A new method for protein domain recognition

Received: 9 November 1998 / Revised version: 20 December 1999 / Accepted: 20 December 1999

Abstract A fuzzy cluster method is presented to recognize protein domains. This algorithm can identify domains globally. A protein structure set was used to test the algorithm. Among 219 proteins, 66.7% yielded results that agreed with the reference definitions, 30.6% showed minor differences, and only 2.7% (six proteins) showed major differences with the reference. The new method is more than 20 times fast than previous algorithms.

Key words Fuzzy cluster analysis · Protein domain · Domain database · Protein structure

Introduction

The three-dimensional (3D) structure of a protein is crucial for understanding its precise function. It is also important for drug design and other biotechnological applications. To date, there are more than 8000 3D structures in the Protein Data Bank (PDB), and this number is increasing with an exponential speed. It is important to analyze these structures and collect useful information for predicting 3D structures of proteins.

Although there still is no strict and widely accepted definition of a domain, the concept of the domain has been widely used to simplify and classify protein structures. Many algorithms have been presented based on different definitions of a domain, such as distance-mapping (Liljas and Rossmann 1974; Nichols and Rose 1995), clustering (Crippen 1978), minimization of interface area (Wodak and Janin 1981; Janin and Wodak 1983), minimization of specific volume (Lesk and Rose

1981), maximization of compactness (Zehfus and Rose 1986; Zehfus 1987, 1993, 1994), and use of a cutting plane (Rose 1979). However, some of these methods can only deal with a single segment (continuous) domain, and some are too computationally expensive. Siddiqui and Barton (1995) applied a more effective algorithm to identify domains, but like most others this method is also a residue-by-residue cutting search procedure. Holm and Sander (1994) presented a global measure to identify domains in protein structures. By using matrix translation and calculating the oscillation time τ , they could recognize domains very quickly. However, many of the domains' definitions disagree with those found in the literature.

Liljas and Rossmann (1974) suggested that a domain has many short residue-residue distances within itself, but few with the rest of the protein. Based on this, here we present a new method using the "similarity of contact environment" (explained below) to build a relationship among residues, then identify domains by means of fuzzy mathematics.

Methods

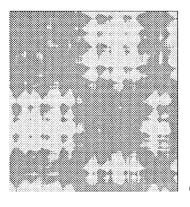

For identifying a domain automatically we defined a vector $E_i = (e_{i1}, e_{i2}, e_{i3}, ...)$ for the *i*th residue, to show the distance relationship between the *i*th residue and each of all the residues. Here

$$e_{ij} = \begin{cases} 0 & \text{if distance between the } i \text{th residue} \\ & \text{and the } j \text{th residue} > \text{BORD} \\ 1 & \text{if distance between the } i \text{th residue} \\ & \text{and the } j \text{th residue} \le \text{BORD} \end{cases}$$

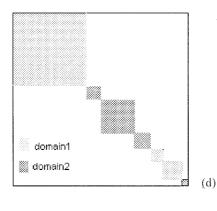

If $e_{ij} = 0$, it means that the distance between the *i*th and *j*th residue is too large and no contact exists; if $e_{ij} = 1$, it means that there exists one contact between the *i*th and the *j*th residue (see Fig. 1a). We simply use the distance between two C^{α} atoms to represent the distance of the

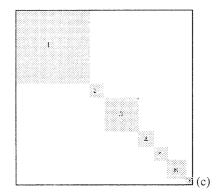

Fig. 1a-e Step-by-step procedure for identifying domain (1pfkα-chain). a In the contact vector plot of residues, each line (or column) is a vector, composed of 0 and 1, to show the contact relationship among one residue and others (light: no contact, 0; dark: existing contact, 1). b The plot for "similarity of contact environment" of residues; each line (or column) is a vector, which is composed of 0 and 1, to show the similarity of contact environment between one residue and others (light: similarity < CUTOFF, 0; dark: similarity \geq CUTOFF, 1). $\mathbf{b} \rightarrow \mathbf{c}$ Clustering and forming fragments. $\mathbf{c} \rightarrow \mathbf{d}$ Gathering and marking all fragments $\mathbf{d} \rightarrow \mathbf{e}$ Assembling each fragment to obey all constraints and identify the domains

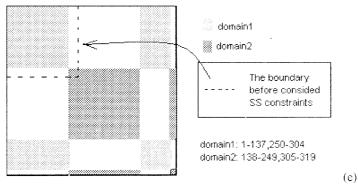

contact vector plot of residues

plot for "similarity of contact environment" of residues

two corresponding residues in order to calculate quickly. BORD is a variable parameter used to define whether there exists contact between two residues (its value is be discussed below).

In order to describe the residue's environment, the concept of "similarity of contact environment" of residues is introduced. This concept is expressed as a vector $S_i = (s_{i1}, s_{i2}, s_{i3}, \ldots, s_{ij}, \ldots)$ where $i = 1, 2, 3 \ldots$ and $j = 1, 2, 3 \ldots$

$$\mathbf{s}_{ij} = \sum_{k=1}^{\text{AANUM}} \delta(\mathbf{e}_{ik}, \mathbf{e}_{jk}) / \text{AANUM} \quad 0 \le \mathbf{s}_{ij} \le 1.0$$
 (1)

where

$$\delta(\mathbf{e}_{ik}, \mathbf{e}_{jk}) = \begin{cases} 0 & \text{if } \mathbf{e}_{ik} \neq \mathbf{e}_{jk} \\ 1 & \text{if } \mathbf{e}_{ik} = \mathbf{e}_{jk} \end{cases}$$

AANUM is the total number of residues in one peptide chain.

Each vector S_i shows the similarity of contact environment between the residue and each of the other residues. So, these vectors include almost all the structural information of one peptide chain. In this way a domain is an assembly of residues which have a similar contact environment. The next step is how to recognize the domains from these vectors. We do this according to following steps: (1) collecting and forming fragments; (2) marking the fragments; (3) dynamic assembly.

Collecting and forming fragments

For simplifying the algorithm, we first converted the float vector S_i to an integer vector of "similarity of

contact environment" $N_i = (\mathbf{n}_{i1}, \mathbf{n}_{i2}, \mathbf{n}_{i3}...)$ which is composed of 0 and 1:

$$\mathbf{\textit{n}}_{ij} = \left\{ egin{array}{ll} 0 & ext{if } \mathbf{\textit{S}}_{ij} \leq ext{CUTOFF} \\ 1 & ext{if } \mathbf{\textit{S}}_{ij} > ext{CUTOFF} \end{array} \right.$$

Figure 1b shows all the n_{ij} of one protein chain. Then some residues, which are adjacent in sequence and have same similarity of contact environment, are collected together to form one fragment. This means that the residues from n_1 to n_2 , whose $n_{ij}(n_1 \le i \le n_2, n_1 \le j \le n_2)$ all equal 1, can be collected on to the same fragment. After this, the residues in the peptide chain are collected to produce many fragments (see Fig. 1c).

The "similarity of contact environment" of each fragment is represented as a vector $W_l = (w_{l1}, w_{l2}, w_{l3}, \dots, w_{li}, \dots), i = 1, 2, 3, \dots, AANUM; l = 1, 2, \dots, m$ where m is the number of fragments. In all k residues (from n_1 to $n_1 + k - 1$) of the lth fragments

$$\mathbf{w}_{li} = \begin{cases} 1 & \text{if } \sum_{j=n_1}^{n_1+k-1} \mathbf{n}_{ij} > \frac{k}{2} \\ & & \\ 0 & \text{if } \sum_{j=n_1}^{n_1+k-1} \mathbf{n}_{ij} \le \frac{k}{2} \end{cases}$$

Marking the fragments

For finding the fragments which are included in the same domain, fuzzy cluster analysis is used (Zadeh 1965; Dubois and Prade 1980) (see Appendix below). After these fragment are clustered, all of the fragments in the same domain will be marked with the same symbol.

In the fuzzy cluster analysis, each fragment is regarded as an object to be clustered. Then we have defined

$$\mathbf{R}_{l_1 l_2} = \sum_{k=0}^{\text{AANUM}} \frac{\delta(\mathbf{w}_{l_1 k}, \mathbf{w}_{l_2 k})}{\text{AANUM}} \quad l_1, l_2 = 1, 2, 3, \dots, \mathbf{m}$$
$$0 \le \mathbf{R}_{l_1 l_2} \le 1.0 \quad (2)$$

as the matrix elements to build the fuzzy similarity matrix $\{R_{l_1 l_2}\}_{m \times m}$. Here

$$\delta(\mathbf{w}_{l_1k}, \mathbf{w}_{l_2k}) = \begin{cases} 0 & \text{if } \mathbf{w}_{l_1k} \neq \mathbf{w}_{l_2k} \\ 1 & \text{if } \mathbf{w}_{l_1k} = \mathbf{w}_{l_2k} \end{cases}$$

Based on the theory of fuzzy mathematics, a fuzzy equivalence matrix was also obtained from a fuzzy similarity matrix. At each clustering level λ (see Appendix below), we can divide all objects (fragments) into different clusters. The fragments that belong to the same cluster (which also means the same domain) are marked with same symbol (see Fig. 1d).

Dynamic assembling

In order to determine the domain rationally, some constraints are needed and are added to the procedure.

The minimum domain size should not be smaller than the MDS (minimal size of domain); the minimum part of one domain, if it is at the end, should be larger than MSSe (minimal size of fragment at the end of chain), and if it is in the middle, should be larger than MSSm (minimal size of fragment in the middle of chain) (Siddiqui and Barton 1995). The secondary structural limitation should also be considered. The split site between the adjacent two domains should not be within a secondary structure and should be at one end of the secondary structure. In our algorithm, the secondary structure definition of a protein in DSSP (Kabsch and Sander 1983) was adopted.

Considering these constraints, we use a link list to simulate the peptide chain. Each node in the link list stands for a fragment. If one fragment did not obey the constraints, it was assembled to the adjacent fragment. If the node was at the end, it was assembled to the adjacent node directly. If the node was in the middle of link list, it was compared to the adjacent two nodes first, then the pair of nodes which has the larger $R_{l_1 l_2}$ will be merged together.

This process is continued until all the fragments obey the constraints; then the domains are identified from the peptide chain. One domain is composed of those nodes that have the same symbol (see Fig. 1e).

In order to evaluate the reliability of the results, we calculated an index $V_{\rm split}$ for each protein chain. If one chain includes more than one domain, using the same definition of $V_{\rm split}$ in Siddiqui and Barton (1995) we calculated each pair of domains' $V_{\rm split}$ and chose the minimum one as the chain index V. If one chain only has one domain, we regarded the amino acid which is at the end of the chain as one "domain" and regarded the remainder as another domain. Then $V_{\rm split}$ was calculated.

Results

In order to compare our results with other groups, we chose the same set of protein structures as Siddiqui and Barton (1995) used. There were a total of 230 protein structures, but 11 of them were not found in the PDB (release #77, July 1996); hence 219 structures were involved in our study. Among these 219 proteins, there were 66.7% of them whose derived domains agreed with the reference definitions, 30.6% showed minor differences, and only 2.7% (six proteins) showed very different definitions (see Tables 1 and 2). The six proteins which show very different definitions compared with the references are listed in Table 3.

The distribution of protein size

Figure 2 shows the size distribution of all the proteins that we used. Most are smaller than 400 residues.

^a Abbreviations used for the headings of each column: A, PDB code; B, chain index; C, domain number; D, derived definition from this work; E, reference definition. "All" indicates that the whole protein chain is a single domain

Table 2 Result statistics

	Agreed (I)	Minor different (II)	Major different (III)
Number Percent	146 66.7%	67 30.6%	6 2.7%
Total		219 protein structures	

Table 3 Proteins which had major different domain definitions

PDB code	Chain	Protein name
1 gal		Oxidoreductase (flavoprotein)
1vsg	Α	Glycoprotein
2mnr		Racemase
1prc	C	Photosynthetic reaction center
2pgd		Oxidoreductase $[CHOH(D) - NADP + (A)]$
7cat	A	Oxidoreductase (H ₂ O ₂ acceptor)

The distribution of domain size

Figure 3 shows the size distribution of all 310 domains. Most are smaller than 300 residues. The distribution is more concentrated than that of the proteins.

The distribution of the domain number of one protein chain

Figure 4 shows that most chains only include one domain. Some protein chains include 2–3 domains, but few have more than 4 domains.

The program was run on a Silicon Graphics Indigo R4400 workstation. It took only 38 min to complete the calculations for all 219 protein structures, which is faster than other algorithms (see Table 4).

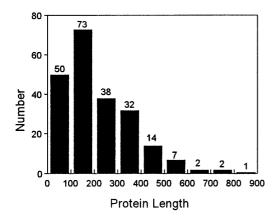

Fig. 2 The size distribution of the proteins used. Most are smaller than 400 residues

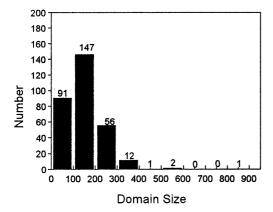

Fig. 3 The size distribution of all 310 domains. Most are smaller than 300 residues

Discussion

Domain identification

Although domain identification is basically a mathematical problem, yet domain-classified information from the research of protein domain recognition is very important for protein design. Comparing these results with previous methods, our algorithm possesses the same precision, but the consumed CPU time is very economized.

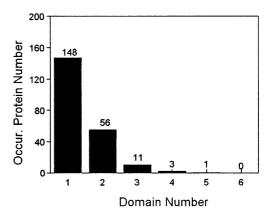

Fig. 4 The domain number distribution of proteins. Many proteins only include one domain. Some had two or three domains. Few proteins have more than four domains

"Gray area" in domain identification

Siddiqui and Barton (1995) had found that there existed a "gray area" (the uncertainty in the split site) while the domain is identified. In our work, we also met this problem (see Fig. 5). The structure of the A-chain of wheat germ agglutinin isolectin (denoted by its PDB code: 2cwg) seemed to consist of two domains (I, II), but each domain can also be regarded as two subdomains (I_a, I_b and II_a, II_b). If the proper parameters were chosen, such as LAMD in our algorithm, it may be helpful for eliminating the "gray area".

Secondary structure constraint

In our method, secondary structure information was a very important constraint to correct the split site. We thought that the secondary structure is a relatively substantive part of a domain, so a split site should not be within a secondary structure (including helix and sheet), but could be at the end of a helix or a sheet. For example, the structure of the contractile system protein (4tnc) had two domains linked by a long helix (from residue 75 to residue 106) (see Fig. 6). In our opinion, the split site should be in the upper stream of residue 75 or down stream of residue 106. We set it at residue 106 after considering the secondary structure constraint; others have set it at residue 88 and some at residue 90 (Siddiqui and Barton 1995).

Table 4 Comparison of some methods

	Total structures	Set I	Set II	Set III	Max. accept	Time cost	Ave. time
This work	220	146 (67%)	67 (30%)	6 (3%)	213 (97%)	38 min	10.38 s
Siddiqui and Barton (1995)	230	161 (70%)	41 (18%)	28 (12%)	202 (88%)	16.5 h	258 s
Holm and Sander (1994)	330		their published ose found in the		nition disagree	40 min	7.27 s

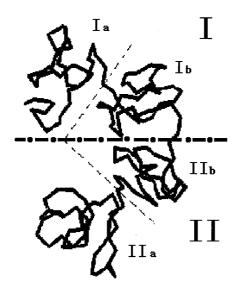

Fig. 5 Plot of gray area of domains. From the 3D structure of protein 2cwg (wheat germ agglutinin isolectin), A-chain, two domains (domain I, II, split by dash-dotted line) can be identified, but it can also be thought that this chain includes four domains (I_a, I_b, and II_a, II_b, split by dashed line and dash-dotted line). So there is a "gray area" in searching the domain. The figure was produced using RasMol 2.5 (Sayle 1995)

The V_{split} index of protein domain recognition

The statistics of $V_{\rm split}$ index are shown in Table 5. The domain definition is correct if the $V_{\rm split}$ index is larger than 100; we would doubt the result if the $V_{\rm split}$ index was less than 50. In our algorithm, if the $V_{\rm split}$ index is less than 10, the two domains from which the $V_{\rm split}$ is calculated would be merged. Eight cases which have $V_{\rm split}$ less than 10 were encountered in our calculation, four in set I (1ace, 1bic, 1rhd, 2tgi), three in set II (2npx, 2plv_1, 3dpv_A), and one in set III (7cat_A). We found that this $V_{\rm split}$ index is very useful for estimating the results.

Choosing reasonable parameters

In our method, several parameters were used.

BORD distinguishes whether contact exists between two residues. Too small a value would create too many small domains, while too large a value could not correctly identify domains. We set BORD = 28 Å in this work. CUTOFF is used to calculated the "similarity of

Table 5 Index statistics^a

	Set I (%)	Set II (%)	Set III (%)
V < 50	1.78	27.87	20.00
V < 100	20.54	50.82	100.00
$100 \le V \le 1000$	75.89	45.90	0.00
V > 1000	3.57	3.28	0.00

^a The results for which one chain has a single domain are not included in these statistics

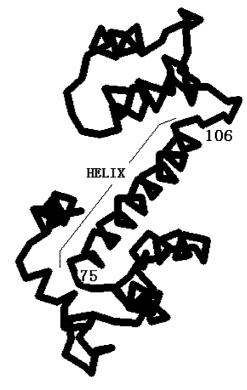

Fig. 6 3D structure of 4tnc. This contractile system protein seems to consist of two domains, and there is a very long α -helix between the two domains. The split site should not be in the middle of the helix. In our method, residue 106 is considered as the split site of two domains from two end sites of this long helix, 75 and 106. The figure was produced using RasMol 2.5 (Sayle 1995)

contact environment" between two residues. It equals 0.5 in our algorithm. LAMD is a parameter needed in cluster analysis. We found that if it is too large, the fragments would be too small, and if it is too small, many structural details would be concealed. After some experiments, we set LAMD equal to 0.8. The other parameters, MDS, MSSe, and MSSm, are used with the same values as in Siddiqui and Barton (1995).

In short, cluster analysis and fuzzy mathematics are very effective tools in domain recognition. Using these methods, we could identify the domains of proteins globally. The methods are also very fast and accurate.

Appendix: fuzzy cluster analysis

Fuzzy set theory, introduced by Zadeh (1965), is a generalization of abstract set theory. It has a wider scope of applicability than abstract set theory in solving

problems that involve, to some degree, subjective evaluation.

Fuzzy set

Intuitively, a fuzzy set is a class that admits the possibility of partial membership in it. Let $X = \{x\}$ denote a space of objects. Then a fuzzy set A in X is a set of ordered pairs:

$$A = \{(x, \chi_{\mathbf{A}}(x))\}, \quad x \in X$$

where $\chi_A(x)$ is termed "the grade of membership of x in A". We assume for simplicity that $\chi_A(x)$ is a number in the interval [0, 1], with the grades 1 and 0 representing, respectively, full membership and nonmembership in a fuzzy set.

Examples of some fuzzy sets are:

Fuzzy set A, labeled "integers approximately equal to 5", may be defined as

$$A = \frac{0.1}{2} + \frac{0.4}{3} + \frac{0.9}{4} + \frac{1.0}{5} + \frac{0.9}{6} + \frac{0.4}{7} + \frac{0.1}{8}$$

Fuzzy set A, labeled "real numbers clustered around 5", may be defined by the grade of membership function

$$\chi_{\mathbf{A}}(x) = \left\{ 1 + \left[\frac{1}{4}(x - 5) \right]^2 \right\}^{-1}$$

or as

$$A = \int_{R} \frac{\left\{1 + \left[\frac{1}{4}(x-5)\right]^{2}\right\}^{-1}}{x} \qquad R = \{\text{real number}\}$$

Fuzzy relationship

If X is the Cartesian product of n universes of discourse X_1, \ldots, X_n , then an n-ary fuzzy relation, R, in X is a fuzzy subset of X. R may be expressed as the union of its consistent fuzzy singletons $\chi_R = (x_1, \ldots, x_n)/(x_1, \ldots, x_n)$, that is

$$R = \int_{\chi_1 \times \cdots \times \chi_n} \frac{\chi_R(x_1, \dots, x_n)}{(x_1, \dots, x_n)}$$

where χ_R is the membership function of R.

Fuzzy cluster analysis

Fuzzy cluster analysis is based on a fuzzy equivalence relationship, but this relationship is hard to obtain directly so we obtain it from a fuzzy similarity relationship. If $U = \{u_1, u_2, \dots, u_n\}$ is a set of the objects discussed,

and $u_i = \{x_{i1}, x_{i2}, \dots, x_{im}\}$ represents the relationship between each object u_i and m kinds of elements, the fuzzy similarity relationship, which can be represented as a fuzzy similarity matrix $R = (S_{ij})_{n \times n}$, has many methods to consider. Our method is shown as Eq. (2) above.

A fuzzy equivalence matrix can be obtained by multiplying R with itself 2^m times. The product operator here is a special one which obeys the rule of fuzzy mathematics:

$$R \to R^2 \to R^4 \to \dots \to R^{2^m}$$

$$m = \begin{cases} \log_2 n & \log_2 n \in \{\text{integer}\}\\ 1 + \log_2 n & \log_2 n \notin \{\text{integer}\} \end{cases}$$

From the fuzzy equivalence matrix R^{2^m} at each clustering level λ we first create a cut-off matrix $R_1^{2^m}$

$$(R_{\lambda}^{2^m})_{nk} = \begin{cases} 1 & (R^{2^m})_{nk} > \lambda \\ 0 & (R^{2^m})_{nk} < \lambda \end{cases}$$

then we divide all objects u_i into clusters from this matrix.

Here is an example:

$$X = \{x_1, x_2, x_3, x_4, x_5\}, x_1 = (5, 5, 3, 2), x_2 = (2, 3, 4, 5),$$

 $x_3 = (5, 5, 2, 3), x_4 = (1, 5, 3, 1), x_5 = (2, 4, 5, 1)$

then a fuzzy similarity matrix is obtained through the fuzzy relationship

$$S_{ij} = 1 - 0.1 \times \sum_{k=1}^{4} |x_{ik} - x_{jk}| \quad (i, j = 1-5)$$

$$m = 1 + [\log_2 5] = 3$$

so a fuzzy equivalence matrix can be created through $R \to R^2 \to R^4 \to R^8$:

$$R = \begin{bmatrix} 1 & 0.1 & 0.8 & 0.5 & 0.3 \\ & 1 & 0.1 & 0.2 & 0.4 \\ & & 1 & 0.3 & 0.1 \\ & & & 1 & 0.6 \\ & & & & 1 \end{bmatrix}$$

$$R^* = R^8 = \begin{bmatrix} 1 & 0.4 & 0.8 & 0.5 & 0.5 \\ & 1 & 0.4 & 0.4 & 0.4 \\ & & 1 & 0.5 & 0.5 \\ & & & 1 & 0.6 \\ & & & & 1 \end{bmatrix}$$

At last, with each λ given, all clusters can be obtained from each cut-off matrix:

$$\lambda = 1, X$$
 is divided into 5 clusters: $\{x_1\}, \{x_2\}, \{x_3\}, \{x_4\}, \{x_5\}$

$$\lambda = 0.8, X$$
 is divided into 4 clusters: $\{x_1, x_3\}, \{x_2\}, \{x_4\}, \{x_5\}$

$$\lambda = 0.6, X$$
 is divided into 3 clusters: $\{x_1, x_3\}, \{x_2\}, \{x_4, x_5\}$

 $\lambda = 0.5, X$ is divided into 2 clusters: $\{x_1, x_3, x_4, x_5\}, \{x_2\}$

 $\lambda = 0.4$, all x_i are in one cluster: $\{x_1, x_2, x_3, x_4, x_5\}$

Some cut-off matrix at each λ :

$$\begin{bmatrix} 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 1 \end{bmatrix}_{\lambda=0.6}, \dots$$
