(Received October 3, 2003; CL-030932)

Photoformed hole and electron on  $\text{TiO}_2$  adsorbing  $\text{NH}_3$  are trapped, respectively, by a  $\text{NH}_3$  species adsorbed on  $\text{TiO}_2$  and  $\text{Ti}^{4+}$  to evolve a  $\text{NH}_2$  radical and a  $\text{Ti}^{3+}$  species. The photoinduced electron transfer takes place between  $\text{Ti}^{4+}$  and adsorbed  $\text{NH}_3$  species efficiently, resulting in the formation of a  $\text{NH}_2$  radical. The  $\text{NH}_2$  radical on  $\text{TiO}_2$  was stably present after the photoirradiation was ceased. It is quenched rapidly just after introduction of  $\text{NO}$  leaving the  $\text{Ti}^{3+}$  species.

$\text{NO}_x$  exhausted from the stationary emission source is removed by the selective catalytic reduction process with  $\text{NH}_3$  ( $\text{NH}_3$ -SCR) over  $\text{V}_2\text{O}_5/\text{TiO}_2$  based oxide catalysts.<sup>1,2</sup> Recently, some authors have uncovered the catalysts activated at low temperatures.<sup>3-5</sup> We reported photo-SCR over  $\text{TiO}_2$  photocatalyst at room temperature where 83% of  $\text{NO}$  conversion and 96% of  $\text{N}_2$  selectivity were achieved in the conventional fixed bed flow system.<sup>6</sup> We have already proposed the reaction mechanism of photo-SCR system as follows.<sup>7</sup>  $\text{NH}_3$  is adsorbed on Lewis acid site of  $\text{TiO}_2$  rapidly. One hydrogen atom of the adsorbed  $\text{NH}_3$  species interacts with a lattice oxygen. Electron transfer takes place from N atom of  $\text{NH}_3$  adsorbed on  $\text{TiO}_2$  to Ti atom of  $\text{TiO}_2$  bulk under photoirradiation. The photoformed hole is captured by the adsorbed  $\text{NH}_3$  to form a  $\text{NH}_2$  radical. The  $\text{NH}_2$  radical was reacted with  $\text{NO}$  in the gas phase readily to generate a  $\text{NH}_2\text{NO}$  spe-

cies as an intermediate. Thus, the formed  $\text{NH}_2\text{NO}$  species is decomposed to  $\text{N}_2$  and  $\text{H}_2\text{O}$  and a  $\text{Ti}^{3+}$  species is reoxidized to a  $\text{Ti}^{4+}$  species by  $\text{O}_2$ . We have already detected a  $\text{NH}_2\text{NO}$  intermediate by FTIR spectroscopy.<sup>7</sup> However, we did not confirmed yet whether or not a  $\text{NH}_2$  radical is generated on  $\text{TiO}_2$  and was reacted with  $\text{NO}$  in the gas phase. In the present paper, we proposed the formation of a  $\text{NH}_2$  radical which was readily reacted with  $\text{NO}$  in the gas phase deduced by EPR spectroscopy.

JRC-TIO-4 (equivalent to Degussa P-25) supplied from the Catalysis Society of Japan was hydrated in distilled water for 2 h at 353 K, followed by filtration with a suction pump. The sample was kept at 383 K for 24 h in an oven, followed by calcination in air at 773 K for 3 h. The specific surface area was evaluated to be  $48 \text{ m}^2 \text{ g}^{-1}$  by the BET method using  $\text{N}_2$  adsorption isotherm at 77 K. Powder XRD tells that the treated JRC-TIO-4 consists of anatase and rutile phases. EPR spectra were recorded using an in situ quartz cell with an X-band EPR spectrometer (JOEL JES-SRE2X) with 100 kHz field modulation at 123 K. Before the measurement, the catalyst sample was heated at 673 K in air and evacuated for 30 min at the same temperature, followed by treatment with 8 kPa  $\text{O}_2$  for 90 min and evacuation for 30 min at 673 K. The  $g$  value and the relative amount of radical species were determined using a Mn marker. The effect of  $\text{NH}_3$  adsorption onto  $\text{TiO}_2$  upon the EPR spectra was investigated by recording the spectra after the equilibrium adsorption of  $\text{NH}_3$  at room temperature followed by evacuation. On the other hand,  $\text{NO}$  was introduced to  $\text{TiO}_2$  adsorbing  $\text{NH}_3$  under the measurement condition. Some spectra were recorded under illumination from a 500-W ultrahigh-pressure mercury lamp.

Figure 1 shows the EPR spectra of  $\text{TiO}_2$  after pretreatment, after introduction of  $\text{NH}_3$  in the dark and under photoirradiation, and after introduction of  $\text{NO}$  in the dark. The lines at  $g = 1.972$ , 1.980 and 1.983 assignable to a  $\text{Ti}^{3+}$  species were observed after pretreatment as shown in Figure 1a. In addition, the lines at  $g = 2.005$  and 2.007 assignable to an electron trapped in an F centre appeared. It is known that a  $\text{Ti}^{3+}$  species and an F centre are formed on  $\text{TiO}_2$  after heat treatment.<sup>8</sup> On introducing  $\text{NH}_3$ , these lines decreased in intensity as shown in Figure 1b. After that, new lines were observed as soon as  $\text{TiO}_2$  adsorbing  $\text{NH}_3$  was illuminated at 123 K in Figure 1c. This new signal was quite stably present even after more than one hour when the irradiation was ceased. Some authors clarified by EPR that a  $\text{NH}_2$  radical is trapped on the surface of various materials under photoirradiation.<sup>9-13</sup> The three  $^{14}\text{N}$  lines are further split into three lines by the hyperfine interaction with two equivalent hydrogen atoms. We measured the EPR spectra of  $\text{TiO}_2$  adsorbing  $\text{NH}_3$  labeled N-15 to clarify the assignment of the lines as shown in Figure 2b. In addition, we determined the magnetic parameters for  $^{14}\text{NH}_2$  and  $^{15}\text{NH}_2$  radical in  $\text{TiO}_2$  as shown in Table 1. The values are consistent with earlier works.<sup>11,13</sup> The lines at

**Figure 1.** The EPR spectra of  $\text{TiO}_2$  (a) after pretreatment, (b) after introduction of  $\text{NH}_3$  in the dark, (c) under photoirradiation and (d) after introduction of  $\text{NO}$  in the dark.

**Figure 2.** The EPR spectra of  $\text{TiO}_2$  after introduction of  $\text{NH}_3$  under photoirradiation (a) by using  $^{14}\text{NH}_3$  and (b) by using  $^{15}\text{NH}_3$ .

$g > 2.004$  in Figure 2b were changed in comparison with those found in introduction of  $^{14}\text{NH}_3$  in Figure 2a. However, the lines at  $g < 2.004$  in Figure 2b remained although  $^{15}\text{NH}_3$  was admitted instead of  $^{14}\text{NH}_3$ . The EPR spectrum of a  $^{15}\text{NH}_2$  radical exhibits five lines.<sup>9,11,12</sup> Evidently, in our case, the lines at  $g > 2.004$  were due to a  $\text{NH}_2$  radical. On the other hand, the lines at  $g < 2.004$  were attributed to the other species. Hurum et al.<sup>8</sup> reported the EPR spectra of Degussa P-25 under photoirradiation. They observed four characteristic lines. A couple of lines at  $g = 1.990$  and  $1.957$  are assignable to lattice electron trapping sites in anatase and the rest two at  $g = 1.975$  and  $1.940$  for rutile; i.e., the lines at  $g < 2.004$  are assignable to  $\text{Ti}^{3+}$  species. We concluded that Figure 1c is identified to the EPR spectrum of a  $\text{NH}_2$  radical overlapped with that of a  $\text{Ti}^{3+}$  species. Photoirradiation to  $\text{TiO}_2$  adsorbing  $\text{NH}_3$  contributes to the formation of a  $\text{NH}_2$  radical and a  $\text{Ti}^{3+}$  species. This suggests that an electron transfer takes place from N atom of  $\text{NH}_3$  adsorbed on  $\text{TiO}_2$  to Ti atom of  $\text{TiO}_2$  bulk. An electron reduced a  $\text{Ti}^{4+}$  cation to a  $\text{Ti}^{3+}$  cation and a hole is captured by the adsorbed  $\text{NH}_3$  on  $\text{TiO}_2$  to form a  $\text{NH}_2$  radical.

After introduction of NO in the dark, the lines of the  $\text{NH}_2$  radical vanished quickly whereas the lines of the  $\text{Ti}^{3+}$  species increased in intensity (Figure 1d). The  $\text{Ti}^{3+}$  species are restored to the  $\text{Ti}^{4+}$  species by gaseous oxygen which we confirmed by

**Table 1.** Magnetic parameters for  $^{14}\text{NH}_2$  and  $^{15}\text{NH}_2$  radical in  $\text{TiO}_2$

Radical	$A^{\text{N}} / \text{G}$	$A^{\text{N}} / \text{G}$	$A^{\text{H}} / \text{G}$
$^{14}\text{NH}_2$	24	3	10
$^{15}\text{NH}_2$	37	6	15

UV-vis spectroscopy. The quick disappearance of a  $\text{NH}_2$  radical suggests whether a  $\text{NH}_2$  radical itself changed to an EPR silent species, or NO in the gas phase attacks to a  $\text{NH}_2$  radical on  $\text{TiO}_2$  to form an intermediate. We have already examined the formation of a  $\text{NH}_2\text{NO}$  intermediate by FTIR spectroscopy after admittance of NO to  $\text{TiO}_2$  adsorbing  $\text{NH}_3$  under photoirradiation.<sup>7</sup> The  $\text{NH}_2\text{NO}$  intermediate is decomposed to  $\text{N}_2$  and  $\text{H}_2\text{O}$ . This is supported by the fact that the detected nitrogen gas was only  $^{15}\text{N}^{14}\text{N}$  in the  $^{15}\text{NO} + ^{14}\text{NH}_3 + \text{O}_2$  reaction. Taking into account these results, we can conclude that NO in the gas phase was reacted with  $\text{NH}_3$  adsorbed on  $\text{TiO}_2$ . In addition, a spin state of NO, a doublet, coincides with that of a  $\text{NH}_2$  radical. In conclusion, it is reasonable that  $^{15}\text{NO}$  in the gas phase attacks a  $^{14}\text{NH}_2$  radical anchored on  $\text{TiO}_2$  to form a  $\text{NH}_2\text{NO}$  intermediate and  $\text{O}_2$  reoxidized a  $\text{Ti}^{3+}$  species to a  $\text{Ti}^{4+}$  species.

Here, we clarified the charge transfer from N atom of  $\text{NH}_3$  adsorbed on  $\text{TiO}_2$  to Ti atom of  $\text{TiO}_2$  (a hole and an electron are localized on a  $\text{NH}_3$  species and a  $\text{Ti}^{4+}$  species, respectively). It is the first report that the charge transfer was confirmed between an adsorbent and an adsorbed species.
