Tyr(Bu$^t$)-Ile-Gln(Trt)-Asn(Trt)-Cys(Trt)-Pro-Leu-Gly-$NH_2$], chosen as a test sequence for the synthesis of a disulfide-bridged protected peptide amide. The linear sequence **7** was smoothly synthesized batchwise using the Fmoc–Bu$^t$ strategy.¶ After incorporation of the last amino acid and removal of the N-terminal Fmoc group, the peptide was cleaved with 10% TFA–$CH_2Cl_2$ over 15 min. To remove the side chain protecting groups, the product was treated with TFA–ethanedithiol(EDT)–thioanisole(TA)–$H_2O$–PhOH (10 : 0.5 : 0.5 : 0.5 : 0.5, v/v/v/v/w), followed by diethyl ether precipitation and lyophilisation. The linear product **7** was obtained in 83 and 90% yield from **6a** and **6b**, respectively, demonstrating the stability of the peptidyl linker bond under the standard basic Fmoc–Bu$^t$ synthetic conditions. The crude reduced oxytocin showed excellent purity (Fig. 2) and was oxidized by air in $NH_4Ac$ buffer.‖

To yield the protected linear oxytocin **9** the cleavage was performed with 1% TFA–$CH_2Cl_2$ for 10 min from **6a** (80% yield) and 5 min from **6b** (93% yield).** The versatility of the linker is further illustrated by the simple and efficient method of oxidation with iodine during the cleavage. To obtain the cyclic protected oxytocin **8**, the product was cleaved with 0.5% TFA–$CH_2Cl_2$ (v/v) and the intramolecular disulfide bridge was simultaneous formed by oxidation with $I_2$ (10 equiv.) over 5 min for **6a** and 3 min for **6b** in 81 and 89% yield, respectively.††

Our results show that the introduction of the methoxy-substituted phenyl residue in position 9 of the xanthenyl system increased the acid lability as expected. The high yields and the excellent purity of the synthetic peptides produced on the resins show that the peptidyl linker bond is stable under the basic Fmoc–Bu$^t$ synthetic conditions and that these new linkers allow a far faster cleavage of peptide amides compared to the commercially available XAL. The linker is also suitable for the convenient preparation of cystine-containing protected peptide amides by simultaneous iodine oxidation and cleavage of the products. Therefore, our new linker can be recommended for the synthesis of peptide amides in both unprotected and protected form, and is almost free of side products.

## Footnotes

† E-mail: mark.meisenbach@uni-tuebingen.de

‡ The chloromethylated polystyrene (1.7 mmol $g^{-1}$) was treated with 2.5 equiv. of 3–hydroxyxanthen-9-one **1** and 2.5 equiv. of MeONa in DMA at 65 °C for 15 h. The Beilstein test and microanalysis for chloride were negative. The Grignard reactions of the 9-oxoxanthen-3-yloxymethyl polystyrene resin **2** were performed in THF refluxing for 12 h with the Mg adducts 4-bromoanisole and 1-bromo-2,4-dimethoxybenzene, respectively. The resins **3a** and **3b** were transformed into the dark red halide forms over 1 h with AcCl in toluene at 70 °C. To yield the orange 9-amino-9-(4-methoxyphenyl)xanthen-3-yloxymethyl and 9-amino-9-(2,4-dimethoxyphenyl)xanthen-3-yloxymethyl polystyrene resins **4a** and **4b**, respectively, the resins were treated with a cold (−45 °C) solution of ammonia in $CH_2Cl_2$ (50%) and allowed to warm to room temperature (1 h).

§ A 100 mg batch of each Fmoc-Gly-resin (**5a**, **5b** and XAL) was placed in a reaction vessel and allowed to swell in $CH_2Cl_2$ for 10 min, then treated with 20 ml of 1% TFA–$CH_2Cl_2$ (v/v); periodically, *ca*. 5 mg samples were taken out and washed immediately (3 × $CH_2Cl_2$, 3 × DMF 3 × MeOH, 2 × $CH_2Cl_2$ and $Et_2O$). To control the release of the amino acid, the remaining Fmoc groups were cleaved with 25% piperidine–DMF for determination by UV spectroscopy at λ = 290 nm, using the rule of Lambert–Beer.

¶ The solid phase syntheses of oxytocin were accomplished by Fmoc batchwise procedures using an ECOSYN P peptide synthesizer (Eppendorf-Biotronik). Carboxy activation was achieved by 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium tetrafluoroborate (TBTU) and Pr$^i_2$EtN in DMF except for the Fmoc-Cys(Trt)OH residues, which were activated with diisopropylcarbodiimide and hydroxybenzotriazole (HOBt) in $CH_2Cl_2$ to prevent epimerization during the activation.[8] The Fmoc group was cleaved with 25% piperidine in DMF.

‖ The air oxidation of the synthetic oxitocin was performed in a $10^{-4}$ M solution in 0.1 M $NH_4Ac$ buffer at pH 7.5 in 2 h.

** The peptidyl resins were treated repeatedly with 1% TFA in $CH_2Cl_2$ and the solutions were filtered off after a short period of time (*ca*. 1 min) into a vessel containing 3% pyridine in $CH_2Cl_2$ to neutralize the TFA. The resulting mixture was extracted three times with $H_2O$, evaporated to remove the $CH_2Cl_2$ and Bu$^t$OH–$H_2O$ (4 : 1) was added before the product **9** was lyophilised.

†† For the cleavage and simultaneous oxidation, the peptidyl resins (**6a** and **6b**) were treated with a solution of 0.5% TFA and 10 equiv. of $I_2$ in $CH_2Cl_2$. The same procedure was then used as described in footnote ††, except that the excess of iodine was removed by an additional washing step with a 0.05 M $Na_2S_2O_3$ solution. The synthetic peptides gave the expected FAB, IS or MALDI-MS data.

# Hydrothermal synthesis and structural determinations of some new polyoxofluorovanadates $[V_{14}O_{36}F_4]^{8-}$ interleaved by water molecules and organic cations $NH_3(CH_2)_nNH_3$ ($n$ = 4–6)

**Cyril Ninclaus, Didier Riou*† and Gérard Férey**

*Institut Lavoisier, UMR-CNRS C 173, Université de Versailles-St Quentin en Yvelines, 45 Avenue des Etats-Unis, 78035 Versailles Cedex, France*

**$[V_{14}O_{36}F_4]^{8-}$ polyanions are built up from two trimers of three edge-sharing $VO_5F$ octahedra, two dimers of two square pyramids related by their basal plane, two $VO_4$ tetrahedra and two $VO_4F$ trigonal bipyramids; between them are intercalated water molecules and diprotonated amines which stabilize the structures by hydrogen bonds.**

In the course of investigations on microporous materials, we first focused our attention on the hydrothermal behaviour of the quinary systems $M_2O_3$ (M = Al, Ga)–$P_2O_5$–HF–organic template–$H_2O$. This led to a new series, denoted ULM-*n*, of fluorinated alumino- and gallo-phosphates of which ULM-5[1] and ULM-16[2] are the more remarkable members. The free apertures of their 16-ring tunnels are 12.2 × 8.3 Å in ULM-5 and 10.4 × 10.4 Å in ULM-16. Recently, we proposed a mechanism for the formation of these phases[3] in which the chemical nature of the metallic element does not play a predominant role. The possibility to substitute completely aluminium or gallium by a 3d transition metal was thus explored and led to the synthesis and characterization of some microporous $Fe^{III}$ compounds with interesting magnetic properties[4–5] and vanadophosphates templated by organic cations.[6,7] We also synthesized the fresnoïte related $(NH_4)_2VO(V_{2-x}P_xO_7)$ (*x ca.* 1), which shows that $V^V$ and P atoms are statistically distributed on the same tetrahedral sites.[8] If such a substitution is possible in the ULM series containing vanadium, then the existence of vanadium oxides with microporous frameworks could become a reality. The only results reported up to now concern vanadium oxides with lamellar structures $V_2O_5$·0.5diamine,[9–11] $NMe_4V_4O_{10}$[12] and $(C_6H_{14}N_2)V_6O_{14}·H_2O$.[13]

The title compounds were synthesized hydrothermally using 1,4-diaminobutane (1,4-DAB), 1,5-diaminopentane (1,5-DAP) and 1,6-diaminohexane (1,6-DAH) as organic templates. The aqueous mixture with molar ratio 1 $V_2O_5$ : 2 HF : 0.8 diamine (1.4 in the case of 1,6-DAH) : 80 $H_2O$ was placed in a stainless-steel autoclave lined with Teflon and heated under autogenous pressure at 180 °C for 24 h. The pH of the liquid phase was constant at *ca*. 4–5 during the reaction. The solid phase was filtered off, washed with deionized water and dried in air at room temperature. The prepared products were pure with yields of around 70%. The crystals appear black but are blue after grinding. The crystal morphology of the compound prepared with 1,5-DAP is very striking. A scanning electron micrograph (Fig. 1), performed on a Hitachi S2300, shows that they grow as big hollow needles. Suitable single crystals of both phases intercalating 1,5-DAP and 1,6-DAH were isolated for structural determination‡ by X-ray diffraction. The quality of the crystals prepared with 1,4-DAB was not sufficient to perform the same study. Nevertheless, the IR spectra of the compounds (Fig. 2), recorded on a Nicolet Magna-IR 550 in the range 2000–300 $cm^{-1}$, show unambiguously that the three polyanions are similar. $\nu(V{=}O_{terminal})$ and $\nu(V{-}O_{bridging})$ are observed at 970 and 750 $cm^{-1}$ respectively, the bands observed around 1500–1600 $cm^{-1}$ are characteristic of $-NH_3^+$. Chemically, we measured for each compound (*i*) the fluorine content by potentiometric titration with a specific electrode, (*ii*) the vanadium content by redox titration using $MnO_4^-$ and $Fe^{2+}$ for $V^{4+}$ and $V^{5+}$ respectively, (*iii*) the amount of organic template and water by thermogravimetry performed on a SETARAM apparatus operating under air. These measurements give with a very good accuracy the general formula $[V^{4+}{}_2V^{5+}{}_{12}O_{36}F_4]$·4diamine·$n$$H_2O$ ($n$ = 6 for 1,4-DAB, 8 for 1,5-DAP and 4 for 1,6-DAH). In addition, some density measurements were realized on a Micromeritic multipycnometer under He flow for the two compounds whose structures have been solved by single-crystal X-ray diffraction [$D_m$ = 2.01(3) g $cm^{-3}$, $D_c$ = 2.016 for 1,5-DAP; $D_m$ = 2.01(4), $D_c$ = 1.982 for 1,6-DAH].

$V_{14}O_{36}F_4·4N_2C_6H_{18}·4H_2O$ **1** is triclinic and can be described as primitive pseudo-cubic stacking of $[V_{14}O_{36}F_4]^{8-}$ polyanions between which are intercalated the organic cations and the water molecules (Fig. 3). $V_{14}O_{36}F_4·4N_2C_5H_{16}·8H_2O$ **2** presents a similar organization but its symmetry is monoclinic and the polyanions are oriented in two different ways. Consequently, two parameters are doubled and $V$(**2**) = 4 $V$(**1**). The decrease of steric hindrance from 1,6-DAH to 1,5-DAP due to the shortening of the aliphatic chain ($C_5$ *vs*. $C_6$) is compensated by the presence of four additional water molecules in **2**.

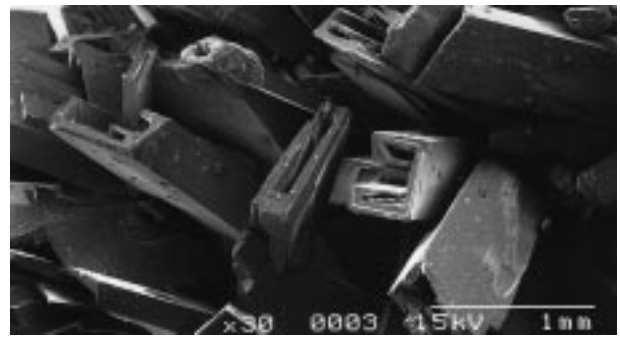

**Fig. 1** SE micrograph of $V_{14}O_{36}F_4·4N_2C_5H_{16}·8H_2O$ crystals

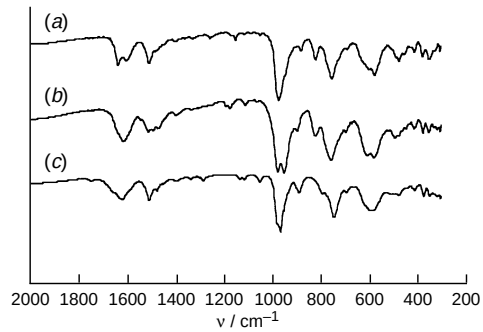

**Fig. 2** IR spectra of the polyanionic phases interleaving organic cations $NH_3(CH_2)_nNH_3$ with $n$ = 6 (*a*), 5 (*b*) and 4 (*c*)

The $[V_{14}O_{36}F_4]^{8-}$ anion contains four types of vanadium polyhedra. Two trimers of edge-sharing $VO_5F$ octahedra form the heart of the polyanion. In each trimer, the vertex shared by the three octahedra is fluorine, $F^-$ being characterized by bond valence analysis[14] and thermal parameters in agreement with the previous chemical analysis. Within each trimer, $V^{4+}$ occupies the octahedron which is not linked by edges to one of the four $V^VO_5$ square pyramids relating the two trimers. The connection exists in such a way that each square pyramid shares an edge with one octahedron of one trimer and the two other O atoms of its basal plane with two octahedra of the opposite trimer (Fig. 4). On the external side of each trimer are grafted a $V^VO_4$ tetrahedron and a $V^VO_4F$ trigonal bipyramid. Each trigonal bipyramid has three free apices, one of them is occupied by a F atom which gives rise to strong interactions with the H atoms of the amino groups. In **1** and **2**, the polyanions realize the same connectivities between the polyhedra. Nevertheless, in **1** the polyanions are built up around an inversion centre and possess $2 \times 7$ independent vanadium atoms whereas in **2**, each polyanion is built up from 14 vanadium atoms resulting from 14 independent crystallographic sites. The attribution of the $V^{4+}$ on one particular site was possible on the basis of the bond valence analysis[14] and on the detailed examination of the distribution of V–O bond lengths in the octahedra (supplementary material available from authors).

The presence of fluorine in a polyanionic phase is generally as encapsulating inside the polyanion where $F^-$ plays the role of template. Recently, we have shown in the $[V_4(HPO_4)(PO_4)_3O_6F]^{8-}$ polyanions[7] a fluorine atom linked to the vanadium atoms and divided between four $VO_5F$ octahedra building the core of the polyanion. This situation is almost comparable to the octahedral trimers described here and also encountered by Müller *et al.*[15] in $Na_6[H_6V_{12}O_{30}F_2]\cdot 22H_2O$. The originality of **1** and **2** is the presence of a third type of fluorine, located at the outer shell of the polyanion and which stabilizes the whole structure by strong hydrogen bonds.

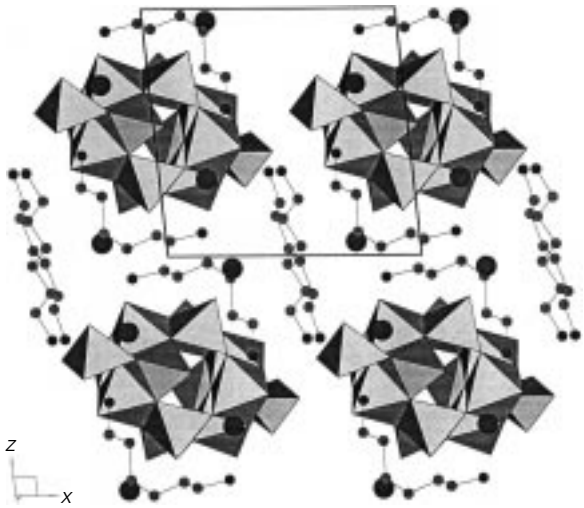

**Fig. 3** Projection along [010] of the structure of $V_{14}O_{36}F_4\cdot 4N_2C_6H_{18}\cdot 4H_2O$ with a polyhedral model for the $[V_{14}O_{36}F_4]^{8-}$ polyanions and a 'ball and stick' model for the diamines and the water molecules. Large circles refer to water and small circles to 1,6-DAH.

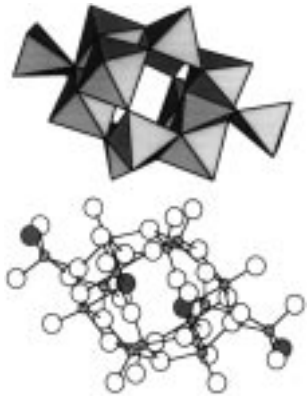

**Fig. 4** Polyhedral and 'ball and stick' representations of the $[V_{14}O_{36}F_4]^{8-}$ polyanion. Vanadium atoms are indicated by small circles, oxygen and fluorine atoms with open and large grey circles, respectively.

‡ *Crystal data*: $V_{14}O_{36}F_4\cdot 4N_2C_5H_{16}\cdot 8H_2O$: $M$ = 1296, monoclinic, space group $P2_1/n$ (no. 14); $a$ = 11.296(4), $b$ = 24.53(2), $c$ = 23.22(1) Å, $\beta$ = 99.34(7)°, $U$ = 6349(6) Å$^3$, $Z$ = 4, $D_c$ = 2.016, $D_m$ = 2.01(3) g cm$^{-3}$, $\mu$(Mo-K$\alpha$) = 20.73 cm$^{-1}$, $\lambda$ = 0.710 73 Å, graphite monochromator, crystal dimensions: 0.200 × 0.082 × 0.536 mm. The data were collected on an Enraf-Nonius CAD4 diffractometer up to $2\theta$ = 60°. A total of 19702 reflections was measured of which 6742 unique reflections ($R_{int}$ = 0.046) with $I \geqslant 2\sigma(I)$ were considered. The data were corrected for Lorentz-polarization effects, an absorption correction based on the crystal morphology did not improve the refinement. The structure was solved by direct methods analysis of SHELXS-86 (option TREF): the vanadium atoms were first located and the all remaining atoms including those of the amine skeleton were revealed from difference Fourier maps. Refinement (812 parameters) was performed by full-matrix least-squares analysis (SHELXL-93). The reliability factors converged to $R_1$ ($F_o$) = 0.052 and $wR_2$ ($F_o^2$) = 0.148. $V_{14}O_{36}F_4\cdot 4N_2C_6H_{18}\cdot 4H_2O$: $M$ = 1910, triclinic, space group $P\bar{1}$ (no. 2); $a$ = 11.746(1), $b$ = 11.960(2), $c$ = 12.717(1) Å, $\alpha$ = 115.547(7), $\beta$ = 93.261(6), $\gamma$ = 94.055(9)°, $U$ = 1600.2(3) Å$^3$, $Z$ = 1, $D_c$ = 1.982, $D_m$ = 2.01(4) g cm$^{-3}$, $\mu$(Mo-K$\alpha$) = 21.70 cm$^{-1}$, $\lambda$ = 0.710 73 Å, graphite monochromator, crystal dimensions: 0.057 × 0.179 × 0.270 mm. The data were collected on a Siemens AED2 four-circle diffractometer up to $2\theta$ = 60°. A total of 9316 reflections was measured of which 5707 with $I \geqslant 2\sigma(I)$ were considered. The data were corrected for Lorentz-polarization and absorption effects. The structure was solved by direct methods analysis of SHELXS-86 (option TREF): the vanadium atoms were first located then all the remaining atoms were deduced from difference Fourier maps. Refinement (400 variables) as above. Two carbon atoms whose thermal motion was rather high, were split over two crystallographic sites. The reliability factors converged to $R_1$ ($F_o$) = 0.046 and $wR_2$ ($F_o^2$) = 0.126. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/388.

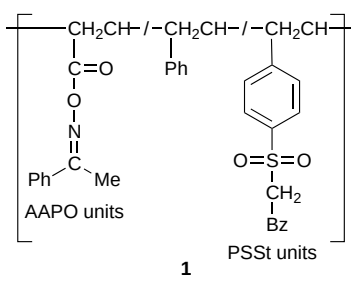
# Solubility control by UV irradiation of a copolymer having both photobase generating groups and photoacid generating groups

**Kanji Suyama*[a]† and Masahiro Tsunooka[b]‡**

[a] *Nissha Printing Co. Ltd., 3 Mibu-Hanai-Cho, Nakagyo, Kyoto 604, Japan*
[b] *Department of Applied Chemistry, College of Engineering, Osaka Prefecture University, 1-1 Gakuen-cho, Sakai, Osaka 593, Japan*



**An insoluble–soluble–insoluble contrast curve is obtained for a polymer film having both photobase and photoacid generating groups when it is developed using a polar solvent; the base groups are introduced before the acid groups.**

The solubility change of polymeric material upon irradiation is a key factor in their application to photoresists because photopatterning utilizes the solubility differences between irradiated and non-irradiated polymers. Many methods have been tried to improve the solubility change upon irradiation to obtain higher sensitivity and resolution. Photoacid generators have attracted increasing attention as a catalyst for high-sensitivity photoresist systems, the 'chemically amplification' type, where generated acids catalyse the thermolyses of carbonate groups into hydroxy groups.[1] Photobase generators have also been studied, including Co-amine salt,[2] polymers bearing *o*-acyloxyimino (AOI) groups,[3] *o*-nitrobenzyloxycarbonyl derivatives,[4,5] benzoyloxycarbonyl derivatives[6,7] and formamides.[8]

We have studied the photochemical behaviour of copolymers of acryloyl acetophenone oxime (AAPO), and found that AOI groups in AAPO units transformed into pendant amino groups upon irradiation, followed by hydrolysis.[3,9,10] On the other hand, we have also found that β-keto sulfone (β-KS) groups in phenacylsulfonyl styrene (PSSt) copolymers were transformed into pendant sulfinic or sulfonic acid groups upon irradiation.[11,12] From these results we expected that polymers bearing both acid and base units in the same polymer-chain would be obtained when a copolymer of AAPO and PSSt is irradiated.

On investigation of the photochemical behaviour of a polymer bearing both units, p(AAPO-St-PSSt) **1**, we found that **1** became soluble upon irradiation and then became insoluble on further irradiation when developed with a polar solvent. When developed with a non-polar solvent, **1** became insoluble. Here we report the dual-photoresist behaviour of **1**, Fig. 1.

Monomers were prepared as described in a previous paper,[9] and polymerized in degassed benzene at 60 °C using 0.2 mass% of AIBN as an initiator. The resulting polymeric material was reprecipitated three times from THF–MeOH to give **1** in 39.9% yield with *M*n = 75 000 (*M*w/*M*n = 1.66) determined by GPC analysis using THF as eluent and polystyrene as standard. The molar ratios of the monomers in **1** were AAPO : PSSt : St = 32.5 : 4.2 : 63.3, obtained from the $^1$H NMR integrated area ratio. The films were prepared by spin-coating a 7.5 mass% diglyme solution on a quartz or borosilicate glass plate, followed by drying in an oven at 85 °C for 20 min. The absorbance at 254 nm was *ca.* 1.5, and the film thickness was 0.35–0.5μm, measured by a Kosaka surface roughness meter ET-10. All irradiations were performed in air at room temperature using a Ushio UV-102 mercury lamp (100 W) without wavelength selection. The intensity of light was 3.01 mW cm$^{-2}$ at 254 nm and 4.62 mW cm$^{-2}$ at 366 nm, measured by an Orcs' UV-Light measure model UV-M02. After irradiation, the films were immersed into a 0.12 M HCl solution for 3 min and then in MeOH or THF for 10 min. All solutions were kept at 23 °C. UV spectra were measured by a Shimadzu UV-3100. The samples for IR spectral measurement were scratched away from the plate and measured on a Perkin-Elmer 1620.

**1**

(AAPO : St : PSSt = 33 : 63 : 4)

**Fig. 1**

Fig. 2 shows the relationship between the irradiation time and the normalized film thickness of **1** developed with MeOH. The dotted line shows the change of normalized film thickness, which were irradiated for a given time, HCl treated and developed with MeOH. As the irradiation time increased, the developed films became thin and dissolved completely after 2–4 min irradiation time. However, gelatinous material was obtained on the glass plate for longer irradiation times such as 10, 15 or 20 min, and it was impossible to measure the film thickness. When the films were cured at 100 °C before MeOH development, the films became hard enough to measure the thickness. In this case, the films dissolved only after 2–4 min irradiation time and became insoluble after further irradiation as indicated by the solid line in Fig. 2.

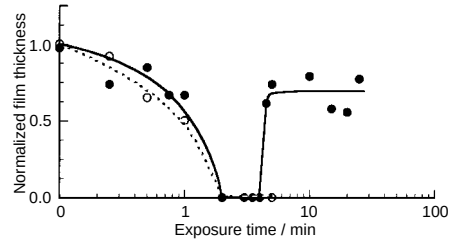


**Fig. 2** Contrast curves of films of **1** developed with MeOH after HCl treatment (- - ○ - -) and MeOH after HCl treatment and curing at 100 °C (—●—)

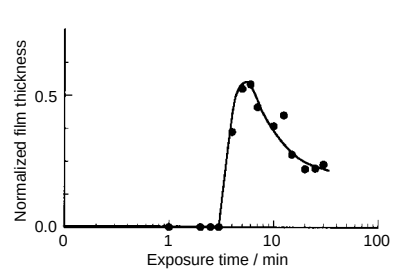

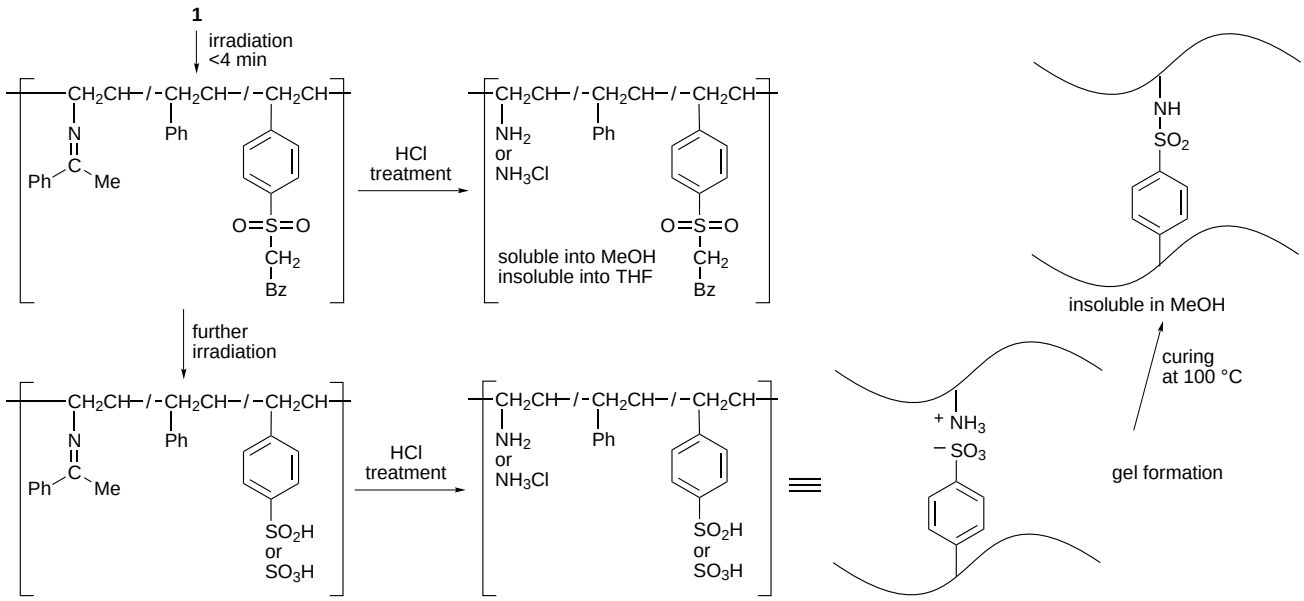

**Fig. 3** Contrast curve of films of **1** developed with THF

**Scheme 1** Photoreaction of **1**

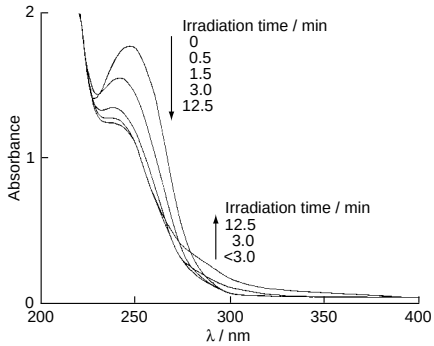

**Fig. 4** UV spectral changes of film of **1** upon irradiation

This film showed a different solubility behaviour when developed with THF. As shown in Fig. 3, the film irradiated for 4 min became insoluble in THF. With longer irradiation time, the thickness of the resulting films gradually decreased. This tendency in the later stage was similar to the phenomenon found in copolymers of PSSt and styrene or MMA.[12]

Fig. 4 shows the changes of the UV absorption spectra of the irradiated films. The peak at *ca.* 250 nm decreased after less than 3 min of irradiation. Upon further irradiation, however, the decrease almost stopped, and a new band appeared in the 260–380 nm region. The latter seems to relate to the β-KS groups because this band appeared in the PSSt and styrene or MMA copolymers upon irradiation[13] and not in those having AAPO units. The changes in the β-KS groups are thus deduced to occur after 3 min irradiation.

The structural change of this copolymer might be explained as shown in Scheme 1. Upon irradiation for less than 3 min, the AOI groups in the AAPO units decompose. The recombination of iminyl radicals and radicals on the main chain results in imino groups which are converted to amino groups by HCl treatment. At this stage the conversion of the β-KS groups appears to be very low. Upon further irradiation most of the AAPO units give imino (or amino) groups, and also β-KS groups are photo-transformed into sulfinic or sulfonic acid groups. The resulting acid groups form interaction points with amino groups, which afford intra- and inter-molecular cross-links. At this stage the film swelled in the developer. It is thus deduced that when cured at 100 °C the cross-links are transformed into sulfonamides.

The photo-decomposition of AOI groups can be explained by an effective energy transfer from β-KS groups to AOI groups, which restricts the photochemical change of β-KS groups until the AOI groups have decomposed almost completely. In fact, the sensitization of the decomposition of the AOI groups by β-KS groups was confirmed by photolysis at 366 nm. Although we used a mercury lamp without a wavelength selector as the light source for our experiments, we assumed that the energy transfer from the β-KS groups to the AOI groups is still important because the direct photolysis of AOI groups is slow compared to **1**.

We thank Mr T. Takemoto, Department of Applied Chemistry, Osaka Prefecture University, for measuring the NMR spectra.

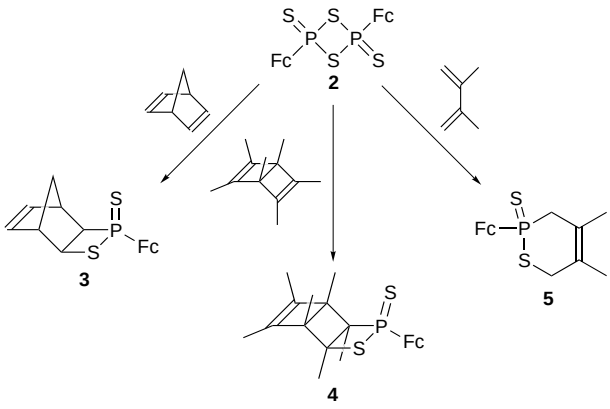
# Novel 1,2-thiaphosphetanes from diferrocenyldithiadiphosphetane disulfide



**Mark R. StJ. Foreman, Alexandra M. Z. Slawin and J. Derek Woollins*†**

*Department of Chemistry, Loughborough University, Loughborough, UK LE11 3TU*

**Diferrocenyldithiadiphosphetane disulfide reacts with bicyclic dienes to form four- and six-membered PS containing rings which are crystallographically characterised.**

We have recently reported on the synthesis[1] of a ferrocene analogue of Lawesson's reagent [*p*-(MeO)$C_6H_4P(S)S_2P(S)$-$C_6H_4$(OMe)] **1**. These types of system are used as reagents in thionation reactions but their potential in the formation of new heterocycles is less well developed although some reactions of **1** with 1,3-dienes to give Diels–Alder adducts at moderate temperatures have been described.[2] Lawesson's reagent has been reported to react with alkenes at high temperature to give anti-sludge additives for engine oils[3] and ferrocene derivatives have been studied as additives for fuels.[4] There have only been a few reports on the isolation of $RPS_2$ systems (R = 'supermesityl')[5] but from NMR studies[1] we have speculated on the transitory existence of $RPS_2$ in **1** and **2**. This observation has led us to investigate the cycloaddition chemistry of **2** and here we describe preliminary investigations into the low temperature reactions of alkenes with **2** together with the X-ray crystal structures of three new organophosphorus–sulfur heterocycles, which are the first examples of these ring types to be characterised crystallographically.[6]

The reactions are shown in Scheme 1. Treatment of **2** with norbornadiene at 80 °C leads to 4-ferrocenyl-3-thia-4λ$^5$-phosphatricyclo[4.2.1.0$^{2,5}$]non-7-ene 4-sulfide **3** in high yield (69%).‡ The X-ray structure§ of **3** reveals (Fig. 1) it to be the *exo*-isomer. The $C_2PS$ (thiaphosphorane) ring is close to planar [max. deviation from the $PSC_2$ mean plane 0.043(6) and −0.050(6) Å for C(16) and C(11) respectively]. The P=S and P–S bond lengths are similar to those in **2** whilst P(1)–C(16)

**Scheme 1**

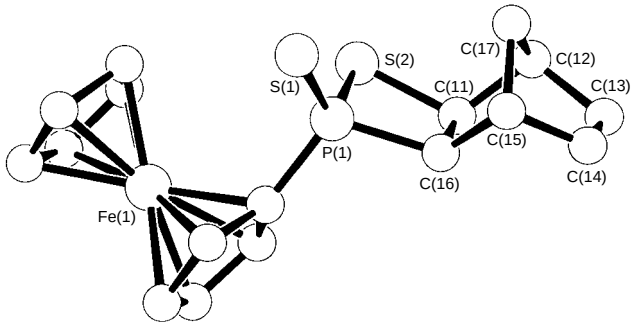


**Fig. 1** The X-ray structure of **3**. **Fig. 2** The X-ray structure of **4**. Selected bond lengths (Å) and angles (°): P(1)–S(1) 1.931(1), P(1)–S(2) 2.095(1), S(2)–C(12) 1.880(5), C(11)–C(12) 1.588(4), P(1)–C(11) 1.844(4), C(12)–C(13) 1.538(5), C(13)–C(14) 1.520(5), C(14)–C(15) 1.322(5), C(15)–C(16) 1.520(5), C(16)–C(11) 1.578(5), C(13)–C(16) 1.584(5), S(1)–P(1)–S(2) 122.9(1), S(1)–P(1)–C(1) 112.3(1), S(1)–P(1)–C(11) 122.4(1), S(2)–P(1)–C(1) 104.7(1), S(2)–P(1)–C(11) 83.7(1) C(1)–P(1)–C(11) 106.6(2), P(1)–S(2)–C(12) 79.9(1), S(2)–C(12)–C(11) 98.5(2).

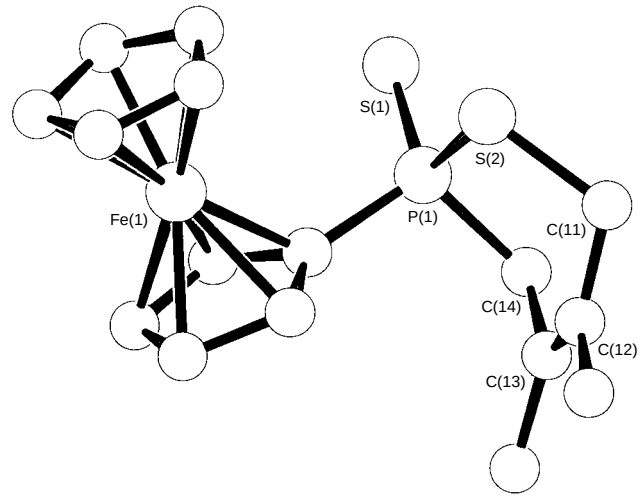

**Fig. 3** The X-ray structure of **5**. Selected bond lengths (Å) and angles (°): P(1)–S(1) 1.944(3), P(1)–S(2) 2.086(4), S(2)–C(11) 1.840(9), C(11)–C(12) 1.50(1), C(12)–C(13) 1.31(1), C(13)–C(14) 1.52(1), P(1)–C(14) 1.816(8), S(1)–P(1)–S(2) 1147.7(2), S(1)–P(1)–C(1) 112.5(3), S(1)–P(1)–C(14) 114.5(3), S(2)–P(1)–C(14) 101.6(3), S(2)–P(1)–C(1) 106.5(3), C(1)–P(1)–C(14) 106.0(4), P(1)–S(2)–C(11) 100.4(4), S(2)–C(11)–C(12) 112.4(6), C(11)–C(12)–C(14) 120.6(8), P(1)–C(14)–C(13) 111.4(6), C(12)–C(13)–C(14) 118.1(8).

[1.847(6) Å] and S(2)–C(11) [1.850(6) Å] are relatively long single bonds. The phosphorus centre is somewhat distorted from tetrahedral, in part because of the reduced angles within the $PSC_2$ ring. The exocyclic sulfur is pointing up (in the same direction as the $CH_2$ of the tricyclic system). No trace could be found of any homo-Diels–Alder adduct in the reaction products.

Reaction of **2** and hexamethyl Dewar benzene in toluene at 80 °C gives 4-ferrocenyl-1,2,5,6,7,8-hexamethyl-3-thia-4λ$^5$-phosphatricyclo[4.2.0.0$^{2,5}$]oct-7-ene 4-sulfide **4** after chromatography and recrystallisation.‡ The X-ray structure§ of **4** reveals (Fig. 2) it to be the *exo*-isomer. The bond lengths and angles in **4** display similar trends to those in **3** although the $PSC_2$ ring is less planar than that in **3** [maximum deviation from the $PSC_2$ mean plane 0.14(1) and −0.14(1) Å for C(12) and C(11) respectively]. The difference may be a consequence of the steric repulsion between the exocyclic methyl groups and the P=S in **4**. Like **3** the phosphorus centre is distorted with reduced angles within the $PSC_2$ ring.

Treatment of **2** with 2,3-dimethylbutadiene at *ca*. 80 °C gave 2-ferrocenyl-4,5-dimethyl-1-thia-2λ$^5$-phosphacyclohex-4-ene 2-sulfide **5** in high yield (86%). The thiaphosphorinine ring in **5** has a pseudo boat conformation (Fig. 3) with the P(1)–S(2)–C(11)–C(14) and C(11)–C(12)–C(13)–C(14) mean planes are inclined by 123° to each other. The bond lengths at phosphorus and sulfur are similar to those in **3** and **4** with, as expected, significantly less angular deviations about the phosphorus centres.

The new compounds described here illustrate the ability of **1** to behave as a source of $PS_2$ in ring forming reactions as well as providing the first structure determinations on two heterocyclic systems. Reactions with other multiple bonds are in progress.

§ *Crystal data*. All measurements were performed at room temperature using a Rigaku AFC7S diffractometer, Cu-Kα radiation, λ = 1.54178 Å, ω-scans (2θ max = 120°). For **3**: $C_{17}H_{17}FePS_2$, $M$ = 372.3 monoclinic, space group $P2_1/c$, $a$ = 11.688(2), $b$ = 9.508(2), $c$ = 14.706(2) Å, β = 104.11(1)°. $U$ = 1585 Å$^3$, $Z$ = 4, $D_c$ = 1.56 g cm$^{-3}$, $F$(000) = 768, μ(Cu-Kα) = 11.0 mm$^{-1}$. Crystal dimensions 0.10 × 0.21 × 0.30 mm. Of 2670 measured data 2559 were unique and 1996 were observed [$I > 3.0\sigma(I)$]. The structure was solved by the heavy atom method and refined using absorption corrected data (Difabs) with the H-atoms in idealised positions to give $R$ = 0.049 and $R_w$ = 0.046. For **4**: $C_{22}H_{27}FePS_2$, $M$ = 442.4, monoclinic, space group $P2_1/n$, $a$ = 10.616(2), $b$ = 9.604(1), $c$ = 21.033(2) Å, β = 101.26(1)°. $U$ = 2103 Å$^3$, $Z$ = 4, $D_c$ = 1.40 g cm$^{-3}$, $F$(000) = 928, μ(Cu-Kα) = 8.33 mm$^{-1}$. Crystal dimensions 0.08 × 0.12 × 0.21 mm. Of 3540 measured data 3339 were unique and 2473 were observed [$I > 2.0\sigma(I)$]. The structure was solved by direct methods and refined using absorption corrected data (Difabs) with the H-atoms in idealised positions to give $R$ = 0.038 and $R_w$ = 0.031. For **5**: $C_{16}H_{19}FePS_2$, $M$ = 362.3 monoclinic, space group $P2_1/n$, $a$ = 6.875(3), $b$ = 12.459(4), $c$ = 19.496(6) Å, β = 96.91(3)°. $U$ = 1658 Å$^3$, $Z$ = 4, $D_c$ = 1.45 g cm$^{-3}$, $F$(000) = 752, μ(Cu-Kα) = 10.5 mm$^{-1}$. Crystal dimensions 0.10 × 0.10 × 0.18 mm. Of 2833 measured data 2708 were unique and 1665 were observed [$I > 3.0\sigma(I)$]. The structure was solved by the heavy atom method and refined to give $R$ = 0.070 and $R_w$ = 0.071. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information to authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/410.

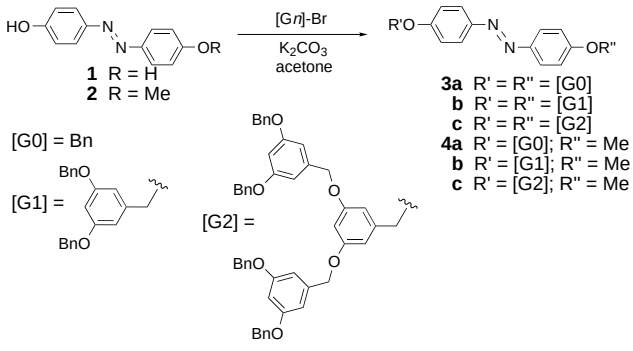
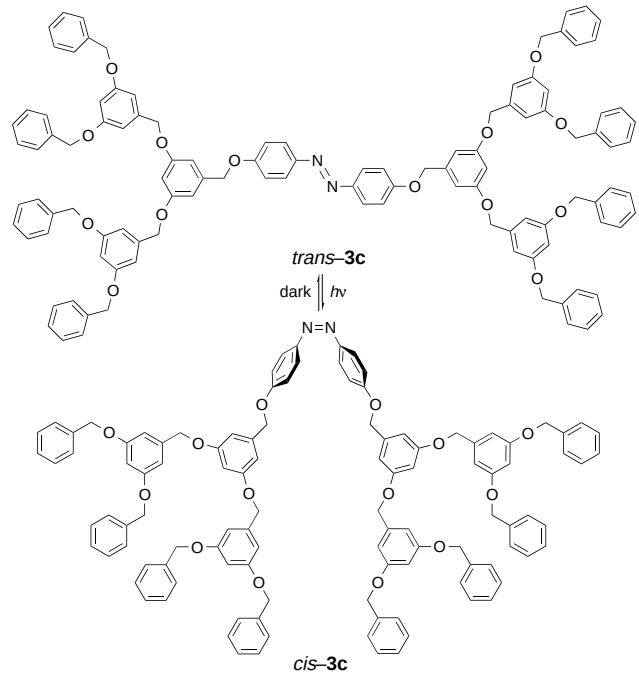
# Photoresponsive dendrimers

**Denise M. Junge and Dominic V. McGrath*†**



*Department of Chemistry, University of Connecticut, 215 Glenbrook Rd., Storrs, CT 06269-4060, USA*

**Benzyl aryl ether dendrimers with azobenzene central linkers undergo reversible *cis*/*trans* isomerization of the azobenzene moiety upon exposure to ultraviolet light.**



The elegance with which nature uses light energy to alter function in photoresponsive systems has led chemists to engage in much mimicry.[1] Progress has been made in designing systems containing photoresponsive moieties in small molecules,[2–4] polymers[5–8] and peptides[9–11] for the photocontrol of ion recognition and transport,[12] membrane permeability[13] and structure,[14] enzyme activity[2] and materials properties.[5,8,15] Typically, small molecule systems are well-understood. Their responsiveness is predictable and easily controlled. Macromolecular systems, however, while abundant and widely studied, are typically ill-defined and the photoresponsive effect is difficult to predict *a priori* or to control in a precise manner. Dendrimers, a new class of macromolecule in which the structure of the material is well-defined, are prepared in a way which would allow precise placement of a photoactive moiety within the dendrimer interior. More predictable control of photoinduced configurational changes should be possible, allowing potential reversible alteration of function. By placing a single photoactive moiety in the centre, rather than on the exterior,[16] of a dendrimer a small configurational change will effect a large conformational change throughout the dendrimer structure. Here we report the synthesis of dendrimers with azobenzene central linkers which undergo reversible configurational changes in response to light energy. This represents the first reversible topological change induced in a dendrimer through configurational change of the central linker.

Photoresponsive dendrimers of the zeroth, first and second generations were prepared by reaction of azobenzene-derivative central linkers **1**[17] and **2**‡ with the appropriate dendritic bromides[18] in the presence of $K_2CO_3$ in acetone (Scheme 1).§ Zeroth and first generation materials **3a** and **b** and **4a** and **b** are pale orange crystalline solids, while second generation materials **3c** and **4c** are orange glasses.¶

Dendrimers **3a–c** and **4a–c** all exhibited the expected photoresponsive behaviour. For example, dark incubation of a dichloromethane solution (40 μM) of second generation dendrimer **3c** served to maximize the absorbtion at 360 nm ($\varepsilon_{max}$ = 32 500) corresponding to the *trans*-azobenzene chromophore. Irradiation of this solution with 350 nm light resulted in clean photoisomerization to *cis*-**3c** (Scheme 2), as evidenced by a decrease in the absorbance at 360 nm and an increase in absorbances 314 and 450 nm (Fig. 1). A photostationary state was reached within approximately 60 s. Thermal reversion to the original dark-incubated spectrum was observed over the

**Scheme 1**

**Scheme 2**

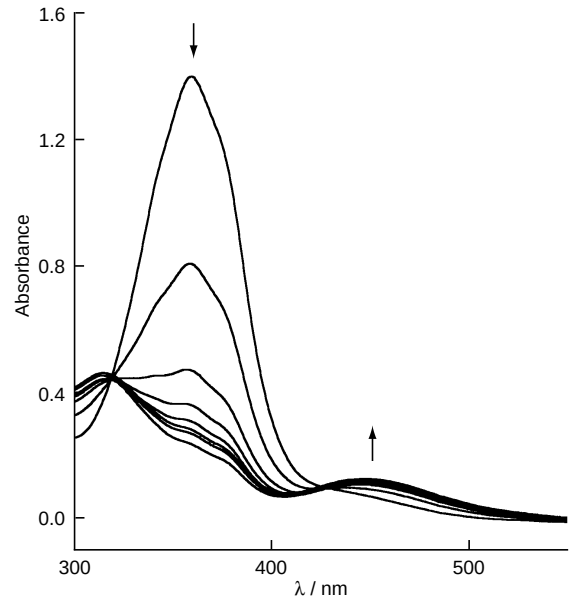


**Fig. 1** UV Absorption spectra of second generation photoresponsive dendrimer **4c** (40 μM in $CH_2Cl_2$) under irradiation conditions (350 nm; 0, 5, 10, 15, 20, 25, 30 and 60 s)

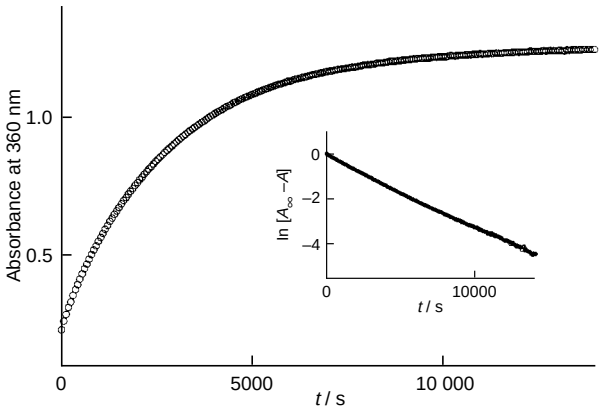

**Fig. 2** Plot of absorbance at 360 nm of a sample of **4c** kept in the dark at 293 K after irradiation (10 min at 350 nm). Inset: first order rate constant plot of $\ln[A_\infty - A]$ *vs.* time.

course of approximately 3 h at 293 K in the dark (Fig. 2). The first-order rate constant for this process ($k = 3 \times 10^{-4}$ s$^{-1}$; $t_{1/2} = 40$ min) is similar in magnitude to that of other azobenzenes.[19] Exposure to bright sunlight for a period of only several seconds also effected almost complete reversion to the *trans* isomer. Second generation compound **4c** serves as a steric control for **3c**. After isomerization to *cis*-**4c** (350 nm, 10 min), thermal isomerization to *trans*-**4c** occurs with an identical first-order rate constant ($k = 3 \times 10^{-4}$ s$^{-1}$; $t_{1/2} = 40$ min). This indicates that there is no strong steric influence on the thermal isomerization of *cis*- to *trans*-**3c**.

The photoinduced conversion of *trans*- to *cis*-dendrimer was also observed by $^1$H NMR spectroscopy. For example, the methoxy groups in *trans*- and *cis*-**4c** appear as singlets at δ 3.87 and 3.74, respectively, in $CDCl_3$. Irradiation of an NMR sample ($CDCl_3$) of **4c** resulted in a dramatic change in the ratio of these peaks, from 87 : 13 to 8 : 92. Similar changes were observed in the aromatic and benzylic regions of the spectrum.‖

We have demonstrated the photoresponsive properties of a series of simple dendrimers with azobenzene central linkers. We anticipate that switchable dendrimers of this type will have applications in transport systems based on the reversible perturbation of their ability to encapsulate small molecules. We hope to demonstrate these applications in our future studies.

‡ Preparation of **2**: a solution of $NaNO_2$ (0.52 g, 7.5 mmol) in $H_2O$ (minimum to dissolve) was added dropwise to a cold (5 °C) solution of 4-methoxyaniline (0.89 g, 7.2 mmol) and 9 M $H_2SO_4$ (4 ml). The resulting solution was added dropwise to a cold (5 °C) solution of phenol (0.70 g, 7.4 mmol) and 2 M NaOH (10 ml). After stirring for an additional 1.5 h, the solution was neutralized (2 M NaOH), extracted with $CH_2Cl_2$ (3 × 50 ml) and the combined organic extracts were dried ($Na_2SO_4$) and concentrated. Chromatography ($SiO_2$, 1 : 3 ethyl acetate–light petroleum) gave **2** (1.06 g, 65%) as a yellow crystalline solid, mp 141.5–142.5 °C (lit.,[20] 142 °C); $^1$H NMR [400 MHz, $(CD_3)_2CO$]: δ 8.98 (s, 1 H), 7.85 (d, *J* 9.0 Hz, 2 H), 7.80 (d, *J* 8.9 Hz, 2 H), 7.07 (d, *J* 9.0 Hz, 2 H), 6.99 (d, *J* 8.9 Hz, 2 H), 3.88 (s, 3 H).

§ Representative dendrimer preparation (**3c**): a solution of **1** (54 mg, 0.25 mmol), [G2]-Br (ref. 18) (0.45 g, 0.55 mmol), $K_2CO_3$ (89 mg, 0.65 mmol) and dry acetone (10 ml) was kept at reflux for 24 h. After removal of the solvent by rotary evaporation, the resulting solid residue was partitioned between $H_2O$ (20 ml) and $CH_2Cl_2$ (20 ml). The organic layer was separated, the aqueous layer was further extracted with $CH_2Cl_2$ (3 × 20 ml) and the combined organic layers were dried ($Na_2SO_4$) and concentrated. Flash chromatography of the residue ($SiO_2$, 1 : 1 $CH_2Cl_2$–light petroleum gradient to $CH_2Cl_2$) gave dendrimer **3c** (0.34 g, 80%) as an orange glassy solid.

¶ Satisfactory elemental analyses and spectroscopic data were obtained for all new compounds reported. *Selected data* for **3c**: glassy solid; $^1$H NMR [400 MHz, $(CD_3)_2CO$]: δ 7.83 (d, *J* 9.1 Hz, 4 H), 7.46–7.30 (m, 40 H), 7.13 (d, *J* 9.1 Hz, 4 H), 6.76 (d, *J* 2.3 Hz, 4 H), 6.74 (d, *J* 2.3 Hz, 8 H), 6.61 (t, *J* 2.3 Hz, 6 H), 5.17 (s, 4 H), 5.09 (s, 16 H), 5.07 (s, 8 H); $^{13}$C NMR [100 MHz, $(CD_3)_2CO$]: δ 160.6, 160.2, 160.1, 147.2, 139.2, 139.1, 139.0, 136.8, 128.6, 128.0, 127.5, 124.4, 115.1, 106.4, 101.6, 70.13, 70.11, 70.0 (Calc. for $C_{110}H_{94}N_2O_{14}$: C, 79.20; H, 5.68; N, 1.68. Found: C, 78.83; H, 5.78; N, 1.54%). For **4c**: glassy solid; $^1$H NMR [400 MHz, $(CD_3)_2CO$]: δ 7.87 (d, *J* 9.1 Hz, 2 H), 7.84 (d, *J* 9.1 Hz, 2 H), 7.46–7.30 (m, 20 H), 7.14 (d, *J* 9.0 Hz, 2 H), 7.08 (d, *J* 9.0 Hz, 2 H) 6.80 (d, *J* 2.3 Hz, 2 H), 6.76 (d, *J* 2.3 Hz, 4 H), 6.62 (t, *J* 2.4 Hz, 3 H), 5.17 (s, 2 H), 5.09 (s, 8 H), 5.07 (s, 4 H), 3.89 (s, 3 H); $^{13}$C NMR [100 MHz, $(CD_3)_2CO$]: 161.6, 160.6, 160.2, 160.1, 147.2, 147.1, 139.2, 139.0, 136.8, 128.6, 128.0, 127.6, 124.4, 124.3, 115.1, 114.2, 106.4, 106.3, 101.7, 101.6, 70.1, 70.084, 70.0, 55.5 (Calc. for $C_{62}H_{54}N_2O_8$: C, 77.96; H, 5.70; N, 2.93. Found: C, 78.01; H, 5.89; N, 2.92%).

‖ *Selected data* for *cis*-**3c**: $^1$H NMR (400 MHz, $CDCl_3$): δ 7.40–7.29 (m, 20 H), 6.78–6.74 (m, 8 H), 6.64 (d, *J* 2.3 Hz, 4 H), 6.60 (d, *J* 2.0 Hz, 2 H), 6.55 (t, *J* 2.8 Hz, 2 H), 6.52 (t, *J* 2.4 Hz, 1 H), 5.01 (s, 8 H), 4.945 (s, 4 H), 4.938 (s, 2 H), 3.74 (s, 3 H).

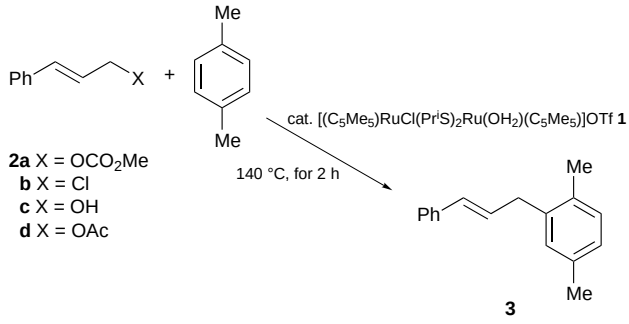
# Allylation of arenes catalysed by thiolate-bridged diruthenium complexes



**Yoshiaki Nishibayashi, Masashi Yamanashi, Yukihiro Takagi and Masanobu Hidai***

*Department of Chemistry and Biotechnology, Graduate School of Engineering, The University of Tokyo, Hongo, Tokyo 113, Japan*

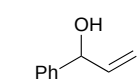
**In the presence of catalytic amounts of cationic thiolate-bridged diruthenium complexes, arenes react with allylic alcohols to afford the corresponding allylated aromatic products in high yields.**

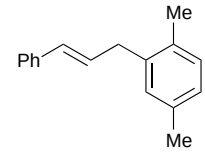
Novel functions of multinuclear complexes in homogeneous catalysis are of current interest because such complexes can be expected to provide new types of reactive sites.[1] We have investigated the synthesis and reactivities of thiolate- or sulfur-bridged multinuclear complexes,[2–7] and have disclosed that a series of thiolate-bridged diruthenium complexes promote unique transformations of various substrates including acetylenes,[3] alkyl halides,[4] hydrazines,[5] aromatic aldehydes[6] and alkenes.[7] Attention has now been focused on the reactivity of allylic compounds at the diruthenium core. Although allylation of nucleophiles or electrophiles with allylic compounds has been extensively studied using various mononuclear transition metal complexes,[8] reactions of allylic compounds with arenes are still limited to the nickel- and palladium-catalysed allylation with arylmagnesium halides.[9] We envisaged the allylation of arenes with allylic compounds catalysed by thiolate-bridged diruthenium complexes, and preliminary results are reported herein.

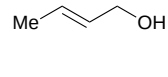
Treatment of cinnamyl methyl carbonate **2a** with *p*-xylene in the presence of a catalytic amount of the cationic thiolate-bridged diruthenium complex $[(C_5Me_5)RuCl(SPr^i)_2Ru(OH_2)(C_5Me_5)]$ **1** at 140 °C for 2 h under nitrogen afforded

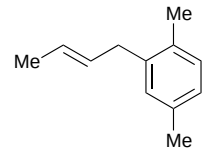
**Scheme 1**

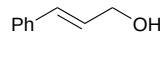
**Table 1** Ruthenium-catalysed allylation of *p*-xylene with cinnamyl compounds[a]

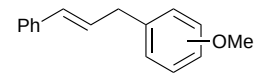


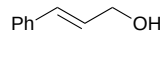


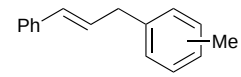


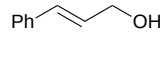


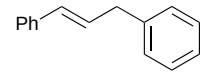


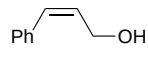


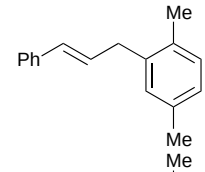


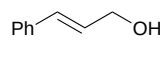


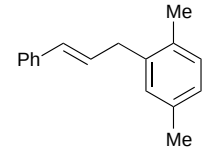






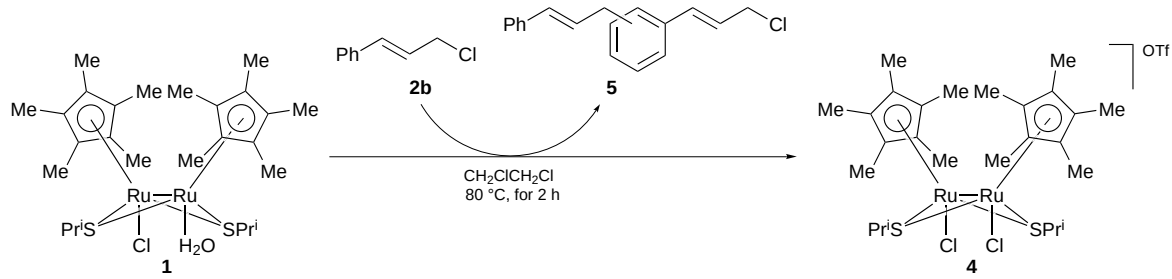






| Run | **1**/mol% | Substrate | Yield of **3** (%)[b] |
|---|---|---|---|
| 1 | 5 | **2a** | 75 |
| 2[c] | 5 | **2a** | > 99 |
| 3 | 5 | **2b** | > 99 |
| 4 | 1 | **2b** | > 99 |
| 5 | 0.2 | **2b** | 60 |
| 6 | 5 | **2c** | > 99 |
| 7 | 1 | **2c** | 30 |
| 8 | 5 | **2d** | 17 |

[a] All the reactions were carried out with a cinnamyl compound (0.25 mmol) and *p*-xylene (10 ml) at 140 °C for 2 h. [b] GLC yield. [c] For 6 h.



(*E*)-2-cinnamyl-1,4-dimethylbenzene **3** in 75% GLC yield (Scheme 1; Table 1, run 1). A longer reaction time (6 h) improved the yield of **3** (run 2). However, no reaction occurred using other thiolate-bridged diruthenium complexes such as $[(C_5Me_5)RuCl(SPr^i)]_2$, $[(C_5Me_5)Ru(SPr^i)_2Ru(C_5Me_5)]$ and $[(C_5Me_5)Ru(SPr^i)_3Ru(C_5Me_5)]$. Furthermore, $[(C_5Me_5)RuCl_2]_2$, which reacts smoothly with **2a** to afford a mononuclear ($\eta^3$-allyl)ruthenium complex,[10] showed only low catalytic activity. When cinnamyl chloride **2b** or *trans*-cinnamyl alcohol **2c** was used instead of **2a**, **3** was obtained in almost quantitative yield (runs 3, 4 and 6). On the other hand, cinnamyl acetate **2d** was less reactive than cinnamyl alcohol **2c** (run 8).

Recently, catalytic reactions that do not use organic halides have been receiving much attention because the production of unnecessary halogen-containing byproducts is avoided. Thus

**Table 2** Ruthenium-catalysed allylation of aromatic compounds[a]

| Run | Allylic compound | Aromatic compound | Product | Yield (%)[b] |
|---|---|---|---|---|
| 1 |  | *p*-Xylene |  | > 99[c] |
| 2[d] |  | *p*-Xylene |  | 64 |
| 3 |  | Anisole |  | 59[e] |
| 4[f] |  | Toluene |  | 52[g] |
| 5[h] |  | Benzene |  | 27 |
| 6 |  | *p*-Xylene |  | 11[c] |
| 7[i] |  | *p*-Xylene |  | > 99[c] |

[a] All the reactions were carried out in the presence of **1** (5 mol%) with an allylic compound (0.50 mmol) and an aromatic compound (20 ml) at 140 °C for 2 h. [b] Isolated yield. [c] GLC yield. [d] For 5 h. [e] Isomer ratio was $o:m:p$ = 12 : 0 : 88. [f] At 110 °C. [g] Isomer ratio was $o:m:p$ = 0 : 65 : 35. [h] At 80 °C. [i] **4** was used instead of **1**.

**Scheme 2**

the reactivities of allylic alcohols have been investigated in detail. The allylation of *p*-xylene, anisole, toluene and benzene with allylic alcohols afforded the corresponding allylic aromatic compounds in good yields. Typical results are given in Table 2. It is noteworthy that both 1-phenylprop-2-en-1-ol and **2c** react with *p*-xylene to give the same product, **3**. This suggests that a common (π-allyl)diruthenium complex is formed as an intermediate. The reactions of anisole and toluene with cinnamyl alcohol produced a 12 : 0 : 88 (*o* : *m* : *p*) mixture of (*E*)-cinnamylmethoxylbenzenes in 59% total yield (run 3) and a 0 : 65 : 35 (*o* : *m* : *p*) mixture of (*E*)-cinnamylmethyl benzenes in 52% total yield (run 4). Interestingly, the reaction between *cis*-cinnamyl alcohol and *p*-xylene proceeded very slowly at 140 °C resulting in the formation of **3** in poor yield. This is in sharp contrast to the reaction of *trans*-cinnamyl alcohol **2c** (*vide supra*).

Treatment of **1** with 5 equiv. of cinnamyl chloride **2b** in 1,2-dichloroethane at 80 °C for 2 h gave the cationic dinuclear ruthenium complex $[(C_5Me_5)Ru(SPr^i)Cl]_2[OTf]$ **4** in 29% yield, together with an allylated cinnamyl chloride **5** (Scheme 2). The structure of the paramagnetic complex **4** has been fully characterized by X-ray crystallography.† Complex **4** can also be used as a catalyst for the allylation of arenes with allylic alcohols (Table 2, run 7).

As described above, toluene was mainly allylated at the 3- and 4-positions (Table 2, run 4). This suggests that the reaction does not proceed *via* classical electrophilic aromatic substitution. Although the reaction mechanism is not yet clear, we assume that the first step involves the formation of a (π-allyl)diruthenium complex, which is followed by attack of arenes on the π-allyl moiety. In connection with this, the stereochemistry of the allyl moiety in allylated products was completely controlled, in contrast to the Lewis acid-catalysed allylation reactions of aromatic compounds.[11] This allylation of arenes with allylic alcohols using diruthenium complexes provides a new methodology for carbon–carbon bond formation. Molybdenum- and tungsten-catalysed allylation of aromatic compounds has very recently been reported, however, the catalytic activities of thiolate-bridged diruthenium complexes are much better than those of molybdenum and tungsten complexes.[12] Further studies on the detailed reaction mechanism and the application to organic synthesis are now in progress.

## Footnote

† Detailed experimental results will be reported in due course.

# Regio- and stereo-selective oxidation of steroids using 2,6-dichloropyridine *N*-oxide catalysed by ruthenium porphyrins

**Tomoteru Shingaki,[a] Keiko Miura,[b] Tsunehiko Higuchi,[a] Masaaki Hirobe[a] and Tetsuo Nagano*[a]†**

[a] *Faculty of Pharmaceutical Sciences, University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113, Japan*
[b] *Tsukuba Res. Inst., Banyu Pharm. Co. Ltd., Okubo 3, Tsukuba 300-26, Japan*

**Ruthenium porphyrins catalyse oxygen transfer from 2,6-dichloropyridine *N*-oxide to steroids with retention of configuration at the asymmetric centre, giving novel steroids.**

Various oxidation systems for steroids have been developed,[1] and recently there has been increasing interest in metalloporphyrin-catalysed oxidation systems as a model of cytochrome P450 for alkanes[2] and steroids.[3] We have already shown that ruthenium porphyrins effectively catalyse the oxidation of alkenes, sulfides and alcohols in the presence of heteroaromatic *N*-oxides.[4] In particular, this catalytic system efficiently oxidizes unactivated aliphatic or aromatic hydrocarbons in high yield with an extremely high turnover number (up to $10^5$ times) in the presence of HCl or HBr. Here we report the regio- and stereo-selectivity of oxidation in steroids using this system.[5]

We investigated the oxidation of 5α-cholestan-3-one **1** with 2,6-dichloropyridine *N*-oxide catalysed by Ru(TPP)CO, Ru(TMP)CO and Ru(TDClPP)CO (Fig. 1) in the presence of HBr (runs 1–3). In the reaction catalysed by Ru(TPP)CO, **1** was oxidized to afford the 25-hydroxy derivative **2** in 11% yield (run 1). When the reaction was catalysed by Ru(TMP)CO or Ru(TDClPP)CO, **1** was oxidized to afford (20*S*)-20,25-dihydroxycholestan-3-one **3**, (20*S*)-20-hydroxycholestan-3-one **4** and 25-hydroxycholestane-3,15-dione **5** in addition to **2** (runs 2 and 3). The structures of these novel steroids **3**–**5** were identified by mass spectroscopy, $^1$H and $^{13}$C NMR analysis and IR analysis. The mass number of **3** was larger than that of the starting material **1** by 32 *m/z*. In the $^{13}$C NMR spectrum, methine carbon signals (δ 36, 28) were replaced by quaternary carbons (δ 74, 71, respectively), and in the $^1$H NMR spectrum, the signals of the methyl protons at the 21-, 25- and 26-positions each appeared as a singlet. The configuration of **3** at the 20-position was determined by an X-ray crystal structure analysis (Fig. 2).‡ Thus, hydroxylation with our catalytic system proceeds with retention of the configuration of the asymmetric centres. It is noteworthy that in the biosynthesis of progesterone, cholesterol is hydroxylated with retention of configuration at the 20-position *in vivo* by P450.[6] At least in this respect, our system can be regarded as a model of P450.

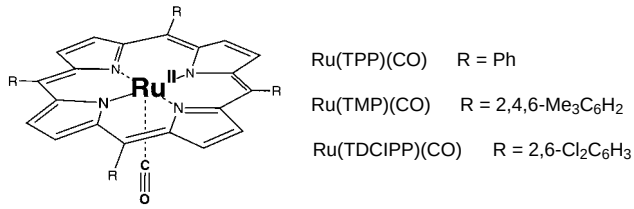

**Fig. 1** Structure of ruthenium porphyrins

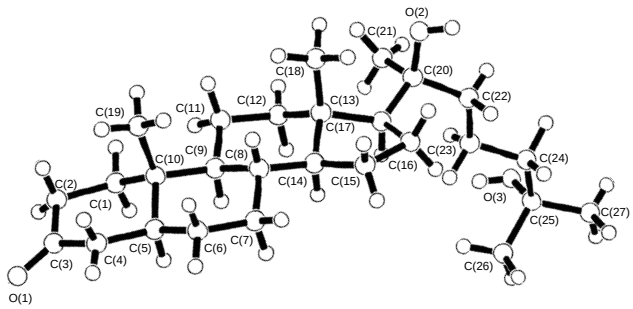

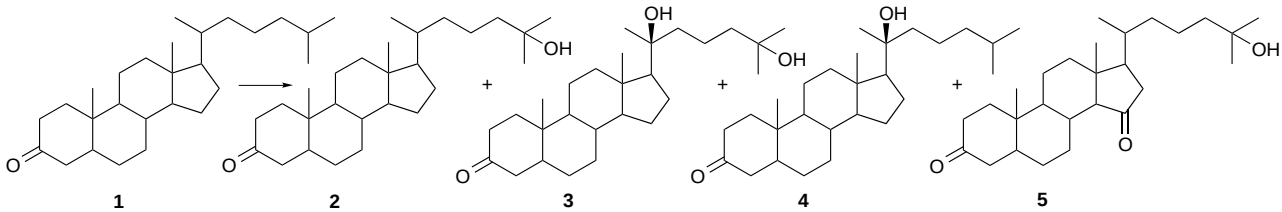

**Fig. 2** Molecular structure of (20*S*)-20,25-dihydroxycholestan-3-one **3**

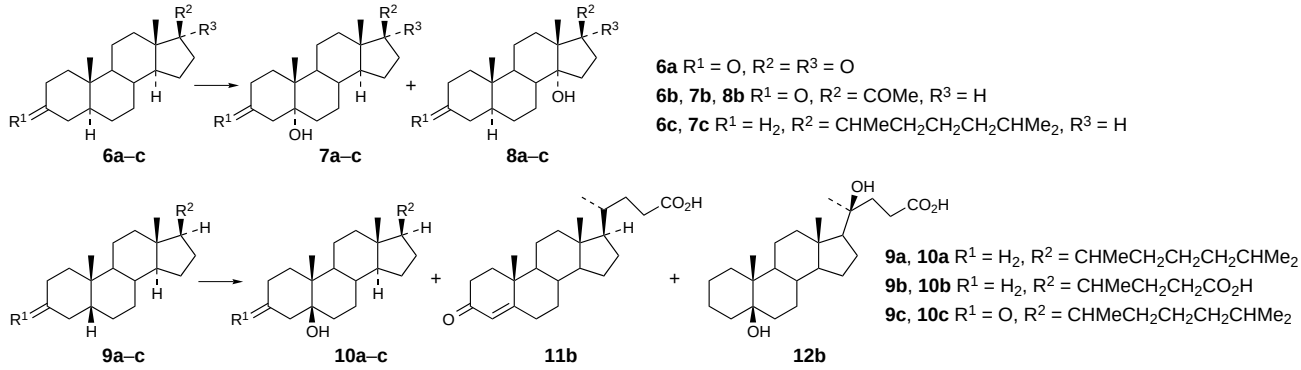
The position of the hydroxy function of **4** and **5** was similarly identified. The location of the carbonyl function of **5** was supported by 2D NMR experiments ($^1$H-$^1$H and $^{13}$C-$^1$H shift correlation). From the results shown in Table 1 it can be suggested that the regioselectivity in the oxidation of **1** depends markedly upon the structure of the porphyrin. Because ruthenium porphyrins which have *o*-substituents on the aromatic ring at the *meso*-position showed higher reactivity than those which had no substituent (runs 2 and 3 *vs*. run 1), the regioselectivity may be influenced by changes in reactivity caused by steric hindrance arising from the *o*-substituents on the aromatic ring at the *meso*-position. Furthermore, Ru(TMP)CO has a different regioselectivity from Ru(TDClPP)CO, although the methyl group is as bulky as the chloride group (runs 2 and 3). This implies that variation of electron density caused by electron-donating or -withdrawing substituents on the aromatic ring at the *meso*-position is also important. Therefore, it can be assumed that the regioselectivity depends upon both the steric and electronic effects of the substituents.

Several other 5α-steroids were treated with this system (Scheme 2). As shown in Table 1, 5α-androstan-3,17-dione **6a** was not oxidized under these conditions and was recovered in 91% yield (run 4). 5α-Pregnan-3,20-dione **6b** was oxidized to afford the 5α- and 14α-hydroxy derivatives, **7b** and **8b**, respectively, in 18 and 6% yields, respectively (run 5). 5α-Cholestane **6c** was also oxidized in 73% yield and the 5α-hydroxy derivative **7c** was isolated in 28% yield (run 6). It



**Scheme 1** Oxidation of 5α-cholestan-3-one **1** with the ruthenium porphyrin-2,6-dichloropyridine *N*-oxide system

**Table 1** Oxidation of steroids with the ruthenium porphyrin-2,6-dichloropyridine *N*-oxide system[a]

| Run | Substrate | Catalyst | Products (yield %) | | | |
|---|---|---|---|---|---|---|
| 1[b] | **1** | Ru(TPP)CO | **2** (11%) | | | |
| 2 | **1** | Ru(TDClPP)CO | **2** (25%) | **3** (19%) | **4** (6%) | |
| 3[c] | **1** | Ru(TMP)CO | **2** (26%) | | **4** (7%) | **5** (12%) |
| 4 | **6a** | Ru(TMP)CO | None | | | |
| 5 | **6b** | Ru(TMP)CO | **7b** (18%) | **8b** (4%) | | |
| 6 | **6c** | Ru(TMP)CO | **7c** (28%) | | | |
| 7 | **6c** | Ru(TMP)CO | **7c** (14%)[d] | | | |
| 8 | **9a** | Ru(TMP)CO | **10c** (64%)[d] | | | |
| 9 | **9b** | Ru(TMP)CO | **10b** (70%) | **11b** (8%) | **12b** (4%) | |
| 10 | **9c** | Ru(TMP)CO | **10c** (42%) | | | |

[a] Reaction conditions: substrate (1 mmol), Ru(porphyrin) (2 μmol), 2,6-dichloropyridine *N*-oxide (3 mmol), 47% HBr (10 μl); molecular sieves 4 Å (150 mg) and benzene (6 ml) at 40 °C under an Ar atmosphere overnight. Yields are based on the substrate used. [b] 0.5 μmol of Ru(TPP)CO was used. [c] 4.5 mmol of 2,6-dichloropyridine *N*-oxide was used. [d] 1.2 mmol of 2,6-dichloropyridine *N*-oxide was used. The yields of **7c** and **10a** were determined by GLC.

**Scheme 2** Oxidation of 5α- and 5β-steroids with the ruthenium porphyrin-2,6-dichloropyridine *N*-oxide system

appears that substrates are oxidized at tertiary carbons in this system.

On the other hand, 5β-steroids were oxidized to the corresponding 5β-hydroxy derivatives in a good yield (Scheme 2). 5β-Cholestane **9a** afforded **10a** in 64% yield (run 8). In contrast, 5α-cholestane **6c** under the same conditions afforded **7c** in 14% yield (run 7). Both **6c** and **9a** were hydroxylated with retention of configuration. It is assumed that this difference in reactivity at the 5-position is due to the difference in steric hindrance of hydrogen at the 5-position. 5β-Cholan-24-oic acid **9b** afforded **10b**, **11b** and **12b**, and **10b** was obtained with the best yield in this report (70%). Since **10b** was oxidized to **11b** with this system, it is assumed that **10b** was an intermediate in the formation of **11b**. The identification of **12b** as a novel steroid was based on $^1$H and $^{13}$C NMR spectra, mass spectra and IR analysis. Compared with **9a** and **9b**, 5β-cholestan-3-one **9c** was less reactive (run 10), so the carbonyl function appears to reduce the reactivity in its vicinity in this oxidation system.

Oxidation of estrogens was also examined. 3-Hydroxyestra-1,3,5(10)-trien-17-one (estrone: **13**) was converted to a mixture of oxidized products which could not be separated. However, estrone methyl ether **14** afforded the 6-keto derivative **15** in 21% yield.

We have shown that the ruthenium porphyrin–2,6-dichloropyridine *N*-oxide system oxidizes steroids with retention of the configuration of the asymmetric centres. This is a critical feature for the synthesis of optically active compounds, so this system could have synthetic applications. It showed moderate regioselectivity in the oxidation of steroids. Since hydroxylation at the 20 and 25 positions is observed when cholesterol and vitamin $D_3$ are metabolized to progesterone[6] and 25-hydroxy vitamin $D_3$[7] *in vivo* by P450, respectively, our system could be useful for research on steroid metabolites. Moreover, four novel steroids were obtained with our oxidizing system. Because the regioselectivity depended markedly upon the structure of the porphyrin, further modification of the porphyrin may afford new oxidized steroids, which could provide clues to novel metabolic pathways *in vivo*.

This work was supported by a Grant-in-Aid for Scientific research from the Ministry of Education, Science, Sports and Culture, Japan.

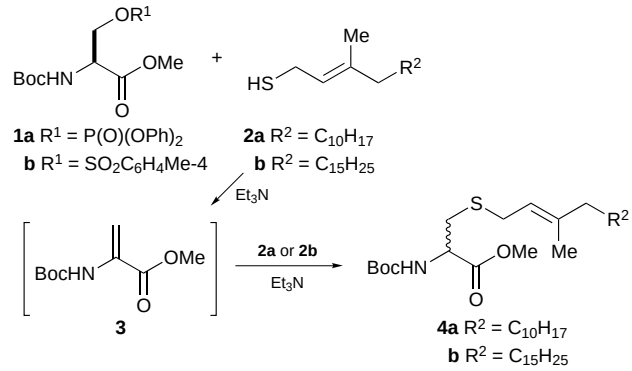
# Synthesis of prenylated cysteines from serine derivatives

**William W. Epstein*† and Zhaolin Wang**

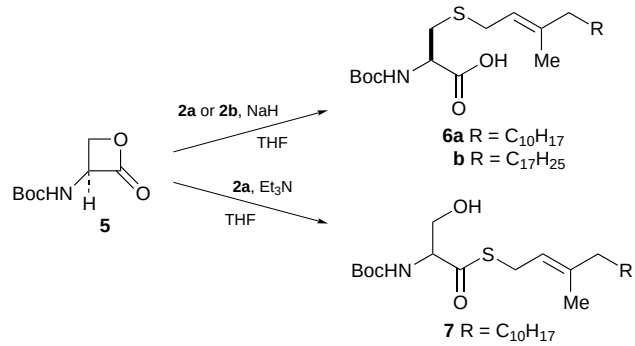
*Department of Chemistry, University of Utah, Salt Lake City, Utah 84112, USA*

**Prenylated cysteines are prepared by the reaction of serine β-lactone with prenyl thiolate.**



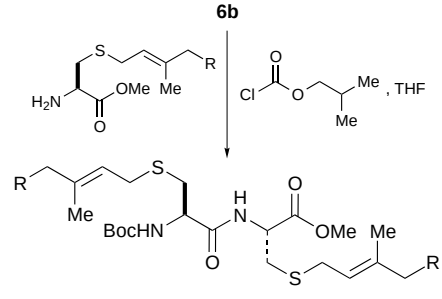
Prenylation, a recently discovered post-translational modification of proteins, has become a topic of substantial interest.[1–5] Prenylation involves covalent attachment of either farnesyl ($C_{15}$) or geranylgeranyl ($C_{20}$) isoprenoids to conserved carboxy-terminal cysteine residues by a family of prenyltransferase enzymes. Three types of carboxy-terminal cysteine sequences are substrates for this modification. The major class of these proteins has a CAAX motif (where C is a cysteine, A is usually an aliphatic amino acid and X is an amino acid that determines whether a protein is farnesylated or geranylgeranylated). The second and third types of proteins have CXC or CC motifs, respectively, in which both cysteines are geranylgeranylated. Subsequent to prenylation, proteins containing the CAAX motif are further processed by proteolytic removal of the three terminal amino acids (AAX) followed by methylation of the prenylcysteine carboxy group. Prenylation is common for many physiologically important proteins. Since oncogenic forms of Ras proteins require farnesylation for their ability to transform cells, inhibition of farnesylation has become a very attractive target for anti-cancer drug design.

Since Kamiya *et al.*[6] first synthesized farnesylcysteine, several methods for the preparation of prenylated cysteines and peptides have been reported.[7–9] These methods are based on alkylation of the sulfhydryl group of cysteine with prenyl halides. Despite the success achieved, there are two potential problems for prenylation of cysteine by this alkylation approach. Since basic conditions are generally required, free amino, hydroxy and carboxylate moieties, and especially other sulfide anions, are potential competing nucleophiles which can lead to major side reactions. The second and less important problem is that the required allylic prenyl halides are hard to purify. These potential difficulties led us to explore a new route to prenylated cysteines. Here we report a method for the synthesis of prenylated cysteines from a suitable serine precursor.



Our initial synthetic plan was based on activation of the serine hydroxy group and subsequent displacement with a prenyl thiol. *N*-Boc-*O*-diphenylphosphoryl-L-serine methyl ester **1a** and *N*- Boc-*O*-tosyl-L-serine methyl ester **1b** were prepared from Boc-L-serine methyl ester. The required prenyl thiols **2a** and **2b** were prepared from the $C_{15}$ and $C_{20}$ prenyl chlorides.[10] The low yields and lack of regiospecificity in the preparation of $C_{15}$ and $C_{20}$ prenyl halides were circumvented by using the method of Collington and Meyers.[11] Treatment of serine derivatives **1a** and **1b** with prenyl thiol **2a‡ or** 2b in the presence of triethylamine yielded racemic prenylated cysteine **4§** (Scheme 1). The isolation of **3** suggested to us that β-elimination may be the initial step of the reaction followed by Michael addition of the anion of **2a** or **2b** to the α,β-unsaturated substrate **3** to give the observed racemic mixture.

In order to avoid the above stereochemical problems, we turned to an alternative sequence. The synthetic methodology developed by Arnold *et al.*[12] for the preparation of β-substituted alanines and their derivatives seemed applicable to our problem. Thus we undertook the synthesis of prenylated cysteines by the stereospecific opening of serine β-lactone with prenyl thiols. The serine β-lactone **5** was prepared by reaction of Boc-serine with triphenylphosphine and diethyl azodicarboxylate (DEAD).[12]



Although there are two possible ways of opening the β-lactone as shown in Scheme 2,[13] alkyl–oxygen cleavage occurred when farnesyl thiolate, prepared by the reaction of farnesyl thiol with sodium hydride, was used to give the desired stereochemically pure prenylated cysteines **6a¶** and **6b** in 52–60% yield. It should be noted that acyl–oxygen fission occurred when triethylamine was used as the base to give thioester **7** as the major product (61%). With **6b** in hand, the dipeptide **9‖** with two geranylgeranylated cysteines was pre-

**Scheme 1**

**Scheme 2**

**Scheme 3**

pared by coupling of **5b** with geranylgeranylated cysteine methyl ester **8** *via* the mixed anhydrides method.[14] Dipeptide **9** may serve as an important model compound to study geranylgeranylated Rab proteins.[2]

In summary we have described a practical and novel route to stereospecifically synthesize prenylated cysteines from serine β-lactone. The optical purity and simplicity of this approach to prenylated cysteines are attractive features compared with previous methods.[8]

# Synthesis of tricarbonylchromium(0) complexes of benzylic halides

**Susan E. Gibson (née Thomas)* and Gavin A. Schmid†**

*Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London, UK SW7 2AY*

**Addition of $BX_3$ (X = Br, I, Cl) to tricarbonylchromium(0) complexes of benzylic alcohols and ethers provides tricarbonylchromium(0) complexes of benzylic halides in excellent yield (90–99%).**

(Arene)tricarbonylchromium(0) complexes have been widely applied in organic, organometallic and materials synthesis over the last thirty years and as a result complexes containing most organic functional groups have been synthesised and characterised.[1] Against this background it is perhaps surprising to find that tricarbonylchromium(0) complexes of benzylic halides are rarely mentioned in the literature. For example, the tricarbonylchromium(0) complex of benzyl bromide is to date unreported, the benzyl iodide complex is mentioned in just one study,‡ and the benzyl chloride complex is found in a mere handful of papers.[3]

The under-representation of benzylic halides in (arene)tricarbonylchromium(0) chemistry may be attributed to difficulties with their preparation. Reacting benzylic bromides, iodides and chlorides with even a labile source of tricarbonylchromium(0) such as $[(CO)_3(NH_3)_3Cr^0]$ under relatively mild conditions leads to insertion of the chromium(0) into the benzylic halide bonds, reductive coupling and the production of 1,2-diarylethanes rather than formation of $\eta^6$-arene complexes.[4] And whilst addition of HCl to (benzyl alcohol)tricarbonylchromium(0) gives (benzyl chloride)tricarbonylchromium(0) in acceptable yield (31–74%)[3] and has thus enabled this complex to be used in both mechanistic studies[3a] and in the synthesis of several heterobimetallic species,[3b–d] the corresponding reactions with HBr and HI are unreported.§

In view of the under-utilisation to date of tricarbonylchromium(0) complexes of benzylic bromides and iodides due to the perceived difficulties associated with their preparation, we report herein our recent discovery that tricarbonylchromium(0) complexes of benzylic halides are readily prepared in excellent yield by treatment of readily available tricarbonylchromium(0) complexes of either benzylic alcohols or benzylic ethers with the appropriate boron trihalide.

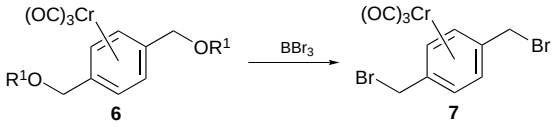
(Benzyl alcohol)tricarbonylchromium(0) **1a**[5] was prepared from benzyl alcohol and hexacarbonylchromium(0) (69%). Addition of two equivalents of $BBr_3$ to a suspension of **1a** in $CH_2Cl_2$ at −78 °C gave a brown–yellow solution which was stirred for 1 h at −78 °C and then quenched with aqueous $NaHCO_3$ [eqn. (1)]. Subsequent work-up gave a yellow solid

**1a–d** **2–5** (1)

which was identified as the novel tricarbonylchromium(0) complex of benzyl bromide **2** on the basis of its spectroscopic and microanalytical data (Table 1, entry 1).¶ Encouraged by the excellent yield obtained for this reaction (99%), the reaction of the benzyl alcohol complex **1a** was performed under identical conditions with $BI_3$ and $BCl_3$. These gave, respectively, the novel benzyl iodide complex **3**¶ in 99% yield and the previously reported[3] but as yet not fully characterised benzyl chloride complex **4**¶ also in 99% yield (Table 1, entries 2 and 3).

Tricarbonylchromium(0) complexes of benzylic ethers are easily synthesised and commonly used as intermediates in (arene)tricarbonylchromium(0) chemistry.[6] In order to ascertain whether or not these complexes may be regarded as precursors to benzylic halide complexes, the methyl and ethyl ether complexes **1b**[7] and **1c**[7] were synthesised by treatment of the alcohol complex **1a** with MeOH and EtOH, respectively, in the presence of $H_2SO_4$ (83 and 89% yield, respectively). Reaction of the methyl ether complex **1b** with $BBr_3$, $BI_3$ and $BCl_3$ and the ethyl ether complex **1c** with $BBr_3$ gave the corresponding benzyl halide complexes **2**–**4** in excellent yields (99–99%) (Table 1, entries 4–7). [It is worthy of comment at this point that reaction of the methyl ether complex **1b** with $BF_3$ failed to produce the corresponding benzyl fluoride complex. A related transformation has been reported recently, however, using cyclic benzylic alcohol complexes and the powerful fluoride source diethylaminosulfur trifluoride (DAST).[8]]

In order to test the effect of substitution at the benzylic centre, the secondary and tertiary benzylic ether complexes **1d** and **1e** were synthesised by Bu$^t$Li-promoted deprotonation of the methyl ether complex **1b** followed by quenching with iodomethane to give **1d**[9] (93%), and then Bu$^t$Li-promoted deprotonation of **1d** and quenching with iodoethane to give the novel complex **1e** (70%). Whilst treatment of **1d** with $BBr_3$ gave an excellent yield of the corresponding novel bromide **5** (99%) indicating that secondary benzylic halide complexes may be synthesised by this approach (Table 1, entry 8), reaction of **1e** with $BBr_3$ resulted in elimination and the production of an α,β-dimethylstyrene complex in significant yield (70%) (Table 1, entry 9).



Finally, in order to test whether or not difunctionalised complexes may be accessed by boron trihalide treatment of alcohols and ethers, the novel dimethyl ether complex **6** was

**Table 1** Reaction of benzylic alcohol and ether complexes **1a**–**e** and **6** with boron trihalides to give benzylic halide complexes **2**–**5** and **7**[a]

| Entry | Substrate | $R^1$ | $R^2$ | $R^3$ | $BX_3$ | Product | $R^2$ | $R^3$ | X | Yield (%) |
|---|---|---|---|---|---|---|---|---|---|---|
| 1 | **1a** | H | H | H | $BBr_3$ | **2** | H | H | Br | 99 |
| 2 | **1a** | H | H | H | $BI_3$ | **3** | H | H | I | 99 |
| 3 | **1a** | H | H | H | $BCl_3$ | **4** | H | H | Cl | 99 |
| 4 | **1b** | Me | H | H | $BBr_3$ | **2** | H | H | Br | 95 |
| 5 | **1b** | Me | H | H | $BI_3$ | **3** | H | H | I | 99 |
| 6 | **1b** | Me | H | H | $BCl_3$ | **4** | H | H | Cl | 97 |
| 7 | **1c** | Et | H | H | $BBr_3$ | **2** | H | H | Br | 90 |
| 8 | **1d** | Me | Me | H | $BBr_3$ | **5** | Me | H | Br | 99 |
| 9 | **1e** | Me | Me | Et | $BBr_3$ | — | — | — | — | —[b] |
| 10 | **6** | Me | — | — | $BBr_3$ | **7** | — | — | Br | 95 |

[a] The experimental procedure for the synthesis of **2** from **1a** is typical: $BBr_3$ (1 M in $CH_2Cl_2$, 2 cm$^3$, 2 mmol) was added to a suspension of **1a** (0.244 g, 1.00 mmol) in $CH_2Cl_2$ (20 cm$^3$) at −78 °C. The resulting brown–yellow solution was stirred at −78 °C for 1 h and then quenched with sat. aq. $NaHCO_3$ (10 cm$^3$). The product mixture was allowed to warm to room temperature and then $H_2O$ (10 cm$^3$) was added before extracting the organic phase with diethyl ether (40 cm$^3$ and 20 cm$^3$). The organic phase was dried ($MgSO_4$), filtered through Celite and concentrated *in vacuo* to give complex **2** as a yellow solid (0.304 g, 99%). [b] Reaction of **1e** with $BBr_3$ resulted in elimination and the production of an α,β-dimethylstyrene complex (70%).

synthesised by methylation of 1,4-benzenedimethanol (NaH–MeI; 50%) and subsequent complexation [$(CO)_6Cr^0$; 85%]. Addition of $BBr_3$ to **6** [eqn. (2)] gave the novel dibromide

**6** **7** (2)

complex **7** in 95% yield (Table 1, entry 10).

# Hydro(solvo)thermal synthesis and structure of a three-dimensional zinc fluorophosphate: $Zn_2(4,4'\text{-bipy})(PO_3F)_2$

**P. Shiv Halasyamani, Mark J. Drewitt and Dermot O'Hare*†**

*Inorganic Chemistry Laboratory, Oxford University, South Parks Road, Oxford, UK OX1 3QR*

**A new three-dimensional zinc fluorophosphate is prepared by using hydro(solvo)thermal conditions with ZnO, $(HF)_x$·py $H_3PO_4$ and 4,4′-bipyridyl; the single-crystal structure is determined.**

Meso- and micro-porous materials are of great industrial and academic interest due to their catalytic, adsorbent, and ion-exchange properties.[1–3] A three-dimensional open framework, with uniform pores, channels and active catalytic sites, facilitates and enhances these properties. One class of these open-framework materials are transition-metal phosphates.[3–5] Various examples with metals such as V,[6] Fe,[7] Co,[8] and Mo,[3] have recently been synthesised and characterised. In contrast to the closed-shell aluminosilicates, these new materials are potential candidates for atom abstraction and redox catalysis. Many of these metal phosphates were synthesised under hydro(solvo)thermal conditions with organic templating agents.

Recently, $(HF)_x$·py [pyridinium poly(hydrogen fluoride), 70% HF by mass] has been utilised to synthesise a variety of new mixed-metal materials.[9–11] The fluoride ion not only acts as a mineralizer, but also participates in the formation and structure of the final compound. Ferey[12] used fluoride in the synthesis of new fluorinated gallophosphates, and determined that temperature, pressure, time, pH, concentration of reactants, and the nature of the template all influence the existence and nature of the microporous phases. It is our aim to synthesise new microporous fluorinated phosphate materials, and in doing so synthesise open-framework compounds with fluoride channels. Here we report the hydro(solvo)thermal synthesis and crystal structure of a new zinc fluorophosphate.

Open-framework zinc phosphates have been prepared previously by mixing $Zn(NO_3)_2$, $H_3PO_4$ and alkaline base, which is then heated for several days at 70 °C. Using this method, analogues of sodalite, $Na_6(H_2O)_8(ZnPO_4)_6$ and zeolite Li–A(BW), $Li_4Zn_4P_4O_{16}$·$4H_2O$ have been synthesized.[5] Within the metal–$PO_3F^{2-}$ system compounds with Ni,[13] Sn,[14] Co,[15] Cu[16] and Zn,[17] have been reported. $Ni(H_2O)_6(NH_4)_2(PO_3F)_2$[13] and $SnPO_3F$[14] are molecular solids with isolated anions and cations, whereas $ZnPO_3F$·2.5 $H_2O$[17] contains both tetrahedrally and octahedrally coordinated $Zn^{2+}$, with the tetrahedral $Zn^{2+}$ coordinated to two oxygens and the fluorophosphate.

$Zn_2(4,4'\text{-bipy})(PO_3F)_2$ was synthesised by heating ZnO, $(HF)_x$·py, 85% $H_3PO_4$ and 4,4′-bipy in a 23 ml Teflon lined Parr autoclave at 180 °C.‡ It crystallises as clear colourless faceted crystals in 9% yield. The single-crystal X-ray structure determination indicates that it is a three-dimensional structure containing layers of zinc fluorophosphate moieties connected by 4,4′-bipy ligands (Fig. 1). Each zinc is tetrahedrally coordinated, bonded to three oxygens [Zn–O (av.) 1.927(3) Å] and one nitrogen [Zn–N 2.020(3) Å]. Each oxygen on the zinc is linked to a phosphorus, whereas the 4,4′-bipy ligands bridge the $Zn^{2+}$ cations in adjacent layers [$Zn^{2+}\cdots Zn^{2+}$ 11.100(1) Å]. The 4,4′-bipy ligand is not planar, rather the rings are twisted at an angle of 15.3(3)°. The fluorophosphate group, $PO_3F^{2-}$, contains tetrahedrally coordinated $P^{5+}$. Each phosphorus is linked to three oxygens [P–O(av.) 1.501(2) Å], that bridge to the $Zn^{2+}$, and a terminal fluoride [P–F(av.) 1.568(2) Å]. In terms of connectivity, the compound can be formulated as $PO_{3/2}F_{1/1}^{+}$ cations linked to $Zn(4,4'\text{-bipy})_{1/2}O_{3/2}^{-}$ anions. Similarly to $CoPO_3F$·$3H_2O$[15] and $CuPO_3F$·$2H_2O$[16] the fluorophosphate groups in $Zn_2(4,4'\text{-bipy})(PO_3F)_2$ bridge the metal exclusively through oxygen, whereas the fluorine atom is always monodentate. The bond distances and angles in $PO_3F^{2-}$ in the reported structure are in excellent agreement with those previously reported. An interesting feature of $Zn_2(4,4'\text{-bipy})(PO_3F)_2$ is the fluoride channel (Fig. 2). The size of this channel is a direct consequence of the Zn–(4,4′-bipy)–Zn linkage. The effect of the 4,4′-bipy ligand is twofold. First, it completes the $Zn^{2+}$ tetrahedra by inhibiting coordination to $F^-$, and second it increases the distance between the $Zn^{2+}$ and produces the observed channel. Experiments are currently in progress to

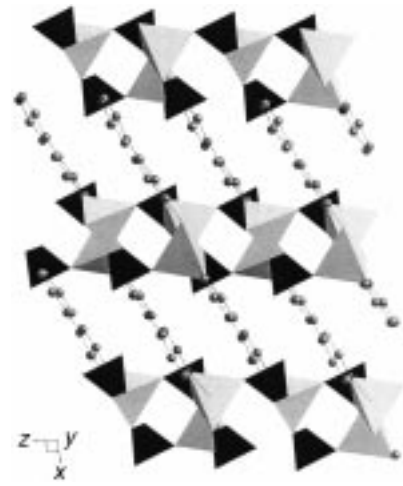

**Fig. 1** View of the single-crystal structure of $Zn_2(4,4'\text{-bipy})(PO_3F)_2$ along the crystallographic 010 direction

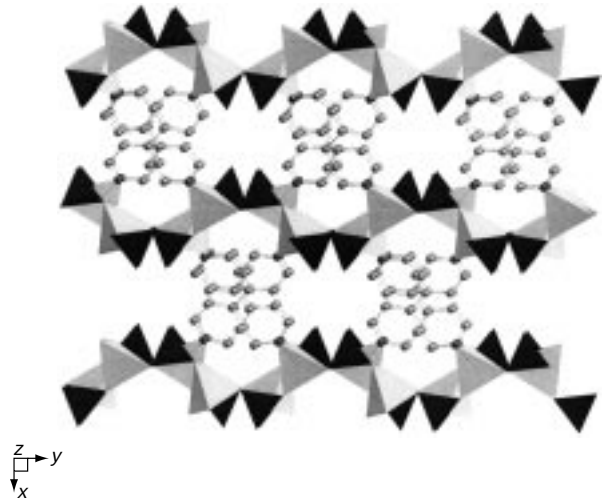

**Fig. 2** View of the single-crystal structure of $Zn_2(4,4'\text{-bipy})(PO_3F)_2$ along the crystallograpic 001 direction

increase this channel by using 1,4-bis(4-pyridyl)benzene and 1,4-bis(4-pyridylethenyl)benzene[18] as bridging ligands.

† D. O'Hare is the Royal Society of Chemistry Sir Edward Frankland Fellow.
‡ *Synthesis*: $Zn_2(4,4'\text{-bipy})(PO_3F)_2$ was synthesised by adding 0.048 g ZnO, 0.51 g $(HF)_x{\cdot}py$, 0.40 g 85% $H_3PO_4$ and 0.5 g 4,4′-bipy to a 23 ml Teflon lined Parr autoclave. The autoclave was sealed and heated under static conditions for 12 h at 180 °C. To facilitate crystal growth, the reaction was cooled to room temp. over 2 h (starting $Zn : (HF)_x{\cdot}py : H_3PO_4 : 4,4'\text{-bipy}$ ratio 1 : 3.16 : 6.67 : 5.33). The product was filtered and thoroughly washed with acetone to remove recrystallised 4,4′-bipy. $Zn_2(4,4'\text{-bipy})(PO_3F)_2$ was recovered as clear colourless faceted crystals in 9% yield (0.025 g) based on ZnO. Elemental analysis, using the combustion method gave satisfactory C,H, and N values. The IR spectrum revealed P–F bands centred at 833 and 726 $cm^{-1}$ consistent with known phases.[16]

§ *Crystal data*: monoclinic, space group $P2_1/c$, $a$ = 17.996(9), $b$ = 9.813(2), $c$ = 8.229(4) Å, β = 99.727(2)°, $U$ = 1432.3(3) $Å^3$, $Z$ = 4, $D_c$ = 2.24 g $cm^{-3}$, μ = 37.1 $cm^{-1}$, crystal size *ca.* 0.40 × 0.21 × 0.19 mm, 15 188 total (2969 independent) reflections, $R$ = 0.031 and $R_w$ = 0.030 for 2112 reflections with $I > 5\sigma(I)$, max., min. peak in final Fourier difference map 0.54 and −0.68 e $Å^{-3}$ respectively. Data were collected on an image-plate Enraf-Nonius DIP 2000 diffractometer using graphite-monochromated Mo-Kα radiation at 150 K; 90 frames at a step of 2° yielded 15 188 reflections, $\theta_{max}$ = 26°. Corrections were made for Lorentz and polarisation effects.[19] The structure was solved by direct methods using SIR92[20] and refined using full-matrix least squares. Hydrogen atoms were fixed in geometrically idealised positions and allowed to ride on their attached carbon atoms with isotropic thermal parameters according to the atom to which they were connected (these were not refined). No correction was made for absorption. A Chebyshev weighting scheme[22] was applied in the refinement of the structure, the data corrected for the effects of anomalous dispersion and isotropic extinction (*via* an overall extinction parameter)[22] in the final stages of refinement. All crystallographic calculations were performed using the Oxford CRYSTALS system[23] running on a Silicon Graphics Indigo R4000 computer.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/418.

**The ESIMS technique, combined with $^1$H NMR evidence, provides a precise inventory of the catalytic Ti$^{IV}$ precursors and the characterization of the reactive peroxometal complex involved in enantioselective sulfoxidation employing the Ti$^{IV}$–homochiral trialkanolamine–alkylhydroperoxide system.**

In the field of titanium(IV) alkoxide mediated homogeneous enantioselective oxidation using alkyl hydroperoxides as oxygen donors,[1] excellent results have been obtained in the asymmetric epoxidation of allylic alcohols[2] and in the sulfoxidation of sulfur containing compounds.[3] Characterization of the active catalysts in many of these reactions is complicated by the tendency of the alkoxides to form mixtures of polynuclear species equilibrating in solution.[4] In all cases a chiral titanium $\eta^2$-alkylperoxo species has been postulated as the reactive intermediate.[5] In this respect, the solid-state structure of the achiral $\eta^2$-*tert*-butylperoxo titanatrane dimer, in which the peroxide moiety has an $\eta^2$ arrangement, is so far the only characterized titanium(IV) peroxo complex.[6]

We recently developed a highly robust titanium alkoxide catalyst[7] for the enantioselective oxidation of organic sulfides to sulfoxides.[8] Catalyst **2** is generated *in situ* by addition of a stoichiometric amount of the homochiral trialkanolamine **1**, to a $CHCl_3$ solution of $Ti(OPr^i)_4$ (Scheme 1, pathway *a*).[7,8]

Described here is the novel observation that the catalytically active polynuclear titanium(IV)-based species **4** forms from the interaction of **2** and excess of ligand **1** (Scheme 1, pathway *e*). Our results include electrospray ionization mass spectrometric (ESIMS) studies[9]† which, together with $^1$H NMR evidence, allow (*i*) identification of the components in **4**, (*ii*) delineation of their reactivity with oxygen nucleophiles and (*iii*) characterization of the monomeric chiral titanium(IV) peroxo species **3** arising from the interaction of **2** and **4** with Bu$^t$OOH (Scheme 1, pathway *b*).

**Scheme 1** *Reagents and conditions*: *a*, stoichiometric $Ti(OPr^i)_4$, $CHCl_3$, 20 °C; *b*, Bu$^t$OOH; *c*, Pr$^i$OH; *d*, $Ti(OPr^i)_4$ (0.75 equiv.), $CH_2Cl_2$, 20 °C, followed by solvent removal; *e*, excess of **1**

$^1$H NMR studies in $CDCl_3$ indicate that when a precise 1 : 1 ligand : titanium ratio is employed the discrete monomeric complex **2** is formed.‡ Further addition of **1** causes the progressive disappearance of the resonances of the apical isopropoxy ligand in **2** and the synchronous appearance of two broader signals indicating the formation of a mixture of aggregates.§ The room-temperature $^1$H NMR spectrum of **4b** shows broad resonances and the absence of isopropoxy signals.¶ At lower temperature (−20 °C) the system freezes out and a complicated spectrum of sharper signals is obtained, consistent with the presence of a steady composition of aggregates. In contrast, at 60 °C only three broad singlets are observed, each corresponding to a different set of protons. However, regardless of the amount of **1** in excess, addition of Bu$^t$OOH to the system always restores a simple $^1$H NMR spectrum consistent with the mononuclear *tert*-butylperoxotitanium species **3**.[8]

ESIMS analysis, which has already been applied successfully to the characterization of various polynuclear complexes,[9,10] allowed us to identify the diverse species present in solution.

The positive ion ESI mass spectrum of preformed catalyst **4a** using methanol as the mobile phase is shown in Fig. 1.

The most significant ions, whose structures have been assigned on the basis of MS/MS analysis and comparison between the theoretical and experimental cluster ion peaks, are indicated. The overall ESIMS spectrum of Fig. 1 shows the molecular peaks of the species originated in the equilibrium reactions involving the titanium centre and the oxygen nucleophiles available in solution, *i.e.* trialkanolamine **1a**, methanol and water, present in traces in the mobile phase. Interaction of **4a** with water, gives rise to ions **I** (*m/z* 254), **IV** (*m/z* 489) and **VII** (*m/z* 724) which are mono-, di- and tri-nuclear titanium containing species, respectively. Those ions show incorporation of $^{18}$O ($\geqslant$65%) when $H_2{}^{18}O$ is added to the mobile phase. The reaction of **4a** with methanol is responsible for the appearance of ions **II** (*m/z* 268) and **V** (*m/z* 503), whose mass peaks show an increment of four and three mass units, respectively, when $CD_3OD$ is used as the mobile phase. Multiple interaction of **1a** with Ti$^{IV}$ [11] affords species **VIII** (*m/z* 897) and the lower homologue ions **VI** (*m/z* 662) and **III** (*m/z* 427).‖ These latter ions were also observed in the positive-ion ESI mass spectrum collected for an acidic chloroform solution of **4a** *i.e.* under conditions similar to those employed in catalytic sulfoxidation.[8] Complexes **4b** and **4c** give analogous ESI mass spectra where the same reactivity pattern can be recognized.**

Additional support for the NMR results comes from the characterization of the protonated titanium(IV) peroxo complex **3a** (*m/z* 326), achieved by ESIMS[13] when an excess of *tert*-butylhydroperoxide was added to the mobile phase containing **4a**. The structure of the cluster ion peaks and the MS/MS analysis of the 326 mass peak (Fig. 2) are consistent with the

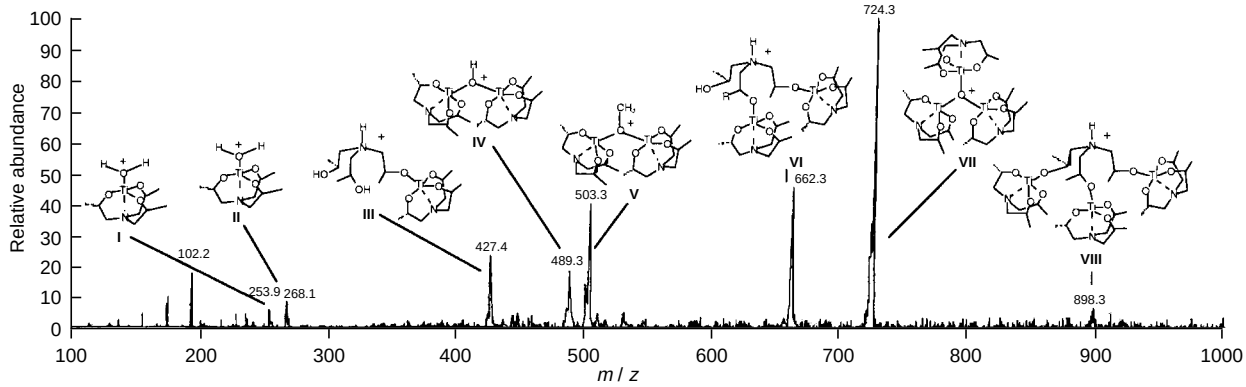

**Fig. 1** ESI mass spectrum of complex **2a** with peak assignments indicated

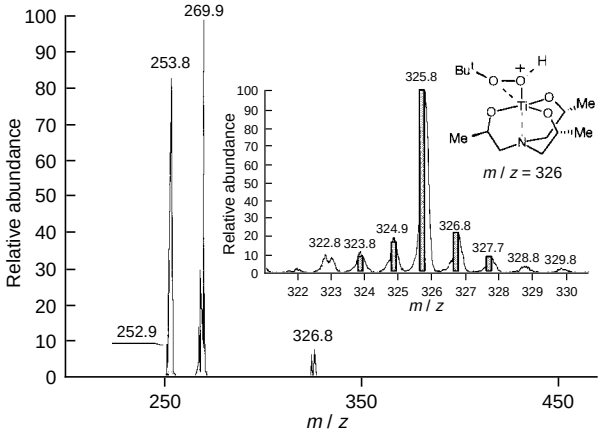

**Fig. 2** MS/MS fragment ions of the *m/z* 326 peak after collision induced dissociation. Calculated and observed isotope distribution patterns are shown in the inset.

monomeric character of the peroxometal complex **3a**.[8]†† Its fragmentation pattern (CID) occurs through the breaking of the O–Bu$^t$ bond (*m/z* 270, $M^+ - C_4H_8$) and of the peroxidic O–O bond yielding the water adduct, ion **I** (*m/z* 254, $M^+ - C_4H_8O$). The latter mode of decomposition is consistent with the proposed O–O bond scission during catalytic sulfoxidation.

ESIMS allowed also the characterization of the achiral peroxometal complex **3c** (*m/z* 284),‡‡ which, under the conditions employed, appears as a monomeric species.[6]

In conclusion, ESIMS allowed us to confirm the identity of the chiral peroxidic intermediate **3a** and that of the achiral analogue **3c**, both of which are monomeric complexes. Moreover, titanium(IV) aggregates with ligand-controlled architecture were identified, which react with *tert*-butylhydroperoxide yielding **3**. The fact that several highly labile and reactive metal complexes survive the conditions of the electrospray experiments bodes well for the extension of this approach to other early transition-metal alkoxide catalysts.

Grateful thanks are due to Dr Mahmoud Hamdan, Glaxo Wellcome, Verona, Italy, for useful discussions. Financial supports by 'Progetto Strategico: Tecnologie Chimiche Innovative' of CNR, MURST and INTAS Association (grant 94-1515) are gratefully acknowledged.

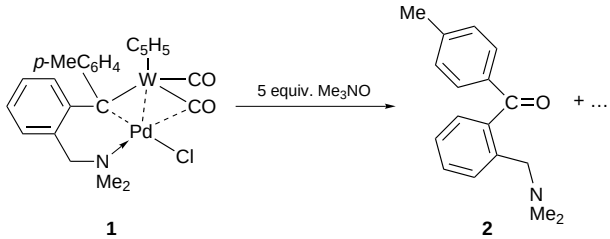
# Stepwise oxidation of a μ-alkylidene palladium–tungsten compound

**Philippus F. Engel,[a] Michel Pfeffer,*[a] André De Cian[b] and Jean Fischer[b]**

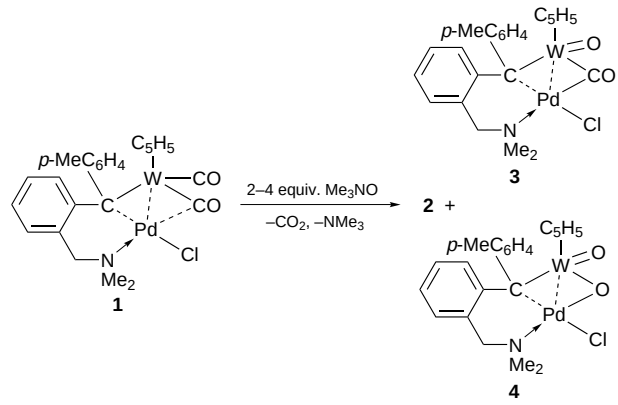
[a] *Laboratoire de Synthèses Métallo-induites, Université Louis Pasteur, 4, rue Blaise Pascal, F-67070 Strasbourg Cedex, France*
[b] *Laboratoire de Cristallochimie (URA 424 du CNRS), Université Louis Pasteur, 4, rue Blaise Pascal, F-67070 Strasbourg Cedex, France*



**The μ-alkylidene unit of a tungsten–palladium compound is oxidized to the corresponding ketone in the presence of an excess of $Me_3NO$, whereas with 2–4 equiv., mono- and di-oxotungsten derivatives, which are likely intermediates in the formation of the ketone, are instead obtained.**

We have recently established a novel synthetic route to μ-alkylidene complexes of palladium and tungsten of molybdenum, in which the carbon atom bridging the two metals has been synthesized through the formal insertion of tungsta- or molybda-alkylidyne units into the Pd–C bonds of cyclopalladated compounds.[1] The structural and spectral data of the complexes we have reported, make it difficult to rationalise the exact nature of the Pd(μ-C)W or Pd(μ-C)Mo bonds, or to assess the importance of the metal–metal interaction. We thus hoped that reactivity studies will allow us to gain a better understanding of the structure of these species. So far, despite the large number of related bimetallic compounds reported in the literature,[2] very few reactivity studies have been performed with them.[3] It is thus of real interest to evaluate their potential in synthetic chemistry.

We have shown recently that whereas the terminal carbonyl ligand can be readily displaced by *tert*-butyl isocyanide,[4] the other carbonyl group of these compounds, which is semibridging to the palladium atom, seemed to be much more strongly bonded to the tungsten or molybdenum atom. In order to labilize this CO ligand with the hope to obtain more reactive species, we treated the palladium–tungsten derivative with an excess of trimethylamine oxide (TAO). Thus, addition of TAO to a solution of complex **1** in dichloromethane induces $CO_2$ evolution and a change from orange to black–yellow. A mixture of several products can be obtained, depending on the quantity of TAO employed.



When ⩾5 equiv. of TAO was used, the reaction is most selective, and from the black residue obtained, the ketone O=C(4-$MeC_6H_4$)(2-$C_6H_4CH_2NMe_2$) **2** can be extracted as an orange–yellow oil in 77% yield (Scheme 1).†

Thus, the reaction between **1** and an excess of TAO leads to a breakdown of the μ-alkylidene geometry and the bridging carbene fragment is oxidized and liberated as a ketone. The remaining metal complexes have not yet been characterized. However further information on the reaction pathway that is followed by the reaction has been obtained by analysis of the reaction products of incomplete reactions. As noted above, the reaction between **1** and TAO usually leads to a mixture of products, in which the ketone **2** may be found. When < 5 equiv. of TAO is used in the reaction with **1** in dichloromethane, a similar gas evolution and colour change are observed, but novel metal complexes whose structures are related to that of **1** can be isolated.

**Scheme 1**

2–4 Equiv. of TAO react with **1** in dichloromethane to afford one major product, which has been identified as the novel oxo complex [{(η-$C_5H_5$)(O)(μ-CO)W}{μ-C(4-$MeC_6H_4$)(2-$C_6H_4CH_2NMe_2$)PdCl] **3** in low yield (21%, Scheme 2).† The structure of **3** has been established by an X-ray diffraction study,‡ and an ORTEP diagram is shown in Fig. 1. A complex similar to **3** which, however, was only obtained in trace amounts

**Scheme 2**

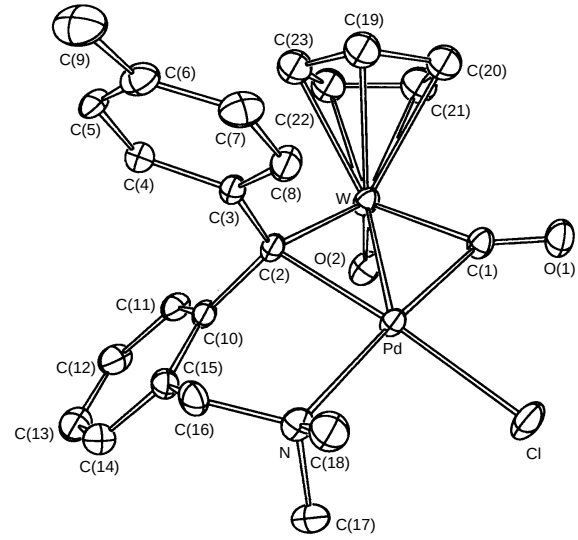


**Fig. 1** ORTEP diagram of **3** with atom labelling scheme (50% ellipsoids). Hydrogen atoms have been omitted for clarity. Bond distances (Å) and angles (°): Pd–Cl 2.409(2), Pd–C(2) 2.142(6), Pd–C(1) 2.009(7), Pd–N 2.268(6), Pd···W 2.6939(6), W–C(1) 2.075(7), W–O(2) 1.694(5), W–C(2) 2.074(6), Cl–Pd–C(2) 175.9(2), C(1)–Pd–C(2) 96.6(3), N–Pd–C(1) 174.2(2), C(2)–W–O(2) 107.2(2), C(1)–W–O(2) 101.2(3), W–C(1)–O(1) 146.6(6), Pd–C(1)–O(1) 130.8(5).

could be separated from **3** by column chromatography, and has also been characterized by an X-ray structure analysis, as the dioxo complex [{(η-$C_5H_5$)(O)(μ-O)W}{μ-C(4-$MeC_6H_4$)(2-$C_6H_4CH_2NMe_2$)}PdCl] **4** (Scheme 2). Attempts to obtain complex **4** in better yields have not been successful so far, and as a result, complex **4** has only been partially characterized.† An X-ray diffraction study‡ could however be carried out on a crystal of complex **4**, and the ORTEP diagram is shown in Fig. 2, together with selected interatomic distances and angles.

The most remarkable feature of the structures of compounds **3** and **4** is their similarity, as far as the interactions within the palladium–tungsten–alkylidene units are concerned, with those of compounds analogous to the starting material **1**, or of the related compound obtained with *tert*-butyl isocyanide[4] even though in these derivatives many fragments of the molecules are different. Thus, in both compounds **3** and **4**, the palladium atom is in close interaction with three atoms of the tungstaalkylidene unit, *i.e.* the tungsten atom, the alkylidene carbon and the C atom of the carbonyl C(1)O(1) or the O(1) atom in **3** and **4**, respectively. The W–C(2) and W–C(1) bond lengths in **3** and **4**, respectively, are close to that expected for tungsten–alkylidene units; in fact they are notably shorter than the corresponding distance in a compound analogous to **1** [2.158(4) Å],[1] in [$(OC)_5W{=}CPh_2$] [2.14(2) Å][5] or in a dimetallacyclopropene compound [$(CO)_5W$(μ-C(OMe)Ph}$Pt(PMe_3)_2$] [2.48(1) Å].[6] The tungsten–oxygen distances are in accord for W=O bonds.[7]

The behaviour of compound **1** towards a moderate oxidant such as $Me_3NO$ leading to a ketone is akin to that of 'classical' monometallic Fischer-type metallacarbenes.[8] It appears thus that compounds related to **1** are most likely to be the result of the interaction of an anionic tungsten–carbene unit with a cationic Pd centre. This would lead to a bonding mode involving a covalent bond between Pd and C(1) in **3** and between Pd and O(1) in **4** together with a $\eta^2$-interaction between the W=C unit and Pd in both compounds which accounts *inter alia* for the short distances found between Pd and W in both compounds. The formation of **3** and **4** establish that the tungsten atom has been oxidised in a stepwise manner by TAO concomitantly with the oxidation of the CO groups to $CO_2$, prior to the oxidation of the alkylidene unit. Somewhat related oxoalkylidene–tungsten complexes have been synthesised recently following completely different routes.[9] The major information that can be drawn from this study is that it demonstrates that not only Fischer-type metallaalkylidene complexes interact with $Pd^{II}$ as in compounds of type **1**, but this can also be encountered with molybda- or tungsta-alkylidenes in which the metal has a +VI oxidation state as in Schrock-type carbene complexes. Further work which makes use of this result is under way.[10]

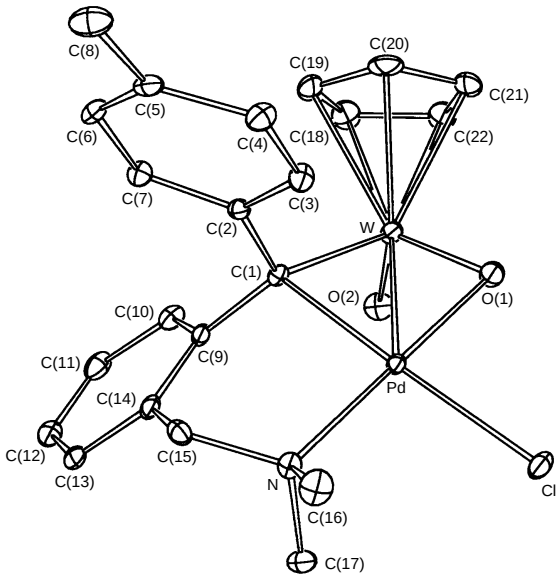

**Fig. 2** ORTEP diagram of **4** with atom labelling scheme (50% ellipsoids). Hydrogen atoms have been omitted for clarity. Bond distances (Å) and angles (°): Pd–Cl 2.395(1), Pd–N 2.121(4), Pd–C(1) 2.125(4), Pd···W 2.6753(4), Pd–O(1) 2.037(3), W–C(1) 2.100(4), W–O(1) 1.817(4), W–O(2) 1.712(4), N–Pd–O(1) 179.6(1), C(1)–Pd–O(1) 90.2(2), C(1)–W–O(1) 97.4(2), C(1)–W–O(2), O(1)–W–O(2) 107.9(2), W–O(1)–Pd 87.7(1).

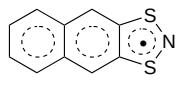
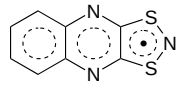
**In the solid state, at room temperature, the radicals 2,3-naphthalene-1,3,2-dithiazolyl (NDTA) and quinoxaline-1,3,2-dithiazolyl (QDTA) are not dimerized; discrete molecules of NDTA are packed in a herringbone fashion, while those of QDTA adopt a slipped π-stack motif; NDTA is essentially paramagnetic at ambient temperatures, with weak antiferromagnetism developing below 190 K; QDTA is diamagnetic at low temperature, but limited paramagnetism sets in above 120 K.**



While derivatives of the 1,3,2-dithiazolyl ring (DTA) have been known for well over a decade,[1,2] relatively little is known of their structural and transport properties. In the solid state the 4,5-dicyano derivative forms the simple cofacial dimer.[3] The pyrazine-based compound (PDTA) also dimerizes cofacially,[4] but the dimers adopt a stacked dimer structure similar to that observed for many dithiadiazolyls.[5] Surprisingly, and despite its structural resemblance to PDTA, the benzo derivative (BDTA)[6] associates in a centrosymmetric manner and does not form π stacks. The trithiatriazapentalenyl radical (TTTA) represents a sharp contrast to the previous examples, in that dimerization is not observed.[7] Instead the crystal structure consists of evenly spaced slipped π stacks. Transport properties, however, have not been reported for this compound. In order to explore the architectural issues behind these diverse structural patterns we have examined the solid-state structures and transport properties of the 2,3-naphthalene- and quinoxaline-based 1,3,2-dithiazolyl radicals NDTA **1** and QDTA **2**.

The two radicals were prepared by standard methods. 2,3-Naphthalenedithiol[8] was oxidized with iodobenzene dichloride to give 2,3-naphthalene-bis(sulfenyl chloride), which was condensed with trimethylsilyl azide in $CH_2Cl_2$ solution to afford 2,3-naphthalene-1,3,2-dithiazolylium chloride. Reduction of this salt with triphenylantimony in acetonitrile afforded NDTA, which was separated by filtration and fractionally sublimed at 80–50 °C ($10^{-2}$ Torr) to give purple plates, mp 149–151 °C. QDTA was prepared by a modification of the literature procedure.[3] Black rod-like crystals of QDTA, mp 137–140 °C, were grown by fractional vacuum sublimation at 70–40 °C ($10^{-2}$ Torr).



The crystal structure of NDTA† consists of discrete molecules of NDTA, with two molecules per asymmetric unit. The internal bond lengths of the two heterocyclic rings [mean *d*(S–N) = 1.645 Å, mean *d*(C–S) = 1.748 Å] are typical of those seen in dimeric derivatives[3,6] and indicative of the fact that dimerization effects minimal electronic reorganization. The crystal structure consists of antiparallel ribbons of radicals running in the *z* direction. Viewed down the *z* direction (Fig. 1) the packing pattern of the ribbons resembles the close-packed herringbone arrangement found many polycyclic aromatics,[9] *e.g.* naphthalene[10] and anthracene.[11] There is no dimerization of NDTA radicals, and the closest intermolecular S···S contacts ($d_1$–$d_5$) are well outside the van der Waals separation of 3.6 Å.[12]

The crystal structure of QDTA† also consists of undimerized radicals. Here too the internal bond lengths of the heterocyclic ring [mean *d*(S–N) = 1.649 Å, mean *d*(C–S) = 1.736 Å] are typical of those seen in simple dimers. As in the case of NDTA, the molecules lie in ribbon-like chains, but the packing of the ribbons (Fig. 2) takes on a slipped π-stack pattern similar to that observed for TTTA. Apart from intermolecular contacts associated with the cell repeat [3.7105(8) Å], there is only one S···S contact inside 4.0 Å ($d_1$) linking radicals in adjacent stacks.

The structural dichotomy observed between NDTA and QDTA is intriguing. The similarity of the NDTA structure to those of simple polycyclic aromatics suggests a similar cause.[9,13] Presumably, when the structure-making CH···ring interactions[14] which favour the herringbone arrangement are reduced by the replacement of peripheral CH groups by N atoms, as in QDTA, the preference for close-packing is diminished, and a slipped stack structure prevails. That dimerization does not occur, as it does in the smaller molecule PDTA, is probably a manifestation of a slightly weakened dimerization enthalpy coupled with the greater tendency for the

**1**

**2**

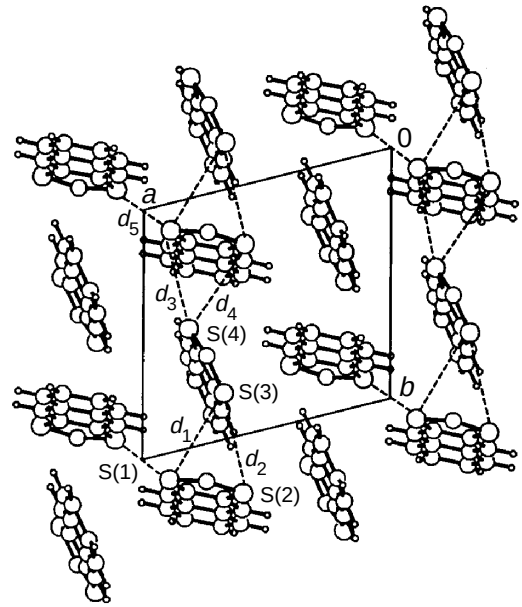


**Fig. 1** Herringbone packing of NDTA. Intermolecular S···S contacts are shown with dashed lines; $d_1$ = 3.869, $d_2$ = 3.868, $d_3$ = 3.821, $d_4$ = 3.863, $d_5$ = 3.602 Å.

crystal structure to be determined by general packing forces rather than local (intermolecular S···S) interactions.

The bulk magnetic susceptibilities of both NDTA and QDTA have been measured over the temperature range 5–400 K on a SQUID magnetometer; plots of $\chi$ *vs.* $T$ are shown in Fig. 3. Analysis of the susceptibility data for NDTA indicate that it is essentially paramagnetic above 200 K, with $\theta$ = 1.3 K and the fraction of the Curie spins per molecule, $f$ = 0.80 mol$^{-1}$. Below 200 K there is a phase transition to a more strongly antiferromagnetically coupled state with $\theta$ = 10.7 K and $f$ = 0.53 mol$^{-1}$. In QDTA the low-temperature susceptibility is consistent with a diamagnetic ground state, with $\chi_0 = -99 \times 10^{-6}$ emu mol$^{-1}$, $\theta = -0.1$ K and $f$ = 0.003 mol$^{-1}$. Above 120 K the susceptibility slowly rises and, at room temperature, $f$ is *ca.* 0.3 mol$^{-1}$. Pressed pellet measurements indicate room temperature conductivities of $< 10^{-6}$ S cm$^{-1}$ for both compounds.

The low conductivity of QDTA at room temperature is at first surprising, given the large fraction of unpaired spins and the fact that its evenly spaced π-stack structure nominally fulfils the prescription for a neutral π-radical conductor.[15] We conclude that, as in the case of stacked dithiadiazolyls,[5,16] the bandwidth associated with the half-filled energy band in QDTA is insufficient to overcome the large Coulombic barrier to charge transfer associated with the high electronegativity of the dithiazolyl ring. Accordingly the material is a Mott insulator.

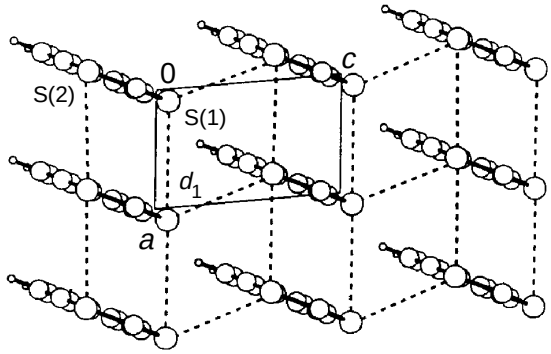

**Fig. 2** Slipped π-stack structure of QDTA. Intermolecular S···S contacts are shown with dashed lines; $d_1$ = 3.840 Å.

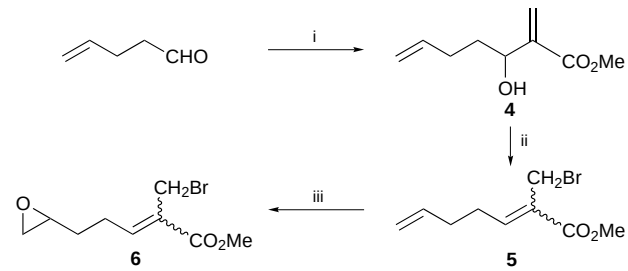
# Selective conversion of bromo oxirane into tetrahydropyranylacrylate by epoxide ring opening

**Munetaka Tokumasu, Asami Sasaoka, Ryukichi Takagi, Yoshikazu Hiraga and Katsuo Ohkata*†**

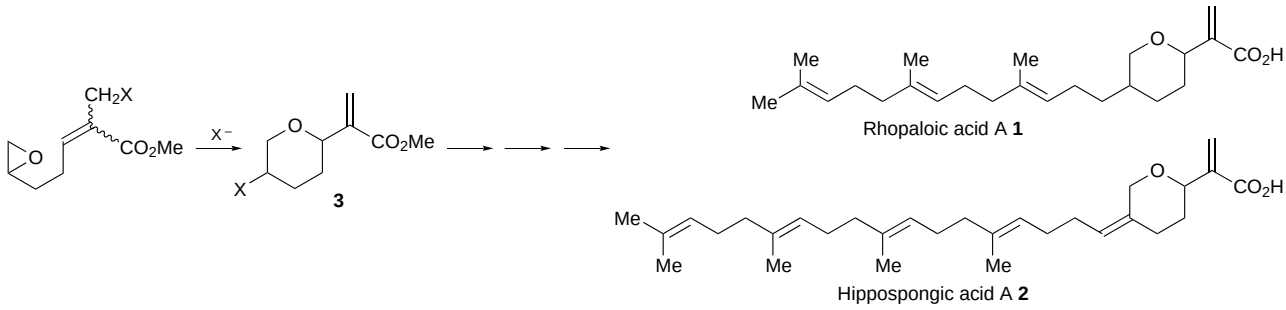
*Department of Chemistry, Faculty of Science, Hiroshima University, 1-3-1 Kagamiyama, Higashi-Hiroshima 739, Japan*

**In order to construct the tetrahydropyran ring of rhopaloic acid A and hippospongic acid A, the ring-expansion of methyl 2-bromomethyl-6,7-epoxyhept-2-enoate with various acids was studied; treatment of the bromo oxirane with Lewis acids ($TiBr_4$, $MgBr_2$ and $ZnBr_2$) afforded a tetrahydrofuran derivative as the major product, while reaction of the oxirane with silver salt ($AgNO_3$/$KPF_6$) gave a tetrahydropyran derivative as the major product.**



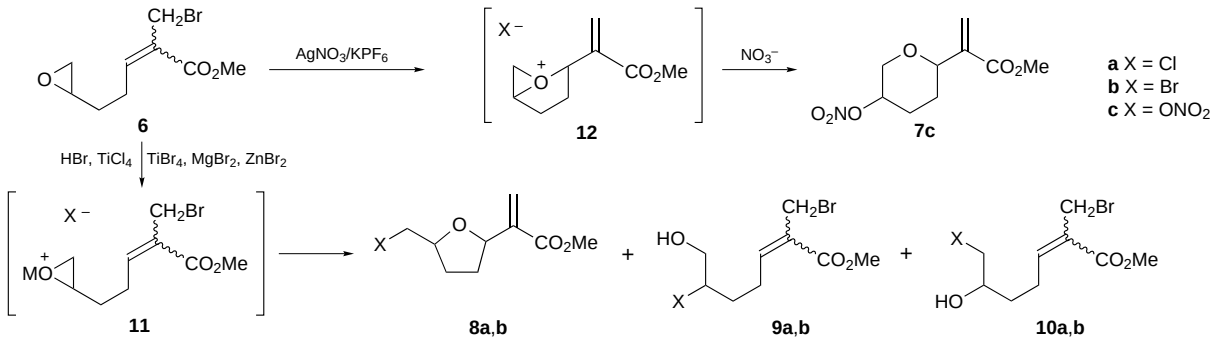
Marine sponges are known to produce structurally and bioactively interesting terpenoids such as rhopaloic acid A (**1**) and hippospongic acid A (**2**) which exhibit potent inhibition in gastrulation of starfish (*Asterina pectinifera*) embryos.[1,2] In particular, rhopaloic acid A, which was isolated from a marine sponge, *Rhopaloeides sp*., exhibited potent cytotoxicities *in vitro* against human myeloid cells, human leukemia cells, *etc*.[1] The interesting structure of these compounds consists of a hydrophilic pyranylacrylic acid moiety and a hydrophobic isoprenoid part. The interest in the structural features and potential of **1** and **2** and their analogues as probes of biological activities prompted us to undertake the selective synthesis of the pyranylacrylate moiety, 2-(1-methoxycarbonylvinyl)tetrahydropyran derivative **3**.

Our synthetic strategy consists of ring-expansion of oxiranes into tetrahydropyran rings followed by connection of various hydrophobic aliphatic chains (Scheme 1). The conversion of oxirane compounds to cyclic ethers is an interesting and useful synthetic methodology. Although extensive work has been reported on *endo*-cyclization of epoxy alcohols,[3] the ring expansion reaction of the epoxy group has hardly been investigated.[4] Recently, Murai and co-workers reported a method for the synthesis of the tetrahydropyran ring by the selective opening of the oxirane ring without directing groups by utilizing the epoxy group as a nucleophile.[4b] Here we describe the selective expansion of the oxirane ring into the tetrahydropyran ring along with simultaneous formation of an acrylate moiety.



Baylis–Hillman reaction of pent-4-enal with methyl acrylate afforded the corresponding ester **4** in 79% yield. Bromination of **4** with $CBr_4$–$PPh_3$ gave bromo ester **5** as a 1 : 1 mixture of geometric isomers in 52% yield. Epoxidation of **5** with MCPBA furnished epoxy bromo ester **6** in 85% yield (Scheme 2).

Treatment of **6** with various acids afforded ring expansion products (tetrahydropyran and tetrahydrofuran derivatives **7a**–**c** and **8a**–**c**) and ring-opened products (**9a**,**b** and **10a**,**b**), Scheme 3 and Table 1. The product distribution was dependent upon the ring-opening reagents. Reaction of **6** (*E*/*Z*, 1 : 1 mixture) with 47% aqueous HBr in THF afforded a mixture of ring-opened products **9b** (11%) and **10b** (57%). Treatment of **6** with $TiCl_4$ gave the analogous chlorides **9a** (47%) and **10a** (44%), while reaction of **6** with $TiBr_4$ gave **8b** (46%), **9b** (14%) and **10b** (32%). Reactions of **6** with $MgBr_2$ and $ZnBr_2$ gave tetrahydrofuran derivative **8b** as a mixture of *cis*/*trans* isomers in 52 and 64% yields, respectively. The *cis*/*trans* ratio of the furan derivatives varied slightly depending on the Lewis acid used.



Since proton acid (HBr) and Lewis acids such as $TiCl_4$, $TiBr_4$, $MgBr_2$ and $ZnBr_2$ are considered to be oxophilic, it is reasonable to assume that the acids reacted with the epoxy group to give the intermediate **11**, followed by inter- or intramolecular nucleophilic attack to give **8a**,**b**, **9a**,**b** and **10a**,**b** (Scheme 3). On the other hand, the silver salt, which is known to have a high halide affinity, might be expected to eliminate bromide ion together with concomitant opening of the epoxy group in **6**. In fact, treatment of **6** with a mixed reagent ($AgNO_3$–$KPF_6$) in $Et_2O$–$H_2O$ (100 : 1) selectively gave tetrahydropyran derivative **7c** (11%; *cis*/*trans* = 0.4 : 1). The use of $CH_2Cl_2$ as solvent resulted in an increase in yield. The relative stereochemistry of the diastereoisomers was determined by the vicinal coupling patterns.‡§ In the silver-promoted reaction, the

[a] The *cis*/*trans* ratio was determined by $^1$H NMR spectroscopy.

bridged oxonium ion **12** can be considered to form in the initial step by the intramolecular nucleophilic attack of the epoxy group. Then, the *endo*-attack to the intermediate **12** by nucleophile ($NO_3^-$) would produce 2-tetrahydropyranylacrylate derivative **7c**.[4–6]

The synthetic methodology shown above could be applied to synthesis of not only rhopaloic acid A (**1**), hippospongic acid A (**2**) and their analogues, but also to other natural products containing 5- and 6-membered oxygen heterocycles.[3]

NMR and MS measurements were made using JEOL GSX-270 and SX-102A spectrometers, respectively, at the Instrument Center for Chemical Analysis, Hiroshima University.

‡ Typical experimental procedure: to a suspension of $AgNO_3$ (70 mg, 0.4 mmol) and $KPF_6$ (80 mg, 0.4 mmol) in $CH_2Cl_2$ (10 ml) was added **6** (10 mg, 0.04 mmol). After stirring for 6 h at room temperature, the reaction mixture was filtered. The filtrate was poured into 5% aq. $NaHCO_3$ and extracted with $CH_2Cl_2$. The extracts were dried and evaporated and the residue was then purified by preparative TLC on silica gel (EtOAc–hexane, 3 : 7 v/v). Each geometric isomer, *trans*-**7c** and *cis*-**7c**, was obtained by recycle HPLC [Japan Analytical Industry Co., Ltd., JAIGEL-H ($CHCl_3$)].

All new compounds were fully characterized by $^1$H NMR spectroscopy and gave satisfactory high resolution mass spectra. Correct elemental analyses were also obtained for selected compounds. *Selected spectroscopic data* for *trans*-**7c**: ν(neat)/cm$^{-1}$ 1717 ($CO_2Me$), 1625, 1277 ($NO_2$); $\delta_H$(270 MHz, $CDCl_3$) 6.31 (dd, *J* 1.5, 1.0, 1 H), 5.98 (t, *J* 1.5, 1 H), 5.00 (m, 1 H), 4.29 (ddd, *J* 13.2, 2.5, 2.0, 1 H), 4.28 (dddd, *J* 9.3, 2.0, 1.5, 1.0, 1 H), 3.80 (dd, *J* 13.2, 1.5, 1 H), 3.77 (s, 3 H), 2.25-2.15 (m, 1 H), 2.09–1.85 (m, 2 H), 1.66–1.51 (m, 1 H); $\delta_C$(270 MHz, $CDCl_3$) 166.1, 140.9, 124.0, 78.0, 75.4, 74.3, 51.8, 31.8, 27.8 (HRMS: found, 185.0815 [M − $NO_2$]$^+$. Calc. for $C_9H_{13}O_4$, 185.0814). For *cis*-**7c**: ν(neat)/cm$^{-1}$ 1720 ($CO_2Me$), 1637, 1280 ($NO_2$); $\delta_H$(270 MHz, $CDCl_3$) 6.25 (t, *J* 1.5, 1 H), 5.94 (dd, *J* 1.5, 1.0, 1 H), 4.75 (tdd, *J* 6.8, 1.5, 1.0, 1 H), 4.61 (dd, *J* 11.7, 3.9, 1 H), 4.50 (dd, *J* 11.7, 5.9, 1 H), 4.29 (m, 1 H), 3.77 (s, 3 H), 2.41–2.31 (m, 1 H), 2.15–2.05 (m, 1 H), 1.81–1.67 (m, 2 H); $\delta_C$(270 MHz, $CDCl_3$) 166.0, 140.6, 125.3, 76.1, 74.9, 68.2, 51.8, 26.8, 26.3 (HRMS: found, 185.0820 [M − $NO_2$]$^+$. Calc. for $C_9H_{13}O_4$, 185.0814).

§ It is considered that the *cis* isomer exists as a nearly equimolar mixture of two indistinguishable conformers, whereas the *trans* isomer consists of two unequally populated conformers, the predominant e,e conformer and the much less abundant a,a conformer which has axial vinyl and nitro groups. The methine proton at C-2 of the tetrahydropyran ring shows a distinct difference in pattern between *cis*- and *trans*-**7c**. The axial disposition of a methine proton of *trans*-**7c** (δ 4.28) is clearly indicated by its coupling constants, which consist of an axial–axial (*J* 9.3), an axial–equatorial (*J* 2.0) and two allyl $^4J$ couplings (*J* 1.5 and 1.0). On the other hand, the coupling constants of the methine proton of *cis*-**7c** (δ 4.75) consist of an averaged vicinal (t, *J* 6.8) and two allyl $^4J$ couplings (*J* 1.5 and 1.0) since the tetrahydropyran ring of *cis*-**7c** is more flexible compared with that of *trans*-**7c**.

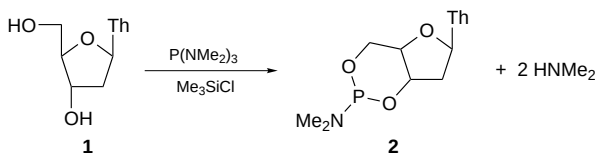
# Trimethylchlorosilane: a novel activating reagent in nucleotide synthesis *via* the phosphoramidite route

**Wojciech Dabkowski,[a] Izabela Tworowska,[a] Jan Michalski*[a] and Friedrich Cramer[b]**

[a] *Centre of Molecular and Macromolecular Studies, Polish Academy of Science, 90-363 Lódź, Sienkiewicza 112, Poland*
[b] *Max-Planck-Institut für experimentelle Medizin, 3400 Göttingen, Hermann-Rein Strasse 3, Germany*



**Trimethylchlorosilane (TMSCl) is a remarkably efficient activator in the reaction of phosphorus(III) amides with nucleosides to give phosphorus(III) esters in excellent yield.**

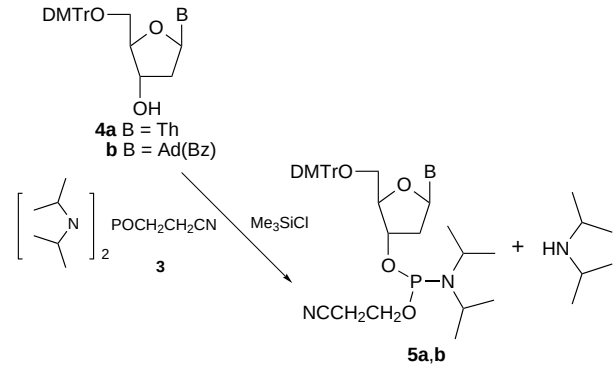
Phosphoramidites are among the most important reagents in the synthesis of phosphates of biological interest by the 'phosphite approach'.[1] Tetrazole, tetrazole salts with amines and structural analogues of this heterocycle are generally used as activators of the reaction between alcohols and phosphoramidites.[2] Tetrazole, the most widely employed activator, must often be used in excess and be of high purity, which involves hazardous sublimation. Other activators like amine hydrochlorides[3] and acyl chlorides that act *via* intermediate formation of phosphorchloridites[4] have been used only occasionally.

In our recent studies on the synthesis of modified nuclotides we were confronted with the challenge of finding an alternative mode of activation without using tetrazole or similar compounds. Our earlier work on interaction of $P^{III}$ amides with halogenosilanes[5] suggested to us that phosphoramidites would react with alcohols in the presence of trimethylchlorosilane (TMSCl) as catalyst. This proved to be so, and was highly efficacious from a preparative point of view. The reaction of $P^{III}$ amidites with an equivalent amount of nucleoside proceeds in the presence of TMSCl in very high yield and at rates comparable or higher than those when tetrazole is used. Phosphitylations activated by TMSCl proceed at room temperature in solvents like THF, $CH_2Cl_2$ or MeCN. On average, the amount of activator required for an efficient coupling is *ca.* 30–60% of the stoichiometrical ratio. Most of our experiments were performed with $P^{III}$ amides derived from diisopropylamine in order to conform to the most popular phosphitylation procedures. Selected examples illustrating our metholology are chosen from nucleotide chemistry.†

A remarkable example of activation in the presence of a catalytic amount of TMSCl (0.6 equiv.) is the reaction of thymidine **1** with tris(dimethylamino)phosphine to give thymidine 3′,5′-cyclic dimethylphosphoramidite **2** in 95% yield. Activation by tetrazole is less effective in this case.The yield of cyclic amidite **2** is poor in the absence of TMSCl.[6]

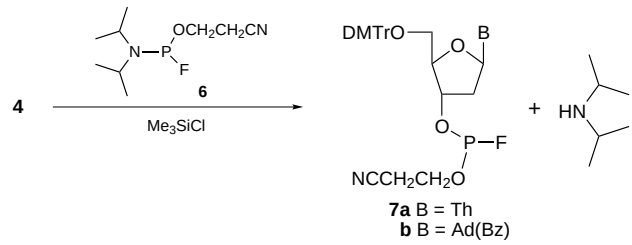
Commercially available bis(diisopropylamino)-2-cyanoethoxyphosphine reacts in the presence of TMSCl (0.6 equiv.) with 5′-*O*-DMTr-nucleoside in a highly selective way to form 5′-*O*-DMTr-thymidine 3′-*O*-(2-cyano-*N*,*N*-diisopropyl)phosphoramidite **5a** and $N^6$-benzoyl-5′-*O*-DMTr-deoxyadenosine 3′-*O*-(2-cyanoethyl-*N*,*N*-diisopropyl)phosphoramidite **5b**‡ in over 97% yield. In this case the yield and purity of amidites **5a,b** are identical to those obtained by activation with tetrazole.[7]

**1** **2**



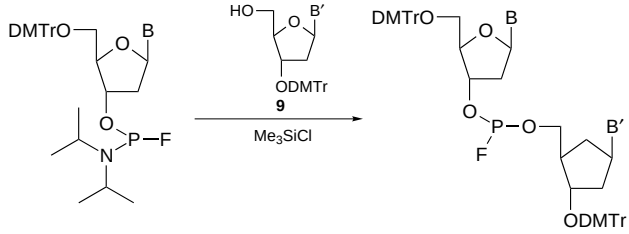
**Scheme 1** *Reagents and conditions*: **1** (1.0 equiv.), $P(NMe_2)_3$ (1.0 equiv.), TMSCl (0.6 equiv.), THF, room temp., 2 h

Excellent coupling procedures activated by TMSCl were noted for $P^{III}$ amides containing a fluorine ligand. For example, fluoro(diisopropylamino)-2-cyanoethoxyphosphine **6**§ reacts with 5′-*O*-DMTr-nucleoside **4a,b** in the presence of TMSCl (0.6 equiv.) to give 5′-*O*-DMTr-thymidine 3′-*O*-(2-cyanoethyl)-fluorophosphite **7a** and $N^6$-benzoyl-5′-*O*-DMTr-adenosine 3′-*O*-(2-cyanoethyl)fluorophosphite **7b**¶ in almost quantitative yield. The analogous reaction activated by tetrazole requires a 5-fold excess of activator and proceeds distinctly more slowly.

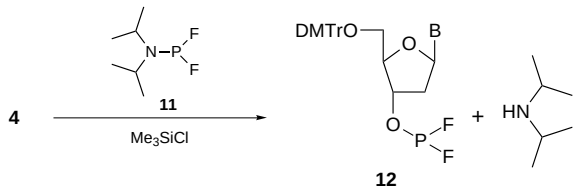


Efficient synthesis of 5′-*O*-DMTr-thymidine (3′-5′) 3′-*O*-DMT-thymidine phosphorfluoridite **10a** and $N^6$-benzoyl-5′-*O*-DMT-2′-deoxyadenosine (3′-5′)-3′-*O*-DMTr-thymidine phosphofluoridite **10b**‖ was achieved by coupling of 3′-*O*-nucleosidyl-phosphorfluoroamidites **8**[8] with a 3′-*O*-protected nucleoside in the presence of TMSCl (0.3 equiv.). The analogous reaction activated by tetrazole proceeds more slowly and requires a large excess of the activator.[9]

Synthesis of the 5′-*O*-DMTr-thymidine difluorophosphine **12**** was achieved by the coupling of diisopropylamino-difluorophosphine **11**[8] with 3′-*O*-protected nucleosides in the presence of TMSCl activator.



The mechanism of activation by TMSCl is presumed to involve its reaction with $P^{III}$ amide. This type of interaction has been discussed in our earlier paper[5] and more recently by Nifantyev.[10] The first step produces salt-like species $R_2P^+(SiMe_3)NR''_2Cl^-$ and $R_2PN^+R''_2(SiMe_3)Cl^-$ which react either



**Scheme 2** *Reagents and conditions*: **4** (1.0 equiv.), **3** (1.0 equiv.), TMSCl (0.6 equiv.), THF, room temp., 1 h

**Scheme 3** *Reagents and conditions*: **4** (1.0 equiv.), **6** (1.0 equiv.), TMSCl (0.6 equiv.), THF, room temp., 1 h

**Scheme 4** *Reagents and conditions*: **8** (1.0 equiv.), **9** (1.0 equiv.), TMSCl (0.30 equiv.), THF, room temp., 1 h

**Scheme 5** *Reagents and conditions*: **4** (1.0 equiv.), **11** (1.1 equiv.), TMSCl (0.6 equiv.), room temp., 1 h

directly with alcohol to give ester $R_2POR'$ or *via* intermediate formation of $R_2PCl$. In both cases TMSCl is regenerated. A mechanistic path may be considered in which TMSCl reacts with alcohol to form hydrogen chloride which then activates an $P^{III}$ amide *in situ*. But it is well known that TMSCl reacts very slowly with alcohols unless a catalyst is present.[11] Formation of hydrogen chloride would effect the removal of the acid labile DMTr group. This is actually observed when the commercial TMSCl contaminated with HCl is used. However when hydrogen chloride free TMSCl is utilized, this is not observed. Work is currently in progress aimed at utilizing the TMSCl activation for the synthesis of oligonucleotides on solids supports and better understanding its mechanistic features.

This work was supported by the State Committee for Scientific Research, Poland (No 3T09A 155 10), German–Polish project (X084-9) and Perstorp Pharma, Perstop, Sweden.

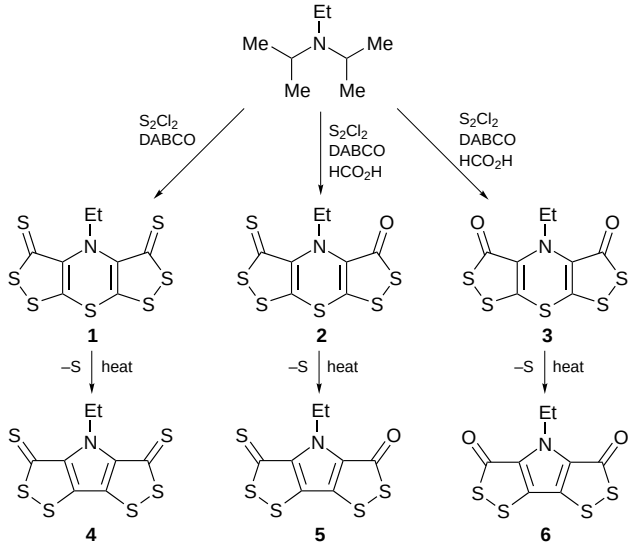
# One-pot synthesis and chemistry of bis[1,2]dithiolopyrroles



**Carlos F. Marcos,[a] Cecilia Polo,[a] Oleg A. Rakitin,[b] Charles W. Rees[c] and Tomás Torroba[a]**

[a] *Departamento de Química Orgánica, Facultad de Veterinaria, Universidad de Extremadura, 10071 Cáceres, Spain*
[b] *N. D. Zelinsky Institute of Organic Chemistry, Russian Academy of Sciences, Leninsky Prospekt 47, Moscow B-334, Russia*
[c] *Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY*

**Hünig's base and $S_2Cl_2$ give the fused 1,4-thiazines 1 and (in the presence of formic acid) 2 and 3, each of which readily extrudes sulfur, selectively and quantitatively, to give the fused pyrroles 4, 5 and 6 respectively; at higher temperatures Hünig's base and $S_2Cl_2$ can be converted into the pyrroles in one pot, and the cycloadducts 8 and 10 are thus readily available in two steps.**

The formation of C–C bonds by thermal or catalytic sulfur extrusion reactions[1] has proved to be valuable in the synthesis of a wide range of organic structures, most notably that of Vitamin $B_{12}$ and the corrins.[2] We describe here the selective and quantitative desulfurisation of some polysulfur–nitrogen heterocyclic compounds which provides a new route to highly substituted fused pyrroles. Derivatives of sulfur heterocycles such as thiophene and 1,3-dithiole have been widely explored as new materials because of their superconducting[3] and optical and electronic switching properties.[4] We have synthesised sulfur–nitrogen systems with potentially similar properties, such as cyclopenta- and cyclohepta-dithiazoles[5] and liquid crystalline pseudoazulene 1,2-dithioles and 1,2-thiazines.[6]

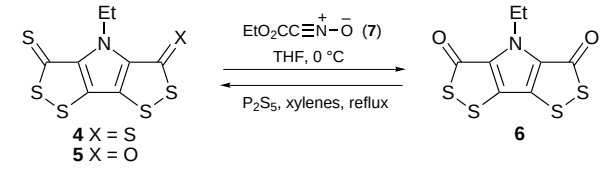
During this work we discovered that ethyldiisopropylamine (Hünig's base), initially added as an inert base, reacted with disulfur dichloride in 1,2-dichloroethane or THF to give the first examples (**1**, **2** and **3**, Scheme 1) of the bis[1,2]dithiolo[5,4-*b*][5′,4′-*e*][1,4]thiazine ring system, in a one-pot process in which all 14 isopropyl C–H bonds of Hünig's base were replaced by C–S, C–O and C–C bonds.[7] The ready availability of these new 1,4-thiazines from commercial reagents, and their potential for sulfur extrusion[1,8] led us to study their thermal behaviour. We found that all three thiazines, **1**, **2** and **3**, underwent very clean and selective thermal extrusion of one sulfur atom only to give the first examples (**4**, **5** and **6**) of the bis[1,2]dithiolo[4,5-*b*][5′,4′-*d*]pyrroles. Furthermore the Hünig's base–$S_2Cl_2$ reaction and the sulfur extrusion could be combined to give immediate access to the new pyrrole ring system which, in turn, could be extended to polyheterocyclic pyrroles by cycloaddition reactions.

**Scheme 1**

Refluxing bisdithiolothiazine-3,5-dithione **1** in xylene for 0.5 h gave a deep purple solution from which **4** ($C_8H_5NS_6$, mp 242–243 °C) was obtained as black needles in quantitative yield.† All spectroscopic data agreed with the formation of a symmetrical structure, which requires the selective extrusion of the central ring sulfur atom to give the bisdithiolopyrrole-3,5-dithione **4**. The same product (42% after purification) was also obtained directly from Hünig's base when treated with an excess of $S_2Cl_2$ (10 equiv.) in chlorobenzene in the presence of 1,4-diazabicyclo[2.2.2]octane (DABCO, 10 equiv.) for 3 days at room temperature, followed by refluxing for 2 h. In these conditions none of the thiazine **1** survived. It is notable that in this overall reaction a carbon–carbon bond is formed between two (formally) unreactive methyl groups in Hünig's base, whilst the ethyl group is unchanged.

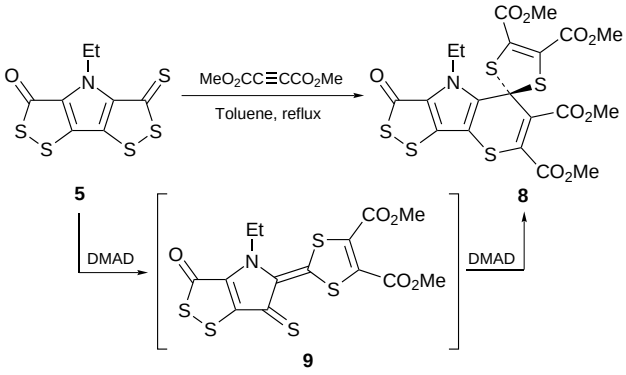
The mono-and bis-oxo thiazines **2** and **3** were equally good substrates for selective sulfur extrusion. Thus, when the 3-oxo 5-thione **2** or the 3,5-dione **3** were refluxed in xylene for 1 and 3 h, respectively, the 3-oxobisdithiolopyrrol-5-thione **5**,† light red crystals, mp 175–176 °C, and the bisdithiolopyrrole-3,5-dione **6**,† yellow crystals, mp 199–200 °C, respectively, were obtained in quantitative yield. All spectroscopic data, notably the $^{13}C$ NMR spectra, agreed with the unsymmetrical structure **5** and the symmetrical structure **6** for these products. Just as the fully sulfurated pyrrole **4** could be prepared directly from Hünig's base and $S_2Cl_2$ in chlorobenzene, so too could the mono- and bis-oxo pyrroles, **5** and **6**, in the presence of an oxygen donor. Thus, treating Hünig's base with $S_2Cl_2$ (10 equiv.) and DABCO (8 equiv.) in chlorobenzene for 3 days at room temperature, followed by addition of formic acid (20 equiv.) and refluxing for 7.5 h, gave the dione **6** (42%) as the only reaction product; TLC monitoring showed the intermediacy of the 1,4-thiazine **3**. If the period of refluxing were restricted to 2 h [with DABCO (10 equiv.) and formic acid (10 equiv.)] the oxo thione **5** (25%) was the main product, together with minor amounts of **4** and **6**.

Compounds **4**, **5** and **6** could be readily interconverted. Thiation of **5** or **6** with excess of $P_2S_5$ in refluxing xylene for 1 h gave the dithione **4** in almost quantitative yield. Similar thiation of the 1,4-thiazines **2** and **3**, under the same conditions, was accompanied by sulfur extrusion to give compound **4**, again in very high yield. Oxidation of **4** with mercuric acetate gave the dione **6** (35%). Nitrile oxides are known to convert 1,2-dithiolo 3-thiones into the 3-keto compounds;[9] treatment of dithione **4** or oxo thione **5** in THF at 0 °C for 15 min with an excess of ethoxycarbonyl nitrile oxide **7**, generated *in situ* from ethyl chlorooximidoacetate and triethylamine, gave the dione **6** (70–75%) (Scheme 2). Lowering the reaction temperature or reducing the amount of the reagent **7** led to mixtures of **5** and **6** with unchanged **4** and thus did not provide a satisfactory route to oxo thione **5**.



1,2-Dithiolo 3-thiones can also act as 1,3-dipoles.[10] Treatment of compound **5** with dimethyl acetylenedicarboxylate

(DMAD) (5 equiv.) in refluxing toluene for 2 h gave yellow crystals of the 1 : 2 adduct **8**,† mp 219–220 °C (65%), as the only recognisable product (Scheme 3). $^1$H NMR spectroscopy showed the presence of the *N*-ethyl group and four ester methyl groups, two of which were identical; $^{13}$C NMR showed four methoxycarbonyl groups (two identical), the carbonyl group, eight alkenyl carbons and one quaternary carbon corresponding to S–$CR_2$–S. Since the 1,2-dithiolo 3-one ring was still intact, both DMAD molecules had added to the 1,2-dithiolo 3-thione moiety to give the spiro[1,3-dithiolo-thiopyran] structure **8**, *via* the intermediate **9**.[11] In an exactly analogous manner dithiole **4** gave the 1 : 4 adduct ($C_{32}H_{29}NO_{16}S_6$), bis-spiro[1,3-dithiolo-thiopyran]pyrrole **10**† as yellow crystals, mp 224–225 °C, in 77% yield (Scheme 4). This symmetrical structure followed, as above, from spectroscopy, particularly $^1$H and $^{13}$C NMR and mass spectrometry; the fully substituted pentacyclic molecule was obtained from commercial Hünig's base in two steps in 32% overall yield.



Thus new tricyclic (**4**, **5**, **6**), tetracyclic (**8**) and pentacyclic (**10**) systems, with pyrroles fused to 5- and 6-membered sulfur rings, are now readily available for assessment as new materials of the 1,2-dithiole type[12] and for biological screening.[13]

The quantitative, uncatalysed conversion of thiazines **1**, **2** and **3** into the respective pyrroles **4**, **5** and **6** occurs under much milder conditions than for other annelated 1,4-thiazines,[8] such as phenothiazines which require strong heating with copper to yield carbazoles.[14] This can be explained by stabilization of the key thiirane intermediates **11** (*cf*. refs. 8 and 14) by electron release from nitrogen and electron withdrawal by the carbonyl and thiocarbonyl groups, giving highly delocalised (**12**) intermediates on the way to the aromatic products (Scheme 5). The ene-thiolate contribution, for X = S, will be more stable than the enolate contribution, for X = O, in agreement with the observed rate of sulfur extrusion (**1** > **2** > **3**).

# New syntheses of aryl isothiocyanates from *N*-arylimino-1,2,3-dithiazoles

**Thierry Besson,[a] Jérôme Guillard,[a] Charles W. Rees[b] and Michel Thérisod[c]**

[a] *Laboratoire de Génie Protéique et Cellulaire, Pôle Sciences et Technologie, Université de La Rochelle, Avenue Marillac, F-17042 La Rochelle cedex 1, France*
[b] *Department of Chemistry, Imperial College of Science, Technology and Medicine, London, UK SW7 2AY*
[c] *S.E.S.N.AB., Pôle Sciences et Technologie, Université de La Rochelle, Avenue Marillac, F-17042 La Rochelle cedex 1, France*

**Treatment of *N*-arylimino-1,2,3-dithiazoles 2 with ethylmagnesium bromide (2 equiv.) gives the corresponding aryl isothiocyanates 13, providing a very mild two-step conversion of $ArNH_2$ into ArNCS avoiding hazardous reagents; alternatively the iminodithiazoles 2 can be converted into cyanothioformanilides 11 which rapidly give the same isothiocyanates with 1 equiv. of the Grignard reagent.**

4,5-Dichloro-1,2,3-dithiazolium choride **1**, which is readily prepared from chloroacetonitrile and disulfur dichloride, reacts rapidly with anilines in dichloromethane at room temperature to give the stable 5-(*N*-arylimino)-4-chloro-5*H*-1,2,3-dithiazoles **2** usually in very high yield.[1–3] These iminodithiazoles are susceptible to intramolecular (*e.g.* **3**) and intermolecular (*e.g.* **4**) nucleophilic substitution at both sulfur and both carbon atoms of the dithiazole ring and, in consequence, have proved to be very versatile synthetic intermediates. They can be converted in one step into the 2-cyano derivatives of benzoxazoles **5**,[2] benzothiazoles **6**,[2] benzimidazoles **7**,[4] benzoxazin-4-ones **8**,[3] benzothiazin-4-ones **9**[3] and 4-alkoxyquinazolines **10**,[5] and into the acyclic *N*-arylcyanothioformamides **11**.[3] Opening of the dithiazole ring by aliphatic amines (*e.g.* **4**) has also been shown by Kim and co-workers to be synthetically useful.[6] In all of these reactions the latent cyano group in the reagent **1** has been generated and retained in the products. We now find that with the more powerfully nucleophilic Grignard reagents, opening of the dithiazole ring is accompanied by elimination of the cyano group. A commercial solution of ethylmagnesium bromide (2 equiv.) in THF was added dropwise to a heated solution of the iminodithiazole **2** in THF under argon, and heated at reflux for 1 h. Hydrolysis followed by extraction of the product with dichloromethane and purification by column chromatography afforded the isothiocyanates **13** (45–60%) (Method A, Table 1). Similar yields were obtained from reactions run at room temperature overnight. Transposing this procedure to a open microwave oven specially designed for organic synthesis gave very similar results (reaction times, yields). An excess of ethylmagnesium bromide (5–6 equiv.) gave more complex reactions with lower yields of isothiocyanates.

The ready conversion of iminodithiazoles **2** into aryl isothiocyanates **13** is a new reaction of the heterocyclic ring, which provides a novel route to isothiocyanates. This mild two-step conversion of primary aromatic amines into isothiocyanates avoids the use of carbon disulfide and thiophosgene, and high temperature reactions.[7]

Opening of the dithiazole ring by the Grignard reagent is probably initiated by attack at S-2 and generation of the cyano group (Scheme 1), as with other nucleophiles.[6] Attack by a second molecule of the Grignard reagent on the same sulfur could result in formation of the isothiocyanate, dialkyl sulfide

[a] All compounds were characterised by IR, NMR and HRMS. [b] Aryl isothiocyanates **13**: typical procedures from 5-(*N*-arylimino)-4-chloro-5*H*-1,2,3-dithiazoles **2**. *Method A*: Under an argon atmosphere, a solution of ethylmagnesium bromide (2 mmol, 1 M in THF) was added dropwise to a solution of the 5-imino-1,2,3-dithiazole **2** (1 mmol) in boiling THF (5 ml). The brown mixture obtained was heated for about 1 h, the reaction being followed by TLC. After addition of $CH_2Cl_2$ (20 ml) the solution was washed with water, the organic layer dried over sodium sulfate and the solvent evaporated. The crude product was then purified by column chromatography with light petroleum–$CH_2Cl_2$. The same procedure was transposed to a open microwave oven in a quartz reactor (Synthewave S402 Prolabo® microwave reactor monomode system which has variable speed rotation, visual control, irradiation monitor, infrared measurement and continuous feedback temperature controlled by PC computer). The products were purified as above. [c] Compound commercially available. [d] (A): method A; (B): method B (see above). [e] Treatment of the iminodithiazole **2g** with benzylmagnesium bromide gave the same yield of isothiocyanate **13g** as EtMgBr. [f] EtMgBr (1 equiv.), THF 50 °C, 30 min.

**Scheme 1**

and cyanide anion, possibly assisted by electrophilic catalysis in a cyclic transition state as shown in **12** (Scheme 1). It has been shown that treatment of some *N*-arylcyanothioformamides **11** with pyrrolidine gave minor amounts of thioureas, where the cyano group had been replaced by the amine, and the corresponding aryl isothiocyanate was proposed as a possible intermediate.[6a]

*N*-Aryliminodithiazoles **2** can be easily converted into cyanothioformanilides **11** in high yield by treatment with triphenylphosphine (2 equiv.) in undried $CH_2Cl_2$ at room temperature for 1–3 h.[3] We now find that HCN is also eliminated from these formanilides **11** by ethylmagnesium bromide (1 equiv.) in THF to give the isothiocyanates **13** in high yield. The two steps, **2** → **11** → **13**, can be readily combined (Method B, Table 1).

We thank the Comité de Charente-Maritime de la Ligue Nationale Contre le Cancer, Prolabo (Merck group) and MDL Information Systems (UK) Ltd for financial support, and the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College.

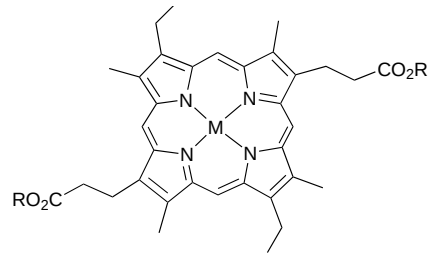
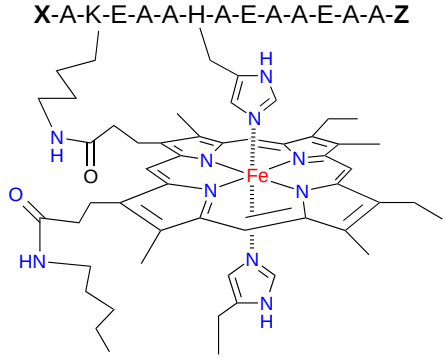
# The bis-*p*-nitrophenyl ester of iron(III) mesoporphyrin II acetate: preparation and incorporation into a model hemoprotein



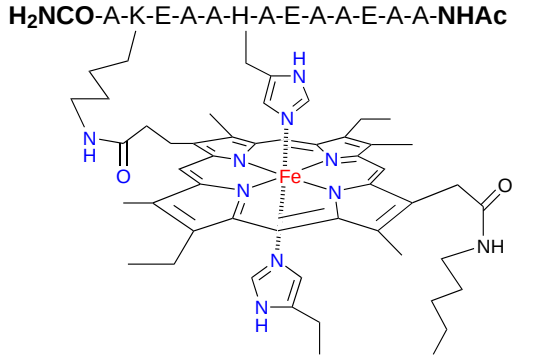
**Manxue Wang, Michelle L. Kennedy, Bradley R. Hart and David R. Benson***

*Department of Chemistry, University of Kansas, Lawrence, KS 66045-0046, USA*



**A method for cleanly inserting iron into the bis-*p*-nitrophenyl ester of mesoporphyrin II, and use of the highly soluble product in the synthesis of a model hemoprotein, is reported.**

We have recently developed a new class of hemoprotein model compounds called peptide sandwiched mesohemes (PSMs; *e.g.* **1** and **2**), which consist of two peptides covalently attached to $Fe^{III}$ mesoporphyrin IX (MPIX).[1] Histidine (His) residues within each peptide coordinate to the mesohemin iron. In **1**[1] and **2**,[2] Fe–His coordination leads the initially random coil peptides to adopt conformations in which peptide helix content approaches 50 and 60%, respectively. A problem that arises with use of MPIX, a commercially available porphyrin, is that each resulting PSM exists as a pair of interconvertible diastereoisomers. Any physical studies done with PSMs assembled from MPIX will be complicated by this equilibrium. Our interest in developing a new generation of PSMs in which only a single stereoisomer is possible (*e.g.* **3**) prompted us to pursue the synthesis of mesoporphyrin II **4**,[3] a $C_{2h}$-symmetric isomer of MPIX. The symmetry properties of **4** have led to its incorporation in several designed receptors,[4–6] systems for the study of electron transfer,[7] and cofacial porphyrin dimers for catalysis of oxygen reduction.[8] The high symmetry of **4** leads to an unfortunate situation: the porphyrin is only soluble in a few, mostly uncommon, solvents including TFA and pyridine. Functionalization of the molecule is limited to reactions which are compatible with such solvents. One reaction which is complicated by lack of solubility is iron insertion. A literature search revealed no references for iron complexes of **4**, nor for any simple ester derivatives of an iron complex. Iron has been inserted into a cofacial porphyrin dimer constructed from **4**.[9] However, this approach may not work in all cases, for example in systems containing more than one metal binding site, or when iron insertion chemistry is not compatible. Because **4** is such an excellent scaffold upon which to build hemoprotein models, including PSMs, we felt it would be useful to explore ways of generating an activated ester derivative of an iron(III) complex of **4**. Our approach was to insert iron into the previously reported bis-*p*-nitrophenyl ester **5** to produce **6**.



Synthesis of **4** followed Dolphin's method,[3] with subsequent conversion to **5** using the procedure of Collman *et al.*[8] Insertion of iron into porphyrins is commonly achieved using $Fe^{II}$ salts in acetic acid (AcOH) at 100 °C, conditions under which **4** and its bis-methyl ester are completely insoluble. Although solubility of **5** in AcOH is slightly higher, no evidence for iron insertion was observed even after refluxing for several days in the presence of $Fe(OAc)_2$. Halogenated solvents, including dichloromethane (DCM) and chloroform, increase the solubility of **5** in AcOH. However, the low boiling points of these solvents leads to unacceptably long reaction times for iron insertion. In contrast, 1,1,2,2-tetrachloroethane (TCE; bp 147 °C) as cosolvent dramatically improved both solubility and rate of metal insertion. Thus, porphyrin **5** (43 mg) was dissolved in 6 ml of a 1 : 1 mixture of dry TCE and glacial acetic acid at 100 °C under $N_2$. Acetic anhydride ($Ac_2O$; 5 vol%) was added to eliminate any adventitious water. A saturated solution of $Fe(OAc)_2$ in AcOH[10] (3 ml; also containing 5% $Ac_2O$) was added to the porphyrin solution *via* syringe and the mixture was stirred at 100 °C until iron insertion was complete as determined by UV–VIS spectroscopy (*ca.* 1 h). The cooled mixture was filtered to

**4** R = H; M = 2H
**5** R = $C_6H_4NO_2$-*p*; M = 2H
**6** R = $C_6H_4NO_2$-*p*; M = $Fe^{III}$-OAc

**1** X = NHAc; Y = $CONH_2$
**2** X = $CONH_2$; Y = NHAc

**3**

remove excess $Fe(OAc)_2$ and the solvent was evaporated *in vacuo*. The dark purple residue was taken up in dry TCE, refiltered, and the solvent was again evaporated. No hydrolysis products were observed by FAB mass spectrometry.† However, a signal corresponding to TCE was present even after the sample had been heated for 12 h at 100 °C *in vacuo*. Elemental analysis† of the recovered material (49 mg; 90%) is consistent with the presence of one equivalent of TCE and an acetate ligand to the iron. The product is highly soluble in AcOH, TCE, DCM, THF, DMF, $Me_2SO$, dioxane, ethyl acetate, acetonitrile and pyridine.

Conversion of **6** to PSM **3** was achieved using our previously reported method for PSMs constructed from $Fe^{III}$–MPIX.[1] The $Fe^{III}$ in **3** is low spin (Soret $\lambda_{max}$ = 403 nm; not shown), demonstrating that it is bis-His coordinated. Helix content of the new compound, as determined by circular dichroism[1] (Fig. 1), is similar to that measured for **2**[2] (*ca.* 60%) at 8 °C in 2 mM potassium phosphate (pH 7). A monopeptide analogue appended on the lysine ε-amine by indoleacetic acid (**7**) exhibits a

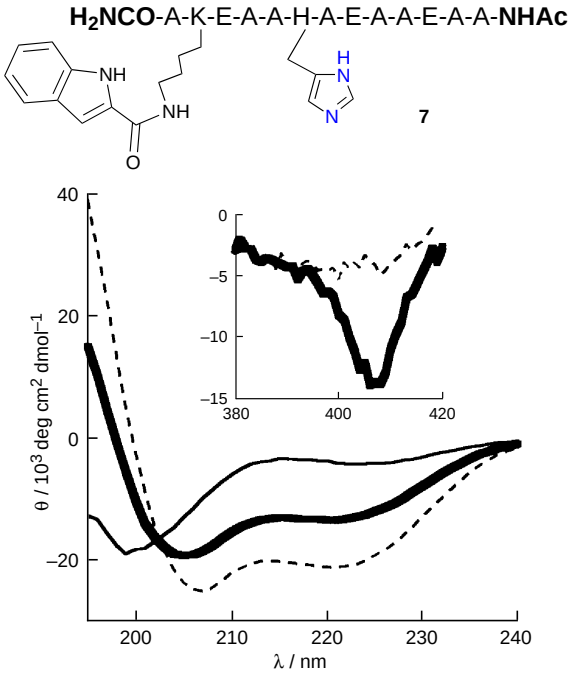


**Fig. 1** CD spectra at 8 °C: 21 μM **7** (thin line) and 8.1 μM **3** (bold line) in water; 8.1 μM **3** (dashed line) in 7 : 3 $H_2O$–PrOH. Each sample is buffered to pH 7 with 2 mM potassium phosphate.

random coil conformation under the same conditions (Fig. 1), confirming that Fe–His coordination in **3** is responsible for helix induction. A Soret induced CD (ICD) signal is recorded as well (Fig. 1), commensurate with the location of the porphyrin within an asymmetric environment. Interestingly, the intensity of this Soret ICD band is only about 25% that of the corresponding band for the two diastereoisomers of **2** (not shown) in aqueous solution. As helix content is increased by addition of propan-1-ol (PrOH), the Soret ICD signal intensity diminishes (Fig. 1) whereas in **2** it increases (not shown).[2] Maximal helix content (*ca.* 95%) is recorded for both **2** and **3** in the presence of 30% (v/v) PrOH (spectrum for **3** is shown in Fig. 1). Additional studies on this and related PSMs will be reported in due course.

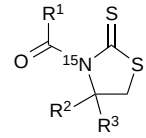
# $^{13}C–^{15}N$ Coupling constants in a series of twisted amides: relationships with C(O)–N twist angles

**Shinji Yamada,*[a]† Maki Nakamura[b] and Ichiro Kawauchi[b]**

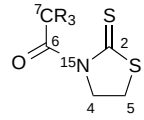
[a] *Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112, Japan*
[b] *Department of Materials Science, Faculty of Science, Kanagawa University, Hiratsuka, Kanagawa 259-12, Japan*



**For a series of $^{15}N$-labelled amides 1a–e with increasing C(O)–N twist angles, the one-bond $^{13}C–^{15}N$ coupling constants decrease, whereas the two-bond $^{13}C–^{15}N$ coupling constants increase.**

It is well-documented that amides have planar geometry due to the partial double bond character of the C(O)–N bond resulting from amide resonance.[1] However, a number of peptides, proteins and enzymes have been proved by X-ray analysis to contain non-planar deformation in the amide moiety.[2] Furthermore, Schreiber and his colleagues have recently suggested that the orthogonally orienting α-keto amide groups of the immunosuppressive agent FK506 and rapamycin may mimic the twisted amide transition-state of peptide substrates of FKBP rotamase.[3] Such twisted structures are of significant interest in relation to their biochemical functions. Synthetic twisted amides have also received considerable attention with regard to their structure and reactivity.[4,5]

The principal method for studying the non-planarity of amide bonds in solution is $^{13}C$, $^{15}N$ and $^{17}O$ NMR spectroscopy.[6,7] Although C–N coupling constants[8] seem to be another promising parameter for elucidation of amide deformation about the C(O)–N bond, no investigations have been reported. Here we describe the relationships between C(O)–N twist angles and $^1J_{C,N}$ and $^2J_{C,N}$ values in a series of twisted amides.



A series of twisted amides **1a–e**,[7]‡ enriched to 99% with $^{15}N$, was synthesized *via* several steps from commercially available [$^{15}N$] glycine and [$^{15}N$] leucine. The C–N coupling constants of **1a–e** were measured at 100.04 MHz using $^{13}C$ NMR spectroscopy. Table 1 shows the $^1J_{C,N}$ and $^2J_{C,N}$ values, and the previously reported C(O)–N twist angles τ and the $\chi_N$ values,[7,9] $^1J_{C(O),N}$ lies in the range of 2.5–7.8 Hz in $CDCl_3$, and 3.2–7.9 Hz in [$^2H_6$]DMSO. The plots of $^1J_{C(O),N}$ *versus* τ are a little scattered, but a rough correlation exists between them, as shown in Fig. 1(*a*). Thus, as the twist angle increases, the $^1J_{C(O),N}$ value decreases. By assuming the Fermi contact mechanism to be dominant, it has been reported that $^1J_{C,N}$ depends on the percentage s-character of the C and N atoms.[10] However, there are no clear-cut relationships between the $^1J_{C(S),N}$ and $^1J_{C4,N}$ values and the $\chi_N$ value, which represents the extent of pyramidalization of the N atom. These suggest that the contribution of the contact term to $^1J_{C(O),N}$ is not predominant in this case. Therefore, the orbital and dipolar terms,[11] which depend upon the p-electron distribution, may be the dominant factors governing $^1J_{C,N}$. The importance of the effect of the p-electron distribution on $^1J_{C,N}$ has been reported in substituted anilines: steric inhibition of nitrogen lone-pair delocalization in *N*,*N*-dimethylaniline derivatives reduces the $^1J_{C,N}$ value.[12] A similar explanation can be applied to the present case. Thus, rotation about the amide bond causes a decrease in the C–N double bond character resulting from amide resonance; consequently, the $J_{C,N}$ decreases. When [$^2H_6$]DMSO was used as the NMR solvent, the slope changed, becoming somewhat gentler compared to that in $CDCl_3$. This is because the polar solvent easily stabilizes the canonical form **II** (Scheme 1).

The $^2J_{C7,N}$ values are in the range 5.6–7.1 Hz, which is much narrower than that of $^1J_{C(O),N}$. On the other hand, $^2J_{C5,N}$ was not observed for any of the amides. In contrast to the relationship between $^1J_{C(O),N}$ and τ, the $^2J_{C7,N}$ value increases with increasing the twist angle, as shown in Fig. 1(*b*). It has been assumed that $^2J_{C,N}$ depends on the dihedral angle between the lone pair orbital and the Cα–Cβ bond. For example, $^2J_{C,N}$ of quinuclidine, whose dihedral angle is 180°, is only 0.2 Hz, whereas that of propylamine is 1.2 Hz.[13] Because the dihedral angle of the series of amides decreases with increasing C(O)–N twist angle, as shown in Fig. 2, the present results may also be

**1a** $R^1$ = Me, $R^2$ = $R^3$ = H
**b** $R^1$ = Bn, $R^2$ = $R^3$ = H
**c** $R^1$ = $R^2$ = $R^3$ = Me
**d** $R^1$ = $Bu^t$, $R^2$ = $R^3$ = H
**e** $R^1$ = $Bu^t$, $R^2$ = $Bu^i$, $R^3$ = H

**Table 1** $J_{C,N}$ values, $\chi_N$ and twist angle τ

| Compound | $^1J_{C(O),N}$[a] /Hz | $^1J_{C(O),N}$[b] /Hz | $^1J_{C(S),N}$[a] /Hz | $^1J_{C4,N}$[a] /Hz | $^2J_{C7,N}$[a] /Hz | $\chi_N$ (°) | τ (°) |
|---|---|---|---|---|---|---|---|
| **1a** | 7.8 | 7.9 | 8.9 | 10.2 | 5.8 | 11.9 | 20.1 |
| **1b** | 7.5 | 7.6 | 8.7 | 10.0 | 5.6 | 13.4 | 10.2 |

ascribed to the directional effect of the nitrogen lone pair orbital.

Kainosho and Nagao reported[14] that the $^{13}C$–$^{15}N$ coupling constant between the Phe-97 carbonyl carbon and the ser-98 nitrogen in *Streptomyces* subtilisin inhibitor is unusually small, and they explained that it is a result of the non-planarity of peptide bonds in β-sheets and α-helices. The present result seems to support their hypothesis.

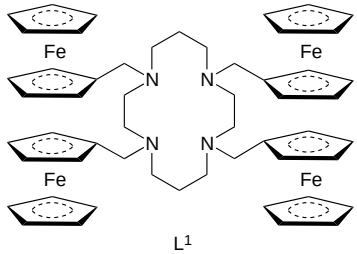
# Quantitative determination of metal ions and anions in aqueous solution by using pH-responsive redox-active receptors



**Miguel E. Padilla-Tosta, Ramón Martínez-Máñez,* Teresa Pardo, Juan Soto and María José L. Tendero**

*Departamento de Química, Universidad Politécnica de Valencia, Camino de Vera s/n, 46071 Valencia, Spain*

**The redox-active polyazacycloalkane 1,4,8,11-ferrocenylmethyl-1,4,8,11-tetraazacyclotetradecane L$^1$ is a versatile receptor for the quantitative electrochemical determination of metal ions ($Cu^{2+}$, $Zn^{2+}$, $Cd^{2+}$) and ATP in aqueous solution.**

In recent years a number of work has been devoted to the development of new receptors containing binding sites and redox-active groups.[1] Two properties are common to those new molecules; their electroactive character and the ability to bind substrates. Some of those receptors bearing different redox-active groups (able to be reduced or oxidized), can electrochemically recognize alkali-metal and alkaline-earth-metal cations,[2] anions[3] and neutral species.[4] Additionally it has recently been reported that transition-metal ions can also adequately be recognised by using ferrocene-functionalised polyamines as receptors.[5,6] That approach leads to pH-responsive redox-active molecules where the shift of the oxidation potential in the presence of transition-metal ions is a function of the pH.[5] Additionally the functionalisation of polyaza molecules with redox groups are good candidates to electrochemically recognize anion coordination based on the property of those systems to act as polybases.[6] To further advance the use of redox-active receptors as practical electrochemical sensors we have performed electrochemical studies, using the redox-functionalised polyazacycloalkane 1,4,8,11-ferrocenylmethyl-1,4,8,11-tetraazacyclotetradecane L$^1$,[7] with the aim of quantitatively determining the concentration of cations and anions in solution.

Fig. 1 shows the variation of the oxidation potential ($E_{1/2}$, from rotating disk electrode techniques) *vs.* pH for the systems L$^1$–H$^+$–M$^{2+}$ (M = $Ni^{2+}$, $Cu^{2+}$, $Zn^{2+}$, $Cd^{2+}$, $Pb^{2+}$, ligand-to-metal ratio = 1:1) in thf–water (70:30 v/v) mixtures. The oxidation potential of L$^1$ shifts to more anodic potentials when the pH is reduced as a consequence of the successive protonation of the amino groups. In the presence of stoichimetric amounts ($M^{2+}/L^1$ = 1) of metal ions different curves are found. Some of them are quite different (for $Cu^{2+}$, $Zn^{2+}$, $Cd^{2+}$) and some quite similar (for $Pb^{2+}$ and $Ni^{2+}$) to that of the free receptor (see Fig. 1). We have also found that for ligand-to-metal ratios $<1$, curves between that of L$^1$ and that with $M^{2+}/L^1$ = 1 are obtained. At a fixed pH, $E_{1/2}$ for a determined $M^{2+}/L^1$ ratio is $E_{1/2} = x_L E_{1/2}{}^L + x_{ML} E_{1/2}{}^{ML}$ where $x_L$ and $x_{ML}$ are the molar fractions of the free receptor and the metal complex, respectively; whereas $E_{1/2}{}^L$ and $E_{1/2}{}^{ML}$ are the oxidation potential of L$^1$ and the oxidation potential of a 1:1 ligand-to-metal molar ratio. Knowing the amount of receptor used in the electrochemical experiments it is possible to determine the concentration of metal ions in solution. In a typical experiment we measured $E_{1/2}$ for an unknown $M^{2+}/L^1$ ratio at at least five different pH values and have determined an average concentration of the metal and the standard deviation. Working with L$^1$ concentrations in the range (4–5) $\times 10^{-4}$ mol dm$^{-3}$ we have been able to determine metal ion concentrations from $5 \times 10^{-5}$ to $4 \times 10^{-4}$ mol dm$^{-3}$. Probably lower limits of detection could be reached by using lower concentrations of receptor L$^1$. Table 1 shows the concentration of $Cu^{2+}$, $Zn^{2+}$ and $Cd^{2+}$ found and compared with the concentration by standard atomic absorption analysis. We have also developed studies on the quantitative determination of two metal ions showing different L$^1$–H$^+$–M$^{2+}$ curves to that of L$^1$ and have found that the simultaneous determination of $Cu^{2+}$, $Cd^{2+}$ and $Cu^{2+}$, $Zn^{2+}$ in mixtures containing both ions is possible if [L$^1$] = [$Cu^{2+}$] + [$Zn^{2+}$] or [L$^1$] = [$Cu^{2+}$] + [$Cd^{2+}$], whereas the method seems not to be accurate enough if the total concentration of the metals is unknown. Additionally the existence of some metal ions, as $Ni^{2+}$ and $Pb^{2+}$, with L$^1$–H$^+$–M$^{2+}$ curves close to that of L$^1$ suggests that the concentration of $Cu^{2+}$ (which probably has a higher stability constant with L$^1$ than $Ni^{2+}$ or $Pb^{2+}$) could be determined in the presence of those metal ions. Data in Table 1 confirm that [$Cu^{2+}$] can be selectively determined in the presence of $Ni^{2+}$ or $Pb^{2+}$. Even with large amounts of $Pb^{2+}$ copper(II) can be quite accurately determined {[$Cu^{2+}$] = $4.9 \times 10^{-5}$, $2.33 \times {}^1 10^{-4}$ and $3.32 \times 10^{-4}$ mol dm$^{-3}$ found in the presence of [$Pb^{2+}$] = $2.23 \times 10^{-3}$ for copper concentrations of $1.33 \times 10^{-4}$, $2.66 \times 10^{-4}$ and 3.33

L$^1$

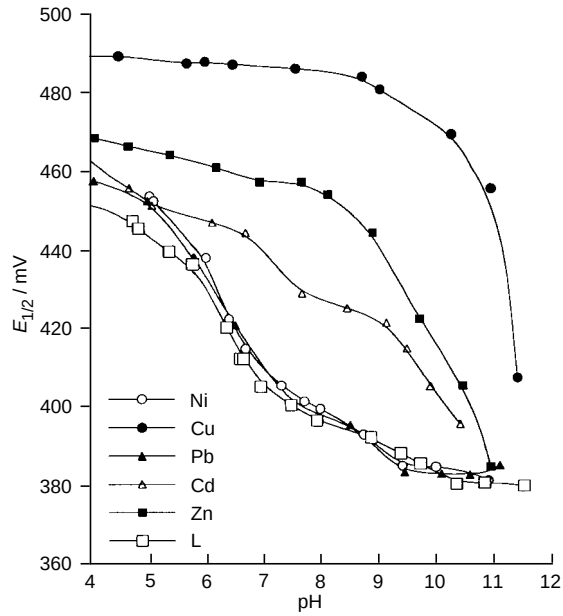


**Fig. 1** Plot of $E_{1/2}$ *vs.* pH for L$^1$–H$^+$ and L$^1$–H$^+$–M$^{2+}$ (M$^{2+}$ = $Ni^{2+}$, $Cu^{2+}$, $Zn^{2+}$, $Cd^{2+}$, $Pb^{2+}$)

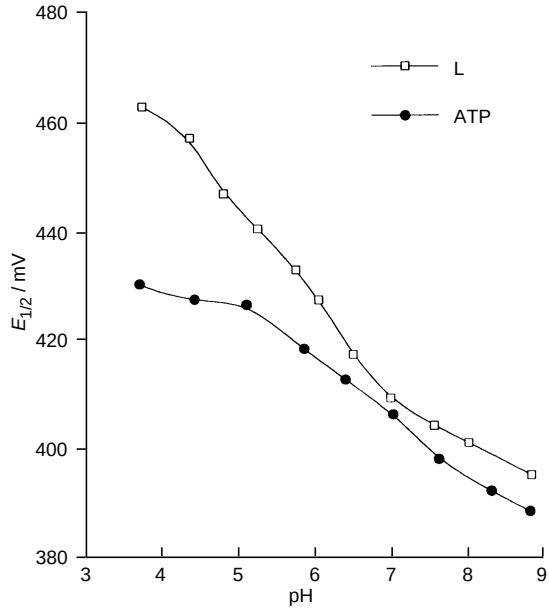

**Fig. 2** Plot of $E_{1/2}$ *vs.* pH for $L^1$–$H^+$ and $L^1$–$H^+$–ATP

$\times 10^{-4}$ mol $dm^{-3}$, respectively, from standard atomic absorption analysis}.

Finally Fig. 2 displays the $E_{1/2}$–pH curve obtained for receptor $L^1$ with ATP. The presence of the anion, as expected, does not change significantly the $E_{1/2}$–pH curve of $L^1$ when the pH is basic, but if the pH is reduced a steady shift to more cathodic potentials is observed. Based on that difference between the two $L^1$–$H^+$ and $L^1$–$H^+$–ATP systems and following a similar method to that used above we have determined ATP concentrations in aqueous solution (see Table 2). The results, which are as acurate as when metal ions are determined, although there is a small difference between $L^1$–$H^+$ and $L^1$–$H^+$–ATP curves, suggest that the method may prove useful in the determination of ATP or other anions using similar systems containing larger numbers of amino groups.

To our knowledge this is a new method for the quantitative determination of metal ions and anions in aqueous solution by using pH-responsive redox-active receptors. As an example molecule $L^1$ has proved to be a versatile receptor which can be used to quantitatively determine metal ions ($Cu^{2+}$, $Zn^{2+}$ or $Cd^{2+}$; mixtures of $Cu^{2+}$, $Cd^{2+}$ and $Cu^{2+}$, $Zn^{2+}$; $Cu^{2+}$ selectively in the presence of $Ni^{2+}$ or $Pb^{2+}$) and anions (ATP). The development of new sensors for quantitative recognition is now being carried out.

**Table 2** Determination of the concentration of ATP by using electrochemical methods and $L^1$ as receptor[a]

| $10^5$ [ATP] |

# First mononuclear organometallics of $Mo^{II}$ and $Mo^{III}$ containing terminal hydroxide ligands. X-Ray structure of $[Mo(\eta^5\text{-}C_5H_5)(OH)(PMe_3)_3]BF_4$

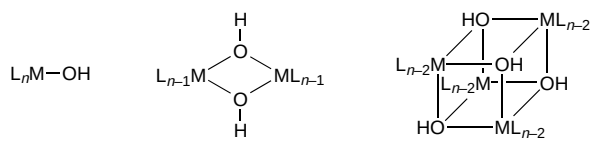
**James C. Fettinger,[a] Heinz-Bernhard Kraatz,[b] Rinaldo Poli*[a,c] and E. Alessandra Quadrelli[a]**

[a] *Department of Chemistry and Biochemistry, University of Maryland, College Park, Maryland 20742, USA*
[b] *Steacie Institute for Molecular Science, National Research Council of Canada, 100 Sussex Drive, Ottawa, Canada, K1N 0R6*
[c] *Laboratoire de Synthèse et d'Electrosynthèse Organometallique, Faculté des Sciences "Gabriel", Université de Bourgogne, 6 Boulevard Gabriel, 21100 Dijon, France*

**The new complexes $[Mo(\eta^5\text{-}C_5H_5)(OH)(PMe_3)_2]$ and $[Mo(\eta^5\text{-}C_5H_5)(OH)(PMe_3)_3]^+$ are unique examples of electronically unsaturated organometallics of $Mo^{II}$ and $Mo^{III}$ containing terminal hydroxide ligands; they show no tendency to dimerize with formation of hydroxo-bridges.**

Hydroxide ligands are ubiquitous of Werner-type coordination chemistry, whereas they are less commonly found in organometallic compounds. The availability of lone pairs on the oxygen atom frequently leads a terminal hydroxide complex (**I**) to lose ligands and afford doubly or triply bridged oligomers, *e.g.* **II** and **III**.[1–4] Organometallic compounds with terminal hydroxide ligands have rarely been observed for early- and late-transition-metal systems,[5–10] and for low-oxidation state saturated (18-electron) systems with tightly bonded ancillary ligands, examples of which are $[Mo(OH)(NO)(dppe)_2]$[11] and $[W(CO)_5(OH)]^-$.[12] We consider it therefore quite surprising to find the existence and stability toward dimerization of a mononuclear and paramagnetic organometallic $Mo^{II}$ hydroxo complex with a 16-electron configuration. To the best of our knowledge, there are only two previous examples of formally 16-electron $Mo^{II}$ complexes with terminal OH ligands, *i.e.* [MoL(NO)(O)(OH)] (L = 1,4,7-triisopropyl-1,4,7-triazacyclononane), and its corresponding protonated form, $[MoL(NO)(OH)_2]^+$.[13] These, however, do not contain M–C bonds and are diamagnetic, probably because extra π donation from the oxo lone pair(s) renders the compounds effectively saturated.

The reaction of $[Mo(\eta^5\text{-}C_5H_5)Cl(PMe_3)_3]$[14] with dry KOH in thf leads to the exchange of the chloride ion and the formation of paramagnetic $[Mo(\eta^5\text{-}C_5H_5)(OH)(PMe_3)_2]$ **1** [eqn. (1)].† The



$$[Mo(\eta^5\text{-}C_5H_5)Cl(PMe_3)_3] + KOH \rightarrow \underset{\mathbf{1}}{[Mo(\eta^5\text{-}C_5H_5)(OH)(PMe_3)_2]} + KCl + PMe_3 \qquad (1)$$

same transformation occurs in $C_6D_6$, allowing the observation of 1 equiv. of free $PMe_3$ by a $^1H$ NMR monitoring experiment (Fig. 1). The $^1H$ NMR spectrum of **1** shows contact-shifted resonances at δ 21.8 and 20.3 in the correct ratio for the $PMe_3$ and $C_5H_5$ protons. The $^{31}P$ NMR spectrum shows only the resonance of free $PMe_3$. The compound is extremely soluble in saturated hydrocarbons, thus preventing its isolation in crystalline form. The formulation of the complex as mononuclear rather than dinuclear is based on a comparison with literature analogues: $[Mo(\eta^5\text{-}C_5Me_5)ClL_2]$ (L = $PMe_3$, $PMe_2Ph$ or $L_2$ = dppe) and $[Mo(\eta^5\text{-}C_5H_5)Cl(PMe_2Ph)_2]$ are also mononuclear paramagnetic ($S$ = 1) complexes,[15] and show contact-shifted $^1H$ NMR resonances similar to those of **1**. On the other hand, $[\{Mo(\eta^5\text{-}C_5H_5)(\mu\text{-}Br)(\eta^4\text{-}C_4H_6)\}_2]$ is dinuclear and diamagnetic.[16] Mononuclear 16-electron $[Mo(\eta^5\text{-}C_5H_5)XL_2]$ complexes also exist with a spin-singlet ground state,[17] whereas there are no paramagnetic 18-electron complexes in this class. A bis(μ-hydroxo) dimeric structure for **1** is therefore ruled out.

It is rather peculiar that **1** is stable not only toward dimerization, but also toward coordination of the $PMe_3$ ligand [eqn. (1)]. The corresponding chloro parent compound does not have any tendency to lose the third $PMe_3$. However, sterically more encumbered $[Mo(\eta^5\text{-}C_5Me_5)Cl(PMe_3)_3]$ and $[Mo(\eta^5\text{-}C_5H_5)Cl(PMe_2Ph)_3]$ exist in equilibrium with the corresponding 16-electron bis-phosphine complexes.[15] This behaviour is in line with the greater π-donating ability of OH *vs.* Cl. The paramagnetism of **1** parallels that of the chloro analogues, but is in contrast with the diamagnetism of the phosphido or arsenido derivatives $[Mo(\eta^5\text{-}C_5Me_5)(PPh_2)L_2]$[17] and $[Mo(\eta^5\text{-}C_5H_5)(AsBu^t_2)(CO)_2]$.[18] We have previously rationalized this phenomenon in terms of differences in MO interactions (single-sided *vs.* double-sided π donors) and pairing energy stabilization.[15,19] Elaborating on those arguments, the paramagnetism of **1** might suggest the involvement of both oxygen lone pairs in two orthogonal two-centre–three electron interactions.[20]

Further treatment of the **1**–$PMe_3$ solution in thf with $[Fe(\eta^5\text{-}C_5H_5)_2]BF_4$ leads to at least two products. Crystallization from acetone–heptane affords yellow needles of $[Mo(\eta^5\text{-}C_5H_5)(OH)(PMe_3)_3]BF_4$ **2** and red cubes of $[Mo(\eta^5\text{-}C_5H_5)O(PMe_3)_2]BF_4$ **3**. The structure of **2** (Fig. 2)‡ shows a terminal mode for the hydroxide ligand in the expected four-legged piano-stool geometry, as found[14] for the related $[Mo(\eta^5\text{-}C_5H_5)Cl(PMe_3)_3]^+$. The structural parameters are normal for this class of compounds,[21] with the Mo–O bond measuring 2.084(2) Å. To the best of our knowledge, **2** is the first reported organometallic hydroxide of $Mo^{III}$, and the first complex of $Mo^{III}$ (including Werner-type and clusters) with a terminally bonded hydroxide.[22–25] A deprotonated form of the $Mo^{III}$ aquo complex $[Mo(H_2O)_6]^{3+}$ is known, but this corresponds to a μ-hydroxo dimer, *i.e.* $[\{Mo(H_2O)_4(\mu\text{-}OH)\}_2]^{4+}$.[26] **3** has been previously reported.[27]§

The formation of **2** by oxidation of **1** occurs according to the stoichiometry of eqn. (2). Half-sandwich $Mo^{III}$ complexes are

**I** **II** **III**

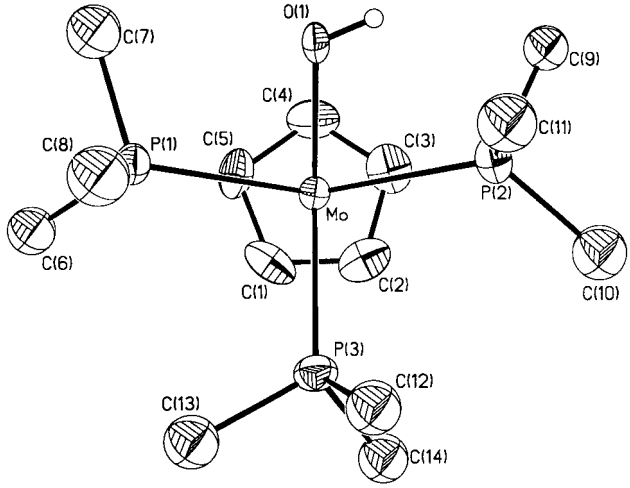

**Fig. 2** Top view of the cation in compound **2**. Ellipsoids drawn at 30% probability. Selected bond lengths (Å) and angles (°): Mo–P(1) 2.4530(12), Mo–P(2) 2.4984(12), Mo–P(3) 2.4741(11), Mo–O(1) 2.084(2), Mo–Cp 1.980(4); P(1)–Mo–P(2) 94.19(5), P(1)–Mo–P(3) 93.21(4), P(1)–Mo–O(1) 139.27(10), P(1)–Mo–Cp 108.5(1), P(2)–Mo–P(3) 132.81(4), P(2)–Mo–O(1) 71.53(8), P(2)–Mo–Cp 110.7(1), P(3)–Mo–O(1) 72.75(8), P(3)–Mo–Cp 110.8(1), O(1)–Mo–Cp 112.2(2). Cp is the $C_5H_5$ ring centroid.

known to prefer the 17-electron configuration.[21,28] The nature of the observed product **2** shows that a bis(μ-hydroxo)-bridged $[\mathbf{1}_2]^{2+}$ complex would be unstable relative to the mononuclear 17-electron $PMe_3$ adduct. The hydroxide proton in complex **2** can be reasonably expected to be acidic. Presumably, the presence of free $PMe_3$ or other adventitious proton acceptors during the formation of **2** induces a deprotonation equilibrium to afford a neutral $Mo^{III}$ oxo species which is then easily oxidized by $[Fe(\eta^5\text{-}C_5H_5)_2]^+$ to afford the observed product **3** [eqn. (3)].

$$[Mo(\eta^5\text{-}C_5H_5)(OH)(PMe_3)_2] + PMe_3 + [Fe(\eta^5\text{-}C_5H_5)_2]^+ \rightarrow [Mo(\eta^5\text{-}C_5H_5)(OH)(PMe_3)_3]^+ + [Fe(\eta^5\text{-}C_5H_5)_2] \quad (2)$$

$$[Mo(\eta^5\text{-}C_5H_5)(OH)(PMe_3)_3]^+ + [Fe(\eta^5\text{-}C_5H_5)_2]^+ \xrightarrow{-H^+\text{-}PMe_3} [Mo(\eta^5\text{-}C_5H_5O)(PMe_3)_2]^+ + [Fe(\eta^5\text{-}C_5H_5)_2] \quad (3)$$

In conclusion, we have reported here for the first time the existence and stability of terminal hydroxo complexes of paramagnetic organometallics of $Mo^{II}$ and $Mo^{III}$ in defiance of the possible dimerization with formation of hydroxo-bridges. For the dimerization process to occur, **2** would have to lose the stabilization of the $Mo^{III}$–$PMe_3$ bond, whereas compound **1** would have to pay the price of pairing the electrons. Terminal hydroxo complexes of $Mo^{IV}$, on the other hand, have been previously reported.[2,29–34]

† By carrying out all operations under a dinitrogen atmosphere, solid KOH (pre-dried at 110 °C and 6 mmHg for 48 h; *ca*. 300 mg, *ca*. 5.3 mmol) was added to a blue solution of $[Mo(\eta^5\text{-}C_5H_5)Cl(PMe_3)_3]$ (215 mg, 0.507 mmol) in 6 ml of thf. After stirring overnight at room temp., complete evaporation of the solvent from the yellow–brown solution yielded an oily residue, which was extracted into heptane (3 × 5 ml). An aliquot of this solution was dried under reduced pressure and the residue was investigated by $^1H$ NMR in $C_6D_6$: δ 21.8 (br, $w_{1/2}$ 90 Hz, 18 H, Me), 20.3 (br, $w_{1/2}$ 75 Hz, 5 H, $C_5H_5$). Concentration of the heptane solution and cooling to −80 °C did not separate any solid.

# A novel organometallic oxide cluster with multi-valley sites: synthesis and structure of $[NBu^n_4]_2[\{(\eta^5\text{-}C_5Me_5)Rh\}_2Mo_6O_{20}(OMe)_2]$ and its framework transformations

**Satoshi Takara, Takanori Nishioka, Isamu Kinoshita and Kiyoshi Isobe***

*Department of Material Science, Faculty of Science, Osaka City University, Sugimoto, Sumiyoshi-ku, Osaka 558, Japan*

**A novel organometallic oxide cluster $[NBu^n_4]_2[\{(\eta^5\text{-}C_5Me_5)Rh\}_2Mo_6O_{20}(OMe)_2]$ 1 with multi-valley sites is synthesized by the reaction of $[NBu^n_4]_2[Mo_2O_7]$ and $\{(\eta^5\text{-}C_5Me_5)RhCl(\mu\text{-}Cl)\}_2$ in a molar ratio of 4:1 in methanol, and displays unique framework transformations upon treatment with organometallic and oxometalate compounds.**

Theoretical studies on catalytic hydrocarbon transformation on metal oxides showed that coordinatively unsaturated metal sites and valley sites in integrated cubic cluster models play an important role for activation of hydrocarbons.[1] Indeed, organometallic oxide clusters, such as the incomplete cubane-type cluster $[\{(\eta^5\text{-}C_5Me_5)Rh\}_2Mo_3O_9(OMe)_4]$ **2**,[2a] the face-shared triply fused cubane-type cluster $[\{(\eta^5\text{-}C_5Me_5)Rh\}_4Mo_4O_{16}]$ **3**,[2b] the valley-site structure $[\{(\eta^5\text{-}C_5Me_5)Rh\}_4V_6O_{19}]$[2c,d] and the planar cluster $[NBu^n_4]_2[\{(\eta^3\text{-}C_4H_7)_2Rh\}_2V_4O_{12}]$[2f] supported on silica, exhibit significant catalytic abilities and higher selectivities for oxidation and metathesis of propene.[3] Thus, our current efforts concentrate on the design and development of synthetic strategies for new organometallic oxide clusters with active sites owing to characteristic structures such as lacunary, incomplete cubic, or valley-site frameworks.[2a–e]

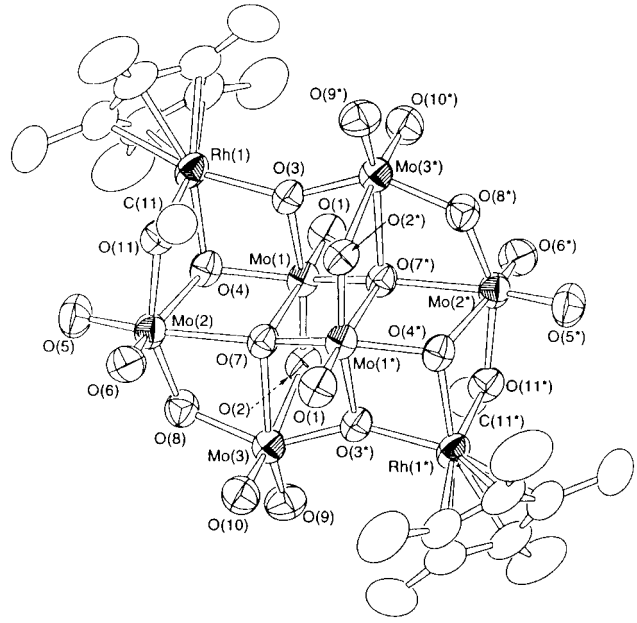
Here, we report on the structure and synthesis of the organometallic oxide cluster $[NBu^n_4]_2[\{(\eta\text{-}C_5Me_5)Rh\}_2Mo_6O_{20}(OMe)_2]$ **1** with multi-valley sites and its framework transformations.

A mixture of $[NBu^n_4]_2[Mo_2O_7]$[4] (2.55 g, 3.24 mmol) and $[\{(\eta^5\text{-}C_5Me_5)RhCl(\mu\text{-}Cl)\}_2]$[5] (0.50 g, 0.81 mmol) in 20 ml of methanol was allowed to stand for 4 h with stirring at room temp. and concentrated to 5 ml. Diethyl ether (80 ml) was then added slowly to give an orange precipitate of **1**. The crude product is recrystallized from methanol–diethyl ether (1.22 g, 79% yield based on Rh).† The formation of **1** may proceed according to eqn. (1).‡

$$[\{(\eta^5\text{-}C_5Me_5)RhCl(\mu\text{-}Cl)\}_2] + 3[NBu^n_4]_2[Mo_2O_7] + 2MeOH \rightarrow [NBu^n_4]_2[\{(\eta^5\text{-}C_5Me_5)Rh\}_2Mo_6O_{20}(OMe)_2] \quad \mathbf{1} \quad + 4[NBu^n_4]Cl + H_2O \qquad (1)$$

An X-ray analysis of **1** reveals that the anion of **1** has $C_i$ symmetry and is composed of four $MoO_6$ and two $MoO_5(\mu\text{-}OMe)$ octahedra interlinked along edges and two $(\eta^5\text{-}C_5Me_5)Rh$ groups each sharing two edges with the octahedra (Fig. 1).§ The framework of **1** is in some respects similar to that of the $\gamma\text{-}[Mo_8O_{26}]^{4-}$ isomer found in $[(Me_3N(CH_2)_6NMe_3]_2[Mo_8O_{26}]\cdot 2H_2O$, which also has $C_i$ symmetry and is composed of six $MoO_6$ octahedra interlinked along edges and two $MoO_5$ trigonal bipyramids each sharing two edges with the octahedra.[6] The structure of **1** can be regarded as a framework which contains two $(\eta^5\text{-}C_5Me_5)Rh(\mu\text{-}OMe)$ groups rather than two $MoO_5$ trigonal bipyramids. It is noteworthy that $(\eta^5\text{-}C_5Me_5)Rh$ moieties and methoxy groups in the framework of **1** form two unique large valley sites, constructed by Rh(1)Mo(3*)Mo(1)Mo(2*) and Rh(1*)Mo(3)Mo(1*)Mo(2), while two small ones are constructed by Mo(1)Mo(2)Mo(3) and Mo(1*)Mo(2*)Mo(3*). For these two kinds of valley sites, a space-filling model¶ suggests that the small sites are much more open with exposed highly basic oxygens [O(2), O(4), O(8)], whereas the larger ones are rimmed with bulky pentamethylcyclopentadienyl, methoxy and Mo=O groups so as to form shallow cavities.

Bearing in mind that **1** might show high reactivity due to the presence of valley sites, we have been prompted to investigate the reactivity of **1** towards organometallic (electrophile) and oxometalate (nucleophile) compounds. Consequently, cluster framework transformations of **1** occur in both, for example, by treatments with $\{(\eta^5\text{-}C_5Me_5)Rh\}^{2+}$ and with $[Mo_2O_7]^{2-}$ in methanol to produce the incomplete double cubane-type cluster of **2** and the triply fused cubane-type cluster of **3**, respectively (Scheme 1).‖ The basic bridging oxygens [O(2), O(4), O(8)] in the small valley sites can interact freely with metal cations, hence in the formation of **2**, landing of the added $\{(\eta^5\text{-}C_5Me_5)Rh\}^{2+}$ cations on the small valley sites probably triggers an initial step of the transformation. On the other hand for the formation of **3**, the added $[Mo_2O_7]^{2-}$ anions will approach the rhodium(III) centres in the shallow cavities by electrostatic force of attraction: the parts of $Rh^{III}$ centres in the shallow cavities are most exposed to attack by nucleophiles. By the action of an excess of $[Mo_2O_7]^{2-}$ some of the weak Rh–O



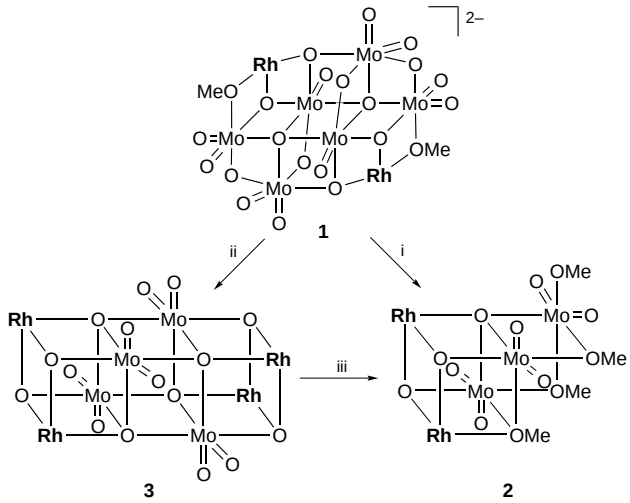


**Fig. 1** Structure of the anion in **1**. Selected bond lengths (Å): Mo(1)–O(1) 1.696(3), Mo(1)–O(2) 1.744(3), Mo(1)–O(3) 2.152(3), Mo(1)–O(4) 1.928(3), Mo(1)–O(7) 1.916(3), Mo(2)–O(4) 2.178(3), Mo(2)–O(5) 1.695(4), Mo(2)–O(6) 1.708(3), Mo(2)–O(7) 2.299(3), Mo(2)–O(8) 1.892(3), Mo(2)–O(11) 1.411(6), Mo(3)–O(2) 2.363(3), Mo(3)–O(3) 1.908(3), Mo(3)–O(7) 2.277(3), Mo(3)–O(8) 1.946(3), Mo(3)–O(9) 1.703(4), Mo(3)–O(10) 1.704(4), Rh(1)–O(3) 2.068(3), Rh(1)–O(4) 2.100(3), Rh(1)–O(11) 2.109(3).

**Scheme 1** **Rh** = Rh($\eta^5$-$C_5Me_5$). *Reagents and conditions:* i, [{($\eta^5$-$C_5Me_5$)RhCl($\mu$-Cl)}$_2$] 1 equiv., MeOH, 27 °C; ii, [$NBu^n_4$]$_2$[$Mo_2O_7$] 4 equiv., MeOH, 27 °C; iii, *p*-hydroquinone, MeOH, reflux; see ref. 2(*a*).

[*e.g.* Rh(1)–O(11) and Rh(1)–O(3)] bonds in the large valley sites may be cleaved to cause a new condensation of oxomolybdates on the vacant sites of the ($\eta$-$C_5Me_5$)Rh centres to afford the most stable species, the triply fused cubane-type cluster [{($\eta^5$-$C_5Me_5$)Rh}$_4$$Mo_4O_{16}$] **3**. Although the transformations mentioned above to form **2** and **3** might contain complicated steps to be elucidated, the unique valley sites of **1** can fulfil its function to initiate the framework transformations and cluster **1** may act as a convenient molecular platform towards other cationic and anionic transition-metal fragments. The transformations are also particularly important for constructing new oxide cluster architecture; the multi-valley sites cluster **1** is a prominent building block for preparation of larger clusters.

The authors gratefully acknowledge Professors Atsushi Yagasaki (Kwansei Gakuin University, Japan) and Vadim Yu. Kukushkin (St. Petersburg State University, Russian Federation) for invaluable discussions. This work was supported by a Grant-in-Aid Scientific Research (No. 07404038) from the Ministry of Education, Science and Culture, Japan and the Sasakawa Scientific Research Grant from The Japan Science Society.

† The cluster was analysed satisfactorily (C, H, N) for **1**. Selected IR data (**1**, Nujol) $\nu$/cm$^{-1}$ 440w, 487w, 522m, 638m, 680s, 742m, 858s, 900s, 1040m, 1063m, 1162w, 1663m, 3500m (br).

‡ Excess dimolybdate acts as a base for deprotonation of methanol molecules coordinated to molybdenum atoms. 1 Equiv. of dimolybdate is insufficient to produce **3**, formation of **3** needing 4 equiv. of $[Mo_2O_7]^{2-}$ relative to **1**, as described in Scheme 1.

§ *Crystal data* for $C_{54}H_{108}Mo_6N_2O_{22}Rh_2$, **1**: single crystals of **1** suitable for X-ray crystallography were grown by slow diffusion of diethyl ether into a methanol solution. An orange crystal of dimensions 0.4 × 0.2 × 0.2 mm was mounted on a glass fibre. Cluster **1** crystallizes in the trigonal space group $R\bar{3}$ (no. 148) with $a$ = 41.954(3), $c$ = 12.925(3) Å, $U$ = 19701(4) Å$^3$, $Z$ = 9, and $D_c$ = 1.455 g cm$^{-3}$. A total of 10 722 reflections were collected on a Rigaku AFC-7 diffractometer with graphite-monochromated Mo-K$\alpha$ radiation *via* a $\omega$-scan technique in the limit of $2\theta \leqslant 55.0°$ at 296 K. The reflections with $I > 3\sigma(I)$ were corrected for Lorentz-polarization factors but not for extinction. An absorption correction was applied using an empirical $\psi$-scan method. All crystallographic calculations were carried out using teXsan programs. The positions of the rhodium and molybdenum atoms were obtained by SHELXS86 direct methods. The remaining atoms were located on difference Fourier maps. Hydrogen atoms were fixed at calculated positions and used for structure-factor calculations. 388 variables were refined by full-matrix least-squares techniques using 5960 independent reflections and converged to $R$ = 0.035, $R_w$ = 0.041 and GOF = 1.21. A final difference Fourier map yielded $\Delta\rho_{max}$ = +0.40 e Å$^{-3}$, $\Delta\rho_{min}$ = −0.38 e Å$^{-3}$. Atomic coordinates, bond lengths, angles and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/428.

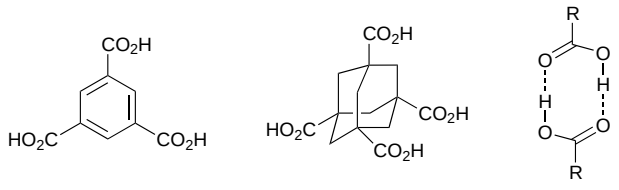
# Hydrothermal synthesis and X-ray structural characterisation of calcium benzene-1,3,5-tricarboxylate

**M. John Platers,* R. Alan Howie and Alexander J. Roberts**

*Department of Chemistry, Aberdeen University, Meston Walk, Aberdeen, UK AB24 3UE*

**Benzene-1,3,5-tricarboxylic acid ($H_3$btc) forms a calcium salt of stoichiometry Ca(hbtc)·2$H_2O$ which possesses an infinite layered structure.**



The synthesis of novel crystal structures from polar tectons by hydrogen-bond directed self-assembly and metal-ion or ligand-directed assembly has allowed the preparation of networked microporous materials with potential applications as absorbents,[1] ion exchangers,[2] protonic conductors[3] and catalysts. An inherent difficulty in the formation of microporous materials by the hydrogen-bond controlled self-assembly of tectons[4] such as benzene-1,3,5-tricarboxylic acid ($H_3$btc) **1** or adamantane-tetracarboxylic acid ($H_4$atc) **2** is the tendency for packing to minimise voids and maximise van der Waals contacts in the crystal lattice.[5] Infinite lattice networks of $H_3$btc[6] and $H_4$atc stabilised by the hydrogen-bond dimers **3** would possess large micropores but in practice the dimeric hydrogen bonding is too weak to stabilise these open frameworks and a different condensed crystal structure forms. Recently Yaghi *et al.* reported a solution to this problem by preparing divalent metal ion (Co, Ni, Zn) salts of $H_3$btc which possess a stable networked structure with hydrated divalent metal ions forming strong ionic bonds between the rigid btc tectons.[7] Heating dehydrates the metal ions leaving micropores in the crystal lattice with the metal ions lining the channels.

The work described here is part of an investigation into the hydrothermal synthesis and structural characterisation of the alkaline-earth metal (Ca, Sr, Ba) salts of benzene-1,3,5-tricarboxylic acid with the aim of producing stable microporous materials.† Heating $H_3$btc with calcium acetate in water in a sealed bomb to 180 °C followed by slow cooling gave colourless crystals whose structure was solved by X-ray analysis.‡ The compound did not have the expected 1 : 2 btc : Ca ratio but instead gave crystals of formula Ca(hbtc)·2$H_2O$.† The IR spectrum also showed a stretch at 1695 $cm^{-1}$ indicative of an aromatic carboxylic acid.

The structure consists of infinite two-dimensional layers of hbtc dianions alternating with layers of Ca and water molecules in the *c*-axis direction. The proton H(5) bonded to O(5) of one of the carboxylate groups forms a strong hydrogen bond O(5)–H(5)···O(35) linking the hbtc anions in chains perpendicular to (1,1,0) (Fig. 1). The layers of hbtc anions are composed of such chains packed side-by-side and related in pairs and therfore inverted in orientation by crystallographic centres of symmetry as are the layers themselves. As a result the O(1)–C(7)–O(2) carboxylate groups of the anions in a particular hydrogen-bonded chain lie on one side of the layer while the same carboxylate groups of the neighbouring chains lie on the other side of the layer.

In the layers of Ca and water molecules lying between the layers of hbtc anions the Ca cations occur in centrosymmetrically related pairs. Ca is irregularly coordinated by eight oxygens with Ca–O distances in the range 2.4121(18)–2.5701(16) Å (Fig. 2). Seven of these contacts arise from interaction of Ca with five distinct carboxylate anions. Three anions operate as monodentate ligands generating the Ca contacts with O(14), O(23) and O(62). The last two anions coordinate in a bidentate fashion to generate pairs of contacts with Ca [O(1) and O(2) and O(31) and O(41) respectively]. The coordination of Ca is completed by a contact with one of the water molecules [Ca–O(1w) 2.4199(20) Å]. A feature of the Ca coordination is the presence of the Ca–O(14) and Ca–O(23) contacts which involve distinct carboxylate anions which are in the same layer but related by a cell translation along the *a* axis. The contacts then produce linked pairs of chains interleaved with symmetry related and differently oriented linked chain pairs.

The molecular formula and the asymmetric unit both contain two water molecules. The presence of water was shown by the IR spectrum which showed OH stretches at 3542 and 3342 $cm^{-1}$. One of these [O(1w), H(11w), H(12w)] is not only involved in the coordination of Ca but also forms hydrogen bonds as O(1w)–H(11w)···O(46) to a carboxylate oxygen and

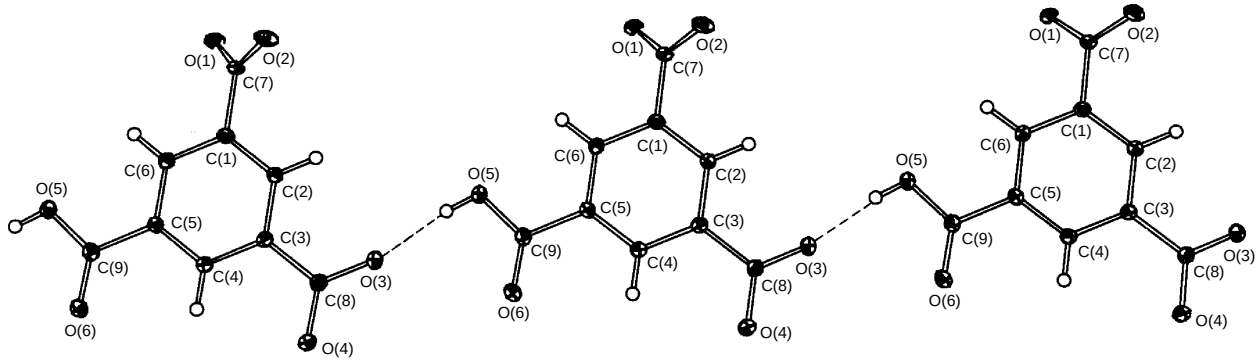


**Fig. 1** Array of hydrogen-bonded hbtc dianions occurring in Ca(hbtc)·2$H_2O$

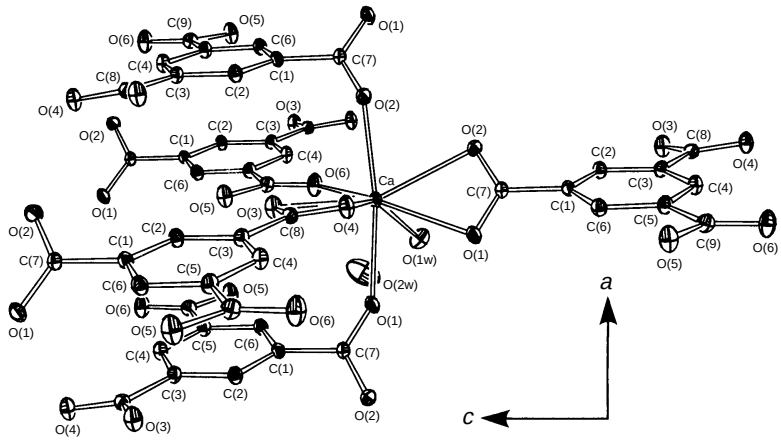

**Fig. 2** The coordination of $Ca^{2+}$ by two bidentate and three monodentate carboxylates and one water molecule

O(1w)–H(12w)···O(2w) to the second water molecule. The hydrogens of the second water molecule involving O(2w) are disordered and have been modelled in terms of three sites two of which, H(21w) and H(23w), have been assigned fixed site occupancy factors of 0.5 while the third, H(22w), is fully occupied. H(22w) participates in the formation of the hydrogen bond O(2w)–H(22w)···O(1w) complementing the O(1w)–H(12w)···O(2w) bond described. Whereas H(23w) is involved in the formation of the O(2w)–H(23w)···O(47) hydrogen bond H(21w) does not participate in hydrogen-bond formation.

Thermal gravimetric analysis from room temperature to 230 °C showed a gradual mass loss finally corresponding to the loss of two water molecules per formula unit showing that both the loosely bound and calcium coordinated water can be eliminated. Upon rehydration the X-ray powder diffraction pattern was virtually identical to that of the hydrated material suggesting that the polymeric anion layers and high Ca carboxylate coordination stabilises micropores after removal of water from the lattice. Further detailed studies on these and related materials will be reported shortly.

## Footnotes

† Prior to the publication of ref. 7 our independent attempts to characterise a calcium salt of $H_3$btc by single-crystal X-ray crystallography were unsuccessful. We were naively following hydrothermal synthesis procedures without slow cooling of the sample which gave poor quality crystals.

*Typical procedure*: $H_3$btc (400 mg, 1.9 mmol) and $Ca(O_2CMe)_2$ (301 mg, 1.9 mmol) in water (25 ml) were sealed in a 45 ml Teflon-lined safety bomb[8] and placed in an oven at 180 °C. After about 10 h the oven temperature was slowly reduced over a 36 h period to 80 °C and then allowed to cool to room temp. Colourless crystals were collected and washed with distilled water (494 mg, 91%). The homogeneity of the sample was shown by satisfactory carbon and hydrogen microanalysis and by the X-ray powder diffraction pattern which was identical to the calculated pattern.

‡ *Crystal data*: **2**: $C_9H_8CaO_8$, triclinic, space group $P\bar{1}$ (no. 1), $a$ = 6.853(5), $b$ = 9.007(9), $c$ = 9.987(6) Å, $\alpha$ = 102.23(6), $\beta$ = 100.53(5), $\gamma$ = 110.21(7), $U$ = 543.2(8) Å$^3$, $Z$ = 2, $D_c$ = 1.737 g cm$^{-3}$, data collection and cell refinement: Nicolet P3 diffractometer using a graphite monochromator with $\mu$(Mo-K$\alpha$) = 0.063 mm$^{-1}$, $T$ = 293 K. Data collection used $\omega$ scan rates of 5.33 ($I_p$ < 150) to 58.6 ($I_p$ > 2500)° min$^{-1}$, where $I_p$ was the prescan intensity. Scan widths $\omega$ were 2.4–2.8°. Data reduction *via* RDNIC.[9] The structure was solved by direct methods to yield positions for all non-hydrogens except the oxygens of the water molecules which were obtained later from difference maps as were the positions of hydrogens attached to oxygens. The final $R$ value was 0.041 ($R_w$ = 0.048). Refinement was by full-matrix least squares. All non-hydrogen atoms were refined anisotropically. For the anion the acid hydrogen H(5) was refined isotropically in the usual manner but the hydrogen attached to carbons were placed in calculated positions with C–H = 0.95 Å and refined with a riding model and common group $U_{iso}$. Hydrogens of the water molecules were also refined with group $U_{iso}$ values, one for each molecule. The disorder of the hydrogen associated with O(2w) has already been described in the text. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/421.

# Double C–H activation in pentamethylcyclopentadienylruthenium complexes

**Shane R. O'Leary, Harry Adams and Peter M. Maitlis***

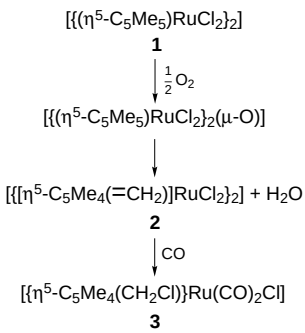
*Department of Chemistry, The University of Sheffield, Sheffield, UK S3 7HF*

**Two methyls in each $\eta^5$-$C_5Me_5$ are activated in [{($\eta^5$-$C_5Me_5$)$RuCl_2$}$_2$] 1 [by (*i*) air, (*ii*) *N*-chlorosuccinimide and (*iii*) air]; after carbonylation a mixture of the 1,3- and 1,2-isomers [{$\eta^5$-$C_5Me_3(CH_2Cl)_2$}$Ru(CO)_2Cl$] 4a,b is obtained; the X-ray structure of 4a is determined.**

There is considerable interest in the activation of methyls in pentamethylcyclopentadienyl complexes. This has been particularly so for ruthenium,[1] where the technique has allowed us to prepare new ranges of molecules that have the potential to act as catalysts, as well as for rhodium and iridium,[2] and for other metals.[3]

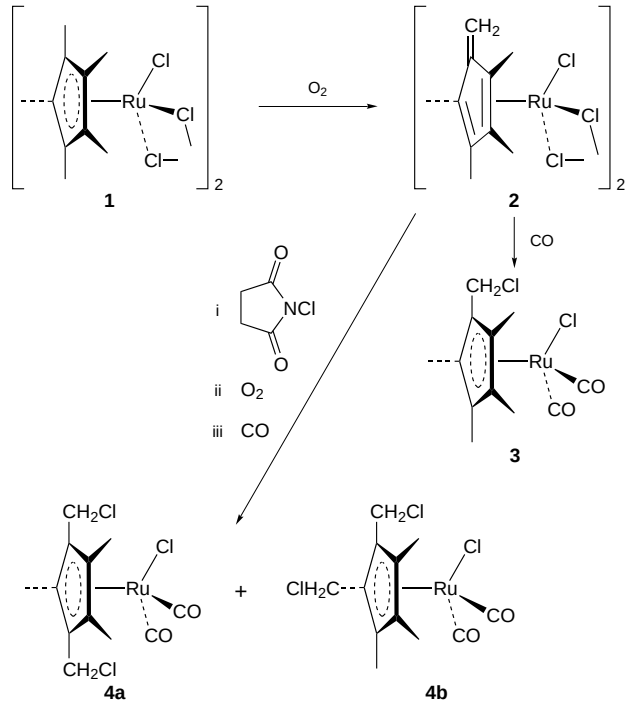
One C–H bond in pentamethylcyclopentadienylruthenium chloride **1** (or bromide) is easily cleaved under the influence of oxygen (1 atm, 20 °C, $CHCl_3$ solution). The reaction sequence has been shown to proceed *via* a μ-oxo dinuclear complex which effectively dehydrates to give the tetramethylfulvene complex **2**.[1] Carbonylation then gives the final product, the chloromethyl dicarbonyl complex **3**, obtained in 82% overall yield from **1** (Scheme 1).

We now report that the reactions can be repeated so that the C–H bonds on two different methyls (either 1,2- or 1,3-) of one ring are activated. To do this the above reaction sequence is carried out as far as the tetramethylfulvene complex **2**. This does not need to be isolated or purified but is treated directly with 2 equiv. of *N*-chlorosuccinimide (NCS) in $CH_2Cl_2$ (Scheme 2). A second aeration is then carried out, followed by a carbonylation (1 atm, 20 °C) to give a mixture of the red isomeric bis(chloromethyl)dicarbonyl chlorides, [{$\eta^5$-$C_5Me_3(CH_2Cl)_2$}-$Ru(CO)_2Cl$] shown by NMR to be composed of **4a**,**b** in a 1 : 1 ratio. The complexes were separated by chromatography on a silica column (3 × 40 cm) in diethyl ether–light petroleum (bp 40–60 °C). Two bands were eluted, the first was shown by NMR spectroscopy and crystallography to be [{$\eta^5$-$C_5Me_3(CH_2Cl)_2$-1,3}$Ru(CO)_2Cl$] **4a** (40% isolated yield),† while the second was shown by NMR to contain [{$\eta^5$-$C_5Me_3(CH_2Cl)_2$-1,2}$Ru(CO)_2Cl$] **4b** (32% isolated yield).†



The isomers were initially identified by the relative positions of the ring methyls in the NMR spectra. As the $CH_2Cl$ substituents deshield it was assumed that the complex with a single methyl signal at higher frequency than the two equivalent methyls was the 1,3 isomer **4a**, since the unique methyl is affected by two neighbouring $CH_2Cl$ groups, while the 1,2 isomer **4b**, has the unique methyl at lower frequency since it lies between two methyls there. The assignments were confirmed by the crystal structure of the 1,3 isomer **4a**.

Similar reactions occurred when complex **1** was reacted with *N*-bromosuccimide but in this case mixtures of isomers were formed that could be separated only with great difficulty.



A crystal of complex **4a** for X-ray analysis was grown by slowly cooling a concentrated diethyl ether solution and leaving it at −23 °C for several days.‡ The structure is illustrated in Fig. 1 and clearly shows the 1,3-arrangement of the chloromethyl substituents. The bond lengths are very similar to those previously found for complex **3**: Ru–Cl 2.409(2), 2.412(2) Å for **4a**; 2.422(3) Å for **3**; C–Cl 1.815(8), 1.812(7), 1.794(8), 1.806(8) Å for **4a**; 1.787(12) Å for **3**. As found in complex **3**, the Ru–C bond lengths to the carbons bearing the $CH_2Cl$ substituents in **4a** are slightly shorter than the other Ru–ring C distances, but the differences are again only just significant.

Reaction of the isomeric mixture of **4a**,**b** dissolved in thf with a small amount of water and 2,4,6-trimethylpyridine gave a mixture of the two bishydroxymethyl complexes **5a**,**b**,[4] which were separated by chromatography on a silica column (eluent 7% MeOH in $CH_2Cl_2$), which gave two bands, the first contained [{$C_5Me_3(CH_2OH)_2$-1,2}$Ru(CO)_2Cl$] **5b**† (37% yield) while the second was found to be [{$C_5Me_3(CH_2OH)_2$-1,3}$Ru(CO)_2Cl$] **5a**† (28% yield).

Although several double activations of $\eta^5$-$C_5Me_5$ ligands in early transition metal complexes are known,[5] they are still rare for the late transition metals. However, we have previously noted sequential reactions[6] and very recently two double activations have been reported. The rhodium and iridium

**Scheme 1**

**Scheme 2**

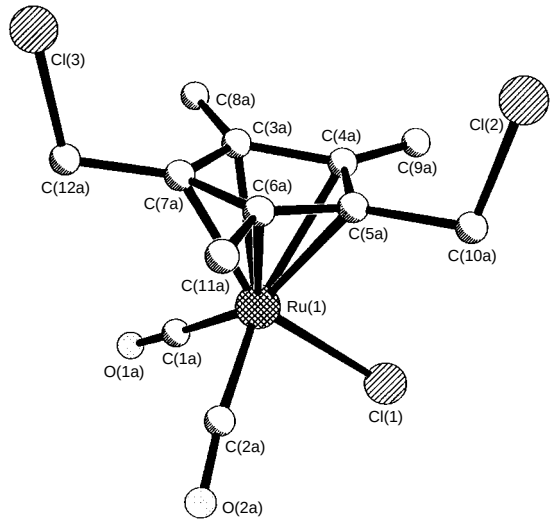


**Fig. 1** Molecular structure of [{$\eta^5$-$C_5Me_3(CH_2Cl)_2$-1,3}$Ru(CO)_2Cl$] **4a** (hydrogens omitted)

complexes [{($\eta^5$-$C_5Me_5$)$MCl_2$}$_2$] (M = Rh, Ir) react with the diphosphine chelate $(C_6F_5)_2PCH_2CH_2P(C_6F_5)_2$ to give [M{$\eta^5$-$C_5Me_3[CH_2C_6F_4P(C_6F_5)CH_2]_2$-1,3}Cl]$^+$ where a C–C bond has been formed by elimination of HF between two *ortho*-C–F groups of the ligand and 1,3-dimethyl groups of the $\eta^5$-$C_5Me_5$ ligand.[7] In the other reaction [{($\eta^5$-$C_5Me_5$)$RhCl_2$}$_2$] undergoes reaction with diphenylvinylphosphine in acetonitrile in the presence of potassium *tert*-butoxide to give a mixture of two complexes [M{$\eta^5$-$C_5Me_3[CH_2CH_2CH_2P(Ph)]_2$}Cl]$^+$ where the C–H groups of two methyl groups (1,2- and 1,3-) have added to the vinyl groups.[8] The mechanisms of neither of these reactions is clear, but ethanol solvent is required for the first, and base plays a significant role in the second. At present it looks as if the formation of **4** from **1** (or **2**) may involve radical intermediates of some type.

We thank the EPSRC for the award of a ROPA grant to support this work.

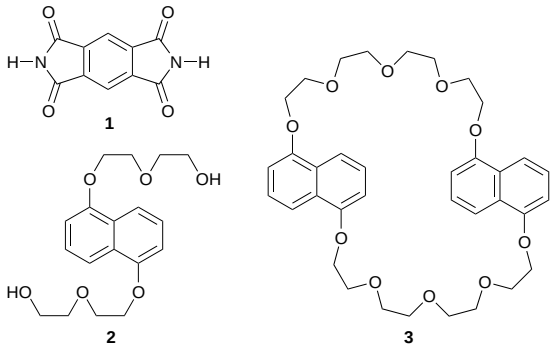
# Neutral [2]catenanes from oxidative coupling of π-stacked components

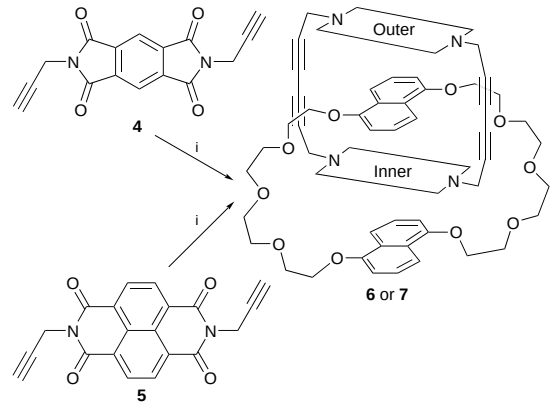


**Darren G. Hamilton,*[a] Jeremy K. M. Sanders,*[a]† John E. Davies,[a] William Clegg[b] and Simon J. Teat[b]**

[a] *Cambridge Centre for Molecular Recognition, University Chemical Laboratory, Lensfield Road, Cambridge, UK CB2 1EW*
[b] *Department of Chemistry, University of Newcastle, Newcastle-Upon-Tyne, UK NE1 7RU*

**Oxidative dimerisation of bis-acetylenic precursors in the presence of a dinaphtho-crown ether affords neutral [2]catenanes in good yields; the interaction of the complementary donor–acceptor π-systems ensures assembly in a geometry favouring catenane formation.**

Recent studies of mechanically interlocked molecules such as catenanes, rotaxanes and knots may be classified according to the nature of the intermolecular association employed in templating their formation. Contemporary organic synthesis has yielded three distinct approaches to such templating: (i) π-stacking of electron-deficient aromatic dications with electronically complementary aromatic molecules,[1] (ii) chelation of metal cations[2] and (iii) amide hydrogen-bonding interactions.[3] Stoddart's methodology for the synthesis of interlocked molecules based on the π-stacking of electron-rich aromatic ethers with electron-poor bipyridinium cations that are generated *in situ* is a landmark in the field.[4,5] Here we describe the synthesis of *neutral* π-stacked interlocked systems from building blocks with pre-programmed recognition characteristics. These systems are structurally and chemically robust, and yet, by virtue of their good solubility characteristics, also amenable to modification using traditional organic chemistry.



The conceptual background to the present work was provided by reports of the inclusion of π-electron-rich aromatic ethers and π-electron-deficient aromatic diimides in a series of donor–acceptor cyclophanes[6] and two self-assembling supramolecular systems.[7] These reports prompted an investigation of some simple co-crystals,[8] such as that formed between pyromellitic diimide **1** and the dialkoxynaphthalene derivative **2**. The solid-state structure of the **1.2** co-crystal reveals alternating stacks of donor (aromatic ether) and acceptor (diimide) molecules; the long axes of the sub-units are approximately perpendicular and a consistent interplanar separation of *ca.* 3.5 Å is maintained between adjacent stack members. These features appeared compatible with the development of a catenane synthesis based on the revealed superstructural design.

Oxidative coupling of terminal acetylenes has previously been applied to the synthesis of a variety of macrocyclic host systems,[9] including some phenanthroline-based catenates,[10] and the butadiyne linker so generated is ideally suited to bridge the *ca.* 7 Å span demanded by our target structure. A pyromellitimide derivative **4** bearing two terminal acetylenes was readily prepared from the condensation of prop-2-ynylamine with pyromellitic dianhydride. An analogous bis-acetylene **5**, derived from the closely related 1,4,5,8-naphthalenetetracarboxylic dianhydride system, was prepared in 67% yield using an identical procedure (Scheme 1). To link two 1,5-substituted naphthalene residues we selected **3**, available in two steps from 1,5-dihydroxynaphthalene by a modification of a literature route.[11] When a 1:2 molar ratio of **3** and **4** are mixed in dry DMF (50 °C, *ca.* 15 mM crown concentration) an immediate orange colour is established in solution, strongly indicative of charge transfer complex formation. Large excesses of anhydrous CuCl (100 equiv.) and $CuCl_2$ (20 equiv.) were added to effect the coupling process. After 2 days stirring in dry air, the [2]catenane **6** could be isolated from the reaction mixture as an orange–red solid by simple work-up and chromatography. Over several runs conducted on various scales the isolated yield of **6** was in the range 25–33%.‡ Under identical reaction conditions (DMF, 50 °C, 15 mM concentration) a 1 : 2 mixture of **3** and **5** gave the [2]catenane **7** as a purple solid in 29% yield. The increased solubility of this system allowed the reaction to be repeated at room temperature. The isolated yield of **7** rose to 52%, an efficiency comparable with those obtained in previous [2]catenane syntheses.

Fast-ion bombardment mass spectrometry of **6** and **7** reveals peaks at *m/z* 1239 and 1339 respectively, corresponding to the addition of a sodium ion to the catenane structures ($M_r$ = 1216 and 1316 respectively). In both spectra the only other significant peak at high mass occurs at *m/z* 769 ([**3** + Cs]$^+$). This behaviour is a spectral characteristic of catenated structures where the first bond scission leads to unravelling of the interlocked structure.[12] Such fragmentation is not observed under electrospray ionisation conditions where for each structure the only detected peak corresponds to the catenane ([*M* + Na]$^+$).

At ambient temperature, the $^1$H NMR spectrum of **6** reveals an AB quartet for the methylene protons of the pyromellitimide macrocycle and upfield shifts of all the aromatic protons relative to the precursors **3** and **4**, as a result of the ordered π-stacking in the molecule. The aromatic pyromellitimide protons appear as a sharp singlet, indicating fast exchange of the inner and outer pyromellitimide sub-units on the chemical shift

**Scheme 1** *Reagents and conditions*: i, CuCl, $CuCl_2$, $O_2$, DMF

time scale. In contrast, two clearly resolved sets of multiplets for the naphthalene sub-units of the crown macrocycle are readily identified revealing the comparatively slower rotation of this component. Catenane **7** exhibits a similar $^1$H NMR spectrum to **6**, indicating similar dynamic behaviour. Variable temperature $^1$H NMR analysis reveals site exchange processes for **6** that parallel those observed in previously reported systems.[4,5]

Very small single crystals of **6** of a quality apparently suitable for an X-ray structural analysis could be readily grown from deuterated dimethyl sulfoxide ([$^2H_6$]$Me_2SO$). However, no reflections could be measured for any of these samples when mounted on commercial diffractometers. The structure presented here was obtained by X-ray synchrotron diffraction.§ This radiation source is several orders of magnitude stronger than that employed in routine crystallographic analyses and allowed the structure to be solved with relative ease (Fig. 1).

The two interlocked neutral macrocycles that comprise the catenane adopt a structure where the respective π-rich and π-poor ring systems can align themselves in a similar manner to that observed in the **1.2** co-crystal. Indeed, the validity of the supramolecular design on which the catenane is based is truly revealed when a packing diagram is generated; individual catenane molecules pack one above another to continue the alternating donor–acceptor stack and the typical interplanar spacings of *ca*. 3.4 Å are observed throughout. Hydrogen bonding interactions between the pyromellitimide methylene protons and oxygen donor atoms in the crown polyether chain are also observed, these interactions may prove to play an important role in the templated synthesis. The unit cell contains two catenane molecules and four molecules of [$^2H_6$]$Me_2SO$ (each disordered over two occupancies). The pyromellitimide ring systems are rotated by 15° relative to each other, inducing a helical twist in this macrocycle, and the connecting butadiyne links are substantially bowed (∠ C–C≡C 169–174°).

[2]Catenanes **6** and **7** represent the first examples of a new class of neutral π-associated interlocked molecules. The electrochemical[13] and photochemical[14] properties of aromatic diimides, and the chemical functionality present in our systems, augur well for the future development of functional and structural derivatives. Indeed, the imide and acetylenic groups are independently reducible and the structural changes so conferred would be likely to alter or destroy the observed π-stacking interactions. Such removal of the templating interaction employed to assemble **6** and **7** would represent an irreversible counterpart to Sauvage's use of transition metal-ion coordination to assemble [*n*]catenates.

# First example of interdigitated U-shape benzimidazolium ionic liquid crystals

**Kwang Ming Lee, Ching Kuan Lee and Ivan J. B. Lin*†**

*Department of Chemistry, Fu-Jen catholic University, Hsinchuang, Taipei 242, Taiwan*

**Self-assembly of U-shaped 1,3-dialkylbenzimidazolium salts through hydrogen bonds and interdigitation of alkyl chains produces a bilayer structure with lamellar α and β mesophases.**

Self-assembly of molecules through hydrogen bonds and hydrophobic interactions to form supramolecular structures is currently an important chemical issue.[1,2] Hydrogen bonds are especially important in biological systems and in the design of new materials.[3] Specifically, hydrogen bonds have been used in the formation of liquid crystalline phases.[4] Here we report a new class of thermotropic ionic liquid crystals, 1,3-dialkyl-benzimidazolium [$(C_n)_2$-Bim] and -imidazolium [$(C_n)_2$-Im] salts. This model system is a good combination of liquid crystalline compounds having (1) extended C–H···X (X = halides) hydrogen bonds, (2) aromatic rigid cores and (3) hydrophobic interactions between alkyl chains.

$[(C_n)_2\text{-Bim}]^+$ (R = $C_nH_{2n+1}$) $[(C_n)_2\text{-Im}]^+$ (R = $C_nH_{2n+1}$)

$(C_n)_2$-Bim chlorides and bromides ($n$ = 12, 14, 16, 18) were obtained by the alkylation of 1-alkylbenzimidazoles as previously reported.[5,6] Crystals of $(C_{12})_2$-Bim chlorides and bromides suitable for X-ray single crystal diffraction were recrystallized from $CH_2Cl_2$.‡ $PF_6$ ($n$ = 6, 12, 14, 16, 18) and iodide salts ($n$ = 16) were prepared quantitatively *via* the simple displacement of anions. $R_2$-Im salts ($n$ = 16, X = Cl, Br and $PF_6$) were prepared in a similar fashion. The purity of all compounds was confirmed by elementary analysis and $^1$H NMR spectroscopy.

The molecular structure of $[(C_{12})_2$-Bim]Cl is shown in Fig. 1(*a*). Two *N*-alkyl chains are approximately orthogonal to the Bim-aromatic plane (5° off the plane normal). The geometry looks like a two-leg stool. Each plane of Bim connects side by side to the neighbouring molecules through C–H···Cl hydrogen bonds, such that the aromatic rings line up in a row with all the legs pointing in the same direction. Each row further connects with the other through hydrogen bonds to form a plane, like a tiled roof and again with all the legs pointing in the same direction. Interdigitation of two such planes with interpenetrating alkyl chains generates a bilayer of 17.7 Å thickness. Each bilayer is further linked with anions through C–H···Cl and C–H···$H_2$O···Cl hydrogen bonds to form a lamellar structure with a separation of 3.4 Å between the bilayers [Fig. 1(*b*)]. Hydrogen bonds play an important role in the formation of this structure and mesophase. Anions are not in the proximity of the positively charged N atoms, rather, each anion forms hydrogen bonds with four C–H groups [H(2), H″(5), H(10A) and H′(22A)] from three neighbouring Bim planes and two additional hydrogen bonds with $H_2O$ molecules which bridge two H(22A) atoms [Fig. 1(*c*)]. The formation of hydrogen bonds between anions and positively charged H(2), H(10A) and H(22A) are known.[7,8] However, such interactions between anions and H″(5) was until now unknown. If one considers each alkyl chain as a rod, the rods exhibit hexagonal close-packing and the distances between the neighbouring rods are 4.1–4.6 Å. $[(C_{12})_2$-Bim]Br has a similar structure except that (1) the separation between neighbouring bilayers is 3.6 Å and (2) the alkyl chains tilt 20° from the plane normal. Therefore the bromide salt has a smaller bilayer thickness (16.8 Å) than that of the chloride (17.7 Å). To the best of our knowledge, this is the first ionic liquid crystal with lamellar structure formed from interdigitated U-shape molecular ions. Recently, imidazolium salts with liquid crystal behaviour were reported.[9] A rod-like structure with alkyl chains parallel to aromatic rings and perpendicular to the layer normal was proposed to produce the mesophase.

For $(C_n)_2$-Bim and $(C_n)_2$-Im salts, formation of mesomorphism depends on the type of anions and the length of the alkyl chains. $(C_n)_2$-Bim salts of chloride ($n$ = 12, 14, 16, 18) and bromide ($n$ = 14, 16, 18), show liquid crystal behaviour but not the iodide and $PF_6$ salts from $n$ = 12 to 18. The ease of anions to form liquid crystals follows the order: Cl > Br > I, $PF_6$. This order is the same as the order of the strength of the C–H···X hydrogen bonds and is the reverse order of the anionic sizes and the separations between the bilayers. Table 1 gives the thermotropic properties of Bim and Im salts obtained from differential scanning calorimetry (DSC) spectra. Taking $[(C_{16})_2$-Bim]Cl as an example, three crystal phases and two mesophases were observed. $[(C_{16})_2$-Bim]Br, however, only

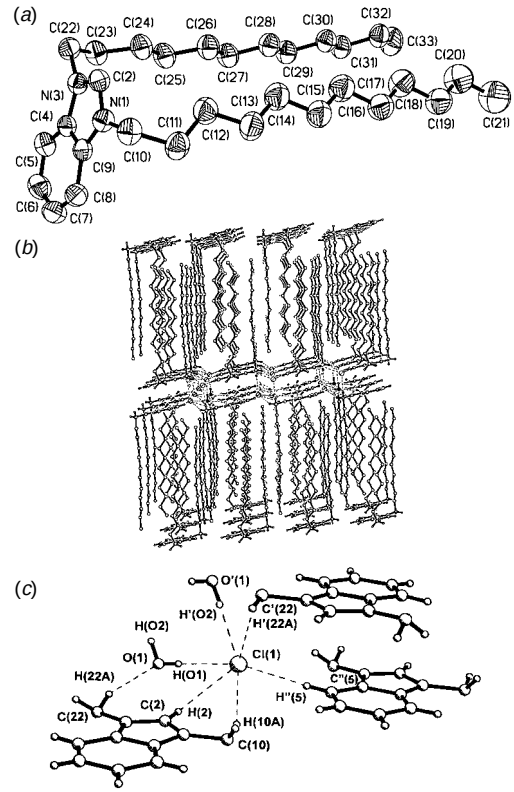

**Fig. 1** (*a*) ORTEP drawing of the cation of $[(C_{12})_2$-Bim]Cl (50% thermal ellipsolids) with atomic numbering, alkyl chain hydrogen atoms being omitted for clarity; (*b*) stacking of the bilayered structure *b*; (*c*) hydrogen bonds between the chloride anion and Bim cations, the tail end of alkyl chains being omitted for clarity

shows one crystal phase and one mesophase. Both chloride and bromide salts have similar K-S transition temperatures irrespective of their anion and carbon chain length differences. Chloride salts have a wider mesophase temperature range than that of the bromide salts of the same carbon chain lengths. The temperature range of mesophase increases upon increasing the carbon chain lengths. $(C_{16})_2$-Im salts have much lower melting points and wider mesophase temperature ranges than those of $(C_{16})_2$-Bim salts (Table 1).

The results of investigations of $[(C_{16})_2$-Bim]Cl using polarized optical microscopy (POM) and X-ray diffraction (XRD) are in close resemblance to those found for 1,2,ψ,ω-*n*-alkanetetraols, which form lamellar thermotropic liquid crystal phases.[10] The fan-like texture at 130 °C (Fig. 2) is characteristic for the lamellar α phase ($L_\alpha$) as it is for that of tetraols. The XRD spectrum [Fig. 3(*a*)] indicates that the mesomorphic structure has a layer period of 28.4 Å and has no order in the lamellar planes. On cooling to 110 °C, the texture has hyperbolic lines across the fans (not shown) and is characteristic for the lamellar β phase ($L_\beta$), as was proposed for that of tetraols. The corresponding XRD spectrum [Fig. 3(*b*)] shows that the $L_\beta$ has a layer period of 34.4 Å and has ordered layers. The layer period in $L_\beta$ is 6 Å longer than the one at 25 °C [Fig. 3(*c*)]. In brief, from crystal to $L_\beta$, there is a sudden elongation of the layer period and there is an order in the layers; from $L_\beta$ to $L_\alpha$ the layer period decreases and the order in the layers disappears. POM and XRD studies show that $[(C_{16})_2$-Bim]Br has a similar mesomorphism, although the DSC spectrum does not detect the $L_\beta$–$L_\alpha$ phase transition.

**Table 1** Transition temperatures (°C) of compounds $[(C_n)_2$-Bim]Cl (**A**-*n*), $[(C_n)_2$-Bim]Br (**B**-*n*) and $[(C_{16})_2$-Im]X (C-X, X = Cl, Br, $PF_6$) (Δ*H* in kJ mol$^{-1}$ in parentheses) determined by DSC at cooling rate of 10 °C min$^{-1}$

In summary, the self assembly of 1,3-dialkyl substituted Bim and Im salts forms bilayered lamellar supramolecules through extended hydrogen bonds. These ionic salts show liquid crystal behaviour of unprecedented mesomorphism compared to other known ionic liquid crystals. An extended mesophase range can be adjusted by altering the aromatic core, alkyl chain length and anion. This system presents an unusual ionic liquid solvent with lamellar structure. Ionic liquid solvents can modify the course of chemical reactions.[11] Lamellar liquid crystal solvents may even have profound effects on chemical reactions, especially when they contain intercalating metal ions, such as $Pd^{2+}$. They are therefore potentially useful ionic solvents and catalysts. This bilayer structure also mimics biological membranes.

We thank Professor C. Y. Lii and Miss C. I. Hsu of the Institute of Chemistry of Academia Sinica of Taiwan for the XRD spectra. A research grant (NSC 86-2113-M-030-001) from National Science Council of Taiwan is greatly appreciated.

# Intrazeolite assembly of a chiral manganese salen epoxidation catalyst

**Steven B. Ogunwumi and Thomas Bein***

*Department of Chemistry, Purdue University, West Lafayette, IN 47907, USA*

**Asymmetric manganese salen epoxidation catalysts are assembled and trapped in a multistep synthesis in the cages of zeolite EMT; these heterogeneous catalysts produce high enantiomeric excess in the epoxidation of aromatic alkenes with NaOCl.**

Asymmetric epoxidation of alkenes is of great interest for the synthesis of chiral intermediates in the pharmaceutical and agrochemical fields.[1,2] Zeolite cage structures are attractive hosts for the design of hybrid systems.[3] Such an inclusion strategy is expected to result in easy recovery or continuous use of the catalyst, diffusional selectivity of the reaction, and potentially increased stability *via* site isolation. Very few asymmetric reactions have been performed on zeolites.[4] Here we present an active, asymmetric epoxidation catalyst that was assembled and trapped in the cages of crystalline zeolite EMT. This novel heterogeneous system produces high enantiomeric excess (ee) in the epoxidation of aromatic alkenes with NaOCl (aq).

Chiral manganese salen epoxidation catalysts[5] are particularly active for the epoxidation of *cis*-substituted aryl alkenes. This family of complexes can be assembled in a stepwise manner in the cages of the zeolite EMT. This zeolite is a hexagonal form of the well known faujasite structure.[6,7] The hypercages of EMT are accessible through three 12-ring windows with free dimensions of 0.69 × 0.74 nm and two 0.74 nm circular apertures, while the hypocages have only three windows. EMT was synthesized as previously reported,[7] followed by calcination at 450 °C, washing with water, and dehydration at 300 °C and $10^{-4}$ Torr before use.

One specific intrazeolite assembly sequence was found to result in active and enantioselective heterogeneous epoxidation catalysts. A mixture of 1.00 g (0.16 mmol) calcined and dehydrated zeolite EMT and 1 equiv. [0.16 mmol (18.4 mg)] of (*R*,*R*)- or (*S*,*S*)-1,2-*trans*-diaminocyclohexane per EMT unit cell were stirred and refluxed in 80 ml of dry thf for 15 h under $N_2$. The solvent was evaporated, and 2.00 equiv. of the required salicylaldehyde (2-hydroxybenzaldehyde or 3-*tert*-butyl-5-methylsalicylaldehyde) were added and stirred at 80 °C under $N_2$ for 1 h, followed by refluxing under stirring in thf for 12 h. The zeolite host turns yellow during this process. 1 Equiv. of $Mn(O_2CMe)_2{\cdot}4H_2O$ (39 mg) per unit cell of EMT was added to the slurry, which was exposed to air to oxidize the $Mn^{II}$. Another 15 h refluxing under air resulted in a brownish slurry, to which was added 1 equiv. of solid LiCl per hypercage, followed by 24 h under reflux in thf, filtration, drying at 80 °C under vacuum, and Soxhlet extraction in $CH_2Cl_2$ for 24 h to remove excess complex, salen ligand, and reactants from the zeolite exterior and interior. Intrazeolite chloro[*N*,*N*′-bis(3-*tert*-butyl-5-methylsalicylidene)cyclohexanediamine]manganese(III) (**1**) is denoted **1–**EMT, chloro[*N*,*N*′-bis(salicylidene)-cyclohexanediamine]manganese(III) (**2**) is denoted **2–**EMT, and chloro[*N*,*N*′-bis(3-*tert*-butyl-5-methylsalicylidene)cyclohexanediamine]manganese(II) **3** (obtained by reacting intrazeolite salen ligand with $Mn^{II}$ under inert conditions) is denoted **3–**EMT. Complexes **1** and **2** were also synthesized in the homogeneous phase according to ref. 5.

Before assembly of the intrazeolite guest, the micropore volume of degassed EMT is 0.325 ml $g^{-1}$.[6] The chiral manganese salen complexes have dimensions of *ca.* 1.5 (**1**) and 1.3 nm (**2**; with modifications from crystallographic data of **1**, kindly provided by E. N. Jacobsen), preventing escape of the assembled complex from within the zeolite (crystallographic data for EMT: see ref. 8; Fig. 1). This general approach has been termed 'ship-in-the-bottle synthesis'.[9] No close van der Waals contacts were observed when the complexes were positioned in the hypercages.

The Soxhlet-extracted samples contain 0.50 ± 0.09 Mn per unit cell of EMT in the case of **1**–EMT, and 0.65 ± 0.09 Mn per unit cell in the case of **2**–EMT (XRF data). The free intrazeolite pore volume remaining after encapsulation of the complexes was determined using *T*-plot analysis from $N_2$ sorption, after evacuating the Soxhlet extracted samples at 120 °C. The original void volume of calcined EMT was reduced to 0.18 ml $g^{-1}$ in both **1**–EMT and **2**–EMT, showing that a significant fraction of the pore volume remains accessible after assembly of the intrazeolite salen complexes in spite of some water remaining in the zeolite after degassing.

Electronic absorption spectra in Fig. 2 show ligand transitions of the brownish oxidized complex **1** (in solution) at 322 and 438 nm and a weak d–d transition at 500 nm [Fig. 2(*a*)].[10] Upon zeolite encapsulation, the former bands shift to 335 and 422 nm, while the weak d–d transition is still observed at about 500 nm [Fig. 2(*b*)]. Strikingly, the d–d transition at 500 nm characteristic for $Mn^{III}$ in these complexes is absent in the spectrum of **3**–EMT [Fig. 2(*c*)], with bands at 266, 333 and 438 nm. In the IR spectrum (not shown), we observe the imine band at 1638 $cm^{-1}$ and a mode at 1458 $cm^{-1}$ for the salen ligand of **1**, assembled in the zeolite and dehydrated at 110 °C ($10^{-5}$ Torr)

**Fig. 1** View of the molecular fit of **1** in EMT (Cerius[2] software)

*in situ* to minimize interference with the zeolite water band at 1635 $cm^{-1}$. In solution, the imine C=N stretch vibration of the free ligand at 1631 $cm^{-1}$ shifts to 1610 $cm^{-1}$ upon complexation with $Mn^{III}$.[10b,11] A striking shift of the imine band to 1583 $cm^{-1}$ occurs upon complexation with $Mn^{II}$ and oxidation to form **1** in the EMT host which shows that a large majority of the ligands is now coordinating the Mn ions.

The encapsulated Mn salen complexes were studied as asymmetric epoxidation catalysts using different substrates (Table 1). In a representative reaction, 1 ml of dichloromethane or acetonitrile, 1 ml NaOCl (5.25%, 0.70 mmol), 0.005 ml $Na_2HPO_4$ (0.05 M), 0.005 ml *n*-decane (GC standard) and 1 drop of 1 M NaOH were added to a solution containing 0.15 mmol of an alkene such as *cis*-β-methylstyrene, along with 100 mg of **1**–EMT catalyst. The slurry was stirred at 4 °C for 1 h, followed by stirring at room temp. for ⩾23 h. The ratio of Mn to alkene was typically adjusted to 5 mol% (commonly used in homogeneous reactions). No conversion was observed when using an $Mn^{II}$-exchanged, air-treated zeolite EMT without the chiral salen ligand. The X-ray crystallinity of the zeolite host is retained after assembly of the intrazeolite complexes, and only slightly reduced after completion of the catalytic experiments.

The following observations can be noted (see also Table 1). (*i*) **1**–EMT with the bulky ligand is more active than **2**–EMT (*e.g.* conversion of *cis*-β-methylstyrene with **1**–EMT was 15% (after 24 h), and with **2**–EMT it was only 1%. The catalytic activity increases significantly on addition of axial ligands such as pyridine *N*-oxide, with which conversion of *cis*-β-methylstyrene was 47%. Formally, 100% conversion corresponds to a lower limit of 20 turnovers, but only a small fraction of the intrazeolite salen complexes may be accessed by the substrate during reaction. (*ii*) With PhIO as oxidant, **2**–EMT showed conversion of styrene and was more active than the sterically more encumbered **1**–EMT, suggesting that the access of the bulky terminal oxidant was hindered in the zeolite–**1** assembly (not in Table 1). (*iii*) The highest ee in epoxide, 88% was achieved with *cis*-β-methylstyrene, **1**–EMT plus pyridine *N*-oxide as catalyst, and NaOCl as oxidant, in dichloroethane. (*iv*) *trans*-β-Methylstyrene gives relatively high yields of *trans*-epoxide but the ee is lower. (*v*) Smaller (non-prochiral) alkenes such as 2,3-dimethylbut-2-ene give higher conversions than the more bulky but more reactive aromatic alkenes, suggesting a strong influence of the zeolite pore structure on diffusional access to the active salen complex encapsulated in the zeolite host. Proof for intrazeolite reactions is obtained by reacting cholesterol with the encapsulated **1**–EMT catalyst. While no conversion was observed with the encapsulated catalyst after 18 h, in solution the epoxidation proceeded to 13% conversion during the same time. This behaviour shows that the catalysis of the smaller substrates truly proceeds in the zeolite pores.

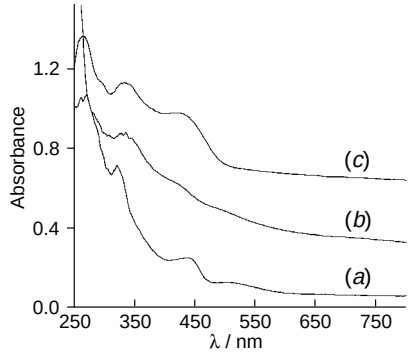

**Fig. 2** UV–VIS spectra (in diffuse reflectance mode) of oxidized **1** in solution (*a*), **1**–EMT (*b*) and **3**–EMT containing $Mn^{II}$ complexed by the salen ligand of **1** (*c*)

**Table 1** Heterogeneous and homogeneous catalysis reactions of [Mn(salen)Cl] in EMT[a]

| Substrate | Substrate conv.(%) | Epoxide selectivity (%) | ee (%) | Confign. |
|---|---|---|---|---|
| Heterogeneous | | | | |
| $Me_2C{=}CMe_2$[b] | 40 | 75 | NC[c] | NC |
| PhC(H)=$CH_2$ | 15 | 87 | 34 | *S*-(−) |
| (*E*)-PhC(H)=CH(Me) | 29 | 62 | 20 | 1*S*,2*S*-(−) |
| (*Z*)-PhC(H)=CH(Me)[d] | 15 | 67 | 80 | 1*S*,2*R*-(−) |

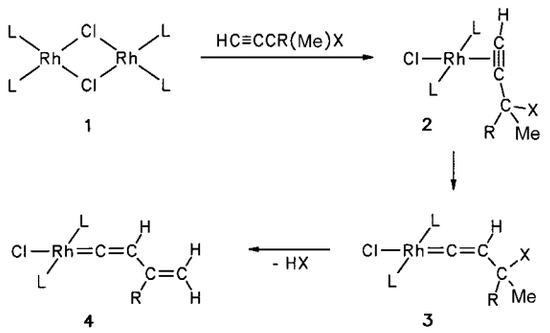
# Allenylidenes: their multifaceted chemistry at rhodium

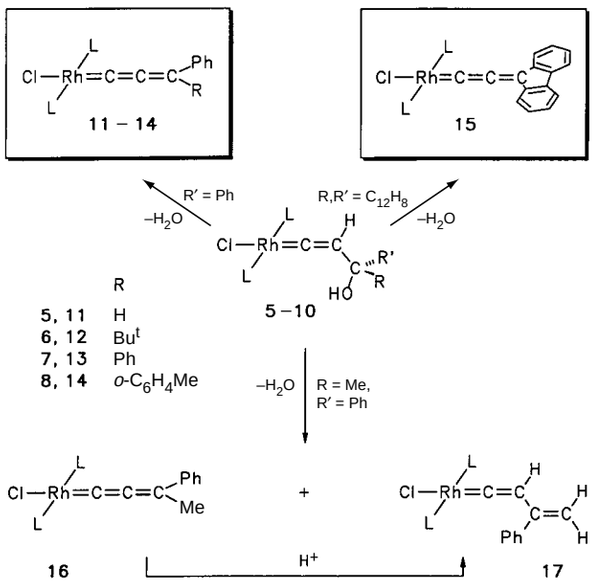
**Helmut Werner**

*Institut für Anorganische Chemie der Universität Würzburg, D-97074 Würzburg, Germany*



**Rhodium allenylidenes, which represent a class of 'flat' metallabutatrienes, are useful tools for the generation of metal-bound species that are hardly accessible (sometimes not accessible at all) by other synthetic routes. In contrast to various *octahedral* allenylidene metal complexes, *e.g.* of $Cr^0$, $Mn^I$ or $Ru^{II}$, the square-planar rhodium compounds *trans*-$[RhX(=C=C=CRR')(PPr^i_3)_2]$ are attacked by both nucleophiles and electrophiles. Moreover, non-polar substrates such as $H_2$ or $Cl_2$ react cleanly with the title complexes to give products in which the allenylidene unit is preserved as part of a newly formed ligand. Attempts to prepare a square-planar cationic metallaheptahexaene, *trans*-$[Rh(=C=C=CRR')_2(PPr^i_3)_2]^+$, unexpectedly led to the formation of two isomeric hexapentaenerhodium(I) complexes of which the isomer having the polyene coordinated in an unsymmetrical fashion is the thermodynamically more stable. C–C coupling reactions also occur on treatment of *trans*-$[RhCl(=C=C=CPh_2)(PPr^i_3)_2]$ with vinyl Grignard reagents or phenylacetylene leading to highly unsaturated $RhC_5$ and $RhC_5P$ frameworks from which vinylallenes and phosphacumuleneylides are obtained.**

## Introduction



One of the most exciting areas in chemical research which emerged in the last decades undoubtedly is that of transition-metal carbene chemistry. Numerous compounds of general composition $[M(=CRR')L_n]$ (L = non-carbene ligands) have been prepared, structurally characterized and used particularly in organic synthesis and homogeneous catalysis.[1] Regarding the date of the landmark report on the isolation of the first carbenemetal complex (1964),[2] and the furious development which started almost immediately thereafter,[3] the chemistry of related metal compounds containing *unsaturated* carbenes as ligands has much more hesitantly explored. As far as *allenylidenes* are concerned, the breakthrough came in 1982 with the paper by Selegue which illustrated that propargylic alcohols HC≡CCRR′OH can be converted quite smoothly into a C=C=CRR′ unit in the coordination sphere of an electron-rich transition-metal centre by elimination of water.[4] Since this report, a variety of allenylidene–metal complexes have been prepared, the elements of the chromium, manganese and iron triads thereby playing a dominant role.[5]

As part of our work on *vinylidene* complexes $[M(=C=CRR')L_n]$ (M = Ru, Os, Rh, Ir),[6] we recently observed that γ-functionalized alkynes HC≡CCR(Me)X (R = H, Me; X = OH, $NH_2$) react with $[RhCl(PPr^i_3)_2]_2$ **1** to give, *via* the alkyne rhodium derivatives **2** as intermediates (Scheme 1), the square-planar compounds **3** which on treatment with $Al_2O_3$ or traces of acid undergo elimination of HX to afford the rhodium vinylvinylidenes **4** in excellent yield.[7] If, however, instead of HC≡CCH(Me)OH or HC≡CC(Me)$_2$OH the corresponding phenyl-substituted alkynols HC≡CCR(Ph)OH (R = H, $Bu^t$, Ph, *o*-$C_6H_4Me$) or the fluorenone-derived species HC≡CC($C_{12}H_8$)OH are used, the four-coordinate allenylidene complexes **11**–**15** (Scheme 2) are exclusively obtained.[8,9] They are formed from the initially generated rhodium vinylidenes **5**–**9** (**9**: R, R′ = $C_{12}H_8$) by abstraction of water. The reaction of **10** (R = Me, R′ = Ph) with neutral alumina gives a mixture of **16** and **17** (ratio *ca.* 1:9) which can be converted quantitatively into **17** by treatment with an excess of acidic $Al_2O_3$ in benzene at room temperature.[8] With regard to the studies described in this paper it should be mentioned that the allenylidene complexes **11**–**15** are crystalline, only moderately air-sensitive solids which are quite easy to handle and can be stored under argon for weeks.

The aim of the present article is to illustrate that compounds of composition *trans*-$[RhCl(=C=C=CRR')(PPr^i_3)_2]$ are not only interesting as far as their synthesis and molecular structure are concerned but that they also offer new insights into the reactivity of metal-containing cumulenes. It will be shown that the behaviour in some respects is different to that of the analogous metal vinylidenes *trans*-$[RhCl(=C=CRR')(PPr^i_3)_2]$ which is not unexpected insofar as the stereochemistry of the

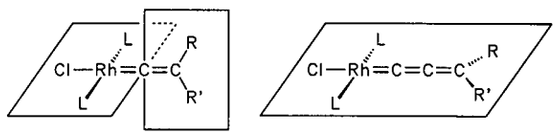
**Scheme 1** L = $PPr^i_3$; R = H, Me; X = OH, $NH_2$

**Scheme 2** L = $PPr^i_3$

latter corresponds to that of *allenes* while the complexes **11**–**15** are relatives of *butatrienes* (Fig. 1).

### Ligand substitution reactions of the metallabutatrienes: Part I

Since allenylidenes like carbon monoxide, isocyanides and vinylidenes (*i.e.* strictly isoelectronic species CX if X is O, NH or $CH_2$) are good π-acceptor ligands,[10] we had anticipated that in square-planar complexes of general composition *trans*-[RhX(=C=C=CRR′)($PPr^i_3$)$_2$] the allenylidene unit would exert a strong influence on the ligand in the *trans* position. Substitution of the chloride in complexes **11**–**15** should therefore be favoured and this has been confirmed with various nucleophiles. While it is not surprising that on treatment of **12**, **13** or **14** with KI or $NaC_5H_5$ products such as **18**, **19** or **20**, **21** are formed, the preparation of the hydroxo derivatives **22**–**24** (Scheme 3) constitutes a more interesting example. This is due to the fact that hydroxo complexes of platinum group metals are not only quite rare,[11] but that compounds **22**–**24** open the gate to a variety of other square-planar rhodium allenylidenes *trans*-[RhX{=C=C=C(Ph)R}($PPr^i_3$)$_2$] (see Scheme 4) which are not accessible *via* any other route.



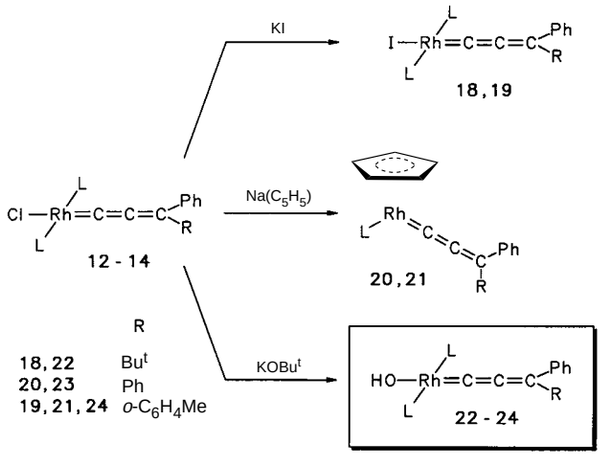


**Fig. 1** Different stereochemistry of rhodium vinylidenes ('metallaallenes') and rhodium allenylidenes ('metallabutatrienes'); L = $PPr^i_3$

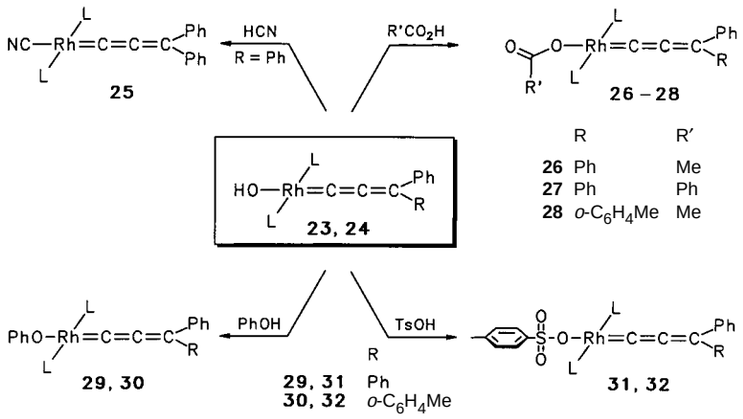


**Scheme 3** L = $PPr^i_3$

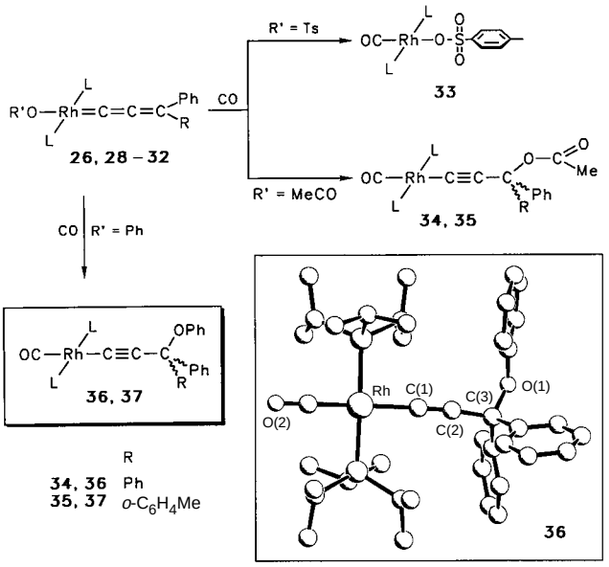
In contrast to the tosylato compounds **31** and **32**, which on treatment with carbon monoxide lose the allenylidene unit to give **33** (Scheme 5), the acetato and phenolato derivatives **26**, **28** and **29**, **30** react with CO to yield the 1 : 1 adducts **34**–**37** almost quantitatively.[12] As the X-ray crystal structure analysis of **36** reveals, a migration of the phenolato ligand to the γ-carbon atom of the allenylidene moiety has taken place and a new functionalized alkynyl unit is formed. The Rh–C$^1$ distance [2.037(4) Å] is significantly longer than in complex **14** [1.855(5) Å][8] and nearly identical to the Rh–C bond lengths in the five-coordinate bis(alkynyl)hydrido rhodium(III) compound [RhH(C≡CC$Pr^i_2$OH)$_2$($PPr^i_3$)$_2$] (**57**, see Scheme 13 later).[13] The Rh–C–C–C chain in **36** is almost linear while the two phenyl substituents at C$^3$ are orthogonal to each other, thus presumably minimizing the repulsion between the C–H units.

For the elucidation of the mechanism of the migratory insertion process leading to **34**–**37** some crossover experiments with **26** and **30** as starting materials were performed. Unfortunately, they did not give a conclusive answer. We found that the Rh–O bond in the acetato and phenolato allenylidene complexes is extremely labile and thus, before CO was passed through the solution of **26** and **30** in benzene, a random exchange took place and a mixture of **26**, **28**, **29** and **30** was formed. The observation, however, that the reaction of **29** with CO in the presence of acetate ions exclusively yields **36** (and not a mixture of **34** and **36**) indicates that the formation of the alkynyl complexes **34**–**37** occurs intramolecularly and does not involve a heterolytic cleavage of the Rh–OR bond. The formal 1,4-shift of the acetato or phenolato group may take place stepwise *via* an OR-substituted allenylmetal intermediate which rapidly rearranges to the final product. Since the reaction of *trans*-[Rh(OMe)(CO)($PPr^i_3$)$_2$] with CO yields *trans*-[Rh($CO_2$Me)(CO)($PPr^i_3$)$_2$],[14] it should be noted that on treatment of **29** and **30** with carbon monoxide no insertion into the Rh–OR bond takes place.

### Ligand substitution reactions of the metallabutatrienes: Part II

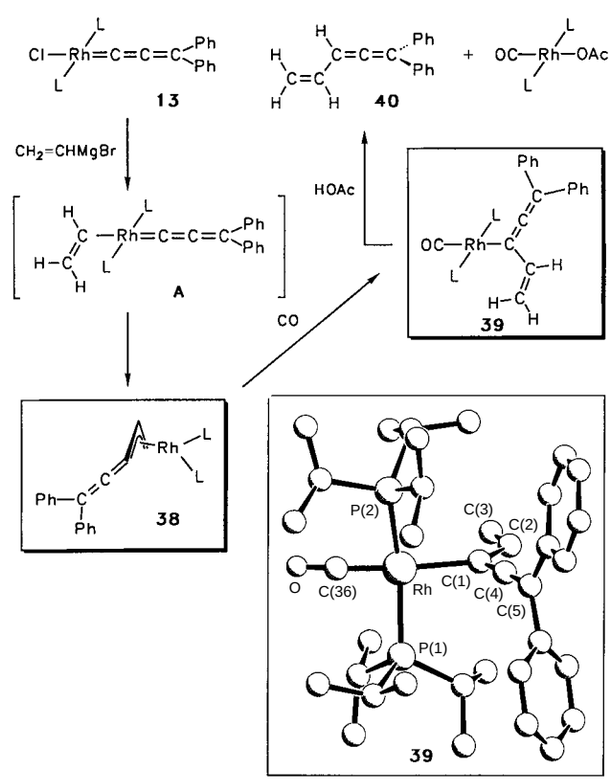
Attempts to replace the halide ligand in the diphenylallenylidene complex **13** by C-nucleophiles such as alkyls, aryls or vinyls led to a surprising result. While the reaction of **13** with MeMgI or PhMgBr gives a mixture of products among which the anticipated species *trans*-[Rh(R)(=C=C=$CPh_2$)($PPr^i_3$)$_2$] (R = Me, Ph) could not be unequivocally identified,[15] on treatment of **13** with $CH_2$=CHMgBr in toluene–thf both the substitution of chloride by vinyl *and* the coupling of the C-nucleophile and the allenylidene ligand occurs.[16] To explain the formation of the π-allylic complex **38** (Scheme 6), we assume that initially a four-coordinate intermediate **A** is generated which rearranges by migratory insertion of the allenylidene unit into the Rh–CH=$CH_2$ bond to give **38**. In this context, it is remarkable that the rhodium vinylidenes *trans*-

**Scheme 4** L = $PPr^i_3$



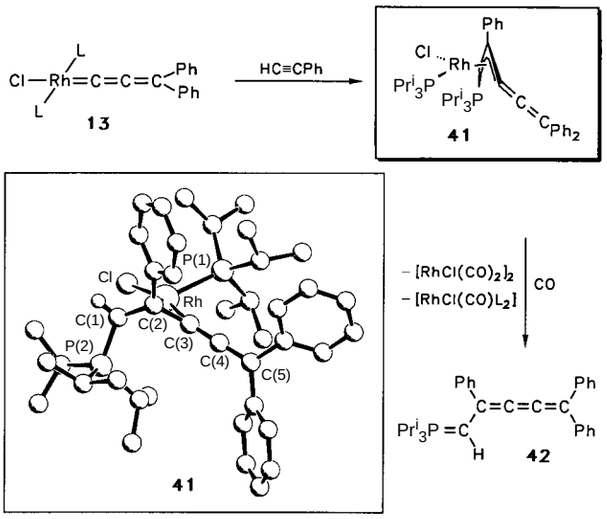
[RhCl(=C=CHR)($PPr^i_3$)$_2$] (R = H, Bu$^t$, Ph) react with $CH_2$=CHMgBr to give the *isolable* complexes *trans*-[Rh(CH=$CH_2$)(=C=CHR)($PPr^i_3$)$_2$] which upon heating to 45–50 °C in benzene slowly isomerize to give the allylic C–C coupling products [Rh($\eta^3$-$CH_2CHC$=CHR)($PPr^i_3$)$_2$].[17]

Compound **38** reacts with CO even below room temperature almost instantaneously to give the yellow crystalline 1 : 1 adduct **39** in excellent yield.[16] The addition of CO to the metal centre is accompanied by a π–σ conversion of the $C_5$ ligand, possibly *via* an 18-electron intermediate [Rh($\eta^3$-$CH_2CHC$=C=$CPh_2$)(CO)($PPr^i_3$)$_2$]. As shown in Scheme 6, the X-ray crystal structure analysis of **39** confirmed a square-planar coordination sphere around rhodium and a nearly linear $C^1$–$C^4$–$C^5$ chain with the vinyl carbon atoms $C^2$ and $C^3$ lying in the same plane as Rh, $C^1$, $C^4$ and $C^5$. The cleavage of the Rh–C σ bond in **39** by an equimolar amount of acetic acid proceeds smoothly and affords the new vinylallene **40** quantitatively.[16]



A second [$C_2$ + $C_3$] coupling reaction which involves one of the phosphine ligands of **13** is even more exceptional. Upon treatment of a solution of **13** in benzene with phenylacetylene at 10 °C, a gradual change of colour occurred and a light-red crystalline product **41**, formally corresponding to a 1 : 1 adduct of the allenylidene complex and the alkyne, was isolated in practically quantitative yield.[16] The $^{31}$P NMR spectrum of **41** already showed the presence of two distinctly different $PPr^i_3$ groups, and the X-ray structural analysis finally confirmed that only one of the phosphines is still coordinated to the metal centre. The other is part of a π-bonded ylide which is formed from the allenylidene, the alkyne and the second phosphine unit. While the $PC_5$ ligand in **41** is coordinated in a π-allylic fashion (see Scheme 7), the distances between the rhodium and the carbon atoms $C^1$, $C^2$ and $C^3$ differ by *ca.* 0.15 Å, probably due to the different hybridization at $C^3$ compared with $C^1$ and $C^2$ and to the different influence of the ligands $Cl^-$ and $PPr^i_3$ in *trans* positions. Although the carbon atoms of the =C=$CPh_2$ unit are not coplanar with the allylic fragment, the $C^3$–$C^4$–$C^5$ chain in **41** is almost linear with $C^3$–$C^4$ and $C^4$–$C^5$ distances that are comparable to those in the allenylidene complex **14** and in **39**. The free ylide **42**, formerly unknown, was generated from **41** on treatment with CO and characterized by $^1$H, $^{13}$C and $^{31}$P NMR spectroscopy.[16]

### Addition reactions of the metallabutatrienes: the unexpected products



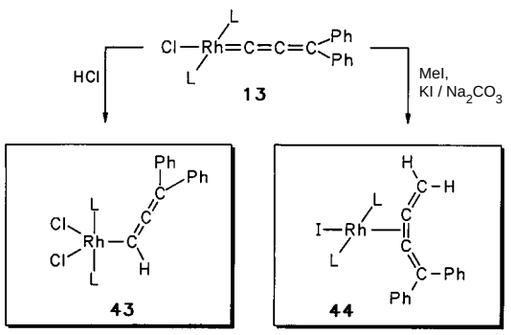
Following the idea that the bonding capabilities of CO and unsaturated carbenes are similar,[10,19] we had anticipated that in analogy to the carbonyl derivative *trans*-[RhCl(CO)($PPr^i_3$)$_2$][20] also the Rh-containing metallabutatrienes would react with substrates such as HCl, MeI and $H_2$ by oxidative addition and formation of octahedral rhodium(III) complexes. This, however, is not the case. Compound **13** (which was chosen for these studies as an easily accessible starting material) adds 1 equiv. of HCl quite rapidly but instead of the six-coordinate hydridorhodium complex [$RhHCl_2$(=C=C=$CPh_2$)($PPr^i_3$)$_2$] the five-coordinate allenyl compound **43** (Scheme 8) is quantitatively formed.[15] To explain the course of this unexpected reaction, we assume that initially the electrophile attacks the Lewis-basic metal centre to give the salt-like intermediate [RhHCl(=C=C=$CPh_2$)($PPr^i_3$)$_2$]$^+$Cl$^-$,[21] which by 1,2-H shift from rhodium to the α-carbon atom of the allenylidene unit, accom-

**Scheme 5** L = $PPr^i_3$

**Scheme 6** L = $PPr^i_3$

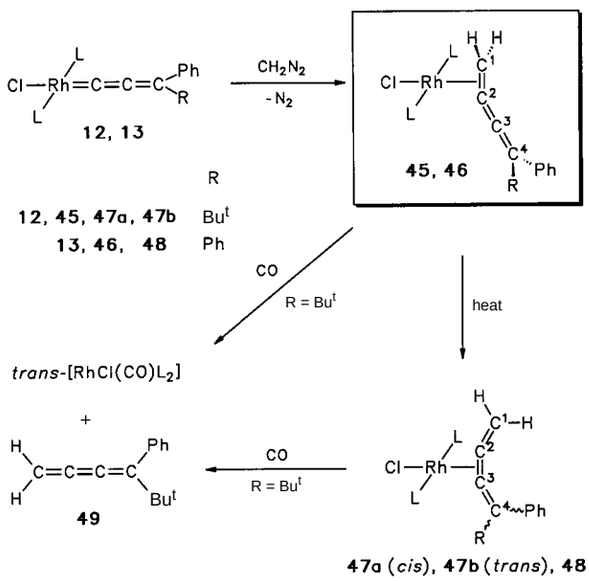
**Scheme 7** L = $PPr^i_3$

panied by nucleophilic addition of $Cl^-$ to the metal, yields the final product. We note that the *octahedral* metallabutatriene complex $[RuCl_2(=C=C=CPh_2)\{Pr^i_2PCH_2C(OMe)=O\text{-}\kappa P\}\{Pr^i_2PCH_2C(OMe)=O\text{-}\kappa^2P,O\}]$ reacts with HCl by attack of the electrophile to the $C_\alpha$–$C_\beta$ and not to the Ru–$C_\alpha$ double bond and attribute this difference to the 18-electron configuration of the metal centre.[22]



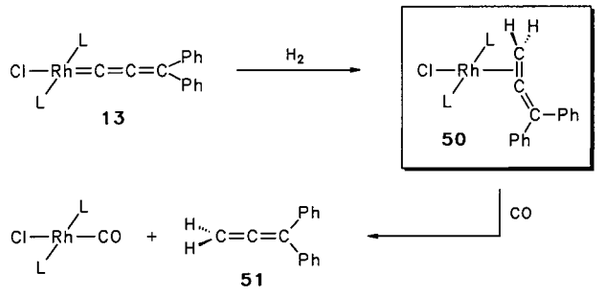
Methyl iodide, which we used as a counterpart to HCl in the course of the investigations into the reactivity of **13**, also reacts in an unexpected way with **13**. While in the absence of a basic substrate the reaction of **13** with MeI proceeds very slowly and gives a mixture of products, the novel 1,1-diphenylbutatriene complex **44** is formed as the major species besides **47** (see below) in the presence of $Na_2CO_3$. Subsequent treatment of the reaction mixture with KI yields **44** almost quantitatively.[23] As far as the mechanism of formation of **44** is concerned, we assume that in the initial step the expected oxidative addition of MeI at the rhodium centre takes place which is followed by an insertion of the allenylidene unit into the Rh–Me bond. The intermediate containing the allene-type $RhC(Me)=C=CPh_2$ moiety then reacts by a β-H shift to give a butatriene(hydrido)-diiodorhodium(III) compound that upon reductive elimination of HI (facilitated by $Na_2CO_3$) generates the final product. Analogous to the first two steps is the formation of $[IrCl(I)\{C(Me)=CH_2\}(PPr^i_3)_2]$ and $[IrI\{C(Me)=CH_2\}\{N(SiMe_2CH_2PPh_2\text{-}\kappa^3N,P,P)_2\}]$ from the corresponding vinylidene complexes and methyl iodide.[24] In this case, however, a subsequent β-H shift does not occur.

There is also a second route to convert a metal-bonded allenylidene unit into a butatriene ligand (Scheme 9). Both compounds **12** and **13** react with excess diazomethane at room temperature to afford the butatriene complexes **45** and **46** in excellent yield.[23] The coordination of the $C_4$ cumulenes *via* the $C=CH_2$ bond is not only supported by the $^1H$ and $^{13}C$ NMR spectra, but also confirmed by the X-ray structure analysis of **46**. This reveals a distorted square-planar geometry around the metal centre with the Cl, Rh and $C^1$–$C^4$ atoms lying in one plane. Although the $C=CH_2$ unit is bonded unsymmetrically to the metal (as is shown by the linearity of the Cl–Rh–$C^2$ axis), the distances Rh–$C^1$ and Rh–$C^2$ are nearly identical and quite similar to the Rh–C bond lengths in structurally related allene rhodium(I) compounds.[25] The P–Rh–P axis in **46** deviates somewhat from linearity which is probably due to the steric requirements of the bulky phosphine ligands.



Both **45** and **46** are thermally labile and upon heating in toluene at 80–90 °C rearrange to the thermodynamically more stable complexes **47** and **48**. For **47**, a mixture of two isomers **47a,b** (see Scheme 9) is formed which differ in the relative positions of the phenyl and *tert*-butyl groups to the rhodium centre. Although isomer **47a** is the dominating and probably preferred species, even after heating the mixture of **47a,b** in toluene at 90 °C for 10 h a complete conversion of **47b** to **47a** does not occur. Nevertheless, complex **47a** could be isolated analytically pure upon fractional crystallization and, by comparison of the NMR data with those of **47b**, identified as the isomer in which the Bu$^t$ group at $C^4$ is directed towards the metal. In all of the previously described 1,1,4,4-tetrasubstituted butatrienerhodium(I) compounds *trans*-$[RhCl(\eta^2\text{-}R_2C=C=C=CR_2)(PPh_3)_2]$, which were prepared from $[RhCl(PPh_3)_3]$ and butatrienes,[26] the *central* C=C bond is linked to the metal. The coordination of a *terminal* $R_2C=C$ bond, as it has been observed for **45** and **46**, was only recently reported by White and Stang for platinum(0) as the central atom.[27] The two isomeric forms **45** and **47a,b** as well as **46** and **48** rapidly react with CO to yield *trans*-$[RhCl(CO)(PPr^i_3)_2]$ by ligand exchange. Of the butatrienes formed in these conversions, the one with $CPh_2$ as the terminal unit is quite labile undergoing secondary reactions whereas the hitherto unknown cumulene **49** has been characterized by GC–MS and spectroscopic techniques.[23]

The allenylidene ligand of **13** can be converted not only to a butatriene but also to an allene. The reaction of **13** with $H_2$ in benzene at room temperature is rather slow but after 40 h, by cleavage of the Rh=C double bond, the square-planar rhodium(I) complex **50** (Scheme 10) is quantitatively formed.[15,23] Remarkably, under the chosen conditions no hydrogenation of the allene ligand occurs. Since the $^1H$ NMR spectrum of **50** displays only one signal for the $CH_2$ protons, there is no doubt that it is the *unsubstituted* double bond of the allene which is bonded to the metal. On treatment of **50** with CO, the alkenic ligand is readily displaced and together with the allene **51** the carbonyl complex *trans*-$[RhCl(CO)(PPr^i_3)_2]$ is formed.

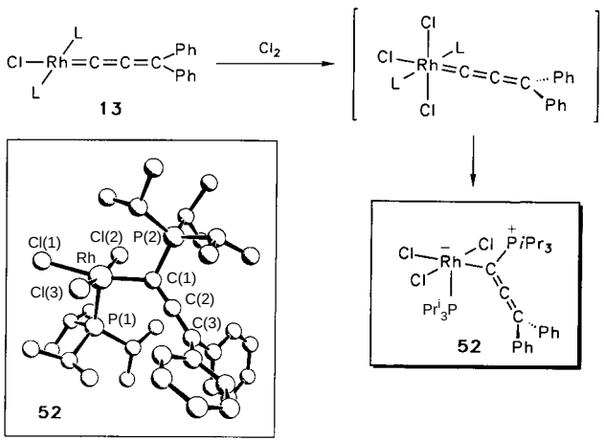


The reaction of **13** with a solution of chlorine in thf–hexane yields a 1 : 1 adduct **52** by oxidative addition which, however, does not have the expected octahedral geometry. The $^1H$, $^{13}C$ and $^{31}P$ NMR spectra display two completely different sets of signals for the hydrogen, carbon and phosphorus atoms of the $PPr^i_3$ groups and, since only one of the $^{31}P$ NMR resonances

**Scheme 8** L = $PPr^i_3$

**Scheme 9** L = $PPr^i_3$

**Scheme 10** L = $PPr^i_3$



shows a strong Rh–P coupling, it is clear that one of the phosphines is not linked to rhodium. The X-ray crystal structure analysis of **52** (Scheme 11) indeed reveals that a five-coordinate rhodium(III) complex has been formed which contains in addition to one phosphine and three chlorides the phosphacumuleneylide $Pr^i_3P{=}C{=}C{=}CPh_2$ as an $\eta^1$-bonded ligand. The geometry around the metal centre is best described as square-pyramidal with the triisopropylphosphine in the apical position. The two planes containing the substituents at $C^1$ (Rh and $P^2$) and $C^3$ (*ipso*-carbons of $C_6H_5$) are orthogonal to each other, in agreement with the allene-type structure of the molecule.[28] Related phosphacumuleneylide ligands to that found in **52** are known from $[(C_5H_5)Mn\{C(PPh_3){=}C{=}CPh_2\}(CO)_2]$ and $[Cr\{C(PPh_3){=}C{=}CPr^i_2\}(CO)_5]$, but have been generated by attack of free triphenylphosphine on allenylidene complexes.[29]

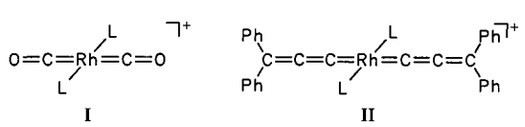
### $[C_3 + C_3]$ coupling reactions: are metallabutatrienes involved?

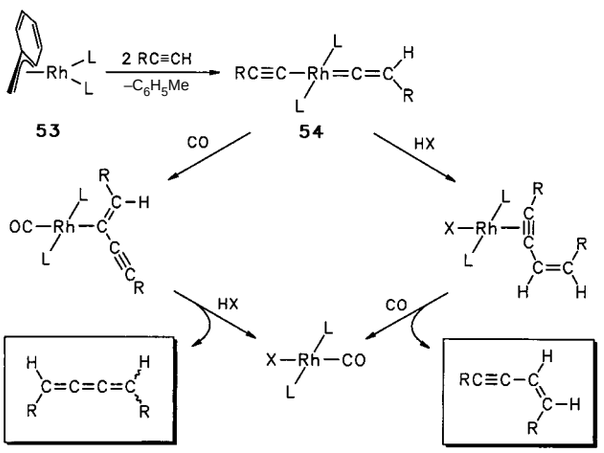
When we considered proceeding one step further in the investigation of rhodium-containing metallacumulenes, the question arose whether it would be possible to generate a cation like **II** (Fig. 2) which would be structurally comparable to the dicarbonyl species **I** recently prepared in our laboratory.[30] For this purpose we attempted to apply a methodology which by using the $\eta^3$-benzyl complex **53** as starting material led to the formation of alkynyl rhodium vinylidenes **54** and, on further reaction with HCl and CO, finally to enynes and butatrienes (Scheme 12).[31]

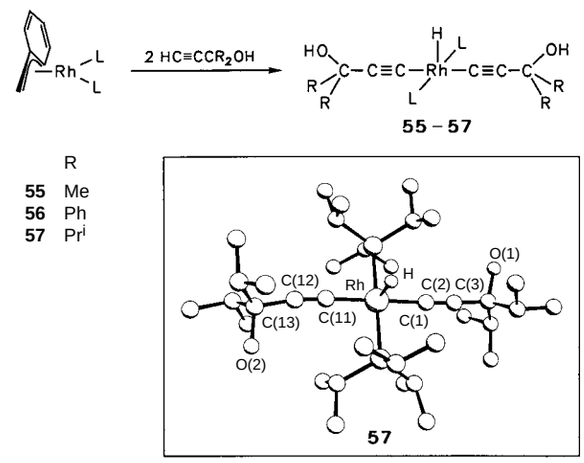
With the reactivity of compound **53** towards terminal alkynes such as HC≡CPh or HC≡CBu$^t$ in mind, we were not surprised that on treatment of **53** with 2 equiv. of $HC{\equiv}CCR_2OH$ (R = Me, Ph, Pr$^i$) a rapid reaction occurred that led to the formation of crystalline, only slightly air-sensitive solids **55**–**57** in *ca.* 70% yield.[13] The IR and NMR spectra of the products illustrated quite clearly that instead of the expected alkynyl(vinylidene)-rhodium(I) complexes *trans*-$[Rh(C{\equiv}CCR_2OH)(=C{=}CHCR_2OH)(PPr^i_3)_2]$ the bis(alkynyl)hydridorhodium(III) isomers $[RhH(C{\equiv}CCR_2OH)_2(PPr^i_3)_2]$ were formed. These five-coordinate compounds possess a square- pyramidal and not trigonal-bipyramidal configuration, as was confirmed by the crystal structure analysis of **57**.[13] The SCHAKAL diagram, which is included in Scheme 13, shows that the basal plane of the pyramid consists of an exactly linear P–Rh–P and an almost linear C–C–Rh–C–C arrangement with Rh–C bond lengths that are nearly identical to those of the octahedral bis(alkynyl)-hydrido complex $[RhH(C{\equiv}CPh)_2(PMe_3)_3]$.[32] The structure of **57** found in the crystal is most probably also preserved in solution since the $^1$H NMR spectrum (like the spectra of **55** and **56**) displays a doublet of triplets at $\delta$ −30.5 which together with a Rh–H coupling constant of 50 Hz is most typical for five-coordinate hydridorhodium(III) species.[33]

Compound **55** is not completely inert in benzene solution and at room temperature reacts slowly to give the OH-functionalized alkynyl(vinylidene)rhodium(I) derivative **58** (Scheme 14) in good yield.[13] The formation of this complex (which is structurally related to the species **54** shown in Scheme 12) is

**Scheme 11** L = $PPr^i_3$







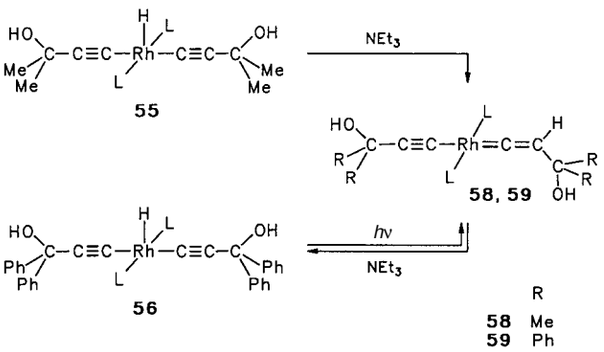


**Fig. 2** Formal relation between the cationic dicarbonylrhodium and bis(allenylidene)rhodium complexes **I** and **II**; L = $PPr^i_3$

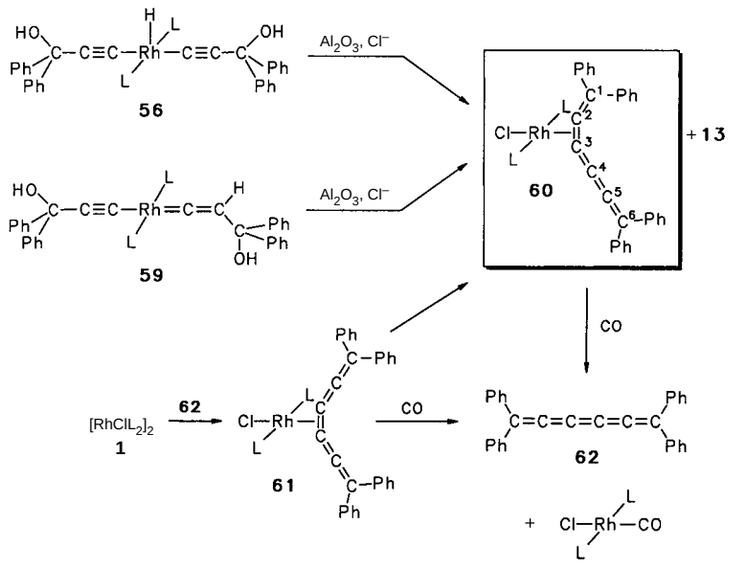
**Scheme 12** L = $PPr^i_3$

**Scheme 13** L = $PPr^i_3$

**Scheme 14** L = $PPr^i_3$

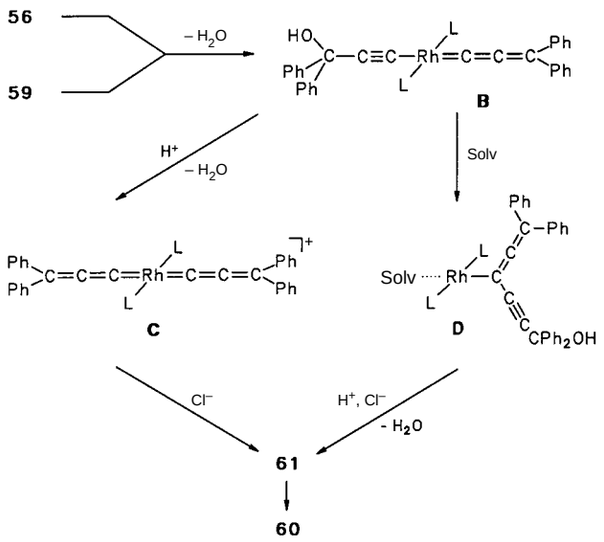
significantly facilitated by addition of $NEt_3$, probably due to a weakening interaction of the amine with the Rh–H bond. A complete rearrangement of **56** to the isomer **59** does not proceed under thermal conditions but takes place on irradiation of the bis(alkynyl)hydrido compound in benzene. Unlike **58**, the analogous complex **59** is not stable in benzene or toluene solution and, particularly in the presence of $NEt_3$, partly rearranges to the isomer **56** until an equilibrium of **56**:**59** = 30:70 is reached. No isomerization of compound **57** occurs, neither thermally nor photochemically, which could be due to the efficient shielding of the β-carbon atom of the alkynyl ligands by the bulky isopropyl groups.[13]

While the reactions of **56** and **59** with CO followed established routes and gave by addition and (in the case of **59**) by migratory insertion the carbonyl complexes $[RhH(C{\equiv}CCPh_2OH)_2(CO)(PPr^i_3)_2]$ and *trans*-$[Rh\{\eta^1$-$(Z)$-$C(C{\equiv}CCPh_2OH){=}CHCPh_2OH\}CO)(PPr^i_3)_2]$, respectively, treatment of **56** and **59** with acidic $Al_2O_3$ in the presence of chloride ions led to a completely unexpected result. In analogy to the preparation of **13** from **7** (see Scheme 2) we anticipated the formation of *trans*-$[Rh(C{\equiv}CCPh_2OH)(=C=C=CPh_2)(PPr^i_3)_2]$ or, hopefully, of a salt of the bis(allenylidene)rhodium(I) cation *trans*-$[Rh(=C=C=CPh_2)_2(PPr^i_3)_2]^+$. However, we isolated (besides small amounts of **13**) the novel hexapentaene complex **60** (Scheme 15) in 70% yield.[13] If the time for the interaction of **56** or **59** with $Al_2O_3/H^+/Cl^-$ is not sufficient, an isomeric mixture of **60** and **61** is formed which, however, can be quantitatively converted to **60** by stirring a solution of **60**/**61** in benzene at room temperature. The assumption that **61** is the kinetically preferred and **60** the thermodynamically preferred isomer could be confirmed by stepwise synthesis of the two compounds from dimer **1**. The more symmetrical complex **61** was exclusively obtained from **1** and the hexapentaene $Ph_2C{=}C{=}C{=}C{=}CPh_2$ **62** in toluene at −30 °C, provided that the solution was worked up quickly at low temperature. The further rearrangement of **61** to **60** proceeded at 25 °C. Both compounds **60** and **61** smoothly react with carbon monoxide by ligand displacement to give *trans*-$[RhCl(CO)(PPr^i_3)_2]$ and the cumulene **62**. With regard to the structure of the more stable isomer **60**, the X-ray analysis showed that the $C_6$ chain is bent, possessing C–C–C angles which are similar to those found in related butatrienerhodium(I) complexes.[23,26] The plane of the carbon atoms $C^1$–$C^6$ is exactly perpendicular to the plane containing the metal, the chloride and the phosphorus atoms, the dihedral angle being 89.8(1)°.



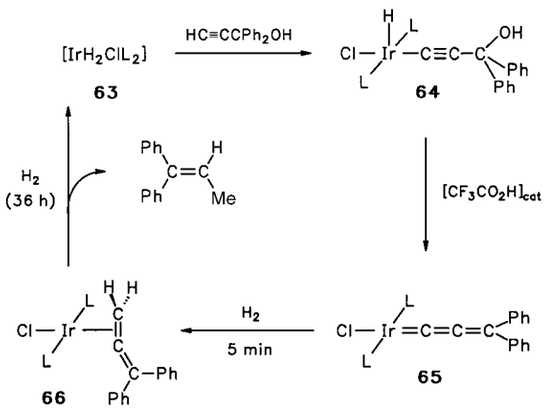
The proposed mechanism of formation of **60** and **61** is outlined in Scheme 16. We assume that in analogy with the preparation of **13** from **7** and $Al_2O_3$ an alkynyl(allenylidene)-rhodium(I) intermediate **B** is generated initially which can be converted either by proton attack (and elimination of water) to the bis(allenylidene)metal cation **C** or, alternatively, by solvent-assisted migration of the alkynyl ligand to the α-carbon atom of the allenylidene unit to give **D**. Coupling of the two $C_3$ fragments of **C** or acid-initiated abstraction of $OH^-$ from **D** could then generate the hexapentaene ligand and, on addition of $Cl^-$, afford complex **61**. There is precedent for the linkage of two allenylidene moieties to give a tetra-substituted hexapentaene insofar as on heating of $[(C_5H_5)Mn(CO)_2(=C=C=CBu^t_2)]$ small quantities of $Bu^t_2C{=}C{=}C{=}C{=}C{=}CBu^t_2$ are formed.[34]

## Why rhodium?

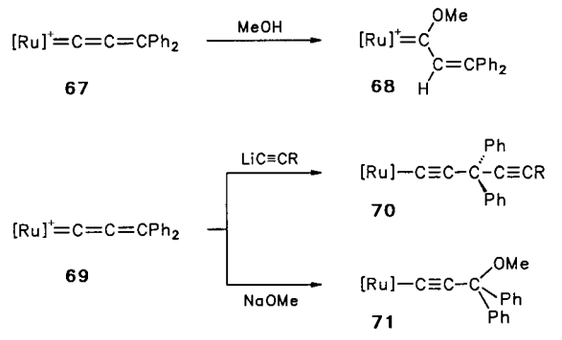


In summarizing the results shown in Schemes 3–16, the question certainly arises whether the square-planar rhodium allenylidenes are unique as far as their reactivity is concerned. Although a conclusive answer is as yet not possible, a few trends emerge which can be described as follows.

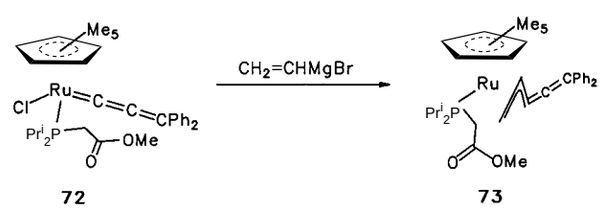
(*i*) The allenylideneiridium(I) compound **65** (Scheme 17), which is prepared from the dihydridoiridium(III) derivative **63** and $HC{\equiv}CCPh_2OH$ *via* **64** as intermediate, reacts rapidly with $H_2$ in dichloromethane at room temperature to give the allene complex **66** in excellent yield.[35] In this respect, compound **65** behaves in an exactly analogous manner to the rhodium counterpart **13** (see Scheme 10). However, in contrast to **13** the iridium allenylidene **65** is rather inert towards HCl and $CH_3I$ which is probably due to the increased kinetic stability of Ir=C compared with Rh=C double bond systems.



(*ii*) Allenylideneruthenium(II) complexes, which since the first studies in this field constitute the largest group of compounds containing an M=C=C=CRR′ unit,[5] are quite reactive towards *nucleophiles*. Work by Dixneuf and coworkers[36] and more recently by Gimeno and coworkers[37] has shown that in particular *cationic* compounds such as **67** and **69** (Scheme 18) are easily attacked by alcohols, alcoholates and also acetylides. The reaction of **69** with NaOMe affords a functionalized alkynyl ligand which is related to the rhodium-bound $C{\equiv}CCPh_2(OPh)$ unit generated on treatment of the neutral allenylidene rhodium complex **29** with CO (see Scheme 5).



**Scheme 15** L = $PPr^i_3$



**Scheme 16** L = $PPr^i_3$

**Scheme 17** L = $PPr^i_3$

**Scheme 18** For **67**, **68**: [Ru] = $(C_6Me_6)RuCl(PMe_3)$; for **69**–**71**: [Ru] = $(C_9H_7)Ru(PPh_3)_2$

**Scheme 19**

Attempts to attack the allenylidene ligand in the *neutral* ruthenabutatrienes $[RuCl_2(=C=C=CPh_2)\{Pr^i_2PCH_2C(OMe)=O\text{-}\kappa P\}\{Pr^i_2PCH_2C(OMe)=O\text{-}\kappa^2P,O\}]$[22] and $[(C_5Me_5)RuCl(=C=C=CPh_2)\{Pr^i_2PCH_2C(OMe)=O\text{-}\kappa P\}]$ **72**[38] by methanol or dimethylamine failed. The half-sandwich type compound **72**, however, cleanly reacts with $CH_2$=CHMgBr in $C_6H_6$–thf to give the $\eta^3$-3,4,5-pentatrienyl complex **73** (Scheme 19) in good yield.[38] We were really surprised that this reaction occurred smoothly even at room temperature since compared with rhodium in the square-planar compound **13** (see Scheme 6) the ruthenium centre in **72** is more effectively shielded and thus a nucleophile attack of the Grignard reagent should be more hindered. For the success of the C–C coupling reaction leading to **73** it could be important that the two C-bonded ligands in the supposed intermediate $[(C_5Me_5)Ru(CH=CH_2)(=C=C=CPh_2)\{Pr^i_2PCH_2C(OMe)=O\text{-}\kappa P\}]$ are *cis* disposed since this should favour the migration of the vinyl group to the α-carbon atom of the allenylidene unit forming the pentatrienyl moiety.

## Conclusion

It is shown in this article that square-planar rhodium allenylidenes of general composition *trans*-$[RhX(=C=C=CRR')(PPr^i_3)_2]$, which are easily accessible from $[RhCl(PPr^i_3)_2]_2$ and propargylic alcohols, react with both nucleophiles and electrophiles. They are also attacked by phenylacetylene as well as by non-polar substrates such as $H_2$ or $Cl_2$ to give products in which the allenylidene unit is preserved as part of a newly formed ligand. In this respect, compounds having a metallabutatriene framework Rh=C=C=CRR′ behave quite differently to those containing a related metallaallene type unit Rh=C=CRR′.

Current work in our laboratory is aimed *inter alia* at the use of the rhodium allenylidenes also for catalytic purposes. The focus will be on reaction conditions which allow the conversion, *e.g.* of the butatriene complexes **45**–**48** upon treatment with $HC{\equiv}CCPh_2OH$ to the starting materials **12** and **13** and free butatrienes. Moreover, the exploration of new C–C coupling reactions using compounds such as **12**–**14** and **22**–**28** as starting materials will be on the agenda for further investigations.

## Acknowledgements

It is a pleasure to acknowledge the efforts and creativity of two coworkers, in particular, who did most of the experimental work discussed in this article: Dr Ralf Wiedemann and Matthias Laubender. I am also indebted to Dr Justin Wolf and Dr Thomas Rappert who laid the foundation of the chemistry of rhodium vinylidenes and allenylidenes, to Dr Oliver Nürnberg, Dr Norbert Mahr, Bettina Windmüller, Paul Steinert and Olaf Gevert who did all the crystallographic work, and to the Deutsche Forschungsgemeinschaft (SFB 347), the Volkswagen Stiftung and the Fonds der Chemischen Industrie for financial support.

---

**Helmut Werner's research interests are in the field of synthetic and mechanistic organometallic chemistry, ranging from triple-decker sandwich complexes to C–H activation and C–C coupling reactions. After obtaining his Diploma degree with Franz Hein at Jena, he escaped from East Germany and went to Munich to work for his PhD with Ernst Otto Fischer. Following postdoctoral work at Caltech (Pasadena) and finishing his Habilitation at the Technische Universität in Munich, he joined the Faculty at the University of Zurich, Switzerland, where he became Professor of Inorganic Chemistry in 1970. He returned to Germany at the end of 1975 to take up the chair of Inorganic Chemistry at the University of Würzburg. He has been honoured by the awards of the Pacific West Coast Inorganic Lectureship (1987) by the American Chemical Society, the Alfred-Stock-Gedächtnispreis by the German Chemical Society (1988), the Centenary Lectureship by the Royal Society of Chemistry (1993), the Max-Planck-Forschungspreis (1994), the**

# Synthesis and characterization of mesoporous SAPO

**Basab Chakraborty,[a] Alex C. Pulikottil,[a] Siddhartha Das[b] and Balasubramaniam Viswanathan*[a]**

[a] *Department of Chemistry, Indian Institute of Technology, Madras 600 036, India*
[b] *Department of Metallurgical Engineering, Indian Institute of Technology, Madras 600 036, India*

**Self-assembled ordered cetyltrimethylammonium bromide (CTAB) is used as a template for the synthesis of mesoporous silicoaluminophosphates with varying Si/Al ratio.**

Aluminophosphate-based molecular sieves are known to exist in a wide range of structural and compositional diversity. Substitution of Si in the framework of aluminophosphate molecular sieves imparts acidity to the material and makes it active for a variety of acid catalysed reactions. These materials exhibit characteristics of zeolites and of aluminophosphates and also unusual properties ascribable to its composition. The extent of Si substitution in the aluminophosphate is however limited and is determined by the topology of the structure. The synthesis of phosphate-based molecular sieves has resulted in the formation of large pore materials with ring systems greater than the conventional 12T atom rings present in large-pore zeolites.[1,2] In all these systems, in spite of their large pores, their pore openings do not exceed 10–12 Å.

Self-assembled ordered organic molecules can be used to direct the synthesis of molecular sieves by a cooperative assembly of inorganic matrix over organic arrays. This approach was first used by Kresge *et al*.[3] to synthesize a family of silica-based mesoporous molecular sieves designated as M41S. Sayari *et al*.[4] have adopted this approach to synthesize a lamellar aluminophosphate using long-chain alkyl- or dimethyl-alkyl-amine as structure directing agents. Here, we have extended the use of cetyltrimethylammonium bromide (CTAB) as a structure directing agent for the first time, for the synthesis of silicoaluminophosphates with the aim of obtaining large-pore mesoporous materials.

In a typical synthesis, 8 g of aluminium isopropoxide (Loba Chemie) was mixed with dilute phosphoric acid (6.2 ml $H_3PO_4$ in 60 ml $H_2O$) and stirred vigorously for 1 h at 333 K. This was followed by the addition of CTAB (8 g in 20 ml $H_2O$) with subsequent addition of the appropriate amount of tetraethyl-orthosilicate (Merck) dissolved in 4 ml of tetramethylammonium hydroxide and the gel was stirred for another hour. The pH of the resulting gel was around 2.5. The molar composition of the resulting gel thus obtained was 71.2 $P_2O_5$ : 26.8 $Al_2O_3$ : 1.0 $SiO_2$ : 31.5 CTAB : 6082 $H_2O$.

The gel was autoclaved for 48 h at 383 K without stirring. After crystallization the pH of the mother liquor increased to 7. The crystalline materials were washed several times with hot water and dried in an air oven at 383 K for 12 h. Samples were calcined initially in nitrogen atmosphere for 1 h at 873 K followed by heating in air for 12 h.

All samples were characterized using XRD, TEM, sorption studies and solid-state MAS NMR measurements. X-Ray diffractograms were recorded on a Rich Seifert XRD 3000P instrument using Cu-K$\alpha$ radiation (35 kV, 30 mA, 2° $min^{-1}$). TEM studies were carried out on a Philips CM12 scanning transmission electron microscope operating at 100 kV. Adsorption isotherms were determined at 77 K using a Carlo Erba sorptomatic series 1800 instrument using nitrogen as the adsorbent. MAS NMR spectra were recorded using a JEOL GSX400 instrument. The Larmor frequencies were 104.1, 161.8, 79.4 MHz for $^{27}Al$, $^{31}P$ and $^{29}Si$ respectively. Data were acquired at a MAS speed of 5.5 KHz.

X-Ray diffractograms of all the calcined samples of silicoaluminophosphates (SAPO) shown in Fig. 1 indicate the crystalline nature of all the samples. All the samples exhibit characteristic low-angle peaks typical of mesoporous materials. The low-angle peaks are indexed on the basis of hexagonal symmetry. The $d_{100}$ values for all the samples are given in Table 1. There are two peaks at 2θ 20.39 and 20.74° for sample S-III and in the same 2θ range for the other two samples in the X-ray diffractograms studied. The indexing of these planes from which these reflections arise could not be done immediately as the precise value of both the lattice parameters could not be obtained from indexing the low-angle reflections, namely 100, 110 and 200. Hence these peaks have been left unindexed. However a single-crystal X-ray study will be able to resolve this aspect. The crystal of the calcined SAPO materials as revealed from TEM studies have a faceted nature. From the two dimensional projected image, as obtained from TEM, it appears that the synthesised materials have hexagonal external morphology. The crystals are found to grow along the densely packed plane. The average size of the crystals is found to be 50–75 nm. It can be seen from the chemical analysis results of the synthesised materials given in Table 1 that not all of the silica in the original gel is incorporated in the synthesised materials. No change in phases is also observed in the XRD pattern with increase in silica content of the synthesised SAPO materials.

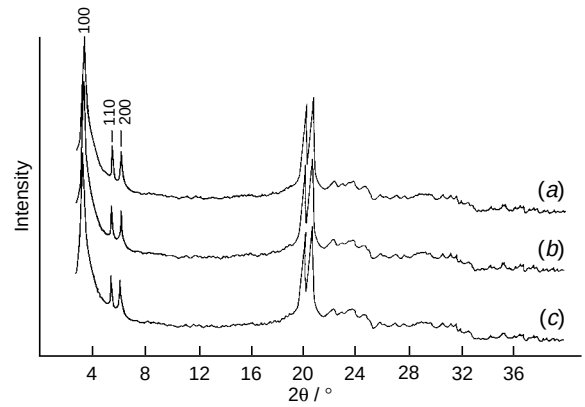

**Fig. 1** XRD patterns of the calcined mesoporous SAPO materials; (*a*) S-I, (*b*) S-II, (*c*) S-III

**Table 1** The molar ratios of the synthesis gel and that of the samples as obtained from elemental analysis along with the surface areas, pore diameters and $d_{100}$ line spacings of the samples

| | Al/P molar ratio | | Al/Si molar ratio | | | | |
|---|---|---|---|---|---|---|---|
| Sample | Gel | As synth. | Gel | As synth. | $d_{100}$/Å | Surface area/ $m^2\ g^{-1}$ | Pore diameter/ Å |
| S-I | 0.38 | 0.81 | 87.1 | 90.02 | 28.14 | 920 | 29 |
| S-II | 0.38 | 1.01 | 53.7 | 61.04 | 28.28 | 940 | 30 |
| S-III | 0.38 | 1.13 | 29.3 | 34.80 | 28.44 | 980 | 30 |

Nitrogen adsorption isotherms of all the samples show type IV isotherm behaviour with hysteresis in the mesopore filling region. The pore size distributions computed on the basis of BJH analysis indicate a narrow distribution with the maximum centred around 30 Å reflecting a uniform pore texture of the samples. All the samples exhibit surface areas around 900 $m^2$ $g^{-1}$. The average pore diameters and the BET surface areas of all the samples are given in Table 1.

Solid-state MAS NMR was carried out in order to understand the local structure and environments in these samples. The solid-state MAS NMR spectra of $^{29}Si$, $^{27}Al$ and $^{31}P$ nucleii of the calcined S-III are shown in Fig. 2. The $^{27}Al$ MAS NMR spectrum of the calcined S-III sample gives a single sharp resonance at δ 37.2 which is typical of Al in tetrahedral coordination.[5] The absence of other resonance lines implies the absence of amorphous or other phases in which aluminium has higher coordination in the synthesised samples. The $^{31}P$ MAS NMR spectrum of the calcined S-III samples [Fig. 2(*b*)] consists of a sharp peak centred at δ −30.9 indicating a uniform environment of the phosphorus atom. This is characteristic of tetrahedrally coordinated phosphorus in silicoaluminophosphates.[5] The single symmetric peak at δ −30.9 can be assigned to a single P(4Al) environment.[6] This resonance is observed for all the three SAPO samples irrespective of the amount of Si present. This is in agreement with the fact that P–O–Si linkages are absent in silicoaluminophosphates. The presence of such a sharp single signal for $^{31}P$ and $^{27}Al$ further confirms the phase homogeneity of the prepared samples. Although much information on the local environment of P and Al could not be directly deduced from the $^{31}P$ and $^{27}Al$ MAS NMR, $^{29}Si$ MAS NMR [Fig. 2(*a*)] provides a better insight into the local ordering of silicon in these mesoporous silicoaluminophosphates. Peaks centred around δ −90.1, −94.3, −98, −104 and −108.2 are observed indicating a multiple environment for Si in these samples. The resonances thus obtained were assigned as follows: δ −90.1 to Si(4Al), δ −94.3 to Si(3Al), δ −98 to Si(2Al), δ −104 to Si(1Al) and δ −108.2 to Si(0Al). Similar assignments are reported in literature for the various environments of Si in SAPOs.[7–9] The absence of any other peak in the range δ −86 to −111 excludes the possibility of P–O–Si linkages.[7] A detailed NMR studies on these materials will be reported soon.

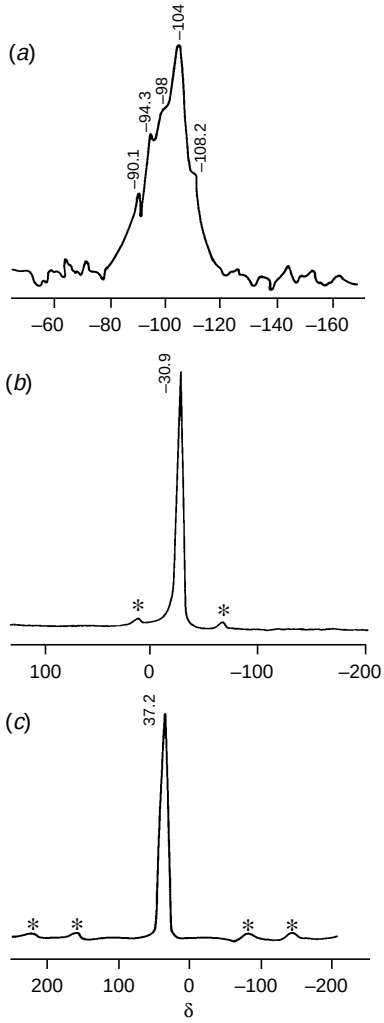

**Fig. 2** Solid-state MAS NMR of the calcined S-III sample, (*a*) $^{29}Si$, (*b*) $^{31}P$ and (*c*) $^{27}Al$; * indicates spinning side bands

Mesoporous silicoaluminophosphates with pore size of *ca*. 30 Å with varying amounts of Si content have been synthesised. The local environment around Si, Al and P is found to be similar in comparison to other SAPO materials.

Financial assistance received from the Council for Scientific and Industrial Research, India and the Department of Science and Technology, India is gratefully acknowledged.

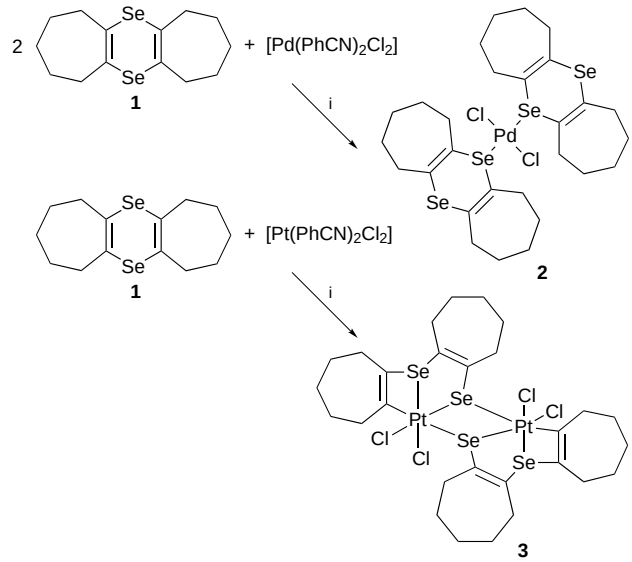
# Oxidative addition of a C–Se bond to a $Pt^{II}$ centre: contrasting reactions of $[MCl_2(PhCN)_2]$ (M = Pd, Pt) with cyclohepteno-1,4-diselenin

**C. Matthew Bates,[a] Pawan K. Khanna,[a] Christopher P. Morley*[a] and Massimo Di Vaira[b]**



[a] *Department of Chemistry, University College of Swansea, Singleton Park, Swansea, UK SA2 8PP*
[b] *Dipartimento di Chimica, Universita degli Studi di Firenze, Via Maragliano 75/77, 50144 Firenze, Italy*

**The reaction of cyclohepteno-1,4-diselenin 1 with $[PtCl_2(PhCN)_2]$ proceeds *via* unprecedented oxidative addition of a C–Se bond to yield a platinum(IV) product, whose novel dimeric structure has been determined by X-ray crystallography; by contrast, 1 reacts with $[PdCl_2(PhCN)_2]$ to form *trans*-$[PdCl_2L_2]$ (L = 1).**

The chemistry of selenium-containing ligands is a subject of growing interest,[1] as a result of both their increasing accessibility, and the realisation that they may display significantly different properties from their sulfur-containing analogues. Despite their ready preparation from 1,2,3-selenadiazoles,[2] and the range of possible bonding modes (mono- or bi-dentate; terminal, bridging or chelating), the coordination chemistry of 1,4-diselenins has scarcely been investigated. Their use as precursors in the preparation of iron diselenolenes has been reported, but these reactions involved fragmentation of the ligand.[3] A number of complexes of the related selenanthrenes have also been prepared.[4,5] We have previously determined the structure of bis(cycloocteno)-1,4-diselenin,[6] and have now studied the reactions of cyclohepteno-1,4-diselenin **1** with the palladium(II) and platinum(II) complexes $[MCl_2(PhCN)_2]$.

Stirring 2 equiv. of **1** with $[PdCl_2(PhCN)_2]$ in dichloromethane solution at room temp. leads to rapid formation of an orange–red product **2**, with stoichiometry $[PdCl_2L_2]$ (L = **1**) (Scheme 1). Compound **2** exhibits a single band in the far IR at *ca*. 360 $cm^{-1}$, characteristic of dichloropalladium(II) complexes having *trans*-geometry.[7] The structure proposed for **2** is one in which each 1,4-diselenin is acting as a monodentate ligand. Analogous complexes of dialkylselenides have been known for a long time.[8]

The corresponding platinum chemistry, however, takes a different course (Scheme 1). The reaction between $[PtCl_2(PhCN)_2]$ and **1** is somewhat slower, and if 2 equiv. of 1,4-diselenin are used then one is recovered unchanged. The NMR spectroscopic data for the product **3** show that the symmetry of the coordinated 1,4-diselenin has been broken: for example, each carbon atom of the ligand gives a separate $^{13}C$ resonance.†

**Scheme 1** *Reagents and conditions*: i, $CH_2Cl_2$, room temp.

The molecular structure of **3** has been determined by X-ray crystallography‡ and is shown in Fig. 1. The platinum has inserted into a carbon–selenium bond of the 1,4-diselenin, so that it has become a tridentate (C, Se, Se) ligand. The typical octahedral coordination of $Pt^{IV}$ is achieved *via* dimerisation using bridging selenium atoms, although there is significant asymmetry in the $Pt_2Se_2$ unit: there are two long Pt–Se bonds of *ca*. 2.62 Å. This reflects the different *trans*-influence of the carbon and chlorine atoms bound to platinum (*vide infra*). There is no evidence that the steric effect of the alicyclic rings is preventing closer approach of the two platinum moieties: the carbon atoms in each half of the molecule are at least 3.3 Å apart. There are small differences between the distances from platinum to the two selenium atoms of a single ligand, the bonds to the disubstituted Se(2) and Se(4) being shorter by *ca*. 0.04 Å than those to Se(1) and Se(3). In fact both pairs of Pt–Se distances (av. 2.422, 2.386 Å) are considerably shorter than those previously reported for $Pt^{IV}$–Se bonds. For example in the complexes $[PtXMe_3(MeSeCH{=}CHSeMe)]$ average values for Pt–Se are 2.528 Å (X = Cl) and 2.533 Å (X = I):[9] this shows how sensitive the Pt–Se bond length is to the influence of the *trans*-ligand (which in these examples is a methyl group). The platinum–chlorine bonds differ in length in a similar fashion, with those to the chlorine atoms *trans* to Se(2) and Se(4) being *ca*. 0.03 Å shorter, so that overall the coordination polyhedra are

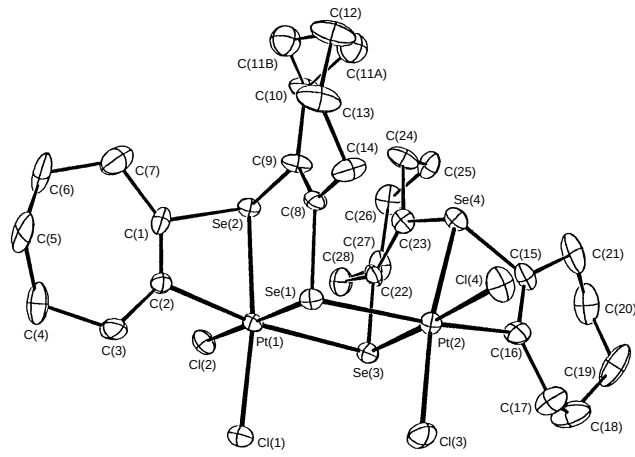


**Fig. 1** Structure of **3** with H atoms omitted for clarity. Selected bond lengths (Å) and angles (°): Pt(1)–Se(1) 2.421(2), Pt(2)–Se(3) 2.423(2), Pt(1)–Se(2) 2.384(2), Pt(2)–Se(4) 2.388(2), Pt(1)–Se(3) 2.620(2), Pt(2)–Se(1) 2.624(2), Pt(1)–Cl(1) 2.342(5), Pt(2)–Cl(3) 2.330(5), Pt(1)–Cl(2) 2.367(5), Pt(2)–Cl(4) 2.359(5), Pt(1)–C(2) 2.103(18), Pt(2)–C(16) 2.079(20); Se(2)–Pt(1)–Se(3) 100.9(1), Se(2)–Pt(1)–C(2) 70.9(5), Pt(1)–Se(2)–C(1) 77.8(6), Se(2)–C(1)–C(2) 103.7(1.4), Pt(1)–C(2)–C(1) 107.6(1.4).

somewhat compressed along one axis. This distortion is not chemically significant, but arises as a consequence of the geometric constraints imposed by the presence of the metal-containing four-membered ring.

The dimeric structure does not appear to be maintained in solution. The $^{77}$Se NMR spectrum of **3** in $CD_2Cl_2$ contains two resonances, each with only one set of $^{195}$Pt satellites: δ 315 [$^1J(^{77}Se^{195}Pt)$ 295 Hz], δ 278 [$^1J(^{77}Se^{195}Pt)$ 154 Hz]. There are few values in the literature for $^1J(^{77}Se^{195}Pt)$, but the coupling constants for **3** are similar in magnitude to those previously observed.[10]

Oxidative addition to platinum(II) centres is common for halogens, alkyl halides, *etc.*,[11] but the reaction reported here represents the first example involving cleavage of a C–Se bond. Indeed a wide range of diorganochalcogen complexes of platinum(II) has previously been prepared.[12] The insertion of a $d^8$ metal centre into a C–Se bond has only previously been observed in an iridium(I) complex of a coordinated selenophene.[13] Clearly the behaviour of the cycloalkeno-1,4-diselenins is unique, and further investigation of their coordination chemistry is in progress.

This work was supported by EPSRC and the Ministero dell' Università e della Ricerca Scientifica e Technologica. † *Synthesis of* **3**: A mixture of $[PtCl_2(PhCN)_2]$ (0.100 g, 0.21 mmol) and **1** (0.073 g, 0.21 mmol) in $CH_2Cl_2$ (10 cm$^3$) was stirred overnight. The solvent was removed by evaporation under reduced pressure and the residue washed with light petroleum, to leave the product as an orange–brown powder. This was purified by recrystallisation from dichloromethane–toluene. Yield: 0.080 g (62%); mp 205 °C (decomp.); $^1$H NMR (400 MHz, $CD_2Cl_2$, $SiMe_4$), δ 3.19 (m, 1 H), 2.85–2.65 (m, 3 H), 2.65–2.35 (m, 11 H), 1.45 (m, 1 H); $^{13}$C NMR (100 MHz, $CD_2Cl_2$, $SiMe_4$), δ 149.1, 133.5, 131.9, 126.1, 39.4, 37.0, 35.9, 34.5, 31.8, 29.2, 29.0, 28.1, 27.6, 25.2; $^{77}$Se NMR (47.7 MHz, $CD_2Cl_2$, external $SeMe_2$), δ 315 [$J(^{77}Se^{195}Pt)$ 295 Hz], 278 [$J(^{77}Se^{195}Pt)$ 154 Hz]; IR (KBr disk), 2921vs, 2849s, 1443s, 1385m, 1359m, 1267m, 1215m, 1071m, 967m cm$^{-1}$; Far IR (Nujol mull, CsI plates): 330m, 310m cm$^{-1}$; UV–VIS ($CH_2Cl_2$): $\lambda_{max}$/nm (ε/dm$^3$ mol$^{-1}$ cm$^{-1}$) = 490 (≈ 200, vbr), 330 (9000), 285 (15000), 260 (17000), 230 (22000); MS (FAB): *m/z* (%), 1187 (≈ 1) [$M^+$ − Cl], 348 (45) [$\mathbf{1}^+$], 267 (100) [$\mathbf{1}^+$ − SeH]; C, H analysis ($C_{28}H_{40}Cl_4Pt_2Se_4$, 1224.46): calc. C 27.45, H 3.27; found C 27.78, H 3.41 %.

‡ *Crystal data for* **3**: $C_{28}H_{40}Cl_4Pt_2Se_4$; $M_r$ = 1224.46; crystal size 0.07 × 0.13 × 0.27 mm; orthorhombic, space group *Pcab*; *a* = 15.203(2), *b* = 17.301(4), *c* = 25.935(4) Å, *U* = 6821(2) Å$^3$, *Z* = 8, *F*(000) = 4544, $D_c$ = 2.384 g cm$^{-3}$, μ(Cu-Kα) = 234.4 cm$^{-1}$. Data collection (Enraf-Nonius CAD4, graphite-monochromated Cu-Kα radiation, λ = 1.5418 Å, *T* = 295 K), ω—2θ scans, 3 < θ < 60°. 4831 measured reflections (+*h*, +*k*, +*l*), 3875 unique, 2887 with $l > 3\sigma_l$ used in final refinement. Structure solution and refinement: direct methods, with SIR,[14] and heavy-atom procedures with SHELX-76. A series of Fourier syntheses provided the positions of all non-hydrogen atoms. An empirical absorption correction (min., max. correction factors 0.92, 1.11) was applied at isotropic convergence.[15] In the final refinement cycles, performed against *F* by full-matrix least squares, all non-hydrogen atoms were assigned anisotropic temperature factors, except for a methylene carbon atom which was found to occupy two positions, in a disordered fashion. Its two fractions were assigned an overall isotropic temperature factor and the complementary occupancy factors of the two sites were refined. The four C–C bond distances formed by the two fractions of the disordered C atom with the other atoms of the ring were linked, allowing for a 0.01 Å σ, to a unique value, which was refined. The hydrogen atoms were introduced in calculated positions, with C–H = 0.96 Å and $U_H$ = 1.2 $U_C$, where $U_C$ is the equivalent isotropic temperature factor of the carrier C atom, and were not refined. With 343 parameters refined the data : parameter ratio was 8.4. Final *R* values: *R* = 0.045, $R_w$ = 0.053. Max., min. values of residual electron density: +0.82, −0.87 e Å$^{-3}$.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/422.

# Crystal and molecular structure of an aluminium clathrate exhibiting an unusual tertiary arrangement and an extraordinary degree of solvation

**Jan Ondráček,[a] Alexandr Jegorov,*[b] Zdeňka Kovářová,[c] Michal Hušák[a] and František Jursík[c]**

[a] *Department of Solid State Chemistry, Prague Institute of Chemical Technology, 166 28 Praha 6, Czech Republic*
[b] *Galena Co., Research Unit, 370 05 České Budějovice, Czech Republic*
[c] *Department of Inorganic Chemistry, Prague Institute of Chemical Technology, 166 28 Praha 6, Czech Republic*

**In the course of our study of aluminium complexes, a new complex with *N*-salicylidene-*o*-aminophenol ($H_2L$) is isolated, which is unique because of its stereochemistry, degree of solvation, the manner of tertiary arrangement and by the crystal packing; the crystal and molecular structure of this complex is established by X-ray structure analysis.**

Adverse effects of elevated aluminium concentration in the environment[1] attract attention to its coordination chemistry in biological systems. Among others, the Schiff bases as typical 'hard donor ligands' exhibit some similarity with ligands present in biological systems. Thus they can serve as a suitable *in vitro* model mimicking the coordination chemistry of Al *in vivo*.

The source material was obtained from *N*-salicylidene-*o*-aminophenol (6 mmol), NaOH (6 mmol), $AlCl_3 \cdot 6H_2O$ (6 mmol) in methanol–water (55 ml, 10 : 1) precipitated with sodium acetate (5% m/v in water, 25 ml). The yellow needles of the complex were obtained in 30–40% yield by the slow diffusion of diethyl ether into the solution containing the crude precipitate (50 mg), acetone (2 ml) and water (50 μl). The fact that the crystals immediately decompose upon removing them from the mother-liquor indicated that appropriate guests are necessary to stabilize the three-dimensional framework structure. Hence, a single crystal was adjusted in a glass capillary filled with diethyl ether for the X-ray analysis.†

Since the discovery of crown ethers a considerable number of various classes of host–guest compounds have been described,[2] including clathrates, framework silicates, Zintl phases, polycations and others. The new aluminium clathrate exhibits a combination of several new structural features. The primary structure of the complex is composed of two independent polynuclear moieties A and B. Moiety A is the binuclear complex $[(H_2O)LAl(\mu\text{-}MeCO_2)(\mu\text{-}OH)AlL(H_2O)]$ (Fig. 1), while moiety B consists of the $[\{LAl(H_2O)(OH_2)\}_2Al(\mu\text{-}OH)_2Al\{LAl(H_2O)(OH)_2\}_2]$ hexanuclear unit which is symmetrical along the twofold crystallographic axis (Fig. 2). Thus, in contrast to many other clathrates of cadmium[3] or nickel[4] cyanides or framework silicates,[2] bridging anions do not create the infinite network, and the structure consists of independent neutral polynuclear coordination compounds. The repeating of hydrogen-bond networks including the $A_2B$ cyclic tertiary arrangement and four methanol molecules leads to infinite channels parallel to the *c* crystallographic axis (Fig. 3). The quite unusual cavity dimension (18 × 15 Å) and degree of solvation have some analogy with pore-forming proteins,[5] but

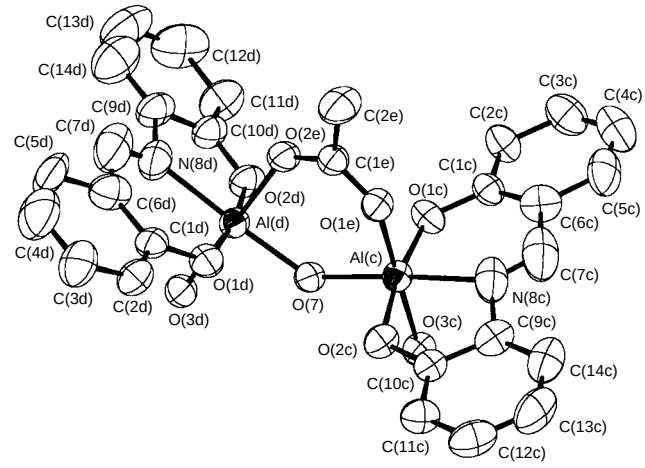

**Fig. 1** Structure of the binuclear $[(H_2O)LAl(\mu\text{-}MeCO_2)(\mu\text{-}OH)AlL(H_2O)]$ complex

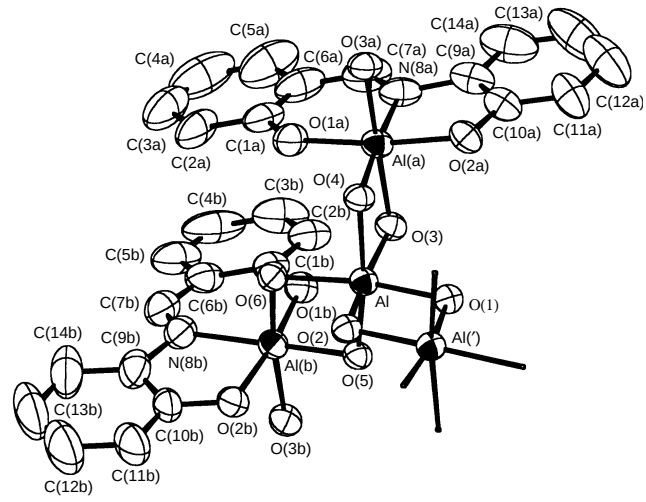

**Fig. 2** Structure of the hexanuclear $[\{LAl(H_2O)(OH)_2\}_2Al(\mu\text{-}OH)_2Al\{LAl(H_2O)(OH)_2\}_2]$ complex [half of the molecule with the bridging $Al(\mu\text{-}OH)_2Al'$ moiety]

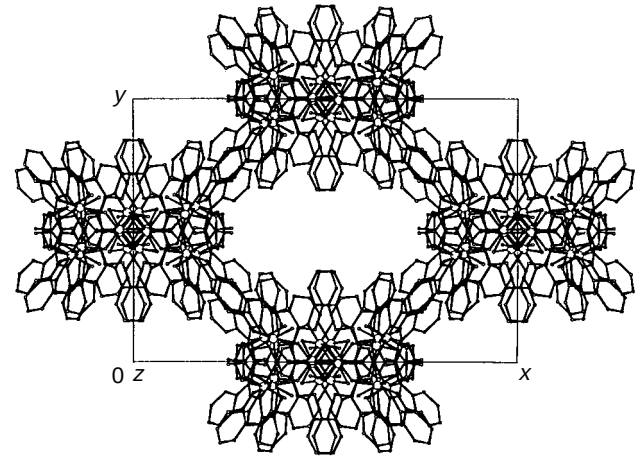

**Fig. 3** Crystal packing of $2[(H_2O)LAl(\mu\text{-}MeCO_2)(\mu\text{-}OH)AlL(H_2O)]\cdot[\{LAl(H_2O)(OH)_2\}_2Al(\mu\text{-}OH)_2Al\{LAl(H_2O)(OH)_2\}_2]\cdot 4MeOH\cdot n Et_2O$

on the other hand, is quite unexpected among coordination compounds. Another unusual feature of the present compound is the high degree of solvation. Since inclusion compounds of highly volatile guests are often unstable,[6] it is quite unexpected, that a compound containing approximately 45% of disordered diethyl ether molecules forms mechanically stable crystals at ambient temperature. In conclusion, the stereochemistry of this complex indicates that the ability of aluminium to create structures mimicking some structures typical of living systems should be considered for the evaluation of its *in vivo* toxicity.

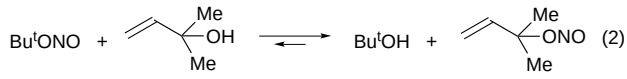
# Oxiranylmethyl radicals: EPR detection by spin trapping

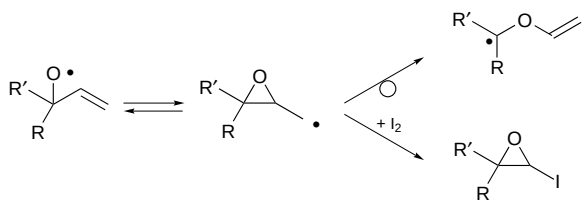
**Loris Grossi* and Samantha Strazzari**

*Dipartimento di Chimica Organica 'A. Mangini', Università di Bologna, Viale Risorgimento, 4, I-40136 Bologna, Italy*



**The EPR detection of oxiranylmethyl radicals, formed *via* a 3-*exo-trig* process from the corresponding allyloxyl radical, is performed with Bu$^t$ONO as a spin trap.**

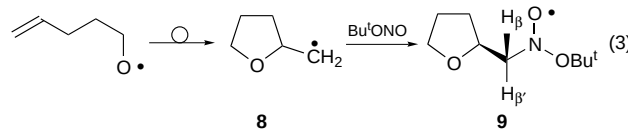
The 3-*exo-trig*[1] process involving allyloxyl radicals could be a useful method for synthesizing epoxides.[2] However, this reaction was usually reported to have failed because the intermediate oxiranylmethyl radical **2** can rapidly undergo either C–O bond fission (to give **1**) or C–C bond fission (to give **3**) [eqn. (1)].



Nevertheless, Galatsis and Millan[2c] have recently reported the preparation of α-iodo epoxides by photolysing tertiary allylic alcohols in the presence of bis(acetoxy)iodobenzene and iodine. This process is based on competition between the two possible reaction pathways that the intermediate oxiranylmethyl radical can follow (Scheme 1), and relies on the more efficient trapping by iodine.

However, no direct EPR evidence for the detection of these radical species has been reported[3] and, to account for this, a fast decay process for **2** has always been claimed.[3,4] One possible method of investigation could be the spin-trap technique, *i.e.* conversion of the oxiranylmethyl radical into a more persistent radical species. Previous experiments conducted by our group had shown the ability of alkyl nitrites to act as a spin trap[5] for short-lived alkyl radicals and, in particular, *tert*-butyl nitrite seemed to be quite efficient. Moreover, since the oxiranylmethyl radicals derive from a rearrangement process involving allyloxyl radicals, it was considered convenient to generate the latter by photolysis of the corresponding nitrites. These can be prepared, in almost quantitative yield, *via* an easy exchange reaction[6] between the corresponding alcohols and *tert*-butyl nitrite, which is known to behave as a nitrosyl source [eqn. (2)].

This method could then be used also to supply the required spin trap directly into the medium. In fact, in performing the nitrosyl transfer to the alcohols with an excess of Bu$^t$ONO it was possible that a part of it could act as the trap.

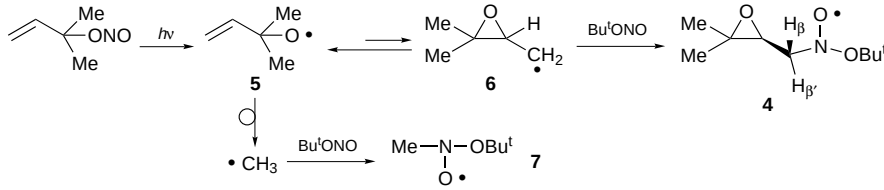


The experiments were conducted under continuous flow conditions on acetonitrile solutions of tertiary allylic alcohols in the presence of an excess of Bu$^t$ONO, which were photolysed in the EPR spectrometer cavity at different temperatures.

**Scheme 1**

When 2-methylbut-3-en-2-ol was investigated, two radical species were detected; the methyl *tert*-butoxy nitroxide **7** (Table 1), formed by trapping of the methyl radical which comes from the competitive β-process that the allyloxyl radical can undergo, and an alkyl alkoxy nitroxide, characterised by an alkyl group with two magnetically inequivalent β-hydrogens. The EPR spectroscopic parameters of this species suggested structure **4**, which is chiral[7] by virtue of the asymmetric oxiranyl group, and therefore justifies the detection of inequivalent β-$CH_2$ hydrogens even if there is rapid internal rotation about the N–$C_\beta$ bond. A possible reaction mechanism for the formation of both radical species could be that outlined in Scheme 2.

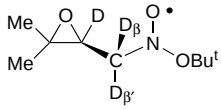
Since, to the best of our knowledge, this is the first spectroscopic evidence for the detection of the oxiranylmethyl radical, it was necessary to confirm the suggested structure of **4** with further experiments. The pent-4-en-1-ol–Bu$^t$ONO system was then studied using the same experimental conditions used for 2-methylbut-3-en-2-ol. It was hypothesized that the tetrahydrofurfuryl radical **8**, formed by the fast 1,5-*exo* ring closure[8] of the intermediate pent-4-enoxyl radical, would react with *tert*-butyl nitrite, leading to the formation of **9**, [eqn. (3)].



As this radical is chiral due to the presence of an asymmetric tetrahydrofuran-2-yl group, the corresponding EPR spectrum should show two magnetically inequivalent β-hydrogens; this proved to be the case. Further support came from experiments with a reduced amount of *tert*-butyl nitrite, which gave the bis(tetrahydrofurfuryl) nitroxide **10** and which confirmed the presence of the rearranged radical **8** in the medium.

Although these results strengthened our hypothesis, it was still necessary to obtain direct confirmation; for example, to

**Table 1** EPR results for **4**, **7** and **9**–**13**



| | Hyperfine coupling constant/Gauss (no. nucleii) | | | | | |
|---|---|---|---|---|---|---|
| Radical | $a_\alpha$ | $^*a_\beta$ | $^*a_{\beta'}$ | $a_\gamma$ | $a_\delta$ | $g$ |
| **4** | 25.65 (1 N) | 5.60 (1 H) | 9.10 (1 H) | 0.22 (1 H) | — | 2.0053 |
| **7** | 25.75 (1 N) | $8.87_5$ (3 H) | — | — | — | 2.0054 |
| **9** | $25.37_5$ (1 N) | 4.00 (1 H) | 12.00 (1 H) | 0.35 (1 H) | $0.17_5$ (2 H) | 2.0053 |
| **10** | 14.25 (1 N) | 6.75 (2 H) | 11.25 (2 H) | — | — | 2.0058 |
| **11** | 25.65 (1 N) | 0.80 (1 D) | 1.35 (1 D) | — | — | 2.0053 |
| **12** | 25.70 (1 N) | $8.12_5$ (2 H) | — | 0.30 (3 H) | — | 2.0053 |
| **13** | 25.72 (1 N) | $5.62_5$ (1 H) | 9.25 (1 H) | 0.25 (1 H) | — | 2.0053 |

* The hfc of $H_\beta$ can be attributed to $H_{\beta'}$ and *vice versa*.

**Scheme 2**

prove that the two inequivalent hydrogens of the $CH_2$ group of radical **4** originate from the vinyl $CH_2$ group in radical **5**. For this purpose, 2-methyl[3,4,4-$^2H_3$]but-3-en-2-ol was synthesized.[9] Experiments conducted on this substrate, using the same experimental conditions used for the analogous hydrogenated compound, led to the detection not only of the methyl *tert*-butoxy nitroxide, but also of the alkoxy alkyl nitroxide **11**, whose EPR spectrum showed a nitrogen coupling constant exactly matching that of the corresponding atom in radical **4**, and two inequivalent deuterium atoms with coupling constants of *ca*. 1/6 of that of the corresponding hydrogen atoms.

**11**

Finally, support for our hypothesis was also obtained from experiments with 3-methylpent-1-en-3-ol, which gave adducts to the *tert*-butyl nitrite of all the radical species deriving from the intermediate allyloxyl radical, *i.e.* the oxiranylmethyl *tert*-butoxy nitroxide **13**, the methyl *tert*-butoxy nitroxide **7** and the ethyl *tert*-butoxy nitroxide **12**.

These results confirmed the involvement of a 3-*exo-trig* process in oxiranylmethyl radical formation from a tertiary allyloxyl radical and showed the utility of *tert*-butyl nitrite as a trap for these species. This work is currently being extended to other tertiary and secondary allylic alcohols.

# Enantioselective synthesis of homoallylic alcohols using (*E*)-but-2-enyltrichlorosilane and chiral diamines

**Richard M. Angell,[b] Anthony G. M. Barrett,*[a] D. Christopher Braddock,[a] Steven Swallow[c] and Benjamin D. Vickery[a]**

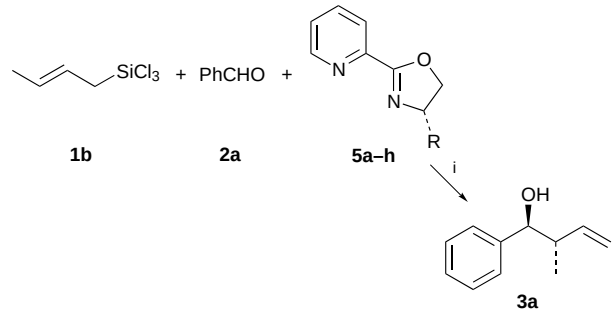
**Condensation of aromatic aldehydes and (*E*)-but-2-enyltrichlorosilane in the presence of (*S*)-(+)-4-(2-methylpropyl)-2-(2-pyridinyl)-2-oxazoline gives the corresponding homoallylic alcohols in excellent *anti*-diastereoselectivity ( > 99%) and good enantioselectivity (36–74%).**



The nucleophilic addition of allylmetal moieties to carbonyl compounds is a powerful method for the construction of carbon–carbon bonds and represents an invaluable tool in organic synthesis.[1] The catalytic use of chiral Lewis acids derived from titanium(IV) complexes and (*R*)- or (*S*)-BINOL developed independently by the groups of Keck and of Tagliavini and Umani-Ronchi for the addition of allylstannane reagents to achiral aldehydes has been demonstrated to furnish homoallylic alcohols both in excellent yield and enantiomeric excess for aromatic and aliphatic aldehydes alike.[2,3] Similarly, modified titanium(IV)–BINOL systems have been found to catalyse the Sakurai–Hosomi allylation of aldehydes.[4–6] Here the advantage lies in the use of inexpensive, non-toxic silicon derivatives. A mechanistically distinct approach is the use of Lewis bases to mediate the addition of crotyltrifluorosilane **1a** to aldehydes. For instance, Sakurai has shown that the addition of stoichiometric amounts of lithium fluoride,[7] dilithium catecholate[8] or catechol[9] furnishes homoallylic alcohols in excellent yield and with relative stereochemical control. Kobayashi has pioneered the use of DMF and HMPA as the Lewis base for the addition of crotyltrichlorosilane **1b** to aldehydes[10] and some success has also been achieved by the replacement of these achiral additives with chiral phosphoramides providing homoallylic alcohols in high yield and variable enantiomeric excess (21–88% ee).[11] Very recently Wang *et al*[12] have shown that (2*R*,3*R*)-(+)-diisopropyl tartrate **4**, a bidentate *O*-donor, can be used as the asymmetric Lewis base additive giving the alcohol product **3** in 27–71% ee, and these results prompt us to disclose our own observations in this area. Herein, we now report the enantioselective crotylation of aldehydes using (*E*)-but-2-enyltrichlorosilane **1b** in the presence of chiral bidentate Lewis bases.

Our investigations commenced with the use of bidentate *O*-donors for the addition of crotyltrifluorosilane **1a** to aromatic aldehydes **2**. Whereas (±)-BINOL and (2*S*,3*S*)-butanediol were ineffective, we found that (2*R*,3*R*)-(+)-diisopropyl tartrate **4** promoted the condensation, but gave only racemic homoallylic alcohol adduct **3**. Employing crotyltrichlorosilane **1b** in place of fluorosilane **1a** resulted in the isolation of enantiomerically enriched products **3** (Scheme 1) and these results closely parallel those reported by Wang.[12]

After further screening of potential bidentate catalysts, we found that 2,2′-bipyridyl also promoted the reaction between crotyltrichlorosilane **1b** and benzaldehyde **2a** (−55 °C, 60 h, 87% yield). This promising result encouraged us to produce and test chiral pyridine derivatives in enantioselective crotylation reactions. To our great delight, use of (*S*)-(−)-4-isopropyl-2-(2-pyridinyl)-2-oxazoline **5d**[13]† provided product **3a** in 59% yield and 43% ee (−55 °C, 60 h). Consequently, a number of chiral pyridinyloxazolines **5a**–**h** were synthesised[14] and used as auxiliaries‡ with varying degrees of success (Scheme 2 and Table 1). Clearly, the leucine derived ligand **5c** gives the best results and we were able to obtain a reproducible 72% yield of exclusively the *anti*-diastereoisomeric adduct **3a** in 74% ee. A

number of aldehydes were examined to test the scope of the reaction (Scheme 3 and Table 2). In most cases alcohols **3a-f** were obtained in good yield and ee.

There has been much discussion about the transition state of the crotylation reaction. That products with *anti* stereochemistry are produced indicates a closed cyclic transition state, probably involving a penta- or hexa-coordinate silicon. However, the precise nature of the factors controlling the degree of asymmetric induction are as yet not clear. Work is currently underway for a clearer mechanistic understanding of this transformation and to apply our knowledge for the design of novel, second generation catalysts.

We thank Glaxo Wellcome Research Ltd. for the most generous endowment (to A.G.M.B.), the Wolfson Foundation for establishing the Wolfson Centre for Organic Chemistry in Medical Science at Imperial College, the EPSRC, the DTI, Glaxo Wellcome Research Ltd. and Roche Discovery Welwyn for a studentship under the Link Asymmetric Scheme (to B. D. V.), and Dr D. J. Berrisford (UMIST) for helpful discussions.

## Footnotes

† Pyridinyloxazolines **5a–f,h**[13] were prepared following literature procedures[14] from 2-cyanopyridine and the respective amino alcohol in good yield. Novel diamine **5g** was prepared according to an analogous procedure and was fully characterised.

‡ In a typical procedure, crotyltrichlorosilane **1b** (0.353 ml, 2.2 mmol) was added to a cold (−78 °C) solution of (*S*)-(+)-4-(2-methylpropyl)-2-(2-pyridinyl)-2-oxazoline **5c** (0.450 g, 2.2 mmol) in dry dichloromethane (3.6 ml). To the bright yellow solution, was added a mixture of benzaldehyde **2a** (0.204 ml, 2.0 mmol) in dichloromethane (0.4 ml) dropwise over a period of five min. After 4 h, the mixture was poured into a mixture of saturated aqueous $NaHCO_3$ (5 ml) and 1 M NaF (5 ml). The aqueous layer was extracted with diethyl ether (3 × 25 ml). The ethereal extracts were dried and concentrated to give a yellow residue, which was chromatographed (silica, hexanes–ethyl acetate 12 : 1) to provide 2-methyl-1-phenylbut-3-en-1-ol **3a** (0.235 g, 72%) as a colourless oil.

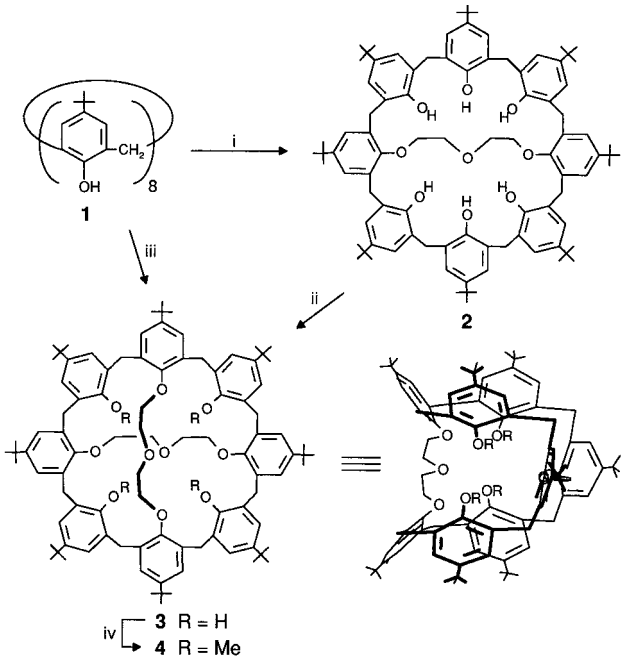
# Cation encapsulation within a ten-oxygen spheroidal cavity of conformationally preorganized 1,5-3,7-calix[8]bis-crown-3 derivatives



**Corrada Geraci, Gianni Chessari, Mario Piattelli and Placido Neri***

*Istituto per lo Studio delle Sostanze Naturali di Interesse Alimentare e Chimico-Farmaceutico, CNR, Via del Santuario 110, I-95028 Valverde (CT), Italy*

**Conformationally preorganized, $D_{2d}$-symmetrical 1,5-3,7-calix[8]bis-crown-3 derivatives have been synthesized which are able to encapsulate cations with a size dependent selectivity.**

In recent years remarkable host properties have been reported for functionalized calix[4]arenes.[1,2] In contrast, calix[8]arenes have shown no complexing abilities worthy of note,[1] apart from the remarkable case of buckminsterfullerene complexation.[3] This can be explained in terms of the preorganization principle[4] and by considering the floppy nature of the larger macrocycle.[5] In order to circumvent this problem, rigidification of calix[8]-arenes has been actively investigated by our[6] and other research groups,[7] giving particular attention to the preorganization by intramolecular bridging. However, notwithstanding the interesting results obtained in this direction,[6–7] to the best of our knowledge no complexing abilities have been registered so far. Here we report the first example of calix[8]arenes that by virtue of their conformational preorganization are able to encapsulate cations with a size-dependent selectivity.

As an extension of our previous studies on the synthesis of calix[8]crowns[6b,d,e] we envisaged that the use of one or more short polyether chains (diethylene glycol) could lead to a better preorganization of the macrocycle.[8] To achieve this aim, we reacted *p-tert*-butylcalix[8]arene **1** with diethylene glycol ditosylate in DMF in the presence of $Cs_2CO_3$ obtaining 1,5-crown-3 derivative **2** in 78% yield (Scheme 1), in accordance with the previously observed regioselectivity under analogous conditions.[6d] Further alkylation of **2** in the presence of NaH in THF–DMF (10 : 1, v/v) resulted in the introduction of another bridge with very high regioselectivity, thus affording 1,5-3,7-calix[8]bis-crown-3 **3** in 85% yield.† Interestingly, direct alkylation of *p-tert*-butylcalix[8]arene **1** in the presence of NaH, under conditions previously found to be well suited for 1,4-bridging with longer chains (tri- to penta-ethylene glycol),[6d] also gave **3** in 10% yield. This result is in line with the observations of Ikeda *et al*., who reported that intrabridging of **1** with bis(bromomomethyl)arenes under similar conditions results in 1,4-bridging with longer and 1,5-bridging with shorter reagents.[7c]

**Scheme 1** *Reagents and conditions*: i, $TsO(CH_2CH_2O)_2Ts$, $Cs_2CO_3$, DMF, 70 °C; ii, $TsO(CH_2CH_2O)_2Ts$, NaH, THF–DMF (10 : 1, v/v), reflux; iii, $TsO(CH_2CH_2O)_2Ts$, NaH, THF–DMF (10 : 1, v/v), reflux; iv, MeI, NaH, DMF, 70 °C

The presence of a single or double bridge in **2** and **3**, respectively, was deduced by FAB(+) mass spectra, while the bridging pattern was assigned on the basis of the molecular symmetry evidenced in NMR spectra. Thus, the presence of three *tert*-butyl signals in the $^1$H NMR spectrum ($CDCl_3$, 330 K) of **2** at δ 1.24, 1.28 and 1.31 (1 : 2 : 1) is clear evidence of a calix[8]arene molecule bisected by two orthogonal 2-fold symmetry elements and hence of the 1,5-bridging pattern. Similarly, the presence in the spectrum of **3** [Fig. 1(*a*)] of two equal intensity *tert*-butyl singlets at δ 1.20 and 1.21 coupled with a single AX system for $ArCH_2Ar$ (δ 3.45 and 4.26, $J$ = 14.6 Hz) is compatible, among the 22 possible isomers, only with the most symmetrical 1,5-3,7-bis-crown structure.

The presence of an AX system for the $ArCH_2Ar$ protons of **3** is clear proof of a strong reduction of the conformational mobility of the macrocycle. This was confirmed by dynamic NMR studies in $CDCl_2CDCl_2$, which showed no hint of coalescence for these signals when raising the temperature up to 380 K, indicating the absence of conformational interconver-

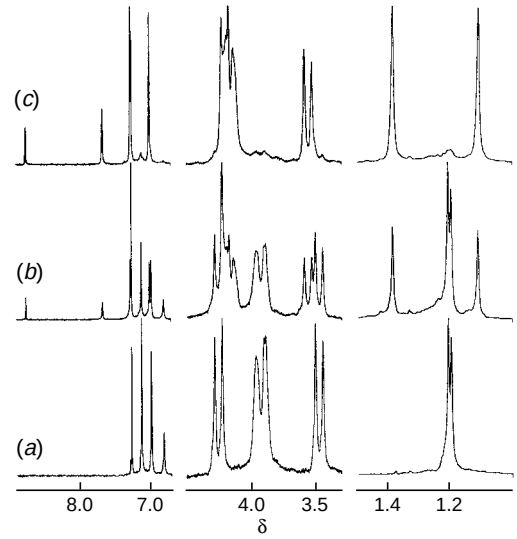


**Fig. 1** Caesium cation encapsulation by 1,5-3,7-bis-crown **3**. $^1$H NMR spectra (250 MHz, $CDCl_3$) of free ligand **3** (*a*), 24 h (*b*) and 48 h (*c*) after addition of solid caesium picrate

sion. The large chemical shift separation of the two doublets of the $ArCH_2Ar$ protons ($\Delta\delta$ = 0.81 ppm) indicates a *syn* orientation of each couple of vicinal aromatic rings with a geometry very similar to that of calix[4]arenes in the cone conformation. This was confirmed by the $^{13}C$ NMR chemical shift value of $\delta$ 32.1 for the $ArCH_2Ar$ groups.

In order to get an insight into the conformation adopted by **3** we undertook a Monte Carlo conformational search using the MacroModel ver.4.5 program[9] and imposed the symmetry equivalences evidenced by NMR. An idealized molecular model was thus obtained (Fig. 2) to be considered as the average structure in solution and possessing four different clefts, each with a structure closely reminiscent of a calix[4]arene cone depleted of an aryl ring ($\frac{3}{4}$ cone). This structure possesses a $D_{2d}$ symmetry and is very similar to that proposed by Ikeda *et al*. for a calix[8]arene 1,5-3,7-doubly-bridged with *ortho* xylene units.[7c] However, this idealized structure does not correspond to an energy minimum and, indeed, its unconstrained full-matrix minimization as well as an independent unconstrained Monte Carlo search originates unsymmetrical geometries with large distortions of the $\frac{3}{4}$ cone units. These deformations can be described as a combination of $C_{4v}$ to $C_{2v}$ transitions typical of calix[4]arene cone[8] for each subunit of the structure.

In the idealized structure the ten oxygens are symmetrically located delimitating a polyhedral, almost spheroidal cavity. The four hydroxylic oxygens describe a planar square with an average diagonal of 6.3 Å, while the central oxygens of the crowns are symmetrically situated at *ca*. 4.1 Å above and below this square. These geometrical features are reminescent of the structure of cryptands, compounds well known as strong complexing agents for alkali metal cations.[10] On the basis of this analogy, we tested the complexing abilities of compound **3**. Thus, preliminary $^1H$ NMR experiments showed that immediately after the addition of solid caesium picrate to a $CDCl_3$ solution of **3** no appreciable changes can be observed in the spectrum, but after standing for 24 h at room temp. a new set of signals appeared, due to the complex $Cs^+\subset$**3** formation [Fig. 1(*b*)]. A further 24 h standing led to complete complexation [Fig. 1(*c*)]. In the homogeneous phase ($CD_3CN$–$CDCl_3$, 9 : 1 v/v) completion of the reaction required only a few minutes. The 1 : 1 stoichiometry was confirmed by signal integration in the spectrum. In the complex $Cs^+\subset$**3** the cation appears to be encapsulated inside the ten-oxygen spheroidal cavity, as indicated by the substantial downfield shift experienced by the protons of the crown chains, the aromatic rings and the hydroxy groups. Downfield shifts were also observed in the $^{13}C$ NMR spectrum for the pertinent carbon signals.

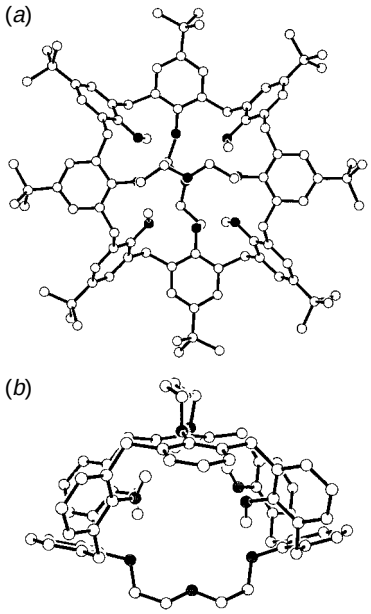

**Fig. 2** Computer model of idealized conformation of **3**: (*a*) top view (H atoms omitted); (*b*) side view (H atoms and *tert*-butyl groups omitted)

The selectivity of complexation was investigated by standard two-phase picrate extraction experiments.[11] Thus, it was shown that different cations can be encapsulated besides $Cs^+$ with the following equilibrium constants: $K_e$ ($dm^6\ mol^{-2}$) = $3.7 \times 10^4$ for $Na^+$, $11 \times 10^4$ for $K^+$, $10 \times 10^4$ $NH_4^+$, $640 \times 10^4$ for $Rb^+$ and $5200 \times 10^4$ for $Cs^+$. The $K_e(Cs^+)/K_e(Na^+)$ selectivity factor is therefore 1400, thus confirming the cation/cavity size complementarity expected for the encapsulation process.‡

It is to be expected that chemical modifications of **3** can have a profound influence on the complexing properties. We prepared the tetramethyl derivative **4** (MeI–NaH–DMF, 80% yield), whose complexing properties toward caesium cations do not differ substantially from that of **3**. Interestingly, an upfield shift from $\delta$ 3.44 to 2.84 is observed, upon $Cs^+$ complexation, for the OMe groups in the $^1H$ NMR spectrum of **4** ($CD_3CN$–$CDCl_3$, 9 : 1 v/v) indicating that they are forced to point inside the shielding $\frac{3}{4}$ cone aromatic cavities. However, the determination of picrate extraction equilibrium constants [$K_e$ ($dm^6\ mol^{-2}$) = $1.3 \times 10^4$ for $Na^+$, $3.9 \times 10^4$ for $K^+$, $4.0 \times 10^4$ for $NH_4^+$, $16 \times 10^4$ for $Rb^+$ and $87 \times 10^4$ for $Cs^+$] revealed a reduced $K_e(Cs^+)/K_e(Na^+)$ selectivity factor (67). A more detailed investigation of the complexation properties of **3**, **4** and other analogues is currently carried out in our laboratory.

Thanks are due to Mr R. Rapisardi (ICTMP, CNR, Catania) for FAB MS measurements and to Mrs C. Rocco (ISSN, CNR, Valverde) for NMR spectra acquisition.

## Footnotes

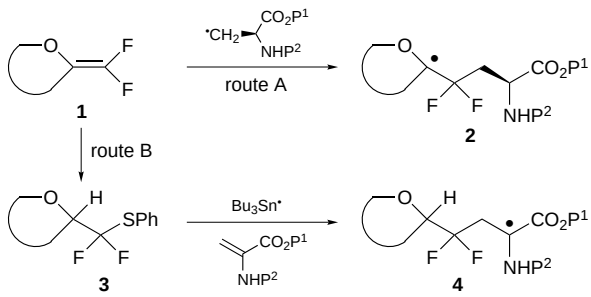
# Two free radical routes for the preparation of novel difluoromethylene-linked serine-*O*-glycopeptide analogues

**Timothée F. Herpin, William B. Motherwell* and Jean-Marc Weibel**

*Christopher Ingold Laboratories, Department of Chemistry, University College London, 20 Gordon Street, London, UK WC1H 0AJ*



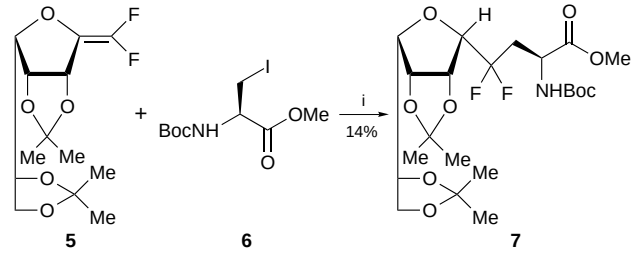
**The first examples of *gem*-difluoromethylene-linked analogues of serine-derived glycopeptides have been prepared in a highly stereoselective manner using two complementary free radical chain reactions.**

The importance of the carbohydrate moiety in molecular recognition processes involving glycoproteins[1,2] and the considerable potential of glycosylated peptide drugs[3] have stimulated intense current research interest in the synthesis of modified glycopeptides, where the customary *O*- or *N*-glycosidic bond linking the amino acid component to the sugar portion is replaced by a carbon-based unit of greater stability and resistance towards enzymatic deglycosylation. Thus, methods have been described, both for the synthesis of *C*-glycosyl amino acids in which the anomeric carbon is directly bound to the α-carbon of the amino acid[4–8] and for methylene-bridged glycopeptides[9–14] in which the additional methylene group can serve as a heteroatom mimic. Even the latter, however, lead to derivatives with a truncated chain when compared with the corresponding serine-*O*-glycopeptides.

Our objective in this area was to achieve site specific replacement of the exocyclic anomeric oxygen atom in a serine-derived glycopeptide fragment by a difluoromethylene group. This tetrahedral and electronegative unit has been shown to be of particular value as an oxygen atom replacement in several difluoromethylene phosphonate analogues of naturally occurring phosphates.[15]

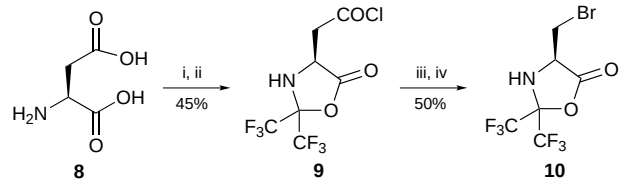
As shown in Scheme 1, our intention was to capitalise on the chemical versatility of readily prepared carbohydrate *gem*-difluoro enol ethers[16] **1**, either as radicophiles[17] for the addition of an amino acid-derived radical to give the anomeric radical **2** (route A), or *via* their thiophenol adducts **3**,[18] as apposite precursors for difluoroalkyl radical trapping by a dehydroalanine derivative to give the carbon centred radical **4** around the amino acid unit (route B).

Thus, in a preliminary study, slow addition of tributylstannane and AIBN as initiator to a refluxing benzene solution of carbohydrate **5** and the iodoalanine reagent[19,20] **6** developed by Baldwin[21,22] afforded out first example of a difluoromethylene-linked serine analogue **7**, albeit in a disappointing 14% yield (Scheme 2). Efforts to optimise this reaction or to extend it to other *gem*-difluoro enol ether substrates were unsuccessful.



**Scheme 1**

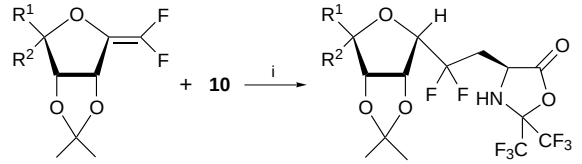
We reasoned that a much more compact and conformationally restricted radical reagent was required, and elected to prepare the cyclic bis(trifluoromethyl)oxazolidinone derivative **10** which should find general use as a convenient bromoalanine reagent. Thus, as shown in Scheme 3, protection of aspartic acid **8** with gaseous hexafluoroacetone[23] was followed by conversion to the acid chloride[24] **9** which was transformed *via* the acylthiohydroxamate to the desired bromide **10** using the radical variant of the Hünsdieker reaction.[25]



Addition of **10** to *gem*-difluoro enol ethers under tributylstannane-mediated conditions proceeded in acceptable yields with a range of substrates (Scheme 4), with abstraction of the hydrogen atom occurring exclusively from the less hindered convex face[14,26] in the case of the gulose **5** → **11** and erythrose **12** → **13** derivatives. Reaction of the ribose derivative **14** however produced an equimolar mixture of both anomers **15**, and on replacement of the methyl ether by the bulky *tert*-butyldimethylsilyl group, no addition products were observed.

The utility of the labile bis(trifluoromethyl)oxazolidinone protecting group was demonstrated by simple treatment of **11** with L-phenylalanine *tert*-butyl ester to afford the dipeptide **16** (Scheme 5).

Finally, we have also carried out a preliminary study of the alternative approach outlined in Scheme 1 route B, which effectively circumvents problems created by the steric bulk of the carbohydrate. The chiral dehydroalanine derivative (2*R*)-*N*-benzoyl-2-(*tert*-butyl)-4-methylidene-1,3-oxazolidin-5-one **17** prepared from (*S*)-alanine and used by Beckwith[13] as a radicophile, was accordingly selected to ensure diastereoselectivity at the α-carbon atom of the amino acid unit. In the final analysis, we also elected to use the phenylselanyl congeners of our previously described[18] thiophenol adducts in order to



**Scheme 2** *Reagents and conditions*: i, AIBN, $Bu_3SnH$ (slow addition), benzene, reflux

facilitate generation of the required difluoroalkyl radicals. The results for the three carbohydrates **18**–**20** in Scheme 6 indicate that this tributylstannane-mediated coupling gives consistently higher yields than those obtained by the previous method. The successful coupling of the hindered ribose derivative **20** is particularly noteworthy since the alternative coupling strategy had been unsuccessful. From a stereochemical standpoint, the ratio of the two diastereoisomers produced in each reaction is consistent with the results obtained by Beckwith[13] with the same chiral auxiliary.

In summary, the two complementary free radical routes described herein provide a convenient approach for the synthesis of a wide range of *C*-glycosylated amino acid units in which the difluoromethylene group serves not only as a potential heteroatom mimic but also contributes to providing the correct number of atoms in the crucial linkage between the carbohydrate and amino acid components of the structures.

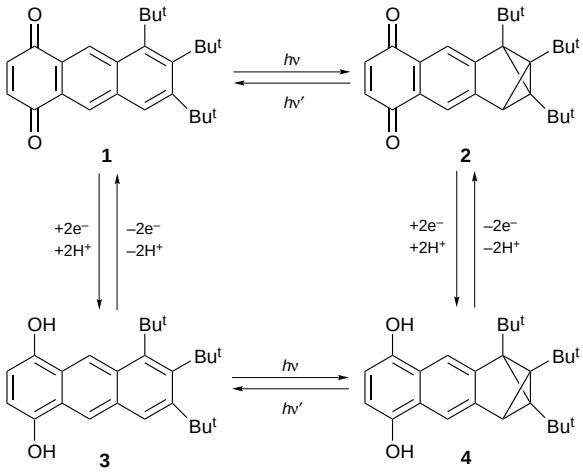
# Photo- and electro-chromism of a 1,4-anthraquinone derivative. A multi-mode responsive molecule

**Sadao Miki,* Ryuki Noda and Koushi Fukunishi**



*Department of Chemistry and Materials Technology, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606, Japan*

**5,6,7-Tri-*tert*-butyl-1,4-anthraquinone shows electro- and photo-chromism, independently based on the electrochemical redox reaction of the carbonyl groups and the χ[2 + 2]-type photo-valence isomerization of the aromatic ring.**

In the context of the importance of multi-mode responsive molecules in chemionics,[1] optical–electrical dual-mode responsive molecular devices have been the subject of much recent interest.[2–4] It is desirable that such a device can be reversibly converted between all of the four possible states,[2] and that the photo- and electro-chromic properties are completely integrated within a single structure.[4] However, among the examples reported so far, the number of molecular systems possessing these characteristics is very limited. Here, we report that 5,6,7-tri-*tert*-butyl-1,4-anthraquinone **1** shows electro- and photo-chromism independently and can be converted reversibly between all of the four possible states (Scheme 1). The 1,4-anthraquinone derivative **1** was synthesized by the thermal decarbonylation of 5,6,7-tri-*tert*-butyl-5,8-oxomethano-5,8-dihydro-1,4-anthraquinone prepared previously by us.[5]

Steady-state photolysis of **1** was performed with a degassed solution of **1** ($5.6 \times 10^{-4}$ M) in hexane at room temperature with 460 nm light from a xenon lamp using a monochromator. As shown in Fig. 1, the absorption spectral changes upon photolysis revealed isobestic points indicating that the photoreaction proceeded without forming by-products. Spectroscopic and analytical data for the product were compatible with the valene-type isomer **2**. The photo-valence isomerization of **1** was photochemically reversible. Upon irradiation of the solution of **2** with 402 nm light (one of the isobestic points), absorption bands for **1** were recovered, reaching a photostationary state with a composition of **1**:**2** = 7.2:1. Spectral changes for the reverse reaction were also accompanied by distinct isobestic points. Thus, the 1,4-anthraquinone derivative **1** shows photochromism based on χ[2 + 2]-type photo-valence isomerisation similar to other tri-*tert*-butyl-substituted polyacenequinones.[5,6]

It is well known that 9,10-anthraquinone undergoes a reversible two-step redox reaction to the hydroanthraquinone dianion *via* a semiquinone radical in aprotic solvents, and correspondingly its polarograph in DMF shows two reduction waves at $E_{1/2}$ = −0.98 and −1.74 V (*vs.* SCE).[7] 1,4-Anthraquinone derivative **1** showed electrochemical behaviour similar to that of 9,10-anthraquinone, and the cyclic voltammogram of **1** in dry DMF containing $Bu_4NClO_4$ revealed two reversible redox waves at $E_{1/2}$ = −0.71 V (*vs.* SCE), assignable to the redox between **1** and its semiquinone radical, and at −1.43 V, for the redox between the semiquinone radical and hydroanthraquinone dianion. Spectral changes upon electrolysis were measured using a thin-layer cell (*ca*. 0.3 mm thickness) made of transparent indium–tin oxide coated glass (ITO glass) and using the indium film on the glass as the working electrode. The spectral changes for the cathodic reduction of **1** in dry DMF (containing $Bu_4NClO_4$) were not simple because of the simultaneous formation of the semiquinone radical and the hydroanthraquinone dianion. Therefore, Fig. 2 shows the time scanning spectral changes for the reduction of **1** at −1.0 V (*vs.* SCE), where most of **1** could be reduced to semiquinone radical, in the presence of acetic acid (0.03 M) as a proton source. The spectral changes showed a simple decrement of the bands (474 and 333 nm) due to **1** and the appearance of a new band (400 nm) and its increment accompanied by distinct isobestic points. In the presence of the proton source, the semiquinone radical of **1** will be protonated rapidly to give monohydroanthraquinone radical, and successive disproportionation of the radical will form 5,6,7-tri-*tert*-butyl-1,4-hydroanthraquinone **3** and **1**. The product responsible for the new absorption was assigned to **3** based on the fact that the new absorption spectrum was in good agreement with that obtained for **3** chemically synthesized from **1** as follows. A diethyl ether solution of **1** and aq. $Na_2S_2O_4$ were mixed together in an optical cell, and after degassing by freeze-thaw cycles the contents were sonicated. In the absorption spectrum of the

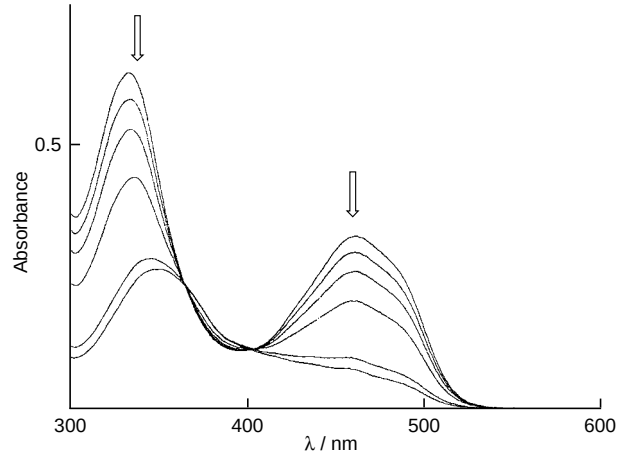

**Fig. 1** Spectral changes upon photolysis of **1** at 460 nm in hexane at room temperature. [**1**] = $5.6 \times 10^{-4}$ M

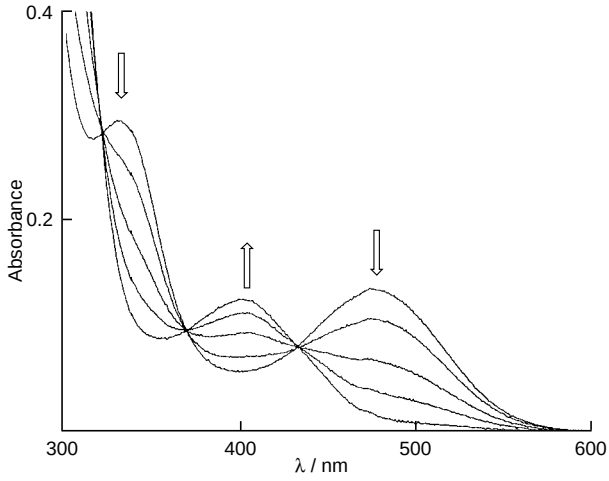

**Fig. 2** Spectral changes upon cathodic reduction of **1** at −1.0 V *vs.* SCE in DMF containing acetic acid (0.03 M) and $Bu_4NClO_4$ (0.1 M)

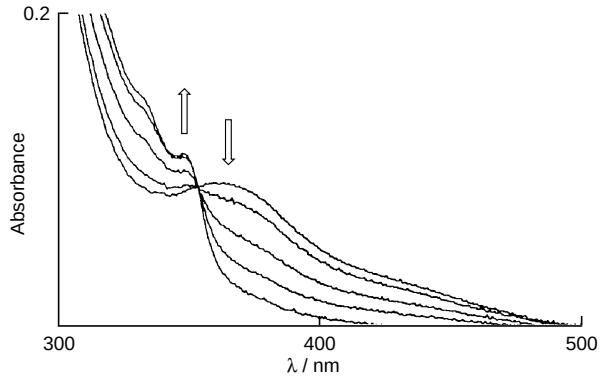

**Fig. 3** Spectral changes upon cathodic reduction of **2** at −1.0 V *vs.* SCE in DMF containing acetic acid (0.03 M) and $Bu_4NClO_4$ (0.1 M)

ethereal layer, the bands due to **1** were not observed and a band at 398 nm appeared. Upon exposure of the ethereal solution to air, the band at 398 nm disappeared and the bands for **1** were recovered completely. $^1$H NMR spectroscopy of the product obtained by $Na_2S_2O_4$ reduction of **1** was consistent with the structure of **3** (*vide infra*).

The electrochemical reaction of **1** was reversible. After cathodic reduction of **1** in the thin-layer cell, the polarity of the electrode was changed and the spectral changes were followed for anodic oxidation at +0.2 V (*vs.* SCE). The band at 400 nm due to **3** decreased with concomitant increases of the bands due to **1** finally giving the complete recovery of the latter.

The electrochemical behaviour of the valene isomer **2** was similar to that of **1**, and its cyclic voltammogram also revealed two reversible redox waves at −0.65 and −1.42 V (*vs.* SCE). Fig. 3 shows the spectral changes that occurred during the cathodic reduction (−1.0 V *vs.* SCE) of **2** in dry DMF containing acetic acid and $Bu_4NClO_4$. The new absorption spectrum was in good agreement with that of the hydronaphthoquinone derivative **4** obtained by $Na_2S_2O_4$ reduction of **2**. The electrochemical reaction was also reversible, and upon anodic oxidation at +0.5 V (*vs.* SCE), **4** disappeared and **2** was recovered completely.

A diethyl ether solution of **3** ($1.06 \times 10^{-4}$ M) was prepared by the method described above. In the spectral changes following the photolysis (436 nm) of the solution (Fig. 4), the band at 398 nm for **3** decreased and new bands at 347 nm and 330 nm appeared and increased. The new absorption spectrum was in good agreement with the spectrum of **4** obtained by $Na_2S_2O_4$ reduction or cathodic reduction of **2**. The reaction was photochemically reversible, and upon photolysis of the photo-

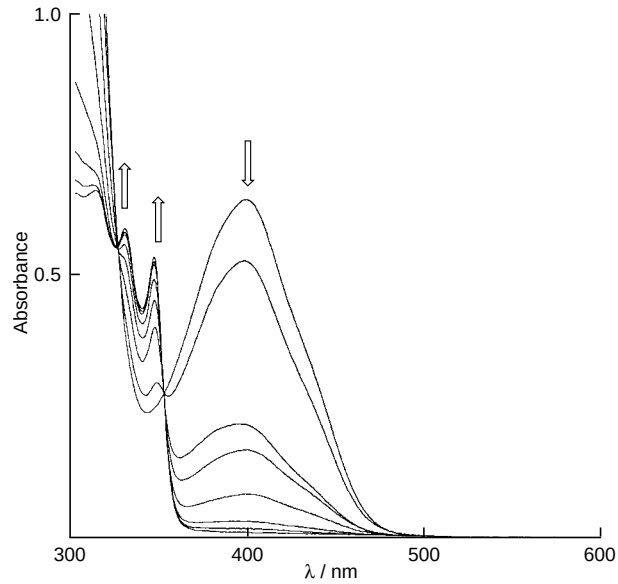

**Fig. 4** Spectral changes upon photolysis of **3** at 436 nm in diethyl ether at room temperature. [**3**] = $1.06 \times 10^{-4}$ M

lysate at 347 nm, the absorption bands for **4** decreased and the bands for **3** were recovered. Spectral changes for both of the forward and the reverse reactions revealed distinct isobestic points. The photochemical interconversion between **3** and **4** was followed also by $^1$H NMR spectroscopy as follows. A solution of **1** in $CDCl_3$ was put in an NMR sample tube and a solution of $Na_2S_2O_4$ in $D_2O$ was added. In the $^1$H NMR spectrum measured after sonication, signals due to **1** disappeared and a set of signals for **3** appeared [δ 8.99 (s, 1 H), 8.32 (s, 1 H), 7.51 (s, 1 H), 6.52 (s, 2 H), 1.76 (s, 9 H), 1.48 (s, 9 H) and 1.37 (s, 9 H)]. After irradiation at 436 nm, the signals for **3** disappeared and a new set of signals for **4** appeared [δ 7.90 (s, 1 H), 7.58 (s, 1 H), 6.50 (ABq, 2 H), 2.36 ( s, 1 H, benzylic H), 1.58 (s, 6 H, two methyl groups of the *tert*-butyl group on benzylic carbon) and 1.22 (s, 21 H, two *tert*-butyl groups and one methyl group); the *tert*-butyl group on the benzylic carbon gave split signals due to restricted rotation]. It was confirmed that the changes in the $^1$H NMR spectra were photochemically reversible.

The present system is considered to be an example of a multimode chemical transducer. All of the four states (**1**, **2**, **3** and **4**) have infinite thermal stability, while in the reported case of phenylazoquinones, the *cis*-phenylazo isomers are kinetically unstable.[2]

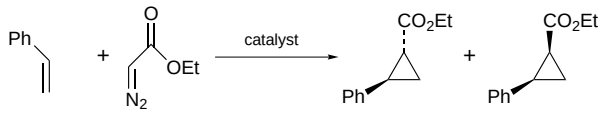
# Cyclopropanation of alkenes with ethyl diazoacetate catalysed by ruthenium porphyrin complexes



**Erwan Galardon, Paul Le Maux and Gérard Simonneaux***

*Laboratoire de Chimie Organométallique et Biologique, associé au CNRS, Université de Rennes 1, 35042 Rennes cedex, France*

**Ruthenium porphyrin complexes are active catalysts for the cyclopropanation of styrene derivatives by ethyl diazoacetate with good to very good diastereoselectivity; moderate enantiomeric excesses (34%) are observed using a chiral porphyrin as catalyst.**

The development of efficient and selective methods for the synthesis of cyclopropanes is of great interest in organic synthesis, in particular because of their role in biological processes.[1] Several years ago, Callot *et al*. reported that rhodium porphyrins catalysed the cyclopropanation of alkenes by ethyl diazoacetate (EDA).[2] Recently, efficient asymmetric cyclopropanation of alkenes with diazoacetates catalysed by bis(oxazolinyl)pyridine ruthenium complexes has been reported by Nishiyama and co-workers.[3,4] Very recently, osmium[5] and iron[6] porphyrins were also found to be active catalysts for the formation of cyclopropanes in good yield. Despite the periodic relationship of ruthenium to iron and osmium, and the syntheses of ethoxycarbonyl carbene complexes of ruthenium 5,10,15,20-tetratolylporphyrin[7] and ruthenium 5,10,15,20-tetramesitylporphyrin,[8] no cyclopropanation reactions were observed using ruthenium porphyrins as catalysts; only the coupling products diethyl maleate and fumarate were found.[8] We present herein the first ruthenium porphyrin-catalysed cyclopropanation of styrene derivatives by ethyl diazoacetate.

The complexes $Ru^{II}$(por)(CO) (por = TPP,† TMP†)[9,10] or $Ru^{VI}$(por)$(O)_2$[10] (por = TMP†), in catalytic amounts, quickly react with ethyl diazoacetate in the presence of an excess of styrene to give quantitatively‡ the corresponding cyclopropyl esters, with a large excess of the *anti* isomer (Scheme 1). The diastereoselectivity (Table 1) is reminiscent of that observed with osmium and iron catalysts and differs from the *syn* selectivity observed with rhodium porphyrins.[2,11] As shown in the data, the porphyrin structure is important since the use of the unencumbered TPP instead of the crowded TMP results in an increase in the *anti* : *syn* ratio of the cyclopropyl esters from 7.9 to 13.1. The cyclopropane formation also exhibits a substrate shape preference that may be useful for selective cyclopropanation of polyalkenes. Only alk-1-enes and 1,1-disubstituted alkenes react efficiently. Thus styrene and α-methylstyrene are cyclopropanated efficiently, whereas with β-methylstyrene and cyclohexene, diethyl maleate and fumarate are formed in very high yield in a ratio of up 30 : 1 under the same conditions.[8] These coupling products are typically produced when the carbene transfer to the alkene is not observed.[8] The catalyst is also sensitive to the electronic nature of the alkene since aromatic alkenes are better substrates, as previously observed with iron or osmium porphyrins.[5,6] For example, only traces of the cyclopropane products are detected when the reaction is carried out with 4-vinylcyclohex-1-ene.

**Scheme 1**

[a] Determined by GC. [b] Diethyl maleate and fumarate.

The reaction of styrene with ethyl diazoacetate in the presence of the dioxoruthenium(VI) picket-fence complex bearing optically active α-methoxy-α-(trifluoromethyl)phenylacetyl residues on both sides of the porphyrin plane (α,β,α,β isomer)[12] (Fig. 1) gave a mixture (*anti* : *syn* = 9 : 1) of optically active cyclopropane derivatives, *e.g*. *anti* and *syn* ethyl 2-phenylcyclopropane-1-carboxylic esters with 14 and 34% enantiomeric excess, respectively.§

We presume that the active intermediate in the ruthenium porphyrin-catalysed reactions is a ruthenium carbene species formed by reaction of ruthenium(II) with ethyl diazoacetate, by analogy to previous work in which it was demonstrated that osmium(II) porphyrin carbenes are catalytically active.[5] Actually, when the reaction is monitored at room temperature, a $Ru^{II}$ carbene complex is detected by $^1$H NMR spectroscopy when Ru(TMP)(CO) is used as the catalyst. As expected,[8] the α-carbon proton appears in the proton spectrum at δ 13.23.¶ The presence of both the carbene ligand and the carbonyl group coordinated to the ruthenium has been confirmed, by IR ($\nu_{CO}$ = 1941 $cm^{-1}$) after isolation of the complex at the end of the reaction, when Ru(TMP)(CO) is used as catalyst. Such a

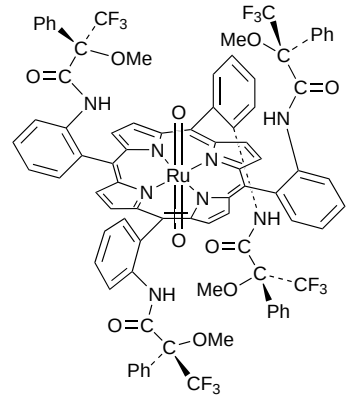

**Fig. 1**

carbene is also observed with ethyl diazoacetate in the presence of the optically active dioxoruthenium(VI) picket-fence complex and a large excess of the alkene, but is not detectable when the porphyrin is the TPP.

In conclusion, the ruthenium porphyrin compounds described here, which are more easily handed than their air-sensitive iron(II) porphyrin analogues, are promising catalysts for cyclopropanation reactions.

† Abbreviations used: TPP = 5,10,15,20-tetraphenylporphyrin dianion; TMP = 5,10,15,20-tetramesitylporphyrin dianion.

‡ Based on ethyl diazoacetate conversion. In a typical experiment, ethyl diazoacetate (1.14 mmol) is slowly added over approximately 4 h to a vigorously stirred solution of the ruthenium catalyst (2.6 μmol) and alkene (1.71 mmol) at room temperature under inert atmosphere. The reaction mixture is then stirred for 1 h and the cyclopropyl ester formation is analysed by GC.

§ Enantiomeric excesses for cyclopropyl esters were determined using the chiral shift reagent tris[3-(heptafluoropropylhydroxymethylene)-(+)-camphorato]europium(III). For the *trans* product, measurement of the optical rotation allowed identification of the absolute configuration as (+)-(1*S*,2*S*).[13]

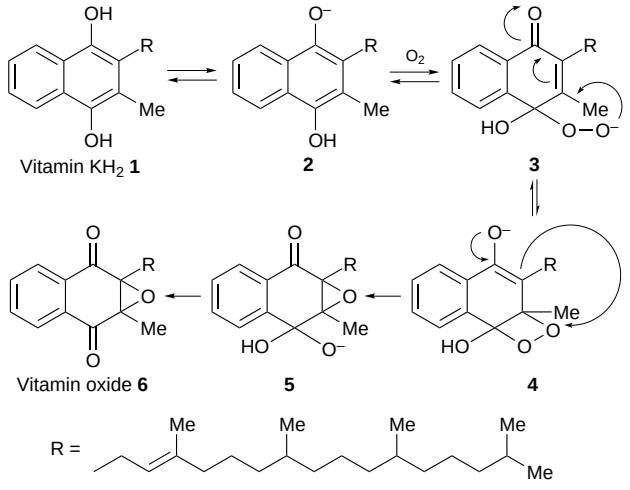
# Mechanism of oxygenation of vitamin K hydroquinone

**Seung Wook Ham* and Ji Sang Yoo**

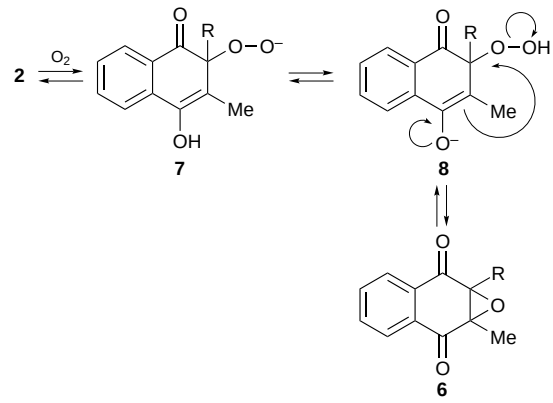
*Department of Chemistry, Chung-Ang University, Seoul 156-760, Korea*

**When the monoanion of vitamin K hydroquinone is treated with $^{18}O_2$ in THF, the product, vitamin K oxide, carries a full atom of $^{18}O$ at the epoxide oxygen and partial incorporation (34%) of a second atom of $^{18}O$ at the carbonyl oxygen, which is most reasonably ascribed to the dioxetane mechanism.**



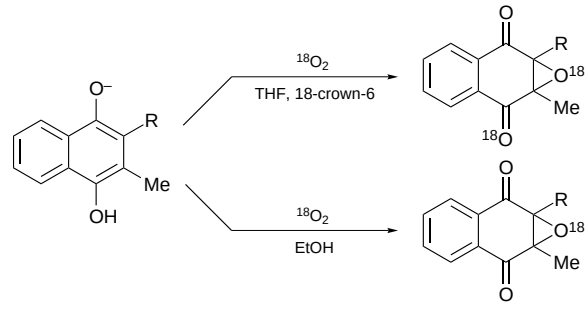
Vitamin K in its hydroquinone form, vitamin $KH_2$, is required as a cofactor for a microsomal enzyme that converts N-terminal glutamates in proteins of the blood clotting cascade to γ-carboxyglutamates.[1] Vitamin $KH_2$ is transformed into vitamin K oxide concurrent with the abstraction of the γ-hydrogen of glutamate, leading to γ-carboxyglutamate.[2] In studies of the mechanism of action of vitamin K, the role of molecular oxygen in the formation of vitamin K oxide was explored.[3,4] Key features of this mechanism are the rearrangement to a strong alkoxide base **5** *via* the dioxetane intermediate **4** (Scheme 1), proposed on the basis of results of a parallel oxygen-16 and oxygen-18 experiment,[3] and the corresponding oxidation of a model system.[4]

The nonenzymic model approach that supports the chemical principle used 2,4-dimethylnaphthol in place of vitamin $KH_2$.[4] However, the most important difference between the model and the vitamin K dependent carboxylase resides in the structure of vitamin K. Vitamin K is a 1,4-dioxygenated naphthalene, whereas the model carries only one oxygen. Since molecular oxygen can add to the 2-position of vitamin $KH_2$ **1** yielding a hydroperoxy anion **7** which might produce vitamin K oxide **6**,[5] it was interesting to compared the *in vivo* oxygenation reaction of vitamin K hydroquinone itself, in the absence of the enzyme.



It is well-established that hydroquinones are unstable in air and rapidly oxidize to yield quinone. Indeed, when a chloroform solution of vitamin K hydroquinone **1** was stirred under an oxygen atmosphere, vitamin K was formed within 30 min. By contrast, when the monoanion of vitamin $KH_2$ **2** was stirred under an oxygen atmosphere, vitamin K oxide **6** was isolated in 88% yield (Scheme 2). These spontaneous oxidations in the chemical model system are clearly important for the mechanism of action of vitamin $KH_2$ in biological systems. Therefore, experiments employing oxygen-18 were next used to examine the involvement of the dioxetane intermediate, as shown in Scheme 1, because 2-hydroperoxide **8** could be differentiated from the dioxetane mechanism by $^{18}O$ labelling experiments.

Typical experimental conditions consisted of stirring a THF solution of a monoanion of vitamin $KH_2$ **2** at room temperature with 18-crown-6 and delivering $^{18}O_2$ from a sealed tube to yield vitamin K oxide **6**.† Examination of the mass spectrum reveals that an atom of $^{18}O$ has been incorporated into the vitamin K oxide **6**, since the molecular ion peak moves from *m/z* 466 to 468. The $^{18}O$ label could, in principle, be located at any of the three oxygen positions, but the mass spectrum is most consistent with location of the $^{18}O$ at the epoxide position. Thus, the *m/z* 423 peak is unchanged when comparing the unlabelled with the labelled spectrum; the $M^+ - 43$ peak at *m/z* 423 arises from cleavage of the epoxide and loss of a MeCO fragment.[3] Moreover, the intensity of the peak at *m/z* 470 was 41% of the parent peak at *m/z* 468, which is much larger than would be expected on the basis of natural abundance $^{13}C$.[6] After correcting for natural abundance $^{13}C$, the presence of 36% of a second atom of $^{18}O$ in the vitamin K oxide from the labelling experiment is indicated, and this is most reasonably ascribed to the dioxetane mechanism (Scheme 3).



In EtOH, the product of oxygenation of vitamin $KH^-$ **2** under $^{18}O_2$ resulted in a shift of the *m/z* 466 peak to 468, with no increase in the intensity of the $M^+ + 4$ peak. The path leading to

**Scheme 1**

**Scheme 2**

**Scheme 3**

the formation of vitamin K oxide in an aprotic solvent could be different from that in protic solvent. In the oxygenation of the vitamin K anion **2** in EtOH, the 2-peroxy anion intermediate **7** might predominate and might be protonated by EtOH, yielding the hydroperoxide **8**. If the phenolic hydroxy group of peroxide **7** is deprotonated by the resulting ethoxide, and with the assistance of a hydrogen bonding of solvent, the hydroperoxide could yield vitamin K oxide.

This solvent-dependent regioselectivity observed in the oxygenation of the vitamin K anion **2** might be rationalized in terms of the stability of the peroxy anion intermediates **3** and **7**. Since it is known that the potassium ion associates with crown ether more strongly than with protic solvents,[7] the peroxy anion intermediate would be naked. The resulting free peroxy anion **7** at the 2-position might experience electronic repulsion by the carbonyl group, whereas the peroxy anion **3** at the 4-position is stabilized by hydrogen bonding with the *gem*-hydroxy group.[8] therefore, the addition of oxygen using THF with 18-crown-6 might be preferred in the 4-position (Fig. 1).

The peroxy anion intermediate in EtOH seems to undergo stabilization by association with the counter cation $K^+$ and partly also by solvation through hydrogen bonding.[7] In this case, the stabilization of the peroxy anion **7** at the 2-position appears to be due to chelation with the carbonyl group of the intermediate.

The biological transformation of vitamin K oxide **6** appears to be shielded from water by the enzyme or membrane environment.[9] Therefore the chemical formation of vitamin K oxide **6** has parallels in the biological formation. However, another possibility for incorporation of $^{18}O$ into vitamin K oxide **6** would involve label exchange between $^{18}O$ labelled hydroxide and the product in THF, even though formation of hydroxide anion might be unfavourable under aprotic conditions. This path cannot be ruled out at present, and the appropriate control reactions remain to be conducted.

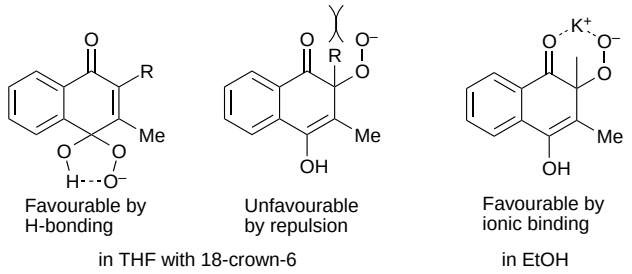


**Fig. 1** Proposed solvent-dependent regioselectivity of peroxide in the oxygenation of the vitamin K hydroquinone monoanion

† Typical experiment: oxygenation of **2** with $^{18}O_2$. A solution of 142.8 mg (0.316 mmol) of vitamin K hydroquinone **1** in 4 ml of dry THF was added to a suspension of 12.6 mg (0.315 mmol) of potassium hydride and 1 ml of dry THF *via* a double tipped needle and stirred for 10 min under an atmosphere of argon at room temperature. 18-Crown-6 (60.0 mg, 0.227 mmol) was then added. $^{18}O_2$ [96% enriched in 18-oxygen (ICON), 100 ml] was added through a break seal. After stirring for 20 min at room temperature, the reaction mixture was quenched with 5 ml of water and extracted with diethyl ether (3 × 10 ml). The combined diethyl ether layers were washed with saturated aqueous potassium chloride, dried over $MgSO_4$ and concentrated to yield 101.8 mg of the crude product as a yellow oil, which was checked by GC–MS (Hewlett-Packard 5890 Series II gas chromatograph and a Hewlett-Packard 5970 mass selective detector).

# Methanol dramatically enhances serine protease activity under anhydrous conditions

**Gillian A. Hutcheon,[a] Marie Claire Parker,[b] Allan James[a] and Barry D. Moore*[a]**

[a] *Department of Pure and Applied Chemistry, University of Strathclyde, Thomas Graham Building, 295 Cathedral Street, Glasgow, UK G1 1XL*

[b] *Edinburgh Centre for Protein Technology, University of Edinburgh, Kings Building, West Mains Road, Edinburgh, UK EH9 3JJ*

**The catalytic activity of rigorously dried lyophilised subtilisin Carlsberg and α-chymotrypsin in anhydrous solvents is enhanced dramatically on addition of dry methanol, while ethanol and propanol produce no effect.**

Enzymes are being increasingly used for catalysis of organic reactions in non-aqueous media. Hence, there is considerable interest in understanding the factors affecting their activity, selectivity, and stability under these conditions.[1] The catalytic activity of lyophilised enzyme powders suspended in organic solvents can often be increased substantially if the protein is hydrated above a critical level.[2] The precise reasons for this are not known but it has been proposed that water acts as a 'molecular lubricant' and enhances the conformational flexibility of the protein.[2] Certain solvents or 'additives' including dimethyl sulfoxide, formamide and ethylene glycol have been reported to increase enzyme activity when added into the organic media along with small amounts of water.[3,4] However, the effects of additives on rigorously dried enzyme preparations, where possible activation by water has been eliminated, have not been well explored. Here we show, for the first time, that methanol is a remarkably efficient promoter of both subtilisin Carlsberg and α-chymotrypsin activity under anhydrous conditions. This effect could be of considerable synthetic utility in enzyme catalysed reactions where the build up of hydrolytic side-products needs to be avoided.

The starting point for this work was a study of subtilisin Carlsberg activity at low hydration levels. Rate comparisons were made between the enzyme catalysed transesterification of acetylphenylalanine ethyl ester (APEE) by propanol or methanol, in hexane, at various known hydration levels.† Hydration was controlled by equilibrating the system with saturated salt solutions of known thermodynamic water activity, $a_w$.[5] Anhydrous conditions were obtained by lyophilisation of the protein followed by repeated dehydration with freshly activated molecular sieves and the use of completely dry solvents.‡ This treatment appears to leave only internally bound water molecules associated with the protein.[6]

As anticipated, under anhydrous conditions the transesterification rate with propanol was low but measurable (see Table 1). Initial hydration of the system to $a_w$ = 0.11 led to an unexpected small drop in catalytic activity but on further hydration to $a_w$ = 0.43 there was a slight increase in enzyme activity as reported previously.[2,7] In sharp contrast, using methanol as the nucleophile, even rigorously dried enzyme exhibited good catalytic activity and higher transesterification rates than with propanol were observed at all hydrations levels, with a 65-fold difference at $a_w$ = 0.43. These remarkable enhancements for methanol compared to propanol were also observed when the ester concentration was varied from 5–15 mM.

Since it was possible the differences arose simply because deacylation was the rate limiting step under these conditions§ a competitive nucleophile experiment was carried out under anhydrous conditions. Fig. 1(*a*) shows the time course of a reaction mixture which initially contained anhydrous subtilisin, APEE and propanol in dry hexane. For the first 50 min very little reaction was observed whereupon 5 μl of dry methanol was added. Immediately rapid formation of both the methyl and propyl esters commenced. A similar effect was seen with another serine protease, α-chymotrypsin, Fig. 1(*b*). The observation of a dramatic increase in the rate of formation of the

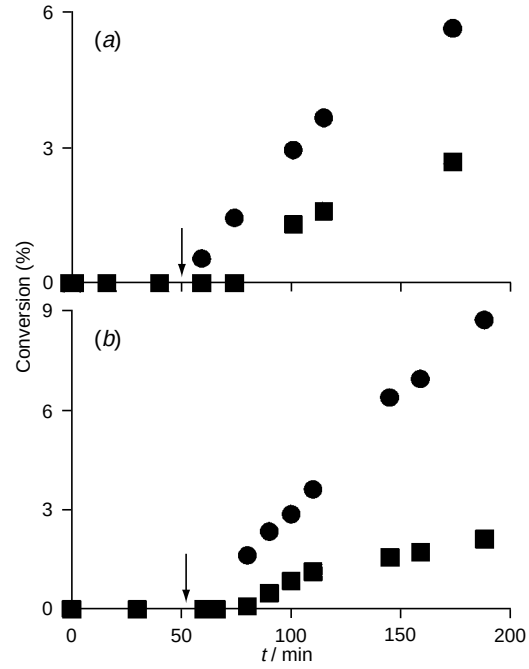

**Fig. 1** Reaction course for the enzyme catalysed transesterification of APEE to the propyl ester (■) and methyl ester (●). The reaction mixture contained 5 mM APEE, 268 mM propanol, 1 mg lyophilised anhydrous enzyme and 1 ml of dry hexane (< 0.005% water). After 50 min (↓) 5 μl of anhydrous methanol, (125 mM) was added. The reaction mixture was shaken at 200 rpm at 20 °C and analysis was by gas chromatography. HPLC analysis of the reaction mixture showed that none of the hydrolysis product, *N*-acetyl-L-phenylalanine, was formed under these conditions. (*a*) Catalysed by subtilisin Carlsberg, (*b*) catalysed by α-chymotrypsin.

propyl ester shows that methanol cannot just be a better nucleophile since then only the rate of methyl ester production would be affected.¶ Rather the results suggest that solvation of the protein by methanol stimulates an increase in the intrinsic catalytic activity of both subtilisin Carlsberg and α-chymotrypsin under anhydrous conditions.‖ Since these serine proteases have very different secondary and tertiary structures similar effects might be expected with other related enzymes.

To eliminate the possibility that trace impurities (*e.g.* drying agent) or changes in particle size were responsible for the activation, a lyophilised powder sample of subtilisin Carlsberg was equilibrated with methanol through the vapour phase in the presence of molecular sieves. Gravimetric measurements showed that this procedure resulted in adsorption of low levels of the solvent onto the protein. Following resuspension in hexane, enzyme activity was assayed using APEE and 0.5 M propanol. Again a transesterification rate enhancement was observed compared to an untreated sample and with no lag period.** However, here the main reaction product was found to be the propyl ester. This suggests that the low levels of methanol adsorbed onto the enzyme were sufficient to activate it but the resultant concentration of methanol in the reaction mixture was not high enough for it to compete as a nucleophile. Importantly equilibration of subtilisin with ethanol or propanol vapour under identical experimental conditions gave absolutely no rate enhancement nor did the addition of ethanol to the reaction mixture. Thus, the effect of methanol is very specific and the activation mechanism cannot be simply ascribed to a hydrogen bonding phenomena.

Further study of the rates in Table 1 reveal an interesting effect when methanol and water were added to the enzyme together. With dry subtilisin and 0.5 M methanol the transesterification rate is 24.5 nmol $min^{-1}$ $mg^{-1}$ while with enzyme equilibrated to $a_w$ = 0.43 and using 0.5 M propanol the rate is 1.6 nmol $min^{-1}$ $mg^{-1}$. If we now compare the rate obtained at $a_w$ = 0.43 and 0.5 M methanol, 102.2 nmol $min^{-1}$ $mg^{-1}$, we see that it is closer to the product than the sum of the individual rates. This observation is not consistent with a single activation mechanism since then the contributions would be expected to be approximately additive. Instead it points to a cooperative effect whereby methanol and water activate the enzyme *via* two or more different processes. As a consequence the ubiquitous 'molecular lubrication model' will need to be revised and we are currently working on this problem.

Finally we sought to show that methanol could activate a serine protease without simultaneously acting as a substrate. Hence, a series of active site titrations were carried out on subtilisin in hexane using the irreversible inhibitor PMSF. Anhydrous enzyme was equilibrated for 3 h in hexane in the presence or absence of either methanol or propanol and with and without PMSF.†† Since in the inhibition process, no deacylation occurs, methanol will not be directly involved in the reaction scheme. Following equilibration the enzyme samples were repeatedly resuspended in pure dry hexane (which removed the PMSF if present) and then dried. The resultant enzymic activities were measured by monitoring transesterification of APEE with methanol in hexane‡‡ and are shown in Table 2. It can be seen that enzyme equilibrated with PMSF in either hexane or hexane–propanol gave very similar activities to the control samples showing only a small percentage of active sites had been titrated. This is consistent with the low activity of the enzyme under these condition (see Table 1). In comparison the presence of methanol during the PMSF equilibration resulted in significant inhibition of the enzyme preparation.§§ This is exactly what would be expected from the transesterification measurements and provides conclusive evidence that methanol activates anhydrous serine proteases *via* a solvation process.

**Table 2** Effect of PMSF titration on subtilisin Carlsberg activity in hexane

| | Initial rate[a]/ nmol $min^{-1}$ $mg^{-1}$ | | |
|---|---|---|---|
| Alcohol | No PMSF[b] | PMSF[b] | Inhibition (%) |
| None | 22.5 | 21.3 | 5.4 |
| Propanol | 11.5 | 10.5 | 13 |
| Methanol | 42 | 4.5 | 89 |

[a] Reaction conditions: 10 mM APEE, 0.5 M methanol and 1 mg $ml^{-1}$ enzyme in hexane. [b] The enzyme was shaken with or without 10 mM PMSF and 0.5 M alcohol in hexane for 3 h, washed with hexane to remove unbound PMSF and dried over molecular sieves prior to rate analysis.

## Footnotes

* E-mail: b.d.moore@strath.ac.uk

† The variation in amount of enzyme bound water as a function of water activity in nonpolar solvents has been measured previously (ref. 8).

‡ Residual water levels in the dried solvents were measured *via* Karl–Fischer titration and found to be hexane < 0.005%, methanol 0.009%, propanol 0.01%.

§ The nucleophilic specificity of methanol relative to propanol has been shown to be 4.61 for this subtilisin catalysed reaction in hexane at $a_w$ = 0.59.[9]

¶ The argument that the methyl ester product may be more reactive is not valid as the acyl intermediate will be identical whichever ester reacts with the enzyme and hence back reaction of the methyl ester cannot lead to an overall increase in rate.

‖ $^2H$ NMR difference measurements in hexane showed 50 deuterated methanol molecules bound per subtilisin molecule at a methanol concentration of 3 mM.

** Transesterification rates were; untreated enzyme, 1 nmol $min^{-1}$ $mg^{-1}$, enzyme equilibrated with propanol, 1 nmol $min^{-1}$ $mg^{-1}$, enzyme equilibrated with methanol, 6.8 nmol $min^{-1}$ $mg^{-1}$.

†† PMSF is inert towards reaction with dry alcohols over the period employed (ref. 10).

‡‡ The exact conditions used for the assay will not affect the findings since it is the remaining activity following titration which is being measured. The assay used was convenient because of the known high activity of dry subtilisin in the presence of methanol.

§§ The increased activity of the control sample in the presence of methanol is reproducible and under study.

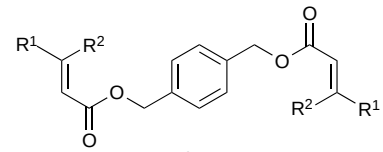
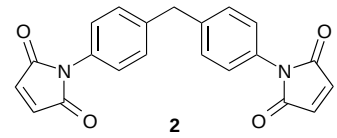
# Asymmetric Diels–Alder polymerization using a chirally modified Lewis acid catalyst



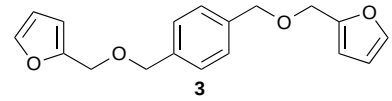
**Shinichi Itsuno,* Shoichi Tada and Koichi Ito**

*Department of Materials Science, Toyohashi University of Technology, Tempaku-cho, Toyohashi 441, Japan*

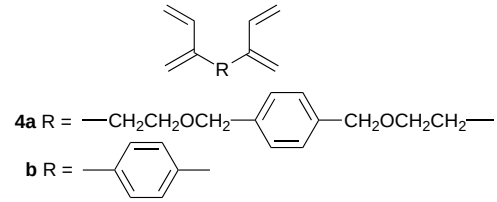


**The asymmetric Diels–Alder reaction between bisdiene and bisdienophile monomers occurs in the presence of a chirally modified Lewis acid catalyst to give optically active polymers.**

Synthesis of optically active polymers has attracted a great deal of interest and a large number of papers on asymmetric polymerization have been published.[1] An important contribution in this area is the preparation of such polymers having macromolecular asymmetry that originates from the helical structure; these include the polymerization of methacrylates,[2] chloral,[3] isocyanides[4–6] and isocyanates.[7] On the other hand, in the recent remarkable development of catalytic asymmetric synthesis, many useful reactions have been proposed for C–C bond formation with induction of chirality. However, there are only a few reports on asymmetric polymerization based on such enantioselective C–C bond formations using chiral catalysts. For example, some successful asymmetric alternating copolymerizations of α-olefins with carbon monoxide have been reported only recently.[8,9] Of the excellent asymmetric transformations developed, the enantioselective Diels–Alder reaction is one of the most important C–C bond formation reactions to create a unique chiral cyclic structure. Indeed, recent extensive studies on designing chiral Lewis acids based on boron, aluminium and titanium led to fruitful results in the control of the absolute stereochemistry of various pericyclic reactions, particularly Diels–Alder reactions producing various enantiopure cyclic adducts, key starting materials for synthesis of complex optically active compounds.[10] This impressive stereoselectivity of chiral Lewis acid catalysts in Diels–Alder reactions presents unprecedented opportunities for the molecular design of polymers that are difficult to prepare with other polymerization methods. Asymmetric, Lewis acid catalysed, Diels–Alder polymerization should provide a novel strategy for the synthesis of optically active polymers whose chirality derives from configurational main-chain stereochemistry. Although polymer synthesis *via* repetitive Diels–Alder reactions is well known for the preparation of thermostable polyimides and conjugated polymers with ladder structures,[11–15] to the best of our knowledge, a chiral polymer has not been synthesized by asymmetric Diels–Alder polymerization. Here we report the asymmetric Diels–Alder polymerization between bisdiene and bisdienophile monomers in the presence of a chirally modified Lewis acid catalyst.



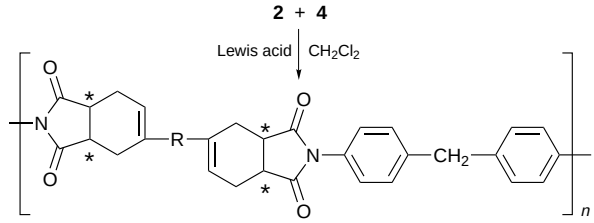
We designed several bifunctional monomers. α,β-Unsaturated esters are well known to be important dienophiles in Diels–Alder reactions. Bisdienophile monomers **1** were thus easily prepared from α,α′-dichloro-*p*-xylene and the appropriate carboxylic acids such as acrylic acid **1a**, monomethyl fumarate **1b** and monomethyl maleate **1c**. *N*-Phenylmaleimide is another reactive dienophile. Useful bisdienophile, 1,1′-(methylenedi-4,1-phenylene)bismaleimide **2** is commercially available, and has often been used as a Diels–Alder monomer.[16,17] Since furyl and butadienyl groups are well known in Diels–Alder chemistry, we designed bisdiene monomers having these structures. Bisdiene **3** and **4a** were prepared from α,α′-dichloro-*p*-xylene and furfuryl alcohol and 3-methylenepent-4-enol,† respectively. The monomer **4b** was also easily prepared by Ni- catalysed Grignard coupling[18] of the bis-Grignard reagent from 1,4-dibromobenzene with chloroprene. Monomer **4a** contains a flexible methylene chain, compared to the relatively rigid structure available in **4b**, in which the butadienyl group links directly to the benzene ring.



**1a** $R^1 = R^2 = H$
**b** $R^1 = CO_2Me$, $R^2 = H$
**c** $R^1 = H$, $R^2 = CO_2Me$

**2**

**3**



**4a** R = $-CH_2CH_2OCH_2-C_6H_4-CH_2OCH_2CH_2-$
**b** R = $-C_6H_4-$

First, we tried to polymerize the bisdienophile **1** with bisdiene monomers. However, we found that the reactivity of **1** is not sufficient to obtain chiral polymers in the presence of Lewis acid catalyst at room temperature. On the other hand, although no reaction between bismaleimide **2** and bisdiene **3** occurred at room temperature in the absence of catalyst, added diethylaluminium chloride ($Et_2AlCl$) as Lewis acid interacted with carbonyl oxygen of **2** and the rate of the reaction with **3** was enhanced considerably to give the Diels–Alder polymer smoothly with high molecular weight (Table 1, run 1). Since enantioselective Diels–Alder reactions have been extensively studied by using chiral metal complexes,[10,19,20] and high enantioselectivities were obtained by using chiral aluminium chloride generated *in situ* from $Me_3Al$ or $Et_2AlCl$ with chiral diols[21,22] and bis(sulfonamide),[23] we first chose chiral aluminum complex **6** as a catalyst for the asymmetric Diels–Alder polymerization of these monomers. The obtained polymer showed optical activity as shown in Table 1 (run 2). The butadienyl group of **4** also reacted with **2** in the presence of a chiral Lewis acid catalyst to afford optically active polymers in quantitative yield (Scheme 1). Asymmetric polymerization of **4a** and **2** with a chiral Lewis acid gave optically active polymer **5a** having somewhat lower molecular weight. The higher molar optical rotation ($[\Phi]_D$ +94) for the polymer from **4a** was

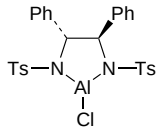
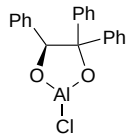


**Scheme 1**



attained when the catalyst **8** was used (Table 1, run 8). Further, use of sterically more rigid bisdiene monomer **4b** having reactive phenylbutadiene units has proved to exhibit excellent polymerization behavior. The corresponding chiral polymers **5b** were obtained with relatively higher molar optical rotations up to $[\Phi]_{435}$ +578 (Table 1, run 4) by using (*R*)-1,1′-binaphth-2-ol derived Lewis acid catalyst **6**. This is the first example of synthesis of the chiral polymer having a high optical rotation value using asymmetric Diels–Alder polymerization.‡

**6**

**7**

**8**

Another feature of this polymerization is that optically active prepolymers with reactive end groups accessible for further reactions can be readily obtained. Nonstoichiometric Diels–Alder polymerization with a slight excess of one monomer should provide the possibility to synthesize such polymers. For example, when a small excess of monomer **2** was polymerized with **3**, a polymer having reactive maleic double bond end groups was obtained, which acts as a good Michael acceptor for further modification of the chiral polymer.

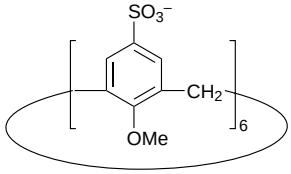
# Solid-state and solution complexation of cobalt(III) sepulchrate by a water-soluble calix[6]arene host

**René Castro,*[a] Luis A. Godínez,[a] Cecil M. Criss,[a] Simon G. Bott[b] and Angel E. Kaifer[a]**

[a] *The Department of Chemistry, University of Miami, Coral Gables, FL 33124-0431, USA*
[b] *The Department of Chemistry, University of North Texas, Denton, TX 76203, USA*

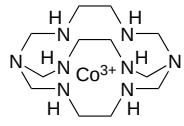
**A calix[6]arene hexasulfonate host forms a stable 1:1 complex with cobalt(III) sepulchrate in aqueous media while a 2:1 guest:host stoichiometry is observed in the solid state.**

Calixarenes are versatile hosts for inclusion complexation due to their flexible cavities, availability in various sizes, and rugged skeletons amenable to diverse functionalization.[1] Various calixarene complexes involving metal ions[2] and organic molecules[3] have been reported. We have also recently reported on ferrocene and viologen complexes involving calixarene hosts.[4]



In 1977 Sargeson and coworkers reported the facile preparation of the caged metal-ion complex cobalt(III) sepulchrate ($\mathbf{2}^{3+}$).[5a] The unusual stabilization of certain metal-ion oxidation states as well as other structural and electronic properties exhibited by this and related complexes prompted numerous investigations.[5] Several prominent examples are the incorporation of sepulchrate complexes in photochemical water-splitting systems,[6a–c] the attachment of sepulchrates to protein backbones to study electron-transfer reactions,[6d] and the recent incorporation of sepulchrate in an electrochemical sensor for $H_2$ and $H_2S$.[6e] The literature also contains several reports of ion-pairing interactions involving sepulchrates and relatively simple anions, but the corresponding association constants are rather low (*e.g.* $K$ = 100 dm$^3$ mol$^{-1}$ for $SO_4^{2-}$ at $I$ = 0.01).[7] Here we report on the complexation of cobalt sepulchrate by sulfonated calix[6]arene host $\mathbf{1}^{6-}$.† While second-sphere coordination of metal-ion complexes is a well known phenomenon,[8] to the best of our knowledge, this is the first report on the complexation of metal-ion sepulchrates.

The strong interaction between $\mathbf{1}^{6-}$ and $\mathbf{2}^{3+}$ was immediately apparent upon preparing a dilute solution of the two compounds in $D_2O$ for NMR analysis. A precipitate appeared which was assumed to be a complex since both compounds are extremely water soluble. Elemental analysis of the dried precipitate revealed a 2:1 stoichiometry ($\mathbf{2}^{3+}:\mathbf{1}^{6-}$) with no counter ions. This ratio makes the complex electrically neutral, thus explaining its low solubility in water. Since the interaction seemed to be largely driven by electrostatics, further studies were conducted in aqueous 0.2 M NaCl in order to be able to use larger concentrations of the compounds without precipitation. A $^1$H NMR spectroscopic binding study performed in $D_2O$ (0.2 M NaCl) gave a binding constant of 1 600 dm$^3$ mol$^{-1}$. This is one of the stronger binding constants reported for a calixarene complex, the strongest ones being around $10^4$ dm$^3$ mol$^{-1}$,[3] and the value would surely be much higher in pure water where there is no electrolyte to shield the charges from each other. The NMR chemical shift data perfectly fit a 1:1 binding model and, therefore, the interaction in high ionic strength media seems to be bimolecular. The direction (to higher field) and magnitude of the complexation induced shifts on the sepulchrate proton resonances ($\Delta\delta_{comp}$ −0.45 ppm) both suggest that the sepulchrate is at least partially included by the anionic calixarene host.



Solution flow calorimetry (in 0.2 M NaCl) was used to corroborate the NMR binding results and to gain insight into the thermodynamic parameters involved.‡ The resulting calorimetric data gave values of −1.0 kcal mol$^{-1}$ (1 cal = 4.184 J) for $\Delta H°$ and 3.4 kcal mol$^{-1}$ for $T\Delta S°$ at 298 K. This translates into a $\Delta G°$ of −4.4 kcal mol$^{-1}$ or $K$ = 1 770 dm$^3$ mol$^{-1}$ (again the data perfectly fit a 1:1 complex stoichiometry). Not only is this in excellent agreement with our NMR data, but it points to a large entropic driving force for complexation. Even though there is a large favourable enthalpic change in bringing two such highly charged species together, this is cancelled by the unfavourable enthalpy associated with unsheathing them from their solvation spheres. The return of these water molecules to the bulk, however, carried with it a substantially favourable and uncompensated entropic change which drives the complexation process.

Crystals suitable for X-ray crystallographic analysis grew from the flow calorimetry effluent solution that was left standing for a few weeks. The unit cell consists of four sepulchrate and two calixarene units along with several water molecules but no counter ions (see Fig. 1).§ This confirms the electroneutral termolecular stoichiometry of the complex in the solid state suggested by the elemental analysis. Interestingly, the calixarene molecules exhibit a configuration similar to that reported for the solid state structure of the pure unmethylated calixarene analogue even though the intramolecular hydrogen bonds involving the partially deprotonated phenolic groups, which are detected in the latter,[2b] are not possible in $\mathbf{1}^{6-}$. To our knowledge, this is the first reported crystal structure for calixarene $\mathbf{1}^{6-}$.

The crystal structure shows the calixarene to be in a rather disorganized conformation with four of the sulfonate groups pointing outwards from the central cavity, one pointing up and the other down. The closest atomic distances between the two ionic components are between the sepulchrate's secondary amine protons and the sulfonate oxygen atoms (dotted lines) on the calixarene. Since hydrogen bonding and electrostatic interactions would be much stronger with the sulfonate groups than with the methoxy groups, these, along with the lack of inclusion complexation, seem to be the main organizing features dominating the structural organization of the solid state lattice. Indeed, the lattice seems to be a net of these ionic/hydrogen bonds with each calixarene bonded to two in-plane sepulchrates through single hydrogen bonds and to one sepulchrate above or below through a bifurcated hydrogen bond. No inclusion complexation is apparent from the crystal structure suggesting the interaction to be mainly ionic in nature. While this does not rule out the possibility of inclusion complexation in solution, it poses interesting questions about

$\mathbf{1}^{6-}$

$\mathbf{2}^{3+}$

the nature of the stable 1 : 1 complex detected in 0.2 M NaCl. The 2 : 1 complex stoichiometry could become prevalent in low ionic strength media, at high concentration, or in a crystal lattice due to packing forces, thus explaining our solid-state data.

The role of the ionic strength of the solvent in mitigating complexation was explored by titrating a 2 : 1 mixture of $\mathbf{1}^{6-}$ and $\mathbf{2}^{3+}$ (0.33 mM $\mathbf{2}^{3+}$, 0.05 M NaCl) in an NMR tube with a 5 M NaCl solution containing the same 2 : 1 mixture of the two compounds. Fig. 2 shows the chemical shift response of the sepulchrate proton resonances as the ionic strength is changed. That the sepulchrate is totally shielded from the calixarene at high NaCl concentrations is shown by the fact that the sepulchrate's proton resonances reach the same chemical shift that they exhibit in the absence of calixarene, thus further proving that its interaction with $\mathbf{1}^{6-}$ is driven by electrostatic forces.

# X-Ray crystallographic structure of $Ga_8(pz)_{12}O_4Cl_4{\cdot}2thf$: a novel gallium pyrazololate complex with a $Ga_4O_4$ core

**Mario V. Capparelli,[a] Paul Hodge,[b] and Brian Piggott*[b]**

[a] *Centro De Quimica, Instituto Venezolano De Investigaciones Cientificas (IVIC), Apartado 21827, Caracas 1020.A, Venezuela*
[b] *Division of Chemistry, University of Hertfordshire, College Lane, Hatfield, Hertfordshire, UK AL10 9AB*

**The reaction of $Na[MeGa(pz)_3]$ with $GaCl_3$ leads to the formation of the novel cubane $Ga_8(pz)_{12}O_4Cl_4{\cdot}2thf$ 1, and not the expected product $[\{MeGa(pz)_3\}_2Ga][GaCl_4]$; the ease with which 1 forms is illustrated by its formation in a subsequent reaction of $Na[MeGa(pz)_3]$ with $GaCl_3$.**

There has been a resurgence of interest in compounds of main-group metals with a heterocubane core.[1–6] The recent work on gallium–group 16 cubanes describes the synthesis and structure of compounds with $Ga_4S_4$, $Ga_4Se_4$ and $Ga_4Te_4$ cores.[7]

However, prior to this communication there are no reported examples of compounds with a $Ga_4O_4$ cubane core. We herein describe the synthesis (albeit serendipitous) and X-ray crystallographic structure of such a compound, namely $Ga_8(pz)_{12}O_4Cl_4{\cdot}2thf$.

In previous publications we drew attention to two significant features of some trispyrazolyl derivatives of group 13 [specifically $HB(3\text{-}Bu^tPz)_3^-$ and $HB(3\text{-}PhPz)_3^-$], namely their stabilisation of low oxidation states and their redox properties with main-group metals.[8,9] We now identify a third significant feature of a member of this class of ligand [specifically $MeGa(pz)_3^-$], *viz*. heterocubane formation.

In an attempt to synthesise a gallium analogue of $[\{MeGa(pz)_3\}_2In][InI_4]$,[10] *i.e*. $[\{MeGa(pz)_3\}_2Ga][GaCl_4]$ **2**, we reacted $Na[MeGa(pz)_3]$ with $GaCl_3$ in dry thf under an atmosphere of argon, filtered the precipitated NaCl and left the filtrate to crystallise at −10 °C. After several months crystals of **1** formed which were subjected to elemental, mass spectral, $^{71}Ga$, $^1H$ and $^{13}C$ NMR analysis.† An X-ray crystal structure determination of **1** was also undertaken. The results are shown in Fig. 1(*a*) and (*b*) with selected bond lengths and angles given in Table 1.‡ The structure is based on a distorted $Ga_4O_4$ cube. Coordinated to and above each cube oxygen is a Ga atom, the centres of which define a tetrahedron. In addition, each of these Ga atoms is coordinated to three pyrazole rings and a chloride such that the five-coordinate Ga, $[OGa(pz)_3Cl]$, is trigonal bipyramidal *TBPY*. The three pyrazole rings of each *TBPY* Ga coordinate

[a] Bond lengths and angles are weighted averages, $x = \Sigma\ \sigma_i^{-2}x_i/\Sigma\sigma_i^{-2}$, where $\sigma_i$ are the e.s.ds from least-squares refinement; errors (within parentheses) are $s = (\Sigma\ \sigma_i^{-2})^{-1/2}$. Values marked with an asterisk are averages of four values; all other values are averages of 12 values. [b] There are two different types of *cis*-O–Ga(c)–N angles, depending if the O and N atoms belong to the same (83.44°) or to different (104.78°) five-membered chelate rings O–Ga(e)–N–N–Ga(c).

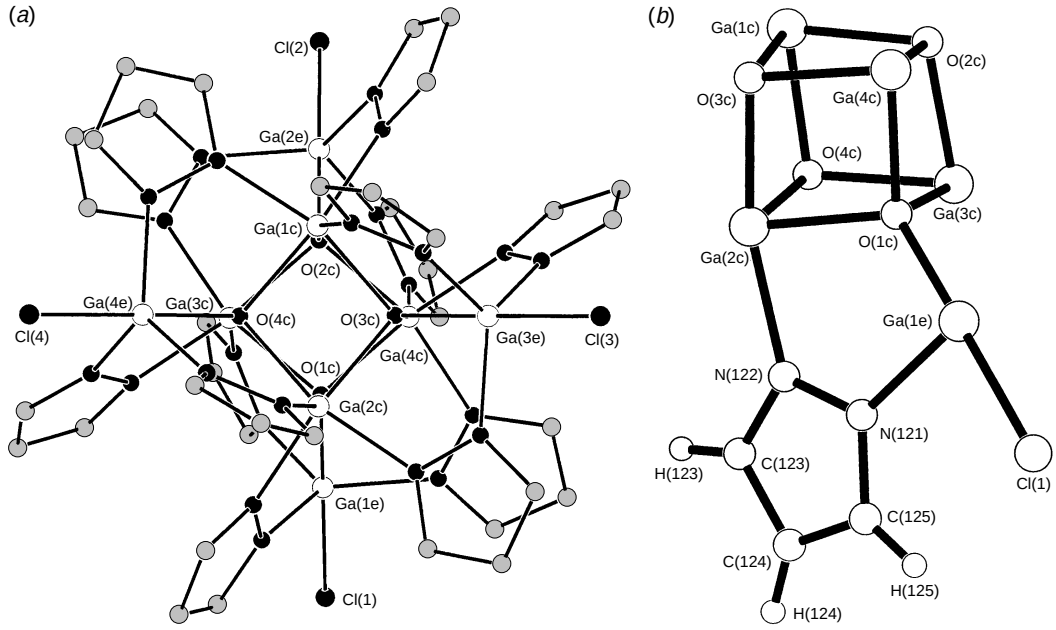

**Fig. 1** (*a*) Structure of compound **1** and (*b*) with some of the 'outer atoms' omitted to show the $Ga_4O_4$ core

through their second nitrogen to the three Ga atoms of the cube that are edge connected to the same oxygen, thus making each cube Ga six-coordinate (3N,3O).

The formation of this compound raises problems, *e.g*. what is the source of the oxygen atoms? A possible solution is that on prolonged standing at low temperature traces of air or water, or both, entered the system resulting in oxygen incorporation. Therefore, to investigate this problem, a second attempt was made to synthesise **2** (the assumption being that this, or a similar gallium complex, is the precursor of **1**) in order to study its controlled hydrolysis. Elemental, mass spectral, $^{71}$Ga, $^{1}$H and $^{13}$C NMR analyses of the small block-like single crystals that formed,† are very similar to those of **1**. These results indicated that this sample and **1** are very probably identical. This was confirmed by an X-ray crystallographic structure determination.

## Footnotes

† *Synthesis*: all manipulations were performed under argon using standard Schlenk techniques and all solvents dried prior to use.

**1** *method A*: to a Schlenk tube charged with $GaCl_3$ (0.04 g 2.27 mmol) in 20 cm$^3$ of thf was added a solution of Na[MeGa(pz)$_3$] (0.52 g 1.68 mmol) in 15 cm$^3$ of thf. An immediate turbidity occurred and the resulting solution stirred for 3 days. The solution was filtered and stored at −30 °C for one week. Attempts were made to filter the large crystals that formed but these redissolved on slight warming. A further 20 cm$^3$ of thf was added to the solution which was then stored at −30 °C for about six months. After this time the small block-like clear crystals that had formed were filtered. These crystals, although twinned, were used for the X-ray crystallographic structure determination. Yield 0.14 g (17%).

*Method B*: Na[MeGa(pz)$_3$] (2.28 g, 7.38 mmol) in 60 cm$^3$ thf was added to a Schlenk tube charged with freshly distilled $GaCl_3$ (1.30 g, 7.38 mmol). The resulting white slurry was stirred for three days after which time the thf was removed under vacuum. 60 cm$^3$ of dichloromethane was added to the resulting white mass, the slurry stirred and then filtered. The filtrate was evaporated to dryness. Dissolution of this in 60 cm$^3$ of MeCN, evaporation under vacuum to about 30 cm$^3$ and storing for one week at −30 °C produced small block-like single crystals of X-ray quality. Yield 1.92 g (61%). $^{1}$H NMR [250 MHz, $(CD_3)_2SO$] δ 8.29 (d, 12 H, Ar H), 6.21 (t, 12 H, Ar H), 5.72 (d, 12 H, Ar H), 3.40 (8 H, thf), 1.28 (8 H, thf). $^{71}$Ga NMR [250 MHz, $(CD_3)_2SO$] (dissolution only achieved with warming and sonication) δ 250.5 (ω 46 Hz), 10.7 (ω 912 Hz). IR (KBr) ν/cm$^{-1}$ 2094, 2871, 1499, 1425, 1381, 1295, 1186, 1163, 1059, 973, 769, 620, 535, 342, 308. MS (FAB) 1570 $(M + H)^+$ < 1%.

‡ *Crystal data* for **1**: $C_{44}H_{52}Cl_4Ga_8N_{24}O_6$, $M$ = 1712.62, triclinic, space group $P\bar{1}$ (no. 2), $a$ = 12.494(4), $b$ = 21.415(4), $c$ = 12.349(4) Å, α = 91.90(2), β = 108.74(3), γ = 90.21(2)°, $U$ = 3126(1) Å$^3$, $Z$ = 2, $D_c$ = 1.819 Mg m$^{-3}$, $F$(000) = 1696, λ = 0.710 69 Å, $T$ = 296 K, μ(Mo-Kα) = 36.23 cm$^{-1}$. Absorption correction with DIFABS. Data were collected on a Rigaku AF7TS diffractometer. Of a total of 6162 collected reflections 5802 were unique. The structure was solved by direct methods. After refining all atoms in the molecule, a difference Fourier synthesis showed a large number of peaks of residual electron density located in empty regions of the unit cell, out of the range of bonding distances of the molecule, which were attributed to disordered solvent (thf) molecules. Two $C_5$ rings could be modelled, each one disordered over two positions, with total occupancies of 0.87 and 0.82. These C atoms were assigned fixed occupancies, fixed coordinates and refined isotropic displacement parameters. In the final difference Fourier synthesis the ten largest peaks (0.34–0.96 e Å$^{-3}$) were located in the vicinity of the $C_5$ ring atoms. Refinement was by full-matrix least squares on $F$, final $R$ indices [$I > 2\sigma(I)$] $R$ = 0.0309, $R_w$ = 0.0381. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/423.

# Solid-state NMR and diffraction studies of *p-tert*-butylcalix[4]arene·nitrobenzene·xenon†

**Eric B. Brouwer,[a,b] Gary D. Enright[a] and John A. Ripmeester*[a,b]**

[a] *Steacie Institute for Molecular Science, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0R6*
[b] *Ottawa-Carleton Chemistry Institute, Department of Chemistry, Carleton University, 1125 Colonel By Drive, Ottawa, Ontario, Canada K1S 5B6*

**Xenon is enclathrated in the *p-tert*-butylcalix[4]arene cavity and behaves both as a guest and a cavity probe; $^{129}$Xe NMR and X-ray diffraction data show Xe to occupy two cavity sites defined by static disordered host *tert*-butyl groups.**

The *p-tert*-butylcalix[4]arene (*t*-BC) cavity (interatomic distance *d ca.* 10 Å at the upper rim, *d ca.* 3.8 Å at the lower rim: with a depth of *ca.* 4 Å) is a micropore‡ that to date, has not been examined by any of the common solid-state void space characterization techniques.[1] $^{129}$Xe NMR spectroscopy is one such technique that is particularly sensitive to micropore geometry and size.[2]

We have previously reported *t*-BC compounds with aliphatic guests prepared by vapour diffusion of the guest into a saturated solution of *t*-BC in nitrobenzene.[3] In a similar fashion (in which Xe replaces the aliphatic guest), *t*-BC·$C_6H_5NO_2$·Xe **1**, is prepared.§ This first example of a *t*-BC·gas clathrate[4] is characterized by both single-crystal X-ray crystallography (XRD) as well as $^{129}$Xe NMR spectroscopy using a complementary approach. Importantly, for the first time, $^{129}$Xe NMR spectral features are related to specific single-crystal XRD structural aspects.

The XRD structure of **1** (Fig. 1)¶ confirms that the host geometry is identical to that of *t*-BC·$C_6H_5NO_2$ **2**.[5] In **1**, 17% of the cavities are occupied by Xe, with the remainder occupied by nitrobenzene. The off-axis orientation of the nitrobenzene guest is similar in the two structures. Whereas substitution of nitrobenzene by Xe does not influence the position of the disordered host *tert*-butylphenol groups (two of the four groups disordered), it does change the ratio of disordering in *tert*-butylphenol group *C* to 0.66 : 0.34 from 0.79 : 0.21 (Fig. 1). If the relationship between nitrobenzene content and the ratio of group *C* *tert*-butylphenol disorder present in **2** is constant, the change in disordering in **1** is consistent with Xe solely occupying a cavity defined by the majority disordered position in group *C*.

Xe sits at the centre of the cavity, 4.33 Å from the basal plane defined by the four phenolic oxygens. Xe shows no protrusion from the cavity and is in fact, located deep in the cavity relative to other *t*-BC·guest species. The closest Xe···host contacts are to the lower three carbons of each *p-tert*-butylphenol unit [C(1),C(2),C(6)], with an average distance of 4.13 Å from these carbons to Xe; these distances are slightly greater than the sum of the van der Waals radii (4.0 Å). The closest approach of a *t*-BC carbon to the Xe along the direction perpendicular to the capping *t*-BC bilayer is 5.4 Å.

The two lines ($\delta_{iso}$ 59, $I$ = 0.6, site I; $\delta_{iso}$ 64, $I$ = 0.4, site II) in the $^{129}$Xe CP MAS NMR spectrum [Fig. 2(*a*)] indicate that Xe samples two inequivalent sites which possess slightly different Xe occupancies and void space volumes, as indicated by the intensity and $\Delta_{iso}$ values respectively.

The components of the chemical shift anisotropy (CSA) tensors are obtained for the two sites from the static $^{129}$Xe CP NMR spectrum [Fig. 2(*b*)], and reflect both the chemical environment and symmetry of the two cavity sites. The spectrum was fitted [Fig. 2(*c*)][6] using a two-site model employing the $^{129}$Xe NMR $\delta_{iso}$ values from the MAS spectrum (site I: $\delta_{iso}$ 59; $\Delta\delta$ = 27 ppm; $\delta_{11}$ 49; $\delta_{22}$ 54; $\delta_{33}$ 76; site II: $\delta_{iso}$ 64, $\Delta\delta$ = 19 ppm, $\delta_{11}$ 56, $\delta_{22}$ 60, $\delta_{33}$ 75).‖

Both Xe powder patterns are characterized by somewhat asymmetric CSA tensors ($\eta$ = 0.3), and accurately reflect the

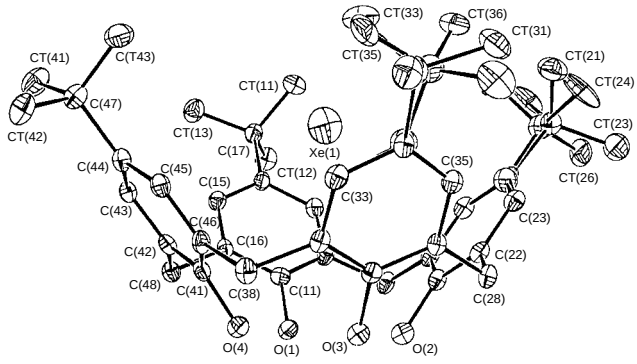

**Fig. 1** ORTEP of **1** showing only the Xe guest; atoms shown in 30% thermal ellipsoids. Hydrogen atoms removed for clarity.

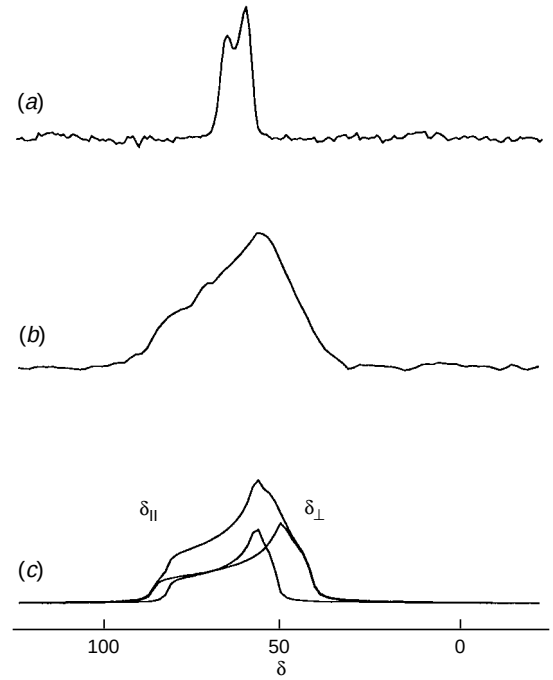

**Fig. 2** 49.8 MHz $^{129}$Xe CP NMR spectra of **1**: (*a*) with MAS, 1219 transients; recycle time: 2 s; TD = 512; 20 Hz line broadening; $\nu$ = 2.65 kHz; (*b*) static 2080 transients; recycle time: 3 s; TD = 256; (*c*) fitted spectra. Both experimental spectra were collected on a Bruker CXP-180 NMR spectrometer with a Doty 7 mm spinning probe: $\pi/2$ pulse = 3.5 μs; contact time = 3.5 ms; 16 K points; SW = 20 kHz.

small departures from axial symmetry of both calix cavities. The least shielded component of both patterns ($\delta_{33} = \delta_{\|}$ is along the *z* axis, and since $\delta_{\|}^{I} = \delta_{\|}^{II}$, the two cavities share similar dimensions along this axis. Since $\delta_{\|}$ is the least shielded CSA component, the CSA tensor has positive anisotropy indicative of a prolate spheroidal cavity.[7,8] The difference in the $\delta_{11}$ and $\delta_{22}$ values for the two patterns indicates that Xe samples different dimensions in the *xy* plane for each cavity.

Because Xe sits in a cavity defined by the majority disordered position in *tert*-butylphenol group *C*, only the positional disordering in *tert*-butylphenol group *B* (0.57 : 0.43) influences cavity size. Disordering in *B* gives two cavities of dimensions of 10.15 × 10.52 Å (majority site) and 10.15 × 10.65 Å (minority site) defined by the central carbon of the *tert*-butyl groups (Fig. 3). Two cavities differing in one dimension in the *xy* plane by 0.17 Å result from the disordering in *B*. The differences along the *z* axis arising from the *tert*-butylphenol disordering are insignificant ($\Delta d < 0.03$ Å).

Specific features of each technique can now be correlated. On the basis of the position and intensities of the two $^{129}$Xe NMR lines I and II are assigned to the majority of (10.15 × 10.52 Å) and minority (10.15 × 10.65 Å) cavities respectively. The intensities of the $^{129}$Xe NMR lines agree with the ratio of *tert*-butylphenol disordering in *B* determined by XRD. The presence of two Xe sites indicates that, in contrast to the dynamic *tert*-butylphenol disordering observed in *t*-BC·$C_6H_5Me$,[9] *tert*-butylphenol *B* disordering in **1** is static. Finally, the degree of $^{129}$Xe NMR δ shielding of the two sites is consistent with the cavity size/$\delta_{iso}$ relationship for void spaces,[7] and is to date the largest clathrate cavity defined by $^{129}$Xe NMR in such a fashion (although ring-current effects[10] from the aromatic host walls likely interfere with any quantitative determinations of the cavity size). For comparison, Xe in zeolite A (one Xe per α cage, *d ca*. 9.8 Å), gives $\delta_{iso}$ 75.[11]

In summary, the *t*-BC·$C_6H_5NO_2$·Xe compound illustrates three key features: (*i*) it is the first example of gas inclusion in the *t*-BC cavity, (*ii*) since Xe behaves both as a guest and a probe, specific XRD and NMR data may (for the first time) be correlated, and (*iii*) NMR data establishes that the host *tert*-butylphenol disordering is static.

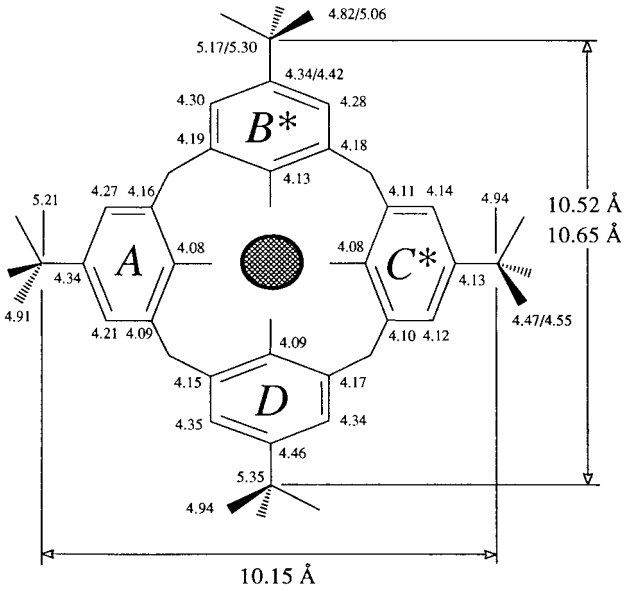

**Fig. 3** The Xe position in the *t*-BC cavity in **1**. The smaller numbers indicate the distance (in Å) to Xe, and the larger numbers indicate the cavity dimensions in the Xe *xy* plane; two values reflect disordering in carbon atoms. The starred letters indicate disordered *p-tert*-butylphenol units: *B* 57 : 43; *C* 66 : 34.

We thank the Natural Sciences and Engineering Research Council of Canada for support in the form of operating (J. A. R.) and post-graduate PGS-B (E. B. B.) awards.

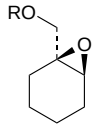
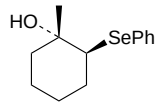
# A concise asymmetric synthesis of the pheromone 1-methylcyclohex-2-enol *via* a 'merged substitution-elimination reaction'

**David P. G. Hamon*† and Kellie L. Tuck**



*Chemistry Department, University of Adelaide, S.A. 5005, Australia*

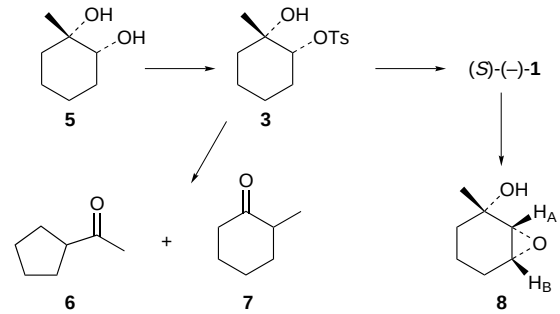
**The title compound is prepared (> 94% ee) by a three step synthesis from 1-methylcyclohexene *via* a 'merged substitution-elimination reaction' involving a phenylselenide ion.**



One of the constituents of the pheromone system of the beetle *Dendroctonus pseudotsugae Hopkins*, an economically important pest of the Douglas fir tree, is the aggregation pheromone 1-methylcyclohex-2-enol **1**. Previous syntheses of the optically active pheromone **1** have involved the conversion of optically active intermediates, prepared by classical resolution,[1] enzymically,[2,3] from the chiral pool,[4] or by multistep asymmetric syntheses.[5,6]

**1**

**2**

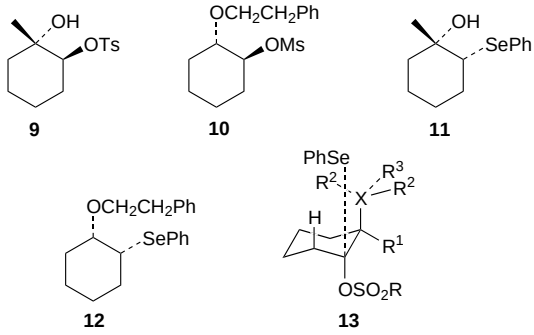


**4**

If asymmetric syntheses are to become important for industrial preparations it is necessary to illustrate that they can be made simple and short. However, this is not necessarily a trivial exercise. With this pedagogical principle in mind, we sought to modify our earlier route[5] in the hope that the separate enantiomers might be more readily prepared. Serendipity has played an important role in providing a simple solution to this problem and we disclose a three step asymmetric synthesis of this pheromone which is applicable to the synthesis of either enantiomer, and which gives the constituent in an enantiomeric purity exceeding 94% ee. Ironically the aggregation pheromone found naturally is only 10% ee[7] but the challenge of the asymmetric synthesis has been pedagogically both useful and exciting. A key step in our earlier synthesis[5] of this pheromone involved nucleophilic substitution of the epoxide **2**. Although both the leaving groups in the epoxide **2** and the tosylate **3** are in a *pseudo* neopentyl location, a study of models suggests that tosylate **3** is considerably more hindered to nucleophilic attack than the epoxide **2**. However, it was considered that with the powerful nucleophile NaSePh, tosylate **3** might also, like epoxide **2**, react to give in this case the selenide **4**. Thermal elimination of the selenoxides[5] derived from **4** would give the pheromone **1**. Asymmetric dihydroxylation of 1-methylcyclohexene should give the optically active diol **5** from which the tosylate **3** could be prepared.

After this work had commenced, Sharpless reported,[9] as a footnote, the ee (52%, by chiral HPLC) for the asymmetric dihydroxylation (AD β mix) of 1-methylcyclohexene to the diol **5**, but no experimental details for the preparation were provided. Owing to the water solubility and considerable volatility of the diol **5**, we have found it necessary to modify, somewhat, the standard work-up procedures for this reaction by removal of the KOH wash normally used to remove methanesulfonamide. The product is then isolated, in 85% yield, by fractional distillation of all solvents, chromatography and sublimation (50 °C/0.5 Torr). Conversion of the diol **5** to the mono secondary tosylate **3** (85% yield, 94% yield for the racemate on a larger scale) gives material which, although it is initially only 75% of the major enantiomer,‡ can nevertheless be fractionally recrystallised to high enantiomeric purity (94% ee after four recrystallisations from diethyl ether–hexane, 37% yield, the racemate is less soluble).

Treatment of the tosylate **3** with NaSePh (PhSeSePh, $NaBH_4$, EtOH[10]), in boiling EtOH, did not give the sought after substitution reaction. Rather surprisingly an elimination reaction occurred instead. The initial reaction gave a mixture of the alcohol **1** and the ketones **6** and **7**. It had been assumed from the outset that base treatment of the tosylate **3** would give the ketones **6** and **7**, by a negative-ion pinacol rearrangement,[11] and this was confirmed by treatment of the tosylate with $KOBu^t$ (in THF at room temperature, **6** : **7** = 8 : 1, 90%). Selenide ion is too weak a base to abstract a proton from an alcohol and it was likely that ketones **6** and **7** were artifacts formed from adventitious sources of base. A wash of the glassware with $NH_4Cl$ solution prior to the reaction of tosylate **3** with NaSePh, obviates the formation of these ketones and the volatile alcohol (*S*)-(−)-**1**§ is isolated, in 78% yield, by fractional distillation. The enantiomeric purity of the tertiary allylic alcohol **1** could not be obtained directly by chiral shift NMR experiments and we did not have access to complexation GC.[1] Conversion of the alcohol to the epoxide **8** (with slow addition of MCPBA to alcohol **1**, $NaHCO_3$, $Et_2O$, 0 °C, 70%, the diastereomer is not formed) and chiral shift NMR experiments‡ on this (94% ee) confirmed that the enantiomeric purity from the tosylate had been maintained.



The mechanism for the elimination reaction observed is intriguing. The reaction of the tosylate **3** with NaSePh in EtOH is not an $E_1$ mechanism since the qualitative observation is that the half-life for the reaction is concentration dependent; because no products from pinacol rearrangement are observed when care is taken to remove adventitious base; and because the tosylate is recovered unchanged after reflux in EtOH. The question arises, therefore, as to why selenide anion, a powerful nucleophile to carbon but non-nucleophilic to hydrogen attached to the oxygen of an alcohol, should suddenly change allegiance and become a nucleophile to hydrogen attached to carbon. Winstein, in a paper published in 1956,[8] first drew attention to the dichotomy of weak bases but good nucleophiles which promote elimination reactions when he wrote about merged substitution-elimination reactions. Since then there has been considerable debate[12,13] as to the veracity of his suggestion but, in our opinion, no clear

**Scheme 1**

explanation has been given for what is actually occurring in these reactions. Since our example appears to be one of the more extreme examples of this phenomenon, we would like to present our observations in the hope that they will rekindle debate on this subject.

Under the same conditions, with NaSePh, as when the tosylate **3** gives only the elimination product **1**, both the racemic isomeric *trans*-tosylate **9** and the racemic mesylate **10** undergo clean substitution reactions to give the selenide derivatives **11**¶[14] and **12** respectively. It has been shown[15] that for the

4-*tert*-butylcyclohexyl derivatives the axial tosylate reacts faster than the equatorial tosylate in $S_N2$ reactions. Conformational mobility is clearly demonstrated for the tosylate **3**, even at room temperature, since it is likely that the compounds **6** and **7** come from two different chair conformers. From a study of models it is seen that when the leaving group is axial not only is the rear-side attack less hindered but, the nucleophile, the reaction centre and the leaving group can stay co-linear throughout the reaction.‖ Perhaps herein lies an explanation for our observations. It is likely that the selenide ion follows a trajectory co-incident with the dipole axis of the molecule and that in both the compounds **9** and **10** the propensity for carbon nucleophilicity is not thwarted by steric barriers since only lone pairs (see **13**) would hinder the approach. In the case of the tosylate **3**, however, the methyl group would clearly present an obstacle to rear-side attack and the deflected nucleophile might then encounter the hydrogen atom, held in an antiperiplanar relationship to the leaving group, with sufficient energy to overcome the barrier to elimination and this then becomes the lower energy process.

In conclusion, therefore, we have developed a three step asymmetric synthesis of the pheromone, from achiral starting materials. The route is probably far more efficient than any to date and will be extremely efficient if further developments to the Sharpless procedure allows a more enantioselective preparation of the diol **5**. Furthermore the synthesis has revealed an intriguing elimination reaction which may help to unravel the paradoxes arising in the mechanism of weak-base elimination reactions.

We thank Rebecca Kennedy for the experiments referred to in ref. 14.

‡ All chiral shift NMR experiments were run in 15% $C_6D_6$ in $CCl_4$ with Eu(hfc)$_3$. Racemic tosylate **6**. $\delta_H$ (200 MHz, $CDCl_3$) 1.14 (s, 3 H, $CH_3$), 1.2–1.8 (complex, 8 H, methylene envelope), 1.59 (s, 1 H, OH), 2.45 (s, 1 H, Ar-$CH_3$), 4.36 (dd, 1 H, *J* 4.04, 9.94 Hz, H1), 7.34 (d, 2 H, *J* 8.22 Hz, Ar-H), 7.80 (d, 2 H, *J* 8.22 Hz, Ar-H). The doublet originally at δ 7.80 separates, to baseline, into two doublets with the shift reagent. Racemic epoxide **8**. $\delta_H$ (200 MHz, $CDCl_3$) 1.2–2.1 (complex, 6 H, methylene envelope), 1.33 (s, 3 H, $CH_3$), 2.40 (br s, 1 H, OH), 3.10 (d, 1 H, *J* 4.0 Hz, H2), 3.36 (m, 1 H, H3). The multiplet originally at δ 3.36 separates, to baseline, into two broadened singlets with the shift reagent.

§ Pheromone **1**. $\delta_H$ (200 MHz, $CDCl_3$) 1.29 (s, 3 H, $CH_3$), 1.5–1.8 (complex, 4 H, methylene envelope), 2.0 (m, 2 H, H4), 5.60 (br d, 1 H, *J* 10.0 Hz, H2), 5.75 (td, 1 H, *J* 4.0, 10.0 Hz, H3). $\delta_C$ (75.5 MHz, $CDCl_3$) 19.5, 25.0, 29.3, 37.8, 67.9, 128.9, 133.7.

¶ A referee has suggested that this compound might have the structure **4** if it arose through double inversion *via* the epoxide. However, optically active compound **4** is already known[5] and the spectral data are different.

‖ A study of a model (axial leaving group down) shows that the reacting centre can move up smoothly towards the nucleophile as overlap of the orbitals takes place. This would give the product in the boat conformation. No such smooth pathway exists for the equatorial leaving group. We believe that this requirement would also account for the known *trans*-diaxial opening of cyclic epoxides.

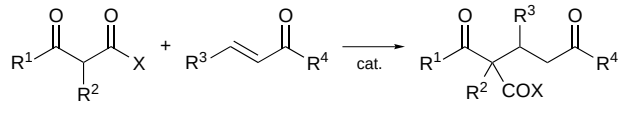
# Iron(III) catalysis of the Michael reaction of 1,3-dicarbonyl compounds and enones

**Jens Christoffers**

*Technische Universität Berlin, Institut für Organische Chemie, Sekretariat TC 2, Straße des 17. Juni 124, D-10623 Berlin, Germany*

**Iron(III) chloride hexahydrate catalyses the Michael reaction of β-dicarbonyl compounds and enones under mild and neutral conditions with excellent yields and product selectivity.**



The reaction of enolates with α,β-unsaturated carbonyl compounds (Michael reaction) is a fundamental C–C bond forming methodology, which classically is a high yielding base catalysed process, and can even be performed with high stereoselection.[1] However, there are some disadvantages of base catalysis, *e.g.* incompatibility with base sensitive or acidic functionalities, ester solvolysis, reverse and other side reactions. In these terms it seems interesting that the Michael reaction is known to be catalysed under neutral conditions by transition metal compounds, in particular by Group VIII 1,3-dionato complexes.[2] Also, some lanthanide catalysts have been reported to be efficient under neutral and mild conditions.[3]

Although the strong tendency of $Fe^{III}$ to form 1,3-dionato complexes is well known,[4] catalysis of the Michael reaction by $FeCl_3·6H_2O$ has not yet been reported to the best of our knowledge,† despite the fact that in terms of economical and ecological considerations iron should be the transition metal of choice.

Iron(III) chloride hexahydrate is an extraordinarily efficient catalyst for the Michael reaction shown in Scheme 1. We have been investigating the catalytic activity of several transition metal halides on the reaction of **1a** with **2a**, and some did show activity, but only with $FeCl_3·6H_2O$ did we observe complete conversion at room temperature. For about the first 30% conversion the turn over number was *ca.* 2 $min^{-1}$, and using 1 mol% $Fe^{III}$ the reaction was quantitative within 3 h. It has to be pointed out that as the product and starting materials are liquid at room temp. and no solvents needed to be used, and since no side reactions have been observed, workup is very simple: filtration using a small column of silica gel removes all iron-containing materials.

The best results were obtained with cyclic ketoesters and methyl vinyl ketone (**2a**; products **3a**, **b**,‡ **d**, **e**§). With only 1 mol% $FeCl_3·6H_2O$ full conversion within a few hours is observed, even if bulkier ester functions are present (**3b**). Although starting from a methyl ester **1e**, some hydrolysis and subsequent decarboxylation reactions, presumably resulting from hydrate water, are noticed. This is negligible if 1 mol% $Fe^{III}$ is applied, but with 5 mol% yield drops significantly to 72%. Using β-diketones or other species other than cyclic ketoesters, conversion is a little slower, but with 5 mol% catalyst results are still satisfying (in Table 1 some optimized examples are listed).

While $Fe^{III}$ catalysis seems to be effective with **2a**, some restrictions have to be made in the use of other enones: although even bulkier *E*-enones like **2b** or **2c** form Michael products (the higher reaction temperature might be due to steric effects; solvent had to be applied in these cases), no reaction was observed with enones with a *Z*-substituent like cyclopentenone or mesityl oxide. This might give some insight into a possible mechanism of the $Fe^{III}$ catalysis (actually, chloride does not play a role, because the same results have been observed using

$Fe^{III}$ nitrate or sulfate). Starting from a diketonato complex **4**, in which the ligand is planar and particularly stabilized by π-delocalization, the enone **2** is proposed to coordinate in a vacant coordination site to form species **5** (Scheme 2). Subsequently, the central carbon centre of the dionato ligand is thought to be alkylated by the coordinated enone, but only if the enone is in the S-*cis* conformation, which is obviously impossible for cyclopentenone and strongly disfavoured in mesityl oxide. In complex **6**, the central carbon centre of the dione ligand is tetrahedral, thus π-delocalization is impossible, and the compound is destabilized. Product **3** is liberated and complex **4** reformed *via* ligand exchange. All together, $Fe^{III}$ catalysis of the Michael reaction seems to show a classic template effect,[6] where both reactants are coordinated at the same time and activated by a metal centre. And in fact $Fe(acac)_3$, which offers no vacant coordination site to an enone, does not catalyse the Michael reaction at all, that means a dionato ligand like acac can not be alkylated by non-coordinated **2a**, which was proved by a stoichiometric experiment. Also, it was impossible to achieve bis-substitution by converting, *e.g*. **3g** with **2a**, at even higher temperatures. This fits into the outlined picture of the mechanism, if we assume that the oxobutyl side chain of **3g** is donating itself to the centre metal and blocking a possibly vacant coordination site.

In summary, catalysis of the Michael reaction of β-dicarbonyl compounds and enone by $FeCl_3 \cdot 6H_2O$ is a very effective alternative to the classic base catalysis. The selectivity of this method is excellent in most cases, reaction conditions are mild and neutral, and performance is reasonably easy (no anhydrous or inert conditions, simple workup procedure), although it seems not to be appliable for enones bearing a *Z*-substituent.

Supplementary Information containing experimental details and characterization data for **3a**–**k** is available from the author on request.

# Hydrothermal synthesis and lanthanide doping of complex fluorides, $LiYF_4$, $KYF_4$ and $BaBeF_4$ under mild conditions

**Chunyan Zhao,[a] Shouhua Feng,*[a] Ruren Xu,[a] Chunsan Shi[b] and Jiazuan Ni[b]**

**The complex fluorides $LiYF_4$, $KYF_4$, $BaBeF_4$ and $AYF_4Eu_x$ (A = Li, K) are hydrothermally synthesized at 140–240 °C and characterized by powder X-ray diffraction, thermogravimetric analysis, IR spectroscopy, scanning electron microscopy and luminescence measurements.**

Recently, we reported on a mild hydrothermal synthesis of the complex fluorides $LiBaF_3$ and $KMgF_3$ with perovskite structures at 120–240 °C,[1] which gives rise to the possibility of making new functional fluoride compounds with various structures and particular properties under mild conditions. It is well known that complex fluorides with strong potential application as luminescence materials can be prepared by solid-state reactions at high temperatures.[2,3] This solid-state synthetic apparatus however requires a complicated set-up due to the erosion of fluorides and thus has limited the study of fluoride chemistry.[4] Mild hydrothermal synthesis, as a low energy-costing and less-polluting method, can enhance the reactivity of reactants in solution and can be used to prepare important crystalline solids which are difficult to prepare or can not be prepared by solid-state reactions, such as in the case of microporous crystals. We have synthesized a number of novel oxides or complex oxides such as microporous solids and solid electrolytes by this moderate preparative technique.[5–10] As an extension of the study on hydrothermal synthesis of complex fluorides with perovskite structures ($ABF_3$), we have investigated the synthesis of $ABF_4$-type complex fluorides as well as hydrothermal doping of photo-sensitive lanthanide elements into the fluorides. The aim of our research is to search for a mild hydrothermal synthesis route to produce a variety of complex fluorides and to study the possibility for hydrothermal equilibrium doping of lanthanide ions into the fluorides.

The starting materials for the syntheses of $LiYF_4$ and $KYF_4$ were LiOH (A.R.), KF (A.R.), $Y_2O_3$ (99.99%) and $HN_4HF_2$ (A.R.). Under typical synthesis conditions the mole ratios of the starting materials were 2.0 LiOH : 1.0 $Y_2O_3$ : 10.0 $NH_4HF_2$ : 500 $H_2O$ and 3.0 KF : 1.0 $Y_2O_3$ : 4.0 $NH_4HF_2$ : 300 $H_2O$ for the syntheses of $LiYF_4$ and $KYF_4$, respectively. The typical synthetic procedure for crystalline $LiYF_4$ was as follows: 0.08 g LiOH, 0.23 g $Y_2O_3$ and 0.57 g $NH_4HF_2$ were added to 9 ml of deionized water (for the synthesis of $KYF_4$, 0.29 g KF, 0.38 g $Y_2O_3$ and 0.38 g $NH_4HF_2$ were used in this step), to form a reaction mixture with a pH of *ca.* 4. The reaction mixture was sealed in a Teflon-lined stainless-steel autoclave and heated at 240 °C under autogenous pressure for 7 days. After the autoclaves were cooled and depressurised, the final powder products were washed with deionized water and air-dried at room temperature. In the hydrothermal doping experiment, $Eu_2O_3$ (99.999%) was used as a reactant in the synthesis of $AYF_4Eu_x$ (A = Li, K), and the reactant mixtures had mole compositions: 2.0 LiOH : 1.0 $Y_2O_3$ : 10.0 $NH_4HF_2$ : 500 $H_2O$ : 0.09 $Eu_2O_3$ and 3.0 KF : 1.0 $Y_2O_3$ : 4.0 $NH_4HF_2$ : 300 $H_2O$ : 0.09 $Eu_2O_3$, for $LiYF_4Eu_x$ and $KYF_4Eu_x$ respectively; the reaction mixtures were heated in Teflon-lined stainless-steel autoclaves at 240 °C for 7 days.

$BaBeF_4$ was prepared by hydrothermal crystallization of a reaction mixture with a mole composition: 1.0 $Ba(OH)_2$ : 2.0 $BeF_2$ : 2.0 $NH_4HF_2$ : 200 $H_2O$ in Teflon-lined autoclaves at 140 °C for 4 days. The typical synthesis procedure was as follows: 0.79 g of barium hydroxide and 0.24 g of beryllium fluoride (A.R.) were dissolved in 9 ml of deionized water to form a solution, then 0.28 g of $NH_4HF_2$ (A.R.) was added dropwise to the solution under magnetic stirring. Hydrofluoric acid (40 mass%, A.R.) was used to adjust the pH to 2–4.

All products were characterized by X-ray diffraction (XRD) on a Rigaku D/max-γA diffractometer with a rotating target with Ni-filtered Cu-Kα radiation at room temperature. The XRD data for indexing and cell-parameter calculation were collected by a scanning mode with a step length of 0.02° and a scanning rate of 0.2° $min^{-1}$. Silicon was used as an internal standard. Observation of the crystallites was performed on a Hitachi X-650 scanning electron microscope (SEM). Thermogravimetric analysis (TGA) was conducted on a TGS-2 thermogravimetric system. IR spectra were obtained with a Nicolet 5DX spectrometer using the KBr pellet technique. Optical measurements were performed at room temperature using a Spex Fluorolog 2 spectrofluorometer.

Table 1 shows the hydrothermal synthesis conditions for $LiYF_4$, $KYF_4$ and $BaBeF_4$. In the syntheses, ratios of initial composition and the pH of the reaction system were found to be crucial to the formation, crystallization and purity of the products. In the synthesis of $BaBeF_4$, the ratio of Ba/Be is a

dominating factor. When the Ba/Be ratio was 0.5, $BaBeF_4$ was formed but when Ba/Be = 2, impurity phases appeared. In the synthesis of $LiYF_4$, when LiOH and $Y_2O_3$ were employed and the ratio of Li/Y was unity, $NH_4HF_2$ must be added and a pH of 3–4 was required, addition of a small excess of $NH_4HF_2$ did not result in the formation of impurities. In the synthesis of the $KYF_4$, when KF and $Y_2O_3$ were utilized as starting materials, a ratio of K/Y of 3/2 was optimal. In this case, $NH_4HF_2$ was also used to supply $F^-$ and to adjust the pH to 2–4.

The pH of the reaction system considerably influences the crystallization of the complex fluorides. For example, using KF and $Y_2O_3$ as starting materials, $KYF_4$ can be synthesized at pH *ca.* 4, whereas when $Y(NO_3)_3$ and KF are used, $KYF_4$ can be prepared at pH *ca.* 2.

It is known that $F^-$ ion is an effective mineralizer in both aqueous and non-aqueous systems.[11–13] In the synthesis of $BaBeF_4$, $LiYF_4$ and $KYF_4$, $F^-$ ion was either a reactant or a mineralizer. Excess $F^-$ ions may lower remarkably the temperature of crystallization. Thus $KYF_4$ can be crystallized even at 180 °C, when excess $F^-$ ions are added. Crystallization temperature and time were also important factors for an effective synthesis. Although $BaBeF_4$ can be crystallized below 240 °C, prolonged reaction times are required. For instance, in the $BeF_2$–$BaF_2$–HF–$H_2O$ system, $BaBeF_4$ is formed after 2 days at 240 °C, but at 140 °C 4 days are required (Table 1).

The XRD patterns of the $BaBeF_4$, $LiYF_4$ and $KYF_4$ can be indexed in orthorhombic, tetragonal and hexagonal systems, respectively (Table 2; full XRD data available from the authors on request). The cell of hydrothermally prepared $KYF_4$ is smaller then that of $KYF_4$ prepared by solid-state reaction. For $BaBeF_4$ and $LiYF_4$, the two synthetic methods give almost the same cell sizes.

The thermal stability of the $BaBeF_4$, $LiYF_4$ and $KYF_4$ were studied by TG–DTA in air. There are no phase transformations up to 600 °C in all three systems and no mass losses were observed between 50 and 600 °C. This indicates that the samples are not hydrated and are stable in air, as confirmed by IR spectroscopy in this temperature range.

The morphology of the samples was examined by SEM at room temperature. The results show that the grain size of the product particles is related to the pH of reaction solutions and the nature of cations used in the synthesis. Uniform grain texture of $BaBeF_4$ can be observed with grain sizes ranging from 0.2 to 5 μm. The SEM morphologies of $LiYF_4$ and $KYF_4$ show regular shapes with grain sizes in the range 0.2–10 μm.

The optimum doping concentrations of $Eu^{3+}$ ions in $LiYF_4$ and $KYF_4$ were $x = 0.09$ mole in $AYF_4Eu_x$ (A = Li, K) and the highest doping concentration of $Eu^{3+}$ ions was $x = 0.2$. Both excitation and emission spectra show the d–f transition typical of $Eu^{3+}$ compounds. The room-temperature excitation spectrum shows a peak at 393 nm, while the emission spectrum shows $^5D_0$–$^7F_J$ ($J = 0, 1, 2, 3, 4$) five-line peaks and a maximum at 615 nm. All hydrothermally prepared samples showed significant luminescence properties. In the room-temperature excitation spectrum of samples obtained from hydrothermal systems, no charge transition states were observed. This indicates there is no oxygen insertion in the samples which usually occurs in solid-state reactions. A comparison of relative emission intensities for both hydrothermally and solid-state prepared samples is in progress to understand if the equilibrium doping concentration is suitable for optimizing luminescence properties.

In summary, the complex fluorides $BaBeF_4$, $LiYF_4$ and $KYF_4$ were hydrothermally prepared at 140–240 °C. The molar ratio and pH in the initial reaction mixture associated with the reaction temperature dominate the crystallization of the products. $BaBeF_4$, $LiYF_4$ and $KYF_4$ crystallize in orthorhombic, tetragonal and hexagonal systems, respectively, and all products have uniform grain sizes. The compounds are air stable and show no insertion of oxygen. Hydrothermal doping of $Eu^{3+}$ ions into $LiYF_4$ and $KYF_4$ is successful and measurements of the excitation and emission spectra of $AYF_4Eu_x$ (A = Li, K) reveal the same energy level schemes as those previously established based on samples prepared by solid-state reactions. In addition, luminescence studies demonstrate that crystallization of our samples in hydrothermal systems is complete. The hydrothermal synthesis and doping routes are apparently advantageous compared with traditional high-temperature solid-state methods.

# A new ambient-pressure organic superconductor $(TMET\text{-}STF)_2BF_4$ [TMET-STF = trimethylene(ethylenedithio)diselenadithiafulvalene]

**Reizo Kato,*[a] Ken Yamamoto,[a] Yoshinori Okano,[a] Hiroyuki Tajima[a] and Hiroshi Sawa[b]**

[a] *The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106, Japan*
[b] *Department of Physics, Faculty of Science, Chiba University, Yayoi-cho, Inage-ku, Chiba 263, Japan*

**Under ambient pressure, the cation radical salt $(TMET\text{-}STF)_2BF_4$, where the tight-binding band calculation suggests coexistence of one- and two-dimensional Fermi surfaces associated with two different conduction layers within the crystal, shows two types of resistivity anomalies around 115 and 13 K, followed by a superconducting transition at 4.1 K (onset).**

Extensive studies on organic superconductors have revealed that they display various electronic structures ranging from the quasi-one-dimensional type (*e.g.* TMTSF salts) to the two-dimensional type (*e.g.* BEDT-TTF salts) (TMTSF = tetramethyltetraselenafulvalene, BEDT-TTF = bis(ethylenedithio)tetrathiafulvalene].[1] The dimensionality of the electronic structure is one of the essential factors which determine the physical properties of the system. The organic donor TMET-STF [trimethylene(ethylenedithio)diselenadithiafulvalene] is a hybrid between BEDT-TTF and HMTSF (hexamethylenetetraselenafulvalene) and was first reported in 1986.[2] We found an improved synthetic route to this molecule *via* a titanocene complex and pointed out the possibility of coexistence of one- and two-dimensional Fermi surfaces in its $ClO_4$ salt, $(TMET\text{-}STF)_2ClO_4$.[3] We report here that the isostructural $BF_4$ salt is an ambient-pressure superconductor with $T_c$ (onset) = 4.1 K.

Plate-like single crystals used for the resistivity and magnetization measurements were grown by galvanostatic electrolysis (1 μA) of TMET-STF (9.8 mg) in the presence of $NBu^n_4BF_4$ (50.2 mg) in thf (20 ml) at 20 °C under Ar. An H-tube and platinum electrodes (1 mm diameter) were used. The electrical resistivity in the crystallographic *ac* plane was measured by the standard four-probe method. Gold leads (15 μm diameter) were attached to the sample with carbon paste. The contacts remained ohmic through the measurement. Resistivity measurements under pressure were performed in a clamp cell with a 1 : 1 mixture of Fluorinert No. FC70 and FC77 as the pressure transmitting medium. The pressure was calibrated with the superconducting transition temperature of Sn. The dc magnetization was measured with a Quantum Design MPMS SQUID magnetometer. Four crystals with a total mass of 0.06 mg were glued onto a sample holder (polypropylene, 1.17 mg) with a small amount of grease (Apiezon N).

Fig. 1 shows the temperature dependence of the resistivity under ambient pressure. The room-temperature resistivity was *ca.* $2 \times 10^{-2}$ Ω cm. With lowering temperature, the resistivity decreased monotonously and displayed a first upturn around 115 K. The resistivity, however, formed a small peak around 100 K and decreased again. The second upturn appeared around 13 K. The ratio of ρ(4.1 K)/ρ(13 K) was sample dependent and ranged between 2 and 9. We did not observe hysteresis at either resistivity anomaly. An abrupt drop of the resistivity occurred at 4.1 K (onset) and we observed this behaviour in all seven samples. An application of pressure effectively suppressed the first upturn of the resistivity, while the second one remained up to *ca.* 7 kbar. The pressure effect on the transition temperature for the abrupt resistivity drop was rather moderate ($dT_c/dP \approx -0.2$ K kbar$^{-1}$).

Fig. 2 shows the zero-field-cooled (ZFC) and field-cooled (FC) temperature dependence of the dc magnetization, uncorrected for demagnetization, at a fixed field of 10 Oe perpendicular (approximately) to the crystallographic *ac* plane. The protocol was as follows: after cooling to 1.8 K in zero field, a magnetic field of 10 Oe was applied and the dc magnetization was measured while warming to 6.0 K (ZFC). The sample was then cooled to 2.0 K under the same field, 10 Oe (FC). The onset of a diamagnetic transition was observed at 3.8 K. This value is consistent with the result of the resistivity measurement. From the ZFC curve, we can roughly estimate that a volume fraction is *ca.* 50% of perfect diamagnetism; accuracy, however, is not high as the amount of the sample was very small. Such a large diamagnetism and the abrupt resistivity drop can be explained only by the appearance of a superconducting phase. Hysteresis

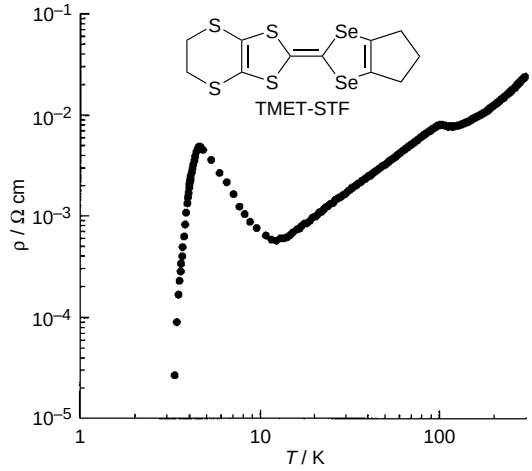

**Fig. 1** Temperature dependence of the resistivity at ambient pressure

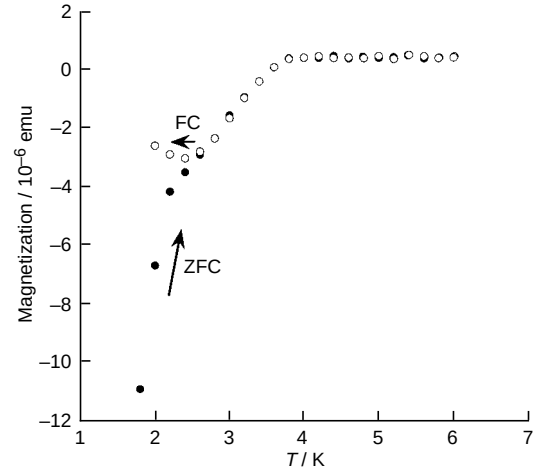

**Fig. 2** Temperature dependence of the zero-field-cooled (ZFC) and field-cooled (FC) dc magnetization with a fixed applied field of 10 Oe

between the FC and ZFC curves indicates that flux is trapped in the sample as it is cooled below the transition temperature.

This $BF_4$ salt is isostructural with the $ClO_4$ salt.[3]† The unit cell contains two crystallographically independent donor molecules (A, B) which are associated with conduction layers A and B, respectively (Fig. 3). In both layers, unsymmetrical donor molecules are stacked alternately in a slightly dimerized fashion. The molecular packing in layer B is very similar to that in TMTSF salts. On the other hand, in layer A, donor molecules are packed more loosely. This can be seen by enlarged interplanar distances and seems to be related to a positional disorder of the terminal ethylene group as reflected by the largely elongated thermal ellipsoids (Fig. 3). By comparison, it should be noted that the ethylene group is completely ordered in layer B. Comparison of the bond lengths in these two donor units (A, B) suggests that the difference in the formal charge is rather small and therefore the formal charge is close to +0.5 for each molecule. Layers A and B are separated from each other by an anion layer.

A very unique feature is that these two donor layers differ in anisotropy of the intermolecular interaction, which has been examined by overlap integrals among the HOMOs obtained by the extended Hückel method.[4] As is the case of the $ClO_4$ salt,[3] the intracolumn interactions in the layer A are largely reduced, which results in a reduction of the anisotropy. The interaction between layers A and B is very small. The conduction band (3/4 filled) is constructed by the HOMO and is composed of two branches associated with the layers A and B, respectively. The tight-binding band calculations, where the interlayer interaction is neglected, indicate that layer A provides a two-dimensional Fermi surface, while layer B provides a quasi-one-dimensional one (Fig. 3).‡ Therefore, the electronic structure of this compound can be described as a hybrid between the TMTSF and BEDT-TTF systems. Almost all superconducting cation radical salts have a single type of conducting layer (column) within the crystal and thus a single type of Fermi surface in the Brillouin zone. In $(TMET\text{-}STF)_2BF_4$, however, there exist two crystallographically independent conduction layers composed of the 'same' molecule, within the 'same' crystal providing different types of Fermi surfaces. Although we neglected the interlayer interaction in the band calculation, there should be small but significant interactions between layers A and B which would affect the physical properties.

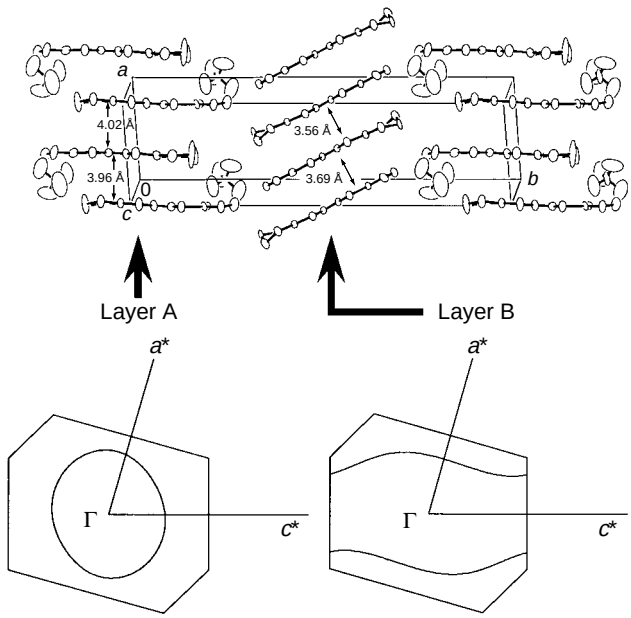

**Fig. 3** Crystal structure and calculated Fermi surfaces of $(TMET\text{-}STF)_2BF_4$

The resistivity measurement clearly suggests two types of anomalies in the metallic state which have never previously been observed in conventional organic superconductors. Although they are suggestive of a special electronic state mechanistic details await clarification.

The resistivity behaviour of the isostructural $ClO_4$ salt was similar to that of the $BF_4$ salt, except that a superconducting transition was not observed down to 1.5 K under pressures from 1 bar to 16.8 kbar.

In summary, the ambient-pressure superconductivity in the cation radical salt $(TMET\text{-}STF)_2BF_4$ has been established by resistivity and magnetization measurements. This system is a 'two-band' system associated with (quasi) one- and two-dimensional conduction layers within the crystal and is of special interest in view of an interplay among one-dimensional charge localization, higher dimensionality, and superconductivity. TMET-STF is known to provide a variety of cation radical salts.[5–7] Detailed studies on structural and physical properties of these salts are in progress.

† *Crystal data* for $(TMET\text{-}STF)_2BF_4$: $C_{22}H_{20}BF_4S_8Se_4$, $M_w$ = 943.50, triclinic, space group $P\bar{1}$, $a$ = 8.030(1), $b$ = 29.646(5), $c$ = 6.546(1) Å, $\alpha$ = 92.48(1), $\beta$ = 105.65(1), $\gamma$ = 93.86(1)°, $U$ = 1494.1(4) Å$^3$, $Z$ = 2, $D_c$ = 2.10 g cm$^{-3}$, $F(000)$ = 914.00, $R$ = 0.079, $R_w$ = 0.077, GOF = 3.77. X-Ray diffraction data were collected on a MAC Science automatic four-circle diffractometer with monochromated Mo-K$\alpha$ ($\lambda$ = 0.710 69 Å; 50 kV, 300 mA) radiation up to $2\theta$ = 60°. The intensities were corrected for Lorentz and polarization effects. The analytical absorption correction was carried out. The structure was solved by the direct method and refined with full-matrix least-squares using 5022 reflections with $I \geqslant 3\sigma(I)$. Anisotropic thermal parameters were used for non-hydrogen atoms. Hydrogen atoms were included but not refined. All calculations were performed with use of the 'teXsan' crystallographic software package of Molecular Structure Corporation. Two carbon atoms of the ethylene group in molecule A exhibit very large thermal parameters due to positional disorder. It was impossible to refine this ethylene group as a superposition of two possible conformations. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 186/439.

‡ It has been assumed that the transfer integral ($t$) is proportional to the overlap integral ($S$), $t = \varepsilon S$ ($\varepsilon$ is a constant of the same order as the orbital energies of the HOMO). Based on the filling of each band, we estimated the formal charge of the molecule A to be +0.4 and that of the molecule B to be +0.6. This is consistent with the result of the bond length analysis; each molecule has a formal charge close to +0.5.

# Synthesis and characterization of mesostructured aluminophosphates using the fluoride route

**Pingyun Feng, Yin Xia, Jianglin Feng, Xianhui Bu and Galen D. Stucky***

*Department of Chemistry, University of California, Santa Barbara, California 93106, USA*

**The room-temperature synthesis of the hexagonal mesostructured aluminophosphate and its phase transition into the lamellar phase are reported.**

Since Mobil researchers first demonstrated in 1992 that through a micelle-assisted crystallization of the inorganic phase, the hexagonally packed mesoporous silicate and aluminosilicate materials (MCM-41) with uniformly sized pores could be synthesized,[1] there has been much interest in synthesizing mesoporous aluminophosphates owing to the previous success in the synthesis of microporous aluminophosphates[2] with framework topology identical or similar to aluminosilicate zeolites. However, so far attempts in synthesizing the mesostructured aluminophosphates have had very limited success.

It has been demonstrated that lamellar aluminophosphates can be made from non-aqueous or aqueous systems by using a liquid-crystal templating approach.[3–7] The presence of the hexagonal mesostructured aluminophosphate has been suggested in a brief description by Kimura *et al.*[8] Here, we demonstrate that in the presence of $F^-$ ions and using EtOH–$H_2O$ as a solvent, pure hexagonal mesostructured aluminophosphate of relatively high quality can be obtained. We have found that the formation of the hexagonal phase precedes the formation of the lamellar phase and that a phase transition from the hexagonal phase to the lamellar phase in the aluminophosphate system can be induced.

A typical sample preparation was: aluminium isopropoxide (4.01 g) was mixed with 7.28 g of ethanol. After stirring, 40.0 g of distilled water was added, followed by the addition of 2.79 g of 85% $H_3PO_4$ and 0.67 g of 49% HF. After further stirring, 1.86 g of $C_{16}H_{33}Me_3NBr$ (surfactant/Al ratio = 0.26) was added. Finally, 10.40 g of 25% $NMe_4OH$ was slowly added until the pH of the solution was *ca*. 8.3. The mixture was stirred at room temp. for 4 h. The pure hexagonal mesostructured phase was obtained after filtering and washing with distilled water. However, if after stirring for 4 h at room temp. the gel was placed in an oven at 70 °C for a few days, the hexagonal phase was converted partially into a mesostructured lamellar phase. At higher temperatures such as 100 °C, the transition to the lamellar phase proceeded at a faster rate and the complete conversion took only 2 days. The X-ray powder patterns with different reaction conditions are shown in Fig. 1.

Postsynthesis treatment was found to enhance the crystalline quality of the hexagonal mesostructured phase.[9] The above-room-temperature synthesized hexagonal sample was further treated by putting the sample into deionized water at 70 °C for about a week, then filtered and dried. The sample was subsequently stirred in ethanol overnight, filtered off and dried. The intensity of the XRD peaks was greatly enhanced by this treatment. The treated sample was used for the subsequent characterization including TEM and $^{27}Al$ MAS NMR.

The hexagonal phase obtained was further confirmed by the TEM image (Fig. 2) which was recorded on a 2000FX JEOL microscope operated at 200 keV. The TEM sample was prepared by collecting a large number of crystallites onto a holey carbon film on a Ni grid. $^{27}Al$ MAS NMR spectra were obtained on a General Electric GN-300 spectrometer system at a frequency of 78.30 MHz with a spinning speed of *ca*. 5 kHz, a delay time of 2 s. and a pulse width of 4.0 μs. A four-pulse composite 90° pulse was used for background suppression.[10] Aluminium nitrate solution was used as external reference. The $^{27}Al$ MAS NMR of the hexagonal mesostructured material gave two lines at δ 43.8 and −8.7 corresponding to tetrahedrally and octahedrally coordinated Al species, respectively. $^{27}Al$ NMR of

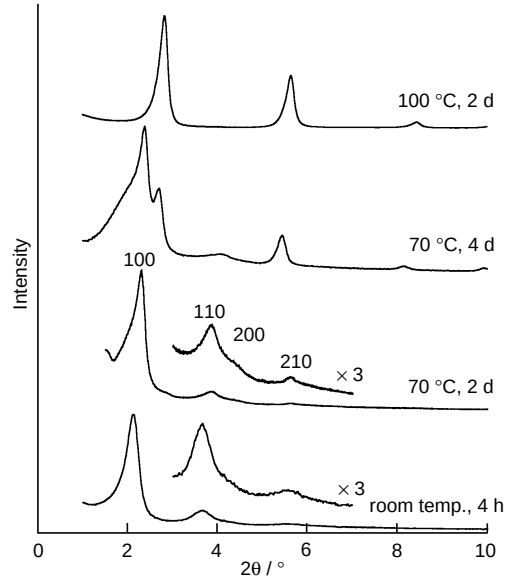

**Fig. 1** Powder diffraction patterns showing the phase transition from the hexagonal phase to the lamellar phase under different reaction conditions

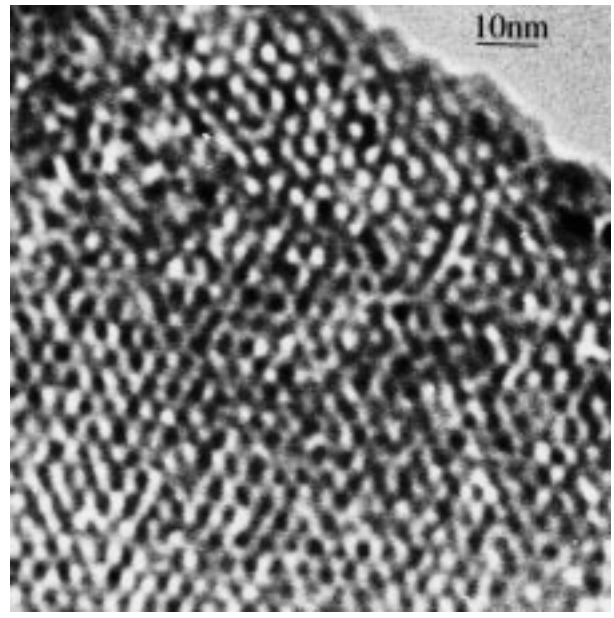

**Fig. 2** The TEM image of the hexagonal mesostructured aluminophosphate

the lamellar mesostructure showed one narrow line at δ 40.06 and a very small bump at δ −8.2 suggesting the tetrahedral coordination for the majority of the Al species in the lamellar phase (Fig. 3). The inclusion of $F^-$ anions into the hexagonal phase was verified by elemental analysis (results in mass%: 9.38 Al, 9.14 P, 3.56 F, 26.19 C, 1.55 N, 7.77 H, < 0.5 Br) which was performed by Galbraith Laboratories, Inc. The molar ratio between polyhedral centres (Al + P) and the surfactant is comparable to that found in the silica-based MCM-41 material.[11] Thermogravimetric analysis (TG) and differential thermal analysis (DTA) on the hexagonal phase showed that the mass loss occurred between 300 and 700 °C accompanied by endothermic events. The calcination of the as-synthesized hexagonal phase into a mesoporous structure has not yet been achieved and further investigation is in progress.

Compared to silica-based mesoporous materials, the formation of aluminophosphate mesostructured phases appears more sensitive to some of the starting materials. For example, both NaOH and $NMe_4OH$ have been successfully used in the synthesis of silica-based mesoporous materials. However, when NaOH, KOH or $NH_4OH$ were used as the base in place of $NMe_4OH$ in the phosphate system, only amorphous materials were obtained. The source of aluminium is another important factor. In our experiments, the use of either $Al(NO_3)_3$ or Catapal B alumina as the aluminium source also led to amorphous materials. However, the surfactant/Al ratio could be varied within a certain range since we found that the same hexagonal phase could be prepared with a surfactant/Al ratio of 0.90. The use of ethanol as the cosolvent together with the addition of HF is necessary in order to synthesize good quality materials.

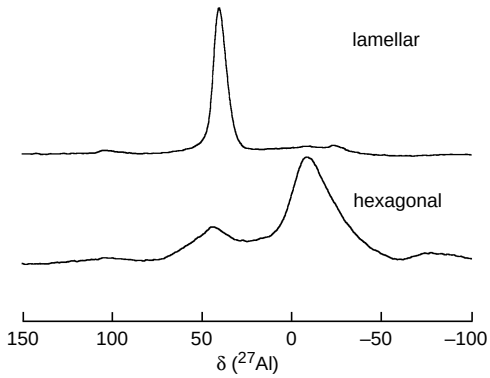

**Fig. 3** $^{27}$Al NMR spectra showing that the hexagonal–lamellar phase transition is accompanied by a change in the Al coordination polyhedra

It is of interest to compare the relative stability of hexagonal and lamellar phases in the aluminophosphate system with those in the silica-based phases. Both lamellar–hexagonal and hexagonal–lamellar phase transitions have been reported for the silica-based materials prepared using $NMe_3(C_{16}H_{33})^+$ and $NMe_3(C_{20}H_{41})^+$.[9,11,12] In the aluminophosphate system, we find that the hexagonally packed aluminophosphate undergoes a phase transition into the lamellar phase under hydrothermal treatment similar to that employed for the silica-based material.[9] Noteworthy in this regard is the tetrahedral coordination of the Al in the lamellar phase, suggesting that condensation of the octahedral aluminium species found in the hexagonal phase is an important factor in the phase transformation of this mesostructured aluminium phosphate.

We would like to thank Dr Qisheng Huo for helpful discussions. This research was supported in part by the National Science Foundation under Grant DMR 95-20971.

# Aryl isonitrile binding to $[Fe_4S_4]$ clusters: formation of $[Fe_4S_4]^+$ and $[\{Fe_4S_4\}_2]^{2+}$ cores

**Michael Harmjanz, Wolfgang Saak,* Detlev Haase and Siegfried Pohl†**

*Fachbereich Chemie, Carl-von-Ossietzky Universität Oldenburg, Postfach 2503, D-26111 Oldenburg, Germany*

**Aryl isonitriles (ArNC; Ar = 2,4,6-$Me_3C_6H_2NC$ 1, 2,6-$Me_2C_6H_3NC$ 2) react with $[Fe_4S_4I_4]^{2-}$ 3 and $[Co(\eta\text{-}C_5H_5)_2]$ to afford $[Fe_4S_4I(ArNC)_9]$ 4a, b; substitution of iodide by $RS^-$ (R = 2,4,6-$Me_3C_6H_2$) yields $[Fe_4S_4(SR)(ArNC)_9]$ 5 and reaction of $[Fe_4S_4I(2,4,6\text{-}Me_3C_6H_2NC)_9]$ 4b with $KB(4\text{-}Cl\text{-}Ph)_4$ leads to $[\{Fe_4S_4(2,4,6\text{-}Me_3C_6H_2NC)_9\}_2][B(4\text{-}ClPh)_4]_2$ 6.**

Among the extended class of cuboidal $Fe_4S_4$ clusters, species with octahedrally coordinated iron atoms are rather uncommon. Typical examples with monodentate ligands are the well known $[Fe_4S_4(CO)_{12}]$[1] and the 2:2 site-differentiated clusters $[Fe_4S_4X_2(Bu^tNC)_6]$ (X = Cl, Br, RS).[2,3] Prior to the present work uncharged mixed-ligand clusters of the latter type with an $[Fe_4S_4]^+$ core were unknown. Even though the relevance of these clusters in biological systems is limited, especially 3:1 functionalized $Fe_4S_4$ clusters could serve as models for the examination of biological and non-biological catalytic processes. As demonstrated in this work these clusters also represent versatile starting materials for the formation of Fe–S clusters of higher nuclearity.

As shown elsewhere[2] alkyl isonitriles readily react with $[Fe_4S_4X_4]^{2-}$ clusters (X = Cl, Br) to yield the [2:2] site-differentiated clusters $[Fe_4S_4X_2(RNC)_6]$ containing an $[Fe_4S_4]^{2+}$ core. Aryl isonitriles (ArNC) which have slightly higher π-acceptor abilities than alkyl isonitriles[4] should stabilize lower $[Fe_4S_4]$ oxidation states. However, the complexation of $Fe_4S_4$ clusters by aryl isonitriles had only been realized in $[Fe_4S_4(LS_3)(ArNC)_3]^-$ ($LS_3$ = trithiolate ligand).[3]

When stoichiometric mixtures of the 2,6-dimethylphenylisonitrile **2** and the tetraiodo cluster anion **3** were combined in the presence of stoichiometric amounts of $[Co(\eta^5\text{-}C_5H_5)_2]$ [eqn. (1)] the novel uncharged cluster $[Fe_4S_4I(2,6\text{-}Me_2C_6H_3NC)_9]$ **4a** precipitated together with $[Co(\eta^5\text{-}C_5H_5)_2]I$ and some $N(CH_2Ph)Bu_3I$. The byproducts can easily be removed by washing the crude product with acetonitrile (yield 90%).‡

$$\underset{\mathbf{3}}{[Fe_4S_4I_4]^{2-}} + 9\ \underset{\mathbf{2}}{2,6\text{-}Me_2C_6H_3NC} + [Co(\eta\text{-}C_5H_5)] \rightarrow \underset{\mathbf{4a}}{[Fe_4S_4I(2,6\text{-}Me_2C_6H_3NC)_9]} + 2\ I^- + [Co(\eta\text{-}C_5H_5)_2]I \quad (1)$$

The formation of $[Fe_4S_4I(ArNC)_9]$ **4b** (Ar = 2,4,6-trimethylphenylisonitrile) can also be achieved as well as analogues with sterically less encumbering aryl isonitriles.

The redox behaviour of **4a** has been examined in thf by cyclic voltammetry. Chemically irreversible reduction takes place at −630 mV *vs.* SCE and a quasi-reversible oxidation wave is observed at −90 mV *vs.* SCE ($i_{pa}/i_{pc}$ = 0.95, $E_{pa} - E_{pc}$ = 100 mV). Chemical oxidation of **4a** involving the oxidation state change $[Fe_4S_4I(ArNC)_9]^{0/+}$ was not successful. Investigation of the chemical reduction of **4a** in the presence of excess isonitrile is currently being carried out in this laboratory. This reaction should lead to $[Fe_4S_4(ArNC)_{12}]$.

Substitution reaction at the iodide site can be accomplished by addition of 1 equiv. of mesitylenethiolate to a suspension of **4a** in thf. On filtration and addition of ether $[Fe_4S_4(2,4,6\text{-}Me_3C_6H_2S)(2,6\text{-}Me_2C_6H_3NC)_9]$ **5** precipitates as red needles (yield 68%).‡ The cyclic voltammogram of the thiolate derivative **5** in thf shows an irreversible reduction at −1040 mV, a quasi-reversible oxidation at −240 mV ($i_{pa}/i_{pc}$ = 0.96, $E_{pa} - E_{pc}$ = 70 mV) and a quasi-reversible oxidation at 420 mV *vs.* SCE ($i_{pa}/i_{pc}$ = 1.2, $E_{pa} - E_{pc}$ = 85 mV).

Single crystals of **5** can be obtained by addition of ether to concentrated solutions of **5** in thf. Compound **5** crystallizes as a thf solvate and its structure is shown in Fig. 1. The trigonal distortion of the $[Fe_4S_4]^+$ core originates from the different coordination environments around the iron atoms. One sulfur atom is surrounded by three octahedrally coordinated $Fe^{II}$ and three sulfur atoms by two octahedrally $Fe^{II}$ and one tetrahedrally coordinated $Fe^{III}$. The Fe–S distances form three sets, with three Fe–S bonds at the tetrahedral site Fe(1) (mean 2.247 Å), three at S(3) (mean 2.347 Å) and six at octahedrally coordinated sites Fe(2,3,4) (mean 2.379 Å). The distortion of the $[Fe_4S_4]^+$ core results in three short Fe···Fe distances (mean 3.014 Å) between the octahedrally and tetrahedrally coordinated iron sites and three long Fe···Fe distances between the octahedrally coordinated iron sites (mean 3.481 Å). The latter are comparable with those in $[Fe_4S_4(CO)_{12}]$ (mean 3.466 Å)[1] and imply no bonding interactions between those iron atoms. The iron–thiolate distance in **5** is comparable with those in $[Fe_4S_4(PhS)_2(Bu^tNC)_6]$ (mean 2.281 Å).[2]

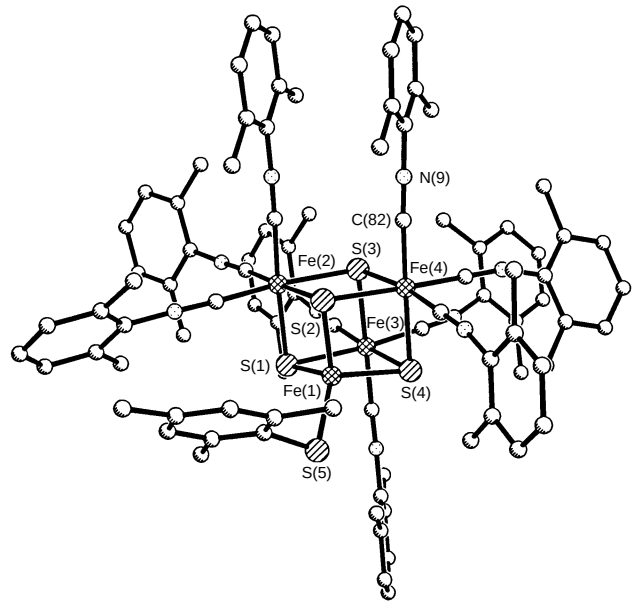

**Fig. 1** Molecular structure of **5** with atom numbering scheme. Selected bond lengths (Å) and angles (°): Fe(1)–S(1) 2.253(2), Fe(1)–S(2) 2.240(2), Fe(1)–S(4) 2.248(2), Fe(1)–S(5) 2.300(2), Fe(1)···Fe(2) 2.9610(10), Fe(1)···Fe(3) 3.078(2) Fe(1)···Fe(4) 3.002(2), Fe(2)–S(1) 2.377(2), Fe(2)–S(2) 2.385(2), Fe(2)–S(3) 2.3459(15), Fe(2)···Fe(3) 3.466(2), Fe(2)···Fe(4) 3.505(2), Fe(3)- S(1) 2.387(2), Fe(3)–S(3) 2.3420(14), Fe(3)–S(4) 2.364(2), Fe(3)···Fe(4) 3.473(2), Fe(4)–S(2) 2.377(2), Fe(4)–S(3) 2.3535(15), Fe(4)–S(4) 2.383(2), Fe–C 1.835 [range 1.820(6)–1.860(6)], C(1)–S(5)–Fe(1) 103.2(2).

A condensation of the 3:1 site-differentiated cluster can easily be achieved upon reaction of $[Fe_4S_4I(2,4,6\text{-}Me_3C_6H_2NC)_9]$ **4b** with stoichiometric amounts of $KB(4\text{-}ClPh)_4$ [eqn. (2); Ar = 2,4,6-$Me_3C_6H_2$].‡

$$\underset{\mathbf{4b}}{2\,[Fe_4S_4I(ArNC)_9]} + 2KB(4\text{-}ClPh)_4 \rightarrow \underset{\mathbf{6}}{[\{Fe_4S_4(ArNC)_9\}_2][B(4\text{-}ClPh)_4]_2} + 2KI \qquad (2)$$

**6** was characterized spectroscopically and the structure of **6** has been established by X-ray structure analysis.§ The differential pulse voltammogram of **6** shows two one-electron reduction steps at −760 and −935 mV *vs.* SCE and two one-electron oxidation steps at 200 and 460 mV *vs*. SCE, respectively.

Apart from the octahedrally ligated iron sites, the core structure of **6** is comparable with the previously synthesized neutral dicubane $[\{Fe_4S_4[P(C_6H_{11})_3]_3\}_2]$.[5] Fe–S dicubane clusters with non-phosphorus ligands are, as yet, not known. Furthermore, $[\{Fe_4S_4(2,4,6\text{-}Me_3C_6H_2NC)_9\}_2]^{2+}$ represents the first dicubane cluster including two charged $[Fe_4S_4]^+$ cores. As shown in Fig. 2 the two $[Fe_4S_4]^+$ cores are linked by two Fe–S bonds forming a central $Fe_2S_2$ rhombus. Compared with $[\{Fe_4S_4[P(C_6H_{11})_3]_3\}_2]$[5] the Fe···Fe distance in **6** [2.766(4) Å] within the central $Fe_2S_2$ unit is elongated [2.681(8) Å)] whereas the Fe–S distances are almost equal {2.285(3) Å, **6**; 2.309(7) Å, $[\{Fe_4S_4[P(C_6H_{11})_3]_3\}_2]$}. Although S(1) is additionally linked with an iron atom [Fe(1a)] of the second cuboidal fragment, the distortion of the $[Fe_4S_4]^+$ fragment from $T_d$ symmetry mainly originates from the two structurally and electronically distinct iron sites. As a consequence the twelve Fe–S distances divide into three sets (3 + 3 + 6) and the Fe···Fe distances into two sets (3 + 3). The mean values of the Fe–S and Fe···Fe distances as well as the Fe–C distances are comparable with those in **5**.

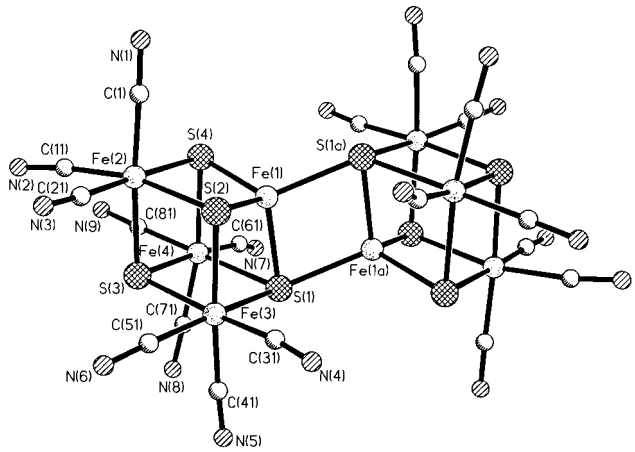

**Fig. 2** Core structure of **6** with atom numbering scheme (arene moiety omitted for clarity). Selected bond lengths (Å) and angles (°): Fe(1)-S(1) 2.253(4), Fe(1)–S(2) 2.219(4), Fe(1)–S(4) 2.215(4), Fe(1)–S(1a) 2.285(3), Fe(1)–Fe(1a) 2.766(4), Fe(1)···Fe(2) 2.934(3), Fe(1)···Fe(3) 2.969(3) Fe(1)···Fe(4) 2.982(3), Fe(2)–S(2) 2.377(4), Fe(2)–S(3) 2.334(4), Fe(2)–S(4) 2.392(4), Fe(2)···Fe(3) 3.470(3), Fe(2)···Fe(4) 3.469(3), Fe(3)–S(1) 2.433(4), Fe(3)–S(2) 2.359(4), Fe(3)–S(3) 2.335(4), Fe(3)···Fe(4) 3.520(3), Fe(4)–S(1) 2.417(4), Fe(4)–S(3) 2.325(4), Fe(4)–S(4) 2.379(4), Fe–C 1.83 [range 1.78(2)–1.88(2)], S(1)–Fe(1)–S(1a) 104.91(12).

§ *Crystal data*: **5**·thf: $C_{94}H_{100}Fe_4N_9OS_5$, $M$ = 1755.53, monoclinic, space group $P2_1/c$, $a$ = 13.802(1), $b$ = 24.633(2), $c$ = 27.829(2) Å, β = 103.93(1)°, $U$ = 9183.2(12) Å$^3$, $T$ = 297(1) K, $Z$ = 4, $D_c$ = 1.270 g $cm^{-3}$, μ(Mo-Kα) = 0.783 $mm^{-1}$. A suitable crystal was mounted on a AED2 Siemens four-circle diffractometer. Data collection using Mo-Kα radiation (λ = 0.710 73 Å) and 2θ scans gave 12789 independent reflections ($\theta_{max}$ 23.01°), of which 9706 with $I > 2\sigma(I)$ were used in all calculations. The structure was solved by direct methods and the solution developed using full-matrix least-squares refinement on $F^2$ and difference Fourier synthesis. Displacement parameters were refined for non-H atoms, H-atoms were included in fixed calculated positions.[8] At convergence, $R$ = 0.0641, $wR_2$ = 0.1541, GOF = 1.182 for 885 parameters.

**6**·MeCN·thf: $C_{234}H_{241}B_2Cl_8Fe_8N_{19}OS_8$, $M$ = 4343.96, triclinic, space group $P\bar{1}$, $a$ = 19.444(8), $b$ = 19.566(6), $c$ = 19.752(7) Å, α = 60.66(4), β = 74.86(3), γ = 61.64(3)°, $U$ = 5760(4) Å$^3$, $T$ = 297(1) K , $Z$ = 1, $D_c$ = 1.252 g $cm^{-3}$, μ(Mo-Kα) = 0.709 $mm^{-1}$, data collection, refinement and solution as above, 10727 independent reflections ($\theta_{max}$ 20.01°), $R$ = 0.1093, $wR_2$ = 0.2419, GOF = 1.195 for 1071 parameters. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/437.

# New strongly coupled dinuclear metal centres in organometallic *s*-indacene complexes

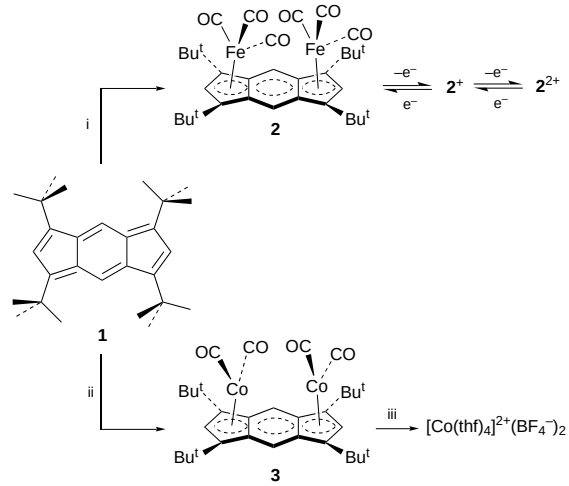
**Douglas R. Cary, Catherine G. Webster, Mark J. Drewitt, Stephen Barlow, Jennifer C. Green and Dermot O'Hare*†**

*Inorganic Chemistry Laboratory, South Parks Road, Oxford, UK OX1 3QR*

**The complexes *cis*-[{Fe(CO)$_3$}$_2$L] and *cis*-[{Co(CO)$_2$}$_2$L] are prepared from 1,3,5,7-tetra-*tert*-butyl-*s*-indacene; in solution, the diiron complexes exhibit very strong electron–electron coupling between iron centres as evidenced by a 810 mV separation between the 0/+ and +/2+ redox waves.**

Oligomers or polymers based on metallocenes bridged by fused-ring ligands such as pentalene or *s*-indacene are anticipated to show interesting delocalised properties.[1,2] Indeed, EPR, Mössbauer, electrochemical and magnetic data show very strong metal–metal interactions in the bimetallic species {L$^1$[M(C$_5$Me$_5$)]$_2$}$^{n+}$ (L$^1$ = pentalene, *s*-indacene; M = Fe, Co, Ni; $n$ = 0, 1 2).[3] However, the stepwise construction of higher oligomers has been hampered by escalating insolubility with increasing oligomerisation.[4] Here we report the use of the stable 1,3,5,7-tetra-*tert*-butyl-*s*-indacene L in the synthesis of new binuclear organometallic derivatives.

According to Hückel's rule, fully conjugated planar polycyclic alkenes with 4$n$ + 2 π-electrons should display benzenoid properties; those with 4$n$ π-electrons are termed antiaromatic.[5] However, it has been shown that some 4$n$ π-systems display 'aromatic character'.[6] *s*-Indacene has an antiaromatic 12 π-electron system and the relationship between its reactivity, aromaticity and stability has been the subject of many studies by theoretical organic chemists. According to LCAO calculations, *s*-indacene should have an electron delocalisation energy similar to that of the tropylium cation, yet the system can be expected to exhibit high reactivity due to the low energy difference of its ground and excited state.[7]



Due to the thermal instability of *s*-indacene, it has been necessary to synthesise more stable substituted derivatives. 1,3,5,7-Tetra-*tert*-butyl-*s*-indacene **1** is kinetically stabilised by the bulky alkyl groups, and has been studied intensively in this respect; its synthesis was briefly outlined by Hafner *et al*.[8]

Refluxing **1** with an excess of [Fe$_2$(CO)$_9$] for 2 h gave an emerald green solution from which dark-green crystals could be obtained by recrystallisation from toluene. Elemental microanalysis and mass spectral data were consistent with the formulation [{Fe(CO)$_3$}$_2$L] **2** (Scheme 1). The room temperature $^1$H and $^{13}$C NMR data indicated that the indacene ligand was complexed to two iron centres in such a way as to produce no change in the local symmetry of the ligand environment. However, the spectroscopic data did not allow us to determine unambiguously the bonding mode of the Fe centres.

The single-crystal X-ray structure determination of **2**‡ revealed that two iron tricarbonyl moieties have been coordinated to the indacene ligand (Fig. 1). This is a rare example of an indacene complex with two metal fragments coordinated to the same face of an indacene ligand. The distances Fe(1) to C(1), C(2), C(3), C(9) and C(10) and the distances Fe(2) to C(5), C(6), C(7), C(11) and C(12) suggest that each iron atom is coordinated to **1** in a very distorted manner. For example, the Fe(1)–C(10) and Fe(2)–C(12) bond lengths are *ca*. 0.11 Å longer than the Fe(1)–C(9) and Fe(2)–C(11) distances, respectively. The average Fe–CO distance is 1.793 Å and is very typical for iron carbonyl complexes. The indacene framework has been distorted in the following manner: the C(1), C(2) and C(3) plane twists [relative to the long $C_2$ axis that is present in the free ligand] so that C(3) becomes closer in space to C(9) than in the free indacene. The distortion also occurs for C(5), C(6) and C(7) plane with C(7) being closer to C(11).

Refluxing **1** with an excess of [Co$_2$(CO)$_8$] in light petroleum (bp 40–60 °C) for 2 h gave a dark-red powder from an orange solution. Dark-red crystals of [{Co(CO)$_2$}$_2$L] **3** could be obtained by recrystallisation of the powder from toluene–pentanes. The single-crystal X-ray structure determination of **3**‡ revealed that two cobalt dicarbonyl units have been coordinated to the same face of **1** (Fig. 2). The distances Co(1)–C(1), Co(1)–C(2), Co(1)–C(3), Co(2)–C(5), Co(2)–C(6) and Co(2)–C(7) are very similar with a mean value of 2.077(2) Å. The two cobalt centres also have longer contacts to the central carbons C(9), C(10), C(11) and C(12) with a mean value of 2.229(2) Å. The average Co–CO distance is 1.738(3) Å.

The solution electrochemistry of **2** and **3** has been investigated in order to gauge the degree of interaction between the two metal centres in these compounds. The cyclic voltammogram (CV) of **2** in dichloromethane clearly shows two reversible waves at $E_{1/2}$ = 0.26 and −0.55 V (*vs.* [Fe(η-C$_5$H$_5$)$_2$]–[Fe(η-C$_5$H$_5$)$_2$]$^+$, in CH$_2$Cl$_2$) corresponding to two successive one-electron transfers *i.e.* oxidation to the mono- and di-cations respectively. The redox waves are separated by 0.81 V, which indicates that the second electron is more difficult to remove than the first. The extremely large value for Δ$E$ is characteristic of strong electronic interactions between the metal centres and extensive delocalisation in the mixed-valence form of the complex. The CV of **3** in CH$_2$Cl$_2$ is much more complex and at moderate scan rates no reversible electrochemical events can be measured.

**Scheme 1** *Reagents and conditions*: i, [Fe$_2$(CO)$_9$] (1.2 mol equiv.), toluene, 2 h reflux, 67%; ii, [Co$_2$(CO)$_8$] (1.2 mol equiv.), light petroleum (bp 40–60 °C), 2 h reflux, 75%; iii, AgBF$_4$ (2 mol equiv.), thf, room temp.

Density functional theory (DFT) has been used to try and rationalise the bonding of the indacene moiety to the $Fe(CO)_3$ and $Co(CO)_2$ metal fragments. Indacene has six occupied π orbitals which bear a close resemblance to linear combinations of the occupied orbitals of two cyclopentadienyl anions, though they include contributions from the π-orbitals of the two central carbons where symmetry allows, *i.e.* for the $b_{1u}$ and $b_{2g}$ combinations. Normal electron counting procedures for **2** and **3**, including all π electrons of the indacene ligand, result in an electron count of 40 for **2** and 38 for **3** for these binuclear systems, four and two electrons in excess of that required for two 18 electron metal centres.

Density functional calculations, including geometry optimisations, have been carried out for both $[Fe_2(CO)_6(C_{12}H_8)]$ **4** and $[Co_2(CO)_4(C_{12}H_8)]$ **5** using a generalised gradient approximation as implemented in the Amsterdam density functional code.[9] Initially the symmetries of **4** and **5** were constrained to $C_{2v}$ symmetry, but subsequently the optimisation was carried out in each case with a constraint of $C_2$ symmetry. In the case of **4** relaxation of the symmetry constraint to $C_2$ led to an optimised geometry with a bond length pattern and buckling of the ring close to that found for **2**. For **5** there was little departure from $C_{2v}$ symmetry for the optimised structure as was found experimentally for **3**.

In the case of **4** both the HOMO ($a_1$ in $C_{2v}$) and the SOMO ($b_1$ in $C_{2v}$) are mainly localised on the metals and the two indacene central carbons, C(4) and C(8). The interaction between the metals and these carbons is antibonding. We suggest that it is the occupancy of these two orbitals by the four excess electrons that leads the metals to be closer to the outer carbons and drives the structural distortion with the consequent relief of the antibonding character of these interactions. Both the HOMO and SOMO are stabilised on distortion, the SOMO more than the HOMO. Lower energy orbitals conform to the expectations for three legged piano stools. In the case of **5** the HOMO is of $b_2$ symmetry, with a node at the central indacene carbons, and metal indacene antibonding though metal CO bonding. The antibonding interaction is evenly distributed along the indacene and leads to less displacement towards the outer carbons than found in **4** and no obvious distortion.

We believe that the indacene ligand will be able to form π complexes with a wide range of metal fragments. The extensive π-electron delocalisation of the ligand orbitals means that the metal centres will be able to interact strongly with each other.

We thank the EPSRC for support, studentships (M. J. D and S. B.) and Mass Spectrometry Services (University of Wales, Swansea). We would also like to thank Dr A. N. Chernega and Grant Taylor for their assistance with crystallography and NMR, respectively.

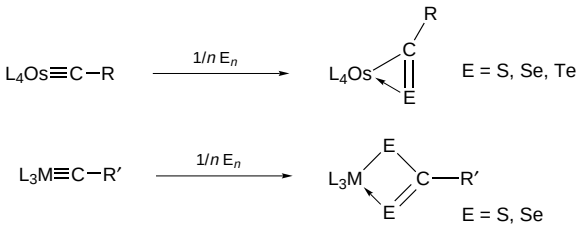
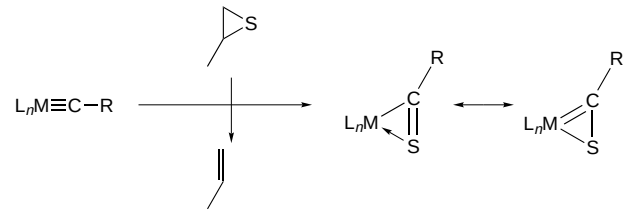
# Thioacyl complexes of molybdenum and tungsten

**Darren J. Cook and Anthony F. Hill***



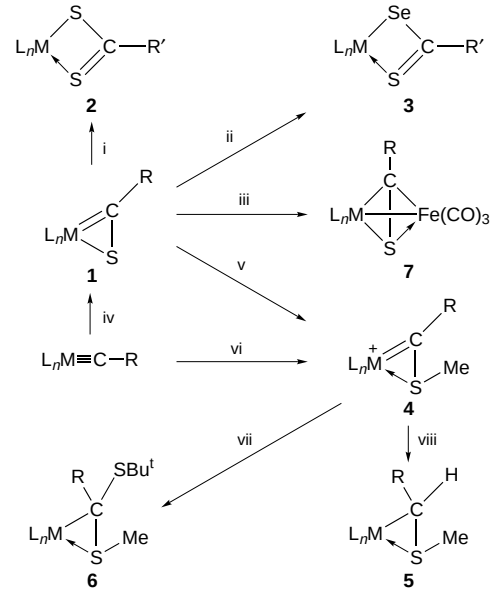
*Department of Chemistry, Imperial College of Science Technology and Medicine, South Kensington, London, UK SW7 2AY*

**The reactions of a range of alkylidyne complexes of molybdenum and tungsten [M(≡CR)$L_n$] with 2-methylthiirane provide the first thioacyl complexes [M(η²-SCR)$L_n$] of these elements, which serve as precursors for complexes bearing dithiocarboxylate, thioselenocarboxylate, thiolatocarbene and α-thioalkyl ligands and thioacyl-bridged binuclear complexes.**



The addition of chalcogens to the metal–carbon multiple bonds of alkylidyne complexes takes one of two courses depending on the metal centre (Scheme 1):[1] Roper and coworkers originally showed that elemental chalcogens add once to group 8 toluidyne complexes to provide chalcotoluoyl ligands.[2] Alkylidyne complexes of molybdenum and tungsten, however, add sulfur or selenium twice to provide dichalcocarboxylate complexes,[3] which Kreißl subsequently obtained from the reaction of these precursors with cyclohexene sulfide.[4] Whilst no intermediate thio- or seleno-acyl complexes have been observed or isolated from these reactions, even for sterically congested systems,[5] Kreißl has shown that [W(η²-$S_2CC_6H_4$Me)-$(CO)_2$(η-$C_5H_5$)] reacts with $PMe_3$ to provide the adduct [W{η²-SC($PMe_3$)$C_6H_4$Me}$(CO)_2$(η-$C_5H_5$)].[6] We have recently shown that thiobenzoyl complexes of ruthenium are obtained from the reaction of [Ru(≡CPh)Cl$(CO)(PPh_3)_2$] with $CS_2$ or isothiocyanates,[7] a result which further prompted our curiosity as to why these ligands appear to be disfavoured for group 6 metals. We report herein that thioacyl complexes of molybdenum and tungsten are indeed accessible and that they are useful precursors to a wide range of mono- and di-nuclear complexes.

Under careful control of reagent stoichiometry and reaction conditions, we find that the alkylidyne complexes shown in Scheme 2 react cleanly with 2-methylthiirane to provide the corresponding thioacyl complexes. The formulation follows from spectroscopic data† and their subsequent reactions with sulfur or excess propylene sulfide to provide the appropriate dithiocarboxylate complex. Most notable amongst these data are the $^{13}C$ NMR chemical shifts for the thioacyl carbon which typically appear in the range δ 260–280, this being to slightly higher field of those previously observed for group 8 metals (δ *ca*. 310).[2,7] Scheme 2 also indicates some instances where this reaction fails: notably alkylidyne complexes of chromium, sterically congested benzylidyne complexes and aminomethylidyne complexes. This last result is perhaps surprising given that thiocarboxamide complexes have been prepared by alternative strategies and are stable and robust species.[8] The M–C multiple bond of aminomethylidyne complexes is, however, well known to be comparatively unreactive.[1] Finally for completeness, it should be noted that ruthenium benzylidynes also react with 2-methylthiirane to provide thiobenzoyl complexes, although this approach offers no advantage over the use of elemental sulfur.



All of the thioacyl complexes obtained are somewhat thermally and photolytically sensitive both as solids and in solution. Nevertheless, these compounds serve as useful precursors for a number of transformations, some of which are summarised in Scheme 3. These include (*i*) the synthesis of mixed thioselenocarboxylate ligands (to our knowledge previously unknown), *e.g.* [Mo(η²-SSeC$C_6H_4$OMe-4)$(CO)_2$-{HB($pz)_3$}] **3** (pz = pyrazol-1-yl); (*ii*) alkylation at sulfur to provide bidentate thiolatocarbene complexes, *e.g.* [Mo(η²-MeSC$C_6H_4$OMe)$(CO)_2${HB($pz)_3$}]$BF_4$ **4**‡ which may be converted to bidentate α-thiolatoalkyl or α,α-bis(thiolato)alkyl

**Scheme 1** Chalcogen addition to alkylidynes of group 6 and 8 metals. R = $C_6H_4$Me-4; R′ = $C_6H_4$Me-4, $CH_2Bu^t$; $L_4Os$ = OsCl$(CO)(PPh_3)_2$;[2] $L_3M$ = Mo{$P(OMe)_3$}$_2$(η-$C_5H_5$), W$(CO)_2$(η-$C_5H_5$).[3]

**Scheme 2** R = Ph, $C_6H_4$Me-4, $C_6H_4$OMe-4, 2-$C_4H_3S$; $L_nM$ = MoBr-(bipy)$(CO)_2$, Mo$(CO)_2${HB($pz)_3$}, WBr(bipy)$(CO)_2$, W$(CO)_2${HB($pz)_3$}, RuCl$(CO)(PPh_3)_2$ (not all combinations). Reaction fails for: R = $C_6H_2Me_3$-2,4,6, $NPr^i_2$; $L_nM$ = CrBr(bipy)$(CO)_2$, MoBr$(CO)_2$(tmeda), MoBr(pico-line)$_2(CO)_2$].

**Scheme 3** R = $C_6H_4$OMe-4; $ML_n$ = Mo$(CO)_2${HB($pz)_3$}. *Reagents and conditions* (25 °C): i, $S_8$ or $C_3H_6S$, $CH_2Cl_2$; ii, Li[$Et_3BH$] : $Se_8$ = 8 : 1, thf; iii, [$Fe_2(CO)_9$] thf; iv, $SC_3H_6$, $CH_2Cl_2$; v, [$Me_3O$]$BF_4$ $CH_2Cl_2$; vi, [$MeSSMe_2$]$BF_4$, $CH_2Cl_2$; vii, $HSBu^t$, DBU, $CH_2Cl_2$; viii, Li[$BHEt_3$], thf.

complexes with Li[BHEt$_3$] or *tert*-butylthiolate, respectively,§ *e.g.* the complexes [Mo{η$^2$-MeSCHC$_6$H$_4$OMe-4}(CO)$_2$-{HB(pz)$_3$}] **5** and [Mo{η$^2$-MeSC(SBu$^t$)C$_6$H$_4$OMe-4}(CO)$_2$-{HB(pz)$_3$}] **6**; (*iii*) bridge-assisted metal–metal bond formation providing the bimetallic complex [MoFe(μ-SCC$_6$H$_4$OMe-4)(CO)$_5${HB(pz)$_3$}] **7**.[11]

The results above show that the previous unavailability of thioacyl complexes of group 6 metals has been due to a lack of suitable synthetic strategy rather than any intrinsic instability in the 'metallathiirene' unit. Furthermore, preliminary studies of the reactivity of these ligands, once constructed, clearly indicate considerable synthetic utility, a feature we are investigating further.

We wish to thank the Engineering and Physical Sciences Research Council (UK) for the award of a studentship (to D. J. C.) and Royal Society for financial support.

# Synthesis and X-ray crystal structure of a novel neutral trinuclear copper(II) hydridotris(3,5-dimethylpyrazolyl)borate complex with 1,1-azido bridges

**Michael H. W. Lam,*[a] Yan-Yee Tang,[a] Ka-Man Fung,[a] Xiao-Zeng You[b] and Wing-Tak Wong[c]**

[a] *Department of Biology & Chemistry, City University of Hong Kong, Tat Chee Ave, Kowloon Tong, Hong Kong*
[b] *Coordination Chemistry Institute, Nanjing University, PR China*
[c] *Department of Chemistry, University of Hong Kong, Pokfulam Road, Hong Kong*

**The X-ray crystal structure and magnetic properties of a neutral trinuclear 1,1-azido bridged copper(II) complex [LCu(μ-$N_3$)$_2$Cu(μ-$N_3$)$_2$CuL] 2 [L = hydridotris(3,5-dimethylpyrazolyl)borate], produced from the reaction between [$Cu_3L_2$]Cl 1 and an excess of trimethylsilyl azide, are reported.**

Recent interest in copper hydridotris(pyrazolyl)borate complexes has been aroused by its resemblance to active sites in some copper-containing metalloproteins[1] and their catalytic properties towards cyclopropanation and aziridination.[2] In this work, we report the reaction between [$Cu_3L_2$]Cl **1**† and trimethylsilyl azide in polar solvents such as acetone and methanol which gives a neutral trinuclear copper(II) hydridotris(3,5-dimethylpyrazolyl)borate complex, [LCu(μ-$N_3$)$_2$Cu(μ-$N_3$)$_2$CuL] **2**,‡ containing four 1,1-azido bridges. To the best of our knowledge, with the exception of one structure containing an infinite chain of $Cu^{II}$–$N_3$ units[3] and a recently reported hexanuclear copper(II) complex with 1,3-azides,[4] all reported copper(II)–μ-azido systems were binuclear.[5]

Complex **1** is obtained by slow addition of 0.5 equiv. of ligand KL to a suspension of copper(I) chloride in acetone. Such an approach is adopted in order to prevent formation of a copper(I)–polypyrazolylborate dimer.[6] The pink–white solid **1** is air-stable but its dichloromethane solution is air-sensitive. FABMS of **1** (noba matrix) gives the highest mass ion at *m/z* 785. This suggests that **1** possesses an oligomeric structure of two L ligands and three Cu metal ions. A trinuclear structure (Fig. 1) is proposed in which each $Cu^{I}$ is coordinated to two 3,5-dimethylpyrazolyl units from two L ligands. $^1$H NMR (300 MHz, $CD_2Cl_2$) of **1** supports the proposed structure. Three sets of protons in 3 : 3 : 1 ratio are observed which can be assigned as follows: δ 1.65 (s, 18 H, pyrazolyl-$CH_3$), 2.42 (s, 18 H, pyrazolyl-$CH_3$) and 5.92 (s, 6 H, pyrazolyl-H). To the best of our knowledge, complex **1** represents a new mode of coordination for the well studied copper(II)–polypyrazolylborate system.

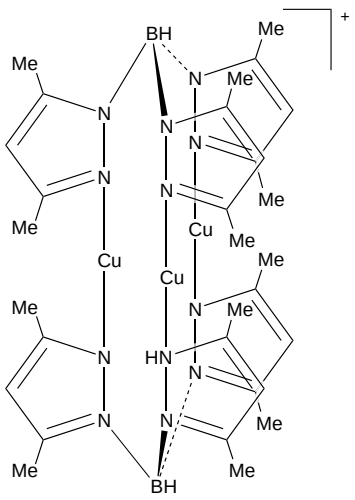

**Fig. 1** The proposed structure of **1**

Complex **2** is obtained by the addition of trimethylsilyl azide to a suspension of **1** in a polar solvent such as acetone or methanol. The ν(B–H) stretch of L in complexes **1** and **2** is observed at 2526 and 2528 $cm^{-1}$, respectively. The asymmetric ν($N_3$) stretch of **2** is found at 2075 $cm^{-1}$ which is consistent with the presence of 1,1-bridging azides. The structure of **2** is shown in Fig. 2.§ The structure contains a square-planar central $Cu^{II}$ and two distorted square-pyramidal terminal $Cu^{II}$ atoms. The molecule is centrosymmetric with only half of the molecule crystallographically independent. The hydridotris(3,5-dimethylpyrazol-1-yl)borate acts as a tripodal ligand coordinating to the terminal $Cu^{II}$ with bond distances and angles (1.96–2.18 Å, 86.9–92.0°) comparable to known copper(I) polypyrazolylborate complexes.[1f,g,6] The three $Cu^{II}$ atoms are bridged by four 1,1-azides with a $Cu^{II}$–N(azido) average distance of 1.99 Å. The average Cu–N(azido)–Cu angle is 101.4° and are typical for the 1,1-azido copper moiety.[5a,c] The μ-azides are considered symmetrical with N–N bond distances of 1.15(2)–1.20(2) Å. The N–N–N angles are all 179.0(3)°. The average Cu···Cu distance is 3.05 Å.

It is known that magnetic orbital interactions between the $Cu^{II}$ ions in many binuclear 1,1-azido systems result in ferromagnetic coupling.[5a,c] However, this is not observed in our trinuclear system (Fig. 3). The $\chi_M T$ is found to be independent of temperature throughout the temperature range of 75.5–300 K. The $\chi_M^{-1}$ *vs.* $T$ variation of **2** shows typical Curie–Weiss behaviour with a Curie constant of 1.34 $cm^3$ K $mol^{-1}$ and a Weiss temperature, θ, of −0.20 K. The $\mu_{eff}$ of **2** within the

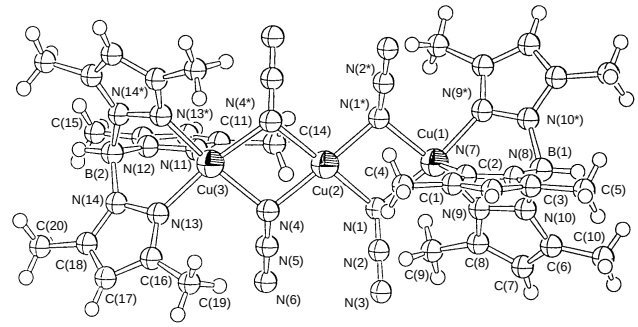

**Fig. 2** Perspective view of [LCu(μ-$N_3$)$_2$Cu(μ-$N_3$)$_2$CuL] **2**. Selected bond lengths (Å) and angles (°): Cu(1)–N(1) 2.03(1), Cu(1)–N(7) 2.15(2), Cu(1)–N(9) 1.96(1), Cu(2)–N(1) 1.95(1), Cu(2)–N(4) 1.96(1), Cu(3)–N(4) 2.00(1), Cu(3)–N(11) 2.18(2), Cu(3)–N(13) 1.96(1), N(1)–N(2) 1.20(2), N(2)–N(3) 1.15(2), N(4)–N(5) 1.18(2), N(5)–N(6) 1.17(2), Cu(1)···Cu(2) 3.082(3), Cu(2)···Cu(3) 3.63(3); N(1)–Cu(1)–N(1*) 76.2(8), N(7)–Cu(1)–N(9) 92.0(5), N(9)–Cu(1)–N(9*) 86.9(7), N(1)–Cu(2)–N(4) 101.0(5), N(1)–Cu(2)–N(4*) 177.5(7), N(4)–Cu(3)–N(4*) 76.2(7), N(11)–Cu(3)–N(13) 91.9(4), N(13)–Cu(3)–N(13*) 87.6(7), Cu(1)–N(1)–Cu(2) 101.5(6), Cu(2)–N(4)–Cu(3) 101.2(6), N(1)–N(2)–N(3) 179(3), N(4)–N(5)–N(6) 179(2).

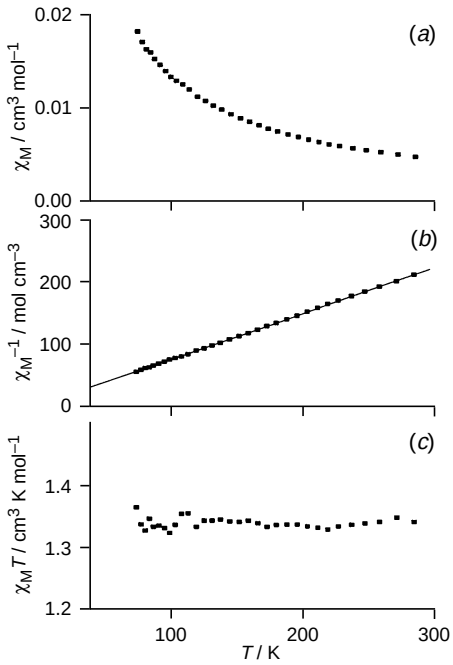

**Fig. 3** Magnetic properties of **2**: (*a*) temperature dependence of $\chi_M$; (*b*) $\chi_M^{-1}$ *vs. T*, the solid line is the best fit for the Curie–Weiss behaviour, $\chi = C/(T - \theta)$, with $C = 1.34$ cm$^3$ K mol$^{-1}$ and $\theta = -0.20$ K; (*c*) temperature dependence of the product $\chi_M T$

above temperature range is found to be fairly constant at *ca.* 3.3 $\mu_B$. These indicate a weak antiferromagnetic coupling[5e,7] among adjacent $Cu^{II}$ centres in **2**. The magnetic properties of this trinuclear 1,1-azido bridged copper(II) system will be further studied.

We would like to acknowledge the City University of Hong Kong for supporting this work.

† **1** was synthesized by slow addition of an acetone solution of potassium tris(3,5-dimethylpyrazolyl)borohydride (0.5 equiv.) to a suspension of copper(I) chloride in acetone under a nitrogen atmosphere. The resultant pink–white suspension was allowed to stir at room temp. in darkness under a nitrogen atmosphere for 12 h. The crude product of **1** was collected by filtration and was washed with diethyl ether. Yield 60%. IR (cm$^{-1}$): 2526 ν(B–H). $^1$H NMR (300 MHz, $CD_2Cl_2$) and FABMS (NOBA matrix) data: see text. The crude product was used in subsequent synthesis without further purification.

‡ **2** was synthesized by addition of 0.45 g of trimethylsilyl azide to a suspension of 0.50 g of **1** in 20 ml methanol in open atmosphere. The suspension immediately turned yellow–green. Further stirring at room temp. (8 h) yielded a green–brown precipitation of crude **2** which was collected by filtration and washed with diethyl ether. Yield 35%. X-Ray quality crystals of **2** were obtained by slow diffusion of diethyl ether into a dichloromethane solution. IR (cm$^{-1}$): 2522 ν(B–H), 2075 ν($N_3$). Satisfactory elemental analysis.

§ *Crystal data*; $C_{30}H_{52}B_2Cu_3N_{24}$ **2**, $M = 961.16$, monoclinic, space group $P2_1/m$ (no. 11), $T = 296$ K, $a = 8.036(2)$, $b = 13.232(3)$, $c = 23.407$ Å, $\beta = 94.41(1)°$, $U = 2481.7(7)$ Å$^3$, crystal size 0.22 × 0.23 × 0.33 mm, $Z = 2$, $D_c = 1.286$ g cm$^{-3}$, $F(000) = 994.00$, graphite monochromated Mo-Kα radiation, $\lambda = 0.71069$ Å, $\mu = 13.22$ cm$^{-1}$, of 3711 reflections, 3428 were unique with $R_{int} = 0.058$; the structure was solved by Patterson methods (DIRDIF92 PATTY) and refined by full-matrix least squares, function minimized: $\Sigma w(|F_o| - |F_c|)^2$ where $w = [\delta_c^2(F_o) + (p^2/4)(F_o)^2]^{-1}$, residuals: $R = 0.054$, $R_w = 0.056$. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. ***trans*-$[Pd(C_6H_4NH_2\text{-}2)I(PPh_3)_2]$ reacts with CO to give the insertion product *trans*-$[Pd\{C(O)(C_6H_4NH_2\text{-}2)\}(PPh_3)_2]O_3SCF_3$ or, in the presence of atmospheric oxygen, $[(PPh_3)_2Pd(NH_2C_6H_4CO_2\text{-}2)Pd\{C(O)C_6H_4NH_2\text{-}2\}(PPh_3)]O_3SCF_3$, whose crystal structure is solved.**

2-Aminophenylpalladium complexes appear to be intermediates in the palladium-catalysed formation of nitrogen-containing heterocycles from *o*-iodo- or *o*-bromo-anilines and, for example, alkynes,[1] dienes,[2] or vinyl cyclopropanes and cyclobutanes,[3] as well as in intramolecular cascade cyclisations.[4] Recently, a one-pot palladium catalysed synthesis of 2-aryl and 2-vinyl-4*H*-3,1-benzoxazin-4-ones from 2-iodoaniline, carbon monoxide and unsaturated halides or triflates has been reported.[5] These results have prompted us to try to isolate intermediates in such carbonylation reactions and to study their reactivity in order to gain more insight into the mechanism of the palladium-catalysed carbon–carbon bond formation.[6] Palladium-catalysed carbonylation of aryl halides and allylic compounds has been shown to occur through (acyl)palladium complexes.[7]

*o*-Iodoaniline reacts with $Pd(dba)_2$ in the presence of 2 equiv. of $PPh_3$ to give *trans*-$[Pd(C_6H_4NH_2\text{-}2)I(PPh_3)_2]$ **1**. When carbon monoxide is bubbled through dichloromethane solutions of **1**, the insertion product *trans*-$[Pd\{C(O)(C_6H_4NH_2\text{-}2)\}I(PPh_3)_2]$ **2** is formed and isolated as a moisture-stable solid (Scheme 1, step i). When complex **2** was reacted with $TlO_3SCF_3$, the dimer $[(PPh_3)_2Pd(NH_2C_6H_4CO_2\text{-}2)Pd\{C(O)C_6H_4NH_2\text{-}2\}(PPh_3)]O_3SCF_3$ **4** was isolated instead of the expected $[Pd\{C(O)C_6H_4NH_2\text{-}2\}(PPh_3)_2]O_3SCF_3$ **3** (Scheme 1, step ii). This product can be viewed as resulting from the replacement of the $PPh_3$ ligand *trans* to the carbonyl group in **3**, for the complex $[Pd\{OC(O)C_6H_4NH_2\text{-}2\}(PPh_3)_2]O_3SCF_3$ **5**. The displaced $PPh_3$ appears in solution as $OPPh_3$ ($^{31}P$ NMR).

Both **3** and **5** can be independently isolated. Thus, if **1** is reacted with $TlO_3SCF_3$ under an atmosphere of CO the expected complex **3** is isolated (Scheme 1, step iii). It is reasonable to assume that **3** is an intermediate in the formation of **4**. In fact, when a solution of **3** is stirred in the open air it transforms into **4** (Scheme 1, step iv).

Contrary to the above mentioned relationship between complexes **3**, **4** and **5**, complexes **3** and **5** do not react with each other. This observation, and the formation of $OPPh_3$, can be interpreted assuming that the oxidation occurs not only on the benzoyl group but also on $PPh_3$ while it is still coordinated. We assume that this process occurs by formation of a peroxobenzoyl complex **6** which interacts with the phosphine *trans* to the carbonyl group in **3**, as depicted in Scheme 1. By reacting **3** or **4** with $PPh_3$ in the presence of oxygen, complex **5** can be isolated. These results can be explained by the cyclic process shown in Scheme 1.

The formation of organoperoxometal, ROO[M], complexes by insertion of $O_2$ into a R–[M] bond has been described.[8] However, we are not aware of such a process with an acyl transition–metal complex such as **3**. Di(acyl)nickel(II) complexes are proposed to be intermediates in reactions of benzyne $Ni^0$ complexes with CO in the presence of traces of air giving phthalatonickel(II) complexes.[9] Photolysis of $Me_3SiC(O)R$ (R = H, Me, Ph) in $O_2$-doped argon matrices gives mainly $Me_3SiOOC(O)R$.[10] Both these results are in accordance with our proposal for the intermediate **6** in Scheme 1. With a less oxophilic metal ion like $Pd^{II}$, the insertion of oxygen into the metal–carbon bond requires stronger oxidizing agents.[11] In addition, peroxo-palladium(II) and platinum(II) complexes $[M(R)(OOR')L_2]$ (M = Pd, Pt; R = activated alkyl; R′ = H, Bu$^t$; L = phosphine),[12] or $[Pt\{OOC(O)Ph\}Cl(PPh_3)_2]$,[13] have

**Scheme 1** L = $PPh_3$. *Reagents and conditions:* i, + 2 CO (1 atm.); ii, + 2 $TlO_3SCF_3$ + $O_2$ − 2 TlI − $OPPh_3$; iii, + 2 $TlO_3SCF_3$ + 2 CO (1 atm.) − 2 TlI; iv, + $O_2$ − $OPPh_3$; v, + $O_2$ + $PPh_3$ − $OPPh_3$; vi + $O_2$ + 2 $PPh_3$ − $OPPh_3$

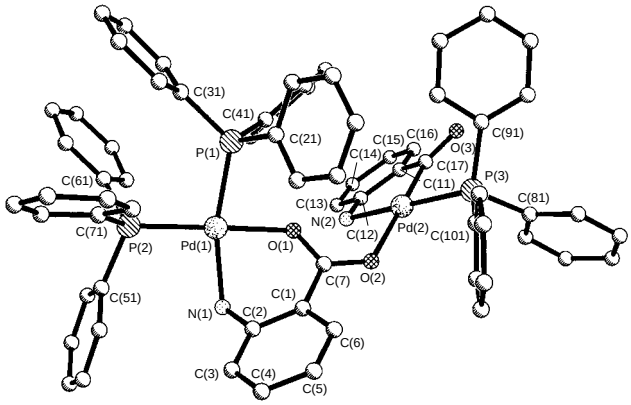

**Fig. 1** Structure of complex **3**. Hydrogen atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): Pd(1)–O(1) 2.074(2), Pd(1)–N(1) 2.116(3), Pd(2)–C(17) 1.959(3), Pd(2)–N(2) 2.129(3), Pd(2)–O(2) 2.165(2), O(1)–C(7) 1.284(4), O(2)–C(7) 1.247(4), O(3)–C(17) 1.209(4); O(1)–Pd(1)–N(1) 81.35(10), N(1)–Pd(1)–P(2) 96.96(8), O(1)–Pd(1)–P(1) 84.59(7), P(2)–Pd(1)–P(1) 97.45(3), C(17)–Pd(2)–N(2) 83.22(13), N(2)–Pd(2)–O(2) 93.14(10), C(17)–Pd(2)–P(3) 90.83(11), O(2)–Pd(2)–P(3) 92.71(7), O(2)–C(7)–O(1) 122.0(3).

been shown to react with free $PPh_3$ to give $OPPh_3$ but not with coordinated phosphines, as occurs in our case.

Acylpalladium(II) complexes are obtained by reacting CO with alkyl-,[7,14–16] π-allyl,[14] or arylpalladium(II)[17] complexes. There are few reported palladium complexes with a phosphine *trans* to an acyl group, however, they are too unstable to be isolated as pure compounds.[16,18] Therefore, as far as we are aware, complex **3** is the first isolated complex containing such ligands in *trans* positions. We believe that the mutual destabilizing effect of carbon and phosphorus ligands in *trans* positions is responsible for the instability of these complexes, the facile oxygen insertion in complex **3**, and the oxidation of the phosphine *trans* to the carbonyl group. We have found that such *trans*phobia[19] leads to C–P bond coupling processes,[20] and believe it is also responsible for other important C–C and C–N coupling reactions.

The isolated complexes **1**–**5** have been fully characterized by C, H, N analyses, IR spectroscopy and $^1$H, $^{31}$P and $^{13}$C NMR (Supplementary material). The X-ray crystal structure of complex **3** (the cation of which is shown in Fig. 1 and Scheme 1),¶ shows it to be dimeric with the *o*-aminobenzoato ligand bridging, *via* the O atoms of the carboxylate group, the two metal centres. The square-planar geometry of the palladium atoms is fulfilled, in the case of Pd(1), by two phosphine ligands and the N and O atoms of the *o*-aminobenzoato group, and for Pd(2) the other O atom of this ligand, one phosphine and the *o*-aminobenzoyl ligand. All bonding distances and angles are unremarkable.

# Fluorocyclohexane ring inversion in a solid thiourea inclusion compound studied by fluorine-19 magic-angle spinning NMR with high-power proton decoupling

**Alison Nordon,[a] Robin K. Harris,*[a] Lily Yeo[b] and Kenneth D. M. Harris[b]**

[a] *Department of Chemistry, University of Durham, South Road, Durham, UK DH1 3LE*
[b] *School of Chemistry, University of Birmingham, Edgbaston, Birmingham, UK B15 2TT*

**Variable-temperature $^{19}F$ magic-angle spinning NMR experiments involving high-power proton decoupling are used to examine the conformational preference and ring-inversion kinetics in the fluorocyclohexane–thiourea inclusion compound.**

One of the most interesting and potentially important aspects of solid-state inclusion chemistry is the fact that the behaviour of molecules constrained as guests within a solid host structure is often very different from the behaviour of the same molecules in other environments (such as in their pure crystalline phase, in dispersed phases, or as guests in other host structures). In this regard, the conformational properties of substituted cyclohexane guest molecules can provide a sensitive probe of the structural constraints imposed by a solid host structure, and form a basis for comparison between different types of host structure. Thiourea forms solid inclusion compounds with cyclohexane and certain substituted cyclohexanes. In such compounds, the thiourea (host) structure contains tunnels in which the guest molecules reside.[1,2] Thiourea inclusion compounds containing mono- and di-substituted cyclohexane guests have been the subject of a number of studies. Much of the interest concerns the conformational dependence of the cyclohexane ring in the thiourea tunnels upon the substituent (X). For monosubstituted cyclohexanes with X = Me, $NH_2$ and OH, the equatorial conformer predominates. In comparison, when X = Cl, Br and I, the axial conformer predominates. Many of these results have been obtained using solid-state $^{13}C$ NMR spectroscopy.[3–5] In this study we have used $^{19}F$ NMR, with high-power proton decoupling, to examine the fluorocyclohexane–thiourea inclusion compound. Previous studies[4,5] indicate that in this system, both conformations of fluorocyclohexane are present in equal proportions. Fluorine-19 NMR has a considerable advantage over $^{13}C$ NMR, namely its greatly superior sensitivity. However, because of the close proximity of the $^{1}H$ and $^{19}F$ frequencies (within 6%) and the high powers required for decoupling in the solid state, a specially designed 'HF' probe[6,7] is needed, so that until very recently $^{19}F$ MAS NMR has been little used for systems containing both fluorine and hydrogen.[8]

Fluorine-19 MAS NMR spectra were recorded with a Chemagnetics CMX 200 NMR spectrometer operating at 200.13 MHz for $^{1}H$ and 188.28 MHz for $^{19}F$. A Chemagnetics HF double-resonance probe was used which accepts 4 mm o.d. zirconia rotors fitted with a Vespel end-cap, spacer and drive tip. Typical spectral conditions were: $\pi/2$ pulse duration, 3 μs; pulse delay, 60 s; $^{1}H$ decoupling power, 105 kHz; spin rate, 7.0 kHz. Variable-temperature operation involved passing cool nitrogen gas over the sample. Temperatures were calibrated using tetrakis(trimethylsilyl)silane soaked in liquid methanol.[9] Fluorine-19 chemical shifts were referenced externally, by rotor replacement, to hexafluorobenzene ($\delta$ −166.4 with respect to $CFCl_3$). The $^{19}F$ chemical shifts obtained from experiments involving $^{1}H$ decoupling have been corrected for the Bloch–Siegert effect.[10]

At room temperature, a single resonance was observed in the $^{19}F$ MAS NMR spectrum. However on lowering the temperature, this resonance broadened and then sharpened to give two peaks of approximately equal intensity at 177 K (Fig. 1). This can be attributed to the well documented ring-inversion process in cyclohexane type molecules. The resonances at $\delta$ −163.9 and −187.0 at 177 K can be assigned to the equatorial and axial conformers respectively using solution-state NMR data.[11] To investigate the kinetics of the ring-inversion process, bandshape analysis was carried out assuming a two-site exchange model. This involved comparing 'by eye' the simulated and experimental data. Bandshape analysis shows that upon increasing the temperature there is a very slight shift in the equilibrium position towards the axial conformer. To demonstrate that ring-inversion occurs on the NMR timescale at temperatures well below coalescence, a two-dimensional $^{19}F$ exchange[12] spectrum was recorded at 227 K. With a mixing time of 50 ms, all four peaks are of equal intensity, indicating that exchange is complete. Away from the coalescence temperature, bandshapes are insensitive to the ring-inversion rate constant, so $^{19}F$ selective polarisation inversion experiments[13] were carried out at 217, 197 and 177 K. The method for selectively inverting one of the resonances involved offsetting the transmitter from one peak by a frequency equal to the

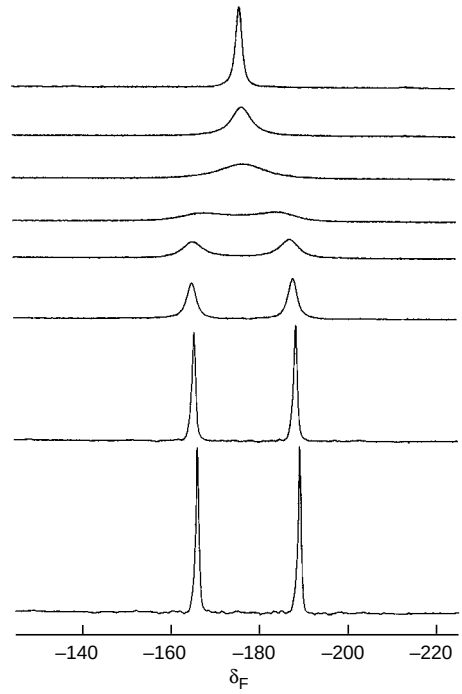

**Fig. 1** Variable-temperature $^{19}F$ MAS NMR spectra, acquired with $^{1}H$ decoupling, of the fluorocyclohexane–thiourea inclusion compound. From bottom to top: 177, 217, 237, 247, 258, 268, 278, 300 K.

separation between the two peaks.[14] Exchange between the two sites was monitored by varying the mixing time, and the results of the experiment performed at 197 K are shown in Fig. 2.

The rate constants determined by the two methods were used to study the thermodynamics of the ring-inversion process. The average activation parameters obtained from an Eyring plot are: $\Delta H^{\ddagger} = 39.4 \pm 2.6$ kJ mol$^{-1}$, $\Delta S^{\ddagger} = -11.9 \pm 11.0$ J mol$^{-1}$ K$^{-1}$ and $\Delta G^{\ddagger}$ (263 K) = 42.5 ± 5.5 kJ mol$^{-1}$. The values that we have obtained for $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ differ from those reported using $^{13}$C NMR in a previous study,[5] although data for $\Delta G^{\ddagger}$ (263 K) are comparable. However, we have studied the ring-inversion process over a wider temperature range (120 K) using the sensitivity advantage of $^{19}$F NMR, and have obtained, with selective polarisation inverson, rate constants in the slow-exchange regime where bandshape analysis lacks precision. For this reason we believe that the studies reported here have led to significantly improved values for the activation parameters.

We have demonstrated that $^{19}$F NMR can be used to probe the ring-inversion process in the fluorocyclohexane–thiourea inclusion compound in the same way that $^{13}$C NMR has been used to investigate other substituted cyclohexane–thiourea inclusion compounds. However, the greater sensitivity of $^{19}$F NMR in comparison to $^{13}$C NMR enables spectra to be obtained in shorter times and hence two-dimensional experiments are more feasible, particularly at low temperatures.

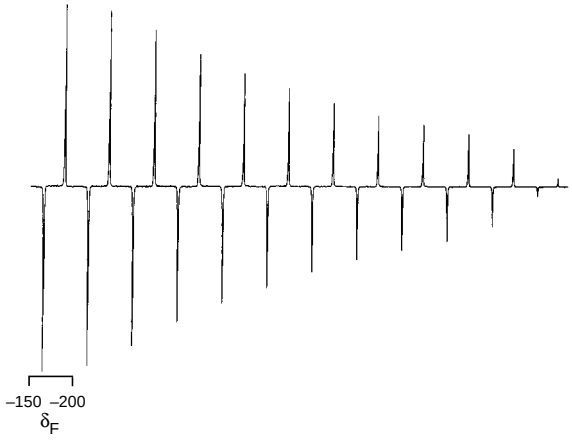

**Fig. 2** Fluorine-19 selective polarisation inversion experiment at 197 K, with mixing times of: 0.001, 1.0, 5.0, 10.0, 15.0, 20.0, 25.0, 30.0, 35.0, 40.0, 50.0 and 100.0 ms (from left to right). A spin rate of 8.6 kHz was used and a time of 116 μs was used to create a phase difference of 180° between the two magnetisation vectors for the axial and equatorial spins.[15]

The fluorocyclohexane–thiourea inclusion compound was prepared by slowly cooling a solution containing fluorocyclohexane and thiourea in methanol. The crystals were collected and washed with 2,2,4-trimethylpentane to remove any fluorocyclohexane molecules adhering to their external surfaces. Powder X-ray diffraction studies at ambient temperature indicated that these crystals have the rhombohedral thiourea tunnel structure,[1] as found for thiourea inclusion compounds containing other cyclohexane-based guest molecules.

We thank EPSRC for a studentship and ICI for a scholarship to one of us (A. N.). We also thank EPSRC for research grant L02906 and for access to the Durham-based research service in solid-state NMR.

# Synthesis, photophysics and crystal structures of hexanuclear copper(I) and silver(I) acetylide complexes

**Vivian Wing-Wah Yam,* Wendy Kit-Mai Fung and Kung-Kai Cheung**

*Department of Chemistry, The University of Hong Kong, Pokfulam Road, Hong Kong*

**The luminescent complexes $[M_3(\mu\text{-}Ph_2PCH_2PPh_2)_3(\mu_3\text{-}\eta^1\text{-}C{\equiv}CC_6H_4C{\equiv}C\text{-}p)M_3(\mu\text{-}Ph_2PCH_2PPh_2)_3][BF_4]_4$ are synthesized by the reaction of $[M_2(\mu\text{-}Ph_2PCH_2PPh_2)_2(MeCN)_2]^{2+}$ and 1,4-diethynylbenzene in the presence of $Bu^nLi$ in thf (M = Cu 1, Ag 2); X-ray crystal structures of both are determined.**

The highly conjugated polyynes and their transition-metal complexes have attracted enormous attention as precursors for non-linear optical materials and rigid-rod molecular wires.[1] Recently, we synthesized the first luminescent binuclear $Re^I$ organometallics with a rigid-rod acetylide backbone.[2] With our recent interest in polynuclear $Cu^I$ and $Ag^I$ acetylide complexes,[3] we believe that these complexes would be ideal building blocks for the design of luminescent rigid-rod oligomers. Here, we report the first synthesis of two novel luminescent diyne-bridged hexanuclear copper(I) and silver(I) complexes $[Cu_3(\mu\text{-}Ph_2PCH_2PPh_2)_3(\mu_3\text{-}\eta^1\text{-}C{\equiv}CC_6H_4C{\equiv}C\text{-}p)Cu_3(\mu\text{-}Ph_2PCH_2PPh_2)_3][BF_4]_4$ **1** and $[Ag_3(\mu\text{-}Ph_2PCH_2PPh_2)_3(\mu_3\text{-}\eta^1\text{-}C{\equiv}CC_6H_4C{\equiv}C\text{-}p)Ag_3(\mu\text{-}Ph_2PCH_2PPh_2)_3][BF_4]_4$ **2**; both of which contain two triangular $M^I_3$ units linked *via* an extended conjugated diyne backbone.

$Bu^nLi$ was added at room temperature to a solution of 1,4-diethynylbenzene[4] in predried, degassed thf under an inert atmosphere of nitrogen; a solid sample of $[Cu_2(\mu\text{-}dppm)_2(MeCN)_2][BF_4]_2$[5] was then added and stirred at room temp. for 24 h. After evaporation to dryness, the resulting solution was extracted with $CH_2Cl_2$. Subsequent diffusion of diethyl ether into the concentrated solution gave **1** as air-stable yellow crystals. Complex **2** was obtained as air-stable pale yellow crystals by a similar method except that $[Ag_2(\mu\text{-}dppm)_2(MeCN)_2][BF_4]_2$[6] was used. Both **1** and **2** have been characterized by elemental analyses, $^1H$ NMR, IR and Raman spectroscopy.† The X-ray crystal structures of **1** and **2** have also been determined.‡

A perspective drawing of the complex cation of **1** with atomic numbering is shown in Fig. 1. The complex cation of **1** consists of two triangular arrays of copper atoms with a dppm ligand bridging each edge to form two roughly planar $Cu_3P_6$ cores bridged by a 1,4-diethynylbenzene unit to form a dumb-bell shaped structure. The Cu···Cu distances, which are comparable to those found in the related monocapped systems,[3a,c,7,8] are suggestive of at best only very weak Cu···Cu interactions. The bridging mode of the alkynyl group is asymmetric and the C≡C bond length is typical of metal–acetylide σ bonding. It is interesting that the phenyl ring of the acetylide unit which sits in the middle of the complex is almost parallel to the two phenyl rings [C(51)–(56), C(51*)–(56*)] of the dppm units, one on each of the triangular core, respectively, indicative of the presence of π-stacking interactions. The complex cation of **2** is isostructural to **1** and similar π-stacking interactions are observed.

The absorption spectra of **1** and **2** display strong absorptions in the UV region at *ca*. 258–324 nm, tentatively assigned as ligand-localized transitions. Longer wavelength absorptions appear as vibronically structured bands at *ca*. 370–416 nm for **1** and *ca*. 324–364 nm for **2** in $CH_2Cl_2$, with vibrational progressional spacings of *ca*. 1475–1500 $cm^{-1}$, typical of ν(C≒C) stretching modes of the aromatic ring in the excited state. Excitation of a solid sample of complex **1** at λ > 350 nm both at 77 K and room temp. produces intense yellow–orange luminescence. The room-temp. solid-state emission spectrum shows an intense band at *ca*. 583 nm, which is also vibronically structured with progressional spacings of *ca*. 1500–1520 $cm^{-1}$, characteristic of the aromatic ν(C≒C) stretch. Upon cooling to 77 K, the emission bands become better resolved. Similar emission bands are observed in fluid solution. Excitation of a solid sample of **2** at λ > 350 nm both at 77 K and room temp. give intense green–yellow luminescence. The solid-state emission spectrum also shows an intense vibronically structured band at *ca*. 513 nm at both room temp. and 77 K (Table 1). The excitation spectra of both **1** and **2** show vibronically structured bands at *ca*. 360–420 and 320–362 nm, respectively, which coincide with those of their respective absorption spectra. The excitation and emission spectra of **2** in degassed dichloromethane at 298 K are shown in Fig. 2.

It is interesting that both the absorption and emission bands of **1** occur at lower energy than those of **2**. A possible assignment for the origin of the emission involves emissive states derived from ligand-to-metal charge transfer (acetylide-to-metal

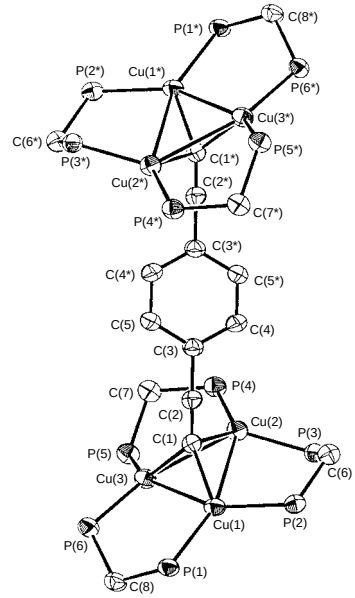

**Fig 1** Perspective drawing of the complex cation of **1** with atomic numbering scheme. Hydrogen atoms and phenyl rings have been omitted for clarity. LMCT) transition mixed with d–s character. The red shift in the 77 K solid-state emission energy of *ca*. 0.28 eV from **2** to **1** is comparable to the value of 0.31 eV reported for the related hexanuclear $Ag^I$ and $Cu^I$ thiocarbamate clusters, $[Ag_6(mtc)_6]$ and $[Cu_6(mtc)_6]$ (mtc = di-*n*-propylmonothiocarbamate), where an origin of mixed d → s and LMCT character has been suggested.[9] Besides, a similar red shift in emission energy (*ca*. 0.27 eV) on going from $Ag^I$ to $Cu^I$ chalcogenido clusters has been reported,[10a–c] in which a mixed d → s/LMCT origin has also been suggested and is supported by molecular orbital calculations.[10d,e] Another possible origin for the observed red shift in energy from **2** *cf*. **1** involves states derived from metal-to-ligand charge transfer [MLCT d(M) → π*(acetylide)] transition. As $Cu^I$ is much more easily oxidized, given the higher energy of the $Cu^I$ 3d orbitals relative to those of the $Ag^I$ 4d orbitals,[11] the MLCT transition for $Cu^I$ should also occur at lower energy than that for $Ag^I$. In view of the fact that the ionization energy of $Ag^+(g)$ is nearly $10^4$ $cm^{-1}$ larger than that for $Cu^+(g)$,[11] an assignment of the emissive state as derived from a MLCT transition for the small energy shift observed from **2** to **1** is unlikely. The long lifetime of the emissive state in the μs range is probably suggestive of triplet origin. However, the possibility of an involvement of an intraligand excited state of 1,4-diethynylbenzene should not be overlooked given the unusually long lifetime of the emissive state and the low-lying π* orbital energy of the diynyl unit. Therefore, it is likely that the low-energy emission is derived from states of LMCT parentage mixed with a metal-centred $nd^9(n + 1)s^1$ state, with large intraligand ππ* character.

# Sensor molecules for silver(I)-selective membranes based on mono- to quadri-dentate podands

**Sarah Chung,[a] Wantae Kim,[a] Sung Bae Park,*[a] Il Yoon,[b] Shim Sung Lee[b] and Dae Dong Sung[c]**

[a] *Department of Chemistry, Inje University, Kimhae 621-749, Korea*

[c] *Department of Chemistry, Dong-A University, Pusan 604-714, Korea*

**A series of podands containing nitrogen and sulfur atoms are utilized as sensing components to prepare $Ag^+$-selective polymeric membrane electrodes whose characteristics are dependent on the structure of each podand used.**

Crown ether type synthetic molecules have been employed in polymeric sensors as ionophores for the determination of metallic ions ($Li^+$, $Na^+$, $K^+$, $Ca^{2+}$).[1–3] Nitrogen- and oxygen-containing cryptands have also been used for the measurement of $Zn^{2+}$ and other heavy-metal ions.[4,5] A group of polythiacrown ethers and acyclic polythia compounds have been exploited for the measurement of $Ag^+$.[6,7] Recently podand structures, acyclic oligoethers, have also been shown to be valuable additions to the above chemical species for ionophores.[8,9] Obtained simply and cheaply, the podand structures containing oxygen and sulfur as the binding sites have been studied in conjunction with the extraction and detection of precious metal ions such as $Ag^+$.[9,10] Soft coordination sites like sulfur of the thia compounds seem to generate great affinity toward the $d^{10}$ transition-metal ions such as $Ag^+$ and $Hg^{2+}$.

It would be interesting to compare the relationship between molecular structure and electrochemical properties for ionophore-based membrane sensors. Employing similarly structured thioethers, Teixidor *et al*. have reported that any molecule with thioether group(s) could be highly selective towards silver(I).[6] The present report may provide an exception to this hypothesis.

Here we report on sensors based on a series of multiarmed podands that have essentially the same type but different numbers of arms (Fig. 1). All the podand structures were prepared as reported previously.[11] PVC-based ion-selective electrode (ISE) membranes were prepared by the method of Simon and coworkers.[12] The membrane compositions in the present work are listed in Table 1. Cell potentials were measured at ambient temperature (18 °C). The potentiometric cell used was as follows: Ag/AgCl(s)/4 M KCl saturated with AgCl/tris buffer/sample solution/ion-selective membrane/1 mM $AgNO_3$/AgCl(s)/Ag. A tris buffer solution consisting of 0.05 M tris(hydroxymethyl)aminomethane (Trizma Base) adjusted with $HNO_3$ solution to pH 9.0 was used as the working buffer for the potentiometric measurements. Selectivity coefficients, $k^{pot}_{Ag/X}$, were obtained by using the separate solution method.[13]

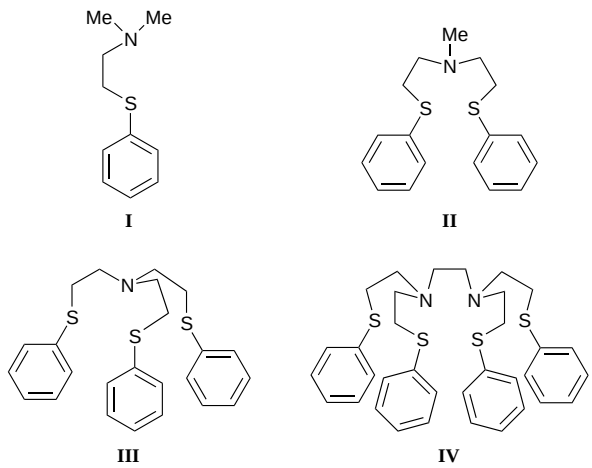

**Fig. 1** Structures of some podand-type ionophores used in the preparation of $Ag^+$-selective membrane electrodes

**Table 1** Formulation and electrochemical properties of podand-based $Ag^+$-selective membrane electrodes

| Electrode | Podand[a,b] | PVC[a] | DIDA[a] | Detection limit/M[c] | Slope/mV decade$^{-1}$[c,d] |
|---|---|---|---|---|---|
| E1 | 4.0, **I** | 32.0 | 64.0 | N/A | N/A |
| E2 | 4.0, **II** | 32.0 | 64.0 | $1.6 \times 10^{-5}$ | 45.5 |
| E3 | 6.0, **III** | 32.0 | 62.0 | $0.8 \times 10^{-6}$ | 58.0 |
| E4 | 4.0, **III** | 32.0 | 64.0 | $0.8 \times 10^{-6}$ | 58.5 |
| E5 | 2.0, **III** | 32.0 | 66.0 | $0.9 \times 10^{-6}$ | 57.0 |
| E6 | 1.0, **III** | 32.0 | 67.0 | $1.4 \times 10^{-6}$ | 47.2 |
| E7 | 4.0, **IV** | 32.0 | 64.0 | $1.0 \times 10^{-6}$ | 58.5 |
| E8 | $Ag_2S$ | | | $0.8 \times 10^{-6}$ | 59.1 |

[a] Numbers indicate mass%. [b] Bold roman characters indicate the podands in Fig. 1. [c] E1–E7, average of three membranes; E8 is a $Ag_2S$-based solid-state electrode. [d] Between detection limit and 1 mM.

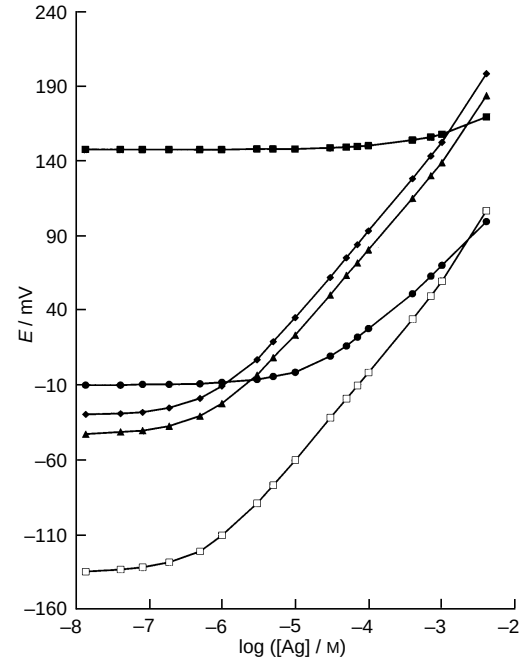

**Fig. 2** Typical potentiometric $Ag^+$ ion responses of the podand-based PVC membrane electrodes: (■) E1, (●) E2, (▲) E4, (◆) E7 and (□) E8 in Table 1. Measurements were made in 0.05 M tris buffer, pH 9.0.

The equilibrium potentiometric responses of the new podand-based PVC membrane electrodes in the concentration range of 0–10 mM are shown in Fig. 2. As summarized in Table 1, almost Nernstian slopes are observed in podand **III**- and **IV**-based membrane electrodes. On the other hand, podand **I**- and **II**-based electrodes give negligible and small response slopes, respectively. The response time of each electrode is short; the time required to reach 90% of the equilibrium mV values was < 2 s. In terms of the lifetime of the PVC membrane electrodes, response stability was observed for over a month.

Table 2 lists the potentiometric selectivity coefficient data of some podand-based PVC membrane electrodes for the interfering cations relative to $Ag^+$.

Among thiapodands, $NS_3$ and $N_2S_4$ donor set podands (**III** and **IV** in Fig. 1) seem to show the best response and selectivity to $Ag^+$. Values of log $k_{Ag/X}$ range from −3.5 for $K^+$ to −5.1 for $Ba^{2+}$, $Ca^{2+}$ and $Mg^{2+}$. The high selectivity toward $Ag^+$ is due to the high affinity of sulfur atoms in the ionophores. It is well known that $Ag^+(d^{10})$ exhibits a strong affinity towards sulfur-derived ligands and shows a remarkable preference for linear coordination.[7] For the $Hg^{2+}$ ion, the selectivity coefficient (log $k_{Ag/Hg}$) was −4.0. Compared to that of an $Ag_2S$-based electrode, the relative selectivity toward $Ag^+$ over $Hg^{2+}$ is much improved.

**Table 2** Static-mode potentiometric selectivity coefficients,[a] log $k^{pot}_{Ag/x}$, of the podand-based membrane electrodes[b]

| | Electrode[c] | | | |
|---|---|---|---|---|
| Cation | E2 (**II**) | E4 (**III**) | E7 (**IV**) | E8 ($Ag_2S$) |
| $Ag^+$ | 0 | 0 | 0 | 0 |
| $NH_4^+$ | −1.8 | −3.7 | −3.5 | −4.0 |
| $Na^+$ | −1.8 | −3.7 | −3.5 | −4.0 |
| $K^+$ | −1.8 | −3.7 | −3.5 | −4.0 |
| $Ba^{2+}$ | −3.1 | −5.1 | −4.9 | −5.2 |
| $Ca^{2+}$ | −3.1 | −5.1 | −4.9 | −5.2 |
| $Mg^{2+}$ | −3.2 | −5.1 | −4.9 | −5.2 |
| $Cu^{2+}$ | −3.2 | −5.0 | −4.8 | −4.7 |
| $Cd^{2+}$ | −2.6 | −4.9 | −4.7 | −5.1 |
| $Co^{2+}$ | −2.4 | −5.0 | −4.5 | −5.1 |
| $Pb^{2+}$ | −2.9 | −4.9 | −4.8 | −5.2 |
| $Ni^{2+}$ | −2.9 | −5.0 | −4.8 | −5.2 |
| $Hg^{2+}$ | −2.9 | −4.0 | −4.0 | −2.1 |

[a] Measured by the separate solution method at 1 mM cation concentrations in 0.05 M tris–nitric acid, pH 9.0. [b] Membrane compositions (E1–E8) listed in Table 1. [c] Bold roman characters in parentheses indicate the podands in Fig. 1.

In our previous study,[11] it was found that all of the podands tested in this study form 1 : 1 stoichiometric complexes with $Ag^+$ in methanol. The sequence of stability constants, log *K*, of complexes was found to be **IV** (12.43 ± 0.22) > **III** (9.29 ± 0.16) > **II** (7.02 ± 0.12) > **I** (3.4 ± 0.3) (assuming the stoichiometry for **I**–$Ag^+$ system is 1 : 1). In the same study, it was also revealed that the complex stability of the podands is mainly enthalpic in origin. From $Ag^+$-induced chemical shift measurements, it was also found that nitrogen atoms behave as strong donors for $Ag^+$ as do sulfur atoms.[11] Because of no or lower selective affinity of nitrogen for soft cations including $Ag^+$, both the total number of nitrogen/sulfur and the fraction of sulfur in a podand system seem to be related to the total response and selectivity of the membrane sensors toward $Ag^+$. The present study shows that the simple hypothesis of Teixidor *et al.*,[6] has exceptions for complex molecules including our nitrogen–sulfur containing podands.

# Stereochemical control of the intramolecular Diels–Alder reaction by remote allylic substituents on the diene

**Michael J. Lilly and Michael S. Sherburn***

*Department of Chemistry, Massey University, Private Bag 11222, Palmerston North, New Zealand*

**Intramolecular Diels–Alder reactions of substrates with stereocontrolling elements attached to the diene terminus provide *exo*-cycloadducts in good yields and high diastereofacial selectivity.**

The Diels–Alder reaction is one of the most powerful and most commonly used reactions in synthetic organic chemistry. The stereochemical consequences of employing chiral precursors or catalysts have been actively studied for several years,[1] with much recent interest directed towards the application of chiral, acyclic dienes in intermolecular reactions,[2] particularly when a stereocentre is present at the allylic position of the diene.[2a] Reported methods for the stereochemical control of intramolecular Diels–Alder (IMDA) reactions[3] involve the placement of suitable substituents on the linking chain (tether) between the diene and dienophile,[4] by attaching auxiliaries to the dienophile[5] and the application of enantioselective catalysis.[6] We were intrigued by the possibility of controlling the diastereofacial selectivity of the IMDA reaction by constructing chiral substrates with a stereocontrolling element at the terminus of an acyclic diene, *i.e.* remote to the linking chain (Fig. 1). This approach offers new insights into the stereochemical preferences of the Diels–Alder reaction, since previous reports in this area employ either stereochemically-biased semicyclic dienes, or are complicated by the presence of tether substituents and dienophile auxiliaries.[7]

We chose to investigate a series of ester-tethered intramolecular cycloadditions with *Z*-alkene dienophiles bearing both internal and terminal ester activating groups, since a previous report indicated reasonably facile thermal reaction and high *exo*-selectivity.[8] The series of enantiopure compounds (**7a**–**d**) was prepared from inexpensive and readily available L-ascorbic acid as shown in Scheme 1. Thus, the α-hydroxy ester **1**[9] was silylated and reduced to afford the α-silyloxy aldehyde **2**. Wittig reaction with stabilised phosphorane **3** gave a mixture of stereoisomers from which the *E*,*E*-diene ester **4** was obtained upon isomerisation. After reduction, esterification of dienol **5** with maleic anhydride gave acid **6**, which was used for the preparation of the four precursors for IMDA reaction. Thus, treatment of **6** with diazomethane furnished the *tert*-butyldimethylsilyloxy methyl ester **7c**. Desilylation of **6** followed by methylation gave hydroxy methyl ester **7a**. The trimethylsilyl and triisopropylsilyl derivatives **7b** and **7d** were prepared by reacting alcohol **7a** with the requisite trialkylsilyl triflate.

Thermolysis of the IMDA precursors under identical conditions (Table 1) produced mixtures containing only two of the four possible cycloadducts in each case.† These products were characterised following derivatisation and extensive NMR studies including HETCOR, COSY and NOESY experiments. Coupling constants pointed to a *trans*-ring junction geometry‡ in each case, indicating that all products isolated were the result of the expected *exo*-cycloaddition mode. The alcohol substrate (**7a**) exhibited only a modest diastereofacial preference between the two *exo*-cycloadducts, but this improved considerably on replacement with silyloxy protecting groups. Furthermore, a progressive improvement in selectivity was observed as the size of the silyl group was increased. The triisopropylsilyl derivative **7d**, the most sterically demanding protecting group examined, provided a remarkably high level of stereocontrol. Interestingly, the major product for the alcohol substrate corresponded to the major product for the silyl ethers.§

It is noteworthy that the π-facial selectivity of these IMDA reactions is of the opposite sense to that witnessed for intermolecular Diels–Alder reactions between simple chiral dienols (and ether derivatives) and maleic anhydride.[2a] The reasons for this difference are not known but the absence of a

*cis*-substituent on the diene and the presence of the dioxolane moiety in the precursors may be contributing factors.[2a] Moreover, recent NMR studies have shown that subtle factors affect the conformational preferences of chiral allylic secondary alcohols and derivatives.[10] Clearly, a complicated situation exists and a detailed explanation of these results must await further studies. The stereochemical outcome of the present series of reactions does, however, follow the same trend as silyl acetal-tethered IMDA reactions[11] in which the stereocontrolling element is part of the tether.¶

In summary, this work demonstrates that the stereochemical outcome of the intramolecular Diels–Alder reaction can be controlled by the incorporation of stereochemical information on the diene remote to the diene–dienophile tether. Remarkably high levels of stereoselectivity can be obtained for thermal (uncatalysed) reactions by judicious selection of the alcohol protecting group in the precursor. The products obtained from these reactions are enantiomerically pure and rich in functionality, offering the prospect of further elaboration into a multitude of useful chiral building blocks.

The authors would like to thank Dr Pat Edwards for assistance with NMR, Massey University for a Graduate Assistant Scholarship (to M. J. L.) and The New Zealand Lotteries Board for funding.

## Footnotes

* E-mail: m.sherburn@massey.ac.nz

† In these experiments we observed small amounts of other compounds which may be the products of *endo*-mode cycloaddition. Thus far we have not been able to isolate sufficient quantities of pure compounds to allow characterisation of these very minor products.

‡ The coupling constants between protons at the ring junction (*J* 13.7 Hz) were consistent throughout this series and compared favourably with literature values for similar compounds (see ref. 8).

§ Silylation of a 1.9:1 mixture of **8a** and **9a** ($Me_3SiCl$, imidazole, DMF, 20 °C, 61%) furnished a 1.9:1 mixture of two compounds identical in all respects to **8b** and **9b**. The major isomer from this experiment corresponded with the major isomer from thermolysis of **7b**.

¶ We thank a referee for drawing our attention to this work.

# Mass spectrometric determination of methyl group positions in long chain methyl ethers and alcohols *via* nitriles

**Stefan Schulz***

*Institut für Organische Chemie, Universität Hamburg, Martin-Luther-King-Platz 6, D-20146 Hamburg, Germany*

**Mass spectra of long chain branched nitriles are used to determine the position of the methyl groups along the chain in naturally occurring methyl ethers, alcohols and fatty acids.**

Recently we showed that lipids occur on the silk of spiders.[1,2] Extracts of this silk contain long chain, methyl branched 1-methoxy alkanes as their major component[2] which are not known from any other natural source. The silk of the golden orb weaver *Nephila clavipes* (Araneidae) is currently being intensively studied because of its high tensile strength and elasticity.[1,3] Investigations of web extracts by GC–MS showed the presence of alkanes, alcohols and 1-methoxy alkanes with multiple methyl branches. The 1-methoxy alkanes exhibit a more complex branching pattern than those previously known from the Linyphiidae.[2] For the determination of the position of the methyl groups in the chain we developed a new method applicable to microgram amounts of complex mixtures.

Methyl branches in long chain alkanes can be determined by their mass spectra and gas chromatographic retention indices.[4] This becomes more difficult with alcohols, aldehydes and 1-methoxy alkanes because they easily loose water or methanol under the mass spectrometric conditions. The localization of the methyl groups is thus only possible in special cases.[5] Methyl ester branches between C-2 and C-4 can be easily determined because of the high ion-density caused by carbonyl induced fragmentations, but methyl groups at other positions are much more difficult to identify due to low ion intensities.[6,7]

Derivatives of such compounds can be used in some cases to determine the branching positions. Fatty acids can be transformed into alkanes *via* reduction, chloride formation and reductive dehalogenation.[7] Free acids can also be converted *via* their acid chlorides into 3-pyridylmethyl esters or pyrrolidides, the mass spectra of which clearly show the branching positions.[8] Long chain branched alcohols have been converted into alkyl chlorides, deuterated alkanes and nicotinic acid derivatives.[8,9] All methods have drawbacks when used on the microgram scale, *i.e.* the low intensity of diagnostic ions and by-products introduced into the sample during derivatization or interference with other compounds present in the extract.

Investigations of branched alkyl nitriles showed that their mass spectra exhibit intense molecular ions and an ion series $C_nH_{2n-2}$ dominating in the region above 100 amu. Branching positions can be easily determined by the ions **A** and **A** + 1 which arise by cleavage besides the methyl group (see Fig. 1). In the higher mass region the ions **B** and **B** + 1 also become prominent. The respective ions **A** − 14 are of low abundance. Nitrogen containing ions dominate the spectrum above 100 amu. The cyano group obviously stabilizes the cations obtained by cleavage of σ-bonds, so that the information on the branching positions is preserved in the spectra (see Fig. 2). Below 100 amu this fragmentation pattern is overlayed with ions arising from other processes,[10] thus making the detection of the methyl groups at C-2, C-3 and C-4 difficult. While a methyl group at C-6 is clearly visible [see Fig. 2(*a*)], a methyl group near the cyano group can only be detected by the ion *m/z* 111, which intensity becomes comparable to the one of the ion *m/z* 97 [see Fig. 2(*b*)]. On the other hand, methyl ethers can be converted in methyl esters on a microscale using $RuO_4$,[2] thus enabling the location of the methyl groups between C-2 and C-4.

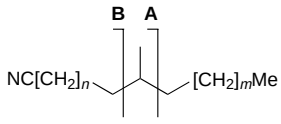

**Fig. 1** Mass spectrometric fragmentation pattern of long chain branched 1-methoxy alkanes

Methyl ethers or alcohols can be cleanly transformed in high yield into nitriles by a microprocedure.† They are first converted into the respective iodides using $Me_3SiI$,[2] followed by reaction with $Et_4NCN$ in dichloromethane. After completion, the solvent is substituted with pentane, leaving a clean derivatized extract, almost free of reagents and impurities. Extracts of silk from *Nephila clavipes* containing complex mixtures of alkanes, alcohols and methyl ethers in microgram amounts were successfully characterized by this method.[11] As an example, 1-methoxy-16,20,24,28-tetramethylhentriacontane

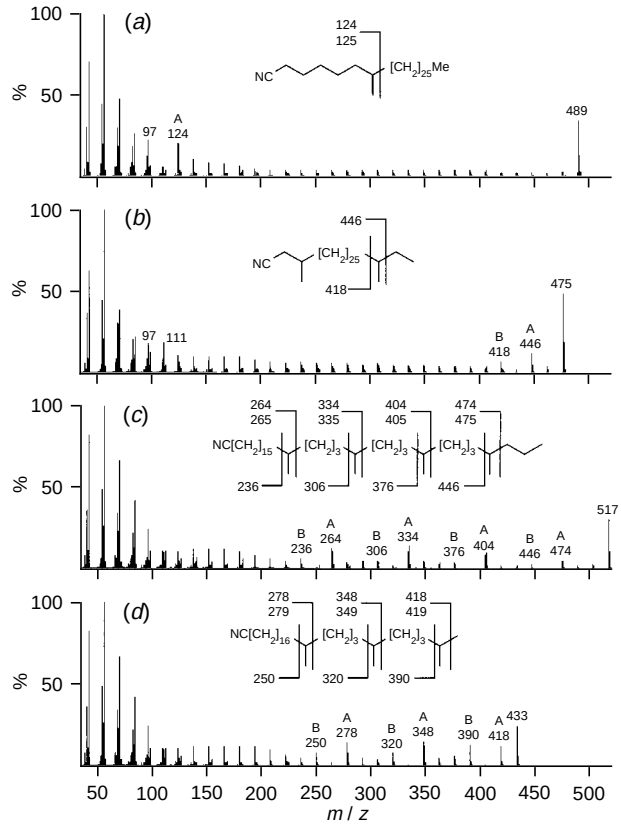

**Fig. 2** Mass spectra (70 eV, EI) of (*a*) 6-methyldotriacontyl cyanide (synthetic); (*b*) 2,28-dimethyltriacontyl cyanide (from *N. clavipes*); (*c*) 16,20,24,28-tetramethylhentriacontyl cyanide (from *N. clavipes*); (*d*) 17,21,25-trimethylhexacosyl cyanide (synthetic)

and 1-methoxy-2,28-dimethyltriacontane could be identified (the mass spectra of their nitriles are shown in Fig. 2). Advantages of the analysis of the methyl branching positions *via* nitriles are the very characteristic mass spectra carrying the information of the functional group position, mild reaction conditions and clean products. In addition, all compounds easily convertible by microprocedures into alcohols, like fatty acids or their esters, can also be analysed.[12]

† *Experimental procedure for the microderivatization of methyl ethers or alcohols.* The reactions were performed in 1 ml mini-vials (Chromatography Research Supplies). To 50 μl of a $CH_2Cl_2$ solution of the educts 20 μl $Me_3SiI$ was added under nitrogen. After 2 h at 60 °C in a dark place (oven) and cooling, 50 μl sat. aq. $NaHCO_3$ and 200 μl $CH_2Cl_2$ were added and the mixture thoroughly shaken. The aqueous phase was removed and NaCl added for drying. The organic phase was transferred into another vial and the NaCl residue was again washed with 200 μl $CH_2Cl_2$. After addition of $Et_4NCN$ (5 mg, washed with pentane prior to use) to the combined organic phases the mixture was stirred overnight, 50 μl $H_2O$ was added and the aqueous phase removed after vigorous stirring. The solvent was evaporated at 45 °C bath temperature, the residue twice taken up in 100 μl pentane, and the combined pentane extracts concentrated to a volume suitable for analysis.

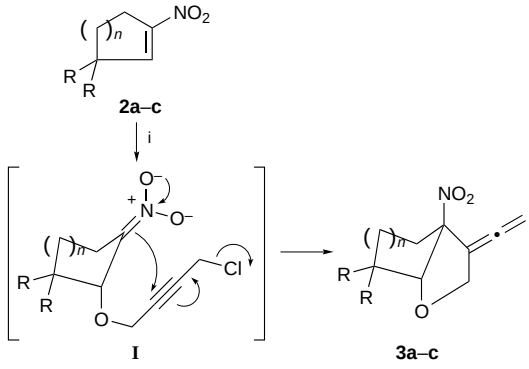
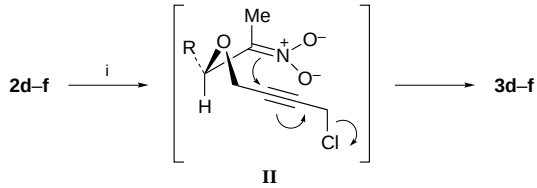
# Tandem oxa-Michael addition–$S_N2'$ substitution of 4-chlorobut-2-yn-1-ol with nitroalkenes: a total allylic 1,3-strain-controlled diastereoselective synthesis of 3-vinylidenetetrahydrofurans

**Jean-Pierre Dulcère* and Estelle Dumez**



*RéSo, Réactivité en Synthèse organique, Faculté des Sciences et Techniques, Centre de St. Jérôme, UMR 6516, av. Esc. Normandie-Niemen, Boîte D 12, F-13397 Marseille Cedex 20, France*

**Bu$^t$OK-promoted reaction of 4-chlorobut-2-yn-1-ol 1 with nitroalkenes 2 affords 3-vinylidenetetrahydrofurans 3 in good yields with total diastereoselectivity.**



The tetrahydrofuran ring is present in a number of biologically significant natural products[1] and the synthesis of tetrahydrofurans bearing unsaturated substituents is of great interest for further transformations. Among these substituents, the allenyl functionality has received very little attention. In a recent report,[2] we disclosed a radical-mediated carbocyclisation of bromoalkynyloxiranes which gave vinylidenetetrahydrofurans. Very recently,[3] oxa-Michael initiated tandem conjugate reactions of 1-nitrocyclohexene with 4-hydroxybut-2-ynoates were shown to afford alkylidenetetrahydrofurans. Provided the oxa-Michael addition is followed by an $S_N2'$ substitution, this tandem reaction should constitute an alternative route to vinylidenetetrahydrofurans.

**Scheme 1** *Reagents and conditions*: i, **2** (1 equiv.), THF, Bu$^t$OK (1.5 equiv.), **1** ($ClCH_2C{\equiv}CCH_2OH$, 1.5 equiv.), 0 °C, 10 min, then room temp., 15–30 min, 70–78%

**Scheme 2** *Reagents and conditions*: i, see Scheme 1

**Scheme 3** *Reagents and conditions*: i, see Scheme 1

We present here our preliminary results on the oxa-Michael–$S_N2'$ substitution of 4-chlorobut-2-yn-1-ol **1** with nitroalkenes **2a**–**f**. Nitroalkenes **2a**–**f**† (Scheme 1) were reacted at 0 °C in THF with **1**, in the presence of Bu$^t$OK. After 10 min the mixture was warmed to room temperature, where it was maintained until completion of the reaction (10–30 min). Vinylidenetetrahydrofurans **3a**–**f** were isolated‡ as the sole products (70–78% yield) after flash chromatography on silica gel.

According to the known reactivity of nitroalkenes with oxygen nucleophiles,[4] the oxa-Michael addition first affords nitronate **I** which then undergoes $S_N2'$ substitution to provide the allenyl moiety[5] (Scheme 2). Bicyclic adducts **3a**–**c** are *cis* ring-fused.

Interestingly, acyclic (*E*)-nitro alkenes **2d**–**f**§ afford, under the same reaction conditions, vinylidenetetrahydrofurans **3d**–**f** in a totally diastereoselective way.¶ We assume that this is due to allylic 1,3-strain, which allows only one conformation **II** for the transition state and thereby leads to the *trans* stereoselectivity observed in the intramolecular cyclisation into vinylidenetetrahydrofurans **3d**–**f** (Scheme 3). Indeed, due to the allylic 1,3-strain effect,[4b,6] excellent diastereoselectivities have been reported for the kinetically controlled protonation of nitrones bearing substituents which differ in steric hindrance[7] and for intermolecular nitrone cycloadditions when a stereogenic centre is present at C-2.[8] However, allylic 1,3-strain does not play a significant role in Michael additions to nitroalkenes bearing a stereogenic centre at C-3, which proceed with remarkable 1,2-asymmetric induction due to steric and stereoelectronic control.[9]

In conclusion, the tandem oxa-Michael addition–intramolecular $S_N2'$ substitution of nitroalkenes constitutes an efficient and stereocontrolled procedure for the preparation of synthetically valuable and relatively unknown vinylidenetetrahydrofurans.

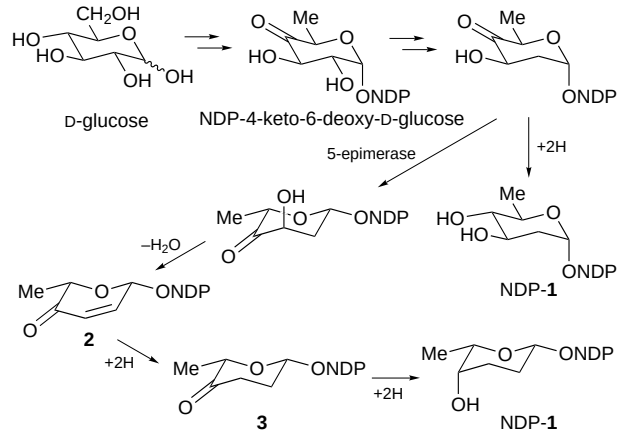
# Biosynthetic short activation of the 2,3,6-trideoxysugar L-rhodinose

**Jürgen Rohr,*[a] Sven-Eric Wohlert,[a] Carsten Oelkers,[a] Andreas Kirschning,*[b] and Monika Ries[b]**

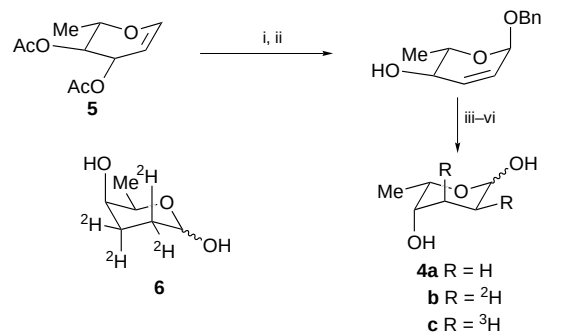
[a] *Institut für Organische Chemie der Universität, Tammannstr. 2, D-37077 Göttingen, Germany*
[b] *Institut für Organische Chemie, TU Clausthal, Leibnizstr. 6, D-38678 Clausthal-Zellerfeld, Germany*

**The successful incorporation of non-activated [2,3-$^2H_2$]-L-rhodinose 4b into landomycin A 7 proves the existence of a short activation pathway for L-rhodinose 4; this result provides evidence of a general saving pathway for deoxysugar building blocks and their biosynthetic intermediates, respectively, which become accidentally deactivated during the biosynthetic deoxygenation cascades.**



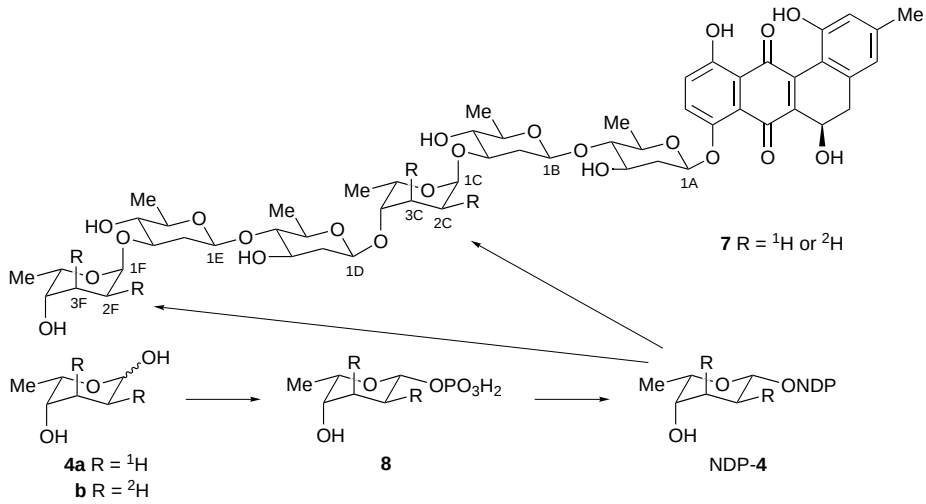
Deoxysugars, for example L-rhodinose **4** and D-olivose **1**, occur as structural moieties of many bioactive natural products and often play an important role in their mechanism of action, in particular for the DNA interaction of anti-cancer drugs.[1] For instance, the cytostatic activity of the different landomycins,[2] anti-tumour antibiotics of the angucycline group[3] which vary only in their oligosaccharide moieties, is directly dependent on the length of the phenolglycosidically-linked deoxyoligosaccharide chains.[2c] Landomycin A **7**, the most active anti-cancer compound of the landomycin family, exhibits the longest glycan moiety. While we have been investigating the biosynthesis of this hexadeoxysaccharide chain and the pathways leading to its two single deoxysugar building blocks,[2d–f] D-olivose (**1**, 2,6-dideoxy-D-*arabino*-hexopyranose) and L-rhodinose (**4**, 2,3,6-trideoxy-L-*threo*-hexopyranose), we have also been working on the development of synthetic methods in this context.

For the biosynthetic formation of deoxyhexoses it is generally accepted that the deoxygenation steps occur on nucleoside diphosphate (NDP) intermediates,[4] which are activated substrates for glycosyl transfer. The activation pathway always starts with a hexose-6-phosphate, which is transformed into the activated NDP-sugar by a pyrophosphorylase after its rearrangement into the corresponding hexose-1-phosphate. This activation mechanism occurs prior to all deoxygenation steps, and thus was assumed to exclude the activation of 6-deoxysugars.



Since diphosphates, and in particular 2-deoxysugar derivatives, are chemically labile,[5] there is a considerably high chance that the activated (deoxy)sugar may be 'deactivated' through hydrolysis, *e.g.* to the trideoxysugar rhodinose (**4**, see Scheme 1). Thus these sugars would be unable to participate in the final biosynthetic glycosyl transfer reactions, if nature did not provide for the possibility of 'recycling', best achieved in a 'short activation pathway'. Such a second activation pathway was first recognized for L-fucose,[6] a 6-deoxysugar, which normally arises as an activated guanosyldiphosphate (GDP)-derivative from GDP-D-mannose.

Feeding experiments, in which synthetically prepared (Scheme 2)[7] unlabelled L-rhodinose **4a** was added to a growing culture of the landomycin A **7** producer *Streptomyces cyanogenus* (strain S-136, DSM 5087) showed that L-rhodinose **4a** was consumed within 12 h (HPLC, RI-detector control), and therefore seemed to be transported into the cells. Furthermore, experiments with radiolabelled [2,3-$^3H_2$]-L-rhodinose **4c** analogously synthesized[7] using $^3H_2$ (prepared[8] from $NaB^3H_4$ and $^3H_2O$) showed incorporation into **7**. However, quenching effects interfered with the scintillation counting and therefore only low specific incorporation was indicated. In addition, it remained unproven whether the radiolabel was exclusively located in the rhodinose moieties of **7**. Thus, the final proof of a successful incorporation of non-activated L-rhodinose into the L-rhodinose moeties of landomycin A (**7**, Scheme 3) was obtained from feeding [2*S*,3*R*-$^2H_2$]-L-rhodinose **4b** (synthesized[7] with $^2H_2$; Scheme 2). The $^2H$ NMR spectrum clearly showed $^2H$ enriched signals exclusively for 2C–$H_e$, 3C–$H_a$, 2F–$H_e$ and 3F–$H_a$ (Fig. 1). The assignment of all the protons of **7** and its octaacetate, respectively, was achieved *via* long range C,H couplings (COLOC, HMBC).[2a,b] Thus, the $^2H$-labelled L-rhodinose **4b** must have been activated through an alternative pathway to the standard deoxygenation pathway (see Scheme 1 for our current hypothesis). This 'short activation pathway' may play the role of a general saving mechanism. A control experiment, in which [2,2,3,3-$^2H_4$]-D-rhodinose **6**, prepared[7] from L-threonine, was fed to *S. cyanogenus*, showed—as expected—no incorporation.



For the short activation it is assumed that L-rhodinose, as was demonstrated for L-fucose,[6] is first converted into the corresponding 1-phosphate **8** by a kinase and then activated into the NDP-derivative (NDP-**4**) through a pyrophosphorylase-mediated coupling reaction (see Scheme 3). That an activation of a 6-deoxyhexose is principally possible has also been indicated

**Scheme 1**

**Scheme 2** *Reagents and conditions*: i, BnOH, $BF_3{\cdot}OEt_2$; ii, MeOH, $NEt_3$, $H_2O$; iii, BzOH, DEAD, $PPh_3$, $OH^-$; iv, Pd–C, $H_2(^2H_2, ^3H_2)$; v, MeOH, NaOMe; vi, $H^+$

**Scheme 3**

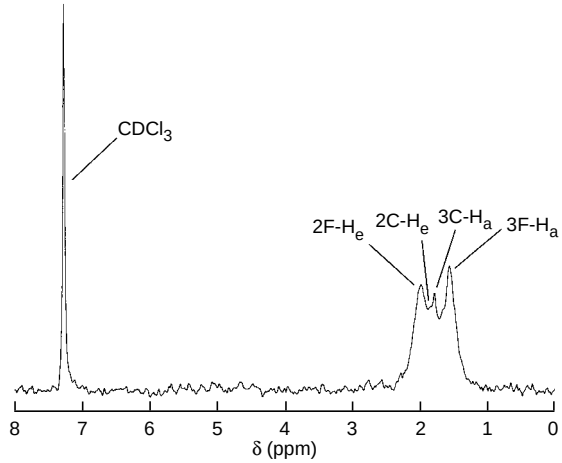


**Fig. 1** $^2$H NMR spectrum of the isolated landomycin A (**7**) after feeding of [2*S*,3*R*-$^2H_2$]-L-rhodinose (**4b**) to growing cultures of *Streptomyces cyanogenus* S-136. $^2$H signals were assigned based on the $^1$H signals [ref. 2(*a*), (*b*)].

from experiments in which 6-deoxy-D-glucose derivatives were successfully incorporated into neomycin.[9]

One can assume for organisms which produce deoxysugar-containing natural products that the short activation is feasible for all deactivated 'intermediates' of a certain biosynthetic deoxygenation cascade. Thus, the results described here open up attractive options in the context of chemical and biochemical aspects of deoxysugars. For instance, they pave the way for more convenient biosynthetic investigations on deoxysugar biosynthesis cascades, since it is obviously possible to feed and incorporate isotope labelled deoxysugars, *i.e.* non-activated analogues of the postulated intermediates of a certain deoxygenation pathway. For our investigations, labelled L-aculose or L-cinerulose, whose NDP-derivatives **2** and **3** respectively we assume to be intermediates of NDP-L-rhodinose (NDP-**4**, see Scheme 1), are important candidates to be fed to cultures of the landomycin producer *S. cyanogenus*. As another consequence of our findings, it will be profitable to look for genes of such short activation pathways, since the corresponding enzymes, preferably a kinase plus a pyrophosphorylase, should express a broad substrate flexibility and thus may be able to activate various deoxyhexoses, presumably at least all intermediates of a given deoxygenation cascade. Therefore, these enzymes may serve as powerful tools in enzymatic oligosaccharide syntheses.

The authors thank the European Community (BIO4-CT96-0068), the Fonds der Chemischen Industrie, and especially the Deutsche Forschungsgemeinschaft (grants Ro 676/5-1, 5-2 and Ki 397/2-1 to 2-3) for generous financial support. Dr David O'Hagan and Dr Ian McKeag, Department of Chemistry, University of Durham, UK, are gratefully acknowledged for excellent $^2$H NMR spectra.

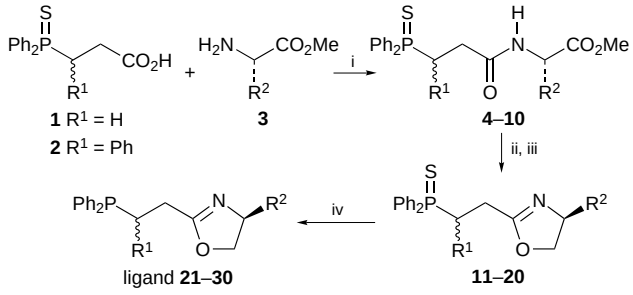
# A modular approach to ligands for asymmetric π-allyl palladium catalysed additions



**Scott R. Gilbertson* and Cheng-Wei T. Chang**

*Department of Chemistry, Washington University, St. Louis, Missouri 63130, USA*

**A route to phosphinodihydrooxazoles is reported, which is used to synthesize ten new ligands whose ability to asymmetrically catalyse the addition of dimethyl malonate to 1,3-diphenylprop-2-enyl acetate is investigated; the best gave a palladium complex which catalyses the addition of dimethyl malonate to 1,3-diphenylprop-2-enyl acetate in 99% yield and 97% ee.**

The pace for the development of new asymmetric ligands is often determined by the availability of new ligand structures. Hence we have been interested in developing a building block based approach to the systematic synthesis of new, structurally varied ligands. Such an approach offers the potential for the discovery of new synthetically useful metal–ligand complexes, as well as the optimization of ligand systems that are known to work to a limited extent. To date, this work has focused on the synthesis and utility of amino acid based phosphine derivatives, for the construction of peptide based ligands.[1–4] We report here that the building blocks used in that approach can also be employed in the synthesis of a variety of phosphinodihydrooxazole ligands. This route allows access to new phosphine ligands without the difficulties often associated with C–P bond formation. We have used this chemistry to synthesize ten new phosphinodihydrooxazole ligands. These ligands have been screened for their ability to control the palladium catalysed asymmetric addition of malonate to 1,3-diphenylprop-2-enyl acetate.[5–7] A number of successful ligands were discovered with the best giving, at room temperature, the addition of malonate with 97% ee. This study also resulted in the observation of an interesting inverse temperature effect, in which the best ligand **28** gives higher ees at room temperature than at −30 °C.

As the starting point for our design we decided to use phosphine dihydrooxazole ligands that were structurally similar to those reported by Pfaltz, Helmchen and Williams.[8–12] This type of ligand has proven useful in asymmetric π-allyl additions[8–12] and asymmetric Heck reactions.[13] To date, the most successful ligands of this type have been six-member chelates with the phosphine attached to the dihydrooxazole through a phenyl ring. To the best of our knowledge only a single system with the phosphine attached to the nitrogen ligand by an alkyl bridge has been reported. That system, which forms a five-member chelate, gave poorer selectivity than the best systems.[10] Our approach makes ligands available that link the phosphine and dihydrooxazole groups with a two-carbon alkyl chain, thus forming a six-member chelate upon metal coordination and allowing a direct comparison to the six-member chelates studied previously by others.[8–12] The use of an alkyl chain to connect the chelating functionality allows the introduction of a second chiral centre, which is next to the phosphine. This results in diastereomeric ligands in which the two chiral centres can, potentially, act in concert or dissonance. Results with both diastereomeric possibilities are reported.

**Scheme 1** *Reagents and conditions:* i, EDC, HOBT, $CH_2Cl_2$, MeCN, room temp.; ii, $LiBH_4$, THF, 0 °C to room temp.; Burgess reagent, THF, reflux; iv, Raney Ni, MeCN, 60–80%

The synthesis of the library of ligands began with modular building blocks **1**, **2** and **3**. We chose to use amino acids **3** and phosphine containing acids (**1** and **2**) as our modules, allowing the synthesis of new ligands by amide bond formation. For the study reported here, we used two phosphine containing acids. One was a diphenylphosphine derivative of acrylate **1**, and the other a derivative of cinnamic acid **2**. The acrylate derivative **1** has been reported earlier as an intermediate in the synthesis of diphenylphosphinoserine.[1,2] The synthesis of the phenyl derivative **2** was performed in the same manner from cinnamic acid.

The synthesis of the ligands began with the coupling of phosphine acids **1** or **2** to a given amino acid yielding the phosphine sulfide amides **4–10** (Scheme 1). The desired ligands were then obtained by a simple three step procedure. Reduction of the methyl ester with $LiBH_4$ followed by cyclization with Burgess reagent[14] [$MeO_2CNSO_2NEt_3$] gave the dihydrooxazole phosphine sulfides **11–20**. Reaction with Raney nickel then removed the sulfur and gave the free phosphines. Reaction of **2** with an amino acid gave two diastereomeric products. These diastereomers were readily separated by chromatography, after $LiBH_4$ reduction, yielding both the (*SS*) and (*RS*) pair of diastereomers. The ligands are fully characterized as the phosphine sulfides. After reduction of the phosphine sulfides to the free phosphines the ligands were treated with palladium and used in catalysis without purification.†

The ligands were investigated in two groups; ligands with one chiral centre (Table 2) and ligands with two chiral centres (Table 3). Of the ligands with one chiral centre, the ligands derived from phenylalanine ($R^2$ = Bn) **22** and valine ($R^2$ = $Pr^i$) **23** gave the highest ees (87 and 86%) (Table 2, entries 2 and 3).

**Table 1** Synthesis of phospine dihydrooxazole ligands

| $R^1$ | $R^2$ | Compound | Yield (%) | Compound | Yield (%) | Ligand |
|---|---|---|---|---|---|---|
| H | Me (*S*) | **4** | 33 | **11** | 62 | **21** |
| H | Bn (*S*) | **5** | 31 | **12** | 66 | **22** |
| H | $Pr^i$ (*S*) | **6** | 64 | **13** | 72 | **23** |
| H | Ph (*S*) | **7** | 56 | **14** | 84 | **24** |
| Ph (*S*) | Bn (*S*) | **8** | 69[a] | **15** | 71 | **25** |
| Ph (*R*) | Bn (*S*) | **8** | 69[a] | **16** | 85 | **26** |
| Ph (*S*) | $Pr^i$ (*S*) | **9** | 62[a] | **17** | 45 | **27** |
| Ph (*R*) | $Pr^i$ (*S*) | **9** | 62[a] | **18** | 91 | **28** |
| Ph (*S*) | Ph (*S*) | **10** | 47[a] | **19** | 48 | **29** |
| Ph (*R*) | Ph (*S*) | **10** | 47[a] | **20** | 90 | **30** |

[a] Yields reported for **8**–**10** are for the mixture of the two diastereomers.

The effect of solvent on the reaction was probed using ligand **23** and the $Bu_4N^+$/BSA cation base combination (entries 3, 8, 9 and 10).[15] Of the solvents tested, $CH_2Cl_2$ was found to be the best solvent for this ligand (entry 3). The counter ion and base associated with the malonate anion have been shown to be important in these additions and so their effect was also investigated (entries 3, 5, 6 and 7). The optimal system for this class of ligand was found to be $(C_6H_{13})_4N^+$/BSA, as the counter ion and base, and $CH_2Cl_2$ as the solvent (entry 6), giving an ee of 90%.

Of the ligands with two chiral centres, the ligands derived from valine were again found to perform the best. Both combinations of the two chiral centres were looked at. It is interesting to note that the chirality at the carbon next to the phosphine had little effect on the selectivity of the catalysis, 90 *vs*. 93% ee for the (*SS*) *vs*. (*RS*) pair (Table 3, entries 3 and 4). Ligand **28** with a (*RS*) configuration, was found to be the most selective ligand (entry 4). The optimal reaction conditions for this ligand were then determined. The best solvent system for this ligand was found to be MeCN, and the best counter ion system was $(C_6H_{13})_4N^+$/BSA (entry 14).

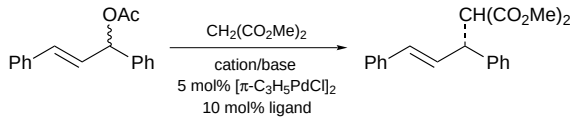


**Table 2** Results with ligand containing single chiral centre

| Entry | Ligand (config.) | Cation/base | Yield (%) | ee (%)[a] | Solvent |
|---|---|---|---|---|---|
| 1 | **21** (*S*) | $Bu_4N^+$/BSA | 67 | 82 | $CH_2Cl_2$ |
| 2 | **22** (*S*) | $Bu_4N^+$/BSA | 78 | 87 | $CH_2Cl_2$ |
| 3 | **23** (*S*) | $Bu_4N^+$/BSA | 94 | 86 | $CH_2Cl_2$ |
| 4 | **24** (*S*) | $Bu_4N^+$/BSA | 82 | 37 | $CH_2Cl_2$ |
| 5 | **23** (*S*) | $K^+$/BSA | 87 | 66 | $CH_2Cl_2$ |
| 6 | **23** (*S*) | $(C_6H_{13})_4N^+$/BSA | 62 | 90 | $CH_2Cl_2$ |
| 7 | **23** (*S*) | $(C_6H_{13})_4NBr$/Me/NaH | 22 | 81 | THF |
| 8 | **23** (*S*) | $Bu_4N^+$/BSA | 93 | 11 | CN |
| 9 | **23** (*S*) | $Bu_4N^+$/BSA | 14 | 64 | THF |
| 10 | **23** (*S*) | $Bu_4N^+$/BSA | 25 | 78 | $C_6H_6$ |

[a] The enantiomeric excesses were determined by chiral shift reagent [Eu(hfbc)$_3$] (ref. 11). BSA = bis(trimethylsilyl)acetamide.

**Table 3** Results with ligands containing two chiral centres[a]

| Entry | Ligand (config.) | Cation/base | Yield (%) | ee (%) | Solvent |
|---|---|---|---|---|---|
| 1 | **25** (*S*,*S*) | $Bu_4N^+$/BSA | 100 | 84 | MeCN |
| 2 | **26** (*R*,*S*) | $Bu_4N^+$/BSA | 53 | 93 | MeCN |
| 3 | **27** (*S*,*S*) | $Bu_4N^+$/BSA | 91 | 90 | MeCN |
| 4 | **28** (*R*,*S*) | $Bu_4N^+$/BSA | 80 | 93 | MeCN |
| 5 | **29** (*S*,*S*) | $Bu_4N^+$/BSA | 56 | 22 | MeCN |
| 6 | **30** (*R*,*S*) | $Bu_4N^+$/BSA | 37 | 54 | MeCN |
| 7 | **27** (*S*,*S*) | $Bu_4N^+$/BSA | 91 | 90 | MeCN |
| 8 | **27** (*S*,*S*) | $Bu_4N^+$/BSA | 43 | 65 | $CH_2Cl_2$ |
| 9 | **28** (*R*,*S*) | $Bu_4N^+$/BSA | 80 | 93 | MeCN |
| 10 | **28** (*R*,*S*) | $Bu_4N^+$/BSA | 33 | 85 | $CH_2Cl_2$ |
| 11 | **28** (*R*,*S*) | $Bu_4N^+$/BSA | 48 | 88 | THF |
| 12 | **28** (*R*,*S*) | $Bu_4N^+$/BSA | 49 | 79 | $C_6H_6$ |
| 13 | **28** (*R*,*S*) | TBAOAc/BSA | 93 | 82 | MeCN |
| 14 | **28** (*R*,*S*) | $(C_6H_{13})_4N^+$/BSA | 99 | 97 | MeCN |

[a] General procedure given in the footnote†.

In the case of the ligands reported by Pfaltz, where the phosphine is attached to the dihydrooxazole through a phenyl ring, a phenyl substituent next to the nitrogen gave the highest selectivities, with isopropyl only slightly poorer.[9] In the system reported here, the best substituent, in the position next to nitrogen, was isopropyl while phenyl was found to be the poorest (ligand **28** *vs*. **30**). The source of the difference between the two systems is unknown, but probably has its origins in different conformational preferences for the two complexes. The positioning of an $sp^3$ hybridized carbon, with a phenyl ring attached, changes the canting of the phenyl rings on the phosphine. This effect may be responsible for the difference between these two ligands.

Through the use of modular building blocks we have developed a new ligand for palladium catalysed π-allyl additions. We are currently studying the use of these ligands in other metal catalysed reactions. We are also using the phosphine acid building blocks discussed here in the synthesis of other collections of ligands for a variety of transition metal catalysed reactions.

We gratefully acknowledge the Washington University High-Resolution NMR Facility, partially supported by NIH 1S10R02004, and the Washington University Mass Spectrometry Resource Center, partially supported by NIHRR00954, for their assistance.

## Footnotes

* E-mail: srg@wuchem.wustl.edu

† *General procedure* for π-allyl addition: The phosphinooxazoline ligand was mixed with $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ in degassed MeCN. After 30 min, 1,3-diphenylprop-2-enyl acetate (10 equiv.) in MeCN was added. To this solution at the desired reaction temperature, a solution of dimethyl malonate (30 equiv.), $Bu_4NF$ (30 equiv.) and BSA (30 equiv.) in MeCN was added over 1 h. After complete reaction, as judged by TLC, the reaction mixture was worked up extractively.

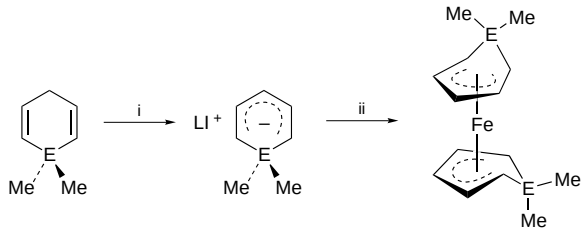
# Synthesis and characterisation of the novel metallocenes $[Fe(\eta^5\text{-}C_5H_5EMe_2)_2]$ (E = Si, Sn) and $[Fe(\eta^5\text{-}C_5H_5SnMe_2)(\eta^6\text{-}C_6H_6)]_2[Fe_2Cl_6]$

**Brian F. G. Johnson,*[a] Caroline M. Martin,[a] Mathias Nowotny,[a] Warwick Palmer[a] and Simon Parsons[b]**

[a] *University Chemical Laboratories, Lensfield Road, Cambridge, UK CB2 1EW*
[b] *Department of Chemistry, University of Edinburgh, West Mains Road, Edinburgh, UK EH9 3JJ*

**The novel bis-heterocyclohexadienyl metallocene complexes $[Fe(\eta^5\text{-}C_5H_5EMe_2)_2]$ (E = Si, Sn) are prepared by reaction of anhydrous $FeCl_2$ with the appropriate lithium salt; $[Fe(\eta^5\text{-}C_5H_5SnMe_2)_2]$ undergoes a further unusual reaction with $CHCl_3$ to displace one $SnMe_2$ fragment and afford the mixed sandwich complex $[Fe(\eta^5\text{-}C_5H_5SnMe_2)(\eta^6\text{-}C_6H_6)]_2[Fe_2Cl_6]$.**

Despite the class of the open metallocenes having been long established by the pioneering work of Ernst,[1] there are few reported examples of systems employing ligands of the type $C_5H_5ER_2$ (E = C[2], P[3,4]), in which the open pentadienyl moiety is stabilised by linking the ends together in a non-conjugative mannar *via* a group 14 or 15 bridging unit $ER_2$.



Such ligands are of interest since they provide both the possibility of introducing sterically controlling groups R, and an electropositive heteroatom E that may increase electron density at the transition-metal centre. The activity of group 4 metallocene Ziegler–Natta catalysts may benefit from the increased electron density on the metal centre imposed by these electropositive ligands.[5]

Here we report the formation of the bis-heterocyclohexadienyl metallocene complexes $[Fe(\eta^5\text{-}C_5H_5EMe_2)_2]$ (E = Si **1**, Sn **2**). The ligand precursors 1,1-dimethyl-1-stannacyclohexa-2,5-diene[6] and 1,1-dimethyl-1-silacyclohexa-2,5-diene[7,8] were prepared by literature methods. The heterocyclohexadienes were deprotonated with LDA and the resulting heterocyclohexadienyl anions were treated with anhydrous $FeCl_2$ to afford the metallocene complexes **1** and **2** (Scheme 1).

A formal displacement of $Me_2SnCl_2$ by $CHCl_3$ caused the precipitation of a few crystals of the mixed-sandwich complex $[Fe(\eta^5\text{-}C_5H_5SnMe_2)(\eta^6\text{-}C_6H_6)]_2[Fe_2Cl_6]$ **3** from a solution of complex **2** in this halogenated solvent within several days, while complex **1** is not noticeably affected by $CHCl_3$.

Complexes **1** and **2** have been fully characterised on the basis of their spectroscopic data.† Single-crystal X-ray structures of **1** and **3** are also presented. The molecular structures of complex **1** and of the mixed-sandwich cation in **3** are shown in Fig. 1 and 2, respectively.‡ The 1,1-dimethyl-1-stannacyclohexadienyl ring in the mixed-sandwich complex **3** is representative of the environment in **2**, and so may be usefully compared to the environment of the 1,1-dimethyl-1-silacyclohexadienyl rings in the symmetrical metallocene complex **1**. The heterocyclohexadienyl moiety in **1**, **2** and **3** bonds to Fe in an $\eta^5$ manner *via* the five essentially planar carbon atoms, the mean deviation from planarity being ±0.078 and ±0.0149 Å for complexes **1** and **3**, respectively. The heteroatom is pushed out of the plane away from the transition metal. The angle between the C(5)–Si(1)–C(1) plane and the C(1)···C(5) plane is 36.9° in **1**. The corresponding angle in complex **3** is of similar magnitude at 37.6°. The non-bonding FeSi(1) distance in **1** is 2.861 Å compared to a non-bonding Fe(2)···Sn(2) distance in **3** of 3.142 Å. These distances are remarkably short though the Fe···Si distance exceeds the shortest, to our knowledge, non-bonding Si···Fe contact at 2.636 Å in $Ph_2Si(C_5H_4)_2Fe$.[9]

The open and closed carbocyclic ligands in **1** and **3** adopt an essentially coplanar arrangement represented by interplanar angles of 3.7 and 3.8°, respectively. The conformational angle of 38.6° adopted by the ligands in **1** is significantly smaller than the value of 59.7° found in the open ferrocene bis(2,4-dimethylpentadienyl)iron **4**.[5] The distances from the heterocyclohexadienyl ring centroids to Fe remain comparable at 1.543 and 1.531 Å for complexes **1** and **3** respectively and are of the same order of magnitude as the distance of 1.50 Å in **4**, while the distance from the benzene ring centroid to Fe in **3** is slightly longer at 1.559 Å. This may be compared with the value

**Scheme 1** Synthesis of the novel metallocenes **1** and **2**. *Reagents and conditions*: i, LDA, thf, 0.5 h, 258 K; ii, $FeCl_2$, thf, 1 h 200 K, 12 h, 298 K, subsequent work-up by filtration through silica and crystallisation of **1** from hexane.

C(1)–Si(1)–C(1m) 113.2(2), C(5)–Si(1)–C(2m) 114.1(2).

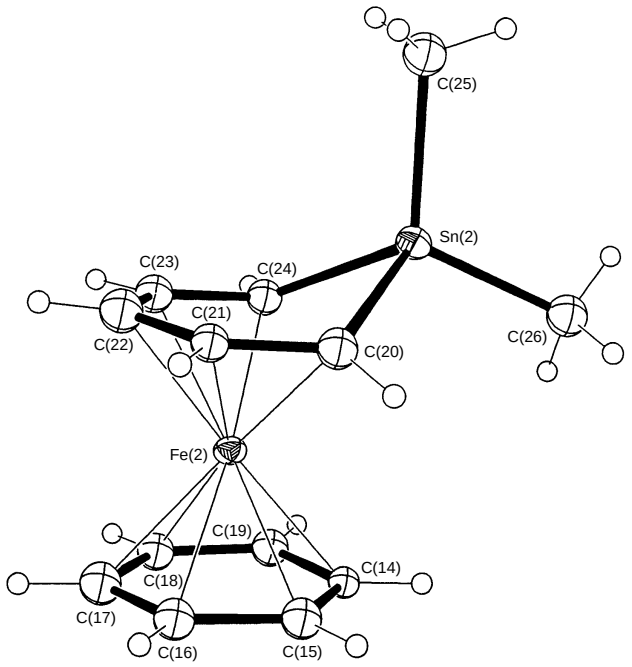


**Fig. 2** Molecular structure of the complex cation **3** with the $Fe_2Cl_6^{2-}$ counter ion omitted for clarity. Selected bond lengths (Å) and angles (°): Sn(2)–C(25) 2.11(2), Sn(2)–C(26) 2.09(2), Sn(2)–C(24) 2.14(2). Sn(2)–C(20) 2.11(2), C(24)–C(23) 1.40(2), C(23)–C(22) 1.41(2), C(22)–C(21) 1.39(2), C(21)–C(20) 1.38(2), Fe(2)–Sn(2) 3.142(1), C(14)–C(15) 1.37(2), C(15)–C(16) 1.41(2), C(16)–C(17) 1.42(2), C(17)–C(18) 1.40(2), C(18)–C(19) 1.38(2), C(19)–C(14) 1.39(2), C(25)–Sn(2)–C(26) 113.6(7), C(20)–Sn(2)–C(24) 82.2(7), C(20)–Sn(2)–C(25) 114.1(7), C(24)–Sn(2)–C(26) 116.4(7), C(21)–C(22)–C(23) 122(2), C(22)–C(23)–C(24) 126(2). C(22)–C(21)–C(20) 127(2), C(21)–C(20)–Sn(2) 122.0(13), C(23)–C(24)–Sn(2) 119.9(14).

of 1.55 Å found in the analogous complex $[Fe(\eta^5\text{-}C_5H_5)(\eta^6\text{-}C_6Et_6)]PF_6$.[10]

Spectroscopic data show that the heteroatom methyl substituents are non-equivalent and may be classified as *mexo* and *mendo*. The difference in chemical shift between the *mendo* and *mexo* methyl groups is a function of the ring carbon–heteroatom distance, since the ring current generated by the heterocyclohexadienyl system decreases in strength away from the ring centroid. The C(24)–Sn(2) distance in **3** is indeed longer, at 2.14(2) Å, than the C(5)–Si(1) distance in **1**, 1.832(5) Å, and the *mendo*–*mexo* methyl NMR signals have a greater difference in **2** than **1** as a result.

The electrochemical behaviour of **1** and **2** resemble that of the open ferrocene **4**[11] with the reversible one-electron oxidation occurring at a far lower potential for **1** than **2** reflecting the greater electron density at the Fe centre for the system with the more electropositive heteroatom.§ Likewise, an orthorhombic *g* tensor is observed in the EPR spectra of both **1** and **2** in frozen solution.

This new class of metallocene complexes employing heterocyclic ligands is being extended to include the early transition-metal elements, and further direct replacement of the $SnMe_2$ moiety by a variety of other heteroatoms is under examination.

We gratefully acknowledge Professor C. Elschenbroich and Drs B. Metz and O. Schiemann for the conduction of EPR and electrochemical measurements and Dr J. E. Davies for the collection of crystallographic data. The EPSRC (W. P., M. N.), Tioxide (W. P.) and Deutsche Forschungsgemeinschaft (M. N.) are acknowledged for financial support.

‡ *Crystal data*: for **1**: $C_{14}H_{22}FeSi_2$, 0.27 × 0.19 × 0.16 mm, $T$ = 150(2) K, $M$ = 302.35, monoclinic, space group $P2_1/c$, $a$ = 13.209(7), $b$ = 9.516(7), $c$ = 11.997(7) Å, β = 100.06(5)°, $U$ = 1485(2) Å$^3$, $Z$ = 4, $D_c$ = 1.353 Mg m$^{-3}$, λ = 0.71073 Å, $F$(000) = 640, $R_1$ = 0.0407 [1914 reflections with $F_o > 4\sigma(F_o)$], $wR_2$ = 0.0902 for 1922 independent reflections corrected for adsorption [μ(Mo-Kα) = 1.154 mm$^{-1}$] and 189 parameters (all non-H atoms anisotropic).

For **3**: $C_{13}H_{17}Cl_3Fe_2Sn$, 0.12 × 0.10 × 0.10 mm, $T$ = 154(2) K, $M$ = 510.01, monoclinic, space group $P2_1/n$, $a$ = 14.843(5), $b$ = 14.209(5), $c$ = 17.098(6) Å, β = 106.97(2)°, $U$ = 3449(2) Å$^3$, $Z$ = 8, $D_c$ = 1.964 Mg m$^{-3}$, λ = 0.71073 Å, $F$(000) = 1984, $R_1$ = 0.0701 [2723 reflections with $F_0 > 4\sigma(F_o)$], $wR_2$ = 0.1844 for 4492 independent reflections and 295 parameters (Fe, Sn and Cl atoms anisotropic). Compound **3** crystallises with two half-dianions and two cations per asymmetric unit; each anion possessing a crystallographic centre of symmetry. The benzene ring of one cation is disordered over two sites with partial occupancies of 0.62 and 0.38.

The structures were solved by direct methods,[12] and a series of difference Fourier maps were used to locate all light atoms except the H atoms, these being added in calculated positions (C–H 0.96 Å) riding on the respective C atoms. All other calculations were performed using SHELXL-93.[13]

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/436.

§ The cyclic voltammograms (CVs) of **1** and **2** were recorded using a glassy-carbon/platinum electrode system referenced to calomel in dme–0.1 M $NBu_4PF_6$, $v$ = 100 mV s$^{-1}$ at 298 K. A one-electron reversible oxidation with $E_{\frac{1}{2}}$(0/+1) {$\Delta E_p$} = 169 {67} and −200 {58} mV was observed for **1** and **2** respectively. Irreversible reduction waves were registered at $E_{pc}$ = −2.315 and −2.191 V for **1** and **2**, respectively.

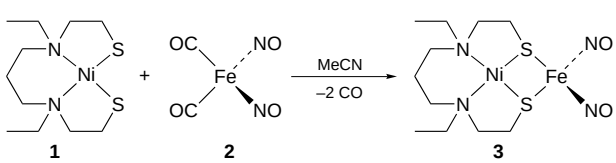
# Synthesis, X-ray structure and electrochemical characterisation of a binuclear thiolate bridged Ni–Fe–nitrosyl complex, related to the active site of NiFe hydrogenase

**Frank Osterloh,* Wolfgang Saak, Detlev Haase and Siegfried Pohl†**

*Fachbereich Chemie, Universität Oldenburg, Postfach 2503, D-26111 Oldenburg, Germany*



**[NiL] 1 (L = *N*,*N*′-diethyl-3,7-diazanonane-1,9-dithiolate) reacts with [Fe(CO)$_2$(NO)$_2$] 2 to afford [Ni(L)Fe(NO)$_2$] 3, in which a Ni$^{II}$ ion and a nitrosylated Fe$^{-II}$ centre are bridged *via* two μ-S atoms from the chelating ligand.**

The NiFe hydrogenase from *D. gigas* catalyses the reversible oxidation of molecular hydrogen. This enzyme utilises a binuclear complex as the active site, in which one Ni and one Fe atom are covalently linked by the S atoms of two cysteine residues and by one unidentified ligand.[1–3] Two additional cysteine S atoms complete the square-pyramidal coordination sphere of Ni, whereas the Fe atom binds to three unidentified diatomic ligands, possible candidates being CO, $CN^-$, NO and $C{\equiv}CH^-$. These non-protein ligands give rise to unusual absorption bands (1800–2100 cm$^{-1}$) in the IR spectra of many NiFe hydrogenases and appear to be a constant feature of these enzymes.[1,4] These observations prompted us to search for synthetic pathways to binuclear, μ-S thiolate bridged NiFe complexes in which NO binds to an Fe atom.

When a solution of the neutral complex [NiL] **1** in acetonitrile is combined with a stoichiometric amount of liquid [Fe(CO)$_2$(NO)$_2$] **2**, the colour changes immediately from purple to deep brown. CO is liberated from the solution, indicating rapid substitution of CO by the Ni complex, a reaction type that has been well established on **2** with other nucleophiles.[5] The mixture was refluxed for 15 min to complete the reaction and then kept at room temperature for 24 h (Scheme 1).

Black needles of [Ni(L)Fe(NO)$_2$] **3** formed, which were filtered off, washed with acetonitrile and dried *in vacuo*. When the volume of the mother-liquor was reduced *in vacuo*, a second crop of **3** could be obtained, which had to be recrystallized from hot acetonitrile; the total yield was 57%.‡

The result of an X-ray structure analysis§ of **3** is shown in Fig. 1 and bond lengths and angles are given in Table 1. The most striking structural feature is the short Ni–Fe distance of 279.7(1) pm, which remains lower than the value of 290 pm of the binuclear complex of the active centre of NiFe hydrogenase.[1] Other known μ-SR bridged NiFe compounds exhibit Ni–Fe distances between 280.6(5) and 376(1) pm.[6–8] The small Ni–Fe separation in **3** is, at least in part, due to the low coordination number of the nitrosylated iron atom which is in a distorted tetrahedral $N_2S_2$ environment. The two NO ligands are slightly bent towards each other resulting in Fe–N–O angles of 167.0(5) and 174.6(5)°. These values are unexceptional; similar Fe–N–O angles were found in other complexes with $S_2Fe(NO)_2$ fragments, *e.g.* [(PhS)$_2$Fe(NO)$_2$]$^-$ [168.5(2), 169.4(2)°].[9] As in the latter complex, the NO groups in **3** are linear and hence must be viewed as three-electron donors to the Fe atom, which is formally at the -II oxidation level and has 18 valence electrons. Judged from structural details no significant electron delocalization from the reduced Fe centre to Ni$^{II}$ takes place. Such a transfer of charge should influence the geometry of the Ni coordination environment, which apart from a decreased S–Ni–S angle (by 4°) and an increased N–Ni–N angle (by 3.7°) is almost identical to that of a similar mononuclear nickel(II) complex.[10]

**1** **2** **3**

**Scheme 1**

The IR spectrum of **3** shows two intense absorption bands at 1663 and 1624 cm$^{-1}$, which were assigned to the symmetrical and the asymmetrical stretching vibration of the nitrosyl ligands. The lowering of these values in comparison to **2** (1810 and 1766 cm$^{-1}$ in cyclohexane)[11] indicates an increased transfer of electron density from Fe into π* orbitals of the NO ligands (back bonding), which is accompanied by a weakening of the NO triple bonds.

Although the IR spectrum of **3** does not reproduce the characteristic absorption pattern of NiFe hydrogenases at 1800–2100 cm$^{-1}$, a nitrosyl ligand at the active centre of NiFe hydrogenase cannot be excluded on the basis of IR spectroscopy. Variations of the band positions could result from

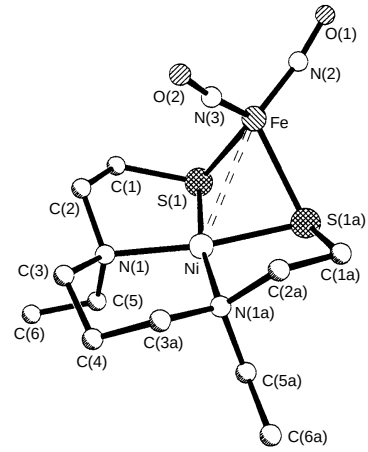


**Fig. 1** Molecular structure of **3** with atom labelling scheme; **3** exhibits crystallographic mirror symmetry; H atoms have been omitted

**Table 1** Selected interatomic distances (pm) and angles (°) for **3**

| | | | |
|---|---|---|---|
| Ni···Fe | 279.7(1) | S(1)–Ni–S(1a) | 81.46(6) |
| Ni–S(1) | 217.6(1) | S(1)–Ni–N(1) | 88.7(1) |
| Ni–N(1) | 198.5(3) | N(1)–Ni–N(1a) | 101.0(2) |

| | | Fe–N(3)–O(2) | 174.6(5) |

different oxidation levels and from the different coordination environments of the Fe centres in both heterobimetallic complexes. However, it should be noted that other μ-SR bridged NiFe complexes, in which CO acts as a ligand to the Fe atom, mimic the IR properties of NiFe hydrogenases well.[8a]

In acetonitrile and dichloromethane solutions **3** can be quasi-reversibly oxidised at −120 mV (*vs*. SCE). Since the oxidation of $N_2S_2$ bound $Ni^{II}$, *e.g.* in $[Ni^{II}(NiL)_2]^{2+}$, cannot be achieved at potentials below +860 mV (*vs*. SCE in MeCN),[12] this process was tentatively assigned to the redox couple $Fe^{-II/-I}$. Interestingly, **2** in dmf solution can be consecutively reduced to the $[Fe(CO)_2(NO)_2]^{2-}$ dianion but has no tendency toward oxidation.[13] The differences in the redox properties of **2** and **3** have to be attributed to the better electron-donating capability of the μ-S thiolates in comparison to CO.

Attempts to oxidise **3** chemically have been unsuccessful. When treated with $[Fe(C_5H_5)_2]BF_4$ in dichloromethane or acetonitrile solution, **3** decomposes into various products, of which $[Ni^{II}(NiL)_2][BF_4]_2$ could be isolated as black or reddish needles, depending on the solvent. The formation of trinuclear cations, such as $[Ni^{II}(NiL)_2]^{2+}$ in which a central $Ni^{II}$ binds to four bridging thiolate S atoms of two [NiL] fragments, has been commonly observed when $Ni^{II}$ complexes like **1** are reacted with oxidising agents.[14]

We thank Dr H. Strasdeit for a critical review of the manuscript. Financial support from the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged.

† Deceased. Correspondence should be addressed to F. Osterloh.

‡ The nickel complex **1** can be obtained as purple crystals by reaction of nickel(II) acetylacetonate with $H_2L$ in thf solution. $H_2L$ is readily available by reaction of *N*,*N*′-diethyl-1,3-diaminopropane (Aldrich) with 2 equiv. of ethylenesulfide in toluene solution according to Karlin and Lippard.[15] **2** was synthesised from $Fe(CO)_5$ and $NaNO_2$–HOAc according to Hieber and Beutner.[16] *Analytical data* for **3**: IR (KBr): ν(NO) 1663vs, 1624vs $cm^{-1}$. UV–VIS spectrum (MeCN): $\lambda_{max}$/nm (ε/$dm^3$ $mol^{-1}$ $cm^{-1}$) = 570 (370), 410 (1620). Satisfactory elemental analysis. Electrochemistry of **3** (in MeCN with $NBu^n_4PF_6$ as electrolyte): $E_0$ = −120 mV (*vs*. SCE); $\Delta E_p$ = 67 mV; $i_c/i_a$ = 0.91; scan rate 100 mV $s^{-1}$. **3** is readily soluble in dmf, MeCN and $CH_2Cl_2$. Crystals isolated from the reaction mixture were sufficient for X-ray crystallography.

§ *Crystal data* for **3**: $C_{11}H_{24}FeN_4NiO_2S_2$, $M$ = 423.02, orthorhombic, space group *Pnma*, $a$ = 1177.0(1), $b$ = 1018.4(1), $c$ = 1471.2(1) pm, $U$ = 1.7635(3) $nm^3$, $T$ = 296 K, $Z$ = 4, $D_c$ = 1.593 Mg $m^{-3}$, μ(Mo-Kα) = 2.134 $mm^{-1}$. A black single crystal of **3** with dimensions 0.72 × 0.40 × 0.28 mm was sealed in a glass capillary and mounted on a Siemens-Stoe AED 2 four-circle diffractometer. Data collection using Mo-Kα radiation (λ = 71.073 pm) and ω–2θ scans gave 1641 independent reflections ($\theta_{max}$ = 25°), of which 1536 with $I > 2\sigma(I)$ were used in the final structure refinement. A semiempirical absorption correction using ψ-scans was applied. The structure was solved by direct methods and the solution developed using full-matrix least-squares refinements on $F^2$ and difference Fourier syntheses. Anisotropic displacement parameters were refined for all non-H atoms. H atoms were included on calculated positions with isotropic displacement parameters tied to those of the corresponding carbon atoms.[17] At convergence, $R_1$ = 0.0497, $wR_2$ = 0.1099, GOF = 1.295 for 106 parameters. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/446.

# Nature of the bonding in a carbene–phosphinidene: a main group analogue of a Fischer carbene complex? Isolation and characterisation of a bis(borane) adduct

**Anthony J. Arduengo, III,[a] Claire J. Carmalt,[b] Jason A. C. Clyburne,[b] Alan H. Cowley*[b] and Radha Pyati[b]**

[a] *DuPont Science and Engineering Laboratory, Experimental Station, Wilmington, Delaware, 19880, USA*
[b] *Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, Texas 78712, USA*

**The reaction of the carbene–phosphinidene (1,3-dimesityl-imidazolin-2-ylidene)PPh 1 with $BH_3$·thf affords the corresponding P-bonded bis(borane) adduct, thus demonstrating the availability of two lone pairs on the phosphorus centre; base competition studies reveal that 1 is a strong phosphorus base and, by means of cyclic voltammetry, it is established that 1 undergoes facile oxidation.**

It has been demonstrated recently[1,2] that stabilised carbenes are sufficiently nucleophilic to depolymerise cyclopolyphosphines such as $(PPh)_5$ and $(PCF_3)_4$ and produce compounds of the type (carbene)PR. Two extreme canonical forms, **A** and **B**, can be written for such species. Form **A** represents a phosphinidene adduct of a carbene and involves a carbon–phosphorus dative bond of order one whilst **B** corresponds to a conventional phosphaalkene and features a double bond between carbon and phosphorus. There is, in fact, an interesting parallel with transition metal carbene complexes, albeit with the roles of metal and carbene being played by carbene and phosphinidene respectively in the cases of forms **A** and **B**. Thus the low-valent form **A** resembles a Fischer-type complex and the high-valent form **B** is akin to a Schrock-type alkylidene complex. In terms of metrical parameters, it has been found[1,2] that the P–C(carbene) bond is only *ca*. 4% longer than the P–C(R) single bond and that the P–C(R) moiety is twisted out of the carbene plane by 18–20°. Taken in concert with the high-field $^{31}P$ chemical shifts, these data imply that the pπ–pπ bond between carbon and phosphorus is not well developed. It occurred to us that further important information regarding the electronic structures of these compounds might stem from Lewis-basicity and electrochemical studies. The Lewis-base behaviour was expected to be particularly revealing since a conspicuous difference between **A** and **B** concerns the fact that these forms feature two and one phosphorus lone pairs, respectively. Treatment of **1**[2] with $BH_3$·thf in toluene solution resulted in the exclusive formation of the bis(borane) adduct **2** (Scheme 1).†

**Scheme 1**

Interestingly, no evidence for a 1:1 $BH_3$ adduct could be found by NMR titration.‡ The X-ray crystal structure of **2** (Fig. 1)§ confirmed the attachment of two $BH_3$ groups to the phosphorus centre and, in addition, showed that the P–C(carbene) bond lengthened by 0.093 Å and the C–P–C angle increased by 4.9° in the conversion of **1** to **2**. An increase in bond length is anticipated if it is assumed that **1** features a modicum of back π-bonding from phosphorus to the carbene carbon atom which is lost upon borane attachment. Such a view finds a parallel in the molecular orbital theory of Fischer-type carbene complexes.[3] It should be noted, however, that some of the increase in the P–C(carbene) bond length could be accounted for by increased steric interactions. The increase in bond angle is consistent with the valence shell electron pair repulsion (VSEPR) model[4] in the sense that two lone pairs in **1** are replaced by two bond pairs in **2**. The P–B bond lengths [av. 1.946(2) Å] are normal and the geometry at phosphorus is approximately tetrahedral. The following additional points are also noteworthy: (*i*) the formation of **2** can be regarded as an example of base-induced coordination[5] of an electrophilic fragment (a phosphinidene in this case), and (*ii*) given that $BH_3$ and $M(CO)_5$ moieties (M = Cr, Mo, W) are isolobal, there is an interesting parallel between **2** and base·$E(R)[M(CO)_5]_2$ (E = P, As) complexes.[6]

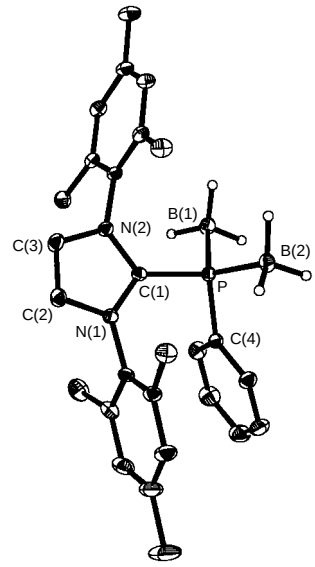

**Fig. 1** Molecular structure of **2** showing the atom numbering scheme. Selected distances (Å) and angles (°): P–C(1) 1.856(2), P–C(4) 1.828(2), P–B(1) 1.945(2), P–B(2) 1.948(2), C(1)–N(1) 1.355(2), N(1)–C(2) 1.377(2), C(2)–C(3) 1.337(2), N(2)–C(3) 1.374(2), C(1)–N(2) 1.358(2); C(1)-P–C(4) 104.78(7), C(1)–P–B(1) 109.33(8), C(1)–P–B(2) 109.20(8), B(1)–P–B(2) 117.46(10), C(4)–P–B(1) 106.60(9), C(4)–P–B(2) 108.71(9), N(1)–C(1)–N(2) 105.14(13), C(1)–N(1)–C(2) 110.33(14), N(1)–C(2)–C(3) 106.9(2), C(2)–C(3)–N(2) 107.6(2), C(3)–N(2)–C(1) 109.96(13).

An attempt at qualitative basicity assessment of **1** was made by treatment of **2** with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), 1,5-diazabicyclo[4.3.0]non-5-ene (DBN), and $PAr_3$ **3** [Ar = $C_6H_2(OMe)_3$-2,4,6]. It was found that both DBU and DBN removed the $BH_3$ moieties from **2** quantitatively whilst **3**, the most basic tertiary phosphine known so far ($pK_a$ 11.2),[7] failed to react. The $pK_a$ of **1** is therefore likely to exceed 11.2.

Further support for the carbene–phosphinidene bonding description (form **A**) stemmed from cyclic voltammetry experiments.¶ Thus, acetonitrile solutions of **1** exhibit an irreversible one-electron oxidation at −0.08 V (*vs.* SCE). Such a low oxidation potential is consistent with an electron-rich phosphorus centre since the one-electron oxidation potentials of typical phosphaalkenes fall in the range 1.07–2.94 V (*vs.* SCE).[8]

Finally, an effort was made to prepare a 1 : 1 adduct of **1** by treatment with an equimolar quantity of the more sterically demanding Lewis acid, $BPh_3$. Interestingly, this reaction resulted in phenylphosphinidene extrusion and formation of the cyclopolyphosphines $(PPh)_3$, $(PPh)_4$, and $(PPh)_5$.[9] The facile oxidation of carbene–phosphinidenes, coupled with the high basicity at phosphorus, portends an interesting reaction chemistry for these species.

We thank the National Science Foundation and the Robert A. Welch Foundation for financial support.

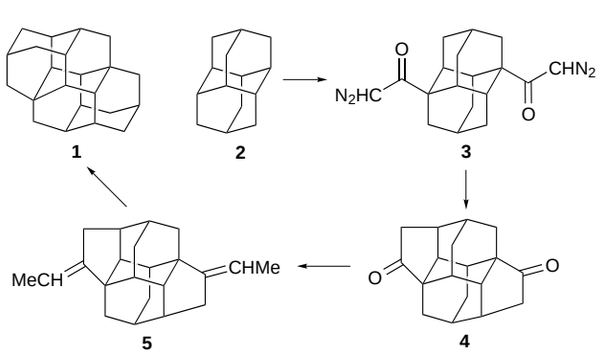
# Recent advances in stereoselective synthesis involving diazocarbonyl intermediates

**Michael P. Doyle[a] and M. Anthony McKervey[b]**



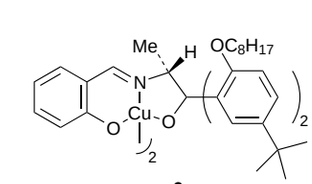
[a] *Department of Chemistry, Trinity University, San Antonio, Texas 78212, USA*
[b] *School of Chemistry, The Queen's University, Belfast, UK BT9 5AG*

**Two aspects of recent developments in enantioselective organic synthesis involving diazocarbonyl intermediates are highlighted: the introduction of chiral catalysts for asymmetric transformations and the use of enantiopure diazoketones derived from amino acids and peptides as chiral educts.**

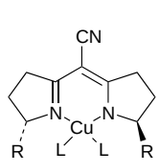
## Introduction

Although much of our recent research in diazocarbonyl chemistry has been directed towards catalysed asymmetric synthesis and the use in synthesis of enantiopure diazoketones derived from natural amino acids and peptides, for one of us the first encounter with diazocarbonyl chemistry in the laboratory occurred in 1976 during the synthesis of the polycyclic hydrocarbon, *anti*-tetramantane **1**, a $C_{22}$ fragment of the diamond lattice.[1] The plan was to transform diamantane **2** into *anti*-tetramantane by establishing new bridgehead positions *via* C–H insertion reactions of α-ketocarbenoid intermediates (Scheme 1). This could be realised by treatment of the diamantane bisdiazoketone **3** with copper sulfate in benzene, whereupon the heptacyclic diketone **4** was produced, albeit in low yield. The carbonyl groups of **4** were then used to add four more carbon atoms to produce diene **5**, an isomer of *anti*-tetramantane; and to complete the synthesis, the rearrangement of one to the other was brought about in the gas phase in hydrogen at 300 °C on a platinum–silica catalyst. Twenty years on there are still few chemical ways of functionalising unactivated C–H bonds as useful and versatile as metal-catalysed decomposition of diazoketones or diazoesters. In fact, C–H insertion is but one of an entire cornucopia of diazocarbonyl reactions with numerous useful applications in organic synthesis. These reactions include cyclopropanation, X–H insertion (X = C, N, O, S, Si, Se, P), aromatic cycloaddition, ylide formation, dipolar cycloaddition, Wolff rearrangement, acid-catalysed cyclisation, α,α-substitution, addition to aldehydes and ketones, β-elimination and oxidation.[2]

Diazocarbonyl chemistry often gets a bad press. While it is unquestionably true that substances such as diazomethane and sulfonyl azides such as tosyl azide and mesyl azide, important reagents in diazocarbonyl synthesis, are hazardous,[3] when due care is taken they can be handled confidently even on a large scale. The Merck thienamycin synthesis,[4] for example, involving a rhodium-catalysed N–H insertion of a diazomalonate whose synthesis requires the use of an arylsulfonyl azide, is routinely conducted on a multikilogram scale.

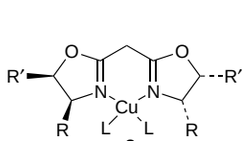


**Scheme 1**



## Asymmetric synthesis of diazocarbonyl reactions: development of chiral catalysts

There are numerous opportunities for asymmetric synthesis employing diazocarbonyl substrates with the option of either covalently attaching a chiral auxiliary to one of the reactants or of using a chiral catalyst (or both). However, when one considers that the most synthetically useful diazocarbonyl reactions are in fact metal catalysed, the attractions of the latter option become very compelling.



Up to the late 1970s,[5] the single most important metal in catalysed diazocarbonyl decomposition was copper and the most frequently used reaction was cyclopropanation. The first successful asymmetric combination was that devised by Aratani[6] who prepared a series of chiral copper(II) chelates **6** from salicylaldehyde and optically active amino alcohols with which to catalyse intermolecular cyclopropanation of alkenes and dienes with ethyl diazoacetate. Enantioselectivities exceeding 90% could be achieved in selected cases as, for example, in the synthesis of ethyl 2,2-dimethylcyclopropane carboxylate [eqn. (1)]. There are now several copper-based catalysts capable of producing ee values up to 99% over a range of alkenes. These include the catalysts of Pfaltz **7**,[7] Masamune **8**,[8] Evans **9**[9] and Ito and Katsuki **10**,[10] all containing heterocyclic $C_2$-symmetric auxiliaries. Eqns. (2–4) illustrate some representative examples of their successes in enantioselective cyclopropanation.

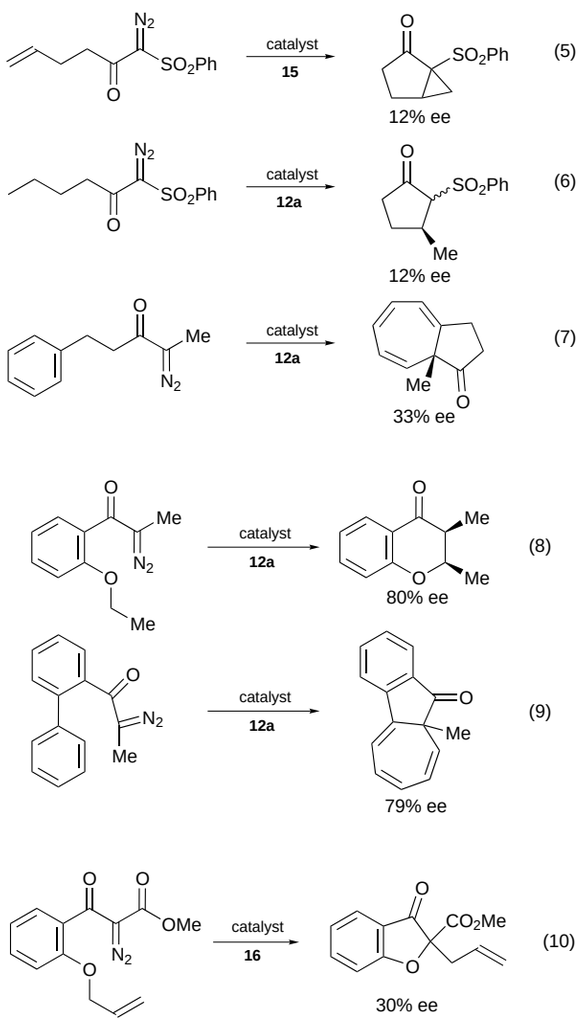
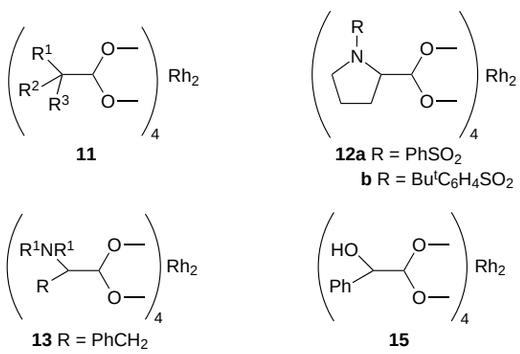
**10**

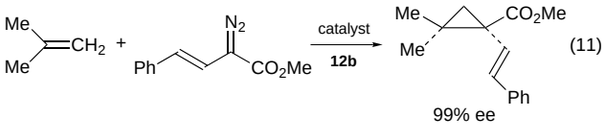
The introduction of rhodium(II) carboxylates for diazocarbonyl decomposition by Teyssie, Hubert and Noels[11] in 1973 opened the way to new initiatives in catalysed asymmetric synthesis. Unlike many of the copper catalysts whose catalytic activity was restricted largely to cyclopropanation, rhodium(II) carboxylates were to display a reactivity that, in addition to cyclopropanation, encompassed C–H, N–H, O–H, S–H, Si–H and Se–H insertion, aromatic and 1,3-dipolar cycloaddition, electrophilic substitution, and ylide formation with sigmatropic rearrangement. It was not surprising therefore that interest turned towards chiral rhodium(II) catalysts. Three groups, those of Brunner,[12] Ikegami[13] and McKervey,[14] independently introduced rhodium(II) salts with chiral carboxylates attached to the metal core. Enantiopure carboxylates of the type $R^1R^2R^3CCO_2$ **11**, whose substituents varied from H, Me and Ph to OH, NHAc and $CF_3$, were assessed by Brunner for enantioselective cyclopropanation of styrene with ethyl diazoacetate with disappointing results ( < 12% ee).



In our own work the availability of a range of enantiopure α-amino acids prompted a survey of their efficacy as rhodium(II) carboxylate catalysts **12**–**14**. Rhodium(II) (*S*)-mandelate **15**,[15] a known compound, was also included in the survey. While these catalysts proved to be very efficient chemically, in some cases at temperatures as low as −80 °C, early results suggested that the extent to which they are capable of exerting enantiocontrol in selected intramolecular reactions, *viz* cyclopropanation, 12% ee [eqn. (5)]; C–H insertion, 12% ee [eqn. (6)] and aromatic cycloaddition, 33% ee [eqn. (7)], was limited.[14] However, recent work with more rigid substrates has shown that significantly higher levels of enantiocontrol can be achieved in C–H insertion where ee values of up to 80% have been realised with the *N*-benzenesulfonyl (*L*)-prolinate catalyst **12a** [eqn. (8)]. Similarly, in the aromatic cycloaddition reaction shown in eqn. (9), use of the prolinate catalyst[16] produced an ee of 79%.[17]

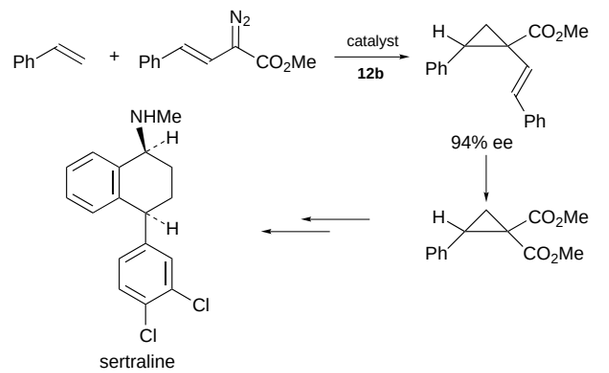


The rhodium(II)-(*S*)-(+)-1,1′-binaphthyl phosphate catalyst **16**[18] introduced in 1992 also shows promise in other diazocarbonyl reactions. For example, the tandem ylide formation–[2,3]sigmatropic rearrangement process in eqn. (10) can be catalysed by **16** to give the furanone product with an ee of 30%.

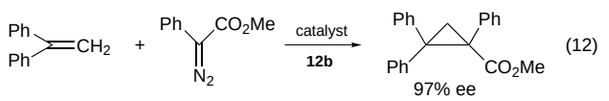


**16**

One feature of the performance of the amino acid based catalysts[19] which offered scope for optimisation was the dependence of the enantioselectivity on the nature of the protecting group on the nitrogen atom. This is nicely illustrated in the use of rhodium(II) prolinates as catalysts for intermolecular cyclopropanation, where enantioselectivities up to 97% have now been achieved. Whereas the benzenesulfonyl derivative **12a** exhibits limited enantiocontrol in cyclopropanation with ethyl diazoacetate, Davies has reported that



the *p-tert*-butylbenzenesulfonyl counterpart **12b** is especially active for highly enantioselective cyclopropanations with vinyl diazoesters, an illustration being that in eqn. (11). Enantiomeric excesses of 59% ($EtOCH{=}CH_2$) and higher, but generally at or greater than 90% were observed for monosubstituted alkenes.[20]

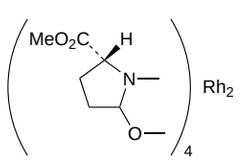


(11)

Higher ee values were reported for reactions in pentane as compared with benzene or dichloromethane. Corey and Grant[21] have used this methodology for cyclopropanation of styrene (94% ee) in an asymmetric synthesis of sertraline (Scheme 2). In a detailed study of the asymmetric synthesis of 2-phenylcyclopropane-1-amino acid, Davies *et al.*[22] concluded that the optimised catalyst for addition of vinyldiazoesters was rhodium *p*-dodecylbenzenesulfonyl prolinate.

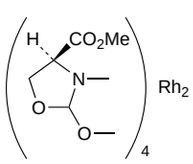
**Scheme 2**

We have established that the *p-tert*-butylbenzenesulfonylprolinate catalyst **12b** gives the highest levels of enantiocontrol relative to either chiral rhodium(II) carboxamidates or bisoxazoline ligated copper(I) **9** for intermolecular cyclopropanation reactions of methyl phenyldiazoacetate, where 97% ee has been realized with 1,1-diphenylethene [eqn. (12)], and we have proposed that solvent enhancement of enantiocontrol is due to solvent-induced favourable orientation of the prolinate ligands.[23]



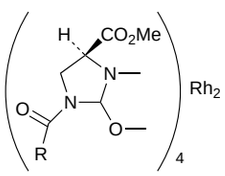
(12)

Efficient syntheses of carboxamidate-ligated dirhodium(II)[24] have made possible the construction of a set of chiral catalysts whose applications have already demonstrated exceptional enantiocontrol for intramolecular and certain intermolecular reactions of diazoacetates and diazoacetamides. Exemplified by $Rh_2$(5*S*-MEPY)$_4$ and its enantiomer $Rh_2$(5*R*-MEPY)$_4$ **17**, where MEPY = methyl 2-oxopyrrolidine-5-carboxylate, the dirhodium(II) core is surrounded by four bridging amide ligands with two oxygen and two nitrogen donor atoms bound to each rhodium in a *cis* configuration. Analogous chiral dirhodium(II) carboxamidates derived from oxazolidinones **18**[25] and imidazolidinones **19** and **20**[26] provide a set of catalysts that effectively control regioselectivity and diastereoselectivity, as well as enantioselectivity in reactions that involve metal carbene intermediates. In each of these catalysts the chiral centre of the ligand is the carbon atom directly bonded to nitrogen, so that the $CO_2Me$ functional attachment lies in a spatial region that influences both the orientation of the bound carbene and the approach of the substrate to the carbene centre.



The exceptional ability of chiral dirhodium(II) carboxamidates to direct highly enantioselective intramolecular cyclopropanation reactions has been demonstrated with allylic and homoallylic diazoacetates and diazoacetamides [eqns. (13) and (14)], where with allylic substrates % ee values > 92% are, with few exceptions, obtained.[27,28] Applications of this catalytic methodology include Martin's synthesis of 1,2,3-trisubstituted cyclopropanes as conformationally restricted peptide isosteres for renin **21**[29] and collagenese[30] inhibitors and Poulter's synthesis of presqualene diphosphate **22** by intramolecular cyclopropanation of farnesyl diazoacetate [eqn. (15)].[31] With homoallylic systems there is a moderate reduction in enantiocontrol with the use of these catalysts (71–90% ee).[27] Other chiral catalysts have not proven to be similarly effective for intramolecular cyclopropanation reactions of this wide range of diazocarbonyl compounds.[32]

Dirhodium(II) catalysts are uniquely effective for intramolecular carbon–hydrogen insertion reactions and, as exemplified in eqn. (16),[25] chiral carboxamidate ligands provide high enantiocontrol for the synthesis of lactones and lactams. The exceptional regiocontrol of these reactions has been demonstrated in the construction of chiral lignan lactones such as (−)-hinokinin **23** in a synthetic process that begins with a cinnamic acid (Scheme 3).[33] The high level of diastereocontrol that can be achieved in these reactions is exemplified in the short synthesis of deoxyxylolactone **24** from 1,3-dichloropropan-2-ol (Scheme 4).[34] Even higher diastereoselectivities have been reported for the syntheses of **25** [eqn. (17)][35] and its fused carbocyclic analogues from cycloalkyl diazoacetates.[26,36] The construction of pyrrolizidine bases such as heliotridane **26**, whose pendant methyl group is *syn* is dependent on the use of chiral carboxamidate ligated dirhodium(II) (Scheme 5).[37] Individual enantiomers of substituted cyclohexyl diazoacetates or 2-octyl diazoacetates matched with a configurationally suitable chiral dirhodium(II) carboxamidate catalyst provide an effective methodology for the synthesis of lactones with exceptional diastereo- and regio-control,[38] forming only one isomer out of at least four that are possible.



Applications to intermolecular cyclopropenation (carbene addition to alk-1-ynes[39] and β-lactam formation by intramolecular C–H insertion[40]) have also been reported. In general, Doyle's chiral carboxamide dirhodium(II) catalysts are recognized as providing the highest levels of stereocontrol in cyclopropanation and C–H insertion reactions of diazoacetates and diazoacetamides. There are other X–H insertion reactions of ketocarbenoids which have not yet reached stages of development comparable to these highly efficient asymmetric C–H insertions. Although several examples of inter- and intramolecular O–H insertions of water and alcohols are known,[2]

high enantioselectivities through the use of chiral catalysts have yet to be realised.[41] There is now one example of the use of chiral catalysts in asymmetric N–H insertion where rhodium(II) (*S*)-mandelate was used to produce the pipecolic acid derivative in eqn. (18) with an ee of 45%.[42] Asymmetric Si–H insertion into $PhMe_2SiH$ with methyl phenydiazoacetate has been reported to occur in 46% ee with the use of $Rh_2(MEPY)_4$ catalysts.[43]

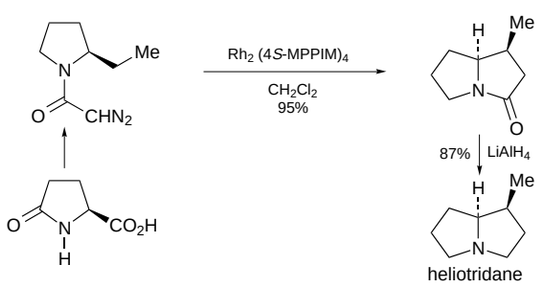
## Transformations of enantiopure α-diazoketones derived from α-amino acids and peptides

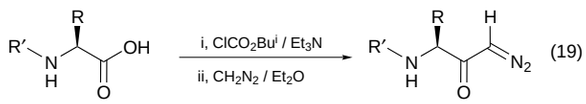


Whereas the primary objective of using chiral catalysts in diazocarbonyl reactions was to achieve high levels of enantiocontrol in selected reactions, that of using α-diazoketones derived from α-amino acids and peptides was to have enantiopure educts for chiral group transfer reactions. With appropriate *N*-protection α-amino acids and peptides can be easily transformed into diazoketones without racemization [eqn. (19)].[44]

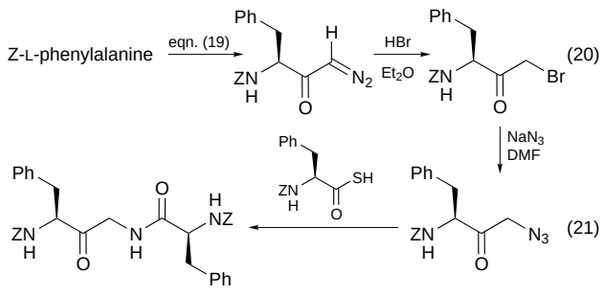
A selection of the many racemization-free reactions which these diazoketones undergo are summarised in eqns. (20–25), the feature common to all being the transfer of an enantiopure α-amino ketone moiety to a new structural or functional group environment. It is possible, for example, to titrate *N*-protected

**24** (3*R*, 4*R*)-2-deoxyxylolactone

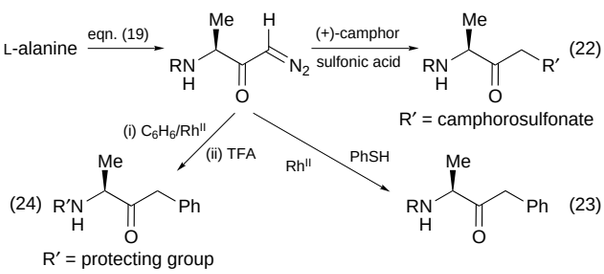
**Scheme 4**



heliotridane
**26**

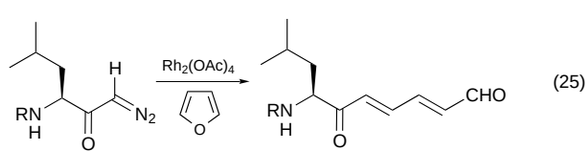


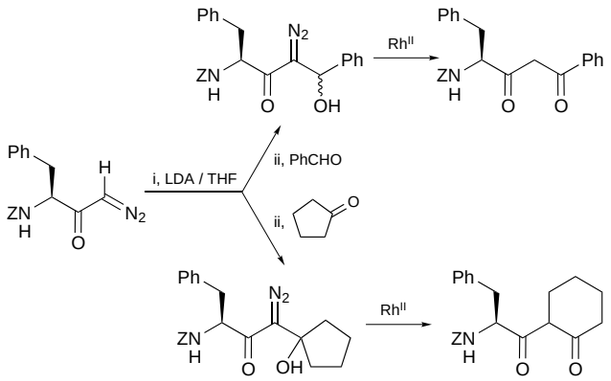
**Scheme 5**



α-amino diazoketones with ethereal hydrogen chloride or bromide to form enantiopure α-halogenoketones[45] [eqn. (20)] which in turn provide access to α-keto azides of the type shown in eqn. (21). Reductive acylation of these α-keto azides using *N*-protected aminothiocarboxylic *S*-acids derived from *N*-protected amino acids produces homopeptides.[46] A typical example of this type of peptide modification is shown in eqn. (21). α-Keto sulfonates can be similarly prepared using sulfonic acids [eqn. (22)].[47] Insertion into S–H bonds under rhodium(II) catalysis provides access to α-sulfenyl ketones [eqn. (23)].[47] Aromatic cycloaddition, again with rhodium(II) assistance, can be used to prepare cycloheptatrienes which rearomatise in the presence of trifluoroacetic acid to yield enantiopure α-amino benzyl ketones [eqn. (24)] from benzene.[48] Rhodium catalysed ring unravelling reactions of furan yield polyfunctional aldehydes (eqn. (25)].[49] Yet another intermolecular process which provides access to enantiopure polyfunctional molecules is that involving the formation of lithium enolates from diazoketones without disturbing the diazofunction using suitable bases, *e.g.* LDA. These enolates can add to aldehydes or ketones to form diazoketols which on brief exposure to catalytic rhodium(II) acetate are smoothly transformed into β-diketones (Scheme 6).[44]

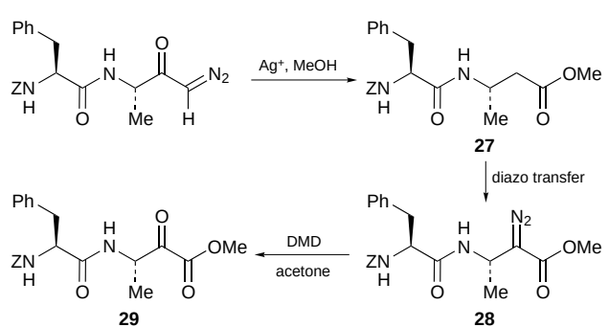
The Arndt–Eistert homologation of diazoketones has long been a popular way of converting α-amino acids into β-amino acids, although with early examples it is not always clear that retention of configuration has been adequately established. However, modern techniques do indicate that in the majority of cases retention is observed. In our own work, we have used the Arndt–Eistert reaction as one step in a process, the overall objective of which was to devise a synthesis of enantiopure α-keto-β-amino carboxylic acids and esters,[50] molecules already known in racemic form to possess significant inhibitory

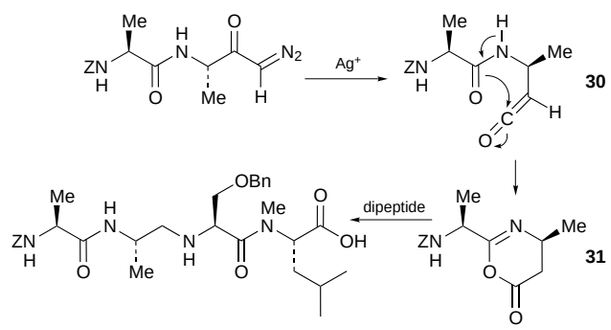




R′ = protecting group or amino acid residue (peptide)

R′ = protecting group

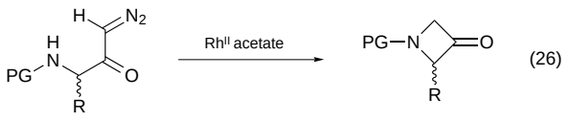




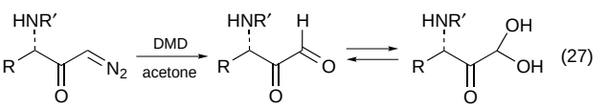
**Scheme 6**

activity towards members of the protease family of enzymes. The process, illustrated in Scheme 7, for the Phe-Ala derivative, commenced with Arndt–Eistert homologation using silver benzoate in methanol. Next, a diazo group was reintroduced alpha to the ester function of **27** to form **28** and in the final stage the diazo group was replaced by a carbonyl group as in **29** *via* oxidation with dimethyldioxirane in acetone. Retention of configuration was maintained throughout the sequence. Seebach and Podlech[51] have recently described a particularly useful application of the Arndt–Eistert process to the formation of homopeptides from diazoketones. The objective was to generate a peptidic ketene **30** from a diazoketone in an non-nucleophilic solvent and trap it intermolecularly with the free amino function of a second amino acid or peptide. An example of the process is shown in Scheme 8 where the ketene is derived from L-alanine and the amino function is that of a dipeptide. Although ketene **30** is undoubtedly an intermediate in the process, closer inspection revealed that it is not the immediate precursor of the homopeptide product. Rather, it was transformed, through involvement of the neighbouring amide bond, into dihydrooxazinone **31**, a reactive cyclic iminoanhydride which is readily attacked to form homopeptides.

Intramolecular insertion reactions of amino acid-derived diazoketones are also possible. We and others have found that

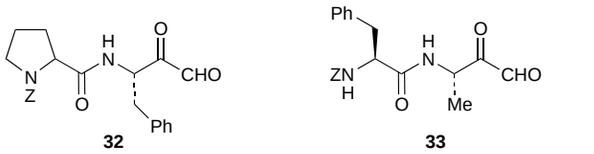


**Scheme 7**



**Scheme 8**

rhodium(II) acetate-catalysed decomposition of the diazoketones in eqn. (26) furnish enantiopure 2-substituted azetidin-3-ones *via* N–H insertion.[52] The product from L-serine was subsequently tranformed by Hanessian[52b] *et al.* into *cis*- and *trans*-polyoximic acid.



We have already touched briefly on the use of dimethyldioxirane in acetone as an oxidant in the synthesis of enantiopure β-amino-α-keto esters **26**. Distilled DMD in acetone offers particular advantages as an oxidant when one wishes to generate delicate intermediates in a clean environment free of extraneous nucleophiles or electrophiles. Terminal diazoketones derived from amino acids or peptides are also prone to DMD oxidation yielding glyoxals which have proved to be useful enantiopure educts.[53] Prior to this work, α-amino glyoxals were unknown; without *N*-protection they would be expected to undergo spontaneous polymerisation. We found that with suitable *N*-protection amino diazoketones can be oxidised to amino glyoxals in quantitative yield. Some representative examples are shown in eqn. (27). The glyoxals were obtained exclusively in the hydrated form. Interestingly, several of the dipeptide glyoxals were found to possess significant protease inhibitory properties.[54] For example, the sequences Z-Pro-Phe-CHO **32** and Z-Phe-Ala-CHO **33** inhibit chymotrypsin and cathepsin B, respectively, with $K_i$ values some 10-fold lower than those for the corresponding peptide aldehydes. These glyoxals could also be used directly as reaction intermediates, there being no by-products of oxidation other than acetone and nitrogen. Among the reactions that we have used to demonstrate the versatility of *N*-protected amino glyoxals as enantiopure educts in amino acid and peptide modification are alkenation with Wittig reagents, *e.g.* eqns. (28), (29) and (30), condensation with amines to form imines, *e.g.* eqn. (31), and with 1,2-diaminobenzene to form quinoxalines,[53] *e.g.* eqn. (32). These compounds are in turn potentially useful enantiopure educts for further amino acid and peptide modification. Their biological properties, particularly their efficacy as protease inhibitors, are under investigation in collaboration with Dr B. Walker, School of Biology and Biochemistry, Queen's University.

## Conclusion

We hope that we have demonstrated that modern organic synthesis with ever increasing requirements for stereocontrol *via* catalysed or uncatalysed transformation continues to benefit from the outstanding versatility of diazocarbonyl compounds.

# A new method for the formation of the P–F bond

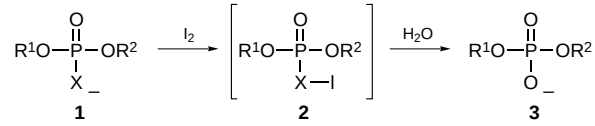
**Martin Bollmark and Jacek Stawinski***

*Department of Organic Chemistry, Arrhenius Laboratory, Stockholm University, S-106 91 Stockholm, Sweden*

**Iodine-promoted desulfurization of phosphorothioate and phosphorodithioate diesters in the presence of triethylamine tris(hydrofluoride) (TAF) furnish a rapid and quantitative formation of the corresponding phosphorofluoridates and phosphorofluoridothioates; under the reaction conditions phosphoroselenoate and phosphoroselenothioate diesters undergo deselenization affording the phosphorofluoridate and phosphorofluoridothioate diesters, respectively.**

The reaction of phosphorochloridate diesters with alkali metal fluorides in aprotic solvents is the method of choice for the preparation of simple dialkyl phosphorofluoridates.[1] However, in the synthesis of natural product derivatives containing the P–F bond, this approach is of limited value owing to the scant availability of the corresponding phosphorochloridates and the often detrimental reaction conditions.

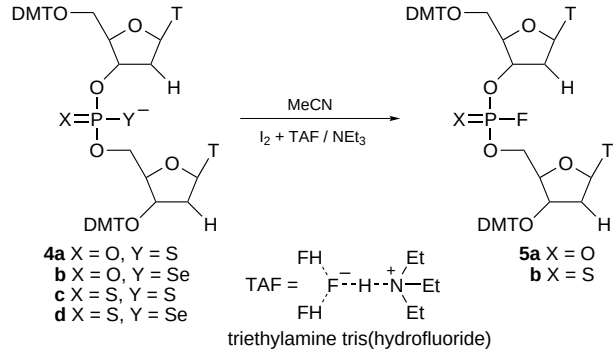
Recently, we have reported on a new, simple and efficient method for the preparation of nucleoside phosphorofluoridate and nucleoside phosphorofluoridothioate diesters[2] and monoesters[3] *via* the iodine promoted oxidation of the corresponding H-phosphonates and H-phosphonothioates in the presence of triethylamine tris(hydrofluoride) (TAF). These studies have been directed towards the development of a synthetic procedure enabling the introduction of fluorine at a preselected phosphorus centre in an oligonucleotide, in order to investigate this kind of DNA surrogates as, *inter alia*, potential antisense/antigene therapeutics.



Although dinucleoside phosphorofluoridate and dinucleoside phosphorofluoridothioate diesters are stable solids, that can be purified by silica gel chromatography, the fluorine atom (particularly that in the phosphorofluoridate derivatives) may undergo nucleophilic substitution. This can happen, *e.g.* during the final deprotection of an oligonucleotide and thus would call for significant changes in a solid phase synthesis protocol (*e.g.* the use of more labile base protecting groups, a special procedure for the cleavage of a modified oligomer from the support). For these reasons we have been searching for a synthetic procedure allowing the introduction of fluorine into an unprotected oligonucleotide and in this way alleviating a potential problem of the degradation of a modified oligonucleotide (or the removal of fluorine) during the deprotection step or during its splitting from a support.

As a possible candidate for this purpose we considered phosphorothioate or phosphoroselenoate diesters bearing a sulfur or a selenium atom in the nonbridging position. Owing to the biochemical and medical importance of nucleoside phosphorothioates,[4] on the one hand, and the advances in the chemical synthesis of oligonucleotides, on the other, this class of compounds has recently emerged as most important oligonucleotide analogues.[5]

Since the reaction of iodine with sulfur is known to be a highly selective process[6–11] that can be carried out on unprotected oligonucleotides, we considered as a viable approach for the formation of the P–F bond an iodine-promoted desulfurization (or deselenization) of a suitable phosphorothioate (or phosphoroselenoate) diester in the presence of fluoride anions. The mechanism of this type of reactions (*e.g.* Scheme 1) is unknown but, most likely, it involves the initial formation of the corresponding oxaphosphoranesulfenyl (or oxaphosphoraneselenenyl) iodide (compounds of type **2**), which may undergo a subsequent nucleophilic substitution at the phosphorus centre.



The efficacy of this approach to the formation of phosphorofluoridate diesters was evaluated by reacting the dinucleoside phosphorothioate **4a**[12] with iodine (2.5 equiv.) in acetonitrile in the presence of TAF (1 equiv.) and triethylamine (2 equiv.), Scheme 2. The reaction was fast and clean, as judged by $^{31}$P NMR spectroscopy. Within 5 min the resonances due to the starting material **4a** ($\delta_P$ 57.5)† completely disappeared and only signals assigned to the expected product, the dinucleoside phosphorofluoridate **5a**[2] [$\delta_P$ −9.8, $^1J_{PF}$ = 978 (d), $^3J_{PH}$ = 7.3 Hz, (q) and $\delta_P$ −10.2, $^1J_{PF}$ = 985 (d), $^3J_{PH}$ = 7.3 Hz, (q); ratio *ca.* 1 : 1], were detected. No changes were observed in the reaction mixture when it was left to stand for 2–3 h. The phosphorofluoridate **5a** was also formed as the sole phosphorus-containing product ($^{31}$P NMR spectroscopy) when the dinucleoside phosphoroselenoate **4b**[7] ($\delta_P$ = 52.1[13]) was subjected to the reaction with iodine under analogous reaction conditions.

We also checked the feasibility of using this approach for the synthesis of phosphorofluoridothioates. To this end, the dinucleoside phosphorodithioate **4c**[12] was treated with iodine (2.5 equiv.) in acetonitrile in the presence of TAF (1 equiv.) and triethylamine (2 equiv.). The reaction proceeded to completion within 5 min ($^{31}$P NMR) as was apparent from the disappearance of the starting material **4c** ($\delta_P$ 115.4) and a clean and quantitative formation of the phosphorofluoridothioate **5b**[2] [$\delta_P$ 62.0, $^1J_{PF}$ = 1076 (d), $^3J_{PH}$ = 8.6 Hz, (q) and $\delta_P$ 61.2, $^1J_{PF}$ = 1085 (d), $^3J_{PH}$ = 8.5 Hz, (q); ratio *ca.* 1 : 1]. We did not observe any desulfurization of **5b** under the reaction conditions. This was, in principle, expected in light of the known inertness of

X = S or Se
$R^1$ and $R^2$ = nucleoside moieties

**Scheme 1**

**Scheme 2**

phosphorothioate triesters (and probably other uncharged phosphorus compounds bearing the thiophosphoryl function) towards iodine.[6]

In dinucleoside phosphoroselenothioate diesters, there are two centres which may react with iodine, *i.e.* selenium and sulfur. Owing to differences in the standard reduction potentials of selenium and sulfur ($E°_{Se} = -0.924$ and $E°_{S} = -0.476$ V), it is the former which should undergo preferential oxidation with iodine. Indeed, the reaction of **4d**[7] ($\delta_P$ 104.2 and 103.7) with iodine in the presence of fluoride anion under the conditions as for **4c** afforded exclusively the phosphorofluoridothioate **5b**, as was apparent from the chemical shift value of the product and the absence of a characteristic $^1J_{PSe}$ coupling.

The above reactions were also run on a preparative scale. In a typical experiment, the dinucleoside phosphorothioate **4a** (triethylammonium salt, 0.05 mmol) was rendered anhydrous by repeated evaporation of the added acetonitrile and dissolution in the same solvent (3 ml) containing triethylamine (2 equiv.) and TAF (1 equiv.). A solution of iodine (2.5 equiv.) in acetonitrile (0.5 ml) was then added. After 10 min the reaction mixture was diluted with chloroform (10 ml) and extracted with aq. 10% $Na_2S_2O_3$ (1 × 10 ml). The organic phase was dried over $NaSO_4$, concentrated *in vacuo*, and the residue was chromatographed on a silica gel column using ethyl acetate–toluene (1 : 1, v/v) as eluent. Using this procedure the phosphorofluoridate **5a** was obtained in 70–85% yield‡ (starting from **4a** or **4b**) and the phosphorofluoridothioate **5b** in > 90% yield (starting from **4c** or **4d**). Compounds **5a** and **5b** prepared in this study were identical (TLC, $^1$H and $^{31}$P NMR and FABMS) with those synthesised *via* the iodine-promoted oxidation of the corresponding dinucleoside H-phosphonate and H-phosphonothioate in the presence of TAF.[2]

The relevance of the procedure to the preparation of oligonucleotide analogues was assessed by carrying out some preliminary $^{31}$P NMR experiments on unprotected dinucleoside phosphorothioates. To this end, dithymidine phosphorothioate (obtained by the detritylation of **4a**, followed by trituration with diethyl ether) was subjected to the reaction with iodine (5 equiv.) in pyridine in the presence of fluoride anion (1 equiv. TAF). A clean formation of the corresponding dithymidine phosphorofluoridate [$\delta_P$ −9.4, $^1J_{PF}$ = 977 Hz (d) and $\delta_P$ −9.8 ppm, $^1J_{PF}$ = 985 Hz (d); ratio *ca.* 1 : 1] was observed (5 min, $^{31}$P NMR). The detritylated dinucleoside phosphorodithioate derived from **4c** reacted similarly under the reaction conditions producing the corresponding phosphorofluoridothioate [$\delta_P$ 61.3, $^1J_{PF}$ = 1078 Hz (d) and $\delta_P$ 60.9, $^1J_{PF}$ = 1085 Hz (d); ratio *ca.* 1 : 1].

In conclusion, iodine promoted desulfurization or deselenization of the appropriate phosphorothioate and phosphoroselenoate diesters in the presence of fluoride anions offers a new means for the formation of the P–F bond under exceedingly mild reaction conditions and using easily accessible substrates. Since the method is based on a highly selective activation of sulfur or selenium centres by iodine, it is compatible with the presence of unprotected functional groups in a substrate molecule. This, and the possibility of replacing fluorine with other functionalities, makes the method of particular relevance to the synthesis of oligonucleotides and other analogues bearing labile modifications at the phosphorus centre.

We are indebted to Professor Per J. Garegg for his interest in this work and to the Swedish Research Council for Engineering Sciences and the Swedish Natural Science Research Council for financial support.

## Footnotes

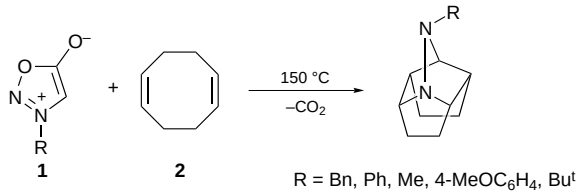
# Tandem 1,3-dipolar cycloadditions of münchnones. Syntheses and molecular structures of 10-azatetracyclo[6.3.0.0$^{4,11}$.0$^{5,9}$]undecanes and azahomopentaprismane



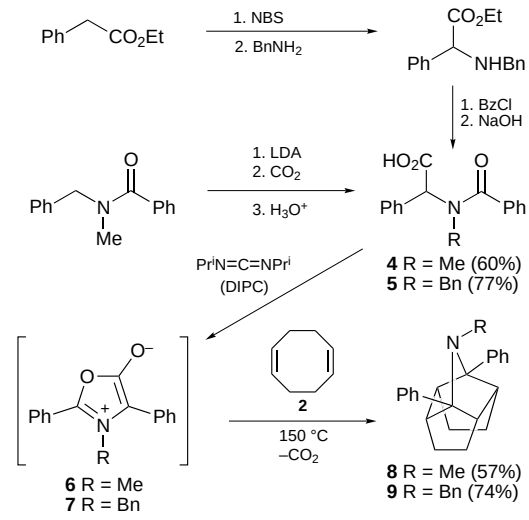
**Gordon W. Gribble,*[a] William R. Sponholtz III,[a] Frank L. Switzer,[a] Ferdinando J. D'Amato[a] and Marianne P. Byrn[b]**

[a] *Department of Chemistry, Dartmouth College, Hanover, NH 03755-3564, USA*
[b] *Department of Chemistry and Biochemistry, The J. D. McCullough X-ray Crystallography Laboratory, University of California, Los Angeles, CA 90095-1569, USA*

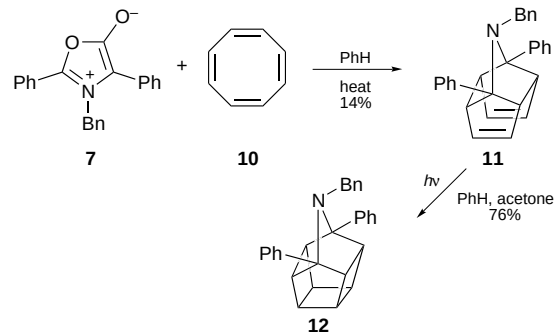
**Photocyclization of 10-benzyl-9,11-diphenyl-10-azatetracyclo[6.3.0.0$^{4,11}$.0$^{5,9}$]undeca-2,6-diene 11, prepared in one step from münchnone 7 and cycloocta-1,3,5,7-tetraene 10, gives azahomopentaprismane 12.**

Although the prismanes and other polycyclic cage compounds are well known and continue to be of great interest,[1] only a few examples of azapolycyclic cage hydrocarbons have been prepared.[2] In continuation of our interest in azapolycyclic compounds[3] we report the first synthesis of an azahomopentaprismane, namely 4-benzyl-3,5-diphenyl-4-azahexacyclo-[5.4.0.0$^{2,6}$.0$^{3,10}$.0$^{5,9}$.0$^{8,11}$]undecane **12**.

Our approach to this ring system for a projected conversion to pentaprismane[4] was inspired by the remarkable reaction that Weintraub reported in 1970.[5] Thus, mesoionic sydnones **1** undergo a tandem 1,3-dipolar cycloaddition reaction with cycloocta-1,5-diene **2** to give the novel 9,10-diazatetracyclo-[6.3.0.0$^{4,11}$.0$^{5,9}$]undecanes **3**.[5,6]



**1** **2**



We have now found that the mesoionic münchnones (1,3-oxazolium-5-olates) react similarly with **2** to afford 9,11-diphenyl-10-azatetracyclo[6.3.0.0$^{4,11}$.0$^{5,9}$]undecanes **8**–**9** as shown in Scheme 1. The münchnone precursor amino acids **4** and **5** were synthesized according to classical methods[6,7] and the münchnones **6** and **7** (3-methyl- and 3-benzyl-2,4-diphenyl-oxazolium-5-olate, respectively) were generated using the original method of Huisgen[8] as modified by Anderson,[9] but using diisopropylcarbodiimide to effect cyclodehydration. Although münchnones **6** and **7** could be isolated as yellow solids, it was found that the yields of **8** and **9** were higher if **6** and **7** were generated and trapped with cycloocta-1,5-diene (COD) **2** *in situ*. The resulting azatetracycles **8**† (oil) and **9**† (mp 167–168 °C) have been fully characterized including an X-ray crystal structure for **9**.[10] As we have recently reported, **8** and **9** exhibit not only the expected restricted nitrogen inversion ($\Delta G^{\ddagger}$ = 12.2 and 10.6 kcal mol$^{-1}$, respectively, 1 cal = 4.184 J), but they also display remarkably slow bridgehead phenyl rotation ($\Delta G^{\ddagger}$ = 9.8 kcal mol$^{-1}$).[10]

In an obvious extension of this tandem 1,3-dipolar cycloaddition reaction, we now report that münchnone **7** reacts with cycloocta-1,3,5,7-tetraene (cot) **10** to afford cycloadduct **11** (10-benzyl-9,11-diphenyl-10-azatetracyclo[6.3.0.0$^{4,11}$.0$^{5,9}$]-undeca-2,6-diene) in low yield (Scheme 2). The X-ray crystallographic molecular structure of **11**‡ is shown in Fig. 1. This product represents one of the very few bis-cycloadducts of cot.[11]

Photolysis of **11** (350 W Hanovia medium pressure lamp, pyrex filter, benzene–acetone, 5 : 1, 4 h, room temperature) was followed by NMR spectroscopy and yielded the desired azahomopentaprismane **12**† (4-benzyl-3,5-diphenyl-4-aza-hexacyclo[5.4.0.0$^{2,6}$.0$^{3,10}$.0$^{5,9}$.0$^{8,11}$]undecane) in good yield. It is interesting to note that a similar photolysis of the oxygen analogue of **11** failed to yield oxahomopentaprismane.[12] The X-ray crystallographic molecular structure of **12** is shown in Fig. 2. This compound represents the first example of this ring system and attempts to convert **12** to the corresponding diphenylpentaprismane are in progress.

# Ultrasound-assisted electrochemical reduction of emulsions in aqueous media

**Frank Marken,[a] Richard G. Compton,*[a] Steven D. Bull[b] and Stephen G. Davies[b]**

[a] *Physical and Theoretical Chemistry Laboratory, Oxford University, South Parks Road, Oxford, UK OX1 3QZ*
[b] *Dyson Perrins Laboratory, Oxford University, South Parks Road, Oxford, UK OX1 3QY*

**The electrochemical reduction of diethylmaleate, diethylfumarate and diethylacetylene dicarboxylate in the form of microscopic droplets generated by applying power ultrasound to aqueous electrolyte media allows a clean hydrogenation of the carbon–carbon double/triple bond whilst providing a novel and versatile methodology for electrochemistry of insoluble materials in aqueous environments.**

In terms of practical applications water can be regarded as an ideal reaction environment for organic electrochemical processes with good conductivity and polarity, stabilizing effects on radical intermediates, and straightforward product isolation by extraction or filtration.[1] Further it is preferable to organic solvents on environmental grounds. Therefore the extension of the range of systems undergoing electrochemical transformations in water is of considerable interest and studies employing surfactant-stabilized emulsions and suspensions have been described.[2]

Ultrasound emitted by a horn source situated in a conventional electrochemical cell[3] allows the formation of emulsions without stabilizing agents simply by mechanical forces which arise at the liquid/liquid phase boundaries.[4] In this study it is demonstrated how this novel experimental approach allows direct voltammetry and electrolysis in aqueous media of materials hitherto thought to be essentially insoluble.

A thermostatted electrochemical cell equipped with an ultrasonic horn probe as shown in Fig. 1 can be used for the study of sonoelectrochemical processes.[3] The cell which has recently been used in the study of homogeneous systems[5] may be used without further modification for voltammetric and bulk electrolysis experiments with emulsions. In Fig. 2 voltammograms obtained for the reduction of emulsions† of diethylfumarate, diethylmaleate and cyclohex-2-en-1-one in aqueous 1.0 M $MgCl_2$ at a 3 mm diameter glassy carbon disc electrode are shown. For diethylfumarate a well defined response for the reduction process at $E_{\frac{1}{2}} = -1.16$ V *vs.* SCE can be observed.

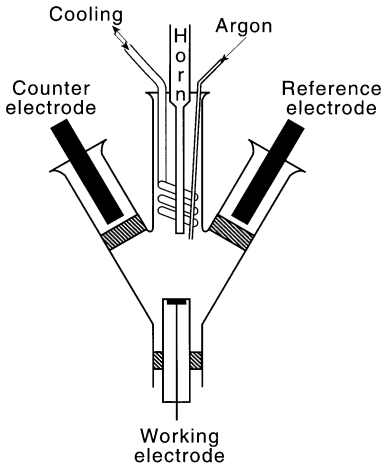

**Fig. 1** Schematic drawing of the thermostatted small volume (20 ml) sonoelectrochemical cell employed for sonovoltammetric and electrolysis experiments

The response is sigmoidally shaped and therefore well behaved even at the very high rates of mass transport applied in the presence of ultrasound. For homogeneous solutions the rate of mass transport[5] is related to the diffusion layer thickness, δ, and the diffusion cofficient, $D$ [eqn. (1)].

$$I_{\text{lim}} = \frac{n F D A C_{\text{total}}}{\delta} \quad (1)$$

In the following we use this equation to quantify the rates of mass transport and for two-phase systems we report 'apparent diffusion coefficients', $D_{\text{app}}$, which have no direct physical significance other than allowing comparison with homogeneous conditions. For the reduction process described here the additional parameters in eqn. (1) are the number of transferred electrons, $n = 2$ (*vide infra*), the Faraday constant, $F$, the electrode area, $A = 7.06 \times 10^{-6}$ m$^2$, the total concentration, $c_{\text{total}}$, and the observed limiting current, $I_{\text{lim}}$. The determined apparent diffusivity for diethylfumarate, $D_{\text{app}} = 0.58 \times 10^{-9}$ m$^2$ s$^{-1}$, is somewhat smaller than the one estimated[6] for the hypothetical case of diethylfumarate dissolved homogeneously in water (Table 1), but is still rather large and sufficient for bulk electrolysis purposes. The physicochemical meaning of the observed magnitude of the limiting currents is more complex and determined either by parameters such as the rate of dissolution, the size of the microdroplets, and the approach distance between microdroplets and the electrode surface or a 'wetting' process.[1] Nevertheless, the magnitude of the $D_{\text{app}}$ values suggests the ability of ultrasound to assist the electrolysis of insoluble materials at efficiencies approaching those that would be accomplished if the substrates were soluble.

For the reduction of diethylfumarate at a glassy carbon electrode the Toměs criterion, $E_{3/4} - E_{1/4} = 80$ mV, suggests an overall fast and in the electrochemical sense almost reversible

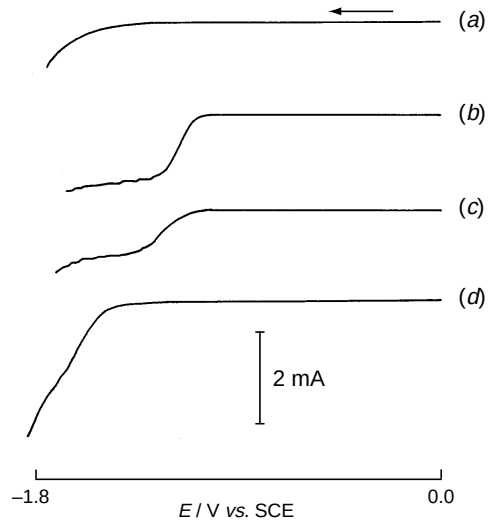

**Fig. 2** Voltammograms obtained for the reduction of 10 μl diethylfumarate (*b*), diethylmaleate (*c*), and cyclohex-2-en-1-one (*d*) emulsified in 20 ml 1.0 M aqueous $MgCl_2$ [(*a*) background] at a 3 mm diameter glassy carbon electrode (25 °C, 150 W cm$^{-2}$, scan rate 0.1 V s$^{-1}$)

**Table 1** Sonovoltammetric data[a] for the reduction of 10 μl insoluble organic compound emulsified in 20 ml aqueous 1.0 M $MgCl_2$ in the presence of 150 W $cm^{-2}$ ultrasound

| Compound | $E_{1/2}$/ V *vs.* SCE | *n* | $10^3$ $c_{total}$/ M | $I_{lim}$/ μA | $10^9$ $D_{sol}$[b]/ $m^2$ $s^{-1}$ | $10^9$ $D_{app}$[c]/ $m^2$ $s^{-1}$ |
|---|---|---|---|---|---|---|
| Diethylfumarate | −1.16 | 2 | 3.0 | 1500 | 0.61 | 0.58 |
| Dimethylmaleate | −1.34 | 2 | 4.0 | 2500 | 0.73 | 0.73 |
| Diethylmaleate | −1.23 | 2 | 3.1 | 1050 | 0.61 | 0.39 |
| Dibutylmaleate | −1.24 | 2 | 2.2 | 180 | 0.50 | 0.09 |
| Diethylacetylene dicarboxylate | −1.28 | 4 | 3.0 | *ca.* 500 | 0.60 | 0.20 |
| Cyclohex-2-en-1-one | −1.58 | 2 | 5.2 | *ca.* 1700 | 0.83 | 0.38 |

[a] Voltammograms obtained at 25 °C, scan rate 0.1 V $s^{-1}$, at a 3 mm diameter glassy carbon disc electrode. $E_{1/2}$ corresponds to the half wave potential for sigmoidal responses. [b] An empirical expression introduced by Wilke and Chang allows the diffusivity, $D_{sol}$, to be estimated to within ± 10% accuracy.[6] [c] The apparent diffusivity $D_{app}$ has been calculated assuming a homogeneous solution based on eqn. (1) and using the approximate diffusion layer thickness δ = 1.6 μm.[5]

electrode process. In the case of diethylmaleate at $E_{1/2}$ = −1.23 V *vs.* SCE also a well defined response can be observed, although now the voltammetric wave is more drawn out ($E_{3/4} - E_{1/4}$ = 100 mV). For comparison, the electrochemical reduction of diethylmaleate dissolved in *N,N*-dimethylformamide described by Bard *et al.*[7] involves the *cis–trans* isomerization of the radical anion formed as a short-lived intermediate in the vicinity of the electrode surface. It was also shown that in *N,N*-dimethylformamide solution the reduction of diethylmaleate occurs at potentials approximately 0.2 V more negative of those for the reduction of the fumarate. In regard of the contrasting voltammetric features in water and in organic media, for the reduction of diethylmaleate in aqueous media an extremely fast rate of the *cis–trans* isomerization possibly due to the solvent polarity may be predicted.

The comparison of the electrochemical reduction of dimethyl-, diethyl-, and dibutyl-maleate emulsions in aqueous 1.0 M $MgCl_2$ demonstrates the effect of the substrate solubility on the cathodic limiting currents (Table 1). The increase in the chain length of the carbon residue significantly alters the magnitude of the apparent diffusivity in agreement with the mechanism generally applied[1] for electrochemical processes in emulsion systems [eqn. (2)–(4)].

$$A_{oil} \rightleftharpoons A_{solution} \quad (2)$$

$$A_{solution} + 2\ e^- + 2\ H^+ \rightarrow B_{solution} \quad (3)$$

$$B_{solution} \rightleftharpoons B_{oil} \quad (4)$$

Under ultrasound condition the oil microdroplets penetrate into the Nernst diffusion layer at the electrode surface and act as a local source of the depolarizer [eqn. (2)]. After the product, $B_{solution}$, has been generated at the electrode surface the reaction step (4) is essential for maintaining an active electrode surface by re-absorbing the product. Depending on the kinetic regime of the process the equilibrium concentration of the depolarizer in the aqueous electrolyte or the rate of dissolution in step (2) govern the limiting current.

In order to analyse the nature of the observed reduction process bulk electrolyses‡ of diethylfumarate, diethylmaleate, and diethylacetylene dicarboxylate emulsified in aqueous 1.0 M $MgCl_2$ were performed. The reduction of emulsions of diethylfumarate and -maleate assisted by additives and special hydrophobic electrodes in the absence of ultrasound has been reported recently[8] by Nonaka and coworkers. Not surprisingly, the scale-up of the sonoelectrochemical process involves a non-simple dependence of the observed limiting current for the reduction reaction on the amount of reactant present. On glassy carbon electrodes a tenfold increase in the amount of organic phase resulted in sonovoltammetric responses with decaying limiting currents characteristic for electrode-blocking processes. However, a clean reduction process at a large surface area gold electrode following a two-electron–two-proton reaction pathway with reduction of the alkenic double bond was observed for diethyl-fumarate and -maleate. Due to the more negative reduction potential diethylacetylene dicarboxylate is reduced directly in a 4e$^-$ process to diethylsuccinate. After passing two- to three-fold excess charge the products were isolated by simple extraction with chloroform and analysed by NMR spectroscopy. Yields of the isolated compounds are typically 50–70% based on the starting material and increase with the amount of charge passed. Side-products due to processes such as hydrodimerization or polymerization have not been observed. The process responsible for the loss of faradaic efficiency appears to be hydrogen evolution.

Although details of the mechanism for sonoelectrochemical redox processes in emulsions remain to be studied, it is clear that the effect of ultrasound, to generate microscopically small droplets whilst ensuring extremely high rates of mass transport, considerably extends and facilitates the possibilities in emulsion electrochemistry.

## Footnotes

* E-mail: compton@ermine.ox.ac.uk

† The ultrasound generator employed was a VCX400 model sonic horn (Sonics and Materials, USA) equipped with a stepped titanium microtip (electrically insulated) of 3 mm diameter emitting 20 kHz sound with a power level set to 150 W $cm^{-2}$ (calorimetrically determined). For electrochemical experiments a thermostatted cell,[5] and a PAR 173 (EG&G) potentiostat controlled by an Oxford Electrodes programmer and connected to a Lloyd P3 plotter were used. Electrodes used were a 3 mm diameter glassy carbon disc (BAS), a graphite rod as a counter, and a saturated calomel reference electrode. Chemical reagents and electrolyte salt (Aldrich) were of highest commercially available quality.

‡ Bulk electrolysis experiments were performed typically with 200 mg substrate in a 20 ml electrolyte volume at a large surface area gold wire electrode and 150 W $cm^{-2}$ ultrasound intensity.

**Reaction of manganese(II) salts ($MnX_2 \cdot nH_2O$, X = Cl, Br, $NO_3$) with tris[(*N*-aldosyl)aminoethyl]amines $L^n$, prepared by the reaction between tris(aminoethyl)amine (tren) with aldose [D-mannose (D-man) ($L^1$)] or L-rhamnose [L-rha = 6-deoxy-L-man) ($L^2$)] *in situ*, affords red–orange crystals formulated as $[(MnL^n)_2Mn(H_2O)]X_3$ (*n* = 2, X = Cl 1; *n* = 2, X = Br 2; *n* = 2, X = $NO_3$ 3; *n* = 1, X = Cl 4), complexes 3 and 4 are characterized by X-ray crystallography.**

Carbohydrates are indispensable building blocks and energy sources to living organisms and play important roles in many biological functions.[1] Interactions of carbohydrates with metal ions have become a significant subject in the bioinorganic field, since many sugar-metabolizing enzymes have been revealed to function with metal ions such as $Mg^{2+}$, $Mn^{2+}$, $Co^{2+}$, and $Zn^{2+}$ in the active sites.[2–6] Xylose isomerases, which promote the aldose–ketose isomerization, involves carboxylate-bridged dinuclear $Mg^{2+}$, $Mn^{2+}$ and $Co^{2+}$ ions in the active site with a *ca*. 4.9 Å metal–metal separation.[4] The similar dinuclear centre of $Mg^{2+}$ or $Mn^{2+}$ with a *ca*. 3.7 Å separation also promotes the cleavage of phosphate esters in fructose 1,6-bisphosphatase.[5] We have studied the chemistry of transition-metal complexes with carbohydrates utilizing *N*-glycosidic bond formation,[7] and wish to report herein the synthesis and characterization of novel trimanganese complexes with a linear $Mn^{II}Mn^{III}Mn^{II}$ core bridged by carbohydrates.

The potentially heptadentate *N*-glycoside ligands, tris[(*N*-aldosyl)aminoethyl]amine $L^n$, prepared by the reaction between tris(aminoethyl)amine (tren) with aldose [D-mannose (D-man) ($L^1$) or L-rhamnose (L-rha = 6-deoxy-L-man) ($L^2$)] *in situ*, were treated with manganese(II) salts ($MnX_2 \cdot nH_2O$; X = Cl, Br, $NO_3$) in methanol. The work-up of the resultant solutions afforded red–orange crystals formulated as $[(MnL^n)_2Mn(H_2O)]X_3 \cdot nH_2O$ in 10–42% yield (**1**·$11H_2O$: *n* = 2, X = Cl; **2**·$10H_2O$: *n* = 2, X = Br; **3**·$8H_2O$: *n* = 2, X = $NO_3$; **4**·$2H_2O$: *n* = 1, X = Cl).† These trimanganese–sugar complexes were assumed to have an almost identical structure to each other on the basis of electronic absorption and circular dichroism spectra[8] and magnetic susceptibilities, $\mu_{eff}$ = 15.1–16.0 $\mu_B$ per $Mn_3$ unit (23 °C, solid state).‡

The structures of **3** and **4** were determined by X-ray crystallography to comprise a linearly ordered trimanganese core bridged by two carbohydrate residues with a Mn···Mn separation of 3.845(2) Å (**3**) and 3.911(5) (av.) Å (**4**) and a Mn–Mn–Mn angle of 180.0° (**3**) and 171.0(1)° (**4**), Fig. 1. The terminal Mn atoms are seven-coordinate with a distorted monoface-capped octahedral geometry ligated by $L^n$ through three oxygen atoms of C-2 hydroxy groups, three *N*-glycosidic nitrogen atoms, and a tertiary amino nitrogen atom, as observed in $[CoL^2]SO_4$ **6**.[7i] The $C_3$ helical configurations and the NO chelate conformations are denoted as Δ-*lel*($\lambda_3$) and Λ-*lel*($\delta_3$), respectively, for **3** and **4**.[7i] The central Mn atoms are five-coordinate ligated by four oxygen atoms of carbohydrate residues in the $L^n$ ligands and one water molecule, resulting in a square-pyramidal geometry. On the basis of the bond lengths, the oxidation states of the terminal and central manganese atoms are assumed to be $Mn^{II}$ and $Mn^{III}$, respectively. This formulation of Mn oxidation states is also consistent with the relatively nitrogen-rich coordination sphere on the terminal Mn atoms. The C-2 and C-3 hydroxy groups of the bridging sugar moieties are also estimated to be deprotonated from the short bond lengths to the central Mn atom (1.88–1.96 Å). Alternatively, the complex cations can be viewed as two seven-coordinate manganese(II) complexes, $[MnL^n]^{2+}$, trapping a $Mn^{III}$ ion through a sugar tentacle. To our knowledge, the present trimanganese complex is the first example of $Mn^{II}$-$Mn^{III}Mn^{II}$ linear assemblage, whereas many $Mn^{II}{}_3$[8] and $Mn^{III}$-$Mn^{II}Mn^{III}$[9] compounds have already been reported.

The structurally characterized examples of dimetal complexes with bridging carbohydrates are extremely rare. Only two structures have been reported, namely, $[Mo_2O_5$(D-lyx)] **7**[10] (lyx = lyxose) and $[Mn_2\{N,N'$-(D-man)$_2$-$N,N'$-$Me_2$en$\}\{N$-(D-man)-$N,N'$-$Me_2$en$\}(MeOH)]Cl_2$ **8**,[7a] both of which involve a

Selected bond lengths (Å) and angles (°): Mn(1)–O(1) 2.16(1), Mn(1)–O(32) 1.891(7), Mn(1)–O(33) 1.921(8), Mn(2)–O(12) 2.299(9), Mn(2)–O(22) 2.579(9), Mn(2)–O(32) 2.250(8), Mn(2)–N(1) 2.25(1), Mn(2)–N(2) 2.24(1), Mn(2)–N(3) 2.23(1), Mn(2)–N(4) 2.43(1) Å; Mn(1)–O(32)–Mn(2) 136.3(4).

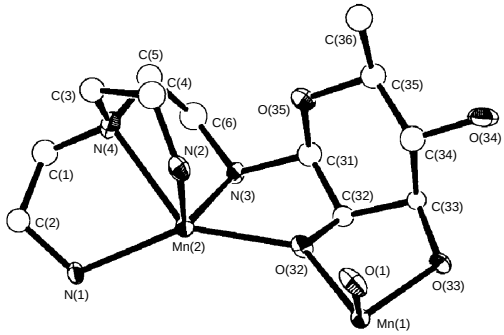

**Fig. 2** A perspective drawing of the sugar bridging part in **3**

β-furanose bridging system. In complexes **3** and **4**, a β-mannopyranosyl skeletal unit with a chair conformation bridges the two manganese ions with the C-2 μ-alkoxo group joining two metal ions and the C-1 *N*-glycosidic amino and the C-3 alkoxo groups coordinating to each metal centre (Fig. 2). These structural features could lead to a new general equatorial–axial–equatorial bridging system of sugars and suggested stronger affinity of the mannose-type aldoses, having 2,3-*cis* configuration, to dimetal centres than that of the glucose type aldoses which possess a 2,3-*trans* configuration.

The present study reports the unprecedented mixed-valence trimanganese(II,III,II) complexes with *N*-glycoside ligands, which could provide useful insight into the interaction of carbohydrates with dimetal ions and interesting physical properties in the multinuclear manganese chemistry.

† Detailed synthetic procedures and analytical, spectral, and magnetic data for **1**–**4** are available on request from the authors.

‡ The preliminary temperature dependent magnetic data showed a very weak antiferromagnetic interaction between the central and terminal metal centres, which could be tentatively ascribable to the relatively long metal–metal distances and the square-pyramidal geometry of the central metal ions (see X-ray structures). The detailed results will be reported in our subsequent full report. The crystals of **4** are very unstable in air and hygroscopic, and a crystal was sealed into a glass-tube capillary with a small amount of mother-liquor at low temperature. This sampling procedure may lead to the low quality of the X-ray structure.

§ *Crystal data*: for **3**·5$H_2O$: orthorhombic, space group $C222_1$ (no. 20), $a$ = 12.925(5), $b$ = 21.255(7), $c$ = 26.871(7) Å, $U$ = 7382 Å$^3$, $Z$ = 4, $D_c$ = 1.461 g cm$^{-3}$, $T$ = −147 °C, $R$ = 0.074, $R_w$ = 0.074 [$w = 1/\sigma^2(F_o)$] for 2319 refs. with $I > 3\sigma(I)$.

**4**·6$H_2O$: trigonal, space group $P3_1$ (no. 144), $a$ = 12.712(8), $c$ = 41.053(9) Å, $U$ = 5744 Å$^3$, $Z$ = 3, $D_c$ = 1.438 g cm$^{-3}$, $T$ = −147 °C, $R$ = 0.083, $R_2$ = 0.091 [$w = 1/\sigma^2(F_o)$] for 3108 refs. with $I > 3\sigma(I)$. The structures were solved and refined with teXsan program package.

Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/431.

¶ An ORTEP plot of the complex cation of **4** is available on request from the authors.

# Stable mixed phenanthroline copper(I) complexes. Key building blocks for supramolecular coordination chemistry†

**Michael Schmittel* and Andrea Ganz**

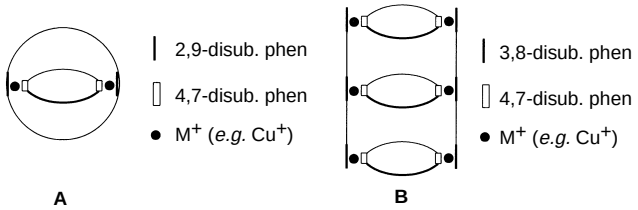
*Institut für Organische Chemie der Universität Würzburg, Am Hubland, D-97074 Würzburg, Germany*

**A simple procedure is presented that is used to synthesise, for the first time, pure mixed phenanthroline copper(I) complexes that do not exchange ligands.**

Our current interest in the coordination chemistry of phenanthroline ligands[1–7] stems from their fascinating potential to allow for the construction of the novel redox-active structures **A** as well as nanotubes **B** (Scheme 1) through the simple self-assembly of (*i*) $Cu^{I}$ as coordinating metal ion with a tetrahedral geometry, (*ii*) a macrocyclic bisphenanthroline with *exo*-coordination sites, and (*iii*) either a macrocyclic bisphenanthroline with *endo*-coordination sites (for **A**) or linear 3,8-linked oligophenanthrolines (for **B**).

As a prerequisite for the successful construction of such novel topologies a strategy is needed for the defined synthesis of mixed phenanthroline copper(I) complexes according to eqn. (1) while avoiding the formation of the two symmetrical complexes, eqn. (2).

$$L^1 + L^2 + Cu^+ \rightarrow [CuL^1L^2]^+ \quad (1)$$

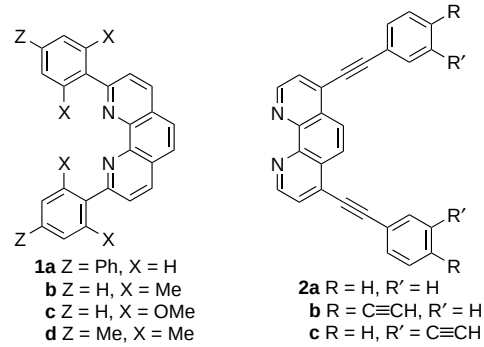


$$2\ L^1 + 2\ L^2 + Cu^+ \rightarrow [CuL^1{}_2]^+ + [CuL^2{}_2]^+ \quad (2)$$

Remarkably, there is no report so far on the clean formation of mixed-phenanthroline copper(I) species[8] except for oligomeric phenanthroline complexes[9] and in cases where the geometrical constraints of a phenanthroline with *endo*-coordination sites embedded in a cyclic ring system prevent formation of symmetrical complexes[3,10] according to eqn. (2).

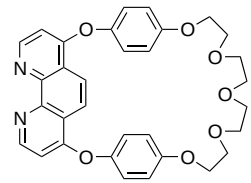
Herein, we report, for the first time, on a general strategy to synthesise mixed phenanthroline copper(I) complexes using acyclic ligands and its use for the preparation of a model complex of **A** demonstrating the feasibility of our approach.

The synthesis of phenanthrolines **1**–**4** is straightforward,[11–14] or is described elsewhere.[15] As expected, the symmetrical copper(I) complexes $[Cu(\mathbf{1a})_2]BF_4$ and $[Cu(\mathbf{2a})_2]BF_4$ formed quantitatively within seconds by mixing 2 equiv. of the ligands with $[Cu(MeCN)_4]BF_4$ in MeCN.[16]



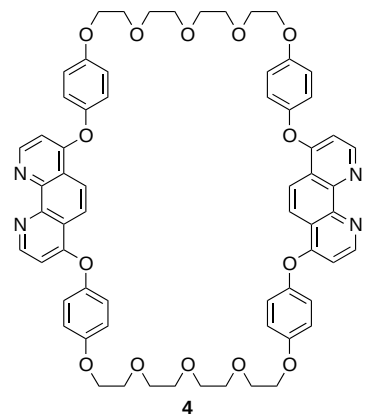
In order to synthesise mixed complexes of type $[CuL^1L^2]^+$ several mechanistic investigations using low-temperature NMR techniques on the influence of solvent, temperature and sequence of addition of the phenanthroline ligand were undertaken. The results proposed that the preparation of the mixed-ligand complex could possibly be achieved by adding 1 equiv. of the 4,7-disubstituted **2a** to $[Cu(MeCN)_4]^+$ followed by addition of **1a** at low temperature in dichloromethane as solvent.

**Scheme 1** Schematic representation of the ball-type structure **A** and nanotube **B** as examples of interesting topologies resulting from mixed phenanthroline copper(I) complexes with tetrahedral coordination

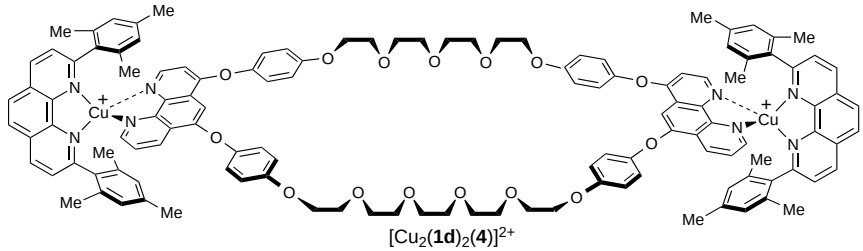


Indeed, after mixing 1 equiv. of **2a** with $[Cu(MeCN)_4]^+$ at −80 °C in $CD_2Cl_2$ and adding 1 equiv. of **1a** complex $[Cu(\mathbf{1a})(\mathbf{2a})]^+$ formed almost quantitatively. However, upon raising the temperature ($T > -50$ °C) increased formation of $[Cu(\mathbf{1a})_2]^+$ was observed. Mixing $[Cu(\mathbf{2a})_2]^+$ with 2 equiv. of ligand **1a** led to formation of the mixed complex $[Cu(\mathbf{1a})(\mathbf{2a})]^+$ besides the symmetrical complex $[Cu(\mathbf{1a})_2]^+$ in a ratio of 1 : 2 remaining constant at −20 °C over several days. Apparently, the thermodynamics of the copper(I) complex equilibria follows qualitatively the course depicted in Fig. 1, but isolation of $[Cu(\mathbf{1a})(\mathbf{2a})]^+$ is precluded because of the rather low barrier for $[Cu(\mathbf{1a})(\mathbf{2a})]^+ \rightarrow [Cu(\mathbf{1a})_2]^+$.

From the above results the use of 2,9-disubstituted phenanthrolines **1b**–**d** is proposed the steric congestion of which through larger groups (X = Me, OMe) precludes formation of symmetrical complexes $[Cu(\mathbf{1})_2]^+$. Indeed, when we reacted $[Cu(MeCN)_4]^+$ with 2 equiv. of sterically encumbered 2,9-disubstituted phenanthrolines **1b**–**d**, formation of $[Cu(\mathbf{1b}–\mathbf{d})_2]^+$ was not observed! Now the reaction of $[Cu(MeCN)_4]^+$ with 1 equiv. of each, **1b**–**d** and **2a**–**c**, resulted in the almost



**1a** Z = Ph, X = H
**b** Z = H, X = Me
**c** Z = H, X = OMe
**d** Z = Me, X = Me



**2a** R = H, R′ = H
**b** R = C≡CH, R′ = H
**c** R = H, R′ = C≡CH

**3**

**4**

**Table 1** Half-wave potentials $E_{1/2}$ (V *vs.* Fc–Fc$^+$)‡ of mixed-ligand copper(I) complexes determined by cyclic voltammetry in dichloromethane at $v$ = 100 mV s$^{-1}$ (electrolyte: $NBu^n_4PF_6$) and yields after purification

| Copper(I) complex | Yield (%) | $E_{1/2}$ | $\Delta E_p$/mV |
|---|---|---|---|
| $[Cu(\mathbf{1a})_2]BF_4$ | 95 | +0.40 | 70 |
| $[Cu(\mathbf{2a})_2]BF_4$ | 83 | −0.05 | 150[a] |
| $[Cu(\mathbf{1b})(\mathbf{2a})]BF_4$ | 86 | +0.36 | 60 |
| $[Cu(\mathbf{1c})(\mathbf{2a})]BF_4$ | 97 | +0.04 | 70 |
| $[Cu(\mathbf{1d})(\mathbf{2a})]BF_4$ | 86 | +0.30 | 70 |
| $[Cu(\mathbf{1d})(\mathbf{3})]BF_4$ | 81 | +0.21 | 130[a] |
| $[Cu_2(\mathbf{1d})_2(\mathbf{4})][BF_4]_2$ | 92 | +0.20 | 220[a] |

[a] Large peak broadening because of slow heterogeneous electron transfer.

quantitative formation of the unsymmetrical complexes $[Cu(\mathbf{1b–d})(\mathbf{2a–c})]^+$ that could easily be isolated at room temperature. All compounds were characterised by NMR, elemental analysis and/or ESI mass spectra.

Cyclic voltammetry investigations on the novel mixed complexes revealed fully or quasi-reversible waves for $Cu^I \rightleftharpoons Cu^{II}$ indicating that the complexes remain intact despite the redox process.

The mixed-complex preparation technique was then used for the first time with macrocyclic phenanthroline ligands with *exo*-coordination sites in order to probe our concept for the preparation of precursors to the novel supramolecular systems **A** and **B**. Reaction of $[Cu(MeCN)_4]^+$ with 1 equiv. of **3** and **1c** or **1d** each provided $[Cu(\mathbf{1c})(\mathbf{3})]^+$ and $[Cu(\mathbf{1d})(\mathbf{3})]^+$, whereas with 1 equiv. of **4** and 2 equiv. of **1d** the complex $[Cu_2(\mathbf{1d})_2(\mathbf{4})]^{2+}$ was furnished.

Upon addition of phenanthroline **2a** to $[Cu(\mathbf{1d})(\mathbf{3})]^+$ the immediate formation of a mixture of $[Cu(\mathbf{1d})(\mathbf{2a})]^+$ and unreacted $[Cu(\mathbf{1d})(\mathbf{3})]^+$ was observed (ratio: 1 : 1). At the same time the $^1$H NMR peaks were broadened indicating a dynamic process on the NMR timescale. Conversely, addition of phenanthroline **1d** to the complex $[Cu(\mathbf{1c})(\mathbf{3})]^+$ also led to a mixture of $[Cu(\mathbf{1d})(\mathbf{3})]^+$ and unreacted $[Cu(\mathbf{1c})(\mathbf{3})]^+$ in a ratio of 1 : 3 that remained constant over several days at room temperature.

To accommodate this observation we have to assume that the mixed complexes $[Cu(\mathbf{1})(\mathbf{3})]^+$ are always in a rapid dissociation–association equilibrium with a small amount of $[Cu(\mathbf{1})]^+$ + **3** as well as $[Cu(\mathbf{3})]^+$ + **1** present. Using sterically hindered 2,9-disubstituted phenanthrolines with X = Me or OMe, however, we have prevented the formation of $[Cu(\mathbf{1b–d})_2]^+$ and forced the system to form the mixed-ligand complexes solely. As a consequence of such controlled ligand exchange processes the straightforward self-assembly of structures **A** and **B** should now be possible.

Financial support from the DFG and the Fonds der Chemischen Industrie is gratefully acknowledged. We are grateful to Professor Dr U. Lüning (Kiel) for the generous gift of phenanthrolines **1b**, **c** and to Dr M. Hederich and Professor Dr P. Schreier (Würzburg) for recording the ESIMS spectra.

# Reaction of $R_3PI_2$ (R = Ph, $Pr^i$, $Pr^n$); structural characterisation of the novel 'subvalent' indium(II) complex $In_2I_4(PPr^n_3)_2$ which contains an In–In bond, the four- and five-coordinate indium(III) complex $InI_3(PPh_3)_2{\cdot}InI_3(PPh_3)$, and the tetrahedral indium(III) complex $InI_3(PPr^i_3)$

*Department of Chemistry, University of Manchester Institute of Science and Technology, Manchester, UK M60 1QD*

**Reaction of $R_3PI_2$ (R = Ph, $Pr^n$, $Pr^i$) with indium metal powder produces a variety of novel indium metal complexes: where R = Ph, the four- and five-coordinate metal(III) complex $InI_3(PPh_3)_2{\cdot}InI_3(PPh_3)$ results; where R = $Pr^n$, the 'subvalent' indium(II) complex $In_2I_4(PPr^n_3)_2$ is formed, the first example of an indium tertiary phosphine complex containing an indium–indium bond; whereas for R = $Pr^i$, the monomeric tetrahedral indium(III) complex $InI_3(PPr^i_3)$ results; these complexes illustrate the subtle effect of the organic substituents on the phosphorus atom for the reaction of $R_3PI_2$ with indium metal powder and the novel indium complexes which are available.**

Virtually nothing was known about the coordination chemistry of indium with tertiary phosphines until the pioneering work of Carty and Tuck,[1–4] who produced tetrahedral $InX_3(PR_3)$, trigonal-bipyramidal $InX_3(PR_3)_2$, and the molecular octahedral species $InX_3(PR_3)_3$, although for this last stoichiometry it was found that one mole of tertiary phosphine was easily removed by the application of a vacuum. No complex of stoichiometry $InX_3(PR_3)$ containing a tertiary phosphine ligand has been crystallographically characterised, but the analogous complexes $InI_3(PHR_2)$ (R = Ph, $Bu^t$) containing secondary phosphines have recently been structurally characterised.[5] The trigonal-bipyramidal molecules $InX_3(PR_3)_2$ have received a little more attention: the first structurally characterised complex of this stoichiometry, $InCl_3(PPh_3)_2$, was reported in 1969,[6] and has the expected trigonal-bipyramidal geometry exhibiting very long axial indium–phosphorus bonds, 2.71(1) Å. The trimethylphosphine derivative $InCl_3(PMe_3)_2$ has been structurally characterised[7] as have $InBr_3(PPhMe_2)_2$ and $InI_3(PPh_2Me)_2$;[8] all these complexes exhibit regular trigonal-bipyramidal geometry.

We are engaged in a study of the oxidising power of a variety of $R_3EX_2$ compounds (E = P, As, Sb; $X_2$ = $Br_2$, $I_2$, IBr) with unactivated metal powders in diethyl ether solution. The strong oxidising power of some of these reagents, *e.g.* $Me_3EI_2$ (E = P, As), is illustrated by their ability to oxidise crude nickel, cobalt[9–14] and even gold[15] metal powders directly to the tripositive oxidation state in a simple one-step reaction.

We have now turned out attention to the reaction of these agents with indium metal powder, principally for three reasons: firstly, little is known concerning the coordination chemistry of indium halides with tertiary phosphine donor ligands; secondly, as we have already seen, novel complexes unobtainable from established synthetic techniques are available from our synthetic route, so there is the possibility of synthesising previously unavailable indium halide tertiary phosphine complexes; if such compounds are available they may have applications in the microelectronics industry as precursors for MOCVD. Finally, indium chemistry has been hampered by the difficulty of synthetic entries, *i.e.* the relatively low activity of the metal and the insolubility of InX and of $InX_3$, and so the approach taken by us represents a significant advance.

$Ph_3PI_2$ reacts with indium metal powder in a 3:2 stoichiometric ratio, eqn. (1).

$$3Ph_3PI_2 + 2In \xrightarrow[N_2,\ \text{room temp.}]{ca.\ 7\text{d},\ Et_2O} \underset{\mathbf{1}}{InI_3(PPh_3)_2{\cdot}InI_3(PPh_3)} \quad (1)$$

Recrystallisation of the pale yellow powder from diethyl ether produced yellow crystals, one of which was selected for analysis by single-crystal X-ray diffraction. The structure of the indium(III) complex was revealed to be $InI_3(PPh_3)_2{\cdot}InI_3(PPh_3)$, **1**. Surprisingly, the structure contains both tetrahedral and trigonal-bipyramidal indium(III) centres within the unit cell. No complex of indium(III) of this stoichiometry has previously been identified.

$Pr^n_3PI_2$ reacts with indium metal powder according to eqn. (2).

$$2Pr^n_3PI_2 + 2In \xrightarrow[N_2,\ \text{room temp.}]{ca.\ 2\text{d},\ Et_2O} \underset{\mathbf{2}}{[InI_2(PPr^n_3)]_2} \quad (2)$$

Recrystallisation of the white powder from diethyl ether solution at 60 °C and subsequent cooling to room temp. produced a large quantity of colourless crystals, from which one was selected for analysis by single-crystal X-ray diffraction,† revealing the dinuclear indium(II) complex $[InI_2(PPr^n_3)]_2$, **2**‡ Fig. 1. This is an unusual result, since we had anticipated a monomeric tetrahedral or a trigonal-bipyramidal indium(III) complex, in agreement with all previous studies of the conventional reaction of indium(III) halides with tertiary phosphines; **2** therefore represents a new, previously unconsidered, indium(II) halide complex containing tertiary phosphine ligands, and the first example of such a complex containing an indium–indium bond; *d*(In–In) in **2** is 2.745(3) Å. Our new synthesis may offer a route to 'subvalent' group 13 metal complexes. Although there are no examples of tertiary phosphine complexes containing an indium–indium bond, the organometallic species $In_2[CH(SiMe_3)_2]_4$ has been characterised by Uhl *et al.*[16] and $In_2IBr_3(C_6H_{16}N_2)_2$ by Tuck and coworkers.[17] The In–In bond distances for these complexes are 2.828(5) and 2.775(2) Å, respectively; both complexes were prepared from the conventional reaction of an indium(II) halide with the appropriate ligand(s).

$Pr^i_3PI_2$ reacts with indium metal powder according to eqn. (3).

$$3Pr^i_3PI_2 + 2In \xrightarrow[N_2,\ \text{room temp.}]{ca.\ 7\text{d},\ Et_2O} \underset{\mathbf{3}}{2InI_3(PPr^i_3)} \quad (3)$$

Recrystallisation of the white powder from diethyl ether produced colourless crystals. One of these was selected for

analysis by single-crystal X-ray diffraction.† The structure of **3**,§ Fig. 2, was revealed to be the tetrahedral monomeric $InI_3(PPr^i_3)$. Although the existence of complexes of this stoichiometry has previously been postulated by Carty and Tuck,[4] this complex nevertheless represents the first indium(III) complex of this stoichiometry containing a tertiary phosphine ligand to be crystallographically characterised. The indium–iodine distances are 2.689(3), 2.701(3) and 2.705(3) Å and the indium–phosphorus distance is 2.569(7) Å.

In conclusion, these new results clearly indicate that subtle changes in the nature of our oxidising agents result in the production of different complexes of indium in different oxidation states, *viz*. reaction of $Ph_3PI_2$ with indium metal powder produces the indium(III) complex $InI_3(PPh_3)_2{\cdot}InI_3(PPh_3)$, containing the indium(III) centres in trigonal-bipyramidal and tetrahedral geometry, and the reaction of $Pr^n_3PI_2$ with indium metal powder produces the unique indium(II) tertiary phosphine complex, $In_2I_4(PPr^n_3)_2$, which contains an indium–indium bond. On the other hand, the reaction of $Pr^i_3PI_2$ with indium metal powder produces the monomeric tetrahedral indium(III) complex $InI_3(PPr^i_3)$. The compound $In_2I_4(PPr^n_3)_2$ represents the first example of a dimeric complex containing tertiary phosphine donor ligands, and since a complex of this type has never previously been observed, its synthesis may be attributed to our synthetic method and it may not be available from conventional techniques.

# Identification of lead(II) sulfide and pararealgar on a 13th century manuscript by Raman microscopy

**Robin J. H. Clark* and Peter J. Gibbs**

*Christopher Ingold Laboratories, University College London, 20 Gordon Street, London, UK WC1H 0AJ*

**The *in situ* non-intrusive chemical analysis by Raman microscopy of a very rare, early 13th century, Byzantine/ Syriac Gospel lectionary implies that the serious pigment blackening of many hues and affecting most of the illuminations is caused by the degradation of lead white to lead(II) sulfide, and that pararealgar ($As_4S_4$) never previously identified on any manuscript was used throughout as a deep yellow pigment.**

Raman microscopy is now established as the analytical procedure which is the most specific, sensitive, spatially refined and immune to interference for the *in situ* analysis of inorganic pigments on manuscripts.[1] The use of Raman microscopy in the field of manuscript analysis has been dominated by the study of illuminated manuscripts in order to characterize the artist's palette,[1–10] but, as shown in this article, this technique can now be used to provide critical information for conservation of a manuscript.

The 13th century Byzantine/Syriac Gospel lectionary, from the British Library Oriental and India Office Collection, dates from 1216–1220 AD and is a heavy (10 kg), large (470 × 395 × 107 mm) volume. It consists of 264 folios with text and sixty illuminations and is valued at more than US$1 million. The large number of illuminations distributed throughout a manuscript of this type is very unusual; they are of high quality and have a rich palette which includes vermilion, lazurite, orpiment, lead white, realgar and pararealgar. Some of the illuminations have suffered serious deterioration of the white pigment, which has turned black in parts. The deterioration is mainly around the edges of the illuminations, and while there are often unaffected central areas for comparison, there are also places where the whole picture is affected. The phenomenon is most striking where the faces of the figures, apparently initially coloured with a mixture of white and red pigments, are affected, creating blackened areas devoid of features (Fig. 1).

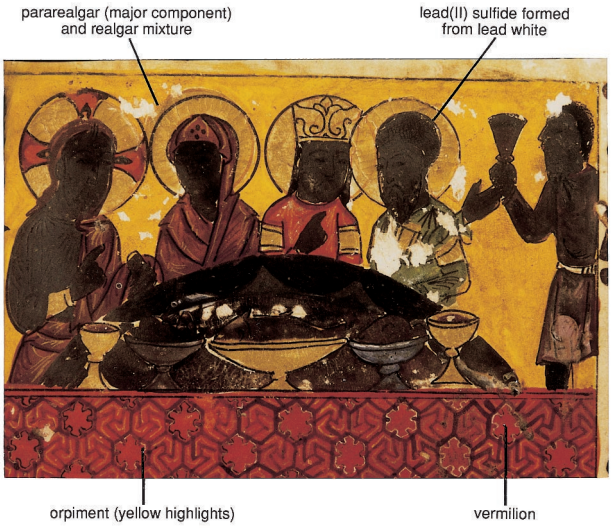

**Fig. 1** A detail of the illumination of *f*.67*r*

The size of the microscope constricted the study to some of the pages and to only a limited area of each page; nevertheless, it was still possible to analyse certain areas of fourteen of the sixty illuminations, sufficient to cover the full palette. Analysis of the inks and illuminations of the lectionary by Raman microscopy revealed unambiguously the presence of seven pigments.

The most important observation was that the black compound which appears to result from the deterioration of a white pigment, basic lead(II) carbonate $2PbCO_3 \cdot Pb(OH)_2$, commonly known as 'lead white' (Fig. 1), was identified unambiguously to be lead(II) sulfide by comparison of its Raman spectrum with that of a standard sample (Fig. 2). Lead white was identified both pure and mixed with red, blue, purple and brown pigments. All of these mixtures were prone to degradation, but it was invariably the lead white that had degraded whereas the intact blue and red pigments, for example, could sometimes still be detected in areas which were heavily discoloured.

The most likely source of sulfur (as $H_2S$) causing the deterioration was the polluted London atmosphere of the latter half of the 19th century and first half of this century.[11] The town-gas lighting in use in the British Museum until the 1880s may also have contributed to the problem.

The only recognized conservation treatment for 'reversing' the darkening of lead white on illuminated manuscripts and paintings involves treatment with hydrogen peroxide.[11] Although such a procedure leads to an aesthetic improvement, the white pigment so generated is lead(II) sulfate. The worry about this procedure is that, since two chemical transformations have been carried out *in situ* on the paper [basic lead(II) carbonate → lead(II) sulfide → lead(II) sulfate], the binding of the pigment (through volume expansion/ contraction) could deteriorate, and the lead(II) sulfate become friable and crumble from the paper.

The study of the palette of the lectionary also led to the identification of vermilion [mercury(II) sulfide] and lazurite $[Na_8(Al_6Si_6O_{24})]S_n$, a sulfur-containing sodium aluminium silicate extracted from the mineral lapis lazuli. The analysis of the yellow pigments was especially interesting. The well known

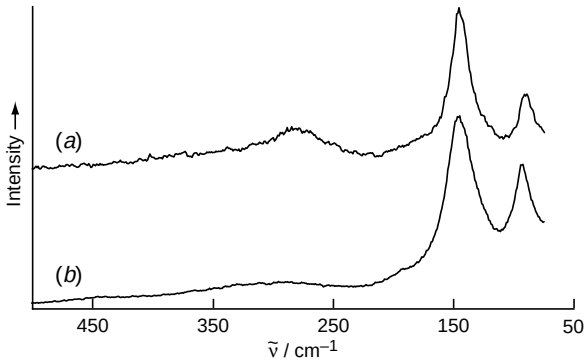

**Fig. 2** Raman spectra (by Raman microscopy, $\lambda_0$ = 514.5 nm) of (*a*) discoloured area of the illumination of *f*.67*r* and (*b*) a standard sample of lead(II) sulfide

throughout the manuscript, but it was not the only yellow pigment used. In thirty-two of the sixty illuminations there are examples of a very rich yellow colouration (see, for example, Fig. 1) which differs significantly in appearance from that of orpiment, which has a much lighter hue. Viewed through the microscope, the pigment appears to be dominated by yellow crystals with a significant number of orange ones. Analysis by Raman microscopy revealed that the orange crystals were realgar,[12] arsenic(II) sulfide ($As_4S_4$), and that the yellow crystals were pararealgar,[13,14] a light-induced transformation product of realgar first identified in 1980 (Fig. 3).[15] There are

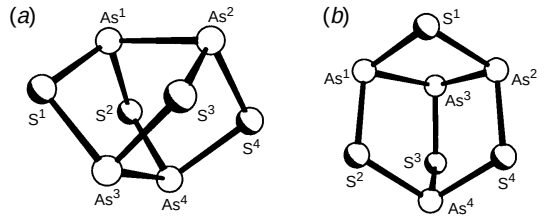

**Fig. 3** Structures of (*a*) realar (both α- and β-polymorphs)[12] and (*b*) pararealgar[13]

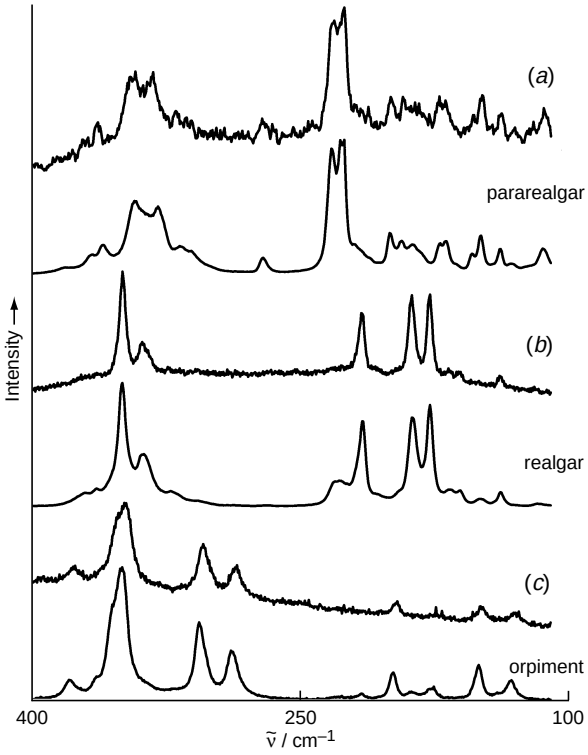

**Fig. 4** Raman spectra (by Raman microscopy, $\lambda_0$ = 647.1 nm) of (*a*) the major component of the yellow–orange pigment on *f*.67*r*, (*b*) the minor component of the yellow–orange pigment on *f*.67*r* and (*c*) the yellow pigment used for highlighting the base of the illumination on *f*.67*r*, and of pararealgar, realgar and orpiment

phase, α-$As_4S_4$, a metastable high-temperature phase, β-$As_4S_4$, and a light-induced form, χ-realgar. All transform to pararealgar on irradiation with light of wavelengths in the range 500–670 nm, most rapidly with those in the range 530–560 nm.[16] The mechanism of transformation is believed to involve photo-induced breakage and reformation of As–As bonds.[14–16] The rich yellow hue of the pigment always appears in the correct context, and the usage of this particular shade of yellow is widespread throughout the manuscript.

It is clear that the artist did not mistake pararealgar for the more common yellow pigment, orpiment: the artist often used both pigments on the same illumination, showing that he had access to and had used them both as distinct yellow pigments. This is the first time that pararealgar has been observed (*in situ* or otherwise) on any manuscript and it was identified unambiguously by comparison with a genuine sample. The Raman spectra of orpiment, realgar and pararealgar are illustrated in Fig. 4, together with spectra obtained from the yellow pigments used in the illumination on *f*.67*r* of the lectionary (Fig. 1).

This study has resulted in the first effective use of Raman microscopy to determine the nature of a serious conservation problem affecting a very valuable manuscript, and also in the first identification of pararealgar on an illuminated manuscript. These results confirm that Raman microscopy is one of the most useful analytical tools for *in situ* and non-intrusive archaeometric analysis, and one that can provide invaluable information for both scientists and conservators alike.

We thank the Leverhulme Trust for support and the British Library for the loan of the lectionary.

# Control of interpenetrating copper(I) adamantoid networks: synthesis and structure of $\{[Cu(bpe)_2]BF_4\}_n$

**Alexander J. Blake, Neil R. Champness,* Simon S. M. Chung, Wan-Sheung Li and Martin Schröder*†**

*Department of Chemistry, The University of Nottingham, Nottingham, UK NG7 2RD*

**Lengthening of linking bipyridyl ligands in interlocking copper(I)-heterocycle adamantoid arrays increases the volume of the adamantoid cages and consequently the number of observed interpenetrating networks: factors influencing the observed structures of these interpenetrating complexes are described in the context of the structure of $\{[Cu(bpe)_2]BF_4\}_n$ [bpe = 1,2-*trans*-(4-pyridyl)ethene].**

The construction of solid-state architectures and crystal engineering has become an area of increasing interest over recent years.[1–4] Much study has been centred upon the use of supramolecular contacts and in particular hydrogen-bonding between suitable organic molecules to generate multi-dimensional arrays and networks.[1–3] The design of inorganic networks is much less well developed[4–8] but recent examples have helped to extend the understanding of this developing area. The construction of adamantoid or super-diamondoid arrays is a common feature amongst some of these infinite three-dimensional networks[4–7] and are often based upon linear bridging ligands bound to tetrahedral metal ions such as $Cu^I$ or $Ag^I$.[5,6] Interpenetration of independent networks is often encountered in adamantoid networks as the crystal avoids the formation of large cavities within the crystalline lattice.[4–7,9,10] The number of independent interpenetrating networks can vary in these three-dimensional polymers[10] from two to as many as eight and nine.[11–13] However, the factors that control the observed degrees of interpenetration in these systems remain largely unknown and/or unproven, and to this end we have begun studies into how ligand functionality can be used to control overall structure of three-dimensional arrays.

Red kite-shaped crystals of a complex product were grown over a period of days at the interface of layered solutions of 1,2-*trans*-(4-pyridyl)ethene (bpe) in MeCN and $[Cu(MeCN)_4]BF_4$ in $CH_2Cl_2$. A single-crystal X-ray structure determination‡ confirmed the product to be a three-dimensional polymer, $\{[Cu(bpe)_2]BF_4\cdot 0.5CH_2Cl_2\}_n$, in which each $Cu^I$ centre is coordinated in a tetrahedral geometry to four bpe ligands [Cu–N 2.003(5)–2.084(6) Å] which are in turn bound to four other $Cu^I$ centres. The three-dimensional structure (Fig. 1) builds through the formation of edge-sharing adamantoid units. The Cu···Cu distances across the edge of each adamantoid unit ranges from 13.33 to 13.82 Å to create large cavities within this first three-dimensional lattice. These cavities are filled with four other $\{[Cu(bpe)_2]^+\}_n$ lattices which are positioned such that they interpenetrate each other to fill the spaces left by each other. All five independent lattices are polycatenated with channels throughout the structure parallel to the direction of translation for the five networks and within the adamantoid units (Fig. 2): these channels accommodate $BF_4^-$ counter ions and $CH_2Cl_2$ solvent molecules.

This structure is related to that observed for $\{[Cu(4,4'\text{-bipy})_2]PF_6\}_n$[5] and $\{[Ag(4,4'\text{-bipy})_2]CF_3SO_3\}_n$[6] in which four independent adamantoid networks are formed. Thus, by lengthening the linking bipyridyl ligand *via* insertion of a *trans* C=C double bond between the pyridyl units the length of the edges of the adamantoid units are extended from 11.16 Å for $\{[Cu(4,4'\text{-bipy})_2]PF_6\}_n$[5] to 13.55 Å (average) in the structure of $\{[Cu(bpe)_2]BF_4\}_n$ reported here. This increase in length of the adamantoid unit edge in $\{[Cu(bpe)_2]BF_4\}_n$ creates a larger cavity within the structure which is filled by the inclusion of one

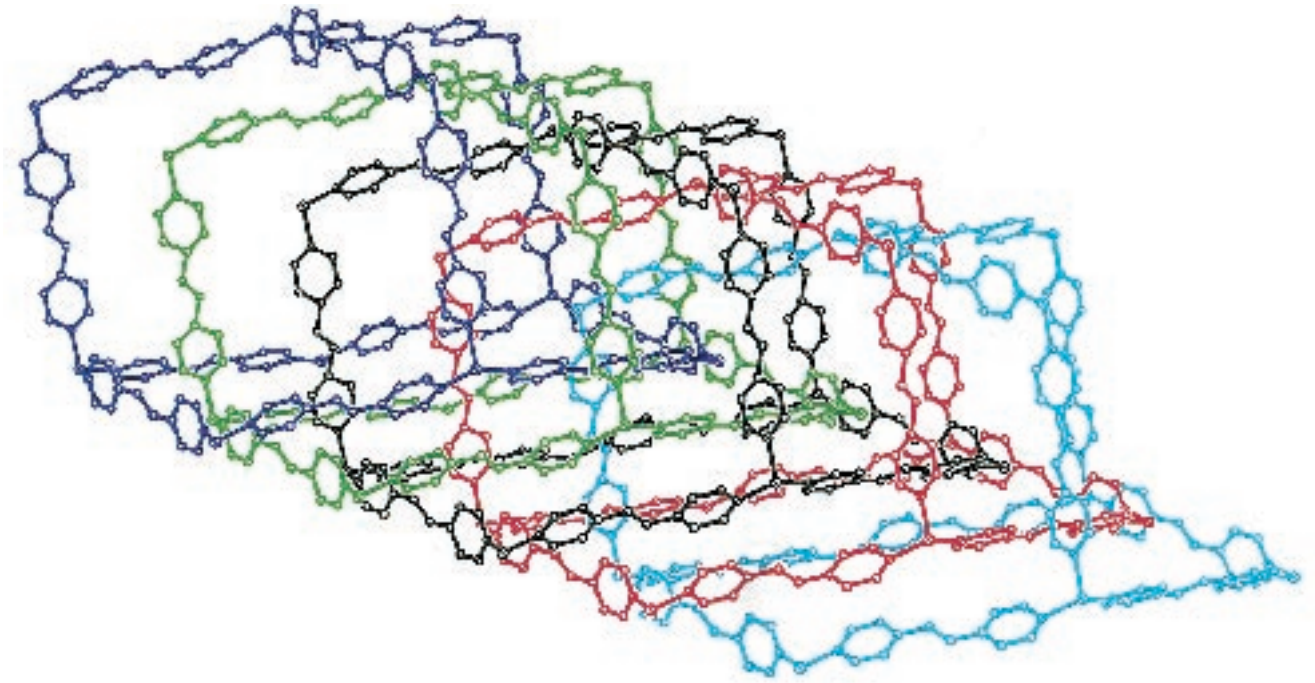

**Fig. 1** View of the structure of $\{[Cu(bpe)_2]BF_4\}_n$ showing five interlocking adamantoid cages

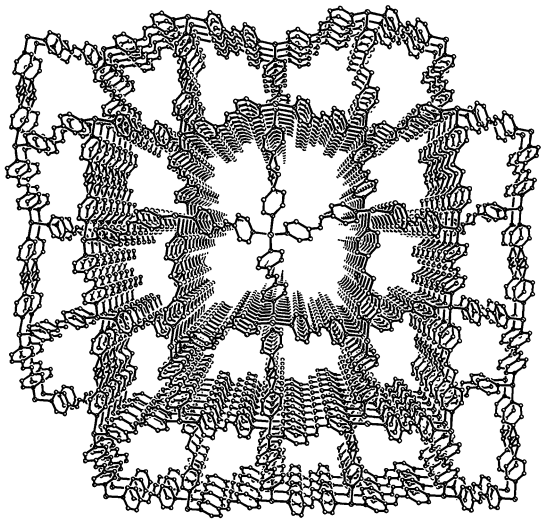

**Fig. 2** View of the structure of $\{[Cu(bpe)_2]BF_4\}_n$

extra independent $\{[Cu(bpe)_2]^+\}_n$ lattice. Also, $CH_2Cl_2$ fills the extra volume created within the counter anion channels. Thus, by altering the ligand length, the degree of interpenetration has been increased from four independent lattices for $\{[Cu(4,4'\text{-bipy})_2]PF_6\}_n$[5] and $\{[Ag(4,4'\text{-bipy})_2]CF_3SO_3\}_n$[6] to five independent arrays, representing control over the degree of interpenetration. There are only two previous examples of systems with five independent interpenetrating arrays, firstly the hydrogen-bonded array of adamantane-1,3,5,7-tetracarboxylic acid[9] and secondly the polymer involving $Cu^I$ and 1,4-dicyanobenzene for which the nature of interpenetration was not fully discussed.[4]

The separations between adjacent adamantoid cages in $\{[Cu(bpe)_2]BF_4\}_n$ is controlled further by face-to-face π–π stacking interactions of 3.659 and 3.855 Å between sets of bpe ligands marked *a* and *b*, respectively, in Fig. 1. Other seemingly adjacent bpe ligands have larger gaps between them along the other sides of the adamantoid cages [*c* in Fig. 1]. Nonetheless, π–π stacking is clearly important in the overall control of this extended structure and the presence of this interaction along the direction in which the adamantoid cages propagate may reveal how such long-range structure is formed during crystallisation. Interestingly, the related complex $\{[Ag\{NC(C_6H_4)_2CN\}_2]PF_6\}_n$ has nine independent adamantoid networks[13] despite only a relatively small increase in the M···M distance of 16.42 Å, compared with 13.55 Å (average) in the present study. This higher degree of interpenetration in $\{[Ag\{NC(C_6H_4)_2CN\}_2]PF_6\}_n$ is enabled by the closer approach of adjacent lattices in this complex: this is not allowed in $\{[Cu(bpe)_2]BF_4\}_n$ due to steric repulsion between pyridyl groups coordinated to Cu centres from adjacent cages.

The present study on $\{[Cu(bpe)_2]BF_4\cdot 0.5CH_2Cl_2\}_n$ reveals direct evidence of control over the fascinating phenomenon of interpenetration and highlights the factors (namely, ligand length, π–π and steric interactions) which will allow design of further supramolecular architectures *via* control of separations between adjacent interlocking cages.

We thank the Nuffield Foundation (to S. S. M. C.) and the EPSRC for support.

‡ *Crystal data* for $[Cu(bpe)_2]BF_4\cdot 0.5CH_2Cl_2$. $C_{24.5}H_{21}BClCuF_4N_4$, $M$ = 557.25, triclinic, space group $P\bar{1}$ (no. 2), $a$ = 7.310(3), $b$ = 13.144(5), $c$ = 13.800(4) Å, α = 83.46(3), β = 82.88(4), γ = 84.71(3)°, $U$ = 1303.0(8) Å$^3$, $Z$ = 2, $F(000)$ = 566, $D_c$ = 1.420 g cm$^{-3}$, μ(Mo-Kα) = 0.989 mm$^{-1}$. Red kite-shaped crystal (0.29 × 0.23 × 0.12 mm). Stoe Stadi-4 four-circle diffractometer, graphite monochromated Mo-Kα radiation, ω–2θ scans with ω-scan width of 1.1°. Numerical absorption corrections were applied to the data ($T_{min}$ = 0.828, $T_{max}$ = 0.900), 4593 unique reflections ($2\theta_{max}$ = 50°, $R_{int}$ = 0.0489), of which 3763 had $F_0 \geqslant 4\sigma(F_0)$, were used in all calculations. The position of the Cu atom was deduced by Patterson synthesis[14] and all the remaining non-H atoms were located from subsequent difference-Fourier methods.[15] Atom C(16), an ethylene carbon on one of the bipyridyl groups, and three of the F-atoms of the $BF_4^-$ anion are each disordered into two equal components. Full-matrix least-squares procedures were used for refinement and all non-F and C atoms [except for C(11), C(12), C(13), C(14), C(15), (one pyridyl unit), and C(1s) from the $CH_2Cl_2$ solvent molecule] were refined with anisotropic displacement parameters; hydrogen atoms were placed geometrically for all non-disordered carbon atoms and thereafter allowed to ride on their parent C-atoms with $U_{iso}(H) = 1.2\,U_{eq}(C)$. The weighting scheme $w^{-1} = [\sigma^2(F_o^2) + (0.1131P)^2 + 8.1717P]$, $P = \frac{1}{3}[\max(F_o^2,0) + 2F_c^2]$, gave satisfactory agreement analyses. Final $R_1$ [$F_o \geqslant 4\sigma(F_o)$] = 0.0892, $wR_2$ (all data) = 0.2553 for 234 refined parameters, $S$ = 1.095, $(\Delta/\sigma)_{max}$ = 0.03, $\Delta\rho_{max}$ = 1.50 e Å$^{-3}$ [in the proximity of the C(1s) and Cl atoms]. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 182/432.

**A two-dimensional array of 10 nm gold colloidal particles is formed by a submonolayer deposition technique using a bifunctional aminosilane followed by a mobility-restoration treatment with alkanethiol, converting the disordered submonolayer deposition to a highly-ordered two-dimensional array.**

Driven by interest in the quantum-confined electronic properties of nanometer scale metal/semiconductor particles, the investigation of nanostructured materials is becoming an exciting area of interdisciplinary research. The device application[1,2] of these nanostructured particles requires techniques of ordering particles in one- , two- or three-dimensional structures; such requirements for nanoarchetecture provide challenges to sample preparation technology. Recently, a method for depositing nanometer-scale gold colloidal particles on $SiO_2$ surfaces was demonstrated using alkylsiloxane molecules as an adhesion agent.[3] The self-limiting nature of this method stopped the deposition at submonolayer coverage density. The compatibility of this method with conventional electron beam lithography was tested and the deposition was carried out only on prescribed positions on the substrate surface. Further, highly-ordered, hexagonally-packed two-dimensional (2D) lattice formation was observed by the electrophoretic deposition of a colloidal gold from the bulk solution onto a carbon-coated electron microscope grid.[4] It was also shown that metal particles including gold and other transition metal clusters can form densely packed monolayers on electron microscope grids when they are ligated by organic surfactant molecules.[5]

In this work, the method of forming a hexagonally-packed 2D lattice of nanoparticles on a $SiO_2$-grown Si substrate is described using a gold colloid solution in combination with organic surfactant treatments of both the substrate and colloid particles. We have been successful in performing surfactant ligation of the gold colloidal particles after they are immobilised on a substrate surface by a bifunctional aminosilane. By this reaction scheme, the switching between mobile/immobile conditions takes place in the gold colloid adsorption.

This method starts with the submonolayer coating of a $SiO_2$ surface with 10 nm gold colloidal particles (GCP) from solution (*viz.* a citrate sol with an average size of *ca.* 10 nm and a size variation of *ca.* 10% standard deviation prepared according to the recipe described in ref. 6) using the method described in ref. 3. A Si substrate covered with a thermally-grown $SiO_2$ (200 nm thick) was cleaned by brief (*ca.* 30 s) oxygen plasma ashing. Immediately afterwards, the sample was immersed in a 2.3 mM aqueous solution of a bifunctional aminosilane [*i.e.* 3-(2-aminoethlyamino)propyltrimethoxysilane, APTMS $[(MeO)_3Si(CH_2)_3NHCH_2CH_2NH_2]$ for 5 min. After the APTMS immersion, the sample was rinsed in two distilled water baths, dried with a nitrogen gun, and placed in a 120 °C oven for 30 min to complete Si–O bond formation. The APTMS treatment replaces the hydroxy groups (OH) adsorbed on the $SiO_2$ substrate with APTMS molecules forming a siloxane bond between the Si on one end of the APTMS molecules and an oxygen atom on the $SiO_2$ surface. As a consequence, the amino group attached on the other end of the APTMS molecule is oriented away from the substrate. These amino groups on the APTMS molecules immobilise gold particles onto the substrate because of the affinity of the amino group to the gold [see Fig. 1(*a*)].[3]

The APTMS treated sample was then immersed in the GCP for 8–12 h, rinsed with two distilled water baths, and dried with a nitrogen gun. This procedure gave a sub-monolayer coating of the GCPs. Since immobilised particles on the substrate are still covered with ionic adsorbates of citrate ions,[7] there is always an electrostatic repulsive force between the colloidal particles. Therefore, the GCP deposition automatically stops before it reaches a close-packing density.[3] Fig. 2(*a*) shows a scanning electron micrograph of the submonolayer coated sample (the observation was carried out using S-900, Hitachi, which has an in-lens type electron optics and a cold cathode electron gun). The micrograph demonstrates a disordered particle deposition with the inter-particle spacing of 10–50 nm.

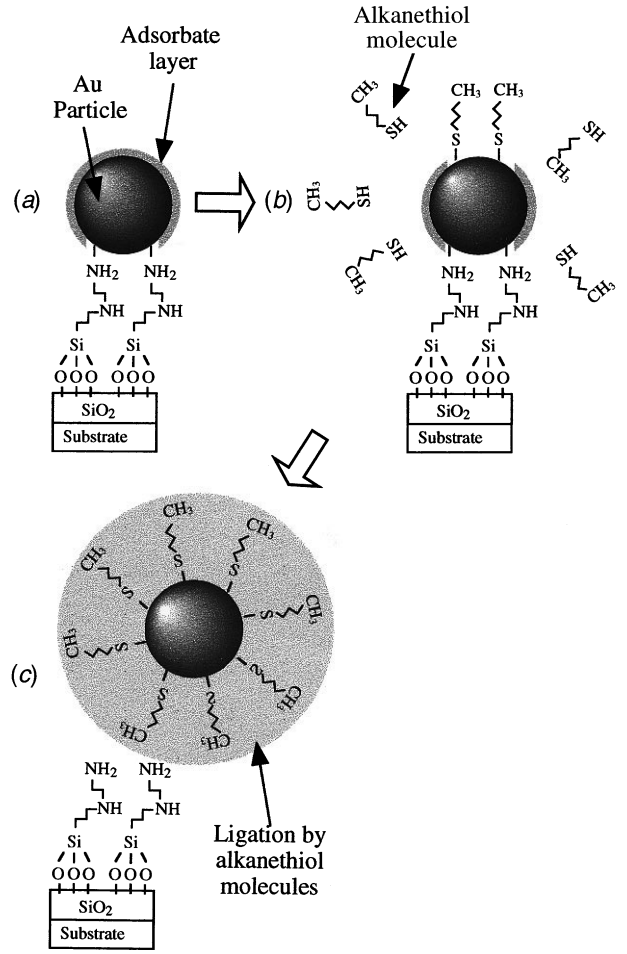

**Fig. 1** Mobility restoration mechanism by a displacement reaction. (*a*) Gold colloidal particle immobilised by a bifunctional aminosilane. (*b*) Ligation of gold particles by alkanethiol molecules displacing the adsorbates and Au–$NH_2$ bonds. (*c*) Mobility restoration by complete ligation of the gold particle.

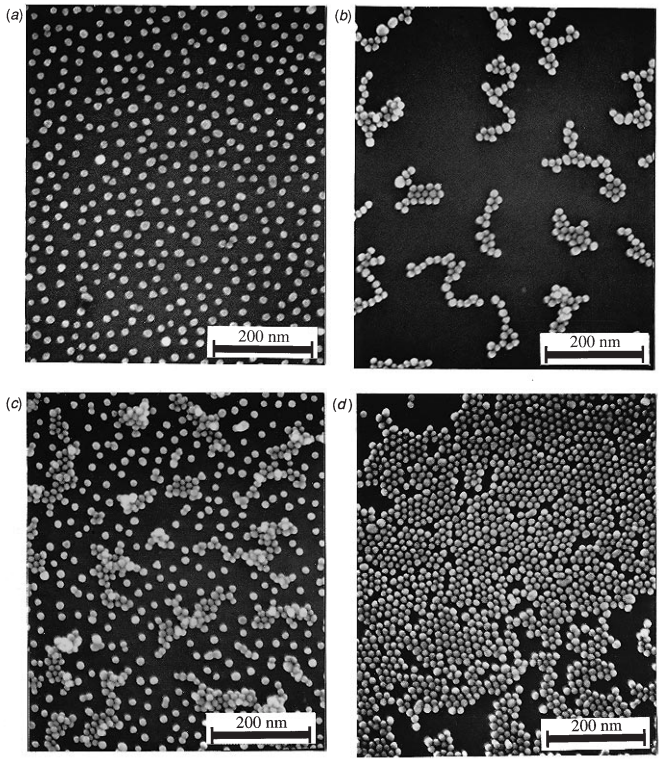

**Fig. 2** Scanning electron micrograph observation of the gold particle crystal nucleation and growth. (*a*) Disordered submonolayer deposition of gold particles from a gold colloid solution using a bifunctional amino silane. Nominal particle size is 10 nm (10% standard deviation). (*b*) Nucleation of gold colloidal crystal initiated by the mobility restoration reaction induced by alkanethiol treatment. (*c*) Additional particle supply from the gold colloid solution on the vacant sites between the nuclei formed in the previous process. (*d*) Highly-ordered two-dimensional gold particle lattice formed by the repetitive application of gold colloid immobilisation and disorder-to-order conversion.

After the sub-monolayer GCP coating, an alkanethiol treatment was carried out to initiate the nucleation of the 2D structure of GCPs. The sample was immersed in a 5 mM ethanolic solution of dodecane-1-thiol [$Me(CH_2)_{11}SH$] for *ca.* 24 h, and rinsed with an ethanol bath, and dried with a nitrogen gun. Because of the strong affinity of sulfur to gold, this treatment replaces citrate adsorbates with the alkanethiol molecules [Fig. 1(*b*)]. In addition to the adsorbate removal, the bonding between the sulfur and gold can even displace the bonding between the amino group and gold. This results in the complete ligation of the gold particle with alkanethiol molecules [Fig. 1(*c*)]; as a consequence, since the molecular binder of the bifunctional aminosilanes are detached from the gold particles, once immobilised particles are now released from the substrate and acquire some mobility on the substrate surface.

Because of the restored surface mobility, particles move and collide with each other on the substrate surface. However, because of the short-range steric repulsion due to the alkanethiol ligation, the particles will not undergo diffusion-limited aggregation which results in 'fractal' structures;[7] instead, they form hexagonally-packed ordered nuclei and grow two-dimensionally given the particle supplies from the migration of GCPs on the substrate surface. Fig. 2(*b*) shows a scanning electron micrograph of a sample after the alkanethiol treatment showing the initiation of ordered 2D nuclei.

Fig. 2(*b*) also shows that the nuclei are deposited with substantial spacing between them. These vacant areas are expected to be covered with the bifunctional aminosilanes. Therefore, when the sample is immersed in the GCP solution again, additional particles can land on those vacant spaces from the GCP solution and are immobilised on the substrate. Fig. 2(*c*) shows a scanning electron micrograph of the sample after the second GCP solution immersion. Individual GCPs are filling the vacant spaces with similar inter-particle distances to that of the first GCP solution immersion.

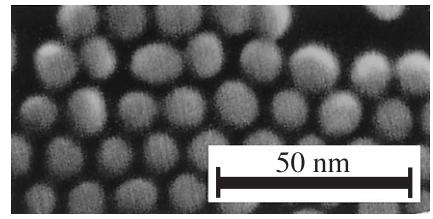

**Fig. 3** Scanning electron micrograph of a highly-ordered two-dimensional array of 10 nm gold particles

Then, the alkanethiol treatment are applied to the sample after the second GCP solution immersion in order to mobilise them and grow the nuclei larger. In this sense, the second GCP solution immersion is playing a role supplying additional materials for the growth of GCP grains. Repetitive application of the GCP immersion with the subsequent alkanethiol treatment enlarges the GCP grain size further. After four repetitions, the grains with different orientations are connected with each other and reach a continuous film of GCP with a densely packed two-dimensional order as is shown in Fig. 2(*d*). Further repetition of the GCP immersion and alkanethiol treatment, however, did not improve the monolayer coverage density; instead, multilayer growth becomes dominant.

From micrographs with a greater magnification as shown in Fig. 3, the average gap between the particles is estimated to be about 2 nm, which is about the twice the thickness of a self-assembled monolayer of dodecanethiol on Au(111) (*i.e.* 1.2 nm).[8] This confirms that the inter-particle distances are determined by the steric repulsion between the alkanethiols attached on the gold particle surfaces.

In conclusion, a highly-ordered two-dimensional array of 10 nm gold particles was formed by the surfactant treatment of both the substrate and gold particles. A bifunctional amino-silane treatment of the substrate immobilised the gold particles from a gold colloid solution with a coverage density of a submonolayer. Subsequent alkanethiol treatment converted the disordered deposition to an ordered one by giving surface mobility to the gold particles. Repetitive applications of immobilisation and disorder-to-order conversion grew the two-dimensionally ordered GCP grains until they were connected together.

The authors wish to acknowledge support given by Professor H. Ahmed (Microelectronics Research Centre, University of Cambridge). This work was performed under the management of FED as a part of the MITI R&D of Industrial Science and Technology Frontier Program (Quantum Functional Device project) supported by NEDO.

# Synthesis of thermally stable mesoporous hexagonal aluminophosphate molecular sieves

**Dongyuan Zhao, Zhaohua Luan and Larry Kevan***

*Department of Chemistry, University of Houston, Houston, Texas 77204-5641, USA*

**Thermally stable mesoporous hexagonal aluminophosphates (UHM-1) and silicoaluminophosphates (UHM-3) are synthesized based on ion-pair interactions of aluminophosphate species in the presence of tetramethylammonium hydroxide with a cationic surfactant [$C_{16}H_{33}NMe_3Cl$].**

Aluminophosphate materials (AlPO-*n*) are recently developed crystalline microporous materials of potential use in catalysis.[1,2] For catalytic processing of larger micelles, mesoporous AlPO-*n* materials are desirable. Lamellar mesostructures of aluminophosphate have been synthesized by using an amphiphilic alkylamine ($C_{10}H_{21}NH_2$) in tetraethylene glycol[3] and by using dimethylalkylamines with $C_8$–$C_{16}$ alkyl groups in water,[4] but these materials are thermally unstable as are lamellar mesostructures of M41S silicates.[5]

The M41S family of silica-based mesoporous molecular sieves is formed by a self-assembly process involving electrostatic interactions between positively charged quaternary ammonium surfactants ($S^+$) and inorganic anions ($I^-$).[5] This process can form hexagonal MCM-41 silica tubes. The electrostatic assembly method has been generalized.[6] A neutral precursor assembly method involving hydrogen bonding between neutral amine surfactants ($S^0$) and neutral silica precursors ($I^0$) in alcohol–water solvent has also been demonstrated.[7]

Here we report the synthesis of thermally stable mesoporous hexagonal aluminophosphate and silicoaluminophosphate molecular sieves by a $S^+I^-$ route. Our approach is based on self-assembly between a cationic surfactant ($S^+$) and an aluminophosphate precursor ($I^-$) in the presence of alkylammonium hydroxide. This method produces stable hexagonal mesostructures of aluminophosphate (UHM-1) and silicoaluminophosphate (UHM-3).

Mesoporous aluminophosphate and silicoaluminophosphate were prepared using cetyltrimethylammonium chloride (CTAC, Aldrich, 25% in water) as a surfactant and the following gel composition: $Al_2O_3 : xP_2O_5 : ySiO_2 : \mu CTAC : \nu NR_4OH : \omega H_2O$, where R = Me, Et, $Bu^n$; $x$ = 0.6–3.4, $y$ = 0–0.6, $\mu$ = 0.24–0.50, $\nu$ = 8.5–47 and $\omega$ = 200–642. In a typical preparation of aluminophosphate, 3.53 g dried aluminium hydroxide (USP Pfaltz & Bauer Inc.) was slowly added to a solution of 4.2 g phosphoric acid (85 mass%, EM Industries) in 15 g water under vigorous stirring. The mixture was added to a solution of 11.6 g CTAC (25 mass%) in 100 g water with stirring. After 0.5 h, 17.3 g tetramethylammonium hydroxide (TMAOH, Aldrich, 25 mass% in water) was slowly added dropwise into the above mixture until pH 9.5 was achieved. In a typical silicoaluminophosphate preparation, an aluminophosphate gel prepared according to the above procedure and 0.79 g tetraethylorthosilicate (TEOS, Aldrich) was added to 11.6 g CTAC in 100 g water with stirring for 3 h. Then 19.0 g TMAOH was added dropwise to obtain pH 9.5. The gels obtained using these procedures were then stirred for 72 h at room temperature. The solid product was recovered, washed and air-dried at 70 °C. The template was removed by calcination at 500 °C for 1 h in flowing nitrogen, followed by 6 h in flowing oxygen.[5]

Powder X-ray diffraction (XRD) patterns of products were obtained on a Siemens D5000 diffractometer with a scan rate of 1° $min^{-1}$ and Cu-K$\alpha$ radiation ($\lambda$ = 0.154 18 nm). Transmission electron micrographs (TEM) were measured on a JEOL 2000 FX microscope with an accelerating voltage of 100 kV. Electron probe microanalysis was performed on a JEOL JXA-8600 spectrometer. Thermogravimetric analysis (TGA) was performed on a DuPont 2100 thermal analyser with a heating rate of 10 °C $min^{-1}$ in air. Surface areas of the samples were measured on a Monosorb (Quantachrome Corp.) surface area analyser by the single point method.

Powder X-ray diffraction patterns of as-synthesized and calcined UHM-1 and UHM-3 are shown in Fig. 1. The XRD patterns show a prominent peak corresponding to (100) reflections and much weaker but clearly present peaks corresponding to (110), (200) and (210) reflections in the as-synthesized material which can be indexed to a hexagonal lattice and which are similar to typical XRD patterns for siliceous hexagonal MCM-41 materials.[5,6] This shows that mesoporous hexagonal mesostructural aluminophosphate and

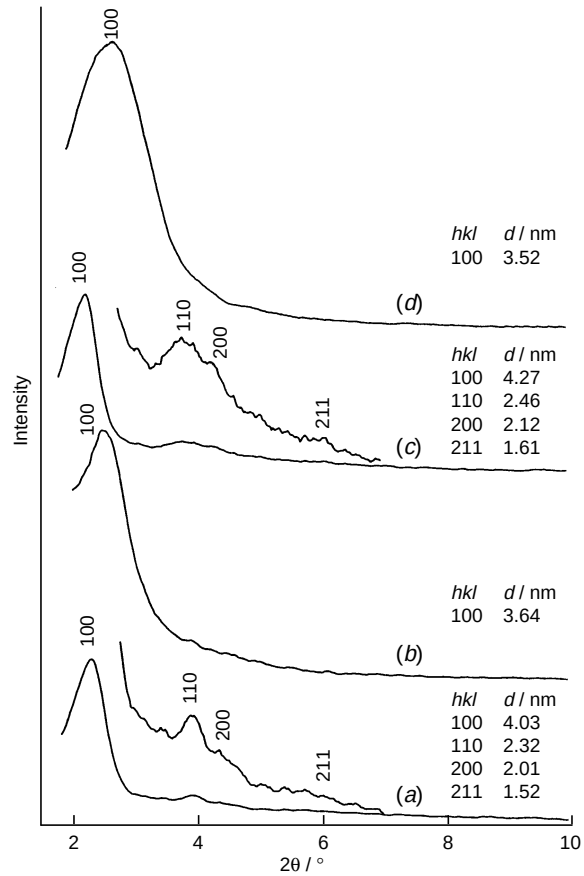

**Fig. 1** Powder XRD patterns of (*a*) as-synthesized UHM-1 (P/Al = 2.0), (*b*) calcined UHM-1 (P/Al = 2.0), (*c*) as-synthesized UHM-3 (P/Al = 0.8, Si/P = 0.2) and (*d*) calcined UHM-3 (P/Al = 0.8, Si/P = 0.2)

silicoaluminophosphate have been synthesized. As-synthesized UHM-1 and UHM-3 show a *d*(100) spacing of 4.1 nm. All XRD patterns of calcined UHM-1 and UHM-3 are similar and exhibit a single broad diffraction peak corresponding to a *d*(100) spacing of 3.6 nm.

The broadening of the (100) reflection on calcination arises from less long-range crystallographic order.[7,8] The intensity of the *d*(100) reflection of calcined UHM-1 and calcined UHM-3 decreases in comparison with that of as-synthesized UHM-1 or UHM-3 as has been observed for hexagonal MCM-41.[5,6,9]

Transmission electron micrographs of as-synthesized UHM-1 (Fig. 2) show hexagonal-shaped pores of about 4 nm diameter which is in agreement with the value (4.1 nm) measured from XRD. These results are similar to, but show more disorder, than those of siliceous MCM-41 materials,[5,6,9] supporting that as-synthesized UHM-1 and UHM-3 essentially have long-range hexagonal packing but with some disorder.

Synthesis of mesoporous aluminophosphate (UHM-1) is successful with aluminium hydroxide but replacement of aluminium hydroxide by Capatal alumina produces only amorphous or lamellar aluminophosphate (designated UHM-2). UHM-2 with *d*(100) of 2.97 nm is similar to the lamellar aluminophosphate previously reported.[4] For the formation of silicoaluminophosphate, TEOS is used as the silica source.

UHM-1 can be formed over a range of P/Al mole ratios (3.4–0.6) in the gel which is different from a fixed P/Al ratio (*ca.* 1.0) required for synthesis of microporous aluminophosphates.[10] However, the P/Al ratio in the product is always less than unity and decreases with decreasing P/Al in the gel. This is perhaps why the products show better resolved XRD with higher P/Al gel ratios. The product P/Al ratio of $< 1$ suggests that hydroxy aluminium species are involved in the mesoporous assembly process. Mesoporous aluminophosphate can be synthesized for a range of surfactant to alumina ratios of 0.24–0.50. At higher surfactant/$Al_2O_3$ ratios of 1–3 only amorphous material is formed.

Mesoporous hexagonal aluminophosphate can be synthesized at pH values from 7.5 to 9.5 at room temperature. At higher temperatures up to 100 °C formation of the hexagonal phase requires pH $> 8.5$. Mesoporous hexagonal aluminophosphate is formed with cationic surfactants only in the presence of alkylammonium hydroxide, $NR_4OH$ (R = Me, Et, $Bu^n$). Replacement of $NR_4OH$ with 0.1 M NaOH led to no mesostructural materials.

The BET surface areas of calcined UHM-1 average 772 $m^2\ g^{-1}$ and of UHM-3 average 928 $m^2\ g^{-1}$ and are independent of the P/Al or Si/P gel ratios. These values reflect the thermal stability of UHM-1 and UHM-3 to calcination at 500 °C as do the TEM results.

Thermogravimetric analysis of UHM-1 shows a large mass loss of *ca.* 70% on heating to 700 °C. Three endothermic losses near 80 °C (15 mass%), 240 °C (30 mass%) and 340 °C (25 mass%) are observed. The 80 °C loss is assigned to water desorption. The 240 and 340 °C losses are assigned to desorption and decomposition of TMAOH and CTAC in either order.

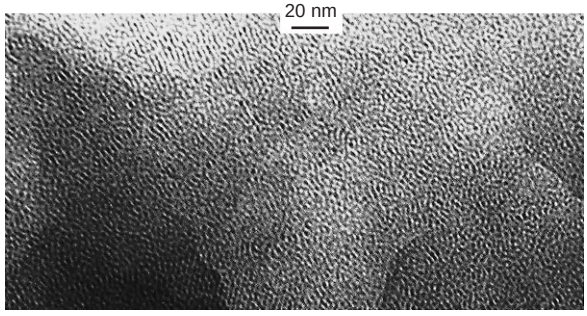

**Fig. 2** Transmission electron micrograph (TEM) of as-synthesized UHM-1. TEMs for calcined UHM-1 and for UHM-3 are similar.

We postulate that the formation of UHM-1 and UHM-3 materials occurs by a modified $S^+I^-$ ion-pair process. The inorganic precursors ($I^-$) are non-ideal aluminophosphate species of low polymerization degree with some hydroxy groups. When TMAOH is added, it reacts with the hydroxy group of these aluminophosphate species to produce a weak ion pair ($I^-\cdots TMA^+$) since the $TMA^+$ cation has a large ionic radius. These ion-pair species diffuse to the surfactant ($S^+$) assembly (micelle) interface and interact strongly with the cationic surfactant headgroups. The interaction of the aluminophosphate species with the cationic surfactant headgroups is stronger than that with $TMA^+$ cation. The micellar structure then organizes the condensation and polymerization of adjacent aluminophosphate species to form an ordered hexagonal mesostructure.[5,11]

The function of the organic ammonium cation from TMAOH seems to be to modify the strength of the electrostatic interaction between the aluminophosphate species and the cationic surfactant micelle assembly to form a $S^+I^-\cdots TMA^+$ ion pair. If NaOH is used the $Na^+$ cation with a smaller ionic radius than $TMA^+$ has a stronger ion-pair interaction with the aluminophosphate species and prevents sufficient interaction with the cationic surfactant assembly. Thus the assembly of mesostructural aluminophosphate fails. Aluminium hydroxide may form a less polymerized aluminophosphate with many hydroxy groups and favour the assembly of the mesostructure compared to Capatal alumina.

We conclude that mesoporous hexagonal aluminophosphate UHM-1 and silicoaluminophosphate UHM-3 molecular sieves can be synthesized *via* modified ion-pair interactions. The calcined materials are characterized by a hexagonal structure with *d*(100) *ca.* 4.0 nm and high surface area which reveals their thermal stability. These materials seem to have greater thermal stability than very large pore AlPO-*n* materials like VPI-5.

# Sulfoxide induced sigmatropic rearrangement (SISR) of methyl 1-methylsulfanylvinyl sulfoxides

**Bianca F. Bonini,[a] Mauro Comes Franchini,[a] Germana Mazzanti,*[a] Jan-Willem Slief,[b] Margreth A. Wegman[b] and Binne Zwanenburg*[b]**

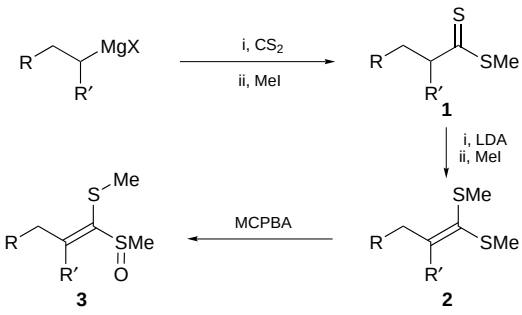
**Treatment of methyl 1-methylsulfanylvinyl sulfoxides with sodium thiophenolate in MeOH gives 1-methylsulfanylalk-1-en-3-ols.**

The sigmatropic rearrangement of allylic sulfoxides in the presence of a thiophilic reagent leads to allylic alcohols.[1] A special sequence which includes this reaction is the rearrangement of α-arylsulfinylacrylates to 4-hydroxyalk-2-enoate esters.[2] In this sequence a thiophilic base first gives an *in situ* isomerization of the vinyl sulfoxide moiety into an allylic sulfoxide, which then undergoes a 2,3-sigmatropic rearrangement and a subsequent thiophilic cleavage of the thus-formed intermediate sulfenic esters by the same base. A practical variant of this synthesis of γ-hydroxyalkenoic esters is the so-called SPAC (sulfoxide piperidine and carbonyl) reaction[3,4] in which the sulfinylacrylates are prepared by a Knoevenagel-type condensation of an appropriate aldehyde and arylsulfinyl acetates, and subsequently rearranged under the same conditions in a one-pot operation.

Here we report on a new related sulfoxide induced sigmatropic rearrangement (SISR) of methyl 1-methylsulfanylvinyl sulfoxides. The required starting materials were conveniently prepared from the corresponding dithiocarboxylic esters by deprotonation with LDA and subsequent *S*-methylation. The ketene dithioacetals thus prepared were oxidized to the *S*-monoxides with 1 equiv. of MCPBA. In all cases the *E*-isomers were formed preferentially. The dithioesters were prepared from Grignard reagents and carbon disulfide, followed by methylation with methyl iodide[5] (Scheme 1). The products **1**–**3** were characterized by IR, mass and NMR spectroscopy. The various compounds **3** prepared in this manner are listed in the Table 1.



It is of interest to note that an alternative preparation of sulfoxides **3** from the *S*-oxides of dithioesters **1**, by deprotonation and subsequent *S*-alkylation of the intermediate vinylsulfenate anion,[6] was unsuccessful due to the limited stability[7] of the dithioesters of *S*-oxides and the formation of complex mixtures of products.

For the SISR reaction, first the recommended conditions for the SPAC reactions were tried for substrate **3a**. Prolonged treatment of **3a** with a large excess of piperidine in MeCN at room temperature did not give any reaction. Reaction at 85 °C for five days, adding 10 equiv. of piperidine every day, gave a 70% yield of 1-methylsulfanylpent-1-en-3-ol **6a** which had almost exclusively the *E* configuration (*E*:*Z* ratio greater than 95:5). More convenient conditions involved treatment with 5 equiv. of sodium thiophenolate in MeOH at room temperature for four days. In this manner **6a** was obtained in 75% yield almost exclusively in the *E* form. The formation of **6a** from **3a** can readily be explained by invoking an initial base-induced prototropic shift to give allylic sulfoxide **4a**, which then undergoes a 2,3-sigmatropic rearrangement to produce sulfenate ester **5a**. Subsequent thiophilic reaction of **5a** with thiophenolate then leads to product **6a**. It is quite surprising that thiophenoxide serves as thiophilic reagent[1] as well as base. These newly established conditions were also successful for the sequential prototropic shifts and sigmatropic rearrangement reactions of the substrates **3b**–**e**. The corresponding 1-methylsulfanylalk-1-en-3-ols **6b**–**e** were all obtained in yields ranging from 75–98%. The products **6a**–**e** have been characterized by IR, mass and NMR spectroscopic data.† The spectral characteristics revealed that all products **6** predominantly have the *E* configuration with *E*:*Z* ratio exceeding 90:10 (Scheme 2, Table 2).

[a] Yields of pure isolated products. [b] Determined by NMR spectroscopy.

It is worth noting that the yield is also high for the formation of **6e**, where the initial isomerization is accompanied by a considerable increase of torsional strain.

The SISR reaction of sulfoxides **3**, of which no precedent is known in the literature, leads to γ-hydroxyvinyl sulfides, which can serve as a synthetic equivalent for β-hydroxy aldehydes[8,9] The synthetic potential of this new SISR reaction is currently under investigation, including chirality transfer from sulfur to carbon when optically active sulfoxides are used as the substrates. Furthermore, the SISR reaction will be investigated for vinyl sulfoxides with other heteroatoms at the geminal position of the sulfoxide group.

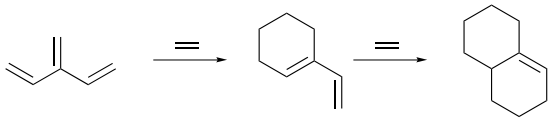
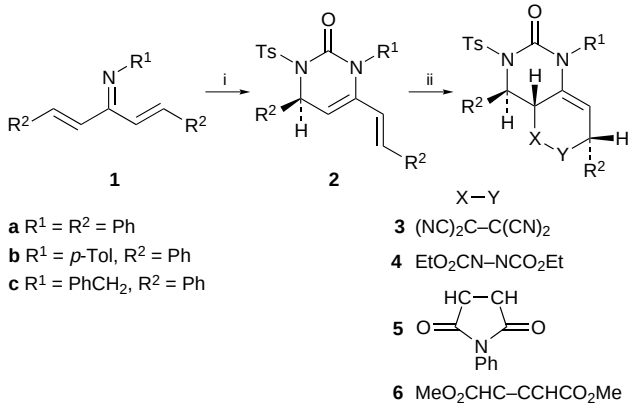
# Diene-transmissive hetero-Diels–Alder reaction of cross-conjugated azatrienes: a novel and efficient method for the synthesis of ring-fused nitrogen heterocycles



**Takao Saito,* Hiroaki Kimura, Tomomichi Chonan, Takayuki Soda and Takayuki Karakasa**

*Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162, Japan*



**A diene-transmissive hetero-Diels–Alder reaction of cross-conjugated azatrienes, which provides a novel and efficient synthetic method for ring-fused, nitrogen-heterocyclic frameworks such as quinazolin-2-ones and pyrimido[5,4-*c*]-pyridazin-6-ones, is described for the first time.**

The diene-transmissive Diels–Alder (DTDA) reaction is defined by two sequential (tandem) DA cycloadditions that involve an initial DA reaction of a cross-conjugated triene (or its equivalent) with a dienophile, followed by a second DA reaction of the mono-adduct on the newly-formed diene unit to give a bis-adduct (Scheme 1).[1] Tsuge *et al.* have developed the DTDA reactions.[2] However, the diene-transmissive hetero-Diels–Alder (DTHDA) reaction, in which one or more heteroatoms are contained within either a triene framework or a dienophile skeleton or both, has not been studied extensively, despite its high potential for construction of a wide range of ring-fused heterocycles; only a few reports have appeared so far.[3–6] In our previous reports, we disclosed the first examples of the DTHDA reactions in both inter- and intra-molecular modes of cycloadditions, in which divinyl thioketones were used as cross-conjugated heterotrienes.[3,4] Recently, Tsuge *et al.* reported the aza-DTHDA reaction of carbotrienes with strong diazo dienophiles such as azodicarboxylate and triazolinedione, and the oxa-DTHDA reaction of divinyl ketones with an enamine (initial cycloaddition) followed by tetracyanoethylene or triazolinedione (second cycloaddition).[5] Spino and Liu showed that cyclic 2-formyl 1,3-dienes also took part in the oxa-DTHDA reaction for the construction of a quassinoid framework.[6] Although azabutadienes constitute a class of widely investigated heterodienes in HDA cycloaddition reactions,[7] there are no reports on the aza-DTHDA cycloaddition of cross-conjugated azatrienes capable of 4π participation. We report here for the first time on the aza-DTHDA reaction of such azatrienes. The methodology constitutes a new facile access to a variety of functionalized, ring-fused nitrogen heterocycles with high efficiency and predictable stereoselectivity.

When the di-β-styrylmethanimine **1**† (16 mmol) was allowed to react with tosyl isocyanate (2–3 equiv.) at room temp. in xylene (15 $cm^3$) for 0.5–1 h, the 1 : 1 cycloadduct **2**‡ was obtained in good yield (Scheme 2, Table 1). Neither the regioisomer nor the bis-adduct were detected in the reaction mixture. A second DA cycloaddition of the diene **2** with tetracyanoethylene (TCNE) proceeded smoothly at room temp. to give a quantitative yield of the cycloadduct **3**‡ with complete stereoselectivity. The stereochemistry of the cycloadduct **3** was deduced from its $^1$H NMR spectrum based mainly on the coupling constants, for example for **3a** $^3J_{4,4a}$ 5.0, $^4J_{4a,7}$ 2.3, $^4J_{4a,8}$ 2.3 and $^3J_{7,8}$ 3.6 Hz, suggesting that, in the second cycloaddition, the dienophile cycloadds from the less hindered bottom side (*anti* to $R^2$) of **2** in which the substituent $R^2$ at C-4 occupies an axial arrangement in accord with the observed coupling constant $J_{4,5}$ (*e.g.* 6.9 Hz for **2a**). Dimethyl azodicarboxylate (DAD) also afforded highly stereoselectively the

[a] TCNE: tetracyanoethylene; DAD: diethyl azodicarboxylate; NPMI: *N*-phenylmaleimide; DMF: dimethyl fumarate. [b] Isolated yield. [c] Ratio (*endo* : *exo*) determined by $^1$H NMR spectroscopy. The term *endo* refers to a *cis*-relationship between $H_{4a}$ and $H_5$ and the term *exo* a *trans*-relationship.

cycloadduct **4**‡ in good yield. With *N*-phenylmaleimide (NPMI) and dimethyl fumarate (DMF) second cycloadditions were effected upon heating in toluene for 4–17 h to produce excellent yields of the cycloadducts **5** and **6** with complete diastereoisoface selectivity but with almost no *endo* : *exo*-selectivity. The results are summarised in Table 2. Fig. 1 shows the most probable stereochemical (conformational and configurational) structures of the mono- (**2**) and bis-cycloadducts (**3**–**6**) which were deduced from $^1$H NMR spectroscopic studies and computational calculations using MOPAC 93, CONFLEX, LAOCOON III and 3JHH2 programs.[4,10,11]

Thus, it has been shown that the DTHDA methodology of cross-conjugated azatrienes is successfully applied to a synthesis of ring-fused nitrogen heterocycles.

## Footnotes

† The imine **1** was prepared by Barluenga's method involving the reaction of iminophosphorane with prop-2-ynyltriphenylphosphonium salt, followed by successive treatment with an aldehyde, butyllithium and an aldehyde (Method B, 60–70% yield).[8] Otherwise, the imine **1** was more conveniently prepared by the condensation reaction of di-β-styryl ketone with an amine in the presence of $TiCl_4$ and triethylamine (method A, 90–95% yield).[9]

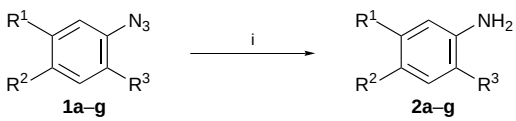
# Novel biocatalytic reduction of aryl azides: chemoenzymatic synthesis of pyrrolo[2,1-*c*][1,4]benzodiazepine antibiotics[1]

**Ahmed Kamal,* Y. Damayanthi, B. S. Narayan Reddy, B. Lakminarayana and B. S. Praveen Reddy**



*Indian Institute of Chemical Technology, Hyderabad 500 007, India*

**The chemoselective reduction of aryl azides to aryl amines, and the synthesis of the imine-containing pyrrolo[2,1-*c*]-[1,4]benzodiazepine DNA-binding antitumour antibiotics by selective biocatalytic reductive cyclization of azido aldehydes, has been achieved by employing baker's yeast.**

In the recent years there has been a growing interest in biocatalysis and, in particular, transformations[2] mediated by baker's yeast (*Saccharomyces cerevisiae*). Reduction of carbonyl compounds by baker's yeast has become a valuable strategy in organic synthesis.[3] A variety of new and novel abilities of baker's yeast have been reported by us,[4,5] for example regeneration of carbonyl compounds and biooxidative conversion of thio to oxo functionality. In continuation of these efforts, we herein report a novel reduction of aryl azides to aryl amines in quantitative yield. This is an exceptionally mild, convenient and facile reduction employing baker's yeast. However, in the literature[6] alkyl keto azides have been reduced by baker's yeast to afford the corresponding alkyl azido alcohols. This is consistent with our finding that various alkyl azides, *e.g.* 1-azido-3-aryloxypropan-2-ols, are resistant to baker's yeast reduction. Further, this biocatalytic reductive methodology has been applied to the chemoenzymatic synthesis of the DNA-binding pyrrolo[2,1-*c*][1,4]benzodiazepine (PBD) system[7] *via* the reductive cyclization of aryl azido aldehydes. Interestingly, this investigation has revealed the unusual chemoselective reduction of the aryl azido group in the presence of an aldehyde group by baker's yeast.

Some representative aryl azides **1a**–**g** have been reduced by baker's yeast to afford the corresponding aryl amines **2a**–**g** (yields 83–92%), as illustrated in Scheme 1.†

This biocatalytic reduction employing baker's yeast has been extended to the chemoenzymatic synthesis of the PBD class of antitumour antibiotics. Although PBDs with either a secondary amine or amide functionalty at N(10)–C(11) are readily synthesised, the introduction of an imine or amino alcohol at this position is problematic due to the reactivity of these functional groups.[8] In the literature, various approaches to the synthesis of these antibiotics have been investigated.[9] Our interest in the design and synthesis of PBD analogues[10] has led us to develop a new chemoenzymatic methodology for the DNA-interactive PBDs. This approach is based on the formation of the seven-membered ring *via* an enzymatic azido reductive cyclization process. This enables cyclization of the diazepine ring to take place under extremely mild and ambient conditions, and involves a simple and rapid work-up procedure.

The initial studies were carried out on the preparation of PBD dilactams by the azido bioreductive cyclization process to assess the scope of this reaction. The starting materials, methyl (2*S*)-*N*-(2-nitrobenzoyl)pyrrolidine-2-carboxylate esters **3**, were prepared[8] from 2-nitrobenzoic acids *via* their acid chlorides, which were coupled with (*S*)-proline methyl ester hydrochloride. The reaction of **3** with $NaN_3$ in HMPA‡ gave the azido derivatives **4** which, upon reduction with baker's yeast, gave the PBD dilactams **5a**–**d** in quantitative yield (Scheme 2).

The precursor for PBD imine **8** was prepared by the reduction of **3** with DIBAL-H to give the corresponding (2*S*)-*N*-(2-nitrobenzoyl)pyrrolidine-2-carboxaldehydes **6**. These, upon subsequent reaction with $NaN_3$ in HMPA followed by reduction with baker's yeast and chromatography of the crude product (silica, chloroform–methanol, 9.8 : 0.2), gave the PBD imines **8a**–**d**.§ This novel biocatalytic methodology has also been extended to the synthesis of the natural product DC-81 **8c**.

The results contained in this report demonstrate that it is not only possible to convert aryl azides to the amino arenes by employing baker's yeast, but also the usefuleness of baker's

yeast in the chemoenzymatic synthesis of natural and synthetic analogues of PBDs. The present approach, which is performed under extremely mild conditions, should maintain the stereochemical integrity at C(11a) and may not effect the DNA binding potential of the PBD imines, unlike other chemical methods.[10d]

† *General procedure*. To a solution of 2-azidobenzoic acid **1a** (0.31 mmol) in aq. EtOH (50%, 2 $cm^3$) was added to a preincubated suspension of baker's yeast (2 g) in phosphate buffer solution of pH 7.2 (20 $cm^3$) and shaken in an orbital shaker for 6 h. The reaction was monitored by TLC (EtOAc–hexane, 1 : 1). On completion of the reaction, EtOAc (20 $cm^3$) was added to the reaction mixture. The organic phase was separated, dried over anhydrous $Na_2SO_4$ and concentrated under reduced pressure. The residue obtained was subjected to column chromatography (silica gel, EtOAc–hexane, 1 : 1) to afford the reduced product, 2-aminobenzoic acid **2a** in 85% yield.

‡ *General procedure*. A solution of nitro esters **3** (514 mg, 1.85 mmol) or nitro aldehydes **6** (459 mg, 1.85 mmol) and sodium azide (247 mg, 3.80 mmol) in HMPA (15 $cm^3$) was stirred at room temperature for 6–8 h. The reaction mixture was poured onto water and then extracted several times with diethyl ether. Evaporation of the combined diethyl ether extract gave the crude azides in 90–95%, which was further purified by column chromatography on silica gel. *Selected spectra data* for **7a**: $^1$H NMR (200 MHz, $CDCl_3$): δ 1.90–2.39 (m, 4 H), 3.32 (t, 2 H, *J* 7.0 Hz), 4.74 (t, 1 H, *J* 7.2 Hz), 7.50–7.98 (m, 3 H), 8.29 (d, 1 H, *J* 6.2 Hz); 9.87 (d, 1 H, *J* 4.2 Hz); *m/z* 244 ($M^+$, 8%).

§ *Selected spectra data* for **8a**: $^1$H NMR (200 MHz, $CDCl_3$): δ 1.56–2.48 (m, 4 H), 3.20–3.89 (m, 3 H), 7.10–7.59 (m, 3 H), 7.66 (d, 1 H *J* 4.2 Hz), 8.02 (d, 1 H, *J* 5.8 Hz); *m/z* 200 ($M^+$ 100%).

# Mild, efficient cleavage of arenesulfonamides by magnesium reduction

**Barthélémy Nyasse,[a] Leif Grehn[b] and Ulf Ragnarsson*[b]**

[a] *Department of Organic Chemistry, University of Yaoundé I, Box 812, Yaoundé, Cameroon*
[b] *Department of Biochemistry, University of Uppsala, Biomedical Center, Box 576, S-751 23 Uppsala, Sweden*

**The cleavage of arenesulfonamides *via* *N*-arenesulfonylcarbamates is achieved within a few minutes under ultrasonic conditions by reaction with magnesium in anhydrous methanol.**

For a long time, aromatic sulfonic acids have been used in the derivatization of amines and the protection of amino functions[1] and the resultant, generally crystalline sulfonamides are very resistant to nucleophilic attack. In addition, sulfonamides derived from primary amines can be readily deprotonated and the anions can serve as nucleophiles in reactions with alkylating reagents.[2] For the cleavage of the prototype *N*-tosyl group, reagents like sodium in liquid ammonia,[3] refluxing strong acid such as HBr in the presence of phenol[3] and sodium naphthalenide have been applied.[4] The need for such drastic conditions in the deprotection step restricted the use of tosyl and similar protecting groups to only very stable molecules and excluded the simultaneous application of many other protecting groups currently used. However, the scope widened with the development of new deprotection methods which included $SmI_2$,[5] $Bu_3SnH$–AIBN[6] and electrolysis.[7a] In the meantime, efforts were made to modify the tosyl group to make it more labile to acid. As a result, a new generation of arenesulfonyl protecting groups have emerged, *e.g.* 4-methoxybenzenesulfonyl (Mbs),[8] and the 2,2,5,7,8-pentamethylchromane-6-sulfonyl[9] and heteroarene-2-sulfonyl groups.[5b–d]

In continuation of our work dealing with the cathodic cleavage of substituted benzenesulfonamides and the corresponding *tert*-butyl sulfonylcarbamates,[7a] we now report a fast and simple method for the deprotection of substituted phenylsulfonylcarbamates using magnesium† in methanol as the cleaving agent under ultrasonic conditions. Although this system has been used previously for the cleavage of primary and secondary alkyl phenyl sulfones,[10,11] only one example dealing with the cleavage of a tosyl group attached to an indole nitrogen with magnesium turnings has been briefly reported.[12]

The *tert*-butyl *N*-arylsulfonylcarbamates and *N*-acylsulfonamides used as starting material in this work were prepared according to the procedures previously described.[7] In general primary amino functions of alkylamines and amino acids were first converted to the corresponding sulfonamides which in turn afforded alkyl arylsulfonylcarbamates almost quantitatively after treatment with $Boc_2O$ under DMAP catalysis.

Initial cleavage experiments were carried out using 20 equiv. of magnesium in methanol at room temperature with stirring. Long reaction times (6–24 h) were thereby required to attain the

[a] Products were identical with reference substances by TLC, $^1$H NMR and/or melting point. [b] Typical experimental procedure: to a solution of substrate (186 mg, 0.5 mmol) in MeOH (6 cm$^3$) was added Mg powder (61 mg, 2.5 mmol, 5 equiv.). The resulting suspension was sonicated for 20 min, when TLC on silica (diethyl ether–light petroleum, 1 : 2) indicated that all starting material had been consumed. The reaction was diluted with dichloromethane (15 cm$^3$) and poured into 0.5 M HCl. The organic phase was washed twice with 1 M $NaHCO_3$ and brine and then dried ($MgSO_4$). Filtering through a short silica column and crystallization gave 103 mg (100%) of white crystalline product, identical with Boc-NHBn. For substrates not readily soluble in MeOH, THF can be added. A mixture of MeOH–THF 3 : 1 worked as well as neat MeOH. [c] New compound (L. Grehn, B. Nyasse and U. Ragnarsson, manuscript in preparation). [d] n.d. = not determined.

complete deprotection of $PhSO_2$, 4-cyanophenylsulfonyl (Cbs), 4-$BrC_6H_4SO_2$ and Ts groups of the corresponding *tert*-butyl arylsulfonylcarbamates, but Mbs did not cleave completely even after 24 h. When the same amount of magnesium was used and the reactions were allowed to proceed under ultrasonic conditions‡ very fast and clean cleavage took place even with Mbs-protected and sterically hindered substrates. Reactions were subsequently optimised with the *tert*-butyl *N*-benzyl derivatives in each case under sonication with the results that (i) 5 equiv. of magnesium powder were sufficient for an efficient deprotection of the $PhSO_2$, 4-$BrC_6H_4SO_2$, Cbs and Ts groups and (ii) 10 equiv. for the 2,4,6-$Me_3C_6H_2SO_2$ and 2,4,6-$Pr^i_3C_6H_2SO_2$ groups, whereas (iii) at least 15 equiv. were required for the cleavage of the Mbs-carbamate. These findings were subsequently applied in the preparative cleavage experiments involving derivatives of alanine, ethylenediamine, hydrazine and *N*-acyl sulfonamides listed in Table 1.

It should be noted that during the experiment involving the 4-$NO_2C_6H_4SO_2$ group (entry 6), a yellow mixture was obtained, probably resulting from reduction of the nitro group. The Troc containing sulfonylcarbamate (entry 14), although cleaved completely, underwent a known alkyl halide reduction mediated by the reagent,[13] giving rise to the 2,2-dichloroethoxycarbonyl (Doc) derivative. Furthermore, transesterification took place (entries 10 and 11) as previously observed during the reduction of an α,β-unsaturated ethyl ester.[14] Concerning the *N*-Ac and *N*-Bz sulfonamides (entries 17 and 18), it is worth mentioning that the cleavage of the tosyl group proceeded more selectively in the former case.

In summary, since arenesulfonamides derived from primary amines are easily converted to *tert*-butyl and similar sulfonylcarbamates by DMAP-catalysed acylation,[7] this reductive cleavage completes a two-step procedure from sulfonamides to carbamates. Furthermore, since the required sulfonylcarbamates can also be directly obtained from alcohols by the Mitsunobu reaction,[2] such carbamates can now also be made more conveniently by the present procedure.

During the tenure of this work, B. N. was a recipient of a fellowship from the Swedish Institute which is gratefully acknowledged. This research is part of a programme supported by the Swedish Natural Science Research Council.

# Time-resolved solid-state REDOR-edited NMR detection of a transient enzyme–intermediate

**Dan J. Mitchell, David L. Jakeman, Tatyana I. Igumenova, Wendy A. Shuttleworth, Keith D. Miller and Jeremy N. S. Evans***

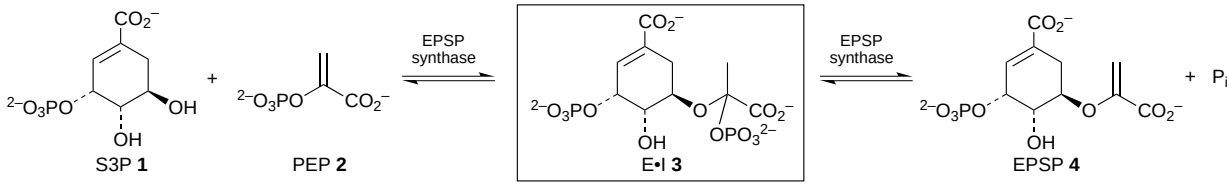
*Department of Biochemistry and Biophysics, Washington State University, Pullman, WA 99164-4660, USA*

**Time-resolved solid-state rotational echo double resonance-edited NMR has been used to detect transient enzyme–intermediates containing two dipolar coupled spins that are unique to the intermediate, so that even resonances buried in the natural abundance background can be detected.**

The technique of time-resolved solid-state NMR spectroscopy was introduced by this laboratory for the direct detection of transient enzyme–intermediates, and first demonstrated for 5-enolpyruvylshikimate-3-phosphate (EPSP) synthase,[1–4] and uridine diphosphate *N*-acetylglucosamine (UDP-NAG) enolpyruvyl transferase.[5] The time-resolved method[6] involves rapid freeze-quench of enzyme–substrate mixtures at discrete time intervals, enabling the pre-steady-state kinetic trapping of transient species as a function of time, followed by low-temperature solid-state NMR analysis of the samples at each time point. Enzymatic reactions which have either single or multiple intermediates can in theory be stopped along the reaction coordinate. When coupled with rotational echo double resonance (REDOR) solid-state NMR, enzyme active site distance information for discrete ground state species can be obtained as a function of time. This laboratory first demonstrated the direct detection of the intermolecular dipolar coupling in the transient enzyme–intermediate complexes of the enzymes EPSP synthase[7] and UDP-NAG enolpyruvyl transferase.[8]

The REDOR technique was introduced by Schaefer and coworkers,[9] and relies on the fact that the effect of the dipolar interaction between two spins on the rotational echo can be manipulated by π-pulses. The dephasing of magnetization of one spin involved in dipolar coupling to another heteronucleus in the presence and absence of these π-pulses, and subsequent refocusing as a function of the magic angle spinning frequency, leads to a variation of resonance intensities. This intensity variation is related to the dipolar coupling constant. The first spectrum is obtained using a standard cross polarization pulse sequence with π-pulses on the observed nucleus (*e.g.* $^{13}$C) in the middle of the evolution period. During this period, the observable magnetization evolves under the influence of the chemical shifts and the heteronuclear dipolar interaction. The π-pulses refocus both interactions, leading to a signal $S_0$ during the acquisition period. The second spectrum is obtained with an additional train of π-pulses on the dipolar-coupled spin (*e.g.* $^{31}$P). These pulses affect the observed signal by preventing rotational refocusing of the dipolar interaction. The magnetization is therefore not completely refocused, and the signal intensity drops by an amount $\Delta S$. For weak dipolar coupling, the change in signal intensity is related to the distance between the coupled spins by[12] eqn. (1), where $N_c$ is the number of

$$\Delta S/S_0 = KD^2N^2_c\nu_r^{-2} \quad (1)$$



rotor cycles during the evolution period, $\nu_r$ is the spinning speed (in Hz), $D$ is the dipolar coupling (in Hz), and $K$ is a dimensionless constant (= 1.066). Measurement of $D$ can be used to calculate internuclear distance ($r$) according to eqn. (2), where $\gamma_I$ and $\gamma_S$ are the gyromagnetic ratios for the

$$D = \left(\frac{\mu_0}{4\pi}\right)\frac{\gamma_I\gamma_S\hbar}{2\pi r^3} \quad (2)$$

two heteronuclear spins involved, and $\hbar$ is Planck's constant divided by 2π. This experiment therefore yields the internuclear distance, which for an isolated spin pair (*e.g.* $^{13}$C–$^{15}$N or $^{31}$P–$^{13}$C) can be determined to an accuracy of around ±0.1 Å. In addition to making quantitative distance measurements, the technique can also be used for qualitative measurements between spins within the distance dictated by the limits of the two nuclei involved in dipolar coupling.[7,8]

Here we report the first application of time-resolved REDOR-edited solid-state NMR spectroscopy to the detection of a reactive intermediate species trapped at the active site of an enzyme containing a strongly dipolar coupled spin pair unique to the intermediate, thereby editing an otherwise crowded solid-state NMR spectrum. To test this approach, we have used a well-characterized enzyme,[10–13] EPSP synthase (EC 2.5.1.19), which catalyses the penultimate step in the aromatic amino acid biosynthetic pathway in higher plants and bacteria. EPSP **4** is formed from shikimate-3-phosphate (S3P) **1** and phosphoenolpyruvate (PEP) **2** (Scheme 1). The enzyme is a monomer with molecular weight $M_r$ = 46 kDa and the cloned *E.coli* gene has been used to generate a hyperexpressing strain,[14] so that the bacterial enzyme is available in gram quantities. Furthermore, EPSP synthase is the primary site of action of the herbicide glyphosate,[15] or *N*-phosphonomethylglycine. Schaefer and coworkers[16–19] have used solid-state REDOR NMR experiments to investigate the conformation of the bound inhibitor glyphosate in the ternary complex, and its relation to the enzyme active site. This is particularly significant, since all attempts to crystallize the ternary complex have failed thus far.

The rationale for selecting EPSP synthase for testing the time-resolved REDOR-edited NMR approach was as follows. Since the enzyme–intermediate has already been thoroughly characterized by our laboratory in solution[11,12] and in the solid-state,[1,2,4] and this enzyme–intermediate contains a unique dipolar coupled spin pair (*e.g* $^{31}$P–$^{13}$C), this then provides an

**Scheme 1**

unusual opportunity to test whether this approach is amenable for application to other enzymes. Fig. 1 shows {$^{31}$P}$^{13}$C CP-MAS REDOR difference ($\Delta S$) and full echo ($S_0$) time-resolved solid-state NMR spectra of EPSP synthase·S3P mixed with [2-$^{13}$C]PEP under pre-steady-state conditions, followed by lyophilisation at low temperature.† The substrates in these experiments were present in an 10-fold excess over the enzyme. At this stage lyophilised solids have been employed because of technical difficulties associated with performing REDOR measurements on frozen solutions. The enzyme–intermediate complex was trapped under time-resolved conditions (the time-resolution being 50 ms in this case), and the sample kept at low temperature ($< 263$ K) throughout the lyophilisation. The spectra were obtained using the REDOR pulse sequence with dephasing π-pulses applied to the $^{31}$P nuclei and detection on $^{13}$C. The rationale for this choice of spin pairs was guided by the fact that apart from enzyme-free or bound [2-$^{13}$C]PEP, none of the species present *except* the tetrahedral intermediate (**3**) contains strongly dipolar coupled $^{13}$C and $^{31}$P. Thus the spectrum is edited with respect to those $^{13}$C atoms which are dipolar coupled to $^{31}$P, and the conditions can be adjusted (determined by the number of dephasing π-pulses) so that *predominantly* C–O–P linkages are detected. In the P–C REDOR difference spectrum ($\Delta S$ in Fig. 1), in addition to the substrate [2-$^{13}$C]PEP and possibly product EPSP at δ 152.5 (both species have closely similar chemical shifts[4]), and their associated rotational sidebands (RSB), which of course also contains a C–O–P linkage, the enzyme–intermediate (E·I) complex is evident at δ 104. This is consistent with our previously published NMR data on the enzyme–intermediate of EPSP synthase both in solution[16,17] and in the solid-state.[1,2,4] With 32 $^{31}$P dephasing π-pulses, the predominant interaction arises from C–O–P linkages and other species experiencing dipolar interactions within a radius of 5 Å. Examples of the latter case are evident in Fig. 1, where resonances due to dipolar coupling between the phosphate of PEP/S3P or EPSP and the $^{13}$C natural abundance of tris buffer can be seen at δ 62.1, both of which were present in excess over the enzyme. Also evident are residual contacts to the enzyme backbone carbonyl resonances at δ 174.5.

These data establish the viability of this approach for picking out resonances due to enzyme–intermediates bearing C–O–P linkages, and indeed any linkage containing a pair of unique isotopic labels. It also provides further evidence that even the unstable transient intermediate of EPSP synthase, formed from the true substrate under pre-steady-state conditions, can survive in the lyophilised solid. Schaefer and co-workers[20,21] have recently reported using P–C REDOR to investigate species that form in very slow reactions catalysed by mutant forms of EPSP synthase in the solid-state, although it is unclear at this stage whether the species they are detecting have any relevance to the mechanistic course of the enzyme. These results therefore represent the first example of the application of time-resolved solid-state REDOR-edited NMR spectroscopy for the detection of transient enzyme–intermediate complexes. The stage is now set for the application of this approach to other enzymes in which a unique dipolar coupled spin pair occurs only in the putative intermediate, so that its mechanistic details may be delineated.

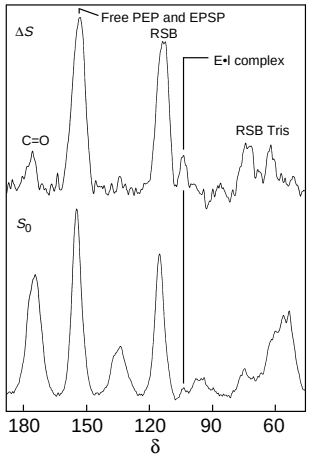


**Fig. 1** 9.4-T {$^{31}$P}$^{13}$C (P–C) CP-MAS REDOR difference NMR spectra of EPSP synthase plus shikimate-3-phosphate reacted with [2-$^{13}$C]PEP for 50 ms followed by lyophilisation at low temperature and obtained with and without $^{31}$P dephasing. The full echo $S_0$ spectrum is without $^{31}$P dephasing, and the $\Delta S$ spectrum is the difference spectrum of that obtained with and without $^{31}$P dephasing.

The technique development aspects of this work were supported by NSF grant MCB-9506117, and the specific application to EPSP synthase supported by NIH grant GM43215. The WSU NMR Center equipment was supported by NIH grant RR0631401 and NSF grants CHE-9115282 and DBI-9604689. We thank Greg Helms for managing our NMR Facility and maintaining the NMR spectrometers.

## Footnotes

† The time-resolved REDOR difference NMR spectra were obtained by rapid mix and freeze-quench (in 50 ms) of EPSP synthase (12.2 Units mg$^{-1}$) S3P with a solution of [2-$^{13}$C]PEP in 50 mM tris·HCl (pH 7.8) buffer to final concentrations of 5.8, 58 and 58 mM, respectively. The rapidly frozen sample was then lyophilised at $< 263$ K for 72 h. Approximately 70 mg of protein was used and the spectra were acquired at 233 K. The freeze-quench apparatus used is described in detail elsewhere (refs. 3 and 4). The EPSP synthase was isolated by literature methods (ref. 14). NMR spectroscopy was carried out as previously described (ref. 8).

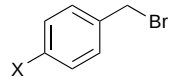
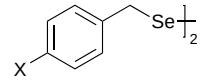
# Highly chemoselective synthesis of functionalized diselenides from alkyl halides using benzyltriethylammonium tetrathiomolybdate

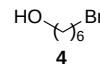
**Kandikere R. Prabhu and Srinivasan Chandrasekaran***

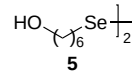
*Department of Organic Chemistry, Indian Institute of Science, Bangalore 560012, India*

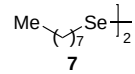
**A variety of functionalized selenocyanates generated *in situ* from the corresponding alkyl halides undergo a facile reductive coupling on treatment with benzyltriethylammonium tetrathiomolybdate 1 under very mild conditions to give the corresponding diselenides in very good yields.**

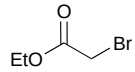


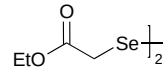


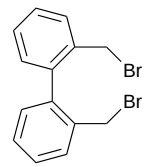


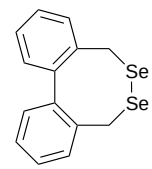


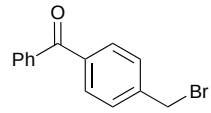


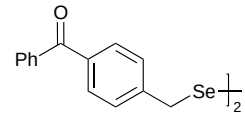






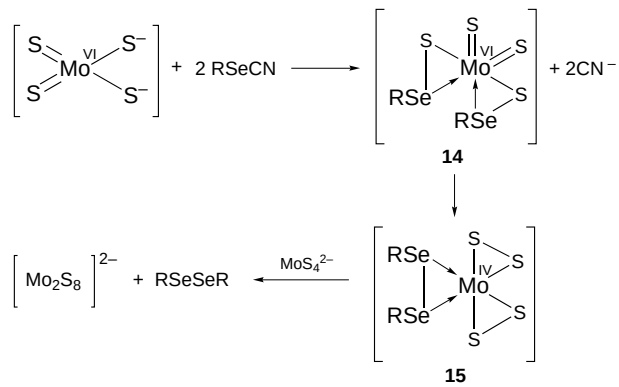






Organoselenium compounds have emerged as important reagents and intermediates in organic synthesis[1] and they also have biological importance as proteins containing selenium are essential components of certain bacterial and mammalian enzyme systems.[2] Hence a convenient synthesis of these selenium compounds in general and functionalised organic diselenides in particular continues to be a challenging task.

From the large number of methods available for the synthesis of diselenides, the most important routes involve either the reaction of metal diselenides on alkyl halides[3] or the preparation of selenols which can be subjected to further oxidation.[4] Recently Salama and Bernad[5] reported that organic selenocyanates, on treatment with $LiEt_3BH$ followed by air oxidation, give the corresponding diselenides in good yields. Most of the methods available are generally useful only for the synthesis of simple diselenides lacking reactive functional groups.



In our earlier work we have demonstrated that benzyltriethylammonium tetrathiomolybdate $[PhCH_2NEt_3]_2MoS_4$ **1** is a useful sulfur transfer reagent in organic synthesis[6] as well as a reagent that can mediate reductive dimerization of alkyl azides[7] and organic thiocyanates.[8] In exploring further the utility of induced internal redox reactions of tetrathiomolybdate **1** in organic synthesis it appeared quite attractive to study the reductive dimerization of organic selenocyanates with **1**. Here we present the results of such an investigation.

Treatment of a number of alkyl halides with KSeCN (1.1 equiv.) in MeCN (25 °C, 0.5 h) generated the corresponding alkyl selenocyanates *in situ* which, on further reaction with tetrathiomolybdate **1** (1.2 equiv., 25 °C, 0.5–24 h), led to the formation of the alkyl diselenides in high yields (85–96%).† The results are summarized in Table 1. As can be seen, except in the case of hydroxy bromide **4** (entry 5), all the substrates reacted with great facility in a short period of time (0.5–6.0 h). Particularly noteworthy are the successful reactions of the substrates **2b**,**c**,**d**, **8** and **12**, which contain easily reducible groups such as nitro, cyano, ester and keto functionalities. The methodology involving use of $LiEt_3BH$[5] or $NaBH_4$[9] for the synthesis of diselenides cannot be applied successfully in many of these cases. This kind of high chemoselectivity obtainable in a room temperature reaction is very unusual. The facile synthesis of a cyclic 8-membered diselenide **11** from dibromide **10** (entry 8) in high yield also demonstrates the high potential of the methodology. Unlike the earlier reported reactions of alkyl selenocyanates, which proceed *via* alkyl selenol intermediates,[5,9] we believe that the present methodology does not involve alkyl selenols as intermediates.‡ A tentative mechanism based on the reactivity of alkyl thiocyanates[8] with tetrathiomolybdate **1** is presented in the Scheme 1. It is likely that, in the reaction of organic selenocyanates, the attack of $MoS_4^{2-}$ on the selenium of selenocyanate leads to mononuclear molybdenum species of type **14**. The second stage of the reaction can be represented as an induced internal electron-transfer from a sulfur ligand to $Mo^{VI}$ to produce $Mo^{IV}$ species **15**.[10] Further reaction of **15** with **1** results in the formation of alkyl diselenides and $Mo_2S_8^{2-}$.§

**Table 1** Formation of diselenides

| Entry | Starting material | *t*/h[a] | Product | Yield (%)[b,c] |
|---|---|---|---|---|
| |  | |  | |
| 1 | **2a** X = H | 0.5 | **3a** | 89 |
| 2 | **2b** X = $NO_2$ | 2 | **3b** | 90 |
| 3 | **2c** X = CN | 1 | **3c** | 86 |
| 4 | **2d** X = $CO_2Et$ | 6 | **3d** | 95 |
| 5 |  **4** | 24 |  **5** | 96 |
| 6 |  **6** | 0.5 |  **7** | 85 |
| 7 |  **8** | 0.5 |  **9** | 90 |
| 8 |  **10** | 0.5 |  **11** | 88 |
| 9 |  **12** | 4 |  **13** | 87 |

[a] Time refers to conversion of selenocyanate to diselenide. [b] Refers to isolated yield. [c] All the products exhibited expected analytical and spectral data.

**Scheme 1**

In conclusion, we have demonstrated that a variety of functionalized alkyl diselenides can be synthesised in high yield from alkyl halides *via* alkyl selenocyanates under mild conditions. Further work is in progress to extend this methodology to unsymmetrical diselenides and seleno sulfides.

We thank the Department of Science and Technology, New Delhi, for financial support of this investigation.

## Footnotes

* E-mail: scn@orgchem.iisc.ernet.in

† No trace of selenol could be detected in the reaction mixture, and tetrathiomolybdate **1** does not convert selenols to diselenides.

‡ *Typical procedure*. To a solution of benzyl bromide **2a** (1 mmol) in MeCN (5 ml) was added KSeCN (1.1 mmol). The mixture was stirred at room temperature (25 °C) for 0.5 h (until the starting material had disappeared, as shown by TLC), and benzyltriethylammonium tetrathiomolybdate **1** (1.2 mmol) was added. The mixture stirred for 0.5 h, the solvent was evaporated *in vacuo* and the black residue thus formed was extracted with $CH_2Cl_2$–$Et_2O$ (1 : 9, 20 ml × 5) and filtered through a Celite pad. The filtrate was concentrated and the crude product was purified by column chromatography (silica gel, light petroleum (60–80 °C)–ethyl acetate, 9 : 1) to yield dibenzyl diselenide **3a** as a solid, mp 90–91 °C (lit.,[3] 90–91 °C) in 87% yield.

§ The IR spectrum (KBr) of the molybdenum byproduct shows a strong absorption at 515 $cm^{-1}$ assignable to a persulfido molybdenum species.

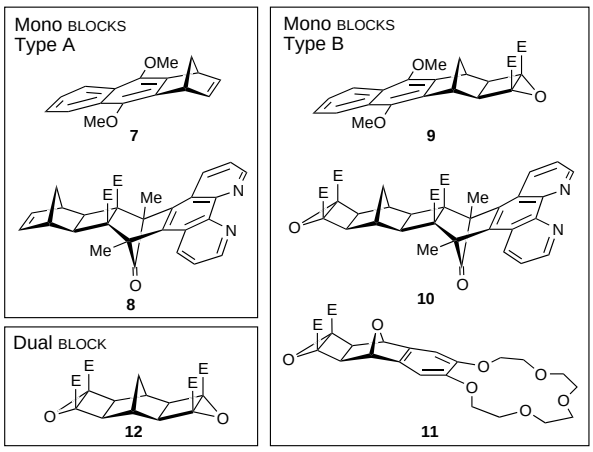
# A new building BLOCK technique based on cycloaddition chemistry for the regiospecific linking of alicyclic sub-units as a route to large, custom-functionalised structures

**Ronald N. Warrener,*[a]† Austin C. Schultz,[a] Douglas N. Butler,[a] Shudong Wang,[a] Indu B. Mahadevan[b] and Richard A. Russell*[b]**



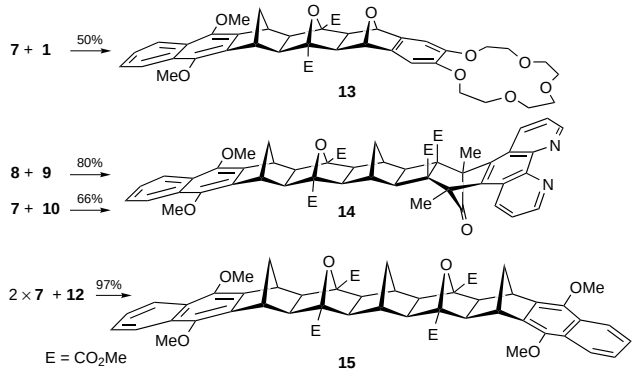
[a] *Centre for Molecular Architecture, Central Queensland University, Rockhampton, Queensland, 4702, Australia*
[b] *School of Biological and Chemical Sciences, Deakin University, Geelong, Victoria, 3217, Australia*

**A new building BLOCK approach to synthesis has been developed where functionalised norbornenes (BLOCK A) are coupled with functionalised cyclobutene epoxides (BLOCK B) to produce A + B structures of defined geometry; use of a dual (spacer) BLOCK allows the formation of large structures where crown ether, ligand and redox centres are incorporated in similar or mixed pairings.**

It is well established that there is a continuing need for the development of new substrates for supramolecular applications[1] which, in turn, requires the development of new synthetic methodology. We have recently reported the synthesis of rigid alicyclic molecules where separate donor and quencher chromophores are fused to the carbocyclic framework[2] using a serial cycloaddition technique, and this has been extended to the production of cavity-shaped crown ethers.[3] We now report a convergent method which uses preformed building BLOCKS with the particular chromophore inbuilt, and joins them thermally in a stereospecific process. The new construction technique lends itself to the production of large structures having inbuilt functional units of different types.

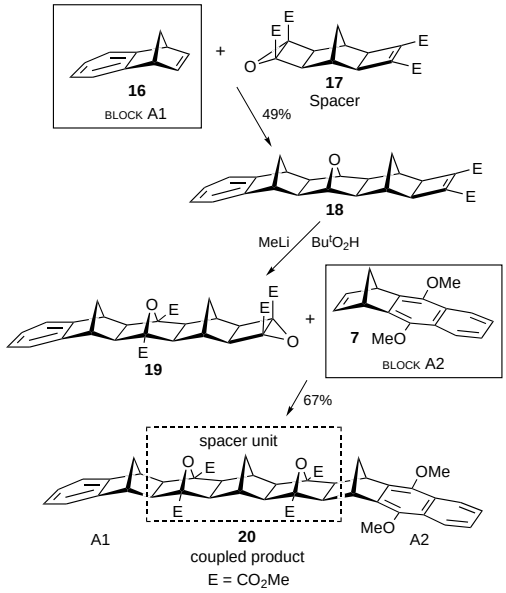
**Scheme 1** *Reagents and conditions*: i, DMAD, $RuH_2CO(PPh_3)_3$ (*cf.* ref. 7); ii, Bu$^t$OOH, MeLi, −78 °C, 75%; iii, 110 °C, 3 h, 64%

This A + B building BLOCK method developed from our discovery that fused, ester-activated cyclobutene epoxides ring-open to 1,3-dipolar species such as **4** which can be trapped stereospecifically by ring-strained alicyclic dipolarophiles.‡ We envisaged that fused norbornenes could act as one building BLOCK and fused cyclobutene epoxides could act as the other. This was confirmed by heating norbornadiene **5** (prototype building BLOCK A) with epoxide **3**§ (prototype building BLOCK B) to produce the *exo,exo*-coupled product **6**§ (Scheme 1).¶ A + B products formed by this coupling process retain their rigid alicyclic character as the newly formed 7-oxanorbornane unit seamlessly joins the two reactants.



To illustrate this building block strategy further, we have assembled a small selection of functionalised molecules which form a pool of A and B reagent BLOCKS **7**–**11**. In the longer term, this pool would grow to cover other functional units and these basic A and B BLOCKS, together with the dual (spacer) BLOCK **12**, would be available in a selection of geometrical configurations (shapes). The building BLOCKS can be drawn upon in A + B pairs, depending on the type of functionality required, and heated together to form the final product. Preparation of the building BLOCKS, which are of two basic types, is made simpler as the fused norbornenes, available as the type A building BLOCK, can be converted to fused cyclobutene epoxides (type B building BLOCKS) in a two-step process involving Ru-catalysed [2 + 2] cycloaddition of dimethyl acetylenedicarboxylate (DMAD),[7] followed by epoxidation (MeLi, Bu$^t$OOH),‖ as illustrated by the conversion of **1** to **3** (Scheme 1). Simply heating BLOCK A with BLOCK B yields the coupled product in good yield and with high stereospecificity.**

While all combinations of type A plus type B BLOCKS are feasible, especially as a combinatorial exercise, only a representative set **13**–**15** (Scheme 2) is reported here. Heating the dipolarophilic norbornene **7**[8] as the type A building BLOCK containing a dimethoxynaphthalene with the cyclobutene epoxide **11** with crown ether functionality as the incipient 1,3-dipole, yielded the specifically *exo,exo*-coupled product **13** (Scheme 2). Similar A + B coupling between dipolarophile **8**[2] as the ligand carrier and epoxide **9** as the transporter for the dimethoxynaphthalene gave coupled product **14**.§ The same product **14** could be formed by the alternative A + B assembly process in which the epoxide **10** provided the ligand and norbornene **7** furnished the dimethoxynaphthalene. These routes to **14** represent new approaches to rigid polyalicyclic structures containing metal chelating centres linked with redox-active components, the first members of which were only recently reported as model systems for the study of electron and energy transfer.[2,9]



Large functionalised polynorbornanes containing two sets of the same functionality can be produced using the combination of the type A BLOCK with a dual epoxide BLOCK (Scheme 2). This approach was used to prepare the polynorbornane **15** by reaction of 2 equiv. of **7** with bis-epoxide **12**. This example illustrates special features of the methodology: (i) it provides a

mechanism for coupling reagents with functional units unstable to the epoxidation conditions, and therefore unsuitable for conversion to type B BLOCKS, by employing epoxide co-reagents; (ii) the polynorbornane framework significantly affects the geometry of the final product, especially the relative orientation of the functional unit; this can be varied by choice of the dual BLOCK.

The final example illustrates the most versatile route to large differentially functionalised structures. Treatment of spacer molecule **17**, where there is one cyclobutane epoxide (the second is latently positioned as the cyclobutene-1,2-diester), with benzonorbornadiene **16** (BLOCK Al, boxed in Scheme 3) provided the coupled product **18**, which was converted to the extended epoxide **19** by epoxidation under the usual conditions. Subsequent reaction of **19** (a standard BLOCK B) with the naphthonorbornadiene **7** (BLOCK A2, boxed in Scheme 3) furnished the large product **20** (the spacer component is designated by a dashed box in Scheme 3). Future work will involve dual BLOCKS as a carrier of separate functionality, thereby opening the way for triad formation.

**Scheme 2**

**Scheme 3**

These results establish the potential of this reaction to act as a coupling method for the construction of large polyalicyclic structures. We are developing fused norbornenes containing other important functionality, so the opportunity for building an array of bioactive products by this or related coupling methods[10,11] is well-advanced and such results will be published in due course.

## Footnotes

† E-mail: r.warrener@cqu.edu.au

‡ Huisgen has reported many examples of epoxide ring-opening to 1,3-dipolar species (ref. 4), and there is one example of the thermal ring-opening of an cyclobutene epoxide with phenyl substituents on the epoxide (ref. 5), but application in the alicyclic field is new. We refer to this type of coupling as the ACE reaction, where the acronym is derived from **a**lkene plus **c**yclobutene **e**poxide coupling.

§ All new compounds gave satisfactory analytical and spectral data.

¶ Norbornene **1** reacts with **3** to produce the dihydro derivative of **6**, which is identical with that formed by an alternative route (ref. 6).

‖ Use of BuLi leads to mixtures where ester exchange products interfere.

** The success of this technique was assured when separate reaction of A or B provided no evidence for self-assembly under the coupling conditions.

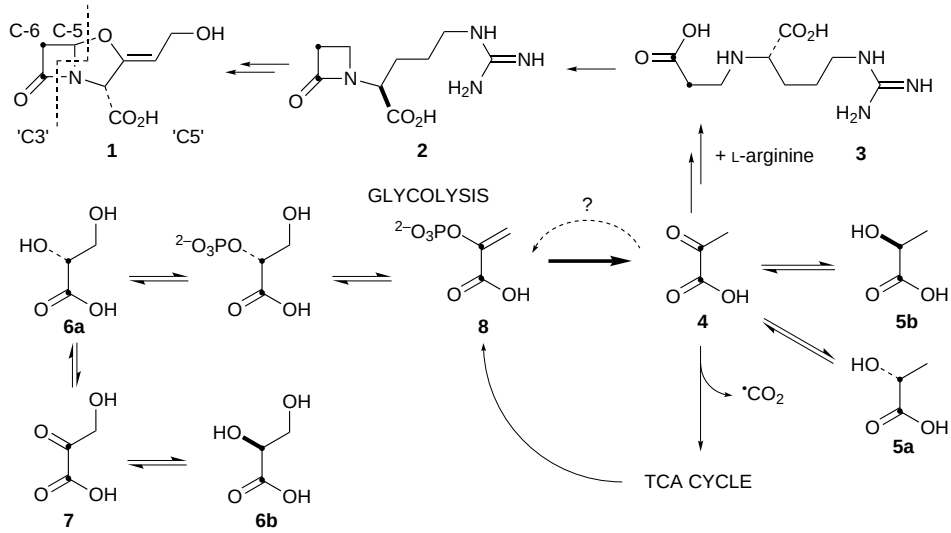
# The origin of the β-lactam carbons of clavulanic acid

**Jan E. Thirkettle,[a] Jack E. Baldwin,[a] Jeff Edwards,[b] John P. Griffin[b] and Christopher J. Schofield*[a]**

[a] *Dyson Perrins Laboratory, South Parks Road, Oxford, UK OX1 3QY*
[b] *SmithKline Beecham Pharmaceuticals, Clarendon Road, Worthing, West Sussex, UK BN14 8QH*

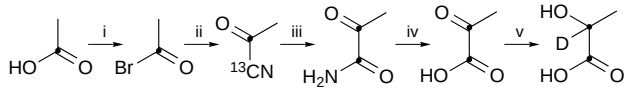
**Pyruvate is the most likely primary metabolic source of the three β-lactam carbons of clavulanic acid.**



Clavulanic acid **1** is a commercially important inhibitor of β-lactamases, and is produced *via* fermentation of *Streptomyces clavuligerus*. It is known that the primary metabolic precursor of the five-carbon unit (Scheme 1) of clavulanic acid is arginine,[1] Pioneering studies by Elson *et al.*[2] and Townsend *et al.*[3] have demonstrated that the precursor of the three-carbon unit is a three-carbon primary metabolite (both pyruvate[2] and glycerate[3] have been proposed) although no conclusive evidence has yet been presented. Monocyclic β-lactam **2** has been identified as an intermediate in clavulanic acid **1** biosynthesis (Scheme 1) and there is evidence[4] that it is precursed by the acyclic compound **3**, but the pathway from primary metabolism to these putative intermediates is unknown.

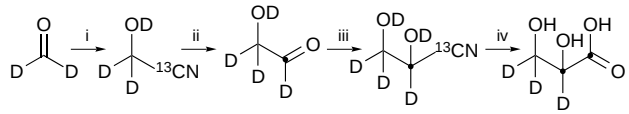
Feeding experiments using labelled precursors have apparently demonstrated that glycerol,[3,5] propionate,[5] β-hydroxypropionate,[6] pyruvate,[3] and D- and L-glycerates[3] are specifically incorporated into the β-lactam ring of **1**. It has been reported that both L- and D-[2-$^{3}$H, 1-$^{14}$C]glycerate are specifically incorporated into **1** to similar levels, but that only in the case of the D-isomer is any $^{3}$H incorporated at C-6 of **1**. A recent study[3b] using racemic [1,2-$^{13}C_2$, 2,3,3,-$^{2}H_3$]glycerate, however, reported that no incorporation of the C-2 label into C-6 of **1** was observed. Other possible 3-carbon precursors such as malonic acid semi-aldehyde, β-hydroxypropionate or acrylate cannot be ruled out by these previous studies.

Herein we report studies using optically active $^{13}$C and $^{2}$H labelled lactates and glycerates which imply that pyruvate **4** and not glycerate is the primary metabolic precursor of the three β-lactam carbons of **1**.† 1,2-$^{13}$C labelled species were used in order to generate doublets in the $^{13}$C NMR spectra separating the signals arising from labelled material from the relatively intense singlet of the unlabelled material, allowing accurate incorporation levels to be determined. Retention levels of $^{2}$H were analysed by the observation of splitting or isotopic shifts of the doublets.



The L- and D-[1,2-$^{13}C_2$, 2-$^{2}$H]lactates **5a**,**b** were synthesised[7,8] in 23% yield (and > 98% isotopic purity) from [1-$^{13}$C]acetic acid (Scheme 2). Notably Tris-HCl buffer was used for the enzyme catalysed reductions of pyruvate to L- and D-lactates rather than phosphate buffer[9] which resulted in a mixture of lactates with $^{1}$H and $^{2}$H at C-2. Synthesis of DL-[1,2-$^{13}C_2$, 2,3,3-$^{2}H_3$]glycerate[10]‡ was achieved from [$^{2}H_2$]formaldehyde (Scheme 3) in an overall yield of 80% and > 98% isotopic purity. DL-[1,2-$^{13}C_2$, 1,1-$^{18}O_2$]glycerate was synthesised in a similar fashion. Resolution of the racemic labelled glycerate was achieved by HPLC on a preparative C-18 column using the method of Horikawa *et al.*[11] In the lactate and glycerate syntheses, hydrolysis of the intermediate nitriles to the acids by literature conditions[12,13] was low yielding. Use of strong acid ion exchange resin however resulted in good yields and trivial product purification.

The labelled precursors were fed to shake flask cultures of a *Streptomyces clavuligerus* wild-type re-isolate (SC2) in a minimal medium.[5] Clavulanic acid **1** was isolated as its benzyl ester after gel and silica chromatography and analysed by $^{13}$C NMR spectroscopy acquired under fully quantitative conditions. It was found that optimisation of the aquisition parameters was required in order to obtain spectra which were suitable for integration due to the large pertubations in signal intensity caused by the $^{13}$C and $^{2}$H isotope effect on spin relaxation rates. Samples were also examined by $^{2}$H NMR spectroscopy to corroborate results. The spectra recorded for **1** derived from the labelled lactates indicated that whilst both D- and L-lactate **5a**,**b** were specifically incorporated into **1** to similar levels (1.2 and 1.9% respectively), in neither case had any retention of $^{2}$H at C-6 of **1** occurred. This implies that lactate **5a**,**b** must pass *via* pyruvate **4** before incorporation into **3**. The spectra recorded for



**Scheme 1** Proposed biosynthesis of clavulanic acid **1** ($^{2}$H labels not shown)

the L- and D-glycerates **6a**,**b** similarly showed no evidence for retention of $^2H$ at C-6 of **1**. In contrast, 80% of the clavulanic acid **1** derived from either D- or L-labelled glycerate was labelled with $^2H$ at C-5. These results are consistent with results reported by Pitlik and Townsend using racemic material.[3b] The total carbon incorporation for D-glycerate **6a** was 1.9% whilst that for L-glycerate **6b** was only 0.3%. The $^2H$ labelling of C-5 of **1** is in good agreement with previous results.[3,14,15] The intact incorporation of the 1,2-$^{13}C$ labels from lactate and glycerate together with the lack of incorporation of the C-2 $^2H$ label from either substrate indicate that neither is the primary metabolic precursor for the β-lactam carbons of **1**. Instead the results imply that pyruvate is the precursor. Oxidation of lactate **5a**,**b** to pyruvate **4** will result in the loss of the 2-$^2H$ label whilst retaining the carbon skeleton. Glycolysis of glycerate **6a**,**b** to pyruvate **4** will similarly remove the 2-$^2H$ label and result in some loss of the 3-$^2H$ label through enolisation. The low level of incorporation of L-glycerate **6b** probably reflects the differences between metabolism of L- and D-glycerate in *S. clavuligerus*. In mammalian systems it is known that L-glycerate may be epimerised to D-glycerate *via* oxidation to hydroxypyruvate[16] **7**. The low incorporation of $^{18}O$ (19%) into the C-7 carbonyl of **1** from DL-[1,2-$^{13}C_2$, 1,1-$^{18}O_2$]glycerate is

**Scheme 2** Synthesis of L- and D-[1,2-$^{13}C_2$, 2-$^2H$]lactates **5a**,**b**. *Reagents and conditions*: i, $PBr_3$; ii, $Cu^{13}CN$; iii, HCl, $Et_2O$ then $H_2O$; iv, DOWEX-50 ($H^+$), $H_2O$, 80 °C; v, D- or L-lactate dehydrogenase, $NAD^+$, yeast alcohol dehydrogenase, Tris-HCl, $CD_3CD_2OD$, pH 8.5, 25 °C.

**Scheme 3** Synthesis of DL-[1,2-$^{13}C_2$, 2,3,3-$^2H_3$]glycerate **6a/b**. *Reagents and conditions*: i, $K^{13}CN$, pH 8.5, 25 °C, $D_2O$; ii, Pd–$BaSO_4$, $D_2$, pH 1.7, $D_2O$; iii, $K^{13}CN$, pH 8.5, 25 °C, $D_2O$; iv, AMBERLITE IR-120 ($H^+$), $D_2O$, 95 °C.

**Table 1** Incorporation data for labelled lactate and glycerate

| Precursor | Carbon[e] incorporation (%) | Retention at C-6[d] (%) | Retention at C-5[d] (%) |
|---|---|---|---|
| L-[1,2-$^{13}C_2$, 2-$^2H$]lactate[a] **5b** | 1.9 | < 2 | n/a |
| D-[1,2-$^{13}C_2$, 2-$^2H$]lactate[a] **5a** | 1.2 | < 2 | n/a |
| DL-[1,2-$^{13}C_2$, 2,3,3-$^2H_3$]glycerate **6a**/**b** | 1.6 | < 1 | 80 |
| L-[1,2-$^{13}C_2$, 2,3,3-$^2H_3$]glycerate[b] **6b** | 0.3 | < 5 | 80 |
| D-[1,2-$^{13}C_2$, 2,3,3-$^2H_3$]glycerate[c] **6a** | 1.9 | < 2 | 80 |
| DL-[1,2-$^{13}C_2$, 1,1-$^{18}O_2$]glycerate[c] | 1.8 | (C-7 retn: 19% $^{18}O$) | |

[a] > 98% ee. [b] > 90% ee. [c] > 95% ee. [d] As a proportion of carbon incorporation; levels measured by $^2H$ NMR were within 5%. [e] Adjusted to allow for the amount of **1** present before addition of labelled species, in order to allow for more reliable comparison of labelling results between different fermentation batches.

an additional indication of the metabolic conversions that this species must undergo before incorporation into **2**. Cell extracts from fermentations of labelled lactate, analysed by $^{13}C$-INADEQUATE NMR, showed that an accumulation of [1,2-$^{13}C_2$]alanine could be detected indicating conversion of lactate **5a**,**b** to pyruvate **4**. It is conceivable that lactate is converted to glycerate before assimilation into **3**, however, metabolism *via* the TCA cycle will break the 1-2 $^{13}C$–$^{13}C$ bond and is thus ruled out. Additionally the direct conversion of pyruvate **4** to phosphoenol pyruvate **8** has not been reported for *Streptomyces* ssp. and would not explain the loss of all the 2-$^2H$ label (and 20% of the 3-$^2H$ labels) in the labelled glycerate fermentions which imply oxidation of C-2 to the ketone. We conclude that the most likely primary metabolic source of the β-lactam carbons of clavulanic acid **1** is pyruvate **4** not glycerate **6a**,**b** or lactate **5a**,**b**.

We thank T. Claridge for advice on NMR, B. Barton, S. W. Elson and H. Holms for helpful discussions and encouragement, and the BBSRC/SmithKline Beecham Pharmaceuticals for a CASE award to J. E. T.

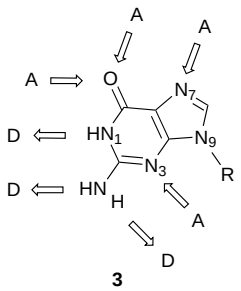
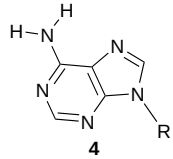
# Fluorescence-mediated sensing of guanosine derivatives based on multitopic hydrogen bonding

**Shigeru Amemiya, Philippe Bühlmann and Yoshio Umezawa***

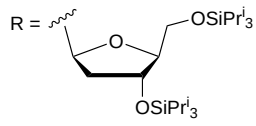


*Department of Chemistry, School of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113, Japan*

**The fluorescence emission of receptor 1 is selectively quenched upon binding of a guanosine derivative by five hydrogen bonds.**



Because of their critical role in nearly all biological processes, molecular recognition of nucleotides has attracted much attention. By analogy with the formation of double-stranded DNA or RNA, many artificial receptors have been designed and synthesized to recognize nucleobases by complementary hydrogen bonding.[1] While a few of them have chromogenic or fluorogenic groups for optical signalling,[2–4] the moderate strengths of their complexes, which are stabilized by only three hydrogen bonds, are still unsatisfactory in view of optical sensor applications. Here we demonstrate very selective quenching of the fluorescence emission of receptors **1** and **2** upon binding of a guanosine derivative by five hydrogen bonds in a binary solvent mixture of chloroform and DMSO, and report on an application of receptor **1** in a fluorescence-based optical sensor[5] for guanosine 5′-triphosphate.



**1** X = O
**2** X = S

**3**

**4**

In addition to the Watson–Crick type hydrogen bonding site on the N-1 side (two hydrogen bond donor atoms and an acceptor in a DDA array), natural guanosine derivatives have an acceptor–donor (AD) and an acceptor–acceptor (AA) hydrogen bonding site on the side of N-3 and N-7, respectively (for instance, see **3**). On the basis of the secondary interaction model,[6] hydrogen bonded complexes with the AA·DD motif are expected to be more stable than those with the AD·DA motif. We therefore linked a urea or thiourea group as DD hydrogen bonding site to the cytosine group by using 8-amino-naphthalene-2-carboxylic acid as rigid spacer, giving receptors† **1** and **2** with a fairly high level of preorganization.

Complexation of receptor **1** or **2** (1.0 mM) with the lipophilic guanosine derivative **3** (0–25 mM) in the binary solvent mixture of $CDCl_3$ and [$^2H_6$]DMSO (4 : 1, v/v) was confirmed by $^1H$ NMR spectroscopy. In this concentration range, neither the receptors nor guest were observed to self-associate. For receptor **1**, complexation-induced downfield shifts for all NH hydrogens of both **1** and **3** were found, confirming the formation of hydrogen bonds. A $^1H$ NMR titration experiment showed the association constant ($K_{ass}$) to be $1.7 \times 10^2$ dm$^3$ mol$^{-1}$.

The occurrence of a downfield shift for all NHs of **1** and **3**, and the similarity of the association constants as determined for $H_a$, $H_b$, $H_c$ and $H_d$, suggest the formation of a 1 : 1 complex based on five hydrogen bonds.‡ To the best of our knowledge this is only the second receptor that forms more than three hydrogen bonds with the guanine base.[7] While improving its preorganization might further increase its binding strength [for a guanine receptor with very high preorganization, $K_{ass} > 1.9 \times 10^5$ dm$^3$ mol$^{-1}$ in $CDCl_3$–[$^2H_6$]DMSO (4 : 1, v/v)],[7] the most interesting aspect of receptor **1** is its fluorescent property (*vide infra*).

Similar results were obtained with thiourea **2**.‡ Upon complexation, downfield shifts were observed for all NH hydrogens of both **2** and **3**. Only the $H_c$ hydrogen of **2** underwent an opposite (upfield) shift. Because the NH hydrogens of thioureas are more acidic than those of ureas, stronger binding was expected for **2** than for **1**.[8] However, the association constant for the complex of **2** and **3** was found to be only $1.2 \times 10^2$ dm$^3$ mol$^{-1}$, which is slightly smaller than for the complex of receptor **1**. A possible explanation for the unexpectedly weak stability of the complex of **2** may be that steric hindrance between the sulfur and the aromatic hydrogen $H_e$ of **2** leads to a loss of coplanarity between the thiourea group and the naphthyl ring, which is unfavorable for the recognition of the planar guanine base. Indeed, crystal structures as found in the Cambridge Structural Database show that arylthioureas are in general less planar than arylureas.§

With a view to applying these receptors in optical sensors, their UV–VIS and fluorescent spectra were investigated in the binary mixture of $CHCl_3$ and DMSO (4 : 1, v/v). While the UV–VIS spectra of **1** or **2** did not change significantly in the presence and absence of **3**, complexation-induced quenching of their fluorescence emission was observed. Solutions of receptor **1** exhibit strong fluorescence emission in the range 420–530 nm. Upon addition of **3**, the fluorescence emission is strongly quenched. A plot of the ratio of the fluorescence intensity in the absence ($I_0$) and in the presence ($I$) of **3** *versus* the concentration of **3** is linear (Fig.1) and allows the determination of the association constant, $K_{ass}$, of the 1 : 1 complex of **1** and **3** according to eqn. (1),

$$I_0/I = 1 + K_{ass}[C] \quad (1)$$

where [C] is the concentration of **3**. The resulting $K_{ass}$ is $1.8 \times 10^2$ dm$^3$ mol$^{-1}$, which is in excellent agreement with $K_{ass}$ as obtained by $^1H$ NMR spectroscopy. This shows that the decrease in fluorescence emission is not due to dynamic quenching based on collision of the receptor and the guest in its

excited state, but to static quenching based on complexation. On the other hand, the fluorescence spectrum of receptor **1** was not perturbed at all by addition of the lipophilic adenosine derivative **4** (Fig.1). Increasing the number of hydrogen bonding sites gives a very selective fluorogenic receptor with a significantly larger binding strength than previously reported for chromogenic or fluorogenic nucleobase receptors with only three hydrogen bonding sites ($K_{ass} = 2.8 \times 10^2$ or $9 \times 10^2$ $dm^3\ mol^{-1}$ in $CDCl_3$ or $CD_2Cl_2$, respectively[2,3]). A highly selective quenching by **3** but not by **4** was also observed for receptor **2** (data not shown). However, the fluorescence intensity of receptor **2** was twenty times smaller than that of **1**, and receptor **2** does not appear to be photostable because the fluorescence intensity increased monotonously in repetitive emission scans of a dilute solution.

The fluorescent responses of an optical sensor based on a plasticized poly(vinyl chloride) membrane containing receptor **1** is shown in Fig. 2.¶ The response mechanism of this sensor (a bulk optode) is based on an anion-exchange equilibrium between the sample solution and the optode membrane.[9] An increase in the nucleotide concentration in the sample solution leads to receptor-assisted uptake of the nucleotide into the membrane in exchange for $Cl^-$, thereby changing the intensity of the receptor fluorescence. As expected, stronger quenching of the emission was observed for 5′-GTP than for 5′-ATP, which is due to preferential complexation of **1** with the guanine moiety of 5′-GTP. This is the first example of an optode based on multitopic hydrogen-bond mediated complexation of an analyte and a synthetic receptor. While this optode is very sensitive for 5′-GTP (detection limit < 10 μM), high background concentrations of $Cl^-$ as occurring in biological samples may make a higher discrimination of $Cl^-$ desirable. To improve the selectivity over $Cl^-$, nucleotide-selective optodes containing two receptor types[10] (receptor **1** and bis-thiourea receptors[8] for binding the nucleobase and phosphate groups, respectively) are conceivable.

This work was supported by grants from the Ministry of Education, Science and Culture, Japan.

† Both receptors gave satisfactory $^1H$ NMR, IR and mass spectra and elemental analyses.

‡ Non-linear regression analysis of the $^1H$ NMR titration data gave the association constants ($K_{ass}$) and the differences in chemical shifts ($\Delta\delta_{max}$) of complexed and uncomplexed receptor using the residual solvent signal (δ 2.55) for [$^2H_6$]DMSO as reference: receptor **1**, $K_{ass}$ = 173, 171, 153 and 174 $dm^3\ mol^{-1}$ and $\Delta\delta_{max}$ = 0.80, 0.39, 0.09 and 1.45 ppm, respectively, for $H_{a–d}$ (δ 10.38, 8.86, 8.60 and 6.09, respectively, in its uncomplexed form); receptor **2**, $K_{ass}$ = 127, 127, 120 and 122 $dm^3\ mol^{-1}$ and $\Delta\delta_{max}$ = 0.56, 0.39, −0.12 and 1.70 ppm, respectively, for $H_{a–d}$ (δ 10.70, 8.87, 9.50 and 7.43, respectively, in its uncomplexed form).

§ The torsional angle C(1)–N–C(2)–C(3) in *N*-phenyl and *N*,*N*′- diphenyl derivatives of urea and thiourea is a good measure of the coplanarity between the aryl ring and urea or thiourea plane. For arylthioureas, the average of the torsional angles in eight cases was found to be 57°, seven of them being in the range from 42 to 87°. For arylureas, the average of the torsional angles in 61 cases was found to be 20°, 50 of them being smaller than 34°.

¶ The membrane was prepared by pouring 200 μl of a THF solution of the membrane components [0.50 mg receptor **1**, 1.94 mg tridodecylmethylammonium chloride (400 mol% relative to receptor **1**), 7.61 mg bis(ethylhexyl) sebacate and 4.95 mg PVC in 5 ml THF] on a glass plate (12 × 25 × 2.5 mm) and letting the solvent evaporate overnight.

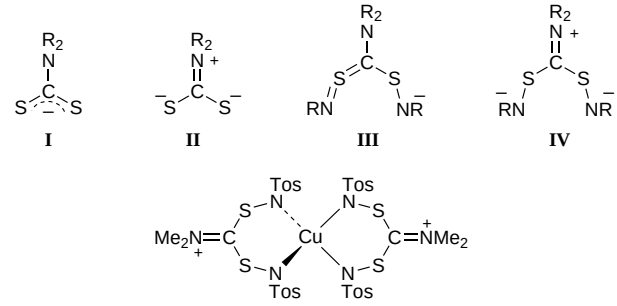
# Multiple nitrene insertions into the copper–sulfur bonds of dithiocarbamate ligands: synthesis and molecular structure of the tetraamido complex [Cu{η²-RNSC(NMe₂)SNR}₂] (R = SO₂C₆H₄Me-*p*)

**Graeme Hogarth,* Andrew Pateman and Andrea Sella**

*Chemistry Department, University College London, 20 Gordon Street, London, UK WC1H 0AJ*

**During the aziridination of styrene with PhI=NR (R = $SO_2C_6H_4Me$-*p*) the copper(III) catalyst [Cu(η²-$S_2CNMe_2$)$_2$][$FeCl_4$] is converted into the crystallographically characterised tetraamido complex [Cu{η²-RNSC($NMe_2$)SNR}$_2$], a result of nitrene insertion into all four copper–sulfur bonds.**



Recent work, primarily by the groups of Evans[1] and Jacobsen,[2] has revealed that a wide range of copper complexes can act as homogeneous catalysts towards the aziridination of alkenes. Although the nature of this catalytic process is not well understood, preliminary results from the Jacobsen group are strongly suggestive of the formation of a copper–nitrene complex.[3] While this would appear to be a sensible proposal, the nitrene (imido) ligand is a strong π donor and is generally associated with high-valent metal centres, that is those with low d electron counts.[4] Thus, while complexes with $d^0$–$d^2$ centres are abundant, those with electron counts of $d^3$–$d^6$ are extremely rare and there are no well authenticated examples of mononuclear complexes of this type with higher electron counts.[4]

Our work in this area has been concerned with gaining a better understanding of the catalytic process with a view to developing new, more efficient and selective, aziridination catalysts.[5] As part of this effort, and in an attempt to elucidate the oxidation state of the active catalyst, we have shown that, under the correct reaction conditions, copper(I)–(III) dithiocarbamate complexes are all highly active catalysts. After a number of these catalytic runs we noted the formation of a small amount of a new green solid which we sought to characterise in order to gain insight into the catalytic process. Herein we report details of the structure of the novel tetraamido complex [Cu{η²-RNSC($NMe_2$)SNR}$_2$] **1**, formally resulting from the insertion of nitrene groups into all four sulfur–copper bonds of the catalyst.

While carrying out the aziridination of styrene using PhI=NR as a nitrene source and the copper(III) dithiocarbamate complex [Cu(η²-$S_2CNMe_2$)$_2$][$FeCl_4$] as catalyst, after the reaction was complete, extraction into dichloromethane and layering with toluene resulted in the deposition of green paramagnetic crystals characterised by X-ray crystallography as the tetraamido copper(II) complex [Cu{η²-RNSC($NMe_2$)SNR}$_2$] **1** as shown in Fig. 1.†

The molecule consists of a four-coordinate copper(II) centre bound by two new chelating ligands, formed as a result of nitrene insertion into the copper–sulfur bonds of the dithiocarbamate ligand. It has overall $D_{2d}$ symmetry, the copper centre being a compressed tetrahedron, with a dihedral angle of 35.4° between $CuN_2$ planes. The ligand has a bite angle of 87.4(2)° and an angle of 97.7(2)° separates the two. The six-membered ring is puckered with the tosyl (Tos) groups on nitrogen adopting an alternating up–down configuration, and copper–nitrogen distances of 2.016(4) and 2.005(4) Å are similar to those found in related copper(II) complexes.[6]

Resonance forms **I** and **II** are commonly used to explain the ability of the dithiocarbamate ligand to stabilise both low- and high-valent metal centres, respectively,[7] and similar structures

**III** and **IV** can be considered for the new ligand in **1**. Close inspection of the structural parameters of the ring reveal that only the diamido form **IV** contributes to any extent. Thus, while the ring itself is severely puckered, the dithiocarbamate unit is quite flat [max. deviation 0.008 Å by C(30)] and planar about N(3). Further, the backbone carbon–nitrogen bond, C(30)–N(3), at 1.330(6) Å is short and similar to those found in related dithiocarbamate complexes.[7,8] That resonance form **III** does not contribute significantly is also shown by the relatively long sulfur–carbon [S(3)–C(30) 1.579(5), S(4)–C(30) 1.781(5)

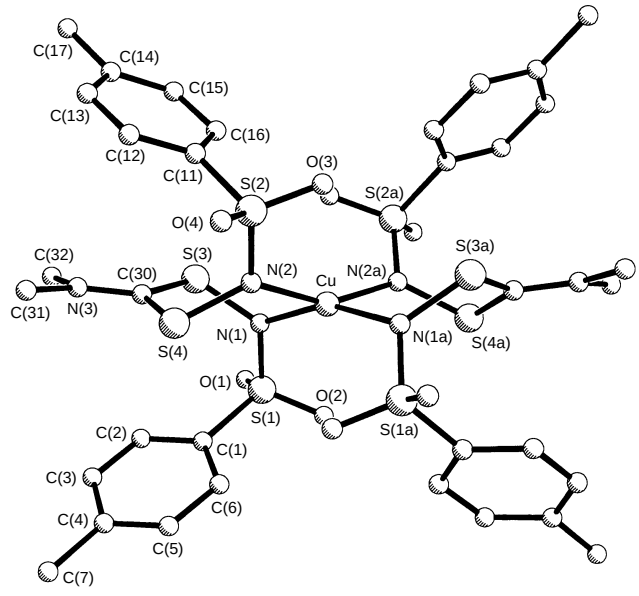


**Fig. 1** Molecular structure of **1** with selected bond lengths (Å) and angles (°): Cu–N(1) 2.005(4), Cu–N(2) 2.016(4), S(1)–N(1) 1.642(4), S(2)–N(2) 1.649(4), S(3)–N(1) 1.687(4), S(4)–N(2) 1.694(4), S(3)–C(30) 1.759(5), S(4)–C(30) 1.781(5), N(3)–C(30) 1.330(6); N(1)–Cu–N(2) 87.4(2), N(1)–Cu–N(2A) 97.7(2), N(1)–Cu–N(1A) 157.0(2), N(2)–Cu–N(2A) 154.5(2), Cu–N(1)–S(3) 124.3(2), N(1)–S(3)–C(30) 103.5(2), S(3)–C(30)–S(4) 119.3(3), C(30)–S(4)–N(2) 103.5(2), S(4)–N(2)–Cu 124.1(2)

Å] and sulfur–nitrogen [N(1)–S(3) 1.687(4), N(2)–S(4) 1.694(4) Å] bonds within the ring, the former being considerably longer than those in related copper(II) dithiocarbamate complexes,[8] while the latter are longer than the sulfur–nitrogen bonds to the tosyl groups [N(1)–S(1) 1.642(4), N(2)–S(2) 1.649(4) Å]. Thus, the zwitterionic diamido formulation **IV** is the most apt ligand description. Further, the ring nitrogens N(1) and N(2) are essentially planar as shown by the sum of the bond angles at each of 359.3 and 358.9°, respectively.

As far as we are aware, the chelating ligand found in **1** has not previously been characterised although it appears to be quite stable. The mode of formation of **1** is also unknown. While a number of novel rearrangements[9] and insertions into the dithiocarbamate backbone[9,10] have been reported, we are unaware of examples of nitrene or related insertions into the metal–sulfur bonds. What is clear, however, from the isolation of **1** is that nitrene coordination to the copper centre must be facile and this supports Jacobsen's recent observations.[3] We have previously reacted known copper aziridination catalysts with the nitrene source and, while in all cases a rapid reaction takes place (as evidenced by the dissolution of the nitrene source), we have previously been unable to characterise the product(s).[5] Copper-catalysed aziridination reactions are generally carried out in the presence of an excess of the alkene, which is known to bind to the copper centre.[11] We speculate, then, that during the normal course of catalysis, nitrene transfer to the precoordinated alkene from the highly reactive copper–nitrene species is facile, giving rise to aziridines. However, in the absence of the alkene, the copper-bound nitrene moiety may react with other metal-bound ligands as is found in **1**.

Since formation of **1** involves the multiple insertion of nitrene fragments we are currently trying to determine whether this is a stepwise process and we are also assessing the ability of **1** to act as an aziridination catalyst. Direct addition of an excess of the nitrene source to $[Cu(\eta^2\text{-}S_2CNMe_2)_2][FeCl_4]$ initially affords a red solution and later a green precipitate. While neither contains **1**, the latter appears to combine nitrene, copper and dithiocarbamate fragments and its identity and relationship to **1** are under investigation.

We thank the EPSRC for the provision of a research studentship to A. P.

# Formation and transformation of mesoporous and layered manganese oxides in the presence of long-chain ammonium hydroxides

**Jian Luo[a] and Steven L. Suib*[a,b]**

[a] *U-60, Department of Chemistry, University of Connecticut, Storrs, CT 06269-4060, USA*
[b] *Department of Chemical Engineering and Institute of Materials Science, University of Connecticut, Storrs, CT 06269-4060, USA*

**Mesoporous manganese oxides are prepared by reduction and oxidation mechanisms and by interconversions of layered materials.**

Two methods (oxidation and reduction) have been developed to synthesize mesoporous manganese oxides ($MnO_x$). Organic ammonium cations are introduced into layered birnessite-type $MnO_x$. Transformations from a mesoporous $MnO_x$ to a layered material and from a layered $MnO_x$ to a mesoporous structure have been observed.

The synthesis of molecular sieves of large micropores (VPI-5[1]) and mesopores (MCM-41[2,3]) has long been a focus of many researchers. Since the development of the Mobil MCM series of mesoporous silicates and aluminosilicates using templates such as long-chain ammonium-type surfactants, several studies[4–7] have been published on the synthesis, characterization, and applications of these mesoporous materials. Some transition metals,[8,9] such as Ti, have also been successfully incorporated into mesoporous structures. In those studies, silica or metallosilicate gel (usually from the hydrolysis of metal ethoxides) is precipitated around the hexagonally packed micelles of surfactant molecules to form a mesoporous inorganic framework. Neither reduction nor oxidation is generally used in the syntheses of these materials.

However, few studies, to our knowledge, have yet been published of the synthesis and related research on manganese containing mesoporous materials. The conversion from a mesoporous structure to a layered structure, and observations that a typical layered $MnO_x$ can be converted into a mesoporous structure have not been reported.

The oxidation of $Mn^{II}$ and reduction of $Mn^{VII}$ are employed herein to prepare mesoporous $MnO_x$ in the presence of long-chain organic ammonium hydroxides. The two methods are thus referred to as oxidation and reduction syntheses, respectively. A method to incorporate organic ammonium cations into a birnessite-type layered manganese oxide to prepare large *d*-spacing layered materials is also presented. The conversions from a mesoporous $MnO_x$ to a layered material and that from a birnessite to a mesoporous structure have been investigated.

For a typical oxidation synthesis, 8.0 g of $MnCl_2{\cdot}4H_2O$ in 50 ml deionized distilled water (DDW) was slowly added to a 1 l beaker containing a 200 ml solution of $(C_{12}H_{25})NMe_3OH$ (*ca.* 30 mass%) with a glass rod, with vigorous stirring with a stirring bar. A gel of $Mn(OH)_2$ having pyrochroite structure was formed and was stirred for 30 min. Oxygen gas from a cylinder was then bubbled in to the solution with a gas flow rate of *ca.* 100 ml $min^{-1}$ *via* a glass frit, without stirring. In order to prevent formation of a foam, a few drops of ethanol are added to the beaker every 10 min. Bubbling was continued for *ca.* 8 h after which the resultant black precipitate was transferred to a 500 ml glass bottle, which was aged in a water-bath at 40 °C.

In the oxidation synthesis, $Mn(OH)_2$ having pyrochroite structure (JCPDS card 18-787) was formed when $MnCl_2$ was added to the $(C_{12}H_{25})NME_3OH$ solution. When oxygen was bubbled for 30 min, $Mn(OH)_2$ was converted to hydrohausmannite [a mixture of β-MnO(OH) and γ-$Mn_3O_4$, JCPDS 18-804 and 24-734, respectively]. Further bubbling of oxygen into the system led to oxidation of hydrohausmannite to a substance having only one broad XRD peak at 2θ *ca.* 18–20°. This broad peak did not change even when oxygen bubbling was continued for a day. The XRD pattern also remained the same when the system was aged at 40 °C for 4 h. However, at $t$ = 10 h, an XRD peak at *ca.* 30 Å *d*-spacing appears, indicating the evolution of mesoporous $MnO_x$ in the system [Fig. 1(*a*)]. Both the *d*-spacing and the intensity of the peak increase with increasing ageing time until at $t$ = 20 h the intensity reaches a maximum for the peak at a *d*-spacing of 46 Å [Fig. 1(*b*)]. During this period mesoporous $MnO_x$ is formed and its amount is increased with increasing ageing time. The time before formation of mesoporous $MnO_x$ is referred to as the induction period. From $t$ = 20 h to $t$ = 36 h both the intensity and *d*-spacing value remain almost constant and this is denoted the steady-state period.

Beyond an ageing time of 48 h, the XRD peak at 45 Å *d*-spacing was found to decrease and continued to decrease with increasing time. The *d*-spacing value also decreased to some extent. Meanwhile, a new set of XRD peaks characteristic of a layered structure appears. The peaks occur at 25.4 Å (001), 12.7 Å (002), 8.6 Å (003), 6.4 Å (004) and 5.1 Å (005) [Fig. 1(*c*)] where the numbers in parentheses are the reflection indices. The 46 Å peak corresponding to a mesoporous structure is shifted to 39 Å at $t$ = 48 h and finally disappears at $t$ = 4 d, with the presence of only peaks for the layered structure, whose

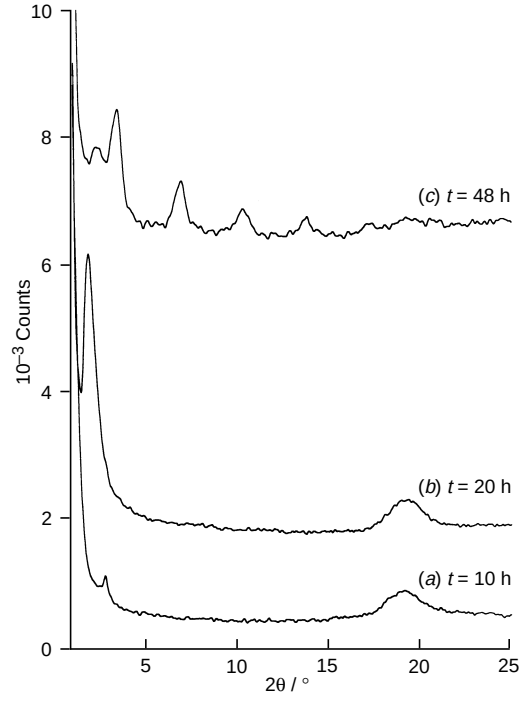

**Fig. 1** XRD patterns showing the formation and transformation of mesoporous $MnO_x$ during the oxidation synthesis at different ageing times

*d*-spacings are also decreased slightly to 23.9 (001), 11.9 (002), 7.9 (003), 6.0 (004) and 4.8 Å (005), respectively. This indicates that the mesoporous $MnO_x$ has completely converted to a layered structure.

The reduction synthesis employs alcohols such as ethanol as reductants to reduce $(C_{12}H_{25})NMe_3MnO_4$ in the presence of $(C_{12}H_{25})NMe_3OH$. Typically a slurry containing 20 g of freshly prepared $(C_{12}H_{25})NMe_3MnO_4$‡ was added to a 100 ml solution of $C_{12}H_{25}NMe_3OH$ (*ca*. 30 mass%) with stirring, forming a uniform slurry. Absolute ethanol (100 ml) was then poured into the slurry. The resultant gel was stirred for *ca*. 30 min and aged at 65–85 °C in an oven.

In the reduction synthesis, the product before ageing was an amorphous $MnO_x$ material. When it was aged at 65 °C for 2 days, the amorphous material became mesoporous, with only one XRD peak at 57 Å. Unlike the mesoporous material produced during the oxidation synthesis, it exhibited no peaks in the range 2θ 18–20. In addition, this material showed no conversion to any layered structure even after ageing at 65 °C for 5 days.

The synthesis of birnessite and subsequent conversion of the layered $MnO_x$ into a mesoporous structure was performed by adding, with stirring, 10 g of $KMnO_4$ dissolved in 150 ml DDW to a mixture of 100 ml absolute ethanol and 50 ml DDW containing 30 g KOH. A brownish gel was formed, which (after 30 min stirring) was kept in an oven at 85 °C for 2 days. After being filtered, the gel was washed with DDW until the pH of the filtrate was < 10. The product was potassium birnessite. While still wet, it was transferred to a beaker containing 200 ml of 1 M $HNO_3$ and stirred at room temp. for 3 h to allow $H^+$ exchange. The exchange was repeated, giving H-birnessite, which was washed, filtered and transferred to a beaker containing 200 ml of DDW while stirring. A solution of 10 ml of 20–40 mass% of different organic ammonium hydroxides was added to introduce different types of ammonium ions into the birnessite.

The XRD pattern of the prepared H-birnessite is shown in Fig. 2(*a*). Only two main peaks with *d*-spacings of 7.3 and 3.6 Å were present in this preferentially oriented XRD pattern.

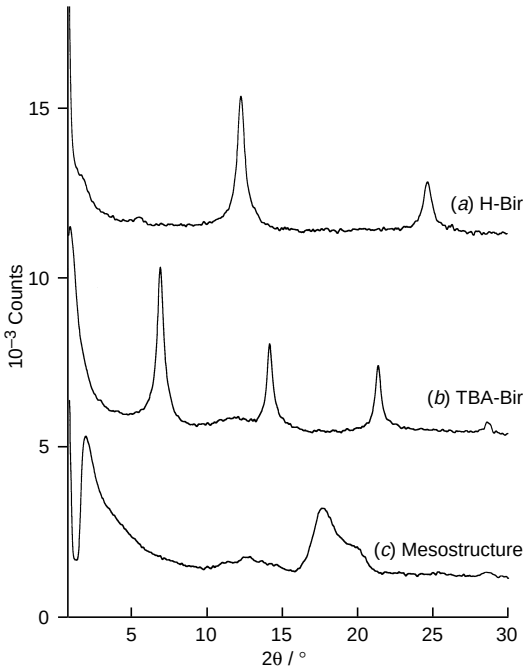

**Fig. 2** XRD patterns showing the conversion of a layered $MnO_x$ birnessite into a mesoporous material

When an organic ammonium species is introduced, the interlayer spacing is increased to an extent which depends on the dimension of the individual organic ammonium ion. For a $(C_{12}H_{25})NME_3$-birnessite, the preferentially oriented XRD reflections were at 24.1 (001), 12.0 (002), 8.0 (003), 6.0 (004), 4.8 (005) and 4.0 Å (006). This is almost identical to that of a layered $MnO_x$ converted from a mesoporous $MnO_x$ which was prepared from the oxidation of $Mn^{II}$ with oxygen in the presence of $(C_{12}H_{25})NMe_3OH$. When a smaller organic ammonium ion, *e.g*. tetrabutylammonium hydroxide (TBAOH), is used the XRD reflections of the layered $MnO_x$ are at 12.8 (001), 6.4 (002), 4.2 (003) and 3.2 Å (004) [Fig. 2(*b*)], *i.e*. at substantially lower values than for $(C_{12}H_{25})NMe_3$-birnessite.

When $Mg(MeCO_2)_2{\cdot}6H_2O$ (20 g) in 50 ml DDW was added to H-birnessite prior to the addition of the organic ammonium hydroxide, no exchange of $Mg^{2+}$ for $H^+$ was observed even if the system was stirred for more than a week. However, when TBAOH was added to H-birnessite containing $Mg^{2+}$ ions and the system was stirred for two days, the layered material was converted to a mesoporous $MnO_x$ structure [Fig. 2(*c*)]. The layered mesoporous $MnO_x$ material exhibits a basal XRD reflection at 42.3 Å, with several broad small peaks at 2θ 15–20°. This XRD pattern is quite similar to that of the mesoporous $MnO_x$ produced in the oxidation syntheses.

IR studies show that the mesoporous materials all have a strong absorption around 700 $cm^{-1}$, arising from Mn–O bond vibrations. The layered materials, including both those converted from mesoporous $MnO_x$ formed during oxidation syntheses and those containing organic ammonium introduced into birnessites, all have framework vibrations similar to those of birnessite. Detailed characterization of the materials, including TEM, thermal properties, sorptive properties, Mn oxidation state, acid–base properties and catalytic properties are under way. The mechanisms of formation and transformations associated with the mesoporous $MnO_x$ are also being studied.

† $(C_{12}H_{25})NME_3OH$ was prepared by adding a slurry of an excess of AgOH (freshly prepared from the reaction of $AgNO_3$ and NaOH and washed to neutral pH) to a solution of $(C_{12}H_{25})NMe_3Br$. The system was stirred overnight and was then filtered to give a solution of $(C_{12}H_{25})NMe_3OH$.

‡ $(C_{12}H_{25})NMe_3MnO_4$ was prepared by addition of a solution of $Ba(MnO_4)_2$ to a slight excess of $H_2SO_4$, with the $BaSO_4$ solid filtered off to give a solution of $HMnO_4$. An excess of $(C_{12}H_{25})NME_3OH$ was then added to the $HMnO_4$ solution to produce $(C_{12}H_{25})NMe_3MnO_4$.

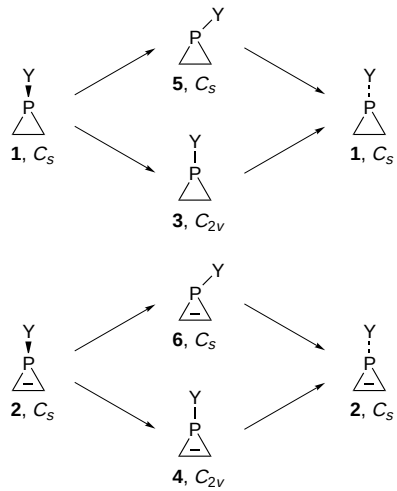
# 1*H*-Phosphiranes and -enes invert at phosphorus *via* a turnstile rotation†

**Andreas Göller and Timothy Clark***



*Computer-Chemie-Centrum, Institut für Organische Chemie, Friedrich-Alexander-Universität Erlangen-Nürnberg, Nägelsbachstraße 25, D-91052 Erlangen, Germany*

***Ab initio* (CCSD(T)/6-31+G*) calculations suggest that 1*H*-phosphiranes and 1*H*-phosphirenes invert their configuration at phosphorus by a rotation of the PX group (X = H, F, Cl, Br) above the $C_2$ moiety, rather than the more usual planar trigonal inversion pathway *via* a $C_{2v}$ transition state.**

Because of the high inherent barrier to inversion at three-coordinate phosphorus, phosphanes can be isolated as pure enantiomers.[1] The additional effect of inclusion in a three-membered ring increases inversion barriers further,[2] so that 1*H*-phosphiranes and, even more so, 1*H*-phosphirenes should have particularly high inversion barriers. However, our recent studies on σ*-aromatic 1*H*-phosphirenium ions[3] have revealed unusual bonding effects and so we have investigated the inversion process in 1*H*-phosphiranes[4] and 1*H*-phosphirenes.[5] Our studies reveal an unusual inversion mechanism caused by the avoidance of large bond angles at phosphorus and, in the unsaturated systems, by the potential antiaromaticity of the trigonal inversion transition states.[2,6] This mechanism is analogous to that for $PF_3$ inversion *via* a T-shaped transition state,[7] but is favoured by additional ring strain and conjugation effects.

1*H*-phosphiranes **1** and 1*H*-phosphirenes **2** can undergo inversion at phosphorus by two distinct mechanisms (absolute energies and geometries are given in Tables 1 and 2 of the Supplementary material,‡ respectively). The first is *via* the $C_{2v}$ structures **3** and **4** for the saturated and unsaturated systems, respectively, as described by Bachrach.[2,8] The structures **3** are found to be real transition states (one calculated imaginary frequency), but **4** is found to be a second-order saddle point (hilltop) for all ligands X except hydrogen, for which **4** is also a transition state. *Ab initio*[9a] [CCSD(T)[10]/6-31+G*[11]//(MP2[12]/6-31+G*)] calculations performed with GAUSSIAN 94[9b] give energy differences between **1** and **3** at 0 K of 66.5 kcal mol$^{-1}$ (1 cal = 4.184 J) (X = H), 99.9 kcal mol$^{-1}$ (X = F), 86.0 kcal mol$^{-1}$ (X = Cl), and 82.3 kcal mol$^{-1}$ (X = Br) and those between **2** and **4** of 85.4 kcal mol$^{-1}$ (X = H), 45.5 kcal mol$^{-1}$ (X = F), 55.4 kcal mol$^{-1}$ (X = Cl), and 50.9 kcal mol$^{-1}$ (X = Br) (see Table 3 of Supplementary material). For the π-donor halogen ligands, the barrier to trigonal inversion is unexpectedly lower for the 1*H*-phosphirenes **2** than for the 1*H*-phosphiranes **1**. This is the result of the partial dissociation of **4** into an aromatic phosphirenylium cation–halide ion pair. This dissociation is analogous to that found for the fluoromethyl anion,[13] which can be regarded as a carbene–fluoride complex. Note that all the above barriers are considerably lower than the 120–130 kcal mol$^{-1}$ found[7] for the 8π-electron $PF_3$.

The second route is the simple rotation of the PX group roughly around an axis through the phosphorus atom and the centre of the C–C bond. This process occurs for the phosphiranes **1** *via* transition state **5** and is found to be more favourable than trigonal inversion for all ligands except hydrogen. The calculated barriers at 0 K are 77.1 kcal mol$^{-1}$ (X = F), 70.6 kcal mol$^{-1}$ (X = Cl) and 65.2 kcal mol$^{-1}$ (X = Br). For X = H, **5** collapses to **3** on geometry optimisation, so that in this

**Scheme 1**

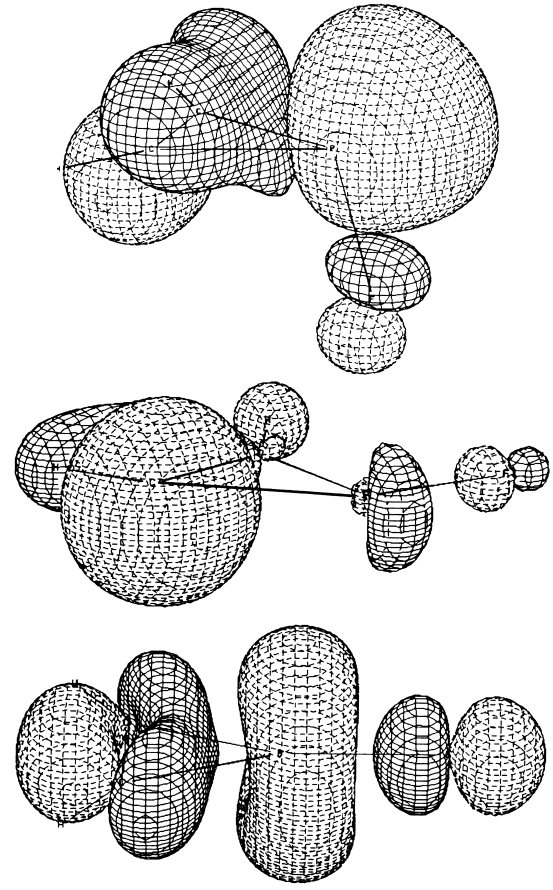


**Fig. 1** MO plots of the 'phosphorus lone pair' for the 1-fluoro-1*H*-phosphirene ground state (top), turnstile transition state (middle) and trigonal inversion transition state (bottom)

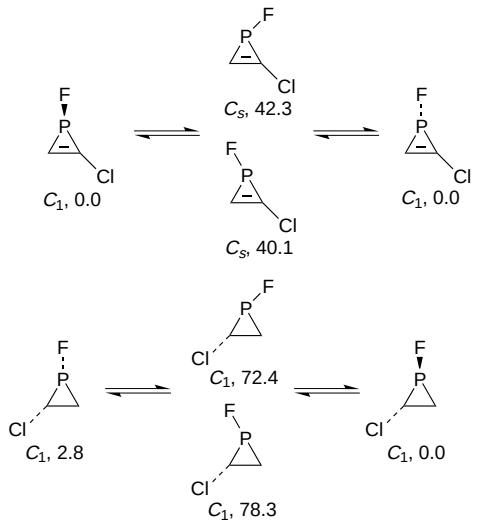
case the trigonal inversion mechanism applies. The $C_s$ structures **5** are found to be transition states for the halogen ligands. Thus, for electronegative ligands on phosphorus, the 1*H*-phosphiranes **1** show a 10–20 kcal mol$^{-1}$ preference for the 'turnstile' inversion process *via* transition states **5**.



The situation is, however, made even clearer in the 1*H*-phosphirenes **2** by the potential antiaromaticity of **2** and **3**. Because of the unfavourable 4π interaction in these species, **2** strongly prefers the turnstile inversion. By rotating, rather than inverting, the PX group, the 4π-antiaromatic interaction can be avoided completely in the transition state. Furthermore, the antiaromatic destabilisation decreases on going from **2** to **6**, thus favouring the turnstile mechanism. The C–P bond *trans* to the ligand X is lengthened by negative hyperconjugation[14] with the phosphorus lone pair in the transition states **6**, even to the extent that for X = H the transition state is essentially ring-opened. The calculated barrier at 0 K are 52.2 kcal mol$^{-1}$ (X = H), 38.4 kcal mol$^{-1}$ (X = F), 43.4 kcal mol$^{-1}$ (X = Cl) and 40.2 kcal mol$^{-1}$ (X = Br).

Fig. 1 shows the HOMOs of **2**, **4** and **6** (X = F) and illustrates the partial dissociation of the P–F bond in **4**. The turnstile rotation (**2** to **6**) involves a simple rotation of the PF-group orbitals with strong negative hyperconjugation into the *anti* C–P bond. **4** avoids antiaromaticity by rotating the F lone-pair component into a σ* orientation relative to phosphorus, rather than forming an extra occupied π orbital. The plots were generated with PSI 88.[15]

The turnstile mechanism of inversion at phosphorus also means that there are two non-equivalent transition states to inversion of 2-substituted phosphirenes and phosphiranes.

This is shown for chlorine-substituted **1** and **2**. As expected, the transition state in which the lone pair can conjugate with the chlorine-substituted P–C bond (F and Cl *anti*) is favoured. Donor substituents should show the opposite trend.

Thus, our results indicate that inversion of configuration at phosphorus in **1** and **2** is an easier process than might have been expected and that it occurs *via* an unusual turnstile mechanism. A strong experimental indication of the proposed mechanism would be the cumulative effect of ring substituents on inversion barriers.

**Scheme 2**

# Synthesis and aqueous solution properties of novel zwitterionic block copolymers

**A. B. Lowe, N. C. Billingham and S. P. Armes***

*School of Chemistry, Physics and Environmental Science, University of Sussex, Falmer, Brighton, UK BN1 9QJ*

**A series of near-monodisperse poly[2-(dimethylamino)ethyl methacrylate-*block*-2-tetrahydropyranyl methacrylate] precursors is synthesised using group-transfer polymerisation chemistry; the 2-tetrahydropyranyl methacrylate protecting group is quantitatively removed under mild conditions and the resulting zwitterionic block copolymers undergo reversible temperature-induced micellisation in aqueous media.**

Over the last decade or so group-transfer polymerisation[1,2] has become recognised as an excellent method for the synthesis of methacrylate (co)polymers of controlled structure and narrow molecular mass distribution. Recently we have used this technique to prepare well defined homopolymers and block copolymers based on 2-(dimethylamino)ethyl methacrylate (DMAEMA).[3,4] DMAEMA homopolymer is a weak polybase which is soluble at neutral pH or in acidic media due to protonation of the tertiary amine groups. Over the last few years we have explored several synthetic routes to zwitterionic DMAEMA-based block copolymers using *tert*-butyl methacrylate and benzyl methacrylate as protected monomers for methacrylic acid residues. GPC analysis of a DMAEMA homopolymer treated under conditions required for quantitative removal of the *tert*-butyl group in poly(*tert*-butyl methacrylate) [toluene-*p*-sulfonic acid, 80 °C for 7 h in toluene–methanol (5 : 1)] indicated some degree of intermolecular cross-linking between the DMAEMA residues, showing this protecting group to be unsuitable.[5] The alternative benzyl protecting group is normally readily removed by catalytic hydrogenolysis[6,7] but we found only minimal deprotection of DMAEMA–benzyl methacrylate block copolymers; this is believed to be due to catalyst poisoning by the tertiary amine groups. Prompted by a recent disclosure by Teyssie and coworkers[8] we now describe a facile route to well defined zwitterionic block copolymers using 2-tetrahydropyranyl methacrylate (THPMA) as the protected monomer.† This protecting group is easily removed by acid hydrolysis at room temp. to yield near-monodisperse zwitterionic DMAEMA–methacrylic acid block copolymers (Fig. 1). In contrast, we found that the deprotection route favoured by Patrickios *et al.*[9]‡ for DMAEMA–methyl methacrylate–THPMA triblocks was unsatisfactory: the appearance of a band at *ca.* 1806 $cm^{-1}$ in the IR spectrum of the deprotected polymer indicated significant anhydride formation had occurred after thermolysis for 48 h at 140 °C. Furthermore, our control experiments with DMAEMA homopolymer suggested that intermolecular cross-linking of the DMAEMA residues occurs under these thermolysis conditions.[5]

A series of DMAEMA–THPMA block copolymers was prepared using group-transfer polymerisation under conditions similar to those previously described.[4] All copolymerisations were carried out using 1-methoxy-1-trimethylsiloxy-2-methylprop-1-ene (MTS) as initiator and tetrabutylammonium dibenzoate (TBADB) as catalyst at 25 °C in dry THF using Schlenk techniques. The DMAEMA monomer was polymerised first and near-quantitative copolymer yields were obtained in all syntheses. The relative proportions of the two comonomers were varied at a fixed monomer/initiator ratio in order to control the copolymer composition. Comonomer/initiator ratios were varied in order to control the copolymer molecular mass. The molecular masses, polydispersities and compositions of the resulting block copolymers are summarised in Table 1. Narrow molecular mass distributions were obtained in all cases ($M_w/M_n \leqslant 1.22$) as judged by gel permeation chromatography (THF eluent, PMMA standards, RI detector). The actual copolymer compositions as determined by $^1$H NMR spectroscopy corresponded within experimental error to those expected from the comonomer feeds. The DMAEMA–THPMA copolymers were either dissolved or dispersed (depending on the DMAEMA content) in 0.1 M HCl at 25 °C. Complete

**Table 1** A summary of the molecular masses, polydispersities, copolymer compositions and isoelectric points of the DMAEMA–THPMA block copolymers determined using gel permeation chromatography, $^1$H NMR spectroscopy and acid titration, respectively

| Sample | Observed $M_n$[a] | DMAEMA–THPMA copolymer composition[b] | $M_w/M_n$[a] | Observed isoelectric point[c] |
|---|---|---|---|---|
| AB1 | 8500 | 77 : 23 | 1.08 | — |
| AB2 | 24700 | 82 : 18 | 1.16 | 8.56 |
| AB3 | 35700 | 64 : 36 | 1.15 | 7.40 |
| AB4 | 34000 | 51 : 49 | 1.22 | 6.74 |

[a] As determined by GPC (THF), calibrated with PMMA standards. [b] As determined by $^1$H NMR spectroscopy. [c] As determined by acid titration.

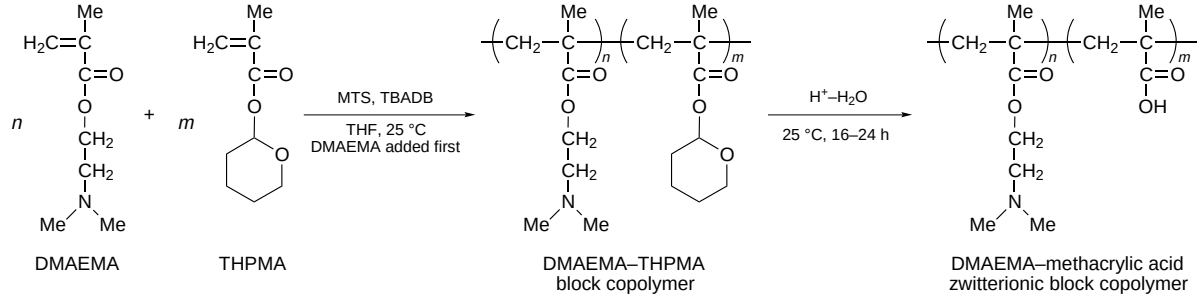

**Fig. 1** Reaction scheme for the synthesis of the DMAEMA–methacrylic acid zwitterionic block copolymers *via* group-transfer polymerisation

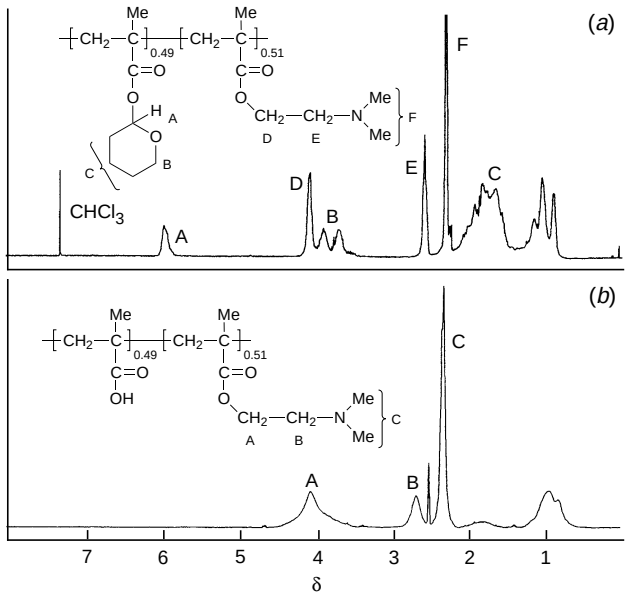

**Fig. 2** Proton NMR spectra of (*a*) a 51 : 49 DMAEMA–THPMA block copolymer dissolved in $CDCl_3$; (*b*) the same block copolymer after acid hydrolysis under mild conditions dissolved in $(CD_3)_2SO$. Note the complete disappearance of the signals due to the THP group.

deprotection was achieved simply by stirring these aqueous solutions for 16–24 h at 25 °C.

Proton NMR spectra of a 51 : 49 DMAEMA–THPMA block copolymer before and after deprotection are shown in Fig. 2. The signals at δ 5.8–6.0 and 3.7–3.8 assigned to the THP protecting group disappear completely after acid hydrolysis. Despite the very mild deprotection conditions, it was considered prudent to verify that no side-reactions (*e.g.* chain scission or cross-linking) had occurred. This was confirmed by analysing the deprotected DMAEMA–methacrylic acid block copolymers using aqueous gel permeation chromatography (Pharmacia Superdex column; RI detector; PEG/PEO standards; TRIZMA pH 8.5 buffer in 1.0 M NaCl eluent at a flow rate of 1.5 ml $min^{-1}$). In all cases narrow, unimodal molecular mass distributions were obtained, with polydispersities comparable to those of the protected precursor blocks ($M_w/M_n$ 1.18–1.24).

The isoelectric points (i.e.p.s) for the DMAEMA–methacrylic acid block copolymers were determined by acid titration and are summarised in Table 1. As expected, the i.e.p.s vary with block copolymer composition, with higher i.e.p.s being obtained for the more DMAEMA-rich copolymers. Precipitation of the copolymers occurred at their respective i.e.p.s: above and below the i.e.p.s the zwitterionic copolymers were soluble in aqueous media.

Examination of a 1.0% m/v solution of the 43 : 57 DMAEMA–methacrylic acid block copolymer in 0.01 M NaCl at pH 9.5 by dynamic light scattering (Malvern 4700 instrument, 80 mW argon ion laser, 90° scattering angle) confirmed very weak light scattering and unimer sizes at 25 °C. Heating this aqueous solution to 50 °C produced much more intense light scattering and visual inspection confirmed that the solution was slightly turbid. CONTIN analysis indicated the formation of near-monodisperse micellar aggregates with an intensity average diameter of 376 nm (see Fig. 3). This aggregation was completely reversible: the copolymer solution became optically transparent again on cooling. In the absence of 0.01 M NaCl, micellar aggregates of *ca*. 700 nm were obtained. At pH 9.5 the methacrylic acid residues should be fully ionised, whereas the DMAEMA residues are almost completely deprotonated.[10] The cloud-point temperature for a 1.0% m/v aqueous solution of

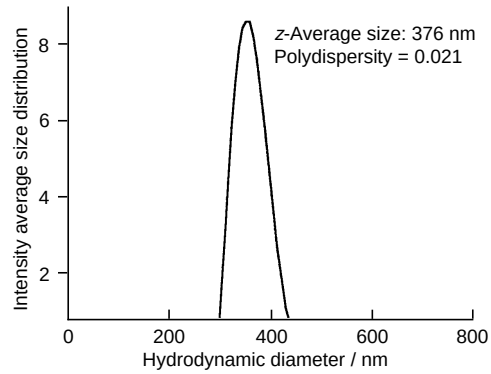

**Fig. 3** Intensity average size distribution of the micellar aggregates formed at 50 °C in a 1.0% m/v aqueous solution of a 43 : 57 DMAEMA–methacrylic acid zwitterionic block copolymer in the presence of 0.01 M NaCl at pH 9.5

DMAEMA homopolymer is in the range 32–46 °C depending on its molecular mass.[11] Thus, at 50 °C the interior of the micellar aggregates most likely contains the now hydrophobic DMAEMA block, with the ionised methacrylic acid block forming the solvated micellar corona.

According to Teyssie and coworkers[8] and Patrickios *et al.*,[9] potential applications for these new zwitterionic copolymers include pigment dispersion and protein separation, respectively. The reversible micellisation behaviour observed in aqueous media also suggests potential drug delivery applications.

The EPSRC and ICI Paints are thanked for a CASE D.Phil. studentship for A. B. L. An EPSRC ROPA grant (GR/K86855) was used to purchase the argon-ion laser for the dynamic light scattering studies.

† The 2-tetrahydropyranyl methacrylate monomer is not commercially available: it was synthesised by reacting methacrylic acid with 3,4-dihydro-2*H*-pyran at 55 °C using 50% sulfuric acid as catalyst. The crude monomer was dried and distilled under vacuum prior to passage through a basic alumina column to remove residual methacrylic acid.

‡ These workers also used trimethylsilyl methacrylate as a protecting group for triblock copolymers containing methacrylic acid residues. There are no deprotection problems associated with this monomer but it is well known that, under GTP conditions, its polymerisation is slow and incomplete (see ref. 7).

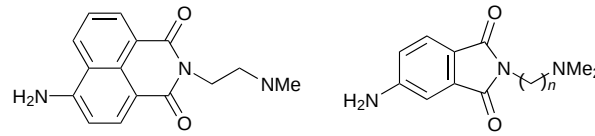
# Modulation of metal–fluorophore communication to develop structurally simple fluorescent sensors for transition metal ions

**B. Ramachandram and A. Samanta***



*School of Chemistry, University of Hyderabad, Hyderabad 500 046, India*

**Fluorophores 2a and 2b show significant fluorescence enhancement in the presence of transition metal ions.**

Molecular systems that contain a guest binding site (receptor) and a photon interaction site (fluorophore) as components with a mechanism of communication between the two are considered useful as chemosensors or molecular switching devices.[1–6] A variety of photoinduced electron transfer (PET) chemosensors in 'Fluorophore–Spacer–Receptor' format have been developed in recent years[1–5] which perform light-induced simple YES or NO logic operations and hence may find application as photonic molecular devices in molecular information processing. While the majority of these chemosensors possess one input and one output functionality, logic systems with two input devices which act as AND gates are also reported.[3]

While molecular signalling systems for several ions have been available for some time, only very recently an anthracene derivative with a cryptand receptor has been developed by Ghosh *et al*. that is described as the first sensor for transition metal ions such as $Ni^{II}$ and $Cu^{II}$.[4] In the PET sensing mechanism, the receptor–fluorophore interaction 'switches off' the fluorescence and the 'switching on' takes place in the presence of a guest (usually protons or metal ions) when the fluorophore is released as a result of guest binding with the receptor. Therefore, the fluorescence sensing mechanism requires the metal ion (M)–fluorophore (F) communication to be less than the M–receptor (R) interaction. Obviously, for transition metal ions, which are efficient quenchers for organic fluorophores, the M–F communication is too strong compared with the other interaction for commonly used receptors. The recent success of Ghosh *et al.* has been ascribed to the special topology of the cryptand receptor that binds M more strongly within the cavity making it unavailable for fluorescence quenching.[4] In other words, the M–R interaction has been increased to reduce indirectly the communication between M and F. We find that no attempt has been made to find out whether direct manipulation of the M–F communication can be made to develop fluorescent sensors or switches for the transition metal ions. Since redox interaction between F and M is one of the important quenching mechanisms,[7] it should be possible to reduce this communication simply by making the fluorophore more electron deficient either by suitable substitution or simple structural modifications. Such modification not only minimises the redox activity between M and F in the metal-bound state but also enhances PET in the unbound state, both favouring an increase in the efficiency of the system. Since no studies based on this approach have been reported, the following work was undertaken.

The proton sensory behaviour of some compounds related to **1** is reported in the literature with low fluorescence enhancement (FE) values.[8] The fluorescence outputs of **1**† in the presence of some transition metal ions are collected in Table 1. These values are too low to consider this system as a possible fluorescent switch for d-block transition metal ions. We ascribe this failure partly to inefficient PET[9] and partly to the quenching interaction between M and F. Since, according to our rationale, both these drawbacks can be rectified by choosing a structurally similar but relatively electronically deficient fluorophore, 4-aminophthalimide (AP),‡ much improved switching functions are expected from **2a** and **2b**. Further, it may be noted that the higher singlet energy of these derivatives is also expected to enhance PET and hence their performance.

**1** **2a** $n = 2$ **b** $n = 3$

The fluorescence spectra of **2a** and **2b**† are characterised by broad bands typical of an intramolecular charge transfer transition within the fluorophore.[10] Attachment of the spacer and receptor results in a reduction of the fluorescence quantum yield of the original fluorophore, AP by a factor of *ca*. 50 in **2a** and 27 in **2b** in acetonitrile§ which is a clear indication of PET in both cases. The driving force ($\Delta G^*$) for the PET process, estimated from the measured redox potentials of the couples

**Table 1** Fluorescence output of **1**, **2a** and **2b** as a function of different metal ion input[a]

| | **1** | | **2a** | | **2b** | |
|---|---|---|---|---|---|---|
| Input metal ion[b] | [M]/ mol dm$^{-3}$[c] | Output[d] FE | [M]/ mol dm$^{-3}$[c] | Output[d] FE | [M]/ mol dm$^{-3}$[c] | Output[d] FE |
| $Cr^{III}$ | $4.3 \times 10^{-5}$ | 1.1 | $1.2 \times 10^{-4}$ | 39 | $1.1 \times 10^{-4}$ | 25 |
| $Fe^{III}$ | $2.6 \times 10^{-5}$ | 1.1 | $1.0 \times 10^{-4}$ | 34 | $1.0 \times 10^{-4}$ | 27 |
| $Co^{II}$ | $1.1 \times 10^{-5}$ | 1.1 | $1.9 \times 10^{-4}$ | 38 | $9.2 \times 10^{-4}$ | 12 |
| $Ni^{II}$ | $1.7 \times 10^{-5}$ | 1.1 | $3.0 \times 10^{-4}$ | 37 | $1.8 \times 10^{-2}$ | 22 |
| $Cu^{II}$ | $2.6 \times 10^{-5}$ | 1.2 | $2.7 \times 10^{-4}$ | 41 | $4.0 \times 10^{-4}$ | 27 |
| $Zn^{II}$ | $2.2 \times 10^{-4}$ | 1.3 | $3.9 \times 10^{-4}$ | 55 | $6.8 \times 10^{-4}$ | 30 |

[a] Experimental conditions: *ca.* $5 \times 10^{-5}$ mol dm$^{-3}$ acetonitrile solution of the compounds was used, at 298 K, $\lambda_{exc}$ = 425 nm for **1** and 400 nm for **2a** and **2b**, excitation and emission band widths were 3 nm. [b] The salts used for the experiments were $CrCl_3 \cdot 6H_2O$, $FeCl_3$, $Co(NO_3)_2 \cdot 6H_2O$, $Ni(ClO_4)_2 \cdot 6H_2O$, $Cu(NO_3)_2 \cdot 3H_2O$ and $Zn(ClO_4)_2 \cdot 6H_2O$. [c] Represents the concentration of the metal ion for which FE was maximum, any further increase in concentration beyond this led to fluorescence quenching. [d] With reference to the fluorescence intensity of the respective compound in the absence of metal ion.

using the Weller equation [$\Delta G^* = E_{ox}$ (R) $- E_{red}$ (F) $- E_{0,0}$] is more negative for **2** [−6.6 kcal mol$^{-1}$ for **1** and −12.7 kcal mol$^{-1}$ for **2** in acetonitrile (1 cal = 4.184 J)].¶ Since the fluorescence decay curves of **2a** and **2b** are biexponential‖ with one short component representing the lifetime of the PET quenched state and a long-lived component whose lifetime is very similar in magnitude to that of the methylated AP, a through-space quenching mechanism with two dominant configurations of the fluorophore is suggested; one in which proximity of the fluorophore and receptor results in quenching and the other in which spatial distribution of the two is unfavourable for PET.

Fig. 1 illustrates the effect of the addition of metal ions on the fluorescence intensity of the compounds. As can be seen, beyond a certain concentration of the metal ion (values of which are indicated in Table 1 for each metal ion) the quenching influence starts becoming visible. The metal ion induced FE is associated with a shift of the fluorescence maximum. Similar shifts with these metal ions are also observed in the case of **1** and **2b**. Since metal ion addition to solutions of AP or 1,8-naphthalimide (ANP) did not produce any shift, the shift does not originate from a change in the polarity of the environment. Further, it also clearly indicates that the M–F interaction alone is not responsible for the shift. Therefore, we conclude that the shift arises from an interaction of the metal ion involving both the receptor and the fluorophore.

The FE values of **2a** and **2b** with the metal ions, collected in Table 1, are large enough to consider these simple systems as efficient fluorosensors for transition metal ions. A comparatively larger FE value for **2a** (for any given metal ion) is due to enhanced PET in the unbound state because of a favourable conformation. The maximum FE value is observed with $Zn^{II}$ due to its non-quenching nature. The fluorescence recovery in this case is nearly 100%. It is gratifying to note a 35-fold enhancement even in the case of $Fe^{III}$, reported to be the most quenching transition metal ion[7] and for which no reported FE data has come to our notice. Further, it can be seen that the quenching influence of the metal ions is more visible at a lower concentration in the case of electron rich **1** than with electron deficient **2a** or **2b**. This is a reflection of the modification of redox activity between M and R.

In summary, we have shown for the first time that metal–fluorophore communication can be directly modulated to develop structurally much simpler PET fluorosensors (OR gate) for the d-block metal ions and as such there is no need to design a receptor with any special topology that involves more synthesis. Further, for the first time, fluorescence enhancement in the presence of metal ions such as $Fe^{III}$ and $Cr^{III}$, known for their high quenching abilities, has been observed.

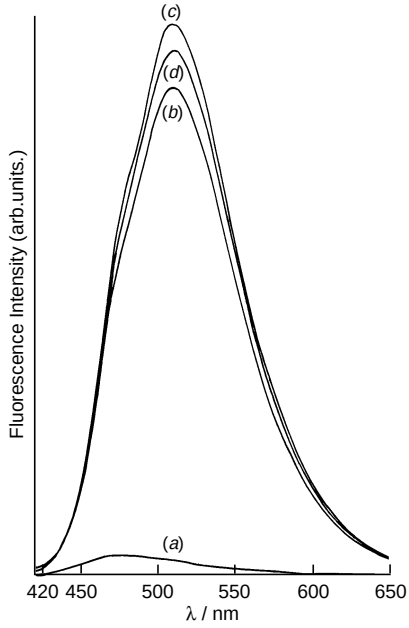


**Fig. 1** Fluorescence spectra of **2a** in acetonitrile for different concentrations of $Fe^{III}$: (*a*) 0, (*b*) 5.3 × 10$^{-5}$, (*c*) 1.0 × 10$^{-4}$ and (*d*) 1.6 × 10$^{-4}$ mol dm$^{-3}$

† **1** was prepared by reacting 4-amino-1,8-naphthalic anhydride with *N*,*N*-dimethylaminoethylamine. **2a** and **2b** were prepared by condensation of 4-aminophthalimide with corresponding dialkylaminoamines.

‡ The measured $E_{ox}$ of AP and 4-amino-1,8-naphthalimide are 1.50 V and 1.27 V (Ag–AgCl reference electrode), respectively.

§ The fluorescence quantum yield of 4-aminophthalimide in acetonitrile, as reported in ref. 10(*a*), is 0.63.

¶ The $E_{ox}$ for triethylamine used for calculation is 0.49 V, ref. 11. The SCE value was corrected for Ag–AgCl electrode by subtracting 0.27 V. The $E_{red}$ values of AP and 4-amino-1,8-naphthalimide (ANP) used for the calculations are −1.66 and −1.61, respectively. $E_{0,0}$ values, estimated from the fluorescence maxima of AP and ANP, are 62.2 and 55.04 kcal mol$^{-1}$.

‖ The lifetimes of the PET quenched state of **2a** and **2b** in acetonitrile are *ca.* 0.5 and 0.8 ns, respectively, with 98 and 64% contribution to the total decay at time $t = 0$. The unquenched component has lifetime in the range 17–18 ns. The measured lifetime of methylated AP in acetonitrile is 18.5 ns.

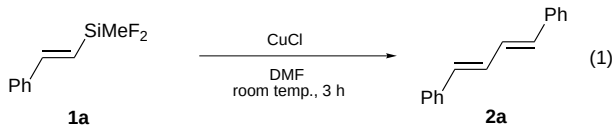
# Copper(I) salt promoted homo-coupling reaction of organosilanes†

**Kazutaka Ikegashira, Yasushi Nishihara, Kazunori Hirabayashi, Atsunori Mori* and Tamejiro Hiyama**

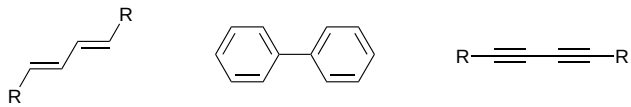
*Research Laboratory of Resources Utilization, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama, Kanagawa 226, Japan*



**Alkenylfluorosilanes, phenylfluorosilanes or alkynylsilanes smoothly dimerize in the presence of a copper(I) salt in a polar solvent such as *N*,*N*-dimethylformamide (DMF) or dimethyl sulfoxide (DMSO) to give the 1,3-conjugated dienes, biphenyl or 1,3-conjugated diynes, respectively.**

We have been studying the Pd-catalysed cross-coupling reaction of organosilanes in the presence of fluoride ion. The reaction has been found to proceed *via* the formation of a pentacoordinate organosilicate, which allows transmetalation of the organic group from Si to Pd *via* activation with the fluoride ion[1] or a corresponding promoter.[2]

A part of our interest has thus been centred on the possibility of transmetalation by other metallic species. Kumada and co-workers documented the fact that treatment of alkenylpentafluorosilicates with a $Cu^{I}$ salt[3] in the solid state at 250 °C resulted in the formation of homo-coupling products (1,3-conjugated dienes). As observed in these reactions, activation by converting tetrahedral organofluorosilanes into organopentafluorosilicates is necessary to attain transmetalation from silicon to copper, although no example of the transmetalation of organosilanes to copper has been reported, to the best of our knowledge.[4]



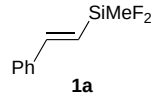
Herein, we report our preliminary results on the transmetalation of organosilane compounds **1** to copper(I) salts, and subsequent homo-coupling reactions under extremely mild and neutral conditions. The reactions proceeded without an activator such as fluoride ion.

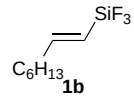
We first investigated the reaction of **1a** with an equimolar amount of KF in the presence of CuCl in *N*,*N*-dimethylformamide (DMF),[5] and found homo-coupling product **2a** was produced in 98% yield. This observation encouraged us to study the reaction in more detail and found that it took place without KF [eqn. (1)].

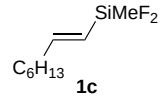
**1a** **2a** (1)

DMSO, a polar solvent, also promoted the reaction, whereas none of the desired product was obtained in THF or diethyl ether. Copper cyanide (CuCN), although effective for transmetalation of organotin reagents,[6] required a longer reaction time (72 h) and gave **2a** in 75% yield. In contrast, CuI[7] and $CuCl_2$[8] were much less reactive.

**2a** R = Ph
**b** R = $C_6H_{13}$







**3**

**4a** R = Ph
**b** R = $C_6H_{13}$

A typical procedure for the homo-coupling reaction of **1a** to **2a** is as follows. DMF (0.5 ml) and **1a** (37 mg, 0.2 mmol) were successively added to CuCl (20 mg, 0.2 mmol) placed in a reaction tube equipped with a magnetic stirrer. The reaction mixture was stirred for 3 h at room temperature and quenched with 1 M hydrochloric acid. The aqueous layer was extracted with diethyl ether, and the organic layer was separated. The combined ethereal layer was washed with water and brine, and dried over $Na_2SO_4$. The homo-coupling product, (*E*,*E*)-1,4-diphenylbuta-2,3-diene **2a**, was obtained in 98% yield.

Results using various organosilicon compounds are summarized in Table 1. It is noteworthy that the reactivity of the silicon substrate is strongly dependent upon the number of fluorine atoms attached to silicon. Thus, the yield of **2b** from trifluoro(oct-1-enyl)silane **1b** is higher than that from difluoro(methyl)(oct-1-enyl)silane **1c** (run 2 *vs*. 3). In all cases the isomeric purity of hexadeca-7,9-diene **2b** was more than 99%, as confirmed by $^1H$ NMR spectroscopy. Thus, these reactions occurred with retention of configuration. The treatment of trifluorophenylsilane **1d** or ethyl(difluoro)phenylsilane **1e** with an equimolar amount of CuCl afforded biphenyl **3** (runs 4 and 5), whereas **1f** gave only a trace amount of **3**. Indeed, it has been reported that phenylcopper decomposes to produce biphenyl and copper metal.[9] The biphenyl formation from fluoro(phenyl)silane **1d** or **1e** is ascribed to transmetalation from Si to

$Cu^I$ to give a phenylcopper intermediate. Alkynyltrimethylsilanes **1g** and **1h** also underwent the homo-coupling reaction to give the corresponding 1,3-diynes[10] in excellent yields. The results are consistent with the fact that the cross-coupling reaction of alkynylsilanes is accomplished by the use of the trimethylsilyl group.[11]

Although the reaction mechanism of the homo-coupling remains unclear, the following results are helpful for understanding of the mechanism of the transmetalation from silicon to copper. The reaction of **1d** with CuCl in DMF under an argon atmosphere at room temperature over 3 h did not give any trace of biphenyl **3**, despite complete consumption of **1d**. However, consequent exposure to the air or treatment with iodine gave **3** in 40% yield or iodobenzene **6** in 68% yield, respectively. These results suggest that the initial step of the homo-coupling reaction promoted by a $Cu^I$ salt is the transmetalation of organosilanes (R*Si*) with $Cu^I$ salt, and that the corresponding organocopper species (R*Cu*) **5** is actually involved as an intermediate [eqn. (2)]. The presence of air or oxygen is crucial for the formation of R–R.

(2)

In summary, the organic group of organosilanes **1** is found to transmetalate to $Cu^I$, and the resulting organocopper species undergo the homo-coupling reaction to give 1,3-dienes, biphenyl or 1,3-diynes. This is the first example of transmetalation of organosilanes to copper without activation of organosilanes with fluoride ion and provides the most practical and convenient method for the preparation of homo-coupling products. Details of the reaction mechanism and further synthetic applications are now under investigation.

The present work was partially supported by a Grant-in-aid for General Scientific Research (No. 0705042) and one for Scientific Research in the Priority Area of Constraction of Organic Molecules (No. 08245218), both from the Ministry of Education, Science, Sports, and Culture, Japan.

# Rationalisation of the regioselective hydrolysis of aliphatic dinitriles with *Rhodococcus rhodochrous* AJ270

**Otto Meth-Cohn* and Mei-Xiang Wang**

*Chemistry Department, Sunderland University, Sunderland, UK SR1 3SD*

**Aliphatic dinitriles undergo regioselective hydrolysis with the title organism to give monoacids with up to four methylenes between the nitrile functions (optimally 2–3) or when either an oxygen is placed β, γ or δ to the nitrile (δ-placement being optimal) or β or γ (optimally γ) but not δ sulfur substituents are present; nitrogen substituents appear to behave as for oxygen but suffer a steric limitation of the size of the nitrogen substituent.**

We have demonstrated[1] that the title organism is a powerful, general nitrile hydrolysing organism, involving two enzymes effecting nitrile-to-amide and amide-to-acid conversions respectively. As a prelude to studying the hydrolysis of prochiral dinitriles we have made a broad study of the effect of structure on the regioselectivity of hydrolysis of aliphatic dinitriles. The literature contains a number of papers on this topic but the overall background picture is decidedly unclear.

In 1980 Yamada showed that a *Fusarium* strain transformed glutaronitrile to 4-cyanobutyric acid[2] and 1,3,6-tricyanohexane to a mixture of diacids,[3] the former transformation also being accomplished by a *Pseudomonas* organism. Gutman[4] observed that the series $NC[CH_2]_nCN$ with $n$ = 3–5 hydrolysed with no selectivity to the diacids with *Rhodococcus rhodochrous* NCIB 11 216 grown on propionitrile while Yamada[5] observed selective monohydrolysis of glutaronitrile ($n$ = 3) using *R. rhodochrous* K22 in quantitative yield. Schneider[6] made similar observations to Yamada with another *R. rhodochrous* strain while Turner[7] showed that succinonitrile gave solely 3-cyanopropionic acid while glutaronitrile gave both mono- and diacids, ratios depending upon time of reaction. Prochiral glutaronitriles were hydrolysed by Kakeya[8] and by Turner[9] to give enantio-efficient monohydrolysis in some cases, although not in others. A chiral malononitrile has been converted[10] into its monoacid monoamide derivative utilising an *R. rhodochrous* strain. Other organisms have been used for the efficient monohydrolysis of 1,4-cycohexanedicarbonitrile,[11] while the conversion of adiponitrile to adipic acid has been closely studied by Moreau[12] utilising a *Brevibacterium*.

We first examined the selectivity of hydrolysis in a series of α,ω-dinitriles, monitoring the reaction against time (Table 1). As we noted in earlier work,[1] the low molecular weight nitriles tended to be metabolised by other enzymes in the organism, limiting overall yields. However, a clear pattern emerged: dinitriles with more than four methylenes separating the functions gave solely diacids irrespective of reaction time. With less than four methylenes, regioselective monohydrolysis occurred.

We next examined a series of α,ω-dinitriles $NC[CH_2]_nX[CH_2]_nCN$ **4** containing a heteroatom X in the chain (Table 2). With the oxygen or sulfur series, reactions were rapid and generally efficient, whereas with NH or NMe the nitriles proved unstable. We therefore included the NAr series which, probably for steric reasons, reacted slowly and with $n$ > 2, not at all, even with added co-solvents such as acetone or methanol. A remarkable feature emerges: regioselectivity is principally dependent upon the placement of the heteroatom, not the overall chain length. Thus a δ-oxygen is optimally efficient, with regiocontrol being effective with a β- or γ-oxygen also. However a γ-sulfur allows optimal regiocontrol, the β-analogue showing selectivity but not the δ-analogue. In the nitrogen series we cannot yet define the limits of regiocontrol with chainlength but good selectivity is shown with a β-nitrogen. Interestingly, in this slowly hydrolysed series, a much greater sensitivity to *p*-substituents is evident than in the hydrolysis of mononitriles.

We explain the regioselectivity on the basis of chelation-deactivation of the enzyme. We believe that hydrolysis occurs by complexation of the nitrile nitrogen to a metal (iron or cobalt) followed by hydration of the nitrile function by the presumed

cofactor present in such nitrile hydratases, pyrroloquinoline quinone, as documented elsewhere.[13] When a suitably placed ligand atom is also present in the nitrile a bidentate complexation to the metal occurs, which interferes with the hydration of the nitrile function. This ligand may be a suitably placed $CO_2H$ function or a heteroatom. The glutaronitrile **1** ($n$ = 3) bears a δ-oxygen ligand as does the ether **4** ($n$ = 4, X = O). The C–S bond is considerably longer than the C–O bond (1.81 and 1.43 Å respectively) and not surprisingly therefore a γ placement lends optimal regioselectivity. If this mechanism is correct, the above ligands should behave as competitive inhibitors in the hydrolysis of other easily hydrolysed nitriles.† This is indeed found to be the case. Thus when the hydrolysis of benzonitrile is followed (by HPLC) in the presence or absence of $NCCH_2CH_2CH_2SCH_2CH_2CH_2CO_2H$, we find that the rate of benzonitrile disappearance is dramatically slower in the former case. Thus after 5 min reaction, about 20% of unreacted benzonitrile remained with no added cyano acid. In the presence of the inhibitor almost 40% remained. After 10 min the figures were *ca*. 2 and 25%. Furthermore the rate of decrease of amide and rate of formation of acid are both significantly slower in the presence of the cyano acid.

When the aliphatic α,ω-dinitrile chain is interrupted by vinyl or aryl substituents, regiocontrol is efficiently observed in almost all cases that we have examined except for *o*-phenylenediacetonitrile (Table 2, entry 3). Although the regiocontrol here (and in the case of aromatic dinitriles[14]) may derive from a different basis, it is tempting to suggest that the π-systems can also act as effective ligands for the iron when chelation allows (Table 3). Also included in Table 3 is *trans*-cyclohexane-1,4-diacetonitrile (entry 6) which shows total regioselective hydrolysis, presumably by way of chelation of its axial or twist–boat conformer.

In conclusion, we have defined the extent to which regiocontrol can be expected in the hydrolysis of dinitriles bearing O, S and to a limited extent N substituents, and considered the control with π-functionalised dinitriles. The application of these ideas to prochiral and chiral systems is now being actively examined.

We thank the BBSRC for a generous research grant that made this work possible.

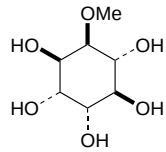
# Total synthesis of (−)-PA-48153C (pironetin) utilising L-quebrachitol as a chiral building block

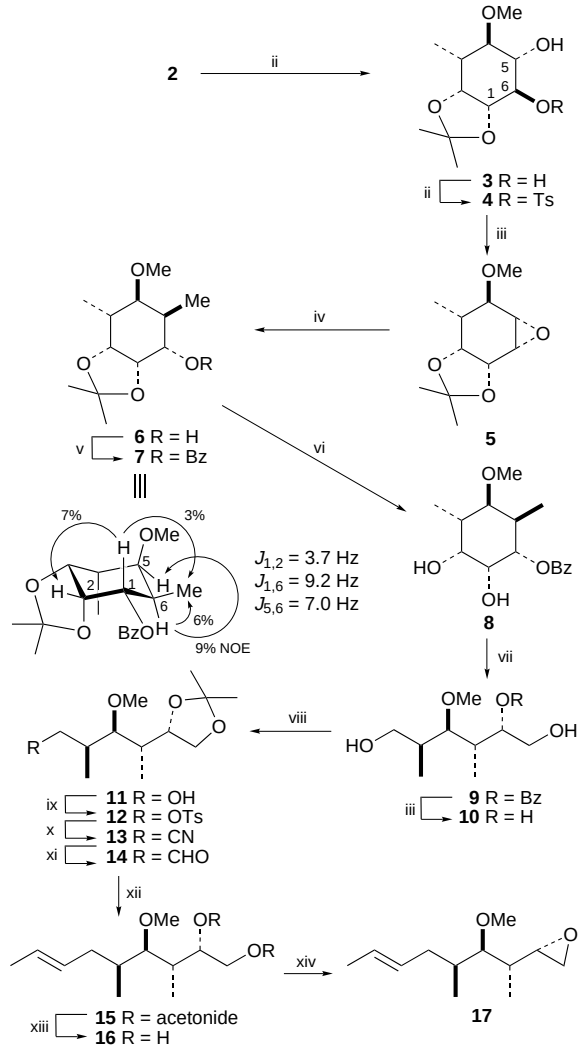
**Noritaka Chida,* Mitsukane Yoshinaga, Takahiko Tobe and Seiichiro Ogawa**



*Department of Applied Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223, Japan*

**The chiral and stereoselective synthesis of (−)-PA-48153C (pironetin) 1, a novel immunosuppressant, is described; the acyclic portion possessing four contiguous chiral centres in 1 was constructed stereoselectively from L-quebrachitol and the 2-pyranone moiety was prepared from L-malic acid.**

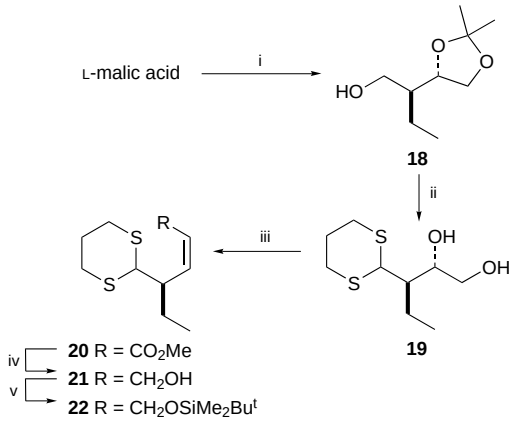
PA-48153C (pironetin) **1** is a novel 2-pyranone derivative isolated from the culture broth of *Streptomyces*[1,2] and is reported to show a potent immunosuppressive,[1] cytotoxic[1] and plant growth regulator activities.[2a] Its interesting mode of action, its suppressive effect on the responses of both T and B lymphocytes to mitogens[1] as well as its unique structure[1,2b] has attracted much synthetic interest and three total syntheses of **1** have been reported to date.[3] Recently, reports on the synthesis and the structure–activity relationship study of the analogues of **1** have appeared.[4] Here we report an alternative approach to **1**, which utilises L-quebrachitol **2**, an optically active cyclitol obtained in a large quantity from the serum of the rubber tree[5,6] as a chiral building block.



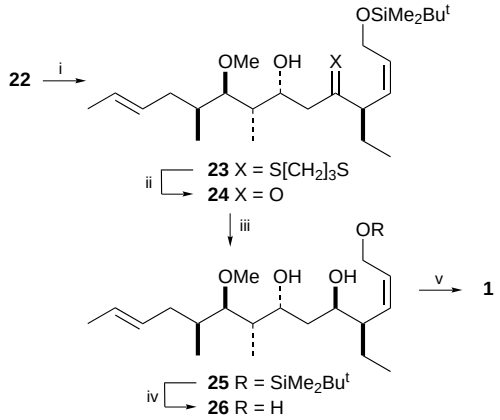
PA-48153C (pironetin) **1**

L-quebrachitol **2**

The known 1D-(1,2,3,5/4,6)-1,2-*O*-isopropylidene-3-methyl-4-*O*-methylcyclohexane-1,2,4,5,6-pentol **3**,[6a] prepared stereoselectively from **2** in five steps, was chosen as the starting material for the preparation of the acyclic moiety in **1**. Reaction of **3** with dibutyltin oxide[7] followed by treatment with *p*-toluenesulfonyl chloride (TsCl) afforded **4** in 82% yield.† Base treatment of **4** provided α-epoxide **5** in 93% yield. Reaction of **5** with trimethylaluminium in $CH_2Cl_2$–hexane at room temp. caused the *trans*-diaxial opening of the epoxide ring with the methyl group to afford **6**, which was isolated after *O*-benzoylation to provide **7** in 56% yield from **5**. The observed coupling constants and NOE of **7** clearly supported the assigned structure. The *O*-isopropylidene group in **7** was removed to give **8** (96%). The cyclohexane ring in **8** was cleaved by periodate oxidation to provide acyclic diformyl derivative, which, without isolation, was reduced with $NaBH_4$ to afford diol **9** in 90% yield. Removal of the *O*-benzoyl group in **9** and protection of the resulting 1,2-diol moiety gave **11** (89% yield from **9**), which was converted into the nitrile derivative **13** *via* *O*-tosylate **12** (97% for two steps). Reduction of the nitrile function in **13** with DIBAL-H, followed by acidic work-up provide **14**. Wittig olefination of **14** with $Ph_3P{=}CHMe$, followed by photo-induced isomerization, showed low *E*-selectivity and gave an inseparable mixture of **15** and its *Z*-isomer in a ratio of 3 : 1 (61% yield from **13**). Fortunately, better results were obtained when **14** was reacted with $MeCHI_2$ in the presence of $CrCl_2$ (Takai reaction)[8] to provide **15** as the major product (*E* : *Z* = 11 : 1, 74% yield from **13**).‡ Acid hydrolysis of the mixture, followed by chromatographic separation afforded geometrically pure **16** in 89% isolated yield. Treatment of **16** under the conditions of Mitsunobu[9] furnished the acyclic moiety, epoxide **17** in 71% yield.



The synthesis of the precursor of the 2-pyranone portion in **1** commenced with known (2*S*,3*S*)-2-ethyl-3,4-isopropylidenedioxypropan-1-ol **18**, obtained from L-malic acid in 6



**Scheme 1** Ts = $SO_2C_6H_4$(*p*-Me) *Reagents and conditions*: i, see ref. 6(*a*); ii, $Bu_2SnO$, MeOH, reflux, then TsCl, DMAP, 1,4-dioxane, room temp.; iii, MeONa, MeOH; iv, $Me_3Al$ (10 equiv.), $CH_2Cl_2$–hexanes (1 : 1), room temp.; v, BzCl, pyridine, DMAP, room temp.; vi, 10-camphorsulfonic acid (CSA, 0.2 equiv.), MeOH, room temp.; vii, $NaIO_4$, acetone–$H_2O$ (1 : 1), 0 °C, then $NaBH_4$, MeOH, 0 °C; viii, acetone, CSA, 0 °C; ix, TsCl, pyridine; x, NaCN, 15-crown-5, DMF 60 °C; xi, DIBAL-H, $CH_2Cl_2$, −78°C, then 5% aqueous $H_2SO_4$–$CH_2Cl_2$, 0 °C, 40 min.; xii, $MeCHI_2$ (2 equiv.), $CrCl_2$ (8 equiv.), THF, room temp., 3 h; xiii, CSA, MeOH, 60 °C; xiv, $Ph_3P$, diethyl azodicarboxylate, toluene, reflux, 36 h

steps.[10] Oxidation of **18** with pyridinium chlorochromate (PCC) on alumina,[11] followed by treatment with propane-1,3-dithiol in the presence of $BF_3{\cdot}OEt_2$ gave diol **19** in 63% yield. Glycol cleavage and subsequent modified Wittig–Horner reaction[12] gave desired *Z*-alkene **20** (63% yield) along with its *E*-isomer (14%). DIBAL-H reduction of **20** followed by protection of the resulting alcohol function provided 2-pyranone precursor **22** in 68% yield from **20**.

Deprotonation of **22** with *tert*-butyllithium in the presence of hexamethylphosphoramide (HMPA),[13] followed by addition of epoxide **17** afforded the coupling product **23** in 56% yield. Deprotection of the dithioacetal function in **23** was achieved by treatment with *N*-chlorosuccinimide (NCS) and $AgNO_3$[14*a*] in the presence of 2,4,6-collidine[14*b*]§ to give **24** quantitatively. Reduction of the ketone carbonyl in **24** with $NaBH(OAc)_3$[15] in MeCN–AcOH afforded *anti*-diol **25** as the major product in 65% isolated yield (*syn* isomer 25% yield). Removal of the *O*-silyl protecting group in **25** afforded triol **26** in 82% yield. The final step was successfully achieved by $MnO_2$ oxidation of

**Scheme 2** *Reagents and conditions*: i, see ref. 10(*a*); ii, PCC, $Al_2O_3$, $CH_2Cl_2$, room temp., then 1,3-propanedithiol (1.5 equiv.), $BF_3{\cdot}OEt_2$ (0.3 equiv.), $CH_2Cl_2$, room temp.; iii, $Pb(OAc)_4$, $K_2CO_3$, benzene, room temp., then $(CF_3CH_2O)_2P(O)CH_2CO_2Me$, $KN(SiMe_3)_2$, 18-crown-6, THF, −78 °C; iv, DIBAL-H $CH_2Cl_2$, −78 °C; v, *tert*-butyldimethylsilyl trifluoromethanesulfonate, 2,6-lutidine, $CH_2Cl_2$, 0 °C

† When this reaction was carried out with TsCl and DMAP in pyridine at 50 °C, compound **4** and its positional isomer (5-*O*-tosylate) were obtained in 37 and 22 isolated yield, respectively.

‡ Reaction of **12** (or its corresponding *O*-triflate derivative) with prop-1-enyllithium in the presence of $Cu^I$ salts directly afforded **15**, however, the yield of **15** was low (less than 10%).

§ In the absence of collidine, the formation of cyclic hemi-ketal derivative, which arose from undesired deprotection of *O*-silyl group, was observed.

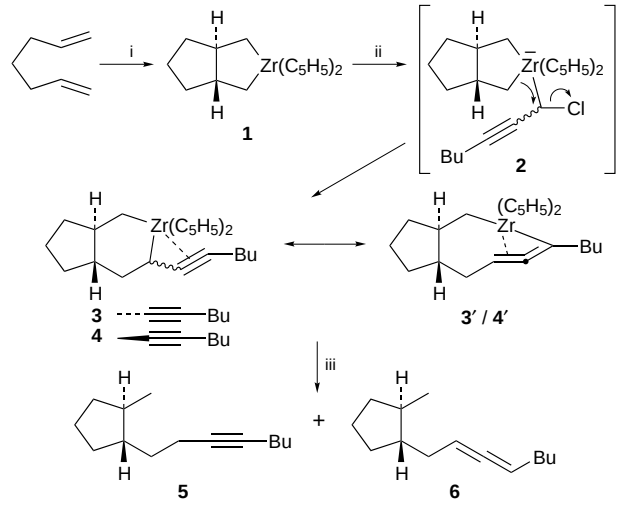
# Tandem prop-2-ynyl carbenoid–aldehyde insertion into zirconacycles

**George J. Gordon and Richard J. Whitby***

*Department of Chemistry, Southampton University, Southampton, Hampshire, UK SO17 1BJ*



**Insertion of 1-lithio-1-chloroalk-2-ynes into zirconacycles gives cyclic zirconocene η³-prop-2-ynyl/allenyl complexes which afford useful organic products on protonation or Lewis acid induced addition of aldehydes.**

The co-cyclisation of alkenes and alkynes induced by the zirconocene equivalent, zirconocenebut-1-ene (generated *in situ* from dibutylzirconocene—the 'Negishi reagent'[1]) is a useful method for carbon–carbon bond formation.[2] Efficient use of the transition metal requires productive methods for elaboration of the intermediate zirconacycles. Although conventional electrophiles such as alkyl halides are unreactive, reagents with carbenic reactivity such as carbon monoxide and isocyanides insert into the carbon–zirconium bonds very rapidly.[3] We recently reported[4] the insertion of lithium chloroallylides into zirconacycles to afford η³-allylzirconium species which could be further elaborated by the addition of a variety of electrophiles. We now describe the extension of this insertion reaction to 1-chloro-1-lithioalk-2-ynes (prop-2-ynyl carbenoids) to give novel η³-prop-2-ynyl/allenyl zirconium species, and their further elaboration.

Co-cyclisation of hepta-1,6-diene using zirconocenebut-1-ene gave the zirconacyclopentane **1**. Addition of 1-chlorohept-2-yne followed by a solution of lithium 2,2,6,6-tetramethylpiperidide (LiTMP) at −78 °C gave clean conversion into a 1 : 1 mixture of the diastereoisomeric zirconacyclohexanes **3** and **4**, presumably *via* the 'ate' complex **2**. Since both the carbenoid and the zirconacycle are chiral, but racemic, the 1 : 1 ratio of **3** : **4** suggests that there is little 'chiral recognition' between the carbenoid and zirconacycle, and little equilibration of the 'ate' complex **2** which could favour one of the two diastereoisomers on rearrangement. Heating the mixture of **3** and **4** did not cause any change in the isomer ratio. The complexes **3** and **4** were remarkably resistant to protonolysis showing no change after eight days dissolved in $CD_3OD$–$C_6D_6$ (1 : 2) (*cf.* **1** which protonates in < 2 min). Acetic acid caused rapid protonation of **4** (< 5 min at room temp.) to give **5**† and **6** (2 : 1) but left **3** untouched. Aqueous work-up followed by recrystallisaton of the crude product from hexane gave **3** as fine white crystals in an overall yield of 27%. The crystallisation liquor was purified by column chromatography to yield 1-methyl-2-(oct-3-ynyl)cyclopentane **5** (31%) and 1-methyl-2-(octa-2,3-dienyl)cyclopentane **6** (14%). Protonation of **3** with acetic acid took 24 h to reach completion and gave a 1 : 1.5 mixture of **5** and **6**.

The NMR shifts of the prop-2-ynyl unit in both **3** ($\delta_C$ 73.6, 115.1, 122.3) and **4** ($\delta_C$ 76.7, 121.1, 123.2) are consistent with η³-bonding (*i.e.* with a substantial contribution from the η³-allenyl representation **3′**/**4′**), and are comparable to those in $(C_5H_5)_2Zr(Me)(\eta^3\text{-}CH_2C{\equiv}CPh)$ ($\delta_C$ 55.5, 114.2, 120.5) reported by Wojecicki.[5] The small number of known η³-prop-2-ynyl complexes of transition metals have recently been reviewed.[6] The relative stereochemistries of **3** and **4** were tentatively assigned as shown based on the marked difference in stability towards hydrolysis. In **3** (chair zirconacyclohexane) the alkyne moiety is ideally positioned for donation of electron density into the empty orbital on zirconium[7] whereas in **4** the zirconacyclohexane ring must adopt a higher energy twisted boat conformation (Fig. 1).‡ We have previously noted a correlation between an 18 electron configuration at a zirconocene centre, and stability of carbon–zirconium bonds towards hydrolysis[8] and believe that hydrolysis occurs *via* the 16 electron η¹-prop-2-ynyl forms of **3** and **4**, more readily attained by the later. By analogy with our successful elaboration of cyclic zirconocene allyl complexes with aldehydes activated with $BF_3{\cdot}Et_2O$[4] we exposed the mixture of **3** and **4** to these conditions, but no reaction occurred. The products isolated after aqueous work-up comprised **5**, **6** and **3**.

We next examined the insertion of prop-2-ynyl carbenoids into unsaturated zirconacycles. Treatment of the bicyclic zirconacyclopentenes **7a** and **7b**, derived from the intramolecular co-cyclisation of enynes, with 1-chloro-3-phenylprop-2-yne or 1-chlorohept-2-yne and LiTMP at −78 °C gave clean conversion to the ring expanded zirconacycles **8a**–**c**, each as a 1 : 1 mixture of diastereoisomers (Scheme 2). Protonolysis of **8a** with methanol was selective for one diastereoisomer (< 5 min for complete protonation of one isomer, half life of around 4 h at room temp. for the other). Unfortunately, we could not cleanly isolate a single isomer which made assignment of NMR data difficult. To avoid the problem we synthesised the monocyclic zirconium species **7c**[9] and treated it with various prop-2-ynyl carbenoids to give the single isomer ring expanded products **8d**–**g** in quantitative yield by NMR spectroscopy. Protonation of the zirconacycles **8a**–**f** gave alkyne **9** and/or allene products **10** in good yields (Table 1), the ratio of products

[a] Diastereoisomer ratio, measured by NMR.

proving to be dependent on the reagent. Quenching with acetic acid favoured formation of the alkyne (exclusive for $R^4$ = alkyl or $SiMe_3$), whereas MeOH favoured the allene, except for the trimethylsilyl substituted case when only the alkyne was obtained.

Reaction of the η$^3$-prop-2-ynyl complexes **8e**–**g** with aldehydes in the presence of $BF_3{\cdot}Et_2O$ or $TiCl_4$ gave adducts **11** in good yield (Table 2), as a mixture of diastereoisomers. Somewhat better diastereocontrol was found using $TiCl_4$ as the Lewis acid. The regiochemistry of insertion into the η$^3$-prop-2-ynyl system is opposite to that previously observed with the analogous η$^3$-allyl complexes.[4] The zirconabicycle **8a** also

**Scheme 3** *Reagents and conditions*: i, PhC≡CCHMeCl, THF, LiTMP, −78 °C; ii, MeOH, −78 °C to room temp.

reacted with aldehydes, but the increased number of diastereoisomeric products formed prevented proper characterisation.

Finally we examined the insertion of a secondary prop-2-ynyl carbenoid, derived by deprotonation of 1-phenyl-3-chlorobut-1-yne, into the zirconacycle **12**. Insertion occurred readily, but the intermediate zirconacycle **13** was too unstable for NMR characterisation, probably due to β-hydride elimination from the methyl group. Protonation with methanol gave exclusively the allene **14**, confirming that insertion had occurred and illustrating that steric hinderence in the carbenoid is well tolerated (Scheme 3).

We have demonstrated a new method for the elaboration of zirconacycles to provide organic products in good yields. We have also synthesised and characterised a range of novel η$^3$-prop-2-ynyl/allenyl zirconacycles, some of which are remarkably unreactive towards air and water.

We thank the EPSRC for a quota award. R. J. W. thanks Pfizer UK and Zeneca for generous uncommitted financial support.

† All organic compounds were fully characterised (high field $^1$H and $^{13}$C NMR, IR, MS, and HRMS) as pure compounds, with the exception of the diastereoisomers of **11** which were not separated.

‡ Structures based on ZINDO (INDO/1)[10] calculations carried out using CACHE software (Oxford Molecular). The calculations indicate that **4** is 6.4 kJ mol$^{-1}$ higher in energy than **3**, and that the chair form of **4** with the alkyne axial, and not coordinated to the metal, is 23 kJ mol$^{-1}$ higher in energy than the η$^3$-prop-2-ynyl boat form.

**The complex $[NaYb(C_5H_5)_3]$ ($C_5H_5$ = cyclopentadienyl), prepared from $Yb(C_5H_5)_3$ and sodium naphthalenide in tetrahydrofuran (thf) or from $Yb(C_5H_5)_2$ and $Na(C_5H_5)$ in tetrahydrofuran and crystallized at *ca.* 400 °C ($< 10^{-4}$ mm Hg), is a three-dimensional polymer in which $\mu$-$\eta^5$:$\eta^5$-$C_5H_5$ groups link sodium and ytterbium (each metal having a pseudo-triangular arrangement of $C_5H_5$ ligands); $Yb(C_5H_5)_2$, similarly crystallized, has a polymeric chain structure with one terminal and two bridging $C_5H_5$ ligands per ytterbium, and there is $\eta^1$-bonding between adjacent chains.**

No X-ray structure of an unsolvated $[MLn^{II}Cp'_3]$ (M = alkali metal, Cp′ = cyclopentadienyl or substituted cyclopentadienyl) complex has been reported,[1] and only one of a solvated analogue, *viz.* $[NaSm(thf)(\mu\text{-}\eta^5:\eta^2\text{-}C_5H_4Bu^t)_3]$ (thf = tetrahydrofuran).[2] Ions of the type $Ln(C_5H_5)_3^-$ (Ln = Eu, Sm, Yb) have been detected electrochemically,[3a] but only $[KSm(C_5H_5)_3]$ has been isolated and in a form unsuitable for X-ray crystallography.[3b] Similarly, X-ray characterized unsolvated bis(cyclopentadienyl)lanthanide(II) complexes are limited to the substituted cyclopentadienyls $[Ln(C_5Me_5)_2]$ (Ln = Sm, Eu, Yb)[4] and $[Ln\{C_5H_3(SiMe_3)_2\text{-}1,3\}_2]$ (Ln = Eu, Yb).[5] Structures of $Ln(C_5H_5)_2$ and $[MLn(C_5H_5)_3]$ would be of great interest, especially as there is disagreement over the colour (red or green) of $Yb(C_5H_5)_2$,[6] but crystallization of these compounds presents difficulties. They are perceived either as involatile or volatile with extreme difficulty [green $Yb(C_5H_5)_2$ is stated to sublime with decomposition at 400 °C ($< 10^{-4}$ mmHg)],[6b] they are insoluble in non-polar solvents, and are complexed by polar solvents. We now report that use of high-temperature sublimation has enabled the preparation of crystallographically characterizable green $[NaYb(C_5H_5)_3]$ [perhaps accounting for green $Yb(C_5H_5)_2$] and red $Yb(C_5H_5)_2$.

Green $[NaYb(C_5H_5)_3]$ has been obtained from the $Yb(C_5H_5)_3$/Na route previously reported to give green $Yb(C_5H_5)_2$.[6b] After reaction of sodium naphthalenide, $Na(C_{10}H_8)$, with $Yb(C_5H_5)_3$ in thf under argon, removal of naphthalene by sublimation (100 °C, $10^{-2}$ mmHg), extraction with thf, followed by elimination of the solvent in vacuo (150 °C, $10^{-2}$ mmHg) gave crystalline $[NaYb(C_5H_5)_3]$ in high yield [eqn. (1)].

$$Yb(C_5H_5)_3 + Na(C_{10}H_8) \rightarrow [NaYb(C_5H_5)_3] + C_{10}H_8 \quad (1)$$

Single crystals of the bimetallic were obtained by sublimation (*ca.* 400 °C, $< 40^{-4}$ mmHg). The compound was also prepared straightforwardly in high yield by reaction of $Yb(C_5H_5)_2$ with sodium cyclopentadienide in thf, and purified by sublimation under vacuum [eqn. (2)].

$$Na(C_5H_5) + Yb(C_5H_5)_2 \rightarrow [NaYb(C_5H_5)_3] \quad (2)$$

The identical nature of the two sublimed products and the unsublimed material was established by near and far† IR spectra. The latter was highly characteristic and remarkably similar to that of $Yb(C_5H_5)_3$ suggesting that $[NaYb(C_5H_5)_3]$ has a triangular arrangement of $C_5H_5$ ring centroids similar to that of $Yb(C_5H_5)_3$.[7]

The X-ray crystal structure of $[NaYb(C_5H_5)_3]$. (Fig. 1)‡ shows a highly symmetrical three-dimensional array of alternating sodium and ytterbium atoms bridged by $\mu$-$\eta^5$:$\eta^5$-cyclopentadienyl groups with a near linear Na–Cp–Yb arrangement. There is a pseudo-triangular arrangement of three $C_5H_5$ ligands around both sodium and ytterbium. The Yb–C distances (av. 2.73 Å) are longer than those in $Yb(C_5Me_5)_2$ (av. 2.67 Å)[4b] but shorter than in $Yb(C_5H_5)_2$, which is considered ten coordinate. Subtraction of an ionic radius for nine-coordinate $Yb^{2+}$, extrapolated from Shannon's values,[8] from Yb–C gives 1.53 Å (av.), rather shorter than the usual value, 1.64 ± 0.4 Å, for the cyclopentadienide ionic radius.[9] The Na–Cp distance (2.58 Å) falls in the range typical for other crystallographically characterised cyclopentadienylsodium derivatives[10] {*e.g.* 2.40 Å in $Na(C_5Me_5)(py)_3$ (py = pyridine)[11] and 2.65 Å in $[Na(C_5H_5)(tmeda)]_n$ (tmeda = *N,N,N′,N′*-tetramethylethylenediamine)[12]}.

Brick-red $Yb(C_5H_5)_2$ from desolvation of $Yb(C_5H_5)_2(dme)$[6d] (dme = 1,2-dimethoxyethane) at 100 °C ($10^{-3}$ to $4 \times 10^{-5}$ mmHg) for 12 h and crystallized in low yield as red crystals by sublimation at 420 °C ($4 \times 10^{-5}$ mmHg) in a sealed tube, has a polymeric, $C_5H_5$-bridged, zigzag chain structure (Fig. 2)‡ within the metal centres related by $C_2$ and $C_i$ symmetry, and there are weak interchain C–Yb interactions. The X-ray data

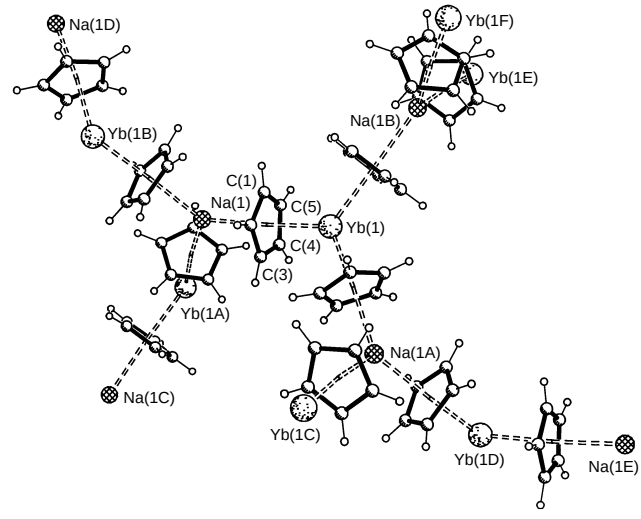

**Fig. 1** Section from the packing diagram of $[NaYb(C_5H_5)_3]$. Selected bond lengths (Å) and angles (°): Yb(1)–C 2.73 (av.), Na–C 2.83 (av.), Yb–Cp 2.46, Na–Cp 2.58; Yb–Cp–Na 176. Cp represents the centroid of the $C_5H_5$ rings.

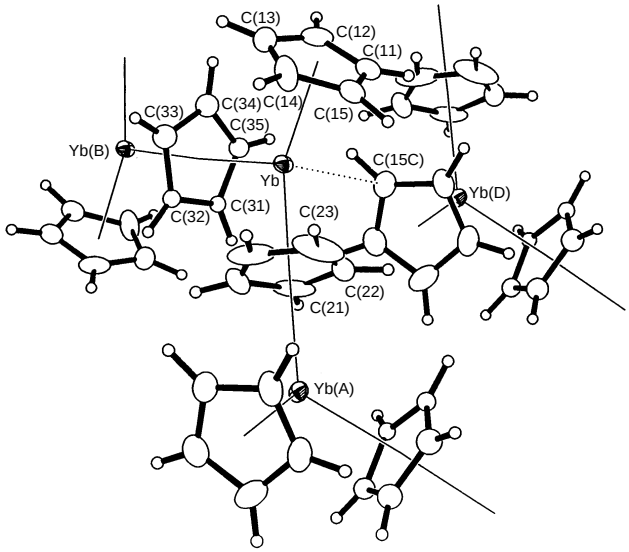

**Fig. 2** Part of the polymeric structure of $Yb(C_5H_5)_2$ [C(31a)–C(35a) of the disordered ring omitted for clarity]. Selected bond lengths (Å) and angles (°): $C_5H_5(1)$ [C(11)–C(15)], Yb–C 2.769 (av.); $C_5H_5(2)$ [C(21), C(22), C(23), C(23b), C(22b)], C(21)–Yb 2.692(4), C(22)–Yb 2.784(10), C(23)–Yb 2.967(12), C(23b)–Yb 2.957(12), C(22b)–Yb 2.821(10); $C_5H_5(3)$ [C(31)–C(35)], Yb–C 2.858 (av.); $C_5H_5(3')$, Yb–C 2.852 (av.); Cp–Yb–Cp 117.6 (av.), Yb–Cp(2)–Yb 164.3, Yb–Cp(3)–Yb 177.6 Interchain Yb–C(15c) 2.996.

show the complex to be isostructural with $Ca(C_5H_5)_2$.[13] Each ytterbium has three $C_5H_5$ ligands, (1)–(3), with $C_5H_5(1)$ essentially terminal (but $\eta^1$-bound to the next chain), $C_5H_5(2)$ bridging on the two-fold axis, and $\mu$-$\eta^5$:$\eta^5$-$C_5H_5(3)$ disordered about the inversion centre. $C_5H_5(2)$, reported as $\mu$-$\eta^3$:$\eta^3$ for $Ca(C_5H_5)_2$,[13] has three shorter Yb–C distances [av. 2.77 Å, comparable with Yb–C of $C_5H_5(1)$] and two longer (av. 2.96 Å). Thus strong $\mu$-$\eta^3$:$\eta^3$ bonding of an allylic four-electron donor unit [C(21), C(22), C(22b)] is indicated, but the more distant C(23), C(23b) are sufficiently close to be $\mu$-$\eta^2$:$\eta^2$ bonded. The distances are comparable with those of formally seven-coordinate $[Yb(C_5Me_5)_2(\eta^2\text{-MeC}{\equiv}\text{CMe})]$ [Yb–C > 2.85(1) Å],[14] and Eu–C (av. 3.00 Å) of nine-coordinate $[Eu(\eta^6\text{-}C_6Me_6)(AlCl_4)_2]_4$,[15] when the potential formal ten coordination of $Yb(C_5H_5)_2$ is considered. They are marginally shorter than the interchain Yb–$\eta^1$-$C_5H_5$ distance (2.996 Å), which is notably ( > 0.1 Å) shorter than the interchain Ca–$\eta^1$-$C_5H_5$ interaction of $Ca(C_5H_5)_2$ ($Ca^{2+}$ and $Yb^{2+}$ have similar ionic radii[8]). Interestingly, there is a close topological relationship between the structures of $Yb(C_5H_5)$ and $Yb(C_5H_4Me)_2(thf)$[16] with the interchain Yb–$\eta^1$-$C_5H_5$ linkage of $Yb(C_5H_5)_2$ replacing Yb–O of the latter.

We are grateful to the Australian Research Council and the Otto-von-Guericke-Universität for financial support and to Monash University for a Postdoctoral Fellowship (to P. McK.).

**The titration of sodium acetate into solutions of the vancomycin group antibiotics eremomycin and chloroeremomycin has been studied by observing the downfield movement of the $^1$H NMR signals due to amide protons in the antibiotic binding pocket; this change in chemical shift has been used to determine the different affinities of the two halves of the dimers for acetate ligand.**

The vancomycin antibiotics are clinically important in the treatment of infections by Gram-positive bacteria and are currently the last line of defence against methicillin-resistant *Staphylococcus aureus* (MRSA).[1,2] They act by binding to the terminal -Lys-D-Ala-D-Ala sequence of bacterial cell wall precursors, inhibiting transglycosylation and ultimately causing cell death.[3,4] In recent work, we have shown that these glycopeptide antibiotics form asymmetric homodimers in solution and that dimerisation is, in all but one case, cooperative with binding to bacterial cell wall precursor analogues.[5] The asymmetry arises from a head-to-head orientation of the saccharide portions attached to residue 4 of the antibiotics, disrupting the $C_2$-symmetry of the head-to-tail peptide backbones.[6–9] A consequence of this asymmetry for the antibiotic ristocetin A is that the two halves of its dimer bind ligands with different affinities.[10,11] However, eremomycin, which also forms an asymmetric dimer, was shown to bind this ligand with approximately equal affinities into each side of such a dimer. Thus, although the asymmetric eremomycin dimer might be expected in principle to bind ligands in each half of the dimer with different affinities, the observation of similar or identical affinities suggested a smaller interaction of the ligand with the disaccharide of eremomycin compared to the tetrasaccharide of ristocetin A.

Previously, it has not been possible to directly measure binding affinities of ligands to antibiotic dimers. This is because binding affinities have been measured at low antibiotic concentrations (typically $\leqslant$50 μm) by UV difference spectrophotometry,[4] capillary zone electrophoresis[12] or isothermal calorimetry.[13] At such concentrations, weakly dimerising antibiotics, such as vancomycin and ristocetin A, are present at $>$90% monomer, and strongly dimerising antibiotics, such as eremomycin and chloroeremomycin, are present at $>$50% monomer.

We now describe a method, analogous to the UV difference spectrophotometric method, for the determination of binding constants of acetate to antibiotic at a concentration of 5 mM ($>$95% dimer). The binding of bacterial cell-wall precursors is crucially dependent on the recognition of their terminal carboxy groups and acetate thus provides the simplest model for the study of this interaction.

UV difference spectrophotometry plots the change in absorbance of the antibiotic as a function of ligand concentration. The method described here plots the change in $^1$H NMR chemical shift of the amide protons $w_2$, $w_3$ and $w_4$ (Fig. 1) as a function of ligand concentration, at pH 4.5 and 300 K. These three protons, and in particular $w_2$, have been extensively studied previously and a strong correlation has been observed between their limiting downfield chemical shift (shift when $>$95% antibiotic is bound) and the free energy of association for a variety of ligands.[14,15] Table 1 lists the chemical shifts of $w_2$, $w_3$ and $w_4$ of eremomycin and chloroeremomycin when free and when fully bound to acetate. For both antibiotics, two signals are observed for each of these protons: one signal for each half of the asymmetric dimer. Each of these signals is time-averaged between the bound and free state, as acetate binding is in fast exchange on the NMR time scale. As a result, they move gradually downfield during titration of acetate into the antibiotic, reflecting the proportion of the antibiotic bound by acetate at a particular ligand concentration. Thus, the chemical shift of each of these protons is analogous to the change in absorbance measured by UV difference spectrophotometry, and a binding

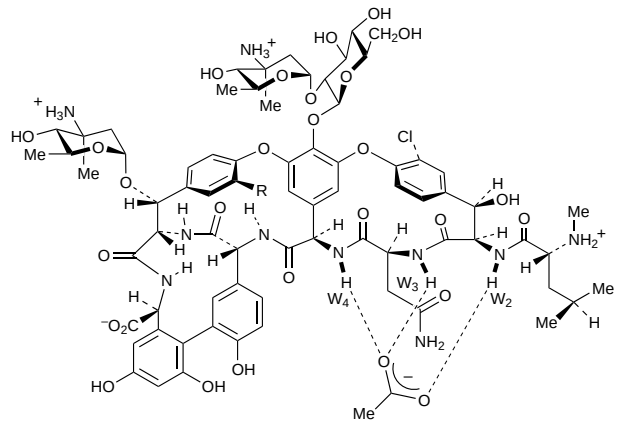

**Fig. 1** Structures of the antibiotics eremomycin (R = H) and chloroeremomycin (R = Cl) binding to acetate. The three amide protons mentioned in the text, $w_2$, $w_3$ and $w_4$, are labelled. Hydrogen bonds to acetate are shown by dashed lines.

**Table 1** Chemical shifts of amide protons in the antibiotic binding pocket when free and when fully bound to acetate. The protons from each half of the dimer are distinguished by the presence or absence of an asterisk (*). All values are in ppm relative to internal trimethylsilyl propionate (TSP, δ = 0)

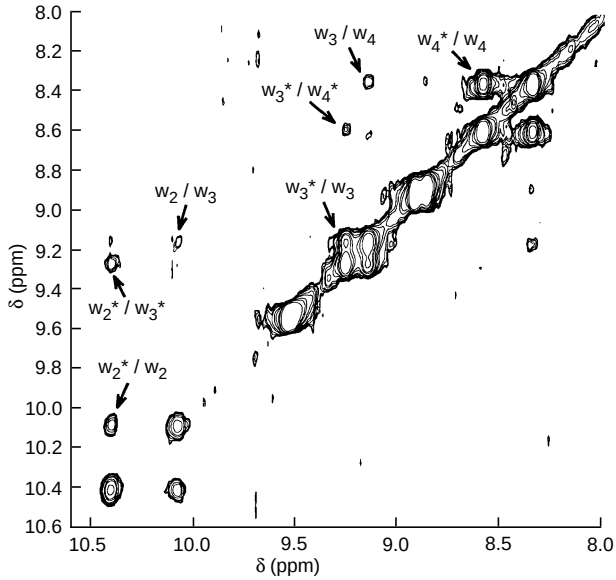

**Fig. 2** Portion of the 50 ms NOESY spectrum of eremomycin fully bound to acetate. Labelled are NOE cross peaks between adjacent protons in the same binding pocket and chemical exchange cross peaks between equivalent protons in each half of the dimer. These confirm the assignments of the separate peaks to a particular half of the dimer.

constant can be calculated from the titration curves using a least-squares curve fitting procedure.[16]

Table 2 shows the binding constants measured from these curves. A two-dimensional NOESY spectrum with a mixing time of 50 ms was used to confirm the assignments of the protons in each of the binding pockets. Due to the short mixing time, the extent of chemical exchange was low and thus strong NOE cross peaks were only observed between signals from protons within the same binding pocket (Fig. 2).

There are two points of note. Firstly, the binding affinities of acetate to chloroeremomycin are greater than those to eremomycin. This is similar to previously measured binding constants which also show ligand affinities for chloroeremomycin which are greater than those for eremomycin.[5] Secondly, for both antibiotics the binding constant for one half of the dimer is greater than that to the other half; by a factor in the region of 1.7–2.8 in the case of eremomycin, and by a factor in the region of 1.2–1.9 in the case of chloroeremomycin.

The resonance of $w_2$ can also be used to demonstrate the very useful correlation between limiting chemical shift and free energy of binding mentioned previously.[14,15] If points for $w_2$ and $w_2$* are added to such a curve for eremomycin, using the binding free energies measured in this study, it can be seen that both lie almost exactly on this curve (Fig. 3), *i.e.* the protons from the half of the dimer with the greater affinity for acetate are also further downfield. This emphasises the sensitivity of the correlation between binding affinity and limiting chemical shift of $w_2$ and how it may potentially be used to extract binding affinities from chemical shift data.

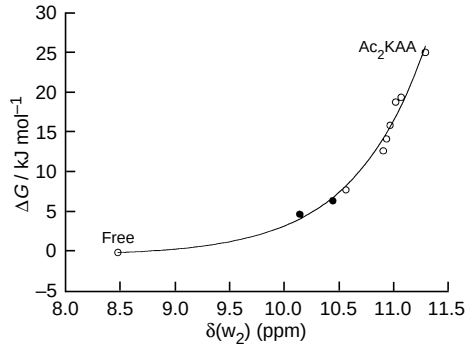

**Fig. 3** Plot of free energy of association against limiting chemical shift of $w_2$ for a variety of bacterial cell-wall precursor analogues binding to eremomycin. The two solid black points are those for $w_2$ and $w_2$* in the eremomycin/acetate complex, as determined in the present study.

We are grateful to SmithKline Beecham (UK) for donations of eremomycin and Eli Lilly (USA) for chloroeremomycin. B. B. thanks the EPSRC and Roussell for financial support.

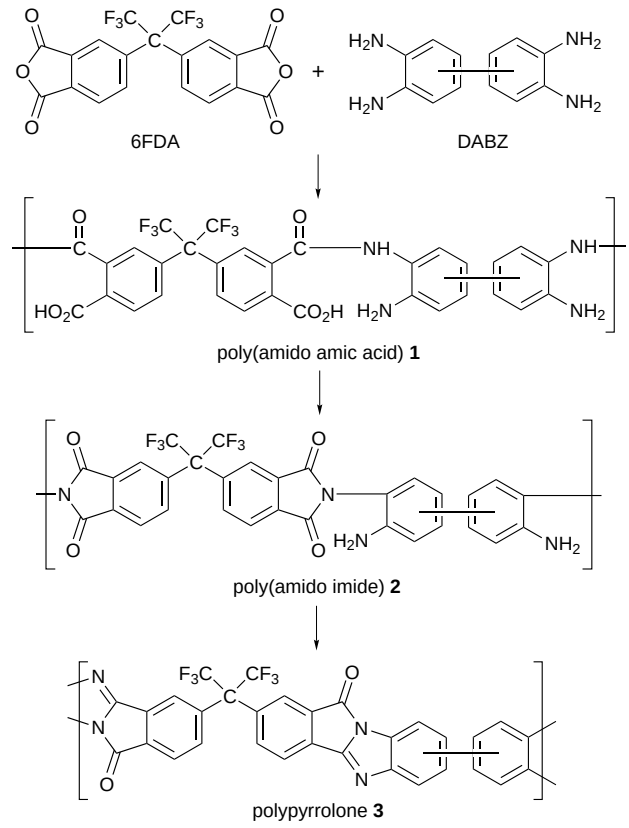
# Gas permselectivity of carbonized polypyrrolone membrane

**Hidetoshi Kita,* Makoto Yoshino, Kazuhiro Tanaka and Ken-ichi Okamoto**

*Department of Advanced Materials Science and Engineering, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube 755, Japan*



**Gas permeability and permselectivity through a polypyrrolone membrane is increased by heat treatment; the selectivity of the membrane carbonized at 700 °C was one or two orders of magnitude higher than that of presently available polymers.**

The development of membrane processes for the separation of gas mixtures has made remarkable progress during the last two decades and strong interest exists in the synthesis of membranes that exhibit both higher gas permeabilities and selectivities than presently available polymers.[1] The objective of recent works is therefore to create, in effect, a 'molecular sieve membrane'. Although carbon molecular sieves produced from the pyrolysis of polymeric materials have been studied extensively in adsorption applications, membrane application of carbon molecular sieves does not satisfactorily exhibit a 'molecular sieve effect' because the measured gas selectivities are very low, sometimes lower than those of the original polymer membranes, due to the presence of cracks or large pores causing gas leaks.[2,3] Here, we report gas permeability and permselectivity through a carbonized polypyrrolone membrane. Recently there have been several reports[4–7] that carbon molecular sieve membranes produced from polyimide precursors have higher separation performance than those of conventional polymer membranes. Polypyrrolone is a step-ladder polymer with high thermal and chemical stability. Because of the rigidity of the main chain of polypyrrolone, intersegmental packing and segmental mobility should be inhibited, providing a precursor for a carbon membrane with higher gas permeability and permselectivity than polyimides.

Polypyrrolone was prepared by a two step synthesis (Scheme 1) as described previously.[8] First, poly(amidoamic acid) **1** was prepared from 3,3′,4,4′-diphenylhexafluoroisopropylidene tetracarboxylic dianhydride (6FDA) and 3,3′-diaminobenzidine (DABZ) in *N*,*N*-dimethylacetamide (DMAc) under nitrogen atmosphere at 0 °C. This prepolymer was cast from DMAc solution at a polymer concentration of 10wt% onto a glass plate. The orange-coloured film was taken off and thermally imidized at 150 °C for 12 h *in vacuo* to give the poly(amino imide) **2**. The intermediate poly(amino imide) was subjected to thermal cyclodehydration at 300 °C for 2 h or at 400 °C for 10 h *in vacuo* to give the polypyrrolone **3**. Polypyrrolone prepared in this way was insoluble and characterized by FTIR spectroscopy and elemental analysis.

Polypyrrolone membranes were heated up to 800 °C at a heating rate of 5–8 °C $min^{-1}$ under nitrogen atmosphere to give carbon membranes which were *ca*. 40–50 μm in thickness. Under nitrogen atmosphere, polypyrrolone exhibited excellent stability up to 500 °C, without weight loss from the membrane. Thermogravimetry was carried out in flowing He at a heating rate of 5 °C $min^{-1}$ up to 1000 °C and the evolved gases were simultaneously determined by mass spectroscopy. The gaseous products evolved include carbon monoxide, carbon dioxide, hydrogen fluoride and carbon tetrafluoride, with traces of ammonia and hydrogen cyanide. The total weight loss up to 800 °C was *ca*. 40%. The membrane rapidly degraded at about 650 °C when heated in air.

Permeability coefficients were measured by the vacuum time-lag method at 35 °C and 1 atm. Two different membranes prepared at each temperature were evaluated. For each membrane, measurements were made three times. The precision in permeability was estimated to be within ±10%. Table 1 shows typical examples of the gas permeability and permselectivity of carbonized polypyrrolone **3** together with the corresponding polyimide **2** and polypyrrolone precursors and the membranes from polyimide precursors.[4–7] The gas permeability and permselectivity of polypyrrolone were larger than those of corresponding polyimide. Introduction of a ladder structure in the backbone chains of polyimide enhanced the gas permeability and maintained the permselectivity of gases, due to simultaneous inhibition of chain packing and intramolecular motion.[8] Furthermore, the permeability of polypyrrolone membranes carbonized at 500–700 °C was enhanced by two orders magnitude compared with the polypyrrolone precursor. The permeability decreased in proportion to the increasing kinetic molecular diameter of the penetrant gas and the permselectivity of the membranes was much higher than those reported in conventional polymeric materials,[1] indicating that the membrane behaves more like a 'molecular sieves'. On the other hand, raising the carbonizing temperature to 800 °C brought about a decrease of permeability and permselectivity. Heating time also affected the membrane performance. Increasing the heating time to 2 h brought about a slight increase of permeability and a sharp decrease of permselectivity. Thus,

**Scheme 1**

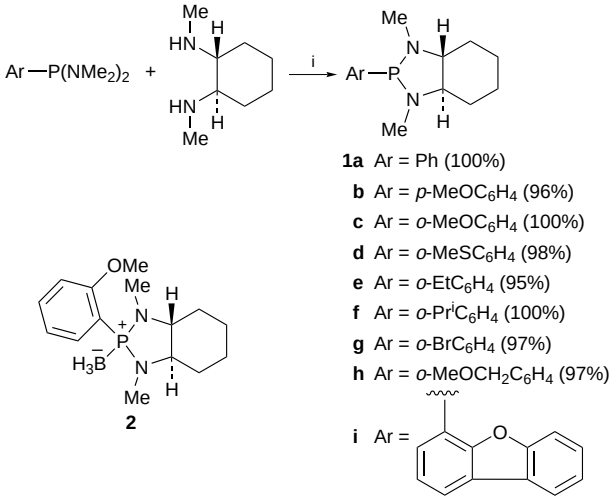
# Synthesis and applications of a new class of phosphorus donor ligands for asymmetric catalysis



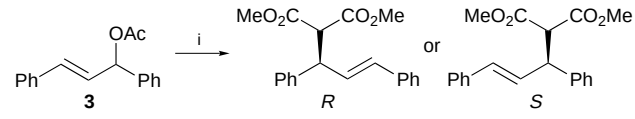
**Heather Tye,[a] Donald Smyth,[a] Colin Eldred[b] and Martin Wills*[a]**

[a] *Department of Chemistry, University of Warwick, Coventry, UK CV4 7AL*
[b] *Glaxo-Wellcome Research and Development Ltd, Glaxo-Wellcome Medicines Research Centre, Gunnels Wood Road, Stevenage, Hertfordshire, UK SG1 2NY*

**The synthesis and applications to allylic substitutions of a range of novel ligands based on diazaphospholidines is described; enantiomeric excesses of up to 89% were achieved in an allylic substitution reaction.**

Recent years have seen dramatic developments in asymmetric catalysis.[1] Allylic substitution reactions in particular have been the subject of attention from a number of research groups and several excellent ligands have been developed for this particular application.[2] Of these, diphosphines and combined phosphine–amine donors have proven to be especially well suited to the required role.[2] As part of an ongoing programme[3] directed at the development of a range of phosphorus donor ligands with a wide range of applications to asymmetric synthesis, we wished to investigate diazaphospholidines **1** in this capacity. We anticipated that such ligands would benefit from a high level of conformational rigidity and would project a suitable chiral environment within organometallic complexes of which they may form a part. Furthermore we were aware of the facile synthesis of such materials from the corresponding $C_2$ symmetric chiral diamines.[4] Although similar compounds have been reported to act as effective chiral shift reagents, we were unaware of any catalytic asymmetric transformations to which they had been applied.[5]

The preparation of a series of ligands was achieved following literature precedents (Scheme 1).[4] The bis(dimethylamino)phosphine precursors to **1a**, **1b**, **1c**, **1e**, **1h** and **1i** were formed by the reaction of the corresponding lithiated aromatic compound with preformed $(Me_2N)_2PCl$. The corresponding precursors for **1d** and **1f** could not be prepared by this method. However lithiation and transmetallation with zinc dichloride, followed by reaction with phosphorus tirchloride and subsequently treatment with an excess of dimethylamine furnished the required intermediates. The precursor to compound **1g** was synthesised following the published procedure of Drewelies and Latscha.[6] Each intermediate bis(dimethylamino)phosphine was heated under reflux with (*R*,*R*)-*N*,*N*′-dimethyl-1,2-diaminocyclohexane until no further dimethylamine could be detected in the nitrogen stream from the reaction. At this point solvent removal provided the pure ligands **1**. Although always handled under an inert atmosphere when in solution, each of the ligands proved to be resistant to atmospheric oxidation when in solid form. Treatment of **1c** with $BH_3{\cdot}SMe_2$ complex resulted in formation of a highly stable borane complex **2** which could be purified by chromatography. We have in previous work demonstrated that related borane complexes could be used as a source of protected ligand[3] (borane may be removed by an amine), however in the case of **2** all attempts to remove the borane resulted in decomposition.



**Scheme 1** *Reagents and conditions*: i, PhMe, heat, 8–24 h

We have applied the series of ligands thus produced to a number of asymmetric transformations. In particular the ligands appear to be particularly well disposed to the nucleophilic allylic substitution reaction of 1,3-diphenyl-3-acetoxyprop-1-ene **3**. In most cases the substitution reaction with dimethyl malonate (Scheme 2) gave good yields and, in the best cases, excellent asymmetric inductions (Table 1). A number of interesting trends become apparent upon analysis of the results. In particular a general improvement and reversal of selectivity is observed upon introduction of an *ortho* substituent. The level of electron density in the aromatic ring does not appear to influence the selectivity to any great extent (compare ligands **1a** and **1b**). Although the best results, 89 and 78% ee in favour of the *R* enantiomer, were achieved using the ligands **1c** and **1d**, the same product enantiomer was obtained using ligands which do not contain coordinating groups (*i.e.* **1e** and **1f**). This suggests that all may share a common mode for directing the asymmetric transformation. The importance of the size of the *ortho* substituent is also difficult to gauge since the ethyl and isopropyl substituted ligands **1e** and **1f** gave similar selectivities. We were unable to prepare the corresponding *tert*-butyl-substituted reagent.

At present there is insufficient evidence to determine the exact means by which asymmetric induction by the ligand is achieved. It would appear that whilst the introduction of an *ortho* substituent in the ligand is crucial to their success, the observation of similar results from coordinating and non-coordinating groups suggests that the ligand is probably only appended to the palladium through the phosphorus atom. If this is the case then their mechanism of action may have a parallel with the phosphine ligand MOP, which has been demonstrated to be effective for this application through the formation of a 1 : 1 phosphine–metal complex.[7]

Of significance is the *pseudo*-$C_2$ symmetry of the ligand and potential participation of a conformational rigidity conferred to

the nitrogen methyl groups by the adjacent chiral centre. Studies by others,[4,8] and our own X-ray crystal structure of the borane complex **2**[9] indicate that the nitrogen atoms are partially tetrahedral, the result of the methyl groups avoiding eclipsing interactions with the adjacent C–C bonds (Fig. 1). The X-ray crystal structure also reveals that the *ortho* substituent favours a position away from the heterocyclic ring (Fig. 1). This suggests that steric interactions may prevent a 180° rotation about the P–C(aryl) bond. This proposition is supported by our observation that 2,6-disubstituted aromatic ring diazaphospholidines failed to be formed using our general method (Scheme 1). If this conformational preference is maintained in the palladium complex then clearly this *ortho* group may be projected into the region of the appended allylic group, and thus provide a means to influence the reaction selectivity. Precisely how this effect is transferred to the asymmetric reaction, however, is at present unclear.

In an attempt to increase the observed selectivity we attempted some studies of diazaphospholidines bearing larger groups on the nitrogen atoms. The dibenzyl derivative of **1c** gave a product of 64% ee in 78% yield for the reaction depicted in Scheme 2. The diisopropyl ligand failed to form using our standard procedure, possibly due to steric hindrance.

Having identified **1c** as the best of the series of ligands, we have examined the use of nitrogen nucleophiles in the substitution reaction (Scheme 3, Table 2). The results obtained using benzylamine and sodium toluene-*p*-sulfonamide compared favourably to those previously reported using other ligands,[2,10] but were significantly lower (although in the same sense) than the selectivity achieved using dimethyl malonate as nucleophile. The presence of a chiral centre in the nucleophile

[a] Enantiomeric excess determined by chiral HPLC using a chiralcel OD column.

(α-methylbenzylamine of either configuration) appeared to have no effect on the enantioselectivity of the reaction or the sense of induction. Use of the cyclic amines pyrrolidine and *N*-benzylpiperazine as nucleophiles resulted in the formation of novel allylic amines **4e** and **4f** respectively, in excellent yields but reduced enantioselectivities.

In conclusion a novel class of diazaphospholidine ligands has been synthesised and their application to palladium-catalysed allylic substitution has been demonstrated. Ongoing work is directed towards the synthesis of improved ligands based on this class for a variety of transition metal-catalysed asymmetric transformations.

We thank the EPSRC and Glaxo-Wellcome Research and Development for support of an Industrial CASE studentship (to H. T.) and Dr J. Ballantine of the EPSRC National Mass Spectroscopic service (Swansea) for HRMS analysis of certain compounds.

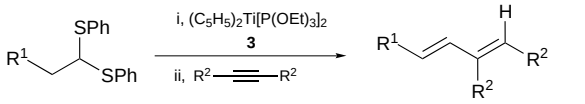
# Titanocene(II)-promoted reaction of thioacetals with alkynes: highly stereoselective preparation of conjugated dienes



**Takeshi Takeda,* Hirohisa Shimokawa, Yoshinaga Miyachi and Tooru Fujiwara**

*Department of Applied Chemistry, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184, Japan*

**The reaction of organotitanium species, prepared by the desulfurizative titanation of thioacetals using $(C_5H_5)_2Ti[P(OEt)_3]_2$, with alkynes gives conjugated dienes in good yields with high stereoselectivity.**

Titanacyclobutene **1** is a useful intermediate for the synthesis of homoallyl alcohols,[1] β,γ-unsaturated ketones,[1,2] conjugated dienes[3] and substituted pyridines.[2] The titanium species **1** is generally prepared by the reaction of Tebbe reagent $[(C_5H_5)_2Ti\text{-}CH_2\cdot AlMe_2Cl]$ or dimethyltitanocene with an alkyne,[4,5] which is believed to proceed *via* methylidenetitanocene. Recently we have shown that the treatment of β,γ-unsaturated thioacetals or their analogues with titanocene(II)–alkene complexes produces vinylcyclopropanes.[6] Olefination of a variety of carbonyl compounds also proceeds using the organotitanium species formed from thioacetals **2** and the alkene-free titanocene(II), $(C_5H_5)_2Ti[P(OEt)_3]_2$ **3**.[7] Since we assumed that the intermediate of these reactions was alkylidenetitanocene **4**, we have also studied the formation of titanacyclobutene **1** by the treatment of the organotitanium intermediate **4** with an alkyne **5**.

It was found that the reaction of hydrocinnamaldehyde diphenyl thioacetal **2a** with **3** at room temperature for 3 h followed by treatment with oct-4-yne **5c** for 20 h gave 1-phenyl-4-propylocta-2,4-diene **6c** in 72% yield. The reaction proceeded with high stereoselectivity and the 2*E*,4*E* isomer was produced with 99% selectivity (Scheme 1).† The use of higher reaction temperature reduced the reaction time (Table 1, entry 3).‡ Similar reactions of several thioacetals **2** with alkynes **5** afforded the corresponding conjugated dienes **6** in good yields.

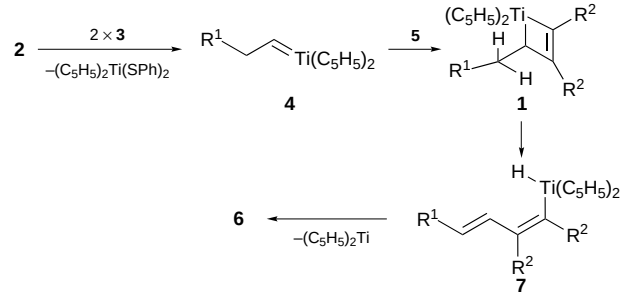
**2a** $R^1$ = Bn
**b** $R^1$ = $C_6H_{13}$
**c** $R^1$ = $Pr^i$

**5a** $R^2$ = Me
**b** $R^2$ = Et
**c** $R^2$ = Pr
**d** $R^2$ = Ph

**6a** $R^1$ = Bn, $R^2$ = Me
**b** $R^1$ = Bn, $R^2$ = Et
**c** $R^1$ = Bn, $R^2$ = Pr
**d** $R^1$ = $C_6H_{13}$, $R^2$ = Pr
**e** $R^1$ = $Pr^i$, $R^2$ = Pr
**f** $R^1$ = $Pr^i$, $R^2$ = Ph

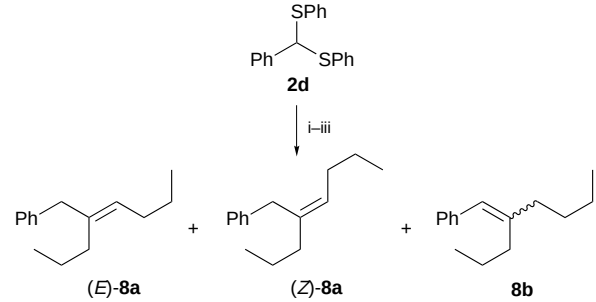
**Scheme 1**

**Table 1** The reaction of thioacetals **2** with alkynes **5**



| Entry | 2 | 5 | 6 (% yield)[a] | E : Z[b] |
|---|---|---|---|---|
| 1[c] | **2a** | **5a** | **6a** (72[d]) | 98 : 2 |
| 2 | **2a** | **5b** | **6b** (71) | 99 : 1 |
| 3 | **2a** | **5c** | **6c** (80) | 99 : 1 |
| 4 | **2b** | **5c** | **6d** (72) | 99 : 1 |
| 5 | **2c** | **5c** | **6e** (76) | 100 : 0 |
| 6 | **2c** | **5d** | **6f** (50) | 2 : 98 |

[a] Isolated yields based on quantity of **5** used. [b] The configuration of trisubstituted double bond. As for the disubstituted double bond, only the *E* isomers were produced. [c] The reaction was carried out using 1.2 equiv. of **5a**. [d] Isolated yield based on quantity of **2a** used.



When an unsymmetrical alkyne was employed, the reaction proceeded with mixed regioselectivity. For example, 3-pentylundeca-2,4-diene and 7-methylpentadeca-6,8-diene were formed in 69% total yield by the reaction of oct-2-yne with **2b** carried out at room temperature for 20 h. The ratio of the two regioisomers was found to be 57 : 43, respectively.

The stereoselective formation of conjugated dienes **6** is explained by the reaction pathway depicted in Scheme 2. As would be expected, the reaction of alkylidenetitanocene **4**, formed by the desulfurizative titanation of thioacetal **2**, with an alkyne **5** produces the titanacyclobutene intermediate **1**. Then β-hydride elimination proceeds to afford the vinyltitanium species **7**. Subsequent reductive elimination gives the diene **6** with retention of configuration of the trisubstituted double bond. This reaction pathway was substantiated by the fact that the reaction of benzaldehyde diphenyl thioacetal **2d** with **5c** gave the structurally isomeric alkenes **8a** and **8b** [(*E*)-**8a**: (*Z*)-**8a**: **8b** = 81 : 1 : 18] in 58% yield (Scheme 3). It is reasonable to assume that these alkenes are formed by protonation of the intermediate titanacyclobutene **1**.

Preparation of higher homologues of methylidenetitanocene *via* titanium–aluminium metallacycles was not successful, owing to decomposition by β-hydride elimination.[8] Although it has been suggested that the alkylidenetitanocenes are produced by thermolysis of dibenzyl-,[9] bis[(trimethylsilyl)methyl]-,[10] dicyclopropyl-,[11] dialkenyl-[5b,d] and alkylalkenyl-titanocene,[5d,12] the formation of simple alkylidene complexes from dialkyltitanocene is improbable because of the preferential formation of titanocene(II)–alkene complexes.[13] The present

**Scheme 2**

**Scheme 3** *Reagents and conditions*: i, **3**, room temp., 10 min; ii, **5c**, room temp., 20 h; iii, 1 M NaOH

work is the first example of formation of titanacyclobutene **1** from an alkylidenetitanocene possessing a β-hydrogen bonded to an $sp^3$ carbon atom and shows that **1** thus formed easily decomposes by β-hydride elimination. In conclusion, the titanocene-promoted reaction of thioacetals with alkynes is an excellent method for the stereoselective preparation of conjugated dienes. Further aspects of this reaction will be reported in due course.

† The configuration of **6** was determined by a NOE experiment.

‡ *Typical experimental procedure*: to a flask charged with finely powdered molecular sieves 4 Å (150 mg), magnesium turnings (1.8 mmol) and titanocene dichloride (1.5 mmol) were added THF (4 ml) and triethyl phosphite (3 mmol) successively with stirring. After 3 h, a THF (2 ml) solution of **2** (0.6 mmol) was added and stirring was continued for 10 min. Then **5** (0.5 mmol) in THF (1 ml) was added dropwise over 15 min. After being refluxed for 3 h, the reaction was quenched with 1 M NaOH, and the insoluble materials were filtered off through Celite. The organic materials were extracted with diethyl ether, dried ($Na_2SO_4$) and concentrated. Purification was accomplished by PTLC providing **6** as a clear, colourless oil.

# Rational approach to the synthesis of meso–meso (5,5′) linked bis-porphyrins

**Richard G. Khoury, Laurent Jaquinod and Kevin M. Smith***

*Department of Chemistry, University of California, Davis, CA 95616, USA*

**A novel approach for the synthesis of 5,5′-directly linked metal-free bis-porphyrins is reported; McMurry type coupling of dipyrroketones (*e.g.* 1) leads to 1,1,2,2-tetra(2-pyrrolyl)ethene 2, which after tetra-formylation (to give 3) and MacDonald macrocyclization with a 1,9-di-unsubstituted dihydrodipyrrin 4, affords the 5,5′-bis-porphyrin 5.**

Publications of structural data on bacterial photosynethetic reaction centres[1] have encouraged interest in the synthesis of oligoporphyrin systems which can act as mimics of reaction centres and antenna systems in photosynthetic bacteria and plants.[2,3] Many porphyrin arrays, including dimers and trimers, have been synthesized for this purpose, and for use in supramolecular photonics.[4] Distance, geometry and orientation have been recognized as important factors for control of the efficiency of energy and electron transfer processes.[5,6] Electronic interaction between porphyrin rings is essential and for this reason we set out to design a number of porphyrin oligomers in which the individual π-systems can interact. A number of dimeric porphyrin arrays, with various spacers, have been synthesized.[7] We surmised that a bis-porphyrin system possessing a direct meso–meso (5,5′) link would be potentially interesting. In the recent publication of Segawa and coworkers[8a] an attempt to prepare a trimeric porphyrin system resulted in serendipitous formation of a bis-porphyrin linked by a single bond between meso positions; this report has caused us to report our rational synthetic approach to this type of bis-porphyrin. After submission of the present paper an additional report of the synthesis of meso–meso bisporphyrins, *via* oxidative coupling of a zinc(II) porphyrin, appeared.[8b]

**Scheme 1**

2,2′-Dipyrroketone[9] **1** was coupled under McMurry conditions[10,11] in the presence of pyridine at room temperature to afford a 56% yield of the 1,1,2,2-tetra(2-pyrrolyl)ethene **2** (Scheme 1).[12]† As observed with simpler 1,2-di(2-pyrrolyl)-ethenes,[13,14] compound **2** was highly fluorescent. In the solid state the 1,1,2,2-tetra(2-pyrrolyl)ethene was stable, but in solution slow decomposition was observed. The molecular structure of **2**‡ was confirmed by X-ray crystallography (Fig. 1).

Attempted MacDonald-type ('2 + 2') macrocyclization of the tetrapyrrolylethene **2** with 1,9-diformyl-2,3,7,8-tetraethyldihydrodipyrrin led to a mixture of products. But tetraformylation of **2** using excess $POCl_3$–DMF, followed by treatment with $K_2CO_3$, afforded the tetra[5-formyl-2-pyrrolyl]ethene **3**§ in 92% yield. Condensation of **3** with 2 equiv. of 2,3,7,8-tetraethyldihydrodipyrrin **4**, followed by oxidation with DDQ and filtration through a plug of silica gel, led to the symmetrical 5,5′-bis-porphyrin **5**¶ in 7% yield. The molecular structure of **5**‡ was confirmed by X-ray crystallography [Fig. 2(*a*)]. Each porphyrin subunit is fairly planar, exhibiting a mean plane

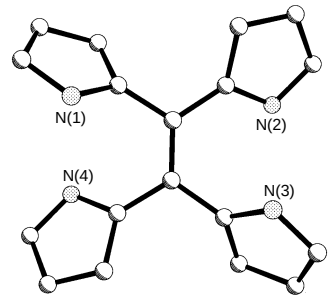

**Fig. 1** Molecular structure of the 1,1,2,2-tetra(2-pyrrolyl)ethene **2**. Hydrogen atoms have been omitted for clarity.

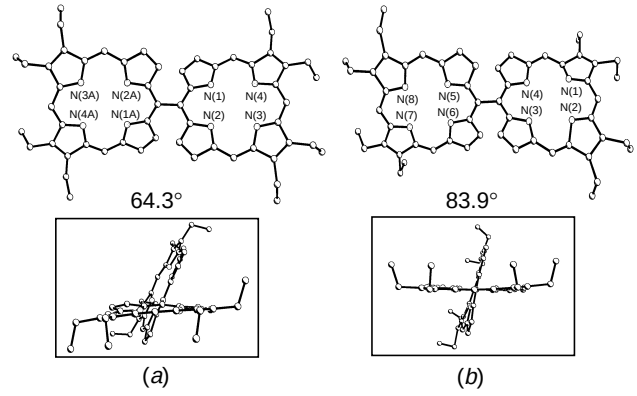

**Fig. 2** Molecular structure of the 5,5′-bis-porphyrin **5**. (*a*) The form crystallized from THF–hexane. (*b*) The form crystallized from dichloromethane–methanol. The boxes beneath each structure show side views along the 5,5′-bond. Hydrogen atoms have been omitted for clarity.

deviation of 0.10 Å from the 24 core atoms. A covalent single bond (1.51 Å) links both porphyrin subunits at the meso position. The angle between both porphyrin planes is 65°, and this is almost certainly a feature of lattice packing. When **5** was crystallized from a different solvent system, a second crystal structure‡ was obtained [Fig. 2(*b*)]; this showed the angle between both macrocyclic planes to be 83.9°.

Further work is aimed at synthesis of unsymmetrically substituted 5,5′-bis-porphyrin systems, and higher oligomers.

This work was supported by grants from the National Science Foundation (CHE-96-23117) and the National Institutes of Health (HL-22252). Mass spectrometric analyses were performed by the University of California, San Francisco, Mass Spectrometry Facility (A. L. Burlingame, Director) supported by the Biomedical Research Technology Program of the National Center of Research Resources, NIH NCRR BRTP 01614.

† *Selected data* for **2**: Mp 180–182 °C UV–VIS $\lambda_{max}$ ($CH_2Cl_2$) 302 nm (ε 9200), 364 (15 800); $\delta_H$ (300 MHz, $CDCl_3$) 6.07 (m, 4 H, β-H), 6.18 (d, 4 H, β-H), 6.69 (d, 4 H, β-H), 7.93 (s, 4 H, NH). HRMS $C_{18}H_{16}N_4$ requires: *m/z* 288.1374, found: 288.1378.

‡ *Crystal data*: The structures were solved by direct methods and refined (based on $F^2$ using all independent data) by full matrix least-squares methods (Siemens SHELXTL V. 5.02). Hydrogen atom positions were located by their idealized geometry and refined using a riding model. For each structure an absorption correction was applied using XABS2.[15] For **2** ($C_{18}H_{16}N_4$): X-ray diffraction data were collected on a Siemens $P2_1$ diffractometer with a fine-focus sealed tube [λ(Cu Kα) = 1.54178 Å] at 130(2) K in θ/2θ scan mode to $2\theta_{max}$ = 112°. Crystals were grown from a mixture of dichloromethane and cyclohexane. A single parallelipeped crystal was selected with dimensions 0.40 × 0.12 × 0.10 mm. The unit cell was triclinic and space group $P\bar{1}$ with cell dimensions: $a$ = 8.231(2), $b$ = 9.335(2), $c$ = 9.671(2) Å, α = 98.64(3), β = 103.22(3), γ = 93.22(3)°, $V$ = 712.0(2) Å$^3$ and $Z$ = 2 (FW = 288.35, $\rho_{calc}$ = 1.345 g cm$^{-3}$, μ = 0.652 mm$^{-1}$). Of 1948 reflections measured (±*h*, ±*k*, +*l*) 1923 were independent and 1431 had $I > 2\sigma$ ($R_{int}$ = 0.012); number of parameters = 199. Final $R$ factors were $R1$ = 0.0524 (based on observed data) and $wR2$ = 0.1304 (based on all data). For **5**: X-ray diffraction data were collected on a Siemens P4 rotating anode diffractometer with a fine-focus sealed tube [λ(Cu Kα) = 1.54178 Å] at 130(2) K in θ/2θ scan mode to $2\theta_{max}$ = 113°. First structure [Fig. 2(*a*)]; single crystals of **5** ($C_{56}H_{58}N_8{\cdot}C_4H_8O{\cdot}1.5H_2O$) were grown from a mixture of THF and hexane. A single pyramidal crystal was selected with dimensions 0.18 × 0.12 × 0.10 mm. The unit cell was monoclinic $C2/c$ with cell dimensions: $a$ = 26.068(6), $b$ = 17.644(3), $c$ = 13.842(3) Å, β = 115.99(2)°, $V$ = 5723(2) Å$^3$, and $Z$ = 4 (FW = 987.25, $\rho_{calc}$ = 0.587 g cm$^{-3}$, μ = 0.555 mm$^{-1}$). Of 4086 reflections measured (±*h*, +*k*, +*l*) 3783 were independent and 2594 had $I > 2\sigma$ ($R_{int}$ = 0.117); number of parameters = 343. Final $R$ factors were $R1$ = 0.0921 (based on observed data) and $wR2$ = 0.3064 (based on all data). Second structure [Fig. 2(*b*)]: Crystals of **5** ($C_{56}H_{58}N_8$) were grown from a mixture of dichloromethane and methanol. A single parallelipeped crystal was selected with dimensions 0.34 × 0.14 × 0.06 mm. The unit cell was triclinic and space group $P\bar{1}$ with cell dimensions $a$ = 8.4926(14), $b$ = 12.859(2), $c$ = 21.648(3) Å, α = 96.469(11), β = 97.470(12), γ = 101.096(12)°, $V$ = 2277(6) Å$^3$ and $Z$ = 2 (FW = 843.10, $\rho_{calc}$ = 1.230 g cm$^{-3}$, μ = 0.567 mm$^{-1}$). Of 6700 reflections measured (±*h*, ±*k*, +*l*) 6006 were independent and 4430 had $I > 2\sigma$ ($R_{int}$ = 0.034); number of parameters = 199. Final $R$ factors were $R1$ = 0.0601 (based on observed data) and $wR2$ = 0.1745 (based on all data). Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1. Any request to the CCDC for this material should quote the full literature citation and the reference number 183/433.

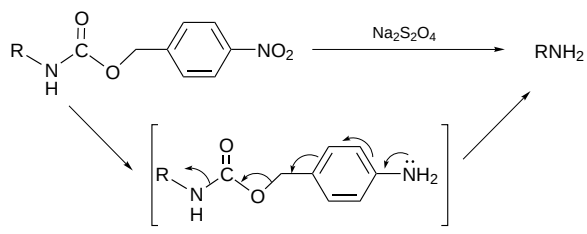
# Use of the *p*-nitrobenzyloxycarbonyl group as an orthogonal amine protecting group in the synthesis of β-GlcNAc terminating glycosides

**Xiangping Qian and Ole Hindsgaul***

*Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2*



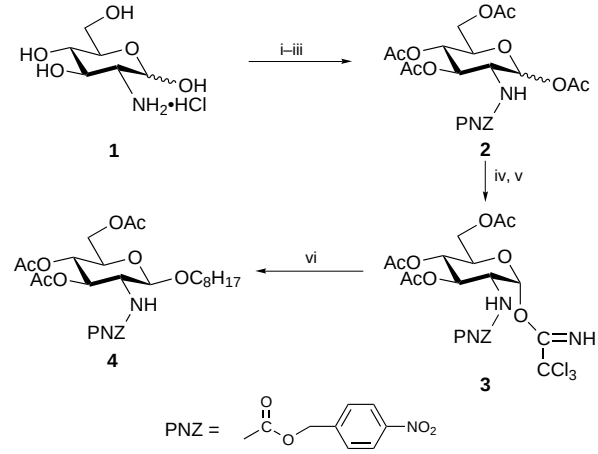
**The *p*-nitrobenzyloxycarbonyl group serves as a participating group in the stereoselective formation of 2-amino-β-glucosides and as an N-protecting group which can be readily removed either by hydrogenolysis or by reaction with sodium dithionite under neutral conditions.**

β-D-Glycosides of *N*-acetyl-2-amino-2-deoxy sugars are widely distributed in living organisms where they constitute building blocks of glycoconjugates.[1] The synthesis of such glycosides requires glycosyl donors where the amino group is protected. The phthalimido (Phth) and azido groups have been the most widely used.[2,3]

More recently, the carbamate functionality has been used for protection of the amino group in peptide, protein and carbohydrate synthesis.[4–7] Boullanger *et al*. conducted a systematic study on the glycosylation of simple acceptor alcohols with various *N*-alkoxycarbonyl derivatives of glucosamine, including the *p*-nitrobenzyloxycarbonyl (PNZ) group.[8] It was found that β-glycosides were obtained stereoselectively in good yield without the formation of an oxazolidinone when the β-acetate of these carbamate derivatives was used as glycosyl donor in the presence of a Lewis acid. The 2,2,2-trichloroethyl and allyl carbamates have since been effectively applied in the synthesis of glycoconjugates containing 2-acetamido glycosides.[7,9] These can be deprotected with zinc dust in acetic acid[7] and with $Pd^0$ complexes,[9] respectively.

We chose to investigate the potential of the *p*-nitrobenzyl carbamates of 2-amino sugars since this group should be selectively cleavable by the reduction of the electron-withdrawing nitro group to the electron-donating amine substituent followed by 1,6-elimination[4] (Scheme 1). As there are many methods for reducing the aromatic nitro group, mild and chemoselective deprotection methods should be readily available. Furthermore, unlike the 2,2,2-trichloroethyl or allyl carbamates, the *p*-nitrobenzyl carbamate can be removed by hydrogenolysis at the end of a synthesis along with the standard *O*-benzyl protecting groups.

As shown in Scheme 2, treatment of glucosamine hydrochloride **1** with 1 equiv. of NaOMe in MeOH, followed by *p*-nitrobenzyl chloroformate–$Et_3N$ and *O*-acetylation gave **2**. The trichloroacetimidate **3**† was formed by regioselective deacetylation at O-1 with benzylamine followed by treatment of the reducing sugar with $CCl_3CN$ in the presence of $K_2CO_3$.[10] Imidate **3** was evaluated as a glycosyl donor in $CH_2Cl_2$ using $BF_3{\cdot}Et_2O$ as a promoter.‡§ The octyl β-glycoside **4** was formed in 82% yield.¶ Glycosylation of **5** gave the β-(1 → 6) linked disaccharide **6** in 91% yield (Scheme 3).†,¶ The reaction of **3** with the less reactive 4-OH groups of **10** and **11** also gave β-(1 → 4) linked disaccharides **12**† and **13** in good yields (79 and 75%,¶ respectively) (Scheme 4). These results indicate that the combination of the PNZ moiety with anomeric trichloroacetimidate activation can afford β-glycosides in high yield with high stereoselectivity.

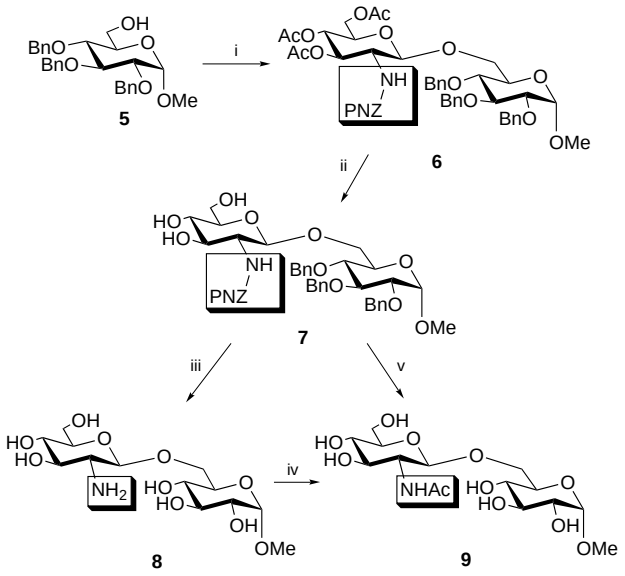


**Scheme 1**

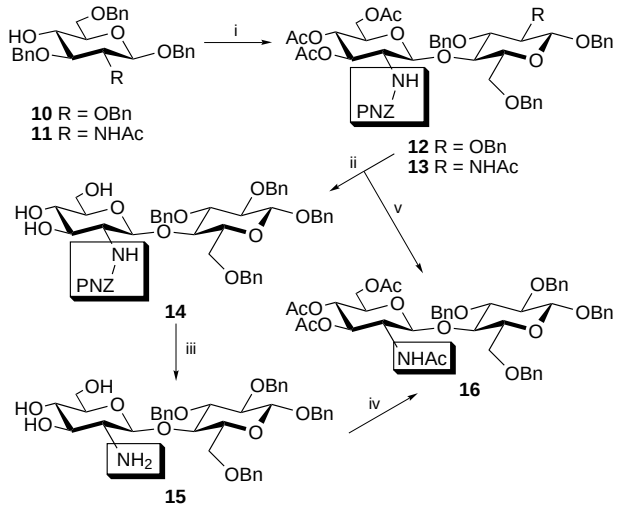
A major disadvantage of using the *N*-phthalimido group in oligosaccharide synthesis is that its deprotection requires vigorous conditions, and esters usually do not survive.[11] Recently, the more reactive tetrachlorophthaloyl (TCP) group was applied as an amine protecting group.[12,13] The TCP group can be removed under milder conditions than the Phth group, either by a slight excess of ethylenediamine at 60 °C or by $NaBH_4$ reduction. Although the extent of cleavage of carboxylate ester groups is significantly reduced under these conditions, yields are still moderate especially in the presence of 3-OAc and 6-OAc groups when using ethylenediamine.[12*b*] Ketone or aldehyde functionalities may also be reduced by $NaBH_4$ during the removal of the TCP group. Clearly, chemoselective removal of the PNZ group under conditions where esters are inert would enhance its utility.

Methods for the removal of the PNZ group were examined using the simple glycoside **4** as a model compound. Removal of the PNZ group and acetylation of the resulting amine can be directly achieved in one step by hydrogenolysis using 10% Pd–C under $H_2$ flow in the presence of $Ac_2O$, yielding **9** in 83% yield.¶ As shown in Scheme 3, the free amine **8** could also be isolated (76%¶) when the hydrogenolysis was performed in the absence of $Ac_2O$.

Attempted reduction with stannous chloride[14] in non-acidic and non-aqueous media (EtOH or EtOAc) was ineffective. *p*-Nitrobenzyl esters can, however, be reductively cleaved by sodium dithionite ($Na_2S_2O_4$) under neutral or slightly alkaline conditions.[15] We found that sodium dithionite was a very



**Scheme 2** *Reagents and conditions*: i, NaOMe (1 equiv.), MeOH, 10 min; ii, *p*-nitrobenzyl chloroformate (1 equiv.), $Et_3N$ (1 equiv.), 0 °C to room temp; iii, $Ac_2O$, pyridine, 16 h, 78% (3 steps); iv, $BnNH_2$ (1.1 equiv.), THF, 16 h; v, $CCl_3CN$ (10 equiv.), $K_2CO_3$, $CH_2Cl_2$, 7 h, 75% (2 steps); vi, $BF_3{\cdot}Et_2O$ (0.5 equiv.), octanol (0.7 equiv.), 4 Å molecular sieves, $CH_2Cl_2$, −30 to 0 °C, 2 h, 82% (based on octanol)



effective reducing agent even in the absence of base. The PNZ group can be readily removed quickly in quantitative yield. As shown in Scheme 4, deacetylation of **12** using NaOMe in MeOH followed by cleavage of PNZ and re-acetylation with $Ac_2O$–pyridine gave **16**.† When disaccharide **12** was treated directly with sodium dithionite in MeCN–EtOH–$H_2O$ solution, followed by *N*-acetylation using $Ac_2O$ in MeOH, disaccharide **16** was obtained, demonstrating the stability of the three *O*-acetate groups to the reduction conditions. The free amine group can also be transformed into the acetamido group in 'one pot' by simply adding $Ac_2O$ directly to the reaction mixture. Disaccharide **16** was thus formed in a 'one pot' reaction in 86% yield.¶

In summary, we have demonstrated that the PNZ group functions as a good participating group for the formation of 2-amino-β-glucosides. This N-protecting group can be conveniently removed either by hydrogenolysis along with *O*-benzyl ethers or selectively by sodium dithionite under neutral conditions where carboxylate esters remain stable. Since *O*-acetyl groups can be removed by treatment with NaOMe–MeOH in the presence of the PNZ group, this group is effectively an orthogonal protecting group and should thus find unique application in oligosaccharide synthesis.

We gratefully acknowledge the Natural Sciences and Engineering Research Council of Canada for financial support and Drs J. C. McAuliffe and Z. G. Wang for helpful suggestions.

**Scheme 3** *Reagents and conditions*: i, $BF_3{\cdot}Et_2O$ (0.5 equiv.), **3** (1.5 equiv.), 4 Å molecular sieves, $CH_2Cl_2$, −30 to 0 °C, 2 h, 91%; ii, NaOMe, MeOH, 2.5 h, 93%; iii, $H_2$, 10% Pd–C, MeOH, 76%; iv, $Ac_2O$, EtOH, 1 h, 87%; v, $H_2$, 10% Pd–C, MeOH, $Ac_2O$, 83%

**Scheme 4** *Reagents and conditions*: i, $BF_3{\cdot}Et_2O$ (0.5 equiv.), **3** (1.5 equiv.), 4 Å molecular sieves, $CH_2Cl_2$, −30 to 0 °C, 2 h, 79% for **12**, 75% for **13**; ii, NaOMe, MeOH, 3.5 h, quant.; iii, $Na_2S_2O_4$ (8 equiv.), EtOH–$H_2O$, 10 min, quant.; iv, $Ac_2O$, pyridine, 16 h, 93%; v, $Na_2S_2O_4$ (8 equiv.), MeCN–EtOH–$H_2O$, 1 h; then $Ac_2O$, 10 min, 86%

† *Selected data* for **3**: $^1$H NMR ($CDCl_3$) δ 8.75 (s, 1 H, C=NH), 6.39 (d, 1 H, $J_{1,2}$ 3.6 Hz, H-1). For **6**: $J_{C1H1}$ 168.5 Hz, $J_{C1'H1'}$ 160.4 Hz; HR-ESMS for $C_{48}H_{54}N_2O_{17}Na$ (M + $Na^+$): calc. 953.3320, found 953.3348. For **12**: $J_{C1H1}$ 160.0 Hz, $J_{C1'H1'}$ 158.1 Hz; HR-ESMS for $C_{54}H_{58}N_2O_{17}Na$ (M + $Na^+$): calc. 1029.3633, found 1029.3634. For **15**: HR-ESMS for $C_{40}H_{47}NO_{10}Na$ (M + $Na^+$): calc. 724.3098, found 724.3119. For **16**: $^1$H NMR ($CDCl_3$) δ 4.55 (d, 1 H, $J_{1,2}$ 8.4 Hz, H-1), 4.45 (d, 1 H, $J_{1',2'}$ 7.6 Hz, H-1′); $J_{C1H1}$ 161.8 Hz, $J_{C1'H'}$ 159.2 Hz.

‡ Typical procedure of glycosylation: compound **3** (236 mg, 0.375 mmol), **5** (116 mg, 0.25 mmol) and powdered 4 Å molecular sieves (250 mg) in dry $CH_2Cl_2$ (5 ml) were stirred for 10 min at −30 °C under nitrogen. Then $BF_3{\cdot}Et_2O$ (15 μl, 0.125 mmol) in dry $CH_2Cl_2$ (0.75 ml) was added, and the reaction mixture was stirred for a further 2 h below 0 °C. After neutralization with $Et_3N$, the reaction mixture was filtered through Celite, washed with $CH_2Cl_2$ and concentrated. Column chromatography (3 : 2, hexane–EtOAc) gave disaccharide **6** (211 mg, 91%).

§ The $^1$H NMR spectra of most disaccharides containing the PNZ moiety gave broad peaks which make assignments difficult. The β-linkage of the disaccharides was confirmed by $^{13}$C–$^1$H HMQC experiments and NMR data for the *N*-acetyl disaccharide obtained by N-acetylation after the reductive cleavage step.

¶ Yields were calculated based on the weight of pure compounds isolated by column chromatography.

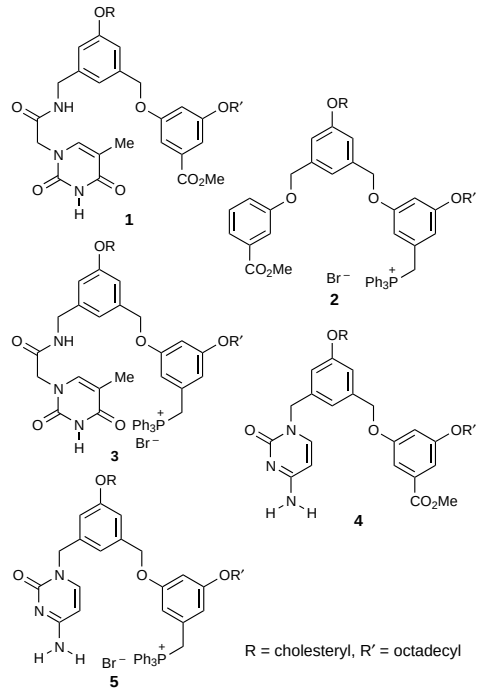
# Improved transport of nucleotide monophosphates by lipophilic phosphonium–nucleobase conjugates

**Yong-Gyu Jung, Woon-Seok Yeo, Sang Bok Lee and Jong-In Hong***

*Department of Chemistry, Seoul National University, Seoul 151-742, Korea*

**Lipophilic phosphonium–nucleobase conjugates 3 and 5 showed improved transport of AMP and GMP in comparison with lipophilic phosphonium salts, lipophilic complementary nucleobases, or a joint co-carrier system consisting of a lipophilic phosphonium salt and a nucleobase.**

Nucleotide analogues which have potential antiviral activity *in vitro* cannot penetrate across lipophilic cell membranes due to their highly charged and hydrophilic nature.[1] Therefore, there has been increasing effort towards developing phosphate-binding receptors.[2] However, there are a few artificial carrier systems known which are capable of transporting phosphate-bearing nucleotides through organic liquid membranes.[3] Recently, lipophilic phosphonium salts were developed as carriers for 5′-AMP (AMP) and 5′-GMP (GMP) in our laboratory.[4] They showed better transport rates for AMP and GMP compared with transport by the structurally similar, lipophilic trioctylmethylammonium chloride.[3c,5] In addition, moderate rate enhancements were observed when a phosphonium salt and a lipophilic nucleoside were used together as joint co-carriers. We expected that lipophilic phosphonium salts connected covalently to a complementary nucleobase would display better transport rates for AMP and GMP in comparison with a joint co-carrier system. Here we report improved extraction and transport of AMP and GMP by lipophilic phosphonium–nucleobase conjugates **3** and **5**.†



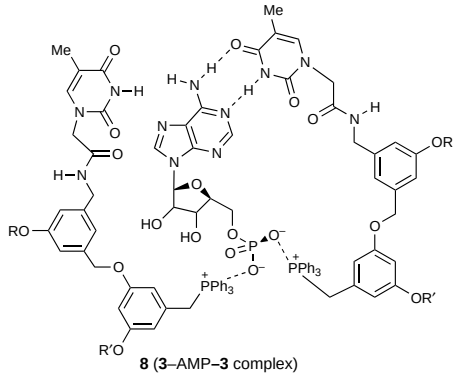


Table 1 shows extraction and transport data for AMP or GMP by lipophilic complementary nucleobases (**1** and **4**), a phosphonium salt (**2**) and phosphonium–nucleobase conjugates (**3** and **5**). There exist qualitative correlations between the extraction and the transport data. AMP (or GMP) is dissociated mostly into its monoanion ($AMP^-$ or $GMP^-$) at pH 5, while only one third of AMP (or GMP) exists as $AMP^-$ or $GMP^-$ at pH 7. As shown in Table 1, the phosphonium carrier (**2**) exhibits a better transport rate for AMP and GMP at pH 5 than at pH 7 for entropic reasons.[4]

The phosphonium carrier is expected to mediate more efficient through-membrane transport of AMP or GMP with the aid of base-pairing in either an inter- or intra-molecular fashion.[3e,h,i,6] Previously we used an organic-soluble nucleobase as a co-carrier to improve through-membrane transport of nucleotide monophosphates by a phosphonium cation.[4]‡ Either at pH 5 or 7, in the presence of lipophilic uridine or cytidine as a co-carrier, moderate rate enhancements were observed in the case of AMP or GMP transport, respectively. To make more effective and selective carriers for AMP or GMP compared to the joint co-carrier system would require the construction of phosphonium–nucleobase conjugates, in which an adenine or guanine recognition unit is appended directly onto the phosphate-binding phosphonium centre. Compounds **3** and **5** extract and transport AMP or GMP, respectively, more efficiently than **2**, presumably because of base-pairing of the complementary nucleobase moiety of **3** or **5** with the nucleobase of AMP or GMP. In fact, the thymine (or cytosine)-bearing phosphonium carrier **3** (or **5**) was found to be much more effective for AMP (or GMP) transport, either at pH 5 or 7. As shown in Table 1, the receptor **3** displayed a higher transport rate for AMP (by a factor of 39 at pH 5 and 157 at pH 7) than the thymine-free phosphonium salt **2**. In the case of GMP transport, the cytosine-substituted phosphonium receptor **5** showed a similar rate enhancement (by a factor of 66 at pH 5 and 103 at pH 7) in comparison with the cytosine-free phosphonium salt **2**. However, control experiments (**5**/AMP and **3**/GMP) employing noncomplementary nucleobase–phosphonium conjugates led to decreased transport of AMP and GMP, respectively, compared to the complementary nucleobase–phosphonium carrier systems (**3**/AMP and **5**/GMP). This clearly shows that selective

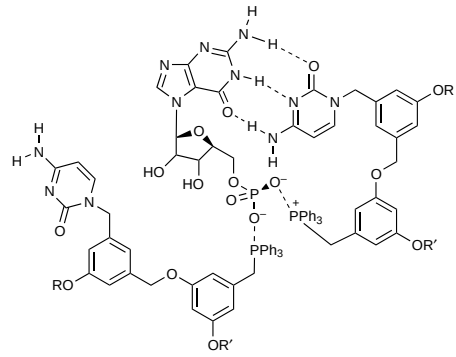

**Table 1** Extraction and transport of AMP and GMP by **1**–**5**

| | | Extraction (%)[a] | | Transport rate/ $10^{-9}$ mol $h^{-1}$ $cm^{-2}$[b] | |
|---|---|---|---|---|---|
| Carrier | Guest | pH 5.0 | pH 7.0 | pH 5.0 | pH 7.0 |
| **1** | AMP | [c] | [c] | [c] | [c] |
| **2** | AMP | 7.4 | 6.3 | 0.14 | 0.03 |
| **3** | AMP | 10 | 9 | 5.4 | 4.7 |
| **5** | AMP | 12 | 7 | 0.5[d] | 0.2 |
| **4** | GMP | 6 | 2 | [c] | [c] |
| **2** | GMP | 13 | 8 | 0.08 | 0.04 |

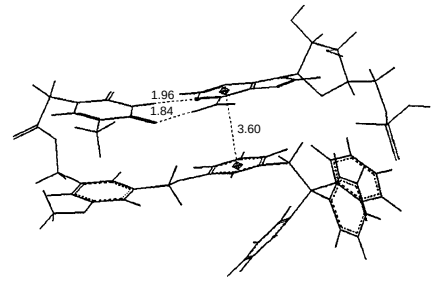
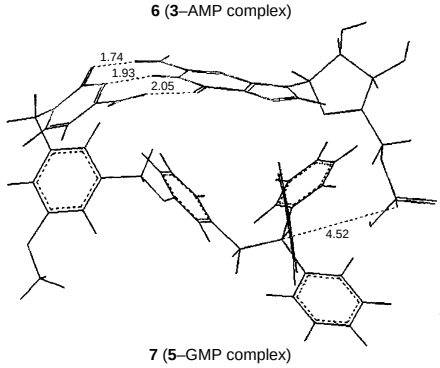
[a] [Carrier] = $1 \times 10^{-2}$ M in $CHCl_3$, [Guest] = $1 \times 10^{-4}$ M in deionized water. [b] Source phase: [AMP] (or [GMP]) = 0.05 M in $H_2O$. Receiving phase: [NaBr] = 0.025 M in $H_2O$. Organic phase: [carrier] = 0.001 M in $CHCl_3$. [c] Not detected. [d] No transport observed after 24 h.



**8** (**3**–AMP–**3** complex)



**9** (**5**–GMP–**5** complex)

R = cholesteryl, R′ = octadecyl

**Fig. 1** Possible structures for the transport complexes **8** and **9** at pH 7

**6** (**3**–AMP complex)

**7** (**5**–GMP complex)

**Fig. 2** Energy-minimized structures of the possible transport complexes **6** and **7** at pH 5 (DISCOVER 95.0 with CVFF force field)

base pairing contributes to increased transport. The fact that a phosphonium-free nucleobase **1** or **4** doesn't transport AMP or GMP at all indicates the importance of the phosphate group solubilization in $CHCl_3$ for transport of nucleotide monophosphates.

A concentration-dependent extraction study supports possible structures for the neutral supramolecular transport complexes between the phosphonium–nucleobase conjugate carriers (**3** or **5**) and nucleotide monophosphates, as depicted in Figs. 1 and 2. When aqueous solutions containing varying amounts of AMP (or GMP) were shaken with a chloroform solution of **3** or **5** ($1.0 \times 10^{-5}$ M), the maximum extractability of AMP (or GMP) was 105% (or 119%) at pH 5 and 54% (or 49%) at pH 7, respectively. This result supports the suggestion that **3** (or **5**) undergoes formation of a 1 : 1 complex (**3**–AMP or **5**–GMP) at pH 5 (Fig. 2) and a 2 : 1 complex (**3**–AMP–**3** or **5**–GMP–**5**) at pH 7 in the organic phase (Fig. 1). Since formation of the bimolecular complex **6** (or **7**) between **3** (or **5**) and the monobasic forms of AMP (or GMP) is entropically more favourable than that of the termolecular complex **8** (or **9**) between two molecules of **3** (or **5**) and the dibasic form of AMP (or GMP), **3** (or **5**) transports either AMP or GMP slightly more efficiently at pH 5 than at pH 7.

Computer-generated structures§ of the possible transport complexes **6** and **7** at pH 5 are shown in Fig. 2. While in the case of **6** hydrogen-bonding (base-pairing), electrostatic interactions, and aromatic stacking interactions are clearly visible, hydrogen-bonding and electrostatic interactions are shown to be operative in the case of **7**.

In summary, we have showed that the transport of normally organic-insoluble AMP or GMP can be improved by using appropriately designed lipophilic nucleobase-substituted phosphonium carriers.

We thank Ministry of Education (BSRI-96-3416), OCRC, and KOSEF (Grant No. 961-0302-008-2) for financial support.

† All new compounds gave satisfactory spectroscopic and analytical data.

‡ A joint co-carrier system showed a better transport rate than the phosphonium carrier, by a factor of 2–3, when an equimolar amount of the phosphonium salt and the nucleobase was used. Increasing the concentration of the co-carrier (nucleobase) led to better transport of the corresponding nucleotide monophosphate (ref. 4).

§ The energy-minimization (CVFF force field) with conjugate gradient algorithm was performed with DISCOVER 95.0 of MSI (1995) on a Silicon Graphics INDY workstation.

# Regioselective oxyfunctionalization of peptides by dimethyldioxirane: tertiary C–H σ-bond oxygen atom insertion into leucine derivatives and leucine-containing dipeptides

**Maurizio Mezzetti, Enrico Mincione* and Raffaele Saladino*†**

*Dipartimento Agrochimico Agrobiologico, Università degli studi di Viterbo 'La Tuscia', via San Camillo de Lellis, 01100 Viterbo, Italy*

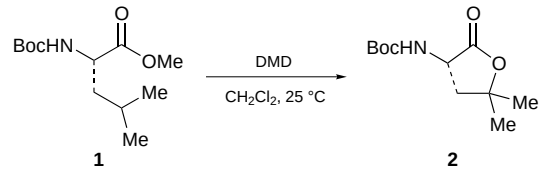
**A simple and straightforward approach to selective C–H σ-bond oxygen atom insertion into Leu residues on peptides using dimethyldioxirane is described; this procedure is compatible with Gly, Ala, Val, Ile and Phe residues.**

Proteins with altered functions can be prepared from existing molecules by genetic manipulations[1] or, particularly in the case of small peptides, by chemical methods, *via* side-chain alteration and backbone modifications. Several chemical methods for performing side-chain alterations have been reported. The tryptophan side-chain is efficiently transformed by $Ru^{VIII}$, generated *in situ* from $RuCl_3$ and $NaIO_4$, to that of aspartic acid.[2] A $Ru^{VIII}$ reagent has subsequently been used to oxidize 13 to the 20 coded α-amino acids[3] and for a novel protein backbone modification by C(α)–C side-chain scission.[4] Moreover, selective modification of serine- and threonine-containing peptides has been accomplished with lead tetraacetate to give α-acyloxyglycine derivatives, which can be easily transformed into α-alkylthio- and α-halogeno-glycines.[5] Recently, a simple approach to selective iodination of tyrosine residues on peptides using $IPy_2BF_4$ (Py = pyridine) has been described,[6] and preliminary studies revealed that the method might be also suitable for iodination of phenylalanine derivatives.

In spite of extensive work on side-chain transformations of aromatic, heterocyclic and heteroatom moieties in peptides, no general methods have been described for oxygen atom insertion into the C–H σ-bond present in the side-chain of α-amino acids, with the exception of the glycine-selective chemical modification by Nickel peroxide,[7] in which case a concomitant backbone modification was observed, probably because of the low reactivity generally shown by this bond.

A powerful and selective oxidant for this purpose,[8] which performs under strictly neutral conditions, is dimethyldioxirane (DMD). The advantages of dioxiranes, especially DMD, in synthetic chemistry have been well documented in alkene epoxidations, heteroatom oxidations and C–H σ-bond insertions. To the best of our knowledge, DMD has been used in the chemistry of α-amino acids and peptides to perform the oxidation of α-diazo ketones derived from α-amino acids,[9] and in the synthesis of enantiomerically pure N-protected β-amino-α-keto esters from α-amino acids and dipeptides.[10] In each case, the possible oxygen atom insertion into the side-chain was not observed. We report here a simple, selective and straightforward approach to the C–H σ-bond oxygen atom insertion into Leucine (Leu) and Leu-containing dipeptides.

The oxidation of Boc-Leu-OMe **1** (1 mmol) performed with a freshly prepared solution of DMD (0.09 mol $dm^{-3}$ acetone solution, 6.0 equiv.)[11] in $CH_2Cl_2$ (5 $cm^3$) at 25 °C for 3 days afforded the 4,4-dimethyl-4-butanolide derivative **2** as the only recovered product in 42% isolated yield (Scheme 1),‡ with some unreacted substrate. Compound **2** is probably formed by selective oxygen atom insertion into the tertiary C–H σ-bond of Leu followed by cyclization.



Some other protected α-amino acids bearing an alkyl side-chain (Boc-Gly-OMe, Boc-Ala-OMe, Boc-Val-OMe, Boc-Ile-OMe and Boc-Phe-OMe) were then studied. The reactions performed with DMD (0.09 mol $dm^{-3}$ acetone solution) in $CH_2Cl_2$ (5 $cm^3$) at 25 °C for 3 days did not give products in appreciable amounts, even in the presence of a large excess of DMD and after longer reaction times.

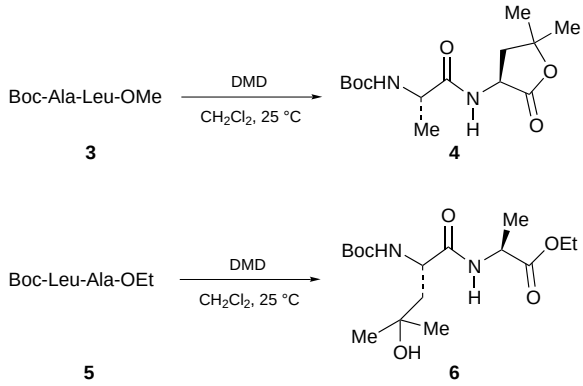
It is known that the DMD oxygen atom insertion into the C–H σ-bond shows a pronounced tertiary–secondary–primary selectivity.[8] Furthermore, this transformation is extremely sensitive to solvent[12] and stereoelectronic effects. In particular, a dipolar group close to the reactive centre may influence the reaction, favouring a chemo- and stereo-specific attack,[13] or preventing the oxidation.[14]

We can put forward only hypotheses to explain the unexpected stability of the valine substrate in the DMD oxidation. A rationalization based on simple electronic deactivation by the amino functionality on the more proximate tertiary C–H σ-bond with respect to leucine seems reasonable. This hypothesis is in accord with the recently reported procedure[15] for the selective oxyfunctionalization of unactivated C–H σ-bonds of alkylamines in acid medium by methyl(trifluoromethyl)dioxirane, in which the strong electron-withdrawing nature of the ammonium group deactivates the oxidation of even tertiary C–H σ-bonds at the α and β positions. In our case, the reaction appears to be operative only when a tertiary C–H σ-bond is in the remote C(γ) position with respect to the amino acid functionality.

The feasibility of transformation of **1** by DMD with respect to the other α-amino acids bearing an alkyl side-chain promped us to evaluate the possibility to obtain a chemo- and regio-selective modification of Leu-containing dipeptides. The oxidation of Boc-Ala-Leu-OMe **3** and Boc-Leu-Ala-OEt **5** with an excess of DMD in $CH_2Cl_2$ (5 $cm^3$) at 25 °C for 3 days afforded the butanolide derivate **4**§ and the peptide derivative 6¶ in 35 and 38% isolated yield, respectively, plus some unreacted substrates (Scheme 2). Compound **4**, which is obtained by selective modification of the Leu residue, may be formed by selective oxygen atom insertion into the tertiary bond present in the side-chain of Leu, followed by cyclization. On the other hand, the presence of a free alcoholic moiety in **6** (as shown by the OH group absorption at 3390 $cm^{-1}$ in the IR spectrum) suggests that, in this case, a spontaneous cyclization process is not operative. This hypothesis was further confirmed by the absence of a detectable amount of the butanolide derivative **2** in the reaction mixture.

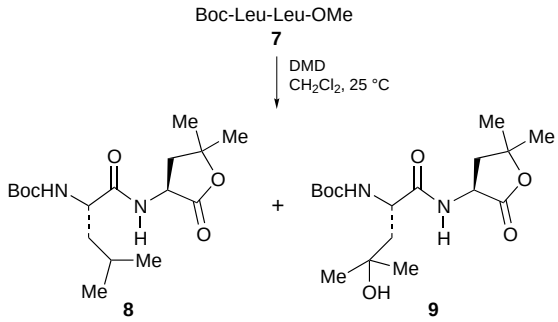
Finally, we studied the oxidation of the dipeptide Boc-Leu-Leu-OMe **7** by DMD under similar experimental conditions.[16]

**1** **2**



**Scheme 1**

The oxidation of **7** with DMD (0.09 mol $dm^{-3}$ acetone solution, 6.0 equiv.) in $CH_2Cl_2$ (5 $cm^3$) at 25 °C for 3 days afforded the butanolide derivative **8** in 33% isolated yield (Scheme 3).‖ Minor amounts of **9** were also formed, as shown by $^1H$ and $^{13}C$ NMR spectral analyses of the crude reaction mixture prior to purification.



These data show that the reactivity of the Leu residue towards DMD is extremely sensitive to the position (C/N-terminal position) of the residue into the peptide. In particular, C-terminal Leu appears to be more reactive than the N-terminal residue towards DMD. In this case, steric factors may operate, since dioxiranes are generally sensitive to steric hinderance,[8] even if electronic deactivation by the two amino acid functionalities of the Leu N-terminal residue cannot be ruled out.

The high selectivity observed for the Cγ–H σ-bond of Leu towards DMD offers a novel synthetic route to modified peptides without backbone modifications. Work is in progress in our laboratories to study the reactivity pattern of the other coded α-amino acids towards DMD oxidation, as well as to transform the newly introduced hydroxy moieties into other useful functionalities.
