Perspectives in Cancer Research

Cell Locomotion and Tumor Penetration

Report on a Workshop of the EORTC Cell Surface Project Group

(Zürich, 8–10 April 1976)

P. STRÄULI* and L. WEISS†

**Division of Cancer Research, Institute of Pathology, University of Zürich, Birchstrasse* 95, 8050 *Zürich, Switzerland*

†*Department of Experimental Pathology, Roswell Park Memorial Institute, Buffalo, N.Y.* 14203, *U.S.A.*

THE PURPOSE of the workshop was to evaluate the role of active locomotory movement in tumor penetration, and to consider aspects of cell locomotion and tumor penetration from morphological, biophysical, and biochemical viewpoints. Within this framework, presently available knowledge on the locomotive apparatus of the non-muscular mammalian cell was discussed.

I. EVIDENCE FOR CELL LOCOMOTION IN TUMOR PENETRATION

In histologic sections, isolated cancer cells or groups of cancer cells are often found, and in many instances the lack of continuity between such elements and a neighboring tumor was proven by means of complete sets of serial sections or even by three-dimensional reconstruction [1]. Taken together, these efforts have established the fact that displaced cancer elements surrounded on all sides by host structures do occur. Can this be accepted as proof that locomotion has taken place?

If one considers in a general way how a tumor cell may be translocated from one position in a normal tissue to another position, at least three possible mechanisms can operate:

(1) The tumor cell may "walk".

(2) The tumor cell may be relatively passive, merely forming adhesions with a normal cell whose membrane flow could transport the tumor cell until it formed new adhesions with an adjacent normal cell, breaking the adhesions with the first one.

(3) The tumor cell may be entirely passive and be pushed by a pressure gradient derived from increasing tumor cell mass or by interstitial fluid flow facilitated by muscle contraction and pulsation of blood vessels.

For discrimination among these possibilities, histology will always offer indirect evidence only. It should be admitted, however, that static morphology has its "*in flagranti*-situations" where indirect evidence of tumor cell locomotion is practically conclusive. It is the same kind of observation as is widely accepted for locomotion of leukocytes, e.g., with regard to migration of lymphocytes across the wall of venules [2, 3].

This, however, does not alter the fact that direct evidence for the role of tumor cell locomotion in penetration should be provided by

Participants: M. ABERCROMBIE (Cambridge), M. BESSIS (Paris), M. M. BURGER (Basel), G. C. EASTY (London), E. F. LÜSCHER (Bern), A. R. POOLE (Cambridge), M. C. SCHAUB (Zürich), P. STRÄULI (Zürich), B. SYLVEN (Stockholm), K. WEBER (Göttingen), L. WEISS (Buffalo), K. E. WOHLFARTH-BOTTERMANN (Bonn).

cinemicrographic observation and recording under appropriate experimental conditions. There are limited possibilities of *in vitro*-studies which appear most promising where natural membranes, like omentum, mesentery and chorioallantois, are utilized. But even under this qualification and with a sophisticated technique, e.g., edge on-view [4, 5], penetration by locomotive tumor cells, so far, has not been demonstrated unequivocally. *In vivo*-studies are not less controversial. There are very few models allowing cinemicrography of tumor cells within compartments of the living organism, and in most instances, the traffic of tumor cells within blood vessels, but not locomotion and penetration, were recorded. In some studies of this type, egress of tumor cells from vessels was again based on indirect histologic evidence [6]. Wood [7], however, can be credited to have provided cinemicrographic documents on penetration of V2 carcinoma cells through the walls of capillaries and venules in the rabbit ear chamber. This has remained an isolated finding. It should be noted that both histologic and cinemicrographic evidence on *in vivo*-locomotion of leukocytes and tumor cells hinges upon escape from blood vessels. This may be due to special environmental conditions (see section IV). Besides, there is ample electron microscopic evidence that in many instances, egress of tumor cells after lodgment of tumor cell emboli [e.g., of the Walker 256 carcinosarcoma: 8, 9] is not accomplished by locomotion, but by intravascular proliferation, resulting in partial or complete destruction of the vascular wall and growth of the tumor focus to the extra-vascular compartment.

So far, emphasis has been laid on penetration by single tumor cells. Its most characteristic expression is infiltration of organs by leukemia cells. This process can hardly be conceived without locomotion, although direct proof under *in vivo*-conditions is lacking. Locomotion is also assumed to be involved in invasion by contiguous sheets or cords of tumor tissue. On indirect histologic evidence, this appears to be a more frequent occurrence than infiltration by single tumor cells (apart from leukemia). It proceeds along pre-existing anatomic planes or into local regions of tissue weakness created by tumor-associated pathologic mechanisms. Progress of tumor-tongues or whole tumor-fronts could conceivably be mediated by movements of cells at the advancing edge, in a manner analogous to epibolic morphogenetic movements of surface cells seen in the amphibian egg [10]. Another possibility could consist in locomotion of tumor cell aggregates. Growth in the form of isolated foci (aggregate replication) was described for a number of animal and human tumors [11]. Such aggregates are a conspicuous feature of the growth and penetration front of the V2 carcinoma of the rabbit. For this tumor it had been demonstrated that small clusters of from three to five cells moved at times as a unit [12]. In recent cinemicrographic studies [13], isolated V2 aggregates were shown to either migrate as units or to dissociate into single cells which display individual locomotion. In accordance with histologic findings, a similar behavior of tumor aggregates in the organism can be expected. Evidence was obtained that a guinea pig hepatoma penetrated into the chorioallantoic membrane as small aggregates rather than as single cells [14].

In conclusion, it can be said that there is vast indirect (histologic) evidence, but hardly sufficient direct (cinemicrographic) proof for the occurrence of cell locomotion in tumor penetration *in vivo*. There is also no direct proof for the role of pressure, fluid currents and other factors acting upon the tumor cells. It appears reasonable to assume that locomotion is of prime importance, but that passive mechanisms can be involved to different degrees in penetration of different tumors, and that different tumors use different mechanisms at different stages of their development.

II. THE CONCEPT OF TUMOR CELL MOBILIZATION

With the exception of leukocytes, the cells of the adult organism, under physiological conditions, are immobilized, though not immovable. If normal or neoplastic tissue cells begin to migrate, they must have been released from immobilization or, in other words, they must have been mobilized.

The term mobilization was originally introduced to designate changes in cultured tissues which increase the amount of migration of cells from them [15–16]. It is suggestive to transfer the concept of mobilization from the tissue culture level to the situation of the tumor *in vivo* [17].

Of the factors responsible for tumor cell mobilization, release from mechanical confinement will be considered first. Mutual attachment of the cells is achieved by specialized structures at the cell surface (junctions) and in the extracellular matrix (fibers), and by submicroscopic physicochemical bonds acting in the intercellular space. Facilitation of cell detachment, a characteristic property of some

but by no means all malignant tumors, may be due to lack of differentiation coinciding with neoplastic transformation and progression; it may also be due to degenerative processes.

Junctions in tumors can be markedly reduced in comparison to the homologous normal tissue [18], but this is by no means a general finding [19]. In mechanical terms, reduction of junctions might reduce adhesion if no other processes were involved. The loss of cell-to-cell passageways for regulators or nutrients can possibly be linked to alterations of growth control [20], or degeneration [21], and could also be conceived as a factor in cellular mobilization.

According to common experience with cell separation procedures, the contribution of enzyme-dissociable bonds to tissue stability cannot be neglected. Sylven's work [22, 23] indicates possible interrelationships of factors acting on physiochemical bonds in the intercellular compartment of tumors. Besides a host of hydrolases, lactate as a naturally occurring chelator of divalent cations may play an important role in tumor cell detachment.

Support for the suggestion that lysosomal enzymes facilitate cell detachment by means of "sublethal autolysis" [24] comes from the observations that exposure of attached cells to demonstrable lysosomal activators, including antisera and vitamin A, promotes their detachment. Studies of hypervitaminotic A animals bearing mammary adenocarcinomas revealed an association between the increased numbers of cells shaken free from excised tumors, and a higher incidence of pulmonary metastasis [25].

Sublethal autolysis is comparable to necrobiosis, which was suggested as another mechanism of tumor cell detachment [26]. The disjunction theory of local spread of cancer is based on two assumptions:

(1) Single cancer cells are detached from a tumor mass due to necrobiotic dissociation.

(2) Such elements are actively or passively translocated into the surrounding host zone where they give rise to so-called micrometastases.

It should be noted that detachment or separation of tumor cells from a tumor mass, as discussed here with respect to tumor cell mobilization, does not necessarily occur at the same plane as adhesion. However, the sequence of the two different phenomena of adhesion and separation is an absolute prerequisite for active movement of an already mobilized cell within its environment, and will therefore be discussed in section IV.

Detachment is not mobilization: It appears unlikely that detached tumor cells are automatically mobilized. The apparent state of non-attachment in which tumor cells exist in many tumors (or parts of them, e.g., at the penetration front) is not necessarily a state of non-contact. What is the general significance of contact? Although it is difficult to transfer the essentially two-dimensional *in vitro*-model of contact inhibition of locomotion to the three-dimensional *in vivo*-situation, one should tentatively accept an extrapolation to the organism, at least in the form that mobilization of cancer cells *in vivo* consists not only in detachment, but also in release from a contact-mediated restraint comparable to contact inhibition of locomotion *in vitro*.

III. PROLIFERATION AND LOCOMOTION OF TUMOR CELLS

Under physiological conditions, division and locomotion, two elementary cellular functions, are under strict homeostatic control. In the neoplastic state, these regulations are impaired, and the result is "uncontrolled" growth and locomotion, a constellation that makes up malignancy. To what extent are growth and locomotion in tumors interconnected?

Resuming the discussion on mobilization, we have to consider the role of mitosis. Decrease of attachment is a regular event during cell division. Judged from *in vitro*-experience, mitotic detachment is more conspicuous in epithelial than in mesenchymal cells, but even in epithelial cells it must not be of a complete round-about nature. The condition is that cellular cleavage is mechanically possible. For the regenerating liver, which produces mitotic cells far in excess of the most malignant tumors, it was shown that parenchymal cells can be detached more easily during a distinct part of the regeneration period [27]. It has to be assumed that cells of the regenerating liver emerging from telophase are reattached rather quickly. There may be a short delay which allows them to display the necessary positional shiftings. It is unlikely, however, that during this interval they migrate in a histologically appreciable degree. This may be due to some kind of restraint comparable to contact inhibition of locomotion *in vitro*. Such a restraint is not required while attachment is operative, nor is it necessary during mitosis, as dividing cells are unable to migrate. But it could be an immobilizing factor during the post-mitotic phase, between the end of telophase and the completion of reattachment. The situation may be similar in tumors with a relatively high

degree of cohesion. In less cohesive ones, proliferation will more or less be restricted to already detached cells, and attachment of postmitotic cells will not occur any longer, in other words: attachment as a measure of immobilization has disappeared. This reflects a permanently altered state of the cell surface inherent to malignant transformation, but does not imply that proliferation *per se* is a mobilizing mechanism.

Although more concrete data are available from investigations *in vitro*, they do not, at the moment, allow a precise disentanglement of proliferation and locomotion. Normal fibroblasts in confluent monolayers are subject to two types of control, density-dependent inhibition of growth [28], and contact inhibition of locomotion. The interdependence of the two inhibitions is a matter of debate [29]. Experimental procedures have been described that stimulate fibroblast locomotion in the absence of proliferation [30, 31], and fibroblast proliferation in the absence of locomotion [32]. Thus, under the special conditions of fibroblast monolayers at confluency, control of proliferation and of locomotion appear to be independent phenomena. No direct comparison to transformed cells with their impaired inhibitions is possible. Factors have been isolated from cultures of transformed cells that stimulate both proliferation and locomotion of normal cells [33, 34]; this means that at the molecular level proliferation and locomotion can not be separated so far. Further information will eventually be provided by Burger's present studies on effects of succinylated Con A, added to cells during mitosis and early G 1, on their subsequent locomotive behavior.

Finally, we do not know to what degree migration factors influence penetration and metastasizing. Isolated observations tell us nothing about causal relationships, and need to be repeated for many different types of metastasizing and non-metastasizing cancer in order to establish the basic correlation.

IV. THE LOCOMOTIVE TUMOR CELL IN ITS ENVIRONMENT

In studying locomotion, we are concerned with cell displacement, that is the distance between the position of a cell at the beginning and at the end of a standard period of time (such displacement is commonly not linear against time). Environmental influences on displacement can induce:

(1) non-directional responses ("kineses")

(2) directional responses ("taxes").

It is practically impossible to analyze these and most other environmental aspects of cell locomotion under *in vivo*-conditions. The bulk of the following discussion, therefore, relates to *in vitro*-studies.

A. In vitro-*studies*

A large amount of experimental work was concentrated on the processes of cellular adhesion and separation [24]. Both are of crucial importance, as any cell migrating in any environment must:

(1) Make contact with and adhere to the substratum, to obtain a "hold" against which it can "push", or "pull", or both. Adhesion cannot be measured directly and rates of adhesion are the usually determined experimental parameter.

(2) Break contact in regions of adhesion with its substratum. This process of focal separation is spatially distinct from the process of adhesion, and must be measured by different techniques.

(3) Be capable of generating the necessary locomotor energy to propel itself.

Adhesion. The substratum to which a moving cell adheres is usually provided by the solid part of the extracellular environment. *In vitro*, nonadhesive substrata can be examined; they completely stop moving cells which collide with them from proceeding any further in that direction. A continuous gradient of adhesiveness may produce a directional response; this is haptotaxis [35]. There may also be non-directional responses to adhesiveness. In general a substratum providing poor adhesion (or structurally weak) or a substratum providing excessive adhesion is likely to diminish speed of locomotion, by interfering with the normal cycle of relations to the substratum.

In order to form adhesive bonds, cell surfaces or molecules attached to them must approach within approximately 0·5 nm of each other. Although in the case of "specific" adhesions the nature of the bonds formed may well be of major importance, in the case of adhesion in relation to cell movement such specificity seems an unlikely requirement. If contact over an adequate area can be achieved, then any level of adhesive strength can be accomplished by bonds of different types ranging from comparatively weak hydrogen bonds to the high energy covalent bonds. Therefore, in connexion with the formation of the non-specific adhesions required for active cell movement, the major

problem is not how cells form adhesions, but rather how they approach closely enough to permit such adhesive bonds to be formed.

All mammalian cells and biological surfaces so far examined carry a net negative surface charge. Therefore, contact between cells and between cells and other surfaces carrying net negative charges including glass, and glass exposed to serum-containing media for example, tends to be prevented by the mutual electrostatic repulsion between them. In colloid systems, which in some important respects are analogous, whether or not contact between charged particles and subsequent flocculation or adhesion occurs, depends in general terms on the balance of the electrostatic forces of repulsion and the Van der Waals' forces of attraction, in relation to Brownian or other movements.

In computing average electrostatic interactions between cellular and other surfaces the key experimental measurement is that of electrophoretic mobility. From this, cell zeta potential and the net surface charge density may be calculated. It is emphasized that these two average quantities relate to the cellular electrokinetic surface. Attempts to predict the adhesive, or contactmaking behavior of cells on the basis of average estimates of the potential energy barriers between them have been largely unsuccessful [36]. From this failure, it may be reasonably concluded that the physical bases of cell contact depend on non-average or heterogeneous properties of the cell periphery. Electron microscopic data on the adsorption of positively charged markers to a variety of cells support the view that negative charges are indeed distributed in clusters at the cell periphery, and that cell projections find and/or create gaps in these clusters in order to make contact with another cell in regions of lower-than-average charge density.

It is probable that potential energy and viscous barriers tend to prevent cells from making contact with, and adhering to, other cell surfaces. Without such contact and adhesion, active translatory movements of cells cannot occur. The suggestion that cells make contact in spite of these apparently insurmountable average barriers by making contact through comparatively small, non-average surface regions is compatible with observations on the comparatively small fractions of the total surface areas of the opposed surfaces of many different types of cells involved in making tight junctions, and in junctions of low electrical resistance.

Separation. Unless the regions by which a cell adheres to a substratum are infinitely extensible, it follows that some sort of separation process must also be associated with adhesion-dependent movement. Whereas detachment of cells from solid tumors involves breaking all their contact regions with the primary lesion, active cell movement does not require the simultaneous breaking of all contact regions associated with the cell periphery in question, but may well be a very localized sub-cellular phenomenon. Although environmental enzymes could contribute to cell separation in relation to active movement, they could also destroy or prevent cell/substratum adhesions by virtue of bond fission at the adhesion interface. While the former activity could promote active cell movement, the latter would effectively prevent them.

Apart from cellular adhesion and separation, *in vitro*-studies on environmental conditions of cellular locomotion have drawn our attention to two further constellations, contact guidance, and contact inhibition of locomotion.

Contact guidance. This is another way by which the extracellular substratum can affect locomotion. It is a directional response for which the form of the substratum, not variations in its adhesiveness, is effective. Contact guidance, on principle, applies both to normal and malignant cells, but at least in the latter, it is by no means of regular occurrence. In cinemicrographic studies on the locomotion of rat leukemia cells and V2 carcinoma islands on mesentery maintained under tissue culture conditions, locomotion of both the single tumor cells and the tumor cell groups took place, after deterioration of the mesothelium, on the submesothelial network of collagen and elastic fibers, but without any expression of contact guidance [13].

Contact inhibition of locomotion. How do locomotive cells react to collisions with other cells? Migrating fibroblasts in culture, the most studied from this point of view, have a special reaction, not so far shown in any encounter with a non-cellular object. This is contact inhibition [37], which, it must be emphasized, is a directional response. A cell whose front-end has made contact with another cell is prevented from continuing its locomotion in that direction. The cell can however move in a different direction. The reaction is easily distinguishable from the block to movement that occurs when a cell collides with a non-adhesive patch of substratum.

The reaction is not confined to fibroblasts. Epithelial cells show something very like fibroblast contact inhibition. There is a reaction

between malignant cells of many kinds which at least has the same outcome as contact inhibition between fibroblasts though precise details are as yet unstudied. It is often said that contact inhibition between malignant cells is deficient. The effectiveness of the homologous contact inhibition (i.e. between like cells) was estimated in a range of human malignant cells by an indirect method (overlap index), and much greater variation was found than in normal fibroblasts, many malignant cells having a lower intensity of contact inhibition, but some a higher [38].

Since *in vivo*, malignant fibroblasts invade populations of normal fibroblasts, heterologous contact inhibition (between unlike cells) is of special interest. It has usually been found to be defective in comparison with the homologous inhibition of normal fibroblasts [37–39], but not always [42]. Malignant fibroblasts, advancing as whole cultures and as detached single (sentinel) cells, were completely stopped when opposed by coherent and compact sheets of normal epithelial cells [43, 44].

B. In vivo-*studies*

It is evident that all extrapolations from *in vitro*-studies to *in vivo*-conditions are fraught with the danger of misinterpretation, one major obstacle being the difference in intercellular connection and organization between monolayers *in vitro* and tissues *in vivo*. To begin with: It is very difficult to describe morphologically the compartment in which cells migrate *in vivo*, to analyze chemically the influence of fluid and solid constituents of the extracellular matrix on locomotive cells. Judged from electron micrographs, leukocytes must possess a very smooth and efficient mechanism of locomoting through the ground substance; they are, for instance, able to pass the basal lamina without producing the slightest alteration [45]. As regards penetrating tumor cells, there is morphological evidence, at the light and electron microscopic level, for both possibilities: lack of lytic action [46] as well as slight to massive destruction of host tissues in the immediate invasion zone. Sylven mentioned the important role of edema at the tumor periphery, which leads to opening up of tissue spaces, thus facilitating the access of tumor cells into preformed tissue spaces. The degree of edema is characteristically correlated to the grade of malignancy and largely influenced by the rate of tumor glycolysis [47]. Pathologists are liable to forget this fluid phase, since it is not seen in their sections and electron micrographs.

It thus appears that on principle, tumors are able to create either directly or indirectly a "penetration space" which enables or facilitates the onset of cellular locomotion. Lysosomal hydrolases may, therefore, not only play a role in cell detachment, but also in penetration [48]. Sylven's earlier work [49, 50] was directed to the fluid interphase of tumors, and separate sampling was undertaken both of interstitial fluid from the tumor periphery as well as the necrotic central regions. Very marked increases in activity of lysosomal hydrolases were noticed but also many other enzymes, present in the soluble part of the cytoplasm, were found. It is clear that added enzymatic components in the tumor compartment can only derive from local sources, either from the tumor cells or host cells. Since the number of host cells is relatively small in solid tumors, we are left with the suggestion that the enzymatic components are derived from tumor cells. This suggestion is strongly substantiated by incubation studies of ascites tumor cells [51]. Living ascites tumor cells were incubated in a full growth medium for short times and the release of enzymes to the medium was studied. The tumor cells were found to leak out or secrete very considerable amounts of both lysosomal and other cytoplasmic enzymes.

The greatest interest regarding these enzymes is focused on proteinases. Neutral proteinases and their activators have been demonstrated in human tumors [52–54], together with the lysosmal enzymes cathepsin D and B. Both lysosmal enzymes have acid pH optima but the most likely candidate in the present context seems to be cathepsin B, since its activity extends up to pH 7.5 [55].

Immunohistochemical studies on the localization of lysosomal cathepsins have been hampered by many methodological difficulties. Recent work on the localization of cathepsin D by antibody markers indicates that at least in some tumors, extracellular enzyme is detectable at their edges and in the surrounding stroma [56]. Thus, the origin of this enzyme could be from the tumor and/or the stroma. In the case of breast neoplasms, both (benign) fibroadenomas and carcinomas may secrete large or small amounts of both proteases, and there is therefore no correlation between enzyme secretion and malignancy or invasion.

It is possible that tumors exert their degradative effects through interactions with nonmalignant cells including fibroblasts, endothelial, lymphoid and monocytoid cells and platelets. In addition, other agents must also be considered. Hypercalcemia in rats having bone destruction due to injected Walker tumor cells was abolished by administration of the anti-

inflammatory, non-steroidal drugs, aspirin and indomethacin, which are used in the treatment of osteoarthritis [57]. As these drugs are known to act mainly by their inhibition or prostaglandin synthetase activity, it is possible that tumor-induced osteolysis is mediated by prostaglandin release from tumors.

In a partly liquefied tumor-host interzone, the fibrinogen–fibrin system may play a particular role. Fibrinogen, as a constituent of the interstitial fluid, can be converted to fibrin by thromboplastin-like agents deriving from the tumor as well as from the host. Fibrin has been claimed to provide contact guidance to tumor cell locomotion, but it has also been credited with a barrier function similar to the one displayed in the spread of certain infections. At any rate, the fibrinogen–fibrin system with its great versatility, based on thromboplastic and fibrinolytic properties of both tumor and host, should be considered a key factor in the events at the penetration front [58].

In recent reports, it has been demonstrated that the upper surface of cultured fibroblasts and epithelial cells lacks adhesivity for other cells [59–60]. These findings have been confirmed for a variety of cells [61]. Macrophages from the rat abdominal cavity, for instance, were found to be unable to spread on rat mesentery. It may be assumed that the particular configuration of cellular surfaces, e.g., the presence of microvilli, prevents other cells from adhering and spreading. On the other hand, the inner surfaces of blood vessels and body cavities are frequent sites of tumor cell adhesion and, therefore, important starting points of penetration. Two mechanisms, acting singly or combined, can accomplish the adhesion of tumor cells to these surfaces:

(1) Microcoagulation around tumor elements.
(2) Exposure of subjacent connective tissue strata after retraction of endothelial and mesothelial cells.

Among the vast literature on the role of microcoagulation in tumor cell lodgment, studies on adhesion of tumor cells to vein walls are particularly relevant [62]. Intravenously injected lymphoma and carcinoma cells first became surrounded by platelets and then adhered to the wall of the inferior vena cava in two ways which were characterized by the presence or absence of damage to the underlying endothelium. On intact endothelium, there was loose adhesion of tumor cell-platelet-emboli with negligible production of fibrin, and these emboli deteriorated rapidly. On the other hand, on areas with damaged or absent endothelium, the tumor cell-platelet-emboli became firmly embedded in fibrin, and progressive passage of the tumor cells through the fibrin layer and the vessel wall could be demonstrated. It is, therefore, possible that in this experimental model the fibrinolytic activity of intact endothelium impedes adhesion and subsequent locomotion of tumor cells.

Retraction of endothelial or mesothelial cells, an interesting phenomenon of cellular motility in itself, can lead to the exposure of the deeper layers, basal lamina and connective tissue. Tumor cells exclusively or preferentially adhere to these denuded zones, as has been shown by scanning electron-microscopy for various tumors implanted into the peritoneal cavity [63–66]. While the exact causes of mesothelial retraction are unknown, some indications for endothelial cells were given concerning the contraction-inducing effect of histamine-type mediators [67] and the corresponding effect of thrombin [68]. Thus, tumor cells obviously are able to mobilize various agents that help them to bypass the relatively nonadhesive endothelial and mesothelial surfaces.

Without doubt, many other factors must be assumed to be operating on locomotive tumor cells in the ecosystem constituted by the tumor-host interzone. Nothing is known, for instance, about effects of antibodies, directed against surface antigens of tumor cells, on the latter's locomotion.

V. THE LOCOMOTIVE APPARATUS OF THE NON-MUSCULAR MAMMALIAN CELL

From a chemical viewpoint, close similarities exist between the proteins involved in contraction of striated muscle and contractile proteins present in non-muscular cells. It is therefore a reasonable assumption that this group of proteins, the actomyosin system, is responsible for movement in both muscular and non-muscular cells. Thus, locomotion of tumor cells can also be expected to depend on the operation of the actomyosin system.

In muscle cells, actin and myosin appear as filaments arranged in segmented arrays, and motive force generation is due to a sliding mechanism of these filaments past each other, driven by repetitive interactions of cross-bridges between them. An exploration of the locomotive apparatus of non-muscular cells, therefore, had to start with an inventory of filamentous structures.

Electron microscopy, so far, indicates the

presence of three types of filamentous organelle in eukaryotic cells:

(1) microfilaments with an approximate diameter of 6 nm

(2) a collection of filaments with diameters of 8–11 nm, called "100 Å filaments"

(3) microtubules: hollow cylinders with a total diameter of 25 nm and an empty channel of 15 nm and composed, most likely, of 13 individual protofilaments.

What is the relation of the actomyosin system to these filamentous structures?

Microtubules consist mainly of tubulin, a structural protein which contains two different polypeptide chains with a molecular weight of 53,000 daltons each. It appears, therefore, that microtubules are not directly linked to motive force generation based on the actomyosin system.

Of the two classes of filaments, the 100 Å filaments, so far, have resisted all attempts of chemical analysis: they are, in biochemical terms, an unknown system.

The situation is different with microfilaments. Heavy meromyosin (HMM) is a specific histochemical stain in electron microscopy for microfilaments, giving rise to characteristic double arrow-headed structures [69]. HMM is the proteolytic headpiece of the myosin molecule which can form specific complexes with polymerized actin, the F-actin. Thus the easiest explanation for the decoration experiment is that F-actin like polymers are the major structure of the microfilament.

More information on actin as a constituent of microfilaments was obtained by the recent introduction of an immunofluorescence microscopy assay [70]. It allowed the demonstration, within cultivated mouse 3T3 cells and a variety of fibroblasts and epithelial cells from different species, of a complex array of straight actin-containing fibers with the following properties:

(1) The actin fibers show no interruptions. The diameters vary within the same cell and especially between different cell lines. In some fibroblasts diameters of 1 μm can be reached.

(2) Different cell lines show a high degree of individuality in pattern formation.

(3) The fibers run often parallel to each other along the long axis of the cell.

(4) The fibers converge at some focal points. The expression of focal points can differ with the cell line.

(5) The fibers are concentrated at the inner side of the plasma membrane as submembraneous bundles.

Furthermore, locally concentrated but not substructured actin organization could be detected within ruffling membranes.

The next step consisted in the demonstration of myosin localization and, here again, the approach by immunofluorescence microscopy was successful. Myosins from non-muscle cells cross-react with smooth-muscle myosin, and it could be shown that antibody against gizzard myosin decorates the same fibers in fibroblasts that are decorated by the actin antibody [71]. There is, however, one important difference: myosin antibody gives rise to interruptions and striations whereas actin antibody gives uninterrupted fibers. Thus, as expected from the chemical features of myosin, the molecule is interspersed into the actin fibers most likely in forms of small oligomers.

This result clearly invites the interpretations that:

(1) myosin is localized close enough to F-actin within the same microfilament system, and that

(2) this localization allows the minimal requirement for the classic principle of actin-myosin interaction as a basis for potential contractility.

Following this first success in the biochemical anatomy of microfilaments, it was shown that other accessory proteins like tropomyosin and α-actinin are also part of the microfilament [72]. So it seems that microfilaments are not a storage form of F-actin but contain the whole contractile apparatus.

On this basis, it appears legitimate to use the term actomyosin filament or fibril for those structures in non-muscular mammalian cells that can be assumed to be directly involved in contractility and motility. That this is indeed the case was demonstrated for stress fibers (=thick bundles of microfilaments) of a fibroblastic cell line derived from a rat mammary adenocarcinoma [73]. Single fibers were cut out from lamellipodia of the spread cells by a laser microdissection technique, and active shortening of the isolated fibers, in presence of ATP and calcium, could be recorded by cinemicrography and studied by single frame analysis.

Thus, the actomyosin fibril of non-muscular mammalian cells has been recognized as a morphological as well as a functional unit of contractility. The role of this unit with regard

to cellular locomotion, however, is far from being clear. In contrast to the contractile proteins in muscle sarcomeres, the cytoplasmic actomyosins have not only the task of transforming chemical energy into mechanical work, they have also to provide the possibility of being themselves translocated over relatively long distances during most cytoplasmic movements, particularly so during locomotion. The transformation of F-actin to shorter chains or to G-actin and vice versa is an obvious advantage, if not a precondition, for such translocations of the contractile system: a transport of G-actin or short-chained actin is presumedly easier to perform than the translocation of F-actin which is a linear molecular aggregate with an extreme length in the μm-range.

In connection with these translocations and with locomotion as a whole, changes of the cytoplasmic consistency are indispensable. Work with slime molds and amoebae [74–76] offers a model of cytoplasmic events that, in all probability, is applicable to every type of locomotive cell. In Physarum as well as in many free living amoebae, there is a permanent transformation between the low viscous endoplasm and the higher viscous, i.e. rigid ectoplasm (sol$\rightleftharpoons$gel transformation). Actin in the flowing endoplasm is largely in the depolymerized state and transforms to F-actin spontaneously within the aging endoplasm. Therefore, it seems to be evident that G$\rightleftharpoons$F-actin transformations are involved in the cyclic change of endoplasm$\rightleftharpoons$ectoplasm in Physarum. There is a dynamic equilibrium between filaments (F-actin) and subunits (short-chained actin or G-actin). Cytologists in the first half of this century paid much attention to cytoplasmic viscosity changes and the "contractile gel-reticulum" of the cell. Today, there is hardly any doubt that the "contractile gel-reticulum" can be identified as cytoplasmic actomyosin, and that viscosity changes can be explained by the known ultrastructural and biochemical properties of cytoplasmic actomyosin.

On this basis, it is not unreasonable to assume that also in non-muscular mammalian cells, the actomyosin system is involved in both volume contraction of the cell body (under isotonic conditions) and in internal stabilization (under isometric conditions), and that these interconnected functions are linked to the non-fibrillar and fibrillar state, respectively, of the contractile proteins.

The concentration on microfilaments should, by no means, express the opinion that 100 Å filaments and microtubuli are not integral parts of the locomotive system. Recent electron microscopic studies in leukemias [77] have shown strikingly different distribution patterns of 100 Å filaments in resting and locomotive cells. The functional significance of this observation, however, is unknown, and the same statement must be made with regard to microtubili, although both organelles are often assumed to act as a cytoskeleton.

There is a very considerable body of knowledge on the nature of the contractile proteins in a wide variety of cells. However, the relationship of these data to cell movement and cell infiltration is unknown. The problem can perhaps be clarified by means of a simple analogy. If we consider a motile cell to be analogous to a car, the question is almost: How much can one predict about the car's speed, performance, direction and "social" behavior with respect to other cars, from inspection of its engine? The answer is: very little! Although we could deduce from comparison of their engines that a racing-car is faster and has more potential for acceleration than a 2-CV, providing their transmission systems are working, how fast they go in traffic between two points depends on the nature of the road—is it greasy, wet or dry?—stop signs, pedestrian crossings etc. and, above all, the driver. In a similar manner, the locomotion of cells cannot be predicted solely from examination of their contractile elements, but the substrata they move over or through must also be taken into account, as indeed must internal and external controlling mechanisms.

Variations of Liver Cell Control During Diethylnitrosamine Carcinogenesis

H. BARBASON, A. FRIDMAN-MANDUZIO, P. LELIEVRE and E. H. BETZ
Laboratoire d'Anatomie Pathologique, Institut de Pathologie Université de Liège au Sart Tilman, 4000 Liège, Belgium

Abstract—*Male Wistar rats chronically treated with diethylnitrosamine (DENA) (80 mg/l in drinking water) develop liver carcinomas mostly after the 90th day of treatment.*

Experiments were planned in order to investigate the cell kinetics of liver during the preneoplastic period (up to the 60th day). The mitotic response of the liver was studied in various conditions: in animals treated with DENA alone and in DENA treated rats submitted to a partial hepatectomy. Furthermore, normal hepatectomized rats were treated with liver extracts obtained in various conditions (normal and DENA treated rats). The extracts were prepared in order to purify mitotic inhibiting substances (chalone activity) normally present in liver tissue.

During the two first weeks of treatment, DENA induces a transient increase of mitotic index; after partial hepatectomy, the mitotic response is approximately normal. The cell divisions present during this period a normal circadian rhythm.

After the 30th day of treatment, the mitotic index decreases significantly, the response to the partial hepatectomy is reduced and the circadian rhythm of divisions is lost. During this period, glycogen retaining areas develop in the liver; no difference is observed between the response of these areas and that of adjacent parenchyma.

An extract obtained from a normal liver inhibits to a large extent the ^3H-thymidine DNA label and the mitotic response induced by a partial hepatectomy. A similar extract obtained from the liver tissue taken 24 hr after hepatectomy has no inhibitory effect. Extracts from liver of rats treated during 30 and 60 days with DENA behave in the same way as an extract from regenerating liver and produce no inhibition.

The results indicate that the preneoplastic period shows at least two successive phases. During the two first weeks, the mechanisms controlling the cell homeostasis of liver tissue seem to function normally. Later on, there seems to be an important disturbance of these mechanisms.

INTRODUCTION

RATS continuously fed with a diet containing diethyl- or dimethylnitrosamine develop a high percentage of liver carcinomas [1]. The appearance of the tumors is preceded by a latent period the length of which varies according to the experimental conditions. It has been shown that during this preneoplastic period, enzymic changes occur in circumscribed areas of the liver parenchyma. The decrease of glucose-6-phosphatase and adenosine triphosphatase activity in these areas is well documented [2, 3].

Very little is known about the disturbances of the organ specific mechanisms which control the cell proliferation and function. It is likely that these homeostatic mechanisms undergo also changes during the preneoplastic period. It is possible to investigate the homeostatic regulation by measuring the proliferation rate of liver cells after partial hepatectomy. Rabes *et al.* [4] have followed the changes of labelling index and enzymic content of liver cells during the latent period in diethylnitrosamine (DENA) treated rats. They have described three successive phases in the liver response:

(1) Period of weakening of the activities of glucose-6-phosphatase and adenosine triphosphatase activity of acinocentral hepatocytes coincidently with loss of ability to proliferate even after organ specific stimulation of growth;

(2) Period of complete loss of the activities of glucose-6-phosphatase and adenosine tri-

Accepted 25 August 1976.

phosphatase within circumscribed acinocentrally localized groups of hepatocytes, coincidently with return to ability to proliferate, but for almost all hepatocytes of the enzyme deficient cell groups only after specific stimulation by partial hepatectomy;

(3) Period of autonomous proliferation of these enzyme deficient cells without an additional growth stimulus, accompanied by a loss of response to organ specific homeostatic control."

There is good evidence also that the tissue homeostasis is controlled by substances released by differentiated cells. These so-called "chalones" [5] depress specifically the mitotic activity in the tissue from which they are extracted. It is possible to prepare a liver extract which depresses specifically the mitotic activity in hepatocytes after partial hepatectomy [6–9].

The aim of the present work was to study the influence of DENA treatment on the mitotic response following partial hepatectomy and on the "chalone activity" of liver tissue. The attention was focused on the preneoplastic period extending up to the 60th day of treatment. During this period, nodular areas appear in which glycogen is retained after fasting owing to enzymatic disturbances.

On the other hand, previous results have shown that the mitotic activity induced by partial hepatectomy varies significantly in the course of the day [10–14]. This circadian rhythm of mitoses which is also part of the tissue homeostasis has to be taken in account in planning the experiments.

MATERIAL AND METHODS

Male Wistar rats, weighing approximately 180 g, were treated chronically by diethylnitrosamine (DENA) given in drinking water (80 mg/l) which represents an ingested dose of about 10 mg/kg. The experiment was divided into two parts. The first was devised in order to test the ability of hepatocytes to divide at different stages of the preneoplastic period: 7th, 15th, 30th and 60th day after beginning DENA administration.

At each delay, 5 treated animals were sacrificed at 10 a.m. and 5 at 10 p.m. At the same time, 10 animals were submitted to a partial hepatectomy [15] at 10 a.m.; among them, 5 were sacrificed at the 48th (morning) and 5 at the 60th (night) post-operative hour. The mitotic indices were calculated for all experimental groups and were compared to those of control hepatectomized animals, not receiving DENA.

In order to rule out an acute toxic effect of the drug, a supplementary group was treated by DENA during 50 days and then left 10 days without treatment before being hepatectomized in the same conditions.

After 30 and 60 days of treatment, the mitotic activity was also measured in the "hyperplastic nodules" visible by glycogen storage after 18 hr fasting. Animals have been used as control to test the eventual influence of fasting on the liver cell response to hepatectomy. The hyperplastic areas were stained by P.A.S. after freezing-substitution fixation.

The second part of experiments was planned in order to measure the "chalone" activity of liver tissue during the preneoplastic stage.

At the 15th, 30th and 60th day of DENA treatment, 20 rats were sacrificed. In each group, hepatic extracts were prepared according to the method described by Verly *et al.* [8]. The 105·000 G supernatant of liver homogenate is treated by ethanol and the precipitate obtained between a 70 and 87% of ethanol concentration is used. This extract was diluted in saline and injected (1 ml i.p.) in normal hepatectomized animals at the 1st and 6th post-operative hour; the amount of product injected corresponded to the amount extracted from 70% of the whole normal hepatic mass. In order to estimate the "chalone" activity, the ^{3}H-thymidine labelling index and the mitotic index were measured respectively at the 24th and 28th postoperative hour and compared to the same indices found in control hepatectomized rats treated with saline solution instead of liver extract.

The results were also compared to those obtained when the extract is prepared from a normal and a regenerating liver. In the last case, the animals were sacrificed at the 24th postoperative hour at the moment of the DNA synthesis peak [11, 12]. The labelling index is measured 1 hr after administration of ^{3}H-thymidine (2 μCi/g i.p.).

All labelling and mitotic indices given in the tables are the mean of counts made in at least 5 animals. The standard error of the mean has been calculated.

RESULTS

1. *Response of liver tissue to hepatectomy*

The results of the first group of experiments are summarized in Table 1.

In the control unoperated rats, either on a

Table 1. *Mitotic activity induced by partial hepatectomy in various conditions. Results are expressed in number of mitoses/*1000 *nuclei*

	Unoperated animals			Post-operative delays			
				48 hr		60 hr	
	Normal parenchyma		Glycogen retaining nodules	Normal parenchyma	Glycogen retaining nodules	Normal parenchyma	Glycogen retaining nodules
Killing time	10 a.m.	10 p.m.	10 a.m.	10 a.m.	—	10 p.m.	—
Normal control	0	0	—	24·0(±2·0)	—	7·0(±2·0)	—
Fasting control	0	0	—	23·0(±2·0)	—	8·0(±1·3)	—
DENA for 7 days	0·5(±0·1)	0·4(±0·2)	—	26·0(±2·0)	—	6·2(±0·6)	—
DENA for 15 days	2·7(±0·5)	0·2(±0·1)	—	18·3(±2·3)	—	7·4(±1·0)	—
DENA for 30 days	0·6(±0·2)	1·2(±0·3)	1·0(±0·3)	11·0(±0·7)	6·0(±2·0)	10·3(±1·3)	6·1(±2·8)
DENA for 60 days	1·2(±0·2)	0·8(±0·2)	1·2(±0·4)	8·3(±2·0)	8·9(±2·1)	5·7(±2·3)	6·0(±2·5)
50 days of DENA treatment, interruption and killing 10 d. later on	0·2(±0·2)	0·24(±0·1)	—	5·6(±0·9)	—	5·1(±0·7)	—

normal diet or after a 18 hours fasting, mitoses were not detected.

In unoperated but DENA-treated animals, numerous necrotic foci develop and mitoses appear in the liver; the mitotic index reaches a maximum after 15 days. At this time, a circadian rhythm of mitoses is clearly visible the mitotic activity being higher at 10 a.m. When the DENA treatment is prolonged for 30 or 60 days, the mitotic activity is stabilized at rather low values and the circadian rhythm is lost. When the animals are treated during 50 days and kept at a normal diet for 10 more days, the mitotic activity is significantly lower than that found in rats receiving DENA until sacrifice at day 60.

In normal animals, a partial hepatectomy (at 10 a.m.) triggers the mitotic activity. The mitotic index presents a higher value during day time (48th post-operative hour) than during night (60th post-operative hour).

No difference is observed in regenerating liver between normally fed and fasting animals.

After 7 days of DENA feeding, the response of liver tissue to partial hepatectomy is normal. As the DENA treatment progresses, the hepatectomy triggers fewer and fewer mitoses and the circadian rhythms gradually dissappears.

Glycogen retaining nodules could be detected 30 days after beginning DENA administration. The results indicate that the mitotic activity in those areas is not statistically different from that observed in the adjacent liver parenchyma. This is true for hepatectomized rats as well as for unoperated animals.

When the drug administration has been interrupted at day 50, i.e. 10 days before the hepatectomy, the results obtained are similar to those observed after a continuous feeding of DENA for 60 days.

2. *Variations of "chalone" activity in liver during DENA treatment*

The Table 2 summarizes the changes of activity when the extracts are obtained from livers in various experimental conditions. This activity is estimated by the degree of inhibition of mitoses in normally regenerating liver.

The extract from a normal liver has a strong inhibitory effect on the mitotic and labelling indices measured in the normal liver after partial hepatectomy. On the contrary, the extract from a regenerating liver has no inhibiting effect.

When the extract is obtained from animals treated by DENA for 15 days, the inhibitory effect is still present. However, when the extract originates from liver of animals treated for 30 or 60 days, there is no more "chalone" activity to be detected. In all the experiments, mitotic and labelling indices change in parallel.

DISCUSSION

The results described in the present paper indicate that the normal control of liver homeo-

Table 2. "Chalone" activity of liver extracts in various experimental conditions. The preparations are injected to normal hepatectomized rats. Labelling and mitotic indices are measured respectively 24 and 28 hours after operation

Product injected	Labelled nuclei/1000 cells measured at the 24th post-operative hour	Mitotic index measured at the 28th post-operative hour
Saline	258(±24)	22(±2)
Normal liver extract	60(±14)	4(±1)
Liver extract after 15 days DENA feeding	24(±5)	14(±2)
Liver extract after 30 days DENA feeding	210(±20)	16(±2)
Liver extract after 60 days DENA feeding	248(±22)	22(±2)
Extract of regenerating liver (24th post-operative hour)	265(±34)	30(±4)

stasis is disturbed in rats continuously fed with a diet containing DENA. This change is revealed by the reduced ability of liver tissue to respond by a mitotic wave to a partial hepatectomy and by the absence of a circadian rhythm in this reduced mitotic activity. According to previous results of Rabes *et al.* [4, 16], such a loss of the normal control can be demonstrated long before the development of liver cancers. In fact, the liver cells seem to respond normally to a partial hepatectomy during the two first weeks after beginning DENA feeding. After a 30 day treatment, the mitotic response is already significantly decreased. It is striking that at the same time, the circadian variations of the mitotic activity have completely disappeared. Whereas in normal liver the mitotic response is higher during day time than during night time, the mitotic indices found in DENA treated animals are the same whatever the moment, day or night time. It is noteworthy that there is no significant difference between the response of the normal looking tissue and the glycogen retaining areas which are detectable after the 30th day.

The DENA feeding induces by itself a certain mitotic activity in response to the liver damage. Up to day 15, the mitotic index shows a circadian rhythm with a higher peak at day time.

After a 30 day treatment, the mitotic activity decreases, as compared to a 15 day treatment. This could indicate that the number of cells able to respond by mitoses to the DENA damage decreases. It seems however that these cells still able to respond to the stimulus inducing mitosis have escaped the circadian control. This could be a consequence of a toxic effect of DENA given in rather large dose. When DENA treatment is interrupted at day 50, the mitotic activity is still decreased 10 days after this interruption. This observation is compatible with a possible decrease of cell destruction and hence a reduction of the mitotic stimulus.

If a small number of cells seem still able to divide the largest part of the liver cells have not recovered their ability to respond normally to a partial hepatectomy. The loss of homeostatic control cannot be ascribed to an acute toxic effect of DENA on liver cells. The damage induced does not disappear after a 10 day interruption of DENA administration. It is likely that a DENA treatment of a certain duration induces a more permanent damage.

It seems that in our experimental conditions the preneoplastic period can be divided at least in two different phases. During the first one, lasting about 15 days, the liver tissue remains under its homeostatic control; in the second phase, this control is getting less and less effective.

There is good evidence that neuro-hormonal factors play an important role in modulating the circadian variations of mitosis [5, 14, 17, 18]. It could be that in DENA treated animals, either the neuro-hormonal activity is disturbed or the dividing liver cells escape its control. There is yet no evidence to support any of these possibilities.

As far as the induction of mitotic activity is concerned, an important role is ascribed to the suppression of the so-called "chalone activity". It is thought that substances produced by the differentiated cells have an inhibitory effect on the mitotic activity. Our results show that

inhibitory factors can be demonstrated in normal but not from regenerating liver. This suggests that at least in normal liver such factors are produced by the cells when in G_0 but not by the cells engaged in a cycle.

When the "chalone" activity of liver parenchyma is measured during DENA treatment, it appears that this activity decreases when the treatment progresses. A preparation obtained from a liver exposed to a 30 day DENA treatment has lost most of its inhibitory activity. It is easy to understand that the removal of a large part of such a liver does not influence anymore the response in the remaining hepatic tissue. One may wonder why the amount of inhibitory factors decreases during chronic DENA feeding. This could be due to a direct toxic effect of the carcinogen on the liver cells in G_0. Another possibility could be that in such livers, the number of cells entering a cycle is sufficient to reduce significantly the "chalone" production. Preliminary results indicate that during the DENA treatment, a progressive endo-polyploidization of the liver cell nuclei takes place [19]. This observation, as well as the presence of cells with intermediate DNA values suggests that a DNA synthesis is going on [20]. The cells undergoing such changes are engaged in an atypical cell cycle and it is likely that they are unable to produce the factors responsible for mitotic inhibition. Further experiments are needed to confirm this hypothesis.

Evaluation of Routine Pre-Operative Bone Scintigraphy in Patients with Breast Cancer

R. M. J. M. BUTZELAAR*, J. A. VAN DONGEN†, J. B. VAN DER SCHOOT‡, and B. J. G. VAN ULDEN§

Abstract—*A prospective study on bone scanning was undertaken in patients with a clinical operable breast carcinoma to investigate its use in the staging of these patients. From 90 patients with a proven breast carcinoma, stages T_1, T_2, N_0, N_{1a}, the pre-operative whole body skeletal scintigraphy was positive in 7 cases. Four of these could be excluded because other reasons than metastases could be demonstrated to be the cause of the positive scan.*

So in only 3 cases (3·4%) the scan was positive, suggesting bone metastases.

These lesions could, up to now in no way be proven to be metastases. The final percentage of pre-operative detection of bone metastasis after a longer follow up period may therefore even be less than 3·4%. We therefore decided to omit routine pre-operative bone scanning in patients with a breast carcinoma stages T_1, T_2, N_0, N_{1a}.

INTRODUCTION

BONE scintigraphy has been performed for 15 years and in that time has become widely used as a diagnostic aid in many branches of medicine. During the past few years many changes and technical improvements have been introduced both in the field of radiopharmaceuticals and detection equipment.

Originally examinations were cumbersome, involving the use of Strontium^{85} or Fluorine^{18}, but these have now been replaced by modern radiopharmaceuticals such as technetium^{99m} labelled diphosphonates [1–6]. Simultaneous improvements have also occurred in detection technology, so nowadays skeletal scintigraphy examination by gammacamera [7] or dual probe rectilinear scanner is usually completed more rapidly than an equivalent conventional radiological examination of the same structures. In the presence of metastases, destruction and new bone formation occur simultaneously. New bone formation occurs by deposition of hydroxyapetite crystals in a matrix of osteoid tissue and the labelled diphosphonates, used in scintigraphy are bound to these hydroxyapetite crystals. This occurs at an early stage at the time conventional radiological examination reveals no abnormalities. In world literature there is general agreement concerning the superiority of skeletal scintigraphy over skeletal radiological examination for detection of metastatic bone lesions [8–12].

These facts encouraged us to undertake a prospective study of the value of bone scanning as a routine pre-operative investigation to help in the staging of patients with breast cancer. It has been estimated that about 30% of patients treated by radical mastectomy die within 5 years from direct effects of their carcinoma and in 71% of these, bone metastases can be found at autopsy [8]. Mutilating operations such as Halsteds mastectomy remain the operation of choice in cases of operable breast cancer. If bone metastases could be demonstrated in an early stage unnecessary mutilating surgical treatment would be avoided.

Accepted 24 August 1976.

MATERIAL

In the Antoni van Leeuwenhoek Ziekenhuis and the St. Lucas Hospital between October 1974 and January 1976 all patients with palpable breast tumors, clinically suspected to be carcinoma in stages T_1, T_2, N_0, N_{1a} were investigated. In all cases a conventional radiological examination of skull, thoracic cage, spine, pelvis and extremities was performed.

A skeletal scan was performed 3 hr after i.v. administration of 15mCi of ^{99m}Tc-diphosphonate (Osteoscan). The scans were made in 43 patients with an Elscint Dual Probe Whole body scanner equipped with 55-hole 90 mm-focal-length collimator (FMHW 11 mm) and in 47 patients with a Toshiba Jumbo Gamma-camera G.C.A. 401 with a 42·000-parallel-hole-resolution collimator (FWHM 8·1 mm on 10 cm). The results of the analog scans were recorded as negative, when no abnormal accumulations of radioactivity were seen, positive when there were clearly discernable hot-spots suggesting bone metastasis and equivocal when only slight or questionable local augmentations of radioactivity were seen. From every abnormal scan, positive or equivocal, extensive radiological examination was done and whenever possible a direct biopsy was performed.

RESULTS

Our series involved 110 patients (age 27–80 years). Twenty patients proved on histological examination to have benign breast lesions. From the remaining 90 patients an abnormal scan was obtained from 14, of which 7 were recorded as equivocal. In the 7 patients with equivocal scans there was no radiological or clinical evidence of metastasis and in some there were signs of degenerative bone lesions. The other 7 patients had hot-spots suggesting bone metastases. In one patient the positive scan was due to a simple healing ribfracture, confirmed by X-rays and open biopsy. A second patient with a positive scan of the lumbar vertebra's had radiological signs of severe degeneration of the lumbar spine, which was considered to be the cause of the positive scan. This opinion was strengthened by a second scan six months later, which showed no increase in activity. A hot-spot of the right maxillary sinus of the third patient was later shown by sinus tomography to be caused by pansinusitis. The fourth and fifth patient underwent biopsy for positive lesions in the lumbar spine and tenth rib and lumbar spine respectively. These lesions were normal on radiological examination. The biopsies were histologically negative for tumor although the pathologist considered one biopsy showed early signs of Paget's disease. Indeed review of appropriate radiographs tended to substantiate this diagnosis.

The remaining two patients with positive scans had hot-spots, one in the left mandible and the other in the fifth lumbar vertebra.

In these cases no biopsies were taken for various reasons, but X-ray tomography was negative. No biochemical changes indicating bone metastases were obtained in any of the patients.

DISCUSSION

From 90 patients with histologically proven breast carcinoma clinical stages T_1, T_2, N_0, N_{1a}, whole body skeletal scintigraphy revealed in 7 cases a hot-spot, suggesting bone metastasis. In four of these a benign lesion could be demonstrated to be the cause. The remaining 3 cases (3·4%) had a hot-spot, not otherwise explicable, suggesting a bone metastasis, but these could not definitely be proven to be so. This percentage is a maximum because with a longer follow up period some of these lesions may show not to be caused by metastases after all. Statistically our results mean that the chance a hot-spot suggesting bone metastases may be found on scanning, in a patient with breast cancer stages T_1, T_2, N_0, N_{1a}, can not exceed 8·4% with a confidence of 95%. There is considerable disagreement in world literature concerning the incidence of positive scans. Galasko [12, 13] in a 1975 publication described 24% positive bone scan results from a series of 50 patients with breast carcinoma stages T_1, T_2, T_3 (2 patients with large breasts), N_0, N_1.

Ten of these 12 patients died within five years from effects of the carcinoma.

Citrin [14] reported on a series of 83 patients with "primary breast cancer" from which he found 22 (27%) suspected to have bone metastases. In only a few cases metastases were proven.

Green [15] studied a series of 71 breast cancer patients in stages T_1, T_2, N_0, N_1, of whom 7 had positive scans. After one year 3 of them had definite bone metastases. He considered a percentage of 4% proven positive bone scans too small to justify routine skeletal scintigraphy in all patients suspected to have breast cancer.

Sauer [16] included all stages of breast carcinoma in his group of 127 patients and found 12% to have positive bone scans. There was no definite confirmation of the positive scan findings.

Charkes [17] detected a 9% positive scan rate in his series of 34 patients which included all stages of breast carcinoma. In the follow up of these patients all lesions were proven to be caused by metastases.

We consider the high percentages of positive scans found by some workers might be due to an other selection of patients entering their investigations.

Considering our results it would appear that routine pre-operative skeletal scintigraphy is a superfluous examination in patients clinically suspected to have a breast carcinoma stages T_1, T_2, N_0, N_{1a}.

Certainly there appears to be no indication to do routine skeletal X-ray surveys in these groups.

We therefore decided to omit routine bone scanning in patients with breast carcinoma stages T_1, T_2, N_0, N_{1a}. In the small group of patients with more advanced, but still operable breast cancer, we think the study should be continued.

Kinetic Response of an *In Vitro* "Tumour-Model" (V 79 Spheroids) to 42°C Hyperthermia

CHRISTINE LÜCKE-HUHLE and HERMANN DERTINGER
Institut für Strahlenbiologie, Kernforschungszentrum Karlsruhe, Postfach 3640, 7500 *Karlsruhe* 1, *Federal Republic of Germany*

Abstract—*The proliferative changes in multicellular spheroids of Chinese hamster lung cells were investigated under conditions of hyperthermia which lead in combination with radiation treatment to a TER (thermal enhancement ratio) of* 1·63 *By fractionated trypsinization single cell suspensions from successive shells of spheroids were prepared. Cells from the outer region (cycling cells) were found to be partially synchronized by heat and killed in S-phase whereas cells from the center of spheroids (non-cycling cells) became actively proliferating after heat treatment.*

INTRODUCTION

THE APPLICATION of hyperthermia for the treatment of cancer, especially in combination with radiation therapy, is presently under discussion as an alternative to high LET irradiations. There is abundant evidence that cancer cells grown *in vivo* and *in vitro*, are sensitive to elevated temperatures (review: [1]) and that the efficiency of cell inactivation is cell cycle dependent [2–4]. Most of the quantitative data on the cytotoxic effect of heat have been obtained from studies on monolayer cell cultures leaving some uncertainty as to their applicability to the *in vivo* situation. Multicellular spheroids grown from single cell suspensions as first described by Sutherland and co-workers [5] provide a more realistic test system simulating conditions of nodular carcinomas in that cell cycle redistributions and hypoxia occur as they increase in size [6, 7]. These properties make spheroids especially well suited for kinetic studies since both cycling and noncycling cells can be examined concurrently in three-dimensional contact. The kinetic response of exponentially growing V 79 monolayer cultures after hyperthermic treatment has been analyzed in a recent publication [8]. In view of the importance of cell-kinetic alterations for the hyperthermic treatment of cancer we now describe the kinetic response of V 79 spheroid cells after 4 hours at 42°C.

Accepted 16 August 1976.

MATERIAL AND METHODS

Cell culture

Spheroids of Chinese hamster lung cells (line V 79, obtained from Dr. R. B. Painter, San Francisco) were grown to a diameter of 250 ± 20 μm in 100 ml spinner flasks using Eagle's basal medium supplemented with 5% foetal calf serum (Gibco Biocult, BCL 005a) and neomycin sulfate (0·1 g/l). A more detailed description of the culturing technique applied has been published earlier [9].

Fractionated trypsinization of spheroids

The regularly-shaped spheroids offer the unique advantage of removing shell by shell simply by exposing them to a dilute (0·05%) trypsin solution at room temperature. By means of a stereo microscope (magnification 40-fold) with zoom optics this successive detachment of cells from the 250 μm spheroid can easily be followed: During about 6 min cells from a shell of about 20 μm thickness became detached from the spheroids. After stopping the trypsin action by adding an equal amount of medium to the sample the resulting single cell suspension was decanted. This procedure was repeated until the trypsin action had loosened all inner

cells resulting in a complete break up of the spheroid core. Normally, four fractions of single cells representing successive shells of the spheroids could reproducibly be obtained.

Heat treatment and irradiation

Heat treatment was carried out by placing the culture flasks into a waterbath of 42°C whose temperature was kept constant within ± 0·1 °C. After different periods of heat exposure (up to 9 hr) spheroids were subjected to fractionated trypsinization as described above. Only cells of the outer and inner shell, representing cell populations in different state of growth, were tested for survival and prepared for analysis by flow-microfluorometry (FMF).

In another set of experiments spheroids exposed to 42°C for 4 hr were reincubated at 37°C for defined periods of time before trypsinization and preparation for FMF-analysis. Irradiations were performed at 37°C or at 42°C in a ^{60}Co-γ-source at a dose rate of 22 krad/hr as determined by ferrous sulfate dosimetry. Whole spheroids or spheroids trypsinized into single cells were irradiated in small plastic vessels under aerobic conditions and plated as single cells for survival assay. All samples irradiated at 42°C were pretreated with heat as to yield a total hyperthermia of 4 hr.

For survival assay aliquots of single cell suspensions were plated into Falcon tissue culture flasks and incubated for 7 days. Cells yielding colonies with more than 50 cells each were considered as survivors.

Flow-microfluorometry (FMF)

DNA measurements were performed by flow-microfluorometry technique with the "Cytofluorograf" (Model 4801; Bio/Physics Systems) equipped with a 100-channel analyzer. For preparation cells were fixed in 70% ethanol, treated with RNase (0·1% in Tris buffer) for 1 hr at 37°C and subsequently stained with ethidium bromide (0·01 mg/ml) [8]. Under these conditions the amount of dye bound is proportional to the DNA content of the cells [10]. The distribution of fluorescence intensity of the stained nuclear DNA (usually 40,000 cells) was displayed as conventional histogram (cell number vs fluorescence intensity). The percentage of cells in the individual phases of the cell cycle (G_1, S, G_2+M) was calculated from the area under the DNA histograms assuming a rectangular distribution of S-cells between the G_1 and G_2 peak [11]. The reproducibility of independent experiments was better than ± 3%.

RESULTS

The dose–effect curves in Fig. 1 clearly demonstrate the enhanced effectivity for the combination of irradiation with heat exposure compared to irradiation alone. Especially noteworthy is the fact that the second shoulder of the survival at 37°C, indicative of hypoxic cells,

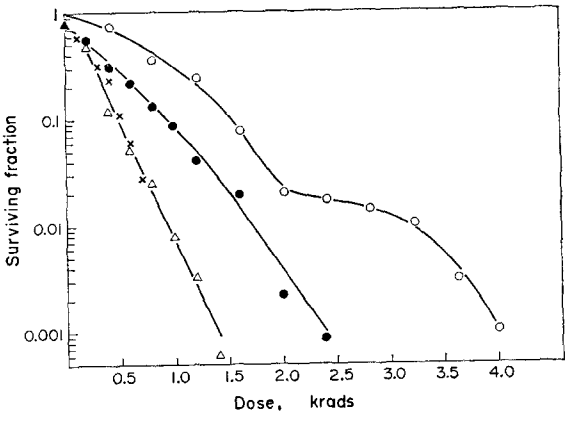

Fig. 1. *Radiation survival curves of V 79 spheroid cells with or without preceding heat treatment. Each point represents the mean from* 3–4 *separate experiments (relative error* ≈ 9·5%).

× *V* 79 *monolayer cells heat treated* (1 *hr*, 42°C) *prior to irradiation.*

has vanished. The dose–response curves obtained at 42° are related to the net thermal survival of the controls (D = 0) without normalizing these figures to one. Thus, inactivation by heat as well as its radio-sensitizing action can be visualized from Fig. 1. If we define the TER (thermal enhancement ratio) as the ratio of doses at 37°C and at 42°C required to reduce survival to 10% it amounts to 1·63 for whole spheroids. A further depression in survival is obtained when spheroids are trypsinized into single cells prior to irradiation. In this case, the response to hyperthermic irradiation is similar to monolayer cultures irradiated after 1-hr exposure to 42°C (Schlag and Lücke-Huhle, unpublished results).

Figure 2 shows cell cycle distributions of untreated control spheroids trypsinized into four fractions of single cell suspensions (see methods: fractionated trypsinization). Evidently, the percentage of S-phase cells decreases while the number of G_1-like cells increases indicating cells to become pro-

gressively noncycling with increasing depth in the spheroid.

Figure 3 shows the decrease in survival of cells originating from the outer and inner fraction of spheroids after heat treatment at 42°C for different periods of time. Though the inner cells are more resistant to heat exposure both survival curves exhibit a plateau at 50% and 74% survival level, respectively. A comparison with the heat treated monolayer of the same cell line either in exponential or in the plateau phase of growth [8] clearly demonstrates a greater resistance for the spheroid system. Hyperthermia applied for 4 hr leads to small changes only in the fractions G_1, S and G_2+M if cells from totally trypsinized spheroids are analyzed by flow-microfluorometry (Figs. 4a and 4b). With the fractionated trypsinization procedure a more specific investigation of proliferative changes in spheroids is possible as demonstrated by the DNA-distributions in Figs. 4c and 4d. The quantitative difference between the two results can be explained by the presence of a great number of noncycling (G_1-like) cells in theDNA histograms of Figs. 4a and 4b.

Alterations of cell cycle distributions *during* heat exposure are shown in more detail in Fig. 5. The percentages of the individual phases (G_1, S and G_2+M) of outer and inner spheroid cells are plotted against the time of

treatment. While the inner cells show only minor proliferative changes, significant effects are observed within the outer fraction. During heat exposure we find a depletion of G_1-cells indicating a block in $G_2 + M$. The accumulation of cells in $G_2 + M$ is only moderate because cells are simultaneously arrested in S-phase as evident from the increasing level of S-phase cells in the outer exponentially growing spheroid fraction. The sudden decrease of cells in S-phase after 9 hours is not due to a real proliferative event but rather to a staining artifact: Dead S-phase cells being at that time severely damaged appear no longer at the normal position in the cytofluorogram corresponding to their DNA-content but instead as debris on the left hand side of the G_1-peak (Fig. 6).

In Fig. 7 the percentages of G_1, S and $G_2 + M$ cells are plotted against time following a 4 hr heat treatment. The proliferation kinetics of the outer cells after hyperthermia is characterized by the following steps: the $G_2 + M$ block is immediately released followed by the release of the S-block 8 hr later. This generates a wave of synchronous cells which reach maximal values in $G_2 + M$ 12 hr after heat treatment. Fourteen hours after hyperthermia the G_1-compartment is repopulated and after 20 hr the cell cycle distribution approximates that of the control. With the inner cells the situation is different. Four hours after the return to 37°C we find a steady increase of S-phase cells whereas the G_1-fraction decreases.

DISCUSSION

Multicellular spheroids enabled us to study various proliferative effects of heat in a three-dimensional cell culture system without the necessity of generating conditions such as hypoxia or plateau growth in an artificial way. Since the TER of 1·63 as calculated for the spheroids from Fig. 1 comprises both heat-induced cytotoxicity and radiosensitization it is tempting to estimate the fractional effect of pure radiosensitization. This can be done by calculating the ratio of doses at 37°C and 42°C required to reduce survival to 10% of the zero-dose figure. This quantity amounts to 1·46 indicating that under our conditions the effectivity of a combined heat- and radiation treatment is determined mostly by thermal radiosensitization.

The obvious difference in radio-sensitivity between spheroids and single cells after identical preceding heat treatment (Fig. 1) must be ascribed to the phenomenon of extensive intercellular cooperation within three-dimensional cell clones. This contact phenomenon has been shown to render the proliferative cells from the outer spheroid shell more resistant to γ-irradiation at 37°C as compared to exponentially growing monolayers [9]. Recent irradiation experiments with negative pions revealed that the spheroid cells exhibit contact resistance even with respect to radiation of higher LET [12]. From Fig. 3 it is evident that spheroid cells can tolerate more hyperthermic damage: although the outer spheroid cells have the same cycle distribution as the exponentially growing monolayer they are exceptionally thermoresistant. Similarly, the inner spheroid cells are more resistant to heat than the plateau phase monolayers. In addition, Fig. 3 shows that cycling cells are more sensitive to heat than noncycling cells. The plateau in the spheroid survival curves indicates that, after some initial cell killing, the surviving cells are perfectly protected by intercellular contact against further heat damage. Since the final rate of inactivation compares fairly well with the frequency of S-phase cells we may conclude that spheroid cells in S-phase are most heat sensitive and therefore most efficiently killed by heat. This view is supported by the results of the proliferation kinetic studies during heat exposure. From Fig. 4 it can be seen that part of the cells accumulated in S-phase during hyperthermia leave that phase as cell debris (Fig. 6) suggesting lethal damage to these cells. Pronounced heat sensitivity of S-phase cells was also observed for monolayers of V 79 cells heated both in logarithmic and plateau phase [8] and is in agreement with the results by other authors [3, 4].

Elimination of hypoxic cells is evident from the lack of the hypoxic shoulder in the survival curve of spheroids irradiated after heat treatment. However, our results do not allow a distinct conclusion as to the process leading to this elimination. Although reoxygenation of the inner cells due to killing of the outer cells cannot be completely ruled out we prefer the explanation based on the results by Schulman and Hall [13] according to which hypoxic V 79 cells are more sensitive than aerobic cells. As only a few per cent of the inner spheroid cells are hypoxic their preferential inactivation by heat would not contradict the interpretation offered for the curves in Fig. 3 (see above). Synchronization of the outer exponentially growing spheroid cells is evident from Fig. 7. The pattern of synchronization is similar to that observed after heat treatment of exponentially growing V 79 monolayers [8] and agrees with the findings described for other cell lines [14]. In contrast to the outer cell fraction the G_1-like inner cells of spheroids do not participate appreciably in synchronous growth, the kinetic changes being rather moderate during and after heat exposure. Therefore, we may assume that a large portion if not all of the inner G_1-like cells reside in a resting (G_0)-phase which is not resolvable by the staining technique applied. The steady increase of S-phase cells with the concomittant decrease of the G_1-like cells, however, indicates a progressive transition of the inner cells into the proliferative state. Clearly, this is the consequence of renutrition and reoxygenation of the noncycling cells due to killing of the outer cells by heat treatment. Kal and Hahn [15] presented evidence for a recruitment of noncycling cells after combined heat- and X-ray treatment of EMT-6 tumour by applying a mathematical model. But so far recruitment of this type was not shown directly and only the method of fractionated trypsinization offered the possibility to follow the kinetic response of cycling *and noncycling cells* in a three-dimensional system.

Abstract—*Male hamsters, 3 months of age, were treated for 9 months by thrice weekly injections of diethylstilboestrol (DES). All animals developed kidney tumours and histopathological examination showed that the intermediate lobes of the pituitary were hyperplastic and neoplastic. The content of melanocyte-stimulating hormone (MSH) in the pituitary glands of 17 control and 12 DES-treated animals was measured by bioassay and radioimmunoassay. Whan compared with control pituitaries, the concentration of immunoreactive a-MSH in treated animals was significantly elevated* ($P < 0.005$) *with significant positive correlation between pituitary weight and total a-MSH content. The levels of bioactive MSH were also raised. Serum levels of immunoreactive a-MSH were consistently higher in treated animals.*

The possibility exists that the induction of kidney tumours by oestrogens in the male hamster is mediated via the pituitary gland and that MSH may be of significance in the process of carcinogenesis.

INTRODUCTION

THE METHOD by which oestrogens induce renal tumours in the male hamster is uncertain. Kirkman [1] considered the possibility that such hormones acted directly on the kidney since stilboestrol implanted in the spleen and, therefore, in the path of hepatic drainage failed to induce renal tumours. Algard [2] supported this view since he found that organ cultures of renal tumours were oestrogen dependent.

Another suggestion was that oestrogen-induced tumours resulted from changes in the pituitary gland. Long-term oestrogen treatment has been shown to cause a significant increase in the number of prolactin-secreting cells while a prolactin-inhibiting drug (CB154), when given in combination with stilboestrol, reduced the incidence and severity of kidney tumours in the hamster [3]. Oestrogen treatment also has been found to induce hyperplastic and neoplastic change in the intermediate lobe of the pituitary gland of the hamster [3–5].

Melanocyte-stimulating hormone (MSH) is produced in the intermediate lobe of the pituitary [6] and, in the present study, the possibility has been examined that increased amounts of MSH are produced by the enlarged intermediate lobe resulting from prolonged oestrogen treatment.

MATERIAL AND METHODS

Fifty-four male Syrian golden hamsters (*Mesocricetus auratus*), aged 3 months at the beginning of the experiment, were used. The animals were housed individually in a light- and temperature-controlled room, weighed at weekly intervals and maintained on dog-chow and tap water *ad libitum*, supplemented twice weekly with cabbage. The hamsters were divided randomly into two groups, each of 27 animals. One group consisted of untreated controls while the animals of the second group were treated with diethylstilboestrol (DES). Each animal received one s.c. injection of 0·6 mg DES (Sigma) suspended in 0·2 ml distilled water three times per week. After a total dose of 65 mg DES over a period of 9 months, the animals were finally weighed, killed by cervical dislocation and autopsied.

Accepted 4 June 1976.

*This work was made possible by the financial support of the Yorkshire Cancer Research Campaign.

The pituitaries of 17 control and of 12 DES-treated hamsters were removed immediately, weighed and placed in separate phials containing 1 ml of 0·25% glacial acetic acid and stored at −20°C for MSH assay. Pituitary glands from the remaining treated and control animals were weighed, fixed in 10% formal-sublimate and stained by Herlant's tetrachrome method for cytological examination. At post-mortem, testes and kidneys were weighed and fixed in 10% formal-saline together with representative portions of liver, spleen, lungs and brain. The tissues were embedded in paraffin-wax, sectioned at 5 μm and stained with haematoxylin and eosin for histopathological examination.

MSH assays

The method of Howe and Thody [7] was used for the bioassay of total MSH activity in extracts of pituitary tissue. A radioimmunoassay [8, 9] was used for the measurement of pituitary and serum a-MSH levels.

Statistical analysis was done by the 2-tailed Student's *t*-test using a Data General Corporation Nova 820 computer programmed to correct for inter-group variance difference when computing *P* values.

RESULTS

Of the 27 DES-treated animals, 3 died early in the course of the experiment and were discarded. In the remaining animals, statistical analysis failed to show any significant difference in body weight between treated and control animals ($P > 0·05$) (Table 1) and, consequently, it was possible to make direct comparisons of organ weights. The kidneys of the DES-treated animals were significantly heavier than those of controls ($P < 0·0005$) (Table 1). This difference in weight was clearly associated with the presence of tumour tissue in the kidneys of all treated animals. In general, kidneys were enlarged, irregular in outline with protruding tumour nodules and showed multiple neoplastic foci of varying size—3 mm to 2 cm in diameter—that were mainly bilateral and cortical in distribution. Lesions were solid, cream coloured or, often, consisted of haemorrhagic cysts intermixed with solid tumour. Central necrosis was prominent in the larger lesions. Four of the animals had haemorrhagic ascites with metastatic deposits on the serosal surfaces of abdominal organs. Histopathologically, a gradation of change from increased basophilia and hyperplasia of tubular epithelial cells to frank neoplasia could be observed within any one kidney. Because of origin from tubular epithelium and their invasive tendencies, the tumours were classified as carcinomas.

The pituitary glands from DES-treated animals were larger and significantly heavier than those from control animals ($P < 0·005$) (Table 1). The anterior lobe was compressed to a thin shell of tissue covering a bulging intermediate lobe. The main alteration lay in the cellular composition of the adenohypophysis with a significant increase in the number of prolactin-secreting cells and a decrease in the number of somatotrophin-secreting cells and in the basophils. Histopathological examination showed that the considerable enlargement of the pituitary was mainly restricted to the intermediate lobe. The cells were hypertrophic and hyperplastic with frequent evidence of mitosis. Neoplastic change had supervened and infiltration of the posterior lobe and infundibular stalk by cells of the intermedia was common with, in some cases, almost total replacement of the posterior lobe. Occasionally, invasion of the anterior lobe was in evidence. Those findings confirm our previous results [3].

The results of the MSH assays are shown in Table 2 and Fig. 1 and 2. The mean level of immunoreactive a-MSH in the pituitary glands of the 17 control animals was 471 ± 50 ng/pituitary. By bioassay, the mean MSH activity in 5 of those pituitaries was equivalent to 3980 ± 370 ng a-MSH/pituitary. Thus a-MSH accounted for approximately 10% of the total bioassayable MSH in the hamster pituitary.

There was a significant increase ($P < 0·005$) in the mean level of immunoreactive a-MSH (16,100 ± 430 ng/pituitary; 386 ± 69 ng/mg pituitary) in the pituitaries of DES-treated animals when compared with controls (Fig. 1). A significant positive correlation was found

The values of P *denote the significance of difference between groups, calculated by two-tailed Student's* t*-test.*

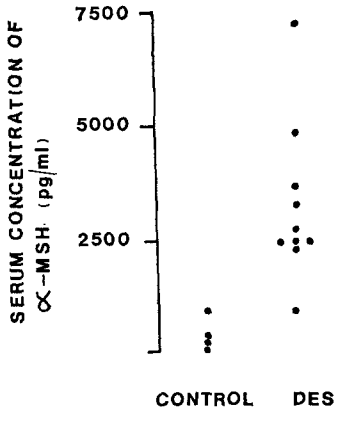

Fig. 2. Effect of DES treatment on serum levels of α-MSH in male hamsters.

between pituitary weight and total content of a-MSH ($r = 0{\cdot}6$; $P < 0{\cdot}02$). Three pituitaries from DES-treated animals bioassayed for MSH were found to contain markedly increased activity (equivalent to 119,260 ± 47,840 ng α-MSH/pituitary). The immunoreactive/bioactive ratio in the pituitaries of 2 of those animals was higher than normal and suggested a preferential increase in the α-MSH content of the glands.

To measure serum levels of immunoreactive α-MSH it was necessary to pool sera from several animals so that ultimately there were insufficient numbers for statistical analysis. However, the values illustrated in Fig. 2 indicate that serum α-MSH levels were consistently higher in DES-treated than in control animals.

There have been several reports that prolonged oestrogen treatment of the hamster leads to hyperplastic and neoplastic changes in the intermediate lobe of the pituitary [3–5]. The present results confirm those findings but also show that the enlarged intermediate lobes are capable of producing and releasing increased amounts of MSH.

Various forms of MSH exist and, in the normal hamster, Penny and Thody (unpublished data) have estimated that α-MSH accounts for approximately 10% of the total bioassayable MSH of the pituitary. That figure was confirmed in the present study. However, in 2 of the 3 DES-treated hamsters, the pituitaries of which had also been bioassayed, a greater proportion of α-MSH was found indicating that the hyperplastic and neoplastic intermediate lobes were preferentially producing α-MSH. That may have been a common feature of all the enlarged lobes since most of them contained exceedingly high levels of immunoreactive α-MSH.

Hamilton *et al.* [3] have reported that a prolactin inhibitor (CB154), when given concurrently with stilboestrol, reduced the incidence and severity of kidney tumours. The effect of CB154 may be related to interference with prolactin secretion although Hamilton *et al.* (unpublished data) failed to induce renal tumours with prolonged prolactin treatment and was unable to demonstrate that, when given concurrently with DES, prolactin influenced the induction or severity of the kidney tumours. However, Penny and Thody (unpublished data) have found recently that, in the rat, CB154 inhibits the secretion of MSH and that finding suggests the possibility of a relationship between renal carcinogenesis and MSH secretion. There is emerging evidence that indicates that MSH acts on the kidney.

Orias and McCann [10] reported that α-MSH and β-MSH induced natriuresis in the rat while increased levels of immunoreactive β-MSH have been found in patients with chronic renal failure [11, 12]. Smith and Shuster (personal communication) consider that, in man, the kidney may metabolise MSH-like peptides. Such metabolites may occur in the hamster and under conditions of increased MSH secretion may lead to neoplastic change in the kidney. That possibility must now be examined.

The Effect of BCG on *In Vitro* Immune Reactivity and Clinical Course in Dogs Treated Surgically for Osteosarcoma*

STEEN BECH-NIELSEN†, ROBERT S. BRODEY†, ISAIAH J. FIDLER‡, DONALD A. ABT† and JOHN S. REIF†

†*From the Department of Clinical Studies, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, Pennsylvania* 19174, *U.S.A.*

‡*Frederick Cancer Research Center, P.O. Box B, Frederick, Maryland* 21701, *U.S.A.*

Abstract—*Cell mediated reactivity (CMR) and serum blocking activity (SBA) were assessed postsurgically in* 11 *dogs treated surgically for osteosarcoma. Six dogs received Bacillus Calmette-Guérin (BCG) and* 5 *served as controls. SBA decreased significantly soon after surgery in both groups. Two to three months after surgery SBA was slightly higher in the controls than in the BCG group. However, the postsurgical SBA in BCG recipients rose to about the same level as in the controls at* 4–12 *months, correlating in time with radiographic appearance of metastasis. This suggested that BCG delayed SBA for several months.*

The median survival time of the BCG treated dogs was 40 *weeks, significantly longer than the* 13 *week median survival time in the control group. The cumulative life table method for estimation of survival rate failed to show an effect of BCG on survival.*

INTRODUCTION

BACILLE CALMETTE-GUÉRIN (BCG) is a non-specific immunestimulant, which enhances the immune response to a wide variety of antigens including tumor specific antigens [1–3]. It can be used either locally or systemically. Several investigators have demonstrated that BCG vaccine given before or after tumor grafting in a syngeneic murine host can retard subsequent tumor growth [4–7]. The suppressive effect of BCG on tumor growth can be most readily demonstrated when the tumor has antigens differing from those of the host [4] and when the tumor mass is low [4, 5, 8]. An immunocompetent host is a requisite for the manifestation of BCG effects.

BCG immunotherapy has been utilized for human acute lymphocytic leukemia and malignant melanoma. Host immune responses to tumor specific antigens can be demonstrated in both neoplasms [9, 10].

Mathé *et al.* [11] showed significant prolongation of remission in leukemia patients treated with BCG. Rosenthal *et al.* [12] suggested the value of prior BCG vaccination in preventing leukemia in children. Morten *et al.* [10, 13, 14] and Nathansen [15] showed that BCG injected into the site of cutaneous melanoma retarded distant as well as local lesions while others found regression of only the injected lesions [16, 17].

In a recent study on the use of BCG in the treatment of metastatic melanoma, Prehn *et al.* [18, 19] reported that the *in vitro* lymphocyte cytoxicity in the presence of patient's serum showed correlation with the status of the clinical disease.

The treatment regimens employed have been empirical with regard to dose, type of BCG and route of administration [14–17, 20–27]. Whether BCG will cause inhibition or stimulation of tumor growth when administered *in vivo* is determined by a number of factors, among which the dosage [28] and route of administration, tumor volume at the time of treatment, and status of tumor immunity, appear to be of major importance [29]. The best preparation for treatment of a given tumor, the optimum dose and route of administration

‡HOP.—Hypertrophic pulmonary osteoarthropathy

have only recently undergone clinical investigation [2, 30]. The route of BCG administration may determine whether tumor suppression or enhancement is induced [31] and may influence the severity of complications [32]. Side effects reported include fever, nausea, rash, local skin necrosis, lymphopenia and leukopenia [15].

The aim of this work was to determine the effects of immunotherapy with BCG on dogs treated surgically for osteosarcoma. The effects of BCG on the clinical course of disease were correlated with 2 *in vitro* parameters, cell mediated reactivity (CMR) expressed as the percentage inhibition or stimulation of target cell numbers in an average of 6 replicates and serum blocking activity (SBA) expressed as the percentage change in the number of target cells in the presence of patient's lymphocytes and serum compared to normal serum in an average of 6 replicates.

MATERIAL AND METHODS

Animals bearing tumors

Eleven dogs with histologically diagnosed osteosarcoma and without clinical or radiographic evidence of metastasis were studied (Table 1). All were patients at the Small Animal Hospital, University of Pennsylvania, School of Veterinary Medicine. Amputation of the tumor bearing limb was performed at the time of initial diagnosis. Post-operatively dogs were immunologically tested and examined clinically and radiographically at monthly intervals whenever possible. Complete blood counts were performed at each examination.

Eleven dogs were selected sequentially

between May 1973 and September 1974 from patients seen at our hospital. The first 6 of these dogs were given BCG* and the last 5 served as controls. A standard dose of 1 ml of $1{\cdot}5+10^7$ viable organisms was injected intradermally in the flank area in each of the six dogs given BCG. The total dose was divided into 0·20 ml. portions administered at five separate sites. The first dose was administered 9 days after surgery. The BCG treatment was repeated at 2-week intervals for one year.

Tumor growth stimulation-inhibition test

The microcytotoxicity assay, colony inhibition test, described by Hellstrom [33], and modified by Fidler for the tumor growth stimulation-inhibition test [34] was used as a routine procedure. This modification increased the plating efficiency of tumor cells which improved the accuracy of initial lymphocyte to target cell ratios. This test has been described in detail [34–36]. Briefly, tumor tissue was obtained aseptically at surgery and prepared in the laboratory within 30 minutes. The tumor was minced, trypsinized and resuspended in complete Eagle's minimum essential medium (CMEM). The tumor cells were then plated after being passed through a gauze covered funnel to give a single tumor cell suspension. Viable, plastic adherent cells were harvested after 12 hr. After viability tests, the number of live target cells was adjusted to 30,000/ml media. Tumor cell preparations were incubated in CMEM; 50% CMEM and 50% autologous serum; 50% CMEM and 50% normal dog serum for 15 min. Fibroblasts from skin biopsy (dog 6) were prepared as described for tumor cells.

White blood cells were obtained by sedimenting heparinized blood on dextran-citrate (1·5 ml of 2·4% sodium citrate and 1·5 ml of 10% dextran 250,000 M.W., mixed with 7 ml of heparinized blood) [37]. After sedimentation, the cell suspension was passed through a glass-wool column to remove adherent cells, washed and diluted. Viability was determined by trypan blue exclusion and exceeded 95% in all cases. The yield of non-glass adherent, mononuclear cells (lymphocytes) was approximately 35% using this method.

Tumor cells and lymphocytes were combined to yield target cell to lymphocyte ratios of 1:100, 1:1000 and 1:10,000. After rotation for 90 min. to enhance cell to cell interaction the tumor-lymphocyte mixtures were placed in Falcon Microtest I plates and incubated at 37°C in 5% CO_2. Six wells per test group per assay day (2 and 5) were filled. Each well contained 30 tumor cells and varying numbers of lymphocytes in a 0·02 ml suspension. To achieve accurate cell dispensing, a sterile disposable 1 ml tuberculine syringe inserted into a Hamilton repeating dispenser was utilized (Hamilton Co., Nevada, USA). Plates were harvested and stained on days 2 and 5.

Analysis of CMR and SBA

The *in vitro* CMR response of all patients to their tumors was measured sequentially. Serum blocking activity (SBA) and cell mediated reactivity (CMR) were determined at surgery, at monthly intervals after the first BCG injection and either at post mortem or 12 months after initiation of treatment. In the measurement of SBA all sera collected during the observation period were evaluated simultaneously and compared to presurgical serum used as a base line reference.

Standard statistical procedures were used to evaluate results. Survival time refers to the interval between excision of the primary tumor and euthanasia (9 dogs) or natural death (2 dogs). Inasmuch as 9 dogs were euthanatized at different stages of their terminal disease (dog 7 before developing terminal osteosarcoma), the survival times are biased toward a minimum in contrast to the situation in humans where death occurs naturally.

Lymphocyte count refers to the absolute number of lymphocytes from differential blood count.

RESULTS

CMR and SBA levels

The number of dogs with presurgical CMR inhibition in the BCG group were not significantly different from those in the control group, $\chi^2 = 0{\cdot}736$, $d.f. = 1$, $P > 0{\cdot}30$. Therefore BCG and CMR were treated as independent variables.

No consistent relationship between CMR and SBA and clinical metastasis was found during the follow up period in either the BCG treated dogs or the controls.

Experiments were done comparing our CMR results with lymphocytes from tumor hosts to lymphocytes from normal dogs. The addition of normal lymphocyte preparations may have some non-specific effect of growth of the target cells [38–42]. The effect of fibroblasts was tested using normal dog lymphocytes from different donors. The significance of these

*Obtained from Trudeau Institute, Saranac Lake, N.Y.

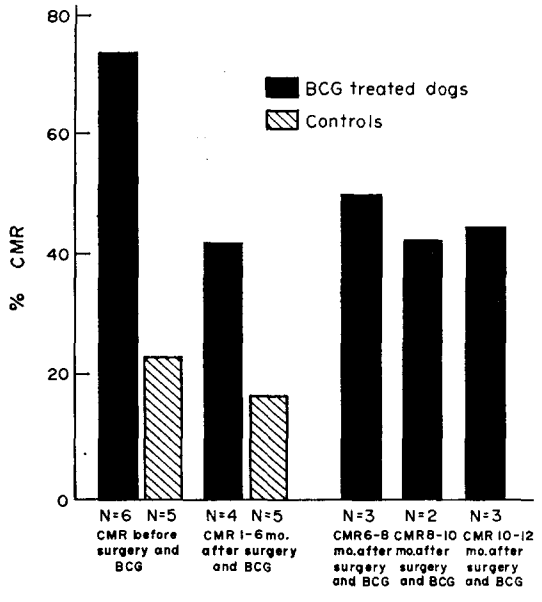

Fig. 1. CMR = Cell mediated reactivity, N = Number of dogs tested at each time interval, BCG = Bacillus Calmette-Guérin.

experiments was to demonstrate that lymphocytes from normal individuals may occasionally react against malignant and normal cells in a non-tumor specific fashion. Normal fibroblasts were destroyed by normal lymphocytes in two out of seven experiments.

Removal of the primary tumor was associated with a 93% decrease in the SBA. The decrease in CMR was not statistically significant even though the means dropped from 73 to 40% during the first six months.

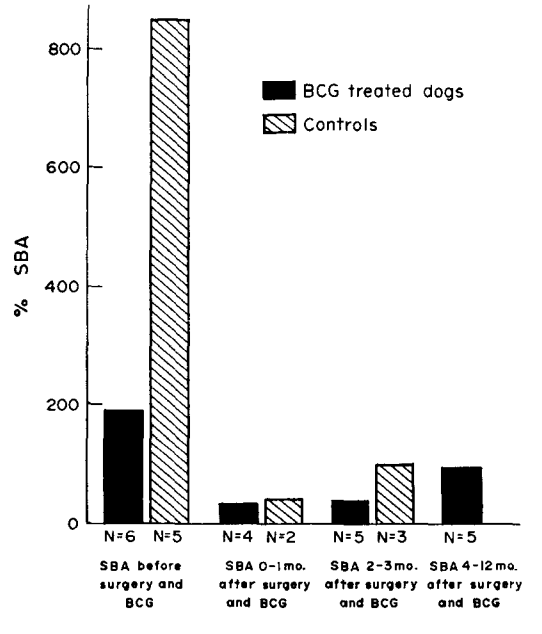

Fig. 2. SBA = Serum blocking activity, N = Number of dogs tested at each time interval, BCG = Bacillus Calmette-Guérin.

Figures 1 and 2 illustrate the sequential means of CMR and SBA in BCG treated and control groups 1–12 months after surgery. SBA values show significant decreases from presurgical levels in test and control groups to low levels 1 month after surgery. At 2–3 months after surgery the SBA levels were slightly higher (statistically insignificant) in the control group than in the BCG group. However, SBA in BCG treated dogs rose to about the same level as in controls 4–12 months after surgery.

Radiographic evidence of metastatic disease was present in 1 of 6 BCG dogs 2–3 months postsurgically and in 4 of 6 dogs, 4–12 months after surgery. Figure 3 illustrates the changes in SBA in the combined BCG and control groups.

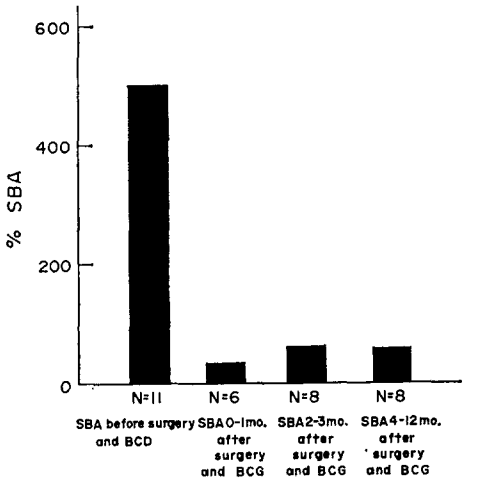

Fig. 3. SBA = Serum blocking activity, N = Number of dogs tested at each time interval, BCG = Bacillus Calmette-Guérin.

Effects of BCG on lymphocyte counts

Although the mean postsurgical lymphocyte counts in the 6 BCG dogs increased 45·5% above the presurgical values (mean went from 2128 at surgery to 3096 at the end of the experiment), this gradual rise in the numbers of lymphocytes was not significant when evaluated by least squares regression analysis ($b = 0{\cdot}794$, $d.f. = 38$, $P > 0{\cdot}05$).

The median absolute lymphocyte count in the presurgical period was 1830 (6 BCG treated and 5 control dogs) while in the dogs with terminal disease the corresponding value was 1410. The decrease in absolute numbers of lymphocytes in terminally ill animals was statistically significant, $P < 0{\cdot}05$.

Effects of BCG on survival time

The median survival time of 40 weeks in the BCG group was significantly prolonged when

analyzed by the median test ($\chi^2 = 4.0$, $d.f. = 1$, $P < 0.05$), as contrasted to 13 weeks in the control group.

The life table method was used for estimation of survival rates [43, 44]. Survival rates were calculated for the 6 dogs which received BCG and for 65 "historical controls" which had undergone amputation for osteosarcoma at this institution [45]. Based on these survival rates, 7·8% of the 65 historical controls would be expected to survive for 19 months postsurgery in contrast to the 50% of the 6 BCG dogs which

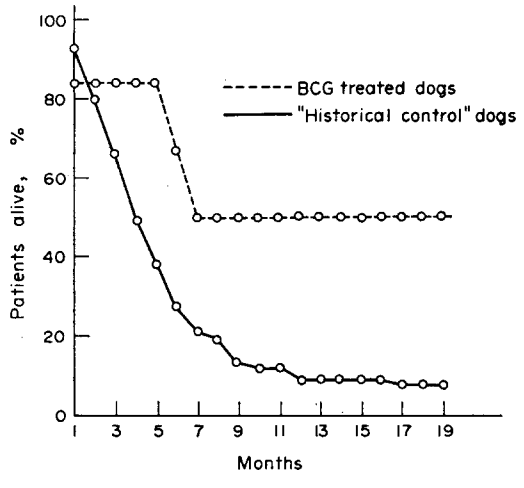

Fig. 4. Proportion of dogs alive vs. the number of dogs at risk at each point in time in 65 historical control dogs and 6 BCG treated dogs respectively.

were alive at that point in time (Fig. 4). However, the 95% confidence limits for the survival rates expressed as percentage of BCG dogs surviving were 10 and 90% while for the "historical controls" they were 0 and 17·6%.

In order to calculate the expected survivors in the BCG group the cumulative probabilities for surviving for different periods of time found in the life table for the "historical controls" were used, Table 2 [46]. A total of 1·692 survivors and 4·308 deaths was expected in the 6 BCG treated dogs. The actual cumulative survival of 3 BCG treated dogs for 19 months was not statistically significant, $\chi^2 = 1.408$, $d.f. = 1$, $P > 0.20$.

Rates of metastasis were also analysed by the life table method [43, 44, 47]. In Fig. 5, the proportion of dogs free of metastasis vs the number of dogs at risk at each point in time was plotted. No significant difference was found between the proportion of BCG treated and control dogs free of metastasis.

Pathologically no gross differences were noted in the number of size of metastases between BCG and control dogs.

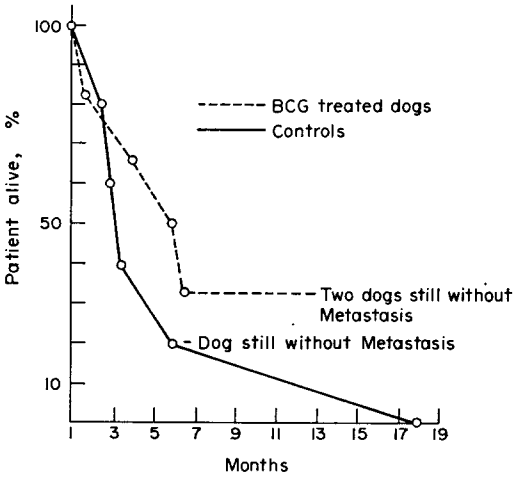

Fig. 5. Proportion of dogs free of metastasis vs. the number of dogs at risk at each point in time in 6 BCG treated and 5 control dogs respectively.

Local effects of BCG

The dogs were reexamined at 2 week intervals. No local changes except for some induration in the skin were noted 28 days after the initial injection of BCG. However, at 42 days after the initiation of BCG therapy, local ulcerations 0·2–1 cm in diameter were noted at the initial sites of injection. Upon subsequent examination 2 weeks later the lesions were healing well. They were completely healed 28 days after initially observed.

Table 2. Expected survival in 6 BCG-treated dogs at 19 months

Observation time (months)	Dogs	Expected survivors	Observed survivors
1	1	1 × 0·939 = 0·939	5
6	1	1 × 0·276 = 0·276	3
7	1	1 × 0·215 = 0·215	3
13	2	2 × 0·092 = 0·184	3
19	1	1 × 0·078 = 0·078	3
	6	Total: 1·692 Survivors expected	

DISCUSSION

These studies examined the possibility of immunostimulatory-inhibitory effects following BCG injection by measuring differences in *in vitro* immunoreactivity before and after surgery and BCG injection. The data were compared with similar data from a control group which did not receive BCG. By only using dogs with surgically extirpated tumors and no radiographic evidence of metastasis, it was hoped to avoid blocking factors which, in some human cancer patients, have been shown to disappear soon after the heavy tumor burden has been removed [48]. By BCG treating only dogs with surgically extirpated tumors it was hoped to minimize the risk of stimulating SBA and tumor growth by BCG.

Stolfi *et al.* [49] found that SBA of tumor bearing mice became undetectable within 15 days after surgery. This gives support to the idea that blocking factors are circulating complexes of tumor antigens, and antibody formed by the host. When a tumor antigen and specific antibody are mixed, the mixture blocks, although neither the antigen nor the specific antibody alone blocks when tested under standard conditions [50]. If, however, the antigen is added to immune lymphocytes, it can block as well [51]. Regarding the class of antibody involved, Jose *et al.* [52] demonstrated blocking activity associated with subclasses IgG_1 and IgG_3, and lesser activity in IgG_4. Most other workers associate them with the IgG_2 fraction [53, 54].

Surgical removal of grossly detectable tumor was associated with decreased SBA, a change that should favor destruction of residual tumor cells. SBA decreased 1 month after surgery, probably due to elimination of tumor antigens from the primary osteosarcoma. It is noteworthy that even in these dogs in which a beneficial shift in immunological reactivity had occurred, tumor metastasis became clinically overt later.

The mechanism by which the immune system responds to BCG is still not clear. Zbar *et al.* [55] postulated the mechanism of intralesionally injected BCG mediated tumor cell death in a guinea pig model in 3 steps: (a) the host produces lymphocytes which recognize antigen of BCG, (b) specifically sensitized lymphocytes react with BCG, leading to the production of soluble mediators of cellular immunity. One of these factors (migration inhibition factor) promotes local accumulation of monocytes essential for tumor cell destruction, and (c) monocytes process tumor antigens leading to the formation of sensitized lymphocytes that recognize the distinctive antigens on the tumor cells.

Snodgrass *et al.* [56] presented histologic evidence suggesting that a non-specific granulomatous reaction, characterized by infiltrating histiocytes was a necessary part of the anti-tumor response in BCG treated animals. Non-specific destruction of tumor cells accompanied a specific reaction of lymphocytes with the sensitizing antigen in close proximity to the neoplastic cells.

Further, Borsos *et al.* [57] verified the presence of common antigens between BCG organisms, line 10 hepatocarcinoma of strain 2 guinea pigs and a human melanoma cell culture. One question has now been raised with regard to BCG immunotherapy by Hanna and Bucana [58]. Does the humoral immune reactivity to common antigens under certain conditions antagonize development of CMR? An early and pronounced humoral immune response to BCG may block cell mediated immunity either on the sensitized lymphocyte or on the tumor cell level. This could depend on the nature of the BCG used for the therapy and the quantitative levels of common antigenic sites on the tumor cells. A specific humoral antibody response to BCG in the dog has not been demonstrated, but probably exists. The general nature of the immunologic cross reactivity between tumors of different histologic types with BCG or other microorganisms needs to be nvestigated.

The significant difference in median survival times of the 6 BCG treated dogs and the 5 control dogs indicates a possible effect of BCG on duration of survival of surgically treated osteosarcoma bearing dogs. As of 1 February, 1976, 2 of the BCG treated dogs and 1 control dog in the present study were still alive and well at 131, 106 and 84 weeks after surgery respectively.

More dogs should be studied to evaluate fully the significance of treatment with the particular strain and dose level of BCG used in this study. Probably due to the small number of dogs tested the cumulative life table method did not demonstrate a significant therapeutic effect of BCG.

However, our findings are compatible with those described in a recent paper by Owen *et al.* who also treated 6 dogs with BCG. Of the 6 BCG treated dogs 3 died 16, 25 and 52 weeks after amputation and 3 were still alive, 1 with metastasis 53 weeks after surgery and 2 with no evidence of disease 46 and 53 weeks after

surgery was performed. Survival times in 5 dogs receiving amputation alone ranged from 6–17 weeks (mean 11). A dose of 50–250 × 10^6 of viable organisms of BCG* was given by the intravenous route to all dogs irrespective of size at 1, 2, 4 and 8 weeks post-operatively.

The dose of BCG organisms administered was within the range of 10^6–10^7 viable organisms in both studies. Doses within the same range have been administered when treating human cancer patients with BCG [2, 3]. However, many studies in human patients have used considerably smaller doses of BCG. Some question still exists as to the possible effects of varying doses of viable BCG organisms on the rate of relapse and the disease-free period in human cancer patients [3]. Owen and Bostock did not determine if the survival times in the two groups of dogs were significantly different. Even though the survival times of 3 of the 5 control dogs used by Owen and Bostock were not reported the median test indicated that the BCG treated dogs had prolonged survival as compared to the controls ($\chi^2 = 7{\cdot}083$, $d.f. = 1$, $P < 0{\cdot}01$). When combining the test and control dogs from the present study with those of Owens there was a statistically significant difference in survival times ($\chi^2 = 6.783$, $d.f. = 1$, $P < 0{\cdot}01$). Although the strain of BCG and route of administration differed in the two studies the results were compatible.

Monitoring of *in vitro* CMR in tumor bearing dogs undergoing therapy with BCG and in controls gave information of clinical significance with respect as to how immunotherapy may influence the immune response. The findings in this study suggest that such an approach is possible, using the techniques employed. More trials are needed in which larger patient groups can be followed using standardized assay techniques in many independent laboratories.

Plasma Dehydroepiandrosterone Sulfate, Androstenedione and Cortisol, and Urinary Free Cortisol Excretion in Breast Cancer*

D. P. ROSE†, P. STAUBER†, A. THIEL†, J. J. CROWLEY‡ and J. R. MILBRATH§

†*Division of Clinical Oncology and* ‡*Biostatistics Unit, Wisconsin Clinical Cancer Center, University of Wisconsin, Madison, Wisconsin* 53706 *and* §*Breast Cancer Detection Center, Medical College of Wisconsin, Milwaukee, Wisconsin* 53226, *U.S.A.*

Abstract—*The concentrations of plasma dehydroepiandrosterone sulfate (DS), androstenedione (A2) and cortisol (C), and the urinary free cortisol (UFC) excretion were measured in* 24 *women with breast cancer before mastectomy and another* 45 *approximately* 1 *month after surgery, and in* 49 *cases of advanced breast cancer. The results were compared with those from a group of healthy women.*

Plasma DS was negatively correlated with age, and all 3 *breast cancer groups showed significantly reduced levels compared with age-comparable controls. Plasma A2 was also negatively correlated with age; no significant difference was found between the cancer patients and controls.*

The mean levels of plasma C and UFC in the breast cancer patients were normal, but 7 *of the* 49 (14%) *cases of advanced disease did have elevated UFC excretions.*

INTRODUCTION

IN A SERIES of publications, Bulbrook and his colleagues reported that subnormal excretions of urinary 11-deoxy-17-ketosteroids are associated with an increased risk of breast cancer recurrence after mastectomy [1] and the likelihood that the advanced disease is resistant to endocrine ablative therapy [2–4]. Further, they found that subnormal excretions of etiocholanolone and androsterone, the principal 11-deoxy-17-ketosteroids in urine, by apparently healthy women are indicative of an increased risk of breast cancer [5]. These observations suggest that it may be possible to use the determination of urinary androgens to identify those women in whom the breast cancer detection rate would justify annual screening by mammography, physical examination and, perhaps, thermography.

Accepted 18 August 1976.

*This work was supported by Grant numbers CA 14520 and CA 16405 awarded to the Wisconsin Clinical Cancer Center by the National Cancer Institute, and NCI Contract NO1-CN-55308 and American Cancer Society Grant DPBC No. 5 awarded to the Medical College of Wisconsin.

There is a strong positive correlation between the urinary 11-deoxy-17-ketosteroid excretion and the concentration of dehydroepiandrosterone sulfate (DS) in plasma, but there have been conflicting reports regarding the plasma DS in breast cancer [6, 7]. The issue is of practical importance because if patients with a low excretion of androgen metabolites also have subnormal plasma DS, it follows that the assay of blood samples, instead of 24 hr urine collections, could be used when screening women for those with an increased breast cancer risk.

In the study reported here, the plasma DS has been determined in patients with early or advanced breast cancer, and healthy female controls. The opportunity was taken also to measure the plasma androstenedione (A2) and cortisol (C) levels, and the urinary free cortisol (UFC) excretion. Androstenedione is of special interest in the endocrinology of breast cancer because it is both an androgen and the principal precursor of estrogens in postmenopausal women [8]. The UFC provides a measure of the cortisol production rate [9]; it is elevated when there is an adrenal response to stress, which might, itself, alter the plasma DS and A2 levels.

MATERIAL AND METHODS

Twenty-four women with breast cancer, aged 44–69 years, were studied while in the hospital awaiting mastectomy, and another 45, aged 22–73 years, approximately 4–6 weeks after surgery. There were a further 25 patients with locally recurrent breast cancer, and 24 with distant metastases. Their ages ranged from 37–68 years. None of these cases had been treated by endocrine ablative surgery or additive hormone therapy, but some had received chemotherapy in the past.

Sixty-two healthy women aged 35–69 years constituted the control group for the plasma DS and A2 studies. None of these vo unt eers,who were attending the Milwaukee Breast Cancer Detection Clinic, had been receiving oral contraceptives, or any other form of steroids, for at least 6 months.

Plasma was obtained from heparinized blood taken between 8:00 and 10:00 a.m. A 24 hr urine collection for the determination of UFC was commenced as soon as the blood had been taken for the plasma steroid assays. The normal values for plasma C and UFC had been established in earlier studies; they were not influenced by age [10, 11]. Plasma DS [12] and A2 [13] were determined by radioimmunoassay, and plasma C and UFC by competitive protein-binding techniques [10].

Logarithmic transformation of the plasma steroid data were used because for a given age the steroid levels were closer to a logarithm-normal than a normal distribution. Natural logarithms were taken for this purpose. Statistical comparison between the various groups was by analysis of covariance.

RESULTS

The controls showed negative correlations with age for both plasma DS ($r = -0{\cdot}342$; $P < 0{\cdot}01$) and A2 ($r = -0{\cdot}497$; $P < 0{\cdot}001$), while the two steroids were positively correlated with each other ($r = 0{\cdot}544$; $P < 0{\cdot}001$). Because of the influence of age, appropriate regression lines were calculated for comparisons between the controls and the various breast cancer groups.

In Fig. 1 the regression lines of plasma DS on age are given. The preoperative and postoperative early breast cancer patients are shown separately, although there was no statistically significant difference between the two groups ($F = 0{\cdot}66$; $P > 0{\cdot}50$). The plasma DS concentrations for the patients awaiting mastectomy were lower than those of the controls ($F = 3{\cdot}82$; $P < 0{\cdot}05$), due to a significant difference in the two intercepts ($F = 7{\cdot}04$; $P < 0{\cdot}01$), but not in the slopes of the regression lines ($F = 0{\cdot}60$; $P > 0.25$). Similarly the plasma DS for the postoperative early breast cancer group was subnormal ($F = 3{\cdot}27$; $P < 0{\cdot}05$),

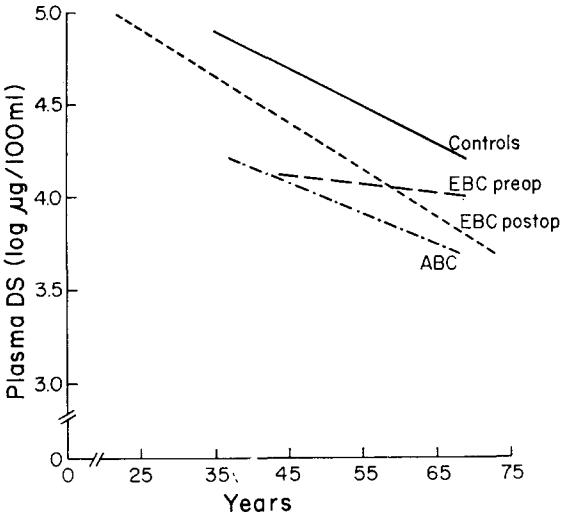

Fig. 1. Plasma DS in controls, early breast cancer before mastectomy (EBC preop), early breast cancer after surgery (EBC postop) and advanced breast cancer (ABC).
Regression lines of plasma DS on age were calculated; the statistical analysis is described in the text.

with intercepts differing from the controls ($F = 6{\cdot}38$; $P < 0{\cdot}05$). When the early breast cancer patients were combined into a single group, the differences from the control group were highly significant for the plasma DS ($F = 4{\cdot}79$; $P < 0{\cdot}01$) due to differences in the intercepts ($F = 9{\cdot}55$; $P < 0{\cdot}01$), but not the slopes ($F = 0{\cdot}02$; $P > 0{\cdot}50$).

The plasma DS concentrations of the patients with local recurrence did not differ from those with systemic metastases, and so they have been considered as a combined group in Fig. 1. This steroid was reduced markedly in the advanced breast cancer patients compared with the controls ($F = 10{\cdot}03$; $P < 0{\cdot}01$), and there was a highly significant difference in the intercepts ($F = 20{\cdot}01$; $P < 0{\cdot}001$). The two slopes of the regression lines were similar ($F = 0{\cdot}07$; $P > 0{\cdot}50$).

The results for the plasma A2 assays are summarized in Fig. 2. There was no difference between the two early breast cancer groups ($F = 0{\cdot}22$; $P > 0{\cdot}50$), nor between those with local recurrence or systemic metastases ($F = 0{\cdot}91$; $P > 0{\cdot}25$). Although it appeared that the early breast cancer patients had higher plasma A2 concentrations than the controls, the difference achieved only borderline statistical

significance ($F = 2{\cdot}97$; $P \simeq 0{\cdot}05$); the advanced breast cancer cases had unequivocally normal plasma A2 levels ($F = 0{\cdot}89$; $P > 0{\cdot}25$).

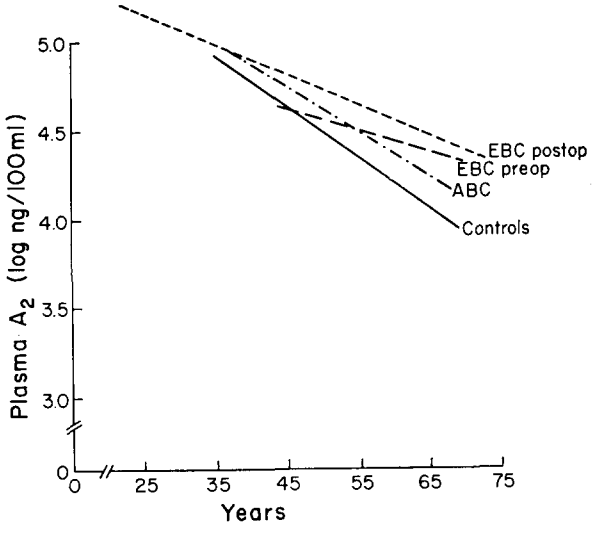

Fig. 2. Plasma A2 in controls, early breast cancer before mastectomy (EBC preop), early breast cancer after surgery (EBC postop) and advanced breast cancer (ABC).
Regression lines of plasma A2 on age were calculated; the statistical analysis is described in the text.

The plasma C and UFC results are summarized in Table 1. None of the breast cancer groups showed abnormal corticosteroid levels, although 7 of the 49 [14%] patients with advanced breast cancer did have an elevated UFC excretion.

Table 1. The plasma cortisol and urinary free cortisol in controls and breast cancer patients

Group (No.)	Plasma cortisol ln μg/100 ml	Urinary free cortisol μg/24 hr
Controls (31)	2·67 ± 0·36	57·3 ± 22.6
Early breast cancer: preop. (24)	2·72 ± 0·39	51·6 ± 29·5
Early breast cancer: postop. (45)	2·42 ± 0·66	47·7 ± 28·7
Advanced breast cancer (49)	2·53 ± 0·54	60·1 ± 31·9

No significant differences between groups for either the plasma cortisol or urinary free cortisol excretion.

DISCUSSION

Previous reports have indicated that the plasma DS in breast cancer may be influenced by the stage of the disease, and the time of blood sampling relative to mastectomy. Brownsey *et al.* [6] found the plasma DS to be reduced in advanced breast cancer, but normal in early breast cancer. In retrospect, it is unfortunate that they did not state whether blood was obtained from their early cases before or after mastectomy. The importance of this point emerged later when Wang *et al.* [7] measured the plasma DS in the same group of patients on the day before mastectomy, and again 10–14 days after surgery. Although the mean plasma DS for the preoperative samples was lower than that of controls, the difference was not statistically significant; in contrast, the mean postoperative plasma DS level was unequivocally subnormal.

In the present study, we did not find a difference between the DS levels in preoperative and postoperative plasma samples, and both groups of early breast cancer patients, like those with recurrent disease, had significantly reduced plasma DS concentrations compared with comparably aged controls. It should be noted that our study did differ from that performed by Wang *et al.* [7] in two respects: the two early breast cancer groups were not composed of the same patients, and our post-operative samples were obtained at least a month after mastectomy.

The mechanism by which mastectomy could affect the plasma DS is unclear. Wang *et al.* [7] postulated that preoperative psychological stress might be responsible, and noted that the urinary total 17-hydroxycorticosteroid excretion was significantly higher before mastectomy than afterwards. However, although the cortisol production rate is increased in advanced breast cancer, it is unchanged in patients awaiting mastectomy, and is not correlated with the urinary 17-hydroxycorticosteroids [14]. We chose, therefore, to measure UFC, which does give an indication of the cortisol production rate over a 24 hr period [9], and found it to be elevated only in some of the advanced breast cancer patients. The plasma cortisol was unchanged, which is in agreement with the results of Brownsey *et al.* [6], but at variance with the other reports that the plasma hydroxycorticosteroids are reduced in early breast cancer [15], and elevated in the advanced disease [16].

Recently, it was shown that plasma dehydroepiandrosterone is subnormal in both preoperative and postoperative early breast cancer [17], although the free steroid is considerably more sensitive to ACTH stimulation [18]. In conjunction with our results, these observations make it unlikely that psychological preoperative stress has any significant effect on plasma androgen levels.

Androstenedione is secreted from the ovaries

and adrenal glands; before the menopause the ovaries produce approximately 50% of the circulating steroid. In postmenopausal women adrenal A2 is the source of most of the plasma estrogens, and it has been postulated that increased aromatization of A2 to yield estrone is an important factor in the etiology of breast cancer [19]. However, in a study of 8 postmenopausal controls and 7 breast cancer patients, no difference was found in the conversion rate of A2 to estrone, although the cancer cases did show a small, statistically insignificant, elevation in metabolic clearance rate of A2 and a decrease in its plasma concentration [20].

We did not find reduced plasma A2 levels in breast cancer; indeed, the concentration of this steroid tended to be higher when compared with controls of similar age. Further investigations are underway in which we are measuring both plasma A2 and estrone in a group of postmenopausal breast cancer patients.

Acknowledgements—We are grateful to Dr. Lina Liskowski for help in setting up the radioimmunoassay procedures.

Abstract—*Bleomycin was administered intramuscularly on one of four schedules in a phase I–II trial conducted by the Eastern Cooperative Oncology Group. A total of* 168 *evaluable patients received either bleomycin* 5 *mg/m² daily,* 5 *mg/m² weekly,* 20 *mg/m² weekly or* 40 *mg/m² weekly. The latter dose proved to be toxic and was discontinued. Comparable toxicity was seen with the other three schedules. The toxicity was qualitatively and quantitatively similar to that reported with other bleomycin doses, schedules and routes of administration except that no radiographic evidence of pulmonary toxicity was seen. Patients with hematologic malignancies and solid tumors responded equally well to the low dose and high dose bleomycin schedules. The highest response rates were seen in patients with testicular tumors and lymphomas. The median duration of response was* 1–2 *months.*

INTRODUCTION

BLEOMYCIN, an antitumor antibiotic produced from Streptomyces verticillus, has therapeutic activity in a variety of human neoplasms [1–3]. Despite intensive investigation, however, the optimal dose and schedule of bleomycin administration for maximal therapeutic benefit with minimal toxicity is not known. The most commonly used dose and schedule has been 15 mg/m² twice weekly intravenously (range of 4 mg/m² to 35 mg/m² [1, 4]. Other evaluated schedules include weekly [5], daily to toxicity [2], daily intermittent [3, 6] and continuous intravenous infusions in cyclic courses [7]. A range of drug doses have been used with these schedules.

In 1971 the Eastern Cooperative Oncology Group initiated a phase I–II bleomycin study. The aims of this study were to evaluate a less commonly used route of bleomycin administration (intramuscular) to compare toxicity and therapeutic benefit of low dose bleomycin (5 mg/m²) on a daily and weekly schedule, and to establish an optimal bleomycin dose for weekly intramuscular administration.

MATERIAL AND METHODS

A total of 168 patients having a variety of histologically proven inoperable malignancies were entered on study. Ten patients were subsequently declared invalid either because of

Accepted 18 August 1976.

protocol violations or early death unrelated to therapy leaving 158 evaluable patients. All patients had measurable or evaluable disease. Seventy-six (48%) of the 158 evaluable patients had had previous chemotherapy. No patient had received radiation therapy during the month prior to study and disease progression of the irradiated lesion was required for protocol entry if that was the only area of measurable or evaluable disease. All patients had adequate hematologic, renal and hepatic function, and none had significant underlying pulmonary disease. All patients volunteered informed consent.

Laboratory and clinical studies

The following tests were to be performed weekly: determination of WBC, differential, platelet, and reticulocyte counts and timed inspiratory and expiratory vital capacity. Tests done every 2 weeks included BUN and/or creatinine, alkaline phosphatase, chest X-ray, tidal volumes and blood gases. Tumor measurements using the product of the longest perpendicular tumor diameters were done biweekly.

Study plan

Four treatment schedules were evaluated.

A. Daily 5 mg/m^2 i.m. for 5–7 days weekly
B. Weekly 5 mg/m^2 i.m.
C. Weekly 20 mg/m^2 i.m.
D. Weekly 40 mg/m^2 i.m.

The total dose of bleomycin administered was not to exceed 200 mg/m^2. For patients treated on schedules B and C, if no response was seen after one month their dose could be increased to 40 mg/m^2. When a 50% or greater response was achieved bleomycin was stopped for one month and was then reinstituted at the original dose and schedule.

Standard response criteria were used with partial response indicating a 50% or greater shrinkage in the product of the longest perpendicular tumor diameters without progression of any lesion or the appearance of a new lesion. Progression indicated a 50% or greater increase in the product of tumor diameters or the appearance of new lesions.

RESULTS

Table 1 indicates the drug toxicity seen in regimens A, B and C. Regimen D (bleomycin 40 mg/m^2 i.m. weekly) was discontinued early in the study after two patients expired in the first week of therapy after developing severe and prolonged chills and fever with the initial dose. Chills and fever were more often observed at higher bleomycin doses occurring in 20% of patients on schedule C as opposed to 7 and 9% of patients respectively on schedules A and B. These symptoms generally appeared within several hours of bleomycin administration and were relieved, in large part, by antipyretics. There did not appear to be a predisposition for patients with hematologic malignancies to develop any greater toxicity than did solid tumor patients.

Skin and mucous membrane toxicity occurred with the same frequency on all three schedules. Mild to moderate skin toxicity included erythematous, painful, indurated areas on the hands, elbows and other pressure areas of the skin. More severe skin toxicity consisted of a diffuse morbilliform skin eruption. Mucous membrane toxicity in the form of stomatitis was neither severe nor dose limiting in any patient. Alopecia was infrequent and was never complete.

Nausea and vomiting following bleomycin was severe in only two of the 158 patients in this study. Both patients were treated on the daily bleomycin schedule and this toxicity was dose limiting in both patients. Hematologic toxicity with white blood cell counts and/or platelet counts transiently below 1500/mm^3 and 50,000/mm^3 respectively were noted in one patient each on schedules B and C. Over 90% of patients on all schedules had no evident hematologic toxicity.

Respiratory toxicity was clinically manifested by development of increased cough and shortness of breath with or without the presence of bibasilar rales on physical exam. These symptoms were classified as mild to moderate in 5 patients treated on schedule A, and 4 patients on schedule C, and were severe in 2 patients on schedule A and in one patient on each of the other two schedules. No patients developed radiographic evidence of pulmonary infiltrates or fibrosis. Pulmonary function studies were only performed sporadically on these patients but where information was available, no correlation between pulmonary function abnormalities and clinical symptoms and/or signs was noted.

Tumor response

Tumor responses were noted in each of the four treatment schedules (Table 2). The response by tumor site is indicated in Table 3. Responses in lymphoma patients occurred on all of the schedules. Four of the five testicular cancer patients who responded were treated

Dose escalation

Following the rules of the protocol, 27 patients on schedule C (20 mg/m^2 weekly) and 6 patients on schedule B (5 mg/m^2 weekly) had their dose increased to 40 mg/m^2 after 1 month of treatment. For all 33 patients the dose increase was stopped before the completion of a further month's treatment. One patient on schedule C achieved a partial tumor response after the dose increase. Several patients had further toxicity following the dose increase but in only 2 cases was this severe (one patient had chills and fever, the other had mental confusion).

DISCUSSION

The toxicity seen with intramuscular administration of bleomycin given as 5 mg/m^2 daily or weekly or as 20 mg/m^2 weekly was both qualitatively similar to that reported with a variety of other bleomycin schedules [1–6] and with intravenous or intraarterial drug administration [1]. Administration of 40 mg/m^2 of bleomycin weekly was clearly too toxic for continued use. It was interesting that the amount of drug toxicity on the above three schedules was similar with patients on the low dose schedule (5 mg/m^2 weekly) having no fewer toxic reactions than patients on 5 mg/m^2 daily or 20 mg/m^2 weekly. The median bleomycin dose received was 125 mg/m^2, 40 mg/m^2 and 160 mg/m^2 on the daily, low dose weekly and high dose weekly schedules respectively. At these dose levels one would expect radiologic manifestations of pulmonary toxicity in 4% of treated individuals [1]. No definite radiographic bleomycin pulmonary toxicity was noted in this study. Further study of large numbers of patients treated with intramuscular bleomycin will be necessary to determine whether the risk of pulmonary toxicity is decreased by this route of drug administration.

The therapeutic responses were primarily in tumor types known to be responsive to bleomycin therapy, i.e., lymphomas, testicular tumors, and epidermoid carcinomas of the lung, head and neck, breast and uterine cervix. Responses were seen with all bleomycin schedules used. A therapeutic superiority for any of the schedules cannot be demonstrated as patients with responsive tumors were not uniformly distributed. Also, patient performance status, another important prognostic variable for response [8], was unbalanced with 58% of patients receiving 20 mg/m^2 of bleomycin weekly being ambulatory at the start of treatment as opposed to only 40% ambulatory patients on the other two schedules. Response rates for bleomycin given intramuscularly appear comparable to those obtained with bleomycin given intravenously. Further, it appears that solid tumors as well as hematologic malignancies may respond equally to low dose bleomycin administration and to high drug doses. Response durations in this study were relatively short (median duration 1–2 months) suggesting that bleomycin usefulness will be in combination chemotherapy regimens.

The Inhibitory Effects of a 4-Hydroxy-Pentenal: Cysteine Adduct Against Sarcoma 180 Cells in Mice*

P. J. CONROY, J. T. NODES, T. F. SLATER and G. W. WHITE
Brunel University, Biochemistry Department, Kingston Lane, Uxbridge, Middlesex, UB8 3PH, Great Britain

Abstract—*The carcinostatic activity of a 4-hydroxy 2,3-trans-pent-en-1-al(HPE): cysteine adduct was studied against the ascitic form of Sarcoma 180 both* in vitro *and* in vivo. *The effect of HPE treatment* in vitro *(at concentrations in excess of 0·16 mM) was to depress primarily the incorporation of ^{3}H-thymidine into DNA; ^{3}H-uridine and ^{3}H-leucine incorporations into RNA and protein respectively were considerably less affected. The addition of 0·16 mM cysteine before treatment of Sarcoma 180 cell suspensions with HPE provided partial protection in relation to the depression of ^{3}H-thymidine incorporation. Tumour cell suspensions were preincubated* in vitro *for 30–120 min at 37°C with 0·04–1·28 mM HPE, HPE-cysteine or cysteine before the addition of ^{3}H-thymidine. The effectiveness of different types of preincubation procedure, in depressing the subsequent incorporation of ^{3}H-thymidine into Sarcoma 180 tumour cells* in vitro, *were compared. The results obtained indicate that HPE-cysteine was 4–7 times less effective on a molar basis than treatment of tumour cells* in vitro *with HPE alone.*

The LD_{50} *in mice for a single i.p. injection of HPE-cysteine was 362 mg/kg body weight (expressed as mg HPE); thus the adduct is approx. 7 times less toxic than the free aldehyde injected i.p. Extensions in survival time were produced by i.p. injection of increasing doses of HPE-cysteine* in vivo, *in mice bearing the ascitic form of Sarcoma 180. Treated animals received, on days 3–7 following transplantation, a single daily dose of the HPE-cysteine adduct equivalent to a dose of HPE alone of 8–256 mg/kg body weight. Significant increases in survival time were obtained at doses of HPE-cysteine in excess of 32 mg/kg body wt./day. Mice treated with the adduct responded with increases in survival time, compared to untreated control animals, of 50%, 94% and 129% at doses of the adduct equivalent to doses of HPE alone of 64, 128 and 256 mg/kg body wt./day respectively.*

The results obtained are consistent with the view that the extended breakdown of an adduct of HPE and cysteine, releasing the reactive aldehyde, increases the half-life of HPE both in vitro *and* in vivo.

1. INTRODUCTION

In a previous publication [1] we reported the results obtained by treating murine tumour cells with added HPE *in vitro* and the increases in survival time observed on re-injection of the treated cells into groups of mice. The data demonstrated that HPE was a relatively potent carcinostatic agent *in vitro* against the tumour lines tested. Preliminary work [2] *in vitro* has indicated that HPE (0·16–0·20 mM) severely depressed ^{3}H-thymidine incorporation into DNA in Ehrlich carcinoma, Gardner lymphosarcoma, and Sarcoma 180; ^{3}H-uridine and ^{3}H-leucine incorporation into RNA and protein were considerably less affected. The addition of cysteine before treatment of the above tumour lines with added HPE provided partial protection [3].

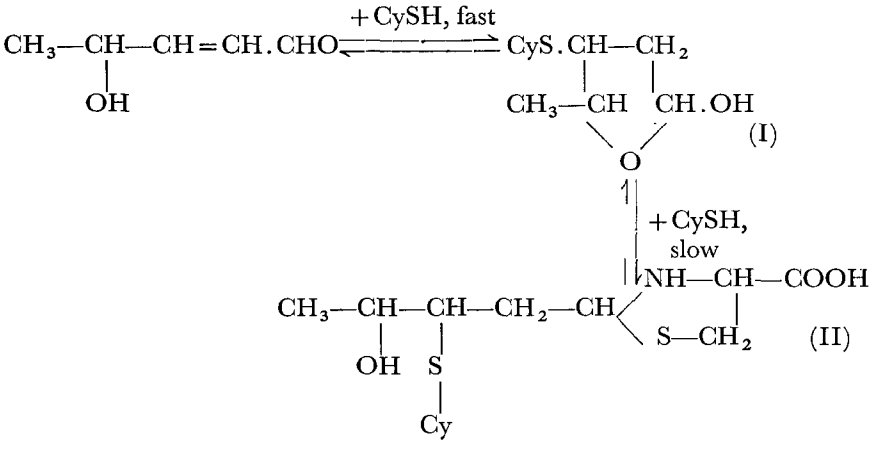
Treatment *in vivo* of these cell lines with multiple i.p. injections of HPE resulted in no significant increase in survival time, compared to untreated controls, for Ehrlich carcinoma

Accepted 18 August 1976.

*This investigation was supported by the Cancer Research Campaign, London.

and Gardner lymphosarcoma; Sarcoma 180 responded with a moderate inhibition of tumour growth [1]. The relatively short half-life ($t_{\frac{1}{2}}$) of HPE is probably of major significance to the poor carcinostatic activity of the compound when administered other than peritumourally [4–7]. One possible way of increasing the $t_{\frac{1}{2}}$ of HPE *in vivo* may be via the formation of an adduct of the aldehyde with cysteine. Guidotti *et al.* [8] suggested that aliphatic aldehydes condense with exogenous cysteine forming thiazolidine-4-carboxylic acid derivitives [8–10], thus depriving cells of that amino acid. These effects received confirmation in cultured mammalian cells [11] and in bacteria [12]. The resulting inhibition of protein synthesis could then explain the encouraging results reported by a number of other workers [13–15] on the survival of leukaemia and Ehrlich ascites tumour-injected rodents upon treatment with aliphatic aldehydes.

Esterbauer *et al.* [16] have recently demonstrated that HPE forms a thiazolidine-4-carboxylic acid derivative with cysteine in the following manner:



The rate constants for the reaction of HPE with cysteine increases with increasing pH, approaching a maximum at pH10. The rate limiting step at any pH is the addition of the sulphydryl anions $^{-}SCH_2CH(NH_3^{+})COO^{-}$ and $^{-}SCH_2CH(NH_2)COO^{-}$ to the C=C bond of HPE. The thiazolidine derivative (II) loses a cysteine residue fairly rapidly and the resultant Michael-type monoadduct then dissociates further in a slower reaction to release the aldehyde and cysteine. A purified HPE-cysteine adduct (molar ratio 1:1) of defined structure has been shown to possess significant carcinostatic activity against the ascitic form of Ehrlich carcinoma in mice [17]. Under the reaction conditions employed herein (see materials and methods) the present authors cannot be certain of the precise structure or homogeneity of the HPE cysteine adduct investigated in this study; it is important, however, to note that the adduct tested here was found to have potent biological reactivity. We have investigated the effects of such an adduct of HPE and cysteine in two ways:

(1) on the incorporation *in vitro* of ^{3}H-thymidine into DNA of suspensions of Sarcoma 180 tumour cells;
(2) the extension in survival time produced by i.p. injection of increasing doses of the adduct *in vivo*, in mice bearing the ascitic form of Sarcoma 180.

2. MATERIAL AND METHODS

L-Cysteine hydrochloride, sodium chloride, tris(hydroxymethyl) methylamine, perchloric acid, concentrated hydrochloric acid and Whatman GF/C glass fibre discs were purchased from B.D.H. Chemicals Ltd., Poole, England. All reagents were of Analar or Aristar grade. Scintillation grade PPO (2,5-diphenyloxazole) and POPOP (1,4-Di[2-5-phenyloxazoyl] benzene) were purchased from Koch-Light Laboratories Ltd., Colnbrook, England. Tissue culture medium (TC 199) and horse serum 5 [inactivated] (HS5) were obtained from Wellcome Reagents Ltd., Beckenham, England. Radioactive precursors listed below came from the Radiochemical Centre, Amersham, England. Female CBA/CA mice, produced from an inbred colony maintained at Brunel, were used throughout.

Tumour maintenance

Sarcoma 180 in the ascitic form was maintained in female CBA/CA mice (20–25g). Routine passaging and harvesting of tumour cells occurred on the 7th day following intraperitoneal injection of 2×10^{6} cells/animal.

Methods

Preparation of 4-hydroxy-2,3-trans-pent-en-1-al (HPE). The compound was synthesized and purified as previously described [1].

Preparation of HPE-cysteine adduct. A solution of HPE (100 mg, 1×10^{-3} mole) in chloroform (18 ml) was shaken with a solution of L-cysteine hydrochloride (473 mg, 2×10^{-3} mole) in water (0·5 ml) until HPE could no longer be detected in the chloroform layer by u.v. spectroscopy (approx. 1 hr.). The mixture was left to stand overnight after which the chloroform was removed on a rotary evaporator. Thin layer chromotography (TLC) on Silica gel with the solvent system *n*-butanol: acetic acid: water (12:3:5) showed one major product clearly separated from the excess cysteine. Preparative TLC (1 mm layer thickness) of the product mixture using the same solvent system produced a white solid (50 mg), insoluble in all common pure solvents tested except water.

Preparation of HPE-cysteine adduct for testing in vitro. (i) The HPE-cysteine adduct (41·6 mg, $1{\cdot}28 \times 10^{-4}$ mole) purified by TLC was dissolved in 0·9% saline (1 ml) and serially diluted to give a range of concentrations (1·3–41·6 mg/ml, 4-128 mM). The addition of 0·1 ml of the above HPE-cysteine solutions to tumour cell suspensions (10 ml) gave final concentrations of 0·04–1·28 mM.

(ii) A graded series of HPE solutions (0·4–12·8 mg, $0{\cdot}04$–$1{\cdot}28 \times 10^{-5}$ mole) in 0·9% saline (0·5 ml) were mixed with a similar graded series of solutions of L-cysteine hydrochloride (1·26–40·5 mg, $0{\cdot}08$–$2{\cdot}56 \times 10^{-5}$ mole) in 0·9% saline (0·4 ml) and incubated with shaking for 1 hr at 37°C. The resulting mixtures were neutralized to pH 7·2 and made up to 1·0 ml. As in (i) above, the final concentrations of the HPE-cysteine adduct in tumour cell suspensions (10 ml) were 0·04–1·28 mM.

Radioactive precursor incorporation procedures. The following quantities of labelled precursors were used per ml of tumour cell suspension: thymidine-6-H, 5·0 Ci/mmole, 0·25 μCi/ml; uridine-5-^{3}H, 5·0 Ci/mmole, 0·25 Ci/ml; DL-leucine-4,5-^{3}H, 1·0 Ci/mmole, 2·5 μCi/ml.

Ascites tumour cells were harvested from the peritoneal cavity of the mouse into 5 ml of sterile 0·9% saline containing 0·1 ml heparin. The cells were then washed with sterile "lysing buffer" (7·47 g NH_4Cl; 2·06 g Tris–HCl in 1 l. of distilled water brought to pH 7·2 with 11·6 M HCl) to remove erythrocytes and sedimented at 700 g_{av} for 5 min. The process was repeated until an erythrocyte-free pellet was produced. The pellet was gently resuspended in 5 ml sterile 0·9% saline and a count taken on a Coulter Model D Particle Counter. The cells were then resuspended in tissue culture medium 199: horse serum 5-(60:40) at a concentration of 1×10^6 cells/ml. Aliquots (10 ml) of the tumour cell suspension were removed into sterile, stoppered Ehrlenmeyer flasks (25 ml) and were incubated with shaking at 37°C before the addition of HPE, HPE-cysteine, or solvent as control. Cells were then further incubated with shaking for 30–120 min in the presence of these drugs, before the addition of labelled precursors. At time intervals 1 ml samples were removed and filtered onto Whatman GF/C glass fibre discs wetted with 0·9% saline, 10 volumes of 0·2 N perchloric acid, and a further 10 volumes of 0·9% saline. The filters were placed in scintillation vials and dried at 100°C for 1 hr. 5 ml of scintillation fluid (Toluene: 4g/l PPO [2,5-phenyloxazole]; 0·2 g/l POPOP [1,4-Di(2-5-phenyloxazoyl)benzene]) was added directly to the dried filters and the samples counted in a Packard Tri-carb Model 2425 liquid scintillation spectrometer.

Preparation of HPE-cysteine adduct for testing in vivo. A solution of HPE (410 mg, $4{\cdot}1 \times 10^{-3}$ mole) in 0·9% saline was mixed with a solution of L-cysteine hydrochloride (1290 mg, $8{\cdot}2 \times 10^{-3}$ mole) in 0·9% saline (7 ml) and incubated with shaking for 1 hr at 37°C. This mixture was neutralized to pH 7·2 and made up to 16 ml. Assuming that the HPE-cysteine adduct breaks down completely over an extended period, this would produce 25·6 mg/ml of free HPE. Serial dilution in 0·9% saline produced a range of concentrations of the adduct (equivalent to a solution of HPE alone of 0·8–25·6 mg/ml). Treated animals received a solution of HPE-cysteine adduct in 0·9% saline on the basis of 10 ml of drug solution per kg body weight.

In vivo *testing of the HPE-cysteine adduct.* The method employed has been described previously [1].

3. RESULTS

Effects on the incorporation of ^{3}H-precursors into Sarcoma 180 cell suspensions treated with added HPE in vitro

Sarcoma 180 ascites cells were incubated at 37°C in tissue culture medium 199: horse serum in the presence and absence of HPE for 30 min and ^{3}H-precursors added to detect drug-induced alterations in bio-synthetic reactions. The incorporation of ^{3}H-thymidine (TdR) appears to be primarily affected at doses

of HPE in excess of 0·16 mM. Total incorporation of labelled thymidine into DNA is reduced to approximately 10% of the control level at 0·16 mM HPE, whereas ^{3}H-uridine (Ud) incorporation into RNA and ^{3}H-leucine (Leu) incorporation into protein are reduced to approximately 50% of the control incorporation at 0·16 mM HPE. The depression of incorporation of these labelled precursors into Sarcoma 180 tumour cells, produced by exposure to the drug, is concentration dependent.

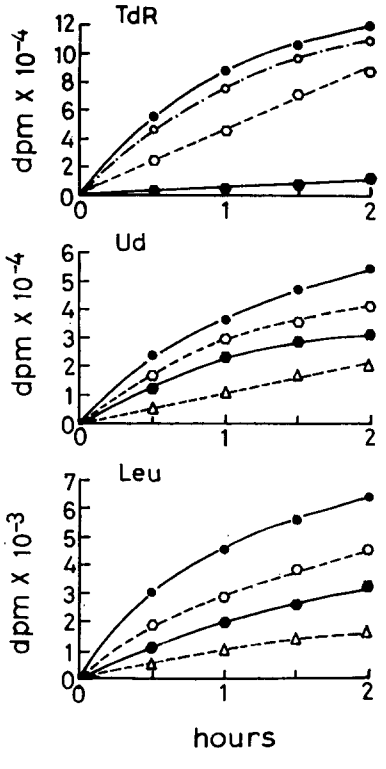


Fig. 1. Effect of 30 min preincubation of Sarcoma 180 cells (1 x 10⁶/ml) with 0·04–0·32 mH HPE per ml of cell suspension on the subsequent incorporation of isotopic precursors for cell components over 2 hr at 37°C. ^{3}H-thymidine (TdR) was incorporated into DNA; ^{3}H-uridine (Ud) principally into RNA; ^{3}H-leucine (Leu) into protein. ●—●, control cultures; ○—·—○, 0·04 mH HPE; ◇– – –◇, 0·08 mM HPE; ◆ — ◆ 0·16 mH HPE; △– – –△, 0·32 mM HPE. All points represent the mean of at least 3 expts.

Figure 1 illustrates that for each doubling of the concentration of added HPE the incorporation of ^{3}H-uridine and ^{3}H-leucine declines by approx. 50%. However, the uptake of ^{3}H-thymidine into DNA of the tumour cells exhibits a sigmoidal response to HPE treatment. Since the effect of HPE treatment is to primarily depress incorporation of labelled thymidine into DNA, this tritiated precursor was selected to investigate the protective effects of cysteine against added aldehyde and the response of tumour cells *in vitro* to pretreatment in various ways with the adduct formed between HPE and cysteine.

Comparison of the effects of HPE and HPE-cysteine on the incorporation of ^{3}H-thymidine into Sarcoma 180 *tumour cells* in vitro

The types of preincubation at 37°C of tumour cells with different drug regimes before the addition of ^{3}H-thymidine (TdR) are shown in Fig. 2. The effectiveness of different types of preincubation were compared to two control procedures: (1) and (2).

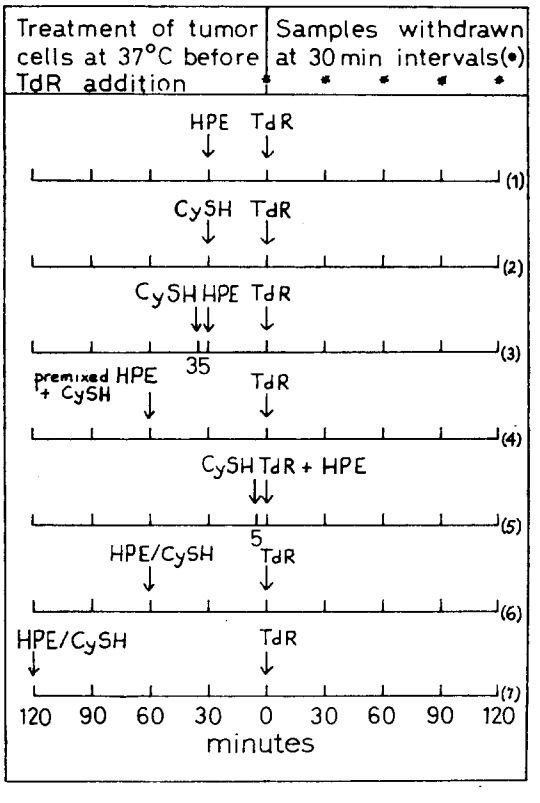

Fig. 2. Plan of various types of preincubation of Sarcoma 180 cells (1 x 10⁶/ml) at 37°C before addition of ^{3}H-thymidine (TdR). Samples were withdrawn at 30 min intervals over 2 hr for radioactivity assay. The types of procedure were (1) *0·04–1·28 mM HPE per ml of cell suspension added 30 min before TdR addition;* (2) *0·04–1·28 mM cysteine per ml of cell suspension added 30 min before TdR addition;* (3) *0·16 mM cysteine added at 35 min followed by 0·04–1·28 mM HPE added 30 min before TdR addition;* (4) *0·04–1·28 mM HPE premixed with 0·08–2·56 mM cysteine added 60 min before TdR addition;* (5) *0·16 mM cysteine added at 5 min and 0·04–1·28 mM HPE and TdR added simultaneously;* (6) *0·04–1·28 mM HPE-cysteine added 60 min before TdR addition;* (7) *0·04–1·28 mM HPE-cysteine added 120 min before TdR addition.*

The dose–response relationship of these two treatments is shown in Fig. 3 and repeated for comparative purposes in each dose–response plot. Treatment of tumour cells with HPE

alone or cysteine, as above, depresses ^{3}H-thymidine incorporation compared to untreated controls and produces a sigmoidal response.

In preincubation procedure (3) the dose–response plot is shifted slightly to the right, indicating a small degree of protection by the cysteine against added aldehyde. The addition of 0·16 mM cysteine alone to the cell suspension only reduces the rate of incorporation of precursor by 4% compared to solvent treated controls.

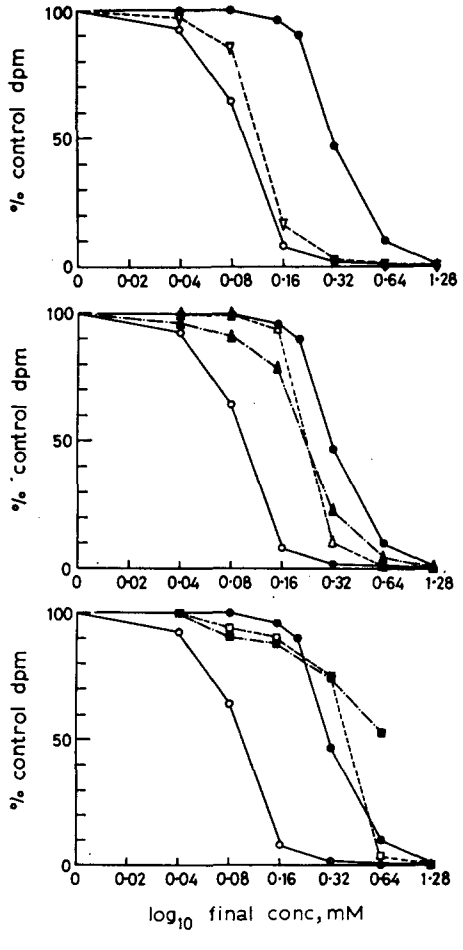

Fig. 3. Effect of drug concentration during preincubation at 37°C on the subsequent rate of incorporation of ^{3}H-thymidine into DNA of Sarcoma 180 tumour cells (1×10^6/ml). Procedures as outlined in Fig. 2 (1) ○—○, HPE added alone 30 min before TdR addition; (2) ●—●, cysteine alone added 30 min before TdR addition; (3) ▽– – –▽, 0·16 mM cysteine added at 35 min followed by HPE at 30 min before TdR addition; (4) △– – –△, HPE premixed with cysteine and added 60 min before TdR addition; (5) ▲—·—▲, 0·16 mM cysteine added at 5 min before the simultaneous addition of HPE and TdR; (6) ■—·—■, HPE-cysteine added 60 min before TdR addition; (7) □– –□, HPE-cysteine added 120 min before addition of TdR. Plotted points represent the mean values obtained from at least 3 experiments.

Premixing the HPE and cysteine at a molar ratio of 1:2 (see Materials and Methods) as in preincubation procedure (4) produced a much more pronounced shift of the dose–response plot towards that of cells treated with cysteine alone. A broadly similar effect was obtained in preincubation procedure (5). It is significant that the responses of tumour cells to preincubation procedures (4) and (5) lie between the plot indicated as controls, procedures (1) and (2). The result of procedure (5), when compared to that obtained in procedure (3), suggests that the preincubation period of 30 min is sufficient to allow a proportion of the HPE-cysteine adduct formed *in situ* to decay, releasing HPE and cysteine.

This suggestion receives confirmation when comparing the response of tumour cells to the addition of the HPE-cysteine adduct (purified by TLC as in Materials and Methods). Preincubation procedure (6) illustrates the response obtained from a 60 min incubation period with the purified adduct. Comparing the responses produced on a dose for dose basis, the adduct is less effective than treatment of tumour cells with cysteine alone at concentrations in excess of 0·20 mM. Increasing the preincubation period when Sarcoma 180 cells are exposed to the purified HPE–cysteine adduct to 120 min produces a similar response up to 0·32 mM. Thereafter it declines rapidly to 3% of the untreated control at 0·64 mM. The adduct appears to be breaking down with time in the medium, releasing two moles of cysteine for every mole of HPE. It is possible that cysteine and HPE, at concentrations in excess of 0·32 mM, act synergistically in depressing ^{3}H-thymidine incorporation into DNA.

These results are summarized in Table 1. A quantitative comparison of different preincubation treatments can be made if we compare the dose required (mM) to reduce ^{3}H-thymidine incorporation to 50% or 10% of the untreated control incorporation (ID_{50} and ID_{90}). The ratio of the ID_{50} or ID_{90} for tumour cells treated with HPE alone to that for cells treated in any other manner is an index of molar effectiveness of that treatment. The effects of procedure (3) are comparatively slight. Preincubation procedures (4) and (5) are broadly equivalent. To obtain the same degree of depression of ^{3}H-thymidine incorporation compared to treatment of HPE alone procedure (1) between 2 to 3 times the dose is required. Similarly procedures (6) and (7) are between 4 and 7 times less effective on a molar basis than treatment of Sarcoma 180 cells with HPE alone.

Activity of the HPE-cystine adduct against Sarcoma 180 in vivo

The LD_{50} in mice for a single i.p. injection of HPE, as the free aldehyde, is 55 mg/kg body wt. [1]. HPE injected i.p. in 4 equal doses spaced at 2-hourly intervals, gives an LD_{50} in CBA/CA mice of 180 mg/kg body wt./day [1]. Injection i.p. of the HPE-cysteine adduct into mice produced an LD_{50} value of 362 mg/kg body wt./day (expressed as mg HPE assumed to be released from the adduct). Thus the HPE-cysteine adduct is much less toxic than the free aldehyde injected i.p.; in comparison to a single i.p. injection of HPE as the free aldehyde, HPE-cysteine is approx. 7 times less toxic.

The extensions in survival time produced by i.p. injection of increasing doses of the HPE-cysteine adduct *in vivo*, in mice bearing the ascitic form of Sarcoma 180, are given in Table 2. Significant increases in survival time,

†Only solid tumour present on death.

compared to untreated controls, were obtained at doses of HPE-cysteine in excess of 32 mg/kg body wt./day ($P < 0{\cdot}001$). Mice treated with HPE-cysteine responded with increases in survival time of 50%, 94% and 129% at doses of the adduct equivalent to doses of HPE alone of 64, 128 and 256 mg/kg body wt./day respectively. Animals receiving 64 mg/kg body wt./day of the adduct all had both ascitic fluid and a solid tumour present on death. Only one mouse in the group of 10 animals treated 128 mg/kg body wt./day with HPE-cysteine died with both a solid tumour and ascitic fluid present. The remaining animals in this group, together with mice receiving 256 mg/kg body wt./day of the adduct, all died with a proliferated solid tumour and the absence of ascites in the peritoneal cavity. Solid tumours were detected initially as small subcutaneous nodules (2–3 mm. dia) at or near the tumour injection site between days 14–21 following transplantation. The final tumour weight on death ranged between 8–11 g, 2·5–3·5 cm dia. Within the group of 20 untreated control animals, 3 mice developed small solid tumours (1–2 mm dia) subcutaneously at the injection site. Normal proliferation of Sarcoma 180 cells, in the ascitic form, within the peritoneal cavity of the untreated mouse far outstrips that of tumour cells growing subcutaneously as a solid. Such animals invariably die with gross ascites containing up to 5×10^8 cells, 16–18 days following the transplantation of 1×10^6 viable tumour cells. The incidence of solid tumours in mice transplanted with the ascitic form of Sarcoma 180 may be related to the time at which drug injections were given (days 3–7) and the total number of injections (5) received per treated mouse. 15% (3/20) of the untreated control animals developed small solid tumours at the site of the single injection received at transplantation. Whereas 69% (31/45) of the treated animals produced solid tumour at the injection site(s). It appears likely that an influx of a mixture of viable and non-viable tumour cells, from the ascitic fluid, may occur in the small lesion in the abdominal wall caused by the withdrawal of the hypodermic needle. The probability of development of a subsequent solid tumour at this site will then depend on the degree of invasiveness of the tumour and the amount of cytotoxic drug reaching the site.

The *in vivo* carcinostatic activity of the HPE-cysteine adduct, compared to HPE alone, against Sarcoma 180 in CBA/CA mice is shown in Fig. 4. For the HPE–cysteine adduct, the plotted dose is that dose of HPE which is assumed to be released on the breakdown with time of the adduct. For any given dose, in excess of 32 mg/kg body wt./day, treatment with HPE-cysteine i.p. is between 2–3 times more effective than HPE given as the free aldehyde.

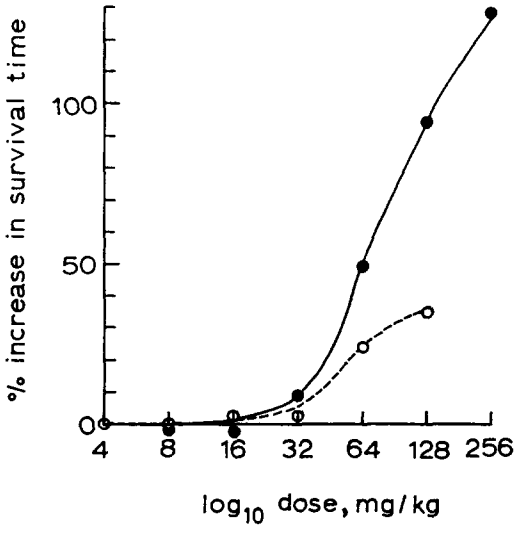

Fig. 4. Carcinostatic activity of a HPE-cysteine adduct in vivo *compared to HPE alone against Sarcoma* 180 *in female CBA/CA mice* (20–25 g). 1×10^6 *cells injected per mouse. The* % *increase in survival time, compared to untreated control animals, is plotted against* $\log_{10}$ *dose in mg/kg body wt./day;* O – – – O *HPE alone given on days* 3 *and* 4 *following transplantation in* 4 *divided doses* [1]*;* ●—●*, HPE–cysteine given on days* 3–7 *following transplantation in single doses.*

The results obtained are consistent with the view that the extended breakdown of an adduct of HPE and cysteine, releasing the reactive aldehyde, increases the half-life of HPE *in vivo*.

4. DISCUSSION

In this study, we have demonstrated that the incorporation of ^{3}H-thymidine into DNA of Sarcoma 180 tumour cells *in vitro* appears to be primarily affected, in a sigmoidal manner, at doses of HPE in excess of 0·16 mM. ^{3}H-uridine incorporation into RNA and ^{3}H-leucine incorporation into protein were considerably less depressed and declined linearly with increasing doses of added aldehyde *in vitro*. Therefore the mechanism of action of HPE against Sarcoma 180 and other tumours tested [3] in primarily depressing labelled thymidine incorporation into DNA *in vitro* appears to differ from that of most other aliphatic aldehydes which primarily depress protein synthesis *in vitro* [15].

The doses of added HPE required to reduce labelled thymidine incorporation into Sarcoma

180 cells *in vitro* by 50% (ID_{50}) and 90% (ID_{90}) were 0·09 mM and 0·157 mM respectively. We can compare those values with those obtained by Klamerth [18] on the depression of labelled thymidine incorporation produced by exposure for 5 hr of human fibroblasts in culture to increasing doses of malonaldehyde *in vitro*. HPE is approx. 7 times more effective than malonaldehyde on a molar basis in depressing thymidine incorporation into DNA over a considerably shorter exposure period (30 min compared to 5 hr). A small degree of protection against the effects of added aldehyde was obtained by the addition of 0·16 mM cysteine before preincubation of Sarcoma 180 cell suspensions with HPE *in vitro*. Preincubation of tumour cell suspensions with a premixed solution of cysteine and HPE was 2–3 times less effective, on a molar basis, than preincubation with HPE alone on the subsequent incorporation of ^{3}H-thymidine into DNA, compared to solvent treated control cultures. The results with HPE-cysteine (purified by TLC) indicated that a 1 hr preincubation of Sarcoma 180 cell suspensions was approx. 7 times less effective on a molar basis than treatment with with HPE alone *in vitro*. A 2 hr preincubation period in the presence of the adduct before the addition of labelled thymidine was approx. 4 times less effective than treatment with aldehyde alone. These results suggest that the HPE-cystine adduct is breaking down in the tissue culture medium, releasing 2 moles of cysteine for every mole of HPE, thus increasing the $t_{\frac{1}{2}}$ of HPE *in vitro*.

The effect of treating mice bearing the ascitic form of Sarcoma 180 with increasing doses of the HPE-cysteine adduct resulted in a series of dose-dependent increases in survival time, compared to untreated control animals. Within the group of tumour bearing animals treated at 128 and 256 mg/kg body wt./day of the adduct (expressed as mg of HPE assumed to be released) only 1 mouse in 20 had a mixture of ascitic fluid and a solid tumour present on death. The remainder (19 in 20) died with a large proliferated solid tumour (8–11 g. in wt., 2·5–3·5 cm in diameter) and the absence of ascitic fluid on death. It is significant that such solid tumours initially developed between days 14–21 following transplantation, at least 7 days after the last injection of HPE-cysteine. The initial development of these small solid tumours was correlated with the dose of the HPE-cysteine adduct received by the treated animals. Mice receiving 256 mg/kg body wt./day developed solid tumours later than those receiving smaller doses of the adduct. It appears likely that the concentration of cysteine and HPE circulating in the blood plasma following an i.p. injection of HPE–cysteine will be rather low. Certainly the normal detoxicification functions of the liver and other normal tissues [19] will ensure that within a few hours significant quantities will not be detected in the plasma following an i.p. injection of the adduct.

Treatment of mice implanted i.p. with the ascitic form of Sarcoma 180 with single daily injections i.p. of HPE-cysteine was 2–3 times more effective on a dose for dose basis than treatment of such animals with multiple daily injections i.p. of HPE alone [1]. The greatly lowered toxicity of the HPE-cysteine adduct compared to the free aldehyde injected i.p. has markedly improved the carcinostatic activity of HPE *in vivo*.

Effect of Hyperthermia on the Radiation Response of two Mammalian Cell Lines*

GLORIA C. LI and HENDRIK B. KAL†

Department of Radiology, Stanford University, School of Medicine, Stanford, California 94305, *U.S.A.*

Abstract—*The interaction of* 43°C *hyperthermia and X-irradiation was compared* in vitro *in two cell lines: Chinese hamster ovary (HA-*1*) and mouse mammary sarcoma (EMT-*6*). In HA-*1 *cells the sequence of heating followed by X-irradiation resulted in appreciably more sensitization than the opposite sequence; in EMT-*6 *cells the opposite occurred. When time at* 37°C *was introduced between the two treatments, the degree of interaction was reduced, depending upon sequence and the duration of the* 37°C *time interval. In both cell lines, maximum toxicity was seen if the two treatments followed each other immediately.*

INTRODUCTION

THERE IS considerable evidence in the literature suggesting that elevated temperatures may be used as either the primary mode of tumor eradication or as an adjunct to other treatments; a review by Overgaard and Overgaard lists 131 references [1]. In order to develop methods for rational application, quantitative data on the effect of elevated temperatures on cells *in vitro* and *in vivo* as well as on tumors and normal tissues are required. Furthermore, in combined modalities, the optimal sequence of heat application and radiation or drugs must be evaluated.

Survival curves (surviving fractions vs duration of heat treatment) have been obtained for cells *in vitro*. These curves have a shape resembling that of X-ray survival curves [2, 3], although some observations indicate that heat survival curves have a resistant "tail" [4–6]. Cell inactivation by hyperthermia has been found to vary with position in the cell cycle [2–4], to depend on nutritional conditions and to some extent on the oxygen concentration [3–5, 7, 8]. Synergism is sometimes observed when cells are treated with drugs at an elevated temperature [9, 10], and when hyperthermia is combined with radiation [11–13]. For example, synchronous Chinese hamster cells were most sensitive when hyperthermic treatment (45·5°C for 7 or 11 min) was applied before irradiation [12]. In contrast, survival curves of V79 cells irradiated at 0°C with or without incubation at 42°C for 2 hr are virtually identical [13], and the degree of sensitization of Chinese hamster lung cells is approximately the same when thermal treatment at 42°C for up to 2 hr was applied either before or after irradiation [11]. It appears that the effect of hyperthermia on the radiation response depends on cell line, the temperature and duration of heat shock employed as well as on the sequence of the hyperthermia and irradiation.

We report here the effect of hyperthermia on the radiation sensitivity of a strain of Chinese hamster cells (HA-1), and on cells derived from a mouse mammary sarcoma (EMT-6). Specifically we compare the effects of ordering the X-irradiation and hyperthermia, and the effect of elapsed time between the two treatments.

Accepted 16 August 1976.

MATERIAL AND METHODS

Cells and culture conditions

One of the cell lines used was an established Chinese hamster ovary line, HA-1 [14]. The cells were maintained in Eagle's minimal essential medium (MEM) supplemented with 15% fetal calf serum, penicillin and strepto-

mycin. Plating efficiencies in the experiments reported here were between 80% and 90%.

The other cell line was derived from a mouse mammary sarcoma, EMT-6 [15]. These cells were grown in Waymouth's medium supplemented with 15% fetal calf serum and antibiotics. Plating efficiencies with EMT-6 cells were usually between 50 and 70%.

Survival experiments

Two types of procedures were compared:

A. *Experiments on single cells.* Cells were trypsinized from exponentially growing cultures, counted and plated in 60 mm Petri dishes with fresh medium. The cells were incubated at 37°C for 3–4 hr to allow cells to attach to the plastic dish, and then were exposed to heat and/or X-ray irradiation. Afterwards, they were placed in an incubator at 37°C for 10 days without any additional manipulation to allow colony formation.

B. *Experiments on monolayers.* Exponentially growing cells were obtained by seeding 2×10^5 cells into 60 mm Petri dishes. Cultures were heated and/or irradiated at a cell density of approximately 10^5 cells/cm^2. After treatment, cells were trypsinized, counted and plated for colony formation.

Irradiation

Cells were irradiated at room temperature on a rotating platform. The X-ray parameters were 85 kvp, 9·6 mA, 1·5 mm Al-filter at an average dose rate of 130 rad/min.

Heating

Single cells or monolayers of cells on plastic Petri dishes were exposed to 43°C in specially designed hot water baths in incubators [5]. The dishes were placed on perforated trays so that the bottoms of the dishes were always in contact with the hot water. The temperature was maintained to ± 0·1°C and the pH of approximately 7·2 was maintained by a regulated gas flow of a mixture of 5% CO_2 and 95% air.

Definition and notation

We define the sequence of X-ray followed by 43°C temperature as postheat and the reverse as preheat. We use the following notation describing postheating experiments: dose + 43°C/t_H means the cells were irradiated with a dose of X-ray and then heated at 43°C for t_H min. Similarly, preheat experiments are described by 43°C/t_H + dose. The interaction experiments, i.e. experiments in which a sojourn at 37°C intervenes between the two

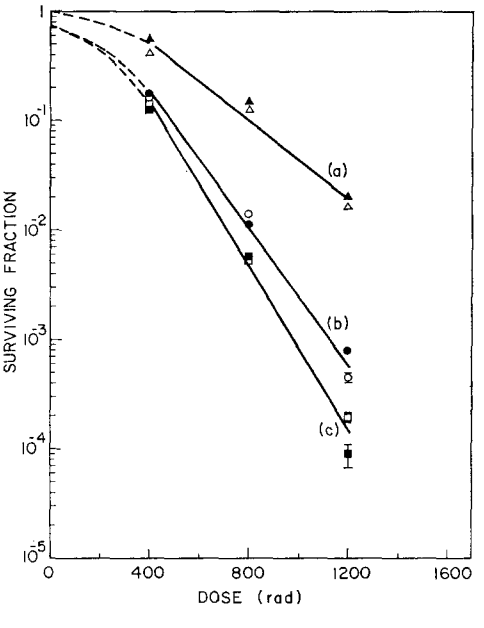

Fig. 1b. *EMT-6 cells in Waymouth medium (with 15% FBS). (a) X-ray alone; (b) 43°C/60 min + X-ray; (c) X-ray + 43°C/60 min.*

Fig. 1. *Dose–response curves of exponentially growing HA-1 and EMT-6 cells after sequential treatment of X-ray and 43°C heating. Closed triangles, squares and circles represent data points obtained from experiments on single cells, open triangles, squares and circles represent data points obtained from experiments on monolayer cells (see Material and Methods). The lines in the linear part of the survival curves are fitted to the data point according to the least squares method. Data points with bars represent mean values and the range of measured values obtained in at least two experiments.*

treatments, are described according to dose + 37°C/T_I+43°C/t_H (postheat) and 43°C/t_H+37°C/T_I+dose (preheat), thus T_I is the time (hr) at 37°C.

RESULTS

X-ray response

Survival values for HA-1 cells and EMT-6 cells exposed to graded dose of X-rays are shown in Fig. 1. The results are in good agreement with previously published data [16], and are used as controls for the experiments.

No statistically significant differences between survival values for cells which were treated either as single cells or monolayer cultures were observed. These results were observed for both HA-1 cells and EMT-6 cells, and in all experiments described in the text.

Heat response

The fraction of cells surviving heat exposure to 43°C for 60 min can be read from Fig. 1 (zero X-ray dose), and is approximately 80% for both cell lines.

Preheat response

Cells were exposed at 43°C for 60 min, then irradiated with graded doses of X-rays. Survival values immediately after the combined treatment of 43°C/60 min + dose are shown in Fig. 1a and Fig. 1b for HA-1 cells and EMT-6 cells respectively. The toxicity immediately after 43°C preheating and X-rays was more than additive. If it is assumed that the two types of damage (43°C and X-rays) are independent, then the cell survival for HA-1 cells after 43°C/60 min + 800 rad, should have been $\sim 1{\cdot}2 \times 10^{-1}$. However, a survival value of 5×10^{-3} was observed. Similarly, the survival for EMT-6 cells after 43°C/60 min + 800 rad should have been 4×10^{-2}; however, a survival value of 2×10^{-3} was observed. The almost 24-fold reduction in the survival of HA-1 cells (20-fold reduction for EMT-6 cells) implies an interaction between heat and X-ray damage and this is consistent with the observation of others [6, 11, 12, 13, 17]. As indicated by the different slopes of the survival curves in Fig. 1, the amount of reduction in survival values after preheating is dose-dependent.

Postheat response

Figure 1 also shows survival curves of cells which were irradiated with graded doses of X-ray and then exposed to 43°C for 60 min. If the assay was performed immediately after X-ray and postheating, then cell toxicity was again more than additive. A slightly lower

survival value was seen for EMT-6 cells immediately after the combined treatment dose + 43°C/60 min as compared to preheating, while a higher survival value for HA-1 cells was noted immediately after the combined postheating treatment dose + 43°C/60 min as compared to preheating. In all cases the amount of reduction in survival values was dose-dependent.

Effect of time (37°*C*) *between treatments*

Cells were given 600 rad, afterwards either immediately exposed to 43°C for 60 min or incubated at 37°C for 1–4 hr, and then exposed to 43°C for 60 min. The surviving fractions for 600 rad + 37°C/T_I + 43°C/60 min are shown in Fig. 2a and Fig. 2b for HA-1 cells and EMT-6 cells respectively. Similar experiments between 43°C preheating and X-ray were also performed. Cells were exposed to

43°C for 60 min, afterwards either exposed to 600 rad immediately or incubated at 37°C for 1–8 hr and then exposed to 600 rad of X-ray. The resulting surviving fractions for 43°C/60 min + 37°C/T_I + 600 rad are shown in Fig. 2a and Fig. 2b for HA-1 and EMT-6 cells respectively. In these experiments the amount of radiation given was the same and the amount of heating was also identical; the only two variables were the time interval (37°C/T_I) between the radiation and heat exposure and the sequence of the treatments.

What is of interest here is the comparison between survival values predicted on the basis of additivity of 43°C and X-ray (curves C in Fig. 2a and 2b) and the actual measurements. In the postheating experiments, there was a 5-fold difference for HA-1 cells and a 20-fold difference for EMT-6 cells if 43°C exposure was immediately followed by X-ray, and a 2-fold difference for both HA-1 and EMT-6 cells if heating was delayed by 2 hr (T_I = 2 hr). This 2-fold difference remained constant even if the heating was delayed by 4 hr (T_I = 4 hr).

In the preheating experiments there was a 20-fold difference for HA-1 cells and a 10-fold difference for EMT-6 cells if irradiation followed immediately after heating, but only a 5-fold difference for both HA-1 and EMT-6 cells if X-ray was delayed by 4 hr (T_I = 4 hr). This 5-fold reduction in survival remained unchanged even if irradiation was delayed by 8 hr for both cell lines.

DISCUSSION

Treatment of cells as either single cells or in monolayer cultures resulted in identical surviving fractions (within statistical fluctuations). This is observed for both EMT-6 and HA-1 cell lines, and it indicates that any possible interference of trypsin with repair processes, if such interference exists at all, has very little effect on cell survival. Furthermore, cell to cell contact at the time of heating appears not to be of importance.

For HA-1 cells, there is greater initial sensitization in the case of preheating than postheating, while for EMT-6 cells greater initial sensitization is observed in the case of postheating. We cannot offer any explanation for this difference between the two cell lines.

Our results confirm that X-ray and 43°C postheating interact in the sense that the combined treatment is more cytotoxic than the sum of the individual treatments. The maximum toxicity occurs when heat follows immediately after X-ray. This irradiation-induced heat sensitivity then is reduced as the two treatments are separated by time interval at 37°C. However, survival values do not reach those calculated on the basis of additivity, even if the time at 37°C exceeds 4 hr. Somewhat similar results are observed in plateau phase HA-1 cells [17], although there once the repair of X-ray induced damage was completed ($T_I \geqq 4$ hr), the cells surviving the X-irradiation responded to 43°C heat shock as if they had never been exposed to X-ray. For exponentially growing HA-1 and EMT-6 cells, the difference in surviving fractions between predicted value (based on simple additivity) and actual measurements for $T_I \geqq 4$ hr can be explained on the basis of differences in the age response of cells to X-ray and hyperthermia, and possibly the X-ray induced para-synchronization of the cell population. Westra and Dewey [2] have shown that X-ray resistant late S phase cells are particularly sensitive to hyperthermia.

Preheating and X-irradiation also interact. Again maximum toxicity is observed when the two treatments immediately follow each other. As T_I increases, the survival increases. At $T_I \geqq 4$ hr it reaches 25% of the value predicted on the basis of additivity. The rate of increase in surviving fraction is only half the rate seen for postheating. It seems that heat introduces a transitory state during which cells are radiation sensitive. This state decays gradually and this represents a partial recovery from heat induced damage. In an earlier paper [18] it was reported that after a 1 hr heat exposure at 43°C cells accumulate in the S phase during the first 4–6 hr after heat treatment and subsequently accumulated in G_2+M. For both HA-1 and EMT-6 lines, cells in late S as well as in early G_1 are radio-resistent, cells in late G_1, early S and G_2 + M are radio-sensitive [19]. The 1-hr and 2-hr points of Fig. 2 (preheating) represent surviving fractions of populations with relatively large fractions of cells in late G_1 and early S. These are relatively radiosensitive, however, for the 4–8 hr points, relatively large fractions of cells are accumulated in late S and these are radio-resistant. Consequently the increase in survival may well be explained by a competition of this para-synchronization with a recovery process from heat induced X-ray sensitivity and the variation in sensitivity of cells to heat over the cell cycle.

Role of Fetal Antigens in Tumor Immunity

SAVITA GAUTAM and B. K. AIKAT

Department of Pathology, Postgraduate Institute of Medical Education and Research, Chandigarh, India

Abstract—*Studies were undertaken to demonstrate the role of fetal antigens in tumor immunity. Viable fetal cells inoculation followed by challenge with transplanted methylcholanthrene induced tumor cells after* 7, 14 *and* 21 *days significantly delayed the time of appearance of tumors. Transfer of lymphoid cells from mice immunized with fetal cells followed by tumor challenge resulted in delayed appearance of tumors. Inoculation of viable tumor cells pre-treated* in vitro *with serum from mice immunized with fetal cells shortened the time of appearance of tumors in mice.*

INTRODUCTION

THE DEMONSTRATION of tumor specific transplantation antigens in tumors and the demonstration of both humoral and cell-mediated immunity to these antigens have opened up great possibilities of immunologic control of cancer [1, 2]. Several workers from time to time have suggested that animal and human tumor antigens are, in fact, reexpressed fetal components which appear in early fetal life [3–6].

However, the role of these tumor-associated fetal antigens in tumor rejection response remains controversial. Prehn [7], Lemevel and Wells [8], Bendich *et al.* [9] reported protection of C57B1/6 and C57 BL mice against methylcholanthrene-induced tumors by pre-immunizing with embryo cells or by exposure to fetal antigens during pregnancy. Grant *et al.* [10] also reported significant protective effect to chemically induced tumor challenge following immunization with fetal tissue. However, Blair [11], Castro *et al.* [12], Baldwin *et al.* [13], Parmiani and Lembo [14] reported that immunization with fetal tissue does not elicit resistance to challenge with chemically induced hepatomas and sarcomas. Brawn [15], Girardi *et al.* [16]. Grant *et al.* [10] showed that multiparous female animals were resistant to tumor challenge and they possessed cytotoxic lymph node cells that destroyed several viral and methylcholanthrene-induced tumor cells *in vitro* and *in vivo*. By means of blocking antibody studies, Baldwin *et al.* [6, 13], Hellstrom and Hellstrom [17, 18] demonstrated that serum from multiparous rats blocked the cytotoxicity of lymph node cells from multiparous rats both to tumour cells as well as to fetal cells.

The present studies were undertaken to explore the possible immunological similarity between the antigens of fetus and methylcholanthrene-induced fibrosarcoma in inbred mice of C57 strain. The effect of fetal cells inoculation followed by tumor challenge at different intervals, the effect of lymphoid cells and sera from mice immunized with fetal cells and the effect of lymphoid cell transfer from multiparous pregnant mice on the time of appearance of tumors was studied in different groups and compared with appropriate control groups.

MATERIAL AND METHODS

Animals

All animals used belonged to an inbred strain C57 (Jet black, ICRC) mice maintained by of continuous single line brother to sister mating. The purity of inbred lines was tested routinely by acceptance of the reciprocal skin grafts.

Tumors

Primary fibrosarcomas were produced by 20-methylcholanthrene (MC) according to the method of Reiner and Southam [19]. Tumors were then routinely passaged by subcutaneous

transplantation in syngeneic mice. Inoculation of C57 inbred mice with 1×10^6 viable tumor cells has always given 100% tumor incidence in a large group of animals challenged. The tumors become palpable within 8–10 days. All experiments were conducted on passaged tumors. The demonstration of transplantation immunity in syngeneic animals after surgical removal of the tumor was in support of the fact that this tumor is antigenic.

Cell viability test

Viability of cells was tested by trypan blue dye exclusion test.

Immunization with fetal cells

First litters from 12 week old C57 mice were used as a source of fetal tissue. Timed matings were achieved and the number of vaginal plugs was recorded. The day the plug was recorded was considered day 0. Embryos 8–10 days old, from primiparous female mice, were removed under aseptic conditions, dissected free of placenta and membranes with sharp forceps and were placed in cold Eagle's minimum essential medium (MEM). The fetuses were then homogenized gently in glass homogenizer. Cells were sieved through a sterile stainless steel (80 mesh) gauze and washed twice in MEM. Trypan blue dye exclusion test was performed for cell viability, 2×10^8 viable cells/0·1 ml were then inoculated under the kidney capsule of adult male mice, with a very fine needle. These mice were then divided into five groups. Mice of these different groups were then challenged with 1×10^6 viable tumor cells at interval of 0, 7, 14, 21 and 28 days respectively by subcutaneous route. Simultaneously, a control group was challenged with tumor cells only. In another set of experiments the mice were inoculated with 2×10^8/0·1 ml normal adult spleen cells under the kidney capsule and challenged at different intervals with 1×10^6 viable tumor cells. The initial time of appearance of tumors in mice of different groups was recorded and statistically compared. In addition, unchallenged recipients injected with fetal cells were sacrificed at intervals to study the histology of the growing fetal tissues under the kidney capsule.

Lymphoid cell transfer

To study the effect of embryonic antigen sensitized lymphoid cells, lymph node cell suspensions were prepared separately from mice of following three groups:

Group I: Normal virgin mice.

Group II: Mice immunized with fetal cells (after 8 days of immunization).

Group III: Multiparous pregnant mice previously having had more than 4 pregnancies.

The cell suspensions were passed through 80 mesh stainless steel screen and washed twice in BSS. Cells were finally suspended in MEM.

Normal adult male mice were divided into three groups and each mouse of each group received two doses of 4×10^8/0·5 ml lymph-node cells from mice of above groups respectively at four days interval by intra-peritoneal route. After 7 days of last transfer, these mice were challenged with 1×10^6 viable tumor cells. Initial time of appearance of tumors in all mice was noted and compared.

Inoculation of tumor cells treated with serum

To study the effect of serum from fetal cells immunized mice, normal syngeneic mice were injected subcutaneously in three different groups with 1×10^5 viable tumor cells/mouse incubated previously for 30 min. at 37°C with 0·5 ml of MEM medium, with 0·5 ml of normal virgin mice serum and with 0·5 ml of serum from mice immunized with fetal cells respectively. These mice were then observed to record the initial time of appearance of tumors. Serum was collected after 28 days of fetal cells injection.

RESULTS

Histological studies

Normal adult male mice were inoculated under the kidney capsule with cells from syngeneic 8–10 days old fetuses. These mice were then divided in 4 groups of 4 mice in each group and sacrificed at intervals of 7 days, 14 days and 28 days. Their kidneys were examined macroscopically and microscopically. Figure 1 shows a mouse kidney with a fetal growth on its surface. Kidney sections from mice killed after seven days of fetal cells inoculation revealed proliferation of undifferentiated cells under capsule of kidney (Fig. 2). After fourteen days of fetal cells injection, there was beginning of formation of more organized structures with cavity formation (Fig. 3). Kidney sections from mice sacrificed after 28 days of fetal cells inoculation, showed the development of teratomatous elements consisting of mature bone with bone marrow cells, cavities lined by columnar epithelium, cartilage and undifferentiated cells showing more organized pattern of development (Fig. 4).

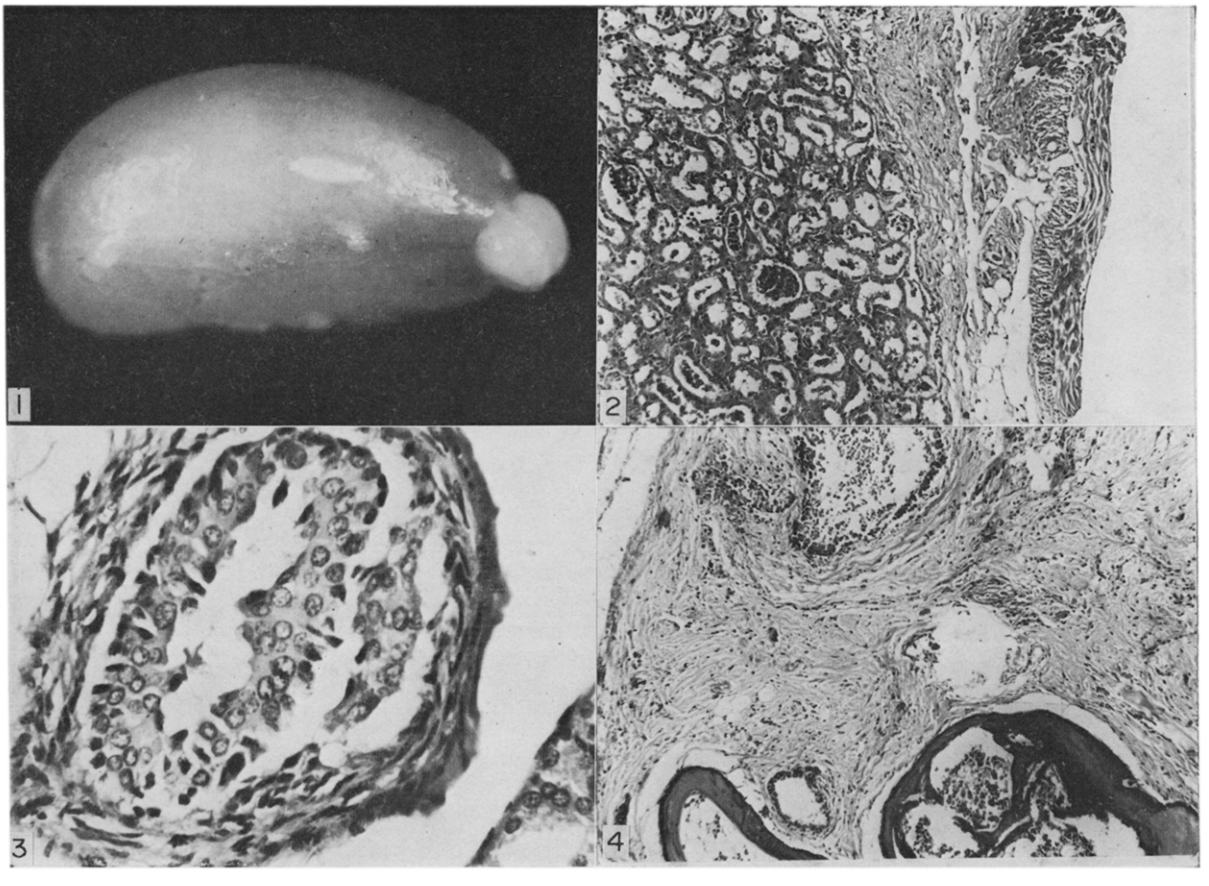

Fig. 1. *A mouse kidney showing a subcapsular growth of fetal cells.*

Fig. 2. *Microphotograph of a kidney section from mouse sacrificed after* 7 *days of fetal cell inoculation showing proliferation of undifferentiated cells under kidney capsule* (*H and E* × 110).

Fig. 3. *Microphotograph of a kidney section of mouse sacrificed after* 14 *days of fetal cell inoculation showing cavity formation* (*H and E* × 440).

Effect of fetal cell inoculation

Figure 5 compares the time of appearance of tumors in mice injected with fetal cells followed by tumor challenge at different intervals. Mean time of appearance of tumors in control mice was $8{\cdot}62 \pm 0{\cdot}93$ and in mice inoculated with fetal cells followed by tumor challenge after 7, 14 and 21 days, the mean time of appearance of tumors was $22{\cdot}9 \pm 5{\cdot}17$ days, $17{\cdot}6 \pm 3{\cdot}75$ days and $15{\cdot}1 \pm 2{\cdot}68$ days respectively. These mean values are significantly different when compared to those of control mice ($P < 0{\cdot}05$). The mean time of appearance of tumors in mice challenged on 0 day and after 28 days of fetal cell inoculation was $10{\cdot}5 \pm 2{\cdot}14$ and $10{\cdot}8 \pm 1{\cdot}76$ days respectively. These values are not significantly different from the control mice ($P > 0{\cdot}05$). The mean time of tumor appearance in mice inoculated with normal adult spleen cells followed by tumor challenge after 0, 7, 14, 21 and 28 days was $8{\cdot}25 \pm 0{\cdot}78$ days, $9{\cdot}25 \pm 1{\cdot}03$ days, $9{\cdot}0 \pm 1{\cdot}32$ days, $8{\cdot}75 \pm 1{\cdot}03$ days and $9{\cdot}0 \pm 1{\cdot}32$ days respectively. These values are not significantly different as compared to that of control mice ($P > 0{\cdot}05$). Except for 0 and 28 days, all these mean values are significantly different ($P < 0{\cdot}05$) as compared to the mean values of corresponding groups of mice inoculated with fetal cells under the kidney capsule.

Effect of lymphoid cells from fetal cells immunized from multiparous mice

Figure 6 compares the effect of lymphoid cells from fetal cells inoculated mice and from multiparous pregnant mice for their capacity to adoptively transfer resistance to tumor challenge. Mean time of appearance of tumors in control mice challenged with tumor cells only was $9{\cdot}4 \pm 1{\cdot}35$ days. Normal lymphoid cells did not affect the time of appearance of tumors since the mean time of appearance of tumors in these mice was $9{\cdot}6 \pm 2{\cdot}33$ days. Mean time of tumor appearance in mice transferred with lymphoid cells from fetal cells immunized mice and from multiparous pregnant mice was $17{\cdot}2 \pm 2{\cdot}4$ days and $14{\cdot}0 \pm 1{\cdot}76$ respectively. These mean values are significantly different as compared to both the control groups ($P < 0{\cdot}05$).

Effect of serum

The results of this experiment are presented in Fig. 7. Pre-treatment of tumor cells with serum from fetal cells injected mice did not delay the tumor appearance. On the other hand, it shortened the time of appearance of tumors. The mean time of appearance of tumors in mice injected with tumor cells treated with serum from fetal cells immunized mice was $14{\cdot}0 \pm 1{\cdot}5$ days and in mice injected with normal serum treated tumor cells and MEM medium treated tumor cells was $18{\cdot}25 \pm 1{\cdot}7$ days and $19{\cdot}25 \pm 1{\cdot}3$ days respectively. These mean values are significantly different as compared to that of experimental animals ($P < 0{\cdot}05$).

DISCUSSION

There is considerable evidence to suggest the existence of a variety of fetal antigens in association with human tumors [3, 4, 20, 21]. Experimental studies have further proved the association of embryonic antigen with chemically induced tumors [6, 22, 23]. Tumors induced by viruses have also been shown to share antigens with embryos [24, 25].

Prehn [7] for the first time found suppression of transplanted MC induced tumor growth in mice pre-immunized with viable embryo cells. Blair [11], Ting *et al.* [26], Castro *et al.* [12], Baldwin *et al.* [13], Parmiani and Lembo [14] failed to find transplantation immunity against virus induced mammary tumors, SV40 induced tumors and chemically induced tumors after immunization with fetal cells. But studies of Buttle and Frayn [27], Coggin *et al.* [24], Girardi *et al.* [16] Lemevel and Wells [8], Bendich *et al.* [9] and Grant *et al.* [10] encouraged various workers to carry on further studies with other tumor types since these workers showed that preimmunization with fetal antigens produced significant resistance against development and suppression in growth of imferon induced sarcoma, SV40 induced tumors, adeno virus induced tumors, Rouscher leukemia virus injected cells, plasma cell tumors and MC induced tumors.

In the present studies, inoculation of fetal cells followed by tumor challenge after 7, 14 and 21 days resulted in significant delay in tumor appearance as compared to the control mice. Tumor challenge on 0 day and after 28 days of fetal cells inoculation did not affect the time of appearance of tumors (Fig. 5).

Failure of different investigators to induce immunity against various types of tumors following immunization with fetal cells may be attributed to several factors and different experimental conditions. First and most important may be the strain dependent sensitivity. Whether the host responds to these fetal antigens or not will determine their suitability for immunotherapy. Ting *et al.* [25] could produce anti fetal serum in C57 mice which was found to be highly reactive. Antisera

produced by the same schedule in C3H mice was weakly reactive whereas repeated hyper-immunization of BALB/C or CBFI mice with X irradiated fetal cells failed to produce serum that would react with tumor antigen or fetal antigen. Several workers reported the induction of immunity against tumors in C57 mice by preimmunizing them with fetal cells [8, 9], while Blair [11], Ting *et al.* [26], Parmiani and Lembo [14] failed to induce such immunity in BALB/C mice. Similarly hamsters have been found to be good responders to fetal antigen as compared to BALB/C mice [25, 10].

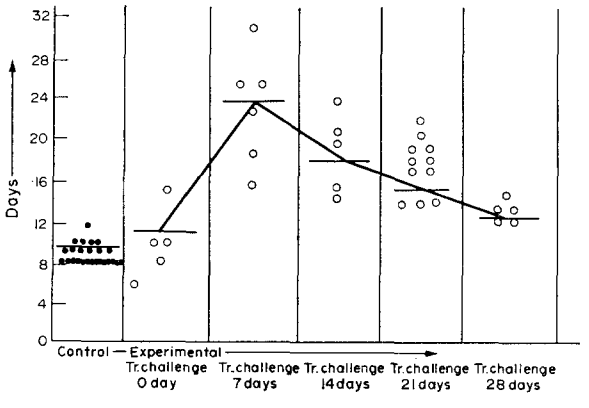

Fig. 5. *Figure showing the effect of fetal cells inoculation followed by tumor challenge at different intervals on time of appearance of tumors in mice.*

Whether sex plays any significant role in response to fetal antigens is again a controversial question. Some workers found that males responded better to fetal antigen immunization [24, 16]. However, Grant *et al.* [10] did not find any such sex difference in case of MC induced tumors.

The degree of immunity also depends upon the immunization schedule, latent period etc. In the present study, failure of viable fetal cells to induce resistance in mice challenged with tumor cells after 28 days may be explained on the basis that fetal tissues become mature in adult hormonal environment as has been discussed by Coggin *et al.* [24]. This is confirmed by the histological study of fetal cell growth below the kidney capsule in mice sacrificed after 28 days of fetal cell injection which constituted almost all mature structures like bone with bone marrow, cartilage, cavities lined by columnar epithelium (Fig. 4). However, it is difficult to suggest whether the tumor associated fetal antigens were present at this stage or not. Appearance of blocking antibodies by this time may be another factor. Buttle and Frayn [27] found that degree of tumor inhibition was highest if the interval between fetal cells injection and tumor challenge was 7 days and the effect gradually reduced as this interval was increased.

Under natural conditions only females are exposed to fetal antigens during pregnancy. Blair *et al.* [28] reported that spontaneous tumor development in the virgin females occurs at a later time than in the parous females. On the other hand, Fraumeni *et al.* [29] after studying a large group of patients concluded that unmarried females are more susceptible to tumors of the colon, breast, corpus uteri and ovary. Apart from hormonal influences, the cause of this difference may be that during pregnancy females are exposed to fetal antigens which sensitize the lymphoid cells. Baldwin *et al.* [5, 6], Steele and Sjogren [23], Hellstrom and Hellstrom [17, 18] reported that multiparous female animals possess cytotoxic lymph node cells that destroy several viral and MC induced tumors *in vitro*. Very few investigators have tried to demonstrate the *in vivo* role of fetal antigen sensitized lymphocytes in tumor rejection response. Only few contradictory reports are available. In the present investigation studies were undertaken to examine the capacity of lymphoid cells from fetal cells injected mice and from multiparous pregnant mice to transfer adoptively the resistance to tumor challenge. It was found that lymphoid cells from fetal cells immunized mice and from multiparous pregnant mice significantly delayed the time of appearance of tumors as compared to the control mice whereas the normal lymphoid cells did not (Fig. 6).

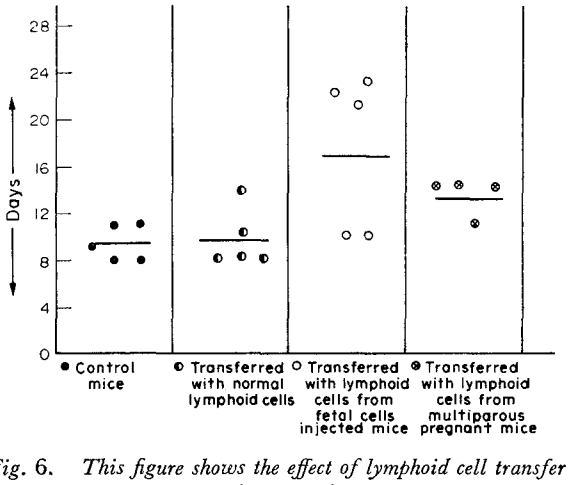

Fig. 6. *This figure shows the effect of lymphoid cell transfer from mice immunized with fetal cells and from multiparous pregnant mice on appearance of tumors.*

Hanna *et al.* [30] reported that transfer of spleen cells from multiparous mice protected the normal mice from infection with Rouse leukemia virus. Girardi *et al.* [16] showed that

lymphoid cells from primiparous and multiparous hamsters protected normal male hamsters against SV40 induced tumor challenge. On the other hand, studies of Baldwin *et al.* [13], Parmiani and Lembo [14] showed that lymphoid cells from multiparous rats and mice were ineffective in adoptively transferring tumor immunity to normal animals.

In the next set of experiments, three groups of normal mice received tumor cells incubated previously with MEM, with serum from normal virgin female mice, with serum from fetal cells immunized mice respectively. Inoculation of mice with tumor cells treated with serum from fetal cells immunized mice did not protect them against tumor formation (Fig. 7). Surprisingly, the tumor appearance time was shortened in these mice as compared to the control groups.

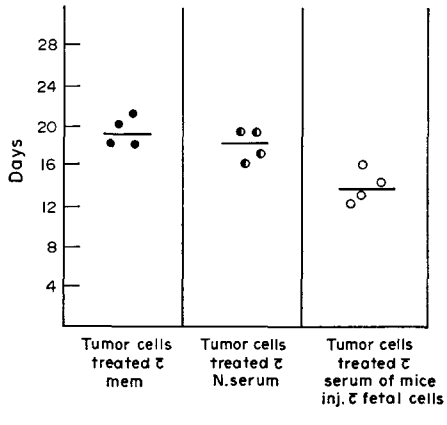

Fig. 7. This figure shows the effect of in vitro *treatment of tumor cells with serum from normal mice and from mice immunized with fetal cells on time of appearance of tumors.*

Coggin and Anderson [31] demonstrated that females splenectomized to reduce the antibody forming capacity react protectively to fetal vaccine. Antibody response against fetal antigens is more because these antigens contain more antigenic sites as compared to the tumor antigen. Recently in a series of their *in vitro* studies, Baldwin *et al.* [6, 13] have shown that lymph node cells from multiparous pregnant mice were cytotoxic *in vitro* for cultured tumor cells and fetal cells. But this cytotoxicity for tumor cells and fetal cells was blocked in presence of serum from multiparous mice (Fig. 8). Similar findings have been given by Hellstrom and Hellstrom [17, 18] who ascribed the inability of fetal antigens to induce tumor resistance in body to these blocking antibodies.

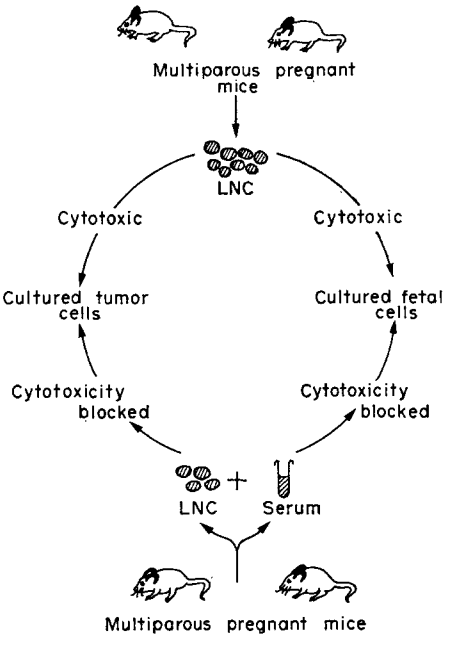

Fig. 8. Diagrammatic presentation of in vitro *cytotoxicity of lymphoid cells from multiparous mice against tumor cells, fetal cells and blocking of this cytotoxicity by serum from multiparous mice.*

Recently, Tamerius *et al.* [32] described that fetal antigens have a special property to form blocking factors. These factors prevent either the development of cell mediated immunity or act against the expression of an already developed cell mediated immunity.

Prediction of Marrow Toxicity in Patients Treated by Intravenous Infusion of 5 Fluorouracil*

B. L. HILLCOAT†‡, M. BANERJEE†, P. B. McCULLOCH‡ and C. K. O. WILLIAMS‡§

†*Department of Biochemistry, Health Science Centre, McMaster University, Hamilton, Ontario, Canada*

‡*Cancer Clinic, Henderson Hospital, Hamilton, Ontario, Canada,* §*Department of Neoplastic Diseases, Mount Sinai Hospital, 100th Street and 5th Avenue, New York, N.Y.* 10029, *U.S.A.*

Abstract—*Bone marrow aspirates from patients receiving intravenous infusions of* 5 *fluorouracil* (5*FU*)¶ *for gastrointestinal malignancies were tested by measuring the rate of incorporation of* ^{3}*H-UdR and* ^{3}*H-TdR into DNA in the presence of* 5*FU and the effect of* 5*FU on the ability of marrow cells to form granulocytic colonies* (*CFU-C*) *in methyl cellulose. The best correlation found was between toxicity and the ratio of the rate of* ^{3}*H-TdR and* ^{3}*H-UdR incorporation before infusion, after the addition of* 5*FU to the incubations. Seven of eight cases showed less inhibition of* ^{3}*H-UdR incorporation by* 5*FU after completing their infusion, representing a drug-induced resistance not apparently related to the proliferative state of the marrow. Two patients with the lowest peripheral granulocyte count relative to pre-treatment values also showed the greatest depression of granulocyte colony forming ability when their marrow cells were treated with* 5*FU at a concentration of* $1 \times 10^{-5} M$. *Although further cases need to be studied, these techniques appear to be of predictive value in determining marrow toxicity to* 5*FU.*

THE DRUG, 5 fluorouracil (5FU), produces less toxicity when given by intravenous infusion for five days than when given as a single intravenous injection [1, 2]. Nevertheless, mucositis occurred in all of 34 patients treated by infusion of drug for five days and leukopenia in four patients [2]. If such toxicity could be predicted, discomfort and danger to the patient could be avoided and dosage increased in those patients who do not show toxic effects. The aim of this study was to predict toxic effects of the drug on bone marrow by determining the sensitivity of DNA synthesis in bone marrow cells to 5FU added *in vitro*, before and after infusion. Synthesis of DNA was measured by the rate at which ^{3}H-TdR and ^{3}H-UdR were incorporated into acid insoluble material. The former is a measure of the rate of incorporation of TTP into DNA by the "salvage" pathway and the latter rate, incorporation of TTP by the "de novo" pathway which is specifically inhibited by 5FUdRP formed from 5FU [3]. As well, the number of CFU-C's formed after treating marrow cells with 5FU *in vitro* was compared to the number formed by untreated marrow cells.

MATERIAL AND METHODS

Patients

Patients with malignant disease of the gastrointestinal tract received intravenous infusions of 5FU for five days at a dosage of 30 mg/kg/day in 5 % dextrose at a rate of one litre per day. Peripheral blood counts were performed and the nadir of the granulocyte count expressed as a percentage of the granulocyte count before infusion. Platelet counts were little affected by the treatment and stomatitis, contrary to the

findings of Seifert *et al.* [2], was absent or mild in all cases.

Bone marrow samples

Bone marrow was aspirated before infusion of drug and within five hours of stopping the infusion. The number of nucleated cells were counted by means of a hemocytometer using the method described by Dacie and Lewis [4].

Incorporation of isotope

Bone marrow cells were washed, then resuspended in RPMI 1640 medium containing 10% fetal calf serum, Two ml of the suspension ($0{\cdot}5 \times 10^6$ to 3×10^6 cells) were dispensed in 10-ml conical flasks, gassed with 5% carbon dioxide and incubated at 37° in a shaking bath for 30 min. We then added 5FU to give a concentration of 1×10^{-5}M and incubated for 1 hr. ^{3}H-TdR or ^{3}H-UdR was then added to give a final concentration of 1×10^{-6}M and 1 μcurie per ml. After 30 minutes, we added 8 ml of 10% cold trichloroacetic acid (TCA) and cooled the flasks at 4°C for a further 30 min. The precipitate was washed twice with cold 10% TCA, dissolved in 1 ml of NCS and added to 10 ml of scintillation fluid for counting: duplicate or triplicate samples were used when enough cells were available. Results were calculated as dis/min per 10^6 nucleated cells and as a percentage of the untreated control.

Bone marrow culture

Buffy coats prepared from bone marrow aspirates obtained prior to treatment were washed once in 10 ml of complete alpha-medium (Flow Laboratories, Bethesda, Maryland). An incubation mixture consisting of 0·7 ml of cell suspension, 0·1 ml of 5FU diluted with incomplete alpha-medium and 0·2 ml of fetal calf serum (Grand Island Biological Company) was prepared and incubated at 37°C for 1 hr. In three cases, the nucleated bone marrow cells were exposed only to one drug concentration, 1×10^{-5}M. In all other cases, three drug concentrations, 1×10^{-5}M, 1×10^{-4}M and 1×10^{-3}M were used. The rationale for the use of incomplete alpha-medium (i.e. without nucleosides and deoxynucleosides) is discussed by Madoc-Jones *et al.* [5]. Following the incubation, the cells were washed once in 40–50 ml of incomplete alpha-medium, resuspended in complete alpha-medium and plated in methyl-cellulose according to the method of Iscove *et al.* [6]. The final cell concentration in the plating mixture varied from 1×10^4 to 2×10^5, depending on the number of available cells. Control cell samples (the patient's own cells) were similarly treated, except that the drug solution was omitted from the incubation mixture. The mixture was plated in 35 mm Petri Lux-dishes (Flow Laboratories) and the cells were allowed to grow in a moist atmosphere with 7·5% CO_2 and air. The number of CFU-C's present on day 14 of incubation was determined using an inverted microscope and the criteria of Messner *et al.* [7]. The number of colonies obtained from untreated cells ranged from 40 to 80 per 2×10^5 nucleated cells plated. This number was taken as 100%, while those obtained from cells treated with various drug concentrations were expressed as a percentage of those control values.

RESULTS

Tables 1 and 2 show that the rate of incorporation of ^{3}H-UdR into bone marrow cells vary from 1638 to 25,400 dis/min per 10^6 nucleated cells before treatment and in the absence of added 5FU. That for ^{3}H-TdR showed a similarly marked variation from 3262 to 64,800 dis/min per 10^6 nucleated cell. Such large variations probably represent an increased proliferative state of the nucleated cells in the marrows of patients one and seven. The remaining six patients show a much smaller variation, from 1638 to 6302 for ^{3}H-UdR and 3262 to 9569 for ^{3}H-TdR. The ratios of the rates of ^{3}H-TdR and ^{3}H-UdR incorporation, shown in Table 3, show less variation from 1·5 to 6·2 before treatment and without added 5FU. With added 5FU, however, the variation is much greater, from a ratio of 1·3 to 23·2. This table also shows that patients with the highest ratios had the most severe depression of circulating granulocytes after infusion of 5FU. Figures 1 and 2 confirm this and show a good correlation between the ratios of TdR and UdR rates before treatment and the percentage granulocytes at nadir rather than with the same ratio after infusion and/or with the absolute granulocyte number. One or two patients did not show this correlation.

Colony-forming units in vitro

Figure 3 shows a linear relationship between the number of cells plated and the number of granulocyte colonies grown from cells not exposed to drugs (control) and those exposed to 1×10^{-5}M concentration of 5FU. Only in two of the eight cell samples studied did this drug concentration produce a significant depression of surviving CFU-C. Figure 4 shows the dose-survival curves obtained by plotting on a semi-logarithm scale the percentage surviving CFU-C against four concentrations of 5FU, 1 ×

10^{-5}M, 1×10^{-4}M, 5×10^{-4}M and 1×10^{-3}M. The limited amount of nucleated cells available for the experiments did not permit us to study the effects of intermediate drug concentrations.

When the degree of inhibition of colony formation of the various cell samples was matched against the nadir of peripheral granulocyte count obtained following five-day 5FU infusion as a percentage of the initial granulocyte number, a definite pattern emerged (Fig. 5). The two patients with the most marked granulocytic depression (the granulocyte count at nadir being 6% and 35% of initial granulocytic count) were the ones whose CFU-C's were most markedly inhibited by the lowest 5FU concentration of 1×10^{-5}M. On the other hand, the cells of two patients who did not show any significant depression of their granulocyte count after five days of 5FU infusion showed the least degree of colony inhibition when their cells were exposed to the highest drug concentration of 1×10^{-3}M. Furthermore, three patterns of dose-survival curves were observed, one in the two patients 7 and 8, who had no myelotoxicity, another in patients 3, 4 and 5 and a third in patient 2.

DISCUSSION

Effective chemotherapy of cancer requires that a maximum number of malignant cells be killed while enough normal cells survive to maintain life. This differential killing has been measured by comparing the decrease in colony forming units of untreated tumor and bone marrow cells after their injection into lethally irradiated mice [8, 9]. Also, Ogawa, Bergsagel and McCulloch, have applied the same principle to study the effect of chemotherapeutic agents on tumor and bone marrow cells in culture [10, 11]. Attempts have also been made to predict whether malignant cells are sensitive to chemotherapeutic agents by exposing the cells to the drug *in vitro*, and measuring some biochemical or biological parameter [12]. Fewer studies have attempted to predict bone marrow toxicity in patients treated with such

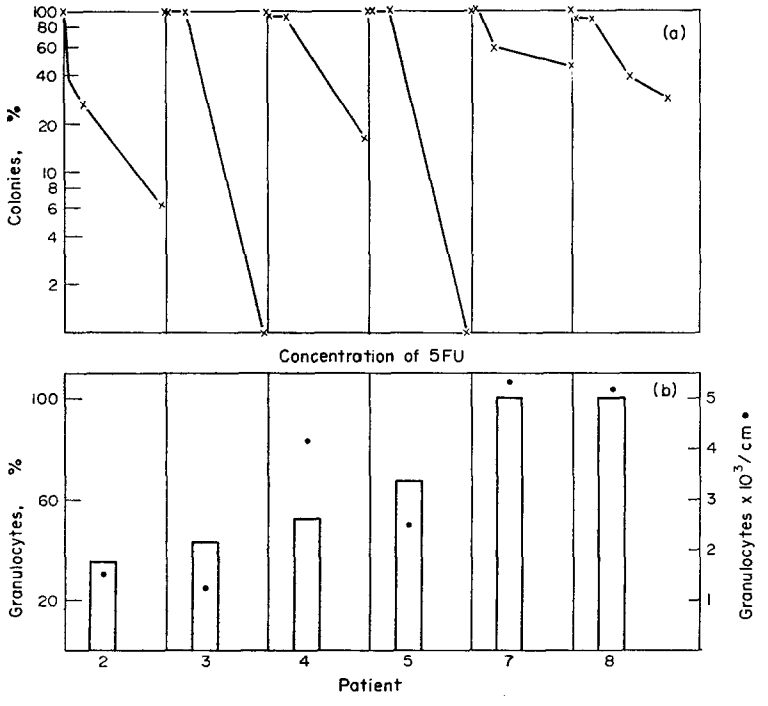

Fig. 4(a). Dose-survival curves of CFU-C's from marrow cells of six patients. The cells from patients 2, 3, 4, 5 and 7 were treated with the three concentrations of 5FU, $1 \times 10^{-5}M$, $1 \times 10^{-4}M$ and $1 \times 10^{-3}M$ for 1 hr. Cells from patient 8 were given an additional treatment with $4 \times 10^{-4}M$ 5FU. Patients 1 and 6 were studied only with one concentration, $1 \times 10^{-5}M$, and these results are not shown here.

Fig. 4(b). Peripheral granulocyte count at nadir expressed as percentuge of count before treatment (boxes) and as an absolute value, ●.

agents. In one such study, Herbert *et al.* [13] measured TdR incorporation into tumor and marrow cells in the absence and presence of drugs, including 5FU. They observed no depression of TdR incorporation with marrow cells in the presence of 5FU, as our results confirm. Herbert *et al.* [13] did not measure UdR incorporation. Absolute rates of ^{3}H-TdR and ^{3}H-UdR incorporation varied over a 20 to 14 fold respectively before treatment in the absence of 5FU. The TdR/UdR ratios varied only 4 fold, indicating that both the "salvage" and the *de novo* pathways increased together and thus did represent increased DNA synthesis in these cases.

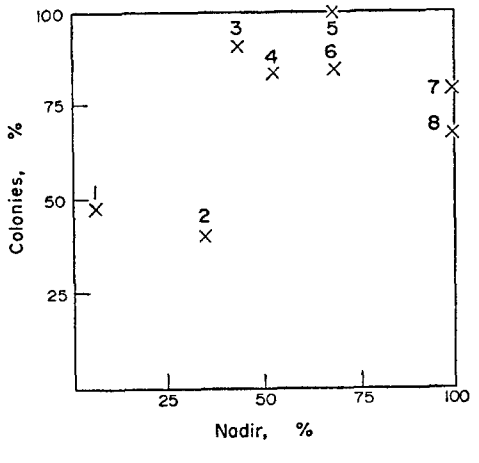

Fig. 5. Relation between marrow toxicity as shown by the nadir of the peripheral granulocyte count after treatment with 5FU as a percentage of the count before treatment and the inhibition of CFU-C formation by $1 \times 10^{-5}M$ 5FU. The numbers 1 to 8 refer to the patient studied.

After the addition of 5FU, however, a variation of 17 fold occurred in this ratio and high ratios correlated in most patients with marrow toxicity. This could be explained if such cases had a pool of thymidine triphosphate (TTP) susceptible to 5FU inhibition. This would reduce the TTP pool in these cells as shown by Tattersall and Harrap in other cells [14] and produce inhibition of growth of marrow cells. At the same time, the specific radioactivity of ^{3}H-TTP, formed from ^{3}H-TdR, would be increased due to the small pool of TTP so that the rate of ^{3}H-TdR incorporation would apparently increase. As well, ^{3}H-UdR incorporation would increase due to the inhibition of its conversion to ^{3}H-thymidylate. Thus the ratio of TdR/UdR rates would show the greatest increase in those cells most sensitive to the effect of 5FU. A significant decrease in the inhibition by 5FU of ^{3}H-UdR incorporation occurred after infusion of the drug into

patients for five days. The reason for this is not clear. The effect was present whether or not there was an increase in DNA synthesis in the same cells as shown by the rate of ^{3}H-UdR or ^{3}H-TdR incorporation in the absence of the drug *in vitro*. This suggests that the proliferative state of the marrow was not a factor in the induced resistance to 5FU or in toxic effects observed on peripheral granulocytes. Also the rate of ^{3}H-UdR incorporation varied in the same way as the ^{3}H-TdR incorporation in post-treatment samples, indicating that the induced resistance to 5FU did not result from a conversion from the *de novo* to the "salvage" pathway in those cells.

Granulocytic colony formation was another index of drug toxicity since the most marked inhibition *in vitro* was seen in those cases with most marked depression of the peripheral granulocyte counts. This probably resulted from similar *in vitro* and *in vivo* injury to granulocytic stem cells by the drug.

While the biochemical parameters we measured correlated with the observed toxicity, other parameters also might. For example, Nahas, Savlov and Hall [15] have found differences in the ratio of the activities of phosphoribosyl transferase and thymidine kinase in colon tumors and normal mucosa which related to tumor responsiveness. These and other enzyme activities in marrow cells might also correlate with toxicity of 5FU.

All of our dose-survival curves for marrow cells treated with 5FU are biphasic. This is different from the dose-survival curves obtained by Ogawa *et al.* [11] who studies the effect of 5FU in concentrations between 1×10^{-2}M and 3×10^{-2}M and obtained exponential curves. The difference between our findings and theirs might be due to the wider range of concentrations used in our experiments. Our lowest concentration, 1×10^{-5}M, is 1,000 times lower than theirs. Furthermore, their dose-survival curve was plotted only for concentrations between $1{\cdot}0 \times 10^{-2}$M and $3{\cdot}0 \times 10^{-2}$M while we used a much wider range of drug concentration, $1{\cdot}0 \times 10^{-5}$M to $1{\cdot}0 \times 10^{-3}$M. Because our dose-survival curves were plotted over that range of 5FU which spans the range of 5FU concentrations obtained during clinical use of 5FU [16], our results more correctly reflect the response of human CFU-C to varying concentrations of 5FU. Thus, the dose-survival curve of human CFU-C is biphasic when plotted over a wide concentration of 5FU but is exponential over a narrower range of concentration.

In addition to the biphasic nature of the dose–survival curves, the pattern of the curves varied suggesting a heterogenous lethal action of 5FU. Cells grown in the presence of TdR and/or uridine (UR) showed a change in the shape of their dose–survival curves which become less steep as well [5]. The difference in the patterns of the dose-survival curves that we have observed cannot be explained by a varying content of nucleosides and deoxynucleosides in the medium used, since these had been added in excess of those found, for example, in fetal calf serum [5]. A possible explanation therefore is that the cells from some patients could be more easily rescued by these agents than the cells from others. The dose–survival curves of patients 7 and 8, for example, suggests that these cells were more protected against the lethal effects of 5FU. To support this thesis, similar experiments could be done, using cells treated with 5FU, in medium with and without added nucleosides and deoxynucleosides. In our case, all cell samples were plated in methyl-cellulose enriched with nucleosides and deoxynucleosides, hence the colony forming cells of patients showing toxic effects perhaps were unable to be rescued both *in vivo* and *in vitro* from the lethal effects of 5FU. Conversely, colony forming cells of patients who demonstrated some degree of resistance both *in vivo* and *in vitro* to the effects of 5FU may have been rescued with TdR and/or UR.

Although a possible correlation exists between the sensitivity of granulocyte colony forming ability to 5FU and in clinical marrow toxicity to the drug, this measurement takes too long to be useful during infusion unless the marrow cells were tested and the result obtained before the infusion began. The biochemical parameters described, however, can be obtained more rapidly. If marrow toxicity could be quantitated in these ways and in terms of 5FU concentration in the patients' blood and related to the dose of 5FU to be given to patients, those with less sensitive marrows could be given higher doses of drug, and those with more sensitive marrows, lower doses. In this way more effective therapy with 5FU may be achieved.

The following protocol of evaluation of results is a modified version of protocol first used by the National Cancer Institute (N.C.I.) Breast Cooperative Group and by the European Organization for Research on Treatment of Cancer (E.O.R.T.C.) Breast Cooperative Group. This has now been tested extensively and is proposed to a still wider audience. It is being published simultaneously in several cancer journals.

INTRODUCTION

In 1975, a project was initiated by the Programme on Clinical Oncology of the UICC to formulate a system for the evaluation of response to treatment of advanced cancer. It was considered that a single uniform system, used internationally, would be invaluable for the accurate comparison of published results from different centres. Advanced breast cancer was selected as the first tumour for consideration because a number of different evaluation methods were already in use [1–6], and it was felt that agreement on a common system might readily be achieved. A preliminary document describing such a system was prepared which was then circulated to many workers in the field for comment, after which it was revised accordingly. The final document is now presented below. It is hoped that this system will be widely adopted and that it may eventually be used as a model for the assessment of therapy of other tumours.

1. *Aim*

These guidelines are intended for use in designing clinical trials to assess the objective response of locally advanced or metastatic mammary cancer to treatment; subjective response to treatment is not considered.

2. *Criteria of eligibility*

2.1. Histological evidence of breast cancer available for review.

2.2. Objective evidence of progression of disease, i.e. new lesions appear or existing lesions become larger.

2.3. Bulk of clinical disease must be evaluable by either direct measurement or photography and/or radiography.

3. *Exclusions*

3.1. It is recognised that many factors may affect a patient's ability to tolerate specific therapy. The following should, therefore, be considered in the selection of patients for study:

3.1.1. Debility.

3.1.2. Associated medical conditions.

3.1.3. Previous antitumour therapy (especially chemotherapy and radiotherapy).

3.1.4. Other previous or concurrent treatment.

3.2. The following are factors which may compromise seriously the evaluation of results and lead to the exclusion of patients from a study of systematic therapy:

3.2.1. Previous or current malignancies at other sites, with the exception of cone-biopsied *in situ* carcinoma of the cervix uteri and adequately-treated basal or squamous cell carcinoma of the skin.

3.2.2. Patients in whom one of the following is the sole manifestation of disease: lymphoedema, hilar enlargement, pleural effusion, ascites, metastases in the central nervous system, marrow suppression and osteoblastic skeletal lesions.

3.2.3. Previous systemic antitumour treatment with the agent(s) under study.

3.2.4. In order to avoid confusion with a withdrawal response or a delayed response to treatment it is suggested that patients within 4 weeks of endocrine ablation or of cessation of additive hormone therapy be excluded. In the case of long acting hormones or depot preparations, this period may have to be increased. When previous chemotherapy or radiotherapy has been used, the toxic manifestations of these treatments, which affect subsequent specific therapy, must have resolved. After 4 weeks the patient can be included only if there is evidence of progressive disease.

4. *Base-line studies*

4.1. *History.* A standard history should be obtained in all cases, with special attention to:

4.1.1. Stage of primary disease at the time of initial presentation, expressed in the TNM Classification [7] if possible, and its histology and pathological extent.

4.1.2. Recording of race, and dates of birth, diagnosis of breast cancer and last menstrual period.

4.1.3. The extent and date of treatment of the primary tumour and the time of first recurrence should be noted. The date of first recurrence should be given as the time of documentation of the first sign, not symptom, confirmed subsequently to be a recurrence.

4.1.4. Dates, agents and the recorded result of previous treatment of recurrent breast cancer.

4.1.5. Concurrent diseases.

4.1.6. Other past and present treatment.

4.2. *Performance.* An estimation of performance may be an important part of evaluation. The Karnofsky system [8] would be appropriate or the following five-grade system could be used:

Grade	Performance
0	Fully active, able to carry on all usual activities without restriction and without the aid of analgesia.
1	Restricted in strenuous activity but ambulatory and able to carry out light work or pursue a sedentary occupation. This group also contains patients who are fully active, as in Grade 0, but only with the aid of analgesics.
2	Ambulatory and capable of all self-care but unable to work. Up and about more than 50% of waking hours.
3	Capable of only limited self-care, confined to bed or chair more than 50% of waking hours.
4	Completely disabled, unable to carry out any self-care and confined totally to bed or chair.

4.3. *Physical examination.* Before starting new treatment, a full physical examination including measurement of height and weight should be done on all patients. Special attention should be directed to tissues or organs where toxic manifestations of treatment might be expected to develop.

Superficial and palpable lesions should be measured directly (in centimeters) along two axes—one being the longest and, the other, the longest perpendicular to it. Callipers may improve the accuracy of the measurements.

4.4. *Photographs.* Colour photographs of all visible lesions together with identifications, date and rule (centimeters) should be taken.

4.5. *Radiographs.* The following sites should be radiographed for baseline information with standardised exposures if possible: chest, skull, total spine, pelvis, femora, and an isotopic bone scan should be done.

4.6. *Laboratory studies.* Because therapeutic agents and/or cancer may affect normal function, appropriate investigations should be carried out to evaluate cardiac, pulmonary, metabolic, hepatic, renal, endocrine and marrow status before treatment is started.

4.7. *Additional studies.* When appropriate and feasible the following might be helpful: radio-isotope scans of brain, bone and liver, computerised axial transverse (C.A.T.) scans, mammography, bone marrow biopsy, laparoscopy, thoracoscopy, hormone receptor assays, potential markers of disease, e.g. CEA HCG, dimethyl-guanosine, ultra-sonography, im-

munological evaluation, hydroxyproline excretion.

5. *Measurement of lesions*

Normally this will be by physical examination, photography or radiography.

5.1. *Breast.* Measurements should be made as in 4.3 and superficial lesions should be photographed. Measurements from mammography may be useful. Diffuse infiltration of the breast is difficult to assess. It is recommended that cutaneous marks be made 10 cm apart, centered on the nipple. The distance between these marks is measured after digital compression of the breast and recorded as "compression at 10 cm = x cm".

5.2. *Skin.* Individual lesions should be measured as in 4.3. Diffuse lesions should be recorded by photography.

5.3. *Lymph nodes.* (a) superficial nodes: if possible, measurement as in 4.3, otherwise in one dimension. Xeroradiography may be useful.

(b) mediastinal nodes: chest X-ray, tomograms.

Generally, comparison of mediastinal size during treatment may be possible by comparing radiographs, and the width of the mediastinum could be taken as a unidimensional measurement at a stated level. The site of mediastinal nodes should be confirmed by a lateral chest X-ray.

(c) lymphoedema: measurement of limb circumference at a stated level above and below the olecranon.

5.4. *Bone.* An assessment of skeletal involvement should be made and individual lesions can be evaluated from selected films. Comparison of sequential bone scans may provide additional information. It should be noted that other processes can produce increased uptake of radionucleides in bone scans and that both progression and regression of lesions may be reflected by an increase in uptake.

5.5. *Lung.* (a) nodular: measurement in two dimensions from radiograph whenever possible.

(b) diffuse: this should be evaluated and compared from serial chest X-rays. It is recognised that comparisons may sometimes be difficult.

5.6. *Pleural effusion.* Pleural effusion should be recorded by chest X-rays (PA and lateral). Frequency and volume of thoracenteses should be noted.

5.7. *Liver.* Histological confirmation of hepatic metastases is desirable when this is the only site of recurrence.

Clinical measurement of the liver should be done with the patient in the supine position. The inferior border of the liver should be measured as a vertical distance below the costal margin or xiphisternal notch, at a fixed distance from the mid-line and/or at the mid-line. The same reference point must be used at all examinations in the same patient. The phase of respiration should also be the same. This will normally be either quiet respiration or deep inspiration. It should be remembered that the presence of a right pleural effusion and its subsequent aspiration can affect apparent liver size. Sequential liver scans can be used for comparison.

5.8. *Ascites.* The girth of the abdomen should be measured at a fixed point. Weight should be recorded periodically. Frequency and volume of required abdominal paracenteses and the use of diuretics should be noted. Increased adiposity may make serial measurements invalid. Ultrasonography and CAT scans may provide additional information.

5.9 *Abdominal mass.* Measurement in two dimensions with callipers where possible. If feasible, ultra-sound and computerized axial transverse scans should be done.

5.10 *Nervous system.* Neurological deficit will be recorded in the physical examination but should not be used to quantify response. Sequential CAT scans may be useful.

6. *Recording of lesions*

This should be done by anatomical site. Dimensions should be stated when applicable and the method of evaluation stated (direct measurement, photograph, radiograph, other).

It is recognised that pleural effusion, ascites, hepatomegaly, pulmonary shadows, etc., may be the result of non-malignant processes. When possible, histological proof of involvement should be obtained if these abnormalities are to be used for evaluation of response or stratification.

6.1. *Soft tissue.* Breast—ipsilateral; contralateral.

Skin—intracutaneous; subcutaneous.

Lymphoedema.

Lymphatic location stated; mediastinal and intra-abdominal nodes excluded here (see 6.3).

6.2. *Bone.* Sites recorded (state whether lytic and/or blastic).

6.3. *Visceral.* Lung (nodular or diffuse), pleura (nodules and/or malignant effusion), mediastinal and intra-abdominal nodes, liver, ascites, abdominal or pelvic masses, central nervous system.

7. *Stratification*

Controlled trials are important in clinical research. Although randomization eliminates bias and selection on the part of the investigator, considerable disparity between groups under study can still arise. Even when no disparity arises, the comparison of treatments can be made more precise by taking prognostic variables into account in the statistical analysis. It is recommended that patients should be classified according to certain factors known to influence prognosis or response to therapy. These factors can be used to stratify patients, using a system of allocation which balances numbers allotted to different treatments within each stratum; alternatively, with non-stratified allocation, they can be used as a basis for statistical analysis of the results of the trial. The factors chosen will depend on the treatment under study. The following may be considered.

7.1. *Menopausal status.* There are three physiological categories of menopausal status which may be classified in various ways. The following is suggested:

7.1.1. Pre-menopausal—a menstrual period has occurred within the previous year.

7.1.2. Early post-menopausal—last period: 1–5 yr.

7.1.3. Late post-menopausal—last period $>$ 5 yr ago.

Women who have had a hysterectomy with one or both ovaries left in place may be excluded or considered pre-menopausal if $<$ 50 yr of age and post-menopausal if $>$ 55 yr of age (7.1.3.); those aged 50–55 yr are classified as 7.1.2. Vaginal cytology and/or hormone studies may clarify the true menopausal status. Young women who have had an artificial menopause should be excluded or considered separately.

7.2. *Disease-free interval.* (i.e. time from treatment of primary tumour by surgery or radiotherapy to time of first recurrence, see 4.1.2.).

7.2.1. No free interval.
7.2.2. $<$ 2 yr.
7.2.3. $\geqslant$ 2 yr.

All patients presenting with Stage IV(M_1) disease have no free interval. Patients receiving radiotherapy as the sole treatment of the primary tumour should be stratified separately.

7.3. *Other groups.* When appropriate, other factors can be chosen for stratification, e.g. site of disease, age, performance, histological grade, previous therapy, residual toxicity, hormone receptors, immune status etc.

8. *Follow-up studies*

8.1. The standard follow-up time for patients under study will normally be 4 weeks, but it is recognised that, for specific protocols (e.g., chemotherapy), this may have to be modified. However, it is important that each group in a controlled study be evaluated regularly at similar intervals.

8.2. Base-line studies should be repeated regularly at intervals of not more than 6 months, unless symptoms develop which demand earlier examination.

8.3. Photographs should be repeated every 3 months or sooner if changes occur.

9. *Definition of response*

9.1. *Measurable lesions.* Ideally, all lesions should be measured at each assessment. When multiple lesions are present, this may not be possible and, under such circumstances, a representative number of eight or more lesions may be selected for measurement.

9.1.1. In the case of *bidimensional lesions,* regression will be defined as when either: (i) all lesions disappear, (ii) the sum of the products of the diameters of each individual lesion, or those selected for study, decreases by 50% or more, with no lesion increasing in size.

In each case, no new lesions should appear.

Progression is defined as when either: (i) new lesions appear, (ii) there is a 25% or more increase in the sum of the products of the diameters of each lesion measured, except that if an increase of less than 25% makes additional treatment necessary, this is also regarded as progression.

9.1.2. *For unidimensional lesions,* in the case of regression the same rules apply as in 9.1.1., except that regression is taken as a decrease of 50% or more in one measurement. In situations such as infiltration of the breast, liver involvement and mediastinal enlargement, objective regression is a 50% or greater decrease in that measurement which is regarded as being in excess of that usual for the site under consideration.

9.2. *Evaluable, but non-measurable lesions.* (e.g. osseous metastases, pulmonary infiltration, pleural effusion, skin infiltration). Serial evidence of appreciable change documented by radiography or photography must be obtained and be available for subsequent review. The assessment must always be objective.

Pathological fractures or collapse of bones are not necessarily evidence of progressive disease.

Neither the development nor healing of skin ulcers should be taken as sole evidence of change.

10. *Categories of response*

10.1 *Objective regression.*

10.1.1. *Complete response*—disappearance of *all* known disease. In the case of lytic bone metastases these must be shown radiologically to have calcified.

10.1.2. *Partial response*—$\geqslant$ 50% decrease in measurable lesions as defined in 9.1.1. and 9.1.2., and objective improvement in evaluable, but non-measurable lesions. No new lesions. It is not necessary for every lesion to have regressed to qualify for partial response, but no lesion should have progressed.

10.2. *No change.* Lesions unchanged (i.e. $<$ 50% decrease or $<$ 25% increase in the size of measurable lesions).

Note: If non-measurable, but evaluable lesions represent the bulk of disease and these clearly do not respond, even though measurable lesions have improved, then this is considered as "no change" not "objective regression".

10.3. *Progressive disease.*

10.3.1. *Mixed*—some lesions regress while others progress or new lesions appear.

10.3.2. *Failure*—progression of some or all lesions and/or appearance of new lesions. No lesions regress.

11. *Duration of response*

In a patient who has an objective regression, this is to be dated from the start of therapy until either new lesions appear or any one existing lesion increases by 25% or more above its smallest size recorded.

It is essential to categorize a patient as having a regression at a stated time. It is also essential that *all* baseline studies should have been repeated at this time.

12. *Survival*

Survival dated from time of commencement of treatment to death should be recorded.

13. *Extramural review*

It is recommended that the records of all patients under study be assessed by extramural reviewers.

Announcements

ONE-WEEK CANCER CHEMOTHERAPY COURSE SLATED FOR DECEMBER

Memorial Sloan–Kettering Cancer Center will present a one week course in Cancer Chemotherapy, 3–10 December, 1976.

This course is designed principally for physicians interested in medical oncology and clinical investigations in cancer chemotherapy. It will include lectures and panels on screening methods, pharmacological techniques and methods for clinical evaluation of potential chemotherapeutic agents. The chemistry and pharmacology of agents used in the treatment of cancer will be reviewed. There will be a strong emphasis on disease oriented "workshops" which will consider optimal methods of patient management relating medical oncology to other relevant disciplines.

Applications should be submitted as soon as possible as enrollment is limited. The fee of $150 is payable at the time of application. Requests for registration forms and program details should be addressed to CHARLES W. YOUNG, M.D., Memorial Sloan–Kettering Cancer Center, 1275 York Avenue, New York, N.Y. 10021, U.S.A.

SYMPOSIUM—"PLATELETS: A MULTIDISCIPLINARY APPROACH"

An International Symposium on "Platelets: a multidisciplinary approach" will be held in Florence (Italy), on 28–30 September, 1977.

The scope of this Symposium is to focus attention on platelets both as a model in pharmacology, biochemistry, immunology, inflammation and related fields and as a cell involved in physiopathological phenomena not directly connected to haemostasis and thrombosis mechanisms. Internationally acknowledged experts have been invited to present and discuss data, hypotheses, problems.

The following Sessions are scheduled:

1. Platelet morphology, biochemistry, pharmacology: introductory lectures.
2. Platelet as a model of smooth muscle cell.
3. Platelets and endothelium.
4. Platelet as an inflammatory cell.
5. Platelet as a model of monoaminergic nerve endings.
6. Platelets and immunological reactions.
7. Platelets, cancer growth and metastasis formation.

Barr Body Frequency in the Human Breast Cancer Tissue.

A Prospective Study on its Prognostic Value and its Correlation with Specific Oestradiol Receptors

SESHADRI RAJESWARI, S. N. GHOSH, P. N. SHAH and V. J. BORAH

Division of Endocrinology, Cancer Research Institute, Parel, Bombay 400 012, *India*

Abstract—*This communication describes the study on the Barr body frequency from* 93 *tumour specimens. From the results, it appears that this biological determinant provides an accurate and reliable prediction about the clinical course of the disease in a given patient. Analysis of Barr body frequency* vis-à-vis *oestradiol receptors in* 50 *unselected breast cancer tissues did not reveal any significant correlation.*

INTRODUCTION

RECENT clinical data have pinpointed that breast cancer is a systemic disease and it is the early recurrence followed by metastases that decides the quality of life and duration of survival of the patient. Friedell *et al.* [1] analysed various clinical, pathological, and urinary steroid variables in patients with breast cancer treated by radical mastectomy and found that the extent of regional lymph node involvement appeared to be the most important single factor of prognostic significance for early recurrence after primary surgery. Ideally speaking, one would prefer some intrinsic characteristics of the tumour cells in a given case for prognostic value, but it is surprising to note that very little work has been published so far on this subject. A preliminary communication from this laboratory [2] on a retrospective study has highlighted the prognostic value of Barr body frequency in tumour cells in a given patient—the parameter used being 2 yr disease free interval of distant metastases.

Further, a group of investigators [3–7] have recently suggested that tumours showing high Barr body frequency are oestrogen-dependent. So a study wherein correlation between the Barr body percentage and oestrogen receptors is determined appears to be necessary for obvious reasons. The purpose of this communication therefore is two-fold; (a) to confirm preliminary observations reported earlier [2] by a prospective study and (b) to assess the correlation, if any, between the frequency of Barr body and the presence of significant amounts of specific oestradiol receptors in the tumour tissue of an individual patient.

Accepted 27 August 1976.

MATERIAL AND METHODS

In all, 93 patients were studied. When these cases were classified according to the UICC, AJC, TNM classification of Geneva, 1972, 36% belonged to Stage 1, 50% to Stage II, and the remaining 14% to Stage III. No treatment was given to any patient before operation. After radical mastectomy, only those patients exhibiting involvement of axillary nodes underwent Cobalt therapy. The histological diagnosis in 95% of these tumours was infiltrating duct carcinoma—Grade III. Although the patients' age ranged from 21 to 77 yr, the majority of them were between 35 and 55 yr old.

In order to assess the recurrence of the disease, patients were regularly followed-up once every 3 months after radical mastectomy. Following careful clinical scrutiny, in suspicious cases, lungs and bones were X-rayed. Liver scans were carried out whenever it was deemed necessary. However, bone scintigraphies were not carried out before or after the primary operative treatment due to lack of this facility at our hospital.

Smear preparations were made from 93 fresh tumours obtained for frozen section at the time of mastectomy. Smears were fixed in ether:alcohol (1:1) for 24 hr and stained with 1% cresyl echt violet. In each tumour, at least 300 nuclei were counted by two independent observers under oil immersion, and the percentage of Barr body was scored. There was no significant discrepancy in the percentage counts of Barr bodies in individual smears as counted by two independent observers. As reported earlier [2] tissues having less than 20% Barr body constituted the "negative group" and those showing above 20% were classed under the "positive group". The age distribution of the patients in the "positive" and "negative" groups was similar.

In addition, 10 unselected tumour explants were grown in organ culture (using McCoy 5A medium containing 20% foetal calf serum) for a period of 25 days and the Barr body frequency was studied before and after culture. The viability of the tumour cells was checked after termination of culture by Trypan blue exclusion test.

For the specific oestradiol receptors, 50 unselected tumours were analysed. Specific binding of ^{3}H 17B oestradiol(6,7-^{3}H oestradiol Sp. Act. 40 Ci/m mole from Radiochemical Centre, Amersham, England) in the high speed cytosols were quantified using the Agar-gel electrophoresis method of Wagner *et al.* [8]. As suggested by McGuire [9] tissues with binding of oestradiol more than 3 femtomoles/mg cytosol protein were categorised in the receptor "positive" group.

RESULTS

The pattern of Barr body in a representative group of both, "negative" and "positive" tumours, did not alter significantly after 25 days of *in vitro* culture (Table 1).

When lymph node status and duration of disease-free interval up to 2 yr were compared (Table 2), there was only a border-line significance ($P < 0{\cdot}05$). There was no significant correlation between Barr body frequency in the tumour cells and lymph node status in 93 patients (Table 3). On the other hand, as shown in Table 4, the correlation between Barr body frequency and duration of disease free interval by the end of 2 yr was highly significant ($P < 0{\cdot}001$). Table 5 demonstrates the absence of correlation between the Barr body frequency and the presence or absence of specific receptors for oestradiol in 50 unselected tumour tissues ($P > 0{\cdot}5$).

> 2 yr (41)	20	21
Total	67	26

$\chi^2 = 19{\cdot}538$; $P < 0{\cdot}001$.

DISCUSSION

In our preliminary report [2] it was shown that the percentage of Barr body in different parts of a cancerous tissue was consistent as assayed by the smear method. However, report of a case of colon carcinoma [10] wherein the "negative" group of Barr body frequency was changed into a "positive" group after *in vitro* culture, and the fact that Gropp *et al.* [11] are quoted to have reported on "regaining of the sex chromatin body after culture", prompted the present investigators to test whether such a phenomenon occurs in the human breast cancer tissue. As aforesaid, even after 25 days of *in vitro* culture, there was

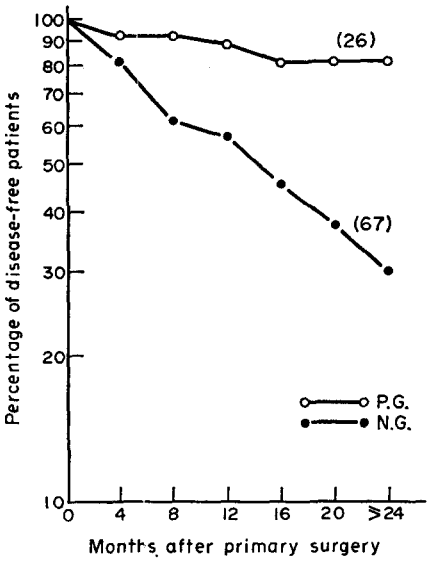

Fig. 1. *Shows the percentage of patients (irrespective of their lymph node status) with recurrence in time up to* 24 *months in the Positive Group (P.G.) and Negative Group (N.G.)*

no significant change in the Barr body frequency of the tumour tissue as compared to that seen in the fresh smears studied from 10 breast cancerous tissues belonging to both "negative" and "positive" Groups (Table 1). In other words, the fixation of the Barr body in tumours of the breast is an intrinsic, unalterable characteristic of the tumour.

After having established the consistency of the Barr body pattern in the malignant breast tissue, its significance in prognostication was considered. Our earlier publication [2], which mostly dealt with observations on a retrospective study, had established a significant positive correlation between the Barr body percentage and a 2 yr disease-free interval of distant metastases and 5 yr survival. Figure 1 graphically represents the results on this prospective study on 93 patients wherein a distinct dichotomy can be observed between patients in the "negative" and "positive" groups when followed up for 2 yr of disease-free interval. In other words, distant metastases occur in 66% of the patients in the "negative" group within 2 yr as compared to only 20% in the "positive" group and this difference is statistically significant ($P < 0{\cdot}001$). This observation was further analysed on the basis of the lymph node status in association with "negative" and "positive" tumours (Fig. 2). There was no significant difference in the percentage of patients having recurrence

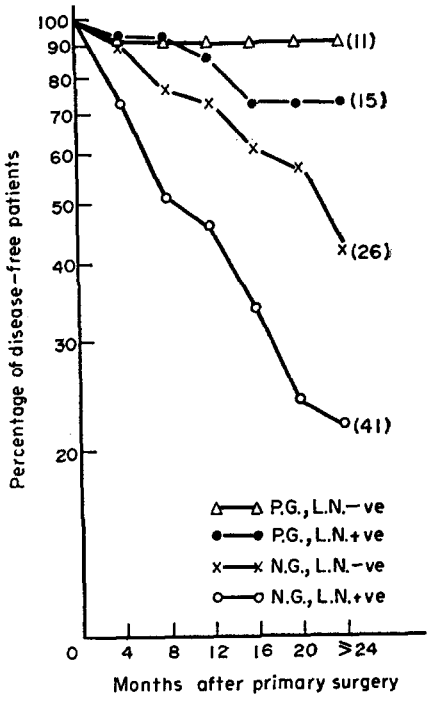

Fig. 2. *Reveals the percentage of patients with and without lymph node involvement (L.N.+and L.N.−ve) when considered along with recurrence in time up to* 24 *months in the Positive Group (P.G.) and Negative Group (N.G.)*

within 2 yr in the same group with or without lymph node involvement. This provides further evidence to indicate that Barr body frequency appears to be a more accurate and reliable parameter and convinces its superiority as a single prognostic biological determinant.

Although there is hardly any published report on the Barr body frequency in tumour cells with presence or absence of oestradiol receptors, there are a few reports [3–7] in the literature on the correlation between Barr body frequency and response to endocrine treatments in breast cancer patients. According to these investigators, patients with tumours having high Barr body frequency respond favourably to hormonal manipulations. With the current

Table 5. *Correlation between Barr body frequency and specific receptors for* 17*B oestradiol in* 50 *tumour tissues*

Receptors for 17B-oestradiol	Groups based on Barr body frequency	
	Negative	Positive
Negative (32)	19	13
*Positive (18)	10	8
Total	29	21

*Positive = 3 fmole/mg Cytosol Protein.

χ^2 = 0·0689; Not significant.

consensus [9] regarding poor response to such manipulations in patients having tumours showing absence or negligible oestrogen receptors, it becomes imperative to see if there exists any correlation between these two intrinsic characteristics of the tumour tissue in a given patient. As is evident from Table 5, at least in the 50 unselected tumours studied at this laboratory, no correlation was found to exist. In other words, it seems that Barr body frequency and presence of significant amounts of oestradiol receptors in human breast cancerous tissue are unrelated characteristics.

Further, for total management in a given patient it still remains to be established whether information on Barr body frequency and the lymph node involvement could be exploited to delineate cases for prophylactic combination chemotherapy with a hope to give a longer and better qualitative life.

Acknowledgements—The authors are grateful to Dr. D. J. Jussawalla, Director, Tata Memorial Centre for his continued interest and encouragement during this period of study. Thanks are due to the staff of the Departments of Surgery, Pathology and Records of Tata Memorial Hospital for their cooperation. The authors are particularly grateful to Mr. D. N. Rao of Records Section for advice and help in carrying out statistical evaluation of the data.

The Effects of Dietary Deficiencies of Magnesium and Potassium on the Growth and Chemistry of Transplanted Tumours and Host Tissues in the Rat

G. A. YOUNG and F. M. PARSONS

Renal Research Unit, General Infirmary, Leeds, Great Britain

Abstract—1. *Weanling rats on control diet or a diet deficient in magnesium and/or potassium for* 1–3 *weeks were transplanted with Yoshida or Walker tumours. Restricted intakes were given to prevent nutritional differences between the groups. Cation depletion was assessed from plasma and muscle concentrations.*

2. *Organ weights and tissue biochemistry showed that metabolic differences between control and cation deficient rats were due predominantly to cation deficiency and the tumour growth rather than other nutritional deficiencies.*

3. *Reduction in tumour size occurred in Mg deficiency (up to* 40%), *K deficiency* (30–60%) *and in combined deficiency* (45–85%). *Tumour size showed the best correlation with the combined concentration of plasma Mg and K or muscle-K.*

4. *Significant reduction in tumour K was observed only in marked combined deficiency.*

5. *Correlation between Mg and K was found in tumour but not in muscle.*

6. *Dietary depletion of both Mg and K cause the removal of K from tissues and may affect the replication and survival of tumour cells by inhibiting metabolic activity and causing the loss of intracellular K.*

INTRODUCTION

PREVIOUS investigations of patients have shown that combined dietary deficiency of magnesium (Mg) and potassium (K), particularly if enhanced by intermittent haemodialysis against a dialysis fluid low in these elements, is associated with tumour regression [1]. Studies with rodents have also suggested that tumour growth is adversely affected by dietary deficiencies of these elements. Mg deficiency alone was thought to cause a 95% growth reduction of Flexner Jobling carcinoma [2] and of Walker carcinosarcoma 256 [3]. However, growth reduction of Landschutz ascites tumour in mice occurred only when Mg and K or K alone were deficient in the diet [4]. Unfortunately, the relative weights of rodents, daily dietary intake or plasma concentrations of Mg and K were not recorded in any of these earlier experiments. Growth retardation of an adenocarcinoma in mice receiving an *ad lib* K free diet has been reported [5], but there were marked weight differences between control and deficient animals. There is considerable evidence (reviewed by White [6]) that nutritional and weight differences between control and underfed rodents may cause growth retardation of many tumours. Consequently, observed reduction of tumour growth in these earlier experiments might have been caused partly by the poor nutrition of experimental animals compared with controls. These factors have been incorporated into this investigation of the effects of Mg and K deficiency on the growth and chemistry of two transplantable tumours in rats.

Accepted 26 August 1976.

MATERIAL AND METHODS

Male, inbred, Wistar rats, 3–4 weeks from Chester Beatty Research Institute, London, were maintained on semi-synthetic diets based on those described by Heaton and Anderson [7]. The control rats received the diet containing adequate Mg (650 ppm) and K (4500 ppm) whilst all other rats received similar diet but deficient in Mg (15 ppm) or K (50 ppm) or

both. In preliminary experiments it was found undesirable to give an unrestricted amount of diet because control rats gained far more weight than deficient rats and also those receiving the Mg deficient diet were so rapidly depleted that some died within 10 days. In addition, control rats on unrestricted intakes (exceeding 15 g/day) for 3–4 weeks developed larger tumours than those underfed with only 8 g as described previously [6]. Consequently, restricted amounts of the diet that were not in excess of the appetite of any one group of rats were given, usually between 8 and 10·5 g/day. In some experiments the same daily amount of diet was given to all groups whereas in the other experiments different quantities were given to each group and this quantity was adjusted when necessary to obtain comparable mean body weights between the groups prior to transplantation.

The rats were maintained throughout on their respective diet and were given Yoshida ascites tumour (about 1×10^6 cells) subcutaneously in the inguinal region or the Walker carcinosarcoma 256 into the right flank [8] 7–27 days after commencing the semi-synthetic diet.

The animals were decapitated 8–10 days later and shed blood was collected in heparinised tubes. The tumours were dissected out and weighed. Samples of muscle and viable tumour tissue were removed for chemical analysis. Tissues were dried for 24 hr at 105°C and extracted for 24 hr with 0·15 N nitric acid for electrolyte analysis [9]. In several experiments spleen, kidneys, liver, lungs and heart were removed and weighed. Mg was determined by atomic absorption spectroscopy; Na and K by flame photometry. Urea nitrogen, calcium and inorganic phosphorus were measured on the Technicon autoanalyser, albumin by radial immunodiffusion, haemoglobin by the cyanomethaemoglobin method and chloride using a Corning-Eel chloride meter. Extracellular space of the muscle and tumour tissue was not determined. The total concentration of each element was expressed in mmol/kg of dry tissue or m-mol/l of tissue water and, therefore, does not indicate the distribution or nature of the element within the cell.

RESULTS

The effects of Mg and K deficient diets on tumour growth

Table 1 shows the percentage reduction in tumour size in rats maintained on diets deficient in Mg or K or both as compared with those receiving control diet after a total period of 2–5 weeks. The same daily intake of diet was given to all four groups in two experiments (3 and 4) both before and after transplantation with Walker tumour. In the other five experiments, different dietary intakes were given (8–10 g) to achieve comparable mean body weights between the groups prior to transplantation with Yoshida tumour (experiments 1 and 2) or Walker tumour (experiments 5–7). Comparability of weight between groups was not achieved in all experiments, but, the coefficient of variation did not exceed 13% and was less than 5·5% in experiments 4–7. However, following implantation the gain in weight of the controls was usually greater than for the rats on the deficient diets causing a slightly greater difference in the mean weights

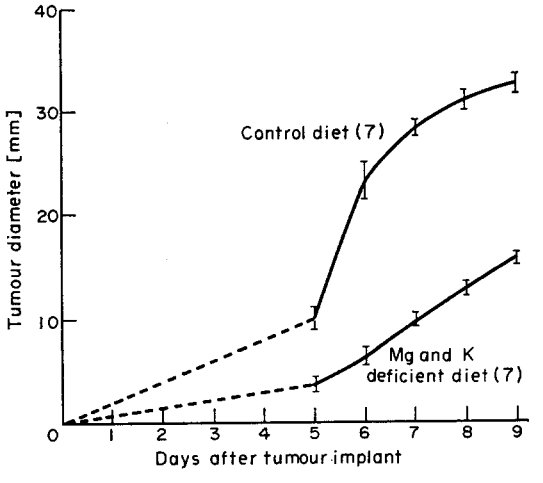

Fig. 1. Growth of Walker tumour in male rats after 19 days pretreatment. Tumour growth was markedly reduced in Mg and K deficient group. Mean values ± S.E. are shown.

at death. Table 2 compares organ weights in rats receiving either control or Mg and K deficient diet by pair feeding, both with and without tumour implants. There were no differences between the mean weight of the liver in any of the groups. However, the lung, spleen and heart were enlarged in control rats with tumours but not in those without tumours or in the Mg and K deficient group where tumour growth was retarded. The kidneys of rats receiving the Mg and K deficient diets were grossly enlarged.

Tumour size was significantly less for rats receiving the cation deficient diets than for controls. The smallest tumours occurred when both Mg and K were deficient in the diet, particularly after longer periods of depletion, (3–5 weeks) as in experiments 6 and 7, when a reduction of 85% was observed (Table 1).

In both these experiments the mean body weights for the groups of control and deficient rats were the same at the time of transplantation and, subsequently, these rats were given the same weight of diet. The reduction of growth of Walker tumour in rats receiving Mg and K deficient diet compared with those on control diet is shown in Fig. 1 and the reduction in tumour to body weight ratio in Table 2. This effect on tumour growth occurred in all the pair feeding and weight matching experiments and was unlikely to be caused by the small nutritional differences between the groups.

Cation composition of tissues

(a) *Plasma.* Table 3 shows the mean plasma concentrations of Mg, K and Na in four groups of 10–12 rats (Table 1, experiment 1) maintained on control diet or a diet deficient in Mg, or K or both. In this experiment, 9 g/day of diet was given to each rat but after 10 days it was necessary to alter the intake of two groups to maintain comparable mean body weights for each group. The diet for the control rats was reduced to 7 g and that for the magnesium deficient rats to 8 g. Yoshida tumour was transplanted on day 20 and the rats killed on day 29.

In the other experiments similar plasma concentrations were obtained, depending on the initial weights of the rats, the period of depletion and the quantity of diet given. The lowest concentrations of Mg or K in plasma were usually in rats receiving the diet deficient in that single element, although there was a moderate reduction of each cation when both were deficient. In K deficiency, plasma-Mg was sometimes increased, Plasma-Na was similar in control and depleted rats. The biochemical data in Table 4 compares Mg and K deficient rats with controls and shows that plasma chloride was lower; urea nitrogen was increased indicating mild azotaemia; haemoglobin was not decreased probably because tumour growth was retarded; whilst calcium, inorganic phosphorous and albumin were not significantly affected.

(b) *Muscle.* Table 5 shows the mean muscle concentrations of Mg, K and Na in experiment 1 (Table 1) although similar results were obtained in the other experiments. In Mg

deficiency alone the concentrations of Mg and K in muscle were each up to 10% less than for controls. K deficiency alone usually caused more than 30% decrease in muscle-K, but when combined with Mg deficiency the decrease was greater than 40% and in several experiments there was an increase in muscle-Mg. A decrease in muscle-Mg and/or K was always coupled by a gain in Na. The water content of muscle was about 75% and was not changed significantly by cation depletion.

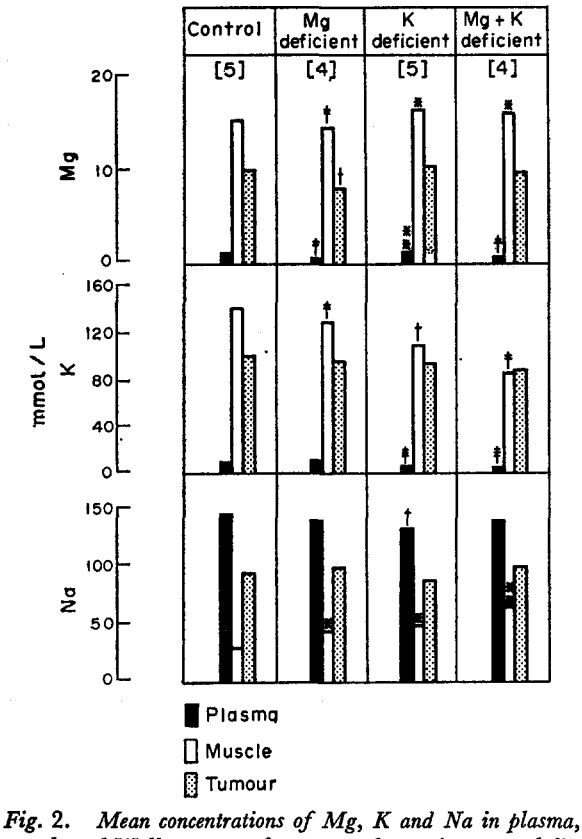

*Fig. 2. Mean concentrations of Mg, K and Na in plasma, muscle and Walker tumour for groups of rats given control diet or a diet deficient in Mg and/or K (experiment 4). Single, double or triple † or * $P < 0{\cdot}05$, 0·01 or 0·001.*

(c) *Tumour.* Figure 2 shows the mean concentrations of Mg, K and Na in tumour tissue together with the values for plasma and muscle obtained in experiment 4 (Table 1). The concentration of Mg in tumour, as in muscle and plasma, for single Mg deficiency and sometimes when combined with K deficiency, was significantly less than for values observed in rats on control diets. In the majority of experiments tumour-K, unlike the concentration in muscle and plasma, was unaffected by

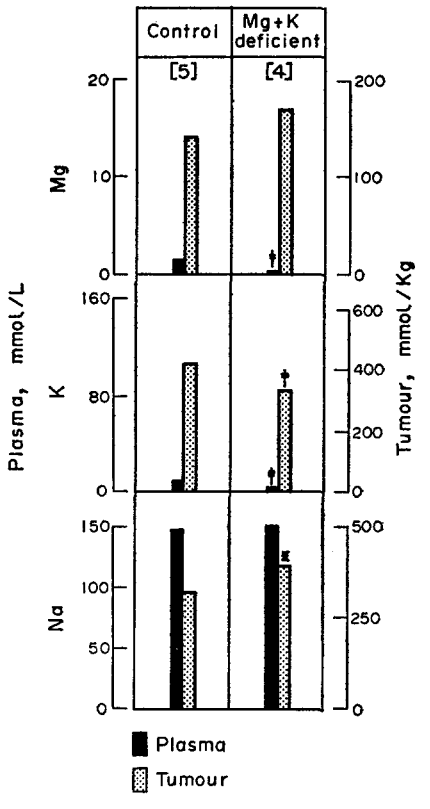

Fig. 3. Mean concentrations of Mg, K and Na in plasma and Walker tumour for groups of rats given control diet or a diet deficient in Mg and K for a longer period (experiment 6).

either single or combined deficiency. However, in experiments 6 and 7, where the sum of the plasma concentrations of Mg and K was low, with a consequent 85% reduction in tumour size, there was a significant reduction in the potassium concentration in the tumour of about 20% as compared with the 40% usually found in muscle, but also coupled by gain in Na. (Fig. 3). The water content of tumour tissue was about 80% and was not changed significantly by cation depletion.

Correlation between tumour size and Mg and/or K in plasma or muscle

There was a significant positive correlation in all experiments between tumour size and the sum of the concentrations of Mg and K in plasma (Table 1). The combined data for the experiments with the Walker tumour are shown in the correlations between tumour size and the sum of the concentrations of Mg and K in plasma or muscle (Fig. 4). These correlations include the group of rats on different diets and are not strictly homogeneous other than that they represent varying degrees of Mg and K deficiency. However, using the collective data for all the rats with a particular deficiency and transplanted with the Walker tumour there was also a correlation between tumour size and the plasma concentration of the specific cation for Mg deficient rats: tumour size vs plasma Mg; $P < 0{\cdot}001$ and Mg and K deficient rats: tumour size vs plasma Mg + K; $P < 0{\cdot}05$. There was no correlation in the K deficient rats between tumour size and plasma-K because the tumours of several rats (experiments 3 and 4, Table 1) were large despite the low plasma concentrations but the muscle-K concentrations were only 10% less than the controls indicating that the period of depletion was inadequate. However, there was a significant correlation in the K deficient rats between tumour size and muscle-K ($P < 0{\cdot}05$). Figure 5 shows the correlation for all the groups in experiments 3–5 between tumour size and muscle-K ($P < 0{\cdot}001$). Similar correlations were obtained when cations were expressed in mmol or mEq/l of tissue water or /kg of dry tissue. These results suggest that the ultimate size of a transplanted tumour in

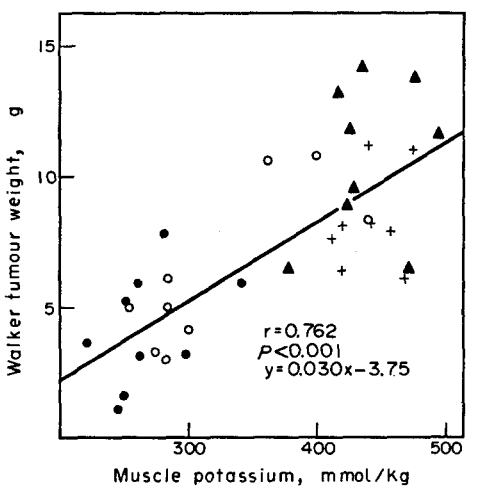

Fig. 5. Correlation between tumour size and the concentration of K in muscle of rats transplanted with Walker tumour. Diet: control ▲; Mg deficient +; K deficient ○; Mg+K deficient ●.

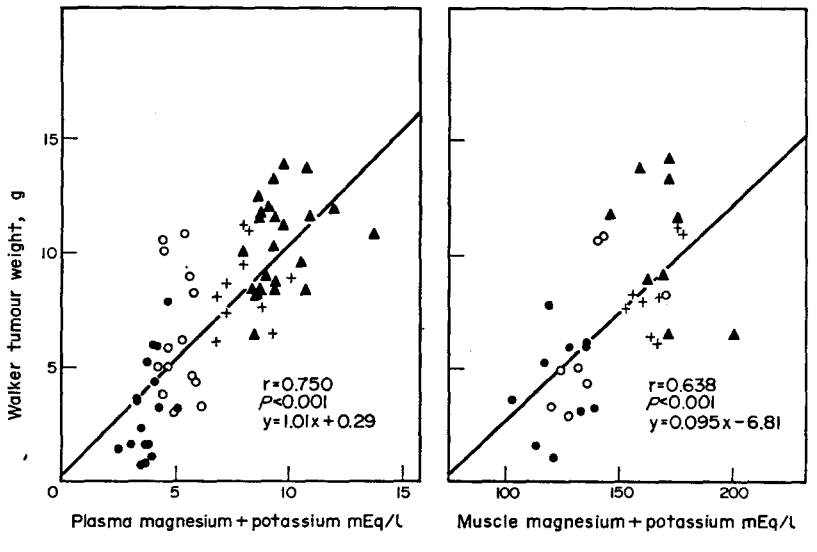

Fig. 4. Correlations between tumour size and the concentrations of Mg+K in plasma or muscle of rats transplanted with Walker tumour. Diet: control ▲; Mg deficient +; K deficient ○; Mg+K deficient ●.

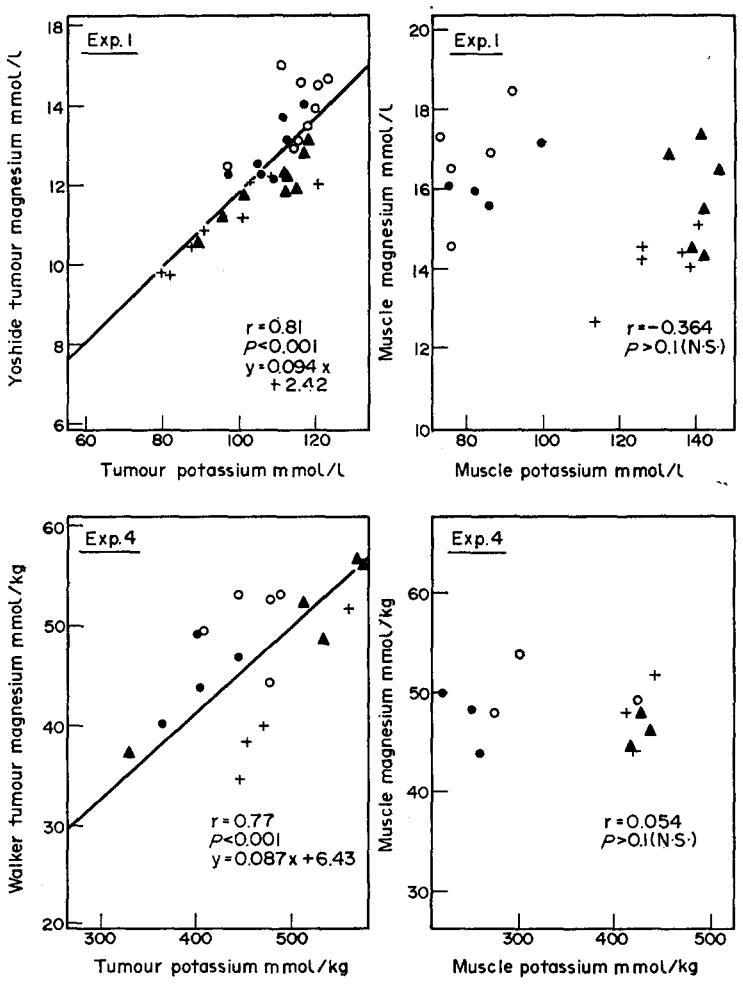

Fig. 6. Correlation between the concentration of Mg and K in both Yoshida and Walker tumour tissue but not in muscle. Diet: control ▲; Mg deficient + ; K deficient ○; Mg+K deficient ●.

the rat is partly determined by the availability of Mg and K. Maximum retardation of growth is favoured by a low concentration of Mg and K but maintained long enough to obtain maximum depletion of K in the tissues.

Differences between cation compositions of muscle and tumour tissues

In all experiments cation deficient diets caused the loss of up to 40% of muscle-K with coupled gain in Na (Mg and K deficient > K deficient > Mg deficient). Muscle-Mg was decreased by about 10% in Mg deficiency, but was frequently unaffected or even increased by the other cation deficiencies. These disproportionate losses and gains caused wide variation in the content and proportions of Mg and K in muscle. Consequently, there was no correlation between Mg and K concentrations in muscle (Fig. 6).

However, the cation deficiencies in the short term experiments (1–5) were insufficient to cause any significant loss of K from tumour tissue (never in excess of 10%). The proportions of Mg and K in tumour remained unaffected by cation deficiency and there was correlation between the concentrations of Mg and K ($P < 0{\cdot}001$) in both Yoshida and Walker tumour (Fig. 6). Similar correlations were obtained when the cations were expressed in either m-mole/l of tissue water or in mmole/kg of dry tissue and, therefore, were not caused by changes in water content.

In the combined Mg and K deficiency of longer duration (experiments 6 and 7) there was a significant loss of K from tumours (20%) frequently with gain in Na or Mg and in consequence there was no correlation between tumour Mg and K concentrations.

DISCUSSION

Mg and K deficiency both cause impairment of growth and increasing mortality between 4 and 5 weeks. Consequently, pair feeding and weight matching were necessary to minimise

nutritional differences between the different groups of rats, during the limited period of investigation. Many of the metabolic differences between the groups were characteristic of Mg and K deficiency. Modest azotaemia occurs in Mg deficiency [10]; hypochloraemia and enlargement of kidneys due to increased enzyme protein synthesis are associated with K deficiency [11]. The severe anaemia and enlargement of the spleen in the control rats with Walker tumour did not occur in those without tumours or where tumour was retarded by combined deficiency. Splenomegaly is probably an antigenic effect related to tumour size [12]. Pair feeding did not eliminate weight differences between control and combined Mg and K deficient rats particularly after tumour implantation indicating some impairment of normal tissue growth but there was no significant difference between liver weights or in plasma albumin suggesting that nutritional differences were small and unlikely to account for the reduction in tumour or tumour to body weight ratio.

Our results show that both single and combined deficiencies of Mg and K cause significant reduction in the sizes of Yoshida and Walker tumours in rats. If nutritional comparability is not maintained by pair feeding or weight matching the control and experimental animals with one another, different results may be obtained. In Mg deficiency, tumours are up to 40% smaller than matched controls but if compared with *ad lib.* fed animals the apparent growth reduction is greater and similar to that found by Sigiura [2], and Mills [3]. Potassium deficiency retards the growth of Yoshida and Walker tumours by 30–60% which is slightly less than that found in mice with an adenocarcinoma [5] and also Landschutz mouse ascites tumour [4]. However, the solid tumours, unlike the ascites tumour, are restricted most by combined deficiency (45–85%). Ryan *et al.* [4] did not give any information concerning the dietary intake or the nutritional state of their mice. Their K deficient group may have had smaller tumours than the combined deficient animals because they were more undernourished.

The retardation of tumour growth caused by Mg and/or K deficiency may be predicted from the correlation between tumour size and plasma concentrations, if the depletion is of sufficient duration (Fig. 4). Mg deficiency alone may affect growth due to the low Mg concentration in plasma, muscle and tumour, however, it also causes loss of K from muscle. Consequently, in all the cation deficiencies tumour growth is retarded by the decrease in the plasma Mg and K causing loss of K from muscle with coupled gain in Na (Mg + K deficiency > K deficiency > Mg deficiency) (Fig. 5). Combined deficiency is unlikely to be merely an additive depletion of the two elements as the Mg concentrations of tumour, muscle and plasma were sometimes increased. The disproportionate losses of K and gain in Mg of muscle caused wide variation in the content and proportions of Mg and K, consequently, there is no correlation between muscle-Mg and K (Fig. 6).

In contrast, tumour tissue accumulates K even when muscle-K is less than 60% of normal, as was also found in Sarcoma 180 in K deficient mice [13]. This accumulation of K correlates with the Mg content of tumour (Fig. 6) and is compatible with a high proportion of bound or fixed K in tumour tissue [14]. However, in combined Mg and K deficiency of longer duration there was a significant loss of K from tumours (20%), frequently with gain in Na or Mg and in consequence there was no correlation between tumour Mg and K concentrations. These observations suggest that with increasing Mg and K deficiency there is a gradual transition in tumour tissue from K accumulation, to K loss, with an associated retardation of growth.

Dietary deficiency of Mg and K increases the concentration gradient between extracellular and intracellular fluid in most mammalian tissues. An intracellular depletion of either of these elements is likely to be of greatest consequence in a rapidly metabolising cell and may retard energy producing biosynthetic pathways directly or indirectly by restricting the cell membrane monovalent pump. Cell membrane transport requires the activity of membrane ATPases which are either Mg dependent or Na–K dependent enzymes. However, *in vitro* experiments with Ehrlich ascites tumour cells [15] suggest that it is unlikely that the reduced ATP generation that occurs in K depleted cells is primarily due to inoperability of the Na^+-K^+ transport system. Such cells, with low metabolic activity, have a decreased rate of glycolysis [16, 17] and a low rate of respiration [15, 18], both processes being stimulated by an increase in K. Similar observations have been made with Morris's hepatoma cells [14]. K deficiency may exert its effect on mitochondrial oxidation by reducing the availability of substrate e.g. glutamate [15].

Mg and K depletion causes growth reduction of fast growing tumour cells in the rat. We have not yet attempted to retard growth of an

established slow growing tumour or to show necrosis and tumour regression as was observed in patients [1]. However, it is known that interference with the supply of ATP or with transport systems, as probably occurs in Mg and K depletion, does relate to or result in rapid progression through stages leading to cell death and necrosis [19]. These authors have shown by *in vitro* studies that cell death is related to a fall in cell K, or Mg or ATP. Following the loss of cell K or Mg there is usually an associated uptake of Na^+ (Fig. 3) and probably H^+ and Ca^{2+} which may also have a damaging effect on the cell. Additional anti-tumour effects due to metabolic abnormalities associated with Mg and K deficiency cannot yet be excluded.

In these experiments with rats, three observations were common to those found in patients: (i) Maximum effect on tumour was noted in combined depletion (1); (ii) Correlation between tumour Mg and K and (iii) Difficulty of removing tumour K (unpublished observations). It is suggested that dietary depletion of both Mg and K may affect replication and survival of tumour cells by inhibiting metabolic activity and causing the loss of intracellular K.

Abstract—*Varying doses of BCG, levamisole or glucan alone, or in combination with different numbers of irradiated tumour cells were given at multiple sites on a single occasion before or after excision of the B16 melanoma growing in the hind limbs of syngeneic C57Bl/6J mice. Facilitation or suppression of spontaneous metastatic spread to the lung was observed with all of the agents studied and depended on the dose of the agent and the time point at which it was administered.*

The result of combining irradiated cells with an immunomodulator could not be predicted from the effects observed when similar doses of these agents were used alone.

INTRODUCTION

"IMMUNOTHERAPY", the practice of attempting to augment the anti-tumour immune response with agents which largely stimulate the reticuloendothelial system, is being increasingly employed in human cancer. Reports on animals and/or man have indicated that treatment with tumour cells [1–3] or treatment with a number of immunomodulators both bacterial, such as BCG [4, 5] and *Corynebacterium parvum* [6], and chemicals such as levamisole [7] and glucan [8, 9] might be useful anti-cancer agents.

To date, most reports on animal models have concerned the effects on local tumours rather than on spontaneous metastatic spread. A few reports involving spontaneous bloodborne metastatic spread [1–3, 7–10] have been moderately encouraging, and since cancer patients die predominantly from metastases such reports must also be considered as more relevant to the problem in man. However, little attempt has been made to compare the effects of one agent with another [6].

We report here on a comparative study of the effects of different doses of three immunomodulators, glucan, levamisole and BCG on bloodborne metastatic spread from the B16 mouse melanoma and the effects of combining various doses of these agents with selected numbers of irradiated tumour cells.

An attempt has been made to assess whether it is possible to predict the effects of combining an immunomodulator with irradiated cells having prior knowledge of their separate effects when used alone.

MATERIAL AND METHODS

Mice

Conventionally housed 8-week-old inbred male C57Bl/6J were obtained from Jackson Laboratories and maintained on rat cake and tap water *ad libitum* in all experiments.

Tumour

The B16 melanoma, which arose spontaneously in the above strain and which has been maintained by long-term transplantation, metastasizes reproducibly to the lung in 100% of animals when grown as a subcutaneous implant in the right hind limb in this laboratory.

Tumour vaccine

Areas of the leg tumour which appeared most viable were selected and incubated at room temperature for 1 hr in 25 ml of MEM medium containing 13 mg trypsin, 15 mg collagenase and a trace of DNAase (all Sigma Type 1, England) with a magnetic stirrer. The resulting suspension was filtered through gauze to obtain a single cell suspension of greater the 97% viability on phase microscopy. Following overnight incubation at 4°C in MEM medium (Grand Island Biological Co., U.S.A.) containing 10% syngeneic mouse serum the cells were irradiated on a conventional X-Ray machine at 800 R/minute to a level of 15,000 R and 2×10^5, 2×10^4 or 2×10^3 cells injected in 0·05 ml volumes into each of five sites (i.p. and i.d. to four limbs)/mouse.

BCG

Doses of 2·5, 25 and 250 μg of lyophilized viable BCG (Institut Microbiologie et Hygiene strain, Montreal) in a 0·25 ml volume of saline were injected in divided doses of 0·05 ml, into each of five sites (i.p. and i.d. to four limbs)/mouse for groups of 11 mice on a single occasion.

Glucan

Doses of 2·5, 25 and 250 μg of glucan (obtained from Dr. DiLusio, Tulane University, U.S.A.) were injected as for BCG.

Levamisole

Doses of 2·5, 25 and 250 μg of levamisole (McNeill Laboratories, Canada) were injected as for BCG and glucan.

Immunomodulators and irradiated cells

The doses of agents outlined above were injected into five sites as above in 0·05-ml volumes containing either 4×10^5 or 4×10^3 tumour cells/ml.

Experimental design

A total of 10^3 tumour cells were injected into the right hind limb of 726 mice which were divided into 62 experimental groups of 11 and a control group of 44 mice. Half of the experimental groups were treated on Day 8, and the remainder on Day 19. The tumours were excised, by disarticulation of the femoral head of the tumour bearing limb, from 6 mice of each group on Day 18, and 5 on Day 19, as the number of mice in the experiment rendered it impossible to remove all the tumours on the same day. The tumour bearing and contralateral hind limbs were weighed to the nearest 0·1 g and the values for the latter subtracted from the former to give an approximate estimate of the tumour weight.

Analysis of experiments

Thirty one days after tumour excision the mice were exsanguinated under ether anaesthesia, the lungs removed and the metastases (mostly pigmented) counted macroscopically. There were no significant differences in the leg tumour weights or the numbers of metastases found within groups amputated on Day 18 compared to those amputated on Day 19, and the data are tabulated together.

The results were analysed using the Mann Whitney non-parametric test and values of $P < 0{\cdot}05$ were considered significant. The predicted mean number of metastases following treatment with a combination of immunomodulator and autovaccine was compared retrospectively with the observed mean number of metastases in these groups on the basis of the formula below.

Let the mean number of metastases following autovaccine alone = X and the mean number of metastases following treatment with an immunomodulator = Y.

Predicted number of metastases = $(X+Y)/2$.

Agreement within 2 metastases/mouse was considered arbitrarily to represent an accurate prediction and would represent neither an antagonistic nor a synergistic effect. Antagonistic effects would result in observed values of $> (X+Y)/2$ while synergistic effects would be represented by values of $< (X+Y)/2$. Significant antagonism was considered to have occurred when observed values reached $X+Y$, and synergism when values reached $(X+Y)/4$.

RESULTS

Groups of 11 mice were treated with irradiated cells and/or immunomodulators, and the weight of the primary tumour (grams wet weight) and the incidence and number of macroscopic lung metastases compared to those in the 44 controls.

No significant alterations in leg tumour weights were observed, the average for the control groups being 1·19 g while the range for experimental groups was 0·94–1·48 g (Table 1).

At autopsy, a few mice (up to two in any one group) were observed to have tumour recurrence at the site of excision; these were excluded from the analysis. The incidence of metastases in the controls was 97% and although in one experimental group, it was as

low as 50%, these differences were not considered significant (Table 2).

The average number of macroscopic metastases/mouse in the control groups was 9·2 and a statistically significant degree of suppression or facilitation of metastatic spread occurred in a number of experimental groups (see below).

The effect of irradiated tumour cells (Table 3)

When treated prior to tumour excision, a progressive reduction in metastatic spread occurred as the number of irradiated cells increased from 10^4 to 10^7 and the values for treatment with 10^6 and 10^7 cells were statistically significant.

A similar reduction occurred when mice were treated following tumour excision, except in the group immunized with 10^7 cells in which there was a significant increase in metastatic spread when compared to the controls.

The effect of non-specific adjuvant therapy (Table 3)

A significant reduction in metastatic spread resulted from treatment prior to tumour excision with either 2·5 μg of glucan, 25 μg or 2·5 μg of levamisole or 25 or 250 μg of BCG. In contrast treatment with 250 μg of levamisole produced a significant degree of facilitation, while other treatment schedules resulted in no detectable effects. Treatment with 250 μg of glucan or 250 μg of levamisole after surgical removal of the leg tumour resulted in a significant suppression of metastatic spread while treatment with 2·5 μg of BCG produced a significant increase in the number of pulmonary metastases. Other treatment schedules neither significantly facilitated nor suppressed metastatic spread.

The effect of combining immunomodulators with irradiated tumour cells (Tables 3, 4 and 5)

A significant reduction in metastatic spread resulted from pre-operative treatment with 10^6 irradiated tumour cells combined with either 25 μg or 2·5 μg of glucan and 250 μg or 2·5 μg of levamisole. Similar results followed an injection of 10^4 irradiated tumour cells combined with 2·5 μg of glucan, 250 μg and 2·5 μg of levamisole. A significant degree of facilitation resulted in only two groups, those treated with 25 μg of BCG and 10^4 irradiated tumour cells or 250 μg of glucan and 10^6 irradiated cells.

Following post-operative treatment with a combination of 10^6 irradiated tumour cells with 250 μg of levamisole or 250 μg of BCG resulted in a decrease in the number of metastases, while a significant degree of facilitation occurred on combination with 2·5 μg of levamisole. In groups treated with 10^4 irradiated cells post-operatively, suppression of metastases resulted from combination with 25 μg and 2·5 μg of glucan and 25 μg of levamisole while an increased number of metastases occurred following combination with 25 μg and 2·5 μg of BCG.

An attempt was made to assess the predictability of combining immunomodulators with irradiated cells on the basis of the results

obtained by treatment with the immunomodulator or the autograft alone.

Thus, (Table 4), the mean numbers of metastases observed from the combination of specific and non-specific therapy are compared to the numbers which might have been predicted from the results obtained following the relevant groups treated specifically or non-specifically alone. A difference of less than two metastases/mouse between expected and observed values was considered arbitrarily to denote an accurate prediction of a negligible effect (e.g., neither antagonistic nor synergistic). Out of a total of 36 therapeutic attempts, a significant reduction in metastatic spread occurred in 12 groups and facilitation of metastatic spread in five groups. Accurate predictions (a difference of less than two metastases/mouse between expected and observed values) could have been made for 2/12 (16·7%) of the groups in which suppression might have been expected compared to 0/5 (0%) for those in which facilitation might have been expected and 8/19 (47·3%) in which no effect might have been predicted. An overall accurate prediction might have been made for 10/36 (27·8%) of all groups.

On the basis of the arbitrary formulation (see Methodology) antagonistic effects were seen in 12/36, synergistic effects in 8/36 and no alteration in 16/36 groups undergoing combination therapy indicating no obvious pattern overall (Table 5). Nevertheless, antagonistic effects occurred more readily following combination with BCG than with glucan and levamisole, and following combination with 10^6 than with 10^4 irradiated tumour cells. Furthermore, such effects occurred more commonly post-operatively than pre-operatively (Table 6).

DISCUSSION

Statistically significant differences in the numbers of lung metastases compared to the control animals were observed in a surprisingly high number of experimental groups.

We feel that this may reflect the fact that immunization was carried out at fairly optimum time points in order to either prevent metastases by immunization at 8 days or to influence existing metastases by immunization at 20 days.

The groups immunized at 8 days constituted an attempt at immunoprophylaxis, since metastases do not develop in these experiments until 15–18 days after implantation (Proctor, unpublished observations) and thus some 7 to 10 days after immunization. In the other half of the experiment the tumours were removed prior to immunization at a time point when the size of individual metastases was minute, and immunity in the bloodstream has been shown to return within 7 days of B16 tumour excision despite the presence of lung metastases (Proctor *et al.*, in preparation).

The effects of irradiated tumour cells were similar to those described previously for other models [1–3] in which metastatic spread varied with the number of tumour cells used for immunization and the amount of tumour present.

Thus very large numbers of irradiated tumour cells may facilitate metastatic spread while more moderate numbers may suppress this event [3], as in the case of the present experiment. Furthermore as the tumour burden increases the number of cells producing facilitation decreases (Proctor *et al.*, in preparation).

The reasons why immunization should facilitate rather than suppress tumour spread are not established. However, one of the most widely held concepts relating to the success of tumours in the face of a detectable immune response resolves around the so-called" blocking mechanisms". These are believed to include effects mediated by antibody, antigen, or antigen/antibody complexes. Immunization with irradiated tumour cells will probably provoke a rise in soluble antigen levels, as described for non irradiated tumour cells [11] due to the fairly rapid cell death following injection of the tumour [12]. Stimulation of many lymph node areas distant from the primary could be expected to boost the anti-tumour immune products, and it is probable that there is an upper limit. Too many irradiated tumour cells may produce an excess of circulating soluble antigen and encourage blocking of immunity. While more likely to occur in the face of large tumour burdens, since immunity is likely to be weak in these instances, the most devastating effects may be expected following tumour removal in the presence of minimal residual disease. In terms of their anti-tumour effect, similar variations (facilitation or suppression) were observed in the present study following treatment with two of the three immunomodulators used, and appeared to depend on the dose of agent and the amount of tumour present at the time of treatment. For a single dose at a single time point one often appeared superior to the others, but overall, since each of them alone or in combination with irradiated tumour cells produced facilitation and suppression in one dose or another, they cannot be regarded necessarily as quantitatively different in their anti-tumour activity.

This finding of facilitation is in agreement with those made on the subcutaneous growth of a variety of tumours in association with levamisole [13] or BCG treatment in which facilitation was observed [14–16]. Chee and Bodurtha [16] showed that the effect of BCG on the growth of subcutaneous B16 melanoma was dose dependant. The reasons for potentiation of tumour growth by the non specific agents are obscure. Either immunostimulation such as that described by Prehn [17], or antigenic competition as described by Liacopoulos *et al.* [18] are possible explanations for the findings made with BCG.

The facilitation observed with 250 μg levamisole in a preoperative group is less easy to explain, as this compound is not an immunogen. A toxic effect could be considered, except that facilitation did not occur in other groups treated with the same dose, which is less than 1/10 of the LD 50 in our experience (Proctor, unpublished observations). Facilitation was not observed with glucan alone, and in this respect glucan differed from levamisole and BCG. We have found that the effect of BCG varies with the route of administration and the site of B16 tumour growth [19]. Our study, like that of Pimm and Baldwin [20], showed that intravenous administration of BCG produced the best effect on systemic tumour. In man, intravenous administration of BCG is strongly contraindicated as the risk of systemic injection is high in patients who are compromised immunologically. Levamisole, however, reaches high bloodstream concentrations following oral administration, and this agent and glucan, which is broken down finally to glucose, have a definite potential as systemic agents.

The results of combining the non-specific adjuvants with irradiated cells were disappointing in that the effects proved unpredictable. The value of analyses such as those we have described on such small numbers of groups is perhaps questionable. Nevertheless, they do demonstrate that both antagonistic and synergistic effects can occur.

In the past we have reported that a combination of a dose of *C. parvum* which was ineffective on its own with a number of tumour cells known to facilitate metastatic spread, was beneficial [3]. Conversely, in another model a dose of *C. parvum* which was ineffective on its own produced a facilitating effect when combined with a number of irradiated tumour cells known to produce a beneficial effect when used alone (Ghaffar, personal communication), and in this respect the present results are similar.

In summary, the treatment with tumour vaccine or immunomodulators appears to be capable of suppressing or facilitating blood-borne metastatic spread depending on the doses used and the amount of tumour present at the time of treatment. The significance of such findings to man is not known, and it is unacceptable to extrapolate findings made in animal models to human cancer patients. Nevertheless, should man be similar in respect to treatment with tumour vaccine or immunomodulators there is a potential risk. Furthermore, a feature of many groups of cancer patients is their heterogeneity. Thus, the prognosis in melanoma patients is intensely variable and depends on a number of factors. Should immunotherapy of the type discussed in this report depend in man on the dose of the agent used, the amount of the tumour present, the immunocompetence of the host, and the immunogenicity of the tumour as appears to be the case in animals, it is unlikely that a dose of an immunotherapeutic agent which succeeds in one patient will benefit more than a small percentage of the succeeding cases.

A Late Clonal Evolution of a Human Leukemic Line: Sequential Cytogenetic Studies*

A. M. VENUAT, B. DUTRILLAUX,† and C. ROSENFELD
Institut de Cancérologie et d'Immunogénétique, 94800 Villejuif, France, and †Institut de Progénèse, Faculté de Médecine, Paris, France

Abstract—*Cytogenetic evolution* in vitro *of a human leukemic cell line has been followed for more than 4 yr. At the beginning of the establishment the karyotype seems normal with some pseudodiploid cells. Then endomitosis and two chromosome markers are observed in a few percentage of the cell population. Some chromosomes show a partial despiralisation of their distal part. After more than 3 yr in culture these abnormalities are present in every cell, demonstrating a late clonal evolution* in vitro. *Studies performed with controlled heating denaturation technic allow identification of the markers and analyse of structural rearrangements.*

INTRODUCTION

THE *in vitro* cytogenetic evolution of human lymphoblastoid cell lines established from normal or leukemic donors has already been studied [1–4], but contradictory results were obtained. Most authors found no differences between cell lines of normal or abnormal origin. Henle described a lesion which involved a C group chromosome, attributed to Epstein–Barr Virus [5]. More recently, Steel has noticed a late clonal-type evolution in one human lymphoblastoid line [6]. Data reported here are concerned with the cytogenetic evolution of a lymphoblastoid line initiated from a leukemic donor.

MATERIAL AND METHODS

The blood cells from a female patient, Mrs HUE, with an acute myeloid leukemia were originated (T_0) and maintained in 1640 RPMI medium supplemented with 20% fetal calf serum using a previously described technique [7]. After an early period during which cell death predominates, (T_d), a multiplication phase occurs indicating the establishment of the lymphoblastoid line (T_i), followed by the exponential phase of growth (T_e) (Fig. 1).

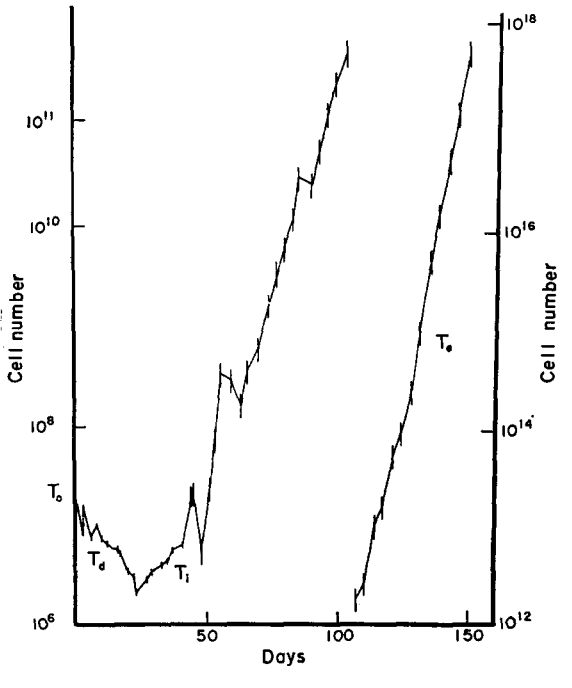

Fig. 1. Curve of the kinetics of the establishment of the HUE lymphoblastoid cell line; T_0*—seeding into culture,* T_d*—death phase,* T_i*—first cell multiplication phase,* T_e*—exponential phase of growth.*

The first cytogenetic study was done three months and 10 days after T_0 (seeding time). The other samples were examined at T_i and at various time intervals during the exponential growth phase (T_e). For each experiment 0·5 to 1 $\times 10^7$ cells were withdrawn from culture

flasks and treated by conventional techniques for chromosome analysis [8, 9]. The technique of controlled heating denaturation was also used [10].

For each sample studied, 50–100 metaphases were photographed. From the chromosome counts we were able to establish distribution histograms. Twenty-five or more karyotypes were studied for each sample using both classic and denaturation techniques when possible.

RESULTS

When examined 3 months, and 6 months and 25 days, after the initial *in vitro* seeding of the culture (T_0), a normal female karyotype was observed in most of the cells, although some cells were psuedodiploid, showing a loss or gain of one or several elements. Using only the classical method for studying chromosomes, we noted that these abnormalities were obviously non systematized. Nevertheless, their relatively high frequency when compared to normal controls allowed us to exclude the possibility of a technical artefact being responsible.

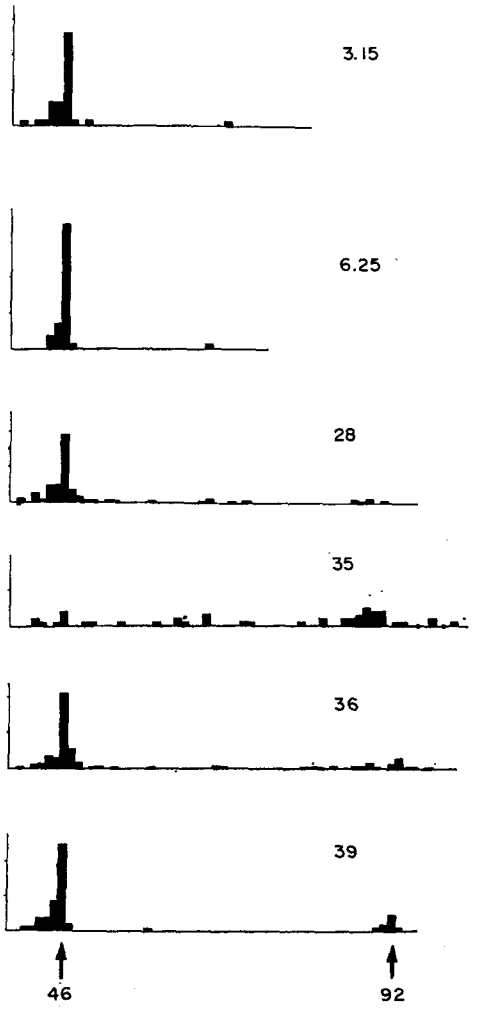

Fig. 2. Histogram depicting the distribution of chromosome number from cell samples of the HUE line at different times in culture. Numbers—months and days.

A third examination, using the same techniques and made 28 months after T_0, showed the following facts.

The number of chromosomes was found to range from hypodiploidy to hypotetraploidy (Fig. 2) with a diploid modal maximum. Numerous endomitosis were observed. Ten karyotypes from diploid cells were analysed. One C and one F elements were missing, but two chromosomes, one of which could be a Cq+ and the other either a Fp− or a Fq− were present (Fig. 3). In one of the 10 karyotypes a slight despiralisation of the end of the arms of chromosome 3 was seen. In another karyotype a despiralisation of the end of the short arms from a B element was observed. At least in several cells, an accentuation of the secondary constriction of chromosomes 1 and 16 (Table 1 and Fig. 4) was also noted. At the 4th and 5th examinations, 35 months and 3 days, and 35 months and 8 days, the respective chromosome numbers had clearly shifted towards pseudotetraploidy (Fig. 2). All the cells contained the elements previously described as Cq+ and Fp− or Fq−. The terminal despiralisation of chromosomes 3 and B was again observed (Fig. 5). Nine days later, an aliquot of the culture was frozen and stored. The remaining cells were carried on in culture and 15 days later analysed again. The same data were found but with an increase in the frequency of 3 and B chromosome terminal despiralisation. Two other samples were studied at 36 months and at 36 months and 4 days. The abnormalities already described were present but the number of pseudotetraploid cells was found to have decreased (Fig. 2). When the controlled heating

Fig. 6. a.b.c.—*Several dicentric chromosomes found in HUE line cells at* 39 *months. They are partially constituted with* 6 *q*+. d—*great abnormal monocentric element observed in a cell sample after* 47 *months* in vitro.

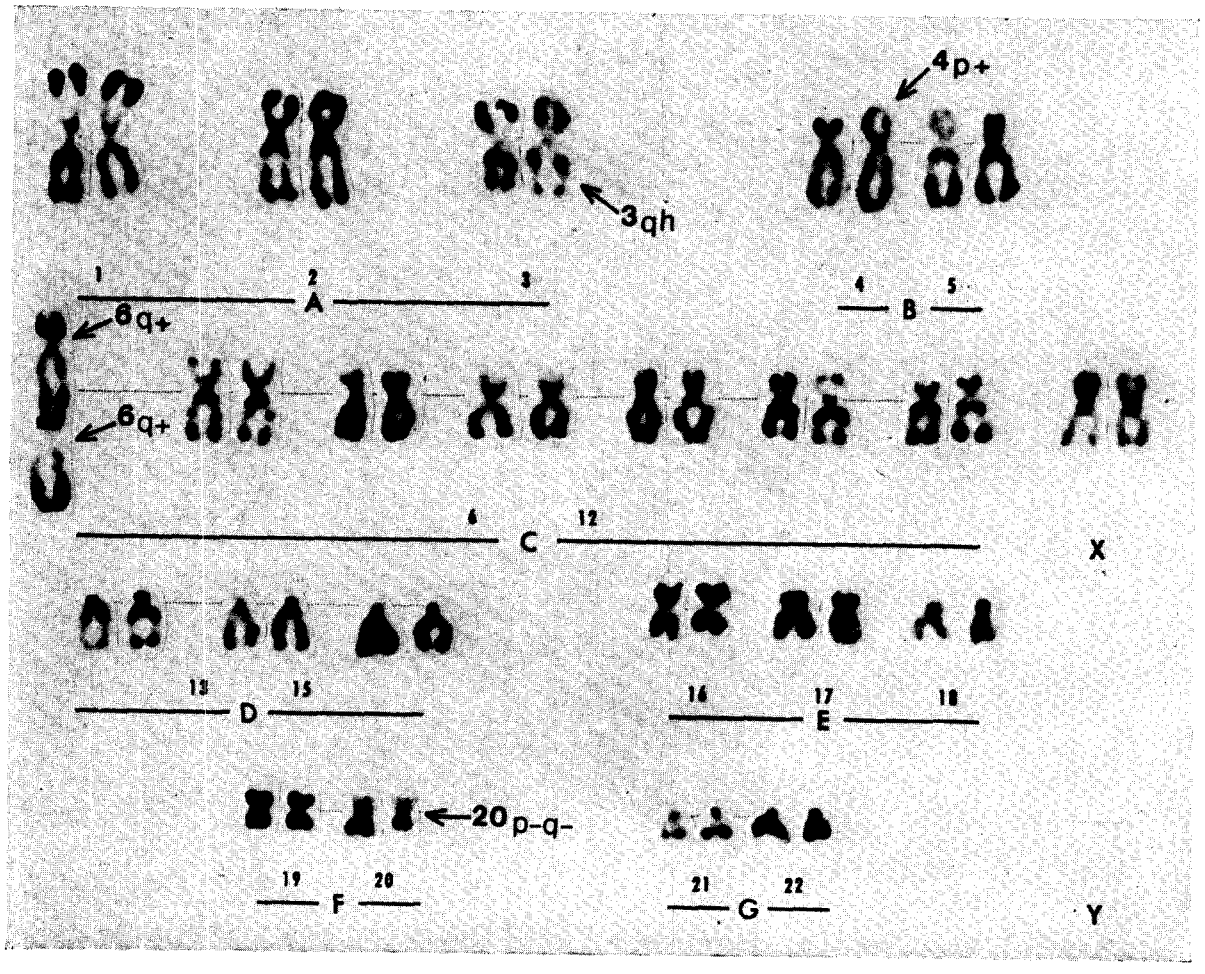

Fig. 7. Karyotype of HUE Cell at 39 months showing the 4 markers: 3 qh, 4 p+; 6 q+ (forming a dicentric chromosome) and 20 p−q−.

denaturation technique was applied to a sample of this culture 39 months and 3 days after T_0, the number of chromosomes had decreased towards diploidy (Fig. 2) with a small fraction of the population being tetraploid. In all cells, one or two 6 chromosomes and one 20 chromosomes were absent. When a 6 element was missing, it was always replaced by a 6q+ as proved by banding techniques. When the two 6 were missing, they were replaced either by one or two 6q+. A dicentric element was found in a few cells. The chromatid analysis with banding showed a partial constitution with a 6q+ and in one case with two 6q+ (Fig. 6a, b, c). In all cases, the presence of a dicentric is counter-balanced by the absence of a 6 chromosome or a 6q+ so that, for the number 6 pair, the total material is roughly comparable to normal diploid cell. Likewise, a small metacentric 20p−q− took the place of a missing 20.

The despiralisation of number 3 chromosome was observed either on the short or on the long arm and sometimes on both. It is placed on the p24 and q26 band according to the Paris classification.

The despiralised B chromosome was a number 4 and the incriminated band was the p16 on the short arm (Fig. 7).

Compared to the preceding observation a higher frequency of the secondary constriction with a lengthening of number 1 and 16 chromosomes was found at 28 months in culture (Table 1).

After 47 months *in vitro*, the controlled heating denaturation technique showed that the previously described abnormalities (3ph, 3qh, 3phqh, 4ph, 6q+ and a 20p−q−) were remarkably stable. Genuine dicentric elements were not found again but some great monocentric chromosomes could be observed. Their banding pattern was very similar to that of the dicentric found at 39 months. The presumed site of one of the centromeres was indicated by a constriction of an apparently secondary nature (Fig. 6d). In many cells an increase in the frequency of secondary constriction with a lengthening was observed on homologues (Table 1). Moreover, in many cells one or several elements were missing without evident systematisation. These abnormalities were less frequent than previously and this suggests karyotype stability. Finally, the sample frozen at 35 months was thawed at 50 months and again maintained in culture. Four months later, i.e. 39 months after the beginning of the culture, the abnormalities already described were again found: 3ph, 3qh, 3phqh, 4ph, 6q+, 20p−q−. In another cell a dicentric element partially composed of a 6 chromosome was also observed.

DISCUSSION AND CONCLUSION

The great variation in distribution of the chromosome number in this leukemic cell line is the first noticeable fact. After an initial diploid period, cells become heteroploid at 35 months. Then, at 39 months they return to a diploid state with a certain number of tetraploid cells. The transition to a tetraploid state, which could be due to endomitosis, does not result in any modification of the abnormalities observed at 28 months. At this time distal despiralisations appear on number 3 and B chromosomes. The number of mitoses affected by this phenomenon increases and involves all the cells at 39 months. We also observed an increasing frequency in the secondary constrictions of number 1 and 16 chromosomes, while the 9th pair was never affected. This phenomenon has already been reported by Zur Hausen [11] and it seems to be correlated more with the duration of the lines *in vitro* than with their normal or leukemic origin, for we also found it in normal cell lines.

The controlled heating denaturation technique enabled us to identify the chromosomes affected by structural rearrangements and to demonstrate that these late appearing markers remain stable for many generations (19 months for 6q+).

One can see that after freezing and thawing, the cells followed the same evolution within the same timespan, independent of the length of conservation.

The problem of the presence of dicentric chromosomes, which were seen for several generations, has already been discussed [12]. This dicentric element always occurs with a 6q+ and seems to be the result of chromatides joining together affording the separation of the two initial constituent chromosomes in anaphase.

Study of the HUE line since its establishment demonstrates a "trying of brushing type" evolution by malsegregation which does not lead to karyotype stabilisation, whereas, in comparison, an evolution by structural rearrangements leads to a stable karyotype. This clonal-type evolution affords a means of stabilisation and survival for the line. Steel proposed that such an event should be used as a criterium for the establishment of a cell line, which, until now, was determined by growth curves [6, 7].

Late clone constitution with marker chromosomes demonstrates a sequence of morphological transformation different from that described by study of growth curves for the establishment of such line. The formation of this late clone must be taken into account when looking for properties which can differentiate between lymphoblastoid cell lines according to their normal or leukemic origin.

†*Département de Microbiologie et d'Immunologie,*
Université de Montréal, Montréal, Canada

Abstract—*The immunotherapeutic effects of the methanol extraction residue (MER) of BCG were investigated in strain 2 guinea pigs injected with cells of the transplantable, diethylnitrosamine-induced, line 10 hepatocarcinoma. MER was more effective in mediating tumour regression in guinea pigs obtained from the Weizmann Institute of Science, Rehovot, Israel than in animals obtained from the National Institutes of Health. Repeated skin testing with solubilized tumour antigen of MER-treated animals whose tumours had regressed led to recurrent tumour growth and/or susceptibility to rechallenge in six of nine guinea pigs so treated. These results suggest the existence of minimal residual disease even in animals which respond positively to immunotherapy.*

INTRODUCTION

BOTH BCG and the methanol extraction residue (MER) fraction [1] of BCG are non-specific stimulants of cellular and humoral immunity [2–4], and have been successfully employed in tumour immunotherapy in a number of animal systems [5–7]. The tumour model we have been studying is the inbred strain 2 guinea pig diethylnitrosamine-induced, transplantable line 10 hepatocarcinoma [8]. Previous workers have shown with this model that injection of viable BCG directly into growing tumour nodules, at seven days following intradermal implantation of 10^6 tumour cells, leads to regression and cure in approximately 60% of animals so treated [9, 10]. We attempted to duplicate these findings with MER, a substance which offers the advantages of being both non-living and more readily quantifiable on a weight basis than the intact organism [11]. In addition, we investigated the effects of repeated skin testing with solubilized preparations of line 10 tumour antigen on guinea pigs whose tumours had regressed following immunotherapy.

This communication describes experiments showing that the effectiveness of MER as an immunotherapeutic agent for the line 10 hepatocarcinoma was dependent on the substrain of guinea pigs used for experimentation. Furthermore, repeated skin testing with soluble tumour antigens of animals which had apparently been cured by immunotherapy of line 10 disease led to tumour re-appearance followed by death in a substantial proportion of cases.

MATERIAL AND METHODS

Animals, tumour cells and immunotherapy

Sewall–Wright inbred strain 2 guinea pigs were obtained from the breeding colonies of the Laboratory Aids Branch, Division of Research Services, National Institutes of Health (NIH guinea pigs) and the Weizmann Institute of Science, Rehovot, Israel (WI guinea pigs). WI strain 2 animals were derived from the NIH colony in 1970.

The ascites form of the line 10 hepatocarcinoma was kindly provided in the fourteenth transplant generation by Dr. B. Zbar, National Cancer Institute, Bethesda, Md., and passaged i.p. at least four times in each of NIH and WI guinea pigs before use. Tumour cell suspensions for intradermal (i.d.) challenge were prepared immediately before use as described previously [12], and adjusted to a concentration of 10^7 hepatoma cells per ml of Hanks' balanced salt solution (BSS). Animals were injected i.d. into the right flank with 10^6

tumour cells in 0·1 ml BSS. After 7 days, experimental animals were inoculated with MER (0·5–1·0 mg in 0·1 ml BSS) (kindly supplied by the Division of Cancer Treatment, National Cancer Institute, Bethesda, Md.) directly into developing tumour nodules. Tumour-injected guinea pigs not receiving immunotherapy served as controls. Female animals only were used in these experiments.

Soluble tissue extracts and delayed cutaneous hypersensitivity (DCH) studies

Soluble tissue components were prepared by 3 M KCl extraction from both ascites-grown line 10 tumour cells (SA-10) and from perfused normal adult liver tissue (SA-N) by a modification of the procedure of Meltzer *et al.* [13] as previously described [14], and stored at −20°C until use. Protein concentrations were determined by the method of Lowry *et al.* [15]. These extracts were used in DCH studies in both MER-treated and control tumour cell-injected guinea pigs. Skin testing was also carried out with purified protein derivative (PPD) of *Mycobacterium tuberculosis*, kindly supplied by the Ministry of Agriculture, Weybridge, England. All skin test inocula were administered in 0·1 ml of 0·15 M NaCl, and areas of induration measured after 24 and 48 hr.

Lymphocyte stimulation

Blood from strain 2 guinea pigs were drawn into heparin by cardiac puncture, and the mononuclear fraction purified by Ficoll–Isopaque gradient centrifugation [16]. This fraction, which consisted largely of lymphocytes, was collected by aspiration, washed twice by centrifugation for 15 min at 500 *g* in BSS and the cells resuspended in bicarbonate-buffered medium RPMI (supplemented with 10% fetal calf serum, 100 units/ml penicillin, 100 μg/ml streptomycin) to a final concentration of 10^6/ml. Cultures containing 1 ml of cell suspension in 17 × 100 mm tubes were incubated in the presence or absence of various test antigens (i.e. 100 μg SA-N; 100 μg SA-10) for 72 hr at 37°C. Tritiated thymidine (1 μCi/tube; New England Nuclear, Boston, Mass.) was added to the culture tubes for the final 16 hr of incubation, following which the samples were processed by trichloroacetic acid precipitation on to filter pads and the amount of incorporated radioactivity determined.

RESULTS

Comparison of MER immunotherapy effectiveness in guinea pigs derived from different breeding nuclei

The results of a preliminary experiment indicated that five of a group of 14 WI strain 2 guinea pigs were cured of developing line 10 skin tumours by intra-tumour inoculation of 0·5 mg MER at 7 days following implantation of 10^6 tumour cells. These five animals were subsequently all found to be resistant to id challenge with 10^7 tumour cells, 2 months after the initial implantation event, indicating the development of tumour transplantation immunity. These same animals were still alive 14 months later, and showed no trace of recurrent malignant disease. Although the rate of success following immunotherapy with MER was less than that which had been previously reported for living BCG [9, 10], it was decided to investigate this subject further, and to employ guinea pigs derived from different breeding nuclei. The results (Table 1) confirmed that MER could apparently be used to eliminate tumour growth in 18 of 46 or approximately 40% of the animals of WI origin developing line

Table 1. *Effect of MER on line* 10 *hepatoma growth in guinea pigs of NIH and Weizmann Institute origin*

Group	Animal origin	Treatment	No. in group	No. of survivors	Average day of death of non-survivors
1	NIH	0·5 mg MER	12	2	65
2	NIH	1·0 mg MER	12	2	70
3	NIH	—	15	0	71
		% Experimental animals responding = 16%			
4	Weizmann	0·5 mg MER	23	9	75
5	Weizmann	1·0 mg MER	23	9	79
6	Weizmann	—	8	0	64
		% Experimental animals responding = 39%			

10 tumours. A much smaller proportion (i.e., 16%) of NIH-derived pigs, however, responded to the same treatment ($P < 0{\cdot}01$; χ^2 test). All animals with growing tumour died of widespread metastatic disease between 60–90 days after line 10 hepatocarcinoma implantation. By contrast, successful MER immunotherapy generally led to complete tumour disappearance by 3–4 weeks after treatment.

Desensitization of effective anti-tumour immunity by skin testing

The 18-MER treated WI guinea pigs of the experiment of Table 1 whose tumours had regressed were divided into two groups of nine animals each. One such group was skin tested weekly for four consecutive weeks commencing seven weeks after tumour implantation with 0·1 ml of each of SA-10 (100 μg protein), SA-N (100 μg protein), PPD (2 μg protein) and isotonic saline. The second group of nine MER-treated animals were similarly skin tested with SA-N, PPD and saline; SA-10 challenge was omitted. All skin test injections were administered by the i.d. route. Areas of induration were measured after 24 and 48 hr. None of the animals in either group responded to SA-N or saline, while 16 of 18 had delayed cutaneous hypersensitivity (DCH) reactions on at least two occasions against PPD. All 9 guinea pigs of the first group showed strong DCH reactions to SA-10 following each weekly skin test challenge. We further observed that four of the nine animals in the first group, as opposed to none of nine in the control group, developed regional lymph node metastatic tumours and eventually died. Two of these tumours appeared between 3–4 weeks after the commencement of skin testing while the others did not become palpable until after 6 weeks (Table 2). These findings suggested that skin testing with soluble tumour antigen had in some way desensitized the anti-tumour immune response and permitted tumour recurrence.

Table 2. Effect of repeated skin testing with soluble tumour antigen (SA-10) and other antigens on MER-treated, apparently tumour-free guinea pigs

Group	Skin tested with	Animal	Time of appearance of metastatic tumour (days following onset of skin testing)	Date of death (days following initial tumour cell injection)

Animals 5–18 were re-challenged with 10^7 tumour cells 102 days following initial tumour implantation.

In order to test this possibility, the five survivors of group 1 and the nine animals of group 2 were challenged i.d. with 10^7 tumour cells as described above, 102 days following initial tumour cell implantation. Two of the five guinea pigs of group 1, and none of the nine of group 2 developed growing tumours at the site of reinoculation and eventually succumbed (Table 2). Thus, skin testing with high concentrations of soluble tumour antigen (1 mg/ml) apparently caused recurrent tumour growth and susceptibility to rechallenge in 6 of 9 MER-treated guinea pigs which otherwise would apparently have remained disease-free ($P < 0{\cdot}001$; χ^2 test).

We also studied the effect of repeated skin testing of these animals on immune responsiveness to SA-10 and SA-N as measured by lymphocyte blastogenesis. This technique has previously been employed as a monitor of specific anti-tumour immunity for the line 10 system [17]. Guinea pigs were bled 10 days following final skin test challenge and 10^6 lymphocytes, obtained by Ficoll–Hypaque gradient centrifugation, were incubated in 1 ml of medium RPMI containing 10% fetal calf serum and various test antigens for 72 hr at 37°C. Tritiated thymidine was added to the culture tubes for the final 16 hr of incubation, and the samples processed as described above. The results (Table 3) demonstrated that most of the guinea pigs tested which had survived tumour challenge following immunotherapy with MER had demonstrable levels of cellular anti-tumour (i.e., anti SA-10) immunity by this technique. Incorporation of label in response to SA-N was generally below background. No differences in either levels or frequency of responsiveness were observed, between that group of animals which had been skin tested with each of SA-10, SA-N and PPD and that group which received SA-N and PPD only. Thus, effective desensitization of anti-tumour immunity, indicated by tumour recurrence and susceptibility to rechallenge following repeated skin testing, could not be correlated with decreased levels of such immunity as measured by standard *in vitro* testing procedures.

DISCUSSION

These data indicate that repeated skin testing with solubilized tumour antigens can apparently cause the recurrence of neoplastic growth in apparently tumour free animals which had previously been treated at a primary tumour growth site with MER. In addition, we have shown that MER is a more effective immunotherapeutic agent for the transplantable line 10 hepatocarcinoma when used in WI than in NIH guinea pigs. This report thus complements a previous study [18] in which it was shown that MER effectiveness in the

immunoprophylaxis of the line 10 tumour was restricted to guinea pigs derived from breeding colonies other than that of the NIH.

Several possible explanations come to mind with which to explain these experimental discrepancies. First, it is possible that some degree of genetic drift could have occurred between the NIH and WI breeding stocks since 1970, the year of separation, and that NIH animals may possess an inherent lesser reactivity to MER stimulation. Alternatively, histocompatibility antigen differences may have resulted in an increase in antigenicity of line 10 tumour cells for animals of either NIH or WI origin, thus contributing to the success of BCG or MER immunotherapy in these respective guinea pigs populations. Indeed, should histocompatibility differences exist, then at least part of the tumour rejection phenomenon which both we and others [9, 10] have observed may be due to homograft rather than tumour immunity. If this is the case, however, it is nonetheless obvious that the histocompatibility differences must only be minor, since tumour inoculation in the absence of immunotherapy has been invariably fatal for the animals we have studied. For this reason, it is fair to speak of anti-tumour immunity in this system. These difficulties may be intrinsic to many or all tumour transplantation models. Another explanation for the observed differences is suggested by the recent findings of several groups [14, 19, 20] that BCG cross-reacts antigenically with line 10 tumour cells. Conceivably, injection of substances like MER or BCG may, in some substrains more than others, stimulate the formation of specific antibodies or cellular immune elements, capable either of bestowing heightened resistance or enhancing tumour growth [21]. This finding of shared antigenicity with BCG may also explain the superior results others have obtained in the immunotherapy of the line 10 tumour with either living BCG or BCG walls in admixture with mineral oil.

The mechanism responsible for observed tumour recurrence in the desensitized, MER-treated guinea pigs remains obscure, but it is possible that repeated skin testing with SA-10 may have led to the formation of tumour growth enhancing antibodies [22]. Alternatively, specifically antigenic SA-10 molecules may have found their way into the circulation and interfered with effective humoral and/or cellular immunity [23, 24]. Our results also suggest the apparent survival of residual numbers of viable tumour cells for as long as 4 weeks after disappearance of a palpable tumour mass. These cells are apparently present in the form of micrometastases in the regional lymph node, which was the site of tumour recurrence in each instance studied.

On the basis of an antigen-dependent lymphocyte blastogenesis assay, we were not able to differentiate immunologically between those skin tested guinea pigs which succumbed to recurrent tumour growth and those which survived. It is especially noteworthy that the guinea pigs in our experiment showed DCH reactivity to SA-10 following each skin testing event. This points to the difficulties involved in attempting to prognosticate from the results of either *in vitro* or *in vivo* testing procedures, and complements earlier results obtained with this tumour model [17, 25].

It is not known whether similar results would have been obtained had repeated skin testing been performed with lower concentrations of soluble tumour antigen (e.g. 10 μg which also elicits positive DCH responsiveness). In addition, it is conceivable that 3 M KCl extracts of tumour tissue, as opposed to extracts obtained by other procedures, may contain components which are especially enhancing to neoplastic growth. Finally, since BCG is apparently more effective than MER in the immunotherapy of this tumour, treatment with the former agent may more successfully eliminate residual viable tumour cells.

Nevertheless, these results suggest the continuing existence of minimal residual disease in at least some animals which respond positively to cancer immunotherapy. While such minimal residual disease may frequently be held in check by the animal's defense mechanisms, experimental manipulation can apparently upset this delicate balance and lead to recurrent tumour growth. As such, these results raise questions as to the safety of repeated skin testing with human tumour antigens in a clinical setting.

Changes in Nuclear RNA Transport Incident to Carcinogenesis*

D. E. SCHUMM, M. HANAUSEK-WALASZEK,† A. YANNARELL and T. E. WEBB
Department of Physiological Chemistry, The Ohio State University, College of Medicine, Columbus, Ohio, 43210, U.S.A.

Abstract—*Rats were treated with the hepatocarcinogens thioacetamide and dimethylnitrosamine and the release (transport) of RNA from the isolated liver nuclei to homologous or heterologous liver cytosol was evaluated in a cell-free system at various times after treatment. Within 24 hr of treatment, cytosol from the carcinogen-treated animals enhanced the release of RNA from liver nuclei of untreated rats. This enhanced transport capacity of the cytosol persisted up to 4 months after treatment; furthermore, the RNA transport from the liver nuclei of carcinogen-treated animals showed a partial loss of its ATP-dependence. Although the capacity of cytosol from treated animals to support RNA transport dropped below control levels by 9 months after treatment, the RNA transport from nuclei of the carcinogen-treated animals remained partially ATP-independent. This ATP-independence, which is also a characteristic of nuclei from hepatomas, is not a characteristic of the age of the animal, nor is it due to differences in the pool size of nuclear ATP or the requirement for polyadenylation of messenger RNA for transport.*

INTRODUCTION

ACCORDING to current theory both messenger and ribosomal RNA are derived from large nuclear precursors by non-conservative processing [1, 2]. There is also accumulating evidence that this nuclear processing and/or nucleocytoplasmic transport of the processed RNA are under post-transcriptional controls. For example, the proportion of potential messenger, or ribosomal RNA reaching the cytoplasm varies during development [3], with growth rate [4] and upon neoplastic transformation [5]. The limitations imposed on the study of the regulation of RNA processing and transport in the intact cell, has led to the development of cell-free systems which support these processes [6–11]. One of these systems developed in this laboratory to study nucleocytoplasmic controls, shows a dependence of ribosomal and messenger RNA release as ribonucleoprotein particles from either normal, or tumor cell nuclei, on macromolecules in the cytosol [7, 8, 12]; some cytosol-dependence has been observed by other investigators [11, 12]. However, other cell-free systems release their nuclear RNA to incubation media of different composition in the absence of cytoplasmic macromolecules [6, 9].

Despite the apparent differences in cytosol-dependence, both types of cell-free systems exhibit an ATP-dependence of RNA release when the nuclei are derived from normal liver [6–8, 13–15]. In contrast, liver nuclei from the liver of donor animals treated with the hepatocarcinogens dimethylaminoazobenzene, acetylaminofluorene, or thioacetamide was first reported by Smuckler and coworkers [15–17] to show a significant loss of their ATP-dependence. The release of RNA from myeloma cell nuclei was also reported [10] to be ATP-independent. In order to resolve the apparent discrepancies between ATP-dependence in normal liver nuclei and independence in myeloma cell nuclei (i.e. 2 cell types of different origin) a comparison was made of the ATP-dependence of RNA release from the nuclei of normal rat liver, a differentiated rat hepatoma (Hepatoma 5123D) and an undifferentiated rat hepatoma (Novikoff hepatoma). The RNA release was found [14] to be totally dependent, partially dependent and independent of ATP, respectively, suggesting that ATP-dependence

†Present address: Institute of Oncology, Department of Tumor Biology, 44–101 Gilwice, Poland.

is related to the degree of differentiation of the tumor. The present study analyzes the loss of ATP-dependent release of RNA from liver nuclei incident to treatment of the host animals with hepatocarcinogens, using the cytosol-dependent RNA transport system; special emphasis is placed on localizing the cellular site at which ATP-independence develops and the time-course of its development.

MATERIAL AND METHODS

The donors of liver tissue were 200–250-g male rats of the Sprague–Dawley strain (Laboratory) Supply Co., Indianapolis, Indiana) before (controls) or after treatment with the well known hepatocarcinogens thioacetamide (Apache Chemicals, Seward, Illinois) or dimethylnitrosamine (freshly redistilled; Eastman Kodak, Rochester, New York). The carcinogenic regimens involved a course of nine daily injections of 50 mg/kg of body weight of thioacetamide [18] or a single injection of dimethylnitrosamine (5·0 mg/kg of body weight) 24 hr after partial hepatectomy [19]. Although dimethylnitrosamine in particular may produce tumors at other sites (e.g. kidney tumors), when given to partially hepatectomized rats according to the indicated protocol, it induces hepatocellular carcinomas in at least 35% of the rats [19]. The protocols selected for dimethylnitrosamine and thioacetamide, besides inducing hepatomas, are particularly suited to the present study since the treatment is of short duration, allowing one to study the irreversible effects of the drugs after cessation of treatment. The nuclear RNA was prelabeled *in vivo* for 30 min with [6-^{14}C] orotic acid (40 μCi/250 g) prior to removal of the liver for nuclear isolation. Non-specific toxicity of the carcinogens is a minor problem in the present study since most of the measurements were made weeks or months after cessation of treatment. All injections were via the intraperitoneal route and the animals were fasted for 17 hr (overnight) prior to use in order to deplete liver glycogen.

The ascites form of the rapidly growing dedifferentiated Novikoff hepatoma was carried i.p. in 140 g female rats of the Sprague–Dawley strain. After washing with 0·9% saline, the nuclear RNA of the hepatoma cells was prelabeled by incubation (10^7 cells/ml) at 37°C for 20 min in Eagles minimal essential medium (Schwartz–Mann, Orangeburg, New York) containing 2 μCi/ml of [5,6-^{3}H] uridine (S.A. = 39·3 Ci/m-mole). Before homogenization the cells were removed from the incubation medium, washed once with 0·9% saline and once with 2·0 vol of the homogenization buffer.

Nuclei were isolated from liver tissue by homogenization in 15 vol of 2·3 M sucrose, 3·3 mM calcium acetate as previously described [7, 20]. Novikoff hepatoma cells were disrupted by suspension in one volume of homogenizing medium composed of 30 mM sucrose, 2·0 mM $MgCl_2$, 3·0 mM $CaCl_2$, 10 mM Tris–HCl (pH 8·0), 0·1% Triton X-100, 0·5 mM dithiothreitol [21] followed by 20 strokes of a tight-fitting Dounce homogenizer. The nuclei were purified by layering the homogenate over 20 ml of 2·0 M sucrose, 3·3 mM calcium acetate and centrifuging for 60 min at 34,000 ***g***. After washing in 1·0 M sucrose-1·0 mM calcium acetate (300 ***g*** for 5 min), the nuclei were resuspended in the same buffer for addition to the cell-free transport system.

Liver cytosol (105,000 ***g*** supernatant) which contains RNA transport factors was prepared from a 1:2 homogenate and dialyzed at 4°C for 18 hr against TMK buffer (50 mM Tris–HCl, pH 7·5, 2·5 mM $MgCl_2$, 25 mM KCl) as previously described [7, 8]. Cytosol was similarly prepared from the Novikoff hepatoma by swelling the washed cells for 10 min at 0°C in 2 volumes of TMK buffer, centrifuging out the cells, followed by a Dounce homogenization (20 strokes with a tight pestle) of the cell pellet. The resulting homogenate was centrifuged, dialyzed against TMK buffer and frozen until use. The protein concentration of the dialyzed cytosol was determined by the Biuret method [8].

The cell-free system which was used to study the release of labeled messenger-like RNA consisted [8] of approximately 5×10^6 prelabeled nuclei/ml of medium containing 12 mg dialyzed cytosol protein/ml, 50 mM Tris–HCl (pH 7·5), 25 mM KCl, 2·5 mM $MgCl_2$, 0·5 mM $CaCl_2$, 0·3 mM $MnCl_2$, 5·0 mM NaCl, 2·5 mM Na_2HPO_4, 5·0 mM sperimidine, 2·0 mM dithiothreitol, an energy source and 300 μg/ml of yeast RNA. Where indicated the energy source, composed of 2·0 mM ATP, 2·5 mM phosphoenolpyruvate and 35 units/ml of pyruvate kinase, was omitted from the reaction. The mixture was incubated at 30°C for 30 min, or for the specified time interval. During the initial 30 min of incubation over 80% of the labeled nuclear RNA released to the medium is messenger-like [8, 20, 22].

The amount of RNA release from the nuclei was estimated as follows. After incubation, the assay mixtures were chilled on ice, and then centrifuged at 1000 ***g*** for 10 min to remove

the nuclei. RNA was precipitated by the addition of 1/10 volume of 50% trichloroacetic acid. Following a wash with cold 95% ethanol the precipitate was dissolved in solubilizer for radioassay in liquid scintillant [20].

Alternatively when a measure of the proportion of the labeled transported RNA containing poly (A) tracts was desired, the RNA was purified from the nuclei-freed incubation medium by phenol:chloroform (1:1) extraction as previously described [22]. The RNA was then passed through a column of oligo-dT-cellulose (Collaborative Research Inc., Waltham, Mass.) to separate the poly A containing RNA, which binds to the column in 0·5 M NaCl, from the RNA lacking poly A, which does not bind under these conditions [23].

RESULTS

Effect of hepatocarcinogens on RNA transport

Preliminary to studying the prolonged (irreversible) effects of the hepatocarcinogens on the energy-dependence of RNA transport, the acute effect of these agents was investigated using the cell-free system described by Schumm and Webb [8]. In these experiments, the livers of the carcinogen-treated rats were tested 24 hr after a single injection of dimethylnitrosamine [19] or the last of 9 daily injections of thioacetamide [18]. The specific dosages are given under Material and Methods.

Figure 1 shows the acute effect of (a) thioacetamide or (b) dimethylnitrosamine treatment on RNA transport. The release of RNA from normal liver nuclei to normal liver cytosol (i.e. the control) is shown for comparison; note that the transport of labeled RNA essentially ceases after 30 min of incubation. The release of [^{14}C]-RNA from the nuclei to homologous cytosol prepared from liver 24 hr after cessation of treatment with thioacetamide was depressed to within 25% of the control value after 30 min incubation.

Thioacetamide-induced liver damage is observed despite the fact that the specific activity of the nuclear RNA is equivalent in the control and treated rats. In contrast, the release of messenger-like RNA from normal liver nuclei is markedly enhanced by incubation in medium containing cytosol from thioacetamide-treated rats. This enhancement, which amounted to 165% of the control value at 30 min incubation, was not observed when cytosol was prepared from an animal 2 hr after a single injection of thioacetamide (M. Hanausek-Walaszek, unpublished observations).

Similarly within 24, but not 2, hr of dimethylnitrosamine treatment (Fig. 1b), there is a 230% increase in the capacity of cytosol to support RNA release from normal liver nuclei during the 30-min incubation. However, in contrast to thioacetamide treatment, nuclei from dimethylnitrosamine-treated rats release considerably more RNA to either homologous, or control liver cytosol than do control nuclei, the release at 30 min being 250% for homologous cytosol and 175% for control cytosol. This enhanced release is not observed with partial hepatectomy alone. Thus, the nuclear

damage, which may be due to the toxicity of the carcinogens, as estimated by RNA release, is either different from that produced by thioacetamide, or it is repaired within the 24 hr period. The molecular basis for this early enhanced transport is not clear; however, the possibility that it is due to increased nuclease activity was ruled out since there was no change in the soluble counts and the addition of exogenous ribonuclease inhibitor prepared from rat liver (Searle Diagnostic, Arlington Heights, Illinois) did not decrease the amount of RNA transported. Furthermore, none of the RNA

Table 1. Temporal changes in the capacity of cytosol from hepatocarinogen-treated rats to support messenger RNA release from nuclei of normal (control) liver

Cytosol derived from liver of	Percentage of normal liver homologous system at 2 hr	1 day	5 days	1 month	2·5 months	4 months	9 months
Thioacetamide-treated (9 daily doses, 50 mg/kg)	82*	175	155	157	200	162	81
Dimethylnitrosamine-treated (one dose, 24 hr after partial hepatectomy, 50 mg/kg)	83	236	248	248	234	200	60

*This rat received a single dose of thioacetamide. Duplicate experiments checked to within 10% in this and subsequent experiments.

release can be attributed to nuclear leakage of the RNA, since essentially all was dependent on the presence of cytosol proteins (M. Hanausek-Walaszek, unpublished observations).

The temporal changes in the transport of messenger RNA in response to thioacetamide or dimethylnitrosamine treatment are summarized in Table 1. The enhanced capacity of cytosol from the carcinogen-treated rats to support [^{14}C]-RNA release from normal liver nuclei is observed as early as one day and persists for at least 4 months (i.e. in Table 1 the transport of RNA from normal liver nuclei of untreated or control rats to cytosol derived from the liver of carcinogen-treated rats is compared to transport from normal liver nuclei to homologous cytosol). The enhancement than falls to below control levels at approximately 9 months after the final treatment. This decline is not attributable to aging, as transport in systems derived from normal rats of equivalent age were similar to those of young adults. Thus approximately 5% of the total nuclear counts were being transported in systems derived from the livers of 9-month-old rats during a 30-min incubation (A. Yannarell, unpublished observations). Note that these changes, observed from several days to months after cessation of treatment, must represent permanent or semi-permanent changes in regulatory mechanisms of the cell rather than to non-specific toxic effects. Also since the animals appeared healthy and any tumors present at time of assay, when present, were extremely small and were excised before processing of the liver, the presence of tumor tissue could not account for the effects observed. It should be emphasized that the main point of these experiments is that the enhanced capacity of the cytosol from carcinogen treated rats to support RNA release persists for at least 4 months but is lost by 9 months.

The data in Table 2 describe the ATP-dependence of RNA transport from the liver nuclei isolated from rats 4 months and 9 months after the cessation of treatment with hepatocarcinogens. As shown previously [14], the release of RNA from normal liver nuclei is essentially ATP-dependent. In contrast, the

release of RNA from normal liver nuclei to the liver cytosol derived from hepatocarcinogen-treated rats was significantly ATP-independent. The ATP-independence varied from 30% in systems derived from dimethylamine-treated rats to 58% in comparable systems derived from thioacetamide-treated rats, both at 4 months after treatment. From an analysis of transport in the homologous and heterologous systems, it can be concluded that both the nuclei and cytosol contribute to this ATP-independent component. Furthermore, the loss of ATP-dependence does not appear to be fully accounted for by the enhanced capacity of the cytosol to support RNA transport since significant ATP-independent transport exists even beyond 9 months after termination of treatment despite the fact that the amount of [^{14}C] RNA released after 30 min of incubation is significantly lower than normal. (Note that the data in Fig. 1 show the acute affects of the carcinogens on RNA transport while the data in Table 2 show the effects observed 4 or 9 months after treatment.)

Effect of neoplastic transformation on RNA transport

As shown earlier [14], RNA transport in homologous systems derived from the moderately differentiated hepatoma 5123D and dedifferentiated Novikoff hepatoma is partially and completely ATP-dependent, respectively. Table 3 presents data on crossover experiments

Table 3. ATP-dependence of RNA release in homologous and heterologous cell-free systems derived from normal liver and the Novikoff hepatoma

Source of		Percentage of nuclear RNA transported

hepatoma	hepatoma	3·1	3·1

The data shown are the average of triplicate experiments; the standard errors were less than 10%.

between liver and the Novikoff hepatoma designed to identify the site of the lesion leading to ATP-independent RNA release. The hepatoma system is simpler to study than the hepatocarcinogen-treated liver system since the uncharacterized cytosol component responsible for enhanced RNA release is not present; in fact, normal liver nuclei release less RNA to cytosol from the Novikoff hepatoma than to cytosol from normal liver. The data in Table 3 clearly show that, in the case of the hepatoma, modification from ATP-dependence to independence which accompanies transformation resides solely in the nucleus; i.e., transport in the liver (nuclei): liver (cytosol) and hepatoma: liver systems is 0·1 and 3·5% respectively, and in liver: hepatoma and hepatoma: hepatoma 0·3 and 3·1%, respectively.

The existence of a pool of ATP in the nucleus of the Novikoff hepatoma cell could produce an apparent loss of ATP-dependent RNA transport. In order to eliminate this possibility, cells were incubated with ^{3}H-uridine for 10 min, followed by further incubation after the addition of 10 mM deoxyglucose, or 2 mM sodium cyanide for an additional 10 min prior to cellular disruption and nuclear isolation. As indicated in Table 4, this procedure did not alter the ATP-independence of the RNA release, although both the total counts in the

*The intact cells were pretreated with the inhibitors before isolation of the nuclei.

nucleus and the percent released after 30 min of incubation were decreased. This decrease was predictable since the reduction of the cellular ATP pools by cyanide and deoxyglucose would tend to inhibit RNA synthesis.

Under conditions employed in the present experiments (i.e. a 30-min prelabel *in vivo* followed by a 30-min *in vitro* transport) over 80% of the labelled RNA transported resembles messenger RNA since it is released as ribonucleoprotein particles with the density of informosomes [8, 20]. Because the nuclear processing of a significant fraction of the heterogeneous nuclear (pre-messenger) RNA includes the addition of a poly (A) tract to the 3′-end of the molecule [1], it was desirable to determine whether the proportion of transported messenger containing poly (A) tracts was affected by the elimination of ATP from the cell-free system. Therefore, the proportion of labeled poly (A)-containing RNA released

from Novikoff hepatoma nuclei to homologous, or heterologous cytosol in the presence and absence of ATP, was estimated by determining the percentage of transported RNA which bound to an oligo-dT-cellulose column [23]. The results of these experiments are shown in Table 5. Surprisingly, the proportion of transported labeled RNA containing poly (A) tracts was the same in the absence and presence of ATP in both liver and Novikoff cytosols. The fact that there is no reduction in the poly (A) content is consistent with the earlier observation [26] that interference with polyadenylate formation *in vivo* leads to decreased RNA transport *in vitro*. In agreement with this finding, it was observed that treatment of Novikoff hepatoma cells with cordycepin (3'-deoxyadenosine) caused a reduction in the percent of RNA transported but no change in the ATP-independence of the transport (Table 4). The validity of the results of the cordycepin experiments rests on the premise that cordycepin does not interfere with ATP metabolism.

DISCUSSION

Although the release of RNA from cell-free systems derived from the liver of hepatocarcinogen-treated rats clearly acquires a partial but significant ATP-independent component, the results also show an enhanced RNA transport during the first 4 months after treatment and a depressed transport after 9 months. However, when taken together the experimental evidence strongly suggests that a portion, if not all, of the ATP-independent transport observed after treatment with carcinogens is due to a specific lesion in RNA processing and, or transport. There is, however, one observation, not yet explicable, between the lesions(s) which characterizes the loss of ATP-dependence of RNA transport in the liver of hepatocarcinogen-treated rats (i.e. preneoplastic liver) and the Novikoff hepatoma (neoplastic liver). In the former, both the nuclei and the cytosol appear to contribute to the phenomenon, while in the latter, the lesion is clearly localized to the nucleus. The observed loss of ATP-dependence of RNA transport following pretreatment with liver carcinogens are in general agreement with previous studies [15–17], the results of which are discussed below. The results of the present study rule out mere leakage of RNA from the nuclei since the transport in both the liver and hepatoma systems is completely dependent on macromolecules in the cytosol.

As noted above the loss of ATP-dependence of RNA transport, as exemplified by the Novikoff hepatoma, is attributable to an alteration in the nucleus. The fact that there was no decrease in the proportions of messenger RNA containing poly(A)-tracts transported from the Novikoff hepatoma nuclei when ATP (and phosphoenolpyruvate) was omitted from the incubation medium, suggests that in tumor cells the poly(A) tracts may be added to the nuclear pre-messenger RNA much sooner after synthesis than in the normal cell, although a number of other explanations are possible. It does not appear to be due to a large nuclear pool of ATP in the tumor cells. The elucidation of this difference awaits further study.

On the other hand, ATP also appears to be necessary for RNA transport through the nuclear pores of normal liver tissue both *in vivo* and *in vitro* (i.e. in the cell-free system). Thus beryllium nitrate, an inhibitor of nuclear pore phosphatase inhibits messenger RNA release from normal and neoplastic cell nuclei in proportion to their ATP-dependence [14]. For example, RNA transport in the cell-free systems derived from normal liver, Hepatoma 5123D and the Novikoff hepatoma were inhibited approximately 80%, 35% and 2% by 30 mg/ml of beryllium nitrate; the corresponding energy-dependence of RNA transport in these systems are 100%, 25% and 0%, respectively. Together these results suggest that the loss of energy-dependence in the tumor is due to changes at the level of the nuclear pore complex. In this regard, it is of interest that in precancerous liver, cell foci induced by diethylnitrosamine can be identified as adenosine triphosphatase-deficient islands [27, 28]. It is tempting to speculate that this enzyme deficiency and the loss of ATP-dependent transport are related. However, the fact that the adenosine-triphosphate-deficient islands in the livers of carcinogen-treated rats account for less than 1% of the tissue mass [27] makes it unlikely that such islands alone account for the ATP-

Table 5. Proportion of labeled RNA containing poly (A) tracts released from Novikoff hepatoma nuclei to Novikoff and liver cytosol in the presence and absence of ATP

–	22	19
+	22	18

independent transport observed in the hepatocarcinogen-treated livers. One explanation is that the treatment with carcinogen may lead not only to a complete deletion of adenosine triphosphatase in a few cells which constitute the foci of precursor tumor cells, but rather to a partial reduction in the activity of this enzyme in most of the parenchymal cells and that the latter decrease is not observed by the histochemical test. It is clear that further studies are required to determine whether the loss of this enzyme and the ATP-dependence of RNA transport are related events.

Aside from the locallization of the apparent lesion in tumor cells to nuclear RNA processing and/or transport the ATP-independent transport of RNA from nuclei of the Novikoff hepatoma provides further clues concerning the site of action of ATP. Thus the fact that RNA release from Novikoff nuclei is ATP-independent whether they are incubated in normal liver or hepatoma cytosol, and conversely the ATP-dependence of RNA transport from normal liver nuclei when incubated in either cytosol, rules out the possibility that the ATP-requirement in the normal cell is related to phosphorylation of the cytoplasmic proteins required for RNA transport. The possibility that energy donors other than ATP contribute to this ATP-independent-transport is doubtful. Since the cytosol is dialyzed, such pools, which are obviously absent from normal liver nuclei would have to be sufficient to support RNA transport for 30 min and this despite the loss of nucleotides during nuclear preparation. Furthermore, regeneration of such nucleotides would require ATP.

It is clear that the *enhanced* RNA transport characteristic of cell-free systems derived from hepatocarcinogen-treated rats is due to an increase in the capacity of the cytosol to support RNA transport. Such a change may result from an increase in the positive feed-back, or a decrease in the negative feedback transport factors, both of which have been shown to regulate messenger RNA release in the cell-free system [13]. The modified RNA transport and/or loss of ATP-dependence may account for the defective regulation of hepatic tyrosine transaminase observed after treatment of the rats with dimethylnitrosamine or thioacetamide [29].

The results of the present study relative to the development of ATP-independence of RNA release from liver nuclei following treatment of rats with hepatocarcinogens are in general agreement with the results of Smuckler and coworkers who studied the effect of acute intoxication [16] with thioacetamide; these studies were restricted to the period zero to 72 hr after a single dose of 50 or 200 mg/kg of body weight. These workers observed an initial drop in RNA (RNP) transport and a release of significant portion of RNA from the treated livers in the absence of ATP. In a further study utilizing this protocol, they reported [17] that the acute thioacetamide intoxication was associated with the appearance of more cytoplasmic RNA's (*in vivo*) with migrations of 9–16S, with increases in the proportion containing poly(A) and an enhanced leakiness of the nuclei toward 9S RNA *in vitro*. The *in vitro* studies utilized in modified form the RNA transport system originally developed by Ishikawa *et al.* [6], which in contrast to the system used in the present study does not show cytosol-dependence of RNA release. The RNA release in the Ishikawa system is also much higher than that of Schumm *et al.* (i.e. over 20% cf. 5%). This difference may be partially accounted for by the longer (40 min) *in vivo* labeling period employed [16] which would be expected to result in the transport of considerable labeled ribosomal RNA together with labeled messenger and 4S RNA. It should be noted in this regard that the degree of conversion of heterogeneous nuclear RNA to messenger RNA in some eukaryotic cells may vary from 4 to 20% [30]; furthermore, a large fraction of this labeled nuclear RNA is ribosomal precursor which after a 30-min *in vivo* label, is not transported in our system unless the *in vitro* incubation is extended beyond 30 min [8]. The reason for the difference in cytosol dependence of the two cell-free systems is less clear. Recent evidence from this laboratory indicates that the cytoplasmic transport factors are very specific and in low concentration in the cytosol [22, 31]; they can not be replaced by non-specific proteins such as dialyzed normal plasma [32], or 10 mg/ml of β-macroglobulin or serum albumin (D. E. Schumm, unpublished observations). The system of Schumm *et al.* [8] would appear to be useful for the study of nucleocytoplasmic controls in normal and neoplastic cells; however, both systems have detected changes in ATP-dependence of RNA transport incident to carcinogenesis.

Effect of Drostanolone Propionate on the Binding of Oestradiol and Dihydrotestosterone by Normal and Malignant Target Tissues*

GÜNTHER TRAMS

Department of Obstetrics and Gynecology, University of Hamburg, Hamburg-Eppendorf, Germany

Abstract—*The influence of drostanolone propionate, an anticancer agent, was tested on the binding of 17β-oestradiol and dihydrotestosterone to specific receptor proteins in tissue of normal and neoplastic target organs. Steroid binding capacity was measured by agar gel electrophoresis of tissue extracts.*

Drostanolone was found to compete with androgen binding sites but not with oestrogen receptors. Therefore it is unlikely that the growth inhibitory effect of drostanolone propionate in human breast cancer is mediated through interaction with oestradiol binding proteins as suggested earlier by other authors.

INTRODUCTION

DROSTANOLONE propionate (2α-methyl-dihydrotestosterone propionate, Masterid,® Fig. 1) has been reported to be an anti-cancer agent for advanced human breast cancers [1–4] and also for 7,12-dimethylbenzanthracene(DMBA)-induced mammary tumours of the rat [5].

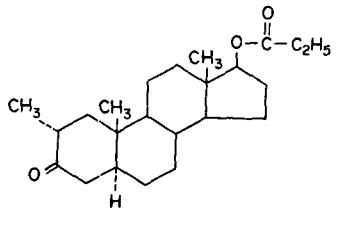

Fig. 1. Structure of 2α-methyl dihydrotestosterone propionate.

Deshpande *et al.* [6] had shown that pretreatment with this compound decreased the uptake of injected ^{3}H-oestradiol in human mammary tumors compared with normal breast or other tissues. Therefore they draw the conclusion that the growth inhibitory effect of drostanolone propionate is mediated through a reduced uptake of oestradiol by the tumor. Under this aspect it was of interest to study the influence of drostanolone propionate on the binding of 17β-oestradiol and 5α-dihydrotestosterone (5α-DHT) to specific cytoplasmic receptor proteins and to the sex hormone binding globulin (SHBG) of the plasma.

MATERIAL AND METHODS

Chemicals

(6,7-^{3}H) 17β-oestradiol (spec.act. 48 Ci/mM) and (1,2-^{3}H)-5α-dihydrotestosterone (spec.act. 49 Ci/mM) were purchased from New England Nuclear Corp., Boston, Mass. The purity (> 94·0%) was checked by thin layer chromatography. The anti-oestrogenic compound U. 11·100 (nafoxidine) was a gift from the Upjohn Company, Kalamazoo, Mich., drostanolone propionate was provided by the Chemie Grünenthal, Stolberg, and cyproterone acetate by the Schering AG, Berlin. All other chemicals were purchased from E. Merck, Darmstadt or Boehringer, Mannheim and were of analytical grade.

Tumour induction

Mammary carcinomas were induced in female Sprague–Dawley rats by a single feeding of 50 mg DMBA at day 50. DMBA was

Accepted 31 August 1976.

*This work was supported by DFG, Sonderforschungsbereich 34, "Endokrinologie".

dissolved in sesame oil (50 mg/ml). Starting 4 weeks after the carcinogen appearance of tumors was assessed by palpation. Tumor sizes were measured weekly by calipers in the two greatest dimensions (D and d). Tumor mass was calculated by the formula $V = D \times (d)^2/2$ [7]. Ovariectomy in rats was performed at the time when tumors had reached a diameter of at least 2 cm. Those tumors which regressed after removal of the ovaries were called "hormone dependent".

Receptor assay by agar gel electrophoresis

Tissue was frozen in liquid nitrogen immediately after removal and pulverized with the Mikro-Dismembrator (Braun, Melsungen). The fine powder was transferred to a centrifuge tube and four volumes (vol/weight) Tris–HCl buffer (0·01 M, pH 7·5, 1 mM NaN_3) were added. After thawing the sample was centrifuged for 90 min at 40,000 rev/min. (157,000 g_{av}) and 2°C (L2–65B, Beckman Instr.). The supernatant was removed by pipetting and used immediately. Aliquots of the extract were incubated at 4°C overnight with (6·7-^{3}H)-oestradiol or ^{3}H-5α-DHT in presence or absence of radioinert compounds without shaking. The concentrations used are defined in the legends of the figures. At the end of the incubation period, aliquots (50 μl per well) of each sample were subjected to gel electrophoresis, which was performed according to Wagner [8]. Gel layers were prepared with a 1% agar solution (0·05 M Michaelis buffer, pH 8·2). In the centre line of the gel plate, wells were punched out and 50-μl aliquots of the labelled extracts were applied. Two wells were charged with material from one sample. The prepared gel plates were then placed on a teflon coated brass plate within an airtight electrophoresis chamber. The plate was cooled to 2°C. Electrophoresis was carried out for 90 min at 110 mA/300 V. After the run, the gel was divided lengthwise and then cut into 3 mm wide sections. Radioactivity was eluted from the strips with scintillation fluid (7·0 g PPO, 0·3 g dimethyl-POPOP, 100 g naphthalene in 1000 ml dioxane) for at least 4 hr before counting.

Total protein content of tissue extracts was determined according to Lowry *et al.* [9].

RESULTS

In a first series of experiments we tested the effect of drostanolone on the oestrogen binding capacity of normal and neoplastic target organs. Aliquots of cytosols prepared from calf uterus or human breast cancer tissue were incubated with ^{3}H-oestradiol in presence or absence of Nafoxidine or drostanolone propionate. The electrophoretic analyses of the labelled extracts are demonstrated in Figs. 2 and 3. The anodical peak, stretching from the starting line (indicated by the arrow) to fraction 20, represents the receptor bound steroid, while the free hormone is shifted towards the cathode (left side in the figures).

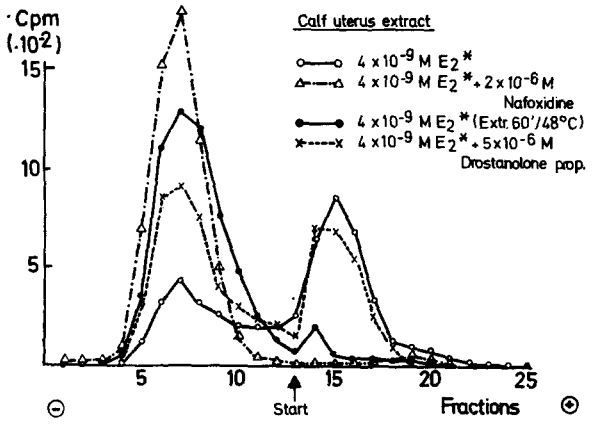

Fig. 2. Determination of oestradiol binding in calf uterus cytosol by agar gel electrophoresis in absence and presence of Nafoxidine and drostanolone propionate, respectively. Protein content of the cytosol was 8·2 mg/ml.

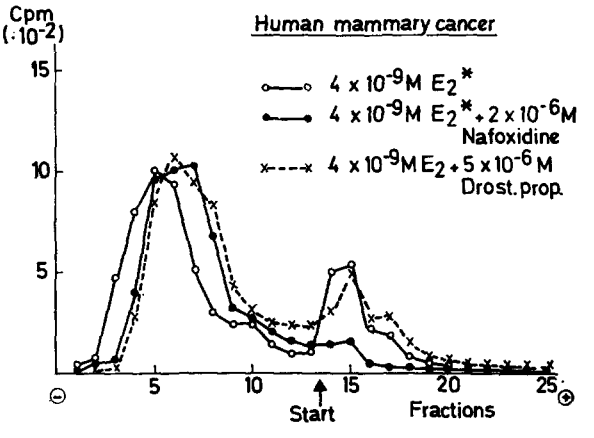

Fig. 3. Determination of oestradiol binding in human mammary cancer cytosol by agar gel electrophoresis in absence and presence of Nafoxidine and drostanolone propionate, respectively. Protein content of the cytosol was 12·4 mg/ml.

Inactivation of the binding protein by heat (60 min at 48°C) or displacement of the labelled oestradiol by the anti-oestrogenic compound Nafoxidine results in a disappearance of the receptor bound labelled hormone and in an increase of the cathodical peak by the liberated steroid. In contrast to this finding drostanolone propionate added in a 1000-fold excess does not compete at the oestrogen-specific binding sites. This holds true both for

calf uterus (Fig. 2) and for human breast cancer tissue (Fig. 3) demonstrated by the persistence of the receptor peak (broken line).

With respect to the fact that drostanolone propionate is a testosterone derivative it was obvious to test this compound on its androgen binding characteristics. As the simultaneous occurrence of oestrogen and androgen receptors was described as well for calf uterus [10] as for human mammary cancer [11–14] the cytosols of these tissues were likewise assayed for their androgen binding capacity. Extracts were incubated with ^{3}H-5α-DHT and analysed electrophoretically in the same manner as described above (Figs. 4 and 5). The 5α-DHT-receptor-complex is characterized by the same mobility as the oestrogen binding protein. The analysis of the tumour extract (Fig. 5) moreover illustrates the clear discrimination between receptor protein and the sex hormone binding globulin (SHBG) from the serum. The last one binds favouredly 5α-DHT and migrates towards the cathode. Addition of a

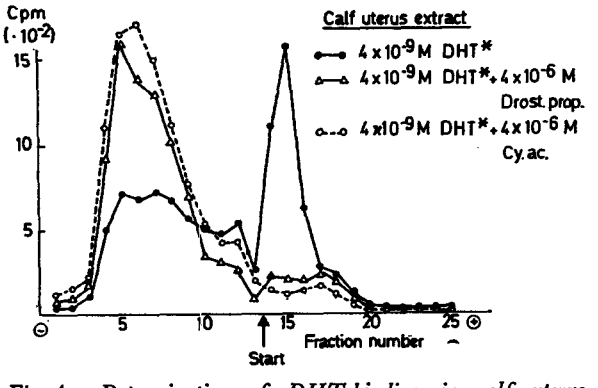

Fig. 4. Determination of DHT-binding in calf uterus cytosol by agar gel electrophoresis in absence and presence of drostanolone propionate and cyproterone acetate, respectively. Protein content of the cytosol was 7·2 mg/ml.

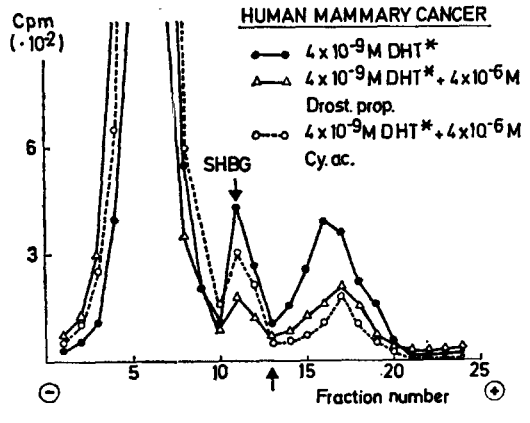

Fig. 5. Determination of DHT-binding in human mammary cancer cytosol by agar gel electrophoresis in absence and presence of drostanolone propionate and cyproterone acetate, respectively. Protein content of the cytosol was 8·0 mg/ml.

1000-fold excess of the anti-androgen cyproterone acetate or of drostanolone propionate results in a decrease of radioactivity at the anodical peak, which is due to competition at specific receptors sites. This competition is less pronounced for SHBG by cyproterone acetate than for drostanolone propionate. Figure 6 shows the electrophoretic pattern of a cutaneous metastasis, which was assayed for oestrogen and androgen receptors. This specimen was derived from a patient with metastatic breast cancer who showed remission after treatment with drostanolone propionate. This medicament

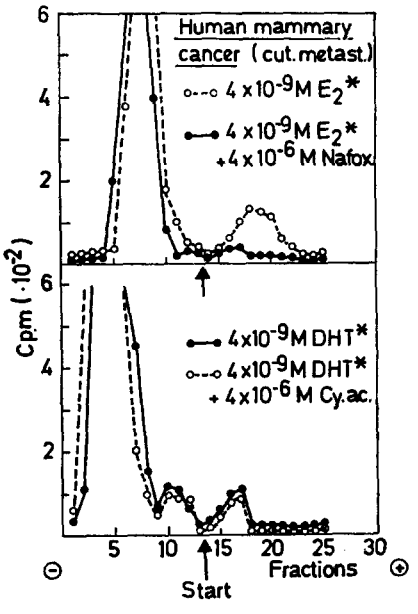

Fig. 6. Determination of oestradiol and DHT-binding in human mammary cancer. Because of cutaneous metastases the patient was treated with drostanolone propionate before excision of metastatic tissue for receptor assay (for further details see text). Protein content of the cytosol was 5·6 mg/ml.

was given (3 × 100 mg/week) over a period of 17 months up to 7 days prior to excision of the tumor. This tumor possesses oestrogen receptors (34 fmole/mg protein), but no DHT-binding is obtained (lower panel). This effect may be due to a primary lack of androgen receptors or it is due to a depletion of spare DHT-receptor sites by the abundance of circulating drostanolone. Kinetic studies [15] have shown, that after a single injection of drostanolone propionate the maximal concentration of free drostanolone in serum remains at a constant level between day 4 and 12 after administration.

DISCUSSION

This investigation was undertaken to obtain some more insight into the mechanism by

which drostanolone propionate exerts its growth inhibitory effect on a variety of mammary tumours. The data presented clearly indicate a competition for androgen binding sites in the cytosols of uterus as well as human breast cancer tissue. In contrast to these findings drostanolone propionate does not affect the oestrogen binding capacity of these target tissues.

Because of these findings it is unlikely that drostanolone propionate exerts its growth inhibitory effect in mammary tumors by competition for specific oestradiol receptor proteins. This is contradictory to the findings of Deshpande *et al.* [6] who noticed a pronounced reduction of 17β-oestradiol in breast cancer tissue after pretreatment with the androgenic compound. Discussing this point it must surely be stressed that the experimental conditions of the studies mentioned were different. Deshpande *et al.* and Braunsberg *et al.* measured the uptake of ^{3}H-oestradiol, which was applicated *in vivo* after pretreatment of the patient with drostanolone propionate. Heise and Görlich and our group determined the specific binding of ^{3}H-oestradiol *in vitro* adding the androgenic compound simultaneously with the labelled steroid. That means that the results obtained by Deshpande *et al.* and Braunsberg *et al.* are comparable regarding the experimental procedures. But in contrast to Deshpande's work the infusion experiments of Braunsberg *et al.* as well as the *in vitro* studies of Heise and Görlich support our results. Both groups likewise could not demonstrate an effect of drostanolone propionate on oestrogen binding in their assay systems.

Recent studies [15] have shown, that drostanolone propionate itself is the active growth inhibitory compound and not a metabolite.

Based on studies on DMBA-induced mammary tumors in rat Van Der Gugten [18] and Hagen *et al.* [19] have suggested that the effect of drostanolone propionate is mediated through a decrease of prolactin secretion by the pituitary gland. Our investigations did not deal with this possibility and it is still open whether the results of these authors are true for human breast cancer.

Abstract—*Six cases of massive liver involvement by metastatic breast cancer who responded to combination chemotherapy are reported. Prior to treatment, positive liver biopsy was obtained in five patients. Liver size was accurately measured by scintigraphy. The relative volume of neoplastic tissue was assessed on the scans by a stereological method and ranged from* 42 *to* 77%. *Improvement of liver involvement under chemotherapy was remarkable both with regard to liver size and relative neoplastic volume which decreased to between* 5 *and* 55% *of the initial value. Control liver biopsies were obtained in four patients and were negative.*

INTRODUCTION

MASSIVE liver involvement by metastatic breast cancer is notoriously resistant to endocrine therapies [1]. Thus Nemoto *et al.* [2] reported that regression occurred in only one out of 13 patients subjected to adrenalectomy or ovariectomy, who had more than one third of the liver replaced by tumour tissue. In contrast, nine out of 21 patients with limited liver involvement responded to these treatments. The use of single-agent chemotherapy has not improved the therapeutic response of liver metastases [3], the remission rate being around 20%. The introduction of multiple drug chemotherapy of breast cancer seems however to have improved the situation [4, 5]. Nevertheless documentation of liver involvement and response to treatment is difficult because there is no irrefutable method of assessment [6, 7]. Although there is a controversy as to the accuracy of liver scanning in detecting liver disease it could provide the most accurate measurements of the liver size, an exact anatomical localization and recognition of filling defect [8, 9].

Our purpose is to report six cases of massive liver involvement by metastatic breast cancer, i.e. replacement of more than one third of the organ by tumour tissue, who dramatically responded to combination chemotherapy. Assessment of response was carried out by means of stereological method of estimation of the relative metastatic tissue volume from liver photoscans.

MATERIAL AND METHODS

Six cases of metastatic breast cancer patients were selected on the basis of their massive liver involvement and most impressive response to combination chemotherapy, as judged by serial scintigrams. No attempt was made at estimating the exact proportion of liver responses by a systematic analysis of all cases treated.

The median age of the patients was 60

(range 49–78). Biopsy proof of breast carcinoma was obtained in each. All but one (patient No. 5) were postmenopausal. They had widespread disease, always involving both liver and other sites except for patient 5 who had only liver involvement. All but one (patient 1) had undergone surgery and radiotherapy as treatment of the primary. Patient 1 had been subjected to adrenalectomy. All had progressive disease at the time of the study.

The liver status was assessed prior to treatment by clinical examination, liver function tests, liver scanning and liver biopsy under direct visualisation (patient 3 had neither peritoneoscopy nor liver biopsy prior to treatment). In most patients liver function tests were repeated about every 6 weeks after initiation of therapy and liver scanning approximately every 3 months. At least two control scans were performed in the course of treatment except in patient 6, for whom only one was available. Control laparoscopy was carried out and control biopsies were obtained in all cases except for patients 1 and 5.

Patients 1 and 2 received a five-drug combination chemotherapy as described by Cooper [10]. Patients 3–6 received a hormonal–cytotoxic combination chemotherapy that is currently being tried by the European Organization for Research on Treatment of Cancer (E.O.R.T.C.) Breast Cancer Cooperative Group (study protocol 10741; preliminary results reported by Engelsman *et al.* [11]). This chemotherapy comprises tamoxifen (ICI 46474), an antioestrogen, given orally at the dosage of 20 mg twice daily and cytoxic agents given as two alternating cycles of 28 days; first cycle: adriamycin 75 mg/m^2 i.v. on day 1 and vincristine, 1·4 mg/m^2 i.v. on days 1 and 8; second cycle: 5-fluorouracil, 600 mg/m^2 i.v. on days 1 and 8, methotrexate, 60 mg/m^2 i.v. on days 1 and 8 and cyclophosphamide, 100 mg/m^2 orally from days 1 to 15. Patient 4 had dexamethasone in addition.

Liver scintigraphy was performed with a conventional rectilinear scanner. ^{198}Au (150 μCi) was injected i.v. 1 hr before scintigraphy. Relative volume of metastatic tissue was calculated from photoscans by a method derived from the stereological technique described by E. R. Weibel for applications in electron microscopy [12]. For that purpose a regular point lattice was drawn on transparent paper, each point (intersection of two lines) being one cm apart. This lattice, larger than the photoscan, was placed at random on it. A differential count of the points lying on normal (P_n) or pathological images (P_p) was made, the total number of points (P_t) lying on the image being $P_t = P_n + P_p$. From these data, relative volume of metastatic tissue (V_p) is obtained, $V_p = P_p/P_t$. Counting was carried out independently by two of the authors. The results used are the means of the two independent countings. Pathological foci were defined as areas of hypocaptation with at least 24% less activity than the surrounding tissue. This value was established from phantom experiments on the scanner used.

RESULTS

Liver status prior to treatment is described in Table 1. Physical examination revealed a hard and irregular enlargement of the liver in all patients (liver edge palpated from 5 to 20 cm below the costal margin on the midclavicular line). The enlargement was painful in most patients. Direct visualisation by laparoscopy (4 cases) or laparotomy (1 case) and liver biopsy confirmed the physical findings; gross metastatic involvement was present in all. All liver biopsies were positive. Serum alkaline phosphatase and γ-glutamyl trans-

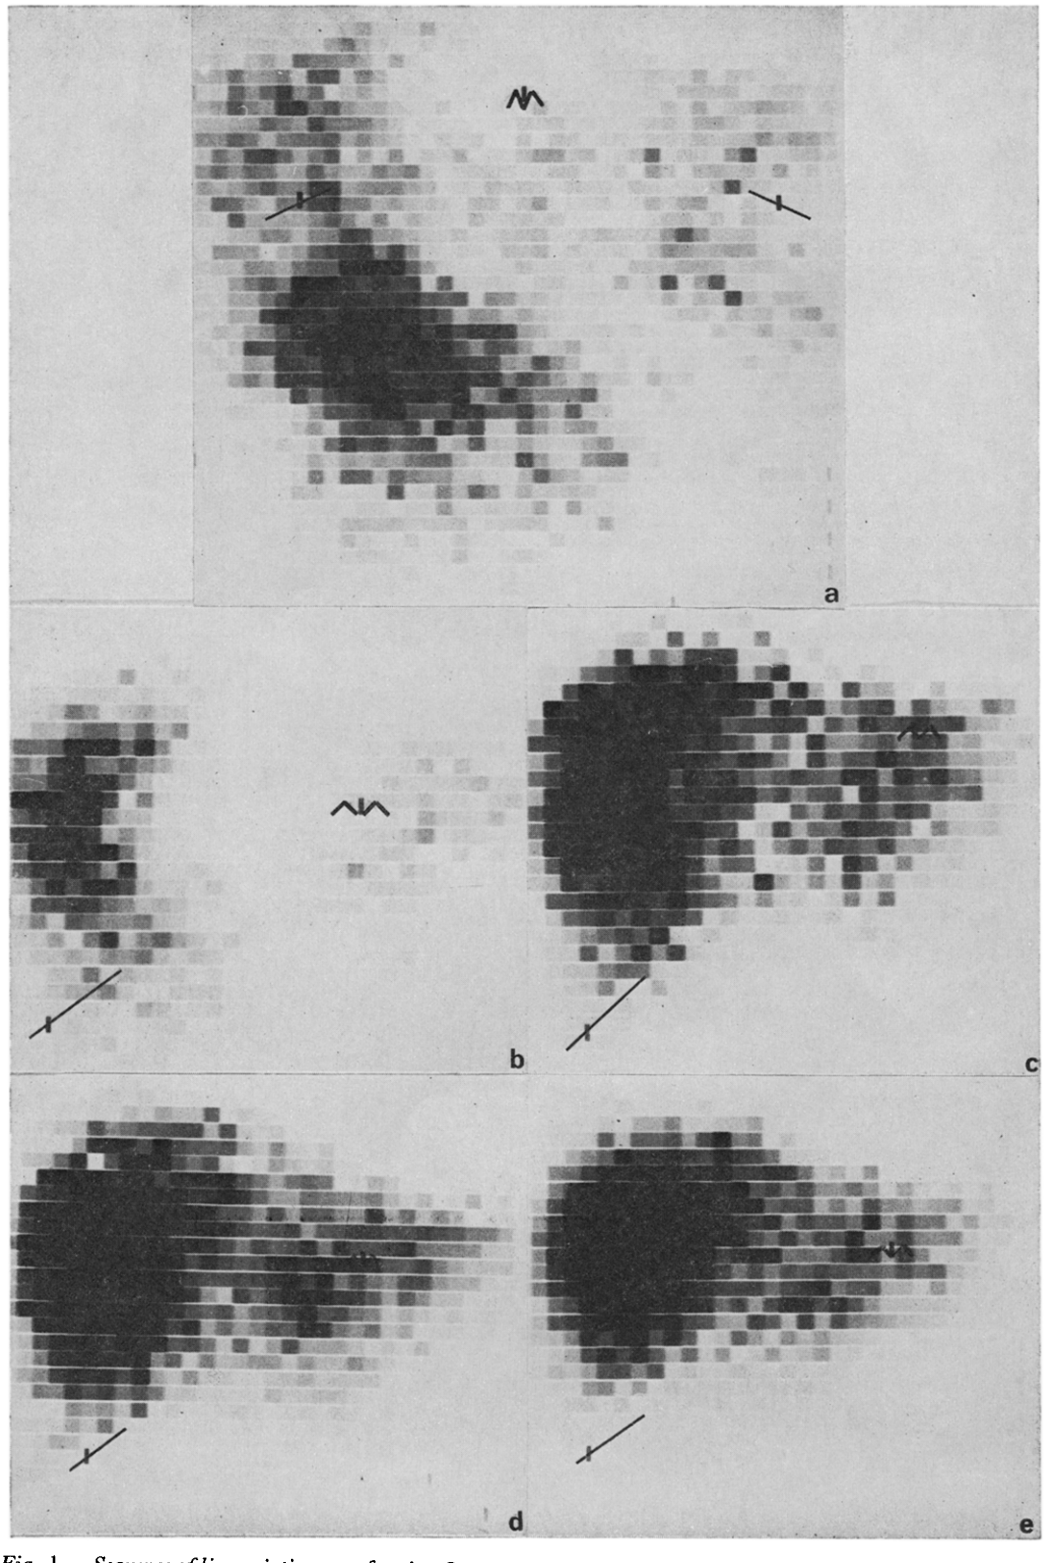

Fig. 1. *Sequence of liver scintigrams of patient* 3 *: picture* "a" *represents the scan made prior to treatment— pictures* "b" *to* "e" *are done* 3, 6, 9 *and* 14 *months after onset of treatment.*

peptidase were elevated in all cases. Serum transaminases were also abnormally elevated in all and total bilirubin in three. No patient had signs of severe liver failure.

Scintigraphy disclosed enlargement of the liver and multiple filling defects in all cases. Mean height of right lobe was 22·8 cm (21–27), (normal < 16 cm) and of left lobe 15 cm (12–18) (normal < 8 cm). Mean relative volume of neoplastic tissue was 51% (42–77%).

Evolution of liver involvement was estimated on consecutive scans. As illustrative of the evolution of all cases sequence of scans for patient 3 is shown in Fig. 1. Figure 2 represents the change in estimated relative neoplastic volume for all patients. It is expressed as per-

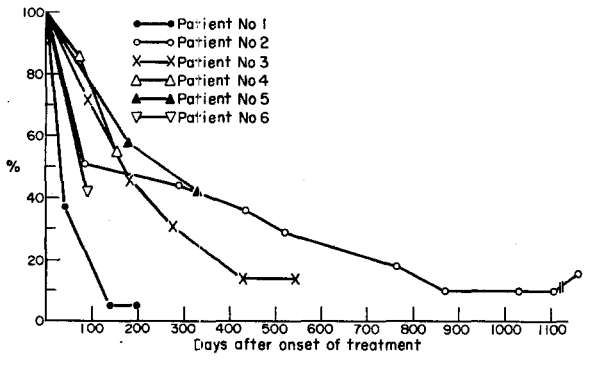

Fig. 2. Evolution of the relative volume of metastatic tissue in the liver, from onset of treatment, expressed as percentage of the initial value.

centage of the initial value. Already on the first control scan done between 40 and 182 days (average 94) after onset of therapy, the estimated relative neoplastic volume had dropped on the average to 58% (37–86%) of the initial value. At the time of the second control scan done between 141 and 382 days (average 219) (five patients) it had further dropped to 38% (5–55%). In patient 1, relative involvement dropped to 5% already after 140 days of treatment. In patients 2 and 3, relative neoplastic volume was reduced to lower than 15%; this value was maintained on subsequent scans for both patients. At the time of the last scan patient 2 had been off treatment for 22 months; six scans have been obtained since, the sixth shows an increase of the metastatic volume. Patient 3 was on treatment for 24 months and is now off treatment since 3 months. The remaining patients had a reduction of more than 50% of the neoplastic volume except for patient 4 who had a reduction of only 45%. Liver size decreased within normal limits both on liver scan and physical examination except in patient 4. Liver function tests came back to normal in all but one patient (patient 1) at time of the first control scan with the exception of alkaline phosphatase for which normalization occurred a few months later. Patient 1 had only a marked improvement of liver function tests. After a few months of treatment a control peritoneoscopy and needle liver biopsy could be performed in all patients except patients 1 and 5. There was no evidence of neoplastic disease neither on macroscopic visual inspection nor on microscopic examination. Patient 6 had a second control liver biopsy with still no evidence of neoplastic disease. Patient 1 died 3 months after treatment had been stopped (8 months after onset of treatment); no details are available concerning the cause of death. Patient 2, over 3 yr after onset of treatment and being off treatment for the last 22 months, relapsed with brain metastasis and hepatic reoccurrence (filling defect appeared on the scan and there was an increase to 15% of the relative metastatic volume). Patient 3 was treated for 2 yr and is off treatment for 3 months. Patient 4 died 2 months after cessation of treatment (9 months after onset of treatment); no details are available concerning the cause of death. Patient 5 is still on treatment for nearly over a year now. Patient 6 who had two control liver biopsies without evidence of neoplastic disease died of hepatitis (most probably of viral origin) two months after arrest of treatment (7·5 months after onset of treatment). The second biopsy was done a few weeks before death and showed signs of hepatitis and cirrhosis but no neoplastic cells.

DISCUSSION

This paper describes the cases of six patients with massive liver involvement from metastatic breast cancer. Involvement was convincingly documented by physical examination, liver function tests, liver scintigraphy and in five cases confirmed by laparoscopy or peritoneoscopy and positive liver biopsies. An original procedure of assessment using a stereological method indicated that the proportion of liver replaced by neoplastic tissue exceeded one third.

These patients were thus characterized by two factors of ominous therapeutic response as far as the liver is concerned, i.e. involvement of more than one third [2] and changes in the liver function tests due to metastatic disease [13]. Such patients are considered far too advanced to be likely to respond to endocrine treatments [1] and even to chemotherapy when single drug regimens are used [3]. Recent

reports [4–6, 13] suggest that the response rate of extensive liver metastases has considerably improved since the introduction of combination chemotherapy although assessment of response of liver metastases is admittedly difficult to carry out with accuracy [6, 7]. In our series of patients, the initial proportion of the relative liver volume occupied by metastatic tissue was ranging from 42 to 77%. This proportion dropped to between 3 and 24% after treatment. In five out of six cases, there was at least a 50% reduction. With regard to the remaining involvement it is difficult to differentiate between actual metastatic tissue and healing-related fibrosis. It is noteworthy that those patients who had a positive laparoscopy and liver biopsy prior to treatments became negative by these tests. These results were obtained with two different combination chemotherapies. Two patients received the original Cooper regimen. The remaining four were receiving a combination of an antioestrogen and cytotoxic drugs, which was recently reported as being one of the most effective chemotherapeutic regimens now available for breast cancer [11]. It remains to be established what proportion of patients with massive liver involvement will significantly benefit from these forms of treatment.

Besides illustrating the remarkable quality of response that can be obtained in these patients by combination chemotherapy both with regard to the extent of tumour regression and duration of remission, this paper presents a possible way of monitoring therapeutic response of metastatic liver. Clinical findings and liver function tests are part of the routine for the overall evaluation of metastatic involvement and evolution but are not completely reliable. It appears that liver scintigraphy brings about a suitable means of objective assessment of liver size and the method used of stereological estimation of relative metastatic tissue volume adds valuable information for monitoring therapeutic response. However, it should be stressed that laparoscopy and needle biopsy are required to ascertain the metastatic nature of the liver disease and particularly of its regression.

Limitation of the Potentialities of Nephroblastoma Differentiation *In Vitro**

M. F. ROUSSEAU-MERCK,† M. N. LOMBARD‡ C. NEZELOF,† and H. MOULY†

†*Pathologie Pédiatrique, INSERM U 77, Hôpital Necker-Enfants Malades,* 75730 *Paris Cedex* 15, *and* ‡*INSERM U* 22, *Institut du Radium,* 91405 *Orsay, France*

Abstract—*The capacity of* 15 *human nephroblastomas to differentiate* in vitro *was studied. Chick and mouse embryonic tissues were used as inducers. Associating nephroblastomas with inducing tissues improved in* 6 *cases the growth and the survival of the explants and favoured in* 3 *cases a quantitative increase in the number of tubules when such structures were already present in the tumour* in situ. *No change was observed in* 9 *associated tumours and induction of tubules was not demonstrated with nephroblastomas which did not already contained such structures* in situ.

INTRODUCTION

An embryonic origin has often been suggested for nephroblastomas. A localized error in induction would allow an island of metanephrogenic mesenchymal cells to remain undifferentiated and dormant. The slow proliferation of this island could then progress unnoticed for several months or years to burst forth suddenly at a rate comparable to a normal growth of renal blastema [1] or with an accelerated and malignant evolution [2]. We therefore decided to study the *in vitro* potentialities of this tumour to differentiate or to continue to differentiate.

Our previous study on the behaviour of nephroblastoma in organ culture [3] has suggested the applicability of the *in vitro* association techniques between inductor and reactor tissues as first described by Grobstein [4] and currently used in studies of organogenesis [5]. These techniques have been applied to the study of a few tumours in man and in experimental animals [6–10] but only in a single case of a human embryonic tumour [6].

The differentiation of the metanephrogenic mesenchyme depends on ureteric induction in the chick embryo as was shown by Boyden [11] and by Grunwald [12]; Grobstein [13] later studied *in vitro* the epithelio-mesenchymal interactions required in the process of such differentiation of the mouse embryonic kidney. His collaborators later demonstrated that heterologous tissues could also induce the formation of tubules in metanephrogenic mesenchyme [14, 15].

Since human ureteric buds of 6–7 weeks-old embryos are not routinely available, we used chick ureteric bud [16] and mice mesencephalon [14] as inducer tissues. The validity of such an approach has been demonstrated by Waddington [17] concerning the zoological heterospecificity of induction and by Lustig *et al.* [9] concerning the application of such an induction to human tumours.

MATERIAL AND METHODS

Control associations

Combinations between embryonic tissues were made on 32 series of 12 chick embryos (5½ days) by cultivating during one week the metanephrogenic mesenchyme either alone or in combination either with the homologous ureter or with embryonic chick or mouse mesencephalon. Dissociation of ureter from metanephrogenic mesenchyme were made mechanically and the absence of any remaining metanephric mesenchyme was carefully checked under dissecting microscope.

Associations with nephroblastoma

Fifteen Wilms' tumours of varying histology were used (Table 1). Tubular and pseudo glomerular differentiations were particularly

Table 1. *Nephroblastomas associated with embryonic inducers*

ch = chick, M = mouse, ur = ureter, Mes = mesencephalon

clear in eight of them. Three nephroblastomas, including one irradiated metastasis, showed no tubular structures. Five of the patients had been treated preoperatively with chemotherapy or irradiation. The patients' age varied from 4 months to 9 years.

The tumours were grown as organ cultures using "Falcon" plastic organ culture dishes and disks of "Millipore" filter supports [3]. The cultures were grown at 37°C in Eagle's medium (Institut Pasteur, Paris) which was supplemented with 10% decomplemented calf serum and antibiotics (penicillin 200 u/ml, streptomycin 0·1 mg/ml) in the presence of air containing 5% CO_2.

The inducer tissues (the ureter or the mesencephalon taken from 3½ or 5½ day chick embryos or the mesencephalon of 11–15 day-mouse embryos) were combined with human tumour fragments *in vitro* (Table 1). The associations of embryonic tissue with tumour were made during the first two weeks of the organ culture of the tumour and were cultivated together for an additional 8 days. This association of the two tissues was carried out by placing directly adjacent to each tumour explant an identical volume of inductor tissue freshly removed from an embryo.

For each nephroblastoma, a minimum of 12 tumour explants were brought into contact with the inductive tissue. After termination of the experiments the explants were fixed in alcoholic Bouin solution, embedded in paraffin and 5μm sections were cut and stained with hematoxylin-eosin or with periodic acid–Schiff.

RESULTS

Control associations (*Table* 2)

Cultivated alone for one week the chick metanephrogenic mesenchyme condensed (Figs. 1 and 2) but did not form real tubular structures. If the metanephrogenic mesenchyme was cultivated together with ureter for one week it underwent differentiation and formed tubules (Fig. 3). Similar results were obtained when ureter and metanephrogenic mesenchyme were removed and cultured as one block. The appearance of these tubules was variable. Tubules of secretory type, edified from the mesenchyme, are seen close to rather large ureteric tubules. Secretory type of tubules are small and dark, showing sometimes a well differentiated S shaped tubule. A few preglomerular formations were also observed. When the chick metanephrogenic mesenchyme was associated with either homologous mesencephalon or with the mesencephalon of 11- to 15-day-mice embryos, it was found that the chick mesencephalic tissue had an inductive capacity comparable to that of homologous ureter, while mouse-chick associations were less powerful in inducing renal differentiations. The results are summarized in Table 2.

Associations with nephroblastoma

The survival of tumour fragments in organ culture was similar to what we have pre-

viously observed [3] and is generally reduced by preoperative treatment of the patient or the presence of muscular elements in the explants. No new tubule formation was induced by any of the combinations used with the 3 nephroblastomas which did not contain tubules *in situ*. In the nephroblastomas which originally contained tubules no further qualitative maturation became evident. Nevertheless, a quantitative increase of the tubules was observed in 3 cases.

Only one nephroblastoma (# 5) gave necrotic results in culture whether combined or not with inducer tissues. This result may be explained by the presence of muscular components in the tumour and by the preoperative treatment of the patient.

The combinations of tumour explants with chick embryo ureter led to a good intermixing of the cells. Eight nephroblastomas were combined (Table 1). One tumour was necrotic before combination (# 5). Three tumours, two differentiated (# 7, 8) and one not (# 4, Fig. 4) seemed unaffected by the association procedure since no difference was noted with the control explants. In the four other tumours we noticed a better survival of the explants when associated with chick embryo ureters. The size of combined explants increased or was maintained with culture time; the cellular aspect looked more "healthy" (nucleoli of normal size, good delimitation of the cells, mitoses) than in the control explants. In two of these nephroblastomas (# 9, 10) the number of tubules was also increased as compared with the *in vitro* isolated tumour (Table 3 and Figs. 5–7). In the third case (# 3) tubules were absent and in the fourth (# 6) only rosettes were present.

The nephroblastoma explants associated with chick or mouse mesencephalon remained in contact with each other but less completely than when associated with ureteric bud. Only 1 out of 6 combinations of the tumour explants with chick mesencephalon showed a survival of the culture which was comparable to the tumour–ureter combinations (# 6).

Nine tumours were associated with mouse embryo mesencephalon (Table 1). In 5 cases, two well differentiated (# 7, 8) and three not (# 11, 12, 13), no change occurred in the combined explants as compared with the

control explants. In the four other cases a longer survival was noted in the combined explants. In three such cases (# 9, 10, 15) associated nephroblastoma explants contained more tubules than the growing alone controls (Table 3 and Figs. 8–10). In the fourth case tubules were not numerous enough to be significantly evaluated in the explants.

With three differentiated nephroblastomas (# 9, 10, 15) the number of tubules per explant was calculated in relation with experimental conditions. From these measures the mean number of tubules per nephroblastoma explant was established and reported on Table 3 in relation with the association procedure and the duration of the culture. A two factor variance analysis was performed (# 9) = it showed that the factors association and time played a role (5% signification in both cases). A comparison of the mean number of tubules of the three groups (nephroblastoma alone, nephroblastoma + chick ureter, nephroblastoma + mouse mesencephalon showed that

(1) combination with ureter differs significantly from controls ($P = 0{\cdot}02$)
(2) combination with mouse mesencephalon differs at the limit of significance ($0{\cdot}10 > P > 0{\cdot}05$) for case 9 but was significant for case 10 ($P = 0{\cdot}05$).

With regard to the time factor the results during the first week *in vitro* differed from longer culture periods due to the fact that nine day cultures showed the higher relative incidence of tubules.

DISCUSSION

The purpose of our experiments was to test the possibility of nephroblastoma cells either to differentiate or to continue a differentiation which was already underway.

In the control experiments we tested the tubule inducing capability of several kinds of embryonic inducers some of which were heterospecific. Furthermore, we showed that chick mesencephalon can induce chick metanephrogenic mesenchyme to differentiate. We also demonstrated that heterospecific induction of renal differentiation is possible while using the combination of chick metanephrogenic mesenchyme with mouse mesencephalon. These latter two combinations were not previously tried by others. The inductive capability of chick ureter and mouse mesencephalon on homospecific metanephrogenic mesenchyme has already been demonstrated *in vitro* [14, 16]. Lombard and Grobstein [14] were also able to demonstrate the inducing capacity of 9 day chick embryonic mesencephalon on mouse metanephrogenic mesenchyme.

In our studies of nephroblastomas, we observed that they retained their general characteristics in organ culture. The association of tumour fragments with various embryonic tissues improved in some cases (6 out of 15) the *in vitro* survival of the fragments and maintained differentiation within them. Such *in vitro* stimulation of tumoral growth has been previously obtained by combining some embryonic tissues with tumours [18]. It is believed that embryonic tissues and yeast extracts [19] bring trophic factors to the culture, thus prolonging survival of the tumour cells. Biochemical analysis has also been attempted to demonstrate the nature of such stimulation [20]. Such studies suggest a metabolic cooperation (by enzyme product exchange) between the tumour and the embryonic cells as it has been observed in certain mixed cultures of mutant and non mutant cells [21].

Our results show an increase in the number of tubules in 3 nephroblastomas associated with embryonic tissues. This increase may be related to the nutrient action of embryonic tissues. A specific stimulation of tubule elongation produced by the inducer tissue during the second step of renal tubulogenesis [22] is an alternative possibility. Ellison *et al.* [8] have observed renal differentiation in 1 of 28 transplantable tumours which originated spontaneously in rat kidney when they associated rat or mouse embryonic tissues *in vitro* with tumour explants. This tumour originally had a few tubular formations *in situ* and differentiation appeared while the number of tubules in the associated tumour explants increased as the duration of culturing increased. The authors concluded that these tissue interactions showed no inductive capacity but were enhancing the latent ability of the renal tumour to differentiate.

Successful *in vitro* induction of another type of embryonic renal neoplasm have been reported. This tumour, a congenital mesoblastic nephroma, was often identified as congenital Wilms' tumour before it was described as a separate entity by Bolande *et al.* [23]. Crocker and Vernier [6] described *in vitro* induction of renal structures in such a tumour using 11-day-old fetal mouse dorsal brain or spinal chord as inducers. The renal differentiation progressed for 96 hr and produced "typical s-shaped fetal nephrons". This capacity to differentiate would appear to be correlated with the embryonic origin of the congenital nephroma and may be

one of the reasons for its benign clinical behaviour. Bolande [24] did not agree with the conclusions drawn by Crocker and Vernier because, in his experience, that type of tumour contains a natural mixture of normal and dysplasic nephronal elements. We had the opportunity to make *in vitro* inductive associations of two mesoblastic nephroma with mouse embryonic mesencephalon. Tubular structures were present in both tumours *in situ* as well as in the explants, whether combined with the inducer or cultured alone. However, the *in vitro* survival of the explants was not prolonged enough to permit a final conclusion on this matter.

The nephroblastomas which we studied responded only partially to the inducer tissues and for the most part retained without any change their more or less blastematous appearance. Induction of tubules was not demonstrated with the nephroblastomas which did not already contain such structures *in situ*. The reason for this may be that the embryonic inducers we used were not adequate, and further experiments using human embryonic inducers are certainly needed. The availability of such material is, unfortunately, very limited. Nevertheless, the numerous examples of heterospecific renal induction indicate that species differences are probably not the major obstacle to morphogenetic stimuli in our culture situation.

Acknowledgements—We are very grateful to Drs. O. Schweisguth, D. Pellerin and J. P. Gubler for giving us an opportunity to obtain tumour specimens under the best conditions, to Drs. A. Borit and J. Feingold for their helpful advice during the preparation of the manuscript and to Dr. D. Lawrence for reviewing the English version. We wish to thank Mrs. M. Grun for the histological preparations and Mrs. R. Salviat for breeding the mice.

Carcinoembryonic Antigen (CEA) in Patients with Breast Cancer*

NEIL M. BORTHWICK, DOUGLAS W. WILSON and PHILIP A. BELL

Tenovus Institute for Cancer Research, Welsh National School of Medicine, Heath, Cardiff, CF4 4XX, Wales, United Kingdom

Abstract—*Plasma CEA concentrations were measured in normal women and in patients with both primary and advanced breast carcinoma by means of a radioimmunoassay utilising rabbit anti-CEA antiserum. Fifty-five per cent of women with primary breast cancer had detectable levels of CEA (>0.1 U/ml), as compared to 13% in a random selection of the female population. The incidence of detectable CEA levels in benign conditions of the breast was less than 10%, but the largest incidence of detectable levels of CEA (70%) was in the group of patients with advanced breast carcinoma.*

In patients with primary cancer, no correlation was observed between the plasma CEA levels and either the presence of oestradiol-17β receptor proteins in the tumours or the menstrual status of the patient.

The effect of anti-oestrogen therapy on plasma CEA concentration in patients with advanced breast cancer was studied. A greater proportion of patients classified as clinical non-responders showed increased plasma CEA concentrations and fewer showed decreased CEA levels than in the case of the patients who responded to treatment.

INTRODUCTION

SINCE the first demonstration of the presence of carcinoembryonic antigen (CEA) in neoplastic tissue [1], elevated plasma levels of CEA have been observed in patients with tumours at various sites [2–5]. There has been considerable interest in using plasma CEA level measurements as an *in vitro* cancer test, but it has been shown that such measurements in apparently healthy individuals are not a suitable method for screening a population because negative results may be obtained in subjects with early carcinomata, whilst some non-malignant disorders are associated with elevated CEA levels [2, 4].

The value of plasma CEA measurement is more apparent in the management of patients whose diagnosis has already been established. It has been reported [2] that metastatic spread of breast cancer correlates with plasma CEA levels and that women with detectable CEA levels (> 2·5 ng/ml) had a faster recurrence rate after mastectomy than patients with lower CEA titres [6].

Accepted 13 September 1976.

*The authors are extremely grateful to the Tenovus Organisation for continuing financial support.

The present study was designed to determine the significance of plasma CEA levels in patients with advanced and primary breast cancer and in predicting the response to therapy with the anti-oestrogens clomiphene and tamoxifen which have been utilised in the management of breast cancer [7, 8].

MATERIAL AND METHODS

1. *Subjects*

The normal women in this study were volunteers resident in South Wales and were totally unselected women from the general population. We are grateful to Dr. P. C. Elwood of the M.R.C. Epidemiology Unit (South Wales) for providing these plasma samples.

The patients with primary breast cancer consisted of 74 women from whom blood was taken at the time of mastectomy.

The advanced breast cancer group comprised 95 patients with either local or widespread recurrence of the disease. In the groups treated with anti-oestrogens, samples were collected before the commencement of the therapy and at 3 months afterwards. Patients were given either tamoxifen (ICI 46474)

20 mg twice a day or clomiphene 100 mg orally twice a day for a minimum of one month. The clinical response was assessed as described by Golder *et al.* [9].

The plasma samples from the bronchial carcinoma patients were provided by Dr. J. V. Pritchard of Velindre Hospital, Cardiff.

The concentration of oestradiol-17β receptor proteins in the tumours was determined by the method of Powell-Jones *et al.* [10].

Blood was taken into lithium-sequestrene tubes and, after centrifugation, the plasma was stored at −20°C. Aliquots of plasma were transported frozen to the Tenovus Institute.

2. *CEA, ^{125}I-CEA, and anti-CEA antiserum*

CEA was a generous gift from Dr. D. J. R. Laurence of the Chester Beatty Institute, London. CEA was iodinated with $^{125}I^-$ by the method of Greenwood *et al.* [11]; the specific activity ranged from 80–120 μCi/μg.

Anti-CEA antiserum was raised in New Zealand white rabbits by intradermal injection [12] and was used throughout at a dilution of 1:4800 with normal rabbit serum (NRS) diluted 1:300. At this dilution, 30% of the radioactively labelled CEA was precipitated in the radioimmunoassay.

3. *Radioimmunoassay for CEA*

All dilutions were made in PBSE (0·05 M phosphate pH 7·4 containing 0·9% (w/v) NaCl and 1 mM EDTA). 100 μl (about 10^4 cpm) of ^{125}I-labelled CEA was mixed with 200 μl of either pooled plasma, pooled plasma containing a known amount of CEA, or the unknown sample. The plasma samples used to constitute the pool contained no detectable CEA. 200 μl Anti-CEA antiserum diluted 1:4800 in normal rabbit serum (NRS) 1:300 was added and the mixture incubated for 24 hr at 4°. 200 μl of sheep anti-rabbit antiserum diluted 1:30 was then added and the mixture incubated for a further 24 hr at 4°. The precipitate was separated by centrifugation in a Mistral 4L for 30 min at 800 *g* at 4° and counted in a Nuclear Chicago Gamma Counter.

For each level of non-labelled CEA and each plasma sample, incubations were carried out in duplicate. The results are expressed in units (U) of the First British Standard for Carcinoembryonic Antigen (CEA) C73/601 [13]. A mean value of 24 ng of the local standard of CEA was found to be equivalent to 1 U of the British Standard CEA.

4. *Analysis of RIA data*

A composite standard curve is shown in Fig. 1, together with values for the Coefficient of Variation of the estimations. The values of the response metameter B/B_0 were fitted to the CEA concentration using a 4-parameter model [14]. From the standard curve the maximum sensitivity of the assay, defined according to Kaiser and Specker [15], was found to be 0·1 U/ml and the probability of detection of

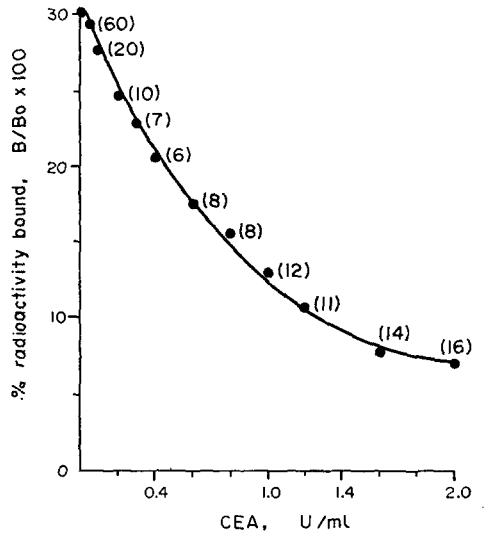

Fig. 1. Composition of standard curves prepared with anti-CEA antiserum from 6 successive assays. The coefficient of variation of the determination at each point on the curve is indicated.

this quantity from zero for the duplicate estimates used in this analysis was approximately 84%. The actual assay sensitivity for specified ranges was estimated by the method of Snedecor [16]; the results are shown in Table 1.

Table 1. Precision of plasma CEA determination expressed as estimates of the standard deviation (s) of results from the means

Range of CEA concentrations (U/ml)	*N*	s	Sensitivity ($P = 0·01$)
0 –0·4	46	0·03	±0·06
0·41–0·8	18	0·07	±0·13
0·81–1·6	10	0·18	±0·33

Pre- and post-treatment CEA levels of patients in the tamoxifen/clomiphene trial were compared using Student's *t* test. Values were considered different if $P < 0·05$. Patients whose pre-treatment CEA levels were below the

limit of sensitivity of the assay were excluded from this analysis.

RESULTS

Plasma CEA levels in normal women and patients with primary breast cancer

The levels of plasma CEA for an unselected group of women in a normal population and for patients with a variety of malignant diseases are shown in Table 2. The results show that detectable levels of CEA occurred in about 13–14% of a random selection of the female population when no account had been taken of the state of health of the volunteers.

In patients diagnosed as having primary breast carcinoma, the incidence of elevated CEA levels was about 54%, while less than 10% of a small group with benign breast disease had detectable CEA titres. However, in patients with advanced breast cancer, there was a marked increase in the number with elevated CEA levels, about 70% having levels greater than 0·1 U/ml and about 40% of these being greater than 0·4 U/ml. In comparison, a non-steroid-dependent tumour, bronchial carcinoma, showed detectable levels in about 45% of cases.

The relationship between plasma CEA levels in patients with primary breast cancer and the presence of oestradiol receptors in these tumours is shown in Table 3a. Patients with an oestradiol receptor concentration of less than 5 fmol/mg protein were defined as being receptor negative while those with a value greater than 5 fmol/mg protein were classified as receptor positive. In both receptor positive and receptor negative tumour bearing patients, the plasma CEA levels were elevated in 50–55% of cases.

A similar percentage of elevated plasma CEA levels was observed when the primary breast cancer patients were classified according to their menstrual status (Table 3b).

Plasma CEA levels in patients with advanced breast cancer and response to treatment with anti-oestrogens

The pretreatment plasma CEA levels in a group of 21 women with advanced breast cancer who were subsequently treated with tamoxifen

Table 2. Plasma CEA levels in the normal population and in various disorders

		Plasma CEA (U/ml)		
Condition	*N*	<0·1 (not detectable)	0·1–0·4	>0·4
Normal women	200	173 (86·5%)	27 (13·5%)	0
Primary breast cancer	74	33 (44·8%)	38 (51·3%)	3 (3·9%)
Advanced breast cancer	95	31 (32·6%)	36 (37·9%)	28 (29·5%)
Benign breast disease	22	20 (90·9%)	2 (9·1%)	0
Bronchial cancer	49	27 (55·1%)	15 (30·6%)	7 (14·3%)

Table 3. Comparison between plasma CEA levels, tumour oestradiol-receptor concentrations, and menstrual status in patients with primary breast cancer

a. Plasma CEA levels and oestradiol-receptor concentrations.

Plasma CEA (U/ml)	E_2 receptor +ve	E_2 receptor −ve
<0·1	14 (48·3%)	14 (45·1%)
0·1–0·4	14 (48·3%)	16 (51·6%)
>0·4	1 (3·4%)	1 (3·3%)
	N = 29	31

b. Plasma CEA levels and menstrual status

Plasma CEA (U/ml)	Pre-menopausal	Post-menopausal
<0·1	9 (50·0%)	19 (48·7%)
0·1–0·4	9 (50·0%)	17 (43·6%)
>0·4	0	3 (7·7%)
	N = 18	39

are shown in Table 4a, which also shows the levels in a group of 30 women subsequently treated with clomiphene. In the case of the tamoxifen series, elevated plasma CEA levels were present in about 60–70% of responders and non-responders alike, while this proportion was even higher in both classifications of the clomiphene series.

The effects of treatment with anti-oestrogens on plasma CEA levels are shown in Table 4b. Those patients whose pre-treatment plasma CEA levels were below the limit of sensitivity of the assay were excluded from this analysis; no positive pre-treatment value fell below the limit of sensitivity following treatment. Three months after the commencement of treatment, 19 patients were classified as responding to either therapy. Of these, 37% (7/19) showed no alteration in plasma CEA levels, while in 6/19 the level of CEA decreased in response to treatment. However, in 6 cases there was a significant increase in plasma CEA levels after 3 months.

Of the 22 patients classified as non-responders to either treatment 50% showed no changes in CEA levels after treatment. However the CEA titre fell in only one patient, and rose significantly in 10/22.

When the results were expressed as percentages of the initial CEA level (Fig. 2), there was a significant difference between the responders and non-responders. The mean and standard error for the responders was $101{\cdot}1 \pm 13{\cdot}5$ compared to $143{\cdot}6 \pm 13{\cdot}6$ for the non-responders.

DISCUSSION

In this study elevated plasma CEA levels have been demonstrated to occur in about 13% of a totally unselected number of the female population. This finding is in agreement with two previous studies [17, 18] in which elevated CEA levels in plasma were found in 11–16% of the population. In contrast to this, however, some studies [2, 19] have shown no positive CEA levels, while that of Wang *et al.* [6] found

Table 4. Pre-treatment plasma CEA levels in advanced breast cancer and the clinical response to anti-oestrogen therapy

a. Pre-treatment CEA levels

Patients	Treatment	Plasma CEA (U/ml) <0·1	0·1–0·4	0·4–1·0	>1·0
Responders ($N = 23$)	Tamoxifen	4	4	2	0
	Clomiphene	0	9	1	3
	Total	4	13	3	3
Non-responders ($N = 28$)	Tamoxifen	3	6	2	0
	Clomiphene	1	9	5	2
	Total	4	15	7	2

b. Response to anti-oestrogen therapy after 3 months

Patients	Treatment	Serial CEA levels Increase	No change	Decrease
Responders $N = 19$)	Tamoxifen	2	2	2
	Clomiphene	4	5	4
	Total	6	7	6
Non-responders ($N = 22$)	Tamoxifen	4	4	0
	Clomiphene*	6	7	1
	Total	10	11	1

*Two non-responders to clomiphene were not sampled at 3 months.

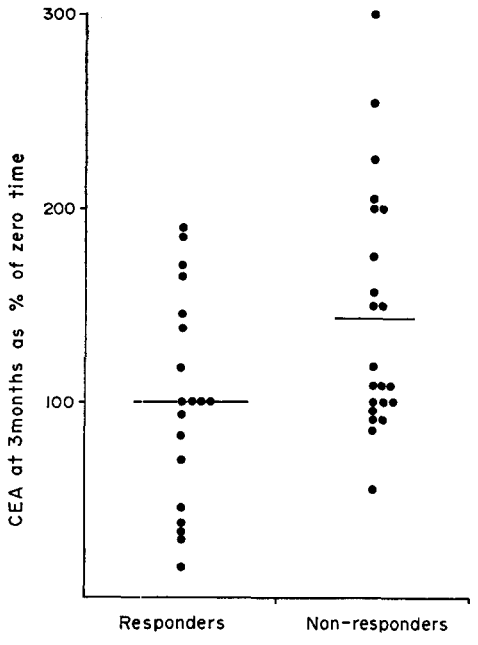

Fig. 2. Effect of anti-oestrogens on plasma CEA levels. Plasma CEA concentrations at 3 months are plotted as a percentage of pre-treatment values. Mean ± S.E.M. for responders was 101·1 ± 13·5 *and for non-responders was* 143·6 ± 13·6.

approximately 35% of a random group of women with raised levels of CEA.

The percentage of patients with primary breast carcinoma with an increase in plasma CEA concentrations was about 55%, a figure which is higher than the previously recorded values of 33–46% [2, 6]. However, the CEA levels tended to be lower than those from patients with advanced breast cancer. The incidence of high CEA levels in benign conditions of the breast was low (< 10%) in agreement with the findings of Laurence *et al.* [2]. None of these samples had levels in excess of 0·4 U/ml.

The comparison between plasma CEA levels and the presence or absence of oestradiol-17β receptor proteins in the tumour (Table 2) shows that in both the hormone-dependent and hormone-independent tumours, elevated CEA levels occur in approximately 50% of cases. Similarly, with the menstrual status of the patient, about 50% of both pre- and post-menopausal women had increased levels of CEA. Thus it is apparent that there is no correlation between the plasma CEA level and the hormonal status of the patient.

A much larger proportion of elevated plasma CEA levels can be seen in patients with advanced or metastatic breast carcinoma. In this series, 68% of patients had positive CEA levels and about 30% had levels in excess of 0·4 U/ml. These values are comparable to those from previous studies where 60–80% of patients with advanced breast cancer had increased plasma CEA levels [5, 17, 18].

The most valuable aspect of CEA measurement at present appears to be in the monitoring of therapy. In this study we have investigated the effect of anti-oestrogen therapy on plasma CEA levels in patients with advanced breast cancer. Although there was no correlation between pre-treatment levels of CEA and clinical responsiveness, there were marked differences between the groups assessed as responding or not responding to treatment when changes in CEA levels over the 3-month treatment period were considered. A significant fall in plasma CEA was observed in only one clinical non-responder, but in 6/19 responders. Although raised CEA levels were observed in patients in both groups, the percentage of patients with increased values was higher among the non-responders. Similar results have been obtained for breast cancer patients in response to chemotherapy [20]. Figure 2 shows that a partial separation of the populations of responders and non-responders is possible on the basis of the data presented here, but more detailed studies are clearly required before the value of serial determination of CEA as a means of assessing tumour regression can be assessed.

Tissue Culture and Virus Laboratory, E.R., C.N.R.S., No. 38, *Institut Gustave-Roussy and Centre National de la Recherche Scientifique* 94800-*Villejuif, France*

Abstract—*The effect of BCG administration on the evolution of* in vitro *cell-mediated immunity in relation to tumor growth was studied in C3HeB/Fe mice carrying transplantable, syngeneic mammary TM*1 *tumors. Intradermal (i.d.) injection of BCG, 7 days before inoculation of tumor cells, inhibited significantly the tumor growth, whereas similar injection of BCG, 7 days after tumor graft, when the mice had already a palpable nodule, showed no effect. These results were correlated to a great extent with those obtained from* in vitro *colony inhibition (CI) tests using peritoneal cells (PC) of the same mice: from the beginning of the tumor growth, the CI activity of PC from mice which received BCG before tumor graft was significantly higher than those of the other groups of mice and this elevated activity was still high at the* 35*th day after tumor graft, when the PC from control non-treated mice or from mice which received BCG after tumor graft were entirely inactive. When BCG was inoculated directly into the growing tumors, significant retardation of the tumor growth was observed. This tumor inhibiting effect following intratumoral (i.t.) inoculation of BCG was much more pronounced in mice that had been presensitized with BCG before tumor graft. The* in vitro *PC-mediated immunity of these mice showed concurrently a significant increase at* 2 *weeks after i.t. inoculation of BCG, while that of the control non-treated mice was still at the lowered level of activity. Intradermal injection of BCG* 7 *days before tumor operation accelerated significantly the post-operative recovery of PC-mediated immunity, whereas similar inoculation of BCG* 3 *days after tumor operation resulted a rather adverse effect.*

INTRODUCTION

SINCE the demonstration that BCG was a potent non-specific immunostimulant enhancing host resistance against a variety of animal tumors [1, 2], numerous attempts have been made to interfere, using this microorganism, with the growth of experimental tumors in different animal species [3–5] as well as in clinical malignancies [6, 7]. Encouraging results were reported along this line, but still, optimal conditions in which the most beneficial effect of tumor inhibition can be obtained in relation to the mechanisms governing the action of the BCG are not well established. Moreover, confusingly enhancing effects on tumor growth after BCG administration in certain situations have been described [8–10].

In a more general way, it can be assumed that regression or enhancement of growth of a tumor which possesses tumor specific antigens will result from a balance between specific cell-mediated immune response acting mainly in favor of tumor rejection, and serum blocking factors, supposedly weakening or suppressing this reaction [11]. Procedures increasing cell-mediated immunity and, eventually, lowering or eliminating the action of the blocking factors might be an essential clue for successful tumor

Accepted 13 September 1976.

inhibition according to this concept. The precise role possibly played by BCG in this complex system of antitumor immune reactivity has still to be explored.

We have previously reported several series of experiments concerning a characteristic pattern of evolution of specific cell-mediated antitumor immunity studied by *in vitro* tests in several tumor-host systems [12–18]. We could demonstrate in this way that cell-mediated immunity was evident at the onset of tumor growth, but disappeared when tumors grew to a larger size, the animal entering an immunological "eclipse" state. This immunity, however, reappeared after a delay of 2 to 3 weeks following tumor removal.

The purpose of the present study was, on the basis of previously established trends of "natural" evolution of cell-mediated tumor-specific immunity, to check the additional effect of BCG treatment.

MATERIAL AND METHODS

Mice

One-month-old female inbred C3HeB/Fe mice were used. They were obtained from the Animal Selection Center, Orléans, France. Five to 7 mice were caged and supplied with food pellets and water *ad libitum*.

Tumor-cell line

A transplantable tumor-cell line, TM1, originally developed from a spontaneous mammary tumor of a C3H mouse, was used [14]. It was routinely cultivated in Eagle's minimum essential medium (MEM) supplemented with 10% non-inactivated fetal calf serum, 100 I.U. of penicillin and 100 μg of streptomycin per ml. Monodispersed cell suspensions were prepared by treatment of cultured cell monolayers with 0·05% trypsin-EDTA solution and used for production of tumors in mice or as a source of tumor target cells for *in vitro* cytotoxic tests. Tumor-specific antigenicity of these cells was proved *in vivo* by rejection of tumor cell challenge inoculation by syngeneic mice which had been actively immunized with irradiated tumor cells.

Bacillus Calmette-Guérin (BCG)

BCG Pasteur stain was obtained from the Pasteur Institute, Paris, as freeze-dried vaccine. The microorganisms were routinely cultivated on Jensen's solid medium from which serial subcultures were made in Dubos liquid medium to obtain homogenous BCG suspensions. After 3 washings with saline by centrifugation, final BCG suspensions were prepared in saline for animal inoculations. The wet weights of the bacteria were determined by comparing their densities with those of standard BCG opacimeter scale (Institut Pasteur, lot No. 179 bis, 5×10^6 viable units/mg) with the aid of a spectrophotometer.

In vitro *cytotoxicity tests*

Our modified *in vitro* colony inhibition (CI) technique and the procedure for collecting peritoneal cells (PC) from mice were previously described [12–18]. Briefly, aliquots of 100 monodispersed target tumor cells, obtained from trypsinized suspensions, were seeded in 1 ml of medium into each of 24 wells of Disposo trays (Linbro Chemical Co., New Haven, Conn., U.S.A.). The plates were incubated overnight at 37°C in a humidified 5% CO_2 atmosphere. The next day, PC were collected by peritoneal washings, using specially designed multi-perforated needles, from mice of experimental groups as well as from normal control mice, and 5×10^5 PC in 1 ml of culture medium were overlaid on the previously plated target cells. At least 4 parallel wells were used for each PC preparation. Twenty-four hours later, the culture media in wells were renewed and plates were reincubated for 5 more days. They were then stained with a 0·1% crystal violet solution and the number of colonies of tumor cells was counted under a stereomicroscope. The results were expressed as % CI by calculating the average number of colonies in the presence of PC from mice of experimental groups as compared with those in parallel wells exposed to an equal number of PC from normal control mice.

For *in vitro* blocking assays with sera from experimental and control mice, microcytotoxicity tests, using Falcon microplates (Falcon 3040), were performed as follows: one hundred tumor cells in 0·1 ml of culture medium were seeded in each microwell of the plates with the aid of Eppendord pipette. The plates were incubated overnight at 37°C in a humidified 5% CO_2 atmosphere. The next day, the medium in wells was pipetted off and 0·1 ml of 1:3 diluted sera to be tested as well as 10^5 sensitized non-adhering PC in 0·1 ml of culture medium were added simultaneously. The non-adhering PC were used preferentially in order to avoid confusion with target tumor cells. The specifically sensitized PC were obtained by peritoneal washings from groups of 15–20 adult female C3HeB/Fe mice actively hyperimmunized with heavily irradiated (10,000 γ) TM1 tumor cells. To obtain from total PC the

fraction of non-adhering cells, freshly harvested whole PC were incubated at 37°C for 2 hr in Falcon Petri-dishes and the supernatants containing these cells collected after gentle agitation. The plates were incubated for 2 days then fixed in methyl alcohol and stained with 10% Giemsa solution. The number of remaining tumor cells on the bottoms of wells were counted under a stereomicroscope. Blocking activity was calculated by comparing the % cytotoxicity obtained after incubation with a test serum with parallel % cytotoxicity with control serum from normal mice. On the whole, quite satisfactory concordance was obtained when the CI and the microcytotoxicity tests were run parallely [17].

Statistical analyses

They were performed using the Student *t* test and differences were considered to be significant if $P \leqslant 0{\cdot}05$.

RESULTS

Effects of BCG on the in vivo *growth of TMI tumors*

Adult female C3HeB/Fe mice were divided into 3 groups. The mice of the first group (A) were injected intradermally (i.d.) on the left flank with a standard dose of 200 μG of BCG in 0·01 ml of saline. The remaining groups (B & C) were injected by the same route with 0·1 ml of saline. Seven days later, all mice were inoculated subcutaneously (s.c.) on the opposite flank with 10^6 TM1 cells, a dose which gave 100% tumor takes in normal syngeneic adult mice. At the 7th day after inoculation of tumor cells, mice of the group B received the standard dose of 200 μg of BCG whereas the mice of the other 2 groups received 0·1 ml of saline. All inoculated mice were checked twice a week for tumor development by measuring two perpendicular diameters with calipers.

The tumor growth in these 3 groups of mice is represented by the curves of Fig. 1. All 17 mice inoculated with TM1 tumor cells without treatment with BCG (group C) developed relatively rapidly growing tumors whose average diameter at day 35 attained 12 mm. The mice treated with BCG 7 days *before* inoculation of tumor cells (group A) showed obviously a slower tumor growth and the average diameter of their tumors at the corresponding day was only of 7 mm. Statistical analysis revealed that the difference was highly significant ($P < 0{\cdot}001$). Furthermore, complete regressions of the tumors were observed in 2 out of 10 mice of the latter group. On the contrary, the mice treated with BCG 7 days *after* inoculation of tumor cells (group B), at the time when small but palpable nodules were already present, have shown a rather accelerated growth if compared with the control untreated mice, though this difference was at the limit of significance.

Parallely, the same 3 groups of experimental and control mice were submitted to peritoneal washings regularly once a week starting from day 7 after inoculation of the tumor cells. Pooled PC from each group of mice were tested for their immunological activity by *in vitro* CI technique as described in Material and Methods.

As shown in Fig. 2, PC taken from the control group C mice, not treated with BCG, showed, as expected [12–15], a characteristic pattern of evolution of *in vitro* tested immunological activity. The PC inhibited significantly (40% CI at day 7) *in vitro* growth of the tumor target cells when taken from animals at the early stage of the tumor growth but have lost this activity almost completely at day 14, this state lasting until the death of the tumor bearing mice. The *in vitro* activity of PC from the group B mice, treated with BCG 7 days *after* inoculation of the tumor cells, showed a similar evolution toward a loss of cytotoxic activity showing even a significant inversion of this activity demonstrated as enhancement of growth of the tumor target cells (−33% CI at day 28). In contrast, PC from mice of the group A, treated with BCG 7 days *before* inoculation of the tumor cells, exhibited a very high cytotoxicity (77% CI) at day 14 and maintained this level up to day 35. Thus, a good correlation could be established between the effect of BCG on tumor growth *in vivo* and its effect on the evolution of specific cell-mediated antitumor immunity as revealed by *in vitro* tests.

In order to check for the possible effect of BCG on the evolution of serum blocking factor(s) supposedly capable to abrogate specific *in vitro* cytotoxicity, the mice of the above 3 groups were bled repeatedly every 2 weeks after tumor inoculation by tail cuttings and pooled sera of each group of mice were prepared and kept frozen for appropriate tests. Control normal sera were obtained from normal adult C3HeB/Fe mice. All sera were inactivated at 56°C for 30 min, diluted 1:3 with MEM and used for blocking assays. The results are represented on the graphs of Fig. 3. The sera obtained at day 7 from the group C mice having received TM1 cells only, abrogated significantly (16% blocking) ($P < 0{\cdot}05$) the cytotoxic activities of the sensitized PC. Later

the levels of blocking factors progressively increased along with the tumor growth. However, the blocking activities of sera from mice of both groups A and B (treated with BCG) regardless of time relationships in respect to the tumor inoculation, were significantly lower than those of sera from the group C mice bearing tumors but non treated with BCG. Some variance of levels of serum blocking factor between the groups B and A was observed at days 28 and 42 but the differences were statistically hardly significant ($P < 0{\cdot}1$).

Effect of intratumoral (i.t.) BCG inoculation on the growth of TM1 tumors

The experimental design was as follows. Adult female C3HeB/Fe mice were divided into 4 groups, each comprising 12 mice. BCG, 200 μg in 0·2 ml of saline, was administered i.d. on the left flank of mice of 2 groups (groups a and b); 0·2 ml of saline was given to mice of the remaining 2 groups (groups c and d). Seven days later (day 0), all mice were inoculated s.c. on the opposite flank with 10^6 TM1 tumor cells. At day 28, the same standard doses of BCG were injected directly into tumors of mice of the groups a and c. Mice of the other groups received 0·2 ml of i.t. injection of saline. Tumor growth as well as *in vitro* CI activities of PC from these mice were checked regularly as in the previous experiments.

The evolution of tumor growth in these 4 groups of mice was represented by the curves in Fig. 4. The mice of the group b, which received BCG once i.d. 7 days before inoculation of the tumor cells, showed, in confirmation of the previous results, significantly ($P = 0{\cdot}05$) slower growth of their tumors than those of the control group d mice that did not receive BCG. Subsequent additional inoculation of BCG into the tumors at day 28, when the tumor size attained in average 7 mm in diameter (group a), resulted in further retardation of tumor growth. The average diameter of tumors at the 21st day after i.t. BCG inoculation (or day 49 after inoculation of the tumors) was 13 mm while that of tumors on the control group d mice was 18 mm ($P < 0{\cdot}01$). However, no regression of tumors was observed in mice treated by i.t. injection of BCG. The mice of the group c which received once i.t. BCG inoculation at day 28 showed also a slightly retarded growth of their tumor in comparison with that of the control group d mice. On the whole, the most pronounced and statistically highly significant retardation effect of tumor growth was obtained in presensitized mice receiving additional i.t. BCG inoculation.

The evolution of *in vitro* cell-mediated immunity in the above 4 groups of mice are shown in Fig. 5. PC from the group b mice that received BCG once 7 days before inoculation of TM1 tumor cells, exhibited, as in the previous experiments, earlier and longer lasting capacity to inhibit *in vitro* growth of the tumor target cells than those from the control group d mice not treated with BCG. If the BCG presensitized mice were reinoculated with BCG into their tumors at day 28 (group a), their PC showed significantly increased and accelerated inhibition (2% CI) at the 21st day after the second BCG challenge (or at day 49 after tumor inoculation). PC from the parallel mice which received only one sensitizing preinoculation of BCG (group b) showed very low activity (4% CI) at that time. However, PC from the group c mice, that received only i.t. BCG inoculation, without prior sensitization, revealed also an abrupt increased activity 21 days after BCG inoculation ($-18{\cdot}6$% CI at day 35 and 46% CI at day 49).

Comparative effects of BCG inoculated before or after surgical removal of tumor on the evolution of in vitro *cell-mediated immunity*

In order to investigate the most appropriate timing of BCG inoculation in relation to the surgical removal of the tumors, we have undertaken the following experiments. Adult female C3HeB/Fe mice were divided into 3 groups, each comprising 12 to 15 mice. All mice were inoculated s.c. with 10^6 TM1 tumor cells at day 0. At day 22, when the tumors measured 7–9 mm dia, the mice of the group I received BCG, 500 μg i.p. and 500 μg i.d. at the opposite site of tumor inoculation. The mice of the remaining groups II and III received similarly the same volume of saline. Seven days later (or at day 29 after tumor cell inoculation), all tumors were radically removed by surgical resection and BCG was inoculated similarly, 3 days later, into the operated mice of the group II. The mice of group III served as control (operated mice not treated with BCG).

All the operated mice were submitted to weekly peritoneal washings thereafter and their pooled PC were assayed by *in vitro* CI techniques. As shown in Fig. 6, the tumor cell inhibiting activity of PC from control operated mice, appeared significantly (42% CI) at day 16 after tumor operation and the same level of activity was maintained by day 24. However, PC from group I mice, that received BCG before tumor operation; attained a similar level of activity already at day 8 after tumor operation. This activity increased progressively

reaching 83% CI at day 24. In contrast, immune reactivity of PC from group II mice that received BCG 3 days after tumor operation were found to be at particularly low levels. Thus, it is concluded that in this TM1 tumor system, BCG administration *before* tumor operation shortened significantly the post-operative eclipse period, whereas similar inoculation of BCG *after* tumor operation showe d a rather adverse effect on the post-operative recovery of the specific antitumor immunity of PC.

DISCUSSION

Since the first trials of Old *et al.* [1] and Halpern *et al.* [2], the treatment with living BCG was frequently applied with the aim to stimulate the immunological antitumor reactivity in experimental [3–5] and more recently in clinical malignancies [6, 7]. Different protocols of treatment were followed and the results visibly depended on various parameters corresponding to conditions of tumor growth and treatment by conventional methods, surgical removal of the tumor mass at the first place, as related to the timing and way of treatment with BCG.

In the here reported series of investigations we tried to answer some precise questions concerning the relationship between these parameters and the action of BCG. We used uniformly a C3HeB/Fe mammary tumor *in vitro* adapted TM1 cell line which was previously the subject of a series of experimental studies dealing with the evolution of cell-mediated immunity in syngeneic mice [14, 16, 18]. A quite stable tumor producing capacity and a rather weak but constant antigenicity as well as a quite uniform behaviour *in vitro* in terms of plating efficiency were characteristic for this cell line. This point was of importance since we tried throughout this whole study to establish in different circumstances a parallel between the rate of tumor growth or inhibition *in vivo* and the specific cell-mediated immunity as checked in the same animals by *in vitro* tests using lymphoid cells. These cells collected periodically by peritoneal washings were confronted with the TM1 target tumor cells.

From the first series of experiments we could conclude that the time of treatment with BCG with regard to the inoculation of TM1 tumor cells was essential. Injection of BCG by i.d. route 7 days *before* inoculation of tumor cells was efficient in terms of inhibition of tumor growth, whereas a similar inoculation of BCG 7 days *after* tumor graft, when the mice had already a palpable nodule, showed no effect or even enhanced their growth. These results were well correlated with those obtained from *in vitro* CI tests with PC of the same animals: from the beginning of the tumor growth inhibiting activity of PC from mice which received BCG *before* tumor graft was significantly higher than those of the other groups of mice and this elevated activity was still high at the 35th day when the PC from control mice or from mice that received BCG *after* tumor graft were entirely inactive.

Thus, our results confirm once more the "preventive" value of antitumor treatment with BCG operating most certainly by a non-specific stimulation of immunological reactivity.

These results were, as a whole, in concor-

dance with those obtained in another host–tumor system by Bansal and Sjögren [19]. These authors reported that BCG administration at the time of rat polyma tumor isografting, or 2 weeks before, inhibited tumor growth and induced an increased level of cell-mediated immunity whereas similar inoculation of BCG at the time when the tumor isograft had already grown out to a palpable nodule did not inhibit tumor growth and caused rather its enhancement.

Blocking activities of sera from mice, whether they received BCG *before* or *after* tumor graft, were lower in both groups than those of sera from the control tumor bearing mice and one can suppose that this effect may play a certain if not essential role in the activation of specific, cell-mediated immunity of the tumor bearing host. However, the flagrant difference in *in vivo* tumor growth depending on whether the BCG was given *before* or *after* inoculation of tumor cells did not appear in tests checking the serum blocking factors and it may be assumed that mechanisms other than those conditioning the presence of this factor (or factors) are involved in stimulation of cell-mediated antitumor immunity by BCG.

In our expeiments in which BCG was inoculated directly into the growing tumors, a significant retardation of the tumor growth has been observed not unlike that reported by other authors [3, 5, 20, 21]. The *in vitro* PC-mediated specific antitumor immunity of these mice showed concurrently an abrupt increase around 2 weeks after the BCG inoculation, while that of the control non treated mice was still at a rather low level of activity. Thus again a satisfactory correlation was observed between results obtained *in vivo* and *in vitro*. It is remarkable that in mice preimmunized with BCG the tumor inhibition effect following i.t. inoculation of BCG was much more pronounced. Increased inhibition of tumor growth by such preimmunization before i.t. inoculation of BCG was reported also in a mouse fibrosarcoma [22]. Nevertheless, no complete regression of tumor was observed even in presensitized animals in our experiments. Tumor size at the moment of intratumoral inoculation of BCG seemed to be a critical limitation for successful effect of immunostimulating adjuvants [21]. In our experiments BCG was inoculated into tumors measuring approximately 8–10 mm dia. It was reported elsewhere [23] that an autochthnous methylcholanthrene-induced murine fibrosarcoma of less than 8 mm dia was more susceptible to regression induced by BCG than were tumors of larger size [23].

The third series of experiments was undertaken in order to find out optimal time-relationship between administration of BCG and surgical removal of tumors as expressed particularly in terms of the evolution of cell-mediated immunity checked by *in vitro* tests. Clearly, in the used system, the administration of BCG, 7 days *before* tumor operation, resulted in shortening of the immunological eclipse period in this tumor–host system.

Concordantly, Smith *et al.* [24] demonstrated that in another host–tumor system (a guinea pig hepatoma) i.d. injection of BCG *before* local excision of the tumor eradicated lymph node metastases. On the other hand, Sparks *et al.* [25] have shown that administration of BCG both *before and after* surgery were effective in inhibiting growth of a syngeneic mammary adenocarcinoma in rats. So, it seems premature to generalize the indication appearing clearly in our C3H mouse–TM1 tumor system that pre-operative treatment with BCG is generally recommendable and efficient in stimulating the anti-tumor immune reaction. As a matter of fact, in a limited number of experiments (unpublished data) performed with BALB/c mice and a syngeneic tumor cell line, chronically infected with a low leucemogenic murine leukemia virus variant, we observed that the immunological eclipse state was not shortened but, on the contrary, prolonged in mice treated with BCG one week before surgery as compared with operated, non treated animals. These results which seem to branch off from the others may be due to the particular character of the chronically virus-infected tumor cell line.

Further work using different host-tumor models and correlating *in vivo* and *in vitro* results is necessary to supply clear and unequivocal indications concerning the most beneficial way and timing of treatment with BCG or other immunostimulants. The here reported results indicate that the judicious choice of the protocol of this treatment is of paramount and critical importance.

Plasma Androstenedione Levels in Women with Breast Cancer

D. Y. WANG,* R. D. BULBROOK* and J. L. HAYWARD†

**Dept. of Clinical Endocrinology, Imperial Cancer Research Fund Laboratories, Lincoln's Inn Fields, London, WC2A 3PX*

†*Breast Unit, Guy's Hospital, London, SE1 9RT, Great Britain*

Abstract—*The levels of plasma androstenedione have been measured in 79 normal women, 65 and 61 patients with early breast cancer (Stage I or II) one day before and ten days after mastectomy, respectively, and 69 patients with advanced metastatic disease.*

There was no significant difference between the mean levels of androstenedione in normal women and subjects with early breast cancer, before mastectomy. However, the general level of androstenedione was significantly subnormal after mastectomy, or in patients with advanced breast cancer. Also there was a significant reduction in the general level of plasma androstenedione associated with mastectomy.

In all categories of women the plasma level of androstenedione was highly correlated with the plasma concentrations of dehydroepiandrosterone sulphate and the excretion of urinary 11-deoxy-17-ketosteroids.

INTRODUCTION

THERE is now considerable literature dealing with androgen status in women with an enhanced risk of breast cancer or in patients with the disease [1–9]. The general finding is that urinary and plasma androgens are subnormal [10–16] but normal [17–19] or high [20] values have also been reported.

We have recently found that plasma androgen sulphates [16] and dehydroepiandrosterone (DHA) [21] are subnormal in women with either early or advanced breast cancer and have now measured the plasma levels of androstenedione.

MATERIAL AND METHODS

Subjects

The 79 ostensibly healthy women volunteers (mean age 48·7 yr) constituted the normal control group. The patients with early breast cancer (Stage I or II) were 65 (mean age 51·5) and 61 (mean age 50·9) women from whom blood was taken one day before and 10 days after mastectomy, respectively. There were 69 patients (mean age 50·9) with advanced disseminated disease. Plasmas from heparinised bloods from these women were stored at −20°C until analyzed.

Androstenedione measurement

Plasma (0·2 ml) was shaken with 2 ml hexane for 15 minutes and centrifuged (700 *g*) for 10 min. Aliquots (0·2 ml) of the hexane layer were evaporated and borate buffer (pH 8·0; 0·05 M), antibody (final concentration 1:10,000) and [1·2-H^3] androstenedione (4000 dis/min; 10 pg) added and the mixture (final volume 0·2 ml) incubated overnight at 4°C. Dextran coated charcoal was added, shaken and the assay tubes left in an ice-bath for 15 min, after which the tubes were centrifuged (700 *g* × 10 min) and aliquots of the supernatant counted in a liquid-scintillation counter. The amounts of androstenedione were estimated from a standard curve and the results corrected for 78% recovery. This recovery figure was arrived at by estimating the recovery of tritiated androstenedione from plasma at various times and with different batches of hexane. The coefficients of variation for 12 such estimations was 2·5%. Hexane blanks and quality control plasmas were included in each run to test for non-specific interference and reproducibility of the assay, respectively.

The antibody to androstenedione was raised

Accepted 30 August 1976.

in rabbit using androstenedione conjugated in the 6 position to bovine serum albumin. The cross reaction of this antibody to steroids likely to be present in plasma in appreciable concentrations was negligible except for testosterone and 11β-hydroxyandrostenedione, which cross-reacted at a level of less than 5%. Under the conditions of the assay only about 20% of testosterone or 11β-hydroxyandrostenedione are extracted by hexane. Thus the addition of a large amount of 11β-hydroxyandrostenedione to plasma, equivalent to 800 ng/100 ml, resulted in an apparent increase in androstenedione of 17 ng/100 ml (125 ng to 142 ng/100 ml).

Assay precisions were measured by comparing duplicate estimations and gave coefficients of variation of 8%, 6% and 7% for ranges of androstenedione of 0–50, 51–100 and greater than 101 ng per 100 ml plasma, respectively. There were 20 duplicate estimations in each group.

Plasma dehydroepiandrosterone sulphate (DS) and androsterone sulphate (AS) were measured by gas–liquid chromatography by the method of Wang *et al.* [9, 22]. The urinary 11-deoxy-17-ketosteroids (11-DKS) were determined in normal women and patients, 10–14 days after surgery, with early breast cancer using the method outlined by Bulbrook *et al.* [12].

RESULTS

The mean levels of plasma androstenedione in normal women, patients with breast cancer before and after mastectomy and those with advanced breast cancer are shown in Fig. 1. The elevation of the regression line of steroid on age for normal women is significantly higher than that for patients with advanced breast cancer ($F = 8{\cdot}36$; $P < 0{\cdot}005$) and for patients with early breast cancer after mastectomy ($F = 33{\cdot}4$; $P < 0{\cdot}001$). But it is clear from Fig. 1 that the mean level before mastectomy is not significantly different from that found in normal women. A similar result is obtained when the data are analysed with reference to menopausal status. The mean levels in pre- or post-menopausal controls and in the three groups of patients with breast

Table 1. *Mean plasma androstenedione levels in pre- and post-menopausal women*

	Pre-menopausal	Post-menopausal
Control	2·016 ± 0·124 (39)	1·929 ± 0·108 (40)
Early breast cancer Before mastectomy	1·980 ± 0·260 (36)	1·915 ± 0·252 (29)
t;P	0·78 N.S.	0·32 N.S.
Early breast cancer After mastectomy	1·855 ± 0·291 (34)	1·672 ± 0·242 (27)
t;P	3·17 $P < 0{\cdot}001$	5·91 $P < 0{\cdot}001$
Advanced breast cancer	1·887 ± 0·358 (33)	1·827 ± 0·290 (36)
t;P	2·12 $P < 0{\cdot}05$	2·07 $P < 0{\cdot}05$

Results are expressed as log mean (ng/100 ml) ± S.D. with the number of subjects in parenthesis. "t" and "P" refer to the comparison with the mean normal levels.

cancer are given in Table 1. The pre-mastectomy levels of androstenedione do not differ from those found in the controls but the concentration of this steroid is significantly decreased after mastectomy and in the advanced disease.

Mastectomy itself is associated with a decrease in androstenedione and in 44 patients from whom blood was obtained before and after mastectomy a comparison by paired *t*-test showed this decrease to be highly significant ($t = 4{\cdot}76$; $P < 0{\cdot}001$).

Relationship between plasma androstenedione and plasma DS, AS and urinary 11-*DKS*

(*a*) *Plasma DS and AS.* In all the groups studied the amounts of plasma androstenedione are highly correlated ($P < 0{\cdot}001$) with plasma DS levels (both concentrations expressed logarithmically). In controls and patients with early breast cancer before surgery, the levels of both plasma DS and androstenedione are significantly correlated with age (Reference [16] and Table 2). Calculation of the partial correlation coefficient [23] for these categories (Table 2) shows that the significant correlation between DS and androstenedione is independent of age. In contrast to the high degree of correlation between androstenedione and DS, in all categories of women, the correlation between androstenedione and AS reached formal significance levels in only normal control women ($P < 0{\cdot}05$) and patients with advanced breast cancer ($P < 0{\cdot}01$) (Table 2).

(*b*) *Urinary* 11-*DKS.* The concentrations of plasma androstenedione are significantly correlated with the amount of urinary 11-DKS excreted for normal women and in both groups of patients with early breast cancer (Table 2). Since the amount of urinary 11-DKS excreted is correlated with age [16] the partial correlation coefficient has been calculated, where plasma androstenedione is also correlated with age, and shows that the significant relationship between plasma androstenedione and urinary 11-DKS is independent of age.

DISCUSSION

There is now sufficient evidence in the literature to assemble a persuasive argument that androgen metabolism is abnormal in women with breast cancer. Thus urinary androgen metabolites are subnormal in women with early and advanced breast cancer and this is reflected by low levels of plasma DS, AS and DHA [10–16, 21]. This present report confirms and extends the results of Poortman *et al.* [24–26] and shows that the general level of plasma androstenedione is significantly subnormal in women with early breast cancer ten days after surgery, and patients with advanced breast cancer. Furthermore, these subnormal levels of plasma androstenedione are not a

*r** = partial correlations coefficient (Snedecor); *P** indicates that the relationship between the parameter is independent of age. Androstenedione is expressed as ng/100 ml and DS and AS as μg/100 ml. The excretion of 11-DKS is expressed as mg/24 hr.

result of abnormalities in plasma protein binding in women with breast cancer [27].

Androstenedione levels before mastectomy in women with early breast cancer were not significantly abnormal, and this difference between pre- and post-operative patients stems from the changes in plasma androstenedione associated with mastectomy.

A similar alteration has been reported for plasma DS and AS levels and the urinary excretion of 11-DKS [16]. It is not possible with the present data to assess how near either the pre- or post-operative androstenedione levels are to basal levels. It is possible that the trauma of surgery could result in a decreased level, whilst it is equally possible that stress results in an increase in pre-operative levels (see 16). Since plasma androstenedione levels in patients with early breast cancer are significantly correlated with the amount of urinary 11-DKS excreted, and the level of urinary 11-DKS is subnormal in women who subsequently develop clinical breast cancer [3, 4], it would appear that the post-operative levels approximate to a non-stressed basal level.

It will be noticed that in the statistical analysis of androstenedione levels in pre-menopausal women, no account is made for the stage of the cycle. The justification for this stems from the large between-person variation found in androstenedione levels. Our experience in not being able to detect differences in mean androstenedione levels in the luteal phase and other parts of the cycle are similar to that of Horton [28]. In fact, the changes in androstenedione levels during the menstrual cycle, as reported by Baird *et al.* [29], was only demonstrable if serial blood samples from the same subjects are analyzed.

This study shows that in addition to the urinary 11-DKS, plasma DS, AS and DHA [10–16, 21], plasma androstenedione levels are also generally low in women with breast cancer. However, the greatest difference occurred in post-menopausal women. Since the ovaries can contribute 20–50% of the blood production rate of androstenedione, depending on the stage of the menstrual cycle [30, 31], it is possible that any abnormality in the adrenal production of androstenedione in pre-menopausal women could be obscured by such a substantial ovarian production. Certainly the results on plasma DS [16] would suggest that the abnormality in androgen status in breast cancer patients is of adrenal origin, and this conclusion is supported by the significant correlation between the levels of plasma DS and androstenedione. There is, in fact, no conclusive evidence that ovarian hormone production is abnormal in patients with breast cancer, and measurements of plasma oestrogen and progesterone levels have generally shown that these hormones are within the normal range in women with breast-cancer or with a high risk of breast cancer [7, 32–35]. Also, no abnormalities have been found in the conversion of androstenedione to oestrone in women with breast cancer [24–26]. If further work substantiate these findings, then it would appear that the main endocrine abnormality in breast cancer is of adrenal rather than of ovarian origin.

Letter to the Editor

Comments on Yerushalmi's Article (Reference 1)

E. R. ATKINSON

Physical Science Project Officer, National Cancer Institute, Division of Cancer Treatment, Bethesda, Maryland 20014, *U.S.A.*

YERUSHALMI has recently reported that the treatment of tumors by whole body hyperthermia (WBH) led to more rapid metastasis than in untreated controls. He also reports that local hyperthermia led to a delay in metastasis. These conclusions are based on experiments with transplanted lewis lung carcinoma. Relevance to clinical WBH for the treatment of patients with metastatic tumors was indicated [1].

Yerushalmi appears, as have previous investigators [2], to have difficulty producing tumor temperatures above 41·5°C with WBH. In what he describes as WBH, tumor temperatures barely exceed 41·5°C for a few minutes, at most, but do involve maintenance at less than 41·0°C for periods of about twenty minutes. In what he describes as local hyperthermia, tumor temperatures exceeded 43·5°C and were maintained at temperatures in excess of 42·0°C for over twenty minutes. Thus, whole body temperatures of therapeutic interest were not employed although they appear to be well within the critical thermal maxima (ca. 43·5°C) reported for mice [3].

In view of data indicating a sharp threshold for tumor cell death beginning at about 41·5°C (see, for example, reference 4), it appears that Yerushalmi's results were simply the product of inadequate treatment by WBH paralleled with perhaps excessive treatment by local hyperthermia. The precision of ±0·5°C which Yerushalmi reports for his temperature measurements [5], however, casts serious doubt on any experimental conclusions.

Accepted 9 September 1976.

We have been investigating the supposition that inadequate hyperthermia treatment, consisting of prolonged exposure to temperatures less than 41·5°C, leads to increased tumor proliferation *in vivo*. Our work employs both local and WBH and involves the lewis lung carcinoma as well as other transplantable tumors with differing mechanisms of metastasis. To the extent that we can interpret Yerushalmi's data they appear to be in substantial agreement with our own but we differ greatly on what may be concluded from these data.

In our experiments, we employ careful confinement of endogenous metabolic heat by regulated air flow with control of evaporative losses, to produce WBH. In order to produce local hyperthermia we employ electromagnetic radiation of known, limited tissue penetration. In this manner, transcutaneous heat flow is kept small in both instances since it is electromagnetic radiation, not heat, which passes through the skin. It is difficult for us to see the relevance of air temperature, somewhere else in the apparatus, which Yerushalmi ascribes to *in vivo* hyperthermia and uses to compare local and WBH effects [1]. For this reason, we employ the output of tissue implanted temperature transducers to feed back tissue temperature controls with a precision of ±0·05°C.

We feel that the lowest temperature attained by tumor cells in a treatment regime, rather than the highest, could be an important indicator of treatment quality. It would be most unfortunate if this indicator were confused with anatomical extent of treatment, as Yerushalmi has done, prior to its careful validation.

Announcements

FIRST SYMPOSIUM AND TASK FORCE ON: EXPERIMENTAL APPROACHES TO THE TREATMENT OF GASTROINTESTINAL TUMORS

This symposium, organized by the EORTC Gastrointestinal Tract Cancer Cooperative Group, will be held in Brussels on 14–15 April, 1977.

Three topics will be discussed:

1. Experimental models in G.I. tract oncology, excluding hepatoma.

2. Precancerous states of the G.I. tract.

3. Clinical trials in G.I. tract cancers.

Number of participants will be limited to 200. Abstracts (in English) of free communications must be submitted by 1 March, 1977. For details and registration, write to: Dr. M. Staquet, EORTC Data Center, Institut Jules Bordet, rue Héger-Bordet 1, 1000 Bruxelles, Belgium. The symposium will be held 2, rue Evers, 1000 Brussels. Registration fee: 2500 Belgian Francs (to be paid in advance).

PAG SYMPOSIUM ON SAFETY OF SINGLE CELL PROTEIN FOR ANIMAL AND HUMAN FEEDING

(31 *March and* 1 *April* 1977)

This technical symposium, sponsored by the Protein-Calorie Advisory Group of the United Nations System will be held at the Istituto di Ricerche Farmacologiche "Mario Negri", Via Eritrea, 62 - 20157 Milano Italy. Telephone: (02) 35.54.546 and 35.70.546; Telex: 37268 NEGRINST.

This International Symposium is being planned and will be held with the full cooperation and support of the "Mario Negri" Institute for Pharmacological Research. The proposed program consists of four technical sessions devoted to scientific discussions on Toxonomy and Pathogenicity, Metabolism and Safety of Alkanes and Odd Numbered Carbon Chain Fatty Acids (2 sessions), and Allergic Reactions in Man. Each invited speaker has played a key role in the area of investigation he will cover. The working language of the Symposium will be English.

There is no registration fee for attendance and participation in the symposium discussions. For more details please contact: Dr. Silvio Garattini, Director of Institute and Organizing Joint Secretary of the Symposium at the above address.

SECOND CONFERENCE ON LUNG CANCER TREATMENT

Airlie House, Virginia

(22–24 *May*, 1977)

This conference is sponsored by the Cancer Therapy Evaluation Program of the National Cancer Institute. Current trends in the treatment of lung cancer will be analyzed and prospects for further therapeutic approaches will be discussed. Workshops are planned for the following topics: pathology (chairmen: M. Matthews and R. Yesner), surgery (C. Mountain), adjuvant chemotherapy (G. Bonadonna), adjuvant immunotherapy (R. Ritts), staging and followup (H. Hansen), radiotherapy (C. Perez), chemotherapy of non-small cell carcinoma (P. Alberto and M. Cohen), small cell carcinoma (Y. Kenis and J. Minna), tumor immunology (P. Chretien), experimental chemotherapy and kinetics (F. Schabel), and new modalities (P. Rubin). Each workshop will be introduced with invited papers. Some papers will also be selected from submitted abstracts. Attendance will be limited to 120 persons. There is no registration fee.

For further information contact Dr. Franco M. Muggia, Second Conference on Lung Cancer Treatment, National Cancer Institute, Building 37, Room 6A17, Bethesda, Maryland 20014.

Effects of Oestradiol-17β and Tamoxifen on Nuclear Oestradiol-17β Receptors in DMBA-Induced Rat Mammary Tumours

R. I. NICHOLSON, P. DAVIES and K. GRIFFITHS

Tenovus Institute for Cancer Research, Welsh National School of Medicine, Heath, Cardiff, CF4 4XX, Great Britain

Abstract—*An exchange assay has been established for the measurement of nuclear oestradiol-17β binding sites in DMBA-induced mammary tumours of the rat. The assay was used to examine the nuclear concentration of binding sites following the administration* in vivo *of tamoxifen and oestradiol-17β. Both compounds translocate receptor protein to the nucleus and cause an early elevation in cytoplasmic receptor levels. By 24 and 48 hr after tamoxifen administration, the intranuclear concentration of oestrogen receptor complex has returned to levels indistinguishable from pretreatment values. At this time, replenishment of the cytoplasmic receptor had not occurred and tumours were non-responsive to oestradiol-17β.*

INTRODUCTION

THE INITIAL event in the antioestrogenic action of tamoxifen (ICI 46474; trans 1-(p-β-dimethylaminoethoxyphenyl)-1,2-diphenylbut-1-ene) on mammary tumours induced in rats by 7,12-dimethylbenz(a)anthracene (DMBA) is the reduction of both total [1] and accessible [1–3] cytoplasmic binding sites for oestradiol-17β *in vitro*. Although the final result of tamoxifen administration i.e. tumour regression [2, 4] is obvious, the precise sequence of events leading to this end-point remains unclear. This study examines the nuclear uptake of oestradiol-17β and tamoxifen as determined by an exchange assay, with the aim of providing further information as to the means by which antioestrogens can influence tumour growth.

MATERIAL AND METHODS

Animals

Mammary tumours were induced in virgin female Sprague–Dawley rats (50 ± 2 days old) by intubation with a single dose of DMBA (20 mg in 1 ml sesame oil). Animals were housed in groups of four and allowed diet and water *ad libitum*. Beginning 5 weeks after intubation with DMBA, rats were palpated for tumours at weekly intervals and tumour size recorded as the mean of two perpendicular diameters, one measured across the greatest width. Tumours which did not attain an approximate size of 20 mm mean diameter in the 23-week period following carcinogen administration were not used in the study.

Preparation of nuclear fractions and determination of oestradiol-17β/tamoxifen binding sites by the [^{3}H]-oestradiol-17β exchange assay

Animals were given oestradiol-17β (5 μg) or tamoxifen (100 μg) in 100 μl vehicle (10% v/v ethanol in 0·15 M NaCl) by intravenous injection 1 hr before sacrifice. The tumours were removed and dissected free of fat, washed with 0·25 M sucrose (adjusted to pH 7·4 with $NaHCO_3$), cut into small pieces and passed through a stainless steel press (pore diameter, 1·5 mm). The brei was collected in a beaker containing 0·25 M sucrose and homogenised with a Potter–Elvehjem glass-on-teflon homogeniser of clearance 14–16 μm (6 strokes, speed 2500 rev/min). Such a procedure has been demonstrated to give maximum breakdown of tumour cell membranes with minimal damage to cell organelles [5]. A nuclear preparation was

Accepted 7 September 1976.

obtained by centrifugation of the homogenate at 800 *g* for 10 min at 4°C. Nuclei were washed twice by resuspension and resedimentation from 0·25 M sucrose-3 mM $MgCl_2$ containing 0·1% (w/v) triton X-100, then washed and resuspended in 0·25 M sucrose-3 mM $MgCl_2$. Aliquots of the nuclear fraction (200 μl) were mixed with an equal volume of protamine sulphate [1 mg/ml in medium A (50 mM Tris-HCl buffer, pH 7·4, containing 5 mM EDTA and 1 mM dithiothreitol)] and re-sedimented at 800 *g* for 10 min. Precipitated receptor was incubated for various times at various temperatures (see Results) with 200 μl [2,4,6,7-^{3}H]oestradiol-17β (specific radioactivity 85 Ci/m-mole; Radiochemical Centre, Amersham, Bucks., U.K.) in medium A (final steroid concentration 20 nmole/l), in the absence or presence of unlabelled diethylstilboestrol (20 μmole/l). After incubation precipitates were cooled to 4°C and washed with cold medium A (three washes, each followed by centrifugation at 800 *g* for 10 min). The final pellet was extracted overnight with ethanol (0·5 ml), centrifuged and the ethanolic supernatant decanted into vials. The extracts were dried and counted in 6 ml scintillation fluid (4 g, 2,5-diphenyloxazole, 0·05 g of 1,4-di [2-(5-phenyloxazolyl)]-benzene, 1,1-toluene) in a Nuclear Chicago (Mark II) liquid scintillation spectrophotometer using external standardisation.

In other experiments, animals were injected with 20 μCi [^{3}H]oestradiol-17β 1 hr prior to removal of tumours. Under these conditions approximately 70% of the tumour-associated radioactivity was found in the nuclear fraction. Aliquots of the nuclear fraction (200 μl) were treated with protamine sulphate as previously described, centrifuged and the precipitated receptor incubated with a saturating concentration of either oestradiol-17β (20 nmole/l) or tamoxifen (20 nmole/l) at 4, 10, 15, 25 or 37°C for periods up to 4 hr.

Saturation analysis of the binding of [^{3}H] oestradiol-17β to otherwise occupied nuclear sites was estimated by incubating aliquots of the protamine sulphate precipitated receptor in medium A containing various concentrations of [^{3}H]oestradiol-17β (1–25 nmole/l) in the presence and absence of a 1000-fold higher concentration of unlabelled diethylstilboestrol for 2 hr at 15°C. After incubation tubes were treated as previously described.

The method for the determination of accessible cytoplasmic oestradiol-17β binding sites has been described in a previous communication [1]. Briefly, the supernatant from the 800 *g* centrifugation stage was subjected to further centrifugation at 105,000 *g* for 45 min at 4°C. Aliquots of cytosol were incubated for 16 hr at 4°C with equal volumes of medium A containing a saturating concentration of [^{3}H]-oestradiol-17β (5 nmole/l) in the presence and absence of a 100-fold higher concentration of unlabelled diethylstilboestrol. Excess steroid was removed by charcoal adsorption and aliquots of the charcoal-free supernatant counted for radioactivity.

For competitive binding studies various amounts of non-radioactive oestradiol-17β or other potential ligands (25–10,000 nmole/l) were added with [^{3}H]oestradiol-17β (either 5 nmole/l for accessible cytoplasmic binding sites or 20 nmole/l for nuclear binding sites) to the reaction mixture and incubated as described previously. All values were corrected by subtraction of the binding value obtained in the presence of a 1000-fold excess of unlabelled oestradiol-17β.

The DNA content of nuclear fractions and the protein content of cytosol fractions were estimated using the methods of Burton [6] and Lowry *et al.* [7] respectively.

Determination of nuclear and cytoplasmic binding sites by the [^{3}H]*oestradiol-17β-exchange assay following the* in vivo *administration of either oestradiol-17β or tamoxifen*

Three experiments were undertaken.

(i) Eighteen rats bearing 25 tumours were divided randomly into five groups (5 tumours per group). Each group received either oestradiol-17β (0·5 μg or 5μg) or tamoxifen (10 μg or 100 μg) in 0·1 ml vehicle [10% (v/v) ethanol in 0·15 M NaCl] by intravenous injection. Control animals received vehicle alone. Tumour biopsy samples (approximately 200 mg tissue) were removed aseptically from Nembutal ® anaesthetized animals at time 0 (prior to injection) and at 18, 25, 40 and 60 min after injection. Cytosol and nuclear preparations were obtained as previously described and portions incubated for either 2 hr at 15°C (total nuclear sites) or 16 hr at 4°C (accessible cytoplasmic sites) with a saturating concentration of [^{3}H]oestradiol-17β (20 nmole/l) with and without unlabelled stilboestrol (20 μmole/l).

(ii) Fifteen animals were divided randomly into three groups (5 tumours per group). The experimental design was as described in (i) except that animals were treated with either oestradiol-17β (5 μg), tamoxifen (100 μg) or vehicle alone and tumour tissue was biopsied at time 0, and at 0·5, 1, 2, 4, 8, 16, 24 and 48 hr after injection.

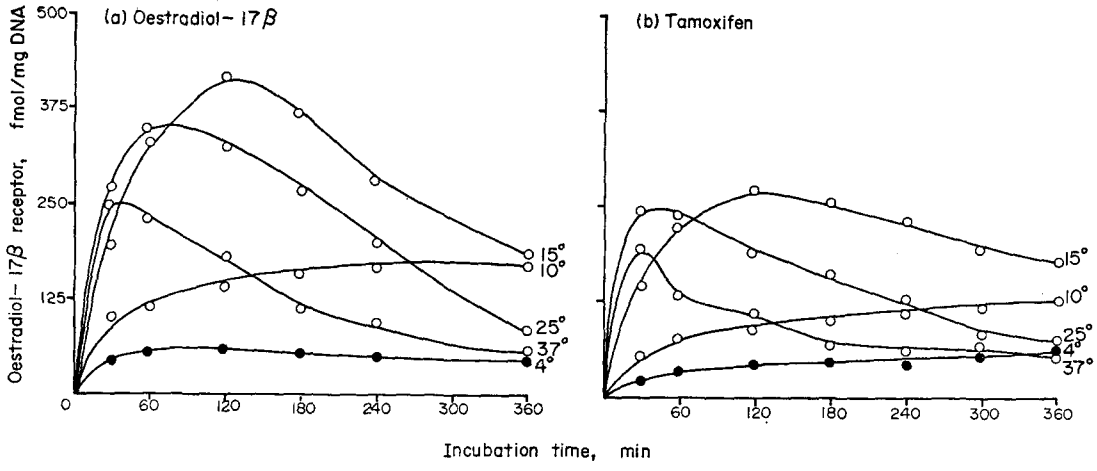

Fig. 1. Determination of binding sites—effect of temperature. Animals were given (a) *oestradiol-17β* (5 μg) *or* (b) *Tamoxifen* (100 μg) 1 *hr before sacrifice. Tumour nuclear preparations were incubated at* 4, 10, 15, 25 *and* 37°C *for periods up to* 360 *min with either* (1) *a saturating concentration of* [^{3}H] *oestradiol-17β* (20 *nmole/l*) *or plus* [^{3}H]*-oestradiol-17β* (2). *Plus a* 1000*-fold excess of unlabelled diethylstilboestrol. Specific oestradiol-17β binding was obtained by subtraction of* (2) *from* (1).

(iii) Animals were treated as follows: Group 1, 4 animals bearing six tumours received injections of tamoxifen (100 μg) on two consecutive days. After a further 24 hr, animals were given oestradiol-17β (5 μg). Group 2 animals (four animals bearing five tumours) received saline injections for the first two days followed by oestradiol-17β (5 μg) on the third. Group 3 animals (three animals bearing five tumours) received saline injections alone. Tumour biopsy samples were removed at time 0, 24, 48, 52, 56 and 60 hr and assayed for cytoplasmic and nuclear oestradiol-17β binding sites.

RESULTS

Measurement of nuclear oestradiol-17β binding sites

The establishment of conditions for the exchange of [^{3}H]oestradiol-17β with endogenous oestradiol-17β or tamoxifen specifically bound to nuclear oestradiol-17β receptors involved (a) determination of the optimum temperature to ensure the greatest rate of exchange with the minimum rate of degradation of binding sites and (b) reduction of the interference of non-specific binding components.

(a) *Temperature optimisation of incubation conditions.* Nuclear fractions prepared from mammary tumours pretreated *in vivo* with oestradiol-17β contain elements that bind [^{3}H]oestradiol-17β (Fig. 1a). Rapid uptake of [^{3}H]oestradiol-17β was observed at 15, 25 and 37°C. Continued incubation of the receptor complex resulted in thermal inactivation. This phenomenon was most evident at 25 and 37°C. Incubations of nuclear fractions at 4°C caused little [^{3}H]oestradiol-17β binding. The maximum [^{3}H]oestradiol-17β binding value was observed after a 2 hr incubation period at 15°C. Similar results were obtained when animals were pretreated with tamoxifen (Fig. 1b).

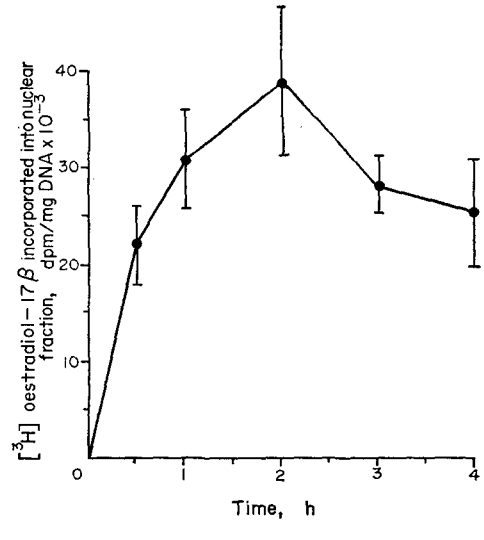

Fig. 2. Nuclear uptake of [^{3}H]*oestradiol-17β. Animals were given* 20 μCi [^{3}H]*oestradiol-17β and tumour biopsy samples removed at time* 0, 0·5, 1, 2, 3, *and* 4 *hr after injection. Nuclear preparations from the biopsies were counted for radioactivity and expressed as dis/min incorporated/mg DNA. Results are the mean ± S.E.M. of five separate tumours.*

Pretreatment of animals with [^{3}H]oestradiol-17β caused the rapid incorporation of radioactivity into mammary tumour nuclear fractions (Fig. 2). The uptake was maximal at 2 hr. Thin layer chromatography of acetone extracts of the nuclear fractions showed the radioactivity

to be associated with oestradiol-17β. Further incubation of the nuclear preparation at 15°C for periods up to 4 hr resulted in a considerable loss of bound radioactivity (Fig. 3). No loss of [^{3}H]oestradiol-17β was observed at 4°C. Inclusion of either oestradiol-17β (20 nmole/l) or tamoxifen (20 nmole/l) in the incubation mixture had no appreciable effect on the amount of radioactivity released.

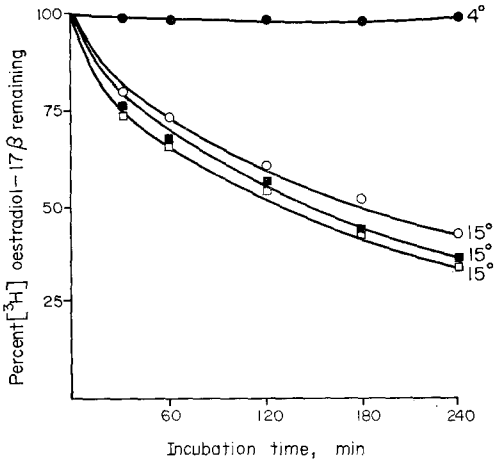

Fig. 3. Rate of exchange of bound [^{3}H]*oestradiol-17β. Animals were given* 20 μCi [3H]*oestradiol-17β 1 hr before sacrifice. Aliquots of the nuclear fraction were treated with protamine sulphate, centrifuged and the precipitated receptor incubated with either Tris buffer,* ●, ○, *oestradiol-17β (20 nmole/l),* ■, *or tamoxifen (20 nmole/l),* □, *at* 4°C *or* 15°C *for periods up to* 4 *hr.*

In view of these results it was considered reasonable that an incubation performed for 2 hr at 15°C would provide an estimate of the oestradiol-17β binding sites present in nuclear fractions of DMBA-induced mammary tumours. Extension of the incubation period or an elevation in the incubation temperature resulted in a nett loss of bound material.

4a). Subtraction of this non-specific binding from the value obtained in the presence of [^{3}H]oestradiol-17β alone, produced a curve demonstrating saturability of binding sites at approximately 15 nmole/l. Analysis of the corrected values by the method of Scatchard [8] gives an apparent dissociation constant, K_D, of 180 pmole/l (Fig. 4b).

Specificity of (a) the accessible cytoplasmic oestradiol-17β binding assay and (b) nuclear oestradiol-17β exchange assay

(a) The affinity of various steroid and non-steroid antioestrogens for the cytoplasmic oestradiol-17β receptor was examined by a competitive binding assay. This involved the incubation of cytosol with a fixed concentration of [^{3}H]oestradiol-17β (5 nmole/l) in the presence and absence of increasing concentrations of the potential oestrogen antagonists (Fig. 5a). Addition of 25 nmole/l oestradiol-17β decreased the binding of [^{3}H]oestradiol-17β to 41% of the control value. The binding continued to decrease with increasing oestradiol-17β concentrations. Testosterone slightly decreased the uptake of [^{3}H]oestradiol-17β whereas corticosterone was without effect. Of the non-steroidal compounds examined diethylstilboestrol, tamoxifen and CI628 were the most effective antagonists.

(b) Competitive binding assays performed on nuclear exchangeable material gave a similar gradation of results (Fig. 5b).

In vivo *effects of oestradiol-17β and tamoxifen*

Within 30 min following *in vivo* administration of 0·5 μg oestradiol-17β a 50% reduction in the binding of [^{3}H]oestradiol-17β to specific cytoplasmic binding proteins was observed (Fig. 6a). The effect was associated with a concomitant progressive increase in specific nuclear oestradiol-17β binding sites. The number of nuclear oestradiol-17β binding sites had increased from a control value of 133 fmole/mg DNA to 369 fmole/mg DNA by 60 min after oestradiol-17β treatment. Elevation of the level of oestradiol-17β (5 μg) administered *in vivo* caused a more pronounced depletion of cytoplasmic binding sites. Nuclear oestradiol-17β binding sites increased to 478 fmole/mg DNA after 60 min. Tamoxifen, like oestradiol-17β, showed similar properties although the response was not as great (Fig. 6b). Injection of saline vehicle had no appreciable effect on either cytoplasmic or nuclear binding sites (Fig. 6c). A secondary period of elevated cytoplasmic

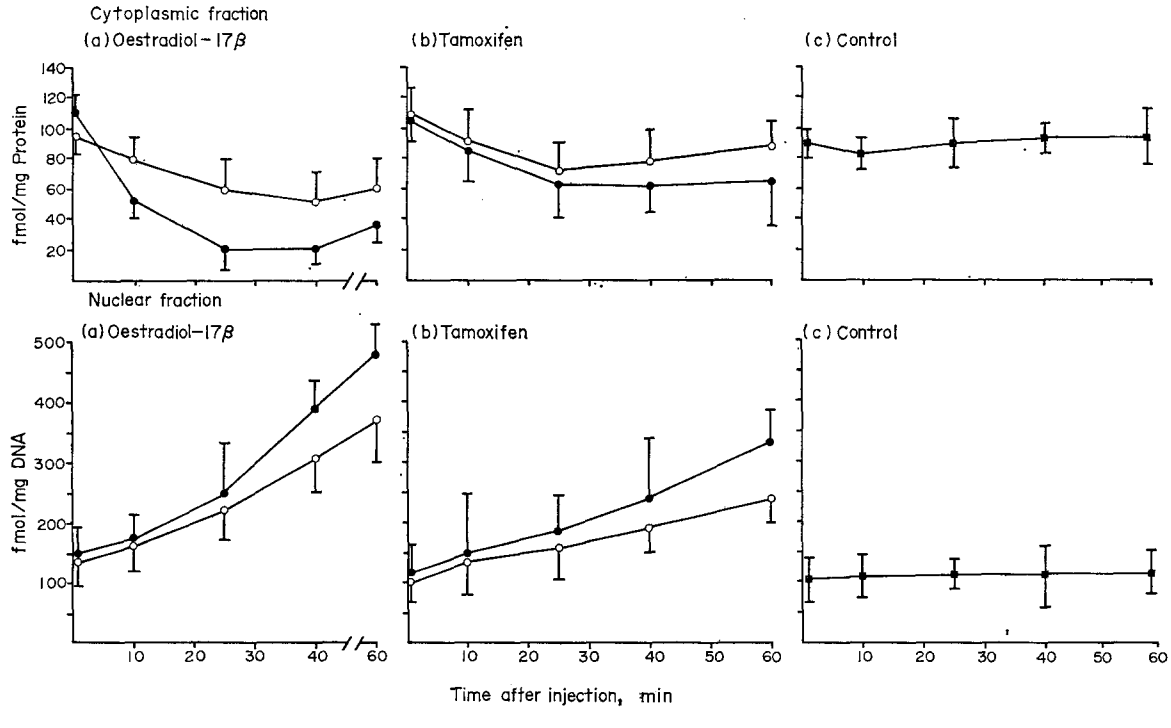

Fig. 6. Effect of in vivo *administration of oestradiol-17β and tamoxifen on cytoplasmic and nuclear oestradiol-17β binding sites. Rats were injected with either* (a) *oestradiol-17β* (0·5 μg, ○ *or* 5 μg, ●), (b) *tamoxifen* (10 μg, ○, *or* 100 μg, ●) *or* (c) *vehicle alone. oestradiol-17β binding was observed after either tamoxifen or oestradiol-17β administration (Fig. 7). The results indicate that accessible receptor levels are considerably increased during the 4–24 hr period following oestradiol-17β injection and during the 4–16 hr period following tamoxifen treatment. Tamoxifen, unlike oestradiol-17β, was unable to maintain elevated receptor levels, which showed a considerable decrease in concentration during the 24–48 hr experimental period. Saline injections had no appreciable effect on accessible receptor levels. The concentration of nuclear oestradiol-17β binding sites increased to a

maximum (979 fmole/mg DNA) 2 hr after oestradiol-17β administration (Fig. 7) and were still elevated over control values after 24 hr. Administration of tamoxifen produced a less rapid accumulation of nuclear oestradiol-17β binding sites which reached maximum value at 4 hr and returned to pre-stimulation levels at 24 hr.

The administration of tamoxifen (100 μg/day) to tumour-bearing animals on two consecutive days reduced the capacity of the mammary tumour cytosol to bind [^{3}H]-oestradiol-17β (Fig. 8). A further injection of oestradiol-17β (5 μg) at this time did not result in any appreciable nuclear uptake of exchangeable oestradiol-17β or in a stimulation of accessible cytoplasmic oestradiol-17β binding sites. Mammary tumours present in saline treated animals retained their capacity to respond to oestradiol-17β administered *in vivo*.

DISCUSSION

This report describes the development and use of an exchange assay for the determination

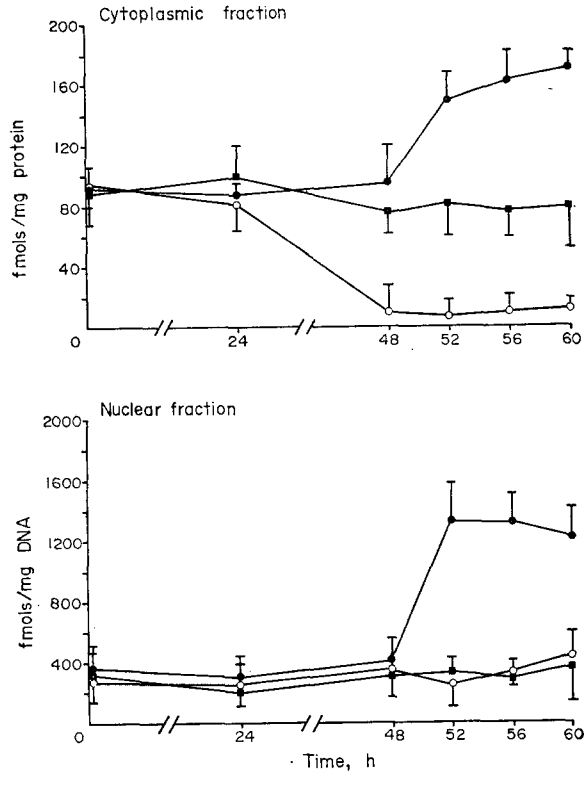

Fig. 8. Effect of tamoxifen pretreatment on the tumour response to oestradiol-17β. Animals were divided into three groups: Group 1 (○) *animals received injections of tamoxifen* (100 μg) *on two consecutive days. After a further* 24 *hr animals were administered oestradiol-17β* (5 μg). *Group* 2 (●) *animals received saline injections for the first two days followed by oestradiol-17β* (5 μg) *on the third. of nuclear oestradiol-17β binding sites present in DMBA-induced mammary adenocarcinomata of rats, irrespective of whether the sites are occupied by oestradiol-17β or tamoxifen. The criteria of minimum loss of binding sites with relatively high rates of exchange were met using an assay temperature of 15°C and an incubation period of 2 hr. The conditions of assay are therefore identical to those described for the estimation of total oestradiol-17β binding sites present in cytoplasmic fractions of DMBA-induced rat mammary tumours [1]. Specificity studies carried out on the binding of

[^{3}H]oestradiol-17β to filled (nuclear) or unfilled (accessible cytoplasmic) binding sites demonstrates that the receptor protein has similar affinity characteristics for non-steroidal oestrogen antagonists in each state. These data suggest a common origin.

The relative ability of the non-steroidal oestrogen antagonists in competing for oestradiol-17β binding sites correlates closely with (a) their relative effectiveness in reducing the *in vitro* capacity of the DMBA-induced mammary tumour to bind [^{3}H]oestradiol-17β following their *in vivo* administration and (b) their ability to cause a regression in tumour mass [2]. It was not possible in that earlier study to determine whether the loss of receptor-binding was due to a decrease of receptor protein or to a strong association of the ligand to the receptor complex, which through steric or transport effects resulted in a biologically inactive complex. The present study demonstrates that tamoxifen can compete with oestradiol-17β for its cytoplasmic receptor protein, although this may be allosteric rather than a direct competition [9]. Other investigations have also demonstrated that tamoxifen can effectively block the association of the oestradiol-17β molecule with its specific receptor protein in DMBA-induced mammary adenocarcinomata [3, 10]. Indeed, we have ascribed an affinity constant of $0{\cdot}213 \times 10^{-2}$l/nmol (cmf $0{\cdot}643 \times 10^{-1}$l/nmol for oestradiol-17$\beta$) to the interaction between tamoxifen and the oestradiol-17β receptor protein [11]. Sedimentation analysis of tamoxifen treated cytosol fractions [3, 10] demonstrates that the anti-oestrogen competes for 8S-oestrogen binding components.

Although the initial association of tamoxifen with its specific cytoplasmic binding site is undoubtedly important, this present study indicates that it forms only part of the complex mechanism by which tamoxifen influences tumour growth. After the *in vivo* injection of tamoxifen or oestradiol-17β, a rapid dose-dependent accumulation of nuclear [^{3}H]-oestradiol-17β exchangeable material occurs. Maximum [^{3}H]oestradiol-17β binding values were observed 2 hr following the administration of oestradiol-17β and 4 hr after tamoxifen treatment. Oestradiol-17β more effectively promoted the translocation process than did tamoxifen, which may reflect either their relative rates of entry into the tumour cells [1, 10, 12], or their different affinities for the oestradiol-17β receptor protein.

The translocation of the receptor complex to the nucleus results in an initial depletion of both total [1] and accessible cytoplasmic oestradiol-17β binding sites. Tamoxifen is able to elicit further oestrogen-like actions which result in elevated cytoplasmic binding site levels. The above data are not compatible with the hypothesis that the sole action of tamoxifen lies in its ability to compete with oestradiol-17β for its cytoplasmic binding sites. It would appear that tamoxifen, bound to the cytoplasmic binding protein, enters the nucleus and associates with chromatin acceptor sites, thus affecting the rates of transcription of the DNA template. Such a phenomenon has been demonstrated in other studies from this group [13] which show that the administration *in vivo* of either oestradiol-17β or tamoxifen brings about an early elevation in nuclear RNA polymerase B activity. It would seem reasonable that the secondary effects observed in the cytoplasmic oestradiol-17β receptor levels following tamoxifen treatment are a direct consequence of an interaction of the tamoxifen-receptor complex with chromatin, resulting in the production of mRNA species coding for specific proteins including the receptor for oestradiol-17β.

Tamoxifen, unlike oestradiol-17β, is unable to maintain elevated cytoplasmic receptor levels, which diminish during the 24–48 hr experimental period. The effect was also reported by Clark, Anderson and Peck [14] and Rochefort and Capony [15] for nafoxidine and for CI628 by Katzenellenbogen and Furguson [16] using rat uteri. The results of Clark *et al.* [14] clearly indicate that nafoxidine acts as an atypical oestrogen in that it can stimulate uterine growth over extended periods of time (up to 19 days), but when administered either simultaneously with oestradiol-17β or when injected 24 hr before oestradiol-17β, acts as an oestrogen-antagonist. Furthermore, the nafoxidine-receptor complex present in nuclear fractions remains elevated, although there is no apparent replenishment of the cytoplasmic oestradiol-17β binding protein. The elevated retention of the ligand-receptor complex was not noted in DMBA-tumour nuclear fractions following the administration of tamoxifen. This may in part account for its anti-tumour activity since continued high levels of ligand-receptor complex seem to be equatable with oestrogen-like responses. However, the small amounts of [^{3}H]oestradiol-17β exchangeable material present in rat mammary tumour nuclei 24 hr and 48 hr after tamoxifen treatment should not be disregarded. It may represent a limited number of tamoxifen–receptor complexes in chromatin resulting from

either a relatively strong association of the receptor with specific acceptor sites or it may be a consequence of a low clearance rate for tamoxifen and its metabolites from the animal [17].

Tamoxifen treatment therefore results in a depletion of tumour cytoplasmic oestradiol-17β binding sites, a condition which appears to be refractory to further oestrogen action, since *in vivo* administration of oestradiol-17β at this time fails to stimulate receptor uptake into tumour cells nuclei or replenish cytoplasmic binding sites. The tumour is therefore in an oestradiol-17β non-responsive state, a condition which must ultimately result in a regression of tumour mass.

Abstract—*In a previous report three year survival rates in breast cancer were related to geography, socio-economic status and age at first pregnancy. Here, results from 5 years of follow-up observations are summarized with respect to incidence risk factors. Age-adjusted 5 year survival rates were 57·3% in Boston, Massachusetts, 49·5% in Glamorgan, Wales, 41·9% in Slovenia, Yugoslavia, and 74·9% in Tokyo, Japan; corresponding age-adjusted annual incidence rates per 100,000 were 55·0, 38·8, 24·4 and 12·9. Although survival rates varied markedly among these areas, there was not a consistent relationship between incidence rate and probability of survival. Differences in survival rates between Boston, Glamorgan and Slovenia were reduced when examined according to extent of disease at diagnosis, but the relatively high survival rate in Tokyo was not explained. Survival rates tended to increase, although inconsistently, with increasing socioeconomic status as measured by duration of schooling. Probability of survival was not related to childbearing or, for parous patients, to age at first full-term birth.*

THREE year survival rates of female breast cancer patients in Boston, Massachusetts, Glamorgan, Wales, and Tokyo, Japan, were related previously to incidence rate of the disease, and to duration of schooling and age at first pregnancy, two variables which are associated with risk of developing the disease [1]. The survival rate was highest in Tokyo, where the incidence rate is very low. However, the lowest survival rate was observed in Glamorgan, where the incidence rate is lower than in Boston, but much higher than in Tokyo. Differences in survival rates between these areas were not explained by differences in the extent of disease at diagnosis. The probability of survival was only inconsistently related to duration of schooling, and was unrelated both to childbearing and to the age at which parous patients first became pregnant. The purposes of the present report are: (1) to present survival data from five years of observation in these three areas and in an additional area, Slovenia, Yugoslavia, and (2) to summarize available evidence on the relationship of incidence factors to survival.

MATERIAL AND METHODS

The series of patients described here were assembled during a collaborative international study of etiologic factors in female breast cancer [2]. In Boston, Glamorgan and Slovenia nearly all newly diagnosed cases of breast cancer in geographically defined populations were ascertained during the period of observation. Ascertainment was not complete in Tokyo, but the cases are believed to be about half of those in the prefecture of Tokyo-to, and to be representative of new cases in the area. The characteristics of the patient series have been reported [3–6].

Accepted 30 August 1976.

*This study was supported by grants from the U.S. National Cancer Institute (5 PO1 CA 06373), the Boris Kidrič Fund of Yugoslavia (302/5-70) and from the World Health Organization.

The extent of tumor at diagnosis was assessed from information in the record of the initial hospitalization for breast cancer. Only information obtained before biopsy or treatment was used for the clinical assessment. For pathologic assessment, a patient was required to have had regional lymph nodes examined histologically or to have had a histologically confirmed metastasis. Otherwise, the pathologic extent of disease was considered "unknown". A tumour was classified as "localized" if there was no evidence of extension beyond the breast. Evidence of spread no further than to ipsilateral skin, chest wall or axillary or subclavicular lymph nodes was considered "regional". Greater extent was designated as "distant" disease.

The original patient series numbered 758 in Boston, 710 in Glamorgan, 831 in Slovenia and 861 in Tokyo. Five cases in Boston, two in Glamorgan, one in Slovenia and six in Yokyo subsequently were found not to be eligible index cases and were excluded. Survival was measured from the date of the first hospitalization during which a diagnosis of breast cancer was made. The proportions of eligible patients successfully followed to five years were high—98·9% in Boston, 97·9% in Glamorgan, 99·4% in Slovenia and 98·5% in Tokyo. Therefore, the present report is based on the successfully followed patients only, without consideration of patients lost to follow-up.

Survival rates have been adjusted for age by the direct method of standardization [7] and these rates are accompanied by their standard errors. In the tables, numbers in parentheses are the numbers on which the survival rates are based. Rates are not given for categories with less than 25 patients.

RESULTS

Table 1 gives adjusted rates of survival to the end of each year of observation, crude five-year survival rates, and age-adjusted incidence rates in each area. After each year of observation, the survival rate was highest in Tokyo, followed, in descending order, by the rates in Boston, Glamorgan and Slovenia. Among these areas, the disparity in survival rates is considerable; the five year survival rate in Tokyo is 1·8 times the rate in Slovenia. The relationship of survival rate to incidence rate is irregular: the highest survival rate, in Tokyo, is associated with the lowest incidence rate but the lowest survival rate, that in Slovenia, was observed in the area with the next lowest incidence rate.

Distributions of patients according to clinical extent of disease at diagnosis are presented in Table 2. The highest percentage of patients with localized disease was observed in Boston and the lowest percentage in Slovenia. Patients in Tokyo had the lowest percentage of distant disease. As with survival rates, there is no simple relationship between incidence risk and extent of disease. Comparisons of pathologic extent are not presented since these distributions could be affected very greatly by therapeutic practices. In Slovenia, for example, where non-surgical management of breast cancer is relatively frequent [8], pathologic extent was "unknown" for 49·2% of patients.

Survival rates according to clinical extent of disease are presented in Table 3. Data for each year of follow-up are given for local and regional disease, where the numbers of patients were greatest. Except for the few patients with unknown extent, the high survival rate of the Japanese patients was evident in each extent category and after each year of follow-up observation. Differences in survival rate between Boston, Glamorgan and Slovenia were small among patients with localized tumors. For patients in these areas who had tumors classified as regional, the survival rate after each year of follow-up was highest in Boston, as was the rate in the total group of patients. After one year, the survival rate was slightly higher in Slovenia than in Glamorgan. In successive years, the survival rate was higher in Glamorgan, the greatest difference between these two areas occurring after three years.

Five year survival rates according to pathologic extent are given in Table 4. Again, the favorable survival experience of the Japanese patients is observed consistently. Extent-specific differences in survival rates between Boston, Glamorgan and Slovenia tended to be smaller than the differences in the overall rates, but the large numbers of patients with unknown pathologic extent, particularly in Glamorgan and Slovenia, make interpretation of these results difficult.

Five year survival rates are shown by duration of schooling in Table 5. Generally, the rates tended to rise with increasing duration of schooling. In Tokyo the increase in survival was small compared to that in the other centers. Although there was a marked rise in survival rate from the first to the second level of education in Slovenia, the survival rate of patients who had 12 to 15 years of schooling was again quite low.

Survival rates also were examined in relation to childbearing and to the age at first full-term

birth of parous women (Table 6). Probability of survival to five years following diagnosis was neither strongly nor regularly related to either of these characteristics.

DISCUSSION

Principally because of the relatively high survival rate in Japan, where the incidence rate is very low, consideration has been given to the possibility that the survival rate of breast cancer patients is inversely related to the incidence rate of the source population [1, 9, 10]. The observation that breast cancer in Japan appears less aggressive, histologically, than does breast cancer in the United States [11, 12] has tended to support this idea.

Accumulating data, however, strongly suggest that survival does not have a simple relationship to incidence risk. (A) Although the survival rate of patients in Japan is high, the relationship between incidence and survival is

not regular. For instance, the survival rate in the United States consistently has been higher than that in England [9], where the incidence rate is lower than in the U.S. (B) Although duration of schooling is related, albeit somewhat irregularly, to survival rate, the patients with most education, representative of those at highest incidence risk on this variable, have the highest survival rates. The basic geographic observation, high survival rates in Japan where risk is low, is in the opposite direction. (C) Age at first birth, a stronger risk factor than duration of schooling, has appeared unrelated to survival. (D) Removal of the ovaries before age 35 is associated with a substantial reduction in breast cancer risk [13, 14]. The probability of survival of breast cancer patients was observed to be related to pelvic surgery before development of the malignancy [15, 16]. However, the survival advantage associated with prior pelvic surgery did not appear to depend on removal of the ovaries nor on whether the operation was performed before natural menopause [16]. (E) International differences in histology have not explained the high survival rate in Japan despite the relatively frequent occurrence of favorable histologic characteristics among breast cancer patients there [10–12, 17].

In conclusion, the major known indicators of breast cancer risk do not appear to be important determinants of the survival of patients affected with the disease. Because breast cancer is a commonly occurring malignancy, and because the overall outlook for patients with this disease is not favorable, investigation of the natural history of breast cancer should continue.

Studies of the Effects of Busulphan on the Regeneration of Rat Liver

P. D. BROWN and P. F. ZAGALSKY

Biochemistry Department, Bedford College, Regent's Park, London NW1 4NS, Great Britain

Abstract—*Regeneration of rat liver is retarded by busulphan (4·4 mg/kg of body weight) given interperitoneally at the time of partial hepatectomy. The incorporation of tritiated thymidine into liver DNA is diminished in busulphan-treated animals and it is suggested that the drug prevents cells from entering the proliferative stage. Busulphan is without effect on the duration of the mitotic phase of the cell cycle of the parenchyma, but causes a slight prolongation of the durations of the S and G_2 phases and a partial inhibition of the passage of cells from the G_2 to the M phase of the cycle.*

INTRODUCTION

THE WIDE use of busulphan (1,4-dimethanesulphonyloxybutane, "Myleran") and its derivatives in the treatment of leukaemia stems from their selectivity of action on haemopoietic tissues [1]. The primary site of action of busulphan and other alkylating agents is considered by some authors [2–4] to be the mitotic apparatus. Busulphan presents many of the features of a monofunctional alkylating agent toward DNA [5, 6; but see 2] and its action has been attributed to depurination and consequent single-strand breakage of the nucleic acid [5]. It is well documented, however, that busulphan has effects other than on the mitotic apparatus [4, 7] and part of the injury to the chromosomes could arise indirectly from lysosomal damage [8]; the drug binds not only to DNA but also to RNA and protein [2]. The multiplicity of possible reactions of alkylating agents with tissue components makes it difficult to designate any single reaction as the cause of cytotoxicity [7, 9].

There are conflicting reports concerning the phase(s) in the cell cycle at which busulphan acts. It has been concluded that busulphan and "Myleran-type" drugs arrest bone marrow "stem cells" in the resting, G_0 phase of the cell cycle rendering them unable to produce a normal differentiated population [10]. In rat epithelium, however, there is evidence that the drug acts in the G_1 phase of the cell cycle in a manner that allows cells to initiate and complete DNA synthesis normally but that prevents their subsequent mitotic division [11].

In the use of chemotherapeutic agents it is desirable to know what consequences these have on cells of normal tissues and on the ability of such cells to respond to proliferative stimulus subsequent to repair or regeneration. Busulphan is known to cause marked cellular changes in organs other than bone marrow during the treatment of patients with chronic myelogenous leukaemia [12]. The effects of a single dose of busulphan on a rapidly proliferating tissue, regenerating liver, are presented here, together with studies into the possible points of action of the drug in the cell cycle of the parenchyma.

Accepted 14 September 1976.

MATERIAL AND METHODS

Animals

Four to six-week old male rats, *Mus norwegicus* of the hooded Lister strain, random bred and weighing between 80–150 g were used in the studies.

Partial hepatectomy and drug administration

Partial hepatectomy of *ca.* 70·2% (determined by direct measurement on 10 rats) of the liver, consisting of removal of the median and left lateral lobes, was performed under ether anaesthesia by the method of Higgins and Anderson [13]. Operations were carried out between 6 a.m. and noon to minimise diurnal variation in regenerative ability [14]. Animals were allowed food (Oxoid diet 41B; Oxoid, London, Eng.) and 5% dextrose *ad libitum*

following operation and were maintained at 22°C.

Busulphan (1,4-dimethanesulphonyloxybutane) was administered (4·4 mg/kg of body weight, in an emulsion of dimethyl sulphoxide–arachis oil, (9/1, v/v) [10]. Doses (0·5 ml) of busulphan suspension or, for control animals, drug-free dimethylsulphoxide–arachis oil emulsion were given intraperitoneally before completion of suturing.

Histological preparation and autoradiography

Animals were sacrificed by heavy ether anesthesia and cervical dislocation. Histological sections were prepared from portions of the right laterial lobe of livers and examined by high resolution autoradiography using the liquid emulsion-dipping method, as described by Fabrikant [15]; slides were stained with haematoxylin and eosin after autoradiography. Parenchymal mitoses were scored as labelled if an arbitrary lower limit of 5 grains per mitotic figure was exceeded.

Estimation of nucleic acids

The contents of RNA and DNA in liver samples were determined by a modification of the Schmidt–Thannhauser method [16], estimating RNA spectrophotometrically [17] and DNA using an improved diphenylamine method [18]. The phosphorus content of calf thymus DNA (BDH Chemicals Ltd., Poole, Eng.), used as DNA standard, was determined by the method of Allen [19].

Incorporation of tritiated thymidine (TdR-6 ^{3}H) into DNA

Partially hepatectomized rats were injected at 6 hr intervals with TdR-6 ^{3}H (specific activity 20–30 Ci/mM, purchased from Radiochemical Centre, Amersham, England; 0·5 μCi/g of body weight in 0·5 ml normal saline given intraperitoneally) and sacrificed after 45 min. Assays of radioactivity in DNA extracts, prepared as above, were carried out with a Packard tri-Carb liquid scintillation counter (Packard Instruments Co., Ill., USA) using the emulsion technique (tT21) of Patterson and Green [20]. DNA samples (1 ml in 1N $HClO_4$ with 10 ml scintillant) were counted with an efficiency of *ca.* 27%. A quench curve was prepared by addition of 8–10 μl of nitromethane to vials containing 10 ml scintillant and 1 ml N $HClO_4$ containing a known amount of TdR-6 ^{3}H.

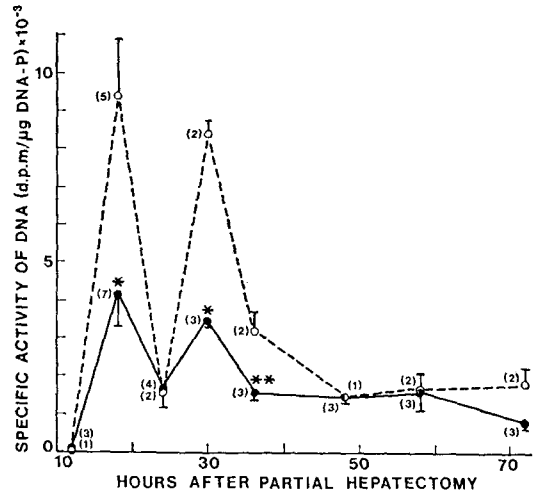

Fig. 1. Incorporation of tritiated thymidine into DNA of regenerating rat liver.

Legend: The mean values for control (○) and busulphan-treated animals (●) are shown. The number of rats employed are given in brackets; 4 analyses were made on each of two duplicate samples of liver from each rat. The vertical lines illustrate S.E.M. Values which differ significantly from those of controls ($P < 0·05$ and $P < 0·1$**) are indicated.*

Duration of cell cycle phases

Rats were injected intraperitoneally with TdR-6 ^{3}H (0.5 μCi/g of body weight in 0.5 ml normal saline) 16 hrs after partial hepatectomy, killed at hourly intervals, and the fraction of labelled (5 grains or more) parenchymal mitoses counted. A minimum of a hundred mitoses

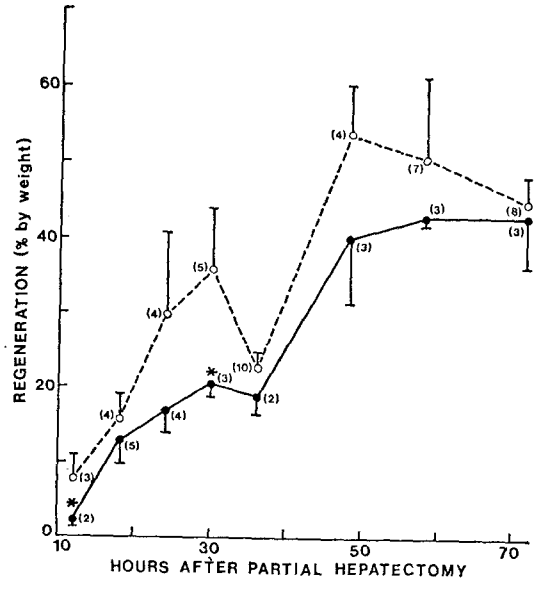

Fig. 2. Restoration of liver mass following partial hepatectomy.

were scored for each rat and the phases of the mitoses (pro-, meta-, ana- or telo-phase) were recorded. The proportion of abnormal mitotic figures in each phase was noted, taking the criteria of abnormality given by Horst and Rudnicki [21]. The durations of the cell cycle phases (T_{G_1}, T_S, T_{G_2} and T_M) were determined by analyses of percentage labelled mitoses curves [22]. The means and standard deviations of T_{G_2} and T_S were derived from probit plots of the faction of labelled mitoses [23]. An approximate value for the duration of the complete cell cycle (T_C) for control rats was estimated from corresponding points on the first and second waves of labelled mitoses. The durations of G_2 (minimum) + M/2 were taken as the distance on the abscissae from the times of injection of tritiated thymidine to the mid-points of the ascending limbs of the waves of labelled mitoses. Prophase durations were derived from the differences of the times of interception on the abscissa of the prophase and metaphase labelling curves or from the half-maximal labelling intercepts of the ascending limbs of these curves; the times of the other mitotic phases, and thus of T_M, were calculated from the percent of mitoses in each phase over the period (19–28 hr after operation) of study [24]. The approximate duration of the G_1 phase of the cell cycle (T_{G_1}) was derived from T_C and the length of the other cell cycle phases.

Mitotic indices curves were plotted with values corrected for the increasing mass of liver [15].

RESULTS

The effect of busulphan on the incorporation of TdR (6-^{3}H) into DNA of regenerating rat liver is shown in Fig. 4. The rate of DNA synthesis is considerably reduced during the first 48 hr of regeneration following treatment with the drug and the specific activity of DNA is lowered by *ca.* 60% at the peaks (18 and 30 hr) of synthesis. The restoration of liver weight is, arguably, retarded by busulphan during this time interval (Fig. 2); the DNA and RNA contents of the regenerating tissue, however, are not significantly changed by the drug. (Fig. 3a, b).

The percentage labelled mitoses curve of the parenchymal cells of busulphan-treated rats, obtained following pulse-labelling with TdR-^{3}H, is displaced on the time axis by *ca.* 1 hr (Fig. 4). The mean durations of the DNA synthetic period, or S phase of the cell cycle (T_S), and of the premitotic G_2 phase (T_{G_2}), estimated by probit analyses of the curves, are slightly prolonged following drug-treatment (Table 1) without any appreciable change in the spread of the durations (cf. coefficients of variance); an increase in the minimum duration of the G_2 phase is also found. The single dose of busulphan does not alter the duration of the mitotic phase (T_M) since the time taken for the ascending limb of the curve to rise to maximal labelling ($\approx T_M$) remains unaltered.

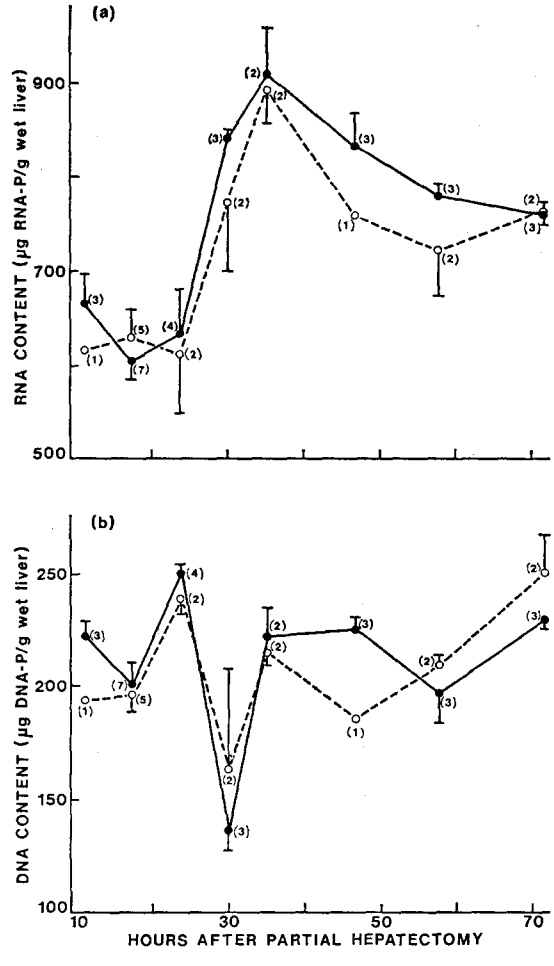

Fig. 3. Effect of busulphan on (a) the RNA content and (b) the DNA content of regenerating rat liver.

Legend: The mean values for control (○) and busulphan-treated animals (●) are shown. The number of rats used are given in brackets; 4 analyses of DNA were made on each of two duplicate samples of liver from each rat; one determination of RNA content was made for each rat. The vertical lines represent S.E.M. Experimental values do not differ significantly from control values ($P > 0{\cdot}1$).

Similarly, a study of curves of labelled mitoses for the individual mitotic phases (Fig. 5), which are displaced by *ca.* 1 hr for busulphan-treated rats, provides no evidence that the drug causes any significant alteration in the durations of phases or in the total time of mitosis (Table 2); a partial blockage in any of the mitotic phases would have led to a change in

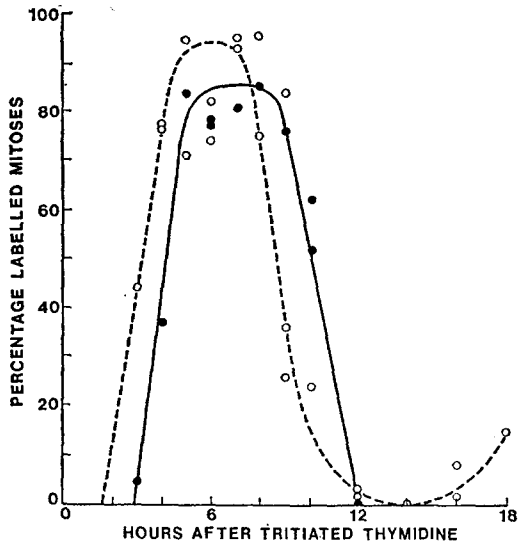

Fig. 4. Percentage labelled mitoses of parenchymal cells of partially hepatectomised rats recorded at intervals after pulse-labelling with tritiated thumidine.

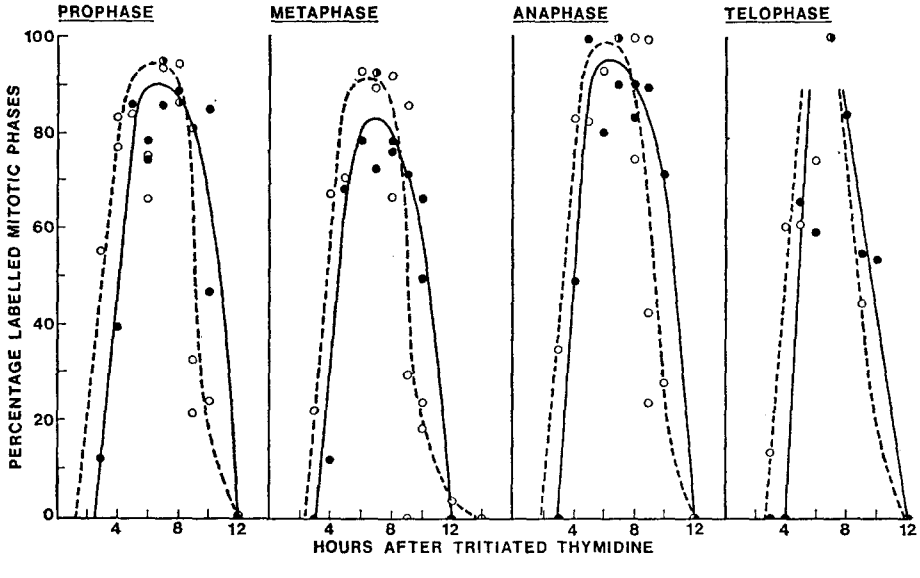

Fig. 5. Percentage labelled mitotic phases of parenchymal cells of partially hepatectomised rats recorded at intervals after pulse labelling with tritiated thymidine.

Legend: ○, controls; ●, animals treated with busulphan. Both groups were injected with tritiated thymidine at 16 hr after partial hepatectomy, which corresponds to the origin (0 hr) on the abscissa. Each circle represents the number of mitotic phases in 100 mitoses scored for one rat.

the estimate of duration of the phase and subsequent phases. Lower maximal values of percentage labelled mitoses (and mitotic phases) are reached, however, following administration of the drug.

It was not possible to calculate the total cell cycle time (T_C) for busulphan-treated animals as they showed only one wave of mitotic labelling (Fig. 4).

An increase (< 15% of the total number of mitoses) was observed in the level of abnormal mitotic figures for drug-treated animals be-

Table 2. Durations of the individual mitotic phases of parenchyma in regenerating rat liver

Phase	Duration (hr)	
	Control rats	Busulphan-treated rats
Prophase	1·0[a]	1·1[b]
Metaphase	0·72	0·65
Anaphase	0·16	0·18
Telophase	0·05	0·09

Legend: [a]Derived from half-maximal labelling intercepts of ascending limbs of prophase and metaphase labelling curves. [b]Obtained from differences of times of interception on abscissa of prophase and metaphase labelling curves.

tween 16 and 30 hr after partial hepatectomy; the abnormalities were not restricted to any particular phase of mitosis.

The parenchyma of control animals showed a major peak of mitotic activity (mitotic index, 5%) at 26 hr and a minor peak of activity (mitotic index, 2%) at 22 hr following operation. Measurements of mitotic index for drug-treated animals were too variable to ascribe to the drug an effect on mitotic activity.

DISCUSSION

The dose of busulphan used in the present study was chosen so as to be less than the total amount (mg/kg body weight) administered over a period of several weeks, to achieve remission status, to patients with chronic myelocytic leukaemia [25]; it is well below the lethal level for rats [1]. The long half-life of the drug (11–12 hr [26]) ensures that it is viable, when administered interperitioneally immediately following partial hepatectomy, throughout the first cycle of the stimulated proliferative growth of the parenchymal cells; young rats show two peaks of DNA synthesis, in contrast to older animals [14].

The single dose of busulphan caused a small increase in the level of parenchymal mitotic abnormalities, but these were not restricted to a particular mitotic phase [11]; continued administration of busulphan is known to cause injury to the mitotic apparatus [3].

The relatively minor effects of busulphan on the S and G_2 phases of proliferating parenchymal cells and its lack of action on the durations of the mitotic phases is consistent with the insensitivity of the later phases of the cell cycle of "stem cells" to the drug [10].

The reduced level of labelled mitoses (and mitotic phases) following administration of the drug can not be attributed to increased spread in the duration of the G_2 phase. It may be explained [27] by an increased flux of cells from a higher-order polyploid G_2 population or, more likely, by a partial blockage in the G_2 phase due to cross-linking of completed DNA strands, thereby inhibiting mitosis [11].

The reduced incorporation of tritiated thymidine into DNA is indicative of an action of the drug, extending to both proliferative waves, on the G_0 phase of the cell cycle of the parenchyma. The lower specific activity of the liver DNA may also be due, in part, to an influence of the drug on the activities of thymidine and thymidylate kinases. The levels of the kinases follow the mitotic activity of the parenchyma [28] and are reduced in leukocytes from leukaemic patients after busulphan therapy [29]. Partial inhibition of the enzymes would account for the (small) increase in duration of the S phase of the parenchyma following busulphan treatment. Busulphan (or its derivatives) has been reported to decrease the incorporation of tritiated thymidine into the DNA of bone marrow cells [30] and murine leukaemic cells [31] *in vitro*, but to be without effect on the incorporation of the labelled precursor into DNA of mouse seminous epithelium [32], rat lens epithelium [11] and mouse thymocytes [33].

The slower restoration of liver weight for busulphan-treated rats during the first 30 hr following operation is unlikely to have been due to differences in glycogen content, resulting from reduced feeding, or to an effect on the increased fluid uptake following partial hepatectomy [13], since significant differences between control and experimental animals in DNA and RNA contents were not observed over this time period.

It is probable, therefore, that the drug arrests cells, directly or through action on the endoplasmic reticulum [34], in the resting, G_0 phase (or lowers the transition probability for transfer from the A-state to B-phase [35]), thus reducing the number of cells entering the proliferative state. An effect on the G_0 phase of the parenchymal cells should be apparent in reduced values of mitotic index for experimental animals, provided that the proportion of mitotic abnormalities is low and that they are evenly distributed within the tissue. In practice, a consistent reduction in the values of the mitotic index for experimental animals over the period 20–30 hr following operation could not be substantiated. A greater variation in these

values for drug-treated animals suggests, possibly, that mitotic abnormalities were not evenly distributed within tissue slices [11].

The duration of the G_1 phase following drug treatment was not obtainable from the labelled mitoses curve. An increase in the duration of this phase would depress further the rate of entry of cells into the S phase and cause the peak values for tritiated thymidine incorporation to occur at correspondingly later times. The time interval between measurements of thymidine incorporation was too long for a difference to be observed between control and experimental animals of < 3 hr in the peak rates of DNA synthesis for the first and second wave of proliferation. The symmetry of the thymidine incorporation curves make it unlikely, however, that the duration of the G_1 phase is appreciably affected by the drug.

Oestrogen Receptor Activity and Endocrine Status in DMBA-Induced Rat Mammary Tumours

R. A. HAWKINS, A. HILL, B. FREEDMAN, ENID KILLEN, P. BUCHAN, W. R. MILLER and A. P. M. FORREST

Department of Clinical Surgery, University of Edinburgh, Great Britain

Abstract—*Oestrogen receptor activity (unfilled sites) has been determined in DMBA-induced rat mammary tumours and at sacrifice, the plasma concentrations of oestradiol-17β and prolactin were determined by radioimmunoassay.*

In intact animals, receptor levels were found to fluctuate in inverse relationship with the plasma oestrogen concentration, but following ovariectomy, levels were significantly reduced. Administration of oestrogen to ovariectomized animals did not detectably change receptor levels but administration of perphenazine significantly increased receptor levels towards those seen in intact animals.

In animals bearing two or more tumours, similar receptor concentrations were detected in tumours from the same animal.

It is concluded that the concentration of oestrogen receptor sites in rat mammary tumours is influenced by the circulating levels of both oestrogen and prolactin.

INTRODUCTION

DMBA-INDUCED rat mammary tumours, like some human breast cancers, are hormone-sensitive [1]. They contain receptors for oestrogen [2–6], prolactin [7, 8] and progesterone [9]. The oestrogen receptors in these rat tumours have been shown to be similar to those in human breast cancers chemically [10] and in their relation to response to endocrine surgery [4]. Prior to evaluating further the relationship between receptor measurements and the endocrine responsiveness of experimental mammary tumours, we have investigated the influence of endocrine status on the level of receptor activity.

MATERIAL AND METHODS

Tumours

Female Sprague–Dawley rats were given DMBA (30 mg) by intragastric instillation. Tumours induced within 6 months were measured with calipers twice weekly. Size was expressed as the product of measurements in two dimensions. On reaching 1·5 × 1·5 cm tumours were either studied directly or subjected to endocrine manipulation prior to receptor assay. Tumours were excised after exsanguination of the rat under ether anaesthesia. Vaginal smears were taken daily from 45 intact animals and the stage in the oestrous cycle was classified as described by Yoshinaga *et al.* [11].

Accepted 15 September 1976.

Endocrine manipulation

Fourteen tumour-bearing rats were injected subcutaneously (s.c.) with perphenazine (5 mg/kg body weight) for 14 days.

A further 57 tumour-bearing rats were ovariectomized under ether anaesthesia and divided into three groups which were treated differently. In one group (OVX) of 11 rats, no further treatment was given until sacrifice 14 days later. In a second group (OVX+OE_2), 33 animals were left for 9–14 days and then injected s.c. with oestradiol 17-β (1–5 mg day in corn oil) for a further 6 days. In the third (OVX+Perphen) 13 animals were treated either immediately (9 rats) or after a period of 6–13 days of no treatment (4 rats) by subcutaneous injection of perphenazine (5 mg/kg body weight) for 6–14 days.

Multiple tumours in the same rat

In a total of 24 animals in various reproductive states (intact or endocrine manipulated),

oestrogen receptor activity was determined in two or more tumours from the same animal.

Determination of oestrogen receptor concentration

Tumour receptor concentrations were determined by a modification of a method described previously [12]. This modification was necessary to improve assay precision since by the original method, the low concentrations of receptor activity encountered in rat tumours lead frequently to non-linearity of the resulting Scatchard [13] graph.

Tumours were left in Tris buffer solution (0·25 M sucrose, 10 mM Tris and 1 mM ethylene diamine tetra-acetate pH 8·0) containing 0·5 mM dithiothreitol (14) for 1 hr at 4°C prior to homogenization at the rate of 300 mg/ml of Tris buffer and centrifugation of the homogenate at 105,000 *g* for 50 min (based on 15). The resulting cytosol was subjected to saturation analysis as previously described [12].

Determination of plasma hormone levels

Animals were exsanguinated at death through the abdominal aorta under ether anaesthesia, and the blood was used for the determination of plasma oestradiol-17β and plasma prolactin concentrations [16]. Since the quantity of blood collected was sometimes limited, assay sensitivity for plasma oestradiol-17β calculated for 4·0 ml plasma, was 0·13 ng/100 ml.

For plasma prolactin assay, ^{125}I-iodo-prolactin was prepared by the method of Redshaw and Lynch [17] a procedure which we found more reproducible than that previously employed. The sensitivity for 22 assays varied from 1 to 7·6 ng prolactin/ml with a mean value of 3·3 ng/ml. Inevitable deterioration of prolactin standard occurs on storage (NIAMDD instructions) and a correction for this has been made using the quality control data, a procedure which results in slightly lower values than those we reported previously.

Determination of cytosol protein concentrations

Protein concentration was determined by the method of Lowry, Rosebrough, Farr and Randall [18] using bovine serum albumin as standard.

Statistical analysis

Except where otherwise stated, statistical evaluation was carried out by the Wilcoxon rank test.

RESULTS

For most rat mammary tumours, the dissociation constant of binding (K_d) was found to be $0{\cdot}4$–$0{\cdot}5 \times 10^{-10}$ molar (see Table 1), in agreement with our earlier report [12].

The values found for tumour receptor concentration (P_0) by the method described in this paper are, however, $1{\cdot}67 \pm 0{\cdot}29$ (s.e., $N = 11$) times lower than those derived by the earlier method. By the modified method, a linear Scatchard plot was obtained for most of the tumours examined, and tumours with apparent receptor concentrations down to 0·05 fmoles/mg tissue clearly showed increasing displacement of (^{3}H) oestradiol-17β with increasing mass of non-radioactive oestradiol-17β added.

Effect of the oestrous cycle on tumour receptor concentration

In 45 cycling rats, tumour receptor concentration varied during the oestrous cycle (Fig. 1 and Table 1) reaching a minimum in proestrous which was significantly lower than the values in all other stages in the cycle ($P < 0{\cdot}01$), and

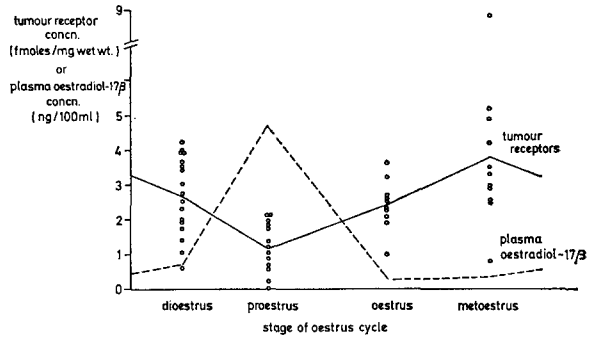

Fig. 1. The effect of stage in the oestrous cycle upon tumour oestrogen receptor concentration and plasma oestradiol-17β concentration. Each circle represents the oestrogen receptor concentration in an individual tumour. Lines join the mean receptor concentration (——) and mean plasma oestradiol-17β concentration (– – –). The standard errors for plasma oestradiol-17β concentration have been omitted for clarity but are to be found in Table 1.

a maximum in metoestrus. The changes in receptor concentration were in inverse relation to those in plasma oestradiol-17β (Fig. 1). The changes in plasma prolactin concentration followed, with a delay, those in oestradiol-17β but did not reach statistically significant levels.

Effect of ovariectomy and oestrogen administration

Following ovariectomy, tumour receptor concentrations (Fig. 2) and the plasma levels of both prolactin and oestradiol-17β (Table 1)

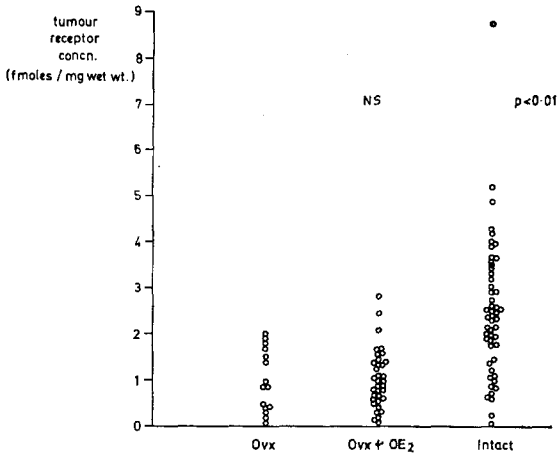

Fig. 2. The effects of ovariectomy and of ovariectomy followed by administration of oestradiol-17β on tumour receptor activity. The values for the tumours from the intact animals shown in Fig. 1 are reproduced for comparison. Each circle represents the value for an individual tumour P values refer to comparison with the concentrations in ovariectomised animals.

were significantly diminished relative to the values found in the tumours of intact animals ($P < 0{\cdot}01$).

Administration of oestrogen to ovariectomized rats caused an insignificant increase in detectable receptor activity (Fig. 2), and a restoration of prolactin levels to those seen in intact animals (Table 1).

Effect of perphenazine administration

Tumour concentrations of receptor activity in untreated rats were compared with the values in perphenazine-treated rats for both intact and ovariectomized states. The results are shown in Fig. 3 and Table 1.

In the intact animal, neither the mean tumour receptor concentration nor the plasma oestradiol-17β concentration after perphenazine-treatment was significantly different from the value found in untreated animals in dioestrus. Although perphenazine-treatment significantly increased the plasma prolactin concentration over the value found in untreated rats in dioestrus ($P < 0{\cdot}01$), the increased concentration was not significantly greater than the highest concentration observed in untreated animals at proestrus.

In ovariectomized animals, perphenazine-treatment caused a significant elevation in plasma prolactin concentration and in tumour receptor concentration ($P < 0{\cdot}01$), whilst dissociation constant of oestrogen binding by the

tumour was significantly reduced ($P < 0{\cdot}01$) following perphenazine-treatment. No differences were noted between the values found for rats treated immediately after ovariectomy and those in which the start of treatment was delayed: accordingly the data for these two, slightly different modes of treatment have not been separated.

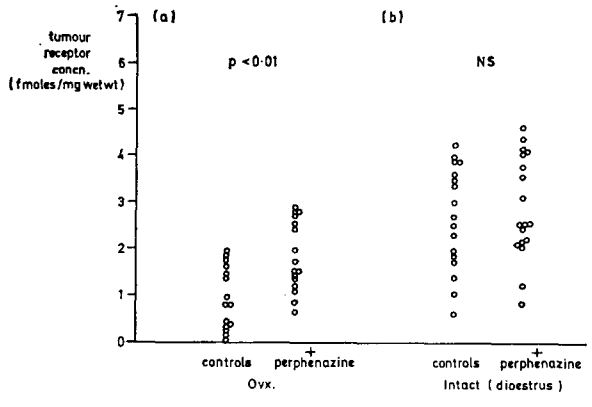

Fig. 3. The effect of perphenazine-administration in vivo upon tumour oestrogen receptor concentration in (a) ovariectomised and (b) intact rats. Each circle represents the value from an individual tumour. P values refer to the effect of perphenazine within each endocrine state.

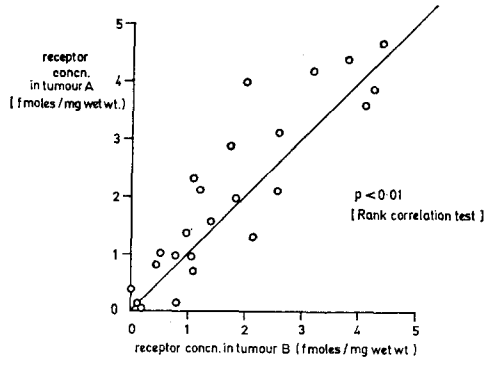

Fig. 4. Tumour receptor concentrations in rats bearing 2 tumours: receptor concentration for one tumour, A is plotted against that for the second tumour, B from the same rat. The rats were sacrificed in various reproductive states. Each circle represents the value from a single rat.

Receptor concentrations in multiple tumours from the same rat

When two or more tumours from the same animal were examined, the receptor concentration found for one tumour ("A") was more or less identical to the value for a second tumour ("B") from the same animal (Fig. 4). For animals with more than two tumours, only two values, selected by random selection (tables of random numbers), have been plotted.

In most cases, tumours from the same animal contained very similar concentrations of oestrogen receptors. By the Rank Correlation test, there was a highly significant ($P < 0{\cdot}01$) correlation between the receptor levels in tumours from the same animal.

DISCUSSION

Oestrogen receptor activity has been determined in mammary tumours of the rat in various endocrine states. It was found necessary to modify the method previously employed [12] in three respects (based on 14 and 15) to permit accurate determination of the relatively low concentration of receptor binding sites present in these tissues. By this modified method, oestrogen receptor activity was detected in 98·5% of the 136 DMBA-induced mammary tumours examined. The receptor activity in these tumours was characterized by a dissociation constant of binding ranging from $0{\cdot}16\text{–}1{\cdot}80 \times 10^{-10}$ molar, and in most tumours dissociation constant was in the range 0·4–$0{\cdot}5 \times 10^{-10}$ molar.

The range of oestrogen receptor concentrations encountered in rat mammary tumours is approximately ten times lower than that found in human breast cancers [12]. A similar difference is seen between the concentrations of plasma oestradiol-17β in the two species [16, 19].

Although most methods for determining oestrogen receptor concentrations detect only empty receptor sites, in general workers do not report the stage in the cycle at which tumours have been harvested for receptor assay or estimate plasma oestrogens at the time the tumour is harvested. We have shown that receptor concentrations fluctuate in inverse relationship with the prevailing oestradiol-17β concentration, and that the tumour receptor concentration is a function of the stage in the oestrous cycle at which the tumour was excised.

This finding is in contrast to the recent work of Jordan and Jasper [20] who conducted receptor assays at 30°C, a temperature at which exchange between (^{3}H) oestradiol-17β and endogenous oestrogen at filled receptor sites might occur. However, our results agree with those of Lee and Jacobson [21] and of Trams, Engel, Lehmann and Maass [22] in the rat and human uterus respectively, and of Maass, Engel, Nowakowski, Stolzenbach and Trams [23] in human breast cancer.

It is known that the effects of oestrogen upon the oestrogen receptor concentration within a tissue are complex: cytoplasmic receptor levels can be altered by increases in circulating oestrogen in two ways. In addition to (i)

filling empty receptors, which are then translocated to the cell nucleus, oestrogen may also (ii) stimulate the synthesis of new receptors [24, 25]. Our observations that tumour receptor levels firstly vary during the oestrous cycle and secondly, fall after ovariectomy, are, respectively, in keeping with these two effects.

In the rat, changes in circulating oestrogen level can also lead to alterations in the concentration of plasma prolactin (see e.g. [26].) This hormone has also been reported to influence oestrogen receptor levels in the rat mammary tumour [27–29]. In view of this, it is difficult to ascribe changes in receptor level to the effect of a single hormone. Nevertheless, in intact cycling animals, the tumour levels of detectable receptor activity found in this study were inversely related to changes in circulating oestradiol-17β concentration and apparently unrelated to changes in plasma prolactin concentration.

In the ovariectomised rats treated with perphenazine, tumour receptor levels were clearly elevated in association with a significant increase in prolactin secretion, but in the absence of detectable oestrogen. This effect of prolactin on oestrogen receptor levels is in agreement with the findings of Leung and Sasaki [27, 28] and of Vignon and Rochefort [29]. Although perphenazine-treatment in ovariectomised rats also increased the affinity of the receptors for oestrogen (see Table 1), this apparent difference probably reflects the less accurate determination of Kd at low receptor levels rather than a specific effect of prolactin.

In ovariectomised rats treated with oestrogen, tumour receptor levels were not detectably changed relative to untreated controls, possibly due to the filling of empty sites by the injected oestrogen. The failure to detect any effect of perphenazine-treatment upon tumour receptor levels in intact animals may either be due to the fact that the plasma prolactin concentrations found after treatment were not significantly greater than those found in untreated animals at proestrus and oestrus, or may indicate that the latter concentrations are already sufficient to maximally stimulate tumour receptor formation.

In animals bearing two or more tumours, despite the existence of a different clone of cells in each tumour, receptor levels were strongly correlated between tumours from the same animal, indicating that the endocrine milieu may be the major determinant of tumour receptor level.

These results support the view that endocrine status markedly influences tumour receptor level. In particular, we have indicated that oestrogen receptor levels may be increased by prolactin or reduced by the filling of empty receptor sites with oestrogen. If a similar situation obtains in women with breast cancer, then endocrine status at biopsy for receptor assay would influence the receptor levels detected and hence the predictive value of this parameter. The adoption of an exchange assay for measuring total cellular receptors should help by reducing the effect of circulating oestrogens on detectable receptor level for (i) clinical, predictive purposes and (ii) separating the effects of oestrogen and prolactin on receptor levels in the rat mammary tumour model.

Effects of BCG and *Corynebacterium Parvum* on the Haemopoietic Precursor Cells in Continuously Irradiated Mice: Possible Mechanisms of Action in Immunotherapy*

M. Y. GORDON, M. AGUADO and N. M. BLACKETT
Department of Biophysics, Institute of Cancer Research, Belmont, Sutton, Surrey, Great Britain

Abstract—*Single or repeated administration of BCG or* Corynebacterium Parvum (C. Parvum) *to continuously irradiated mice resulted in increased numbers of haemopoietic precursor cells in their bone marrow and spleen. These cells were detected by their ability to form nodules in the spleen of irradiated transplanted recipients or monocyte/granulocyte colonies in agar diffusion chambers. This increase in haemopoietic progenitor cells did not, however, confer any advantage, in terms of survival when the mice were challenged with further doses of irradiation. The relevance of these findings to the available clinical data is discussed.*

INTRODUCTION

AGENTS, such as BCG and *C. Parvum*, have been used as non-specific stimulators of the immune system in cancer immunotherapy in man and in experimental animals [1]. These agents have also been shown to stimulate macrophage production [2–5] and these cells play an important part in the action of the host against the tumour [6]. Macrophages are derived from monocytes which are produced in the bone marrow and they have also been shown to be closely related to granulocyte production [7]. For this reason we decided to investigate the effects of BCG and *C. Parvum* on the haemopoietic stem cells in mice.

Mathé [8] found that immunotherapy in mice was successful only if the burden of tumour cells was very small and suggested that leukaemia would be an ideal situation for the investigation of immunotherapy in man [9]. Prior to remission, patients receive a considerable amount of cytoxic chemotherapy which results in marked marrow hypoplasia. Although the patients regain adequate peripheral blood counts during immunotherapy maintained remission, their marrow tends to remain hypoplastic [10].

For this reason we investigated the effects of BCG and *C. Parvum* on the haemopoietic colony forming cells in mice whose marrow had been depleted by continuous exposure to ^{137}Cs irradiation at approximately 35 rad/day for 1–2 weeks [11]. Accordingly, groups of mice were maintained under continuous irradiation and treated with BCG or *C. Parvum* as single or repeated doses. The effects of BCG or *C. Parvum* on the marrow were measured using the spleen colony assay [12] and the agar diffusion chamber technique [13]. In other experiments, the ability of mice treated with BCG or *C. Parvum* to survive further acute or chronic doses of irradiation was compared with that of untreated control groups.

The results show that although BCG and *C. Parvum* exert stimulatory effects on haemopoietic precursor cells this does not increase their survival after further treatment.

MATERIAL AND METHODS

Experimental animals

C57 Bl mice were used in all experiments.

Accepted 15 September 1976.

*This work was supported by a grant from the National Cancer Institute, Contract Number N.C.I.-CM-23717.

At the beginning of the experiments they were between 2 and 3 months old.

BCG and C. Parvum

BCG (Glaxo Ltd.) was injected intradermally (approx. 10^7 live organisms) while *C. Parvum* (Wellcome Research Laboratories) was injected intraperitoneally (0·35 mg dry weight/mouse).

Irradiation facilities

Continuous irradiation (CI) was carried out in a ^{137}Cs unit. The required dose rates for the experiments (38 or 100 rad/day) were achieved by varying the distance of the animals from the central source. Acute doses of radiation were delivered from a ^{60}Co source at a dose rate of approximately 60 rad/min.

Assay systems

Pluripotential haemopoietic stem cells were measured using the spleen colony assay of Till and McCulloch [12] and the committed granulocytic stem cells were detected by their ability to form colonies (ADC-C) in agar diffusion chambers [13].

RESULTS

The effects of continuous irradiation (CI) alone on the spleen colony forming cells (CFU-S) and the granulopoietic cells forming colonies in agar diffusion chambers (ADC-C) are shown in Fig. 1. Both cell populations measured by these assays were depleted by CI; the CFU-S reached a new steady state of approximately 5% of normal values within 1 week after the onset of irradiation and then maintained this level while the ADC-C showed an initial rapid decline to 30% of control values followed by a slower fall to 6% over the 5 week period.

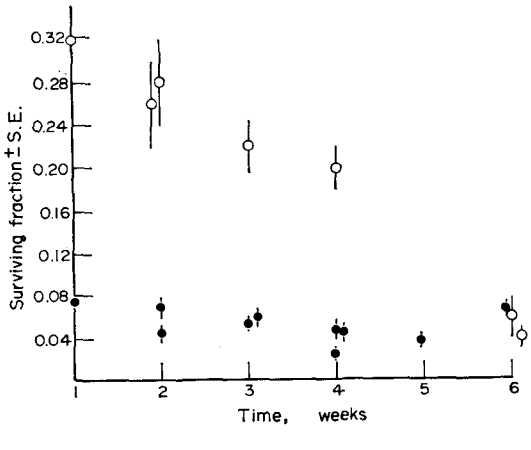

Fig. 1. The effect of CI on the CFU-S (●) and the ADC-C (○) in C57B1 mouse marrow.

Effects of BCG and C. Parvum *on CFU-S*

Figures 2(a) and 2(b) show the effects of BCG or *C. Parvum*, either as single or as repeated weekly doses, on the CFU-S in the bone marrow and spleen of CI mice. The results are expressed in terms of colony forming cells per femur, or per spleen, relative to the number of colony forming cells in mice treated with CI alone. Single doses of BCG or *C. Parvum* resulted in a two-fold increase in bone marrow CFU-S one week after administration followed by a decline to less than the control

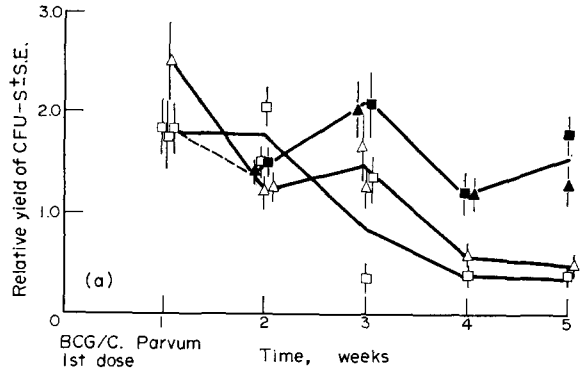

Fig. 2(a). The effects of BCG (■) and C. Parvum *(▲) on the CFU-S in the marrow of CI mice. Open symbols refer to single doses, closed symbols refer to weekly doses.*

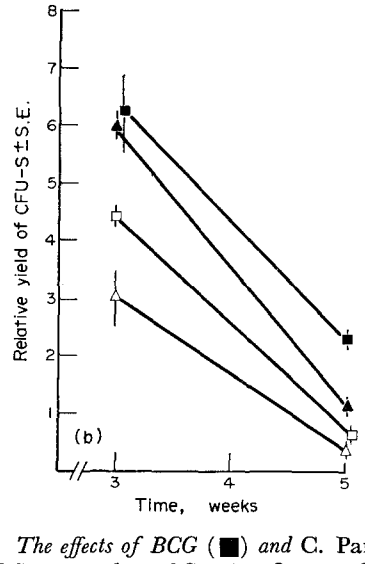

Fig. 2(b). The effects of BCG (■) and C. Parvum *(▲) on the CFU-S in the spleen of CI mice. Open symbols refer to single doses: closed symbols refer to weekly doses.*

(CI only) value by the 5th week. Weekly doses of BCG or *C. Parvum* maintained the levels of CFU-S above those observed with single doses but there was no increase in their number as the number of doses was increased.

The numbers of CFU-S in the spleen were measured only at 3 and 5 weeks after single or repeated doses of BCG or *C. Parvum*. Much greater increases were seen in the spleen than in the bone marrow, relative to the effects of CI alone. At 3 weeks the single doses resulted in a 3–4 fold increase and repeated doses gave a 6-fold increase but by the 5th week the measured values approximated the control levels.

Effects of BCG and C. Parvum *on ADC-C*

Figures 3(a) and 3(b) show the responses of the committed granulopoietic progenitor cells

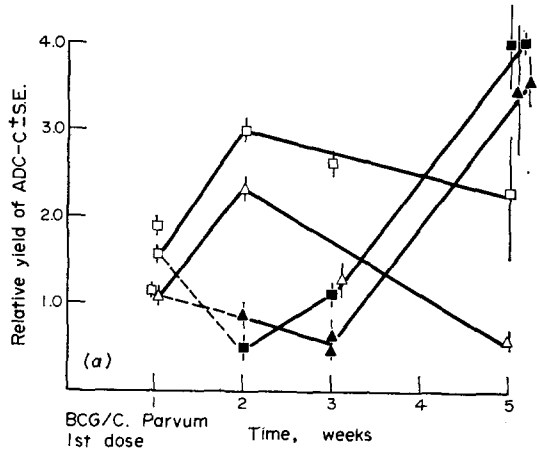

Fig. 3(a). The effects of BCG (■) and C. Parvum (▲) on the ADC-C in the marrow of CI mice. Open symbols refer to single doses; closed symbols refer to weekly doses.

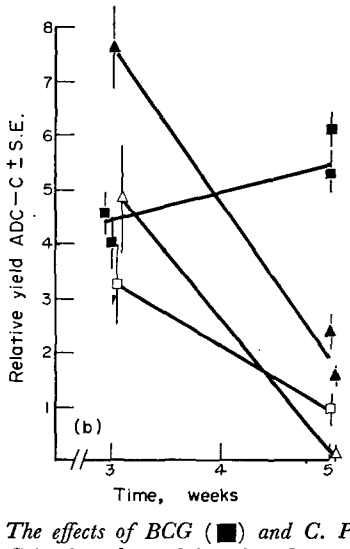

Fig. 3(b). The effects of BCG (■) and C. Parvum (▲) on the ADC-C in the spleen of CI mice. Open symbols refer to single doses; closed symbols refer to weekly doses.

in the bone marrow and spleen of CI mice to treatment with BCG or *C. Parvum*. The time pattern of the bone marrow response to these agents, measured using the ADC technique, differed from that seen with the CFU-S assay in that the greatest numbers following single doses were seen at 2 weeks, not one week. after administration. At 2 and 3 weeks the effect of repeated weekly doses was less than that seen 2–3 weeks after a single dose, but by the 5th week the continuation of weekly doses had resulted in a four-fold increase which was greater than the residual effect of a single dose given 5 weeks earlier.

The response of ADC-C in the spleen 3 and 5 weeks after a single dose of BCG or *C. Parvum*, or repeated *C. Parvum*, was similar to that seen for spleen derived CFU-S. However, a difference was seen after repeated doses of BCG when the splenic ADC-C level was higher at 5 weeks than at 3 weeks.

To determine whether the increases in progenitor cell levels resulting from treatment with BCG or *C. Parvum* prolonged animal survival after further challenge, treated or control groups of mice were subjected to either chronic (100 rad/day) or acute (60 rad/min) doses of irradiation. For the chronic irradiation survival experiment groups of animals were given BCG or *C. Parvum* at weekly intervals during exposure while the control groups were subjected to CI alone. For the acute irradiation survival experiment, mice were exposed to CI for 2 weeks during which time they were given BCG, *C. Parvum* or no treatment. A further dose of BCG or *C. Parvum* was given to the treated animals 1 day after exposure to 900 rad ^{60}Co γ-irradiation.

The graphs of animal survival following CI or acute irradiation show that the apparent improvement in marrow status resulting from treatment with BCG or *C. Parvum* did not markedly improve their ability to withstand further insult. In the case of chronic irradiation (Fig. 4), treatment with BCG or *C. Parvum* slightly delayed the onset of death, thus increasing the mean lifespan of the animals, but the maximum survival in each group was the same (45–46 days). Pretreatment with CI alone improved animal survival following acute irradiation when compared with the survival of normal animals given 900 rad (Fig. 5). However, the animals which had received BCG or *C. Parvum* in addition to CI died sooner than the untreated CI controls. In fact, those animals treated with CI + BCG survived less well than the normal animals given 900 rad.

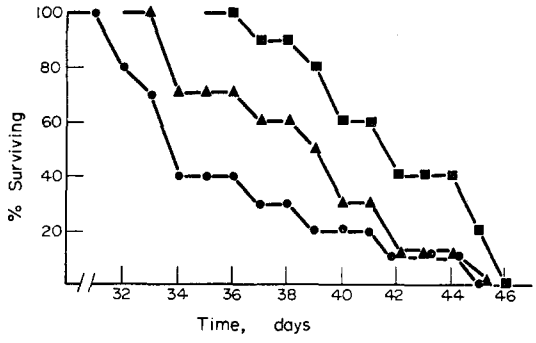

Fig. 4. The effects of BCG (■) and C. Parvum *(▲) on the survival of CI mice compared with the survival of mice receiving CI alone (●).*

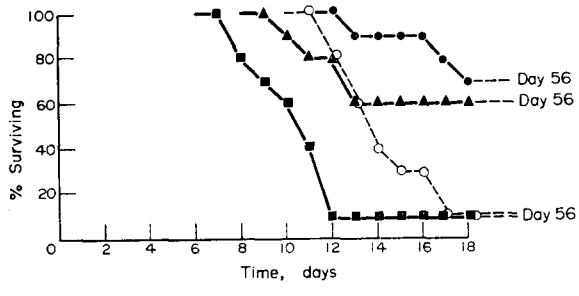

Fig. 5. The effects of BCG (■) and C. Parvum *(▲) on the survival of CI mice given acute irradiation compared with the survival of mice pretreated with CI alone (●) or given no pretreatment (○).*

DISCUSSION

The present study was carried out to determine whether treatment with BCG or *C. Parvum* could increase the number of haemopoietic progenitor cells in mice subjected to continuous irradiation and whether any increase in these cells improved survival following a second insult. The rationale for these experiments is based on the suggestion that the prolonged survival of patients maintained on immunotherapy during acute myeloid leukaemia in remission results, at least in part, from a non-specific immuno-stimulation of the marrow precursor cell pool; such stimulation of haemopoietic precursor cells may allow patients who had relapsed better to withstand the myelotoxic effects of reinduction chemotherapy [14].

Most published reports have concentrated on the effects of BCG and *C. Parvum* on macrophage production in the bone marrow using *in vitro* systems for the growth of macrophage colonies. These studies have also looked at relatively short time periods but, since patients are maintained on immunotherapy for months or even years [15] we attempted a longer term investigation of the effects of these agents. Furthermore, previous work has been done using tumour bearing animals, but the continuously irradiated mouse may more closely parallel the situation in immunotherapy patients since in both cases adequate peripheral blood counts are maintained in spite of bone marrow depletion [10].

The work of Wolmark and Fisher [2], Fisher *et al.* [3], Dimitrov *et al.* [4] and Baum and Breese [5] supports the idea that BCG and *C. Parvum* stimulate precursor cells in the bone marrow to increase the production of macrophages. In these studies the longest time interval investigated was 10 days after a single injection of *C. Parvum* into normal mice [5], or 18 days after injection of BCG into normal or tumour bearing mice [3]. Dimitrov *et al.* [4] also investigated the effect of *C. Parvum* on the levels of colony stimulating activity in serum and found an inhibitory effect. This finding is in agreement with our results which failed to detect any humoral stimulation when animals treated with BCG or *C. Parvum* were used as hosts for agar diffusion chambers containing normal mouse bone marrow (Gordon—unpublished data).

The present studies have shown that BCG and *C. Parvum* can maintain haemopoietic precursor cell levels above control (CI only) values, in spite of the cell killing effects of continuous irradiation, for up to 5 weeks. However, this increase does not markedly improve animal survival following continuous irradiation and reduces survival following acute irradiation.

Immunogenicity Induced *In Vivo* by DIC in Relatively Non-Immunogenic Leukemias*

ANGELO NICOLIN, MICAELA CAVALLI, ANDREA MISSIROLI and ABRAHAM GOLDIN
Institute of Pharmacology, School of Medicine, Via Vanvitelli 32, *Milan, Italy*

Abstract—*Following a cycle of treatment with the compound* 5-(3, 3-*dimethyl*-1-*triazeno*)*imidazole*-4-*carboxamide* (*DIC*), *two murine tumors, the chemically induced EL4 leukemia and the Gross-virus induced GL leukemia evidenced new immunogenic properties in syngeneic hosts. The increased survival-time and the increased effectiveness of a single BCNU treatment of animals challenged with the drug-treated cells, relative to that observed in animals challenged with parental, drug-untreated tumors or in immunosuppressed animals challenged with DIC-treated leukemias provide indirect evidence for increased immunogenicity of the tumor cells.*

In experiments involving immunization of syngeneic animals with X-ray-inactivated DIC-altered cells, clear evidence for a specific primary and a specific secondary immune-response was obtained. As observed previously in studies with other experimental tumors, the immunogenic properties were retained by the drug-treated cells over a long series of transplantations in normal or immunosuppressed syngeneic animals.

INTRODUCTION

IT HAS been reported [1–7] that treatment of tumor-bearing animals with antineoplastic compounds can lead to modification of tumor cell immunogenicity as evidenced by the prolonged or indefinite survival of syngeneic hosts challenged with the drug-treated neoplasms. An immune response to the drug-modified cells has been observed both in *in vivo* [8, 9] and in *in vitro* experiments [10, 11]. As the drug-induced alteration persisted indefinitely after the withdrawal of the chemotherapeutic treatment, the antigenic sublines are considered of interest for cancer cell biology and for experimental immunotherapy.

Most of the studies pertaining to drug induced alteration of tumor cell immunogenicity have been performed with lymphomas that originated in DBA/2 mice (H-2^d), and 5-(3,3-dimethyl-1-triazeno)imidazole-4-carboxamide (DIC) has been among the most active compounds.

In the current study, alteration of the immunologic properties of two ascitic murine leukemias, the chemically-induced EL4 lymphoma in C57Bl/6 mice (H-2^b) and a Gross-virus induced leukemia in C3H mice (H-2^k), was obtained following *in vivo* treatment with DIC. These leukemic lines were chosen since they differ in the major H-2 histocompatibility region from the previously studied DBA/2 lymphomas. Also, in preliminary experiments, they failed to evoke any appreciable immuno-response in syngeneic hosts.

Accepted 16 September 1976.

MATERIAL AND METHODS

Animals and tumors

Inbred C3H/HeCr and hybrid (DBA/2 ♀ × C57Bl/6 ♂) F_1 male mice, hereafter called BDF_1, 6 to 10 weeks old, obtained from the Mammalian Genetics and Animal Production Section of the National Cancer Institute, NIH, were used. The chemically induced EL4 lymphoma and the Gross virus induced leukemia (GL), obtained as previously indicated [11], were maintained by intraperitoneal (i.p.) passage of 10^6 ascitic cells in BDF_1 and C3H mice respectively.

For the development of DIC-sublines the procedure previously described [3] was fol-

lowed with minor modifications. Briefly, 10^7 EL4 cells and 10^6 GL cells were injected i.p. (day 0) into compatible animals. BDF_1 mice inoculated with EL4 cells were treated with 100 mg/kg i.p. of DIC for 10 consecutive days, starting one day after leukemic inoculation. C3H mice inoculated with GL were treated for 5 consecutive days, also starting one day after leukemic inoculation; drug treatment was then discontinued for two days and resumed for three additional days. EL4 lymphoma was treated for 12 transplant generations and GL leukemia for 8 transplant generations. Once established, the DIC-sublines were maintained in mice immunosuppressed with cyclophosphamide (200 mg/kg, administered i.p. 24 hr before tumor challenge). Cell viability was checked by dye-exclusion and inocula with at least 90% viability were employed.

Chemicals

DIC (NSC-45388) was dissolved in chilled saline immediately before use after addition of equal parts (w/w) of citric acid; BCNU (NSC-409962) was dissolved in a few drops of ethyl alcohol and the volume adjusted with saline; cyclophosphamide (NSC-26271) was dissolved in saline. The drugs were obtained through the courtesy of Dr. H. B. Wood, Jr. (Drug Research and Development Program, National Cancer Institute, Bethesda, Md., U.S.A.).

Immunization

Single i.p. injections of 4×10^7 X-irradiated cells (5000 R—200 kV, 12 mA, 0·5 mm Cu–Al filter, 100 R/min) were given 21 days before challenge with viable cells.

RESULTS

The occurrence of drug-mediated increase in immunogenicity was tested by injection of tumor cells from DIC treated tumors at each successive transplant generation into normal or immunosuppressed hosts. The survival was then followed for ninety days. For both the drug treated EL4 leukemia (EL4/DIC) and the GL leukemia (GL/DIC), when injected into normal recipients there was a progressive increase in survival time following successive generations of treatment as compared with previously untreated parental leukemic cells. For the EL4 leukemia (EL4/DIC) the maximum increase in median survival time (MST) was obtained

on transplant of the tumor into normal recipients following DIC treatment for 12 transplant generations (Table 1). For the GL leukemia (GL/DIC) the maximum effect was observed after 8 transplant generations (Table 2). Challenge of normal mice with tumor cells from animals treated with DIC for more than 12 or 8 transplant generations respectively did not produce any further increase in the survival time of the animals.

The EL4 leukemia was naturally insensitive to the DIC treatment, so that the MST of EL4 leukemic mice treated with DIC did not change significantly in the course of treatment over a series of transplant generations. The GL leukemia, which was originally sensitive to the chemotherapeutic activity of DIC, became progressively more resistant as reflected in a reduction of the MST treated animals.

For both the EL4/DIC (Table 1) and GL/DIC (Table 2) sublines a decrease in MST was observed in immunosuppressed animals. This finding, in agreement with previous data obtained with other immunogenic sublines, indicates that the increased survival of animals challenged with the drug-treated sublines is dependent upon the presence of an intact immune apparatus in the host.

It is of interest, but not clear as to why immunodepressed mice bearing the EL4 leukemia succumbed in a shorter time than the corresponding normal animals, despite the failure of the tumor to exert any appreciable antigenic effect in syngeneic animals.

Further evidence for the occurrence of an immune reaction of the host to a DIC-subline was obtained in the experiment shown in Table 3. BCNU (20 mg/kg) was administered as a single s.c. treatment on day 6 to normal or immunosuppressed animals challenged with the parental or EL4/DIC leukemia. The synergistic increase in MST of animals bearing the EL4/DIC leukemia, resulting from the chemotherapeutic treatment plus host immunoresponse [3], was reversed following reduction of animal immunoreactivity by X-irradiation (400 R).

Direct evidence for drug-induced immunogenicity of EL4 leukemia is provided by the specific immunization of syngeneic mice to the DIC treated subline. X-ray-inactivated EL4/DIC cells inoculated into compatible BDF_1 mice elicited specific sensitization as evidenced by animal survival to the challenge of EL4/DIC viable cells (Table 4). The low immunogenicity of the parental EL4 leukemia and the absence of immunogenicity of GL leukemia indicate that the treatment with DIC has induced new immunologic properties not detectable in the original leukemias that had not been subjected to treatment with the drug.

It has been demonstrated that an appropriate dose of X-rays may inhibit primary but not secondary immune response [12]. An experiment was conducted in which animals previously immunized with inactivated EL4 or EL4/DIC tumor cells were X-irradiated 24 hr before challenge with viable EL4 or EL4/DIC cells (Table 5). Further evidence for specific drug-induced immunogenicity is provided by the observation of specific sensitization by EL4/DIC in animals that were X-irradiated prior to secondary challenge with EL4/DIC. Increased survival of the mice was observed only in that group following challenge with viable leukemic cells.

DISCUSSION

In previous studies L1210 and L5178Y lymphomas, both originally chemically-induced in DBA/2 mice, are the tumors that have been employed primarily to obtain antigenic alteration and to investigate the new immunologic properties.

As *in vivo* immunologic alteration of tumor cells might be of some interest to exploit as a new tool for the specific immunotherapy of experimental tumors, it appeared to be important to determine the reproducibility of the previous findings with a wider range of tumors.

The difference in genetic origin of the EL4 ($H\text{-}2^b$) and Gross-virus induced ($H\text{-}2^k$) leukemias as compared with L1210 and L5178Y ($H\text{-}2^d$), the low immunogenicity of EL4 leukemia and the virus origin of the GL leukemia have been considered as properties of interest.

In the present studies increased immunogenicity of the two leukemias has been obtained following *in vivo* treatment with DIC. Indirect evidence, such as the increased survival time of normal animals bearing the drug-treated tumors and its partial reversal by immunodepression, the synergism between host immunoresponse and chemotherapeutic treatment, and direct evidence involving specific immunization assays, have substantiated the new immunologic properties in EL4/DIC and GL/DIC tumors.

In comparison with the previous DIC-treated DBA/2 lymphomas some minor differences have been observed. The increased immunogenicity was reached with a longer delay than that obtained with L1210 and L5178Y ($H\text{-}2^d$) lymphomas. Furthermore, a

Animals have been irradiated (400 R) 24 hr. before tumor challenge.

less extensive host-immune reaction was elicited by the EL4/DIC and GL/DIC tumors. Animals bearing these DIC-altered leukemias showed increased survival time but except at reduced inoculum levels failed to reject the neoplasms completely.

Nevertheless, *in vivo* induction of tumor immunogenicity did occur with these additional leukemic lines. Also, the possibility exists that with other schedules of treatment with DIC or with other antineoplastic compounds immunologic alterations may be achieved which will be sufficiently extensive to induce definitive tumor rejection of these leukemias by a syngeneic host.

It has been suggested [13] that the inhibition of naturally occurring immunoselection by antineoplastic drugs might permit the growth of immunogenic clones. In regard to this it may be noted that the immunogenic property of the drug-altered leukemic cells has been maintained over a long period of time (100 transplant generations) both in normal as well as immunosuppressed mice. If the assumption of selection of immunogenic clones were true it might have been expected that over a few transplant generations in normal animals, a loss of the immunogenicity would occur.

The mechanism by which DIC or other drugs produces the immunologic alterations on tumor cells is still unknown. Several hypotheses have been advanced and discussed in previous papers [3–7]. In any event, the possibility of the drug acting as a hapten is irreconcilable with the stability and heritability of the cellular modification.

Experimental models for study of immune response by syngeneic hosts against two tumor-cell populations, the original and a subline of

differing immunogenicity obtained by pharmacologic manipulation, provide interesting possibilities for investigation. The utilization of drug-induced immunogenicity for experimental immunotherapy remains to be exploited.

Acknowledgements—We wish to thank Dr. J. G. Mayo and Mr. C. Reeder of the Mammalian Genetics and Animal Production Section of the National Cancer Institute, NIH, for breeding and providing the animals. The proficient help of Mr. R. Fagnani and Ms. D. Peroni is gratefully acknowledged.

Organ Distribution of Exogenous Murine Mammary Tumour Virus as Determined by Bioassay*

P. BENTVELZEN and J. BRINKHOF
Radiobiological Institute TNO, Lange Kleiweg 151, *Rijswijk, The Netherlands*

Abstract—*Cell-free mammary tumour virus activity was exhibited by extracts from the following organs of exogenously infected BALB/cfC3H mice: salivary gland, kidney, testis and epididymis. This was tested for by bioassay in female BALB/c mice, which were then forced bred for mammary tumour production. Mammary tumour inducing activity was demonstrated for intact cells of thymus, spleen, bone marrow and liver. Radiation* (3000 *rad*) *largely destroyed the cell-bound viral activity. No cell-free or cell-bound activity was found in lung, brain or pancreas. Epigenetic factors seem to have a great influence on the expression of exogenous mammary tumour virus.*

INTRODUCTION

THE MILKBORNE murine mammary tumour virus (MTV-S [1]) can be recovered not only from milk and mammary glands but also from blood and hemopoietic tissues and male secondary sex organs (for a review, see ref. [2]). The virus is known to transform only mammary cells. The mammary tumour virus, therefore, provides a good model for a study of the role of epigenetic factors in the expression of various genes of the murine mammary tumour virus. For that reason, we have begun an extensive research program on the organ distribution of MTV-S, employing electron microscopical, biochemical and immunological methods. This presentation is a report on the results of bioassays done on several organs of BALB/c mice which were exogenously infected with MTV-S.

MATERIAL AND METHODS

A chronically infected BALB/c mouse colony was established in 1970 by inoculation of a BALB/c female with MTV-S isolated from a C3H mammary tumour (kindly provided by Dr. Philomena Hageman, Netherlands Cancer Institute, Amsterdam). The descendants of this female had been sib-mated in our laboratory for 18 generations at the beginning of this investigation. The virus proved to be continuously transmitted to all females tested. The tumour incidence in breeding females is 100%, with an average latency period of seven months. Skin grafting at the 21st inbred generation proved the infected subline, indicated as BALB/cfC3H, to be completely histocompatible with the parental BALB/c strain which was used as recipient in this study.

Two-month-old BALB/cfC3H males were killed by cervical dislocation; organs were taken immediately thereafter. Cell suspensions were prepared by pushing cells with a spatula through a nylon gauze while immersed in Hanks balanced salt solution (HBSS). Viable cells were then counted by trypan blue dye exclusion and the original suspension was diluted with HBSS to different cell concentrations ranging from 10^6 to 10^3 per ml.

For the preparation of cell suspensions from liver and kidney, the kidneys and livers were first perfused *in situ* with Hommes medium without EDTA but supplemented with 0·05% collagenase (Sigma, St. Louis, Missouri, U.S.A.) and 0·10% hyaluronidase (Sigma) [3], in order to remove blood cells. The cell preparations were immediately injected intraperitoneally into 6-week-old BALB/c females, which then were subjected to forced breeding.

Accepted 17 September 1976.

*Part of this investigation was supported by contract NO1-CP 43328 of the Virus Cancer Program, National Cancer Institute, Bethesda, Md., U.S.A.

Each group consisted of 20 females per dilution. Three females were caged with one uninfected BALB/c male. The cages were inspected daily for litters; these were immediately removed. The mice were inspected for the presence of mammary tumours or other signs of disease twice a week. The experiment was terminated when the animals were one year of age, because uninfected BALB/c females start to produce mammary tumours at that age.

In one series of experiments, cells were irradiated with a Philips–Müller X-ray machine (300 kv, 10 mA, HVL 3 mm Cu) at a dose rate of 110 rad/min to give a total dose of 3000 rad and injected immediately thereafter.

Cell-free extracts were prepared by homogenizing freshly taken tissue in cold HBSS (10 ml/g of tissue) in a Sorvall omnimixer (19,000 rev/min) for 50 sec. The preparation was then spun in a Sorvall superspeed RC 2-B centrifuge for 20 min at 15,000 rev/min (4°C). The supernatant was withdrawn and filtered through a 0·45 μ Millipore disposable filter unit (Millipore SA, Bue, France). Dilutions were made in HBSS and then injected intraperitoneally into mice. The undiluted inoculum corresponded with approximately 10^7 cells/mouse. Each group consisted of 20 animals.

RESULTS

The mammary tumour incidences at 1 year of age for the experimental groups injected with different cell numbers from various organs are given in Table 1; lung, pancreas and brain were completely negative. Even when 10^7 cells from these tissues were injected, no mammary tumours were found in the recipients. Relatively large cell numbers were needed for liver, kidney and testis.

Irradiation did not completely destroy the oncogenic activity of cells from various organs, but the number of cells from hemopoietic organs needed to produce a tumour is approximately a hundredfold higher (Table 2). This procedure had little effect on kidneys and epididymis cells in this respect.

Cell-free extracts from kidney, testis, epididymis and salivary gland were the only ones active in the bioassays (Table 3). Although for mammary tumour induction relatively few intact cells were needed from hemopoietic

Table 1. *Mammary tumour-inducing activity of intact cells from BALB/cfC3H mice in forced bred BALB/c female mice*

Organ	Number of cells:	Tumour incidences (%) at 1 year of age			
		10^6	10^5	10^4	10^3
Thymus		100	65	75	70
Spleen		90	50	30	25
Bone marrow		75	90	60	30
Salivary gland		100	100	80	40
Brain		0	0	0	0
Lung		0	0	0	0
Liver		80	60	10	0
Pancreas		0	0	0	0
Kidney		75	50	20	10
Testis		90	100	40	5
Epididymis		100	100	60	55

Table 2. *Effect of irradiation* (3000 *rad*) *on mammary tumour-inducing activity of BALB/cfC3H cells*

Organ	Number of cells:	Tumour incidences (%) at 1 year of age			
		10^6	10^5	10^4	10^3
Thymus		80	35	5	0
Spleen		30	40	0	0
Bone marrow		40	5	0	0
Liver		0	0	0	0
Kidney		50	70	30	20
Epididymis		70	30	45	30

Table 3. Mammary tumour-inducing activity of cell-free extracts of organs from BALB/cfC3H mice

Organ	Dilutions:	Tumour incidence (%) at 1 year of age			
		undiluted	10^{-1}	10^{-2}	10^{-3}
Thymus		0	0	0	0
Spleen		0	0	0	0
Bone marrow		0	0	0	0
Salivary gland		40	45	10	0
Liver		0	0	0	0
Kidney		50	10	20	0
Testis		25	5	0	5
Epididymis		75	25	55	20

tissues, such as thymus, bone marrow or spleens, cell-free extracts from these tissues were completely negative in the induction of mammary tumours. Extracts from perfused liver also failed to show mammary tumour-inducing activity.

DISCUSSION

The finding of infectious virus in the epididymis of BALB/cfC3H mice is in accord with the demonstration of MTV-S in that organ of other high cancer strains [4–6]. Mature MTV virions (B-type particles [7]) have been detected in the salivary glands of wild mice [8]. The demonstration of infectious virus in salivary glands of exogenously infected mice is therefore not so surprising.

We failed to find a report on the presence of infectious virus or B-type particles in kidneys from high cancer strain mice, but Parks *et al.* [9] found a relatively high titer of MTV-specific antigens in kidneys of the C3H strain. Cultures of kidney cells from various strains after treatment with various compounds release B type particles [10–13]. They represent endogenous viruses, however. It would be interesting to determine whether kidneys from exogenously infected mice would release MTV-S spontaneously. It has been claimed that BALB/c kidney cells could be productively infected *in vitro* [11].

The presence of MTV-S in the testis is in agreement with a similar finding of Pogossiantz [14] in another mouse strain. However, the testis has been reported to be negative for MTV antigens [15]. Since Leydig cell tumours of MTV-infected mice produce intracytoplasmic A particles [16] which are thought to be the precursory stages of B-type particles [7, 17], it is possible that the virus will be replicated in only a limited number of cells in the testis. A relatively small quantity of MTV-S is needed for the induction of mammary tumours in BALB/c mice [18], but considerably larger amounts of viral antigens are required for detection by immunological methods.

No B-type particles have been found in the pancreas, liver and spleen [19], which explains the lack of infectivity of cell-free extracts of these organs. B-type particles have been found in an epididymoblastoma [20] as well as in a pulmonary carcinoma [21]. MTV will probably not be expressed as complete virion in nonneoplastic cells. MTV-specific antigens have been found in the lungs of C3H mice [9] and, in our laboratory, also in the lungs of BALB/cfC3H mice. The negative bioassays may be explained by only partial expression of the viral genome.

Most attention has been paid to the presence of MTV-S in hemopoietic tissues [18, 22]. Viral antigens can be detected in low amounts in the spleen [9, 23]. Intracytoplasmic A-type particles have been found in several hemopoietic tissues of RIII mice with mammary tumours [6] and in neoplasms of such tissues [2, 6, 24]. As in other studies, cell-free tumour-inducing activity could not be obtained from thymus, spleen and bone marrow, probably because no complete virions were produced [25]. The radiosensitivity of the cell-bound infectivity of hemopoietic cells in contrast to that of kidney or epididymis suggests that viable hemopoietic cells are needed for the transfer of exogenous MTV-S. The infectivity of kidney or epididymis cells is probably due to complete virions, which are highly radioresistant [26].

The oncogenic activity of liver cells might be due to the presence of hemopoietic cells. However, the cell separation procedure followed by us removes all cell types other than parenchymal cells [3].

According to Michalides *et al.* [27], the DNA of liver cells from mice exogenously infected with MTV-S lacks significant parts (approx.

25%) of the MTV proviral sequences found in mammary tumours of these mice. This would imply that no somatic provirus of MTV-S is present in the liver. The detected homology (75%) would represent endogenous MTV. It is possible, however, that, as in the testis, only a small percentage of cells is infected with MTV-S. This would not be detectable by molecular hybridization and would explain why approximately 100× more liver than thymus cells are needed for infection. The lack of infectivity of cell-free liver extracts indicates that a similar virogenic relationship as in the haemopoietic tissues exists in the liver.

Exogenous mammary tumour virus seems to have a relatively wide organ distribution. It is only partially expressed in several tissues. This illustrates the important role of epigenetic factors in the expression of MTV.

IgG-, IgA- and IgM-Antibodies to Herpes Simplex Virus Type 2 in Sera from Patients with Cancer of the Uterine Cervix*

I. H. EL FALAKY and B. F. VESTERGAARD
Institute of Medical Microbiology, University of Copenhagen, 22 Juliane Maries Vej, DK-210 Copenhagen Ø, Denmark

Abstract—*A total of 60 sera from patients with cervical cancer, 60 sera from matched controls, and 22 sera from 13 patients with recent herpes genitalis were examined by the indirect fluorescent antibody method for the presence of IgG-, IgA- and IgM-antibodies to herpes simplex virus (HSV) type 2. IgG-antibody titres in the patients with cervical cancer were significantly higher than those found in the control group, while IgA- and IgM-antibodies were normal. IgG-, IgA- and IgM-antibodies were found to be elevated in patients with frequent recurrent HSV type 2 infections. The elevation of a single class of immunoglobulin to HSV type 2 infection is serologically unusual and distinguish the patients with cervical cancer not only from normal controls but also from patients with frequent recurrent or chronic genital herpes.*

INTRODUCTION

SEROEPIDEMIOLOGICAL studies of herpes simplex virus (HSV) type 2 and carcinoma of the cervix have almost consistently shown that women with cervical cancer possess antibodies to HSV type 2 more frequently and in higher titres than matched controls [1–3]. Because of the cross-reactivity of antibodies to HSV type 1 and type 2 and because of the high incidence of antibodies to HSV type 1 in the community in general, the identification of HSV type 2 antibodies in human sera is difficult [4].

The variety of serological techniques used for the comparative titration of antibodies to HSV type 1 and type 2 have not been concerned with the type of immunoglobulin reacting in the test. According to Nahmias and Roizman [1] IgA- and IgM-antibodies to HSV seem to persist in measurable titres in patients with recurrent HSV infections. In a recent study made in our laboratory [5] we found a significant rise in IgA-antibodies to HSV following recurrent HSV infection. Furthermore this IgA-antibody response was type specific, as patients with genital herpes lesions responded with a marked rise in IgA-antibodies to HSV type 2 with only a weak and transient rise of IgA-antibody titre to HSV type 1.

If one accepts the hypothesis that a chronic or frequently recurrent HSV type 2 cervicitis is the underlying stimulus leading to malignant transformation of the cervical epithelium, then such a condition might serologically be better clarified through an analysis of the proportions of IgG-, IgA- and IgM-antibodies to HSV type 2, rather than by measurement of the total neutralizing activity of HSV type 2 of a given serum.

Accepted 20 September 1976.

MATERIAL AND METHODS

Sera examined

Blood from 60 patients with cervical cancer was furnished by the Finsen Institute in Copenhagen. The staging of the malignancy followed the international classification of carcinoma of the uterine cervix. Blood was collected only

from newly diagnosed patients before treatment was started. Blood samples from 60 normal controls were supplied by the blood bank at Rigshospitalet in Copenhagen and from the geriatric unit at "De Gamles By" (a major home for old people in Copenhagen). Twenty-two blood samples from 13 patients with recent herpes genitalis (virologically confirmed HSV type 2 infections) were included as a special control group.

The cases and normal controls were classified into five socio-economic classes according to the criteria used by the Danish National Institute of Social Research [6]. In the analysis of the results of the present study the subjects in social classes 1, 2 and 3 were placed in one group.

Measurement of HSV type 2 IgG-, IgA- and IgM-antibodies by indirect immunofluorescence

(1) *Antigen.* Confluent monolayers of VERO-cells maintained in Eagle's MEM in Earle's BSS and 2% foetal bovine serum were infected with the MS strain of HSV type 2 (ATCC lot: 1-D) at a multiplicity of 2 and harvested after 18–20 hr by shaking the cells off the glass surface. The cells were further dispersed by pipetting and washed three times with PBS. Smears of infected cells were made by placing one drop of the cell suspension on each of eight spots left clear on PTFE Plasti-Brand-coated microscope slides. After air drying, the cells were fixed in acetone for 15 min at room temperature. Slides were stored at −20°C. Control smears of uninfected VERO-cells were prepared in the same way, the cells being scraped off the glass surface.

(2) *Staining procedure.* Patients' sera were titrated for the presence of HSV type 2 IgG-, IgA- and IgM-antibodies by the indirect fluorescent antibody staining. Two-fold dilutions of the sera were prepared and drops of each dilution were applied on the smears of HSV type 2 infected VERO-cells. Control titrations of sera on uninfected cells were run in parallel. The slides were incubated at 37°C in a moist chamber for one hour when titrating IgG and IgA, and for two hours in the case of IgM. After incubation, the slides were thoroughly washed in PBS for ten minutes and for another ten minutes in deionized water by magnetic stirring.

Fluorescein-labelled rabbit immunoglobulins to human IgG, IgA and IgM (obtained from Dako Immunoglobulins A/S, Denmark) were used. The working dilutions of these conjugates were 1/20 ,1/15, and 1/15 respectively, and no fluorescence was seen when conjugates were used alone. The same batch of each antiglobulin was used throughout the study.

Air-dried smears were covered with one drop of the diluted conjugate. Slides were incubated at 37°C for 30 min in a moist chamber and then washed in PBS and water, as described before. After air drying, the slides were mounted in 10% elvanol/Tris–HCl buffer, pH 8.

A Leitz–Wetzlar microscope equipped with a halogen quartz lamp (Phillips, 12 V), an interference filter (Werner Olsen, Copenhagen), and a 515 nm barrier filter, was used to read the slides.

The serum fluorescent antibody titre was expressed as the reciprocal of the highest serum dilution giving bright green fluorescence of at least 50% of the infected cells.

The neutralization data used in this paper were extracted from the kinetic neutralization test performed on the same sera in a previous study [3].

In the calculation of the arithmetic mean and standard deviation of the antibody titres, titres $\leqq 8$ for IgG and IgA and $\leqq 4$ for IgM, were considered 0. Titres $\geqq 2048$ were considered 2048. The distribution of antibody titres in the cancer group, normal control group and special control group was compared by the chi square test. Spearman's rank correlation coefficient analysis was used in the statistical analysis of the correlation between fluorescent IgG-, IgA- and IgM-titres and neutralizing activity of the same sera.

RESULTS

Age distribution and socio-economic status of the material

The age distribution of the patients with cervical cancer and the controls was almost identical (Table 1). The distribution of the cervical cancer patients did not differ from the distribution found in the control group with respect to socio-economic classes (Table 2).

Table 1. Age distribution of patients with cervical cancer and controls

Age (yr)	Cervical cancer	Controls
30–39	6	10
40–49	16	20
50–59	20	19
60–69	14	8
70–79	4	3
Total	60	60

Table 2. Distribution of patients with cervical cancer and controls according to socio-economic status

Socio-economic class	Cervical cancer	Controls
1, 2, 3	11	11
4	36	37
5	13	12
Total	60	60

The majority of women in both groups belonged in social group 4 (lower middle class).

Antibody titres in general

The mean fluorescent antibody titres (MAT) of IgG, IgA and IgM to HSV type 2 are shown in Table 3. The mean-IgG titre was higher in the cancer group as compared with the normal control group. The different distribution of IgG-titres in the two groups was found to be statistically significant, $0{\cdot}02 > P > 0{\cdot}01$, while no significant differences were found in the distribution of IgA- and IgM-titres between the cancer and normal control groups.

Table 3. IgG, IgA and IgM mean fluorescent antibody titre (MAT) to HSV type 2 in sera from 60 patients with cervical cancer, 60 normal controls, and 22 sera from 13 patients with recent herpes genitalis

	Cervical cancer	Normal controls	Herpes genitalis
IgG	502 ± 160	348 ± 158	522 ± 110
IgA	33 ± 12	27 ± 15	62 ± 22
IgM	22 ± 13	17 ± 10	42 ± 12

Statistical comparison between the cancer group and the group of patients with genital herpes showed no differences in the distribution of IgG-titres. IgA- and IgM-titres, however, were significantly higher in the patients with herpes genitalis than in the patients with cervical cancer.

Antibody titres in relation to age and socio-economic status

The youngest age groups of both cancer patients and controls had higher IgA antibody titres than the rest of the material, but the difference was not significant. Neither IgG-titres, nor IgM-titres to HSV type 2 had any relation to age.

Low socio-economic status could be correlated to high titres to HSV type 2 in all three immunoglobulin classes in the normal control group. In the cancer group there was no correlation between antibody titres and socio-economic status.

Antibody titres in relation to stages of malignancy

Table 4 shows that the mean titre of IgG-antibodies increased with increasing development of the malignant process, while IgA- and IgM-antibody titre had no relation to the severity of the disease.

Table 4. IgG, IgA and IgM mean fluorescent antibody titre (MAT) to HSV type 2 in sera from 60 patients with cervical cancer in relation to stages of the malignancy

	Number of patients	IgG	IgA	IgM
Stage 1	27	382 ± 150	27 ± 12	20 ± 14
Stage 2	20	460 ± 160	32 ± 11	24 ± 11
Stage 3	13	640 ± 190	27 ± 12	17 ± 14

Comparison of HSV type 2 neutralizing activity and fluorescent IgG-, IgA- and IgM-antibody titres to HSV type 2 in the individual sera

The fluorescent IgG-antibody titres and the neutralizing activity against HSV type 2 showed a high degree of correlation. Rank correlation analysis gave a correlation coefficient of 0·59, corresponding to a T value of 4·44 or $P \geqq 0{\cdot}001$. No correlation was found between IgA- or IgM-antibody titre and neutralization. Sera from the cancer group and the normal control group showed the same pattern.

DISCUSSION

Indirect fluorescent assay of different classes of immunoglobulins performed on whole sera raises the question as to whether the observed titres represent true changes in the amount of different immunoglobulins reacting with HSV antigens, or merely reflect the result of competition between the different immunoglobulins for the same antigenic sites. This possibility was tested in a previous study [5] by fractionation of the immunoglobulins on sucrose gradient and by analysis of the kinetics of IgG- and IgA-antibodies in serial blood samples from the same individual. We reached the conclusion that competition between IgG- and IgM-antibodies did not occur, and that competition between IgG- and IgA-antibodies, although likely, could not be demonstrated.

Raised titres of IgA- and IgM-antibodies in relation to recent or chronic infection with HSV and other viruses have been demonstrated in a number of studies [1, 5, 7–9].

Aurelian and co-workers [10] have demonstrated an IgM-response in cervical cancer patients directed against an HSV-coded membrane-associated antigen (Ag-4). The reason that we failed to demonstrate a rise in IgM-titre by the indirect fluorescent antibody method could be that the VERO-cells infected for 24 hr and used as indicator cells did not produce Ag-4.

The cancer patients were found to have an IgG-antibody titre to HSV type 2 which was not only significantly higher than that of the controls, but reached the same level as found in patients with recent genital infection with HSV type 2. This elevated fluorescent IgG-antibody titre could be correlated with the higher neutralizing activity of HSV type 2 found in the same cancer sera as compared with the controls. This means that the elevated IgG-antibodies must be directed against structural antigens in the viral envelope [11, 12] and do not necessarily represent antibodies to non-structural or tumor-associated HSV antigens.

Vos and co-workers [13] have shown cervical tumor tissue to contain large amounts of immunoglobulins, predominantly IgG. These antibodies had a marked lymphocytotoxic activity against a known lymphocyte panel used by routine for HL-A typing. The authors suggest that the formation of such partly autoimmune antibodies might impair the function of the host's own cell-mediated immune system and in turn lead to an unrestricted synthesis of immunoglobulin. This hypothesis is supported by our finding that increasing titres of IgG against HSV type 2 infected cells were found in patients with increasing spread of the malignant process and, as found by others [14], that titres of neutralizing antibodies to HSV type 2 frequently increased during prolonged disease.

However, Sprecher-Goldberger and co-workers [15] found that blood cells from patients with cervical cancer were stimulated with HSV type 2 and HSV type 2 transformed cells above the level found in healthy women. This effect could even be demonstrated in cancer patients with a decreased cell-mediated responsiveness in general, as measured by phytohemagglutinin stimulation.

The answer to the pertinent question as to whether the increased antibody titres against HSV type 2 found in patients with cervical cancer are caused by a disturbance of the immunological system brought about by the malignant process, or are the result of a stimulation of the humoral response to HSV specified antigens present on the tumor cells, must await further studies.

Acknowledgements—The authors are grateful for the help given by the blood bank at Rigshospitalet, Copenhagen, De Gamles By, and the Dermatovenerological clinic, Copenhagen Municipal Hospital, who supplied the blood samples investigated.

Establishment and Characterization of the Cell-Line of a Human Edonmetrial Adenoacanthoma

HIROYUKI KURAMOTO and MIEKO HAMANO

Department of Obstetrics and Gynecology, and Preventive Medicine System, School of Medicine, Kitasato University, Sagamihara, Japan

Abstract—*A new cell-line of a human endometrial adenoacanthoma, designated as HEC–6, has been established and propagates well with a permanent stability. The population doubling time of the line is calculated as 52 hr. The* in vitro *morphology reveals the features of a well-differentiated adenocarcinoma such as a jig-saw puzzle-like arrangement and the formation of an acinous cell-free space in the monolayer culture. Each cell consists of a round atypical nucleus with 2 or 3 marked nucleoli and a vacuolated cytoplasm. A piling-up tendency is a prominent feature and forms an obvious palisade-like or glandular structure. The karyotype of the stem cell is a pseudo-diploid in which variant chromosomes occur at random in various groups. When transplanted into a hamster cheek pouch, line HEC–6 demonstrated an adenocarcinoma in addition to a stratified epithelial component. The original characteristics of an adenoacanthoma of the corpus uteri have been maintained in the culture system.*

INTRODUCTION

THE ENDOMETRIUM, a target of sex steroid hormones, undergoes a cyclic alteration by the effects of the hormones. It is important to know if the endometrial gland still preserves the ability as a hormone target even after its maligant transformation. The various characteristics of human endometrial carcinoma should include the relation to hormones, however, because of the lack of a suitable experimental tool they have yet to be identified in detail. An *in vitro* cellular system might contribute to these purposes, supplying a convenient research method. We have established line HEC–1 originating from an adenocarcinoma of the corpus uteri and identified various features of the tumour using this *in vitro* experimental system [1–3].

The present paper reports the establishment of the new corpus tumour cell-line, its morphology, cytogenetic features and heterotransplantability as well as tissue reproducibility.

MATERIAL AND METHODS

Case history of the culture material

The fresh tumour material was obtained from a 48-year-old patient with carcinoma of the body of the uterus. This nulliparous patient has been well with regular menstrual cycle until she first complained of intermittent bloody discharge for 2 months duration. She used to live in Hiroshima and was 25 when an atomic bomb exploded there during World War II. An endometrial curettage showed an adenoacanthoma of the endometrium and the portion of a squamous epithelium was rather atypical in shape (Fig. 1). The patient was treated by total hysterectomy, bilateral salpingo-oophorectomy and pelvic lymphadenectomy on July 24, 1970. The uterus, the size of a small goose egg, showed a circumscribed tumour on the fundus, bulging into the cavity. The specimen adjacent to the cultured material revealed a well-differentiated adenocarcinoma.

Culture method

A monolayer culture method was used. The tumour material from the excised uterus was first washed twice in a phosphate buffered solution (Ca^{2+} and Mg^{2+} free) and minced into fragments with fine scissors and ventilated in 0·25% trypsin solution. The fluid and the minced tumour were stirred slowly by a magnetic stirrer (500 rev/min) for 15 min.

Accepted 11 October 1976.

The trypsin solution was changed 4 times. Then the turbid fluid in which the explant materials were dispersed into a single-cell suspension was aspirated and centrifuged twice after mixing with a culture medium. Subsequently, the sediment was resuspended in medium and placed on a stationary culture in 5% carbon dioxide and 95% air or, occasionally, in a closed vessel. Subcultures were made after treating them with solution of 0·1% trypsin and 0·02% ethylendiamine tetraacetate (EDTA).

Growth medium

Tissue culture medium No. 199 supplemented with 15% calf serum was used, containing penicillin in 100 U/ml and streptomycin in 100 μg/ml.

Morphologic and chromosome analyses

Approximately 5×10^4 to 1×10^5 cells were inoculated on a square test tube (40 by 17 by 8 mm in size; MA–8 Miharu) containing a cover glass, 32 by 12 mm, and cultured for 3–7 days.

The living cells were observed with an inverted phase-contrast microscope. Cells on a cover slip were also fixed with absolute methanol and stained with 10% Giemsa solution. Periodic Acid Schiff (PAS) and Alcian blue stains were made using twice the normal staining time.

For chromosome analysis, the medium was exchanged to one containing Colcemid, 5×10^{-7} M and the cells were incubated for 1 to 2 hr at 37°C to arrest those in metaphase. The cover slip with the cells was treated by a hypotonic solution, placed carefully in one minute in 0·7% and 0·5% sodium chloride solution and then in 0·2% sodium chloride solution for 20 to 40 min. Then the cells were fixed by passing through 1, 10 and 100% Carnoy solution (3:1 aceto-alcohol) for 1 to 2 min and finally for 15 min in the fresh 100% Carnoy solution. The specimens were air dried and stained with 10% Giemsa solution (pH 6·8). Three hundred and sixteen of the metaphase cells were observed to calculate the modal ploidy and 25 of the modal range were counted exactly to determine the chromosomal number. The karyotype of the cells with the modal of chromosomes was carefully analysed in accordance with Denver nomenclature.

Cell cultivation for growth curve

After being dispersed by a mixed solution of 0·1% trypsin and 0·02% EDTA, the cell suspension containing 2×10^5 cells was inoculated into plastic Petri dishes (60 mm in diameter; Lux Plastics) and grown as replicate cultures [4] in a humidified atmosphere containing 5% CO_2 and 95% air. Every 2 days after the subculture, two dishes were harvested to count the number of cells. The media in the remaining dishes was changed. The number of cells in each dish was counted 4 times, using a Burker–Türk counter plate. The mean was calculated for each dish and for every harvest. The data was plotted as a semilogarithmic graph.

Transplantation into a hamster

A female hamster, 4 weeks old and weighing about 50 grams, was used for the experiment. The cell cultures were dispersed into a suspension of single cells by the trypsin-EDTA solution, and then were washed with culture media and centrifuged twice. The cells, 42·0 or $75·0 \times 10^5$ in number, were injected into the submucosa of a hamster cheek pouch by a syringe with a No. 22 gauge needle. The hamster was anaesthetised by 2 mg of sodium pentobarbital intraperitoneally, and also immunosuppressed by giving cortisone acetate 2·5 mg per 50 g of body weight once every 4 days, starting on the day of transplanation.

RESULTS

Culture course to the establishment

The cells were attached well on the bottom of a culture bottle on the first day of the primary culture forming multiple sheets. The culture was apparently successful from the beginning, in contrast to other unsuccessful attempts. The primary culture was grown for 18 days before the first subculture. Since then the cells have been subcultured every 7–14 days, being diluted to three- or four-fold on each passage.

The cell proliferation has been maintained except for 4 accidental growth-suppressive periods. It seemed, however, that they happened to be due to inappropriate calf serum, or inappropriate incubation conditions, rather than a characteristic feature of these cancer cells in culture. The line was designated as HEC–6 (human endometrial cancer—6).

When confluent, HEC–6 cells pile up easily from a monolayer sheet. However, if the cells are not subcultured the sheet often will shed cells and debris into the medium. On the other hand the cells are not easy to trypsinize into single cell suspension, especially in logarithmic growth periods but become easy when confluent.

Fig. 9. The reconstruction of a stratified pavement epithelium is also demonstrated on the other view. H-E stain. × 150.

Morphology

Since the primary culture the cells have remained homogenous and polygonal shaped. No fibroblastic cells have been seen. The arrangement of the actively growing cell sheet appears stream-shaped in polarity, showing a jig-saw puzzle-like or a wheeled pattern (Fig. 2). When the growth progresses HEC–6 cells grow in multilayers and seemingly reconstruct an original structure obviously forming a palisade-like formation (Fig. 3). Conversely, when the cells grow in a monolayer sheet they proliferate most readily around the cell-free spaces. This seems to be an expression of acinous formation.

The cells of the primary culture were classified as malignant columnar cells according to the criteria of a diagnostic exfoliative cytology. They had hyperchromatic nuclei, of varying size, irregular chromatin distribution and one or more large nucleoli. The plasma membrane was ill defined. There was abundant cytoplasm containing many vacuoles (Fig. 4). PAS-positive granules, that were removed by digestion with saliva, were present in the cytoplasm. Alcian blue staining was negative. These morphologic features have been retained by the culture cells. However, the PAS-positive granules disappeared at 30th generation until then they had been a constant feature of the cytoplasm.

Growth kinetics

The growth curve of HEC–6 cells was examined at 37th passage generation (Fig. 5). The growth showed lag phase, lasting 5 days, followed by a logarithmic growth phase until the 11th day. Subsequently, the growing rate declined to enter a stationary phase. The population doubling time of the line HEC–6 during the logarithmic growth phase was 52 hours.

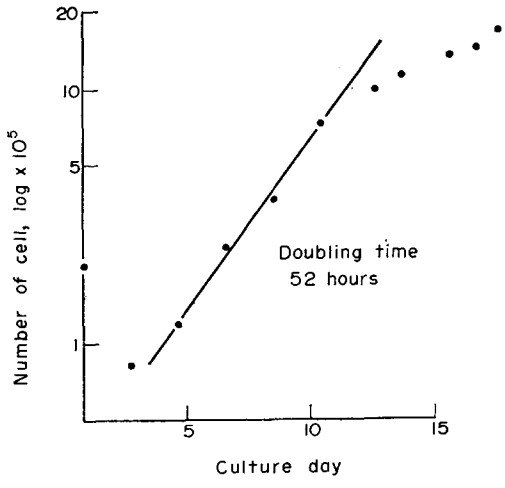

Fig. 5. Growth curve of HEC–6 at 37th generation. The population doubling time is calculated as 52 hours.

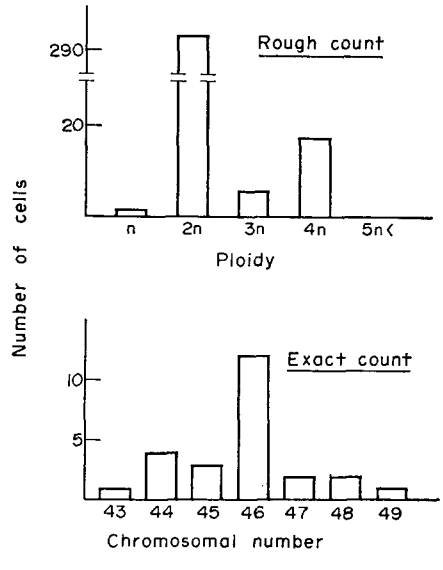

Fig. 6. Distribution of the chromosomal number at the primary culture. The majority of 316 metaphase cells appeared to be on a diploid range by a rough-counting (above) and the exact counting of 25 cells on the diploid mode showed the peak on 46 in number (below).

Chromosome constitution

The chromosome analysis was performed on the primary culture. The modal ploidy of 316 metaphase cells appeared to be obviously diploid by approximate counting. Very few cells deviated from the diploid mode. The exact counting of chromosome number showed the modal peak to be 46 (Fig. 6). The karyotype of the mode was analysed. There was no specific chromosome aberration or marker chromosome (Fig. 7), but irregular increase or decrease of chromosome number in each group was noted. Chromosomes exhibiting slight morphological aberrations were present in almost every group (Table 1). From these findings, it is deduced that the HEC–6 line arose from a pseudo-diploid stem cell.

Heterotransplantation

The HEC–6 cells at 11th, 16th and 26th generation respectively were transplanted into the submucosa of a hamster cheek pouch and produced a definite tumour. Histologically in some areas these tumours were typical of adenocarcinoma (Fig. 8). In another field, there appeared to be no gland formation or cells with cytoplasm of a secretory type, but there was construction of a stratified epithelium which was considered as a squamous meta-

morphosis (Fig. 9). The findings coincide well with those of the original adenoacanthoma.

DISCUSSION

One of the authors was the first to report the established line, HEC–1, of human corpus tumour in 1972, originating from a moderately differentiated adenocarcinoma [1, 2], and mechanism of the progesterone therapy upon endometrial carcinoma was studied by using this line. The suppressive effect on the growth kinetics and the morphological alterations were reported elsewhere [3]. The characteristic features of line HEC–6 such as the cellular arrangement, diploid modal chromosomal number and heterotransplantability are similar to the HEC–1 line. Conversely, there is the detailed histology of the reconstructed tumour grown as a xenograft and absence of a marker chromosome.

Adenoacanthoma of the uterine corpus may be defined as a lesion composed of anaplastic glandular element in addition to which there is an epidermoid epithelial component. The latter is usually benign [5]. The histogenesis of the squamous-metaplastic change has been debated. The indifferent or reserve cell, lying between the cylindrical cells and the basement membrane, may give rise to stratified squamous epithelium in response to a variety of stimuli. This might possibly arise in malignant as well as benign endometrial glands. The carcinoma cells may have keen capable of differentiating into squamous epithelium; rather than squamous metaplasia of the normal endometrium, as the result of an inflammatory response from the adjacent carcinoma. The xenograft of the HEC–6 cells seems to give an answer to this question, since no normal endometrial components which may transform to a squamous epithelium are present in the graft site. The cultured cell differentiates both adenomatous and squamous elements in an appropriate environment *in vivo*. The individual cell characteristics determine the malignancy of the lesion.

The stem cell of line HEC–6 is a pseudo-diploid. Likewise, various investigators [6–12] have reported, using squash or flame-dry methods, that endometrial cancer has a diploid or near diploid mode. Tseng and Jones [13], and Katayama and Jones [10] found an entirely normal karyotype in endometrial tumours including an adenoacanthoma which has never been reported in other malignant neoplasms. However, Wagner *et al.* [14] observed a wide variety of aneuploidy states based on the distribution of nuclear DNA content, and Takemura [6] found polyploid modes in two cases. Katayama and Jones [10] also stated that in an anaplastic adeno-carcinoma and an adenosquamous carcinoma more than half of the cells had hyperdiploid chromosomes. On the other hand, Atkin *et al.* [15] demonstrated all of the 7 well-differentiated corpus tumours were diploid or hypodiploid, whereas there were relatively fewer corpus tumours in the tetraploid region and none with DNA values above tetraploid. There may be evidence of a correlation between the histologic grading of malignancy and the extent of chromosome aberrations in the carcinoma of the endometrium, although the majority of the reported cases as well as HEC–6 gather to a diploid range.

The Role of T and Suppressor Cells in MTV-Directed Cellular Immunity*

PAULA CREEMERS and PETER BENTVELZEN
Radiobiological Institute TNO, Rijswijk, The Netherlands

Abstract—*The lymphocyte population from mice immunized with mammary tumour virus (MTV) which responds* in vitro *with blastogenesis in the presence of MTV, proves to be T cells. In mice bearing spontaneous MTV-induced mammary tumours, this T cell reactivity was very often depressed. The depression was partly due to the presence of suppressor cells which have adherent properties. These suppressor cells appear early during tumour growth and exert their greatest influence when the tumour weighs* 0·5–1·5 *g. In animals bearing larger tumours less suppressor cells were present and the hyporeactivity in the lymphocyte stimulation test must also be due to other factors.*

INTRODUCTION

WHEN incubated with mammary tumour virus (MTV) leukocytes of mice with virally induced mammary tumours show virus-specific blastogenesis in the leukocyte stimulation (LS) test (preceding paper).

Blair and Lane [1] state that MTV-specific cytotoxicity is a property of T cells and null cells which are recruited by an MTV specific factor produced by B cells. These null cells are found in the cell fraction that does not adhere to nylon wool, but they cannot be killed by antitheta serum and complement.

However, despite these immune responses, primary mammary tumours show progressive growth. It is reported by Blair and Lane [1] that, as the tumours of the female mice increase tn size, the null cell cytotoxic activity is no longer detectable, but they do not mention a loss of T cell dependent cytotoxicity in the microcytotoxicity (MC) test. MTV-specific leukocyte stimulation and Leukocyte Adherence Inhibition (LAI) in mice decreased to almost zero when the tumour reached a weight of about 2 g (preceding paper). In human breast cancer, LAI reactivity decreased with increasing tumour burden [2].

It has been shown that some *in vitro* lymphocyte functions, as for instance stimulation by plant lectins, can be inhibited by suppressor cells present in the spleen of animals bearing progressively growing tumours: Glaser *et al.* [3] demonstrated this in animals with Gross Leukemia Virus induced tumours. The same phenomenon was also shown in the Moloney Sarcoma Virus (MSV) system [4, 5]. The suppressor cells were thought to be macrophages.

To further study the mechanisms of MTV-directed cellular immunity in mice bearing primary mammary tumours, we again used the LS test. Evidence is presented that T cells are most likely responsible for the reactivity observed, and that the decline in blastogenesis with increasing tumour weight is caused, among others, by the presence of suppressor cells which have adherent properties.

Accepted 15 October 1976.

*This investigation was performed pursuant to NIH Contract NO1 CP 43328 with the National Cancer Institute, Division of Cancer Cause and Prevention, Viral Oncology, Department of Health, Education and Welfare, Bethesda, Md., U.S.A.

MATERIAL AND METHODS

BALB/cfC3H mice carrying MTV-S and GR, which spontaneously releases the endogenous MTV-P, were used. Tumours were induced in these mice by forced breeding. Male mice of 12 weeks of age were used as positive controls, they were immunized i.p. with 1 μg disrupted alum precipitated virus and killed 5 days later. Male mice not older than 10 weeks served as normal controls, because they do not release endogenous MTV at that age. All mice were killed by cervical dislocation.

Virus

The standard strain of mouse mammary tumour virus (MTV-S) was isolated from

BALB/cfC3H mammary tumours, as described in the preceding paper. Again, virus content was estimated on the basis of the amount of protein, as measured by the Folin method. Before use as antigen, the virus was disrupted by repeated freezing and thawing.

LS test

This test was carried out as described in the preceding paper. Blast formation was estimated by the incorporation of 2-^{14}C-thymidine. In all experiments 10^{-4} mg MTV/ml was added; purified RLV (10^{-4} mg/ml) was used as a control throughout. The cultures were run in triplicate. Statistical significance was established by means of the two-tailed Student's *t*-test. Per cent stimulation was calculated according to the formula: $a-b/b \times 100\%$ in which a is the average counts/min (cpm) of the cultures incubated with MTV and b is that in the cultures incubated with RLV. To detect whether the spleen of animals bearing tumours of different sizes contained suppressor cells, individual animals were tested: A T-cell-enriched cell fraction was made (see below) and $0{\cdot}5 \times 10^6$ spleen cells derived from the same animal in 0·2 ml medium supplemented with 20% foetal calf serum were added to each culture. Cultures to which normal spleen cells in the same concentration were added served as controls. All cultures were incubated with MTV. Per cent inhibition was calculated by: $(1-c/d) \times 100\%$, in which d is the average cpm of the cultures containing T-cell-enriched populations to which spleen cells containing suppressor cells were added and d is that in the cultures to which normal spleen cells in the same concentration were added.

Separation of cell subpopulations

B-cell-enriched fractions were obtained by incubating 4×10^6 macrophage-depleted spleen cells with mouse antitheta serum and complement for 1 hr. The anti theta serum was made by injecting 2×10^7 thymocytes derived from C3H mice intraperitoneally into AKR mice. This was done six times with intervals of 14 days. Then the AKR mice were bled; the resulting ant tiheta serum killed 70% of C3H thymocytes up to a dilution of 1/16. As a source of complement guinea pig serum absorbed with agarose and stored in liquid nitrogen was used. The complement was active up to a dilution of 1/8. After treatment, the cells were washed and used for the LS test.

T-cell-enriched cell populations were obtained by adherence on a nylon wool column [6]. After elution about 20% of the original cell population was recovered. Of the eluted cell population, 60–70% could be killed with antitheta serum and complement, whereas 10% were shown to be Ig-positive B cells in direct membrane fluorescence studies.

Adherent cells were removed by incubation of spleen cells (4×10^6/ml) in Falcon tissue culture flasks (25 cm^2) during 2–3 hr. When adherent cells in combination with T-cell-enriched populations were tested, the adherent cells present in $2{\cdot}5 \times 10^6$ spleen cells were allowed to adhere in the tubes in which the LS-test was performed; the supernatant was then removed and the adherent cells were washed three times with medium, after which T-cell-enriched cell fractions were added. The approximate number of adherent cells was estimated by subtracting the number of cells that did not adhere from the original concentration.

Membrane fluorescence

For the detection of viral antigen that could be attached to the cells, adherent cells were grown in microtitre plates as is described by Sorg [7]. They were washed three times and then incubated for 1 hr with goat polyvalent anti-MTV-S serum at 37°C in a humidified atmosphere. After three washings in PBS, the cells were treated with fluorescein conjugated antigoat Ig serum (Nordic, Tilburg, The Netherlands) which was diluted 1:20 in PBS and incubated for 30 min. They were again washed three times prior to observation.

Antibody attached to the cells was determined by treatment with fluorescein conjugated antimouse Ig serum, which was also used in a 1:20 dilution.

RESULTS

MTV-specific blast forming cells

In every experiment, the spleen cells used were derived from at least 3 positive control animals. If lymphocytes, T-cell-enriched and B-cell-enriched cell populations prepared from the same pool of spleen cells were compared, the T-cell-enriched fraction showed the highest stimulation as compared to the RLV-control, whereas the degree of blastogenesis observed with the same number of cells of the B-cell-enriched cell population was not noteworthy (Table 1). Even if stimulation of the spleen cells was not significant, significant stimulation emerged when T-cell-enriched cell fractions were used.

Stimulation of the T-cell-enriched fraction was not increased if adherent cells were added

as compared to T cells to which adherent cells derived from normal animals were added (Table 2).

Suppressor cells

In both GR and BALB/cfC3H mice bearing large MTV-induced tumours (2 g or larger), it was repeatedly observed that the T cell response was markedly depressed if adherent cells derived from the same animals were added, as compared to cultures to which adherent cells derived from normal animals were added (Table 3). When different concentrations of adherent cells derived from mice bearing large tumours were added to T-cell-enriched fractions derived from mice bearing very small tumours, blast formation in the presence of MTV decreased gradually. This was not the case when adherent cells from normal animals were added (Fig. 1).

To determine whether the cellular hyporeactivity seen at a tumour weight exceeding 2 g (preceding paper) can be attributed to suppressor cells, individual BALB/cfC3H mice bearing tumours of varying sizes were tested for the presence of such cells. To T-cell-enriched cell fractions from such animals, spleen cells derived from the same animal were added as described under Material and Methods; cultures to which normal spleen cells were added in the same concentration served as controls. Both sets of cultures were incubated with MTV and per cent inhibition was calculated. The results are shown in Fig. 2. From the results, it is clear that suppressor cells are present early during the growth of the tumour: the first significant inhibition was seen at a tumour weight of 0·5 g. Greatest inhibition is seen at a tumour weight between 0·5 and 1·5 g; also at about 4 g a considerable inhibition occurs.

In animals bearing large tumours, spleen cell cultures containing suppressor cells sometimes gave significantly lower counts than did

the RLV-control; removing the suppressor cells gave equal values for MTV and RLV cultures; even then, no MTV-specific proliferation was obtained. This was not seen in animals bearing small tumours. This is demonstrated in Table 4. Average per cent stimulation of T-cell-enriched cell fractions of 9 animals with small tumours (average 0·9 ± 0·2 g) was 83·1, and varied from 23 to 154; for 10 animals tested with large tumours (average 3·5 ± 0·2 g) this value was 15·2 with a variation of 0–62%.

Neither antigen nor antibody could be detected on the surface of adherent suppressor cells by membrane fluorescence studies.

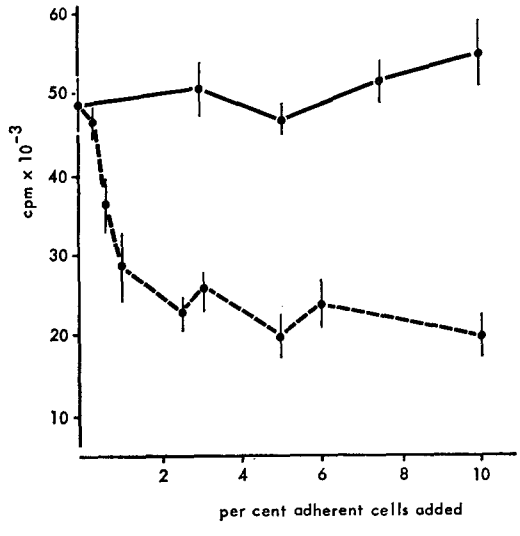

Fig. 1. Inhibition of MTV-specific response of T-cell-enriched cell populations derived from 3 BALB/cfC3H mice bearing very small tumours (average 0·27 g) when varying amounts of adherent suppressor cells derived from 4 BALB/cfC3H mice bearing large tumours (average 3.10 g) are added.

DISCUSSION

From results with the fractions enriched for T-cells it can be concluded that the MTV-specific blast formation observed in splenic cell cultures derived from BALB/cfC3H and GR mice primed with MTV is due primarily to activities of T cells. Blair and Lane [1] claim that a major part of mammary tumour cell killing in the MC test is T-cell dependent. They also report on antibody-dependent null cell activity in this system. Such activity could not be detected in our leukocyte stimulation assays. Fractions enriched for B cells which also would contain null cells did not give any significant proliferation upon incubation with MTV.

The addition of adherent cells derived from positive control animals did not enhance the blastogenesis of T cells as compared to when normal adherent cells were added. It is therefore not likely that macrophages are required

in large quantities for induction of specific T cell proliferation. In the previous paper the LS and the LAI tests gave parallelar results in the MTV-system. Holt [8] claims that the production of LAIF, which is responsible for the inhibition of adherence of neighbouring leukocytes, is T-cell-dependent. We have confirmed this for the MTV-system (Creemers, unpublished results). It seems that T cells play a major part in different systems of cellular reactivity to MTV.

In the present study, it was demonstrated that the MTV specific response in tumour bearing animals was depressed by the presence of adherent cells. This suppression appeared not to be a tissue culture artifact, since increasing the cell density by adding an equal number of normal adherent cells had no inhibitory effect. The suppressive effect was already seen when about 0·5% adherent suppressive spleen cells were added to a responding cell population and about 5% was enough to reach the maximal inhibitory effect. These results are in accord with those of Glaser *et al.* [3] in rats bearing progressively growing Gross Leukemia Virus induced tumours. Kirchner *et al.* [4, 5] found suppression of the PHA response of lymphocytes from mice bearing primary MSV induced tumours. Surprisingly, they found an inverse relationship between the development of suppressor cells and virus-specific cytotoxicity. It is therefore possible that no depression will be found in T-cell-dependent cytotoxicity in the MC test with increasing tumour weights. However, Eggers and Wunderlich [9] reported the presence of adherent suppressor cells in the MC test in methylcholanthrene induced tumour bearing animals.

Kirchner *et al.* [4, 5] observed a good correlation between the growth pattern of MSV-induced tumours and suppressor cells were detected before the tumour had reached an appreciable size. In this system, suppressor cells could already be demonstrated at a tumour weight of 0·5 g. The greatest inhibitory effect was seen at a tumour weight between 0·5 and 1·5 g; there was also a considerable effect at 4 g. The decline in spleen cell reactivity when the tumour exceeds one gram in weight can be attributed to increasing suppressor cell activity. At 2 g, when the spleen cell activity in the blastogenesis test is at a minimum (preceding paper), the maximum suppressor cell activity has already disappeared.

Removal of adherent cells did not result in a significant T cell reaction at heavier tumour weights in most cases. Thus, suppressor cells cannot be the only cause of the hyporeactivity observed at a large tumour burden; other factors which make the T cell unresponsive must be involved. Studies on this subject are now in progress in our laboratory.

The mode of action of suppressor cells remains unclear. Membrane fluorescence studies for the detection of antigen or antibody on the surface of the suppressor cells gave negative results. Eggers and Wunderlich [9] found no evidence for the mediation of suppression by soluble factors. In this study it was not investigated whether the suppressor adherent cells are T lymphocytes [10]. Suppressor cells are found only in cases in which animals are overloaded with antigen and the possibility must be considered that suppressor cells are part of a tolerance inducing mechanism that is activated when the immune system is confronted with excess tumour antigen.

Abstract—*Seventeen patients with advanced malignancies received escalating doses of chemotherapy with adriamycin and cyclophosphamide. Sixty-five per cent of the courses produced circulating granulocyte counts of* 500 *cells/mm*^{3} *or less. Febrile episodes occurred in only* 15% *of courses and were seen only with doses of chemotherapy that produced granulocyte nadirs of less than* 200 *cells/mm*^{3}. *There were no episodes of septicaemia. Ten of the* 17 *patients received an intensive dose followed by reinfusion of cryopreserved, autologous bone marrow. In* 5 *of these patients, recovery to* 500 *granulocytes/mm*^{3} *was more rapid following the intensive, marrow-supported course by comparison with the prior, less intensive, unsupported course. We conclude that higher doses of adriamycin and cyclophosphamide than are conventionally used can be given without serious toxicity. Autologous bone marrow reinfusion may have a role in reducing the period of drug-induced granulocytopenia, but effective storage and recovery of human bone marrow remains a major problem.*

INTRODUCTION

MOST evidence from experimental animal systems indicates that the dose–response curves for antitumour effect and toxicity are steep [1, 2]. For most antitumour agents, myelosuppression is dose limiting. An increase in the severity of granulocytopenia has been shown to predispose to the risk of infection in patients with acute leukaemia [3]. Likewise, in patients with solid tumours, fatal infections are becoming more frequent, possibly related to more intensive and more widespread use of chemotherapy [4].

Reinfusion of autologous bone marrow has been used experimentally in attempts to circumvent myelosuppression, but the efficacy of this approach has not yet been fully established in man [5–8]. In animals, however, effective marrow reconstitution has been achieved [9–11], and has resulted in prolonged survival. Moreover, myelosuppression from sublethal treatment has been effectively shortened by infusion of fresh or cryopreserved isogeneic bone marrow [12].

The chief aim of this study was to investigate the haematological tolerance and safety of high doses of chemotherapy. Cryopreserved autologous bone marrow was employed as a potential means of reducing the duration of drug-induced granulocytopenia, thus permitting the safer administration of high dosage of myelotoxic agents. Each patient served as his own control. This report represents an initial summary of our experience with this approach and emphasizes the haematological response and the problems of marrow storage and reinfusion. The 10 patients who have

completed the programme are also evaluated for tumour response.

MATERIAL AND METHODS

Patient population and chemotherapy design

Seventeen patients with tissue-proven metastatic carcinoma were entered into this study. Eleven patients had stage III/IV ovarian cancer, untreated except for previous surgery. One patient had stage III ovarian cancer previously treated with surgery and chemotherapy. One patient had stage III teratocarcinoma of the testis previously treated by surgery. One patient had primary peritoneal mesothelioma. Three patients had carcinoma of the breast. Of these, one had been treated with chest wall irradiation following simple mastectomy. This patient underwent adrenalectomy and oophorectomy prior to entry into this study, and was given replacement steroid therapy throughout the period of treatment. Two further patients were treated with radical mastectomy and chest wall irradiation. In one of these patients, irradiation was given concurrently with low-dose chemotherapy prior to treatment with high-dose chemotherapy on this programme. In the other patient, irradiation was completed eight months before entry into the study.

All patients were treated with increasing doses of adriamycin (ADR) and cyclophosphamide (CY) according to the scheme presented in Fig. 1. Initial doses were ADR 45 mg/m^2 and CY 500 mg/m^2. All drugs were given intravenously over two consecutive days (ADR day 1, CY day 2), and dosage was rapidly escalated at three-weekly intervals.

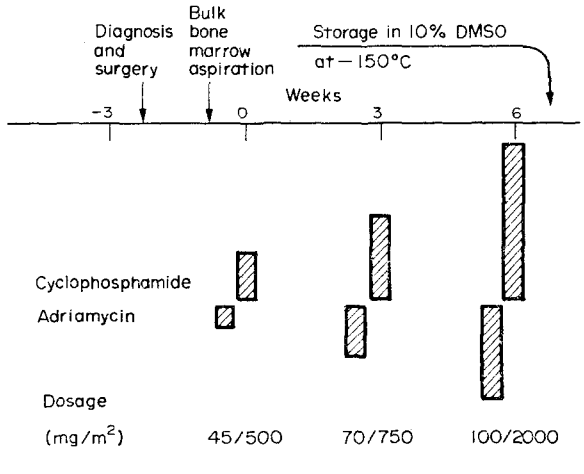

Fig. 1. Schematic presentation of intensive chemotherapy programme with autologous marrow aspiration, storage and reinfusion. Chemotherapy was rapidly escalated and marrow reinfusion took place 72 hours after the intensive course.

Haematological response was closely monitored and all patients had complete blood counts including differential and platelet counts at least 3 times weekly and more frequently during periods of critical myelosuppression. All patients received at least one course of therapy consisting of ADR 70 mg/m^2 plus CY 750 mg/m^2. Ten patients received a more intensive course usually consisting of ADR 100 mg/m^2 and CY 2000 mg/m^2. The additional seven patients are included in the evaluation of marrow procurement and haematological tolerance to the chemotherapy. A total of 99 courses of ADR/CY was given. No patient received more than 450 mg/m^2 of ADR as a total dose.

Marrow aspiration and cryopreservation

Prior to chemotherapy, bulk marrow aspiration was carried out under general anaesthesia by a modification of the method of Thomas and Storb [13]. Briefly, marrow was obtained from the posterior superior iliac spines and posterior iliac crests using heparin (Weddel Pharmaceuticals, London) 50 units/cc in Hanks' balanced salt solution as an anticoagulant. After filtration to remove marrow spicules, mononuclear cells were concentrated by centrifugation. The net number of marrow cells was calculated by subtracting peripheral blood leukocytes from the total nucleated cell count of the bulk marrow aspirate. Dimethylsulfoxide (DMSO) was added to a final concentration of 10%, and the marrow was cooled in Hemoflex bags (Union Carbide, Chicago, Illinois) at 1°C/min to −40°C and then rapidly to −100°C in an automated liquid nitrogen freezer (Planer Instruments, Middlesex). The sample was maintained in the vapour phase of liquid nitrogen (−150°C) for 2 to 4 months. The viability of myelocytic progenitor cells was assessed both in fresh specimens and in aliquots of cryopreserved specimens by the *in vitro* colony assay (CFU-C) using the method of Iscove *et al.* [14].

Infusion of autologous bone marrow

In all 10 patients receiving the intensive ADR/CY course the autologous marrow was reinfused 72 hr after the administration of ADR. Marrow was rapidly thawed in a 40°C water bath, diluted with plasma/saline, centrifuged and resuspended for infusion as described elsewhere [15]. An aliquot of the infused marrow was used to determine the total number of cells, viability by trypan blue exclusion and CFU-C content. In all cases, the level of ADR equivalents at the time of marrow in-

fusion was determined using the radioimmunoassay described by Van Vunakis *et al.* [16]; more complete ADR clearance studies were carried out in five patients.

The ability of autologous bone marrow to alter the period of granulocytopenia was evaluated by comparing total granulocyte counts during the intensive marrow-supported course (transplant course) with granulocyte counts during the prior, less intensive and unsupported course of chemotherapy (pre-transplant course). Specifically, the number of days spent with granulocyte counts less than 500/mm^3 for these 2 courses were compared in each patient. The granulocyte and platelet nadirs for the courses were also compared. Effectiveness of marrow infusion was assessed by determining the number of days from the start of therapy to the day at which recovery to 500 granulocytes/mm^3 took place.

Evaluation of tumour response

Evaluation of response in this report is limited to those patients who underwent reinfusion of autologous marrow. Complete response (CR) refers to the disappearance of all objective evidence of disease for a period of at least two months. Partial response (PR) refers to reduction of measurable tumour by greater than 50%. Patients who responded less than 50% or who had no change in their tumour status were designated as having stable disease (SD). All other patients were considered to have tumour progression (TP). Subjective improvement was not a criterion for response. For patients with ovarian cancer, all responses were verified by laparoscopy and laparoscopic biopsy of areas of disease known to be present after primary surgery.

RESULTS

Bone marrow aspiration and processing

In the 17 patients from whom marrow was aspirated, the median yield of bone marrow cells was $1{\cdot}9 \times 10^{10}$ (range $0{\cdot}9$–$2{\cdot}9 \times 10^{10}$) (Table 1). The median net number of nucleated bone marrow cells after correction for peripheral blood contamination was $1{\cdot}0 \times 10^{10}$ (range 0–$1{\cdot}8 \times 10^{10}$). There was no clear relationship between the volume of bone marrow aspirated and the net cell harvest. After processing, the median number of cells preserved was $1{\cdot}3 \times 10^{10}$ (range $0{\cdot}6$–$2{\cdot}8 \times 10^{10}$). This figure includes peripheral blood mononuclear cells and is therefore higher than the figure for the net yield of bone marrow harvested. Marrow aspiration resulted in a fall in hematocrit from $36{\cdot}3\% \pm 1{\cdot}5$ to $29{\cdot}8\% \pm 1{\cdot}6$ in 8 patients who were not transfused; the other 9 patients received red cell support immediately following the aspiration.

Table 1. *Bone marrow aspiration and storage*

14	1137	2·8	*	1·9
15	393	1·6	1·3	1·6
16	711	1·9	1·5	1·3
17	1152	1·9	1·1	1·2
Median	935	1·9	1·0	1·3

*Leukocyte counts on bone marrow aspirate and peripheral blood were 27,000 and 28,000 respectively.

This table shows data on aspiration, processing and storage of bone marrow. "Net marrow cells" refers to gross cell yield minus cells derived from the peripheral blood (obtained by subtracting peripheral white blood count multiplied by volume of aspirate, from total cells aspirated). "Total cells frozen": usually less than gross yield because of losses in processing. Greater than "net marrow cells", since peripheral blood mononuclear cells are included.

Assays for CFU-C content were performed on 4 ml aspirates obtained from each patient prior to bulk bone marrow harvest. In 14 patients, the median CFU-C concentration was 53 (range 7–117)/10^5 sedimented cells.

Myelosuppression and fever

The mean granulocyte nadir following doses of ADR 45/m^2 and CY 500 mg/m^2 was 695 ± 75/mm^3 (Table 3), and the mean platelet nadir was $198{,}000 \pm 12{,}000$/mm^3. At the higher dose of ADR 70 mg/m^2 and CY 750 mg/m^2, the mean granulocyte and platelet nadirs were 266 ± 39/mm^3 and $147{,}000 \pm 10{,}000$/mm^3 respectively. In the 3 patients who had received previous irradiation, both the granulocyte and platelet nadirs were lower; at the dose of ADR 45 mg/m^2 and CY 500 mg/m^2, the difference for both granulocytes and platelets

was statistically highly significant ($P < 0{\cdot}001$, Mann–Whitney U Test).

A characteristic curve of granulocyte depression following chemotherapy was derived by superimposing the granulocyte counts from all courses at each dose level (Fig. 2). The curves shown represent the median of these points. Similar curves were drawn for the platelet counts. At the dose of ADR 70 mg/m^2 and CY 750 mg/m^2, the rise in total leukocyte count preceded granulocyte recovery. This was due to an absolute monocytosis commencing on day 12 (Fig. 3).

Table 2. Bone marrow reinfusion

Pt.	Total cells reinfused ($\times 10^{10}$)	Total cells per kg ($\times 10^8$)	Viable cells per kg ($\times 10^8$)	Total CFU-C reinfused ($\times 10^6$)
1	1·0	1·7	0·9	0·4
2	1·6	2·8	1·4	1·1
3	1·3	2·2	1·1	3·5
4	1·1	1·5	0·8	0·4
5	0·7	1·6	0·8	0
6	0·8	1·1	0·2	0
7	0·8	1·2	0·8	0·3
8	0·6	1·6	0·5	0·4
9	0·6	1·0	0·7	2·8
10	1·2	2·9	1·9	2·2
Median	0·8	1·6	0·8	0·4

This table shows data on reinfusion of cryopreserved bone marrow. "Total cells reinfused": usually less than "total cells frozen" because of losses during freezing. "Viable cells" refers to Trypan blue exclusion. Total CFU-C reinfused was calculated by total volume of infusion multiplied by CFU-C content of marrow.

In the 99 courses of chemotherapy, granulocytopenia to less than 500 cells/mm^3 occurred in 64 courses (65%), and in 29 of the 64 courses, the granulocyte nadir was less than 200 cells/mm^3. Of the latter 29 courses, 14 were complicated by fever (48%) (Table 4). Only one additional febrile episode occurred during this study; this was the result of a wound infection following paracentesis in a patient whose granulocyte count was greater than 1000 cells/mm^3.

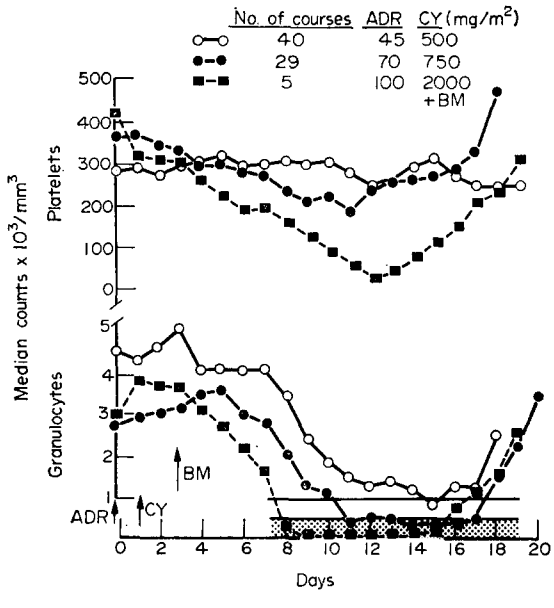

Fig. 2. Myelosuppression following increaing doses of ADR/CY chemotherapy. Curves were obtained by superimposing the counts from all courses for each dose and taking the median. Bone marrow was reinfused 72 hours after the intensive course. Horizontal lines show duration of granulocytopenia at 1000 cells/mm^3 and 500 cells/mm^3 (hatched). BM: bone marrow reinfusion.

Table 3. Haematological tolerance to ADR/CY chemotherapy

Dose (mg/m^2)	All courses	Prior X-ray	No prior X-ray
ADR 45/CY 500			
Number of courses	40	11	29
Gran nadir (per mm^3)	695 ± 75	399 ± 53	797 ± 96
Platelet nadir ($\times 10^3$/mm^3)	198 ± 12	146 ± 16	221 ± 15
ADR 70/CY 750			
Number of courses	29	4	25
Gran nadir (per mm^3)	266 ± 39	215 ± 146	270 ± 37
Platelet nadir ($\times 10^3$/mm^3)	147 ± 10	97 ± 28	160 ± 10

All values represent mean ± 1 S.E.M.

This table shows absolute granulocyte and platelet nadirs for two doses of chemotherapy. Sixty-nine courses of chemotherapy are analysed: 40 courses of ADR 45 mg/m^2 and CY 500 mg/m^2, and 29 courses of ADR 70 mg/m^2 and CY 750 mg/m^2. Previously irradiated patients experienced lower nadirs (both granulocyte and platelet counts) than patients not previously irradiated. For the lower dosage, this difference was statistically highly significant ($P < 0{\cdot}001$, Mann–Whitney U test).

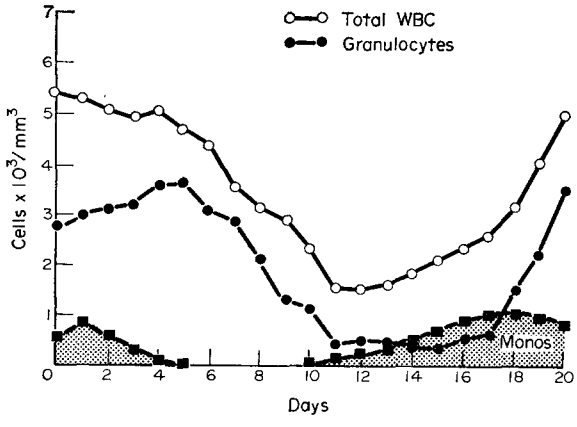

Fig. 3. Total leukocyte, granulocyte, and monocyte counts following ADR 70 mg/m² and CY 750 mg/m². Curves were obtained by superimposing the counts from all courses and taking the median. Monos: absolute circulating monocyte count.

Table 4. Fever and granulocytopenia

Depth

Granulocyte nadir (cells/mm³)	Total courses	Febrile courses	
500–400	4	0	0%
399–300	17	0	
299–200	14	0	
199–100	7	1	48%
<100	22	13	

Duration

Duration of grans <200 (days)	Total courses	Febrile courses	
1–2	7	0	(0%)
3–6	19	11	(58%)
7–8	3	3	(100%)

This table shows the relationship between granulocytopenia and the likelihood of fever during that course of chemotherapy. No fevers were observed in the 35 courses of chemotherapy which produced granulocyte nadirs between 200 cells/mm³ and 500 cells/mm³. When this nadir was exceeded, the risk of fever was 48% (14 febrile courses out of 29 courses). Fever also correlated with duration of granulocytopenia. An increased duration of granulocytopenia carried a steeply increasing risk of fever.

The number of febrile episodes was also related to the duration of granulocytopenia. Fever occurred in 0/7 (0%) courses in which granulocytopenia (less than 200 cells/mm³) lasted less than 3 days, in 11/19 (58%) courses in which granulocytopenia lasted 3–6 days, and 3/3 (100%) courses in which granulocytopenia lasted 7–8 days. In only 2 courses was there bacteriological documentation of infection despite vigorous attempts at culturing blood, urine, sputum, nose and throat. One patient had a staphylococcal cellulitis and one had a coliform urinary infection. There were no signs of septicaemia in any of the patients, and all recovered within seven days after the onset of fever.

Non-haematological toxicity

Alopecia was universal and was usually complete after three courses of ADR/CY therapy. Mild mucositis, consisting of buccal ulceration and soreness, occurred in 0/40 (0%) courses of ADR 45 mg/m² and CY 500 mg/m²; in 2/29 (7%) courses of ADR 70 mg/m² and CY 750 mg/m²; and in 2/8 (25%) courses of ADR 100 mg/m² and CY 1000–2000 mg/m². Mild, transient, haemorrhagic cystitis occurred during two courses of ADR 70 mg/m² and CY 750 mg/m² in one patient. Nausea and vomiting occurred in almost all patients following CY administration. It was usually transient (mean duration of vomiting 8 hr; mean duration of nausea 24 hr) and well controlled with oral, intramuscular or rectal prochlorperazine and/or pentobarbitone. Since heavy sedation was given to all patients receiving high dose ADR/CY therapy, it was not possible to correlate dosage with degree of nausea and vomiting. In 12/99 (12%) courses, there was significant residual nausea and/or vomiting which lasted beyond 24 hr. All patients had frequent electrocardiographic examinations prior to and during therapy. No patient developed signs or symptoms of cardiac failure at any time. In one patient, proteinuria had been noted prior to therapy. In this patient, transient nephrotic syndrome developed during therapy. Renal function remained normal and all signs of nephrotic syndrome (including proteinuria) resolved within the two months following intensive therapy.

Bone marrow infusion and haematological recovery

In the 10 patients receiving bone marrow transfusion, the median number of mononuclear cells thawed and reinfused was $0{\cdot}8 \times 10^{10}$ (range $0{\cdot}6$–$1{\cdot}6 \times 10^{10}$) (Table 2). Median Trypan blue viability was 50% (range 18–70%). An aliquot of the final marrow suspension yielded a median CFU-C concentration of $6{\cdot}0/1 \times 10^5$ cells plated (range 0–46). The median number of CFU-Cs infused was 4×10^5 (range 0–25). This was derived from the product if the total number of cells and the CFU-C content of the infused marrow.

In all patients the marrow reinfusion was

accompanied by the typical pungent odour associated with DMSO infusion. The estimated total dose of DMSO was 1–5 g per patient. Five patients experienced no difficulty with the marrow infusion. Two patients had paroxysmal cough for approximately one hour, and chest X-rays were negative in both. One patient had chills and weakness for 2 hr, and three patients complained of local irritation and burning at the injection site. Five patients were reinfused with bone marrow as outpatients and all of the patients were hospitalized when the granulocyte count reached 500 cells/mm^3 or less.

Following intensive chemotherapy with ADR 100 mg/m^2 and CY 2000 mg/m^2, granulocyte counts dropped more rapidly by comparison with previous courses. The median granulocyte count by day 8 was 300 cells/mm^3, in contrast to a median granulocyte count of 2000 cells/mm^3 in patients given ADR 70 mg/m^2 plus CY 750 mg/m^2. In 5 of 10 patients, recovery from the start of therapy to 500 granulocytes/mm^3 was more rapid in the transplant course than the pre-transplant course (Table 5). In 3 cases, the rate of recovery was the same, and in 2 cases, it was slower. The absolute granulocyte nadir was 245 ± 89/mm^3 in the pre-transplant courses and 42 ± 23/mm^3 in the transplant courses. Thus, recovery from the transplant courses was at least as rapid as from the pre-transplant courses despite a more profound granulocyte nadir. However, the number of days spent with a circulating granulocyte count of less than 500 cells/mm^3 was greater (6·7 days) for the transplant course than for the pre-transplant course (4·5 days) (Table 5). This was entirely due to the earlier fall in granulocyte counts produced by the more intensive ADR/CY therapy (Fig. 2). In one patient, recovery during the transplant course was particularly rapid (Fig. 4).

At the time of marrow transfusion, the median plasma ADR level was 10 nM, with a range of 6–15 nM (Fig. 5). There was little interpatient variability in ADR clearance. In the patient who demonstrated the most rapid recovery of circulating granulocytes, the level of ADR at 72 hr was 15 nM. This value was similar to the levels observed in the other patients.

Tumour response

Nine of the 10 patients who received intensive therapy with marrow reinfusion were evaluable for antitumour response. Six of these patients had stage III/IV ovarian cancer, one had peritoneal mesothelioma, one had teratocarcinoma and one had carcinoma of

All values represent mean ± 1 S.E.M.

This table shows data on intensive chemotherapy, bone marrow reinfusion and haematological recovery (10 patients). Granulocyte nadir was more profound after the intensive chemotherapy by comparison with the previous course, but the number of days from start of therapy to recovery (500 granulocytes/mm^3) was fewer following intensive chemotherapy/marrow reinfusion, in 5 patients. However, absolute number of days spent with a circulating granulocyte count < 500 cells/mm^3 was usually greater in the intensive course, since intensive chemotherapy produced a more rapid fall in the circulating granulocyte count (see Fig. 2).

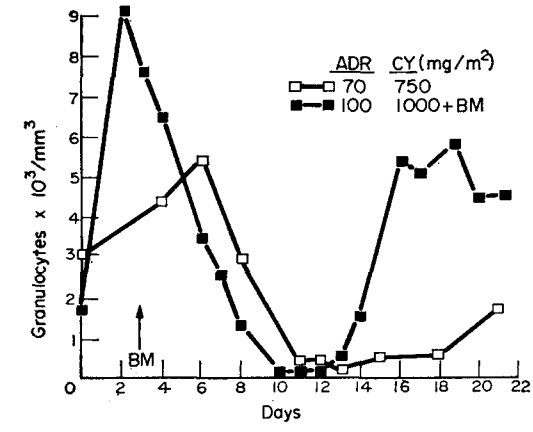

Fig. 4. Granulocytopenia in patient No. 3 following intensive chemotherapy with and without marrow support. BM: bone marrow reinfusion. Duration of granulocytopenia was reduced during the marrow-supported course despite increase in chemotherapy dosage.

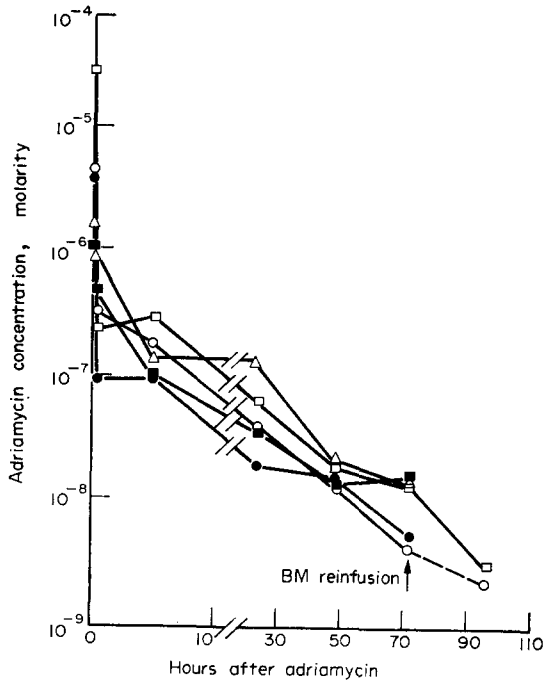

Fig. 5. Plasma clearance of ADR in patients undergoing reinfusion of autologous bone marrow. Four patients received ADR 100 mg/m² at time zero: one patient (●——●) received ADR 60 mg/m² at time zero. (Dotted line represents value below limit of assay.)

the breast. Objective responses were seen in 6 patients. Four of these responses (1 complete) were seen in the 6 patients with stage III/IV ovarian cancer. A PR was seen in one of the patients with breast cancer and the patient with teratocarcinoma, and no response was seen in the patient with peritoneal mesothelioma. Further data on ADR/CY in patients with advanced ovarian cancer has been presented by us elsewhere [17].

DISCUSSION

Attempts to demonstrate the value of autologous marrow following chemotherapy in man have been frustrated by the relatively short duration of granulocytopenia even with very intensive doses of drugs [18]. Buckner *et al.* gave high doses of CY (120 mg/kg) followed by autologous marrow to patients with a variety of disseminated malignancies [5]. No firm conclusions regarding the value of autologous marrow could be drawn although there was a slight trend towards earlier recovery from leukopenia in the reinfused patients. Previous work had shown that in primates, spontaneous recovery from CY occurred so rapidly that the additional benefit of infused marrow could not be documented [19]. We anticipated that improved haematological recovery following marrow infusion would be easier to demonstrate in patients given combination ADR/CY therapy than in patients given CY alone since the granulocyte nadir following ADR characteristically occurs later [20].

In only one patient was there clear-cut reduction in the duration of granulocytopenia following bone marrow reinfusion. We assumed that this was due to early reconstitution of bone marrow from the reinfused stem cells. In four of the other patients, recovery to 500 granulocytes/mm³ from the marrow-supported course was more rapid that it was after the prior, less intensive course. However, the overall duration of granulocytopenia was greater during the intensive course, and this was entirely due to the more rapid fall in granulocyte count seen with the larger dose of chemotherapy. Thus is would appear that the infused bone marrow contributed to earlier reconstitution but that no clinical benefit was derived because the onset of granulocytopenia was so rapid following intensive chemotherapy.

The viability of the transfused marrow, as measured by the CFU-C assay, was poor in most patients (Table 2). Although long-term preservation of murine, canine and primate bone marrow has been repeatedly accomplished [21–23], there is little evidence that large volumes of marrow can be successfully cryopreserved in man. Gray and Robinson demonstrated that storage up to 14 days did not result in significant loss of CFU-C [24]. Ragab *et al.* noted a substantial decrease in CFU-C, however, after cryopreservation of leukaemic marrow for periods of up to 16 weeks [25]. Schaefer and Dicke demonstrated

that the technique of dilution after thawing may be critical for optimal CFU-C recovery [26], and several methods are currently being studied. In our series, cell recovery was 62% and trypan blue viability was 50%. The CFU-C recovery was variable despite optimal rate of cooling, temperature of storage and choice of cryopreservative.

Attempts to establish the value of intensive chemotherapy have been hindered by morbidity from myelosuppression. Buckner *et al.* demonstrated that high doses of CY alone were capable of inducing responses in sensitive tumours, although it was not demonstrated that the response rates were unequivocally higher than those seen with more conventional dosage [5, 27, 28]. The present study has shown that it is possible to deliver intensive combination therapy without serious toxicity to the patient. Non-myelosuppressive toxicity was acceptable, and rarely precluded dose escalation. Although myelosuppression was frequently severe (65% of courses producing granulocyte counts less than 500/mm^3) there were no episodes of life-threatening infection. There was a clear relationship between fever and granulocytopenia. No fevers were seen in the 30 courses of therapy which produced granulocyte counts between 200 and 500 cells/mm^3. The risk was considerably increased only if this nadir was exceeded. Patients experiencing three or more days with circulating granulocyte counts less than 200 cells/mm^3 were more likely to become febrile (i.e., presumably infected) with increasing periods spent at this level. The study by Bodey *et al.* in patients with acute leukaemia clearly demonstrated a close relationship between granulocytopenia and probability of infection at all levels up to 1500 granulocytes/mm^3 [3]. Clearly, patients with solid tumours can tolerate a far greater degree of granulocytopenia than patients with acute leukaemia; this difference probably reflects the superior marrow reserve of patients with malignancy not involving the marrow, by comparison to those with a haematological malignancy.

This study therefore supports the concept that patients with solid tumours can tolerate more intensive chemotherapy than is usually employed. In addition, reinfusion of autologous marrow may play a part in hastening marrow recovery from such therapy, although satisfactory storage of human bone marrow with reliable maintenance of viability has not yet been achieved. Future investigation and use of autologous bone marrow transplantation as support for intensive chemotherapy will depend largely on improvements in storage and recovery techniques. It is not yet possible to assess duration of response to high-dose chemotherapy in this series, but the initial findings are encouraging.

Acknowledgements—We are indebted to Ms Monica Bowers, RN, for valuable assistance in these studies; also to Ms Charlene Heiser and Mr. Neil Binder for skilled technical help. Dr. Vic Raso was responsible for developing the Adriamycin radioimmunoassay in this institution using materials kindly supplied by Dr. H. Van Vunakis. Ms Jeanne Vlajnick aided in the preparation of the manuscript. Finally, we gratefully acknowledge the constant support, criticisms and encouragement of Dr. Emil Frei, III.

The Effect of Methotrexate on the Uptake of *De Novo* and *Salvage* Precursors into the DNA of Rat Tumours and Normal Tissues

KENNETH D. TEW and DAVID M. TAYLOR

Radiopharmacology Department, Division of Biophysics, Institute of Cancer Research, Royal Marsden Hospital, Sutton, Surrey SM2 5PT, England

Abstract—*The effects of two single doses of methotrexate (MTX) upon the incorporation of labelled* de novo *and* salvage *precursors into the DNA of tumour (BICR A*15*-kidney carcinoma), bone marrow, intestinal mucosa and spleen have been monitored in inbred August female rats. Fractional incorporation, used as an index of therapeutic response, has proved effective in estimating levels of tissue DNA synthesis. MTX has been shown to exert its cytotoxic effect in rats by blocking the* de novo *synthesis of thymidylate. The intestinal mucosa was shown to be extremely sensitive to MTX treatment. A dose of* 14 *mg/kg destroyed large areas of mucosa and resulted in the death of the animal after* 4 *days. The tumour appeared to overcome the MTX induced reduction in* de novo *thymidylate synthesis by utilising a* salvage *supply of thymidine thus by-passing a potentially lethal block through an alternative metabolic pathway. This difference between the response of the tumour and of a critical normal tissue, the intestinal mucosa, would severely limit the effectiveness of MTX for tumour therapy.*

INTRODUCTION

THE PRESENCE of alternative metabolic pathways in both normal and tumour cells is a factor which can lead to complications when scheduling cytotoxic drug treatment. The relevance of such anabolic alternatives has been realized for many years [1]. However, a further complication is that cells are rarely in a biochemical "steady state" condition. A given cell type is usually "totipotent" with respect to the various pathways to a given product. Sneider and Potter [2] have shown that cells may turn on to different metabolic pathways during various stages of differentiation. Since tumour cells may be regarded, in some cases, as cells frozen at various stages of differentiation [3, 4], information concerning essential metabolic pathways used by tumour and normal cells, proves important in consideration of possible vital tissue sparing drug regimens.

Methotrexate (MTX) is clinically a widely used antimetabolite [5], acting through competitive inhibition of the enzyme dihydrofolate reductase (EC 1.5.1.3.). Current concepts of the specific cytotoxic action of MTX are varied. Inhibition of *de novo* thymidylate production [6, 7] and inhibition of *de novo* purine production [8] have been cited. In addition, prevention of amino acid and RNA synthesis [9] or a combination of all three effects [10] have been considered.

The object of this present study was to investigate the cytotoxic action of MTX by following its effect upon the uptake of labelled precursors into DNA. The precursors used and the biochemical pathways in which they participate are shown in Fig. 1, this shows that thymidylate may be synthesised either by *de novo* or *salvage* procedures. The possibility of a *salvage* by-pass of a MTX-induced block in the *de novo* synthesis of thymidylate was considered by monitoring the incorporation of thymidine-3H (TdR) into tissue DNA. Deoxyuridine-3H (UdR) and sodium formate-14C were used as *de novo* precursors. The pattern of response of these three precursors, following drug treatment, has been shown to correlate with

Accepted 4 October 1976.

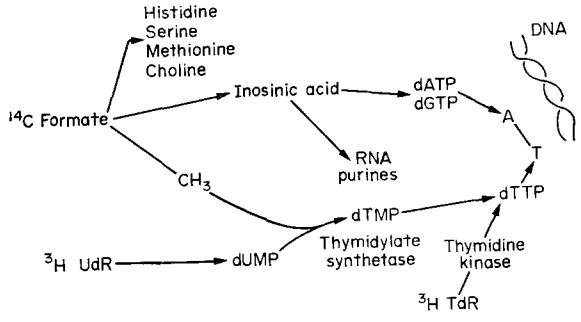

Fig. 1. *Metabolic fate of labelled precursors: simplified biochemical pathways.*

the therapeutic response observed in various tumours and normal tissues [11, 12].

Chabner and Young [13] have demonstrated a MTX induced block in deoxyuridylate to thymidylate by expressing the uptake of UdR-3H into DNA as DPM/μg DNA. Myers *et al.* [14] have shown that the incorporation of UdR into DNA of normal and neoplastic tissues after 5FU is dependent not only upon the rate of conversion of dUMP to dTMP but also on changes in the endogenous dUMP pool sizes. These authors used correction factors which, by correcting to time zero, compensated for alterations in dUMP pool sizes. The method used in this study utilises the systemic distribution of labelled precursors over a one hour pulse label and expresses DNA synthesis as the percent of the total label reaching the tissue which is incorporated into the DNA, i.e.,

$$\text{Fractional incorporation (F.I.)} = \frac{\text{DPM DNA}}{\text{Total tissue DPM}}$$

Thus, whilst this measure takes no account of the chemical form of the label in the acid soluble fraction, it will compensate for large variations in endogenous radioactivity. F.I. also has the advantage of being independent of drug-induced fluctuations in total tissue DNA content; a fact of not inconsiderable importance when dealing with solid tumours [15].

For these reasons F.I. has been used to study the response of both *de novo* and *salvage* DNA syntheses to single dose MTX treatment.

MATERIAL AND METHODS

The animals used in these studies were 5- to 6-month-old inbred August female rats bearing subcutaneous (s.c.) A15 carcinomata. Methotrexate (Lederle Labs) was administered intraperitoneally (i.p.) to lightly anaesthetised rats, in single doses. Thymidine-3H (TdR) 24 Ci/mmol; deoxyuridine-3H (UdR) 21 Ci/mmol and sodium formate-14C (formate) 50 mCi/mmol were also administered i.p. 1 hr prior to death (Radiochemical Centre, Amersham).

Animals were killed by cervical dislocation, tissues removed and stored at −70°C until used. Excised tumours were stripped of encapsulating tissue. All adipose tissue was removed from the spleens. The marrow from both tibias was blown into cold 0·2N perchloric acid. The mucosa was stripped from a 10 to 15 cm segment of jejunum and transferred into 0·2N perchloric acid. An additional 1 cm length of jejunum was fixed in formol saline, sectioned and stained with haematoxylin and eosin.

Nucleic acid extractions were carried out using a modification of the Schmidt–Thannhauser technique [16]. DNA [17] and protein [18] were estimated colourimetrically.

Radioactivity was measured on an ABAC SL 40 β scintillation counter using a scintillant consisting of 7 vol of butyl—PBD (0·6% wt/vol) in toluene plus 3 vol of tergitol TP9 (Union Carbide Ltd.). For dual isotope studies, appropriate corrections were made for quenching a channel crossover. Cross contamination of the DNA fraction with protein or RNA [19] was checked colourimetrically and compensated mathematically.

In order to distinguish labelled thymine, adenine and guanine after formate-14C administration, DNA bases were hydrolysed with 98% formic acid at 175°C for 30 min. The resultant free bases were adsorbed onto acid washed, neutralised charcoal [20] and eluted overnight at 37°C with an ethanol/ammonia/water solution (2:1:2) [21]. This solution was concentrated by evaporation in a stream of warm air. Base separation was achieved by one dimensional PEI cellulose thin layer chromatography with isopropanol/conc. HCl/H_2O (170/41/39 v/v) [22]. Rf values were similar to those obtained with either paper or cellulose t.l.c. i.e., thymine 0·82; cytosine 0·49; adenine 0·38; guanine 0·26.

Areas of cellulose absorbing u.v. light at the Rf values stated were scraped into glass vials and the radioactivity was eluted with 1 ml of 1 N perchloric acid for 2 hr at room temperature. After the addition of 10 ml scintillant, samples were shaken and counted. Counting efficiency was not impaired by the presence of cellulose particles and 95–100% recovery of ^{14}C was achieved. The TLC sheets used were Schleicher and Schull TLC Ready Plastic Sheets F1440 PEI/LS 254 PEI cellulose 20 × 20 cm.

Tumour volumes were calculated from the formula $V = \pi d^3/6$ where d is the mean caliper diameter of the subcutaneous tumour. Drugs were administered to groups of rats when the tumour volumes were about 1 cm^3. Pair feeding of controls involved giving animals in the control groups the same amount of food as was consumed by the MTX treated groups during the previous 24 hr. Both treated and control animals were allowed water *ad libitum.*

Fractional Incorporation values are calculated from the dis/min of each fraction, i.e.,

$$\frac{\text{DNA dmp}}{(\text{DNA} + \text{Acid soluble} + \text{RNA} + \text{Protein dpm})}$$

This measure has been shown to be similar and in some cases superior to [23] specific activity (dis/min per unit DNA) as a method of assessing DNA synthesis.

RESULTS AND DISCUSSION

The differing sizes of the precursor pools in specific individual tissues limit the inter-tissue comparison of either F.I. or specific activity values. This is especially true for comparisons of the three precursors used in this study. Whilst F.I. values are expressed as ratios, and therefore have inherent correction of such pool differences, the chemical nature of the label in the acid soluble fraction is not known. Moreover, with ^{14}C-formate, not only is the label incorporated into DNA-thymine, but also into the purines of DNA and RNA and into protein amino acids. Such diversification of biochemical endpoints means that not all of the ^{14}C is channeled into a single precursor pool. In addition, the balance of these pools within the acid soluble cell fraction may be altered following drug treatment. Table 1 shows the uptake of ^{14}C-formate into the RNA and protein fractions of the same tissue samples used for DNA estimates. MTX reduced protein synthesis only in the gut, for a period of 24–72 hr after treatment. F.I. values which are significantly higher than the control level may be the result of a redirection of ^{14}C from MTX-inhibited DNA synthesis to protein and RNA precursor synthesis. Spleen DNA synthesis was so high at 264 hr post MTX therapy that the supply of ^{14}C to RNA and protein synthesis was restricted. Thus, the values at this point were low, not because of reduced rates of RNA and protein synthesis, but because of a competitive use of label for DNA synthesis. This would suggest that, in an actively dividing tissue, ^{14}C formate is used preferentially for synthesis of DNA precursors.

Control values of F.I. and specific activity for four tissues are shown in Table 2. The specific activity values for the gut were higher than F.I. values of the same samples for all three precursors. In all cases specific activity is dependent upon precursor supply.

MTX has been shown to exert its cytotoxic effect in Ehrlich ascites carcinoma cells [24],

Table 2. *Control values for fractional incorporation and specific activity*

	Spleen	Tumour	Gut	Bone marrow
TdR	82(60)	57(40)	62(190)	91(73)
UdR	37(31)	6(5)	27(40)	57(48)
Formate	41(56)	10(19)	10(28)	48(47)

Figures in parenthesis are specific activities expressed as dis/min per μg DNA.

Fractional incorporation values are as described in text.

Each value is the mean of at least 6 experiments. Standard errors < 10%.

spleen tissue [25] and bone marrow [26] by blocking the folate cofactor-mediated methylation of deoxyuridylic acid to thymidylate. In the spleens of mice with advanced L1210 leukaemia, thymine synthesis could proceed even with an impaired folate reductase system [27] and in other studies prevention of *de novo* purine synthesis has been cited as the cytotoxic effect of MTX [28].

Three factors suggested that, in August rat tissues, the cytotoxicity of MTX was mediated through a reduction of *de novo* thymidylate synthesis. These were:

1. The continued generally unimpaired incorporation of ^{14}C formate into RNA purines after treatment, Table 1.

2. The ^{14}C labelling of individual bases isolated from tissue DNA. Table 3 shows ^{14}C formate incorporation into bases 12 hr after

Table 3. *^{14}C labelled bases* 12 *hours after* 14*mg/kg MTX*

	Adenine	Guanine	Thymine
Spleen	20(29)	30(9)	4(62)
Tumour	78(37)	87(11)	22(52)
Gut	99(34)	91(19)	45(47)
BM	72(30)	79(19)	28(51)

Values represent percentage of control values. Results were calculated as dis/min associated with base/μg DNA. Figures in parentheses represent the percentage of ^{14}C associated with each individual base; i.e., 62% of ^{14}C isolated from the spleen extract was thymine.

a dose of 14 mg/kg MTX. These results indicate a substantial reduction of labelled thymine with a lesser effect upon adenine and guanine. Approximately 50% of the ^{14}C from formate was incorporated into DNA as thymine. Whilst there were smaller reductions in the level of labelled purines, the large reduction in labelled thymine probably accounts for the toxic effect of MTX.

3. A comparison of the fractional incorporation of ^{14}C formate and ^{3}H UdR (Fig. 2–5) shows that formate incorporation was not reduced as much as UdR in any of the tissues. Deoxyuridine is solely a *de novo* thymidine precursor, whereas formate is involved both in this pathway and in *de novo* purine synthesis. Hence, the difference between the uptake of the two precursors may represent continued *de novo* purine incorporation.

Biochemically this phenomenon has already been observed [29] and can be explained by the fact that the formation of the purine skeleton results in the regeneration of tetrahydrofolic acid which can recycle. Thymidylate synthesis, on the other hand, involves the conversion of the intermediate N^5, N^{10}) methylene-tetrahydrofolic acid ($h^{5-10}FH_4$) to dihydrofolic acid, and the reduction of the latter to the tetrahydro form is inhibited by the antifolate.

Because the cytotoxicity of MTX appeared to be mediated through prevention of *de novo* thymidylate production, the relative importance of an alternative thymidylate *salvage* synthesis had to be considered. In rats treated with MTX the possibility existed of a compensatory effect,

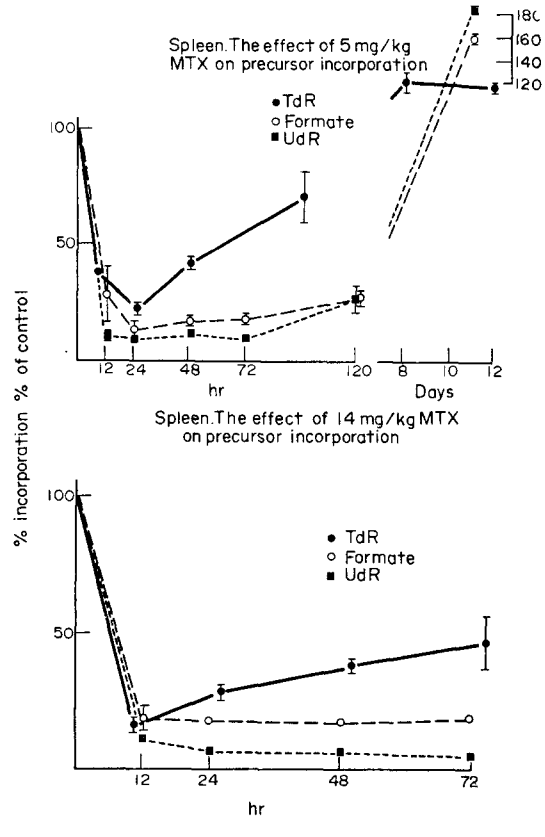

Fig. 2. *The effects of* 5 *mg and* 14 *mg/kg MTX on DNA precursor uptake in spleens of tumour bearing rats. The ordinate represents F.I. values as percent of controls. or "rescue", of certain tissues with salvaged thymidylate via the thymidine kinase pathway. The uptakes of both *de novo* and *salvage* precursors are shown in Fig. 2–5 expressed as a percent of control. By this method, it was possible to compare the depression and subsequent recovery of each tissue with regard to possible differences between normal and tumour tissues.

Although not a dose-limiting tissue, the spleen has shown some interesting responses

to MTX (Fig. 2). A depression in spleen weight after MTX treatment was followed by a recovery and overshoot to 3–5 times the control weight by 10 days. This phenomenon was closely mirrored by DNA precursor uptake. Whilst the *de novo* precursor incorporations appeared to have increased more than the *salvage* at 10 days in terms of the control values for each, (cf. Table 2) the absolute increases were similar. Microscopy of the stimulated spleen has revealed an increase in the number of giant cells at 10 days. Such

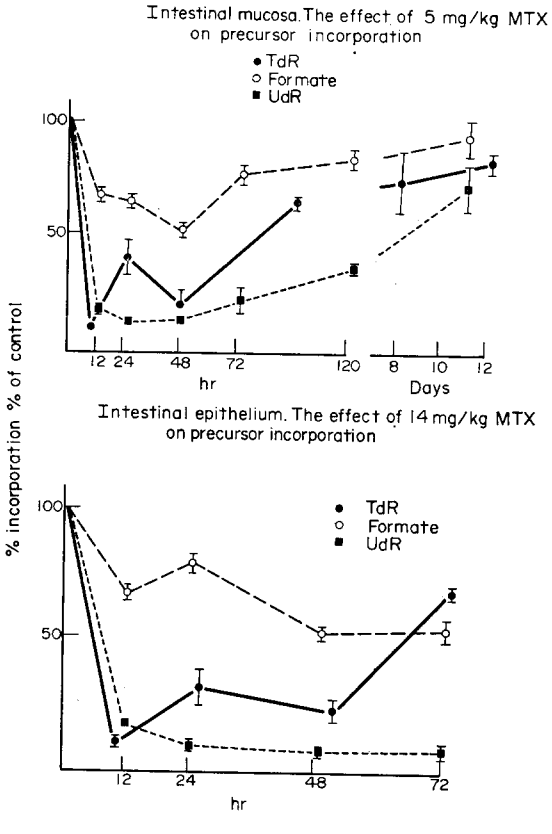

Fig. 3. The effects of 5 mg and 14 mg/kg MTX on DNA precursor uptake in jejunal mucosa. The ordinate represents F.I. values as percent of controls. The abscissa is the time after a single dose of MTX. Each point is the mean of 4 experiments. Error bars represent ± SEM.

spond to gut failure [9, 30]. Thus, the gut appeared to be the dose limiting tissue with respect to MTX treatment. Figure 3 showed that breakdown of gut function was reflected in the inhibition of precursor uptake. The apparent lack of inhibition of formate incorporation has already been attributed to continued *de novo* purine synthesis. Incorporation of UdR was reduced to 10% or less of control by 24 hr. At the higher dose there was no recovery by 3 days. At the lower dose UdR incorporation was approaching control levels

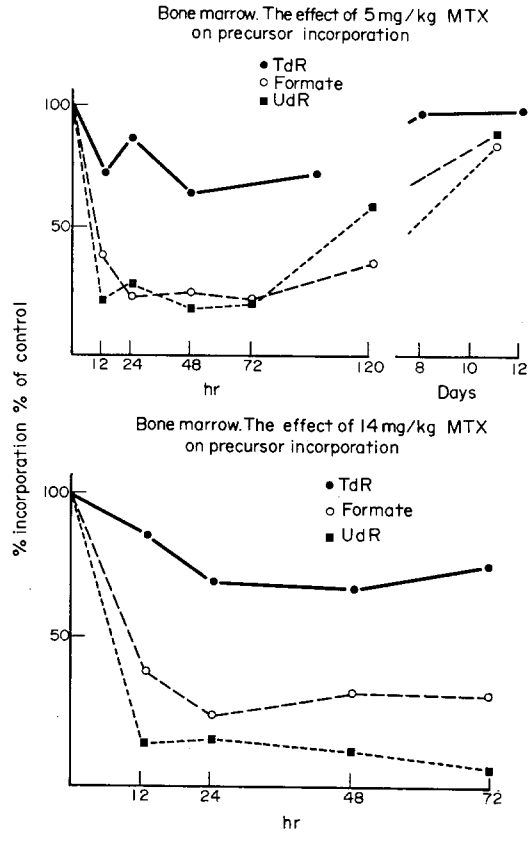

Fig. 4. The effects of 5 mg and 14 mg/kg MTX on DNA precursor uptake in bone marrow. The ordinate represents F.I. values as percent of controls. The abscissa is the time after a single dose of MTX. Each point is the mean of 4 experiments. Error bars represent ± SEM.

increased splenic activity may be linked with increased lymphocyte production, which may have been a direct drug effect, or a response to, infection. Macroscopic and microscopic pyorrhoeic inflammations have been observed suggesting that the latter may be the more likely cause of such activity.

Toxicity studies in the August rat have shown that animals receiving lethal doses of MTX die between 3 and 5 days after treatment. Animals which survive this period, recover completely. This period of time has been shown to correby 11 days. MTX should not have a direct effect upon TdR incorporation. Therefore, the marked reduction seen at both doses was attributed to resultant cell death. In other words the restriction of *de novo* thymine supply was sufficient to prevent compensation by *salvage* synthesis, resulting in cell toxicity and the reduction in scheduled DNA synthesis.

Microscopic examination of the jejunum after a single lethal dose of MTX has shown a

massive destruction of vullus and crypt integrity at 3 days (plates1–4). Gross macroscopic swellings of the Peyers patches were visible and a section through such a swelling revealed an unusual protective effect. Crypt and villi in the immediate area of the swollen lymph nodes were intact and in some cases slightly hyperplastic. Why such "pockets" of actively dividing cells should occur was not clear. Supply of drug via the blood stream may have been limited, however blood vessels in the area appeared to be healthy. A further

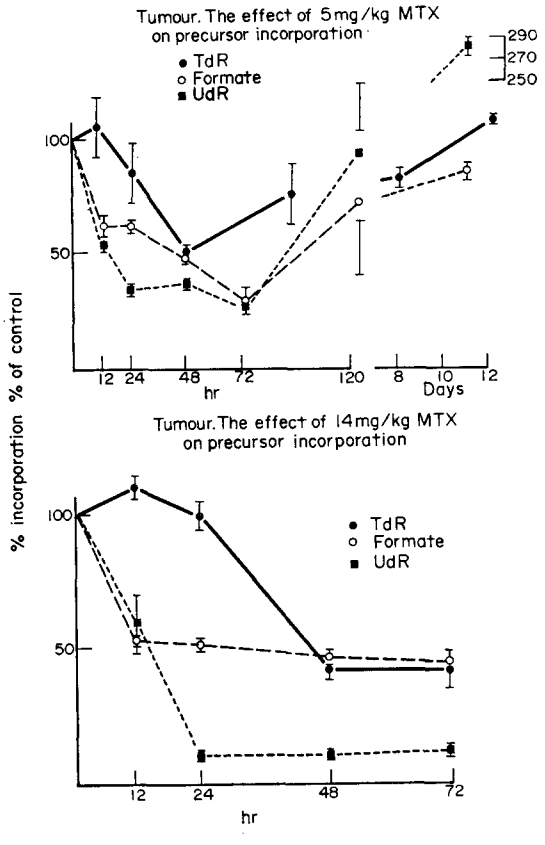

Fig. 5. The effects of 5 mg and 14 mg/kg MTX on DNA precursor uptake in tumour. The ordinate represents F.I. values as percent of controls. The abscissa is the time after a single dose of MTX. Each point is the mean of 6 experiments. Error bars represent ± SEM.

possibility was that, in some obscure manner, the lymphocytes "mopped up" the MTX before it reached the mucosal cells. This may in turn, have stimulated lymphocyte production and thus resulted in the observed swellings. Finally, it is possible that there were mucosal cells resistant to MTX and these continued to divide even after therapy. These isolated areas of mucosa were obviously insufficient to allow normal gut function, since the animals still died between 3 and 5 days.

Precursor uptakes in the bone marrow (Fig. 4) showed a pattern similar to gut for formate and UdR, but dissimilar for TdR. Both the *de novo* precursors were depressed to around 20% of control at both doses.

TdR *salvage* remained around 80% of control. This continued level of *salvage* synthesis may have enabled a partial by-pass of the MTX induced *de novo* block and thus accounted for the reduced toxicity of MTX to bone marrow. Rabbit bone marrow has been shown to lack the intrinsic enzymes needed for *de novo* purine synthesis [31]. If the same is true for rat bone marrow, the ^{14}C-formate uptake will be a measure of blood-borne purines. Presumably these will be supplied by the liver which has been shown to incorporate ^{14}C-formate into purine nucleotides [32]. It was not possible, in this study, to estimate the proportions of formed purine nucleotides derived from liver and from synthesis *in situ*, however, it is possible that a balance between the two sources exists in all tissues.

In contrast to the three tissues already discussed, the tumour (Fig. 5) showed no initial suppression of TdR incorporation. In fact, at 14 mg/kg MTX a slight increase in *salvage* synthesis was observed. This is in common with the results of Tattersall and Harrap [33] who observed a steady rise in TdR incorporation in L5178Y cells up to 8 hr after a dose of MTX. In contrast both UdR and formate incorporation were reduced. Additionally, this dose increased the level of acid soluble ^{3}H with TdR, whilst concomitantly reducing that of UdR (Table 4). The MTX induced reduction in *de novo* thymidylate must, in effect, reduce the levels of intracellular TMP. The alternative *salvage* thymidylate pathway is under cellular regulation. Such a reduction in the intracellular levels of TMP results in increased thymidine kinase activity [34] and therefore a rise in incorporation of ^{3}H-TdR. This feedback mechanism may operate at different intracellular TMP levels in different tissues. Thus, the tumour may be stimulated to "turn on" to *salvage* synthesis when levels of TMP are not at as critical a level as those of, for example, intestinal mucosa. The extent and rate of enzyme induction may be critical to the recovery of the tissue and these factors may have accounted for the extra gut toxicity in these rats. In the tumour, at both 5 and 14 mg/kg there was a drop in TdR incorporation at 48 hr. This would suggest that the early burst of *salvage* synthesis was insufficient to compensate for the reduced *de novo* supply and ultimately this led to cell

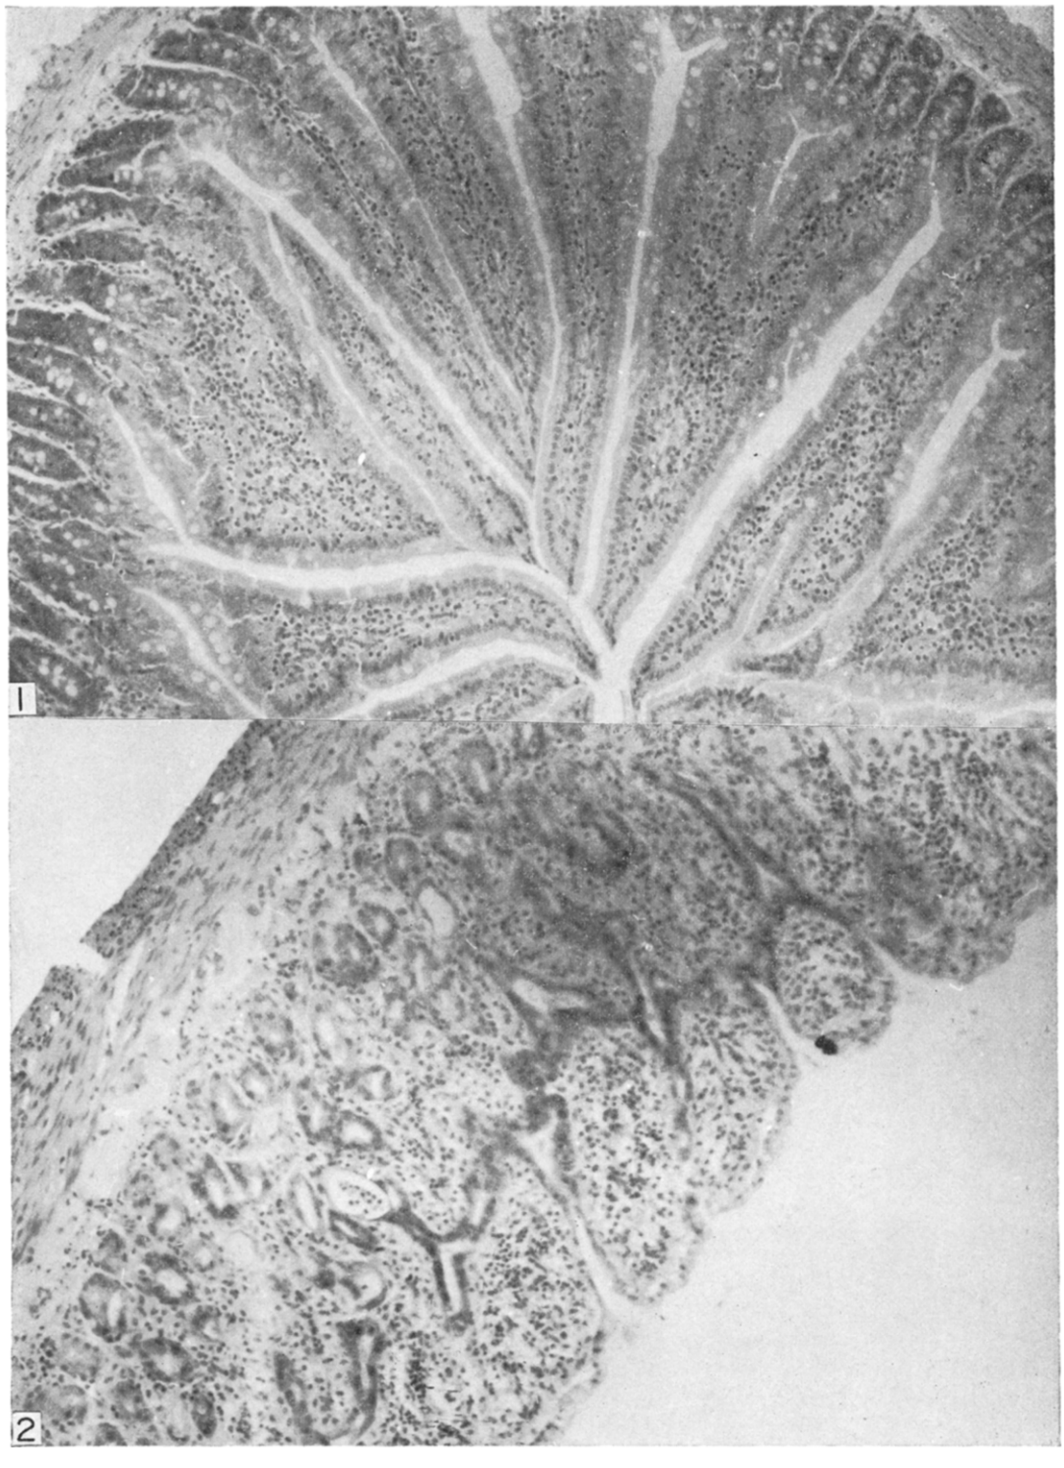

PLATE 1. *Low power cross section of untreated jejunum, showing normal crypt and villus structure.*

PLATE 2. *Low power cross section of jejunum, 3 days after a dose of 14 mg/kg MTX. Gross morphological abnormalities include atritic, vacuolised crypts denuded of cells. Bottom left centre is a clear example of a vacuolised crypt containing dead cells and lymphocytes; as a result of the crypt abnormalities, the villi are flattened, fused and irregularly shaped.*

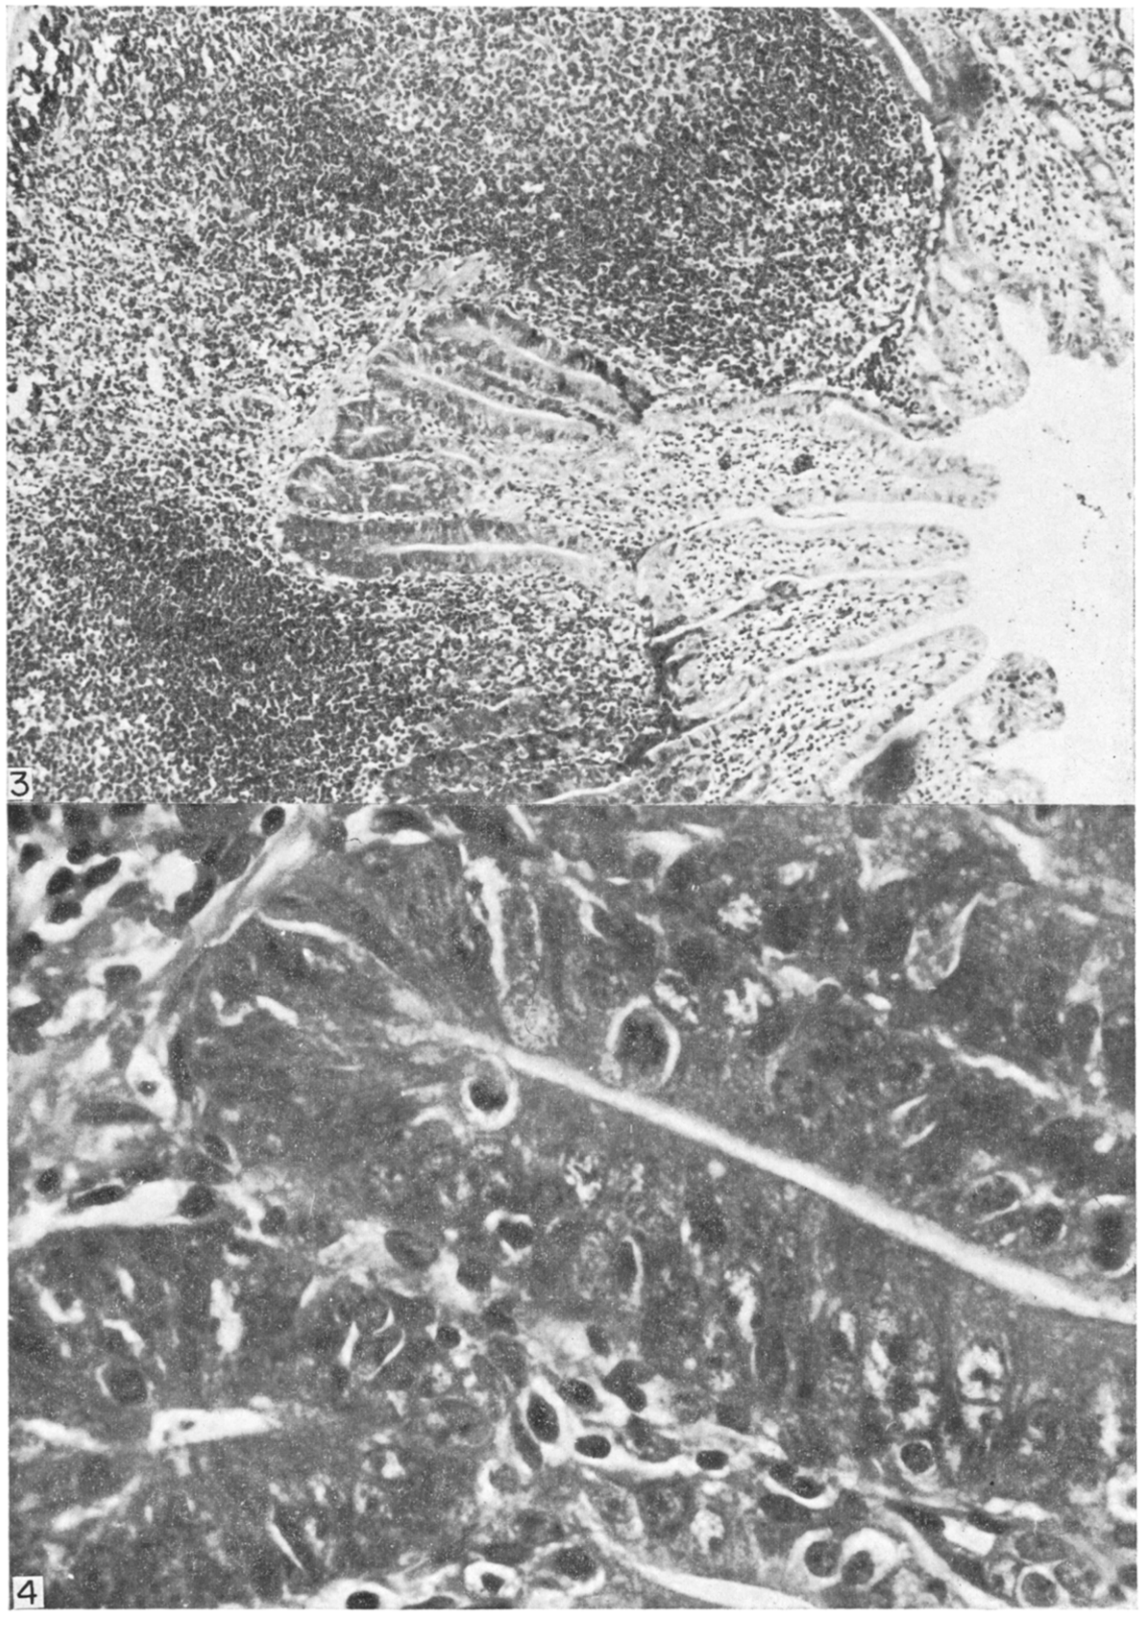

PLATE 3. *Low power cross section of the same section as* [2] *which includes the Peyers patch area. The two large lymph nodes show the dark staining mature lymphocytes which are pushed outward from the lighter stained, actively dividing core. Between the nodes are hyperplastic crypts which, uncommon with the remainder of the section, are undergoing mitoses* [4]. *The crypts are approximately* 2–3 *times as long as those of controls. The villi associated with these crypts appear fairly regular in structure.*

PLATE 4. *High power view of part of crypt shown in* [3]. *Five definite mitoses can be seen in this view.*

death. It may be possible, by extending these studies, to gain a quantitative relationship between the suppression of *de novo* synthesis and the requisite compensatory *salvage*, by relating these parameters to gut and tumour toxicity plus animal survival.

The increase in UdR incorporation to three times control level, 10 days after 5 mg/kg MTX, was unexpected. There was no decrease in acid soluble ^{3}H levels which could have suggested intracellular pool changes. A possible explanation was that the drug selected a population of tumour cells high in thymidylate synthetase activity and thus, by 11 days the tumour had a population of cells more adapted to utilising UdR. Although this should have caused a concurrent increase in formate incorporation. Alternatively the drug may have reduced the level of UdR catabolising enzymes, with the result that more is converted to thymidylate.

The tumour volume responses shown in Fig. 6 correlated well with the biochemical data. The volume continued to increase for 2 days after treatment. This fact concurred with results obtained using cyclophosphamide [35] and *cis*-dichlorodiammino platinum [36]. After this, volumes regressed for 4–6 days, before resuming exponential growth. This period of volume regression correlated with the reduction in DNA precursor incorporation. By day 6 post-therapy near control levels of precursor incorporation had been reached.

In conclusion, the therapeutic efficacy of MTX toward tumours in the August rat was reduced because of extreme toxicity to the intestinal mucosa. The reduction of *de novo* thymidylate to the bone marrow and tumour was apparently less toxic. These tissues were more efficient at overcoming this block with an alternative *salvage* pathway.

Letter to the Editor

Magnesium Concentration Changes in Blood and in "Target" Tissue During Carcinogenesis*

L. J. ANGHILERI† and M. HEIDBREDER
Innere Klinik und Poliklinik (Tumorforschung)
Universitätsklinikum der GHS Essen, Hufelandstrasse 55, 4300 *Essen* 1, *German Federal Republic*

THE HEPATOCARCINOGENESIS induced by 4-dimethylaminoazobenzene (DAB) provokes changes in cell membrane permeability which are reflected by increased influx of extracellular cations [1].

In order to establish if there is a relationship between the ionic contents of blood and liver tissues during the carcinogenesis, samples of both tissues were analyzed for their mineral content. For this purpose male Wistar rats (100–110 g of body weight) were fed a basal semisynthetic diet supplemented with 0·06% of DAB. The animals were allowed to eat *ad libitum* and they were killed after different periods of feeding. Rats without DAB were used as controls. Before the sacrifice blood samples were drawn by cardiac punction. After mineralization by ashing at 700°C and dissolution in 1 N HCl, calcium, magnesium, sodium and potassium were determined by Atomic Absorption Spectrometry. Total phosphorus was assayed by means of the 4-aminonaphtol reagent [2].

The results showed that DAB-feeding provokes an immediate increase of magnesium and phosphorus in total blood. At the beginning of the period of development of liver tumor (5–10 months of DAB-feeding) those values showed a slight decrease and they remained all the time almost constant but significantly higher than in the control group (Fig. 1). The surviving animals presented a higher than in the control group magnesium concentration while phosphorus decreased

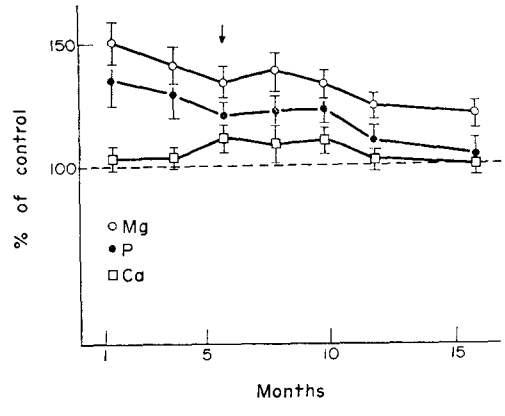

Fig. 1. *Magnesium, calcium and phosphorus in whole blood of animals fed* 4-*dimethylaminoazobenzene. The values are the percent of the concentration corresponding to the control group and the mean value* ± *S.E. of a* 10-*animal group. The arrow indicates the onset of macroscopically observable liver tumors.*

sharply to almost the control values. Blood calcium did not show significant changes and only during the period of development of tumor a noticeable increase was observed. In tumor-bearing animals blood magnesium and phosphorus were significantly increased with respect to the controls. The increase of blood magnesium (approximately 50%) accompanies a significant decrease of this element in neoplastic liver (approximately 30%). On the other hand, the very high increases of calcium and sodium in tumor issue did not show a correlation with their contents in

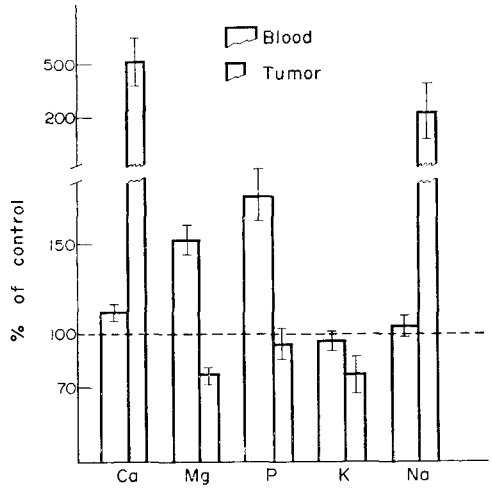

Fig. 2. Magnesium, calcium, sodium, potassium and phosphorus in whole blood and in liver tumor tissue from tumor-bearing animals. The values of liver tumor are compared with the values corresponding to normal liver tissue from the animals of the control group. The values are the percentage of the concentration corresponding to the control group and the mean value ± S.E. of a 20-animal group.

blood (Fig. 2). The electrophoresis of blood serum showed that in tumor-bearing animals there is a slight increase (9·5%) of α-globulins accompanied by a decrease of β- (12%) and γ-globulins (19%), and at the same time the total serum protein was lower (14%).

The high blood magnesium right after starting DAB-feeding seems to be related to its decrease in liver tissue observed at this time of the carcinogenesis [3]. The fact that the ratio intracellular magnesium to extracellular magnesium in liver is approximately 20·0 while the same ratio for calcium is 0·55 [4], and that liver is one of the tissues with the highest concentration of magnesium [5], may explain the increase of blood magnesium as the result of a lost and/or an exclusion of this element from liver tissue. On the other hand, it seems evident that the differences of magnitude between the blood pool of calcium and its content in liver can explain the observation that modifications of its concentration in liver tissue are not reflected on its blood content as it is in the case of magnesium.

The absence of significant differences in the protein composition of blood serum indicates that they do not seem to play an important role in the modification of magnesium and calcium homeostasis during carcinogenesis by DAB.

These experimental results point out that in this type of chemical carcinogenesis there are changes in homeostasis which appear to be related to modifications of the balance of cations in the target tissue. In addition, these observations are consistent with the concept of changed cell membrane permeability as one of the factors triggering the development of neoplasia [3].

Letter to the Editor

Heterogeneity and Specificity of Circulating Carcinoembryonic Antigen*

G. T. ROGERS, B. A. LEAKE, F. SEARLE and K. D. BAGSHAWE
Department of Medical Oncology, Charing Cross Hospital, London W.6 8 RF, Great Britain

CARCINOEMBRYONIC antigen (CEA), first described by Gold and Freedman [1], is a tumour associated macromolecular glycoprotein found in the cellular membrane of digestive system epithelia. While its presence in high concentration in serum is indicative of metastatic cancer [2], low to moderate levels are associated with both primary cancer and a number of non-malignant conditions particularly inflammatory diseases [2, 3]. This has indicated a need for greater specificity in the CEA assay if it is to be used diagnostically or to monitor less advanced cancer. In our approach to this problem we have applied concanavalin A affinity fractionation to a study of CEA in serum and we suggest that two forms of CEA may be of diagnostic significance.

Earlier work in this [4–6] and other [7, 8] laboratories has shown that CEA, prepared essentially by the method of Coligan *et al.* [9] from metastatic colonic tumour, can be fractionated by affinity chromatography on Con A–Sepharose. An unbound fraction 1 and three bound fractions designated 2A, 2B and 3 can be successively eluted from the column using sodium acetate buffer (0·1 M pH 6 containing 1 M NaCl), sodium borate/phosphate buffer (0·1 M pH 6), 2% methyl glucoside and 10% methyl glucoside [6].

In our approach reported here in preliminary form, we have fractionated patients' sera on Con A–Sepharose and assayed conventionally the CEA recovered in the fractions obtained. The carbohydrate binding site of Con A appears to be directed primarily towards unmodified hydroxyl groups at the C-3, C-4 and C-6 positions of α-D-mannose and α-D-*N* acetylglucosamine in the outer chains of CEA [10]. It follows, therefore, that these chains must differ chemically in the CEA fractions. Perchloric acid extracts of serum pools containing a total of at least 100 ng of CEA were dialyzed for 3 days against tap water, concentrated to 5 ml by ultrafiltration using an Amicon PM 10 membrane and the CEA measured by our conventional assay. The extract was then separated into 4 fractions (1, 2A, 2B and 3) as previously described [6]. Each fraction was collected, dialyzed against tap water to remove buffer salts and methyl glucoside and concentrated to known volumes (2–8 ml depending on the total CEA applied to the column). The CEA in each fraction was determined by our conventional assay and the results expressed as μg CEA/10 l of original serum. As a control, sera known to contain less than 2·5 μg CEA/l was fractionated in the same way.

The results, shown in the table, are classified into the three disease groups; (a) local cancer including some cases with local or regional lymph node involvement and where the routine assay value is moderately elevated, (b) cases with advanced cancer involving distant nodes or liver metastases and (c) non-malignant diseases where the serum CEA value was raised. In group (a) CEA was detectable in significant amounts in fraction 2B and as expected the levels were moderately raised. CEA was below detectable levels in fractions 1 and 2A and, with the exception of one experiment where the value was low, CEA was also undetectable in fraction 3. This is in contrast to group (b) where the CEA values were much higher. In this case small amounts of CEA were detected in fractions 1 and 2A. However, since this may be a quantitative effect where the CEA values in these two fractions may be raised to significant levels due to the higher concentration of CEA, no diagnostic significance can be attributed to this finding. Most of the CEA in

Accepted 20 September 1976.

*The CEA values are lower than those assayed in the original serum owing to loss of CEA on extraction with perchloric acid, loss of CEA which is irretrievably bound to Con A–Sepharose and experimental loss of CEA during concentration of fractions.

†% recovery calculated as CEA recovered from column × 100/CEA applied.

‡CEA in the dialysed fraction after concentration less than 5 μg/l.

the sera of group (b) was eluted in fractions 2B and 3 and the relative levels in these two fractions suggest a distinct qualitative difference in the elution pattern compared to sera from group (a). In the case of sera from the non-malignant group (c), it appears from the limited data so far available that CEA is elevated in fraction 3.

Our results indicate that the chemical differences which exist between the different Con A fractions [5, 10] may be implicated in the specificity of the CEA molecule for cancer. It appears that one particular form of CEA may be associated with both early and advanced cancer. Another form which binds more strongly to Con A, appears to be associated with metabolic changes found both in advanced cancer and in certain non-malignant inflammatory diseases. Our results also suggest that certain CEA molecules have a cancer specific grouping which is distinct from the dominant immunogenic group.

Conventional assays and modified assays based on labelled CEA fractions, although useful for follow-up studies and detecting recurrent cancer [11, 12], are severely limited in specificity due to the cross-reactive nature of the antibody. Our studies suggest that it may be possible to design more specific CEA assays. One possibility would be to incorporate a separation stage prior to a conventional assay, although the ease of handling large numbers of specimens on a routine basis would be an important factor in its acceptibility. At the same time the search for antisera with high specificity for particular CEA fractions as suggested by Vrba *et al.* [13] also remains appropriate.

Medical Oncology Society

INTRODUCTION

ONCOLOGY comprises several disciplines which include surgery, radiology and medical oncology, whose objective is to eradicate cancer.

Medical oncology poses several problems today for which solutions are not being found and applied quickly enough in the interest of patients.

Medical oncology develops along a geometrical curve. For ten years, in the strict sense, it has cured the following conditions: acute lymphoid leukaemia, Hodgkin's Disease and a certain number of lymphosarcomas and, for three years, it has appeared to be able to prevent the occurrence of metastases of six solid tumours: breast, colon, and stomach cancers and osteosarcomas by systemic post-operative chemotherapy, and cancer of the lung and melanomas by systemic post-operative immunotherapy.

This work has not yielded 100% results: intensive research has to be carried out if we are ever going to approach this goal.

These results require rapid mutual information amongst medical oncologists, their co-operation and an appropriate status for them, the preparation by them of younger colleagues, and the adaptation of the best logistics to their activities.

The creation of the Medical Oncology Society was vital to find and speed-up solutions to these problems.

The number of participants, the range of nationalities, and the quality of work presented at its first annual congress confirms the need for such a society and augurs well for the success of this venture.

G. MATHE,
President

La "Société de Médecine Interne Cancérologique"

La cancérologie met en oeuvre plusieurs disciplines technologiques, dont la chirurgie, la radiologie, et la médecine interne cancérologique, qui coopèrent dans le traitement de la plupart des tumeurs.

La médecine interne cancérologique pose aujourd'hui plusieurs problèmes auxquels les solutions ne sont pas apportées aussi rapidement que l'exige l'intérêt des malades.

Cette discipline se développe à une vitesse pour le moins géométrique; depuis dix ans, elle permet de guérir *stricto sensu* des patients porteurs de cancers disséminés d'emblée: la leucémie aiguë lymphoide, la maladie de Hodgkin, certains lymphosarcomes; depuis trois ans, elle promet de prévenir les métastases de 6 tumeurs solides au moins: les cancers du sein, du colon, de l'estomac, et l'ostéosarcome, par la chimiothérapie post-opératoire systématique, les cancers du poumon et les mélanomes par l'immunothérapie post-opératoire systématique.

Nous n'obtenons pas 100% de résultats positifs; des travaux intensifs doivent être menés pour approcher ce taux.

Ces travaux demandent une information mutuelle rapide des médecins internistes cancérologues, leur coopération, l'affirmation de leur rôle, la formation, par eux, de jeunes collègues, et l'adaptation de la logistique cancérologique aux activités de cette discipline.

La création de la Société de Médecine Interne Cancérologique était indispensable pour apporter et accélérer les solutions à ces problèmes.

Son premier Congrès annuel, le nombre de ses participants, la multiplicité de leur nationalité, et la qualité de ses travaux, confirme le besoin de cette Société et augure le succès de cette entreprise.

An Immunological Classification of Leukemias and Non Hodgkin's Hematosarcomas Based on T and B Cell Membrane Markers with Special Reference to Null "Cell" Disorders

D. BELPOMME,*† N. LELARGE,* R. JOSEPH*† and G. MATHE*†
*Institut de Cancérologie et d'Immungénétique (INSERM), Hôpital Paul-Brousse,** *and Service d'Hématologie de l'Institut Gustave-Roussy†*

THE IDENTIFICATION, several years ago, of membrane markers on the mononuclear cell population of both animals [1] and humans [2–9] has permitted differentiation of this population into T (thymodependent) and B (thymoindependent) lymphocytes and a third cell category which includes monocytes [10, 11].

The presence of these markers on normal as well as on neoplastic cells of lymphomonocytoid proliferative disorders has led to effort to reclassify human hematologic malignancies into different immunological categories [4, 9, 12–16].

The clinical usefulness of this new classification still remains uncertain, but it is evident from these studies that new concepts concerning the mechanism of cancerogenesis and the origin of these neoplastic cell proliferations have emerged [4, 12, 16, 17].

In previous papers we have shown that acute lymphoid leukemia (ALL) is a T cell disorder in 25% of cases, while chronic lymphoid leukemia (CLL) is a B cell disorder in 90% [4, 12].

We have shown in addition, that while non-Hodgkin's hematosarcomas (lymphomas) are B cell diseases in the majority of cases, they are of the T cell type in some of them [14, 18, 19].

We have, in fact, emphasized that by using these markers in ALL, as well as in non-Hodgkin's hematosarcomas, there were neoplasias which could not be typed as T or B, and that those proliferations may be related to so-called null cell disorders [4, 14, 18, 19].

These findings, however, need a critical evaluation since (a) technical problems are still encountered in the detection of lymphocyte membrane markers and since (b) results published in the literature dealing with so-called null cell disorders most often concern limited series of cases [20, 21].

The purpose of this paper is firstly, to assess the value of the immunological methods available for the characterisation of normal human mononuclear cells and, secondly, to report our findings, based on these techniques, in an attempt to classify 150 cases of mononuclear cell proliferative disorders. This study will evaluate the frequency of so-called null cell diseases, and will give a clinical summary of these cases.

MATERIAL AND METHODS

1. *Immunological methods*

Table 1 shows different membrane markers and the tests used to characterize T and B lymphocytes and monocytes. Table 2 presents the membrane phenotypes of the different normal human mononuclear cells.

Details of the test procedures used have already been reported [4].

mIg Membrane immunoglobulins.
FcagIg Fc receptors for antigen Ig antibody complexes.
Fc Fc "receptors" for free immunoglobulins.
C'3 Activated C'3 complement receptors; two subvarieties C'_3b and C'_3d.
E Spontaneous rosette formation with sheep red blood cells.
Em Spontaneous rosette formation with murine red blood cells.
Tag Specific T heteroantigen(s).
Bag Specific B heteroantigen(s).

Table 3 gives the values obtained by these techniques for mononuclear cells from the peripheral blood, bone marrow and thymus of 50 normal subjects used as controls. This data concurs with that published in the report of a WHO/IARC sponsored workshop [22].

Although most of the techniques described here are now well standardized, the practice of these tests, as well as the interpretation of the results, needs critical evaluation. From Table 4 it can be seen that there are some difficulties:

(1) The formation of spontaneous E rosettes (E rosette test) with sheep red blood cells (SRBC) requires special attention since a minor technical modification may induce major variations in the results. From Fig. 1 it can be seen that there are at least 4 variable parameters involved in the test [14, 18].

(2) The detection of membrane immunoglobulins (mIg), should not be confused with the evidence of surface immunoglobulins (sIg). Only the former seems to be specific for B lymphocytes, since the latter (sIg) may be:

Table 3. T and B cell markers in normal peripheral blood, bone marrow and thymus

	ROSETTES (%)*						mIg*	
	E		EA		EAC		(%)	
Peripheral blood (50 normal subjects)	50†	25–80‡	10	5–15	15	5–25	23	10–40

Thymus (6 normal subjects)	97	83–100	ND	ND	ND	ND	3	2–5

*See Tables 1 and 2 for abbreviations. Results are expressed as the ratio of total number of positive cells on total number of mononuclear cells.
†Mean values.
‡Extreme values.
§Increased mean value are now obtained in our laboratory, by using a sensitized test (see Joseph 1976a, 1976b).

Table 4. Critical evaluation of the test procedures for detecting membrane markers

E Rosette tests	Variability of the test (differing techniques and results according to authors).
EA Rosette tests	EA receptors may be detected on some educated T lymphocytes, on some B cells, as well as on monocytes and K cells.
EAC Rosette tests	No good control distinguishing EA from EAC receptors.
Membrane immunofluorescence	Difficult to obtain specific antisera. Membrane Ig have to be distinguished from surface Ig. Ig monoclonicity is required for neoplastic B lymphoid cells.
Specific anti T or B heterosera	Difficult to obtain true specific hetero antisera. Immunofluorescence tests are not specific. Cytotoxicity tests do not allow correlation with morphological studies.
EBV membrane receptors	Difficulty due to the quality of the EBV+permanent cell line used in the test.

For abbreviations see Tables 1 and 2; for references, see text.

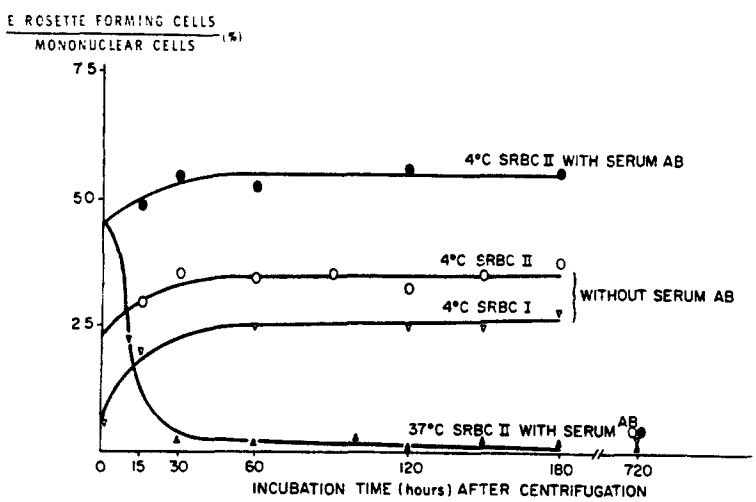

Fig. 1. Variable parameters involved in the E rosette test procedure. Experimental data concern the peripheral blood of six normal adult subjects. Note that the temperature, the quantity of SRBC, the incubation time and the eventual addition of human serum which has been heat decompleted and absorbed with SRBC, have to be considered.

(a) free immunoglobulins (Ig) (including antibodies) [14, 18], or (b) Aggregated Ig [23], coating the membrane of various cells, or (c) serum immune antigen-antibody complexes adhering to Fc receptors of monocytes [10], B lymphocytes, [4, 12, 13] of (activated?) T lymphocytes, or K cells [24, 25] or adhering to activated C'3 receptors of monocytes [10] or B lymphocytes [8, 26].

These various possibilities make the direct immunofluorescence test for mIg difficult to interpret and require proof that mIg are, in fact, synthetized by the B lymphocytes [9].

(3) Other difficulties concern the application of the immunologic techniques used for normal circulating cells, to neoplastic solid tissues: (a) there is a loss of cells during purification of mononuclear elements and thus possibly a cell selection; (b) presence of both normal and neoplastic cells in tumour tissues requires systematic morphological control to verify which cells possess the markers.

(4) Finally data on cell membrane typing using immunological criteria have to be correlated with other diagnostic methods such as the clinical picture, cytology, histology and conventional and scanning electron microscopy [19, 27–29]. These general considerations stress the need to use a battery of tests, rather than any single one, when applying these techniques in the classification of hematologic neoplastic disorders.

2. *Diagnosis criteria*

All the disorders described here have been classified according to the criteria recommended by the W.H.O. classification of leukemias and hematosarcomas [30], and all the material has been studied in patients in an active phase of their disease.

Pathological cells from the peripheral bloods and/or the bone marrow of 132 patients with leukemic syndrome or dysglobulinemia have been investigated. These cases include: chronic lymphoid leukemia (CLL): 45 cases, typical primary acute lymphoid leukemia (typical primary ALL): 30 cases; typical acute myeloid leukemia (AML): 19 cases; leukemic lymphosarcoma (LLS): 15 cases; blastic crisis of chronic myeloid leukemia (CML): 6 cases; primary immunoblastic acute lymphoid leukemia (primary IALL) [31]: 4 cases; hairy cell leukemia (HCL): 4 cases; myeloma: 3 cases; primary macroglobulinemia: 2 cases; acute monocytoid leukemia (AMoL): 2 cases; chronic proplasmocytic leukemia (with macroglobulinemia) (CPL): 1 case; [32] chronic monocytoid leukemia (CMOL): 1 case.

In addition, pathological cells from lymph node biopsies of 18 patients with non Hodgkin's hematosarcomas, including 16 non leukemic lymphosarcomas (non leukemic LS) and two reticulosarcomas (RS) have been studied.

RESULTS

1. *General classification*

Table 5 presents the four different membrane phenotypes which have been encountered in this study, when classifying diseases according to immunological markers: 10·6% of the cases studied (16/150) have been typed as T (Group I), 44% (67/150) as B (Group II), while 40% of cases (61/150) were found to have cells with no detectable membrane markers in the technical conditions used (Group III), and 4% (6/150) to have cell bearing activated complement and/or Fc receptors, which make these disorders difficult to identify (Group IV).

Table 5. *Four different membrane phenotypes in human neoplastic hematological disorders*

I	mIg (−), Fc ag Ig (−)[*],	C_3 (−), E (+), Em (−)	T
II	mIg (+), Fc ag Ig (+),	C_3 (+), E (−), Em (+)	B
III	mIg (−), Fc ag Ig (−),	C_3 (−), E (−), Em (−)	NDMM
IV	mIg (−), Fc ag Ig (+),	C_3 (+), E (−), Em (−)	?

[*] may be (+) on certain T neoplastic cells.

For abbreviations, see Table 2.

2. *Analysis of the different disorders according to the four immunological groups*

2.1. *T cell neoplasia* (Group I). Table 6 summarizes our results: 50% of cases (8/16) of T cell disorders are primary ALL, while 50% of the remaining cases include five cases of LS,

Table 6. T cell neoplastic disorders

Observed membrane phenotype: mIg (−), Fc ag Ig (−), Fc (−), C_3 (−), E (+)		
1. Primary immunoblastic acute lymphoid leukemia	25%	1/4*
2. Typical primary acute lymphoid leukemia	23%	7/30
3. Non leukemic and leukemic lymphosarcomas	16%	5/31
4. Blastic crisis of chronic myeloid leukemia	16%	1/6
5. Chronic lymphoid leukemia	4%	2/45
Total	10·6%	16/150

*Fc ag Ig (+).

two cases of CLL and one case of blastic crisis of CML.

From this data, it is confirmed that in ALL, one case out of four is classified as T, while so called T cell CLL remains quite exceptional since we found only two such cases out of 45 typical CLL investigated for membrane markers.

2.2. *B cell neoplasia* (Group II). Table 7 summarizes our data. Most B cell proliferation were CLL, leukemic and non leukemic LS. Multiple myeloma and primary macroglobulinemia were, as expected, also of B cell type.

All these disorders have been shown to be monoclonal, most often of the IgM type, since the same immunoglobulin has been detected on the majority of neoplastic cells. In CLL (Table 8) the membrane IgM was often found to be associated with an IgD of the same light chain, while this association was less frequent in the case of leukemic and non leukemic LS [33].

2.3. *Neoplastic disorders with no detectable membrane markers* (Group III). As presented in Table 9, this category of disease includes all cases of AML (19/19) and all cases of RS (2/2) which were studied as well as a majority of cases of primary typical ALL (23/30) and of blastic crisis of CML (5/6). Note that in 26% of cases of non leukemic and leukemic LS (8/31) there were no detectable T and B membrane

Table 7. B cell neoplastic disorders

Observed membrane phenotype: mIg (+), Fc (+), C'3 (+), E (−)		
1. Myeloma (Kahler)	100%	3/3*
2. Primary macroglobulinemia (Waldenstrom)	100%	2/2
3. Chronic proplasmocytic leukemia (with macroglobulinemia)		1/1
4. Chronic lymphoid leukemia	88%	40/45
5. Non leukemic and leukemic lymphosarcomas	58%	18/31
6. Hairy cell leukemia	50%	2/4
7. Primary immunoblastic acute lymphoid leukemia	25%	1/4
Total	44%	67/150

*Positive intracytoplasmic immunofluorescence when using fixed smear.

Table 8. Immunological heterogeneity in chronic lymphoid leukemia (CLL)

I:	40/45 cases: B CLL because of prevalence of mIg (+) cells.
II:	36/40 cases monoclonal IgM: 29, IgG: 6, IgA: 1, mixed pattern: 4.
III:	All mIg (+) cells do not possess other receptors mIg (+), Fc ag Ig (+), C_3 (+), Em (+). 85% 30% 40% 51%
IV:	Monoclonal Ig D with the same light chain are detected on 15 to 80% of IgM (+) cells.
V:	5/45 cases: CLL without B membrane markers 2 cases: T CLL because of prevalence of E rosettes forming cells 3 cases: Unclassified CLL because of absence of detectable T and B cell membrane markers.

Table 9. *Neoplastic disorders with no detectable membrane markers*

Observed membrane phenotype: mIg (−), Fc ag Ig (−), C_3 (−), E (−)		
1. Acute myeloid leukemia	100%	19/19*
2. Reticulosarcomas	100%	2/2
3. Blastic crisis of chronic myeloid leukemia	83%	5/5
4. Primary acute lymphoid leukemia	76%	23/30
5. Primary immunoblastic acute lymphoid leukemia	50%	2/4
6. Acute monocytoid leukemia	50%	1/2
7. Leukemic and non leukemic lymphosarcomas	26%	8/31
8. Chronic lymphoid leukemia	2%	1/45†
Total	40%	61/150

*Including acute myelomonocytoid leukemia.
†RFC with murine RBC.

markers. A similar result was found in one case of CLL.

2.4. *Neoplastic disorders with complement and/or Fc receptors* (Group IV). Results dealing with this group are presented in Table 10. There are two cases of HCL, two cases of CLL, one case of AMoL and one case of CMoL.

DISCUSSION

From the data reported here, hematological neoplastic disorders have been classified into three main groups, the T and B cell neoplasias and a third group of null cell disorders characterized by the proliferation of neoplastic cells having no detectable membrane markers T or B.

This immunological classification led us to several conclusions.

1. B cell neoplasias are the most frequent diseases in our series, since they represent about 50% of the cases studied.

All the B cell proliferations studied for monoclonicity have been found to be monoclonal, confirming other reports [9, 34, 35].

In our series, the monoclonal Ig is most often of the IgM type, and this monoclonal IgM is found to be associated in several cases studied with an IgD having the same light chain, also confirming previous reports [36–38].

Except for some cases including immunoblastic acute lymphoid leukemias [31] and lymphosarcomas [19, 33], all the disorders of this group have been found to possess various common characteristics. They occur in adults, they have a chronic or subacute evolution, and the neoplastic cells appear relatively well differentiated. These disorders however, may represent different neoplastic processes. There is a temptation to assume, as do Salmon and Seligman [17] that these various proliferations may be due to the blocking of the B cell maturation, at different levels, but this concept needs further investigation.

2. In contrast, T cell neoplasias are less frequent since this group represents only about 10% of our series. Except for two cases of CLL, this group is composed of acute diseases including leukemias and lymphosarcomas. It is worth mentioning that most of the patients in this group are children or young adults [16, 33, 34].

Table 10. *Neoplastic disorders with activated complement and/or Fc receptors*

I—Observed membrane phenotype: mIg (−), Fc ag Ig (+), C_3 (+), E (−)		
Hairy cell leukemia	50%	2/4
Chronic lymphoid leukemia	4%	2/45
II—Observed membrane phenotype: mIg (−), Fc ag Ig (−), C_3 (+), E (−)		
Acute monocytoid leukemia	50%	1/2
Chronic monocytoid leukemia		1/1
Total	4%	6/150

These observations suggest that T cell diseases may be related to thymic anomalies since they affect young patients whose thymus should normally be functional and since experimental data exist demonstrating the role of the thymus in animal leukemogenesis [4, 12, 15, 16]. This hypothesis needs further experimental confirmation.

3. In our series, 40% of the cases have not been classified as T or B cell diseases, and thus have been called "null" cell disorders. Except for one case of CLL, this group was found to be composed of a majority of the cases of acute leukemias and of 26% of the non-Hodgkin hematosarcomas studied. These data led us to hypothesize that this group of null cell disorders may, in fact, cover at least two types of diseases.

The first type includes non-lymphoid neoplastic proliferation, i.e. diseases of myeloid or monocytoid origin, since all the AML cases investigated for T and B membrane markers were included in this group. In contrast, the second type may be composed of true lymphoid disorders in which neoplastic cells are characterized by a lack (or a loss) of T or B membrane markers, probably due to modifications induced through the neoplastic process: this hypothesis could explain the presence of several cases of undifferentiated leukemias and non-Hodgkin's hematosarcomas in this group.

The demonstration of the individualisation of null cell diseases, however, raises the question of the existence of undifferentiated diseases not related either to the lymphoid or to the myelomonocytoid series. These may be disorders of the stem cells (Davies, 1975).

It is evident that more sophisticated investigations including the use of cytochemistry [39, 40] and of specific hetero-antisera [21, 41] will be helpful to elucidate this problem.

4. We described a fourth group of neoplasias which includes a limited number of cases (4% of our series). In this group the neoplastic cells possess activated receptors for complement and/or Fc receptors and thus could not be definitely typed as B lymphocytes or monocytes in nature. It is believed that these disorders may, in fact, have a B lymphoid or monocytoid origin and that the lack (or the loss) of the other markers of the B or monocytoid series may be due to the occurrence of a time related functional variation of the synthesis of these receptors.

From these data it is obvious that it is through an extended use of such immunological investigations that progress will be made in the improvement of lympho-monocytoid proliferative disorders. However, definite progress cannot be achieved if immunological data are not correlated with other parameters such as the clinical picture, the prognosis factors as well as the results of cytology, histology and other conventional techniques. The search for such a correlation between clinical and morphological data will be the subject of other papers [19, 33, 42,].

Increase in E. Active Rosette Forming Lymphocytes in Melanoma Patients Treated with BCG*

J. BERTOGLIO, D. GERLIER, A. BOURGOIN, K. GRONNEBERG and J. F. DORE†

Laboratoire d'Immunologie et de Cancérologie Expérimentale, Centre Léon Bérard, 28 Rue Laënnec, 69 373 Lyon, Cedex 2, France

Abstract—*E active rosette forming lymphocytes, a subpopulation of T lymphocytes, were studied in 14 tumor free melanoma patients undergoing BCG immunostimulation. In 7 patients, low values of Ea rosettes were observed before or at the beginning of the treatment, while total T lymphocytes were found to be within the normal range. In these patients, after BCG treatment was instored Ea rosettes increased and reached the normal range, suggesting that BCG could act on T lymphocytes.*

INTRODUCTION

SEVERAL authors [1–3] have described T cell deficiency in cancer patients at various stages of the disease. Recently, Wybran *et al.* [4] have introduced a new marker for a sub-population of T lymphocytes: the Active Rosette test which detects a sub-population of T lymphocytes which may be decreased in some pathologic circumstances including cancer. We studied this test in melanoma patients submitted to BCG immunostimulation.

MATERIAL AND METHODS

Patients

Fourteen melanoma patients were studied. All of them were bearing localised melanoma, histologically confirmed and classified as Clark's grades 3 and 4. After surgical removing of the tumor, they were submitted to BCG treatment according to the E.O.R.T.C. protocol: 6×10^8 living bacteria from Pasteur Institute were administered intradermally, using the Heaf Gun multiple puncture apparatus Eschman's Mark [5]. Stimulation was performed weekly, then once a month according to the skin reaction of the patient.

Laboratory investigation

Venous blood samples were collected on calciparin and lymphocytes were isolated by centrifugation on Ficoll Radio selectan Gradient [6].

Total rosette forming lymphocytes were appreciated using a slight modification of the technique described by Jondal [7].

Active rosette forming lymphocytes were determined according to Wybran [4]. Immunoglobulin bearing lymphocytes as detected by immunofluorescence using a goat anti-immunoglobulin conjugate (Meloy Laboratories, Inc. Springfield, Va, U.S.A.) were considered as B lymphocytes.

RESULTS

The normal value of active rosette forming lymphocytes was found to be $28 \pm 4{\cdot}9\%$ as determined in 30 healthy donors. Three patients showed normal values of Ea rosettes before the beginning of BCG treatment and these values did not vary during the first five months of the treatment.

Seven patients were demonstrated to have low values (from 10·8 to 25%) before or at the beginning of BCG treatment. These values increased during BCG treatment, more or less rapidly according to the patient, then stabilized within the normal range (Fig. 1).

Four patients entered the study after the 6th or the 12th month of BCG stimulation. They

*Supported by INSERM (A.T.P. 2.73.23) and Fédération des Centres de Lutte contre le Cancer.

†Maitre de Recherche à l'INSERM.

presented normal values of Ea rosettes and these values were stable within the normal range for the 5 subsequent months.

In none of these patients, B and total T lymphocytes could be demonstrated to vary out of the normal range.

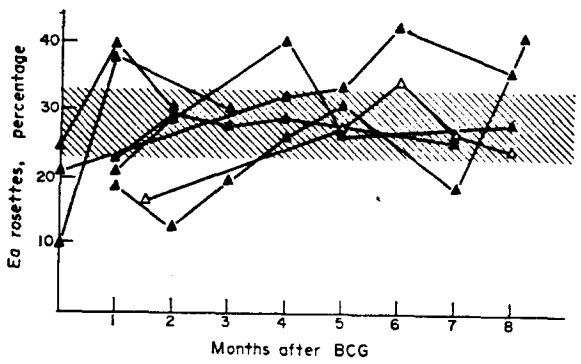

Fig. 1. Variations of Ea rosettes percentage in melanoma patients treated by BCG—the hatched area corresponds to normal values.

DISCUSSION

Since attempts to stimulate immunity have been introduced in solid tumors treatment [8, 9] few studies have dealt with a biological test which could allow to follow up the treated patients [10–12].

Using Active rosette test we were able to detect T cell deficiency in 7/10 melanoma patients, at the localised stage of their disease and who presented at that time normal values of total T lymphocytes as determined by total red cell rosetting.

Furthermore in these patients BCG treatment seemed to induce a restoration of this subpopulation and showed no biological effect in patients having normal values of Ea rosettes. Parts of these results are in agreement with those of Claudy *et al.* [13]; however, these authors did not detect any increase of Ea rosettes under BCG, but there were differences in the dose and mode of BCG administration.

It has been assumed that T lymphocytes with high affinity receptors for sheep red cells detected by Active rosette test are actively engaged in cellular immunity [4], and it is possible to make the hypothesis that BCG could act through activation or induction of T cell differentiation. However, there is very few information on the precise function of this T lymphocyte subpopulation [14] and it cannot be excluded that increase in Ea rosettes is only a sign of BCG effect, but without relation with its precise mechanism of action in immunotherapy.

Serum Migration Inhibitory Activity in Patients with Infectious Diseases and Various Neoplasia*

M. BRULEY-ROSSET, H. G. BOTTO and A. GOUTNER

Institut de Cancérologie et d'Immunogénétique (INSERM), Hôpital Paul-Brousse, 94800-Villejuif, France

Abstract—*The presence of leucocyte migration inhibition activity was studied in the sera of healthy donors and of patients with tuberculosis, infectious mononucleosis and various cancers, namely carcinoma of the bronchus and breast and glioblastoma. Normal subjects do not exhibit any LIF activity in their sera. In contrast, 39 of 50 patients with tuberculosis and 4 of 5 patients with mononucleosis showed a positive reaction.*

In the cancer group, LIF activity was detected in 52 of 99 cases of bronchus carcinoma, 13 of 49 with breast carcinoma and 21 of 45 with glioblastoma. These results were obtained by using an improved technique which detects the presence of migration inhibitory factors produced in vivo in the serum and suggest that a persistent antigenic stimulation is required for the production of such an inhibitory activity.

INTRODUCTION

METHODS for detection of migration inhibitory activity in the serum are commonly used as parameters of delayed hypersensitivity [1]. Numerous techniques have been developed using human peripheral leucocytes as indicators cells and considerable variation in the results has been observed [2, 3].

In a number of studies, it was possible to detect a migration inhibitory factor (MIF) in the serum of animals with delayed type hypersensitivity reactions [4–6]. Moreover the presence of MIF or MIF-like activity has been reported in the serum of patients with various lymphoproliferative diseases, Hodgkin disease, chronic lymphocytic leukemia, myeloma [7] and Sezary syndrome [8], in patients with post transplantation hepatic dysfunction [9] and in the joint fluid of patients with rheumatoid arthritis.

In this study MIF activity was detected in the sera of patients suffering from infectious diseases, namely tuberculosis and mononucleosis, and three types of cancer disease, bronchus and mammary carcinoma and glioblastoma. The technique, originally described by Beaulieu, employs unidirectional migration of leucocytes in microhematocrit capillaries.

This work was supported by the grant C.L. No. 75.5.104.2 from INSERM.

MATERIAL AND METHODS

Patients

Twenty-four normal subjects ranging in the same age as the patients served as controls. Of a total of 247 patients studied; 50 suffered from tuberculosis confirmed by X-rays and cultures, in another 5 the diagnosis of infectious mononucleosis was established on the presence of atypical lymphocytes in the blood smear with a normal bone marrow and the presence of heterophil antibody in the serum.

The cancer patients were selected as follows: 99 cases of non-resectable squamous cell bronchial carcinoma, 95 cases of post-resectional recurrent relapse of glioblastoma multiformis and 49 cases of metastatic or disseminated breast carcinoma.

Sera

Ten ml of blood were collected from each patient and from 24 healthy volunteers. The blood was centrifuged at 800 *g* for 10 min and the sera stored at 4°C until testing within two-weeks' time.

Leucocyte migration inhibition (LMI) assay

An original technique, developed by Beaulieu [10], was used in this work. 20 ml of whole blood was drawn from a normal donor and was allowed to settle with 6% dextran in saline into a plastic syringe containing sodium citrate as an anticoagulant. After sedimentation of red

blood cells, the plasma layer was centrifuged and the white blood cells pellet was incubated for 7 min at 37°C in a 0·83% solution of ammonium chloride to lyse erythrocytes. The cell suspension was then washed and adjusted to 4×10^7 cells per ml in RPMI 1640 culture medium supplemented with antibiotics. This suspension was aspirated under negative pressure into disposable polystyrene tubes PP20 plugged at one end by parafine wax. The capillaries were spun for 3 min at 500 *g*, cut with a blade at the cell-fluid interface and inserted into microhematocrit chambers filled with a medium containing 50% decomplemented serum of the patients to be tested and 50% RPMI 1640 culture medium. The hematocrit chamber was sealed, fixed on a glass slip with silicone grease and incubated for 18 hr at 37°C.

The migration inhibition index (MI) was calculated as follows:

$$MI = \frac{\text{Migration length in medium containing serum sample}}{\text{Migration length in control serum}}$$

Two independent assays, each consisting of two capillary tube preparations were performed for each serum. Inhibition of 20% or more was considered as significant.

RESULTS

This modified leucocyte migration inhibition assay was able to detect an inhibitory activity in the serum of patients suffering from the infectious diseases already mentioned, the results having been summarized in Table 1.

Table 1. Leucocyte migration inhibition (LMI) by sera of normal donors and patients with various diseases

	Positive LMI assay	Negative LMI assay	Total
Normal donors	1	23	24
Tuberculosis	29	21	50
Mononucleosis	4	1	5
Squamous cell bronchial carcinoma	52	47	99
Breast carcinoma	13	36	49
Glioblastoma multiformis	21	24	45

No inhibition could be detected in the sera of 24 healthy subjects with the exception of one. In contrast, inhibition was observed in 39 of 50 cases of tuberculosis (78%) and 4 of 5 patients with mononucleosis (80%).

In the cancer groups we obtained positive results in 52/99 cases of squamous cell bronchial carcinoma (53%), 13 of 49 patients with breast carcinoma (27%) and 21 of 45 cases of glioblastoma (46%). The variation of the migration index showed no differences among diseases, ranging from 0·42 to 1·12.

We obtained reproducibility between replicates, the error being almost always within 10%.

DISCUSSION

The microtechnique employed in this work for detecting LIF activity in the serum offers considerable advantage as allowing a large number of replicates for a small amount of blood as source of indicator cells and very small quantities of serum for testing. Besides, the unidirectional migration of the cells is very easy to read and is not affected by external factors. This contributes to a good reproducibility of the test and to a minimal variance between replicates.

Both mononuclear and polymorphonuclear leucocytes are present as migrating cells in the capillary tubes [11, 12]. The indirect migration assays already described [13] detect migration inhibitory factors (MIF, LIF, etc. . . .) produced *in vitro* by sensitized lymphocytes whereas in our study, we tested the inhibitory activity of such factors already produced *in vivo*.

Healthy controls did not usually yield an inhibitory activity in their sera in contrast to the patients with tuberculosis, mononucleosis and the various cancers. The results suggest that the stimulus required to produce inhibitory factors in amounts sufficient to allow their detection in serum could be a persistent stimulation by virus, bacilli and tumor antigens.

In this study, the nature of the factor(s) responsible for the inhibition of leucocyte migration is not elucidated and antigen-antibody complexes or immunoglobulins cannot be excluded in the populations [14, 15]. The lack of response in the populations studied especially in the cancer patients, suggests that an antigenic stimulation is not enough to cause LIF production. Immune competence of the host is required as there is a very close correlation between delayed hypersensitivity skin responses to various antigens and positive migration inhibition assays [12, 16–18]. We were able to confirm this correlation, the results appearing in our next paper.

Acknowledgements—We are deeply indebted to Dr. R. Beaulieu (of the Hôpital Hotel Dieu in Montreal) who introduced us to the technique used in this paper.

Correlation of Delayed Hypersensitivity and Leukocyte Migration Inhibition Factor in the Serum of Cancer Patients

H. G. BOTTO,* H. GAUTHIER,† P. POUILLART,* M. BRULEY-ROSSET* and P. HUGUENIN†

**Institut de Cancérologie et d'Immunogénétique (INSERM), Hôpital Paul-Brousse,‡ 94800-Villejuif and †Centre Médico-Chirurgical de Bligny, 91640-Briis-sous-Forges, France*

Abstract—*Cellular immunity was evaluated in patients with three types of cancers: squamous cell bronchial carcinoma, breast carcinoma and glioblastoma multiformis.*

Delayed hypersensitivity skin responses to DNCB as primary antigen and to PPD, candidin and mumps as recall antigens were measured in these patients. At the same time, the presence of leucocyte inhibition factor (LIF) in the serum was assayed.

A good correlation between the degree of inhibition of migration and the size of the skin reaction was found in patients with bronchus and breast carcinoma but not glioblastoma.

Following these patients up during the course of their disease, by the in vivo *and* in vitro *tests, a good evaluation of the immunological reactivity of the patients could be obtained.*

INTRODUCTION

CELL MEDIATED immunity (CMI) in patients with malignancies has been clinically evaluated *in vivo* by delayed skin reactivity to a battery of antigens injected intradermally. The use of dinitrochlorobenzene (DNCB) has recently offered an advantage over bacterial antigens since exposure to DNCB does not usually occur and initial application evokes a true primary sensitization [1, 2]. *In vitro* assays for testing cell mediated immunity include lymphocyte responsiveness to non-specific mitogens and tumor specific lymphocytotoxicity tests.

Many attempts to compare the results obtained from different *in vivo* and *in vitro* assays have often failed to yield significant correlations [3–5].

In a previous paper [6] we were able to detect, in the sera of patients, the presence of a leukocyte inhibitory activity which is considered as an *in vitro* reflection of CMI [7–9].

Our purpose in this study is to compare the results obtained by two assays: the elicitation of delayed cutaneous hypersensitivity to DNCB and recall antigens, and the presence of LIF in the serum of patients with squamous cell bronchial carcinoma, breast carcinoma and glioblastoma multiformis. We have, moreover, followed the variation of the results of these assays during the course of the diseases mentioned.

‡14–16, avenue Paul-Valliant Couturier.

MATERIAL AND METHODS

Cancer patients studied in this work are those already described in the previous paper [6]. They all received intermittent chemotherapy treatment but the tests were performed 30 days after the end of the cycle.

Skin test with DNCB

Patients were sensitized locally with 2000 μg of 2,4-dinitrochlorobenzene (DNCB), and were challenged with a dose of 200 μg, 14 days after

sensitization. The skin was examined 48 hr later. The reaction was considered positive if induration and erythema were present on at least the half of the sensitization area.

Skin tests with recall antigens

These included tuberculin 10 U, mumps antigen 2 U, and candidin 2 U. One tenth ml of each preparation was injected intradermally on the volar surface of the forearm. Skin tests were read at 36 hr and 48 hr, and were considered positive if induration in the erythema area exceeded 5 mm dia (in two of three reactions) [10].

Leukocyte migration inhibition assay (LMI)

This test is described in detail in the previous paper [6]. Statistical analysis was performed by chi square test (χ^2) using Yates correction.

RESULTS

Impaired reactivity to DNCB and to recall antigens was observed in 28/42 and 37/99 respectively for bronchial carcinoma patients, in 9/10 and 39/49 for breast carcinoma patients and in 13/22 and 20/45 for glioblastoma patients (Table 1). The number of patients tested with DNCB is lower because the two-weeks' interval needed for sensitization and challenge was considered to delay treatment too much. Statistical analysis showed that there existed a significant correlation ($P < 0{\cdot}001$) between the LMI assay and the skin tests, both DNCB and recall antigens, for the patients with bronchus and breast carcinoma (Table 1). However, as far as the glioblastoma patients were concerned no correlation between skin tests and LMI assay was found. It appears that LMI assay correlates better with the response to DNCB but the number of patients tested is rather low to confirm this.

In the bronchus carcinoma group which included non-operable patients, it was more frequent to find negative LMI assay and positive skin tests rather than the opposite. Furthermore, the mean peripheral lymphocyte count was significantly lower in patients with negative LMI assays and negative skin tests.

In the breast carcinoma group, including stage III and IV patients, both LMI assays and skin tests were more frequently found to be negative.

We performed LMI assays and skin tests serially in three patients of each group during the course of their disease. In the case of bronchial carcinoma, time 0 corresponded to the pre-chemotherapy period. Several comments could be made on the results shown on Table 2.

In both bronchus and breast carcinoma, there exists a good correlation between skin tests and LMI assays, both showing the same variation during the evolution of the disease. This, however, is not true for the glioblastoma patients. In the terminal stages, both tests become negative, the LMI being the first. Fluctuations of the tests including conversion from an initial anergy to a positive status, and the opposite were observed to correlate well with remission and clinical improvement, or extension of the disease respectively. Finally, the size of the dermal reaction seems to correlate well to the degree of LMI.

DISCUSSION

This study shows that a significant depression of delayed cutaneous hypersensitivity could be observed in a variable proportion of patients particularly in patients with breast carcinoma (78%) who were all in an advanced stage of their disease. Correlation between anergy, as evaluated by skin tests, and absence of leukocyte migration inhibitory activity in the sera of patients with bronchus and breast carcinoma has been established in this study, suggesting that the detection of leukocyte migration inhibitory factor(s) (LIF) provides a meaningful *in vitro* correlate of cell-mediated immunity. The use of various antigens for skin tests, instead of one, is necessary to demonstrate this relationship. The reasons underlying the lack of correlation in glioblastoma patients could be the special localisation and histology of the tumour.

Other assays have been described and widely used for the evaluation of cell mediated immunity namely mitogen induced lymphocyte transformation, mixed lymphocyte culture (MLC), cell-mediated lymphocytotoxicity (CML) and the detection of lymphokine activity, results varying from significant correlation with delayed-type skin hypersensitivity to discrepancy [5, 11–15].

The good correlation found in this study may be due to the fact that skin test and LIF production are both dependent on sensitized lymphocytes capable of releasing soluble mediators of the cellular immunity.

Moreover, delayed hypersensitivity skin reactions are known to correlate well with the clinical course of the disease. Since the disappearance of LIF in the serum preceeds skin anergy, this LMI assay may be useful as an

in vitro test for prognosis. In conclusion, the LIF production requires both immunological competence and antigenic stimulation, the performance of the two tests allowing a good evaluation of the alteration of the immune status.

Table 1. Correlation between leucocyte migration inhition (LMI) assay, response to skin tests with primary and recall antigens and peripheral lymphocyte count (PLC)

Disease	*In vitro* test / *In vivo* test		Skin test with recall antigens +	Skin test with recall antigens −	Skin test with primary antigens (DNCB) +	Skin test with primary antigens (DNCB) −	P.L.C.
Squamous cell bronchial carcinoma	LMI	+	48	4	14	3	m = 1320 range: 370–3400
	LMI	−	14	33	0	25	m = 812 range: 150–3000

Abstract—*Cell electrophoresis allows separation of normal human blood lymphocytes into two main groups which are a function of their relative rates of migration, with regard to the reference speed* (1 $\mu m.sec^{-1}.V^{-1}.cm$) *: the lymphocytes which have a greater mobility than this value seem to be T-lymphocytes* (80·1 *per cent for* 42 *healthy adults*) *: on the contrary, B-lymphocytes have an inferior mobility* (19·9 *per cent*).

Two known methods are used for the selection of the lymphoid populations : spontaneous rosetting with sheep's red blood cells, which is characteristic of T lymphocytes, and adherence to nylon wool columns, which is dominant in the case of B-lymphocytes. This method confirms the fact that T-lymphocytes have a rapid migration and that B-lymphocytes a slow migration. We have isolated a third population, having neither the T markers nor the B markers. It has a very homogeneous migration, centered on the two classes 1·05 *and* 1·10 $\mu m.sec^{-1}.V^{-1}.cm$.

Lymphocyte electrophoresis, either analytical or preparative, allows the separation of cell populations, according to their rates of migration in an electric field [1].

We have carried out analytical electrophoresis on circulating lymphocytes with the same apparatus as described by Bangham *et al.* [2]. Generally two main kinds of lymphoid cells can be found in human blood: slow- and fast-moving lymphocytes. The electrophoretic mobility (E.M.) is less than 1 $\mu m.sec^{-1}.V^{-1}.cm$ for the slow-moving, and greater than 1 $\mu m.sec^{-1}.V^{-1}.cm$ for the fast-moving class. These two groups of cells can usually be subdivided into smaller, distinct sub-groups.

Several arguments allow us to believe that the rapid lymphocytes are the T-lymphocytes, and the slow-moving cells, the B-lymphocytes. These results have been obtained almost exclusively from animal experiments, in general with mice [1–5].

In man, there are only a few corresponding results [6–8]. In a group of 42 normal adults, we found approximately 20% of slow-moving lymphocytes; these results are similar to those of other authors [7], and approximate known figures on the distribution of normal B and T populations.

In an earlier work [9], we used methods known to enrich lymphoid populations: the separation of lymphocytes that do not form E-rosettes with SRBC, and the separation of cells adherent and non-adherent to nylon wool columns. This work showed the usual predominance of slow-moving lymphocytes among cells adhering to nylon wool and non E-RFC (rosette forming cells): while effluent lymphocytes on the columns have a rapid migration almost exclusively.

These results, correlated with immunofluorescence [10] seem to be supplementary arguments to affirm the T-nature of the fast-moving lymphocytes, and the B-nature of the slow-moving lymphocytes. In this work, the same methods of cell separation are used, in a combined utilisation which would allow us to obtain 3–4 different cell populations: for example, adherent or effluent lymphocytes, forming or non-forming E-rosettes.

MATERIAL AND METHODS

The procedure, using 300 ml of normal human blood, has been described in detail elsewhere [10].

(a) *Lymphocyte separation* was performed by centrifugation on a Ficoll-metrizoate mixture (s.g. 1·077). The blood was diluted to 1/3 with 0·9% Na Cl, and centrifugated at 400 *g* for 30 mn [10].

(b) *Spontaneous rosetting with SRBC* was done in Erlenmeyer flasks according to a monothermic technique derived from that of Wybran *et al.* [11]. Each flask contained 2 ml of GIBCO foetal calf serum, 2 ml lymphocytes (10,000/mm^3) and 4 ml SRBC in Alsever (250,000/mm^3). After 3 hr at 25°C, or 16–18 hr at 4°C, and gentle manual resuspension, the cells were put through a second separation at 250 *g* on Ficoll–metrizoate [10]. In the second experimental series, E-RFC were collected on a new gradient after mechanical breaking up of E-rosettes, or after SRBC lysis with NH_4Cl, 0·87 percent.

(c) *Nylon wool column method* was very similar to that of Trizio and Cudkowicz [12], using 2 ml of the lymphocyte suspension (10–30,000/mm^3) per column [10].

(d) *Cell electrophoresis* technique uses the Rank Bros Mark 1 analytical electrophoresis apparatus [1] and has been fully described previously [6, 10].

(e) *Surface immunoglobulin staining* used Wellcome fluoresceinconjugated antisera [10].

RESULTS

The separation experiments were carried out on 11 healthy subjects, independent from the normal subjects used as a reference.

(a) *Electrophoresis on total lymphocyte blood population* allowed us to see a normal electrophoretic distribution, superposable to that of the control group (19·9 ± 5·6% of slow-moving, and 80·1 ± 5·6% of fast-moving lymphocytes in 42 normal, healthy adults whose average age was 46·5 years): (Tables 1 and 2).

(b) *First series: First E-Rosettes.* Five experiments were carried out with this protocol. The totality of the isolated lymphocytes was used to form E-rosettes with SRBC for 3 hr at 20–25°C. The percentage of E-rosettes were from 70, 69, 73, 70, 70% (the mean: 70%).

After a new separation on a Ficoll-metrizoate gradient, the cells which did not form E-rosettes were put on nylon wool columns. The RFC were recuperated by a mechanical breaking down, followed by a new gradient (see Methods).

Figure 1 shows that the three populations separated in this way have an E.M. that is quite different:

Population 1 corresponds to the ERFC, thus to an almost exclusive T population; its E.M. is found in the most rapid zone of rapid cells (centered around 1·25 μm.sec^{-1}.V^{-1}.cm). Table 1 shows that this population forms 86% E-rosettes, compared to 70% in the total population.

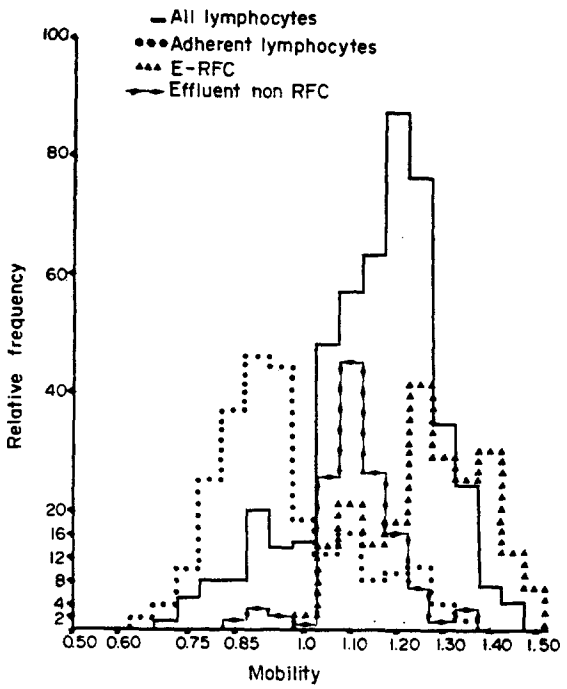

Fig. 1.

Population 2 corresponds to cells not forming E-rosettes, adhering to nylon wool columns. Thus, this population is, presumably, of a B-nature. Its E.M. is found in the slow-cell zone, centered around 0·86 μm.sec^{-1}.V^{-1}.cm. Table 1 shows 58% of these cells with a surface immunofluorescence (21% in the total population).

Population 3 is a population of cells that did not form E-rosettes, and that did not adhere to nylon wool. This population is characterized by a homogeneous E.M., limited to 2–3 classes of mobility, centered on 1·11 μm.sec^{-1}.V^{-1}.cm; and by less than 10% ERFC, or immunofluorescence-positive cells.

(c) *Second Series: First Nylon columns.* Six separation experiments were applied here. The totality of separated cells was placed into the nylon columns. Then, the two populations of adherent and effluent cells started forming

E-rosettes for 16–18 hr at 4°C. As before, the RFC and non RFC cells were recovered. A lesser number of the adhering cells that formed E-rosettes were recovered for electrophoresis on separated populations, compared to the total lymphocytes. (See Fig. 2).

1 *The total adherent population* had an E.M. that corresponds approximately to that of population 2 in the preceding series, and is found in the slow-cell zone. It contains a majority of B cells, and showed 60% of its cells to be surface Ig carriers. Nonetheless, it still contains ERFC (Table 2).

2. *The total effluent population* overlaps approximately the fast-moving cell zone. Its ERFC percentage is increased (80% compared to 68%). It contains only 5% surface Ig-carrier cells.

3. *The effluent RFC population* corresponds to population 1 in the preceding series. Composed almost exclusively of T-lymphocytes, it is characterized by a weak yield of RFC, due to a bad recovery on repeated gradients. The recovery was much better with the E-lysis with NH_4 Cl.

4. *The effluent non-RFC population* had an E.M. comparable to that of population 3 in the first series. As in this latter series, this population is characterized by a weak percentage of ERFC and of immunofluorescence-positive cells.

DISCUSSION

A large quantity of peripheral human lymphocytes form E-rosettes with SRBC under certain technical conditions [13, 14]. The ERFC are T-lymphocytes [15, 16]. In spite of a certain variability, it appears that the majority, if not all, of the circulating T-lymphocytes possess receptors for SRBC [17]. Thus, a great T-lymphocyte depletion could be established by eliminating ERFC. This is what we tried to do with a Ficoll-metrizoate gradient after a 3 hr (Series 1) or 16–18 hr rosetting (Series 2). This allows us to separate the cells that do not form E-rosettes. To obtain the RFC, the same

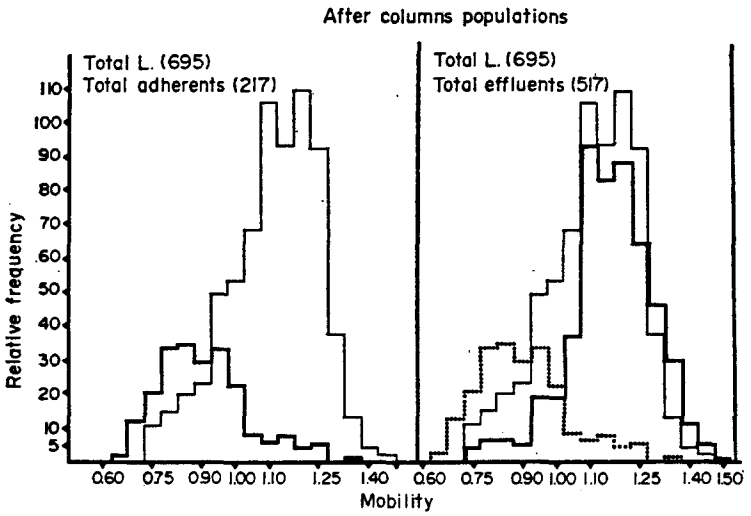

Fig. 2a.

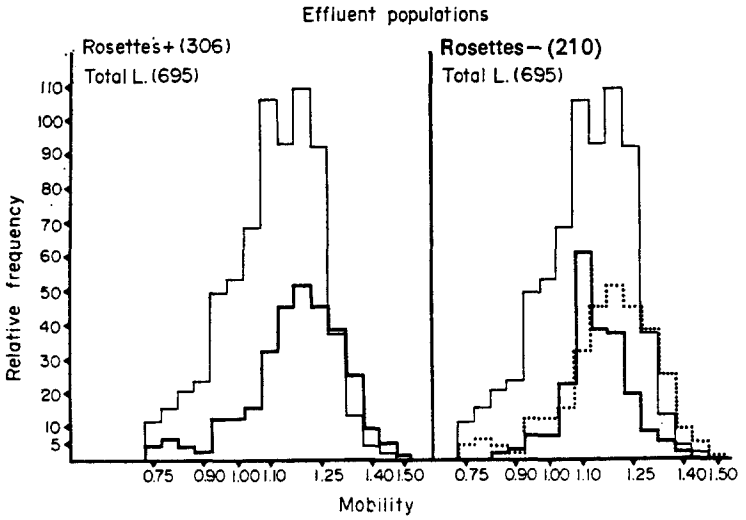

Fig. 2b.

procedure can be utilized again after a mechanical breaking down of the rosettes by manual agitation. But from our experience, the recuperation of RFC by this procedure is often tainted by a bad yield. The erythrocyte lysis by NH_4Cl was much more satisfactory for this purpose.

On the other hand, B-lymphocytes adhere to the nylon fibers more than the T-lymphocytes [17]. Indeed, the cells having a receptor for the complement [18], the precursors of antibody-forming cells [19], or the surface-immunoglobulin carriers [20] seem to adhere more to nylon or cotton wool that the lymphocytes not having these properties, which are characteristic of B-lymphocytes.

Our experimental results (Tables 1 and 2, Figures 1 and 2) show that combining the separation methods by spontaneous rosetting and nylon columns, allows three lymphocyte populations to be separated in normal human blood, whatever be the order in which these two methods are used. These 3 populations are characterized by their distinct electrophoretic mobility:

A population with a strong predominance of T (population 1 of Series 1, effluent E-RFC in Series 2) whose E.M. is centered around 1·20 $\mu m.sec^{-1}.V^{-1}.cm$.

A population having a strong predominance of B (population 2 of Series 1, the total adherent population of Series 2), whose E.M. is centered around 0·90–0·95 $\mu m.sec^{-1}.V^{-1}.cm$.

A third population with a homogeneous E.M., centered around the slow portion of the rapid lymphocyte zone, at 1·10 $\mu m.sec^{-1}.V^{-1}.cm$, neither adhering to nylon wool nor forming E-rosettes. The nature of this popula-

tion can still only be supposed. Almost by definition, since it has neither T nor B-markers, it could correspond to what certain authors call "null" lymphocytes [22].

Several comments could be made on Figs. 1 and 2:

In the separated populations, a gain of very rapid cells is present when the population is predominantly rapid, and there is, equally, a gain of very slow cells in populations that are predominantly slow; the same phenomenon is responsible for the average mobility variations observed in the preceding work [10].

The rapid populations (T and "null" lymphocytes) do not "contaminate" the slow zone or only very weakly (generally, the limit is fixed at 1 $\mu m.sec^{-1}.V^{-1}.cm$ [1, 5, 7, 9, 10]. On the other hand, the B population seems to present a rather notable lag in the rapid moving cells' zone, up to about 1·20 $\mu m.sec^{-1}.V^{-1}.cm$.

The nylon wool method is sometimes criticized for its varying yields. Nonetheless, the yields obtained in our preceding work with nylon wool, were relatively regular and on the order of 63% [10]. Here, they are 75% in the second Series. It might be preferable to use the Sephadex G200 column method, covered with antiserum anti Fab [22]. Nonetheless, the recuperation of adherent cells with this latter method would seem to be rather difficult.

The separated populations here cannot be considered as really pure. Their average purity seems to be around 80%. This imperfect enrichment may be linked to the presence of a small fraction of T-lymphocytes adhering to the columns, and to a small fraction of B-lymphocytes that form E-rosettes. Our results are compatible with hypotheses put forth by other diverse authors. Yet they have shown an actual enrichment.

The loss of cells at each stage of the separation represents one of the major disadvantages of these procedures.

The main interest of this paper seems to us to lie in the fact that we found a lymphocyte population with a homogeneous E.M., and not presenting any T or B markers.

Immunological Study of Axillary Lymph-nodes in Patients with Breast Cancer

A. DESPLACES,* A. BOURGUIGNAT,* A. GENTILE,* P. GUERIN* and R. T. SARACINO*
(With the technical help of M. E. TOUZE)

Abstract—*The comparative study of lymphocytes from peripheral blood and lymph-nodes was carried out by evaluation of the percentage of cells with surface Ig and of E and EAC rosettes in cancer patients and non-cancerous individuals.*

A significant difference could not be shown between the lymphocytes of lymph-nodes from breast cancer subjects and the lymph-nodes of individuals not having cancer, in the same age group.

On the other hand, if the breast cancer patients aged less than 61 *and those older than* 61 *are compared, a significant increase is observed in the number of cells with surface Ig and EAC rosettes, but also a significant reduction in the number of E rosettes.*

THE AIM of this was to study the immuno response at a local level since the exploration of the general response in different cancers usually does not show notable modifications except in lymphoproliferative illnesses.

MATERIAL AND METHODS

Patients with breast cancer

All patients were classed in stages II and III in the BLOOM classification and were aged from 35 to 85 yr. The lymph-nodes were taken after mammectomy in which the lymph-nodes were always shown to be free of metastatic invasion.

Controls

The controls were non-cancerous subjects aged less than 60, who underwent surgical intervention either for thyroid lobectomy or for hysterectomy.

Lymphocytes

The lymphocytes were isolated from peripheral blood on Ficoll gradient and from the lymph-nodes by teasing.

Methods

E rosettes were prepared following the technique of Wybran [1] with the following modifications: the erythrocyte/lymphocyte ratio was 40 and the reading was carried out after overnight conservation at 4°C.

The EAC rosettes were prepared after Bianco *et al.* [2]. The surface immunoglobulins (SIg) of the cells were studied by immunofluorescence according to Papamichail [3].

RESULTS

Comparative study of lymphocytes from peripheral blood and lymph-nodes

With respect to peripheral blood, a very large increase in the percentage of cells with surface Ig and EAC rosettes was observed in the lymph-nodes. On the other hand, the percentage of E rosettes was raised less.

The same variations as in the controls were observed in the lymph-nodes of patients with epithelioma of the breast.

If the patients with breast cancer aged less than 61 are compared with those older than 61, one observes, in the latter, a significant increase in the number of cells with surface Ig and the number of EAC-rosettes as well as a significant lowering in the number of E-rosettes.

If patients and controls of the same age group are compared (61 yr or less), no change is observed in the tests carried out.

DISCUSSION

The results obtained from the tests of E- and EAC-rosettes or from the cells with surface Ig,

show functional modifications in the lymphocytes of axillary lymph-nodes in breast cancer as a function of age of the patients, as has already been reported by Good [4]. Patients and controls appear identical, yet it must be stated that this is with patients free of nodal metastases and it is probable that the results would be different if one turned to individuals with metastases, as was shown by Fischer *et al.* [5] in studying the incorporation of tritiated thymidine [6].

Moreover, Ellis [6], by using the migration inhibition test (MIF), has shown that lymph-node lymphocytes were immunologically more reactive than those from peripheral blood and it will be necessary to use other techniques to advance our knowledge of the immune response at a local level.

Immunoperoxidase Method of B Lymphocyte Recognition

OLIVIER LEES

Laboratoire d'Hematologie (Pr. H. Piguet), Hotel-Dieu 76038 Rouen Cedex, France

Abstract—*The use of antibody-enzyme conjugates allows the labeling of surface-immunoglobulin bearing lymphocytes. This technique gives similar results compared to the fluorescence of surface immunoglobulins. This is a mean of evaluating the ratio of B lymphocytes.*

The immunoperoxidase staining is effected on permanent slides, with fixed cells, and observed with a light microscope.

According to the way of incubation used, the results are shown to be different:

—by incubating antibodies labeled with peroxidase on fixed smears: 20% of normal cells are recognized. The labeling is pericellular and continuous.

—by incubating antibody with living cells, in suspension, 10–12% of the lymphocytes are recognized; labeling appears like caps on the cells. These results are discussed.

INTRODUCTION

IT HAS been shown that the use of antibody-enzymes conjugates allows the labeling of surface immunoglobulin-bearing lymphocytes [1].

Heterologous antiglobulin, labeled with horseradish peroxidase, according to the technique of Avraméas [1] incubated with separated human peripheral blood lymphocytes is used to know the rate of B cells.

The antibody is fixed on surface immunoglobulins during the immunological step of the reaction. An histoenzymatical reaction using diaminobenzidine shows the localisation of peroxidase and thus the place of antibody conjugate. A cytological staining with May–Grünwald–Giemsa shows obviously all the cells of the smear.

MATERIAL AND METHODS

During the systematic trials to set up this technique two ways were possible to obtain the labeling of B cells.

1. Lymphocytes are separated from venous blood by Ficoll [3]. Cells are washed three times with Hanks plus 5% fetal calf serum, to wash out all the human serum immunoglobulins. With the bottom, we effected on one first technique (on the left on Fig. 1) smears with the washed cells. Then these cells are lightly fixed, either with ethyl alcohol (90 parts) and formaldehyde (10 parts), or with methanol, for 5 min. The fixative reaction must be very light and always dehydrating. The antibody conjugate is incubated in wet chambers for 3 hr, at laboratory temperature. The smears are washed with saline, then dived in a solution of diaminobenzidine according to Graham and Karnovski [2]. Hundred ml of Tris–HCl buffer with a tip of spatula 33'diamino-benzidine tetrahydrochloride, filtered and added just before use with 2 drops of hydrogen peroxide 120 vol. Histoenzymatical reaction is

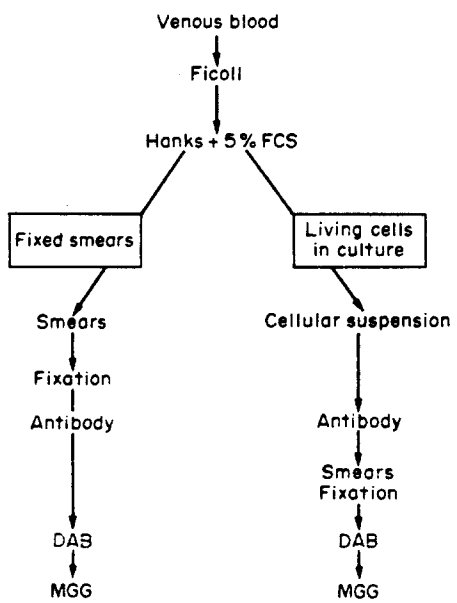

Fig. 1.

effected during 20 min. The smears are washed 3 times in saline, then coloured with Giemsa.

2. A second way (on the right of the Fig. 1) has been used:

The washed lymphocytes are incubated, living, in suspension in antibody for 3 hr, at 22°C. Then the cells are washed 3 times by spinning and resuspending the cells in Hanks and 5% FCS. Smears are effected, fixed, and the reactions with DAB and MGG staining follow the same way than for the first technique.

For each technique (on the left and right on Fig. 1), several smears, positive and controls are effected, as shown on Fig. 2.

Smears 5 and 6 include labeled cells and the count of B cell can be effected.

The most interesting control is the third one, done without antibody, because some cells have endogenous peroxidase that appears without any added enzyme.

Slide number	Interest
1 - Total heparinized blood	- % of lymphocytes
2 - Smears after Ficoll	- Cytological
3 - Without Ab. DAB MGG	- Endogenous peroxydase Polynuclears, Monocytes
4 - Ab. without DAB MGG	- Cytological
5 - Ab. DAB without MGG	- Labelled B Lymphocytes
6 - Ab. DAB MGG	- Labelled B Lymphocytes

Fig. 2.

RESULTS

We described two techniques, and some aspects of the cells are different. There are many things to note, seeing the smears:

1. Endogenous peroxidase is seen on smears 3, 5 and 6 (Fig. 2). The polynuclear cells, eosino on Fig. 3(a), neutro on 3(b), have endogenous peroxidase in lysosomes. The enzyme appears like big granules. These cells, easy to recognise are off count.

2. Reaction with DAB alone, without MGG (5 on Fig. 2) shows positive cells, but the negatives are very difficult to see. It is possible to look at these cells with phase contrast microscopy. Positive cells are surrounded with golden light.

3. With a total chain of reactions (Fig. 2, No. 6) B cells are labeled and it is easy to have the percentage of B cells (Fig. 3(c)).

4. During the two technical trials we saw that the labeling was morphologically different and the rate of the B cells was also quite different. As seen on Fig. 4, the first technique with previously fixed cells provides these results:
20% of normal donor cells are labeled. Labeling is pericellular, continuous, without capping, appearing on Fig. 3(d).

In the second technical way, by incubating living cells in suspension, cultured into antibody conjugates:
10–12% of cells are recognized.
Capping of surface immunoglobulins appears on the lymphoid cells (Fig. 3(e)).

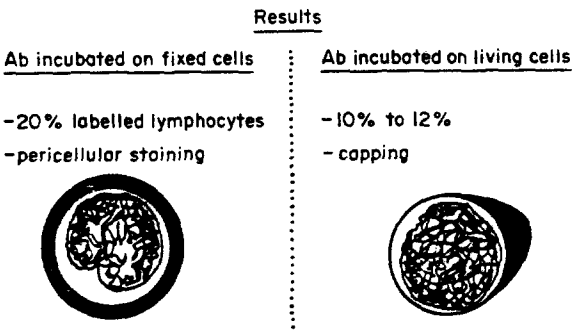

Fig. 4.

DISCUSSION

We think that the discussion of these last two results is interesting, as they appear to be different according to the technique used.

The fixative solution fixes the surface immunoglobulins. They cannot ride around the membrane when meeting a specific determinant [4]. This aspect of capping, observed by immunofluorescence [5] is here obtained according to the second technique in immunoperoxidase method. During the specific contact between surface immunoglobulins and the antiglobulins, the molecules of the cell membrane flock together at the top of the cell. This aspect has been observed by immuno-electron microscopy after incubating cells at 37°C with immunoperoxidase [6]. Capping of surface immunoglobulins appears in some lymphoproliferative diseases [7–8].

The second interesting result is the different rate of B cells obtained in the technical ways on Fig. 1.

We can presume that the good result is obtained by the second technique, by incubating the cells, cultured in antibody dilution. Some cells seem to bear immunoglobulins but cannot synthetise; they are labeled with the first technique, but not with the other. The

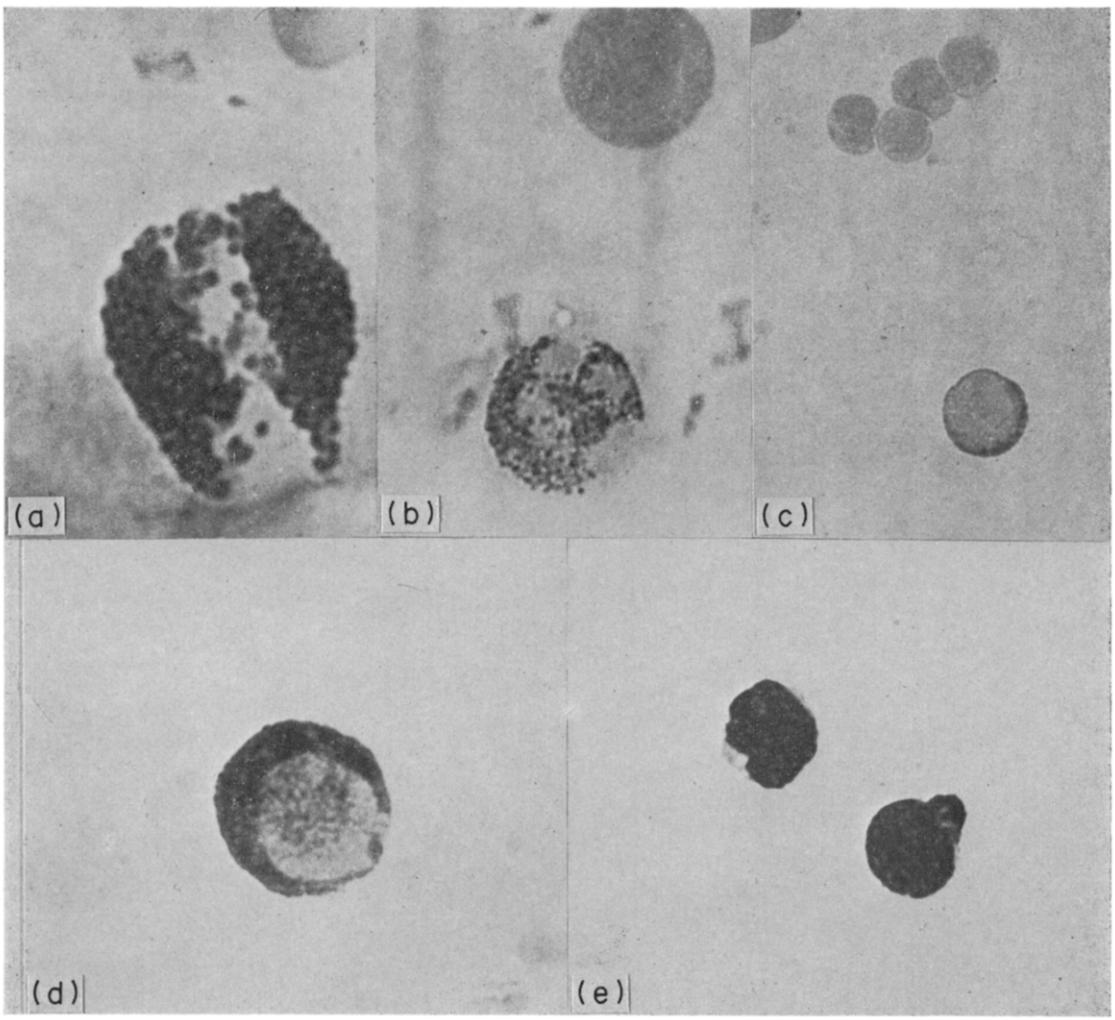

Fig. 3.

incubation during 3 hr with the antibody is equivalent to short term cultures. This seems to be very necessary before the counting of B-lymphocytes [9].

CONCLUSIONS

The immunoperoxidase recognition of B-lymphocytes provides similar results to those obtained with surface immunofluorescence. The immunoperoxidase method has yet been compared to surface immunofluorescence [10–11].

The advantages of this technique for lymphocyte staining include ease of preparation. No expensive material is needed; a light microscope is used to look at the cells. The cells are fixed and mounted on permanent slides. Many observers can see them, now or later on.

This technique is very close to the one used for immunoelectron microscopy [12–13].

Monocyte Function in Cancer Patients

J. G. McVIE,* E. C. M. LOGAN† and A. B. KAY‡
*Senior Lecturer in Clinical Oncology, University of Glasgow
†Registrar, Department of Haematology, Western General Hospital, Edinburgh
‡Senior Lecturer in Pathology, University of Edinburgh

Abstract—*Monocyte function has been studied in patients with lymphoma and lung cancer. Ability of monocytes to phagocytose Staphylococcus aureus was not depressed before treatment but was lowered by cytotoxic drugs. Recovery was then seen after a rest period. Bactericidal capacity was significantly lower in lymphoma patients prior to treatment than in normal controls. Chemotherapy lowered the bactericidal indices further and there was little recovery in between courses of treatment. Monocyte chemotaxis was depressed in untreated patients with advanced lung cancer and in half of a group of nineteen lymphoma patients. The implications of these monocyte defects are discussed.*

INTRODUCTION

MONOCYTE function is a credible requirement for an intact immune system. New roles in defence for the monocyte are projected almost weekly. Depressed monocyte function might be a predisposing factor in development of cancer. It might lead to inadequate containment of metastases and it might explain intercurrent infections frequent in tumour patients. As more aggressive treatment becomes the vogue, more patients develop serious immunodeficiency. It is no longer uncommon to witness resolution of a tumour such as a lymphoma followed by death due to overwhelming opportunist infection.

Peripheral blood monocytes have therefore been assessed for phagocytic and microbiocidal prowess in a group of lymphoma patients and appropriate controls before and after chemotherapy. A further group of lymphoma patients plus a small number of men with lung cancer have been tested for defects of monocyte chemotaxis.

MATERIAL AND METHODS

(1) *Cell preparation.* 20 mls of venous blood was collected into preservative-free heparin and separated on a Ficoll Hypaque column. The mononuclear cells collected from the gradient interface were washed, counted and adjusted to critical concentrations.

Phagocytosis and bactericidal capacity

Monolayers of 1×10^6 mononuclear cells were grown in 30% AB serum and Hepes solution for 22 hr. At that time 20×10^6 bacteria (Staphylococcus aureus) were added to the culture and the supernatants sampled 20 min later. Duplicate monolayers were then washed and lysed in distilled water at 0, 10, 20, and 40 min. The supernatants and lysates were subcultured on mannitol salt agar. From the bacterial counts at 48 hr the phagocytic capacity of the monolayer is calculated as a percentage of bacteria engulfed in 20 min of culture. The bactericidal index is an expression of the rate of killing of Staphylococcus aureus over 40 min.

Chemotaxis

A modification of Boyden's millipore technique was used. The chemo-attractant, either cobra venom factor (2·5%) or casein 5 and 10%, was placed in the bottom of a culture vessel and separated from 0·5 million monocytes in medium 199 by a millipore filter (pore size 5 μm). After incubation in a moist atmosphere at 37°C for 2 hr, the filters were removed, fixed in ethanol and stained with Giemsa solution. The distance that the "leading front" of monocytes had moved through the filter was measured in cultures containing medium 199 alone or medium 199 plus chemo-attractant. The first reading was subtracted from the second and expressed as the "distance migrated". In each experiment monocytes from a cancer patient were compared to those of an age, sex-matched control.

RESULTS

Phagocytosis

Eighteen patients were studied, each on several occasions. Before treatment patients' monocytes were as proficient as controls in phagocytosing Staphylococcus aureus. After one or more courses of combination chemotherapy (COP or MVPP)* phagocytosis was almost invariably inhibited. As shown in Fig. 1, five patients were studied serially: pre-treatment, on day 2 of chemotherapy and after two weeks clear of drug treatment. Depression of phagocytosis was seen while the patients were on treatment and some measure of recovery was seen prior to the next pulse of drugs.

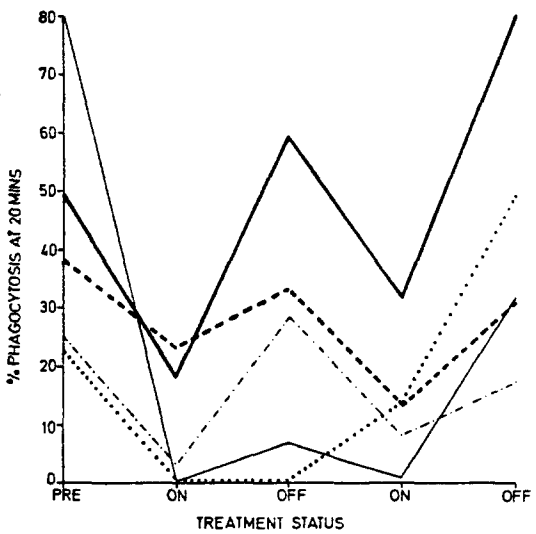

Fig. 1. Effect of cytotoxic drugs on monocyte phagocytosis.

Bactericidal index

Bactericidal capacity was estimated on over fifty occasions on eighteen patients. Their mean bactericidal index before treatment was 23 compared with the control value of 45. The difference was significant ($P < 0{\cdot}05$). The bactericidal indices of the study group fell gradually below pre-treatment values when drug treatment was initiated and did not recover between cycles. Indeed, in two patients the bactericidal index remained low three months after treatment had been discontinued and the patients' lymphomas had entirely remitted. Although monocyte and total white counts varied throughout treatment, fluctuations were shown to be independent of alterations in monocyte function.

Chemotaxis

A pilot study unrelated to the investigation of lymphoma patients above showed a marked chemotactic defect in monocytes from ten patients suffering from advanced lung cancer (Fig. 2). A group of nineteen lymphoma patients were therefore studied using the monocyte chemotaxis assay. None of the patients had received any treatment. The results were not as clear cut as those in the lung cancer group. Ten patients' monocytes were significantly less mobile than age, sex-matched controls; in seven patients the distances migrated by the study monocytes were similar to those of controls and two patients' monocytes were superior to the normals. No obvious correlation was noted between impaired chemotactic ability and histological type or stage of disease. The chemotaxis assays have not yet been repeated after treatment.

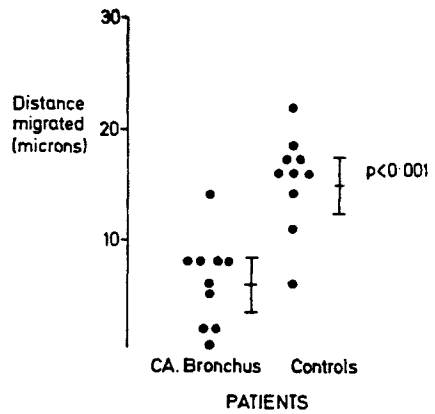

Fig. 2. Monocyte chemotaxis in carcinoma of the bronchus.

DISCUSSION

Impairment of monocyte function has been demonstrated in eight patients, with myelomonocytic leukaemia and two lymphoma patients [1]. Whether the deficiencies reported here represent an intrinsic cell defect or a secondary effect of a circulating factor is not yet elucidated. "Immunosuppressive factors" have been postulated in association with cancer, and in one group of patients [2] a small molecular weight polypeptide has been detected

*COP = cyclophosphamide vincristine prednisolone. MVPP = mustine vinblastine procarbazine prednisolone.

which inhibits phyto-haemagglutinin-induced DNA synthesis in lymphocytes. The latter factor was correlated with anergy, a notable accompaniment of lymphoma, particularly Hodgkin's disease. The drug-induced suppression of monocyte phagocytosis is predictable but would appear to be reversible in contrast to the progressive impairment of bactericidal capacity. It would be more pertinent to measure those functions with a gram negative organism such as Escherichia coli, as the infections incurred by the patients studied were usually of this type. The bacterial assays were, however, extremely unpredictable when gram negatives were employed so Staphylococcus aureus was retained as a standard.

Depression of monocyte chemotaxis is known to occur during viral illnesses such as influenza [3], again in association with loss of delayed cutaneous hyper-sensitivity and possibly a tendency to super-infection. It may be that tumours are not contained because of a defect in monocyte motility. Reversal of such a phenomenon is one of the aims of non-specific immunotherapy. BCG, C. parvum and levamisole may increase the pool of monocytes and conceivably increase their motility. It remains to be seen whether these measures have any anti-tumour effect or whether they may lessen the incidence of secondary immunodeficiency and opportunist infections in cancer patients.

T and B Lymphocytes and Monocytes in the Spleen in Hodgkin's Disease: the increase in T Lymphocytes in Involved Spleens

A. SANTORO,* B. CAILLOU‡ and D. BELPOMME†‡

**Instituto di Patologia Speciale Medica dell'Universita degli Studi di Messina, Messina, Italy*

†*Institut de Cancérologie et d'Immunogénétique, Hôpital Paul Brousse, 14 avenue Paul Vaillant-Couturier, Villejuif, France*

‡*Institut Gustave-Roussy-94800 Villejuif, France, 16 bis, avenue Paul-Vaillant-Couturier, Villejuif, France*

Abstract—*The percentages of T and B lymphocytes in the spleens of 40 patients suffering from Hodgkin's disease were studied. The results are summarized as follows: in involved spleens, i.e. containing Reed–Sternberg cells (RSC), there is significantly more T lymphocytes associated with significantly less B lymphocytes, in comparison to non-involved spleens. No significant difference was found between the two groups in the percentage of EA and EAC rosette-forming cells and non-T non-B mononuclear cells. There was no relationship between the histological type of the spleen and the percentage of either T or B lymphocytes.*

The demonstration of a higher percentage of T lymphocytes in 14 spleens containing detectable Reed–Sternberg cells (RSC) out of the 40 studied confirmed our preliminary data suggesting the existence of a local immunological reaction against Reed–Sternberg cells, in involved spleens in Hodgkin's disease.

INTRODUCTION

DURING the past few years several methods of investigation in man have permitted the identification of T and B lymphocytes [1–14] and of a third mononuclear cells population including monocytes [6, 15].

With different immunological techniques it is possible to characterize the mononuclear cells populations by different cell membrane markers (Table 1).

The purpose of this paper is to report our findings on the application of these techniques to the study of T and B lymphocytes and monocytes in the spleens of patients with Hodgkin's disease.

MATERIAL AND METHODS

1. *Patients*

The spleens of 40 patients with Hodgkin's disease (17 women and 23 men, aged from 11 to 61 years) were investigated.

Hodgkin's disease was diagnosed on clinical and histological criteria, and staging conformed to the Ann Arbor classification.

Before laparotomy, histological examination of pathological lymph nodes showed one patient to have lymphocyte predominance (LP), 21 to have nodular sclerosis (NS) and 11 to have mixed cellularity (MC). There were no cases of lymphocyte depletion (LD); 7 cases showed typical Reed–Sternberg cells (RSC) but could not be histologically subtyped for technical reasons (ND). Clinically, 2 patients were at stage I, 19 at stage II, 16 at stage III and 3 at stage IV.

After staging laparotomy, histological examination of the 14 spleens containing RSC (i.e. involved spleens) showed 6 NS varieties, 5 MC and 3 ND. Only 3 of the 21 patients at clinicals stages I and II had involved spleens whereas 11 out of 19 spleens were involved in the cases at disseminated stages III and IV ($0{\cdot}01 > P > 0{\cdot}001$).

Spleen weight was evaluated in each case. In our series, spleen weight was $309{\cdot}5 \pm 145$ (mean value) for involved spleens, and 176 ± 87

Table 1. Immunological test procedures used to differentiate T and B lymphocytes and monocytes

Immunological test	T lymphocytes	B lymphocytes	Third categories¶ Monocytes and histiocytes

*Spontaneous rosettes with SRBC (see text).
†Rosettes with sensitized SRBC (see text).
‡Rosettes with SRBC antibody complement complexes (see text).
§Membrane immunoglobulins detected by direct immunofluorescence.
¶Non T non B mononuclear cells (see text).
(+)On some mononuclear cells.

(mean value) for non-involved spleens. This difference is significant ($P < 0{\cdot}001$).

2. *Mononuclear spleen cell purification*

The spleen fragments were gently disrupted and the cell suspension washed in Hank's medium. The mononuclear cells were isolated by lowering the suspension on a ficoll–triosil density gradient, according to a technique previously described [1–3].

The purity of the mononuclear cells was always checked by May–Grunwald–Giemsa staining and their viability determined by the trypan blue dye exclusion test.

3. *Immunological tests procedures for T and B cell quantification*

3.1. *T lymphocytes.* T lymphocytes were enumerated by the E rosette test using sheep red blood cells (SRBC) according to a technique already described [1–3].

Rosettes were defined as lymphocytes surrounded by at least 3 SRBC.

3.2. *B lymphocytes.* B lymphocytes were enumerated by determining the membrane immunoglobulins (mIg) by a direct immunofluorescent test using a polyvalent fluorescent isothiocyanate conjugated sheep anti-human immunoglobulin serum, as previously reported [1–3].

3.3 *Ig receptor (EA) and activated complement receptor (EAC) bearing mononuclear cells.* Enumeration of these mononuclear cell categories was performed by the EA and EAC rosette tests respectively. Details of these tests have also been reported elsewhere [1–3].

3.4. *Non-T non-B mononuclear cells (nT nBmc).* In addition, nT nBmc were calculated from the following formula: nT nBmc = mc − (T + B), in which mc = total number of mononuclear cells, T = total number of T lymphocytes, B = total number of B lymphocytes [16].

4. *Controls and statistical analysis*

Peripheral blood lymphocytes from 20 normal subjects were used as control and the results provided the normal range for each test.

Statistical analysis were performed using the Student *t*-test.

RESULTS

(a) *Immunological findings*

The results are summarized in Table 2.

In non-involved spleens (absence of detectable RSC), the mean percentage of E rosettes (T lymphocytes) was 35·5%. Extreme values ranged from 15 to 67%, with only 3 cases above 50%, whereas in involved spleens (presence of RSC), the mean percentage of mononuclear cells forming spontaneous E rosettes (T lymphocytes) was 50%, with extreme values ranging from 33 to 67% and only 3 cases below 42%. This difference is significant ($P < 0{\cdot}01$).

For EA and EAC rosettes, mean percentages were 16·5 and 22% respectively, for non-involved spleens. Extreme values ranged from 3 to 33% for EA rosettes and from 1 to 65% for EAC rosettes. In involved spleens, the mean percentages of EA and EAC rosettes were 17 and 14·5% respectively. Extreme values ranged from 1 to 51% for EA rosettes and from 1 to 35% for EAC. This difference is not significant.

In non-involved spleens, 31·5% of the mono-

†$P < 0{\cdot}01$.

nuclear cells (ranging from 13 to 70%) showed surface bound Ig (B lymphocytes). In involved spleens, the mean percentage of splenic lymphocytes bearing Ig on the cell surface was 23%, with extreme values ranging from 7 to 40%. This difference is significant ($P < 0{\cdot}05$).

Table 2 also shows the percentages of non-T non-B mononuclear cells (nT nBmc). In non-involved spleens the percentage was 31% (range: 0–63%) and in involved spleens 27% (range: 8–40%). No significant difference was detected.

(B) *Search for a correlation between immunological data and variables characterizing the disease*

This search led to three interesting observations:

(1) We found a significantly higher percentage of splenic T lymphocytes in disseminated clinical stages III and IV than in cases of localized disease (stages I and II). We also found a slightly fewer mIg binding mononuclear cells, (B lymphocytes) EAC rosette-forming cells and nT nBmc in the generalized disease. However, these differences were not significant. No variation was detected in the percentage of splenic EA rosette-forming cells in patients at different clinical stages of the disease.

(2) We compared involved spleens in the localized and disseminated stages and found no difference in the percentages of T lymphocytes. Nor was any variation detected when comparing T cells of the non-involved spleens in each clinical group.

(3) Finally, we found no clear-cut relationship in the spleen between the percentages of the different mononuclear cell populations and the histological type of the tissue.

DISCUSSION

The results presented in this paper confirm our previous findings [17–21] as well as those of others [22, 23] that in Hodgkin's disease there is a significantly higher percentage of T lymphocytes present in spleens containing RSC, than in non-involved spleens.

The mechanism of this increase is at present unclear. There are at least two possible explanations:

(1) Since it has been claimed that RSC may be T cell derived, this increase in T mononuclear cells may correspond to an increase in RSC precursors. This hypothesis does not seem plausible, however, because recent reports, including our own [18–21], have suggested that RSC may in fact, be derived from B cells [24, 25] or from histiocytes [26, 27].

(2) This increase in T cells may correspond to a local immune reaction against RSC. This would explain the strikingly close contact seen with conventional [28] and scanning electron microscopy [18–20] between presumed T lymphocytes and RSC. These morphological findings do not, however, prove the existence of a specific immunological reaction.

Our data regarding B lymphocytes confirm reports from other authors [29, 30] who found in using different methods a significant drop in the number of B cells in involved spleens. However, from our data we are unable to

deduce that there is a decrease in the absolute number of B lymphocytes in involved spleens in Hodgkin's disease.

The absence of any significant difference in the percentages of EA and EAC rosette-forming cells suggests that there is no difference in the percentage of cells related to the histiocytic series.

We showed a higher mean percentage of splenic E rosettes (T lymphocytes) in disseminated clinical stages III and IV than in localized stages I and II. According to our findings, there is no difference in the percentage of E rosette forming cells between involved spleens, whether they are localized or disseminated diseases. Our data showing a high mean percentage of splenic T lymphocytes in the generalized clinical stages may in fact be explained by a larger number of involved spleens in the disseminated cases. There is however, no clear correlation between the increase of T lymphocytes in the spleen and the degree of dissemination of the disease.

Our findings suggest that there is no correlation between the percentage of the different mononuclear cells and the histological type in the spleen; however, as our series was exclusively composed of NS and MC varieties, no definite conclusions can be drawn from these data.

Finally, from this study it is suggested that the detection of an increased number of T lymphocytes in involved spleens may be clinically helpful in the evaluation of the clinical stage of Hodgkin's disease when pathological analysis remains difficult to interpret.

Abstract—*T-lymphocytes respectively respond to Phytohemagglutinin (PHA-P), to Concanavalin A (ConA) and Pokeweed Mitogen (PWM). The response to mitogens of T-lymphocyte sub-populations has been evaluated. These lymphocytes have been purified by carbonyl iron treatment and separation on Immunoabsorbant columns (anti-$(Fab)_2$ on G 200 Sephadex). Then separation of this population was achieved by density gradient. Sixty-seven per cent of T lymphocytes were recovered at a buoyant density of 1·072 and 1·095 (respectively 54% and 13%). These two sub-populations presented the same markers: EAC-Rosettes <5% and E-Rosettes > 80%. However, the response to mitogens was different. The 1·072 buoyant density cells responded to the three mitogens in the limits of the total purified T population. Contrary, the response of 1·095 buoyant density population was equal to 1·183 and that of the 1·095 buoyant density population was equal to 1·256 which is more rapid. Quite comparable results were achieved using a total lymphocyte population separated on BSA gradient purification. These results confirm the heterogeneity of the T-lymphocytes population probably related to different functions.*

INTRODUCTION

A NUMBER of studies in animals has demonstrated a functional heterogeneity existing within the T-lymphocyte population [1, 2]. Differences in response to the two mitogens, Phytohemagglutinin (PHA) and Concanavalin A (ConA), have also been reported for these sub-populations of T lymphocytes in animals [1]. It has been suggested that these differences in response reflected differences in maturation in T cells [1, 2]. It has been shown that there exists a distinct population of B and T lymphocytes in man [3, 4]. The studies of human sub-populations of type T and their differences in response to mitogens have drawn little attention until now [5]. In this paper we report results demonstrating the heterogeneity of human T lymphocytes with evidence showing differences in response to mitogens and electrophoretic mobility.

MATERIAL AND METHODS

1. *Extraction of lymphocytes and elimination of monocytes*

Human lymphocytes are obtained from whole blood centrifuged on a cushion of Ficoll–Hypaque according to the method of Boyüm [6]. Monocytes are eliminated by addition of iron carbonyl to the whole blood for 30 min at +37°C with continuous agitation; the monocytes having phagocytized the particles then traverse the cushion of Ficoll–Hypaque.

2. *Separation of T-lymphocytes*

We employ a modified technique of Schlossman and Hudson [7]. Briefly, a column of G-200 Sephadex, activated with cyanogen bromide and conjugated with anti-$(Fab)_2$ human serum, was prepared in a 20 ml syringe previously fitted with a nylon filter at the base and a 3-way stopcock. The column was freshly prepared and equilibrated with RPMI 1640 medium containing 1% Hepes, 5% fetal calf serum (FCS) and 2·5% EDTA (100 mM). This is designated complete medium and kept at +37°C until time of use. Lymphocyte concentrations were adjusted to $2 \cdot 10^7$/ml (total column population of 2×10^8) and are loaded on the column and eluted at the rate of 1 ml/mn. Elution was effected with 45 ml of complete RPMI 1640 medium.

3. *Separation of sub-populations of T-lymphocytes by discontinuous albumin (BSA) gradient*

We use BSA fraction V (Calbiochem) which was previously dialyzed, filtered and lyophilized. The dilutions at different densities (1·058, 1·064, 1·072 and 1·095) were adjusted by refractometer in Shortman's medium [8]. The dilutions of BSA were then sterilized, distributed in 1 ml aliquots and frozen. 10^8 lymphocytes were placed on the gradient and centrifuged for 30 min at $20{,}000 \times g$ at +4°C in an ultracentrifuge (MSE-25) using a swinging bucket rotor. Each lymphocyte band was then removed and washed in complete buffered medium. Viability was evaluated by the trypan-blue dye-exclusion procedure and the viable lymphocytes were then distributed for use in the various immunologic procedures.

4. *Immunological procedures*

E-Rosettes [9]. Sheep red blood cells (SRBC) were washed three times and adjusted to 350×10^6/ml. One then mixed 30 μl of lymphocyte suspension containing 5×10^5 cells, 30 μl of FCS previously adsorbed against SRBC and 60 μl of the sheep cell solution. The cells were then allowed to sediment for 5 min at $400 \times g$ and incubated at laboratory temperature overnight. The cells were then carefully resuspended in solution and the percentage of E-Rosettes was evaluated in duplicate.

EAC-Rosettes. 100 μl of lymphocyte suspension (2×10^6/ml) were added to 100 μl of the complex formed by the SRBC (10^9/ml) and rabbit anti-sheep erythrocyte serum (1/2000) in the presence of mouse complement (C57 B1/6 × DBA2)F1 (1/20). The mixture was then incubated for 5 min at +37°C, centrifuged for 5 min at $120 \times g$ and re-incubated for 30 min at +37°C. 200 cells were then counted in duplicate.

Surface immunoglobulin staining and monocyte peroxydase staining. A human anti-immunoglobulin serum (Institut Pasteur) was previously conjugated to fluorosceine isothiocyanate in the laboratory. 100 μl of lymphocyte suspension (2×10^6 cells) were mixed with 100 μl of serum previously conjugated with marker and this mixture was then incubated for 1 hr at +4°C. The cells were then washed 3 times in cold PBS containing 10% FCS. The cell suspension was then spread on a slide and those monocytes labeled with peroxydase were noted according to the method of Preud' Homme [10]. The lymphocytes were examined under the 25 × objective of an Orthoplan (Leitz) microscope equipped with a Ploem. 200 cells were counted in duplicate.

Blast stimulation of lymphocytes by mitogens. The blast stimulation of human lymphocytes has already been described [11]. Briefly, 20 ml of venous blood was collected in 20 ml of Hanks containing 0·2 ml of heparin. Seven ml of Ficoll-Metrizoate were placed at the bottom of each tube. After centrifugation at $400 \times g$ for 30 min, the lymphocyte band is washed three times in Hanks medium. Viability was controlled by the trypan blue dye exclusion procedure and the cell concentration was adjusted to 1×10^6 viable lymphocytes/ml. 10^5 lymphocytes in buffered medium 199 (20% AB serum) were placed in the wells of a microplate 3040 (Micro Test II; Falcon) followed by the appropriate mitogen (Phytohemagglutin, DIFCO: PHA-P; Concanavalin A, DIFCO: ConA; Pokeweed mitogen, GIBCO: PWM) in the respective concentrations of 75 μg/ml, 100 μg/ml and 75 μg/ml. The cultures were then incubated at +37°C in a humid environment for 72 hr. Sixteen hours prior to termination of incubation, 50 μl of tritiated methyl-thymidine were added to each well at a concentration of 4 μCi/ml (specific activity: 12–15 Ci/mM-CEA, Saclay, France). The cultures were filtered through glass fiber (FUG-France) with the aid of a semi-automatic harvesting collection apparatus (Mash 1–Otto–Hiller–Madison—U.S.A.). A count was made in a Beta counter SL-30 (Intertechnique).

Lymphocytes electrophoresis. Electrophoresis was accomplished by an analytical electrophoresis apparatus (cylindrical cell microelectrophoresis apparatus Mark 1, Rank Brothers). The lymphocytes were resuspended at 3×10^6/ml in PBS buffer, pH 7·2. The technique used was analogous to that of Wioland [12] and Sabolovic [13] with the following being held constant: electrodes Ag/AgCl; a constant voltage of 50 V; a constant temperature of +25°C; and glass capillary tubes of 2 mm dia. with an inner diameter of 100 μm. The slower moving lymphocytes were those which migrate at less than 1 μm $sec^{-1}V^{-1}cm$. The fast moving lymphocytes are those migrating above this value [13].

RESULTS

The experimental results show that populations 1·072 and 1·095 possess the same markers. The response to mitogens PHA, PWM, and ConA, on the contrary, is different. In effect, the population 1·072 responds as well to the three mitogens as the total non-separated population. If the population 1·095 responds in a sub-normal manner to the PHA, then there

is a marked reduction in response to PWM and ConA.

A study of the results of these two sub-populations obtained from T purified lymphocytes shows that the response of these lymphocytes to the three mitogens is very similar to those obtained from the total population. In effect, the 1·072 population responds to the three mitogens employed in a manner approximating the two sub-populations from total lymphocyte pools. On the other hand, a diminished response is seen for the 1·095 population for PHA, and moreover, there is a falling off in the response to PWM and particularly to ConA.

A study of the electrophoretic migration of these two sub-populations shows a different distribution of lymphocytes. The population 1·092 has a mobility equal to 1·164 while population 1·095 shows a mobility of 1·268, that is to say, a more rapid mobility.

Table 1. *For the three mitogens employed, the results are given as the relation of dpm of the sub-population studied* (1·072 *or* 1·095) *to the total non-separated lymphocyte population* (*T and B lymphocytes*). *A significant decrease is noted in the response of the sub-population* 1·095 *to PWM and ConA*

% range	—	50–80	5–27

The results obtained with the markers used do not give evidence of any distinct difference between populations 1·072 and 1·095 which would isolate them from the total mixed lymphocyte population or from a purified population of T lymphocytes.

DISCUSSION

The results presented suggest the existence of, at least, two sub-populations of T lymphocytes, one responding to all three mitogens, that is, PHA, PWM and ConA, and the other responding less to PHA, and very little to PWM and ConA. These two sub-populations exhibit identical markers, of those employed here, but possess different electrophoretic mobility, confirming therefore, that they behave as two sub-populations presenting distinctly different characteristics. In addition, this decreased response of the 1·095 lymphocyte population could not be associated with an absence of monocytes [14], because the monocytes present in the total population (B and T lymphocytes—when monocyte elimination procedure is omitted) are distributed for the most part in the sub-population 1·095, and these 1·095 lymphocytes do not respond to PWM or ConA. In spite of this, we do not observe a difference in response to ConA which varies from the response observed with sub-population 1·095 obtained from purified T lymphocyte population.

Of further interest, these two sub-populations possess a different morphology (R. Senelar, B. Serrou, C. Thierry, unpublished results) which should be noted. The lymphocytes responding well to the three mitogens are cells of greater diameter with remarkable cytoplasm possessing a number of ribosomes and mitochondria, while the cells not responding to ConA and PWM are the cells of smaller diameter with little cytoplasm as well as a number of lysosomes and Golgi apparatus worth noting.

It seems to us that these results should draw concern to the following: whether certain markers, such as those for the Fc receptor, may not be found to be associated with one or the other of two sub-populations, as might be suggested by the recent work of Stout *et al.* [15]. This would lead to the possibility that sub-population 1·095, which does not respond to ConA, would not be a sub-population of T Fc+lymphocytes. Be that as it may, we are presently following up this work by a study of the response of these two sub-populations in mixed lymphocyte culture and in the presence of antigens. The documentation of sub-groups of human T lymphocytes, possessing different functions, seems very interesting to us. The study of variations in distribution of these cells may, in effect, lend itself towards a better evaluation of the immune status of the cancer condition.

Routine Technique of Lymphocyte Cryopreservation Evaluated by *In Vitro* Tests of Immune Response

C. THIERRY,* J. M. TURC,† H. VALLES* and B. SERROU*

**Department of Clinical and Experimental Immunology, Centre Paul Lamarque, Hôpital St.-Eloi, 34059 Montpellier, France*

and †*Centre de Transfusion Sanguine, 8 Boulevard de Lattre de Tassigny, BP 1542 21034 Dijon Cedex*

Abstract—*A reliable technique for cryopreservation of lymphocytes which conserves mitogenic response and surface marker (E-Rosettes and immunofluorescence) capability is presented. Briefly, lymphocytes are separated on Ficoll–Hypaque according to the method of Boyüm, washed twice. Concentration is adjusted and the cells are then placed in an ice-bath at +4°C in 7·5% Dimethyl sulfoxid (DMSO) and medium 199 supplemented with 20% AB serum. The cellular suspension is partitioned equally (1 ml containing 10^7 lymphocytes/vial) into freezing vials and placed in the chamber of a Planer R 201 Programmed Freezer with a cooling rate of 1°C/minute from +4°C to −60°C with rapid intense cooling between −6°C and −8°C to prevent surfusion and then a rapid gradient from −60°C to −160°C. Next, vials are transferred into a container of stored liquid nitrogen. At the moment of their employment, the cryopreserved lymphocytes are placed in a water-bath at +40°C, then diluted 10 fold within 2 min in culture medium 199 with 20% AB serum. Lymphocytes are counted, cell viability is evaluated by the Blue trypan dye exclusion test after which cells are distributed for diverse immunological tests. The data which is presented shows no significant difference between tests involving fresh and cryopreserved lymphocytes.*

THE USE of cryopreserved lymphocytes to follow the immunocompetence of cancer patients becomes absolutely indispensable if one wishes to take into account time variations in the treatment of the lymphocyte response of patients with diverse tumors. A systemic study of different lymphocyte cryopreservation techniques and their effect on measurable immunological parameters has been proposed during the last three years [1–8]. However, perfection of a dependable, reproducable cryopreservation technique, avoiding selection of a lymphocyte sub-population remains a problem still to be resolved.

This article delineates a cryopreservation technique respecting the surface markers and the capabilities of the lymphocyte response to mitogens as well as response to allogenic cells in mixed culture. In addition an excellent cryopreserved lymphocyte viability and satisfactory recuperation percentage would permit this method to pass from an experimental technique to a routine clinical procedure.

MATERIAL AND METHODS

Lymphocyte extraction

Peripheral blood from normal patients is collected in heparin (Calcium salt; Choay Laboratory), diluted 3 fold in Hanks solution (Pasteur Institute) containing 4% Hepes, 5% fetal calf serum (FCS; Gibco) and 80 μg/ml of Gentalline. FCS and Calciparine are present in the washing medium to avoid platelet aggregation.

The suspension is placed on a Ficoll–Metrizoat cushion (density 1·077) according to the method of Boyüm [9]. The lymphocyte band is removed, washed twice in Hanks solution after which the cells are counted and the concentration is adjusted to $2 \cdot 10^7$/ml in 199 Medium (Gibco) containing 4% Hepes, 5 units/ml of Calciparine and 20% fresh AB human serum without complement.

Freezing and thawing procedures

The cell suspension is placed in an ice bath

at +4°C. The cryopreservation medium (Dimethyl-Sulfoxide-DMSO) is then added drop by drop to an equal volume of the lymphocyte suspension. The frozen suspension has a final concentration of 7·5% DMSO, 10% in AB human serum and 10^7 cells/ml. 1 ml aliquots are distributed in freezing tubes (Polylabo Block Ref. 13001) which are placed in a programmed freezing apparatus which has been pre-cooled to +4°C (Planer R201).

Before the program is begun, a 5 min stabilisation period is necessary in order that the temperature in the programmed freezer and that in the freezing tubes are exactly the same. The freezing program is then initiated with a temperature descent gradient of 1°C/min from +4°C to −60°C, including a supplementary chilling between −6°C and −8°C in order to avoid temperature irregularities due to surfusion and then a rapid decline in temperature between −60°C and −150°C. We lower the temperature to −150°C in order to have a temperature safety margin when the aliquots are transferred from the programmed freezer to liquid nitrogen storage containers (RCB 60 Air Liquid).

The samples to be thawed are removed from storage and immediately plunged in an incubator at +40°C with constant agitation until the last crystal of ice has disappeared. The cells are then diluted 10 fold within 2 min in a 199 buffered medium containing 20% AB human serum and then washed twice. The lymphocytes are then counted, their concentration is adjusted and their viability is evaluated by the trypan blue dye exclusion procedure.

E-rosettes

Sheep red blood cells (SRBC) are collected in sodium citrate solution, washed 3 times in Hanks solution and adjusted to 350×10^6 cells/ml. 30 μl containing 5×10^5 lymphocytes are placed in contact with 30 μl of FCS previously adsorbed on SRBC and 60 μl of the SRBC suspension. The mixture is incubated overnight at room temperature after which the cells are gently resuspended. A cell count is performed in duplicate on 200 lymphocytes.

Surface immunoglobulin staining and monocyte staining

Human anti-immunoglobulin serum (Pasteur Institute) is conjugated with Fluorescein in our Laboratory. 100 μl containing 2×10^6 lymphocytes are placed in contact with 100 μl of Fluoresceine conjugated serum and allowed to remain at +4°C for 1 hr. The cells are washed three times in cold PBS containing 10% FCS. The cell suspension is spread on a slide followed by a peroxidase labelling procedure for monocytes as described by Preud' homme [10]. Next, the lymphocytes are examined in a 25× objective of an Orthoplan (Leitz) microscope equipped with a Ploem. 200 cells are counted in duplicate.

Lymphocyte stimulation by mitogens

We use a method previously described [11]. Briefly, 100 μl of the lymphocyte suspension adjusted to 1×10^6/ml is placed in the wells of a microplate (Microtest II—Falcon) and 50 μl of the appropriate mitogen is distributed to its respective lymphocyte sample. The microplates are uncovered by a Blenderm (3M Company) and placed at +37°C in a humid atmosphere during 72 hr. 16 hr before termination of the culture, 50 μl of tritiated Methyl Thymidine (CEA, Saclay, France; specific activity of 15 Ci/mM) containing 0·2 μCi are added to the culture. The cultures are then filtered through fiber glass (Fug, France) with the aid of a multiple automated sample harvester (Mash 1, Otto-Hiller), dried, and then counted in a liquid scintillation counter (SL 30 Intertechnique). The results are evaluated statistically on a Multi 4 Computer (Intertechnique) and are expressed in dis/min ± 2 standard errors (SE).

Mixed lymphocyte culture

We used a microplate (Microtest II, Falcon) technique. The stimulating cells are blocked with Mitomycin C (Sigma; 8 μg/2×10^6 cells) for 30 min at +37°C with constant agitation, after which the cells are washed three times in buffered medium 199. A ratio of 1/1 (i.e. $5 \times 10^5/5 \times 10^5$ stimulating cells/cells stimulated) is used after prior experimental determination of the optimum cell ratio. Culture time was five days. 50 μl of tritiated methylthymidine (4 μCi/ml; specific activity of 15 Ci/mM; CEA, Saclay, France) is added to the cultures 16 hr prior to termination of incubation. Cell collection is effected with the aid of a Mash 1 and the lymphocytes are recovered by filtration through fiber glass. Radioactivity is monitored with a Beta scintillation counter (Intertechnique). Counts are expressed in counts/min ± 2 standard errors.

RESULTS

At the outset, we experimented with 4 freezing protocols: progressive freezing in liquid nitrogen vapor; a programmed decrease in temperature of 0·6°C/mn to −25°C; a programmed decrease of 1°C/mn to −25°C and

lower; a programmed decrease of 1°C/mn to −15°C and 3°C/mn to −25°C. In addition we have also varied the DMSO concentration. We also compared fresh AB serum kept at a maximum of +4°C for 10 days to frozen AB serum.

The cryopreserved lymphocytes under these conditions have been tested in mixed lymphocyte culture. As shown in Fig. 1, protocol 1 was rejected, the results being uninterpretable. On the other hand, protocol 3 (i.e. decrease in temperature of 1°C/mn to −25°C and lower) yielded the optimum results with a DMSO concentration of 7·5%. Use of fresh or frozen AB serum yields no significant difference in the results.

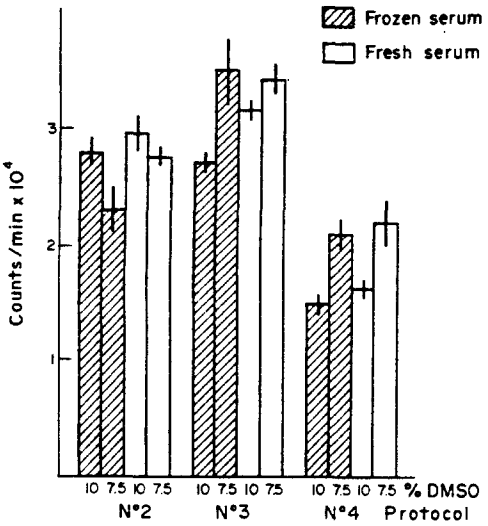

Fig. 1. Comparison of 3 different protocoles of lymphocyte cryopreservation evaluated by the mixed lymphocyte culture. Results are expressed in Counts/min × 10⁴ lymphocytes. Note that the best results are obtained using 7·5% DMSO with the protocol 3 (1°C/min. up to −25°C and minus). The results are similar for fresh or stored AB human serum.

Within the context of these results, we have defined a technique which we are presently employing. Figure 2 shows the freezing curve used which is scrutinized, in the upper and lower regions, in the following manner: stabilization for 5 min at +4°C followed by a programmed decrease in temperature from +4°C to −60°C with intense cooling between −6°C and −8°C, which permits us to obtain a curve approximating linearity. Between −60°C and −150°C the descent is rapid.

As shown in Table 1, the surface markers of fresh and cryopreserved lymphocytes are studied comparatively. The viability of cryopreserved lymphocytes varies between 75% and 92% while the percent recovered is between 42% and 89% with an average of 65%. On the other hand, during the course of 14 experiments

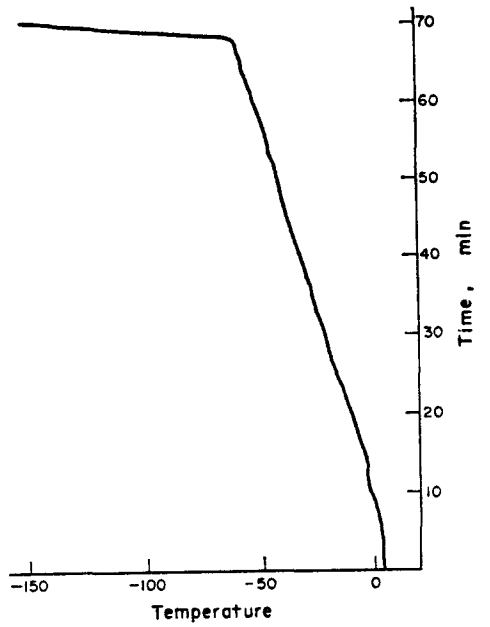

Fig. 2. Temperature curve of lymphocyte cryopreservation used in this work. Note the absence of surfusion phenomenon on this curve due to the intense cooling used between −6°C and −8°C.

performed, the average difference between the fresh and cryopreserved lymphocytes was 5% for the E-Rosettes, 2% for immunofluorescence and 2% for the peroxidase monocyte marker.

Figure 3 shows the distribution of results which we have obtained by comparison of fresh lymphocytes and those cryopreserved, both having been stimulated to a blastic response by Phytohemagglutinin (PHA-A), pokeweed mitogen (PWM-B) or Concanavalin A (ConA-C). Taken together the results are very similar and the average values for fresh and cryopreserved lymphocytes are very close. There is no significant difference. It should be noted that there is a wide dispersion in the results observed for the response to PWM.

DISCUSSION

A number of studies using different protocols to decrease the temperature (1–5°C/mn) as well as employing different concentrations of DMSO (5–10%) have obtained satisfactory results [4, 7, 12, 13]. Studies of the ability of cryopreserved lymphocytes to respond to PHA, PWM and ConA as well as mixed culture procedures have been published with a certain heterogeneity in the results [4, 6, 7, 12, 13]. In addition, certain investigators have proposed the possibility that cryopreservation results in selection of lymphocyte sub-populations [6, 14].

The technique of cryopreservation which we

have presented seems feasible and reproducable. In addition, the results which we have obtained by evaluation of different markers has allowed the *a priori* rejection of subpopulation selectivity. In the time, considering the dispersion of certain results of blastic stimulation by mitogens and the relative percent recovery, we have not yet reached a definitive position. In spite of this, we think that this technique is presently capable of being employed routinely in the immunological laboratory wishing to preserve lymphocytes under the best conditions possible for study of the immunological balance in the tumour patient.

Carcino-Embryonic Antigen Assay in Breast and Bronchus Cancers

B. KREBS, P. TURCHI, C. BONET, M. SCHNEIDER, C. M. LALANNE and N. NAMER

Centre Antoine Lacassagne, 36 Voie-Romaine, 06054 Nice Cedex, France

INTRODUCTION

MANY teams have focussed their attention on carcino-embryonic antigen (CEA) in colonic carcinoma, since its discovery in 1965 by Gold and Freedman [1], Koldovki [2] published a general review concerning this antigen. Since its radioimmunoassay was introduced by Thomson *et al.* [3] then by Martin *et al.* [4], CEA has been assayed in many other localisations, then in colonic carcinoma. This work concerns bronchus and breast cancers.

MATERIAL AND METHODS

(1) The CEA radioimmunoassay has been established thanks to reagents commercialized by the "Commissariat de l'Energie Atomique", Henry *et al.* [5].

(2) *Populations*

(a) 45 assays were performed on 45 bronchus cancer patients, of which 29 were done pre-therapeutically.

(b) 87 assays were performed on 87 breast cancer patients of which 54 were pre-therapeutic.

(c) 48 women were followed up periodically (248 assays).

RESULTS

(1) *Pre-therapeutic levels in bronchus cancers*

Generally pre-therapeutic levels are higher than post-therapeutic ones; nevertheless, low values can be observed ranging from 0 to 800 ng/ml.

Figure 1 shows that there is no relation between primary tumour size and CEA blood level. But this relation does exist as has been shown by several authors [6–8] between blood levels and lymphnode-involvement or metastatic spread.

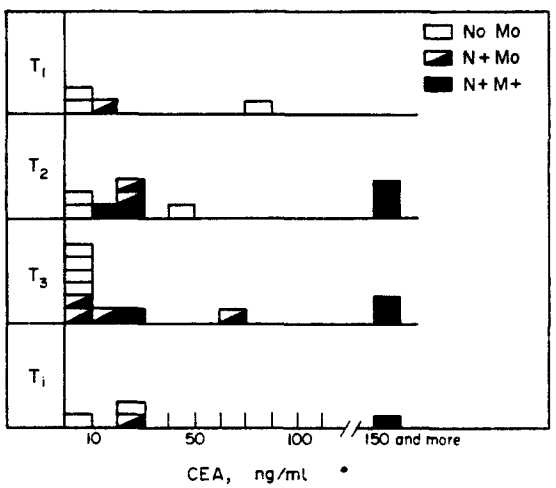

Fig. 1. Pre-therapeutic CEA levels in patients bearing bronchial carnoma with special reference to tumour size, lymph node involvement and metastatic spread.

(2) *CEA levels in breast cancer*

Figure 2 shows, once more, that primary tumour size has no influence on CEA blood level.

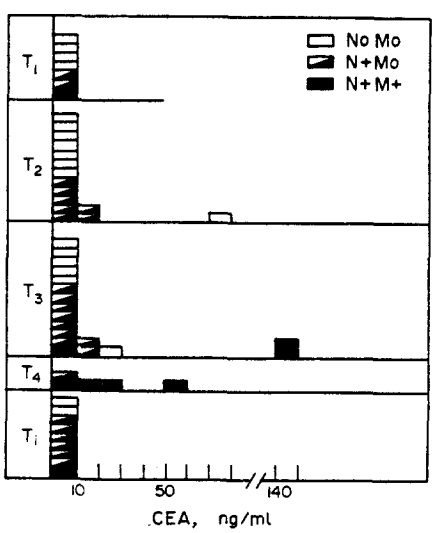

Fig. 2. Pre-therapeutic CEA levels in patients bearing breast cancers with special reference to tumour size, lymph node involvement and metastatic spread.

However, lymphnodes as well as metastases at distance (Table 1) are responsible for CEA blood level increase.

Table 1. *Percentage of plasma CEA levels above* 5 *ng/ml in bronchus and breast cancers*

	Bronchus carcinoma	Breast cancer
NO MO	21	11
N +MO	61	33
M +M+	95	65

This table shows the relative increase of blood levels above 5 ng/ml according to clinical status.

(3) *Follow up of* 48 *breast cancer patients*

Different types of evolution in CEA blood level has been observed.

DISCUSSION

Studies made on patients using one form of assay show an obvious relationship between CEA blood level and clinical extension of disease. They also show that breast cancers produce less CEA than bronchial carcinomas.

But one assay is insufficient [6, 8] and follow up greatly improves the information gained about the marker's behaviour characteristics. Effectively, only one patient (Fig. 3) has an interpretable kinetic.

CONCLUSION

In these series, the radioimmunoassay of carcino-embryonic antigen especially during long term follow-up appeared to be a good indicator of prognosis and of metastatic dissemination.

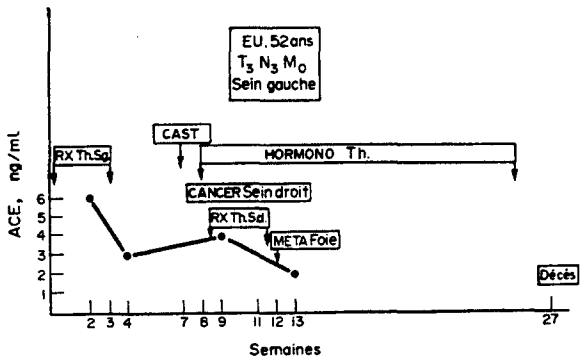

Fig. 3. *Mme EU . . .* (52) *has never shown CEA increase despite bone metastatic complications and control-lateral cancer appearance followed by rapid death.*

Table 2.

Type of kinetic and number		Clinical evolution: Good	Stable*	Death
Increasing levels	8			8
High levels	2			2
Decreasing levels	9	8		1
Low levels (less than 5·0 ng/ml)	18	18		
Fluctuating levels (between 0 and 10 ng/ml)	8	8		
Fluctuating levels (between 10 and 30 ng/ml)	3		3	

*Presence of metastases but without evolution.

Abstract—*We report here an unusual cell line (Reh) initiated from the peripheral blood of a patient with acute lymphoid leukaemia. This line differs from the data we reported previously for other cell lines by its kinetics of establishment, by chromosome markers found on fresh and established cells, by the absence of EBNA and the presence of EBV receptors and other B markers.*

Reh cells are presently utilized for active immunotherapy of patients with acute lymphoid leukaemia.

INTRODUCTION

NUMEROUS lymphoblastoid cell lines have been initiated from the peripheral blood of patients with malignant disease or from healthy donors [1]. Establishment usually occurs after a lag phase of variable duration where neither mitosis nor DNA synthesis can be observed [2–3]. In nearly all cases these lines contain Epstein-Barr virus (EBV) or some antigens determined by the genome of the virus [4], which can be detected in the cellular DNA [5]. All these cell lines demonstrate B cell markers [6]. Very few exceptions have been found, namely T cell lines lacking EBV [7]. More recently Klein and his co-workers have reported B cell lines without the EBV genome and the Epstein–Barr determined nuclear antigen (EBNA), established from biopsies of African or American lymphosarcomas [8].

From this data, it has been claimed that all categories of cell lines originate from a small number of primitive stem cells infected by EBV [1].

However, differences between normal and leukaemic cell lines have been published [9–11].

We report here a cell line initiated from a leukaemic donor which differs from the commonly described lymphoblastoid cell lines by its kinetics of establishment, by chromosome markers already present in leukaemic fresh cells, the absence of EBNA, and the presence of EBV receptors and other B. markers.

MATERIAL AND METHODS

The cells were handled following a procedure previously described [12]. Briefly, they were cultivated in RPMI 1640 medium supplemented with fetal calf serum and antibiotics. The cumulative growth curve has been obtained by plotting the total cell number found in each flask on semi-logarithmic paper. Once established this curve was made by multiplying the ratio between the number of cells at the time of transfer and the respective inoculum by the preceding cell number on the curve [3].

Chromosome studies were performed using the method of Lejeune [13]. At the time of initiation of the culture, the blood cells were cultivated during 24 hr and 48 hr without PHA.

EBV rosettes: the technique described by Jondal and Klein [14] was employed. Briefly 10^5 P_3 HR-1 producing cells were labelled with 50 μl of fluorescein conjugated MA positive antiserum (Tu 125). After two washes with cold BSS the labelled cells were resuspended and incubated at 4°C for one hour. in the presence

*This work was partially supported by ATP INSERM. No. 10-74-31 and No. 74-5-421-36.

of $1 \cdot 10^6$ cells to be tested. The mixture was then gently resuspended. One hundred MA positive P_3 HR-1 cells were examined alternatively in UV and ordinary light and the percentage of producing cells forming rosettes was determined.

EAC rosettes. The formation of EAC rosettes was assayed by the method of Shevach *et al.* [15]. Rabbit antisheep red blood cells were purchased from Gibco. Fresh AkR serum, diluted at 1/20 was used as source of complement.

EBNA determination. Detection of EBNA was performed by anti-complement immunofluorescence according to Reedman and Klein [4].

RESULTS

The cell number, which was initially of $1 \cdot 2 \times 10^8$, did not decrease below 1×10^8 (Fig. 1), with continuous multiplication compensating for cell death (to be published).

Cytogenetic examination at day 0 revealed the presence of aneuploid cells with a 45, XX, −2B, +1C karyotype. Four months later, the whole population of the established cells exhibited this same abnormal karyotype.

It has never been possible to demonstrate the presence of EBNA, even after treatment by Iodo-deoxy-Uridine. Nevertheless, it was possible to show the presence of EBV receptors by the rosette's technique. Approximately 70% of EBV producing cells, P_3J HR-1, formed rosettes with Reh cells. This marker is considered to be a property of B cells [14]. Other B cell markers have been detected such as membrane immunoglobulins and C_3 receptors (to be published).

DISCUSSION

This line is clearly the offspring of the abnormal leukaemic cells from the patient. It demonstrates characteristic features such as proliferation from the beginning of the culture, which differentiates it from other lymphoblastoid cell lines. In this particular case, the establishment could result from the association of immediate proliferation with progressive adaptation of the initially abnormal cells. Such a mechanism would differ from the usual mode of establishment where transformation *in vitro* seems to be a prerequisite of cell multiplication [3, 12].

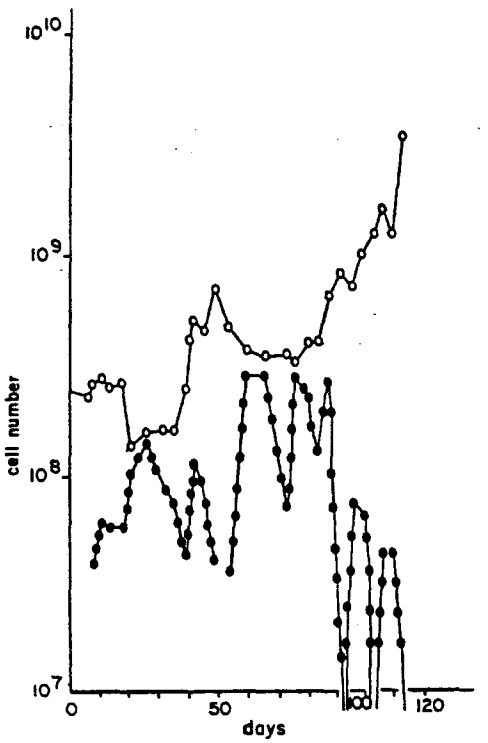

Fig. 1. Growth curve of the human leukaemic cell line: Reh

○——● *living cells*
○——● *dead cells.*

Other characteristics have never been described in leukaemic cell lines which lack EBNA. Until now the few leukaemic cell lines without EBNA demonstrate T type markers [4, 16]. Only exceptional lymphoma cell lines, lacking EBNA, and bearing some B cell markers, have been described before now [8].

We are currently studying some immunological and biochemical properties and the evolution of the cells of this line.

Data already obtained allowed us to utilize Reh cells for active immunotherapy of patients with acute lymphoid leukaemia [17].

Anaplastic Carcinoma of the Thyroid Gland

P. SCHOUMACHER, R. METZ, P. BEY and A. M. CHESNEAU
Centre Alexis Vautrin, Brabois-R.N. 74-54500 Vandoeuvre-les-Nancy, France

Abstract—*Thirty cases of anaplastic thyroid carcinoma are reviewed. Clinical and pathological characteristics are briefly reported. Prognosis is very bad: only 1 patient survived more than 2 years and treatment (surgery and radiotherapy) is rarely efficient; Adriamycin, used in 5 more recent cases, gave one good remission and has to be used in all cases in association with other treatments.*

INTRODUCTION

ANAPLASTIC carcinomas of the thyroid gland appearing in old people grow rapidly and are fatal. They are opposed to well differentiated carcinomas of younger people, which have a slower evolution and well defined treatment. The frequency of the anaplastic type is about 20–25% of all thyroid carcinomas.

MATERIAL AND METHODS

We present observations of anaplastic carcinomas collected at the Centre Regional de Lutte contre le Cancer de NANCY: 30 between 1957 and 1973 and 5 more recent but which concern patients having received adriamycin. During this period, 144 thyroid carcinomas were observed, anaplastic type representing 20%. All these cases have been reviewed by the same pathologist (Dr. Parache).

Pathological aspect

These carcinomas were classified in 2 groups:

(1) Small cell carcinoma (9 cases) with round cells of the same size as lymphocytes, acidophylic cytoplasm, well delimited. There are many mitoses and frequent nuclear abnormalities: the nucleus is round or oval, rich in chromatin, with one or more nucleols. These are either grouped, in dense accumulation, divided by fibrous septa or spread without order, diffusely. The distinction with malignant lymphomas is often difficult.

(2) Giant cell carcinoma (20 cases)

They have a pleomorphic appearance and we can see:

spindle-shaped cells,
giant cells with several nuclei,
polygonal or round great cells, with abundant cytoplasm and hyperchromatic nuclei.

(3) Other aspects

In one observation, the carcinoma was mixed with small and spindle-shaped cells.

In another case, we noted the association of a well differentiated carcinoma with an anaplastic one. One time the metastases were well-differentiated (vesicular in the liver) and the primary was a giant cell anaplastic type.

Clinical data

The extreme ages at time of diagnosis were 30 and 87 (average 66). Sex ratio showed 27 women for 3 men. The small cell type was observed only in women.

Pre-existent goitre was found in 16 cases for at least 4 years (maximum 19 years).

One patient, a 72-year-old woman, was irradiated 35 years before diagnosis for a simple goitre by external radiotherapy.

None of our patients received I131 before diagnosis. Seven patients received iodine or antithyroid drugs many years before diagnosis.

The beginning of the symptoms is usually sudden. Time between the first symptom and the diagnosis is 3 months in average. The first symptoms are:

appearance of a goitre or modification of an old one (2 cases)
cervical or mediastinal compression: dyspnea, dysphagia, dysphonia, pain
asthenia, loss of weight
cervical lymph node involvement (17 cases)
metastatic disease (7 cases, essentially pulmonary).

We never observed dysthyroidism: biological and isotopic examinations were normal or subnormal. Inflammatory signs were often present. Anti-thyroid anti-bodies were found in 3 cases on 6 studied. Thyroid scan showed no fixation on the tumoral region. Metastases never fixed I131.

Table 1. *Summary of observations*

No.	Age	Sex	Old goitre	Pathology	Treatment	Survival	
						From 1st symptom	From diagnosis
1	82	F		Small cells	RX	5 months	3 months

12	69	F		Giant cells	Lobectomy + Neck dis., RX	6 months 1/2	6 months
13	86	F		Small cells		3 months	6 days
14	72	F		Giant cells	Tracheotomy, RX, Chemotherapy	8 months	6 months
15	64	M		Giant cells	T.T., RX, Chemotherapy	8 months	6 months
16	63·5	F		Giant cells	Tracheotomy, RX	4 months	1 month 1/2
17	55·5	F	15 years	Giant cells	RX, Chemotherapy	6 months	4 months 1/2
18	18	F	32 years	Giant cells	Incomplete thyroidectomy	2 months	1 month
19	58·5	F	old	Giant cells	RX, Chemotherapy	5 months	3 months 1/2
20	58·5	F	19 years	Giant cells	RX, Chemotherapy	6 months	5 months
21	75	F	30–40 years	Giant cells	Tracheotomy, RX	4 months	2 months
22	79·5	F		Small cells	RX	5 months	2 months
23	44·5	M		Giant cells	Incomplete Treatment (?) RX, Chemotherapy	18 months	11 months
24	68	F	4 years	Giant cells	RX, local chemotherapy	1 month	18 days
25	67·5	F	old	Giant cells	RX	6 months	3 months 1/2
26	65·5	F	10 years	Giant cells	RX	4–5 months	2 months 1/2
27	69	F		Giant cells	RX, Chemotherapy	9 months	5 months
28	69	F		Giant cells	T.T., Tracheotomy, RX, Chemotherapy	3 months	1 month 1/2
29	87	F		Small cells	RX	2 years	alive
30	69	F	4 years	Small cells	RX	8 months	6 months

RESULTS

The prognosis was very bad: average survival of the serie is 8·4 months (11 months for small cells carcinomas and 7·2 for giant cells carcinomas). Only 33% were alive after 6 months and 25% one year after the diagnosis.

The cause of death was local evolution in 75% and metastatic disease in 25%.

Treatment seemed to have a low influence on the survival:

Surgery was done in 13 cases.

4 total thyroidectomies (maximum survival of 6 months),

5 lobectomies with or without neck dissection (maximum survival of 16 months),

4 cases: palliative surgery (tracheotomy and biopsy).

External irradiation was done in 28 patients. A good tumor response (regression of more than 50% of the initial volume) was observed in 50% of patients who received more than 4000 rads. One patient is in total remission at 2 years without metastases.

I131 was used in one case without effect.

Chemotherapy: multiple drugs treatments were used on one third of the patients: no objective result was noted. Adriamycin was used more recently. Five patients, out of the present study received this drug (Table 2). There was an objective remission in only one case: the patient is still alive 6 months after irradiation and adriamycin treatment, but with a residual tumor.

Table 2. Results of therapy with adriamycin

Age	Sex	Pathology	Adriamycin dosage (mg)	Survival	Objective result		
					>50%	<50%	Unsuccess
72	F	S.C.	215	6 months alive	+		
40	M	G.C.	340	6 months			+
64	F	S.C.	420	4 months		+	
66	M	G.C.	400	3 months alive			+
72	F	G.C.	400	11 months			+

DISCUSSION

The study of this group of patients shows the usual characteristics of anaplastic carcinoma of the thyroid gland. According to publications, we find patients 60 or over, with old goitre which grow suddenly and rapidly, compressing neighbouring organs.

Pathological studies show 2 groups: giant cell carcinomas which when they are of spindle-shaped type must be distinguished with sarcoma and small cells that must not be confused with malignant lymphomas. Histogenesis from well differentiated carcinoma is supposed.

Prognosis stays very bad and, if surgery is efficient in the rare little tumor, I131 is always inefficient and external radiotherapy can sometimes give a remission in the small cell type. With chemotherapy, especially adriamycin, good remissions have been reported, and this treatment has to be used in all cases with surgery or radiotherapy. When a spectacular remission is observed with adriamycin or radiotherapy, the diagnosis of lymphoma can be discussed.

The Clinical Significance of Skeletal Scintigraphy in the Management of Carcinoma

R. E. TREURNIET,* P. H. COX† and A. J. BELFER†‡
**Department of Internal Medicine of the Rotterdamsch Radio-Therapeutisch Instituut, Groene Hilledijk 301, Rotterdam, The Netherlands,*
†Department of Nuclear Medicine of the Rotterdamsch Radio-Therapeutisch Instituut, Groene Hilledijk 301, Rotterdam, The Netherlands

Abstract—*The majority of skeletal metastases originate via localization in the bone marrow. A study of the various $^{99}Tc^{m}$ polyphosfate complexes available for skeletal scintigraphy suggests that the use of short chain polyphosphates with a significant bone marrow uptake is advantageous in detecting skeletal metastases at an early stage.*

MATERIAL AND METHODS

THERE is little doubt that the introduction of skeletal localizing technetium compounds has made a significant contribution to the early diagnosis of pathological changes involving the skeleton. There are a number of complexes in current use and with all of them it has been possible to detect malignancy several months before they become visible to X-ray investigation [1].

Work in our laboratories has shown that the degree of localization in the skeleton is variable and depends upon the nature of the phosphate used. Phosphates with a strong chelating effect, such as diphosphonate, pyrophosphate and monofluorophosphate are rapidly cleared from the blood and localize primarily in bone. Others, such as the short chain polyphosphates also localize to a high degree in bone, but also have a significant uptake in bone marrow [2].

Hashimoto [3] suggested that 80% of bone metastases originated via the bonemarrow and therefore it would appear that the use of polyphosphate with a high degree of bonemarrow uptake should be advantageous in detecting malignancy in comparison with the more bone specific complexes. A comparison of polyphosphate localization in skeletal metastases with pyrophosphate, which has a low bonemarrow uptake, clearly showed a significant difference in the number of lesions detected, the pyrophosphate visualizing 23% less lesions [5]. This would appear to be of some significance since it has been shown that the diagnostic accuracy of polyphosphate scintigrams, in the absence of other clinical signs of malignancy, is in excess of 90% [6].

In this presentation a retrospective review has been made of 259 polyphosphate scintigrams. These have been classified according to the nature of the primary diagnosis (Table 1). For the scintigraphic study 8 mCi $^{99}Tc^{m}$ polyphosphate (Diagnostic Isotopes Inc.) was administered intravenously three hours prior to preparing scintigrams by means of a Nuclear Chicago HP gamma camera. This polyphosphate has a molecular weight of 4–6000 and a bone/bonemarrow uptake ratio of 4:1.

In Table 2 the number of patients with positive scintigrams has been compared with the X-ray examinations. Table 3 shows the results obtained with 118 of the patient samples, who presented with skeletal associated pain as the only clinical sign of metastases. In 5 cases the scintigram was negative and the X-ray positive. Information on these cases is given in Table 4.

DISCUSSION

These first retrospective studies suggest that Tc-polyphosphate complex is a reliable reagent for the early detection of skeletal metastases

Skeletal X-ray	41	21	197

Table 3. Verification of scintigram by follow up in patients with known primary tumours and skeletal associated pain as the only visible symptom of metastatic disease

Scintigram	Positive	Doubtful	Negative
Subsequent identified Skeletal lesions on X-ray	49 / 10	44 / 5	14 / 1
Number of scintigrams verified by follow up (X-ray cytology etc.)	92%	60%	86%
Not verified (possible faulty diagnosis)	8%	14%	14%

Table 4. Verifications negative scintigrams with positive X-ray examination

Scintigrams negative	X-ray positive	Verification
1	1	surgical examination negative for metastases.
1	dubious	post mortem negative.
2	2	not verified.
1	1	irradiated area (see text).

with certain advantages over more bone specific reagents such as pyrophosphate. The diagnostic value in comparison with X-ray is obvious (Table 2) and the degree of accuracy is high (Table 3).

In the few cases with negative scintigrams and positive X-rays the scintigram result was substantiated in 2 cases and not verified in 2 cases. In the fifth case metastatic disease was demonstrated, but the lesion had been irradiated prior to scintigraphy. [7] demonstrated that irradiated regions show reduced $^{99}Tc^{m}$ complex uptake, which explains the negative scintigram.

In clinical terms $^{99}Tc^{m}$ polyphosphate scintigraphy can be used to detect skeletal metastatic disease with a high degree of reliability. In general it was found that lesions could be detected on an average 6·2 months before the X-ray became positive (σ 4·4). The early detection of skeletal lesions facilitates therapy planning and the sensitivity of the technique appears to make the possibility of evaluating the response to therapy. The response of irradiated regions has been clearly demonstrated [8], [7] and we have also observed similar response to steroid therapy.

A typical example of the latter is shown in Fig. 1. In this patient a reduction in polyphosphate uptake following Lynoral treatment can be seen. That this is a positive response of the lesions to the treatment is shown by the fact that new lesions can be seen to be developing in the follow up scintigrams, so that the reduced uptake in the old lesions can only be explained by a therapeutic response.

Therapeutic Effect of Prednimustine (LEO 1031) in Various Types of Leukaemia

L. BRANDT* and I. KÖNYVES†

**Department of Internal Medicine, University Hospital, 221 85 Lund*

†*Research Laboratories, AB Leo, 251 00 Helsingborg, Sweden*

Abstract—*Prednimustine, a chlorambucil ester of prednisolone, is known to be effective in the treatment of chronic lymphocytic leukaemia. In a pilot study the drug was administered to seven patients more than 60 years old (mean 71) with acute myeloid leukaemia (AML). Complete remissions were obtained in two patients. Prednimustine was also given in combination with vincristine to four adults younger than 60 years (mean 43) resulting in two complete remissions. One patient with acute lymphocytic leukaemia also obtained a remission with this treatment. The remission was not preceded by a drug-induced pancytopenic phase in any of these five patients.*

INTRODUCTION

PREDNIMUSTINE, a chlorambucil ester of prednisolone [1] is effective with high therapeutic indices in several animal tumours [2]. It is known that the killing effect on L1210 leukaemia cells compared to the effect on normal resting haematopoietic cells is superior to any other alkylating agent tested in this system [3]. The drug is of value in the treatment of human chronic lymphocytic leukaemia (CLL) [4, 5]. In the present report it is demonstrated that Prednimustine may be useful also in the treatment of acute leukaemia.

It has been stated that patients with acute myeloid leukaemia (AML) have to survive a period of drug-induced bone marrow hypoplasia and pancytopenia before remission can be obtained [6–8]. Current intensive treatment of acute leukaemia in adults will give an overall remission rate of about 50–60% [7]. In patients over the age of 60 a remission frequency of about 15–30% and a median survival time of only 0·5–2 months have been reported [9–13].

With the above considerations in mind we initiated a pilot study in AML patients over the age of 60. It was decided to postpone chemotherapy until a pronounced need for transfusions arose, or neutropenia with infections or thrombocytopenia with a tendency to bleeding, justified an attempt to induce a remission. Moreover it was considered justified to try a chemotherapy regimen known to be associated with a minimum of toxicity to normal haematopoietic tissue. Prednimustine was therefore given in doses known to have an antitumour effect without serious toxicity to normal haematopoietic tissue in lymphocytic lymphoma [4] and in mammary carcinoma [15].

Since it soon became evident that the drug can induce remissions in elderly patients with AML the pilot study was extended to include also younger adults with AML or acute lymphoblastic leukaemia (ALL). Because there is evidence that younger patients may generally tolerate combination chemotherapy better than the older ones, and since the use of combinations of drugs is superior to single drug treatment [7] it was decided to try Prednimustine in combination with vincristine.

MATERIAL AND METHODS

AML group A was comprised of seven patients, six females and one male, aged 61–78 (mean 71) years. It was considered that chemotherapy was indicated when one or more of the following criteria were fulfilled: (1) anaemia requiring frequent transfusions, (2) granulocytopenia with infections, (3) thrombocytopenia with a tendency to bleeding. For remission induction Prednimustine was given orally in a daily dose of 20–60 mg. As maintenance treatment after the remission induction 16–20 mg of Prednimustine was given daily.

AML group B was comprised of four patients, two females and two males, aged 26–60

(mean 43). Treatment began immediately after the diagnosis and for remission induction 60–80 mg Prednimustine was given daily in three or four doses. In addition vincristine 2·5–3·5 mg was given i.v. once a week or once every two weeks. As maintenance treatment after remission induction, a daily dose of 24–30 mg of Prednimustine was given.

ALL. One patient was treated as the patients in AML group B.

Blood transfusions were given to all patients as required. Platelet concentrates were not administered. Infections were treated with various combinations of antibiotics without following any fixed schedule. Patients were considered to be in remission if their bone marrow contained no more than 5% of blast cells and if their blood granulocyte count and platelet count were at least 1500/μl and 100,000/μl respectively.

RESULTS

AML group A

In *two of the seven* patients complete remissions were obtained. The periods for remission induction are shown in Figs. 1 and 2. In patient E.P. remission was induced without a preceding pancytopenic phase. In patient K.G., with an unusually high neutrophil count at diagnosis, the number of neutrophils was just above 1000 μl on one occasion, seven weeks after starting treatment, but otherwise neutropenia or thrombocytopenia were not noted.

AML group B

Remissions were obtained in *two of the four* patients. Haematological data during the period of remission induction are given in Figs. 3 and 4. As in the elderly patients the remissions were not preceded by a drug-induced pancytopenia.

The period of survival after the diagnosis together with the time of survival after the start of chemotherapy, and the duration of remission for each AML patient are given in Table 1.

ALL. In the patient with ALL a remission was also obtained without preceding aggravation of neutropenia and thrombocytopenia (Fig. 5).

DISCUSSION

In this study of eleven adult patients with AML and one with ALL, five complete remissions were obtained, all without a preceding drug-induced pancytopenic phase. These data indicate that the current concept of bone marrow hypoplasia as a pre-requisite for remission in AML must be seriously questioned. It has been demonstrated that chemotherapy programs with only a moderate toxicity to normal haematopoietic tissue may be advantageous in adult AML since with aggressive therapy there is a considerable morbidity and mortality due to bone marrow depression during remission induction [16]. If a non-aggressive treatment results in a remission rate comparable to that obtained in patients treated more aggressively, it would be expected that the time of survival becomes lengthened in AML.

In our group of seven patients over the age of 60 two complete remissions have been obtained which may be comparable to the frequency of 15–30% remissions reported in larger series of aggressively treated elderly patients. In the younger adults three out of five have obtained remissions, two patients with AML and one with ALL. This result may be comparable to the frequency of 50–60% remissions reported in larger series of adult acute leukaemia [7].

Obviously, more patients have to be studied before the remission rate, the periods in remission and the time of survival, can be compared to the results of more intensive treatment. However, nine out of our eleven AML patients (82%) have survived for more than six weeks after the start of chemotherapy.

Previous studies of aggressive treatment of patients with AML report a survival of more than six weeks in 67% [12], 52% [13] and less than 50% [11] of the cases. Although based upon a small number of patients with the high median age of 66, the results of this clinical study compare favourably with those mentioned above.

In cases of acute leukaemia, Prednimustine may reduce the amount of leukaemic tissue without seriously suppressing the normal production of blood cells within the bone marrow tissue. Despite the continuous administration of the drug, there was an increase in neutrophils and thrombocytes in several patients during remission induction. These findings are in good agreement with previous clinical studies [14, 15] regarding the low toxic effect of Prednimustine on normal bone marrow tissue, when patients with lymphocytic lymphoma and mammary carcinoma are exposed to comparable doses. The interesting possibility is indicated, that an alkylating agent may possess a more specific anti-tumour effect and a lower toxicity in normal cells, when bound to a corticosteroid.

Induction Chemotherapy of Non-Hodgkin's Malignant Lymphomas

Preliminary results of a controlled trial*

J. CHAUVERGNE, M. DURAND, B. HOERNI,† G. HOERNI-SIMON, R. BRUNET and C. LAGARDE

Fondation Bergonié, Bordeaux

Abstract—*Thirty-three patients have been included in a randomized trial comparing cyclophosphamide + vincristine + prednisone (CVP) + VM 26 (CVPV) and CVP + adriamycine (CVPA). The tolerance is good for the two regimens. There is no difference between the two protocols, which clearly give better results than CVP alone.*

NON-HODGKIN'S malignant lymphomas are very often disseminated and this requires a systemic treatment by chemotherapy. After two previous controlled trials comparing several modalities of a triple association with cyclophosphamide, vincristine and prednisone (CVP, 1, 2), we have studied the usefulness of adding VM26 or adriamycin to CVP. Preliminary results of this new trial are reported here.

MATERIAL AND METHODS

From 1st April, 1974 to 30th October, 1975, 33 patients were included. For all patients the diagnosis of non-Hodgkin's lymphomas was verified cytologically and histologically and there was an indication of induction chemotherapy before further radiotherapy or maintenance chemotherapy. No patient over 70 years old was included. These patients were assigned randomly to one of the two regimens of chemotherapy. In spite of the randomization, the prognostic factors were significantly worse for the patients of the first group than for those of the other one; the main characteristics are shown in Table 1.

The two regimens of chemotherapy are detailed in Table 2. One cycle only was given to each patient. All applied treatments are evaluable.

Table 1. Main characteristics of patients included in the trial

	IV	7	1

RESULTS

On the whole the tolerance was excellent. No treatment was stopped because of clinical toxicity; 3 treatments with CVPV and one with CVPA were stopped because of hematological toxicity.

The efficiency of treatment, as evaluated immediately after the end of chemotherapy is shown in Table 3. It appears the complete failures were obtained only with CVPV but it seems that this fact is related mainly to osseous

Tumour regression >50%	43	52%	12	73%
Complete regression	4		12	

*Previous personal trials.

localizations treated with this protocol. On the whole there is no significant difference between the two regimens.

COMMENTS

Until now there has been no difference between the effects of the two regimens of chemotherapy studied in this trial. Nevertheless, it is possible to make an historical comparison with previous trials (Table 4). It appears that the addition of VM26 or adriamycine to CVP offers a significant improvement in comparison with CVP alone for complete regression, or all regressions of more than 50%. The toxicity is mild but no patient over 70 years was treated.

This trial is going on currently, and the place of these induction chemotherapeutic regimens in the over-all treatment of non-Hodgkin's lymphomas is now under study.

Remission Induction Chemotherapy in Acute Myeloid Leukemia

Preliminary results

P. DUJARDIN,* M. SCHNEIDER† and P. AUDOLY*

**Hopital de Cimiez, Nice, France,*
†*Centre Antoine Lacassagne, Nice, France*

Abstract—*In 7 cases of proliferative AML, a pre-induction of 5 days of L-asparaginase followed by a chemical induction combining daunorubicine and cytosine arabinoside, has allowed us to obtain 6 complete remissions out of which 5 were durable. This preinduction has shown a very marked decrease of blood cells in 5 cases out of 7.*

INTRODUCTION

INDUCTION treatment of acute myeloid leukemia has made great progress in the last decade, producing in most centres having hematologic support facilities, more than 50% complete remissions during the first phase of the illness.

The application of a protocol combining:

(1) cytosine arabinoside: 100 mg/m² in 8 hr infusion every day, from day 1 to day 7, and

(2) daunorubicine: 60 mg/m² i.v. day 1 and day 2, has allowed us to obtain 60% complete remissions in 20 cases treated with a mean remission of 10·5 months.

The analysis of failures of this treatment shows the importance of age, the frequency of fatal accidents during induction and the resistance of proliferative tumour types with hepatosplenomegaly. For this last type, we have modified our protocol: the increase of dosage did not increase the efficacy and resulted in the increased frequency of lasting and fatal aplasia. The addition of another drug was necessary and we chose L-asparaginase despite the studies against its efficiency in AML [1]. The use of L-asparaginase alone would give only 10% complete remission [2]. However, in most cases, this treatment shows an important drop in circulating myeloblasts [3].

A few new trials have shown good results in chemotherapy combinations using L-asparaginase [4] and have convinced us to make this choice.

L-Asparaginase administered in pre-induction allows a great reduction of myeloblasts without important modification of the normal cells.

MATERIAL AND METHODS

We have used as a scheme:

L-asparaginase: 50,000 U/d i.m. or i.v. d1 and d5,

daunorubicine: 60 mg/m²/d i.v. d6 to d7,

cytosine arabinoside: 100 mg/m²/d in 8 hr infusion d6 to d7.

This treatment was used on 7 patients with a proliferative acute myeloid leukemia. The patients' age varied between 15 and 62; 6 patients were at the first phase of their disease, one at the first relapse.

RESULTS

We have observed one death during induction due to a hemorragic syndrome. Six treatments have succeeded without intercurrent incident. Aplasia was constant and durable in all cases. This aplasia lasted from 18 to 31 days (mean: 24 days) during which time white blood cell transfusions were necessary.

Complete remission was obtained in 6 cases where we applied the treatment completely. In 5 cases this remission was excellent and actually these observations have been noticed for a period of 4 months. In one case, one patient in remission died two months after the treatment from a cardiac accident. In one case of complete remission we noted a first relapse.

The analysis of these remissions showed that, out of 7 cases 5 had a drop of peripheral white

blood cells during preinduction with L-asparaginase, bringing the patients to 3/5000 leucocytes during induction.

This treatment has also been used in 2 cases of transformed CML resulting only in 2 partial remissions.

DISCUSSION

These results led us to simplify our therapeutic protocol:

in the initially low proliferative types, in elderly patients, we use the 2 drug induction combination especially when we cannot count on prolonged hematologic support

in proliferative types, when donors of white blood cells are available, the triple-drug combinations can be used.

This approach can be extended later if the quality and the duration of the remission obtained by this means proves itself superior to the classic treatment.

Treatment of Adult Acute Myeloid Leukemia

D. FIERE, P. A. BRYON, P. FELMAN, C. MARTIN, P. Y. PEAUD and L. REVOL

Unite de Chimiotherapie, Service des maladies du sang, Hopital Edouard Herriot, Pavillon E BIS, F, 69 374 Lyon Cedex 2, France

Abstract—*Between November 1974 and October 1975, 50 acute myeloid leukemias in first perceptible phase received according to their initial stade, an induction treatment either with daunorubicine vincristine cytosine arabinoside or with cyclophosphamide, vincristine, cytosine arabinoside in reduced dose.*

When, in complete remission, patients were treated with consolidation and maintenance cyclic chemotherapy, prevention of central nervous system involvement, androgenotherapy and, by randomisation immunotherapy or not with B.C.G.

An overall remission rate of 68% and 75% with daunorubicine induction regimen were obtained; it is too early for the evaluation of remission duration.

THE TREATMENT of adult acute myeloid leukemia has been significantly improved during the last few years. Combination chemotherapy, improvement in supportive care, immunotherapy or other stimulating factors are responsible for better therapeutic efficiency [1–3]. We report here the preliminary results of a protocol (L 275) for the induction and prolongation of remission in acute myeloid leukemia.

1. PATIENTS AND METHODS

(1) *Patients*

Between November 1974 and October 1975, 50 new patients entered in our center with A.M.L. in first perceptible phase. All these patients were included. There were 27 males and 23 females whose age ranged from 15 to 78. Ten patients were over 65, of these 8 were females, and median age was 72. Other 40 patients were under 65 with a median age of 50.

In all patients, bone marrow smears were classified on the basis of the subdivision of acute leukemias proposed by Mathe *et al.* [4]. 43 were typical myeloblastic leukemias, 5 promyelocytic leukemias, 3 myelomonocytic leukemias.

Peripheral white blood cells count varied widely as shown in the Table 1 and tumoral involvement was noted in 14 patients.

(2) *Treatment protocol*

(2.1) *Remission induction.* Induction treatment was modulated according to the initial state of patients and therapeutic response. Two inductions regimens were used (Table 2):

Either, three drugs: daunorubicine (DNR), vincristine (VCR) and cytosine arabinoside (CAR) were administered in a seven days course which may be prolonged or shortened according to the peripheral white blood cells count.

Or in patients over 65 and/or with cardiac, hepatic or renal disease, thus presenting a high risk of treatment failure, a five days course was

Table 1. *White blood cell count at the onset of treatment*

Vincristine			1				
Cytosine arabinoside				240	240	240	240
"High risk" course.							
Cyclophosphamide	600						
Vincristine		1					
Cytosine arabinoside			210	210	210	210	210

Modulation in normal course: Day 7 if WBC $\geq 1500/mm^3$. Cytosine is given on day 8 WBC $\leq 1000/mm^3$. No Daunorubicine injection on day 7.

performed where cyclophosphamide (CPM), took the place of daunorubicine and cytosine dose was reduced.

During the induction phase, all available supportive care was used: isolation, quick metabolic-defect correction, platelet or white blood cells given if necessary in large amounts, empirical and massive antibiotherapy once fever occurred.

(2.2) *Maintenance therapy.* When patients achieved complete remission (C.R.) three successive phases were set up in the treatment.

(*a*) Consolidation therapy. A new course of induction regimen was given once per month for three months. In normal regimen the last daunorubicine injection was omitted, so that the total daunorubicine dosage at the completion of the consolidation was 540 mg/m^2.

(*b*) Prevention of central nervous system involvement. After a period of 2 weeks rest, 2400 rads were delivered in 18 days over the skull above C2. During the same period of time 5 injections of 12 mg/m^2 of methotrexate were given intrathecally.

(*c*) Maintenance therapy. After another 2 weeks rest, an intermittent five days course of chemotherapy (Table 3) was instaured on every 4 weeks during the first three months, then on every six weeks for three months and then systematically every eight weeks.

Table 3. *Maintenance chemotherapy course dose mg/ b.s.a.*

Day	1	2	3	4	5
Cyclophosphamide	600				
Methylglyoxal	200				
Vincristine		1			
Cytosine arabinoside			210	210	210

After the first course of consolidation therapy a randomisation was made between chemotherapy and chemotherapy plus immunotherapy. In the latter case, Institut Pasteur BCG was applied by means of a heaf gun: 4 multiple punctures at each time, at weekly intervals, and was stopped 2 weeks before the next chemotherapy course.

All patients received also after the first consolidation course, oral androgenotherapy with stanozolol (2 mg/kg).

2. RESULTS

(1) *Remission induction.*

Complete remission was obtained in 34 cases. Failure and death during induction occurred in 16 cases. With the "normal" regimen given to the 40 patients, 30 (75%) were in remission. With the "high risk" regimen, 4 patients out of 10 were in remission (40%). The overall remission rate for all patients was 68%.

Table 4. *Results of induction treatment*

Protocol	Normal	High risk	Total
Total	40	10	50
C.R.	30	4	34
%	75	40	68
Died in induction	10	6	16

In the normal regimen, the remission arises between the fifteenth and the twenty-fifth day, with a median at eighteen days. Thirty patients entered in remission: 27 after one course, and in three cases, complete remission was only achieved after a second induction course. In 25 cases, a complete course was realised, in 7 cases another day of cytosine was administered and in 8 cases, the course was shortened with no daunorubicine injection on the seventh day.

In the regimen for patients with a high risk of failure, 4 complete remissions were obtained after 2 and 3 courses of treatment.

Life threatening complications occurred frequently during the induction phase. Infectious complications with fever for more than five days were almost constant and were the major risk. Hemorrhage due to thrombocytopenia or disseminated intravascular coagulation present in 6 cases were also dangerous.

(2) *Complete remission.*

It is too early for the evaluation of remission duration and there is no sufficient patient to evaluate immunotherapy and androgenotherapy.

Seven patients died, three of which were older than 65. Five patients relapsed and two others died from intercurrent disease in complete remission.

Table 5 shows the duration state of 34 patients in C.R.

Toxicity or side effects of treatment of remission were not limiting. Headaches are frequent during skull irradiation and after lumbar punctures. Alopecia is common.

3. DISCUSSION

Improvement in remission rate of acute myeloid leukemia arises by two ways:

(1) Intensive combination chemotherapy re-

Table 5. *Survival from diagnosis* 34 *patients in C.R.*

Alive		+		+	+				+			
		+		+	+		+	+	+			
		+	+	+	+		+		+			+
In C.R.		+	+	+	+	+	+	+	+	+	+	+
Month	1	2	3	4	5	6	7	8	9	10	11	12
Relapsed					±			±				
and			±			±	±					
died					±			±				

duces quickly the total body burden of leukemic cells and so minimises the duration of aplasia before occurrence of remission [5].

(2) Better and more effective prevention and supportive care overcome more frequently live threatening complications [6]; with such a management in induction, remission rates of 50 percent or more become the rule.

McCredie [7] with adriamycine, vincristine, cytosine arabinoside reports a 83% remission rate in 46 patients. Yates, [8] with cytosine and daunorubicine obtains 87% remission rate, in patients under 60 years old and 25% in patients over 65. Holland [9] shows that seven and three days course of cytosine arabinoside and daunorubicine are better than five and two days course to inducing remission.

In this study, similar results appears with an overall remission rate of 68 and 75% with the normal induction regimen.

Now, improvement in the duration of the remission must be obtained: cyclic chemotherapeutic course, immunotherapy with BCG or extracts, blast cells, or other stimulating factors, like androgenotherapy seem useful and promising and must be investigated [10].

The results of the L 275 protocol to date appear promising but the brevity of the study precludes any prediction at the time, as to the eventual duration of complete remission.

Obtention of C.R. rate as in ALL with less complications during induction, and exploration of the best regimen remission are now the major step in the treatment of AML.

Kinetic Conditions Preventing the Eradication of Human Leukemia*

FELICE GAVOSTO
Istituto di Semeiotica Medica–Università di Torino–Torino, Italy

Abstract—*Attempts to exploit the proliferation kinetics of human leukemic cells in order to improve therapeutic protocols have been made in recent years. While in some instances it has proved possible to eradicate the disease in animals, relapse is a virtually constant feature in humans.*

Failure in this respect can be explained in terms of kinetic data themselves, keeping in mind that there are at least three main kinetic obstacles to the definitive eradication of human leukemia:

— *the presence of a large number of cells that are out of cycle and hence less susceptible to the drug attack;*
— *the persistence, even after treatment, of cells in a Go position with a potentiality of leukemic stem cells;*
— *the persistence of a contrary flux from Proliferating to Go compartment even during the action of drugs.*

INTRODUCTION

THE MANAGEMENT of human leukemia has been improved mainly by the analysis of the proliferation pattern of leukemic cell populations besides the introduction of polychemotherapeutic associations. The fact remains, however, that remissions occur in 90% of lymphoblastic and 50% of myeloblastic forms and, what is worse, relapses are particularly frequent, so that cases of real cure are quite exceptional.

Kinetic studies, even if proved so far incapable of giving a definitive support to a radical treatment of the disease, are prepared to give explanation of their own lack of success that deserves consideration. An analysis will be made, in this paper, of the kinetic conditions present in human acute leukemia, which can be considered the greatest obstacle to the eradication of leukemic cell population with present drugs.

MATERIAL AND METHODS

The results of kinetic investigations on human acute leukemia developed over the last fifteen years in this and other laboratories are considered for the present study. As a conclusion of these investigations a kinetic growth model has been proposed for acute leukemia cell population: it includes a Go phase blast pool, whereas the leukemic stem fraction is considered as consisting of part of the blast population, the majority of the fraction itself being out of cycle (Go) at any given moment: one quota only of stem cells is active and feed the proliferating compartment which, by itself, is not selfmaintaining [1, 2].

ESULTS AND DISCUSSION

The pool of leukemic blast cells out of cycle (Go) that are relatively insensitive to the drug attack and, since they can act as stem cells, able to insure continuous replenishment of the proliferating compartment, is the first main obstacle to the eradication of the acute leukemia in man [3–5]. Only a part of leukemic cells are, in fact, responsive to cycle and phase specific drugs, while non cycle specific drugs have a poor effect on non proliferating blasts at the dose we must employ them. Consequently a more effective killing of leukemic cells cannot be achieved with present drugs except by complete recall into the cycle of blasts that become quiescent during the growth of the leukemic population. It is now clear that even this objective is out of reach and growth fractions (G.F.) near unity have never been attained in acute leukemia by procedures, such as synchronisation or recruitment, performed in

*This work has been supported by CNR (Rome).

order to increase the quota of cycling blasts.

The impossibility of eradicating all blasts in Go is particularly due to the following reasons:

(i) Asynchronous flux of blasts from Go to cycle after recruitment induced by drugs. In fact, the flow from Go into proliferating compartment is always discontinuous, even when it is augmented by drugs. Furthermore, it is always incomplete: the highest labelling index values so far obtained after administration of appropriate drugs are always associated with G.F. increases lower than unity [6]. This means that a Go compartment still persists with the presence of a true pool of leukemic stem cells capable of insuring self-maintenance and re-expansion of the blast population.

(ii) Persistence of a contrary flux from proliferating to Go compartment even during treatment. This fact, already suggested as a hypothetical possibility [6], has been recently proven by Pagliardi *et al.* [7] by studying two cases of acute lymphoblastic leukemia during the action of high doses of methotrexate. Both cases were also injected *in vivo* with tritiated thymidine. The label was given along with the drug in one case and just after its administration in the other. The persistence of a flux from proliferating to Go pool has been proven by the following evidences: blasts, labelled with the pulse of tritiated thymidine, persisted as non proliferating cells, as long as it was possible to detect leukemic cells in the peripheral blood after the administration of the drug; labelled mitoses appeared some days after the administration of the methotrexate: evaluation of DNA content showed that these mitoses gave rise to a population of non proliferating cells behaved as Go cells since they recommenced a proliferating activity after a long period of mitotic rest.

The fact that the existing drugs fail to discriminate between leukemic and normal stem cells is another main obstacle to the eradication of the leukemic cell population.

A marked failure of normal haemotopoiesis is a distinctive feature of leukemia. After remission induced by chemotherapy, however, the persisting normal stem cells are able to repopulate the bone marrow and release almost normally functioning blood cells. This situation can now be maintained for a long time with an appropriate administration of certain drugs, but eventually the leukemic cells return in detectable number and relapse will occur. Knowledge of the source of the cells which repopulate the bone marrow in remission and of the leukemic stem cells which reappear in relapse is scanty. It is probable that, when a high percentage of both leukemic and normal stem cells are destroyed by the therapy, the difference in proliferative speed, migrating and colonizing ability, will favour the return of normal haemopoiesis. In fact, as well known, in leukemia the malignant cells divide more slowly than normal ones. Furthermore, the results of the *in vitro* colony growth technique applied to human leukemic bone marrow revealed the paucity of colony forming cells in relapse and an almost normal number in remission [8, 9]. It is apparent that the activity of normal stem cells is suppressed when leukemic cell population develops. The understanding of the mechanisms leading to the suppression of normal stem cell activity in the course of leukemia is thus of cardinal importance: at present, however, we do not even know whether normal stem cells are reduced in number or merely inhibited in their ability of feeding the normal blood cell population.

We must consider that, when we start with a chemotherapy, we are dealing with a kinetic situation in which exists a marked failure of normal haematopoiesis, whatever this may be. Chemotherapy leads to a considerable reduction of the leukemic cell mass and hence of the leukemic stem cells: however, a persistent activity of leukemic stem cells even during the so-called "complete" remissions, is an almost constant feature [10]. This means that a sufficient number of leukemic stem cells able to insure the re-expansion of the leukemic cell mass have survived the action of the drugs, even if these are given at dosages near to the toxicity, and that remission is mostly based on the kinetic differences between normal and leukemic cells. Consequently, if we want to increase the reduction of leukemic cell population with present drugs incapable to display a discriminative effect between normal and leukemic cells, we have to push the treatment to a limit in which a severe bone marrow asplasia supervenes with the disappearance of the normal stem cells too.

CONCLUSION

From the above kinetic analysis the following conclusions can be drawn: (1) a complete eradication of a leukemic cell population requires the destruction of all its clonogenic cells; (2) the poor discrimination between normal and leukemic stem cells displayed by the drugs now available means that a complete eradication cannot be achieved without destroying at the same time the normal stem cells.

Combination Chemotherapy with Adriamycine, VM 26, Cyclophosphamide and Prednisone in Lymphosarcoma and Reticulosarcoma Stage III and IV

J. L. MISSET, P. POUILLART, D. BELPOMME, L. SCHWARZENBERG, M. DELGADO, M. GIL, C. JASMIN, M. HAYAT and G. MATHE

Institut de Cancérologie et d'Immunogénétique (INSERM) and Service d'Hématologie de l'Institut Gustave Roussy†*

Abstract—*This work presents the results obtained on 34 patients with disseminated lymphosarcoma and reticulosarcoma (Stage III and IV) with a cyclic combination of chemotherapy which combines adriamycin, epipodophyllotoxine (VM 26), cyclophosphamide, and prednisone. The complete remission rate is 56% of the patients who entered the trial, the response rate is 85%. Tolerance of the regimen is good. The study also demonstrated the prognostic value of the new histocytological classification of lymphosarcomas proposed by W.H.O.*

INTRODUCTION

THERAPEUTIC management of lymphosarcoma and reticulosarcoma has been modified in recent years under the influence of (a) better knowledge of the disease which has shown that most cases are already disseminated at the time of diagnosis [1–3] and are therefore, to be treated by chemotherapy, (b) discovery of new drugs which proved efficient in the treatment of these tumors, particularly VM 26 or dimethyl epipodophyllotoxin [1, 4] and adriamycin [5–7].

We present a preliminary study of a new combination of adriamycin, VM 26, cyclophosphamide and prednisone in the treatment of disseminated lymphosarcoma and reticulosarcoma, stage III and IV. This combination is based on the activity of each drug used alone [1, 4–8] and on the synchronization and potentiation obtained by sequential administration of adriamycine, VM 26, cyclophosphamide [9, 10].

It must be emphasized that some patients in the trial had already been treated by other chemotherapeutic regimens and/or radiotherapy. These patients can only make the results appear worse as compared to a population of patients in the first perceptible phase of the disease.

PATIENTS AND METHODS

Thirty-four patients (22 males and 12 females) aged 5 to 67 who received AVmCP regimen, as described in Table 2. All had lymphosarcoma or reticulosarcoma stage III or IV.

Twenty-one percent of the patients were in the first perceptible phase of the disease; 11 had relapsed once, and two were in the third perceptible phase.

The patients were classified according to the new histological classification of lymphosarcomas and reticulosarcomas proposed by W.H.O. [11].

Seven patients had "immunoblastic lymphosarcoma" stage III and IV; 4 had "lymphoblastic lymphosarcoma", 6 had "prolymphocytic lymphosarcoma", among which were the two "nodular lymphosarcoma" of the series; 5 had reticulosarcoma, two of which were bone primary localisation with lymph-node or pulmonary matastases. 12 patients could not be classified because of the lack of cytologic examination of the lymph nodes.

Table 1. *Treatment of lymphosarcoma and reticulosarcoma stage III and IV by AVMCP results*

	C.R.	I.R. 50%	Failure	Total
Immunoblastic	2	3	3	7
Lymphoblastic	4	0	0	4
Prolymphocytic	4	2	0	6
Reticulosarcoma	3	2	0	5
Unclassified	6	3	3	12
Total	16 56%	10 29%	5 15%	34

Table 2. Protocol of treatment of lymphosarcoma and reticulosarcoma stages III and IV with adriamycine, VM 26, cyclophosphamide and prednisone

Day 1	Adriamycine	40 mg/m²	I.V.
Day 2	VM 26 (epipodophyllotoxin)	60 mg/m²	I.V.
Day 3–4	Cyclophosphamide	300 mg/m²	I.M.
Day 3–4–5–6–7	Prednisone	40 mg/m²	P.O.

Table 3. Toxicity

Leucopenia 1·500 WBC	14
Thrombocytopenia 50·000	4
Regressive infection	2
Lethal infection	0
Alopecia	29
Nausea	2
Heart failure	1
Asthenia	0
Severe diabetes	1
Haemorrhagic cystitis	1
Pseudo anaphylactic acute intolerance to VM 26	1
Renal failure	2

Chemotherapeutic regimen is described in Table 2. Each cycle combines, on day I i.v. injection of adriamycine 40 mg/m², on day 2 VM 26 60 mg/m² by intraveinous infusions, on day 3 and 4, cyclophosphamide 300 mg/m² i.m. or i.v., on days 3–7, prednisone given orally at the dose of 40 mg/m².

The interval between two cycles, necessary to hematologic and immunologic restoration is 15–21 days. Eight such cycles are given in about six months.

(1) *Toxicity*

Toxicity is described in Table 3. It is mild or moderate. Leukopenia under 1500 white blood cells was observed in 14 cases with only two cases of regressive infection. Thrombocytopenia under 50,000 platelets occurred in 4 cases. No hemorrhagic complication was observed. Alopecia was practically constant. Nausea was mild. Other complications were rare.

(2) *Anti-tumor effect*

The overall response rate is very high. 85%, with a complete remission rate of 56%. Although the number of patients is still too small to draw definite conclusions, it seems that the various histocytological types have different sensitivity to the regimen. Two patients with immunoblastic lymphosarcoma failed to respond to the regimen, while the four patients with lymphoblastic lymphosarcoma and the four patients with prolymphocytic lymphosarcoma in the first perceptible phase underwent complete remission.

Moreover when complete remission was achieved it never lasted more than six months in immunoblastic lymphosarcoma while the duration of remission was over one year in all patients but one with lymphoblastic or prolymhocytic lymphosarcoma.

The remissions were obtained very rapidly, or often after the first cycle and all patients who underwent complete remission had achieved t after three cycles.

Figures 1 and 2 are tentative survival curves of all patients in the first perceptible phase

(Fig. 1) and of patients who underwent complete remission (Fig. 2). They seem to us very encouraging although they cannot yet be considered as significant.

DISCUSSION

We present a therapeutic regimen which shows a very high degree of efficacy in lymphosarcoma and reticulosarcoma. The drugs were chosen because of their maximal efficacy for minimal toxicity. Drugs with the high degree of toxicity like nitrosoureas were excluded from the regimen and tolerance of the regimen was remarkably good, at least on patients who had not been previously irradiated.

Although further study has to be done with a greater number of patients and longer time of observation, it seems that the classification proposed by W.H.O. for lymphosarcoma is of significant prognostic value.

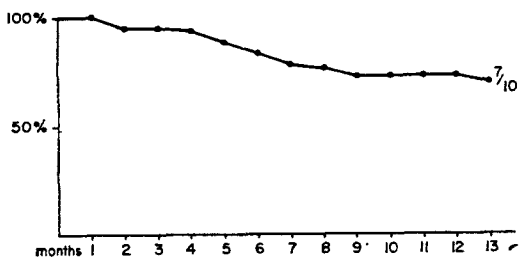

Fig. 1. Survival curve of 21 patients with lymphosarcoma and reticulum cell sarcoma. Stage III and IV treated with AVmCP in first perceptible phase.

Fig. 2. Survival curve of patients in C.R. with lymphosarcoma and reticulo-sarcoma. Stage III and IV treated with ADM, VM 26, CPM and PDN (N = 19 patients).

Cure of Metastatic Tumors by Chemotherapy

E. POMMATAU and M. BRUNAT*
Centre Léon Bérard, 28, rue Laënnec, Lyon, France

Abstract—*Twelve patients presenting metastatic tumors of various origin (testicular, ovary, prostate, uterus, soft part) have been treated more than five years ago by chemotherapy alone. An association of drugs (actinomycin D, cytoxan and methotrexate) or a monochemotherapy (either nitromin, trenimon, thiotepa or alkeran) have been used.*

The twelve patients are alive and well from 15 to 5 yr after.

In view of these good results we have treated all dysembryoplastic testicular tumors with chemotherapy since 1962. We add chemotherapy after surgery (orchidectomy and lymphadenectomy) whether the nodes are involved or not.

All of 17 patients without involved nodes are alive and well more than 3 yr and 13 out of 20 with nodes involved.

1. INTRODUCTION

IT WAS not previously thought possible to cure patients with metastatic disease by chemotherapy alone. Mathé and Kenis in a recent book and Brulé *et al.* state that only uterine choriocarcinoma and Burkitt's lymphoma are cured by chemotherapy alone. Perhaps some children too (such as those with neuroblastoma and sometimes Wilms tumors) can be cured.

Since the Houston Congress on Cancer a number of cases of apparent cures by chemotherapy have been published. We think that a complete regression of metastatic tumor for at least 5 years is a cure.

2. MATERIAL AND METHODS

Twelve patients having metastatic disease from various primary tumors were treated more than 5 years ago by chemotherapy, they are alive and well without evidence of disease.

Report on the first 6 cases was published in the Journal of Surgical Oncology in 1974 [3].

Cases no. 1, 3 and 4 are patients with dysembryoplastic testicular tumors with lung metastases. They were treated by the association of actinomycin D, cytoxan and methotrexate or nitromin. They are alive and well 10, 12 and 15 years afterwards.

Case no. 2 was also a patient with dysembryoplastic testicular tumor with lymph nodes involved and skin metastases. All disappeared with chemotherapy 11 years ago and there has been no recurrence.

Case no. 5 presented recurrent metastatic lymph nodes in the neck after surgery for a trabeculo-vesicular thyroid cancer. All nodes disappeared within two months of chemotherapy. He is alive and well 10 years later.

Case no. 6 was a young man presenting a small-cell sarcoma of the prostate with lung metastases which disappeared after chemotherapy. He is still well 14 years later.

Case no. 7 is a 37 year-old man presenting a large pelvic mass which had been incompletely removed (a mass of 4 cm dia was left. It was a malignant mesenchymoma). He then received a course of actinomycin D, cytoxan and methotrexate every 3 months for 18 months and was operated 19 months after the first surgical treatment because of persistent pain; there remained nothing in front of the sacrum and the histologic biopsy revealed only fibrous tissue.

He received one more course of chemotherapy after surgery and he is still alive and well without evidence of disease 5 years later.

Case no. 8 is a young woman operated on at the age of 10 for a benign right ovary tumor (folliculome). Five years later during an appendicectomy all was found well in her abdomen; 3 years later (she was 18 years old) she had a large tumor in her right side removed, it was a malignant dysembryoplastic tumor.

She had then one pregnancy, delivering a normal child and remained well for 11 years.

When 27 years old she felt pain in her right side and a large mass under her liver was discovered 2 years later. At this time there were lung metastases and a large calcified mass squeezing the right kidney. She received 2 courses of cytoxan, methotrexate and rufocromomycin. All lung metastases disappeared. Then she received actinomycin D, cytoxan and methotrexate and her I.V.P. was normal again. She was operated upon and a mass of 8 cm in diameter was removed, histologically it was necrotic tissue only. She is still alive and well, 7 years later.

Case no. 9: this 39 year-old woman had tumors of both ovaries removed, she had metastatic nodules everywhere in her abdomen even on the liver. She received some cobalt irradiation on her pelvis and a hormonal treatment (i.e. norfor* 80 mg/day for 4 years) and chemotherapy with thiopeta every week for one year, then every two weeks for one year. A further operation for an eventration 4 and a half years later revealed no lesion.

Case no. 10: this 47 year-old patient had bilateral ovarian tumor with ascites and lesions involving the diaphragm. She received first cytoxan without success, then alkeran every two months for a year, then every 6 months (2 courses). She is alive and well 5 years later without evidence of disease.

Case no. 11: this 47 year-old patient had had an hysterectomy for an uterine leiomyosarcoma. At that time she had mediastinal metastatic lymph nodes. She received rufocromomycin, cytoxan and methotrexate every 3 months for a year. All lesions disappeared, she is alive and well 5 years later.

Case no. 12: this 49 year-old patient had an hysterectomy in 1963 for a fibrom. Five years later she was operated upon for large and numerous tumors all over her abdomen. They were classified as "sarcome du chorion cytogene". She then received cytoxan and methotrexate a weekly dose two weeks running each months over a period of 6 months then every two months over a period of 18 months. She is still alive and well 7 years later.

We have left out the cases of uterine choriocarcinoma and those of neuroblastomas which are nowadays easily cured in a certain number of cases, by chemotherapy. We have left out the cases without histologic proof or without distant metastasis even if cured by chemotherapy alone.

*Norethindrone.

3. RESULTS

Twelve patients presenting either lung or lymph nodes metastasis or local recurrence from a testicular tumor in 4 cases, an ovarian tumor in 3 cases and uterine sarcoma in 2 cases and a soft part sarcoma, small cell sarcoma of the prostate and thyroid cancer have been treated with courses of a combination of drugs mostly actinomycin, cytoxan, methotrexate or monochemotherapy.

All their metastases have disappeared and they are alive and well without evidence of disease more than 5 years after.

4. DISCUSSION

All our patients were treated more than 5 years ago. Recurrences may happen 3 years after complete regression of metastatic lesions as Rutledge and we ourselves know such as in ovarian or testicular tumors. Five years is perhaps not long enough but so far we have not seen any recurrence after 5 years, unlike Chabner.

Those 12 patients had different primaries but there is an histologic pattern, only some tumors can regress by chemotherapy alone such as: testicular malignant dysembryoma, soft part sarcoma, adenocarcinoma of the ovary or cancer of the thyroid.

We have not seen cures in melanomas or kidney tumors which have been known to regress spontaneously.

The doubling time of the metastases in the lung had a very wide range of time. In patient no. 3, one metastasis had a doubling time of 6 days and in the same lung another metastasis had a doubling time of 21 days. In some cases the doubling time was very long as in ovarian tumors.

Our patients were rather young, the youngest being 14 years old, the oldest 61 years old, the mean age was 34 years.

Not every metastasis can regress. Here only lung, lymph nodes, intra abdominal nodules or skin nodules regressed. The type of chemotherapy was variable, some patients received only one drug, others had an association of 3 drugs, as done by Li; in 2 cases actinomycin D was replaced by rufocromomycin. As a rule the treatment lasted 2 years but in some cases it was stopped after one year and in 2 cases was pursued 4 or 5 years.

In a case the regression was apparently complete after the first course of treatment.

In some rare cases if we can cure patients with large metastatic tumors, radiologically visible how much more should we be able to

cure lesions only microscopically detectable. Studies on cellular kinetic and tumor volume seem to confirm this; so the fact that some patients can be cured by chemotherapy only is a positive argument for treating patients with adjuvant chemotherapy after surgery so as to try and clean out any metastasis which might be present even if not visible.

We add chemotherapy after surgery (orchidectomy and lymphadenectomy) in all dysembryoplastic testicular tumors whether the lymph nodes are involved or not.

With no nodes microscopically involved all of 17 patients treated more than 3 years ago are well with no evidence of disease and 13 out of 20 with nodes involved.

Treatment of Malignant Gliomas in Adults Using a Combination of Adriamycine, VM 26 and CCNU: Results of a Type II Trial

P. POUILLART,* G. MATHE, T. HOANG THY, J. LHERITIER, M. POISSON,† P. HUGUENIN, H. GAUTIER, P. MORIN and R. PARROT

Abstract—*Forty-three patients with inoperable and/or recurring malignant gliomas were treated with a combination of Adriamycine (45 mg/m²) and 4-dimethyl-epipodophyllotoxin D-thenylidene (VM 26) (60 mg/m² for two days). These cycles of treatment were repeated as soon as the hematological restoration was complete. The treatment was well tolerated and the clinical condition of 31 out of 43 glioblastoma patients improved during the two months after the beginning of the treatment.*

Examination of the results obtained reveals the following characteristics:

1. *A low degree of efficiency of this combination in the treatment of brain metastases, except for breast cancer metastases.*
2. *Absence of complete correlation between the clinical results observed and the cinegammagraphic developments.*
3. *Similarity of the results independent of the initial localization.*
4. *Establishment of a six-months median survival period, with ten patients at present in a state of apparently complete remission, 180–506 days after beginning of the treatment.*

THE CONVENTIONAL treatment applied in malignant brain tumours in adults consists of surgery and irradiation. The prognosis is poor as the mean survival time does not exceed 11 months [1]. The studies of Frankel and German [2] showed that the mean survival time was six months after extensive surgery alone and radiotherapy increases this survival median by about four months.

Experimental results in animals which were later confirmed in man [3–11] have shown the potential value of chemotherapy and led to the development of new therapeutic methods. We disposed of a limited number of effective drugs BCNU, VDR and VM 26.

In the present work, we have analysed the therapeutic results obtained by cyclic and sequential administration of adriamycine, VM 26 and CCNU in 43 patients with non resectable glioblastomas.

†Centre Médico Chirurgical Bligny, 91640, Briis-sous-Forges (France).

MATERIALS

Forty-three patients were included in this study, beginning in October 1973.

The average age of the 43 patients in this trial (12 women and 31 men) was 52·8 years, the youngest being 20 and the oldest, 71.

Age	*No. patients*
40	5
40–50	9
50–60	17
60–71	12

In 22 patients the tumours were surgically non resectable, either because of their size or their site. Seventeen patients had residual tumours following surgery, and six patients a recurring tumour after a first operation.

TREATMENT

Patients were submitted to intermittent cyclic sequential chemotherapy. Each five-day cycle of treatment included direct intravenous

administration on day 1 of 45 mg/m^2 adriamycine: on days 2 and 3, VM 26 (60 mg/m^2 per day) in 250 ml of isotonic glucose solution, in rapid 1·5 hr infusions, and on days 4 and 5, CCNU *per os*, at a dose of 60 mg/m^2 per day.

Each cycle of treatment was only resumed once hematological restoration was completed, that is, when the leucocyte count was 4/5 of the patient's initial treatment count and the platelet count half the initial count.

Before undergoing the first cycle of chemotherapy, all the patients were given an optimal dose of methylprednisolone which made it possible to reduce the intensity of *intra-cranium* hypertension syndrome manifestations. During this initial phase of treatment, before administration of the first chemotherapy cycle, patients were also given a daily 500 ml perfusion of 100% glucose hypertonic solution, a 500 ml infusion of hypertonic mannitol and 100 mg furosemide, injected i.v.

RESULTS

1. *Tolerance*

All patients underwent the trials considered in this study between two and 17 months ago.

(a) *Hematological disorders.* The intervals between chemotherapy cycles were solely determined on the basis of the time required for complete hematological restoration. *Leucopenia* was moderate and recovery was on the average complete between the 15th and 20th day after the end of the cycle. There were no cases of infection, but *thrombopenia* increased from one cycle to another with increasingly slow restoration. During these trials, *combination chemotherapy* was only resumed once the platelet count had resumed to at least 50% of the pretreatment level. The results, shown in Table 1, indicate a steady increase in the average duration of the interval between chemotherapy cycles. From the first to sixth cycles the duration of this interval increased from 31·6 to 42·2 days, the seventh interval lasting 65·5 days. In all, 170 cycles of treatment were administered to the 43 glioblastoma cases included in the trials and the average interval between cycles lasted 36·6 days.

Thrombopenia was never less than 75,000 mm^3 before the 5th chemotherapy cycle. After the sixth cycle, it dropped to 40,000 in seven patients but there were no cases of hemorrhage. Platelet restoration took a long time in six patients—86·6 days on an average, (ranging from 65 to 125 days) during which clinical relapse occurred.

(b) *Neurological disorders.* The only noticeable neurological complication was intensification of the signs intracranium hypertension during or between treatment cycles. It was observed during the 2nd chemotherapy cycle in 11 cases and during the 3rd cycle in three cases. Such signs disappeared within three days and their intensity was always attenuated by absorption of corticoids. No deaths were imputable to the increase of HT/C.

Table 1. Average increase in the intervals between chemotherapy cycles

Interval No.	No. of patients	Length of interval
1	40	31·6 days
2	33	35·5 days
3	25	36·1 days
4	20	37·8 days
5	16	42·2 days
6	13	38·8 days
7	9	65·5 days
Overall number of treatment cycles for 43 patients*	—	36·6 days

*In six cases, clinical relapse occurred in the course of a very long interval which lasted on an average for 86·6 days.

2. *Evaluation of results*

Intra-cranium tumours develop within a restricted space and their evolution depends on three factors: tumour growth, the development of the peritumoural oedema and the extension to vital neurological centres. Results were evaluated taking into account the interaction of these factors. Each patient included in the trial underwent a general, neurological and biological checkup. The diagnosis was either based on a histological study of the tumour to be operated on or on the correlation between the data provided by the patient's clinical development and by gammaencephalography and arteriography [12, 13].

In 24 cases gammaencephalography was repeated every three months. All the patients were under steroid therapy at the beginning of chemotherapy protocol. Clinical development was judged by the modification of focal neurological signs stabilized from corticoides and the patient's general behaviour, was studied every week, and later at longer intervals.

These signs can be classified into four stages in decreasing order of gravity:

stage IV	the patient is in a coma
stage III	the patient is conscious but his neurological condition requires constant assistance

stage II — the patient is conscious and can look after his basic needs
stage I — the patient can resume all his activities

Improvement was defined as a regression of neurological signs enabling the patient to progress by at least two stages within a minimum of two months.

The final overall assessment of the therapeutical effects was based on the evolution of the survival curve for the entire group of patients included in the trial.

3. *Therapeutic results*

Objective clinical improvement as defined above occurred in 31 patients, that is, in 72% of the cases considered. The clinical condition of 12 others continued to worsen despite the treatment administered (Table 2). Whenever clinical improvement was observed it occurred during the first two months following chemotherapy. Mere stabilization of a patient's initial clinical condition or continued progress after the second month were some of the factors for a bad prognosis that occurred in 12 patients, i.e. in 28% of the cases treated.

Table 2. *Malignant gliomas in adults*

Results observed (Subjective neurological improvements)		
Improvement*	31	72%
Stabilization*	3	7%
Failures	9	21%
Total	43	

*Improvement is defined as a regression of the objective neurological symptoms lasting at least two months.

Twenty-five out of the 31 patients whose condition improved as a result of the treatment were subjected to a regular three-monthly cinegammagraphical checkup (Prof. Ag. D. Ancri). Objective regression of the pathological image was noted in 16 cases; it was complete in five cases and partial in eleven. In all, chemotherapy had an objective effect in 21 out of 25 patients studied but in five cases the image was stabilized. The objective clinical effect noted did not completely correspond to the scintigraphic improvements recorded since scintigraphy showed a growth in the size of the infected site in four patients whose objective clinical condition had apparently improved probably related to a delayed effect of steroid therapy (Table 3).

Table 3. *Malignant gliomas in adults*

Scintigraphic results observed after 3 months' treatment	
Spreading of infected site	4
Stabilization of infected site	5
50% regression	6
50% regression	5
Disappearance of site	5
	25

25 out of 31 cases that improved as a result of the treatment were kept under regular cinegammagraphic observation.

The effect of combined chemotherapy on survival is shown in Fig. 1. The survival median is 180 days. Thereafter, the number of deaths roughly equals the number of patients who survive, taken over the same lapse of time: and at the moment out of 22 patients surviving for more than six months; 12 are in satisfactory condition and 10 are in remission, 180–510 days after treatment.

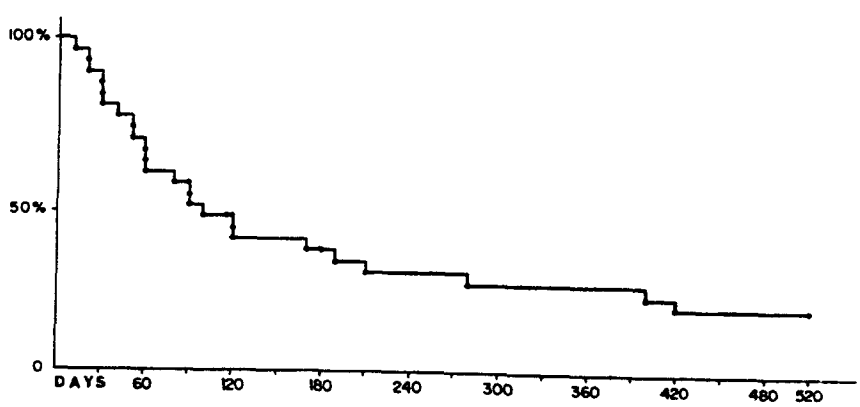

Fig. 1. *Survival curve for* 43 *malignant gliomas patients.*

4. *Factors that may affect chemotherapy results*

The results given in Table 4 show that the initial site of the tumour does not affect the results of chemotherapy, neither does the tumour's extensive but unilateral character have any part in determining its response to drugs. When its initial site is frontal, the survival median is 189 days; when it is temporal, the median is 181 days, when it is parietal, 188 days, and for extensive but unilateral tumours, it is 190 days. It should however be noted that four patients had particularly serious tumours either located in the central grey nucleii or which had spread to the bilateral frontal or callous mass (*corps calleux*). For those patients with right temporal glioblastoma the median survival time is 190 days; and for those left temporal glioblastoma the median survival time is 270 days. This difference led us to suppose that the early diagnosis in relation with the drastic alteration of language, but writing, indicates a smaller tumour, and in this condition a more effective chemotherapy.

Table 4. *Malignant gliomas in adults. Effects of of chemotherapy, classified according to tumour site*

	Frontal	Temporal	Parietal	Extensive tumour
Number of patients	12	14	88	9
Number of survivals on 15.4.1975	5	6	5	3
Survival median	189 days	181 days	188 days	190 days

If one takes into account the treatments received by patients prior to this trial, the survival median for patients having undergone partial tumour *resectioning* is 185 days and may be compared to the 185-day median observed for patients considered inoperable (Table 5).

So far, survival medians have proved identical, but 12 out of 21 patients have survived in the first group and eight out of 22 in the second.

Whatever the results, chemotherapy is regularly applied whenever the patient's hematological state allows. In cases where such treatment continued uninterrupted, *regrowth* occurred mainly after the 6th cycle of treatment (Table 6). In this trial scintigraphic relapses always preceded recurrence of clinical symptoms.

Table 5. *Effects of chemotherapy, according to tumour size*

	Patients included in the trial after partial tumour *exeresis*	Inoperable tumour patients included in the trial
Number of patients	71	22
Survival median on 15.4.75	185 days (30 to 400 d)	188 days (40 to 506 d)
Number of survivals	12	8
Average survival periods for diseased patients	154 days	168 days

Table 6. *Malignant gliomas in adults. Effects of chemotherapy according to tumour site*

	Tumour site	
	Right temporal	Left temporal

Number of patients	8	6
Number of survivals	3	3

DISCUSSION

Forty-three patients with glioblastoma and 30 patients with multiple brain metastasis were treated by sequential administration of adriamycine, VM 26 and CCNU. For the patients suffering from glioblastoma, the clinical response rate was 72% and the objective cinegammagraphic response, 58%.

Taking into account the criteria applied to selection of patients for this non comparative trial, the results are encouraging as far as the duration of survival is concerned. For a series of comparable patients treated by simple outside decompression, the survival median was two months [2, 14]. In our series, 90% of the patients survived into the 2nd month, the overall survival median being six months with the extreme limit up to the 17th month. In the case of four patients who have now had over a year's treatment, there have so far been no neurological or cinegammagraphic consequences due to their initial tumour.

High rates of objective response (50%) were obtained with the administration of BCNU alone [15, 8, 10]. CCNU has a comparable efficiency but seems easier to handle and less

toxic [16, 17]. The results obtained by Sklansky using VM 26 [6] indicate that the drug is especially effective in cases of resistance to nitrousereas. Earlier trials using combinations of individually active drugs (VCR and BCNU) proved disappointing in the treatment of glioblastoma.

A comparison of the results obtained in this trial as regards survival, based on reference to groups treated respectively by surgery only and by surgery combined with radiotherapy shows that for those of our patients who did not respond to other forms of treatment, such combinations of drugs made it possible to achieve results similar to those obtained from a group for which the prognosis was apparently less grim. Using this combination, D. Fewer[18] obtained less satisfactory results than those obtained by the use of BCNU alone.* Using a combination of CCNU, vincristine and methotrexate, J. Hildebrand [19] reported results comparable to those achieved by administering CCNU alone. A non-comparative trial combining VM 26 and CCNU [20] led to a neurological improvement in 60% of patients and a final six months survival median [21]. The small number of patients involved in this trial did not enable its results to be compared to those obtained by administration of CCNU alone.

However, our subsequent trial included 43 glioblastoma cases, and evaluation of the results bring out the following five points for discussion:

(1) Neurological improvement always occurred during the first month of treatment and the absence of effect after the second cycle is the cause of a bad prognosis. Any rises in intracranium hypertension due to chemotherapy were easily kept under control by the treatment and did not cause any deaths.

(2) There was no absolute correlation between the clinical effects and objective cinegammagraphic regression observed. Twenty per cent of the patients who had improved neurologically showed a deterioration on scanning. This discrepancy between results had earlier been noted by Fewer. Apart from cases where chemotherapy did not modify the tumour's clinical development, all patients in whom showed an increase in or only stabilization of the initial tumour size died within the first six months. Consequently, there seems to be an exact correlation between prognosis during chemotherapy and the modifications observed in cinegammagraphy [16, 18].

(3) According to the results given in Tables 5 and 6 initial tumour size does not seem to alter the treatment's effect on survival. The different tumour sites appear to be sensitive to chemotherapy to an identical degree. A significant difference was, however, noted between the two groups of patients whose tumours originated in the left and right temporal zones respectively.

(4) Although it is still too early to formulate a final opinion the survival median observed for the 43 glioblastoma patients who were given the triple drug combination specified above and were all initially inoperable may be compared to the median reported for earlier series of patients treated by radiotherapy after partial or no resectioning [2].

*J. Hildebrand [19], using a combination of CCNU, vincristine and MTO, reported results comparable to those achieved by administrating CCNU alone.

§Present address: ICIG, Hôpital Paul Brousse, 94800 Villejuif, France

Abstract—*Thirty-seven patients with primary unresectable bronchogenic carcinoma were treated by a combination, ("E.M.O.B."), of cyclophosphamide (40 mg/k on day No. 1, or 13·3 mg/k × 3 consecutive days), methotrexate (7·5 mg/m2/d × 6 d, given orally for 6 consecutive days from day 21 to 26), Folinic Acid (15 mg/m2, IM, on day 27 at 8 p.m.). vincristin (0·7 mg/m2, IV at 8 a.m. on days 28 and 31) and bleomycin (10 mg/m2, IM at 2 p.m. on days 28 and 31, i.e. 6 hr after vincristin. The response was evaluated on day 48 and a new course started on day 49 if a regression or a stabilisation had been obtained.*

The 37 cases include 9 small anaplastic carcinomas, 24 squamous cell and large cell anaplastic carcinomas, and 4 cases of undetermined type. Thirty-one patients received almost 1 course of the schedule. Among them, 1 had a complete regression, 5 a regression of more than 50%, 6 a regression of less than 50%, 14 a stabilisation. There were 11 failures. Among 12 objective responders (39%) there were 4 squamous cell carcinomas (22%, median duration: 5 months), and 8 oat cell carcinomas (89%, median duration: 4 months). Four out of 37 patients (10%) were alive after 1 yr.

The toxicity was evaluable in 32 cases representing 77 courses of the schedule: in 3 cases a severe toxicity led to an interruption of the treatment; strong (4 cases) or tolerable (15 cases) toxicity included nausea, vomiting and marrow depression. In 10 cases there were no toxic phenomena (31%).

The over all results of this combination are not significantly better than those that may be obtained with cyclophosphamide or methotrexate as single agents or with vincristin and bleomycin in combination.

INTRODUCTION

AT THE present time, the results obtained with chemotherapy in advanced bronchogenic carcinomas, are poor by both the rate of regression and the duration of response and survival gain. We attempted to associate 4 drugs the efficacy of which is well known though limited: cyclophosphamide [1], methotrexate [2], and vincristin followed 6 hr later by bleomycin [3, 4].

MATERIAL AND METHODS

1. *Treatment schedule*

All the patients received the following treatment:

—Cyclophosphamide, 40 mg/kg, by i.v. perfusion on day no. 1 (or 13·3 mg/kg/day, i.v. on days No. 1, 2 and 3),.

—Methotrexate, *per os*, 7·5 mg/m^2/day × 6 consecutive days, from day No. 21 through day No. 26,

—Folinic Acid, 15 mg/m², was administered intramuscularly at 8 p.m. on day No. 27,
—Vincristin, 0·7 mg/m², i.v., on day No. 28 at 8 p.m.,
—Bleomycin, 10 mg/m², i.m., on day No. 28 at 2 p.m.,
—Vincristin, and bleomycin 6 hr later, were repeated at the same dosage on day No. 31.

This association was called E.M.O.B.*

The response was evaluated 15 days later on day No. 48. If there was no progression of the disease, or a tumor regression, a second course was started on day No. 48; on the contrary, the treatment was stopped if the disease had progressed. Blood counts were performed on days No. 1, 21, 28 and 47: in a few cases, drug doses were reduced to 50% if there existed a moderate hematological toxicity but there was no protocol rule on that topic.

2. *Patients*

From May 1, 1973, through December 31, 1974, 42 consecutive patients entered in that study. All had a primitive bronchogenic carcinoma in an evolutive and advanced state. Their ages ranged between 42 and 81 (mean: 59; median: 62). Three of these patients were women.

Eighteen had been previously treated by either surgery (6 patients), radiotherapy (4 patients), surgery and radiotherapy (3 patients) or surgery, radiotherapy and chemotherapy (5 patients); 24 had not been previously treated.

In five cases, the first course of chemotherapy was arbitrarily suspended. Owing either to a too poor general condition in 3 cases, a too far advanced age (81 years) in one case or to the patient's own refusal in one case. These five cases were excluded.

The 37 remaining patients were included, even if the first course was not completed.

The histologic type is presented in the first table.

Table 1.

Histologic type	Number of patients
Oat cell carcinoma	9
Epidermoid carcinoma and large cell anaplastic carcinoma	24
Undetermined	4
Total	37

*"E. M. O. B." from ENDOXAN (cyclophosphamide), methotrexate, ONCOVIN, bleomycin.

Among these 37 patients, six died during the first course and were nevertheless included in the study of results. Three patients were living at the end of the study (3, 4 and 18 months after the beginning of the first course). One patient was lost to follow up after 7 months of treatment.

RESULTS

1. *Evaluation criteria*

Survival and toxicity data were estimated from the 37 treated patients. The response rate was evaluated from 31 patients in which almost one course was completed and who therefore were defined as "adequately treated patients".

Response criteria were as follows:
—regression of more than 50%: when the products of two perpendicular diameters of the tumor as measured on frontal and sagittal X-ray films, was reduced by more than 50%;
—partial regression of less than 50%: when the radiologic improvement was obvious but not accurately measurable;
—no progression: this was applied to the cases with an atelectasis in which we obtained simultaneously a radiologic and stable functional improvement. The other cases were considered as progression. Nevertheless, when there was a superficial adenopathy the result was evaluated from its volume variations.

2. *Response data* (*Table* 2)

Among 31 treated patients, we obtained 6 regressions of more than 50%; 6 partial regressions of less than 50%. Thus, the objective response rate was 12/31 (39%). But we obtained only 4 objective regressions out of 18 epidermoid and large cell anaplastic carcinomas (22%), when we obtained 8 objective responses in 9 adequately treated patients with oat cell carcinomas (89%).

The median duration of objective responses in epidermoid carcinomas was 5 months. The median duration of the response including regressions and stabilisations was 3·7 months.

The best responses were obtained in small cell anaplastic carcinomas (1 complete regression, 7 partial regressions and 1 stabilisation). The median duration of objective responses was 4 months.

3. *Survival*

Out of 37 patients, only 4 (10%) have survived one year or more. The median survival was 5 months for the whole; 7·7 months for the responders; 5·9 months when the re-

Table 2.

Histologic type	Total (1)	n	Complete regression	Regression > 50% (+)	< 50% regression	Objective regression rate	Stabilization	Progressive disease
Epidermoid and large cell anaplastic carcinoma	24	18		2 (11%) (8%)	2 (11%) (8%)	4 (22%) (17%)	10 (55%) (42%)	4 (22%) (17%)
Oat cell carcinoma	9	9	1 (11%)	3 (33%)	4 (44%)	8 (89%)	1 (11%)	
Undetermined	4	4					3 (75%)	1 (35%)

(1) Number of treated patients.
n Number of adequately treated patients.
(+) The 1st number in the brackets applies to the adequately treated patients; the 2nd number applies to the total number of patients.

sponse was "no progression"; and 1·3 months for the non responding patients.

Table 3.

Response type	Number of patients	Median duration of survival (months)
All patients	37	5
Objective > and < 50%	12	7·7
No progression	14	5·9
Progressive disease	11	1·3

4. *Toxicity*

Toxicity data were available in 32 out of 37 treated patients; these data were missing in five patient files. The toxic events were classified in three groups:

(1) acceptable toxicity.
(2) strong toxicity.
(3) accidents.

The criteria of toxicity are listed in the legend of Table 4. A strong toxicity was observed in 4 patients and severe accidents occurred in 3 patients. Though important this toxicity may appear, in fact, out of 77 courses of the EMOB protocol, we observed no toxicity at all in 40 courses (52%). The three severe accidents are to be included in the same total number of courses, i.e. 3/77 (4%). The toxicity was the same in the different histologic types.

The observation of the 31 patients who had completed at least one course was used to study the toxicity of the components of the association (E.M.O.B.). The methotrexate was responsible for the most frequent and the most severe manifestations (digestive tract troubles, stomatitis).

Table 4.

	No toxicity (1)	Acceptable toxicity (2)	Strong toxicity (3)	Toxic accidents (4)
Numbers of patients	10	15	4	3
Percentage	31%	47%	13%	9%

(1) No physical or biologic sign of toxicity. Yet a transitory leucopenia, almost constant after the cyclophosphamide injection, was not considered as a toxicity sign when it had spontaneously regressed eighteen days later.
(2) Moderate and reversible physical or hematological symptoms.
(3) Severe discomfort (vomiting, stomatitis) and/or deep or prolonged cytopenia. Treatment might be delayed but not definitely stopped.
(4) Treatment had to be definitely stopped and/or was partly responsible for the patient's death.

DISCUSSION

The rationale for the EMOB schedule was the following: the initial loading dose of cyclophosphamide was employed as to reduce tumor volume and, as a consequence, to recruit cells from Go to the cell cycle. Then methotrexate was assumed to be more active. After the six day course of methotrexate, Folinic Acid was administered with the aim to "unblock" cells that could be blocked in the S phase, and to synchronize them. We arbitrarily assumed that 12 hr later these synchronized cells had reached the G2-M period which is the optimal phase for the action of vincristin then bleomycin [3, 4].

In that schedule, the toxicity of each drug was not cumulated for there was a sufficient interval between cyclophosphamide and methotrexate.

Our actual results are not superior to those that may be obtained with cyclophosphamide alone [1] or high dose methotrexate alone [2]. They are not very different from those that were obtained with vincristin and bleomycin in combination [4]. They are inferior to the results obtained with a combination of vincristin, CCNU and Fluoro-Uracil by Pouillart *et al.* [5].

The response rate of EMOB schedule in oat cell carcinomas is likely to be obtained with a number of drug combinations.

We are now studying a combination of the same drugs (cyclophosphamide, methotrexate, Folinic Acid, vincristin, bleomycin) with quite a different schedule; the drugs are administered in a 48 hr period, taking in account the potential cumulated toxicity. This new schedule is randomly compared to the association of vincristin, CCNU and 5 FU.

The study is in progress and no preliminary data are available at the present time.

Synchronization Recruitment Chemotherapy in Non-Hodgkin Hematosarcomas

M. SCHNEIDER, G. MANCINI, C. FELLA, J. M. AUBANEL, M. HOCH and E. VIGUIER

Centre Antoine Lacassagne, 36 voie-romaine, 06054 Nice Cedex, France

Abstract—*Thirty-three patients with poorly differentiated, diffused lymphosarcoma or reticulosarcoma, stages III and IV were treated by a potentiating chemotherapy. The cycles comprised 25 mg/m² Adriamycin on day 1, 40 mg/m² VM 26 on day 2, 300 mg/m² cyclophosphamide and 40 mg/m² prednisone from day 3 to day 6. Tolerance was excellent in most cases. We note 61 % complete and incomplete remissions, 27 % regressions less than 50 % and 12 % failures.*

INTRODUCTION

CHEMOTHERAPY represents the first induction treatment of dissiminated lymphosarcomas and reticulosarcomas. We use it more and more often since modern methods of clinical, biological, radiological, scintigraphical and surgical investigations have shown that many types, classified in the past as local or regional, were in fact disseminated, invading lymph nodes above and below the diaphragm and/or different viscera.

Several substances are effective in these diseases. We have used sequentially adriamycin, epipodophyllotoxin, cyclophosphamide and prednisone in the aim of cell recruitment and synchronisation [1, 2] according to the protocol proposed by G. Mathé at Villejuif. The dosages of adriamycin and prodophyllotoxin (VM 26) had to be modified due to the high mean age of our patients.

1. PATIENTS AND METHODS

1. *Patients*

Thirty-three patients (17 men and 16 women) whose ages ranged from 26 to 86 (median 66) were treated by this chemotherapy. All the patients were in the perceptible phase of their illness: 19 in the 1st phase, 12 in the 2nd, 1 in the 3rd and 1 in the 4th. Histologically and topographically (Table 1) we have noted 18 diffused, poorly differentiated lymphosarcomas, 9 stage III and 9 stage IV; and 15 diffused, poorly differentiated reticulosarcomas, 3 stage III and 12 stage IV. Apart from the usual clinical examination, pre-therapeutic investigation of these patients included: chest X-ray, with mediastinal tomography, abdominal lymphography, spleen, liver and bone scintigraphy, skeletal survey, barium meal, bone-marrow aspiration and biopsy, liver biopsy, immunoelectrophoresis, blood cell count, erythrocyte sedimentation rate and immune exploration. Laparotomy was not used due to the old age of most patients.

Table 1. *Chemotherapy of lymphosarcoma and reticulosarcoma*
Classification of patients

Diffuse poorly differentiated			
Lymphosarcoma stage:		Reticulosarcoma stage:	
III	IV	III	IV
9	9	3	12

2. *Chemotherapy*

As indicated in Table 2, the treatment comprises 6-day-cycles with on day 1, 25 mg/m² adriamycin i.v., on day 2, 40 mg/m² VM 26 i.v. infusion and from day 3 to 6, 300 mg/m² cyclophosphamide i.v. and 40 mg/m² prednisone orally. This treatment is taken again after hematological restoration if the leucocyte level is above 4000/mm³ and platelet level above 100,000/mm³. Hematological restoration usually occurs between 15 and 24

*Centre Antoine Lacassagne, 36 voie-romaine, 06054 NICE Cedex, FRANCE.

days and the interval between cycles is about 21 days. The number of cycles varies from 1 to 10 with a mean of 4.

Table 2. Chemotherapy of lymphosarcoma and reticulosarcoma

Day 1	Adriamycin	25 mg/m²	i.v.
Day 2	VM 26	40 mg/m²	Perf.
Day 3–6	Cyclophosphamide	300 mg/m²	i.m. or i.v.
	+ Prednisone	40 mg/m²	

Interval 21 days.

2. RESULTS

2.1. *Toxicity*

The chief toxic effects are mentioned in Table 3. Leucocytes were constant and it was only in 9 cases that the rate was under 2000/mm³. Thrombocytes were also constant and only 3 cases were under 50,000/mm³. Other toxic effects are essentially asthenia, nausea, alopecia. In one patient, after 2 cycles of chemotherapy, we observed symptoms evoking viral encephalitis which caused death. Unfortunately necropsy was not possible. No cardiac toxicity was observed, but adriamycin dosage was low (25 mg/m²) in view of the patient's age. In 8 cases/33, no clinical or hematological toxicity was observed. Overall tolerance was excellent and we had no difficulty in applying a ten-cycle programme of treatment even in patients whose general condition on arrival was very poor.

Table 3. Chemotherapy of lymphosarcoma and reticulosarcoma

Toxicity in 33 patients	
Leucopenia < 2000/m³	9
Thrombopenia < 50 000/m³	3
Asthenia	10
Nausea	8
Alopecia	4
Lethal encephalitis	1
Cardiac toxicity	0
No toxicity	8

2.2. *Antitumoral effectiveness*

Results are shown in Table 4. We have seen 4 complete remissions, with complete disappearance of clinical, radiological and biological evidence. We have obtained 18 incomplete remissions of more than 50% with a reduction of nearly all lesions. In 9 cases, regression was less than 50% and in 4 cases, the treatment was a failure. In fact, we have observed 61% complete and incomplete remissions, 27% regressions less than 50% and 12% failures.

Results are better in lymphosarcomas than in reticulosarcomas. In the first type, we have obtained 67% complete and incomplete remissions, 33% regressions less than 50% and no failure; in the second type, 53% complete and incomplete remissions, 20% regressions less than 50% and 27% failures.

In these two types of hematosarcomas, good results have been observed not only in disseminated, superficial and deep lymph nodes (mediastinal and lomboaortic) but also in stage IV with visceral lesions (52% complete and incomplete remissions) and in 9 cases, more or less complete regressions of liver involvement was observed; in 2 cases bone lesions dis-

Table 4. Chemotherapy of diffuse poorly differentiated lymphosarcoma and reticulosarcoma stages III and IV. Results

		Complete remission	Remission > 50%	Regression < 50%	Failure	Total
Lymphosarcoma	III	1	5	3	0	9
	IV	—	6	3	0	9
	Total	1	11	6	0	18
Reticulosarcoma	III	2	1	—	—	3
	IV	1	4	3	4	12
	Total	3	5	3	4	15
Total LS+RS		4	16	9	4	33

appeared, in 3 cases pleural or pulmonary lesions and in one case sub-cutaneous disseminated nodules.

The maximum therapeutic effect was observed at the 1st cycle in 2 cases, at the 2nd cycle in 4 cases, at the 3rd cycle in 12 cases and at the 4th cycle in 2 cases.

No statistical evaluation can yet be made regarding the duration of incomplete remissions because patients have undergone subsequent radiotherapy to complete the remission. As for the 4 complete remissions, in one case of lymphosarcoma, stage III the patient was lost to follow-up after 6 months; in 1 case of reticulosarcoma, stage IV, we observed a complete remission without treatment lasting 24 months and in the 2 other patients with reticulosarcoma, stage III, remission was still in progress after 6 and 12 months.

3. DISCUSSION

Many synchronisation chemotherapies are currently in use with variable results, and often toxic effects, particularly hematological, which limit the length of the treatment and make the problem of further treatment more difficult.

The therapeutic protocol studied in this work seems to us of great interest because of its excellent tolerance which has allowed us to administer up to 10 cycles in patients over 60, after sometimes prior administration of other chemotherapy or application of radiotherapy. Antitumoral effect is remarkable since it was observed on superficial and deep adenopathies, but also on visceral and especially hepatic lesions. In lymphosarcomas, no failure was observed on the contrary of reticulosarcomas often more resistant to anti-cancerous treatments. Our results were somewhat inferior to those of Misset *et al.* [3] but our dosages of adriamycin and VM 26 were lower due to our patients' age. Some years are still necessary to tell us if we can improve the prognosis of these diseases which modern means of investigation show are frequently disseminated.

Pharmacokinetics of Adriamycin and Adriamycin–DNA Complex in L1210 Mice and Men

M. STAQUET,*† M. ROZENCWEIG,* M. DUARTE-KARIM* and Y. KENIS*

Abstract—*Adriamycin when linked to desoxyribonucleic acid gives higher plasma concentrations than adriamycin injected at the same dose.*

In mice, under certain conditions, the therapeutic activity of ADM–DNA is higher than ADM.

In men, both forms of the drug induce the same toxicity but for a C × t bigger for ADM–DNA than for ADM.

INTRODUCTION

ADRIAMYCIN is an anthracycline antibiotic which induces objective responses in many solid tumors and hematologic malignancies [1–3]. Its mechanism of action seems to be the binding of the drug to cellular DNA by intercalation between base pairs, and inhibition of RNA synthesis [2, 3].

The therapeutic usefulness of adriamycin is however restricted by its toxicity on the bone marrow and heart muscle. Trouet *et al.* [4, 5], using the concept of lysosomotropic cancer chemotherapy, have been able to decrease toxicity and to increase activity in L1210 leukemia in DBA_2 mice by binding adriamycin and DNA. The concept of lysosomotropic chemotherapy implies that an antitumoral drug firmly linked to an endocytisable and digestible carrier will penetrate only cells with a high endocytic activity. In the cell, the carrier will be digested by the lysosome and the drug will become free to diffuse. Cells which do not possess both high endocytic and mitotic activities would then be protected from the action of the drug.

The present investigation was performed to compare the pharmacokinetic properties of adriamycin when infused alone or complexed with DNA.

*Service de Médecine et d'Investigation Clinique, Institut Jules Bordet, Brussels, Belgium.

†Service de Statistique Médicale, Faculté de Médecine, Université Libre de Bruxelles, Belgium.

MATERIAL AND METHODS

The adriamycin–DNA complex (ADM–DNA) was prepared as described by Trouet *et al.* [4] by mixing adriamycin and a DNA solution (Herring sperm type VII; Sigma, Saint Louis) with a Molar ratio of DNA mononucleotides to adriamycin equal to 20. The apparent binding constant of ADM to DNA is $0{\cdot}41 \cdot 10^6\ M^{-1}$ [5].

L1210 leukemia was obtained from Trouet [5] and maintained in DBA_2 female mice (Ch. Rivers Laboratory). Ascites tumor cells were counted in a hemocytometer and diluted in Hank's balanced solution. 0·1 ml (10^5 cells) was injected i.v. into DBA_2 mice, 8–10 weeks of age, weighing 20–24 g.

A single dose of adriamycin (ADM) or ADM–DNA (6 mg/kg of adriamycin in both cases) was injected intravenously 24 hr after L1210 cells inoculation. At selected intervals, venous blood samples were collected from the inferior vena cava of anesthetized animals. Heparinized pooled blood of 3 groups of 6 mice was centrifuged immediately and the plasma was frozen at −20°C for a maximum of one month. In men, ADM or ADM–DNA was administered by intravenous infusion to 2 groups of 4 patients at the dose of 75 mg/m^2 of body surface area in 1–3 hr. Ten milliliter samples of heparinized venous blood were collected before drug administration and at specified intervals thereafter. The samples were immediately centrifuged, and the plasma

separated, frozen and kept at −20°C for a maximum of one month.

Total plasma fluorescence assay

Total plasma fluorescence was assayed by a modification of the method of Bachur *et al.* [6]. Frozen plasma was thawed and sonicated for dispersion of insoluble material. Absolute ethanol (1·5 ml) and hydrochloric acid 2 N (0·45 ml) were mixed with each plasma sample (1 ml).

The mixture was allowed to stand at 4°C for 24 hr. The samples were centrifuged at 50,000 × *g* in a Beckman Spinco L265B ultracentrifuge, for 25 min and the fluorescence of the plasma acid alcohol extracts was determined in a Zeiss PMQ3 spectrophotofluorimeter.

An activation wavelength of 465 mμ and an emission wavelength of 595 mμ were used. The concentration of adriamycin equivalents in the plasma samples were determined by direct comparison of the relative fluorescence intensity of the plasma extracts with a calibration curve.

A standard curve was performed for each set of estimations. A corresponding blank containing no drug was also carried through the above procedure, and the relative fluorescence intensities were corrected by subtracting the value obtained for the blank (endogenous fluorescing materials) from that of each of the extracts. All samples were analyzed in triplicate. All results are given in adriamycin equivalents.

RESULTS

1. *Recovery studies*

Standard curves obtained when the ADM and ADM–DNA were added to plasma (0·01–5 μg/ml) were identical with curves obtained by adding adriamycin directly to plasma supernatant obtained after protein precipitation. Acid–alcohol extraction of standard solutions of ADM and ADM–DNA in plasma resulted in a 90–100% recovery of both drugs above 0·01 μg/ml concentration in plasma. The relationship between the relative fluorescence intensity and the concentration of ADM and ADM–DNA in the standard solutions is linear in the range of experimental data.

2. *Pharmacokinetics in mice with L1210 leukemia*

Plasma concentrations of ADM equivalent are displayed in Fig. 1. There is a large difference between plasma concentration during the first two hours after drug injection. However, after the third hour, both drugs give the same plasma concentrations.

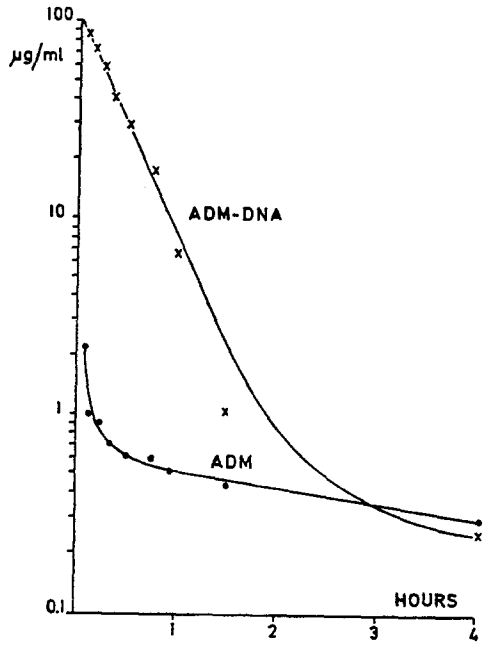

Fig. 1. Plasma concentrations of ADM equivalents in DBA/2 mice with L1210 leukemia after i.v. injection of 6 mg/kg ADM or ADM–DNA. Least square curves and means of experimental values.

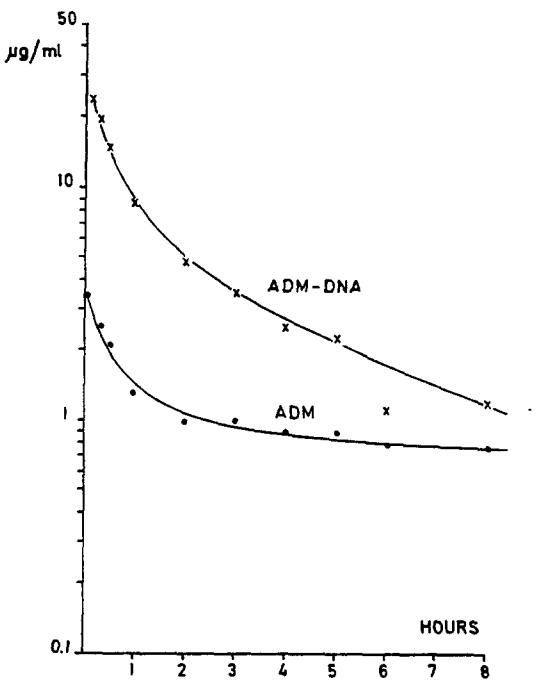

Fig. 2. Plasma concentrations of ADM equivalents in men after i.v. infusion of 70 mg/kg. Least square curve and means of experimental values.

3. *Pharmacokinetics in men with various neoplasia*

Plasma levels of ADM equivalents after cessation of the infusion are shown in Fig. 2. ADM–DNA in spite of a longer infusion time,

gives plasma concentrations of ADM equivalents about 8 times higher than ADM just after cessation of the infusion. At the 10th hr, the same plasma concentration of ADM equivalent is seen with both forms of the drug.

4. *Toxicity and therapeutic efficacy*

It has been shown that ADM–DNA is less toxic than ADM in mice, and an increased activity in some sublines of leukemia L1210 has been demonstrated [7]. In solid tumors, the complex, when given at the dose of 6 mg/day for 5 days, was more active than adriamycin alone in Melanoma B16 when administered i.p. In Lewis Lung carcinoma and L1210 transplanted s.c., adriamycin was shown to be superior to the complex [8, 9].

In men, a phase I study suggested that the toxicity induced by the complex was similar to that observed with the free drug [10].

DISCUSSION

In mice and men, plasma levels of ADM and its metabolites are strikingly different for both forms of the drug. The most important factor playing a role in these differences seems to be the size of the macromolecule of ADM–DNA which hampers the passage through the capillary barrier. After a few hours, plasma levels of ADM equivalents are the same for both drugs in mice and men, as if the complex ADM–DNA is dissociated either by pinocytosis or by the action of circulating desoxyribonuclease.

Therapeutic results observed in mice [8, 9] have indicated that ADM–DNA is superior to ADM in intraperitoneally transplanted malignancies whereas the contrary is seen in solid tumors, although the optimal schedule was not used for ADM. This can be interpreted as due to the slow diffusion of ADM–DNA from well-perfused compartment to the tissues and the tumors. This hypothesis has been confirmed in the case of the isolated perfused heart of the rat where ADM–DNA was shown to be less toxic than ADM [11].

In men, no controlled therapeutic trial has been conducted so far. A recent phase I study [10] suggested that hematologic toxicity is identical with both drugs in spite of a higher $C \times t$ for ADM–DNA.

Intralymphatic Immunization: Current Status*†

GUY J. F. JUILLARD and PAMELA J. J. BOYER
Division of Radiation Therapy, Department of Radiological Sciences, University of California, Los Angeles Center for the Health Sciences, Los Angeles, California, U.S.A.

Abstract—*A progress report and the research plan for a new method of antitumor immunization using the intralymphatic route are presented. A total of* 205 *intralymphatic infusions of intact cellular vaccines have been performed in normal and tumor-bearing dogs.* In vitro *and* in vivo *experiments on normal dogs demonstrated that intralymphatic immunization produces a more rapid and more intense cytotoxic cellular immune response compared to the subcutaneous route. Experiments in tumor-bearing dogs showed reduction or stabilization of tumor mass after intralymphatic infusion of irradiated malignant cells. These data indicate that intralymphatic immunization may be the method of choice for stimulating strong cellular immune responses to weakly immunogenic materials.*

INTRODUCTION

THE FIRST attempt of antineoplastic intralymphatic immunostimulation by infusion of presumedly immunogenic material (irradiated autochthonous tumor cells) was performed on September 8, 1972 on a 75-yr-old patient with disseminated melanoma. Three consecutive infusions via the same afferent lymphatic vessel were done 3 and 4 days apart. During subsequent weeks, all metastases continued to grow with the exception of a nodule of the right thigh which was in the infused area. The patient expired 3 weeks later.

This attempt in a human patient, which was made under exceptional circumstances, stimulated further investigation of the intralymphatic route of immunostimulation as a potentially effective mode of antitumor immunotherapy. However, since neither the benefits nor hazards of this method were known, it was not appropriate to proceed further in humans without undertaking relevant preclinical experiments on animals. Such studies have been in progress since January of 1974 in the Division of Radiation Therapy at UCLA [1, 2, 3].

*This work was supported by the California Institute for Cancer Research.

†Presented at the First Congress of the Medical Oncology Society at Nice on December 3, 1975 by Professor C. M. Lalanne, Director, Centre Antoine Lacassagne, Nice, France.

MATERIAL AND METHODS

All experiments have been done on randomly-bred normal and tumor-bearing dogs which were selected for the following reasons:

1. Dogs develop *spontaneous* malignant tumors that are similar to human malignancies.
2. Injection via the intralymphatic route is technically almost as easy as it is in humans.

Standard lymphangiography techniques were used for cannulation and infusion of the extremities.

RESULTS

1. *Experiments on normal dogs*

Differential immune responses to immunogenic material injected intralymphatically, subcutaneously, or intradermally have been studied on 22 normal, weight-matched dogs.

Evaluation of immune responses to a malignant cell vaccine. Direct cell-mediated cytotoxicity, complement-dependent antibody cytotoxicity, and skin test reactivity to a xenogeneic leukemia cell line was serially assessed in 16 dogs divided into 4 groups which had received respectively:

—Intralymphatically, a suspension of 10^8 leukemia cells.
—Intralymphatically, medium only.
—Subcutaneously, 10^8 leukemia cells.
—Subcutaneously, medium only.

Results of both primary and secondary immunizations showed that cell-mediated

immune responses were preferentially accelerated and significantly greater in the groups which had received leukemic cells intralymphatically.

Evaluation of responses to BCG. In this study, 2 groups of 4 dogs received respectively BCG (Glaxo) intradermally and intralymphatically. The responses were evaluated clinically by tuberculin skin testing, and the sera were serially sampled to assess antibody against BCG.

All dogs which received the BCG intralymphatically developed large regional lymphadenopathies which persisted for several months Two dogs in the "intralymphatic" group developed positive skin tests at 11 and 23 days, and skin test became positive at 45 days in the "intradermal" group. The level of antibodies is not known yet; all the sera will be assessed at the same tine.

2. *Experiments on tumor-bearing dogs*

A. Randomized study of Stage III malignant lymphomas was undertaken in which one group (7 cases) received intralymphatic infusions of irradiated autochthonous tumor cells. The second group (4 cases) received intralymphatically the medium only.

The lymphadenopathies have been found to routinely decrease in size at least temporarily in Group 1 but continue to grow progressively in Group 2. Thus far, the mean survival is 42 ± 30 days in Group 1 and 13 ± 6 in Group 2.

B. Nonrandomized study of intralymphatic immunization in solid tumors:

1. Irradiated autochthonous, allogeneic, or xenogeneic tumor cells were repeatedly infused via the intralymphatic route in:

Two cases of pulmonary metastasis from breast adenocarcinoma;

Two cases of pulmonary metastasis from soft tissue sarcoma;

One case of epidermoid carcinoma of the upper respiratory tract.

All cases showed reduction or stabilization of tumor mass.

2. BCG was administered intralymphatically in 2 cases of melanoma. Both cases expired within 10 days of the first infusion with fulminant tumor growth.

DISCUSSION

From these studies involving 205 intralymphatic infusions in 41 dogs, the following points can be made:

1. The intralymphatic route of administration not only is technically applicable but can be used repetitively if necessary. Up to 9 infusions at the same site have been performed over a 5-month period in the same animal.
2. No side effects, including anaphylactic or allergic reactions, have been observed following intralymphatic injection of autochthonous, allogeneic, or xenogeneic tumor cells.
3. Cellular immune responses are quantitatively greater following intralymphatic immunization than the ones elicited by the subcutaneous immunization.
4. A reduction or stabilization of tumor size has always been observed after intralymphatic infusion of irradiated tumor cells.
5. These tumor reductive responses are not due to a direct toxic effect since they were observed in remote areas (pulmonary metastasis, carcinoma of the upper respiratory tract, distant lymphadenopathies).

CONCLUSION

Our findings indicate that intralymphatic injections may be the route of choice for the immunotherapeutic administration of *weakly immunogenic* cellular materials and that no adverse side effects or complications have thus far been associated with this method of immunostimulation.

Are Circulating Null Cells in Patients Submitted to Long-Term Immunotherapy, Related to K Cells?

R. R. JOSEPH,*† N. LELARGE* and D. BELPOMME*

**Institut de Cancérologie et d'Immunogénétique (INSERM), Hôpital Paul-Brousse, 14–16 Avenue Paul-Vaillant Couturier, 94800-VILLEJUIF, France,*

†*Temple University Health Sciences Center, Philadelphia, Pa. 1940, U.S.A.*

Abstract—*In an attempt to elucidate a possible mode of action of immunotherapy in acute lymphocytic leukemia, we studied the mononuclear subpopulation in a group of patients with ALL in remission on long-term immunotherapy, a similar group on chemotherapy and a group of normal individuals.*

Comparison of the three groups demonstrated a significant increase in the number and percentage of "null cell" in the immunotherapy group relative to the two others. Although the nature of these cells is unknown, the possibilities that they represent persistent abnormal elements, circulating stem cells, "K" cells, or modified T, B or monocytic cells are raised.

INTRODUCTION

IN THE last decade, many reports have attested to the clinical benefits of immunotherapy in the treatment of malignant diseases. Extensive reviews of these publications have recently appeared [1, 2]. Although experimental evidence regarding the mechanism of action of BCG and/or inactivated tumour cells on animal immune systems is abundant [3–7] consistent data in humans is still scanty.

The purpose of the present study is to evaluate the effect of such a therapeutic programme on the circulating mononuclear cell population in patients in complete remission from acute lymphocytic leukemia (ALL). To this end, we compared a group of patients on long term immunotherapy to a similar group receiving standard maintenance chemotherapy and to a group of normal individuals.

MATERIAL AND METHODS

Patients

Thirty-one patients with ALL currently in remission were studied. Twenty of these were receiving immunotherapy and 11, chemotherapy at the time they were tested. Immunotherapy consisted of fresh living BCG (Pasteur) administered by scarification at intervals ranging from once weekly to once monthly and irradiated, formalized allogenic blast cells (10^8) administered by scarification monthly [8]. Chemotherapy consisted of weekly methotrexate (IM 15 mg/m^2) and cyclophosphamide (200 mg/m^2) plus daily 6-Mercaptopurine (P.O. 50 mg/m^2). Precise dosage was adjusted weekly according to the level of neutrophils. These patients were compared with 9 normal subjects as controls.

A summary of the age and sex distribution, plus the duration of maintenance treatment is presented in Table 1. Although the patients investigated were drawn from several different protocols operational over the years, all such protocols consist of a period of post induction chemotherapy followed by immunotherapy. Accordingly the immunotherapy group had received a variable period of post-remission chemotherapy and then a period of immunotherapy ranging, as seen on Table 1, from 13–96 months. The patients in the chemotherapy group are those who have not yet completed the chemotherapy phase of the current ALL protocol and have been treated for periods ranging from 3 to 14 months.

Laboratory procedures

Total and differential white cell counts were performed on all subjects. The absolute number of each category of cells was calculated by multiplying the percentages obtained in the following procedures by the absolute number of mononuclear cells.

Table 1. Study groups (A.L.L. in complete remission)

	Number of patients	Sex	Age (mean + range)	Duration of maintenance treatment (mean + range)
Chemotherapy	11	10 M 1 F	10·1 years (5–31)	8·9 months (3–14)
Immunotherapy†	20	7 M 13 F	11·5 years (4–21)	28·2 months (13–96)
Normals	9	4 M 5 F	30 years (20–50)	—

†Post-chemotherapy.

Peripheral blood was collected in citrate from each subject and the mononuclear cells isolated and purified by a previously described Ficoll gradient procedure [9]. A preparation of 99% pure mononuclear cells was obtained by this method. After at least three washings, these cells were used in the tests described below.

T-lymphocytes

T-lymphocytes were enumerated by the E rosette test using sheep red blood cells (SRBC). Rosettes were defined as lymphocytes surrounded by at least three SRBC. We performed this test in two ways. In the first, or direct test, rosettes resulting from the incubation of mononuclear cells and SRBC alone were counted (ERFC). In the second, or AB serum test, AB human serum, previously decomplemented and absorbed with sheep RBC was added to the incubation mixture (EABRFC). We, as others, have previously shown that this latter procedure gives a higher number of rosettes than the former [10, 11] and we have confirmed this observation in our current work (Table 2). This phenomenon may be related to the detection of the total number of T cells by the sensitized test, while the direct test may define a sub-population of this group.

Table 2. Comparison of rosette formation with and without serum AB

	ERFC		EABRFC	
	(%)	(No.)	(%)	(No.)
Chemotherapy	35	496	42	696
Immunotherapy	32	869	44	1173
Normals	46	1074	56	1299

B-lymphocytes

Enumeration of B-lymphocytes was performed by determination of membrane immunoglobulin (mIg) using a direct immunofluorescent test with a polyvalent fluorescent isothiocyanate conjugated sheep anti-human immunoglobulin serum. Details of this method have been previously described. [9]

Monocytes

Monocytes were enumerated by peroxidase staining as suggested by a recent W.H.O. Workshop [12]. One thousand mononuclear cells were counted for peroxidase positively on each slide.

"Null" cells

After establishing the absolute number of each of the three foregoing groups (EABRFC, mIg + cells, Peroxidase + cells) we calculated the number of so-called "null" cells by the following formula: "Null" cells = mononuclear cells (EABRFC + mIg positive cells + peroxidase positive cells).

Statistical analysis

Statistical analysis were performed by the Student *t*-test.

RESULTS

Table 3 presents a summary of the results of our study and their statistical analysis.

Chemotherapy group

The patients on chemotherapy had a significant reduction in the mean number of mononuclear cells and of the total number of EABRFC in comparison to both the immunotherapy and normal groups. No such difference was noted in either the total number of mIg + or peroxidase + cells. When "null" cells were

Table 3. Summary of results

	Mononuclear cells	EABRFC	mIg Positive	Peroxidase positive	"Null'
Chemotherapy	1470	696	455	344	104 (7%*)
Immunotherapy	2714	1173	467	198	883 (33%*)
Normal	2356	1299	381	396	304 (12%*)
Chemotherapy/ immunotherapy	$P = < 0{\cdot}001$	$P = 0{\cdot}01$	N.S.	N.S.	$P = < 0{\cdot}001$
Normal/chemotherapy	$P = 0{\cdot}02$	$P = 0{\cdot}01$	N.S.	N.S.	N.S.
Normal/immunotherapy	N.S.	N.S.	N.S.	N.S.	$P = < 0{\cdot}01$

*Percent mononuclear cells without markers.

calculated no difference to normal cells was found, but there were far fewer ($P = 0{\cdot}001$) in this group than in the patients receiving immunotherapy.

Immunotherapy group

As discussed above, the immunotherapy patients had a significant elevation of mononuclear cells, EABRFC cells, and "null" cells over the chemotherapy group. Although there were differences in the total number of mononuclear cells and of the subpopulations between the immunotherapy and normal group, the only statistically significant difference was in the calculated "null" cells. There was a much larger number of such cells in the immunotherapy group ($P = 0{\cdot}01$).

DISCUSSION

In our study the percentage and total number of EABRFC, mIg positive, and peroxidase positive cells in normal individuals were in the range previously published [13]. The calculated "null" cells are also in agreement with available data. Our control group was composed of subjects in an older age group than our patients' groups because of the logistic difficulty of obtaining normal paediatric subjects. Several recent reports give conflicting results on the influence of age of the distribution of B and T cells. Weksler and Hutteforth [14], for example, found no change in the absolute number of peripheral lymphocytes or T and B cells with increasing age, and Carosella [15] demonstrated a decreased percentage of T cells occurring somewhere between 46 and 60 yr of age. Since our control group had a mean age (30 yr) considerably younger than this we believe that age difference does not represent a significant problem in the analysis of our results.

The chemotherapy group was marked by a diminution in total mononuclear count. Surprisingly, our data showed that this decrease involved the T rather than B-lymphocytes. Immunoglobulin levels were consistent with our "B cell" results, in that the chemotherapy group did not vary significantly in its IgG, IgA or IgM values compared to the normal group. These findings differ from the report of Sen and Borella [16] who found that T cells were in the normal range while B cells were decreased in patients with acute lymphocytic leukemia on the last day of a 3 year chemotherapy programme. Although the difference in results remains unexplained, the shorter period of chemotherapy in our patients (8–9 months) may in part account for this discrepancy.

A striking finding of our study is the significant elevation in the absolute number and percentage of "null" cells in the immunotherapy group as compared with both the chemotherapy and normal groups. Although the nature of these cells is still unknown, several hypotheses concerning their increase in this situation can be entertained.

1. These cells may represent abnormal elements persisting even during apparently complete remission of acute lymphocytic leukemia. The continued perfect clinical and cytological condition of these patients does not favour this hypothesis.

2. They may be stem cells circulating in the peripheral blood. Although it has been demonstrated that BCG can increase hematopoietic stem cells in mouse bone-marrow [17] human data is lacking.

3. They may be "K" cells. It has been shown that there is increased "K" cell activity in patients on BCG therapy for acute lymphocytic leukemia in comparison to patients receiving no treatment [18]. This hypothesis seems plausible since it has recently been suggested

that "K" cells may be "null" cells [19]. Arguments supporting this hypothesis are now in progress in our laboratory [20]. Lelarge *et al.* unpublished.

4. They may represent T or B lymphocytes or monocytes which have lost any detectable markers, a change possibly induced by immunotherapy.

5. A final possibility is that there may not be a true increase in these cells, but rather a redistribution between the peripheral blood and the various reticulo-endothelial organs.

Further studies are in progress in our laboratory to confirm these preliminary results and to elucidate the nature of these intriguing cells.

Active Immunotherapy Trials on Acute Lymphoid Leukemia Lymphosarcoma and Acute Myeloid Leukemia

G. MATHE, L. SCHWARZENBERG, M. DELGADO and F. DE VASSAL

Institut de Cancérologie et d'Immunogénétique (INSERM) de l'Hôpital Paul-Brousse and Service d'Hématologie de l'Institut Gustave-Roussy†*

Abstract—*Active immunotherapy (A.I.) has given 85% cure expectancy to patients of all ages suffering from acute lymphoid types of leukemia called "microlymphoblastic". Cure expectancy for those with the prolymphocytic or macrolymphoblastic types is 40–50%.*

In the case of terminal leukemic lymphosarcoma, patients submitted to the same protocol as acute lymphoid leukemia protocol are surviving for more than 4 years in perfect condition; this has never been achieved with maintenance chemotherapy.

In the case of acute myeloid leukemia, AI prolongs both remission and survival, and recent methods of treatment give grounds for believing that results can be further improved.

Initial results for chronic myeloid leukemia give reason to hope that immunoprevention of the terminal blastic crisis will prove possible.

As regards chronic lymphoid leukemia, the present aim is immunorestoration.

Immunotherapy is extremely well tolerated—treatment was only stopped in one out of 277 cases—whereas long-term maintenance chemotherapy has a high mortality rate for patients in remission.

Immunotherapy appears to prevent the late relapses which seem frequent in patients undergoing maintenance chemotherapy only.

FROM 1963 to the present day we have submitted 300 leukemia patients to active immunotherapy [1–5].

PRINCIPLE OF IMMUNOTHERAPY

As we have shown in several experimentally-induced leukemias [2, 6, 7], immunotherapy is based on the principle of stimulating immune reactions to leukemia associated antigens. This is done either by a specific process—injection of tumour cells sterilized by *in vitro* irradiation—and/or by a non-specific process that consists of applying one or several immunity adjuvants. In our experimental work, we found it more effective to combine both processes rather than use only one.

Immunotherapy is immune treatment applied to the established illness; this distinguishes it from immunoprevention, which is the administration of treatment before tumour establishment. We found that immunotherapy was able to kill all the tumour cells on condition that their number did not exceed 10^5 [6].

This property indicates the place of immunotherapy among available methods of treating leukemia. Since chemotherapy cannot kill the last cell [8] because it obeys first order kinetics [9, 10, 11] and, when effective, only kills *a certain proportion of cells whatever their number*, it is logical to treat leukemia by a sequential combination of chemotherapy and active immunotherapy.

In patients kept in remission by a single "maintenance" course of chemotherapy, lymphocyte DNA has been shown to have the same virochemical marker as leukemia cells during a perceptible phase of the illness [12,13]. Moreover Jean Bernard has shown that patients undergoing only chemotherapy "maintenance" treatment are often subject to late relapses [14]. For both these reasons we feel fully justified in having fixed the duration of immunotherapy at five years, as early as 1963. In fact, immunotherapy might also have an immunopreventive effect on neoplasia reinduction by viral or virus-dependent factors such as DNA [see reference 15].

*14–16 avenue Paul-Vaillant Couturier, 94800 Villejuif, France.

†16 bis avenue Paul-Vaillant Couturier, 94800 Villejuif, France.

It is logical to apply active immunotherapy exclusively to leukemia if tumour antigens are present in the cells. In our laboratory, Doré and Guibout confirmed this hypothesis [16] and showed that it could not only be applied to acute myeloid leukemia, but also to acute lymphoid leukemia (ALL).

MATERIAL AND METHODS

Active immunotherapy stimulation is therefore of two kinds: specific and non-specific.

Specific stimulation. Our method consisted of administering intradermal or subcutaneous injections of $4 \cdot 10^7$ irradiated cells kept at −196°C*, taken out of a blood pool from patients with the same type of neoplasia. For a month this dose was given weekly and thereafter, monthly [17].

Specific stimulation can also be obtained by administering a strain of acute lymphoid leukemia cells in culture* [18].

Non-specific stimulation. As a non-specific immunity adjuvant, we use fresh live BCG from the Pasteur Institute.† The method of administration, based on studies of the dose/effect relationship in Man [19], is as follows: BCG is applied to scarified areas formed by 5 cm long scratches arranged in a square. Within the square, 10 scarifications are made lengthwise with a vaccinating needle, and 10 widthwise, bringing the total length of the scarifications to one metre. Fifty milligrams of BCG are applied to this area, sufficiently slowly to ensure complete penetration. Slight bleeding is not contraindicated, indeed it is preferable.

The number of scarified areas to which BCG is applied depends on the cutaneous reactions to the various antigens (PPD, mumps and Candida). If the reactions are negative, BCG is only applied to one scarified area on one limb, and the limb is changed every week, which means each of the 4 limbs is given BCG every month.

On the other hand, if at least one reaction is positive, four areas, one on each limb, are scarified for each weekly application, and BCG is applied to all four. Consequently, patients with positive reactions are given four times as much BCG as those with negative reactions.

Scarifications were made three times a week for the first three weeks of treatment, twice a week from the fourth to sixth weeks, and once a week from the seventh week onwards.

Other adjuvants, including Corynebacterium parvum and C. Granulosum, and a polynucleotide [Poly I–Poly C] [see reference 2], were used in addition to BCG in treating some groups of patients, but we were unable to show that these combinations were more effective than BCG alone.

Timing of applications. Although active immunotherapy can only kill a limited number of tumour cells, it can kill the last cell. We, therefore, applied it after the following two phases, designed to reduce the cell load:

*These cells may be obtained by fellow practitioners from the ICIG, Hôpital Payl-Brousse, 14–16 avenue Paul Vaillant-Couturier, 94800 Villejuif, France.

†Currently sold under the trade name of Immuno-BCG-Pasteur-F. We have shown that this preparation, stored at 4°C, enables the bacteria to retain their adjuvant action for three months.

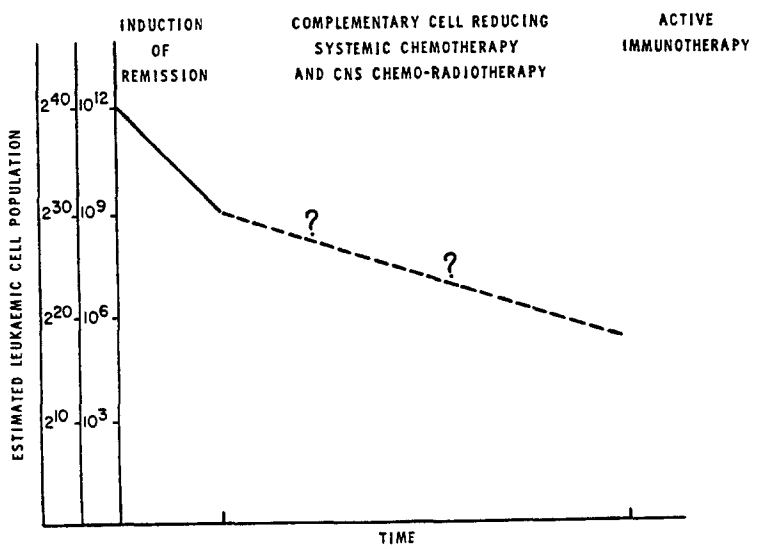

Fig. 1. Combination of remission-inducing sequential chemotherapy, complementary cell-reducing chemo and radiotherapy, and active immunotherapy.

(*a*) the chemotherapy phase, during which remission is obtained and (*b*) the general chemotherapy and complementary cell-reducing meningeal chemoradiotherapy phase [20]. The sequence is illustrated in Fig. 1.

Tolerance. Irradiated leukemia cells were extremely well tolerated. Tolerance of BCG, which we recently assessed in 277 patients, was also remarkably good as we were only obliged to stop administering it in a single case (Table 1).

Table 1. *Comparative toxic cost of active immunotherapy and of "maintenance chemotherapy" in acute lymphoid leukemia treatment*

	Deaths	Severe not lethal toxicity
*Active immunotherapy**		
G. Mathe *et al.* [21]	0/277 patients	
"Maintenance chemotherapy"		
J. V. Simone [22] (Protocol V)	3/31 patients	
J. V. Simone [22] Protocol (VI)	5/94 patients	
J. V. Simone [22] (Protocol VIa)	2/10 patients	
J. V. Simone [22] (Protocol VII)	4/94 patients	
J. V. Simone [22] (Protocol VIII)	2/92 patients 2/17 patients	
R. Aur . . . & J. V. Simone [23]	3/20 patients	6 Crippling Leucoencephalopathy/20
Cl. Jacquillat & J. Bernard [24] (Protocol 06 LA/66)	6/81 children 6/21 adults	
F. Lampert *et al.* [25] (Early irradiation)	4/79 patients	
(Late irradiation)	1/19 patients	
F. Mandelli *et al.* [26]	2/30	
T. S. Gee *et al.* [27]	3/74 children	
A. C. Smith *et al.* [28]	2/17 adults	

*Cure expectancy of the microlymphoblastic type after active immunotherapy: > 80.

The innocuous nature of immunotherapy contrasts sharply with the extremely toxic and particularly lethal effects of "maintenance" chemotherapy, which kills 10 to 20% of patients during remission and sometimes more (Table 1) not to mention the long-term risks it can involve such as carcinogenesis, sterility and genetic changes in descendants [20].

RESULTS

1. *Acute lymphoid leukemia*

1.1. *Initial trial.* In 1963 we conducted a trial with controls, in which we compared the results for 20 randomized patients submitted to chemotherapy, followed by immunotherapy, with those of 10 randomized cases given the same chemotherapy as the first group but no immunotherapy afterwards [1]. Whereas the ten controls all relapsed within 130 days, 7 out of the 20 patients who underwent immunotherapy are still in perfect health, from 7 to 13 years after immunotherapy started (Fig. 2) [3].

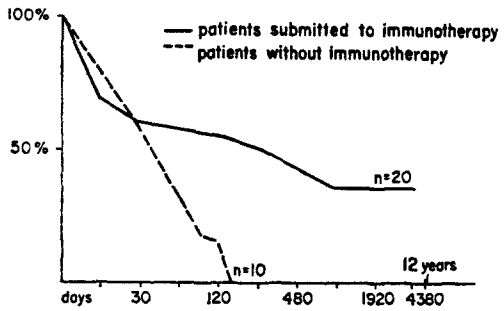

Fig. 2. *Actuarial duration curve for complete remissions in patients undergoing active immunotherapy after cessation of all Chemotherapy (first trial). (Note geometrical time scale.)*

1.2. *Results for the first* 100 *cases.* In 1975 we carried out a retrospective survey of the first 100 patients submitted to immunotherapy whose bone marrow smears were still available for checking diagnosis and establishing their cell type [3, 21].

Their overall cumulative duration of survival while in remission is shown in Fig. 3. It will be noticed that the survival median is over five years, and that in the case of 23 patients, the curve breaks to form a plateau at the 48th month. This plateau is considered as the statistical expression of *cure expectancy.*

Other points worth noting are (*a*) that second remissions after premature relapses

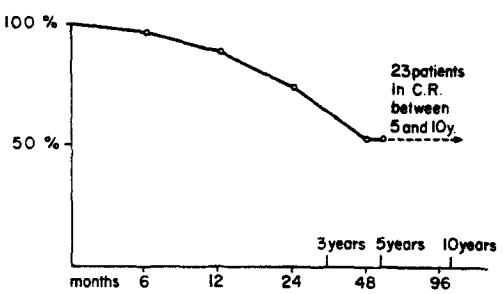

Fig. 3. *Cumulative duration of survival for the first* 100 *ALL patients, in perfect clinical and hematological condition, who underwent active immunotherapy (note geometrical time scale).*

occur with the same frequency (93%) as first remissions [29], and (*b*) that we did not observe any relapses between the fourth and 13th years [3].

Results for immunotherapy are thus in sharp contrast to those for maintenance chemotherapy, for, according to Jean Bernard [14], many patients undergoing the latter treatment have relapses after the fourth year.

1.3. *Confirmation of the effect of immunotherapy on acute lymphoid leukemia.* At first, an MRC group [30] who used Glaxo BCG, which we did not find effective in our experiments [31], was unable to observe the effects of immunotherapy on ALL. They were confirmed, however, by the Hemopathy Working Party of the European Organization for Research in the Treatment of Cancer [32] and by Ekert and Jose in Australia [33].

1.4. *Immunosensitivity and prognosis factors.* All ALLs do not have the same cure expectancy as the one shown in Fig. 3. The factors determining it [2, 3] are not the same as the prognosis factors for patients undergoing a single course of maintenance chemotherapy [24 and 34].

For instance age, which has some bearing in the latter case, makes no difference in immunotherapy.

On the other hand, the size and deposits of neoplastic formations, and more particularly their cell types (Fig. 4) [35, 36], affect our patients and we have been able to show that this last characteristic governs all the others.

Figure 5 shows the different prognoses according to cell type. For patients of all ages with *microlymphoblastic* leukemia, cure expectancy is 85% and for those with the *prolymphocytic* and *macrolymphoblastic* varieties of the disease, it is between 40 and 50%. There is no plateau for those with what is known as the *prolymphoblastic type*, which English-speaking authors call *undifferentiated* and usually discount from ALL statistics.*

It is interesting to observe from Fig. 5 that prognosis based on the cell type is determined by sensitivity to immunotherapy and that such prognosis does not therefore appear in the results Jean Bernard obtained [24, 34] with the patients he submitted to maintenance chemotherapy alone.

Our findings with regard to prognosis factors led us to adapt our protocol to them.

*The 100 cases we studied did not include any patients with the type of leukemia recently described as the acute immunoblastic variety [37].

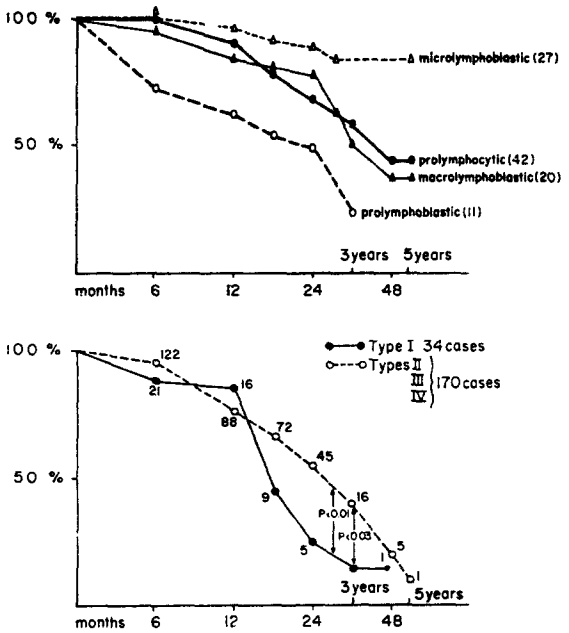

Fig. 5. Upper part: Cumulative duration of survival in patients undergoing active immunotherapy according to the following cell types:

(*a*) *microlymphoblastic*
(*b*) *prolymphocytic*
(*c*) *macrolymphoblastic*
(*d*) *prolymphoblastic (or undifferentiated?)*

The first three types only form a plateau after five years. Lower part: Cumulative duration of survival, for the same cell types, in patients submitted to maintenance chemotherapy by J. Bernard et al. [24, 34]; *This difference in prognosis does not recur in maintenance chemotherapy patients treated by J. Bernard* et al. *It is therefore reasonable to suppose that the difference found in our patients, depending on their cell type, is determined by their respective sensitivity to immunotherapy. (Note that time scale is geometrical for these curves.)*

Figure 6 shows that protocol 12 includes pre-immunotherapy cell-reducing chemotherapy which is more intensive for the cases with the least favourable prognosis.

With regard to our trials, the use of another immunity adjuvant in addition to BCG—in our case Corynebacterium parvum, C.granulosum* or Poly I–Poly C—did not improve the results for BCG [2].

2.

For *leukemic terminal lymphosarcoma* [5] a few patients were treated by active immunotherapy, using a combination of irradiated tumour cells, BCG and C. granulosum. The results were better than those for maintenance chemotherapy (Fig. 7) and five of these patients are today in perfect health, 13 to 66 months after the start of treatment.

*This adjuvant should only be used in extremely specialized centres where the different immune-functions can be measured as it inhibits the T-dependent reactions essential to antitumoral immunity [2].

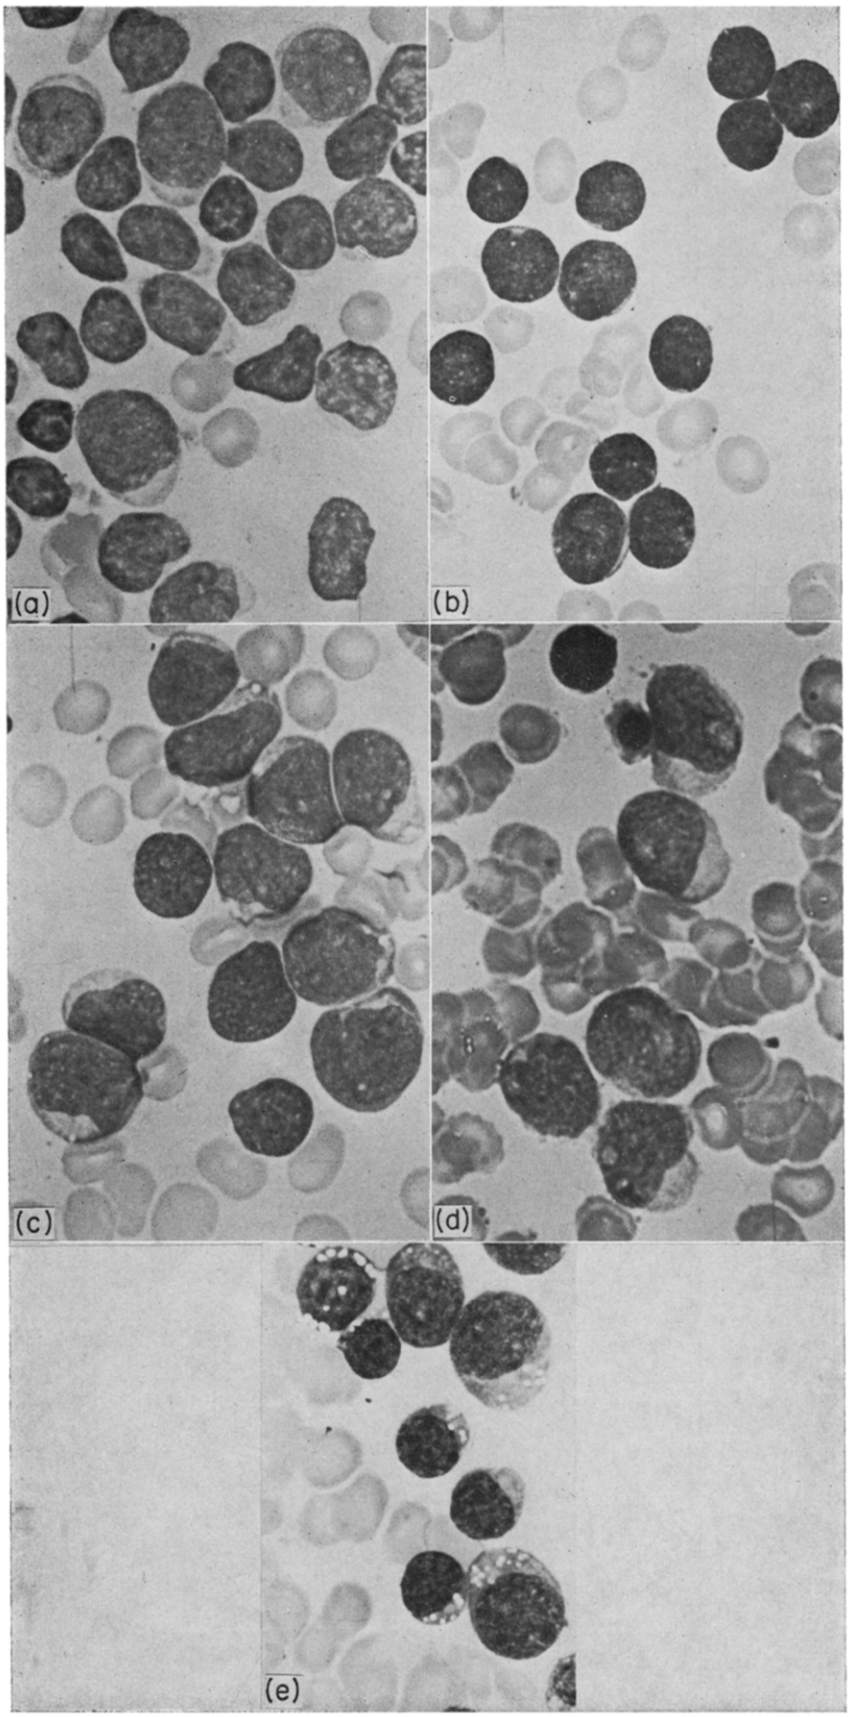

Fig. 4. *The five types of acute lymphoid leukemia: (a) microlymphoblastic, (b) prolymphocytic, (c) macrolymphoblastic, (d) prolymphoblastic, (or undifferentiated?), (e) immunoblastic* [*see* 36 & 37]. *The* 100 *patients studied do not include cases of the immunoblastic type* [38].

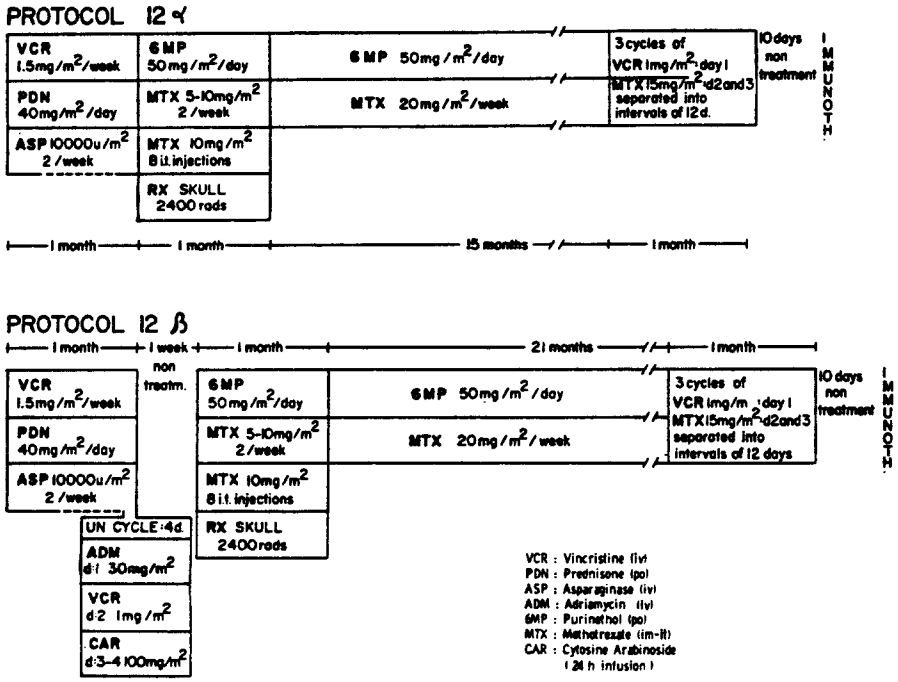

Fig. 6. Protocol 12 currently applied to patients suffering from acute lymphoid leukemia or leukemic lymphosarcoma. α type: patients with signs of a good prognosis, β type: patients with signs of a poorer prognosis. After remission induction, the latter type is given a complementary course of treatment called a reinforcement course, as well as a longer course of cell-reducing chemotherapy than that included in the α type protocol.

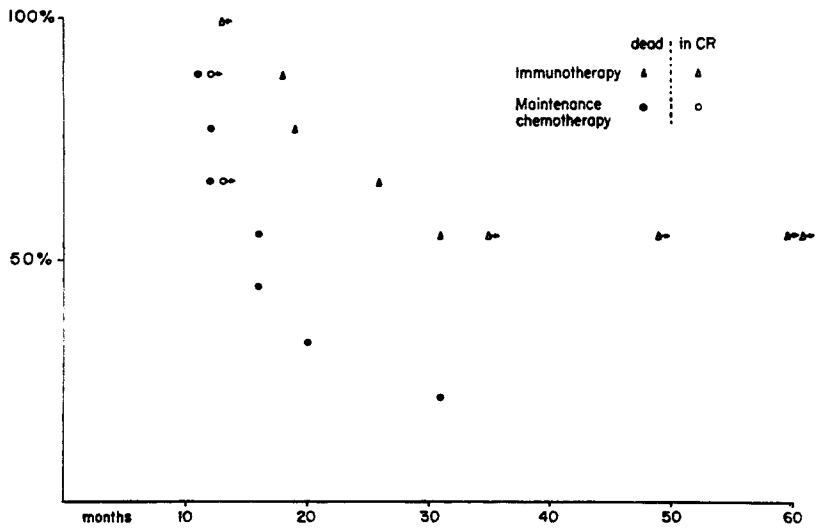

Fig. 7. Comparison of cumulative survival in two groups of patients with terminal leukemic lymphosarcoma. One group followed the same protocol as the ALL cases, including immunotherapy, and the other was treated by maintenance chemotherapy.

3.

In the case of *acute myeloid leukemia*, the results of several trials have been published. They confirm the effects of active immunotherapy using either BCG alone [39, 40] or neuraminidase-treated tumoral cells alone [41], or, again, a combination of BCG and neoplastic cells [4, 42]. The results of our own trials were favourable (Table 2 and Figs. 8 and 9), but less satisfactory than those for ALL or for the trial in which neuraminadase-treated cells were used [41].

The protocol we are applying at present is

Table 2. Acute myeloid leukemia active immunotherapy

		Medians	
		of first complete remissions (FCR)	of survival after FCR
Maintenance chemotherapy	EORTC first trial [43]	32 weeks	55 weeks
	EORTC second trial [44]	34 weeks	N.D.
	EORTC Villejuif patients in both trials	26 weeks	52 weeks
	Vogler and Chan [39]	26 weeks	
	Powles *et al.* [42]	26 weeks	46 weeks
	Gutterman *et al.* [40]	60 weeks	
Chemotherapy interspersed with immunotherapy	Gutterman *et al.* [40]	72 weeks	
	Powles *et al.* [42]	58 weeks	77 weeks

	Mathe *et al.* [4]	60 weeks	104 weeks

N.D. = not determined.

therefore designed to study the use of cells treated by the latter enzyme.*

4. *Chronic myeloid leukemia (CML) and chronic lymphoid leukemia (CLL)*

For CML, Sokal's results [46] are very encouraging. As with his treatment, our present protocol aims at immunoprevention of the blastic crisis.

As regards CLL, our current trial is designed to restore immunity, which is often insufficient [2].

*Doctors may obtain these cells from the Institut de Cancerologie et d'Immunogénétique, Hôpital Paul Brousse, 14–16 avenue Paul-Vaillant Couturier, 94800 Villejuif.

Splenic and Hassall's Corpuscles Modifications Following Injection of Fresh BCG in the Guinea-Pig

R. SENELAR,* B. SERROU,† A. SERRE,‡ J. P. BUREAU* and M. J. ESCOLA*

‡*Laboratory of Immunology, Faculté de Médecine, Bld Henri IV, 34.000, Montpellier, France*

Abstract—*The results indicated that i.v. injection of fresh BCG induced in the guinea-pig thymus a transient increase of lymphocyte mitosis associated with an epithelial hyperplasia in the cortex on day 10. Changes in the medulla were more obvious on day 15. The hyperplasia of Hassall's corpuscles and epithelial cells in the medulla reached its maximum level at a time when many lymphocyte masses appeared in the splenic red pulp and in the T area of the spleen. Evidence suggesting an active secretory function in their external cells was recorded. These findings were consistent with the hypothesis that BCG produces an increase of new lymphocytes input into the T lymphocyte cycle.*

INTRODUCTION

IT HAS been suggested [1] that Hassall's corpuscles were not only a site of lymphoid cells destruction, but were also a privileged area for maturation of medullary lymphocytes, at least in the foetal guinea-pig thymus. Since it has been shown that BCG injections induced a transient proliferation of lymphocytes in the mouse thymus [2], it was interesting to ascertain if Hassall's corpuscles would also be involved in this process. In this regard, Hassall's corpuscle changes might be a marker visualizing a modification of the lymphocyte cellular kinetics in the thymus.

In the present work, both electron and light microscopic and quantitative histological techniques were used to study the development of Hassall's corpuscles and to achieve information on their relationship between thymic and splenic changes during the process of immunization by BCG.

MATERIAL AND METHODS

Experimental animals

One hundred and eight male and female guinea-pigs (3–4 months old) were used. They were randomized into 8 experimental groups and 1 control group. Each group consisted of 12 guinea-pigs.

Treatment

Pasteur Institute BCG was employed. It comprises 7×10^6 viable units per mg. It was a fresh non-lyophilised preparation less than 7 days old. Each guinea-pig was injected with 12 mg of BCG. Intravenous (i.v.), subcutaneous (s.c.), intraperitoneal (i.p.), and intradermal (i.d.) routes of administration were employed. The guinea-pigs were injected on 10th and 15th day before they were sacrificed.

Tissue preparation

The thymus and the spleen were rapidly removed and weighed on electric balance. For light microscopic studies, whole thymic lobes were fixed in Bouin-Holland solution. Twenty-eight to 51 serial sections were cut for each lobe.

These sections, approximately 5 μm thick, were stained with Hematoxylin-Eosin, Methyl-green Pyronin and P.A.S. The spleen was treated in a similar fashion. For quantitative histological studies, at least 28–51 serial sections were micrographied for each thymus. Surface measurements of Hassall's corpuscles and medulla were made on micrographs enlarged photographically to a final magnification of 350 ×. A transparent plastic sheet ruled with a square grid containing 25 squares was placed over each micrograph to subdivide it

into areas for counting. Each square represented an area of 812 μm^2 on the original section. To express the results the index "I" was determined by the expression:

$$I = \frac{\text{Mean Surface Area of Hassall's Corpuscles}}{\text{Mean Surface Area of Medulla}} \times 100$$

The Student *t*-test was employed to statistically evaluate the results.

For electron microscopic studies small pieces of tissue were fixed according to Sabatini *et al.* [3] and embedded in epon [4]. Ultra thin sections were cut with a glass knife on a L.K.B. ultramicrotome, mounted on 200 mesh uncoated grids and doubly stained with saturated uranyl acetate and lead citrate [5]. The grids were examined with a J.E.M. 100 C electron microscope (Jeol).

RESULTS

Macroscopic observations

There was no significant difference of thymic weight in all experimental groups. Significant differences in the splenic weight were noted on day 10 in i.v. and i.p. injected guinea-pigs. On day 15, significant differences were recorded in i.v., s.c. and i.p. injected guinea-pigs, but not in the i.d. injected group. A striking difference in the splenic weight occurred between day 10 and day 15.

Microscopic observations

The thymus: day 10. In the cortex the thymic sections of the i.v. injected guinea-pigs showed an increase of the mitotic activity of lymphocytes associated with an epithelial hyperplasia (Fig. 1).

In the medulla an epithelial hyperplasia was also recorded. Large epithelial cells were gathered in clusters (Fig. 2). Under electronic examination the largest sized cells appeared engaged in a keratinizing process (Fig. 3).

Day 15. The cortical reactions were less obvious or disappeared, but in the medulla the epithelial hyperplasia was more conspicuous. Numerous single epithelial cells resembling Mandel cystic cell [6] were observed (Fig. 4). A great amount of small full Hassall's corpuscles were noted (Fig. 5). Cavity corpuscles were readily invaded by granulocytes. Many degenerating corpuscles were equally observed. The external cells [1] constructing the peripheral zone of the Hassall's corpuscles contained an appreciable number of dilated ergastoplasmic cisternae vacuoles (Figs. 5 and 6). These vacuoles varied in size and sometimes exhibited an amorphous substance having the appearance of secretion (Fig. 7). The wall of the largest vacuoles was provided with short microvilli which protruded into the lumen (Fig. 8). Dense granules similar to glycogen particles were conspicuous in their cytoplasm (Fig. 8). Large and medium sized lymphocytes were located in intimate contact with the external cells (Figs. 5 and 6).

The "I" index changes confirmed (Table 1) that the volume of Hassall's corpuscles increased on day 20 in i.v. injected guinea-pigs. The increase was more striking on day 15 in i.v., s.c. and i.p. injected groups.

Table 1. *This table shows that the volume of Hassall's corpuscles increased on day* 10 *in i.v. injected guinea-pigs. These results were confirmed on day* 15 *in i.v., s.c. and i.p. injected groups*

Days	Routes	I. Index

(a) Mean ± Standard Error.
(b) Student *t*-test
S.: Significant.
N.S.: Non Significant.
(c) Days after injection.

The spleen: day 10. The splenic sections of the i.v. injected guinea-pigs depicted a considerable amount of multiple granulomas in the red pulp cords. They consisted of epithelioid and giant cells (Figs. 9 and 11). The red pulp was enlarged and multiple lymphocytic foci were seen distinctly outside the Malpighian corpuscle (Fig. 9).

Day 15. The splenic red pulp was considerably enlarged. The lymphocytic infiltration also involved the periarteriolar zone of the white pulp (Fig. 11). In s.c. and i.p. injected guinea-pigs these changes were less obvious. They were very attenuated in the i.d. injected group.

DISCUSSION

The results indicated that i.v. injection of

fresh BCG induced in the guinea-pig thymus a transient increase of mitosis and an epithelial hyperplasia in the cortex on day 20. Changes in the medulla were more obvious on day 15. In this area, some epithelial cells were isolated and were similar to cystic cells descirbed by Mandel [6]. Numerous epithelial cells were gathered in clusters identified as new Hassall's corpuscles [1]. Evidences suggesting an active secretory function were obvious in their external cells. Since epithelial cells have been proposed as producing thymic factor(s) involved in immune function [7–13], it is worthy to note that external cells were in close contact with large and medium lymphocytes. The "I" index changes suggested a significant increase in the relative volume of Hassall's corpuscles. The hyperplasia of Hassall's corpuscles and epithelial cells in the medulla reached its maximum level at a time when many lymphocytes masses appeared in the splenic red pulp and in the T-area of the spleen. These findings were consistent with the hypothesis that BCG acts in cancer immunoprophylaxis or immunotherapy [14–24] in increasing the input of many lymphocytes into the T lymphocyte cycle [2, 22]. On a theoretical level, this work offers new evidence of Hassall's corpuscle involvement in certain immunological processes. On a practical level, this paper delineates the importance of BCG route.

Clinical Trial of Poly I – Poly C as an Immunity Adjuvant and an Immunorestoration Agent

M. C. SIMMLER, M. BRULEY-ROSSET, D. BELPOMME and L. SCHWARZENBERG

Institut de Cancérologie et d'Immunogénétique (INSERM), Hôpital Paul-Brousse, 14-16, avenue Paul-Vaillant Couturier 94800-Villejuif, France

Abstract—*We present preliminary results in cancer patients of an attempt at non-specific cell-mediated immunorestoration with poly I – poly C during a treatment of 28 days.*

Two out of 9 patients have shown decreased responses to recall antigens, while the in vivo immune status of 7 out of 9 remained unchanged.

Two out of 9 non-responders to PHA, 2 out of 8 non-responders to PPD, and 4 out of 8 non-responders to an allogeneic lymphocyte population were converted to responders.

Two out of 5 patients without any LIF activity before, presented positive inhibition after the treatment.

Numeration by surface markers of T, B and monocytes gave no noticeable change.

We suggest that null or negative effects on DHR are in keeping with the load of the tumour.

Our in vitro results confirm previously published findings on short-term leucocyte cultures with mitogens and antigens.

INTRODUCTION

SYNTHETIC polynucleotide complexes have been demonstrated as antibacterial and antiviral agents [1–3], and also as adjuvants of immunity by improving immunological competency, as has been widely shown in experimental models [4–7].

Poly A – poly U and poly I – poly C have been found to increase macrophage activity as well as T and B cell responses [8–10].

The capacity of synthetic polynucleotides to enhance both limbs of the immune response, and to increase host resistance against tumours led us to conduct a clinical trial in patients with solid tumours in an attempt to restore or stimulate their immunocapacity.

We will present here preliminary results from the immunological examination of nine cancer patients and on possible changes in their immune status by treating them with a synthetic copolymer of poly-inosinic and poly-cytidylic acids (poly I – poly C) for 28 days.

MATERIAL AND METHODS

1. *Patients*

Six males and 3 females were included in this trial; 4 patients with melanoma, 1 patient with lung carcinoma, 1 patient with gastro-intestinal tract carcinoma and 2 patients with Hodgkin's disease; mean age was 53 yr (30–69).

2. *Preparation of poly I – poly C*

One milligram of a mixture of homopolymer poly I and poly C, and one sample of solvant (Choay, France) are left for 30 min at 37°C in a water bath. One dose of poly I – poly C is then diluted with solvent, and the required dose or doses are added to 125 ml of saline. The product is rapidly administered by i.v. injection.

3. *Dosage and time schedule of administration of poly I – poly C*

Details of administration are listed on Table 1.

Table 1. Dosage and time schedule of administration of poly I – poly C

Length of treatment	= 28 days
Dosage an time schedule	= days 1–3 1 mg days 4–6 2 mg days 7–9 3 mg days 10–28 4 mg
Route of administration	= i.v. injection in 125 ml of saline
In vivo tests	= at days: −1, +15 and +35
In vitro tests	= at days: −1 and +35

Table 2. Screening for an assay of immuno-restoration non specific immuno-exploration

In vivo tests: Skin tests	Recall antigen Protein purified derivative (PPD) (10 U) Mumps (2 U) Candida (1/10000) Streptokinase (1/100)
In vitro tests: Lymphocyte and monocyte counts (per mm^3 of blood) Lymphocyte transformation by: Phytohemagglutinin Pokeweed mitogen PPD Mixed allogeneic lymphocyte reaction (MLR)	Immunoglobulins Electrophoresis and immunodiffusion Percentage of mononuclear cells (a) Forming spontaneous rosettes with sheep erythrocytes (b) Carrying surface immunoglobulins (direct fluorescence) (c) Peroxydase positive cells (d) "Null" cells LIF activity in serum

4. *Surveillance of patients*

All patients are submitted to a non-specific immunological examination: exploration of *in vivo* and *in vitro* reactions. Tests are listed on Table 2.

(*a*) Delayed hypersensitivity reactions to recall antigens are estimated in mm of induration by a double blind estimation. (A positive reaction is an induration of > 5 mm).

(*b*) Lymphoblastic transformation tests by mitogens and antigens have previously been described [11] according to the method of Bréard [12].

(*c*) Numeration of subpopulations of mononuclear cells are tested by surface markers according to the techniques described by Belpomme [13].

(*d*) Leucocyte migration inhibiting factor (LIF) activity in serum is evaluated by a micromethod, according to the technique of Beaulieu (personal communication) which has been previously described [14].

RESULTS

1. *Toxicity*

No manifestation of toxicity was observed in this preliminary trial.

2. *Immunological effect*

2.1. *Delayed hypersensitivity reactions (DHR).* All patients were tested with four recall antigens.

We found no change in DHR after 15 days of treatment. Four out of 4 patients were anergic and remained at that time as non-immunoresponders *in vivo*. Among allergic patients, 3 patients presented one positive reaction with an induration of 10 mm, 1 patient had 2 positive reactions, and one

Table 3. Effect of administration of poly I – poly C on in vivo *and* in vitro *tests*

	On skin tests*		On lymphocyte transformation†			On LIF activity in the patient's serum‡
			PHA	PPD	MLC	
	d+15	d+35	d+35			d+35
Number	9		9	8	8	5
Conversion to positive reactions	0	0	2	2	4	2
Unchanged reactions	9	7	7	5	4	3
Decreased reactions	0	2	0	1	0	0

*Delayed hypersensitivity reactions to recall antigens (PPD, Mumps, candida and streptokinase): A patient is called allergic if he presents at least one positive reaction to a recall antigen with an induration > 5 mm.

†Lymphocyte transformation by PHA: A patient is said to respond to PHA if the incorporation of ^{3}H-thymidine after 4 days incubation is at least of 18·000 counts/min (according to the distribution obtained with 80 normal adult volunteers). By MLC and PPD if the stimulation index is > 5 × the background.

‡LIF activity is present if patient's serum inhibit normal leukocyte migration of at least 20% compared to normal serum.

patient 3 positive reactions. These allergic patients had no variation in their skin reactions at day 15.

But skin tests evaluated one week after the end of the treatment, i.e., at day 35, did not present the same pattern of reactions.

Two patients, 1 with 3 positive reactions and 1 with 2 positive reactions became anergic (Table 3).

2.2. *Analysis of* in vitro *lymphocyte transformation tests.* Critical analysis of these tests in evaluating cell-mediated immunity have been discussed previously [15].

Mitogen responses of lymphocytes are expressed in counts/min. Mean geometric values for PHA and PWM in a control population were respectively 70,000 counts/min and 25,000 counts/min. Confidence intervals were between 18,000 counts/min and 250,000 counts/min for PHA, and between 6500 and 150,000 counts/min for PWM.

Patients with lymphocyte responses less than 18,000 counts/min for PHA and 6500 counts/min for PWM were called non-responders. Values above these limits were considered as normal values.

Five patients presented normal values by PHA transformation before and after treatment. The mean value was 54,805 ± 4876 counts/min before treatment and 69,141 ± 9363 counts/min after poly I – poly C administration.

Two patients with values of ^{3}H-thymidine lymphocyte uptake of 615 ± 78 counts/min and 5566 ± 1057 counts/min before treatment, presented normal incorporation after treatment, with values of 26,914 ± 1648 counts/min and 137,226 ± 6740 counts/min respectively.

Two non-responsive patients remained with the same pattern of abnormal lymphocyte incorporation (181 ± 13 counts/min and 146 ± 19 counts/min before treatment, and 17,630 ± 2846 and 17,520 ± 2066 counts/min respectively after treatment).

Antigen responses of lymphocytes were expressed as a stimulation index (S.I. = counts/min in sensitized lymphocytes / counts / min in lymphocytes with medium alone × 100.) Patients with a S.I. 5 are called non-responders to antigens, i.e. PPD and allogeneic lymphocytes.

Responses of lymphocytes to PPD have been analysed.

Two patients had an increased S.I. after treatment (S.I. were of one and three before treatment and of nineteen and fifteen after treatment).

One patient presented a decreased reaction with a S.I. of 10 before poly I – poly *C* and of one after poly I – poly C.

The 5 other patients studied did not present any change in their responses. All had S.I. of less than 5 and remained non-responders to PPD.

Responses in mixed lymphocyte reactions (MLR) have been analysed.

Two patients had an increased S.I. after treatment (S.I. were of 1 and 3 before treatment and of 19 and 15 after treatment).

Four patients with a low S.I. at the beginning of the treatment have shown increased responses at day 35 (3 of them were totally non-responders and one presented a S.I. of 4 before poly I – poly C); S.I. after treatment have been respectively 17, 35, 75 and 68).

Results are summarized on Table 3.

2.3. *Analysis of* in vitro *LIF activity in the serum.* The activity of leucocyte inhibiting factor (LIF) in the serum was considered as positive if the percentage of inhibition of normal leucocytes was at least 20%. All sera were freshly tested.

Five sera have been evaluated before and after the administration of poly I – poly C.

All sera drawn before the treatment presented no significant inhibition.

Two out of 5 showed a positive inhibition when these sera were taken at day 35. The percentages of inhibition were 20% and 25%.

We did not observe any change in the DHR of these two patients.

Results are summarized on Table 3.

2.4. *The numeration of subpopulations of mononuclear cells.* This has been evaluated by surface marker tests. Results were expressed in absolute numbers of the different populations, and a 25% change more or less in the initial value was considered as a significant change.

T cell numerations have been expressed according to two techniques, with and without AB serum:

(*a*) without AB serum: 6 out of 7 patients showed no significant change, 1 patient presented a significant decrease in this test;

(*b*) with AB serum: 4 out of 7 patients had no significant change; again 1 patient presented a significant decrease, as with the technique without AB serum; and 2 patients, who had shown no change in previous test, had a significant increase in this test: one of these patients presented a significant increase in PHA response, while remaining a non-responder in PPD and MLC tests; the other patient presented no depressed PHA transformation before treatment but no PPD and MLC responses.

This patient has been converted to positive reactions with these antigens after treatment.

B cells numeration by polyvalent serum presented no significant change.

Peroxydase positive cells, i.e., *monocytes*, have shown no significant variation.

2.5. *Correlation between skin reaction tests and* in vitro *lymphocyte transformation by PHA.* Table 4 indicates what had already been observed in a previous study on the effect of BCG on immunodepressed cancer patients [11], that the correlation between *in vivo* DHR and *in vitro* transformation by PHA is only partial [11].

Seven out of 18 tests estimated before and after treatment by poly I – poly C, are correlated. Thus the percentage of correlation between both tests is only 39.

DISCUSSION

Analysis of *in vitro* lymphocyte transformation tests indicated that poly I – poly C might enhance tritiated thymidine incorporation in lymphocytes both with PHA and with antigens. The sensitized lymphocyte response of one patient was depressed. These findings are in accordance with the results of a preliminary report from the Oettgen's group who found, in patients with advanced cancer, 1 enhanced response and 4 depressed responses to PHA[16]. Our results also confirmed the data published by others studying the effect of polynucleotides on short term leucocyte culture, although they systematically found a depressive effect with PHA stimulation, while an enhancing one in sensitized lymphocytes [17, 18].

LIF activity was found to be positive in 2 patients, without any change in their *in vivo* responses. One of them became responsive in *in vitro* transformation tests by PHA and by MLC.

The weak variations in mononuclear cells numeration have been difficult to interpret and it seems possible that for a significant change to appear after a trial of immunotherapy more time is needed; as recently Belpomme *et al.* [19] found no significant change with a 15 days treatment by BCG, while after a long-term immunotherapy they found a significant increase in null cells.

Table 4. Absence of correlation between skin reaction tests in vitro *lymphocyte transformation by PHA*

In vivo tests†	*In vitro* transformation test*	
	Non responders = 9 patients	Responders = 9 patients
Anergic = 10 patients	4	6
Allergic = 8 patients	5	3

*Lymphocyte transformation test by PHA.
†Delayed hypersensitivity reaction to recall antigens (PPD, mumps, candidine, streptokinase).

It has been shown that host resistance against tumours is increased, especially when the tumour load is low as has been demonstrated in patients with acute lymphoblastic leukaemia [20], or when the tumour mass has been diminished by surgery [21]. Thus we postulated that the negative effect in restoring or stimulating DHR in our patients is in keeping with the tumour volume. We cannot however interpret the two depressed *in vivo* reactions found while these patients failed to present any decreased *in vitro* responses.

Levamisole and Human Lymphocyte Cultures*

JOSEPH WYBRAN and ANDRÉ GOVAERTS

Service d'Immunologie, Hôpital Universitaire Saint-Pierre, Brussels

Abstract—*Blood lymphocytes from normal subjects were cultured with levamisole in the absence or presence of phytohemagglutinin (PHA). Levamisole, by itself, did not stimulate the lymphocytes. Levamisole, at 10^{-3} mg/100 ml, significantly increased the response to the mitogen. Other concentrations (from 1 mg to 10^{-8} mg/100 ml) did not alter the response to PHA. The same effect, at the same concentration, was observed for isolated blood T cell rich populations in presence of PHA. Levamisole did not modify the PHA response of T cell poor populations. These experiments suggest that levamisole has an action on human T lymphocytes.*

INTRODUCTION

LEVAMISOLE, an antihelmenthic drug, has recently been much investigated in immunology. This interest lies in the reports that it can stimulate, immune mechanisms in mice and in man [1, 2]. In mice, levamisole has thus been shown to possess stimulatory activity on both humoral and cellular immune responses, when injected into animals at the same time as the antigenic stimulus [1]. Both lymphocytes and macrophages appear to be involved in the mechanisms of levamisole. In man, the drug restores the delayed hypersensitivity responses in the anergic old normal subjects or cancer patients [2]. Little is known regarding the, *in vitro*, effect of levamisole on human lymphocytes. Therefore, we decided to investigate if levamisole can directly stimulate human lymphocytes or influence their response to phytohemagglutinin (PHA), a rather specific T cell mitogen.

MATERIAL AND METHODS

Human lymphocytes were isolated from heparinized blood of six normal volunteers, on a Ficoll–Hypaque gradient. They were washed three times with a Hank's buffered salt solution and resuspended at a final concentration of 20×10^6 cells per ml of medium RPMI 1640 with HEPES (Gibco-Biocult). A fraction of these cells, further referred as unseparated population was used for these cultures [3]. The other fraction was further processed in order to obtain a T cell rich population and a T cell poor population according a rosetting technique previously described [4]. This technique is based on the property of human T lymphocytes to bind to sheep red blood cells (SRBC) in a rosette formation [5]. The SRBC present in the pellet of rosettes (T cells) were lysed with an isotonic solution of NH_4Cl. The same lysis procedure was applied, for control purposes, to the unseparated population and the T cell poor population before culture. A pure preparation of levamisole (Janssen Pharmaceutica, Belgium) was dissolved in medium RPMI 1640 with HEPES and passed through a Millipore filter to sterilize it. The final concentrations of levamisole had a range from 1 to 10^{-8} mg/100 ml. The cultures were done in plastic tubes (16 × 75 mm) containing 200,000 cells in one ml of RPMI 1640 with HEPES, L-glutamine, penicillin, streptomycin and 10% heat inactivated fetal calf serum. In some cultures, one microgramme of a PHA-P was contained in this ml of culture. To each culture was added 0·1 ml of various concentrations of levamisole. The cells were cultured, at 37°C for 3 days. Six hours before harvesting, 0·5 μCi of ^{3}H-thymidine (specific activity: 20 mCi/mmole) were added to each culture. The cells were collected on glass fiber filters (mash filters: Dynatech Lab.), washed in saline and trichloreactic acid. The filter was ethanol dried and transferred in a vial to which scintillation fluid was added. Counting was performed using a beta counter and the results were expressed in counts/min.

Table 1. *Effect of levamisole on PHA response**

	Levamisole concentration (mg/100 ml)								No PHA and no levamisole†
	0	10^{-2}	10^{-3}	10^{-4}	10^{-5}	10^{-6}	10^{-7}	10^{-8}	
Unseparated population	64·657 ± 904	66·241 ± 1·178	76·424‡ ± 773	72·341 ± 1·383	70·421 ± 1·506	68·320 ± 821	62·031 ± 1·172	61·342 ± 714	1·625 ± 67
T cell rich population	48·324 ± 730	46·920 ± 659	57·032‡ ± 510	51·910 ± 552	52·542 ± 681	49·034 ± 608	46·491 ± 495	47·031 ± 612	341 ± 14
T cell poor population	7·174 ± 206	4·324 ± 479	6·834 ± 226	5·921 ± 208	6·834 ± 231	6·901 ± 182	8·362 ± 159	7·930 ± 202	1·906 ± 252

*The results are expressed in counts/min ± S.E.M. (6 experiments).
†The cells were cultured without PHA and levamisole.
‡These results are significantly different ($P < 0·05$) from the cultures done in the absence of levamisole (first column).

RESULTS

The results are reported as the mean of the six experiments ± standard error of the mean for each investigated population (Table 1). It can be seen that a significant increase of PHA response was noted only for 10^{-3} mg/100 ml in the unseparated population and in the T cell rich population. The statistical analyses has been done using the Student's *t*-test for paired data. The level of significance is *P* less than 0·05. Statistical analysis was also done to compare the triplicate control cultures (no levamisole, PHA one microgram) to each other culture. In the unseparated population, levamisole at 10^{-4}, 10^{-5}, 10^{-6}, 10^{-7} and 10^{-8} mg/100 ml increased significantly the response to PHA in only one instance out of six (not the same experiment), in 2 experiments out of 6 at 10^{-2} mg/100 ml, in 4 experiments out of 6 at 10^{-3} mg/100 ml. Similarly, for the T cell rich population, levamisole significantly increased the PHA response 4 times out of 6 for 10^{-3} mg/100 ml, 2 times out of 6 for 10^{-4} and 10^{-7} mg/100 ml in one experiment for 10^{-5} mg/100 ml. In the T cell poor population, levamisole increased the PHA response in only one instance at 10^{-3} mg/100 ml. Levamisole, by itself, in the absence of PHA, never stimulated any of the lymphocyte populations.

DISCUSSION

These experiments, done to investigate the possible, *in vitro*, action of levamisole on human lymphocytes from normal individuals, clearly indicate that, in rather strict conditions, the drug influences the thymidine uptake in presence of PHA. Levamisole, by itself, was not mitogenic for human lymphocytes. This observation is thus different from the situation in mouse where levamisole can be slightly mitogenic [6, 7]. Similar results have recently been published by Hadden *et al.* [7]. On the other hand, levamisole will significantly increase the PHA response of human lymphocytes. This effect is however not very dramatic since the increase is only of 15–20%. Furthermore, it was obtained only at a concentration of 10^{-3} mg/100 ml (roughly 10^{-7} M). This small and narrow ranged action of levamisole on PHA response probably explains the difficulties of many investigators to demonstrate this phenomenon although recently, similar data have been reported [7].

This action is also detected on isolated blood T cell rich populations. The increase is also in the range of 20%. In contrast, levamisole did not increase the PHA responsiveness of T cell poor populations. These results are thus similar to the mice system where pure T cell populations increased by 40% (at 10^{-7} M) the response to PHA [7]. The fact that, in the mouse system, the T cells were isolated from the thymus rather than the blood, the purity of various preparations and T cell heterogeneity may explain these slight discrepancies. These studies have thus shown that levamisole can act on proliferative human T cells. It remains, however, unclear whether the, *in vitro*, experiments can explain the, *in vivo*, observed effects. Indeed the, *in vitro*, range of activity is very small and restricted to higher concentrations than in the, *in vivo*, situation. It is possible that the activity of levamisole, in low concentrations, is party due to its metabolites.

Finally, these data suggest that either levamisole acts preferentially on a stimulated (proliferative) T cell, suggesting some type of antigenic stimulation as a prerequisite for levamisole activity or levamisole enhances the immune response as reflected in the response to mitogens.

A Preliminary Clinical Study of the Use of Mycophenolic Acid as a Radiosensitizer

THELMA BATES

Consultant Radiotherapist and Oncologist, St. Thomas' Hospital, London

Abstract—*Animal experiments have suggested that the drug Mycophenolic Acid may be a radiosensitizer.*

This brief communication describes a clinical trial of the drug in patients with two or more similar skin metastases or with bilateral lung metastases. The patients acted as their own controls, receiving two types of treatment on separate occasions using either Radiotherapy alone or Radiotherapy with Mycophenolic Acid.

The study failed to show synergism between radiotherapy and the drug in metastatic tumours of the breast, stomach, caecum and testes.

INTRODUCTION

BOTH animal experiments [1] and clinical experience [2] at the Lilly Research Centre have suggested that the drug Mycophenolic acid may be a radiosensitizer, i.e. a drug which improves the ratio of the damage of tumour cells to the damage of normal cells by ionising radiation.

This preliminary clinical study of patients with metastatic tumours of the breast, stomach, caecum and testis did not confirm these findings.

MATERIAL AND METHODS

Selection of Patients

Patients were selected because they had either two or more similar skin metastases or bilateral lung metastases from a histologically proven primary tumour. Thus, patients acted as their own controls. They were excluded from the trial if they were clinically unfit for radiotherapy or if the lesions under study were in a previously irradiated zone.

Treatment

Each patient received two types of treatment on separate occasions to similar skin or lung metastases, using either radiotherapy alone or radiotherapy with Mycophenolic acid.

Metastatic skin nodules. Pairs of similar lesions were irradiated to the same dose with superficial X-ray therapy (70 kV, 9 mA, H.V.L. 1·5 mm Al.). A dose of 800, 900 or 1000 R in a single treatment was used for pairs of small lesions up to 2 cm dia. Larger metastases were given 1200, 1300 or 1400 R in 2 treatments over 4–7 days.

During the treatment of one of each pair of lesions oral Mycophenolic acid was given. The drug was started 2 full days before treatment and continued throughout the day or course of treatment. Daily doses ranging from 800 to 2400 mg were given for periods of 3–9 days.

Bilateral lung metastases. Each lung was irradiated with a separate course of Cobalt 60 teletherapy (1·2 MeV, H.V.L. 10·4 mm Pb), one with and one without concurrent intravenous sodium mycophenolate. Two patients were treated. One patient had metastases from a radiosensitive seminoma of testis. He received a maximum tumour dose of 1000 R in 6 treatments over 9 days. The other had metastases from a radioresistant adenocarcinoma of the caecum. She received a maximum tumour dose of 2000 R in 7 treatments over 18 days.

Both patients started intravenous sodium mycophenolate 4 g in 5% Dextrose given over a period of 4 hr each day 2 days before treatment of their right lung. The patient with the seminoma continued this dose daily throughout the treatment course but the other patient, after the first two days, was only prepared to accept an intravenous drip on the day of treatment. Both patients completed the intravenous infusion of sodium mycophenolate

approximately 1 hr before each radiotherapy treatment.

PATIENT RECORDS

A detailed assessment of the present condition, including a description of the lesions to be treated was made before each treatment course. Haematological and biochemical findings were recorded together with diagrams, photographs and X-rays as appropriate.

On completion of treatment and at 1 week, 1 month, 3 months and 6 months after treatment, changes in the treated lesions and in the adjacent irradiated normal tissues, e.g., skin, subcutaneous tissue and lung were observed, compared and recorded with photographs and X-rays if appropriate. A full blood count and biochemical examination were carried out and changes noted.

RESULTS

Skin metastases. Eighteen pairs of skin metastases were treated in 13 patients. Except for one patient who has a carcinoma of the stomach, the rest (17 pairs) had breast carcinoma. The tumour response with and without Mycophenolic acid was similar. The radiation effect on the skin ranged from a mild erythema to a dusky erythema and was similar in both treatment groups. No patient developed any late subcutaneous fibrosis.

Bilateral lung metastases. The first patient treated was a co-operative male journalist aged 53 with metastases from a seminoma of the testis in his intra-abdominal lymph nodes and in both lungs. His left lung was irradiated first to 1000 R. On completion of treatment there had already been a dramatic improvement. His right lung was irradiated similarly but with daily intravenous sodium mycophenolate, again with a dramatic and similar improvement. At exactly one week and approximately 5 weeks after the completion of each course, regression was similar on both sides. He died soon after.

The second patient was a frail elderly lady with bilateral lung metastases, worse on the left side, from an adenocarcinoma of the caecum which had been successfully excised 2½ years previously. Adenocarcinoma cells were present in her sputum. The left lung was irradiated first to a maximum tumour dose of 2000 R with little effect. Similar irradiation was delivered to the right lung with sodium mycophenolate. She received 4 g daily for two days before treatment and then 4 g on the 7 days she was irradiated. The left lung showed some improvement on X-ray at 1 and 2 months after the completion of treatment but then deteriorated. In the right lung which had been irradiated with sodium mycophenolate, the metastases were larger at each time interval.

Neither patient developed a radiation pneumonitis or any other evidence of increased radiosensitivity of the normal tissues.

DRUG TOXICITY

Neither of the patients given sodium mycophenolate experienced toxic symptoms during or after administration.

Oral Mycophenolic acid caused nausea in 8 of 13 patients. The incidence and severity of nausea was related to the daily dose. The experience of this trial suggested that a daily dose of 1200 mg is the maximum which patients will tolerate. Neither haematological nor iochemical changes were produced in any patient.

DISCUSSION

Perhaps with the exception of the development of Neutron therapy, radiotherapy alone is unlikely to offer any major contribution to cancer therapy in the forseeable future. The most likely major advances may be in the field of radiosensitizing drugs.

A radiosensitizer is a chemical which increases the cell-killing effect of a given dose of radiotherapy, but to be of any value in radiotherapy a radiosensitizer must improve the therapeutic ratio (i.e., the ratio of the damage of tumour cells to the damage of normal cells)—otherwise the same effect could be produced simply by increasing the dose of radiation.

There are very few true radiosensitizers and most of the drugs for which this claim has been made have acted by addative rather than by synergistic effect with radiotherapy. Oxygen is the most effective radiosensitizer discovered so far and the most fruitful laboratory research at the moment appears to be in the use of electron-affinic compounds, as yet too toxic for use in man, which act in a similar way to oxygen.

Preliminary work by Sweeney and his colleagues [1] showed synergism between Mycophenolic acid and X-ray therapy in the treatment of Gardner lymphosarcoma in mice. He was not able to show synergism in all tumour type and suggested that synergism was related to high β glucuronidase activity.

This pilot study has failed to show a similar

synergism in the treatment of four human tumours, i.e., carcinoma of the breast, stomach and caecum and seminoma of the testis. It is suggested that this simple clinical experiment could be used to test other possible radiosensitizing drugs.

A Virological Study of Interstitial Pneumoniae in Patients with Acute Lymphoid Leukemia Treated with a Combination of Methotrexate and 6-Mercapto Purine

F. BRICOUT,*§ J. M. HURAUX*§ and C. JASMIN†‡§

**Service de Virologie, Hôpital Trousseau, 75012 Paris, France*

†*Institut de Cancérologie et d'Immunogénétique, 94800 Villejuif, France*

Abstract—*A clinical study of 45 patients and a virological survey of 34 patients with acute lymphoblastic leukemia have been undertaken to detail the characteristics of occurrence of interstitial pneumoniae (IP) under maintenance chemotherapy. Our study confirms the link between IP and treatment with MTX but does not support the hypothesis of an allergic reaction to the drug. The virological study has failed to detect one type of viral agent associated with IP but have shown important modifications of humoral immunity against viruses.*

INTRODUCTION

INFECTION represents the major cause of death in patients with acute leukemia [1, 2] and the lower respiratory tract is the most common localization of infectious agents [3].

In recent years, the association between antileukemic drugs especially Methotrexate (MTX) [4] and interstitial pneumoniae (IP) has emerged as a new clinical entity. The pathogenesis of this pulmonary complication is still a subject of controversy and various causes, such as: allergy to MTX [5], infections by cytomegalovirus or pheumocystis carinii have been evoked. This study was undertaken to detail the clinical, immunological and microbiologic characteristics of IP.

Preliminary results of this study have been published [6]. We report here the results of clinical studies on 45 patients and of the virologic survey of 34 patients with acute lymphoid leukemia.

‡This work was supported by an A.T.P. no. 74.7.06.22 from the D.G.R.S.T. and a contract no. FC 74.A9 from Institute Gustave-Roussy.

§We acknowledge the technical assistance of Y. Augery, M. H. Lourenco-Batista and A. M. de Souto-Almeida, and we thank A. Beaudiment for expert secretarial assistance.

PATIENTS AND MÊTHODS

This study has been done in patients with acute lymphoblastic leukemia who were admitted in the department of Hematology of Institute Gustave-Roussy from November 1971 to January 1974.

The diagnosis of interstitial pneumoniae was made on chest roentgenograms which showed typically bilateral perihilar and rapidly extensive pulmonary infiltration. Usually, these radiological findings were associated with fever, dyspnea but few if any physical signs. In two cases, this interstitial pneumoniae caused the death of the patient. In all other cases, a complete regression was obtained after stopping the administration of MTX and administration of prednisone. Strikingly, we have never observed in our patients the recurrences of IP, even under prolonged periods of treatments with MTX-6MP.

The techniques used for the virological study have been previously described [6]. In all patients, a systematic study during and after the period of treatment with MTX and 6-mercapto purine (GMP) was undertaken.

Surveillance cultures were regularly obtained from throat and urine samples. A serological study of antibodies against 23 viruses was done

at weekly intervals. Statistical analysis were performed with the Chi square test.

RESULTS

Clinical study: population characteristics

During a period of 14 months from November 1971 to December 1972, 18 IP occurred among 45 patients (40%). The sex ratios of male and female patients were 1·7 for IP^- and 0·5 for IP^+, (difference not statistically significant); 17 IP^- and 14 IP^+ patients were in the first perceptible phase of the disease. Other patients had previously relapsed one or more times. The median age was 9 years for IP^- and 7 years for IP^+ patients. Under systemic MTX-6PM associated with intrathecal injections of MTX, 2 IP occurred at the end of the MTX-Prednisone phase and 1 during Vincristine-MTX.

The absolute and relative level of eosinophils in the blood of patients was studied during and after the phase of treatment with MTX-6MP.

As shown in Table 1, a significant increase of eosinophils/mm^3 was observed in patients treated with MTX-6MP, but there was no difference between patients with IP (IP^+) and patients without IP (IP^-).

In order to detect a direct toxicity of MTX, biologic tests of liver functions and the effect of intrathecal injections of MTX on proteins and cells in the cerebrospinal fluid (CSF) were followed. Liver function tests were usually normal. A cytological reaction with raised levels of proteins in CSF was observed in both IP^+ and IP^- (results not shown).

Virological study

The virological study has been completed in 34 patients. In 4 out of 11 patients IP^-, 5 viruses have been isolated: 3 reovirus type 1, 1 parainfluenza 3 and 1 herpes type 1. In 3 out of 23 patients IP^-, 3 viruses have been identified: 2 adenovirus and 1 cytomegalovirus. The difference of frequency of virus isolation between IP^+ and IP^- patients is not significant.

The results of the serological study of these patients are shown in Fig. 1. The main findings can be summarized as follows: (1) many serological modifications (rise in titres or seroconversion) have been observed in patients treated by 6MP-MTX; (2) there are simultaneous rises of antibodies against unrelated types of virus; (3) the same serological variations have been found in IP^+ and IP^- patients; (4) all patients from whom a virus could be isolated did not develop detectable amounts of antibodies against this virus, even after prolonged periods of observation; (5) simultaneous seroconversions against rubella virus have been noted in 5 patients who did not develop subsequently interstitial pneumonia.

Table 1. *Blood eosinophily and interstitial pheumoniae (IP) in all patients treated with 6MP-MTX*

Patients without interstitial pneumonia (27 patients)			
Not treated with 6MP-MTX	$67·3 \pm 25·2/mm^3$	or	$1·29\% \pm 0·5$
Under 6MP-MTX	$28·5 \pm 70$	or	$5·18\% \pm 1·4$
	statistically significant $P > 0·01$		
Patients with interstitial pneumonia (18 patients)			
Treated with 6MP-MTX before the occurrence of IP	$376·7 \pm 196$	or	$5·76\% \pm 2·8$
During the IP	$388·7 \pm 186$	or	$6·47\% \pm 3·6$

The difference of eosinophily between IP^- and IP^+ patients treated with 6MP is not significative.

DISCUSSION AND CONCLUSION

The clinical and virological results reported here bring some interesting conclusions concerning the physiopathology of IP in leukemic patients treated with MTX. The allergic reaction suggested by Clarysse *et al.* is very unlikely. Eosinophily is observed in patients treated with MTX, but there are no differences between IP^+ and IP^- patients. In addition, after regression of the IP, MTX can be readministered with safety to the same patient. We have not found signs of a direct cytotoxicity of MTX on liver and CSF, but this does not exclude a toxicity of this agent on lung parenchyme or on associated cell populations (as macrophages for example). The absence of recurrence of IP even after prolonged period of administration of MTX favour the hypothesis of an immune status to an infectious etiologic agent. The frequent isolation of pneumocystis carinii in lung biopsies of patients

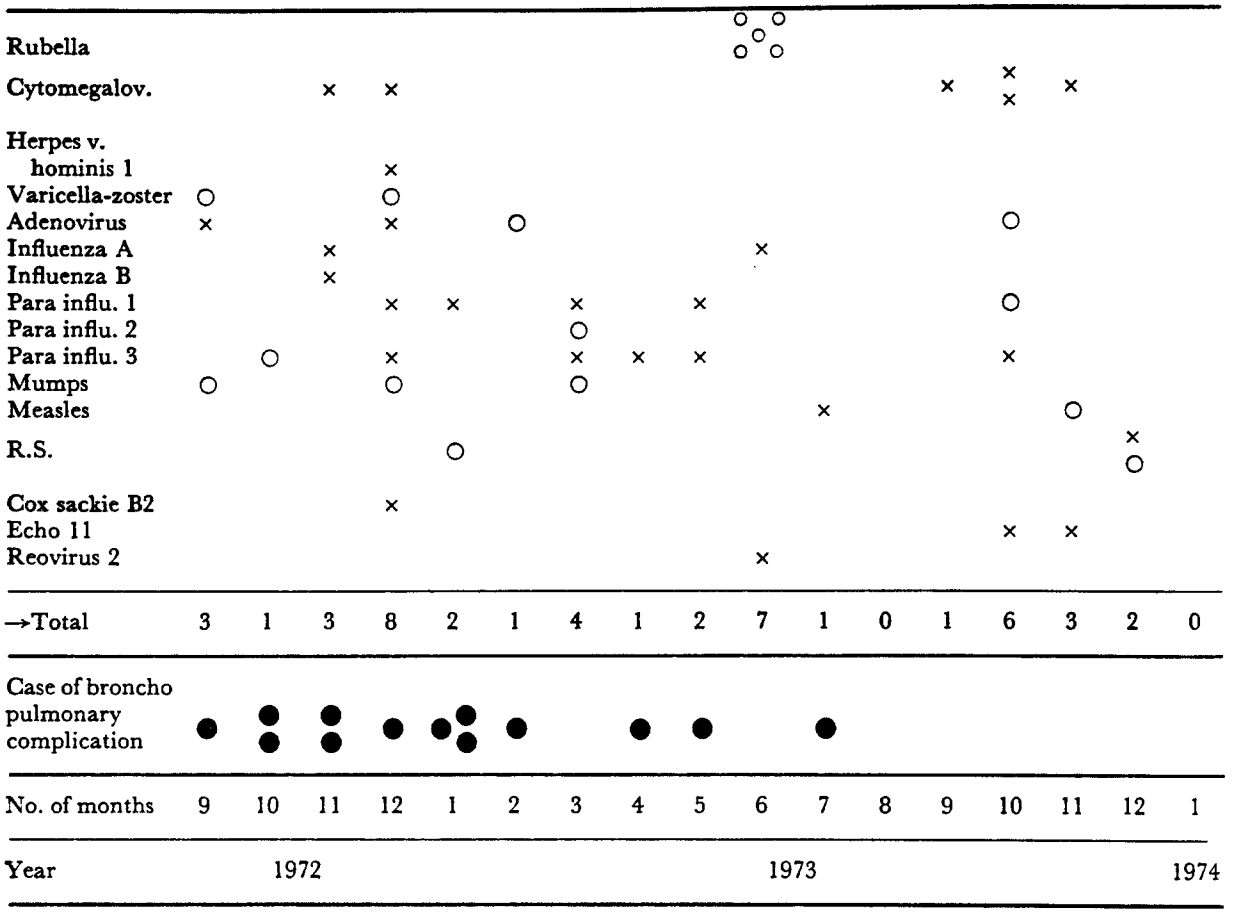

Fig. 1. *Distribution of virus antibody rises in all patients treated with* 6*MP-MTX.*

○ *Seroconversion stricto sensu.*
× *Rise in titer of antibodies already detected before treatment.*

with IP have been reported by some authors. We have not performed lung biopsies in our patients, but the regression obtained without any specific treatment of pneumocystis carinii infections argues against this etiology in our serie. The results of our virological study confirm the existence of important perturbations of humoral immunity in patients treated with immunodepressive agents like MTX and 6MP. The absence of antibodies in all 7 patients from whom a virus was isolated is striking. On the other hand, simultaneous increase of antibodies levels against unrelated types of virus (as in patients with kidney transplants) have been observed. The isolation in 3 patients of reovirus type 1 which is rarely found in humans and simultaneous seroconversions against rubella virus in patients demonstrate the frequence of horizontal transmission of viruses in these patients. However, these contaminations did not correlate with clinical and radiologic signs of IP.

In conclusion, this virological study of all patients treated with MTX demonstrates the existence of important modifications of humoral immunity against viruses. It is therefore probable that it exists similar modifications of immunity against other infectious agents such as pneumocystis carinii. The possible role of cellular immunity and of a direct or indirect toxic effect of MTX on lung deserves further investigations.

Blood and Bone Marrow Response Following Total Body Irradiation in Patients with Lymphosarcomas

M. M. QASIM

Rotterdamsch Radio-Therapeutisch Instituut, Groene Hilledijk 297, Rotterdam-Z, The Netherlands

Abstract—*Marrow depression and associated peripheral blood changes following fractionated T.B.I. are considerable and appear alarming. However, provided the marrow reserve is good and is not compromised by previous chemotherapy and radiation therapy, recovery occurred in all cases and appeared to be complete. Bone marrow of 3 patients with previous T.B.I. did not show recovery after the second course of T.B.I. Extreme caution is indicated when such a therapy is repeated, as this may lead to progressive marrow hypoplasia. Fractionated low dose T.B.I. could be utilized as a useful therapeutic modality in the management of disseminated lymphosarcoma provided the marrow reserve is good.*

INTRODUCTION

DURING recent years whole body radiation has attracted considerable attention. This form of therapy has been used particularly in the management of non-Hodgkin lymphoma [1, 2] and chronic lymphatic leukaemias [3].

In practical localized radiation therapy serious damage of blood seldom occurs. The dangers, however, are increasing as radiological advances introduce larger and larger total dose. With some techniques, such as internal radioactive isotope administration or total body irradiation (T.B.I.), the limiting factor in dosage has already shifted from cutaneous tolerance to haemopoietic tolerance.

Within the last two years 19 patients with lymphosarcomas have been treated with T.B.I. An attempt was made to study the peripheral blood and bone marrow changes in patients so treated. The result of this study is presented below.

MATERIAL AND METHODS

Nineteen patients with lymphosarcoma have been treated by T.B.I. There were 2 stage III and 17 stage IV patients. Nine of these patients had previous chemotherapy and some form of radiation therapy prior to T.B.I. and had some degree of marrow depression. Ten patients, who had no prior therapy, had normal bone marrow activity. The T.B.I. induction course consisted of 10 rads midplane 3 times weekly to a total of 100-300 rads on 6 MeV linear accelerator. The patients were positioned in an attitude of "universal flexion" over a chair and treated alternatively from left and right side. Midplane dose was checked by midrectal dose measurement with lithium fluoride dosimeter, which showed a high degree of correlation to physical dose measurement.

Blood counts were done before each treatment and treatment was stopped if the thrombocytes fell below 50,000 and leucocytes below 2000/cm. Bone marrow study was done before starting the treatment and repeated, if possible, after 100 rads midplane dose was given, and then 2 and 6 weeks after the end of the treatment. In some cases marrow study was done on the last day of therapy. Pre-irradiation of bone marrow was used as a control for further comparison.

All patients received a single induction course of T.B.I. except 3, who received a second course of T.B.I. after an interval of 14 months. Most patients received a radiation dose varying between 180–220 rads.

RESULTS

The effect of T.B.I. on bone marrow and blood was observed. The general sequence of events were as follows.

Changes in the peripheral blood following the first course of T.B.I.

The change began to appear after one week of therapy.

Thrombocytopenia was first to develop and this was very striking. The fall in the total count was gradual in most patients. In a few, however, it was sudden and sharp.

Lymphocytopenia (in patients, who had previously no peripheral blood involvement) accompanied thrombocytopenia.

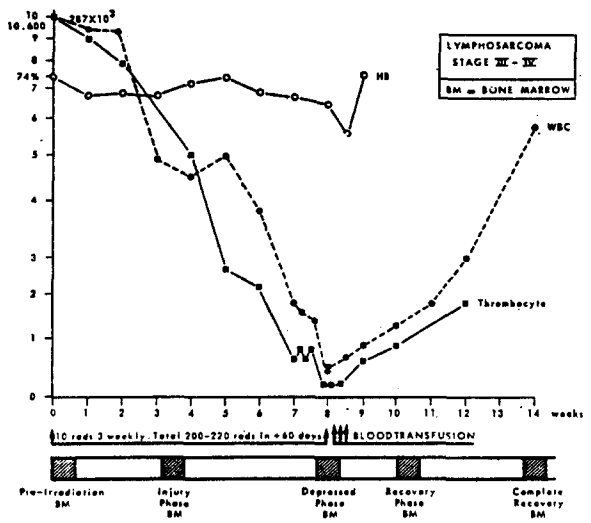

Fig. 1. Total body irradiation. Effect on peripheral blood count and bone marrow.

Granulocytopenia developed more slowly. In most cases the drop in the count was noted in the second week of therapy.

Erythrocytes count was very little affected. Total count remained almost to the pre-irradiation level throughout.

Haemoglobin was also very little affected. The decline in haemoglobin level was minimal except in those who developped auto-immune haemolysis. The haematological depression continued in a progressive manner for at least 2 weeks after the end of T.B.I. Granulocytes recovered first. Thrombocytes and lymphocytes recovered slowly, but completely. The total leucocyte count gradually increased to pre-irradiation level in 3–4 weeks except in one patient, who died soon after T.B.I. due to severe infection and bleeding. By the end of 4 weeks all the elements of peripheral blood had returned to normal in all patients except 3 who had two courses of T.B.I. In these 3 patients the count has remained well below the pre-irradiation level. They have now developed progressive anaemia and thrombopenia. Patients with previous chemotherapy and localized radiation therapy also showed delayed recovery of their peripheral counts.

Marrow changes following the first course of T.B.I.

After receiving 100 rads midplane the marrow was found to be less cellular as compared to the pre-irradiation examination (comparison of bone marrow slides is difficult as no two slides are alike nor are the marrow samples taken from two different sites and this must be borne in mind while making conclusion). Immature blood-forming cells appeared to be reduced as there was clear reduction in number of more matured cells. The formed and matured elements had a normal aspect. No change was seen in the pathological lymphocytes. Bone marrow after receiving 220 rads midplane showed further reduction of cellularity. Developed megakaryocytes were also much less in number and in one case megakaryocytes showed evidence of cell damage.

Again no change was seen in the pathological lymphocytes.

Bone marrow, 2 weeks after the end of T.B.I., showed regenerative changes; the marrow was much more cellular and large numbers of premature haemopoietic cells were seen. There was also an increase in the number of more formed elements of all the haemopoietic series.

Bone marrow, 6 weeks after the end of T.B.I., was found to be highly cellular; the cellularity appeared more marked as compared to pre-irradiation level. Formed elements of haemopoietic series were in abundance. In all aspects the marrow appeared normal and had recovered completely. Pathological lymphocytes again did not show any change. In 3 patients with two courses of T.B.I., the marrow recovery was not complete. The marrow remained less cellular and hypoplastic and hypoplasia is now progressive with again many pathological lymphocytes.

DISCUSSION

T.B.I. produces early dramatic changes in the peripheral blood, especially in thrombocytes. These changes are chiefly a result of damage to the haemopoietic immature cells and are not a direct effect on the circulating cells [4–5]. Radiation damage interrupts the balance by reducing the supply of blood cells in the circulation leading to pancytopenia. These peripheral changes are in turn dependent on the severity of the haemopoietic damage. With sublethal dose given in small fractions over several weeks, similar changes, but of a lesser degree, were also observed in this study. Bone marrow showed partial cessation of

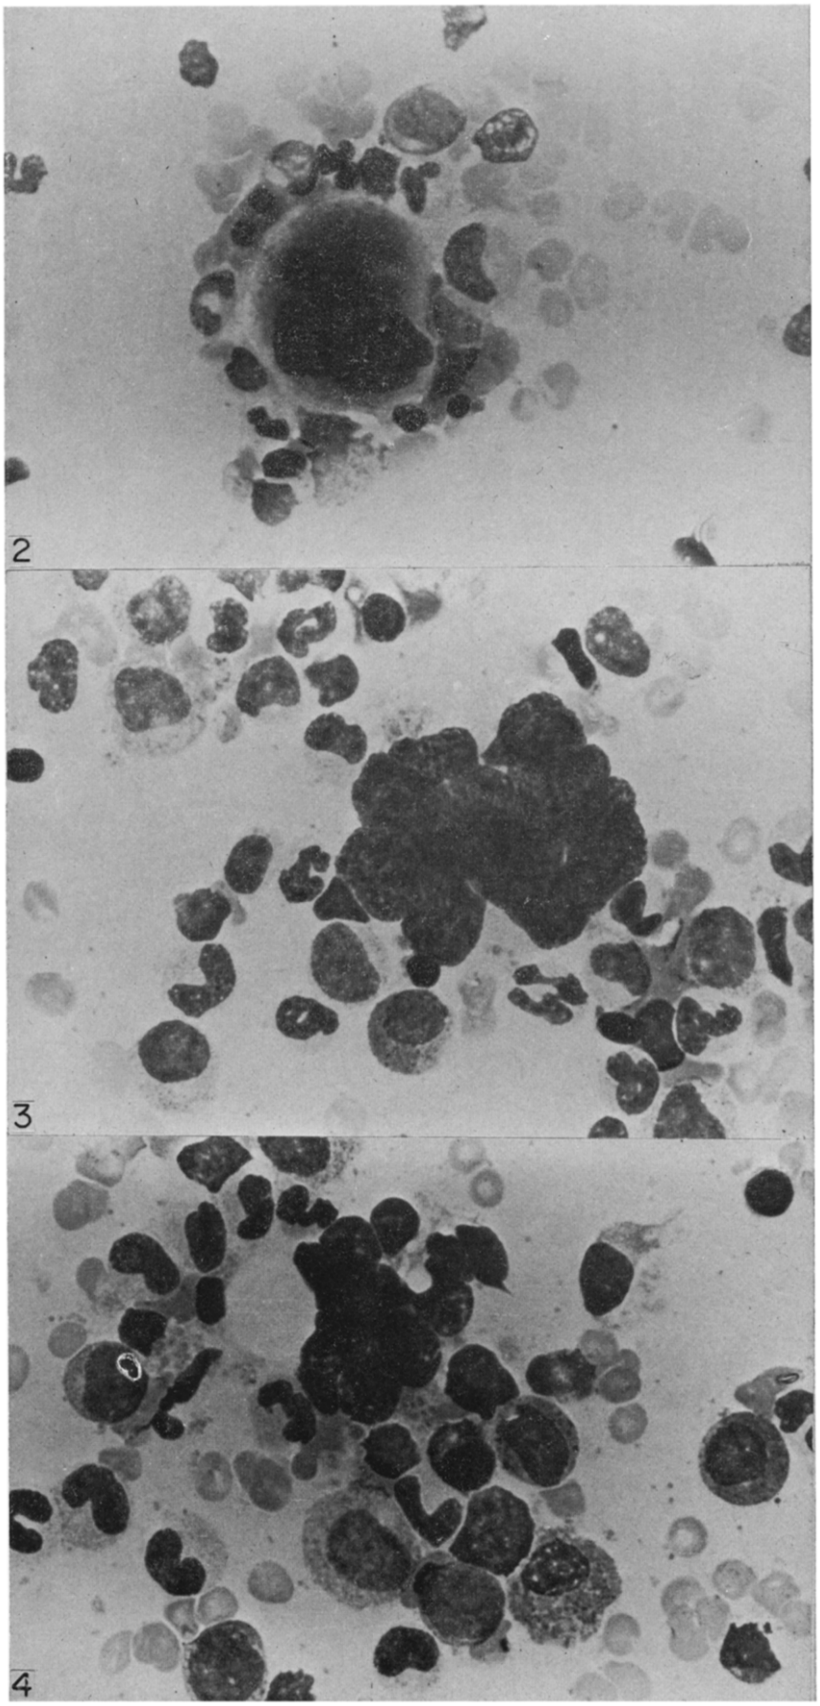

Fig. 2. *Normal megakaryocytes High magnification.*

Figs. 3 *and* 4. *Marrow following T.B.I. showing damaged megakaryocytes.*

Please note: surrounding cells are intact, so artefact is less likely.

proliferation and destruction of sensitive primitive cells. The cellularity was decreased. Matured elements were also much reduced. These changes were progressive and, by the end of therapy, having received up to 220 rads, the cellularity was reduced considerably. Pathological lymphocytes however, remained unchanged throughout.

Once the radiation was stopped, marrow recovery began and, by the end of 2 weeks, large numbers of primitive haemopoietic cells were seen in the marrow. Formed elements were also increased. Apparent complete marrow recovery was seen at the end of 6 weeks after T.B.I. Bone marrow damaged by previous T.B.I. did not show complete recovery as was seen in the 3 patients, who had a second course of T.B.I. Nine patients with previous therapy showed delayed recovery.

Changes in the peripheral blood could be related to the marrow changes. The noticeable change was observed one week after the therapy was started. Thrombocytopenia was the first to be observed. The fall in thrombocytes, normal lymphocytes and granulocytes, was progressive and continued until at least 2 weeks after the end of T.B.I. By the end of 4 weeks the count had returned to pre-irradiation level except in those patients with previous therapy and in 3 patients with a second course of T.B.I. The entire peripheral blood changes could be attributed to maturation-depletion as a result of the failure of cell renewal from more primitive sources in the marrow.

Perhaps the number of haemopoietic stem-cells (HSC) in the body in normal condition remains relatively constant despite continuing demands for differentiation into cells of myeloid, erythroid and megakaryocytic series [6]. Recovery of HSC following irradiation indicates the existence of a sensitive haemostatic mechanism for its repopulation.

Combination of Radiotherapy and Immunotherapy in the Treatment of Lewis's Tumour

B. SERROU* and J. B. DUBOIS†

**Department of Clinical and Experimental Immunology and*

†*Radiotherapy Service Centre Paul Lamarque, Hôpital St. Eloi, 34000, Montpellier—France*

Abstract—*Three groups of 6–8 week old male C57 Bl/6 x DBA2 F1 mice with transplanted Lewis tumour were irradiated by a single dose of Cobalt 60 localized on the tumour in association with intraperitoneal injections of BCG. When the animals were sacrificed, tumour parameters were determined: weight, surface area, volume and lung metastasis. When BCG was applied up to and including the 4th day following the end of the irradiation, tumour growth and the number of lung metastases were significantly decreased in comparison with the control group ($P < 0.01$). In all the groups where BCG treatment was started after the 4th day post-irradiation, there was no effect of BCG when compared with radiotherapy alone. This emphasizes the importance of timing in radiotherapy and immunotherapy association.*

INTRODUCTION

SURGERY and radiotherapy are actually the primary treatment for cancer with chemotherapy and immunotherapy constituting complementary and effectual therapies. Nevertheless, the problem is that most of these therapeutics are immunodepressive. Radiotherapy can encourage the implantation of metastasis [1, 2]. The effect of immunotherapy is actually well-established [3-5] and the association of chemotherapy and immunotherapy [6] seems most favourable in a certain number of tumours. However, the problem remains as to the moment when immunotherapy can be applied relative to chemotherapy [7-9]

The task of this research has been to establish a competent association of radiotherapy and BCG in Lewis tumour by utilising variable dates at the moment of the BCG application after radiotherapy. Consequently it appeared very distinctly that only the BCG applied up to and including the 4 days following the termination of the radiotherapy is effective.

MATERIAL AND METHODS

(1) *The animals*

Six to eight week old male (C57 Bl/6 x DBA2)F1 mice were used for this experiment. The Lewis's tumour is well maintained in our Laboratory and was kindly supplied by the I.C.I.G. (Pr. Mathé). It was implanted into the animals left paw. 2×10^6 viable cells were injected in 0·2 ml of MEM by the subcutaneous route.

(2) *The irradiation*

A local irradiation was performed on the paw where the tumour was injected. Radiation was systematically applied 8 days after the tumour implantation which corresponds to the 4th day after the actual appearance of the implanted tumour, the average tumour surface area being then 120 ± 15 mm^2. The irradiation used a source of Cobalt 60 with an irradiation of 70 rads/min in air at a source-skin distance of 60 cm. The dose delivered to the paw was a unique dose of 2100 rads utilising a fixed field.

(3) *The BCG*

The BCG from the Pasteur Institute with a dose of 1 mg injected i.p. in 0·2 ml of physiological serum was employed.

(4) *The tumour*

The animals were systematically sacrificed the 14th day in the group 1, the 23rd day in the group 2 and the 30th day in the group 3. The weight, the surface area and the volume of the tumours were accordingly evaluated as well as the number of pulmonary metastasis.

(5) *The groups*

The group 1 consisted of 5 sub-groups. Sub-group A was the control sub-group where the animals with the tumour were treated by irradiation, but had not received the BCG; sub-group B received 3 injections of BCG, 2, 5 and 8 days after the tumour implantation and consequently before the irradiation; sub-group C received BCG injections the 1st, 4th and 6th days after the irradiation; sub-group D received the BCG the 4th and 6th day after irradiation; and finally the sub-group E received an injection of BCG 6 days post-irradiation.

In the group 2, the sub-group A was the control; the sub-group B received the BCG the 1st, 4th, 6th, 9th and 13th days post-irradiation; the sub-group C received the BCG injections the 4th, 6th, 9th and 13th days post-irradiation; sub-group D received the BCG injections the 6th, 9th and 13th days post-irradiation; and finally the sub-group E received the BCG injections the 9th and 13th days post-irradiation

In the group 3, the sub-group A was the control; the sub-group B received the BCG injections the 1st, 4th, 6th, 13th, 18th and 26th days after the irradiation; the sub-group C received the BCG the 4th, 6th, 13th, 18th, and 26th days post-irradiation; the sub-group D received the BCG the 6th, 13th, 18th and 26th days post-irradiation; and finally the sub-group E received the BCG injections 13, 18 and 26 days post-irradiation. For each one of these groups a non-treated control tumour was realised. The results were interpreted by statistics on a Multi-4 Intertechnique computer using the Student–Cochran test ($P < 0{\cdot}05$: statistically significant).

RESULTS

(1) *Group* 1 (*Table* 1)

The increase of the tumour surface area in the sub-groups B and C was less important in relation to the control. On the other hand, no statistical difference was noted in the sub-groups D and E. There was a diminution in the tumourous weight of the sub-groups B and C, but this was only significantly noticable in the sub-group C. This applied also to the tumourous volume. Finally, it was noted that there was a significant reduction of the number of pulmonary metastasis in the sub-groups B and C.

(2) *Group* 2 (*Table* 1)

The tumour surface was noticably reduced in the sub-groups B and C. The weight and the volume of the tumours were also reduced for sub-groups B and C and it was noted that there was an important increase in these parameters for the sub-groups D and E compared to the control. Finally, the number of pulmonary metastasis was also significantly diminished in the sub-groups B and C.

(3) *Group* 3 (*Table* 1)

The results were similar enough to those observed in the groups 1 and 2; namely a definite diminution of the surface, weight and volume of the tumour for the sub-group C. The same observation applied to the pulmonary metastasis.

DISCUSSION

The study of these results delineates a significant diminution of the tumourous growth in

Table 1. *This table shows the results for the* 3 *groups of tumour weight and pulmonary metastasis. The data shows the interest of BCG administration up to and including the* 4*th day post-irradiation. A′ is a control sub-group without any treatment*

the animals treated by BCG before and after irradiation. However, when the BCG is given after irradiation, the diminution of the tumourous growth is only observed when this treatment is started up to and including the 4th day following the end of this irradiation. Moreover the number of BCG injections had no influence either on the tumourous growth or on the number of pulmonary metastasis. It is noticed that in certain sub-groups, where the BCG was performed 4 days after the end of the irradiation, an increase was noticed in the growth of the tumour.

These results emphasize once again the importance of the timing of the BCG injection in relation to the immunodepressor treatment and the number of injections realised. This fact revealed by Currie [7] has been emphasized again recently by both Milas [8] who used corynebacterium granulosum and by Mathe [9, 10]. In this way, we must re-state that BCG applied up to and including the 4th day following the end of irradiation is essential.

These results appear to be extremely important considering that it was recently emphasized that Radiotherapy was immunodepressive [1, 11, 12] and could encourage the growth of metastasis [2]. This fact, that the association of Radiotherapy and BCG reduces the number of metastases in a rapidly evolutional system such as the Lewis's tumour, emphasizes the potential interest of the association of Radiotherapy and Immunotherapy in the measure that the timing has been perfectly defined.

Immunostimulation by *Brucella Abortus*. Role of Surface Antigenicity of the Bacteria*

LOUIS TOUJAS,† YVONNE LE GARREC, LÉONTINE DAZORD and ANNE MARTIN

Centre Anticancéreux, Unité INSERM U 49-35000 *Rennes, and Ecole Nationale Vétérinaire,* 94700—*Maisons Alfort, France*

Abstract—*Two suspensions of inactivated* B. abortus *organisms prepared from either the smooth strain B19S or from its rough mutant B19R were compared as to their ability to modulate the mouse immune response against sheep red blood cells (SRBC) antigens. The anti SRBC response was measured by counting the number of spleen cells forming hemolytic foci in agar, 4 days after immunization. Referring to this test B. abortus B19R revealed more immuno-stimulant than B19S. When SRBC and B19R were injected at close time intervals, low doses of bacterial organisms were sufficient to enhance the immune response, the optimal effect being obtained for a simultaneous administration of both materials. When SRBC were given 5 or 10 days after Brucella higher doses of organisms were required to modulate the immune response and only B19R could increase the number of antibody forming cells. These results were correlated with the difference in surface antigenicity between B19R and B19S and with the cellular proliferation induced by the two bacterial preparations.*

INTRODUCTION

KILLED *Brucella abortus* organisms, strain B19 grown in smooth phase (B19S), have been shown to increase the survival time of tumour bearing animals and to enhance the antibody production against SRBC [1, 2]. The latter immunostimulating effect could be still improved by injecting B19S in mice previously treated by an hyperimmune anti-brucella serum [3]. The passive injection of this antiserum also delayed the specific agglutinin response against Brucella antigens. The hypothesis was therefore suggested that an inverse relationship might exist between the immunopotentiating properties of Brucella and its surface antigenicity. In the present work we have tried to confirm this view by comparing the effects of B19S to those of the rough non agglutinogen mutant B19R.

*This work was supported by INSERM grant no. 73.4.014.1 and ATP 11.74.32.

†Centre Régional Anticancéreux 35 000—RENNES, FRANCE.

MATERIAL AND METHODS

Animals

Female (C_{57} $Bl_6 \times DBA_2$) F_1 mice, aged 4–6 weeks, obtained from CNRS Orleans were used throughout the experiments at the rate of 6 mice per group.

Brucella abortus

The strain B19 was cultivated as described previously [1] either in smooth phase (B19S) or in rough phase (B19R), then suspended in phosphate buffered saline and heat inactivated. Bacterial suspensions were injected intravenously at variable doses expressed as dry weights of organisms.

Immune responses against B. abortus *and SRBC*

The anti Brucella agglutinins were measured in the serum with Wright's method. The response against SRBC was measured 4 days after i.v. injection of $2{\cdot}5 \times 10^8$ SRBC by the direct technique of plaque forming cells (PFC) according to Jerne and Nordin.

The number of PFC was related either to the whole spleen or to 10^6 spleen cells. The

final results were expressed as adjuvant indexes. The adjuvant indexes were calculated either from the number of PFC per spleen (AI/spleen) or from the number of PFC per 10^6 spleen cells (AI/10^6C) and in both cases they represented the ratio of the treated to control values. Student's *t*-test was used to compare the numbers of PFC per spleen or per 10^6 spleen cells.

RESULTS

Different experimental situations could be distinguished according to the relative times of injection of *B. abortus* and SRBC.

When *B. abortus* and SRBC were given together B19R was more efficient than B19S in increasing the number of PFC per spleen or per 10^6 cells (Table 1). Increasing the doses of bacteria did not provoke a proportional rise in adjuvant index. Relatively close effects were obtained with doses ranging from 30 to 1000 μg. Table 2 shows that B19R had to be injected mixed with SRBC to be fully efficient. The adjuvant index decreased when the two substances were given separately at 0·5–2 days intervals.

Another interesting experimental situation resulted from the injection of SRBC 5 days after *B. abortus*. In this case the anti SRBC response was increased but only by the use of B19R and only with elevated doses (Table 3). The injection of SRBC ten days after *B. abortus* led to a diminution of immune response, and this was particularly clearcut when B19S was used and when high doses were given.

The i.v. injection of B19S provokes important cellular modifications characterized by spleen and liver enlargement, accelerated renewal of non lymphoid bone marrow derived cells and enrichment of the body in hemopoietic stem cells [1, 4]. Table 4 shows that B19R produced a weaker splenic hypertrophy than than B19S even with doses twice as important. Moreover only B19S gave rise to detectable amounts of anti Brucella agglutinins.

DISCUSSION

The PFC response against SRBC measured 4 days after immunization was increased either by injecting *B. abortus* B19R in mixture with SRBC or by injecting it 5 days before. The agglutinogen preparation B19S did not provoke comparable effects. This confirms the hypothesis of an inverse relationship between the expression of the surface antigens of the bacteria and the ability to potentiate this type of immune

response. The two experimental situations in which B19R was able to increase the anti SRBC response differed greatly from one another. In the first one, corresponding to an adjuvant effect, B19R did not need to be injected at high doses, but had to be injected mixed with the antigen. In the second case an immunostimulant effect was obtained by giving SRBC 5 days after Brucella, but this time, high doses of B19R were required. Such large amounts of B19R provoked an intense cellular proliferation which could play an important part in the mechanism of immunostimulation. These cellular modifications however, do not seem sufficient to explain the results noted since B19S which induced a greater spleen enlargement than B19R did not cause a comparable increase in anti SRBC response.

The immunostimulant effect might finally result at least from two factors, one depending on the cellular proliferation and the other linked to the non expression of *B. abortus* self antigens.

Cellular Immunity to the Mammary Tumour Virus in Mice Bearing Primary Mammary Tumours*

PAULA CREEMERS and PETER BENTVELZEN
Radiobiological Institute TNO, Lange Kleiweg 151, *Rijswijk (ZH), The Netherlands*

Abstract—*The development of cellular immunity directed against the murine mammary tumour virus (MTV) during the growth of primary mammary tumours has been studied in BALB/c, BALB/cfC3H and GR mice, by measuring leukocyte stimulation and leukocyte adherence inhibition in the presence of purified MTV. Leukocytes react against group-specific antigens of different MTV strains in these assays. Purified Rauscher murine leukaemia virus was used as a control.*

In both assays, MTV-specific reactivity peaked at a tumour weight of about one gram; afterwards, it almost completely disappeared. It increased again to about half of the original level when the tumour reached a weight of about three grams. Peak blastogenesis of lymph node cells was observed at a tumour weight somewhat higher than when peak blastogenesis of spleen cells occurred.

The possible causes of the general decrease and oscillation in the cellular immune response during tumour growth are discussed.

INTRODUCTION

THE FAILURE to evoke cross-reactive transplantation immunity to mammary tumours in mice which are neonatally infected with the mammary tumour virus (MTV) has been regarded as indicative for true tolerance to the virus [1–7]. It has been reported, however, that neonatally infected C3H mice produce antiviral antibodies on immunization with MTV [8–10] and the tumour-bearing mice would contain precipitating antibodies to MTV in their serum [9–11].

Utilizing the colony inhibition test, Heppner [12, 13] and Heppner and Pierce [14] found that tumour-bearing mice contain lymphocytes that can arrest the growth of mammary tumour cells but they found no indication that the reactivity was directed against viral antigens. Blair *et al.* [15] claimed to have found virus-specific cellular immunity in tumour-bearing mice by means of the microcytotoxicity (MC) test. The antiviral nature could be demonstrated by the blocking of cytotoxic activity by pretreatment of spleen cells with viral antigens [16]. Also with the macrophage inhibition test virus specific reactivity in infected mice was observed [17]. In the present study cellular immunity to purified MTV has been investigated in tumour bearing mice with two different techniques.

Accepted 15 October 1976.

*This investigation was performed pursuant to NIH contract NO1 CP 43328 with the National Cancer Institute, Division of Cancer Cause and Prevention, Viral Oncology, Department of Health, Education and Welfare, Bethesda, MD, U.S.A.

MATERIAL AND METHODS

Mice

The following inbred mouse strains were used: GR, carrying MTV-P; BALB/cfC3H carrying MTV-S and a BALB/c subline in which the endogenous MTV-O had been passaged [18]. Tumours were induced in these mice by forced breeding. Mice were killed by cervical dislocation; tumours, lymph nodes and the spleen were then taken aseptically. Mice which were immunized intraperitoneally with 10^8 tumour cells suspended in complete Freund's adjuvant and killed 5 days later were used as positive control animals. Male mice not older than 10 weeks served as normal controls.

Virus

The standard strain of mouse mammary tumour virus (MTV-S) was isolated from

BALB/cfC3H mammary tumours. Fifty grams of tumour tissue were homogenized in 500 ml phosphate buffered saline (PBS) in a Sorval omnimixer for 50 sec at 14,000 rev/min. The homogenate was centrifuged for 15 min at 12,000 × *g*. To the supernatant was added 1% M ethylene-diamine tetra-acetic acid (EDTA). This mixture was spun for 15 min at 12,000 × *g*. The supernatant was ultra-centrifuged for 45 min at 75,000 × *g* (Beckman 35 N rotor; 35,000 rev/min). The pellet was then resuspended in 90 ml 1·5 mM Tris–HCl buffer (pH 7·2) and spun for 15 min at 12,000 × *g*.

The resulting supernatant was centrifuged on a discontinuous gradient of 4 ml 50% sucrose (w/w), 12 ml 35% sucrose (w/w) and 8 ml 20% sucrose (w/w) in 1·5 mM Tris–HCl for 180 min at 170,000 × *g* (Beckman SW 27·1 rotor, 27,000 rev/min). Material collected from the interphase between the 50% and 35% sucrose layers was diluted with 1·5 mM Tris–HCl buffer and centrifuged twice on a linear sucrose buffer (20–50% w/w in 1·5 mM Tris–HCl) for 180 min at 17,000 × *g* in a SW 27·1 rotor. The bands at densities 1·16 to 1·18 g/ml were collected and centrifuged for 40 min at 150,000 × *g* (Beckman 50 Ti rotor, 40,000 rev/min). The pellets were resuspended in 0·025 M sucrose in 1·5 mM Tris–HCl buffer. The purified virus was stored in liquid nitrogen. All isolation steps were carried out at 4°C. Rauscher leukaemia virus (RLV) was isolated from leukemic spleens of BALB/c mice in the same manner. Virus content was estimated on the basis of the amount of protein, as measured by the Folin method. Before use as antigen, the virus was disrupted by repeated freezing and thawing.

Leukocyte adherence inhibition (LAI) test

The technique employed is a modification of the method of Halliday and Miller [19]. Killed mice were injected i.p. by means of a Pasteur pipette with 8 ml of ice-cold medium (RPMI 1640 with 100 i.u. penicillin and 100 μg streptomycin per ml) to which Heparin (5 i.u./ml) was added. The peritoneal fluid was withdrawn and reinjected several times and then collected into glass tubes. The cells were washed once by centrifugation at 200 × *g* for 10 min. They were then resuspended in medium containing 7% foetal calf serum (FCS) (Flow, Irvin, Scotland). The final cell concentration was 40×10^3 per ml. Antigen was then added and 20 μl of the suspension were pipetted into the wells of Falcon microtest 3034 plates. The plates were incubated for 2 hr at 37°C in a humidified atmosphere with 5% CO_2. Thereafter, the plates were washed three times in PBS and the adherent cells were fixed, stained and counted. At least ten wells were counted for determination of the average number of cells per well. For MTV and RLV alternating wells were taken. Percent reduction was calculated according to the formula $(1 - a/b) \times 100\%$ in which a is the average number of cells in the wells incubated with MTV and b that in the wells incubated with RLV. Statistical significance was established by means of the two-tailed Student's t-test.

Leukocyte stimulation (LS) test

All tests were performed with pooled cells from 3 mice; when tumour-bearing animals were tested, the cells were derived from 3 mice with tumours of approximately the same size. Spleen and lymph nodes were teased apart by forceps in a Petri dish containing medium. Spleen cells were centrifuged twice at 26 *g* for 10 min in order to remove erythrocytes. They were then again washed two times (200 *g*, 10 min); lymph node cells were spun 4 times at 200 *g* for 10 min. After counting, the cells were resuspended ($2{\cdot}5 \times 10^6$/ml) in medium supplemented with 20% FCS. The cultures (1 ml) were incubated in plastic tubes (75 × 12 mm, Falcon) in the presence of antigen for 80 hr at 37°C in a humidified atmosphere with 5% CO_2. After this, 0·15 μCi of 2-^{14}C-thymidine was added to each culture. Twenty-four hours later, the cells were sucked onto glass fibre filters (Whatman GF/A, Maidstone, England) and incorporation of thymidine was measured in a liquid scintillation counter.

The cultures were run in triplicate. Percentage of stimulation was calculated according to the formula $a - b/b \times 100\%$, in which a = average number of counts/min in cultures incubated with MTV and b that in cultures incubated with RLV. Statistical significance was established by means of the two-tailed Student's t-test.

RESULTS

LAI-assay

The optimum concentration of MTV in this test proved to be 10^{-4} mg viral protein per ml when leukocytes were taken from positive control animals (Fig. 1). This concentration of virus was used therefore in all experiments.

When pooled cells derived from 3 normal animals were tested, sometimes a significant

difference was found between the number of adherent cells in cultures incubated with 10^{-4} mg RLV, and those to which no antigen was added. However, no appreciable differences were found between cultures incubated with RLV and MTV. This is illustrated in Table 1; the experiments were repeated five times for every mouse strain. Also, a significant difference was never found when the normal cells were incubated with 10^{-4} mg RLV as compared to the same amount of ovalbumin (for instance: $95{\cdot}6 \pm 8{\cdot}3$ vs $94{\cdot}3 \pm 7{\cdot}9$ and $59{\cdot}7 \pm 4{\cdot}8$ vs $62{\cdot}1 \pm 3{\cdot}2$). For that reason, in LAI-tests on cells from tumour bearing animals, RLV was always used as a specificity control.

However, when individual BALB/c, BALB/cfC3H and GR mice bearing primary tumours were tested, a significant difference in the number of adherent cells between the wells with MTV and RLV was found in 18 out of 42 animals tested. Table 2 gives some representative results.

During the experiments with individual mice bearing tumours it was repeatedly observed that reactivity was highest when the tumour was small (varying from 0·5 to 1·7 g); with increasing tumour weight reactivity disappeared, whereas animals bearing very large tumours (above 3 to 4 g) showed again some reactitivity. Since differences in the chemicals used may exert some influence on the reactivity measured, individual BALB/c, BALB/cfC3H and GR mice bearing primary tumours of varying size were tested with the same antigen preparation and batch of FCS. The results are shown in Fig. 2.

It was found that reactivity was stronger in BALB/cfC3H mice than in the other two strains. Whether the leukocytes were incubated with the autologous MTV strain (MTV-S) or with homologous MTV-P made no difference (Table 3).

LS test

With leukocytes from positive control mice, the optimal conditions for stimulation, as

measured by ^{14}C-thymidine uptake, are 80 hr of incubation (Fig. 3) and 10^{-4} mg viral protein (Fig. 4).

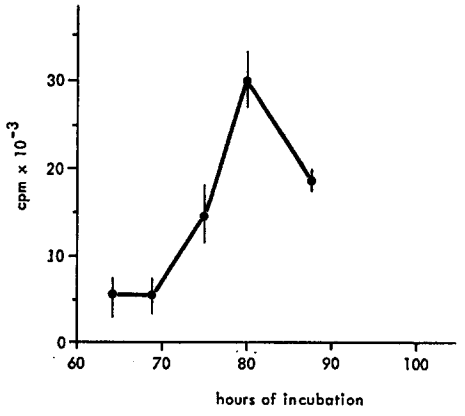

Fig. 3. Proliferation of spleen cells of positive control animals at different incubation times in the presence of MTV. This figure represents one out of 4 experiments. Percent stimulation: see text.

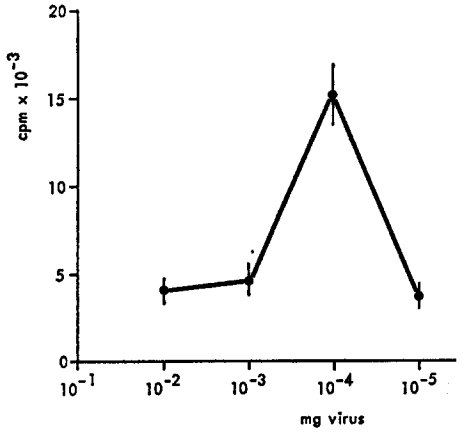

Fig. 4. Proliferation of spleen cells of positive control animals in the presence of different concentrations of MTV. This figure represents one out of 3 experiments.

From repeated experiments (3 for every mouse strain) it became clear that leukocytes from normal animals sometimes show an enhanced response with RLV as compared to the medium control experiment. This is demonstrated in Table 4. Also in this case no different values are found for RLV and MTV. The same holds true for RLV as compared to ovalbumin (for instance: 1·984 ± 489 vs 2·201 ± 312 and 2·391 ± 208 vs 2·208 ± 647). Therefore, also in this test RLV is taken as specificity control.

In contrast, in 29 out of 62 tests performed with leukocytes from tumour-bearing animals a reaction specific for MTV as compared to RLV was observed. The thymidine-uptake is 2–4 times that of the control. In Table 5

some representative results are given. It is remarkable that the results for spleen cells do not parallel those obtained with lymph node cells.

The specific response to MTV is not dependent on the virus strain that is used as antigen. A representative experiment is shown in Table 6; repeated tests yielded similar results.

Also in this assay the fluctuation in response seemed to be related to tumour size. In Fig. 5 are plotted the values for MTV-specific stimulation against tumour weight. The data have been obtained in a very short period (1 month). To keep conditions as standardized as possible, the same antigen preparations and FCS batch were used. A similar fluctuation related to tumour-size is observed as with the LAI-assay. In various other experiments we noticed the same general pattern: peak reactivity when tumour weight is small, a strong decline with increasing tumour weight and partial recovery when tumour size is very large.

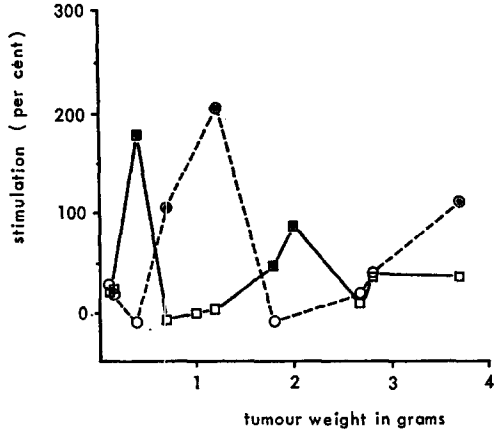

Fig. 5. MTV-specific proliferation of spleen and lymph node cells of mice of different strains bearing spontaneous tumours. All tests are performed with the same antigen preparation and batch of FCS. □: *spleen cells*; ○: *lymph node cells. A dot in the symbols indicate significant stimulation* ($P < 0·025$).

DISCUSSION

With two different techniques, the LAI and the LS test, it was found that mice bearing mammary tumour have cellular immunity to MTV. Specificity of the reaction was mainly deduced from significant differences in reactivity of the leukocytes when relatively small amounts of MTV are added as compared to the addition of similar amounts of an unrelated oncornavirus (RLV) or ovalbumin.

Both tests yielded highly reproducible results. For instance, when in the LAI test 2 microtiter plates in one experiment are compared the difference in reduction proves to be always less than 5%. In both tests it was necessary to have simultaneous controls. In our experience it is not warranted to compare results obtained at different days.

In the LAI test the plating efficiency is relatively low (from 2–10%). This is mainly due to adherence of cells to the sides of the

wells. The stimulation of leukocyte blastogenesis by MTV is relatively low (2–4 times the background) as compared to stimulation by plant lectins. Similar low values have been found in the mixed leukocyte-tumour cell interaction test for a virally induced rat lymphoma [20].

In the present study, there seems to be a good agreement between the LAI and the LS tests, although cells from the same animals have not been compared in both assays. The difference in behaviour between lymph node and spleen cells in the LS test is interesting. This has also been found with the MC test for the B16 mouse melanoma [21]. It must be taken into account that both organs harbour different subpopulations of T cells [22, 23].

The virions of the different MTV-strains show great serological differences, as detected by heterologous antisera [24–26]. By means of blocking experiments, Blair *et al.* [16] found additional indications for type-specificity in the MC test. In the LAI and LS tests, the reaction seems to be mainly group-specific. This may be due to the fact that different subpopulations of leukocytes are involved in the various test systems.

A discrepancy between the results from this study and those obtained with the MC test [15], and those with the macrophage migration inhibition test [17], is that antiviral cell-mediated immunity estimated with the two techniques used here is demonstrable in tumour-bearing mice only, as has also been found for the BALB/cfC3H line by Sigel *et al.* [27]. Most likely, the various techniques employed measure activity of different subpopulations of leukocytes.

Sigel *et al.* [27] reported that using the leukocyte migration inhibition assay and blastogenic transformation test, positive reactions were obtained with MTV-containing milk in cells from uninfected BALB/c mice. They assumed this to be due to activation of an endogenous gene coding for an MTV protein. In our tests normal BALB/c mice were unresponsive, but this may be due to the young age of the mice in our studies.

In both tests highest reactivity was found when the animals had small tumours. This indicates that a relation exists between cellular immunological reactivity and antigenic load, although tumour weight is only a rough estimate of the latter. Also from other animal studies [15, 20, 21, 28] and from clinical observations in breast cancer [29] it is known that immunological reactivity is generally impaired with increasing tumour burden

Table 6. Proliferation of leukocytes from tumour-bearing mice in the presence of different MTV strains

*S.E. = standard error of triplicate cultures.

Diminished reactivity against tumour-specific antigens, as revealed by a reduced transplantation resistance [30] may be associated with the general immunological impairment.

After the initial peak in reactivity at low tumour weight, an almost complete loss of activity was found; however, in animals with very large tumours (above 3 g) the activity reappeared again, but at a lower level than was found with cells from animals with small tumours. Thus, cellular reactivity seems to fluctuate. In rats transplanted with the Walker 256 tumour, a cyclicity in circulating plasma opsonic activity was observed [31] and, probably as a consequence, also in phagocytic activity of macrophages. Cyclic activity of macrophages in the processing of viral antigens may be the cause of a fluctuation in antiviral cellular immunity in the MTV system.

An explanation for the decrease in cellular responsiveness to MTV in both tests may be the saturation of receptors of activated leukocytes with increasing amounts of viral antigens released into the blood stream (32). In the presence of the excess antigen, new populations of leukocytes will be activated, but this process will never keep pace with the antigenic load.

A second possible explanation is the occurrence of suppressor cells which inhibit the response of the otherwise reactive cells to MTV. Glaser *et al.* [20] have produced evidence that in the spleens of rats with a progressively growing transplanted lymphoma suppressor cells occur which inhibit the induction of leukocyte blastogenesis by Concanavalin A or the mixed leukocyte-tumour cell reaction. This latter possibility will be dealt with in the accompanying paper.

The Effects of R 17934 (NSC 238159), a New Antimicrotubular Substance, on the Ultrastructure of Neoplastic Cells *In Vivo**†

M. DE BRABANDER,‡ G. GEUENS, R. VAN DE VEIRE, F. THONÉ, F. AERTS, L. DESPLENTER, J. DE CREE and M. BORGERS

Janssen Pharmaceutica, Research Laboratories, B-2340 Beerse, Belgium

Abstract—*Ultrastructural investigations on 3 experimental neoplasms and on 1 human malignancy show that the* in vivo *antitumoral activity of R 17934 can be explained by its antimicrotubular properties. The induced disappearance of microtubules results in the disorganization and necrosis of dividing and non-dividing cancer cells. Mitotic normal cells (e.g., in the intestinal crypts) seem to be equally sensitive to the antimicrotubular action of R 17934, as malignant cells. Interphase normal cells however are much more resistant than their neoplastic counterparts.*

The lysosomotropic properties of the compound, when given as a micronized suspension, ensure a slow release effect and a local accumulation of the compound which can be favourably exploited in the treatment of malignant effusions.

INTRODUCTION

In a previous paper we have shown that the effects of R 17934, a new experimental antitumoral substance, on tissue cultured cells can be explained by its antimicrotubular properties [1]. It induced the almost immediate disappearance of microtubules from dividing and non-dividing cells in culture. This resulted in the complete disorganization of mitotic cells followed by necrosis or endopolyploidization.

The normal topographical distribution of several cellular organelles and the general cellular polarity was lost in interphase cells too. These effects were identical to those produced by the antimicrotubular plant alkaloids (colchicine, vinblastine, vincristine) as was the appearance of filament bundles and annulate lamellae after prolonged treatment. Since then it has been shown that the compound inhibited the formation of microtubules from tubulin in a cell-free system and that it shared the same binding site on tubulin with colchicine [2].

The aim of the investigations reported here was to see whether the reported antitumoral activity of R 17934 *in vivo* [3, 4] could be correlated with the mechanism of action on tissue cultured cells: disintegration of the microtubular apparatus.

On account of its low aqueous solubility the compound was injected as a micronized suspension. As our previous *in vitro* experiments were performed with a solution in DMSO (dimethylsulfoxide), we have investigated the distribution and activity of the compound as a micronized suspension in the tissue culture system.

MATERIAL AND METHODS

Cell culture

The non-transformed (MO) and transformed mouse embryonal cell line (MO_4) and routine culture methods are described in a previous paper [1].

In short, MO cells show an epitheloid character and form transparent sheets of

polygonal cells at confluency. They show "contact inhibition" of movement and mitosis. The MO_4 cells were derived from MO cells by transformation with the Kirsten strain of murine sarcoma virus [5]. They lack "contact inhibition" of movement and mitosis and form multilayered cultures of pleyomorphic cells. Unlike MO cells the MO_4 cells produce invasively growing fibrosarcomas upon injection in the syngeneic host (C3H mice). Culture was done in Eagle's minimal essential medium (EMEM) supplemented with non-essential amino acids and 10% fetal bovine serum. Passage was done by routine trypsinization.

Cultures of spleen cell suspensions were set up as follows: spleens were dissected from DBA/2 mice that had received 10^5 viable L1210 cells by the intravenous route 5 days previously. The spleens were cut with scissors on a sterile nylon gauze stretched over a sterile recipient. The cells were flushed through the gauze with culture medium. Two millilitre cultures containing 10^6 viable cells/ml were set up in sterile plastic cell culture tubes (Falcon Plastics, Oxnard, California) in EMEM (as above) with 10% fetal bovine serum.

Experimental neoplasms

The strains of L1210, P388 and Lewis Lung cells were obtained from Dr. Atassi [3]. They are routinely transplanted in our laboratory in DBA/2 mice (L1210, P388) or C57BL mice (Lewis Lung).

Phase contrast observation

For observation with an inverted phase-contrast microscope (Reichert-Biovert, Bodson, Luik, Belgium) and for cell counting in quantitative experiments, the cells were seeded in plastic Petri dishes (Falcon Plastics) of 6-cm dia. For time-lapse microcinematography, the cells were seeded in culture chambers consisting of 2 coverglasses on a steel frame.

Ultrastructural observation

For ultrastructural observation, the cells were cultured in plastic Petri dishes of 6-cm dia. At the appropriate moment, the cells were rinsed twice with 0·9% NaCl solution at room temperature and were fixed in 5% glutaraldehyde in 0·1 M sodium cacodylate (pH 7·4) at room temperature for 15 min. Postfixation was done in a mixture containing 4% glutaraldehyde in 0·1 M sodium cacodylate and 1% osmium tetroxide in 0·05 M veronal acetate for 1 hr at 0°. After being stained with 0·5% uranyl acetate (40 min), the cultures were rinsed with sodium cacodylate buffer supplemented with 0·22 M sucrose (minimum 1 hr), dehydrated in a graded series of ethanol, and embedded in epon in the Petri dishes. After polymerization at 50°C (48 hr), the plastic dish was removed and cells were selected by observation with the phase-contrast microscope. The cells were either re-embedded in flat molds in epon for transverse sectioning or a hardened epon capsule was glued to the opposite site for flat sectioning.

Tissue blocks and cell pellets were processed as follows. Fixation was in 3% glutaraldehyde in cacodylate (0·1 M; pH 7·4) for 2 hr at room temperature followed by washing in cacodylate supplemented with 7·4% sucrose overnight at 4°C. Postfixation was done with 2% osmium tetroxide in veronal acetate (0·05 M; pH 7·4 with sucrose 7%) for 1 hr at 4°C. This was followed by a 5-min wash at 4°C in veronal acetate (0·05 M; pH 7·4 with sucrose 7%) and impregnation with uranyl acetate 0·5% in veronal acetate (0·05 M; pH 5·2) for 40 min at 4°C. The blocks were dehydrated in an ethanol series. This was followed by substitution with propylene-oxide (2 × 10 min); mixture propylene oxide-epon (1/1) overnight; and epon for 6 hr. Embedding was done in epon which was polymerized at 50°C during 2 days.

Semi-thin sections (± 2 μm) were stained with toluidine blue for light microscopical observation. Thin sections (± 100 nm) were stained with uranyl acetate and lead citrate and observed in a Philips EM 300 or EM 201 C electron microscope (MBLE, Brussels, Belgium).

For demonstration of acid phosphatase the procedure of Barka and Anderson [6] was used. After fixation with glutaraldehyde 3% at 4°C for 1 hr followed by 1 hr rinsing with cacodylate at 4°C the reaction was carried out in the dishes for 15 min at 37°C. Hereafter the cultures were dehydrated and embedded as described bove.

Experiments

For quantitative cell counting, MO cells were seeded in plastic Petri dishes at a density of 5000/cm^2. After 24 hr, some randomized fields were marked (minimum 4) and the cells were counted at a magnification of 160 ×. At this magnification, each field contains approximately 50 cells at 0 hr. Immediately thereafter, the test solutions were added and the same fields were counted again at the times indicated in the charts.

The uptake of micronized R 17934 was studied as follows. The MO_4 cells were

seeded at a normal passage density ($+5{\cdot}10^5$/75 cm^2) in 2·5 ml in Petri dishes (6 cm dia). After 24 hr the doubly concentrated solutions were added in a volume of 2·5 ml. Fixations for normal ultrastructural observation or for cytochemical purposes were done after 24 and 48 hr. The following experimental groups were taken: control (medium); R 17934 microsuspension (see below) at a final concentration of 100 μg/ml; latex beads with a mean diameter of 0·81 μm (Bacto-Latex 0·81; Difco Labs., Detroit, Michigan) diluted to the same optical density as the microsuspension of R 17934; latex beads with R 17934 at a final concentration of 1 μg/ml diluted from a stock solution in dimethyl sulfoxide (DMSO) of 5 mg/ml.

The following experiments were performed for the ultrastructural observation of experimental neoplasms *in vivo*.

The L1210 (10^5) or P388 (10^5) cells were inoculated intraperitoneally in CDF_1 mice in a volume of 0·2 ml.

After 5 respectively 6 days groups of mice received an intraperitoneal injection of R 17934 micronized (or the solvent) in a volume of 0·2 ml at a dose of 160, 80 or 40 mg/kg. Three mice from each group were sacrificed after 5, 10 and 30 hr respectively. The ascitic fluid was drawn off or, after 30 hr in the treated animals, the peritoneal cavity was washed with Hank's balanced salt solution. The cells were immediately mixed with a large volume of glutaraldehyde 3% and further processed as described above. Pieces of the serosal membranes and the intestines (duodenum, jejunum, colon) were processed as described above.

For i.v. inoculation 10^4 L1210 cells and 10^4 P388 cells were injected in a volume of 0·2 ml into the lateral tail vein. After 5, respectively 6 days groups of mice received an i.v. injection of the R 17934 microsuspension (or the solvent, 0·2 ml) at a dose of 160, 80 or 40 mg/kg. Three mice per group were sacrificed after 5, 10 and 30 hr. Pieces of the spleen, liver and intestine were taken and processed for ultrastructural observation.

The Lewis Lung cells were injected into the right thigh muscle (0·1 ml of 1/50 dilution of a minced tumor). After 10 days groups of mice were treated with the solvent, or R 17934 microsuspension (160, 80 or 40 mg/kg) intravenously and sacrificed after 5, 10 and 30 hr. Samples of the tumour, and the intestines were taken and processed as above. Other mice were treated intravenously with the same dose as above after 21 days. Three mice per group were sacrificed after 6 hr. Samples of the lungs containing small metastatic nodules and intestinal pieces were taken and processed.

A human patient suffering from a gastric carcinoma developed a malignant effusion in the peritoneal cavity. A volume of 3 l. had to be drawn off weekly. R 17934 microsuspension was injected intraperitoneally at a dose of 2 mg/kg. Samples of the ascitic fluid were withdrawn before, and 24 hr after, injection, and processed as described above.

Compounds and solutions

R 17934 (methyl [5–(2–thienylcarbonyl)–1H–benzimidazol–2–yl] carbamate; MW. 301, 31; Janssen Pharmaceutica, B-2340 Beerse, Belgium) was either dissolved in DMSO (5 mg/ml) and diluted to the desired concentration or micronized according to the following procedure. The compound was mixed with the microsuspension vehicle which contained the following components for 100 ml of fluid: 1·0 g Tween 80; 2·2 g $Na_2HPO_4.12H_2O$; 0·25 g $NaH_2PO_4.H_2O$; 0·5 g Plasdone. The pH was adjusted to 7·2. The suspension was put into glass vials (100 ml) containing glass beads and rotated on an axle for 3 days at a speed of 40 rev/min. This suspension contained particles with a maximum diameter of 2 μm. The mean and minimum diameter could not be determined owing to the lower level of efficacy of the Coulter Counter (0·4 μ) (Coulter Electronics Inc., Hialeah, Florida).

RESULTS

Effects of R 17934 micronized on the growth and viability of tissue cultured cells

Treatment of MO or MO_4 cells with a micronized suspension of R 17934 produced effects identical to those obtained with a solution in DMSO [1].

The bilateral symmetry of the cells was lost within 2 hr and the cells assumed a round epitheloid character. Directional cell migration ceased and the saltatory movement of intracellular particles was replaced by cytoplasmic mass streaming which resulted in the dispersion of the perinuclear accumulation of lysosomes.

The effects on cell kinetics were identical too (Chart 1). Mitotic cells accumulated and as a result of endopolyploidization the population gradually became multimicronucleated. The dose dependence was identical with a minimal effective dose of 0·04 μg/ml.

The only difference was the apparent loss of reversibility (Charts 2–4). While the effects were almost immediately reversible when the

DMSO solution was used the micronized suspension showed irreversible effects even after 2 hr incubation only.

The ultrastructure of tissue cultured cells treated with R 17934 micronized

From the ultrastructural point of view the effects of R 17934 on MO_4 cells treated with large numbers. However, microtubules failed to reappear when the micronized suspension was washed away contrary to the DMSO solution [1].

Both extracellular crystalline structures and identical crystals enclosed in endocytic vacuoles were consistently found in the cultures treated with the micronized suspension (Fig. 1). Since

R 17934 micronized were identical to those obtained with the DMSO solution [1]. Microtubules disappeared resulting in the accumulation of aberrant mitotic cells and in the randomization of the topographical distribution of lysosomes and Golgi elements. After 24–48 hr numerous multimicronucleated cells were formed through the separate enveloping of the dispersed chromosomes. Annulate lamellae and bundles of 100 nm filaments appeared in these were never found in untreated cultures or in cultures treated with the DMSO solution these were most probably the micronized R 17934-particles. The crystalline structures appeared as empty profiles delineated by a faint flocculent precipitate. Because of their high solubility in organic solvents the original crystals were most probably dissolved by the procedure for ultrastructural preservation which includes dehydration in ethanol.

It could be of interest to know whether the phagosomes containing R 17934 crystals would fuse with primary lysosomes or not in view of the known inhibitory effect of colchicine on this phenomenon in leukocytes [7] but not in macrophages [8]. This was of particular importance since R 17934 is more soluble in an acid environment such as is present in lysosomes. Unfortunately the normal cytochemical procedure used for the demonstration of acid phosphatase completely obscured the faintly visible crystal ghosts. In order to overcome this

The ultrastructure of malignant and non-malignant cells after intraperitoneal inoculation of L1210 and P388 cells and intraperitoneal injection of R 17934

The ultrastructural morphology of untreated L1210 and P388 cells is shown in Figs. 3–6.

Both cell types were more or less round with many microvilli. The cytoplasm was filled with ribosomes and a variable amount of rough and smooth cisternae of the endoplasmic reticulum (SER, RER). Some P388 cells contained annulate lamellae [9–11].

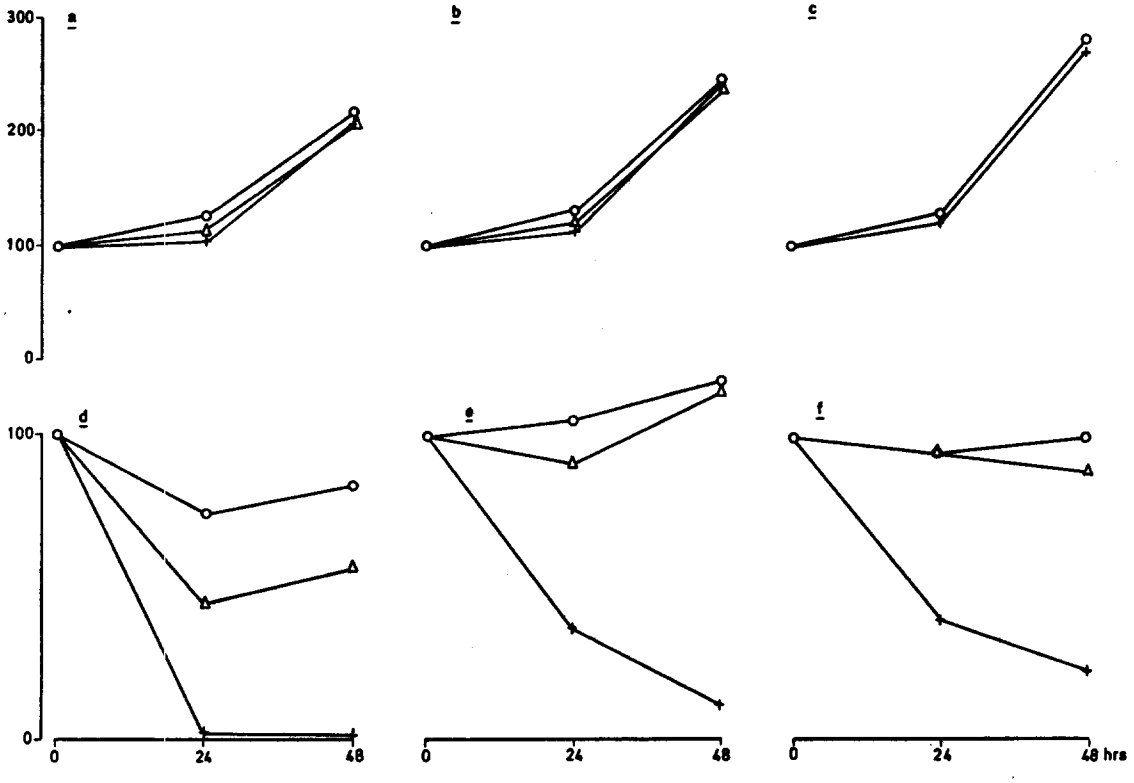

Chart 2. Reversibility of the effects of R 17934 on MO cells. The experimental set-up and symbols are the same as for Chart 1. In a, b and c R 17934 was dissolved in DMSO (5 mg/ml) and further diluted in complete culture medium. In d, e and f a micronized suspension of R 17934 in MSV (10 mg/ml) was diluted in complete culture medium.

a and d, effect of R 17934(1 μg/ml); the compound was present from 0 hr until 2 hr, then the cultures were washed twice during 10 min. and further incubated in normal growth medium; b and e, effect of R 17934 (1 μg/ml) present from 0 to 4 hr; c and f, effect of R 17934 (1 μg/ml) present from 0 to 8 hr.

we incubated the cells with latex beads of a size similar to the R 17934 particles. Both in cells treated concomitantly with a solution of R 17934 (1 μg/ml) and in untreated cells a substantial number of the engulfed latex particles was found to be enclosed in acid phosphatase-positive vacuoles (Fig. 2). Although no extensive quantitative evaluation was made the percentage of latex beads residing in acid phosphatase-positive vacuoles was even larger in the cells treated with R 17934 than in untreated cells 71% (27/38) vs 33% (39/118).

Intracisternal A-type particles were encountered in the endoplasmic reticulum of both cell types as were extracellular C-type particles which could often be seen in the stage of budding from the plasma membrane. The consistent presence of these viral particles was often of great help in excluding ambiguity with regard to the malignant origin of the cells. Lysosomes were scarce but a variable number of lipid droplets was consistently present in both cell types. The nucleus was mostly more lobulated in P388 cells than in L1210 cells where the kidney shape predominated. In both cell

types the cytocentre, formed by some Golgi cisternae surrounding the centriolar complex was located in a concave nuclear invagination. Microtubules could be seen throughout the cytoplasm. A network was present underneath the plasma membrane and a radiating complex converged towards the centrioles.

Mitotic cells showed a normal ultrastructure with a prominent spindle composed of microtubules.

intervals and with the different dosages is given schematically in Table 1.

After treatment the following observations were made on semithin sections. An accumulation of mitotic cells was visible with all doses after 5, 10 and 30 hr with a maximum of 20–50% after 10 hr (see also ref. [4]). Normal anaphase or telophase configurations, however, were completely absent. After 10 hr, and even more markedly after 30 hr, the population

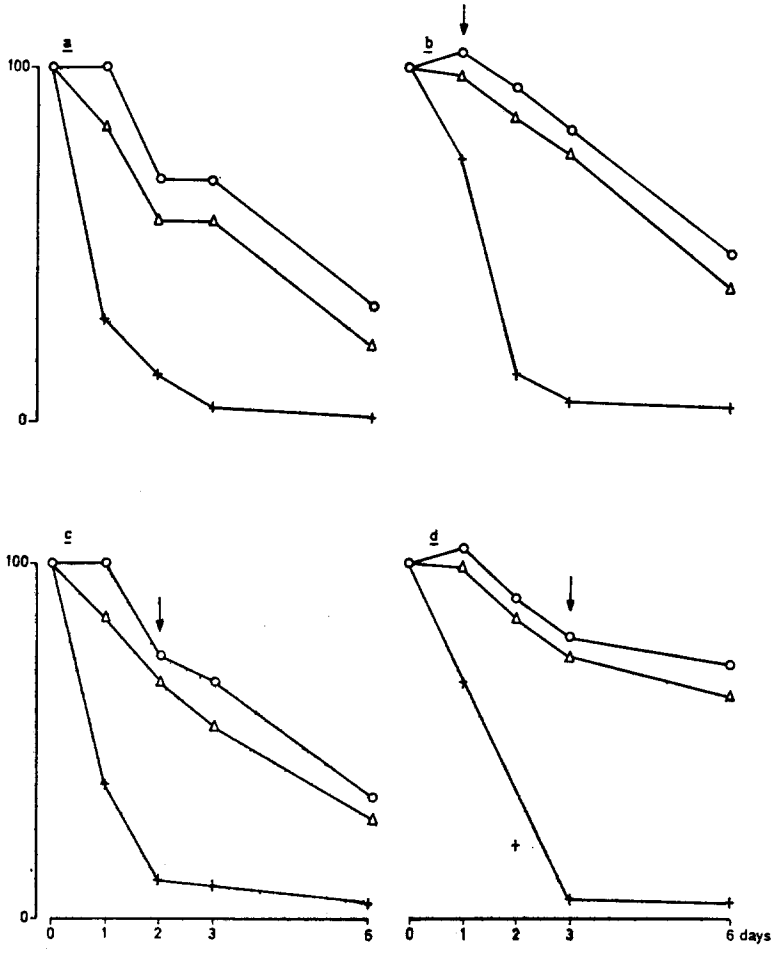

Chart 3. *Reversibility of the effects of a micronized suspension of R* 17934 (1 *μg/ml*) *on MO cultures after prolonged incubation times. The experimental set-up and the meaning of the symbols are the same as for Chart* 1. *In a, the cultures were incubated for the whole observation period with R* 17934(1 *μg/ml*). *In b, c and d, the cultures were washed (arrow) after* 24, 48 *or* 72 *hr respectively, and further incubated in normal growth medium. Control cultures had reached a plateau at* 400–600% *of the starting value after* 6 *days.*

Observation of semithin sections showed a small percentage of mitotic cells (2–5%). A small number of polymorphonuclear leukocytes was consistently present.

The effects of R 17934 on P388 and L1210 cells inoculated intraperitoneally were completely comparable. In order to avoid useless repetition a single description of the essential observations will be given. The extent of the effects in the two systems after different time

consisted predominantly of polymorphonuclear leukocytes (up to 90% after 30 hr) and some monocytes or macrophages and lymphocytes. The remaining L1210 or P388 cells were often necrotic with pyknotic chromatin.

Five and 10 hr after i.p. injection of the micronized suspension of R 17934 microtubules were largely absent from both mitotic and interphase cells at the three dosages used. Vacuoles with crystalline inclusions were most

prominent at the earliest sampling time. They were rarely seen at later intervals. The general cell shape remained round but deviating forms were encountered. The cell surface showed more blunt protrusions of various shapes than untreated cells (Figs. 7, 8, 10, 11, 13, 14).

The structures of other subcellular organelles appeared unaltered. However, the distribution of the Golgi cisternae was completely changed. They were dispersed over the entire cytoplasm and the concentration around the centriolar complex was lost (Figs. 8, 10). Annulate lamellae and bundles of 10 nm filemaents were encountered frequently after 10–30 hr.

Five and 10 hr after treatment the mitotic cells too, were completely devoid of microtubules and the chromosomes were scattered throughout the cytoplasm intermingled with other organelles. Two prominent kinetochores were often visible (Figs. 7, 11, 13, 14).

Thirty hours after treatment the accumulation of ascitic fluid had completely disappeared at all doses. The peritoneal cavity had to be washed with Hank's balanced salt solution in order to recover the remaining cells. The largest percentage of the cells consisted of eosinophilic and neutrophilic leukocytes. Some large mononuclear cells and lymphocytes were also present. The remaining L1210 or P388 cells were either in the disorganized mitotic stage or showed many signs of necrosis (Fig. 7). They contained dispersed masses of pyknotic chromatin and accumulations of membranous structures and lipid droplets. Only very few viable interphase cells were present. Some of these showed a variable number of separate nuclei. The mitotic cells

The meaning of the symbols is as follows:

MT I: microtubules in interphase cells
MT M: microtubules in mitotic cells
−: no microtubules present
−+: extremely few microtubules present
+−: more microtubules present but clearly less than in untreated cells
+: large number of microtubules present, without any obvious difference with untreated cells.

The Lewis Lung data refer to the intramuscular tumor except for the 6 hr interval which refers to the lung nodules.

showed no normal spindle. At 40 mg/kg some cells contained microtubules mostly in the vicinity of the kinetochores and centrioles. Microtubules were mostly absent from interphase cells at 160 mg/kg. Some microtubules were present in the centriolar vicinity at 80 mg/kg and many of them were present at 40 mg/kg. The subcellular organization (e.g., Golgi distribution) was mostly disturbed even at 40 mg/kg.

The leukocytes present in the ascitic fluid contained normal microtubules at all doses

tested and at all sampling times. Even those which contained crystalline inclusions, presumably the R 17934 particles. The Golgi cisternae were always concentrated around the centriolar complex in the nuclear hof. Particularly after 30 hr many of the phagocytes contained lysosomes with cellular debris (Figs. 15, 16).

The cells lining the peritoneal cavity and the intestinal epithelial cells showed a normal microtubular apparatus and cellular substructure too.

At the light microscopic level a mitotic block (ring-mitoses) was evident in the intestinal crypts in the animals that had received 160–80 mg/kg. This was most prominent after 10 hr. After 10 hr and more so after 30 hr many cytolysomes were visible in the intestinal epithelial cells. Presumably these were remnants of mitotic cells [12].

At the ultrastructural level a normal spindle was absent although a substantial number of microtubules could be seen. However, centriolar migration and chromosome separation had mostly failed to occur. No abnormalities were seen at 40 mg/kg.

The ultrastructure of malignant and non-malignant cells after intravenous inoculation of L1210 and P388 cells and intravenous injection of R 17934

Four to five days after intravenous injection of L1210 or P388 cells, neoplastic cell nests were found abundantly in the liver, around the sinuses and in the spleen. The morphology of the cells in untreated animals was comparable to that of the cells in the ascitic fluid after intraperitoneal inoculation. Generally they were spherical and were linked to each other and to other cells by interwoven microvilli.

The presence of multiple A-type and C-type particles was of great help in determining the nature of the cells, especially in the spleen.

Examination of semithin sections showed an accumulation of mitotic cells at all time intervals and at all doses, reaching a maximum after 10 hr, in treated animals. Normal anaphase or telophase configurations were completely absent.

At the ultrastructural level the effects of R 17934 were identical to those described for the cells in the ascitic fluid. The minor differences in time and dose dependency are shown in Table 2. Microtubules disappeared both from mitotic cells and interphase cells. This resulted in a similar disorganization and necrosis as described above.

Intracellular crystals were found after 5 hr only. Similar crystals were found in the Kupffer cells and phagocytic cells in the spleen. Microtubules however, were consistently present in these cells and other cells in the immediate vicinity of the neoplastic cells (liver parenchyma, vascular endothelial cells, splenic leukocytes etc.) at all time intervals and at all dose levels (Figs. 17, 18). However, a C-mitotic block was evident in the intestinal crypts at 160, 80 and 40 mg/kg. And a progressive accumulation of lipid droplets in the liver parenchyma was noted, reaching a maximum after 30 hr.

Table 2. Number of sections through L1210 cells and normal leukocytes with (+) or without (−) visible microtubules after a 5 hr-period of treatment in vitro *with different doses of R 17934. The [%−] gives the number of cells without microtubules as a percentage of the total number of cells. For technical details see "Material and Methods"*

The ultrastructure of malignant and non-malignant cells after intramuscular inoculation of Lewis Lung carcinoma cells and intravenous injection of R 17934

The Lewis Lung cells were round with a large irregular nucleus. A variable amount of mitochondria, endoplasmic reticulum, lysosomes and lipid droplets was present. A small number of viral particles could be seen (A- and C-type). The cytocentre (Golgi cisternae surrounding the centrioles) was present in a perinuclear location. Microtubules could be found throughout the cytoplasm and were most prominent in the vicinity of the centrioles. Mitoses were completely normal.

Some infiltrating leukocytes were present and a variable number of necrotic cells especially in the hemorrhagic centre of the tumor.

The findings after treatment were similar to those in L1210 or P388 cells and will not be repeated (Figs. 9, 12). The exact time-dependency and dose-dependency are given in Table 1. The effects on the host tissues were as described above.

The ultrastructure of ascitic carcinoma cells after intraperitoneal treatment of the patient with R 17934

Before injection of R 17934 the ascitic fluid contained a large number of round cells with many microvilli. In most cells the nucleus was displaced towards the periphery. A central Golgi area was often present. The cytoplasm was filled with large granules containing an amorphous material comparable to the secretory granules of gastric parietal cells [13]. In many cells intracellular canaliculi covered with microvilli were present. Microtubules were present throughout the cytoplasm. Only a few mitotic cells were seen and some leukocytes (Figs. 19A, 19B).

Treatment with R 17934 resulted in the total disappearance of microtubules from both interphase and mitotic cells (Figs. 20, 21). This resulted in the accumulation of disorganized mitoses that became necrotic showing pyknotic chromatin. Many interphase cells too were apparently lysed. A consistent finding was the fusion of the secretory granules into large iregular masses. Several cells contained vacuoles with crystalline particles (Fig. 20).

The leukocytes contained normal microtubules and a normal intracellular organization (Fig. 22). More particularly, the Golgi cisternae remained concentrated around the centrioles in the nuclear hof.

Further treatment of the patient with 2 mg/kg every 3 days resulted in the gradual disappearance of the ascitic fluid. Regular examination of smears from the fluid showed a further accumulation of mitotic cells and a gradual disappearance of malignant cells.

Ultrastructure of malignant and non-malignant cells after treatment with a solution of R 17934 in vitro

Apparently there was a clear-cut difference in sensitivity towards the antimicrotubular action of R 17934 between the malignant and non-malignant cells. This could be due to a difference in uptake of the micronized R 17934 particles and/or a different intracellular solubilization. One other possibility is an intrinsic difference in the sensitivity of the microtubular apparatus.

In order to test the second hypothesis the spleens of animals inoculated 5 days previously with L1210 cells, were filtered through nylon gauze. The cell suspensions were put into short-term culture, and treated with different doses of R 17934 dissolved in DMSO. The L1210 cells could be distinguished from non-malignant cells (among other morphological characteristics) by the presence of the A-type and C-type particles. Normal leukocytes and L1210 cells (in interphase) were scored for the presence or absence of microtubules. The results are given in Table 2. It should be noted that the effect of R 17934 on L1210 cells is a clear-cut underestimation because cells with only 1 microtubular profile were scored as positive. This was mostly the case with the higher dosages. Normal leukocytes on the other hand showed an equal amount of microtubules with all doses. The effect on microtubules in mitotic L1210 cells was complete at 0·04 μg/ml.

DISCUSSION

The *in vitro* experiments have shown that the activity of R 17934 is not altered when the compound is administered to the cells as a micronized suspension. Most probably a minimal amount is freely soluble in aqueous media. In view of the biological activity this amount is certainly larger than 0·04 μg/ml, the minimally effective dose. Apparently the micronized particles are phagocytozed by neoplastic cells *in vitro* and *in vivo* as well as by normal phagocytes.

The immediate reversibility of the activity when the compound is solubilized and the failure of reversibility when the compound is given as a suspension show that at least part of the intracellular store can be solubilized. This is substantiated by the observed gradual disappearance of the crystals with time *in vitro* and *in vivo*.

Since fusion of the crystal-loaden phagosomes with primary lysosomes does occur, the micronized form of R 17934 can be regarded as a true lysosomotropic substance [14]. Apart from the theoretical advantages put forth by Trouet (accumulation in mostly actively phagocytozing cancer cells) the following facts can be noted. The intracellular storage ensures a slow release effect that seems to be essential for the efficacy of R 17934 *in vivo*. Indeed, unpublished observations of ourselves and Atassi [3, 4] have shown that a solution of R 17934 injected *in vivo* must be given for at least 24 hr, with 3 hr intervals, in order to obtain a minimal activity in the L1210 system.

The local accumulation of the compound makes it ideally suitable for the treatment of malignant effusions which can be achieved in human patients without any toxic side-effect (J. De Crée, personal communication).

Although intravenous injection of the micro-

nized suspension seems to be well tolerated, by mice, we have noted severe disturbances of the blood coagulation system in dogs. This precludes, for the moment, further investigations in human patients, with regard to the systemic application, until a more suitable formulation is found.

The ultrastructural investigation on 3 different experimental tumor systems and in 1 human case have shown that the antimicrotubular activity which was evident in cell culture is also apparent *in vivo*. The antitumoral activity is thus most probably related to this activity.

It is probably worth stressing that, as for the vinca alkaloids [15], the antitumoral activity of this compound cannot entirely be explained by the oversimplifying term "mitotic block". The total disorganization of non-mitotic cells should strongly affect all the vital processes which depend on ordered subcellular movements or on an adequate compartmentalization. The interference with directional cell migration could have important consequences for the invasive and metastatic properties of tumoral cells. This could explain the strong activity against Lewis Lung metastasis [3]. At last, both the alteration of the fluid mosaic behavior of the cell membrane [16] and the altered turnover of the cell coat [17] could seriously change the interaction with immune and non-immune host defense mechanisms. In view of this, the apparent difference in sensitivity between interphase malignant and non-malignant cells towards R 17934 could be a favorable factor in determining its therapeutic efficacy.

Apparently this difference in sensitivity is not related to a differing capacity to concentrate the micronized particles since it could be reproduced by using a solution of R 17934 *in vitro*. Theoretically several possibilities remain open. The soluble drug could reach higher concentrations in neoplastic than in normal cells through differing membrane permeabilities. This should be determined with uptake studies using the radiolabeled compound. A faster metabolism of the compound by normal cells is not very likely since we have never seen any metabolization of the compound (*in vitro*) as determined by biological tests. Finally, it may not come as a surprise to learn that the microtubular apparatus of cancer cells which have retained the capacity of division is more labile than that of cells which normally no longer divide. This is substantiated by the recently observed differences between transformed and untransformed cells with regard to their cytoplasmic microtubule complex [18].

The mitotic normal cells, however, (intestinal crypts) are apparently equally sensitive to the antimicrotubular activity of R 17934 as the mitotic malignant cells.

The Use of Macromolecules as Carriers of Antitumor Drugs

MARIA SZEKERKE* and JOHN S. DRISCOLL†

**Institute of Organic Chemistry, Eötvös University, Budapest* 1088, *Hungary*

†*Laboratory of Medicinal Chemistry and Biology, DR & DP, DCT, National Cancer Institute, National Institutes of Health, Bethesda, Maryland* 20014, *U.S.A.*

Abstract—*The purpose of this investigation is an extension of the use of protein carriers to various types of antitumor drugs, including antimetabolites and antitumor antibiotics. The variety of carriers has also been increased by the use of branched chain synthetic polymers with a poly-L-lysine backbone. Most drug-protein combinations were non-covalent in nature. Murine antitumor results are discussed based on the evaluation of activity in the leukemia L1210 and P388 systems. In several cases the therapeutic efficacy of an antitumor drug was increased by macromolecular complexation. This effect was partly due to reduced toxicity and seems to be dependent on the choice of carrier as well as the choice of drug. Actinomycin D, cytosine arabinoside, 5-azacytidine and dichloromethotrexate appear to be good candidates for a macromolecular complex approach to cancer chemotherapy.*

INTRODUCTION

SEVERAL approaches have been made to enhance the efficacy of existing antitumor agents through the discovery of better ways to use these drugs. One successful attempt has been combination therapy, which has been receiving increasing attention. Another recent approach has been the use of large molecular weight materials as carriers of cytotoxic drugs [1, 2]. The high endocytic activity reported for several types of tumor cells might allow a preferential uptake of the drug-macromolecular combinations by the target cell. This device could serve as a means of directing drugs preferentially into a chosen cell type. Since almost any substance can be linked by suitable physical or chemical coupling methods with an appropriate carrier, this field of research offers rich possibilities for a novel kind of drug design.

It has been demonstrated that cytotoxic drugs can be covalently coupled to macromolecules without loss of biological activity [1, 3–5]. Our earlier studies of a series of products in which a nitrogen mustard derivative [*p*-(N, N-bis-2-chloroethyl)aminoaniline] was chemically attached to albumin, fibrinogen, γ-globulin or their poly-alanyl derivatives showed that this type of covalent coupling (conjugate formation) led to an improvement of up to 8 fold in therapeutic index in the ADJ/PC6A plasma cell mouse tumor screen [1]. It was further shown that covalent bond formation was not a necessity and that complex formation by physical association was adequate in many cases [2]. As a result of several studies it has become clear that the strength or stability of bonds between a carrier molecule and a drug plays a critical role in the determination of its biological properties. While covalent bonds are sufficient, they are not necessary since the cumulative energy of multiple ionic and other non-covalent bonds between two molecules may produce very stable complexes [6].

In order to assess the value of different types of protein carriers, and evaluate complexes with antitumor agents other than nitrogen mustard derivatives, a series of new protein-antitumor agent combinations were prepared and evaluated in the leukemia L1210 system. The structural formulas of the various drugs used in these experiments are shown in Fig. 1. All of the antitumor agents evaluated were of some interest to the Division of Cancer Treatment, National Cancer Institute at the time of the study. Included are a broad spectrum of antitumor agents (antibiotics, nucleosides, intercalating agents, antimetabolites). In most instances non-covalent bonding was employed (complexes). In a few cases an

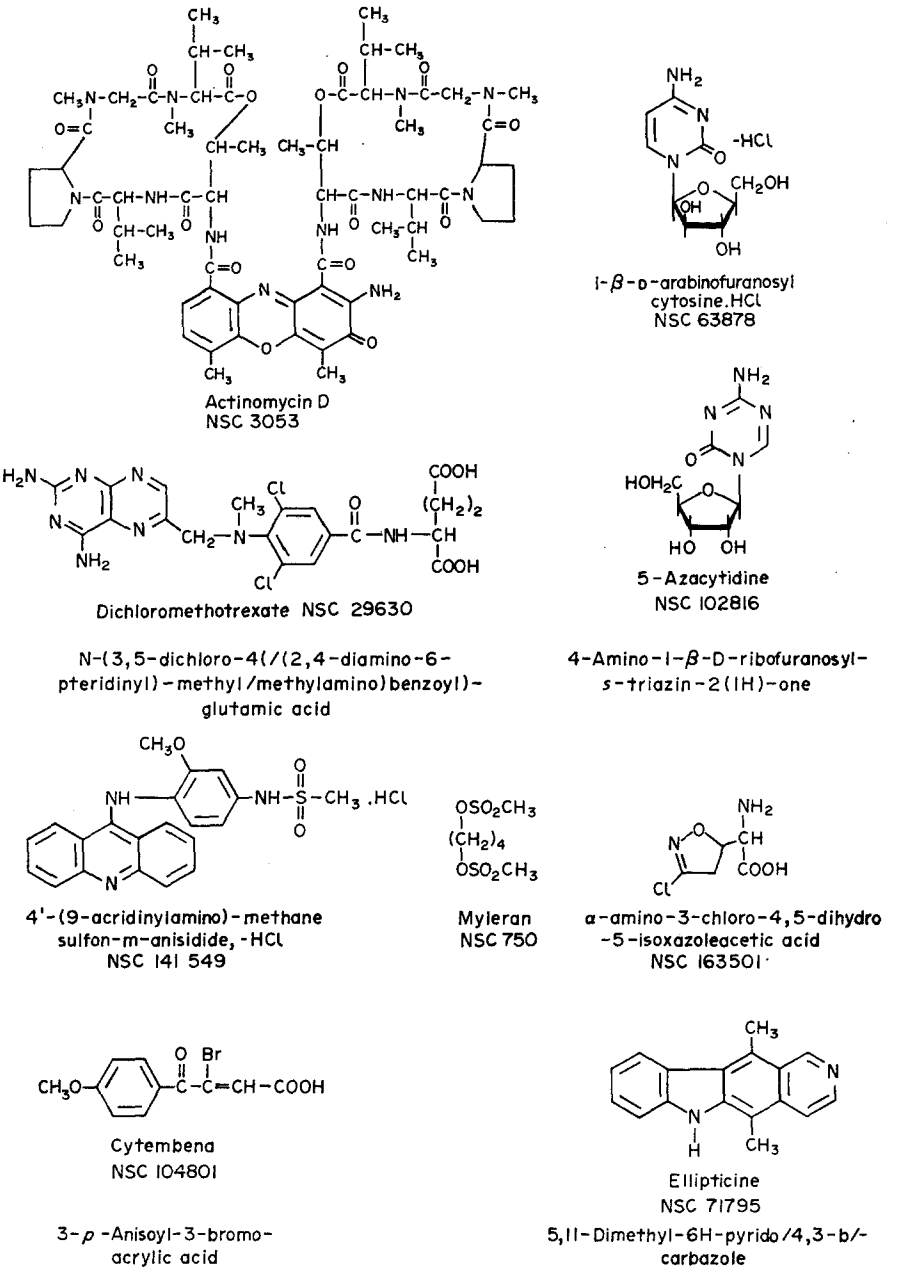

Fig. 1. Structure of antitumor drugs used for coupling to macromolecules.

attempt to form covalent bonds between drug and protein (conjugates) was made. Non-covalent linkages have the great advantage that they can be formed without the help of special chemical technology.

The number of carriers studied was increased relative to previous experiments [1, 2] by the use of synthetic multi-chain polyamino acids with a polylysine backbone. This type of material has been extensively used by Sela *et al.* [7, 8] as model compounds in immunological studies. These structures can be modified easily in many ways (charge, spatial requirements, immunological properties, etc.).

There are indications in the literature that the pinocytic activities of different cell types show some chemical specificity [9]. Our previous results showed that coupling equal amounts of the same drug covalently to different carriers gave rise to considerable variation in the tumor-inhibitory potency of the conjugates. In order to achieve cell-specific effects, additional studies are necessary in order to develop carriers which rely on selective endocytic uptake by the target cells.

MATERIAL AND METHODS

Drugs

The cytotoxic drugs used are shown in Fig. 1. All the drugs were supplied by the Drug Development Branch, National Cancer Institute (Bethesda, Maryland).

Carriers

Three groups of carriers were used. (*a*) Plasma proteins: bovine serum albumin, bovine γ-globulin, bovine fibrinogen, fraction I (Sigma). (*b*) Poly-DL-alanyl proteins. These were prepared as reported previously [1, 10]. (*c*) Synthetic polypeptides. Intermediates: N^{ε}-carbobenzyloxy-L-lysine [11], N^{ε}-carbobenzyloxy-N^{α}-carboxy-L-lysine anhydride [12], N-carboxy-DL-alanine anhydride [13], γ-benzyl L-glutamate [14], γ-benzyl N-carboxy-L-glutamate anhydride [15].

Poly-L-lysine was prepared from N^{ε}-carbobenzyloxy-L-lysine via the N-carboxy-anhydride [12]. Conditions for polymerisation were chosen to obtain a degree of polymerization of approx. 100–300 [16]. The molecular weight of N^{ε}-carbobenzyloxy-poly-L-lysine was estimated by viscosity measurements [12]. The carbobenzyloxy blocking groups were removed by HBr/acetic acid. The purified poly-L-lysine had a molcular weight of 30,000 (approx.).

Multi-poly-DL-alanyl-poly-L-lysine (pDLAla—pLys) was prepared according to Sela *et al.* [17] choosing a Lys:Ala ratio 1:3·65. Amino acid analysis of the polymer indicated a ratio Lys:Ala = 1:3·5.

For the preparation of multi-poly-L-glutamyl-poly-DL-alanyl-poly-L-lysine (pGlu-pDLAla—pLys) the method of Sela *et al.* [18] was adopted. Input amino acid ratio Lys:Glu—1:6·7. Analysis of end product gave Lys:Glu = 1:5·8.

Coupling methods

Method A [2]. A solution of the macromolecule in pH 6 phosphate buffer was incubated at 4°C with a solution of the drug. Agents which had a poor water solubility were applied in an organic solvent (Table 1). Stirring was continued for 3–4 hr in the cold. The macromolecular complex formed was purified in each case by dialysis for 36 hr against several changes of water using Visking tubing with the temperature being maintained below +4°C.

In the case of poly-DL-alanyl fibrinogen derivatives, dialysis was carried out against 0·3% sodium citrate solution. Products were isolated by freeze drying. Estimates of the drug content were based either on microanalytical data obtained for elements not present in proteins (e.g., chlorine) or by u.v. absorption measurements.

Method B. With drugs of reasonable water solubility, complex formation was achieved by mixing a solution of the macromolecule in water with an aqueous solution of a weighed amount of the drug for 30 min at 4°C followed by freeze-drying (Table 1). An advantage of this method is that no further analytical measurement is needed to estimate the drug content.

Method C. Covalent bonds were formed by the aid of a water soluble carbodiimide [1-cyclohexyl-3-(2-morpholinoethyl)-carbodiimide methotoluene-*p*-sulphonate] in pH 6 phosphate buffer, as described previously [1].

Determination of antitumor activity

All *in vivo* antitumor tests were carried out at Hazleton Laboratories, Vienna, Virginia, U.S.A., using previously published National Cancer Institute protocols [19].

With the exception of cytembena and its protein combinations, all products were tested in the murine leukemia L1210 system. Cytembena and its derivatives (B 900302–B 900304) were screened in the P388 lymphocytic leukemia test system since the parent drug is inactive in the L1210 system. In each instance, the uncomplexed parent drug was tested for comparison in the same experiment. None of the macromolecular carriers by themselves inhibited tumor growth. Combinations formed which were found to have a low drug content and a relatively high parent drug optimum dose (e.g., Myleran) were not tested in the tumor model. Water was used as the injection vehicle. Tumor cells (L1210, 1×10^5; P388, 1×10^6) were injected into the peritoneal cavity of the test animals. Intraperitoneal injection of the test compounds began the next day and continued daily for a total of nine injections (QD 1–9 treatment schedule). Six mice were used to evaluate each dose level. Results are reported in percent survival time of treated animals versus untreated tumored control animals [(treated survival ÷ control survival) × 100% = T/C%]. The percent T/C values greater than 125% indicate statistically significant antitumor effects [19].

RESULTS

Results of animal screening are summarized in Figs. 2–9. Graphical presentations were constructed by plotting antitumor activity (percentage T/C) against units of drug dosage.

Attention should be called to the following points:

(*a*) It can be seen from the graphical presentations that if the actual drug content of the macromolecular combination is calculated, the optimal dose levels are almost

identical for the complexes and the parent compounds. However, a number of the complexes show an increased degree of tumor inhibition;

(*b*) Only a few covalent conjugates (Method C, Table 1) were formed. In these cases, a behaviour similar to that reported for the nitrogen mustard derivatives [1] can be recognised, i.e., the optimal dose levels are shifted to higher doses;

(*c*) The effect of the various carrier proteins on the antitumor activity of a drug is different. The use of poly-alanyl proteins seems to offer a consistent advantage in most cases. A similar observation has been made with respect to nitrogen mustard combinations [1,2]. The various polylysine combinations appear to exert different effects, but the pattern is not identical for each drug. The carrier must be capable of binding the drug in a manner that is unaffected by body fluids during the transport process but is reversible in the target cell. A separate study is planned to evaluate the binding parameters of these complexes as

well as the pH and temperature dependence on complex stability.

(*d*) In the case of Actinomycin D (Fig. 2), there is an indication that complex formation can result in reduced toxicity and an increase in the therapeutic index. If therapeutic index (TI) is defined as [the highest dose producing a T/C of 125% divided by the lowest dose producing the same response], then the parent compound, Actinomycin D (Fig. 2, B900325) has a TI of 4·3 while the Actinomycin D-pDLAla-BSA complex (Fig. 2, B900328) has a TI of 10.8. The BSA conjugate (B900326) and complex (B900327) of Actinomycin D are also superior giving TI values of 7·3 and 6·5, respectively. Further experiments are needed to evaluate whether this aspect is general. It appears that in favorable cases, a pharmacological effect can be obtained at distinctly lower drug concentrations. Such derivatives might possibly allow the more extensive use of a number of very active drugs that are presently used with difficulty due to their excessive toxicity.

Besides a decrease in toxicity, other advantages might be expected from macromolecular complexation. It has been reported [20] that the presence of macromolecules has a pro-

tective effect and slows down the rate of hydrolysis of some types of antitumor active nitrogen mustards in aqueous solution. This suggested studies with 5-azacytidine, an antitumor agent given by continuous infusion but which is rapidly decomposed in aqueous solution [21].

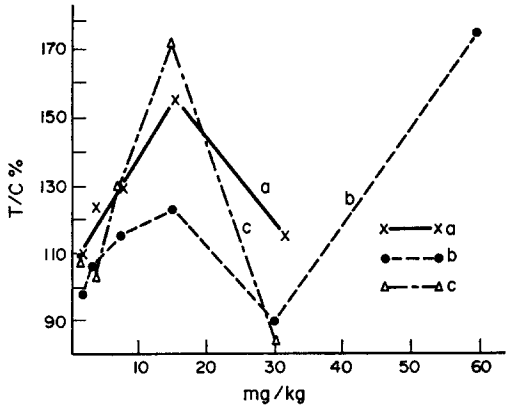

Fig. 9. Effect of ellipticine (NSC 71795)-macromolecular combinations on the growth of the L 1210 system in BDF_1 mice; activity correlated to actual drug content. (a) NSC 71795.(HCl) (B 900307) (b) NSC 71795-BSA, complex (B 900308) (c) NSC 71795-pDLAla—BSA, complex (B 900309).

Another possible advantage of complexation is related to the pharmaceutical formulation of water insoluble compounds. Complexation of these materials with water soluble proteins might enhance the solubility of the parent compound. An active, but relatively insoluble acridine derivative, NSC 141549 (Fig. 1) was used for this purpose.

The effect of complexation on the decomposition of 5-azacytidine was followed with u.v. spectroscopy. The change in u.v. absorption of 5-azacytidine at 243 nm was measured in the presence of different proteins in pH 7·3 phosphate buffer for periods of 30 min to 75 hr after incubation of 4° using a drug-protein ratio 1:9. Retardation of decomposition was largest in the first two hours (up to 30–40%) but with some of the carriers an effect could be demonstrated even 5 hours after incubation. These preliminary results are somewhat difficult to interpret since the binding characteristics of the decomposition products and the proteins are not yet available.

Protein complexes containing 5–9% of the acridine derivative (NSC 141549) retained activity and had better water solubility characteristics than the parent drug. The improvement, however, was not great enough in this instance to provide parenteral formulation possibilities.

DISCUSSION

A reason for an improved therapeutic efficacy with the use of macromolecular carriers may be related to the findings that the administration of radioactive albumin or fibrinogen leads to a relatively high incorpor-

ation of radioactivity into tumors [22–24]. De Duve suggested [9] the term "lysosomotropism" for drug-macromolecular combinations taken up by cellular endocytosis. According to this hypothesis the carrier is transported into the cell and there it is digested by lysosomal enzymes and the drug is released in its active form. The daunorubicin–DNA and adriamycin–DNA complexes were prepared based on this principle. Encouraging animal screening results [25, 26] resulted in clinical trials with these materials in the treatment of leukemia [25, 27]. Lysosomotropism was shown to be operative for the adriamycin–DNA complex [9].

A lysosome-mediated effect should be considered for drug–protein complexes. However, other mechanisms are also possible. Rubens and Dulbecco [28] have shown that chlorambucil and a tumor specific globulin are synergistic, but there is no requirement for physical absorption of the two materials since separate addition of the two components can still bring about the observed effect. The effect of simultaneous injection of separate solutions of the protein carriers and antitumor drugs described here is in progress. This will assess whether a similar synergistic action occurs with these materials. It is hoped that the investigation of complex stability and the nature of the bonds formed between the protein and cytotoxic drugs might offer important information for structure–activity relationships. There is certainly a need for further research work to establish the actual mechanism of antitumor action of the macromolecular derivatives.

With the development of tumor immunology, many investigators have sought to use antibodies to antigenic determinants expressed preferentially on tumor cells as carriers of cytotoxic agents in the hope of increasing the specificity of the drug and reducing its systemic toxicity. Several reports have appeared in which drug–antibody complexes [28–33] and conjugates, i.e., drugs covalently linked to immunoglobulins [3–5, 34] have been studied. For this approach to succeed, both the antibody and the toxic agent must retain activity when the two are linked together. The most powerful antitumor properties were achieved by first loading a poly-L-glutamic acid chain with the drug, followed by coupling of some of the chains to immunoglobulin [34]. This method also seems applicable in other cases, e.g., when hormone activity is to be saved, or when the covalent coupling reaction requires a chemical technique which would extensively denature the protein. We are presently involved in trying in such cases the application of the concept of the "inert intermediate carrier".

Although the idea of using tumor-specific antibodies as carriers is attractive, the isolation and purification of tumor-specific antibodies is presently still rather tedious, preventing general access to larger amounts of carriers of this type. We therefore feel that the exploration of readily obtainable non-specific macromolecular carriers might lead to combinations more easily exploitable for practical application.

An augmenting effect of macromolecules on cytotoxic drug action has been demonstrated and is supported by a number of experimental examples. It is hoped that the results obtained in these preliminary attempts to apply the principle of macromolecular carriers to antitumor drugs will stimulate further efforts in this area.

Biological Activities of Murine Mammary Tumour Virus *In Vitro*

Increased Macromolcular Synetheses in Mouse and Hamster Kidney Cells; Production of B- and C-Particles in the Mouse Cells

J. LINKS, OLGA TOL, JERO CALAFAT and FEMKE BUIJS*
**Division of Virology, Netherlands Cancer Institute, Sarphatistraat 108, Amsterdam, The Netherlands*

Abstract—*Murine mammary tumour virus (MTV) induced an increased net synthesis of DNA, RNA and protein in* short-*term cultures of baby mouse kidney cells (BMKC) made from two different BALB/c mouse substrains (He.A and Crgl.A). The dose–response ratio went through a maximum but growth inhibition was not observed. Similar effects were induced in baby hamster kidney cells (BHK 21/C 13).*

In longer-*term cultures of MTV-infected BMKC foci of piled-up small rounded epithelioid cells appeared on the monolayers. Cell lines derived from these foci grew well in media without serum and produced biologically active MTV (B-particles) and murine leukemia virus (MLV; C-particles). Higher* in vitro *passages of these cell lines induced less early (< 300 days) mammary tumours and more cases of leukemia than the lower passages after intraperitoneal injection. Cell-free extracts induced similar tumours. Not-infected control BMKC did not acquire the described properties. The nature of the induced MTV and MLV is discussed.*

INTRODUCTION

THE MURINE mammary tumour virus (MTV) has a B-type morphology and matures mainly in normal and oncologically transformed murine mammary gland epithelial cells [1–4].

As in human adults about 90% (in children less) of cancers are of epithelioid origin, MTV seems one of the most appropriate models for oncogenic viruses in man. Up to the present MTV can only be titrated with prolonged and large-scale *in vivo* assays [5–7]. So it is important to try to secure an *in vitro* assay for infectious MTV.

A few years ago the growth accelerating effect of highly purified MTV (B-particles) in *short*-term monolayer cultures of baby mouse kidney cells (BMKC) was found [8].

In the present communication we present results on MTV induced stimulation of macromolecular syntheses in *short*-term cultures of BMKC and BHK 21 cells. Further we report the morphological transformation of BMKC by MTV with concomitant induction of MTV (B-particles) release and of Murine Leukemia Virus (MuLV; C-particles) release in *longer*-term cultures. Parts of this work have been published in abstract form [9, 10].

Accepted 21 October 1976.

MATERIAL AND METHODS

Mice

BALB/c substrains He.A and Crgl.A were used for the preparation of BMKC cultures *in vitro*. Generally BALB/c mice get spontaneous mammary tumours at a rather high age (> 300 days) [11]. Substrain BALB/c/He.A does not contain B-particles in these late mammary tumours. But the mammary glands of old female animals were shown to contain MTV antigens and MTV biological activity [12]. Nevertheless this substrain can be used for the *in vitro* titration of MTV(S) (= standard

MTV) if care is taken only to count the early (< 300 days) mammary tumours [6]. BALB/c mice also carry endogenous mouse leukemia virus (MLV) [13, 14].

The endogenous MuLV manifests itself in BALB/c/He.A at a rather high age (Table 1): 75–80% of the leukaemia cases are generalized reticulum cell sarcomas, 15% are lymphoid and 5–10% are myeloid. Substrain BALB/c/Crgl.A, kindly given to us by Drs. K. B. De Ome and S. Nandi (Berkeley, California) is generally considered to be "free of MTV and MLV" [3, 15, 16].

*24 hr media of nearly confluent monolayers were used.
†Ratio of counts/min of dGTP-^{3}H incorporation.

Mouse cells

BMKC were prepared from 5 to 7-day-old male and female BALB/c mice and tissue cultured as essentially described previously [8]. Pimaricin 5 μg/ml was added to the medium. The calf serum was heat inactivated. The primary cultures were started with $5 \cdot 10^6$ living (trypan blue exclusion test) cells per Petri dish. On the 4th day the primary cultures (uninfected and infected; ±95% confluency) were detached by pronase (0·04% in Hanks' buffer) treatment for 3 min at 37°C.

Subcultures were prepared: one primary culture giving three secondary cultures. The medium was kept the same in all passages and was changed 3 times weekly. The secondary cultures consisted for 70–80% of epithelioid cells. The rest was fibroblastic.

Hamster cells

The BHK 21/C 13 cell line used is a cloned diploid Syrian hamster fibroblast line [17]. The cells were cultured in the same medium as the BMKC.

All cell types could be stored in liquid nitrogen [18].

Virus

Highly purified MTV(S) (standard MTV) was isolated from early (< 300 days) mammary tumours of BALB/c/He.A.f C3H.A [6, 19].

Infection of the cell cultures

Primary cultures were washed twice with Hanks' buffer solution on the third day and infected with 0·4 ml virus dilution in buffer solution containing 2% heat inactivated calf serum for 2 hr in the CO_2-incubator.

Cell-free extracts from morphologically transformed BMKC and mammary tumours

Transformed BMKC (100×10^6: ±0·7 g wet weight) were washed and homogenized with T.S.E. buffer (0·05 M Tris–HCl, 0·20 M sucrose, 0·001 M EDTA, pH 7·2) in a Potter–Elvehjem homogenizer (5 ml) during 1 min at 0°C.

Or 3 g of frozen tumours was thawed and cut into small pieces (±1 mm^3). Twenty-one ml TSE buffer, containing hyaluronidase (1 mg/100 ml) was added. After homogenization in a Sorvall Ommimixer (19,000 rev/min for 1 min at 0°C) the suspension was incubated at 23°C for 20 min. Every 5 min the precipitate was resuspended for half a min in the mixer. The homogenate of transformed BMKC or mammary tumours was centrifuged twice at 3300 *g* for 20 min at 0°C. Next the suspension was centrifuged at 10,000 *g* for 15 min three times. Pellets and floating material were discarded.

Finally a small transparant virus containing high speed pellet (Spinco L2, Rotor 50, 198,000 *g* for 15 min at 0°C) was obtained, which was resuspended in Hanks' buffer solution with the homogenizer and immediately used in the bioassay.

Electron microscopy and immuno-electron microscopy

The techniques are described elsewhere [20].

Biological tests

Three- to 4-week old female BALB/c mice were injected intraperitoneally with 10^6 syngeneic cells or an equivalent cell-free extract in 0·25 ml Hanks' balanced salt solution (BSS) and force bred [6].

Mammary tumours were classified either as early tumours (< 300 days) or as late tumours (> 300 days).

Determination of RNA-dependent DNA polymerase (RDDP) activity

Particle bound enzyme activities were measured in the high speed pellets of used media [21] with poly (rC). d(pG) 12–18 (Collaborative Research, Waltham, Mass.) and 8 mM $MgCl_2$ or 0·3 mM $MnCl_2$ as activator [22]. As a non-ionic detergent 0·1% (v/v) Nonidet P-40 (Shell) was used.

Determination of DNA, RNA and protein

The cells of each separate Petri dish were collected after trypsinization (0·25% trypsin in an isotonic saline sodium citrate (SSC), buffer, pH 7·0) at 37°C. The trypsinized cells were washed twice with ice-cold buffer, suspended in 1 ml ice-cold H_20 and if necessary stored at −28°C.

Subsequently the nucleic acids were extracted with $HClO_4$ [23] and quantitated [24, 25]. Purified [26] calf thymus DNA (BDH, Poole, England) and high molecular weight [27] yeast RNA (Sigma) were used as standards. Protein was determined in the acid insoluble fraction [28] with egg albumin (Sigma; 5 × cristallized) as a standard.

RESULTS

Stimulation of macromolecular syntheses in short-term cultures of BMKC by MTV

Many times, but not always, a maximum stimulation was found at virus dilution 10^{-3} or 10^{-2} (Table 2). A MTV induced inhibition was never found. Stimulated BMKC did not show cytopatogenic effects or loss of contact inhibition (no piling up of cells). Nor did they induce early mammary tumours in the bioassay, (not in the Table).

Stimulation of short-term cultures of baby hamster kidney cells by MTV

MTV appeared to induce similar stimulations in cultures of BHK 21/C 13 cells (Table 2). The percentages of stimulation are approximately the same for DNA, RNA and protein. Further, the Table shows that the number of cells per culture at the start of the experiment is critical. A too high cell density of the non-confluent monolayer at the beginning can mask the growth increasing effect by a more rapidly achieved confluency.

†Started with $1.2.10^6$ cells/culture.

Morphological transformation of long-term cultures of BMKC by MTV

In longer-term monolayers of MTV(S) infected BALB/c-BMKC from both substrains foci of smaller rounded up cells appeared. These foci rapidly grew out to macroscopically visible 3-dimensional aggregates (pocks) of small round cells (Figs. 1–4).

We did not get spontaneous transformation in uninfected BALB/c-BMKC. Cell lines could easily be derived from the individual pocks. In contrast to the non-infected control BMKC the transformed cells grew equally well when the serum was omitted. With May–Grünwald–Giemsa staining the transformed BMKC showed a brilliant dark blue colour while the non-transformed cells showed a light-violet colour. Under our conditions the morphological transformation was a rather rare event while the preceding growth stimulation was a general phenomenon. In BALB/c/He.A BMKC the foci appeared once after 47 days (3 foci in 2/5 cultures infected with MTV dilution 10^{-3}) and once after 118–122 days (3 foci in 2/4 cultures infected with MTV dilution 10^{-3}). In BALB/c/Crgl.A BMKC the foci appeared after 18 days (6 foci in 3/3 cultures infected with MTV dilution 10^{-1}).

Release of MTV (B-particles) and MLV (C-particles) by MTV(S) transformed BMKC and their oncogenicity in vivo

The transformed BMKC produced and released both B- (Fig. 5) and C-particles (Fig. 6). When these cells were incubated with *rabbit anti-MTV* followed by incubation with ferritin-labeled goat antirabbit IgG, the B-particles were labeled (Fig. 5, 6) but the C-particles were always unlabeled (Fig. 6). The double oncogenicity of two such MTV(S) transformed BALB/c/He.A—BMKC cell lines (A4 and A5) is represented in Table 3. The A5 cells (passage 3) increased the natural low incidence of early mammary tumours in BALB/c/He.A mice and decreased the age at which these early mammary tumours could be detected. These mammary tumours contained B-particles (Fig. 7). Transformed A5 cells which had been cultured *in vitro* for a longer period (passages 8 and 9) increased the early mammary tumour incidence to a lower degree, but caused a considerable higher leukaemia incidence. Also with leukaemia a higher tumour incidence was correlated with an earlier manifestation of the tumours (Table 3). This corresponded with the electron microscopic observations. The number of B-particles went down and the number of C-particles even went up in the higher passages (Fig. 6). After passage 15 only a few B-particles could still be seen. Control BMKC were negative for B-, C- or budding particles, Only intracisternal A-particles were observed in the controls. A cell-free extract of A5 cells (8th and 9th passage) gave the same type of tumours as the whole cells (Table 3). Further the A5 cells could be inoculated subcutaneously with similar results (Table 3). The experiment with the A4 cell-line gave a result comparable with the outcome of the larger experiment with the A5 cell-line (Table 3). Early mammary tumours induced by A4 cells were used again

Cell-lines A4 and A5 were each derived from a single focus of morphologically transformed cells in two different experiments. The time of *in vitro* growth between the first detection of the transformation and harvesting for the bioassay was in the case of A4, fourth passage 43 days, in case of A5, third passage 39 days, A5 eighth passage 83 days and A5, ninth passage 98 days.
A5 cells of the eighth and ninth passage were pooled in the ratio 1:1.

to prepare a cell-free extract. This extract once more induced early mammary tumours at an age of 182 ± 11 days in all five inoculated hosts (not in the table).

Heterogenicity of MTV(S) transformed BMKC

The A5 cell-line was derived from a single focus (pock) of morphologically transformed BALB/c./He.A—BMKC (Table 3; Methods). Viable A5 cells of the sixth passage (59 days after first subculturing the pock) were frozen and stored. A month later an ampoule with 10×10^6 A5 cells was thawed and distributed as equally as possible over two 10 cm diameter Falcon plastic Petri-dishes. Petri-dish No. 1 showed the expected growth pattern of an epithelioid monolayer with 3-dimensional aggregates (pocks) of rounded cells. Petri-dish No. 2 showed an epithelioid monolayer of more slowly growing cells, which did not form pocks. Subsequent sub-cultures from dish No. 1 and dish No. 2 maintained these different growth patterns. Determinations of the RNA-dependent DNA polymerase activities were carried out in the high speed pellets of media of both A5 cell lines. The ratio of the Mg^{2+} stimulated (largely specific for MTV) and Mn^{2+} stimulated (largely specific for MLV) activities was 1:1·6 for the A5 cells and 1:0·01 for the A5* cells (Table 1). The A5* cells apparently produced much less C-type virus per culture while the B-type virus production kept the same order of magnitude [22].

DISCUSSION

The increased net synthesis of DNA, RNA and protein in MTV infected BMKC, made from two different BALB/c substrains has been studied in more detail. A maximum stimulation was found at a rather high MTV(S) concentration. Still higher virus concentrations were less effective but never caused growth inhibition (Table 2). Some kind of auto-interference mechanism was apparently involved. It may have been caused by homologous incomplete MTV-particles which competed with non-defective MTV-particles at particular receptor sites [29] or our purified physically homogenous B-particles consisted of two (or more) competing types representing two (or more) MTV strains with different biological properties [4, 6, 19, 30–32]. The auto-interference did not act via interferon-like substances [33, 34].

Relevant to our experiments are the results of Lasfargues *et al.* [35] who reported that purified MTV stimulated growth and differentiation in epithelial and stromal elements of mouse mammary organ cultures.

Nair and De Ome [36] described a non-purified high molecular weight factor, which was released by cultured BALB/cfC3H. Crgl mammary tumour cells and which stimulated DNA synthesis in syngeneic BALB/c mouse embryo cells. We think this factor could have been closely related to the growth stimulating components of the MTV virion in our experiments.

Striking is the growth stimulating activity of purified MTV virions in baby hamster kidney cells (Table 2) [37]. The BHK 21/C13 cell line is fibroblastic but may give rise to epithelioid subclones [38].

Recently, similar early post infection increases of cellular DNA synthesis and occasionally of RNA synthesis (and cell multiplication) were reported for tissue cultured animal embryonic cells infected with unpurified C-type oncorna viruses [39–43].

Here the contamination could have caused mimicking effects [44].

It should be recalled that increased cellular DNA synthesis (and stimulation of mitosis) in tissue cultured cells are not only induced by oncorna viruses [45].

A second and rarer biological effect was the MTV induced morphological transformation in long-term BALB/c—BMKC monolayers. These morphologically transformed cells appeared to simultaneously produce MTV (B-particles) and MLV (C-particles) Figs. 5 and 6.

In connection with this *in vitro* two-step mechanism we recall that in most oncogenic process *in vivo* an early localized proliferation of non-neoplastic cells stands out prominently [15, 46].

All cell-lines derived from separate foci of transformed cells (pocks) grew rapidly out into epithelioid monolayers on which pocks were formed again. The comparable good growth in serum-less medium corresponds with their epithelioid nature [47].

The morphologically altered BMKC did not grow out into ascitic tumours after intraperitoneal inoculation (compare [48–50]), but induced early (< 300 days) mammary tumours and leukemia by means of released MTV and MLV (Table 3 and Results).

An important question is the nature of the released MTV variant. In the present case of MTV(S) infected BALB/c—BMKC one can surmise activated endogenous MTV but just as well the progency of the exogenously applied MTV(S). Also genotypic and phenotypic

hybrids of endogenous and exogenous MTV cannot be excluded. Endogenous MTV can be induced in BMKC from BALB/c mice, at least chemically, as we show in a following publication [57]. However it is not yet possible to distinguish the various MTV variants by immunological methods [31, 32], nor by any other good test. A similar question arises to a lesser degree with the released MLV.

Exogenous MLV can probably be excluded as similar highly purified B-particle preparations did not contain C-particles when controlled with the electron microscope [19] and showed no cross reaction with anti-Rauscher leukemia virus antisera in microimmunodiffusion tests [32]. Different endogenous MLV variants can be induced rather easily by various means as is well documented [21, 51, 52].

If we may assume that the released MLV is really of endogenous origin it is conceivable that the described induction of MLV by MTV could play a role in the spontaneous *in vivo* transformation of murine mammary adenocarcinoma into sarcoma [53–56].

Acknowledgements—We wish to thank Mr. W. Bax for the valuable assistance with the chemical determinations, Dr. P. C. Hageman for a part of the purified MTV preparations and the anti-MTV serum and Drs. L. M. Boot and G. Röpcke for the many BALB/c mice. Drs. A. Timmermans, R. van Nie and M. van der Valk, and Mrs. R. Beurs gave expert help with the bioassays and histological examinations.

Immunological Depletion Contributing to Familial Hodgkin's Disease*

ALDONA McBRIDE and J. J. FENNELLY

St. Vincent's Hospital, Elm Park, Dublin 4 and Department of Medicine & Therapeutics, University College, Dublin 4, Ireland

Abstract—*The occurrence of Hodgkin's disease in three sisters of a sibship of five girls, over a period of six years, provided an ideal situation for the investigation of possible aetiological factors. Of note was the occurrence of recurrent herpes labialis in the fourth girl, infectious mononucleosus in the fifth sister and recent Herpes Zoster in the mother. The main findings were (a) a familial depletion of T lymphocyte function as evidenced initially in all members of the family by depressed lymphocyte transformation and (b) the presence of HL-A 1,8 in two affected sisters, the two unaffected sisters and the mother, who had, however, transmitted these antigens in the normal fashion. Of significance was consistent skin anergy to DNCB and tuberculin in the mother (HL-A 1,8) and in the fourth daughter (HL-A 1,8) even two and a half years after she had glandular fever. In addition, the mother, who has no outward signs of disease, had a paraprotein in her serum forming almost 60% of the gammaglobulin fraction.*

INTRODUCTION

FAMILIAL Hodgkin's disease is a well recognised entity, the risk to near relatives being almost three times that of the general population [1, 2]. In this family, where three sisters developed the disease (Fig. 1) we had an ideal opportunity to evaluate aetiological possibilities. The parents, the five sisters and the infant son of the third patient to present were studied. Studies undertaken included tests of T and B lymphocyte function, specific virus titres and genetic studies particularly chromosomal analysis and human leukocyte antigen patterns.

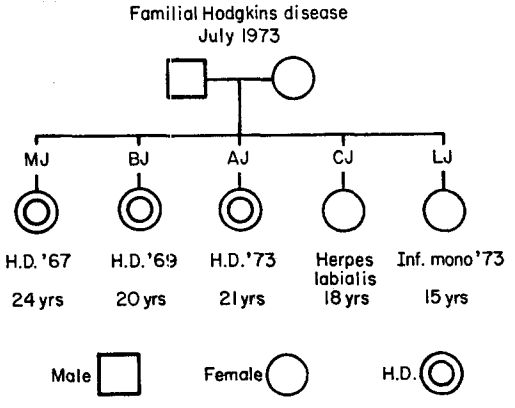

Fig. 1.

MATERIAL AND METHODS

M.J., age 18 years, (date of birth 6/8/'49) presented on 27/6/'67 with bilateral supraclavicular node enlargement and massive enlargement of paratracheal and hilar lymph glands on chest X-ray. A histological diagnosis of nodular sclerosing Hodgkin's disease was made. Initially, the patient received radiotherapy to the involved areas but later was commenced on the MVPP (nitrogen mustard, vinblastine, prednisone, procarbazine) chemotherapeutic regime because of infradiaphragmatic involvement, elevated ESR and anaemia. She has now been off all treatment since Spring 1975 and is in very good health.

B.J., age 16 years (date of birth 28/8/'53) admitted 16/12/'69 with a firm tender sternal mass, present for eight months, and a left supraclavicular node. Again histology revealed nodular sclerosing Hodgkin's disease and, following initial radiotherapy, she also required quadruple chemotherapy because of recurrent abdominal disease. She is now on therapy at 6 monthly intervals and is scheduled

Accepted 9 October 1976.

*This work was supported by a grant from the Irish Cancer Society.

to stop the treatment. She also remains clinically in complete remission.

A.J., married, age 21 years (date of birth 6/10/'51). On 30/5/'73 presented, when six and a half months pregnant, with a history of increasing malaise for about six months. She had enlarged cervical and axillary glands and a swelling of the anterior chest wall. Node biopsy showed mixed cellular Hodgkin's disease. This patient had had an abortion in October 1972 at two and a half months pregnancy. Active therapy was withheld until the delivery of a healthy male infant on 3/7/'73, after which the patient was commenced on quadruple chemotherapy consisting of MVPP. However, E.S.R. was persistently raised on this regime and she was subsequently treated with varying combinations of epipodophyllotoxin, bleomycin, CCNU, vinblastine and adriamycin. At present she is asymptomatic, with normal E.S.R. Specific histological confirmation of diagnosis in the three girls is shown in Fig. 2.

L.J., age 15 years (date of birth 9/5/'57) developed infectious mononucleosus, April 1973, otherwise no illness of note.

C.J., age 18 years (date of birth 21/1/'54), history of recurrent herpes labialis, otherwise clinically normal.

Both parents are apparently healthy, with no clinical evidence of disease.

Family history

(Figure 3)—the maternal grandmother recalled two male sibling deaths at 4 and 7 months of age from? "viral infection". A 14-year-old sister of the mother had died following a brief illness in which she became lethargic and anorexic and about one month prior to her death developed a small crusted scalp lesion which had become increasingly large prior to her death. Unfortunately, the doctor who had attended this girl had died and the hospital record file has been destroyed by fire. A two month old male sibling of the mother had also died—"viral pneumonia". On the paternal side, deaths had occurred from natural causes and there was no history of early or inexplicable death.

Investigations

Immunological assessment—T cell function was assessed using the DNCB and PPD skin tests and *in vitro* lymphocyte transformation test using PHA as stimulant. A total lymphocyte count and serum immunoglobulin estimation was also done. Virological studies included EBV titers, herpes simplex and cytomegalovirus antibody titers. Genetic studies comprised detailed blood group analysis, chromosomal studies and leucocyte HL-A patterns.

RESULTS

The most striking finding was a familial immune depletion of T lymphocyte function (Table 1) as evidenced by consistently negative

Table 1. *Tuberculin and dinitrochlorobenzene skin tests in familial Hodgkin's disease (Family J) showing anergy not only in the three family members with Hodgkin's disease but also in the mother and L.J.*

skin testing in L.J. who had infectious mononucleosus in March 1973, and a similar skin anergy in the mother on repeated tests. The three girls with Hodgkin's disease were anergic also and had poor lymphocyte blastogenesis, but they were on treatment at the time of study. Skin testing was normal in the father and in C.J. The *in vitro* lymphocyte transformation test (L.T.T.) was abnormally low in all the family members as compared to a normal control and the normal response of

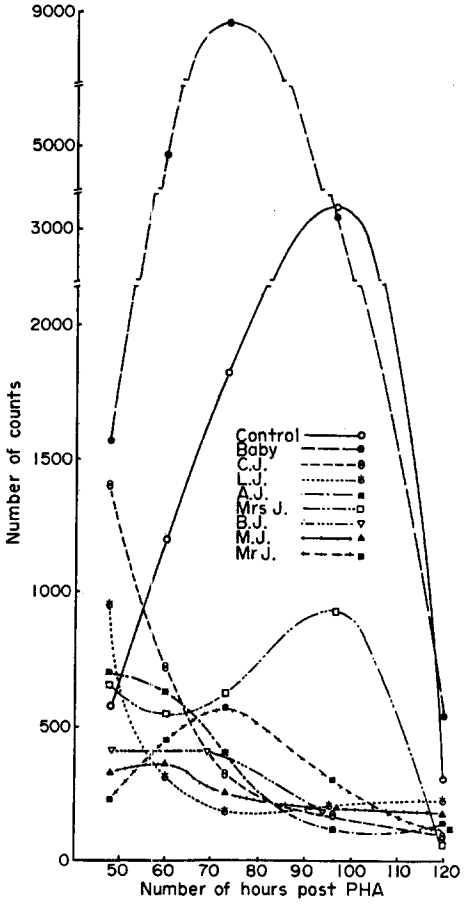

Fig. 4.

A.J.'s baby (Fig. 4). The result was considered very striking and was repeated within three months, again yielded a similar result. On reassessment in September 1975, however, the L.T.T. curve was now in the normal range, the mother and L.J. having a normal lymphocyte transformation, despite their persistent cutaneous anergy. The father and C.J. now showed normal *in vitro* blastogenesis, and their skin responses were, as before, normal. The mother was clinically normal until recent development of Herpes Zoster and there was no elevation of E.S.R. neither in her nor in the other unaffected members of the family. Virological studies i.e., E.B.V., Herpes Simple x Toxoplasma, in general, yielded insignificant antibody titers. Chromosomal studies were normal in all family members apart from aneuploidy in the three affected girls attributed to previous chemotherapy and radiotherapy. A detailed blood group analysis was normal. The result of the human leucocyte antigen system patterns are shown in Fig. 5. HL-A 1,8 were present in the mother, two of the three affected girls and the two unaffected girls. These antigens have been associated with Hodgkin's disease [3] particularly where there is an altered immunological response [4].

The total lymphocyte count in the family members was normal—lymphopenia in M.J. and B.J. was associated with treatment, but had been normal at initial presentation. Immunoglobulin studies revealed little apart from a depression of IgA in M.J. and the paraprotein in the mother.

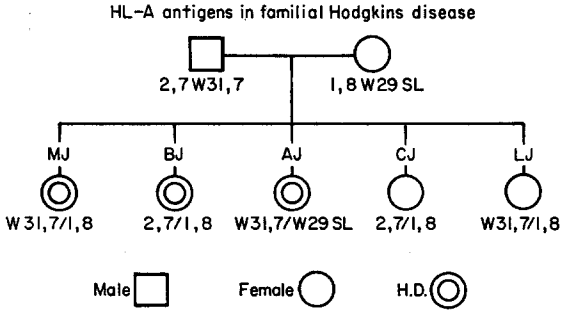

Fig. 5.

DISCUSSION

In this familial instance of Hodgkin's disease, a combination of an environmental factor and a genetic susceptibility or predisposition may have been the operative mechanism [5]. An added factor may have been a linkage between the HL-A genes and the genes controlling immune responsiveness [6]. In our study, we feel an immunological depletion of the thymus dependent "T" lymphocyte has been genetically transmitted from the mother to her daughters rendering their host defences low against an infective agent [7] possibly the Epstein–Barr virus [8–11] resulting in a transformation of the thymus dependent lymphocyte [12]. This infective process might then be presumed to have manifested itself as infectious mononucleosus and recurring herpetic infections in L.J. and C.J., as an asymptomatic paraproteinaemia in the mother, and as Hodgkin's disease in three members of the family. We are unable to explain the discrepancy or lack of

consistency between the latest lymphocyte transformation testing and the skin testing, however, the latter is strikingly negative in the mother and L.J. following repeated applications of D.N.C.B. and P.P.D. One would expect that the anergy associated with infectious mononucleosus should have transformed to allergy two and a half years later in the case of L.J. It would be difficult to discern whether the disease in this family may have been the result of person to person transmission or whether the inherited HL-A antigens 1 and 8 in immunologically incompetent persons could reflect an inherent susceptibility to the disease in the affected individuals [4, 13]. Of interest are the three early male deaths in the maternal pedigree and a very unusual death occurring in the mother's sister. One might speculate that in all four instances immunological depletion could well have been an important factor and ideally, one would wish to perform immune testing on the remaining members of the mother's family. The five girls in this sibship were the result of normal pregnancies and the mother had no history of abortion or stillbirth. The father runs a large hardware store and has been assisted by all members of the family in its management, there has been only rare contact with farm animals and the family keep no pets [13, 14]. Appendectomy and tonsillectomy [15] were considered to be of no aetiological significance, only one of the unaffected girls having had the latter. We feel a maternally transmitted immunological depletion or morphologic abnormality of the thymus derived lymphocyte, rendering it vulnerable to infection by an oncogenic virus or allied environmental agent with subsequent transformation and malignant proliferation, has occurred in the three patients here described with Hodgkin's disease.

Abstract—*The criteria for a suitable experimental breast cancer model are discussed. Only one of a series of nine tumour systems initially studied, consistently showed early lymph node and late lung metastases and fulfilled the criteria. This mammary carcinoma* (2661) *was more fully characterized and was found to be non-antigenic following subcutaneous and intravenous immunity challenge tests. Size of the primary tumour as well as lymph node palpation were shown to be crude indexes for survival. Metastases formation gave rise to changes in lymphatic drainage pathways. Combination adjuvant chemotherapy increased the survival time in treated animals and produced a striking difference in patterns of metastases distribution. Results on immunity, surgery and chemotherapy in regard to this model are discussed.*

INTRODUCTION

IN THE experimental study of the formation of tumour metastases and the influence of surgery, radio- and chemotherapy it would be desirable to use an animal model which resembles the clinical tumour as much as possible [1–3]. Many of the reported breast cancer models consist of induced tumours which usually display marked antigenicity, in contrast with tumours of spontaneous origin [4–6]. Moreover, tumours which metastasize in a similar way as in man are rarely used.

The main and primary route of spread of mammary carcinoma in man is by way of the regional lymph nodes and the main cause of death is from haematogenous metastases. In mice, few tumours show both lymph node and blood borne metastases. While blood borne metastases are frequently observed [7, 8], lymph node metastases, if they occur, are seen only in a very low percentage [5, 9, 10]. Only a few model systems are known in mice which give lymphatic dissimination in a reproducible pattern but these only rarely produce parenchymatous secondaries. These systems use intratibial [11] intratesticular [12], tail [13], thigh and foot pad inoculation [14].

A suitable animal model for breast cancer should fulfil a number of criteria.

1. it should be transplantable and suitable for use in a syngeneic tumour host system and reproducible in this system.
2. the tumour should arise in the same organ for which it serves as a model and the antigenicity should be known and be low.
3. there should be a certain natural staging possible with regard to tumour spread.
4. the tumour should respond to the same therapeutic modalities as in man.

This paper describes the characteristics of a selected mammary carcinoma which fulfils the criteria mentioned.

Accepted 18 October 1976.

MATERIAL AND METHODS

Tumours

Several cell suspensions from tumour-lines of different histological types were injected subcutaneously into the foot pad. For each trial 2×10^5 viable tumour cells were inoculated in a volume of 0·02 ml with a Hamilton microsyringe. After local growth to a critical volume the tumours were removed surgically in order to prevent death from the primary. After death from residual disease all mice were autopsied

to record the extent of metastatic disease. Table 1 indicates those tumour–host systems initially studied. Only one of the tumours tested, mammary adenocarcinoma 2661, which originated spontaneously in a CBA/Rij mouse in 1961, gave metastatic growth in popliteal, inguinal, paraaortic and renal lymph nodes as well as lethal haematogenous metastases in the lungs. Therefore it was selected for further studies. Since a large number of cells of passage 61 had been stored in liquid nitrogen, the majority of the studies could be performed with passages 61–65. Tumour cell suspensions were prepared by the trypsinization method described by Reinhold [15].

Mice

All mice (inbred strains indicated in Table 1) were bred by brother sister mating in our own colony. For the experiments nine to ten week old CBA/Rij females weighing 20 ± 2 g, were the recipients for tumour transplantation. They were fed standard laboratory chow and tap water *ad libitum*.

Antigenicity studies

Two methods were employed to test the antigenicity of the selected tumour.

(*a*) End point dilution titration was carried out by a modification [16] of the method of Hewitt [17]. One further modification was used; the four injections per mouse were administered subcutaneously on the back of the animal, in the neck, the flanks and over the sacrum, rather than in the axillary and inguinal areas. This was done in order to facilitate differentiation between tumour growth at the inoculation sites and possible lymph node metastases. In order to test the suitability of the mammary carcinoma, tests were performed of the effect of prior immunization of the recipients.

(*b*) Boone *et al.* [18] provided a rapid intravenous assay technique of tumour immunity in mice as a substitute for the conventional procedure of Hewitt. Many studies have shown that most pulmonary tumour metastases in mice are found near or on the surface of the lungs [19–22]. Since the contrast between tumours and lung is adequate for counting after adding microspheres to the inoculate and after fixation of the lungs in Bouin's fluid, this method was employed instead of microscopically counting of tumour cell colonies from flattened lobes.

Evaluation of the presence of an oncogenic virus (mammary tumour virus) was done with the quantitative sepharose bead immunofluorescence assay with a polyvalent and a monospecific antiserum and purified mammary tumour virus antigens.

Surgery

Tumour removal was done under general anaesthesia by administering 60 mg/kg of body weight of sodium pentobarbital intraperitoneally, the line of amputation being between tumour and popliteal lymph node. The wound was closed with metal clips, which were removed ten days later.

Adjuvant chemotherapy studies

A combination of cyclophosphamide, 5-fluorouracil and methotrexate was used in a dosage used clinically by Bonadonna *et al.* [23]. This schedule was adapted from man to mouse on the basis of equal dose per m^2 body surface per 4 weeks [24]. The treatment was divided in four weekly cycles, so that each week the mice receive:

Cyclophosphamide*	100 mg/m^2 day 1, 2, 3	i.p.
Methotrexate*	20 mg/m^2 day 1	s.c.
5-Fluorouracil*	300 mg/m^2 day 1	i.v.

RESULTS

All the tumours tested gave rise to metastatic spread causing death after removal of the primary growth. All with exception of 1 line gave lung metastases (Table 1). One mammary adenocarcinoma (3641/75) showed a low percentage of lymph node metastases in addition to lung metastases. Mammary adenocarcinoma 2661 was the only one which gave early lymph node- and later lung metastases in 100% of recipients. Both lymph node and lung metastases can be easily detected at autopsy (Fig. 1). The typical morphology of the tumour cells allows recognition even at early stages of metastazation (Fig. 2, 3, 4).

Antigenicity studies of mammary adenocarcinoma 2661

(*a*) *Subcutaneous challenge.* It is well known that the presence of antigenic differences between tumour and host may interfere with tumour growth and tumour cell survival. To test the effect of prior immunization, two subcutaneous injections of 10^6 tumour cells that had been irradiated *in vitro* with 10,000 rad were given at two-week-intervals before injection of graded numbers of viable tumour cells. Titrations were then performed simultaneously in immunized and non-immunized control mice,

*Gifts of these drugs by Asta-Werke, Lederle and Hoffmann–La Roche respectively are gratefully acknowledged.

(*b*) *Intravenous challenge.* By intravenous injection of different numbers of tumour cells in the tail vein together with 10^6 microspheres the number of cells giving a significant and countable yield of metastases after 15 days was determined, as shown in Table 3.

Subsequently $2{\cdot}5 \times 10^5$ tumour cells were used for tumour immunity studies. Two groups of mice were inoculated intravenously at the same time. The first group consisted of mice from which a 10-day old tumour (10^6 cells in the flank) had been removed three days prior to challenge following the system of Boone *et al.* [18]. The average tumour volume was about 300 mm^3. The second group consisted of normal mice from which a skin flap had been removed, designed to mimic the trauma of tumour excision. three days prior to tumour challenge. Table 4 shows that there is no significant difference in the numbers of lung colonies developing in either group.

Table 3. *Relationship between the number of i.v. injected tumour cells and number of pulmonary metastases after* 15 *days*

Number of cells*	Average number of lung colonies ± S.E.M.
10^5	21 ± 4·9

Immunized	(15)	43·3 ± 4·211

($P > 0{\cdot}10$) Student's two-sample test.

The Sepharose bead immunofluorescence assay showed no antigens of the mouse mammary tumour virus [27].

Surgery and metastases formation

Complete cure in an observation period of 150 days can be obtained when amputation is performed before the 10th day whereas animals die from metastatic disease when amputation after 15 days is performed. In the experiments the median survival time of mice which die after removal of the primary tumour is 45 days. However, the spread of survival from different experiments is great, with several mice surviving over 60 days.

This range of survival in a homogenous system where standard tests did not reveal host resistance indicates the presence of random factors influencing the growth of metastases.

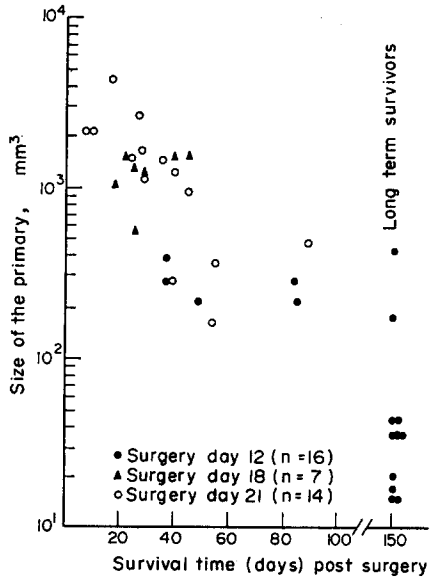

Fig. 5. Survival time post surgery as a function of the size of the primary growth.

Within the range of 10–15 days postoperatively there is no significant correlation between volume of the primary growth and the risk of metastases. Nevertheless mice that had tumours removed when less than 100 mm³ measured by 2 diameters at right angles and the thickness of the tumour, did not initiate metastases, whereas mice that had tumours removed of more than 500 mm³ all died of metastasic disease (Fig. 5). It therefore appears that, as with human breast cancer [28–30], size of the primary growth is a *crude* index of metastatic risk.

Lymph node metastases

The possibility of direct intralymphatic injection, as often used in lymph node metastases models, was unlikely in view of the absence of tumour spread if amputation is performed before day 10. In addition it was excluded histologically. Histological sections of the lymph nodes were made immediately after, 1 day after and every other day until 17 days after injection of the tumour cell suspension. Five female mice were used for each group examined, weights of lymph nodes were measured with a Mettler type B5-balance. The weight of the lymph nodes had already increased the first day after inoculation and continued until tumour cells appeared in the sinus* (Table 5). The first tumour cells appeared in the sinus of the popliteal lymph node

Table 5. Weight in mg of lymph nodes (±S.D.) draining mammary carcinoma 2661

Day	Popliteal	Inguinal	Paraaortic
0 (controls)	1·06 ± 0·09	2·80 ± 0·77	0·52 ± 0·18
1	1·82 ± 0·34	3·04 ± 0·26	0·76 ± 0·11
3	2·84 ± 0·44	3·24 ± 0·80	1·00 ± 0·21
5	3·46 ± 0·46	3·94 ± 0·35	1·46 ± 0·44
7	6·68 ± 1·57	4·64 ± 0·99	2·00 ± 0·90
9	8·04 ± 1·40	4·52 ± 1·05	1·68 ± 0·40
11	13·10 ± 2·15	6·36 ± 1·92	2·62 ± 1·14
13	10·82 ± 1·07	5·38 ± 0·43	3·20 ± 1·31
15	19·96 ± 0·93	9·92 ± 4·75	9·54 ± 3·45
17	25·48 ± 4·03	10·40 ± 0·95	9·76 ± 3·70

at day 13; at day 15 all popliteal lymph nodes contained tumour cells infiltrating and destroying the lymph node while other non regional lymph nodes showed the presence of tumour cells at this time as well. As shown in Table 5 the inguinal lymph node plays an active role as shown by enlargement and subsequent metastasis formation. This finding is surprising in view of the normal lymph drainage from the foot pad. When Patent Blue Violet (2·5% solution for lymphography) is injected into the foot pad in a way similar to tumour cell inoculation, the first node to stain is the popliteal (= regional) lymph node. Afterwards the paraaortic and renal lymph nodes are stained. Even when the liver is blue, indicating the presence of P.B.V. in the circulation, the inguinal lymph node remains unstained, suggesting that metastases formation itself produces changes in the lymphatic drainage pathways.

The nodal status of tumour bearing animals appears to be of interest: all animals have palpable popliteal nodes on day 12. This is mainly due to paracortical hyperplasia and increased germinal centre activity [31]. After surgical removal of the tumour on day 12 some of the nodes regress in volume, whereas others show an increase in volume due to metastatic growth. This phenomenon has also been observed clinically by Edwards *et al.* [32] after simple mastectomy. To investigate the prognostic value of the lymph node status in conjunction with the surgical removal of the tumour, animals were grafted with tumour cells into the foot pad. On day 12 after inoculation the tumours were removed and on day 20 all lymph nodes were palpated and the animals were divided into 3 groups as follows:

1. popliteal and inguinal nodes positive.
2. popliteal node positive and inguinal node negative.
3. popliteal and inguinal nodes negative.

*A detailed morphometric analysis of the immune response to an antigenic and this "non-antigenic" tumour is in preparation [31].

(Positive and negative as judged by enlargement on palpation.) Figure 6 shows the survival curves of these animals, together with untreated ones indicating that the nodal status is a reasonable prognostic indicator for survival.

Chemotherapy

Because of recent interest in the Bonadonna trial [23] we decided to test the drug combination used both for established tumours and in the postoperation adjuvant situation. For the former this was done utilizing objective response criteria (shrinkage of measurable tumour by greater than 50%, standard definition of objective regression). Flank tumours were used for practical reasons and therapy was started when tumours were well established in early log phase of measurable growth and was continued for 4 weeks. The results as shown in Fig. 7 indicate that this schedule is effective but if treatment is stopped all tumours resume growth; no toxic deaths occurred. Only when the dose was doubled mice died of severe bone marrow depression.

As adjuvant therapy this schedule was started 3 days following surgery. Surgical removal was done at 18 days after tumour injection into the foot pad, the average tumour volume being 1280 mm^3. In this stage some animals had already died of their primaries and lymph node metastases were already established. Figure 8 shows the survival of treated and untreated animals demonstrating a significant delay of survival in the treated group ($P < 0{\cdot}05$). A striking difference was found in the site of metastases in the treated group. Whereas all untreated mice showed large lymph node metastases in addition to lung metastases at autopsy; a significant reduction of lymph node metastases occurred in the treated group (Table 6) in contrast to their massive lung metastases. It is our impression that the lungs of animals in the treated group showed more heavy metastases than those from untreated mice dying at the same time.

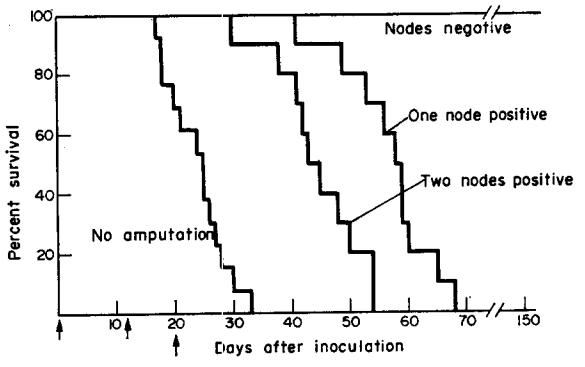

Fig. 6. Survival of mice dependent on node status and treatment. Positive and negative as judged by enlargement on palpation.

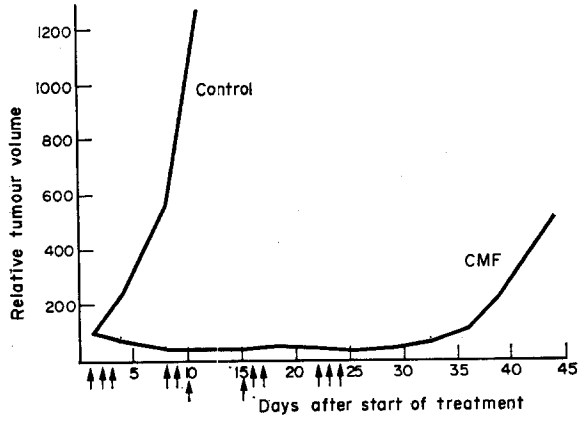

Fig. 7. Growth delay on flank tumours by combination chemotherapy.

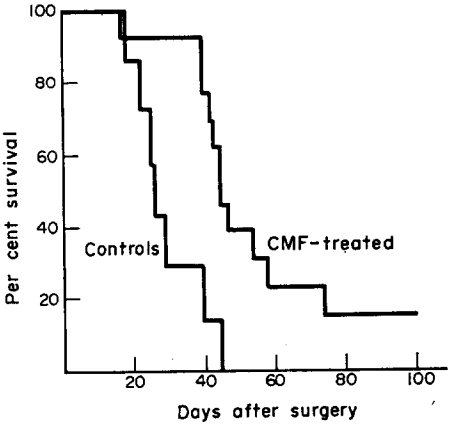

Fig. 8. Survival of mice after removal of the primary growth, given adjuvant chemotherapy.

Table 6. Reduction of lymph node metastases after adjuvant chemotherapy

	Percentage of positive nodes*	
Treated	22·7	$N = 11$
Untreated	100	$N = 6$

$P < 0{\cdot}001$, Cochran's test [49].

*Four nodal areas were examined. The value presented is the percentage of the total number of nodes positive/total nodes. The lymph nodes examined were the popliteal, inguinal, paraaortic and axillary on the ipsilateral side with respect to the primary tumour.

DISCUSSION

The limited insight currently available in the mechanisms of metastases formation may in part be due to limitations of experimental models used to approach this complex problem. With better models a rational basis to found attempts at influencing metastases formation may be investigated. This is especially true for cancers showing two modes of spread. Mammary carcinoma in man is one example: lymph node- and subsequent evidence of haematogenous spread of tumour occurs in general. The main finding which emerges from this work is that there is now an experimental model which shows these two modes of spread in 100% of cases. One way in which the model can be used is as a useful tool in testing effectivity of different types of therapy in different stages on metastases formation. However, we would stress that no animal tumour can represent all of the variations in growth potential and metastasizing characteristics that are encountered in humans. However, it is of significance in this system that the two modes of spread are both 100% phenomena, which may be unrealistic but very convenient to evaluate therapy differences. These special properties of metastases formation have not been met in other useful breast cancer models [1–3]. The validity of a therapeutic model of course should always be confirmed by findings of parallelism in response between the clinical tumour and experimental model.

Special attention was given to experiments testing whether the tumour is antigenic or not in its host of origin. Several investigators [33–35] found that antitumour immunity has a higher level of effectiveness in the lungs than in subcutaneous tissue. It is likely that the passage in the bloodstream for the former type of inoculum exposes the tumour cells more readily to the hazard of elimination by antibody; in the latter case cellular immune responses are more likely to be effective. For that reason an additional intravenous test according to Boone *et al.* [18], was added to the conventional one using subcutaneous challenge [17].

Both tests (see Tables 2 and 4) showed that no antigenicity could be detected, as one would expect for a syngeneically transplanted tumour of spontaneous origin in a low cancer strain. This in contrast to mammary tumour mouse strains such as C3H/+ having a vertically transmitted exogenous virus inducing the tumour. Spontaneous can be used in the true sense of the word here: No identifiable oncogenic agent was involved which could entail artefactual immunity.

The foot pad location was chosen intentionally: s.c. transplants of the mammary carcinoma in the flank of mice can grow to a very large size, yet metastasize with a low frequency. Inoculation into the foot pad leads to a tumour which metastasizes much earlier. Intramuscular inoculation gives lung metastases and a low percentage of lymphogenous metastases (unpublished results). This can possibly be explained by pure mechanical and anatomical reasons. There is an increased pressure in the foot pad rather than the flank when the tumour starts growing, promoted possibly by movements of the foot [36]. Muscle itself does not contain lymphatics. Lymphatics are however present in the fascial planes enclosing and dividing muscles.

The reason why so few rodent tumours metastasize via the lymph nodes is unknown. It is possible that intrinsic properties of the tumour cells themselves help to determine whether they enter local lymphatic vessels or are retained in the draining nodes. Similarly in man, it is unknown why it is common for carcinomas to metastasize to regional lymph nodes while most sarcomas do so infrequently; but differences in fine surface structure of the tumour cells may perhaps be implicated. There is no evidence that sarcoma cells are inherently less capable of invading lymphatic structures.

Whether there is any relation between a lack of immunogenicity and metastasizing capacity of tumours as stated by Davey *et al.* [37] and Kim *et al.* [38, 39] is uncertain. This is especially true because metastasizing tumour models are known with chemically induced antigenic tumours [3] from which the model of Carr *et al.* [40, 41] also utilises foot pad inoculation. Mammary carcinoma 2661 in its present state is an undifferentiated carcinoma. During transplantation passages most tumours change their histological pattern towards anaplasia; this tumour progression has been reported to go together with an increased tendency to form metastases of spontaneous as well as induced tumours by Rudenstam [42]. It is not known if this is the case here since the test for metastases was done only in its 61st passage but another mammary carcinoma (3641/75, Table 1) was tested in its first transplantation generation and also gave lung metastases in 100% of cases.

The ultimate reason why this particular murine tumour when inoculated via the foot pad gives rise to lymph node- and lung metastases remains unknown, as intralymphatic

injection was ruled out but this property makes this model a unique and valuable one. Time, tumour size and lymph node palpation were shown to be reasonable parameters for staging the disease. A late stage of the disease was used in chemotherapy experiments to examine whether cures could be obtained with chemotherapy against the primary tumour. Combinations of drugs have been shown to be more effective than single drugs [43, 44, 45]; for that reason the Bonadonna [23] schedule was applied without analysis of the sensitivity of the tumour to the single drugs. There were however no cures in either experimental groups (Fig. 7). When flank tumours were used, resumed growth occurred for all tumours after an objective regression. However they did not show an increased doubling time in the regrowth phase in contrast to the findings of Shewell [46]. When the same treatment schedule was used in a late stage adjuvant situation a striking difference was found between the sensitivity of lymph node and lung metastases not found in other models [3, 13, 14, 47, 48]. This should be evaluated in future experiments using single drugs and other combinations.

It is evident that this model which fulfils the criteria mentioned in the introduction has essential metastasizing and therapy response characteristics which permit evaluation of therapy combinations and therapy sequences. Although no animal model can completely mimmic mammary carcinoma in man, this model seems to be a very attractive experimental model in mice.

Abstract—*We describe the properties of a dihydrofolate reductase purified from lymphoblastoid cells which acquired methotrexate resistance following long-term culture in presence of the drug. The enzyme showed marked differences in kinetic properties from the parental cell strain. The K_m for dihydrofolate was increased 18-fold, relative to the parent line, and the affinity of the enzyme for methotrexate was decreased by 50-fold. Binding of NADPH, however, was tighter than in the parent line, with a K_m of less than half the original value. The molecular weight of the mutant dihydrofolate reductase, as measured by gel filtration, was unaltered, but the mutant enzyme showed much greater heat lability than the wild-type enzyme. At low drug concentrations, cells possessing the altered reductase possessed a selective advantage over cells with normal dihydrofolate reductase. Increasing the selective pressure, however, by raising the methotrexate concentration in the medium above $1{\cdot}6 \times 10^{-6}$ M, led to selection against the mutant, and cells with normal type dihydrofolate reductase again dominated the population. These results are interpreted in the context of high-affinity and low-affinity sites of action of methotrexate.*

INTRODUCTION

THE CYTOTOXICITY of methotrexate (MTX) is generally attributed to its inhibition of the enzyme dihydrofolate reductase (EC 1.5.1.3) [1], although, in common with most antimetabolites, MTX inhibits at several metabolic sites. In human lymphoblastic cultured cells of the W1-L2 line these other sites of action include thymidylate synthetase (EC 2.1.1.b), serine hydroxymethyltransferase (EC 2.1.2.1) and the membrane transport of reduced folates [2–4]. However, binding of MTX at these secondary sites is 5 or more orders of magnitude weaker than the binding of MTX to dihydrofolate reductase [2, 3]. Nevertheless, the possible importance of these low affinity binding sites for MTX in determining therapeutic response to the drug remains a topic of current interest [5, 6].

Acquired resistance to methotrexate has been the subject of numerous studies, both *in vivo* and *in vitro* (reviewed in ref. 2). The two commonest mechanisms of resistance involve an increase in the cellular activity of dihydrofolate reductase, and a decrease in the permeability of the cell membrane to the drug. Other mechanisms may operate in particular cases; for example, in culture medium enriched with thymidine and a purine, most cells can continue normal growth in the presence of toxic MTX levels, by utilising the salvage pathways [7, 8]. Thymidylate synthetase activity may also be increased following exposure of cells to MTX [9, 10]. The different modes of resistance may occur in combination, and our previous study with W1-L2 cells [2] showed that the most resistant mutants obtained had

Abbreviations used: MTX, methotrexate (amethopterin; ID_{50}, inhibitor concentration that gives 50% growth inhibition in 48 hr; IU, international unit of enzyme activity, = 1 μmole substrate converted/min.; E_t, total molar enzyme concentration; S, molar substrate concentration; I, molar inhibitor concentration; i, fractional inhibition

both impaired MTX transport and greatly elevated dihydrofolate reductase activity.

Several previous reports have examined the mechanism of the increase in dihydrofolate reductase activity, and the nature of the additional enzyme. In L1210 mouse leukaemia cells, moderately resistant mutants, showing a 7-fold increase in dihydrofolate reductase activity, were shown to synthesize enzyme molecules at 7 times the normal rate, and to degrade the enzyme at the normal rate; the enzyme had normal kinetic properties [11–13]. However, a highly resistant L1210 mutant, with the reductase increased 80-fold, only synthesized the enzyme at 65 times the normal rate, and it degraded the enzyme at one-third the normal rate [11]; this enzyme showed electrophoretic differences from normal L1210 dihydrofolate reductase, and the binding of NADPH was tighter than normal [13, 14]. Blumenthal and Greenberg, in a study with a MTX-resistant subline of mouse leukaemia L4946, showed that not only was total dihydrofolate reductase activity increased 20-fold, but that the enzyme in the resistant subline showed qualitative changes [15].

The kinetics of inhibition of dihydrofolate reductase are difficult to study accurately because of the quasi-stoichiometric nature of the inhibition by MTX. Some studies have indicated that the varying intrinsic sensitivity to MTX of different mammalian cell types may correlate with the tightness of binding of MTX by the cell's dihydrofolate reductase [16, 17]. The latter work showed that the Yoshida sarcoma was 70-fold more resistant to MTX than the L1210 leukaemia, despite the fact that the two cell lines had similar activities of dihydrofolate reductase, and similar rates of membrane transport of MTX; the reductase of the Yoshida cells, however, bound MTX 25-times less tightly than the L1210 reductase, and the Yoshida enzyme was thus much less readily inhibited [17]. Acquired resistance to MTX associated with loss of binding power for MTX has not hitherto been described. In the present paper we describe studies with two highly MTX-resistant sublines of the W1-L2 human lymphoblastoid cell culture line, one of which contained a dihydrofolate reductase with greatly altered kinetic properties.

MATERIAL AND METHODS

Chemicals

Methotrexate was obtained from Lederle Laboratories, Pearl River, N.Y. It contained less than 2% of folic acid and other contaminants, and was used without further purification. NADPH and dihydrofolate were purchased from Sigma Chemical Co., St. Louis, MO. The dihydrofolate was 92% pure, and was not purified further. AH-Sepharose-6B was from Pharmacia Fine Chemicals Inc., Piscataway, N.J. and chemicals for polyacrylamide gel electrophoresis were products of Bio-Rad, Richmond, California. Tissue culture supplies were purchased from Grand Island Biological Co. (Grand Island, N.Y.) or from Flow Laboratories (Rockville, MD.). Other chemicals were from local suppliers, and analytical grades were used where available.

Cell culture

The W1-L2 human lymphoblastoid cell line originated in 1968 [18]. Aspects of folic acid metabolism of these cells were discussed in earlier reports [3, 8, 17]. Some properties of the MTX-resistant sublines, and their origin, are discussed in [2] and [4]. The cells were grown in RPMI 1640 medium, supplemented with 10% foetal calf serum, penicillin (100 units/ml) and streptomycin (100 μg/ml). Cultures were tested for mycoplasma contamination at monthly intervals. Stationary suspension cultures were set up at a starting density of 5×10^4 cells/ml, and harvested for enzyme studies in mid-log phase (750,000–1,000,000 cells/ml).

Enzyme assays

About 10^8 cells (per sample) were harvested by centrifugation at 400 *g* for 10 min, then washed by resuspending in Dulbecco's phosphate buffered saline and recentrifuging. The cell pellet was resuspended in 0·05 M tris chloride buffer, pH 7·2, and sonically disrupted (Bronwill "Biosonik" Ultrasonicator, setting 85, 20 sec at 0°C). Particulate material was removed by centrifugation at 105,000 *g* for 30 min, and the resulting supernatant fraction was used for enzyme assays. Thymidylate synthetase was measured isotopically by the method of Lomax and Greenberg [19]. Dihydrofolate reductase was assayed by the method of Mathews and Huennekens [20], modified as described previously [17], except that the assays were conducted at 37°C; these assay conditions employ deoxygenated buffer, but thiol reagents are not present, since these may alter the enzyme kinetic properties.

Purification of dihydrofolate reductase

Dihydrofolate reductase was purified to near-homogeneity by affinity chromatography on MTX-agarose gel columns. The MTX-

agarose was prepared as reported earlier [21] except that AH-Sepharose-6B was used as starting material. The purification method was as described in ref. [17].

Kinetic studies

The low values of the dihydrofolate reductase K_m for dihydrofolate and K_i for MTX necessitate special precautions during their determination, and appropriate statistical techniques for evaluation of data. These were described in detail in an earlier study [17].

Polyacrylamide gel electrophoresis

This was by the method of Davis [22], and gels were run at 4°C. The gels were stained for dihydrofolate reductase activity as described by Dunlap *et al.* [23].

RESULTS

The origin of the MTX-resistant sublines with which these studies were concerned has been described previously [2]. It is important to note that subline WR9.1 was derived from subline WR8.1 by increasing the maintenance level of MTX in the culture medium. These maintenance MTX concentrations, together with the ID_{50} concentrations of the drug for the different sublines, are noted in Table 1. Also shown in Table 1 are thymidylate synthetase activities of the cells. The activity of this enzyme was virtually identical in the parent line and the 2 MTX-resistant sublines. Since thymidylate synthetase has been implicated in some systems as a potentially significant site of action of MTX [24] we studied the kinetic properties of the enzyme from the parent strain of W1-L2 cells in some detail. For this purpose, 1,L-tetrahydrofolate was prepared by enzymatic reduction of dihydrofolate. One-hundred milligrams dihydrofolate was dissolved in 90 ml of tris chloride buffer, 0·05 M, pH 7·6. It was then reduced to 1,L-tetrahydrofolate as described by Huennekens *et al.* [25] using 40 IU of L1210 cell dihydrofolate reductase [21]. Figure 1 shows double-reciprocal plots of saturation curve experiments for 5,10-methylenetetrahydrofolate, in presence and absence of MTX. In these experiments the concentration of deoxyuridylic acid was maintained constant at 10^{-4} M, formaldehyde concentration was constant at 7×10^{-3} M, 1,L-tetrahydrofolate was added in varying amounts, and the actual concentration of 5,10-methylenetetrahydrofolate was calculated from the equilibrium

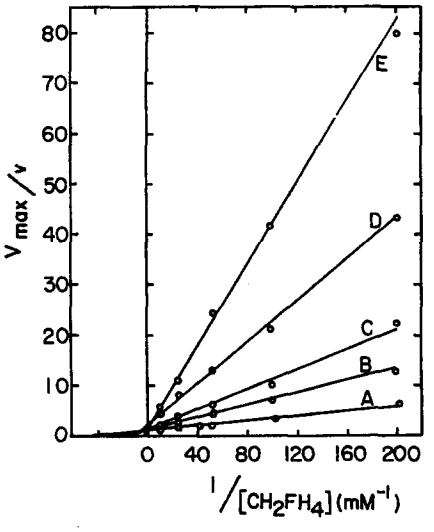

Fig. 1. Double reciprocal plots showing the dependence of W1–L2(WS) thymidylate synthetase activity upon the concentration of 5,10-methylenetetrahydrofolate and the competitive inhibition caused by MTX. A; no MTX; B, MTX 10 μM; C, MTX 20 μM; D, MTX 50 μM; E, MTX 100 μM. Experimental details are given in the text.

Table 1. Properties of W1–L2 cell sublines

Parameter	Sublines		
	WS	WR8.1	WR9.1
ID_{50} (μM)	0·013	2·2	6·8
Resistance (-fold)	(1)	170	523
Maintenance concn. of MTX (μM)	0	1·6	3·2
Thymidylate synthetase (IU/10^9cells)	0·025	0·027	0·024
Properties of dihydrofolate reductase:			
V_{max} (IU/10^9cells)	0·22	49·7	50·7
K_m for NADPH (μM)	3·1 ± 0·3	1·4 ± 0·2	N.D.
K_m for dihydrofolate (μM)	0·13 ± 0·02	2·3 ± 0·3	0·14 ± 0·04
K_i for MTX (pM)	7·3 ± 0·3	367 ± 48	6·8 ± 0·5
Turnover number (min^{-1})	1870	1610	1960

N.D. not determined. Values of kinetic parameters are followed by standard errors.

constant [26]. Other conditions were as described for the standard thymidylate synthetase assay. Results were calculated by the computer program "COMP" of Cleland [27]. The computed K_m for 5,10-methylenetetrahydrofolate of the thymidylate synthetase from parental strain W1-L2 (WS) cells was 23 ± 3 μM. MTX inhibited the enzyme competitively with 5,10-methylenetetrahydrofolate, and the K_i slope was 6·1 ± 0·8 μM; the intercept effect of MTX was very small. These parameters were based on a total of 72 experimental points.

Dihydrofolate reductase activities of the 3 sublines are listed in Table 1. Both the WR8.1 and WR9.1 sublines show an increase of about 230-fold in dihydrofolate reductase activity, relative to the parental cell strain. Subsequent experiments were concerned with the properties of the dihydrofolate reductase preparations isolated from the 3 sublines by affinity chromatography. The rate of dihydrofolate reduction was measured as a function of NADPH concentration, for the WS and WR8.1 enzymes. In each case a range of NADPH concentrations from 0·08 to 100 μM was studied, 32 experimental points for each determination. Results approximated closely to conventional hyperbolic saturation curves, with no indication of high substrate inhibition. K_m values for NADPH were calculated by non-linear regression analysis [28], and results are shown in Table 1. It may be seen that this parameter has decreased in the WR8.1 subline by more than a factor of 2, relative to the parental (WS) dihydrofolate reductase.

The determination of K_m values for dihydrofolate presents a number of practical problems; these were discussed in an earlier paper [17]. A range of dihydrofolate concentrations from 0·08 μM to 100 μM was studied, using a total of 28 points for each determination. Results are listed in Table 1. The K_m of dihydrofolate reductase for dihydrofolate was virtually identical to the normal value in subline WR9.1; in subline WR8.1, however, the binding of dihydrofolate was 18-fold weaker than normal.

The theoretical and practical aspects of the determination of K_i values for the interaction of dihydrofolate reductase and MTX were also discussed in ref. [17]. Figure 2(a) shows MTX titration curves for highly purified dihydrofolate reductase preparations from WR8.1 and WR9.1. Equal amounts of the 2 enzymes were used in these experiments, and equal amounts of dihydrofolate. Up to about 40% inhibition the curves are almost indistinguishable, but at higher inhibitor concentrations the different behaviour of the 2 enzymes becomes apparent. For example, at a total MTX concentration of 50 nM, the residual activity of the WR8.1 reductase is 3 times greater than that of the WR9.1 enzyme. Clearly the WR8.1 enzyme is binding the inhibitor less tightly than the dihydrofolate reductase from WR9.1 cells. Figure 2(b) is a linearized plot of the same data. These plots, for competitive inhibitors, have slope of $K_i(1+S/K_m)$, and the intercept at the ordinate gives enzyme concentration [17]. Thus, if K_m is already known, K_i may be calculated. However, a greatly preferable way of extracting K_i values for tight-binding inhibitors

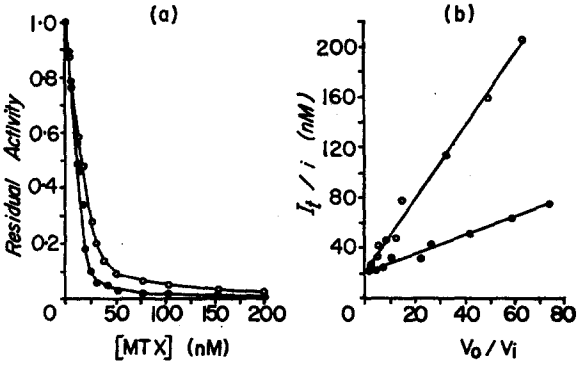

Fig. 2. (a). Titration of purified dihydrofolate reductases from WR9.1 (closed circles ●) and WR8·1 (open circles ○) with MTX. Enzyme concentration in each case was 20 nM and dihydrofolate concentration was 15 μM. NADPH was at 50 μM. (b) Linearized plot of the same data. v_0 is uninhibited velocity, v_i is velocity in presence of inhibitor. A total of 30 points were run for each enzyme, but for clarity not all are plotted. The K_i values plotted from the slopes of these graphs are:

WR 9.1, 0·747/(1+15/0·14) = 0·0069 nM
WR 8.1, 2·88/(1 ± 15 / 2·3) = 0·383 nM (equation is given in text).

is by the statistical method of Henderson [29]. The values listed in Table 1 were obtained by that method, as embodied in a computer program written by Hart [17]. As the results in Table 1 show, the K_i for MTX binding by the dihydrofolate reductase of WR8.1 cells is more than 50 times higher than that of the parental W1-L2(WS) cells; in the mutant subline WR9.1, derived from WR8.1 by selection at even higher MTX concentrations, the K_i has reverted to the original value.

To provide some indication of molecular size, dihydrofolate reductases from the 3 sublines were chromatographed through a 90cm × 3 cm^2 column of Sephadex-G100, eluted with Tris–chloride buffer, pH 7·2, 0·05 M, at 4°C. The column was standardised using ribonuclease A, chymotrypsinogen A, and ovalbumin. Enzyme from all 3 sources gave a

single peak on gel filtration, corresponding to a molecular weight of 22,500 ± 1000. Enzyme activity monitored following application of crude cell extracts to the Sephadex-G100 column also indicated a single peak, eliminating the possibility that minor dihydrofolate reductase components with different molecular weights were present in the cells but lost during the affinity chromatography procedure.

The isolation of essentially homogeneous dihydrofolate reductases made possible a determination of the enzymes' turnover numbers. These values are given in Table 1; they were measured at 30°C, to facilitate comparison with earlier results. No very marked differences in turnover number were seen between the sublines.

Figure 3 shows the results of polyacrylamide gel electrophoresis done with crude and highly purified dihydrofolate reductase preparations

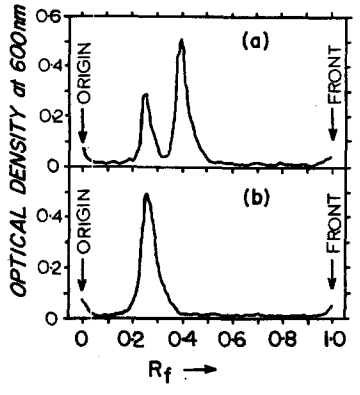

Fig. 3. Optical density scans of polyacrylamide gels stained for dihydrofolate reductase activity. (a) Crude cytosol preparation of WR8.1 (b) purified dihydrofolate reductase from WR8.1. Experimental details are given in the "Methods" section.

from WR8.1; the gels were stained for enzyme activity and then scanned. The crude extract showed peaks of reductase activity at R_f 0·26 (form I) and R_f 0·40 (form II). Peak II accounted for 63% of total activity. Following affinity chromatography only form I was present. Since the recovery of activity in the purification procedure was almost 90%, it is clear that form II was converted to form I in the course of purification. Polyacrylamide gel electrophoresis patterns for W1-L2(WS) and WR9.1 have been presented previously [2].

Finally, Fig. 4 illustrates the heat inactivation at 55°C, of the 3 dihydrofolate reductase preparations, in presence and absence of 0·2 mM NADPH. The rate of inactivation of WR9.1 enzyme was not greatly different from that of WS reductase, but the WR8.1 reductase was markedly less stable than the other two preparations.

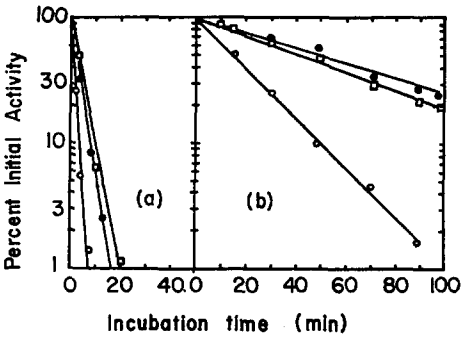

Fig. 4. Heat inactivation of purified dihydrofolate reductases. (a) No NADPH present; (b) 0·2 mM NADPH. Temperature was 55°. Symbols: □ WS; ○ WR8.1; ● WR9.1.

DISCUSSION

These studies have shown that a lymphoblastoid cell line, WR8.1, with acquired resistance to MTX, possesses a dihydrofolate reductase with grossly abnormal kinetic properties. Binding of MTX by this altered enzyme is over 50 times weaker than normal, binding of dihydrofolate is 18-fold weaker, and the K_i/K_m ratio is thus about 3-fold above the normal value in these cells. It is not known at what stage in the process of development of resistance these changes took place. If the mutation responsible for the changes was an early event in the acquired resistance process, cells possessing it would undoubtedly have a selective advantage. Earlier studies concerned with differences in intrinsic MTX resistance between cell strains showed that, when other factors such as total dihydrofolate reductase activity and rates of membrane transport were similar, cell lines with higher K_i values for MTX binding by dihydrofolate reductase were less sensitive to the drug. Figure 2 of the present paper compared MTX inhibition of equimolar amounts of WR8.1 reductase, and a dihydrofolate reductase with the normal K_i value (the enzyme used was actually from WR9.1, which has the same K_i as the WS reductase). Clearly the WR8.1 enzyme required considerably more drug to reach the same degree of inhibition. These studies have thus established that the production of kinetically abnormal dihydrofolate reductase is a possible mechanism of acquired MTX resistance in mammalian cells.

During the process of selection for MTX resistance, by growing cells in drug-containing medium, the total dihydrofolate reductase

activity of the cells increased greatly; both the resistant sublines examined in this study possessed about 230 times the original level of this enzyme. The turnover numbers of the enzymes were not greatly changed, indicating that the increase was due to the presence of more enzyme molecules, not to production of enzyme with greater catalytic potential.

When the WR8.1 subline was subjected to increased selective pressure, by further stepping up the drug concentration, the WR9.1 subline resulted. Table 1 of ref. [2] shows that the WR8.1 and WR9.1 sublines possessed identical activities of dihydrofolate reductase, and identical rates of membrane transport of MTX, yet WR9.1 was 3-fold more resistant to MTX than WR8.1. The present work has now shown that there is a biochemical difference between the 2 sublines, namely the kinetic properties of dihydrofolate reductase; however, on the basis of comparative reductase kinetics we might expect WR8.1 to be more, not less, resistant than WR9.1. This paradoxical state of affairs may be partly explained by consideration of Fig. 5. This diagram shows calculated activities of thymidylate synthetase and dihydrofolate reductase in the different cell lines, as a function of the free MTX concentration. The thymidylate synthetase curve (dotted line) is the same for all the sublines. The solid lines represent dihydrofolate reductase, which differs in amount and properties between the sublines. Consider curve A, representing the W1-L2(WS) cells. Thymidylate synthetase is normally the rate-limiting enzyme in the cycle of oxidation and reduction of folate cofactors (Table 1). However, as the MTX concentration increases, the potential activity of dihydrofolate reductase decreases, and when the free cellular MTX level exceeds 0·026 μM, the reductase becomes rate-limiting, and growth inhibition occurs. Line B represents a hypothetical cell line containing the normal activity of dihydrofolate reductase, but of the kinetically altered form found in WR8.1. This enzyme is more resistant to MTX inhibition, and the reductase curve does not cross the synthetase curve, and become rate-limiting, until a free MTX concentration of 0·083 μM is reached. Inhibition of the synthetase at this MTX concentration is negligible. When the dihydrofolate reductase, with normal kinetics, is increased 230-fold, as in WR9.1, the inhibition curve is given by line C. This situation differs radically from that of line A, in that thymidylate synthetase inhibition by MTX is now very pronounced. The synthetase, in fact, remains rate-limiting until a cellular free MTX concentration of about 30 μM is reached; at this point growth is inhibited to about 20% of the normal rate, and cells start to die. Curve D shows the situation in WR8.1. The altered properties of dihydrofolate reductase again shift the titration curve to the right, but this does the cell no good, because cell division is limited by thymidylate

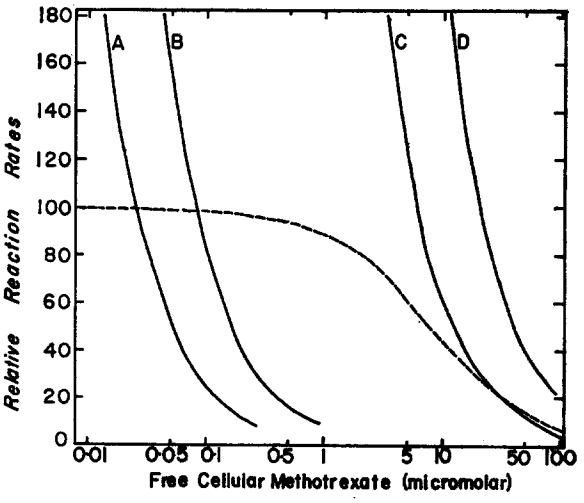

Fig. 5. Rates of thymidylate synthetase and dihydrofolate reductase reactions as a function of free intracellular MTX concentration. The thymidylate synthetase curve (broken line) is the same for all sublines; it was calculated using the competitive inhibition equation and the kinetic parameters reported in this paper. The 5,10-methylenetetrahydrofolate concentration was taken as 6 μM [30]. Saturation with dUMP was assumed since dUMP is known to accumulate in MTX-treated cells [31]. *Dihydrofolate reductase curves (solid lines) were calculated from the tight-binding competitive inhibition equation* [32] *and from the relationship:* $I_{free} = I_{total} - iE$ [32]. *Dihydrofolate (as the functionally active polyglutamate form) is known to accumulate in presence of MTX* [33, 17] *and we assumed a concentration of* 15 μM. *Other values used were: Curve A (WS cells)* $E_t = 0{\cdot}135\ \mu M$, $K_i = 7{\cdot}3 \times 10^{-12} M$; $K_m = 1{\cdot}3 \times 10^{-7} M$. *Curve B (hypothetical subline)* $E_t = 0.135\ \mu M$; $K_i = 3.65 \times 10^{-10} M$, $K_m = 2{\cdot}3 \times 10^{-6} M$. *Curve C (WR9.1 cells)* $E_t = 31{\cdot}6\ \mu M$, K_i *and* K_m *as for curve A. Curve D (WR 8.1 cells)* $E_t = 31{\cdot}6\ \mu M$, K_i *and* K_m *as for curve B. Other details are given in "Discussion" section.*

synthetase activity. Thus, in the highly MTX-resistant sublines, with greatly elevated dihydrofolate reductase, decreased affinity of the reductase for MTX provides no advantage to the cells.

In fact the results showed that possession of the altered dihydrofolate reductase by the highly resistant cells was actually a liability. This may be understood kinetically if we compare not, as in Fig. 5, the steady state, where equal free MTX concentrations are compared, but the situation in the cells before the steady state is reached; we thus compare the comparative effects of equal *total* MTX levels in WR8.1 and WR9.1. Assume $E_t = 31{\cdot}6\ \mu M$, and

dihydrofolate at 0·15 μM. Then, from the kinetic parameters listed in Table 1, and from the Goldstein equation [32] we may calculate free MTX levels in the cell, given the total cellular MTX content. If total MTX = 32 μM, then free MTX = 3·53 μM in WR8.1 and 0·93 μM in WR9.1. This 4-fold greater free MTX in the WR8.1 cells would give appreciably greater inhibition of thymidylate synthetase. The lower stability of the altered reductase, demonstrated in the present study, might also put the WR8.1 cells at a disadvantage.

To conclude, we have demonstrated the existence of a kinetically altered dihydrofolate reductase in cultured human cells. This mutation would have provided the cells bearing it with a selective advantage early in the development of resistance, but when the cells reached such a degree of MTX resistance that inhibition of thymidylate synthetase became significant, the mutation became a disadvantage, and disappeared. This property of conferring a selective advantage over a limited drug concentration range is not without precedent. For example, in mouse leukaemia cells subjected to gradually increasing amounts of MTX, transport mutants with altered K_t first appear, then, at high drug concentrations, disappear [13].

These studies also cast some light upon the importance of the low affinity sites of action of MTX. Of the various sites of action demonstrated for MTX, the inhibition of serine hydroxymethyltransferase may be dismissed as too weak to be of pharmacological significance. The importance of MTX inhibition of cellular uptake of 5-methyltetrahydrofolate is difficult to assess in the experimental system we used, since the culture medium contained folic acid, which utilises a different uptake route [2]. The possibility of MTX binding to low affinity sites on dihydrofolate reductase itself has been suggested [5]. This effect has been best characterised with the dihydrofolate reductase from *Lactobacillus casei* [34, 35]. MTX appeared to bind about 1000 times more weakly to the dihydrofolate reductase apoenzyme than to the enzyme–NADPH complex. However, since free reductase without NADPH cannot exert catalytic activity, binding of MTX to this apoenzyme is without pharmacological effect. Finally, as the present results have demonstrated, binding of MTX to thymidylate synthetase can be of importance. This mechanism of action of MTX would seem, though, only to be effective in the highly drug-resistant cells, with greatly elevated dihydrofolate reductase, where free intracellular MTX can accumulate to sufficient levels to exert significant inhibition of the thymidylate synthetase.

Simultaneous Chemical Induction of MTV and MLV *in vitro*

J. LINKS, JERO CALAFAT, FEMKE BUIJS and OLGA TOL
Netherlands Cancer Institute, Division of Virology, Sarphatistraat 108, *Amsterdam, The Netherlands*

Abstract—*Latent endogenous mammary tumour virus (MTV) and latent endogenous mouse leukemia virus (MLV) were simultaneously chemically induced with concomitant cell morphological alteration in tissue-cultured baby mouse kidney cells (BMKC) derived from the low mammary tumour mouse strains BALB/c (substrains He.A and Crgl.A) and C57BL/Li.A. 3-Methylcholanthrene (MCA) was used with BMKC prepared from BALB/c/He.A and BALB/c/Crgl.A mice and 5-bromodeoxyuridine (BrdU) with BMKC prepared from C57BL/Li.A.*

Aggregates (pocks) of small rounded epithelioid cells appeared on the BMKC monolayers several weeks after chemical treatment. Cell lines produced from single pocks released MTV (B-particles) and MLV (C-particles) as found with electron microscopy and reverse transcriptase determinations. All isolated cell lines grew well when serum was omitted from the medium. In female syngeneic BALB/c/He.A mice MCA altered BMKC induced early (<300 days) mammary tumours and early (<200 days) leukemia. A cell-free extract from these chemically altered BMKC induced similar early tumours. Chemically non-treated control BMKC cultures did not show the described alterations and properties. The data support the conclusion that MTV can be present in "virus-free" mouse cells from which the virus can be chemically induced simultaneously with and in the same way as MLV.

INTRODUCTION

THE INDUCTION of latent endogenous C-type oncorna viruses in tissue cultured "virus–negative" normal and tumorigenic human and animal cells by halogenated pyrimidines [1, 2], chemical carcinogens [3, 4], mutagens [3], deprivation of an essential nutrient [5], aging [6], oncogenic DNA-virus [7], X-rays [8] and still other techniques [9] has been firmly established in recent years. Induction (activation) is defined here in the usual experimental meaning: the endogenous virus genome is made "expressed", so that the virus can be measured [9].

Chemically induced morphological alteration with concomitant induction of an endogenous C-type oncorna virus has been reported also [10].

For the intact animal hormonal and immunological activations may be added to the list of induction techniques for the C-type viruses [9].

On the contrary, the induction of the mouse-mammary tumour virus (MTV), the B-type oncorna virus, has only been described for the intact animal [11–13] and not yet for any type of tissue cultured mouse cells. We now report the simultaneous chemical induction of latent endogenous MTV and latent endogenous murine leukemia virus (MLV) with concomitant morphological transformation in tissue cultured baby mouse kidney cells (BMKC) prepared from the low mammary tumour mouse strains BALB/c (substrains He.A and Crgl.A) and C57BL/Li.A. Parts of this study have been published in abstract form [14, 15].

Accepted 26 October 1976.

MATERIAL AND METHODS

These have been described for the greater part in a previous publication [16].

Mice

BALB/c substrains He.A and Crgl.A have been described in more detail before [16]. Substrain He.A is known to contain endogenous MTV and MLV, which are expressed at a rather high age. Substrain Crgl.A has generally been considered to be "free of MTV" [17–19].

The C57BL/Li.A mouse strain has a very low spontaneous mammary tumour and a low

spontaneous leukemia incidence. B-particles could not be found in the spontaneous or radiation and chemically induced mammary tumour of these mice [12].

Mouse cells

All BMKC subcultures were made by pronase treatment after the cultures had reached 90–95% confluency [16]. So the first subcultures were prepared on the 4th day of *in vitro* transplantation: one primary culture giving three secondary cultures ($1 \rightarrow 3$). The second subcultures were made between the 11th and 17th day ($3 \rightarrow 1$) and the third subcultures between the 18th and 38th day ($1 \rightarrow 1$). The optimal transfer ratios were established in trial experiments.

Chemicals

The stock solution of 3-methylcholanthrene (MCA; Sigma) was made (100 μg/ml) in an acetone-dimethylsulphoxide (DMSO) mixture (50:50, v/v). The final concentration of MCA was 10^{-3} μg/ml and of each of the organic solvents $5 \cdot 10^{-4}$ %. In preliminary experiments we had found this a "non-cytotoxic" dose of MCA when added from the third up to and including the 6th day. The controls in the MCA induction experiments got only the same amount of the acetone–DMSO mixture. The stock solution of 5-bromo-2-deoxyuridine BrdU; Sigma) was made in H_2O. The final concentration of BrdU in the medium was 30 μg/ml.

RESULTS

Cytotoxicity of 3-methylcholanthrene for BALB/c/He.A–BMKC monolayers

In a typical experiment 0, 10^{-3}, 10^{-2} and 10^{-1} μg/ml MCA were added respectively to the media of 4 groups, each consisting of 3 BMKC cultures, from the third up to and including the 6th day. On the 7th day the estimated confluencies were 40–50%, 40–50%, 30–40% and ± 30%. On the 9th day the percentages were: 80–90%, ± 80%, 30–40% and ± 30%. And on the 10th day: ± 90%, ± 90%, ± 60% and 20–30%.

In another experiment 10^{-3} μg/ml MCA was added to the media of 3 groups each consisting of 3 BMKC cultures. In group I from the third up to and including the 6th day (3rd–6th day), in group II from the 7th–10th day and in group III from the 3rd–10th day. On the 11th day the second subcultures were made and on the 15th day the confluencies were estimated.

Control (no MCA): ± 50%, I: ± 50%, II: ± 40%, III: ± 10%. We chose 10^{-3} μg/ml as the MCA concentration for the chemical induction experiments and applied it to the monolayer cultures from the third up to and including the 6th day. From the preliminary cytotoxicity experiments it could be concluded that the application of 10^{-3} μg/ml MCA during a longer (3rd–10th day) or later (7th–10th day) period and higher ($> 10^{-3}$ μg/ml) MCA concentrations were clearly cytotoxic as expressed in cell growth retardation.

Morphological transformation of BALB/c–BMKC with concomitant induction of MTV and MLV by 3-methylcholanthrene

After 3–6 weeks MCA treatment induced the formation of macroscopically visible 3-dimensional aggregates (pocks) of small rounded cells on the BMKC monolayers derived from BALB/c/He.A and from BALB/c/Crgl.A (Table 1; Fig. 1–3). The morphologically altered cells and the pocks appeared microscopically very similar to the pocks induced by exogenous mammary tumour virus (MTV) on BMKC-cultures [16]. Here too, cell lines could easily be derived from individual pocks. The cell lines grew rapidly in our standard medium with and without serum. With May–Grünwald–Giemsa staining the MCA-transformed BMKC showed a brilliant dark blue colour; as did the MTV transformed BMKC [16]. The cell lines formed epithelioid monolayers on which pocks were formed again. The MCA transformed BMKC cultures produced and released both B- and C-particles (Figs. 4, 5). When these cells were incubated with rabbit anti-MTV serum followed by incubation with ferritin labeled goat anti-rabbit IgG as described in [20] the B-particles were labeled but the C-particles produced by the same cells were always negative (Fig. 4).

The oncogenicity of cell line A3, derived from a single pock of MCA induced and morphologically altered BMKC, prepared from BALB/c/He.A mice, is shown in Table 2. Each of the three differently with cell material inoculated groups of mice: (1) intraperitoneally (i.p.) with A3 cells, (2) subcutaneously (s.c.) with A3 cells, (3) i.p. with an A3 cell extract), were divided, for technical reasons, in four nearly equally large subgroups: a–d. Subgroups (a) were inoculated with A3 cells of the 16th subculture (144 days after visible *in vitro* transformation). Subgroups (b) were inoculated with A3 cells of the 19th subculture (164 days). Subgroups (c) got A3 cells of the 21st subculture (178 days) and subgroup (d) of the 23rd subculture (191 days). So the three

†Subculture 16, 19, 21 and 23 of the A3 cells were used for inoculation. For details see text.

differently inoculated groups of animals were treated with A3 cells of practically the same average *in vitro* age. The A3 cells induced early (< 300 days) mammary tumours and early (< 200 days) leukemia along both routes of infection, (i.p. or s.c.). An i.p. introduced A3 cell extract gave similar early tumours (Table 2).

Determinations of the RNA-dependent DNA polymerase activities were carried out in the high speed pellets (Spinco L2, rotor No. 30; 40,000 *g* for 90 min) of the 24 hr media of A3 cell cultures (Table 3).

The ratio of the Mg^{2+} stimulated (largely specific for MTV) and the Mn^{2+} stimulated (largely specific for MLV) activity was 1·3 in the 13th subculture (118 days) and 0·5 in the 23rd subculture (191 days). Thus the B-particle production was lowered as compared with the C-particle production upon *in vitro* aging of the A3 cell line. This is in general agreement with earlier electron microscopic observations [20]. In a previous publication we described the morphological transformation and concomitant production of B- and C- particles in BALB/c–BMKC by exogenous MTV [16]. Now it appeared that MCA and exogenous MTV had a synergistic effect on the morphological alteration (pock formation) and concomitant production of MTV and MLV in BMKC derived from BALB/c/He.A mice (Table 1). MCA was added as described (Methods) and exogenous MTV dilution 10^{-3} was adsorbed on the BMKC monolayers for 2 hr on the 3rd day [16].

The oncogenicity of the MCA induced MTV and MLV in BALB/c/Crgl.A–BMKC is being

investigated in syngeneic female mice. The control BMKC cultures from both BALB/c substrains did not produce B- or C-particles.

Morphological transformation of C57BL/Li.A–BMKC with concomitant induction of MTV and MLV by 5-bromo-2'-deoxyuridine (BrdU)

In a BMKC culture (one out of three) derived from C57BL/Li.A mice and treated with BrdU during 9 days (3rd–11th day) we got a single pock of small rounded cells 25 days after *in vitro* transplantation.

The pock and the morphologically altered cells appeared microscopically very similar to the pocks induced by MCA in BALB/c–BMKC cultures. A rapidly growing cell line could be derived from the pock. The chemically altered epithelioid cells grew equally well in the standard medium without serum.

The cells produced intracytoplasmic A-, B- and C-particles (Fig. 6, 7). The B-particles were labeled after incubation with rabbit anti-MTV serum followed by incubation with ferritin labeled goat antirabbit IgG (Fig. 8). The oncogenicity of the virus producing cells is being investigated with our colleague Dr. A. Timmermans. We did not yet succeed in inducing pocks on C57BL/Li.A–BMKC monolayers with MCA.

DISCUSSION

The described experiments showed (1) that tissue cultured baby mouse kidney cells (BMKC) derived from the low mammary tumour mouse strains BALB/c (substrains He.A and Crgl.A) and C57BL/Li.A contain the genetic information for MTV and MLV in a suppressed form and (2) that these BMKC can be chemically induced to produce and release simultaneously MTV virions and MLV virions. The BMKC derived from all three strains were explanted *in vitro* at the age of 5–7 days when no expression of endogenous MTV was found yet in the animals [21]. The age of 5 days is the lowest up to the present that B-particles could be found or have been made visible in organs of any mouse strain [22]. The induced MTV and MLV in BMKC derived from BALB/c/He.A were biologically active in syngeneic female mice (Table 2).

The induction of B-particle and C-particle production in BMKC derived from mouse strain C57BL/Li.A and substrain BALB/c/Crgl.A is even more striking as these mouse strains were not yet known to carry the information for complete MTV virions [13, 17–19, 23, 24].

Many studies have led to the solidly based conclusion that endogenous C-type oncorna viruses can be vertically transmitted as chromosomal elements [25–29]. Avian and murine systems have been studied most thoroughly in this respect. The viral genetic information of the chromosomes may vary from being unexpressed ("virus-free" state) via partially to fully expressed in the cells. Next to the discovery of the RNA-directed DNA polymerase (RDDP; reverse transcriptase) activity in oncorna virions [30] the inducibility of C-type oncorna viruses in tissue cultured "virus-free" cells [1–9] has contributed greatly to the present day notion of the existence of integrated viral genes from C-type oncorna viruses in the host cell chromosomal complement similar to the lysogenic state of bacteria. The development and acceptance of an equal lysogeny model for endogenous MTV (B-type morphology) paralleled more or less the history of the lysogeny model for C-type viruses [25, 28, 31–35]. Bentvelzen continuing Mühlbock's MTV transmission studies [32] with crosses of GRS (GR) and other mouse strains and their progeny concluded that a mammary tumour controlling factor was present as a single gene locus in the genome of the GR host [25, 33]. To explain this fact he favored a hereditary transmission model in which a DNA copy of MTV-RNA is permanently integrated in the genome of the GR host and is transmitted as a Mendelian factor (B.'s "germinal provirus"). A similar explanation was extended by him to the endogenous MTV of C3Hf mice [33] and comparable *f* mouse strains [35]. He did not completely reject a model in which a dominant susceptibility gene would cause extreme susceptibility of mice with the GR genome to small amounts of not integrated omnipresent (including the seminal fluid) MTV but considered this as "less economical" [33].

Nandi and Helmich repeated and extended the genetic studies of congenital MTV transmission in GR mice. Nandi came also to the conclusion that the genetic studies alone could not discriminate between integrated provirus genes and host susceptibility genes [36, 37].

We believe that the *in vitro* chemical induction of MTV in kidney cells derived from baby BALB/c mice (especially BALB/c/Crgl.A mice) and those derived from C57BL/Li.A mice resulting in the production and release of complete MTV virions, supports the integrated provirus theory for endogenous MTV [33]. The more so as with previous immunofluorescence tests and a nucleic acid hybridization assay, using a tritiated single-stranded DNA

probe complementary to a part of the MTV RNA genome, no MTV could be found in kidneys of young mice belonging to BALB/c/He.A and C57BL/Li.A strains [21, 38].

The existence of integrated endogenous MTV does of course not rule out another part played by host susceptibility (permissive) genes in MTV expression and biological activity [33–37, 39].

The inoculation of MCA induced MTV and MLV producing BALB/c/He.A–BMKC in syngeneic female mice caused early mammary tumours and early leukemia but no tumours on the site of injection (Table 2). The underlying mechanisms may have been the induction of interferon and of specific immunity to the chemically transformed cells without neutralizing all escaped oncorna virus particles on their way to target cells [40].

The A3 cell line, a chemically transformed BMKC derived from BALB/c/He.A, gradually lowered its B-particle production *in vitro* (Table 3). This is in general agreement with electron microscopic observations [20]. Apparently, only during a rather limited period after chemical induction, the BMKC can produce and release B-particles in comparatively large quantities. A similar gradual decrease of B-particle production was found with BMKC induced *in vitro* by exogenous MTV [16] and when B-particle producing mammary tumours of the mouse were explanted into tissue culture [41].

It may be an innate incapability of the MTV producing cells to produce permanently large quantities of B-particles under the presently used tissue culture conditions. One could also think of some kind of intracellular interference of ubiquitous MLV.

The endogenous MLV which is chemically and simultaneously induced with endogenous MTV in experiments with BMKC derived from BALB/c/He.A mice is likely more closely related to BALB/c–MLV No. 1 than to BALB/c-MLV No. 2 of Aaronson and Stephenson [42].

The BMKC cell lines derived respectively from BMKC transformed by exogenous MTV (previous study [16]) and from BMKC transformed by chemicals (MCA and BrdU) have several properties in common.

Both groups have a small and epithelioid morphology, grow equally well in serum—enriched and serum—less medium, produce and release simultaneously MTV virions and MLV virions (both viruses are biologically active in both groups of induced BMKC derived from BALB/c/He.A mice) and gradually lose their B-particle producing capability by aging of the cell lines *in vitro*. Further, exogenously applied MTV and MCA can act synergistically in the morphological alteration of BMKC and the simultaneous induction of MTV and MLV (Table 1). The chains of intracellular reactions following the primary triggering by the chemical and by exogenous MTV and resulting in the production and release of B- and C-particles have apparently several common links from close to the level of gene derepression [28].

However, the final production and release of B-particles and the final production and release of C-particles are not coupled as the relative virus yields change with the *in vitro* age of the host cells (Table 3).

Relevant to this study are the recent results of Lazar *et al.* This team described the chemical induction (with 5-iododeoxyuridine) of an ecotropic endogenous carcinogenic oncorna virus in an epithelioid cell line derived from pooled C57BL/6 mouse embryos [43]. These C57BL/6 mice have like the C57BL/Li.A mice in the present study a very low incidence of spontaneous tumours. The induced epithelial cells and the cells secondarily infected by Lazar's virus became morphologically transformed *in vitro* and produced carcinomas at the site of inoculation in syngeneic mice. It is interesting to note that the observed virus particles had a C-type morphology and caused syncytia formation in the rat sarcoma cell line XC [43].

Cytological and Cytochemical Analysis of Two Mouse Cancer Cell Lines. Caryotype, Number of Nucleoli, DNA, RNA and Protein Contents

R. BASSLEER and F. DE PAERMENTIER
Institut d'Histologie de l'Université de Liège, 20, rue de Pitteurs, 4020 Liège, Belgium

Abstract—*Ehrlich ascites tumour cells (hyperdiploid strain ELD and hypertetraploid strain ELT) propagated in the mouse and TIII mammary carcinoma cells (strains TIII$_t$ and TIII$_r$) cultivated* in vitro *are analysed with cytological and quantitative cytochemical methods. It is shown that, in these cancer cell lines, the number of nucleoli and the DNA, RNA and total protein contents are related to the number of chromosomes. These cellular parameters are also analysed during the cell cycle.*

INTRODUCTION

IN THE present work, two mouse cancer cell lines are analysed with cytological and cytochemical methods: Ehrlich ascites tumour cells growing in the mouse peritoneal cavity and cells from a mammary carcinoma (TIII line) cultivated *in vitro*. Two strains from each of these cell lines are studied here in order to detect eventual relations between the caryotype and various cellular parameters: cell volume, number of nucleoli, nucleic acid and protein contents. The analysis of the two latter was performed with quantitative cytochemical methods which are particularly valuable because measurements in individual cells can be realized.

The results of the present investigation demonstrate that these cellular parameters are in fact related to the number of genomes in these two cancer cell lines. Nucleoli and nucleic acid and protein contents are also studied in these cells, during interphase (preparation for mitosis) and during cell division.

MATERIAL AND METHODS

1. *Cancer cell lines*

(a) *Mouse Ehrlich ascites tumour cells.* Hyperdiploid strain ELD and hypertetraploid strain ELT; these strains have been supplied by the Karolinska Institute (Stockholm) and are propagated in the peritoneal cavity of C57 Bl mice (Laboratory of pathological Anatomy, University of Liège).

(b) Cells from a *mouse mammary carcinoma* are continuously cultivated *in vitro* (line TIII) by Professor J. A. Thomas (Cell Biology Laboratory and Cell Physiology Center, Paris) who very kindly gave us strain TIII$_t$ and strain TIII$_r$ cells [1, 2].

2. *Cytological and cytochemical methods*

(a) Cell staining by von Möllendorff haematoxylin.

(b) Specific staining of *nucleoli* by toluidin blue after neutral deoxyribonuclease (DNase) digestion [3]. The mean number of nucleoli per cell was calculated from results obtained by observing 100–200 cells in each case.

(c) *Caryotype* analysis after treatment with an hypotonic solution and Unna blue staining.

(d) *Cell volume* measurements with an electronic counter (Coulter counter).

(e) *DNA, RNA and protein measurements* in individual cells by quantitative cytochemical methods; 50–100 cells in interphase or in mitosis were measured in each case.

DNA content: measured by absorption cytophotometry after Feulgen reaction (3·5 HCl hydrolysis at 37°C; Barr and Stroud GN2 microdensitometer, wavelength: 543 nm). Smears containing mouse leukocytes were stained under standard conditions in order to

Accepted 16 September 1976.

measure the mouse DNA diploid amount by cytophotometry. Values found and expressed in arbitrary units were converted into absolute values (pg) by using the mouse DNA diploid amount [4] measured by biochemical methods (5·5 pg).

RNA content: measured by absorption cytophotometry after neutral DNase digestion and gallocyanin–chrome alum staining [5]; GN2 microdensitometer, wavelength 550 nm; the results (total cellular RNA content) are expressed in arbitrary units. All the cells to be measured were stained simultaneously.

Total cell protein content: measured by absorption cytophotometry after naphtol yellow S staining [6]: GN2 microdensitometer, wavelength 435 nm; the results are expressed in arbitrary units.

Total cell dry mass: measured by scanning and integrating micro-interferometry (Vickers M86); the results are obtained in absolute amounts (pg) and essentially represent the total cell protein content [7].

RESULTS

A. *Mouse Ehrlich ascites tumour*

The origin of this line is a mouse mammary carcinoma [8, 9]. It is propagated as an ascites tumour in many laboratories.

Our ELD cell strain is *hyperdiploid* (45 chromosomes); our ELT cell strain is *hypertetraploid* (90 chromosomes, see Table 1). The normal mouse caryotype contains 40 chromosomes as it is well known. The *DNA content*, measured by cytophotometry after Feulgen reaction in cells fixed at the beginning of interphase, is hyperdiploid for ELD and hypertetraploid for ELT, when compared to the mean DNA amount of leukocytes from the same animal. The *modal cell volume* is 700 μm^3 and 1220 μm^3 for ELD and ELT respectively.

The mean *number of nucleoli* is 1·69 ± 0·58 for ELD and 3·38 ± 0·92 for ELT (Table 1). In some cells, only one large nucleolus is observed; this fact is usually due to nucleolar fusion. In both strains, large cells at the end of interphase contain particularly prominent nucleoli resulting from nucleolar growth during preparation for mitosis [3, 10].

The total *cellular RNA content* was measured by absorption cytophotometry in visible light. In both Ehrlich cell strains, large intercellular variations of the RNA content are observed. The RNA amounts are situated between minimal and maximal values; the ratio between the two latter is 1:2. The first ones are found in small post-mitotic cells fixed at the beginning of interphase; the second ones are found in mitotic cells and in large interphase cells. Thus these facts demonstrate that the total cellular RNA content doubles during preparation for mitosis, as DNA do. Furthermore, the RNA content in ELT cells is quite twice as high as in ELD cells (Table 1). The same conclusions are drawn from *total cell protein* measurements (by absorption cytophotometry or by micro-interferometry) in ELD and in ELT cells (Table 1). The protein content is doubled during interphase before mitosis starts; the protein content is twice as high in ELT as in ELD cells [11–14].

B. *TIII mouse mammary carcinoma*

The *caryotype* of various strains of this tumour (which are cultivated *in vitro*) was established by Thomas and his collaborators [2]. The modal chromosome number is around 60 for $TIII_r$ and around 100 for $TIII_t$ (Table 1).

We measured the *DNA content* by absorption cytophotometry in these two strains. $TIII_r$ is hypotetraploid, $TIII_t$ is hypertetraploid as to DNA (Table 1). These results thus completely agree with the caryotypes of these strains. Simultaneously stained mouse leukocytes were

Table 1. *Cytological and quantitative cytochemical analysis of four mouse tumour cell strains. Values related to DNA (in pg), RNA (in arbitrary units, a.u.) and to dry mass (in pg) are mean amounts found for cells fixed just after mitosis (in post-telophase)*

		Modal number of chromosomes	DNA content pg	Mean number of nucleoli	RNA content a.u.	Total cell dry mass pg
Ehrlich tumour	ELD	45	6	1·7	8·4	158
	ELT	90	12	3·4	16·0	302
Mammary carcinoma	$TIII_r$	60	7·9	2·0	8·4	238
	$TIII_t$	100	13·4	3·0	16·8	384

used as a reference for the mean DNA diploid amount. It is to be noted that the ratio $TIII_t/TIII_r$ is nearly identical as regards DNA and the modal chromosome numbers.

The *number of nucleoli* (Table 1) is $2{\cdot}06 \pm 1{\cdot}03$ for $TIII_r$ and $3{\cdot}05 \pm 1{\cdot}06$ for $TIII_t$. In some cells, nucleolar fusion is noted; nucleoli with increased volume are observed in late interphase cells.

The results of our absorption cytophotometry measurements in interphase or mitotic $TIII_t$ and $TIII_r$ cells clearly show that the *cellular RNA content* is doubled during preparation for mitosis. Furthermore (Table 1), the RNA content is twice as high in $TIII_t$ cells as in $TIII_r$ cells. Similar conclusions can be drawn from the results of our *total cell protein* measurements performed by cytophotometry or by interferometry in $TIII_t$ and $TIII_r$: the total cell protein content is doubled before mitosis starts and cell protein amounts are quite proportional to the chromosome number in each strain (Table 1).

DISCUSSION

Cell lines derived from *mouse mammary carcinomas* and actively growing *in vivo* or *in vitro* are analyzed with cytological and cytochemical methods. Ehrlich tumour cells are propagated in the mouse peritoneal cavity; TIII tumour cells are cultivated *in vitro* but are oncogenic when inoculated into young mice [1]. These two lines are compared as far as various cellular parameters are concerned. For both types of tumours, strains with different caryotypes are analyzed, thus allowing us to study an eventual relation between the number of chromosomes and these parameters.

Our quantitative cytochemical measurements demonstrate that the DNA, the RNA and the total protein contents of the cells are doubled before mitosis starts and are distributed in quite equal amounts between the daughter-cells. These facts are not different from those observed in other cancer cell lines [7] or in non cancer cells (e.g., fibroblasts *in vitro* [15]). During preparation for mitosis, the number of nucleoli is not modified but their volume and dry mass tend to double [3, 10]. This fact is also observed in the presently studied cancer cell strains.

In each of our cancer cell lines, the DNA content is clearly proportional to the chromosome number. This fact agrees with a classical notion. Our results also show that the cellular RNA content (essentially ribosomal RNA, [5]) and the total cellular protein content are also related to the chromosome number. These cell parameters thus seem to depend on a genetic control. The number of nucleoli is also increased with the number of genomes. This can be explained by the fact that the nucleoli are formed by specific chromosomes bearing a nucleolus organizer. However, nucleolar fusion can occur in some cells which then contain only one nucleolus; the latter is particularly large.

In a previous work [16], we compared ELD to ELT cells (45 and 90 chromosomes respectively) at the ultrastructural level. No morphological differences were noted. An analysis by morphometry showed that *in both strains* the volume occupied by the nucleus and by the mitochondria is 40% of the cell volume and 16% of the cytoplasm volume respectively. In fact, the cell volume is quite twice as large in ELT as in ELD. So, it can be stated that, in Ehrlich tumour cells, the volume of the nucleus and of the cytoplasm and the volume and the number of mitochondria are nearly doubled when the number of chromosomes is doubled. As far as the nucleoli are concerned [17], these organelles (perinucleolar chromatine being excluded) occupy 20% of the nucleus volume as well in ELD as in ELT cells.

When comparing Ehrlich to TIII carcinoma cells, it is observed that the values found for different cell parameters are of the same order of magnitude but, in general, these values are closely related to the chromosome number in each case. In fact, these cells all originate from mouse mammary carcinomas.

Concerning the cell cycle and the cell parameters studied here, no fundamental differences have been detected in these cell strains when they are compared to actively multiplying non cancer cells.

Effective Antitumour Conjugates of Alkylating Drug and Antibody Using Dextran as the Intermediate Carrier

G. F. ROWLAND

Searle Research Laboratories, Lane End Road, High Wycombe, England

Abstract—*The use is described of water-soluble dextran as an intermediate carrier for conjugation of an alkylating agent to antitumour immunoglobulin (Ig). Drug and primary amine are attached to dextran by cyanogen bromide and the drug-carrier preparation linked to Ig by glutaraldehyde. Conjugates prepared in this way are highly effective in suppressing growth of the EL4 mouse lymphoma. It is demonstrated that the effectiveness of the conjugate is related to the effectiveness of the antiserum from which it is prepared and also that the results are unlikely to be due to drug–antibody synergism. Whether a homing mechanism is involved remains, however, obscure.*

INTRODUCTION

THE USE of polyglutamic acid (PGA) as an intermediate carrier of drug in a drug–antibody conjugate has been described previously [1]. This system was effective in suppressing growth of the EL4 lymphoma in syngeneic mice but proved difficult to control [2] as the degree of coupling drug-carrier conjugate to immunoglobulin was variable. Another variable resulting from the use of PGA as a carrier is the residual net negative charge of the conjugate due to the remaining free carboxyl groups. These groups give water-solubility to the preparation but may result in the conjugate being preferentially taken up by reticuloendothelial cells [3]. The present paper describes the use of an alternative carrier, dextran, which is both neutral and water soluble and which after introduction of amino groups can be coupled to Ig by a standard glutaraldehyde method. Results show that conjugates prepared this way are effective in suppression of tumour growth in mice.

MATERIAL AND METHODS

The alkylating agent PDM (N,N-bis(2-chloroethyl)-*p*-phenylene-diamine) was supplied by the Chemical Defence Establishment, Porton, England or synthesized by Dr. S. Coppell in our own laboratories according to the method of Everett and Ross [4]. Soluble Dextran (M. Wt. 17,700) was obtained from Sigma Chemical Co. Ltd., cyanogen bromide (CNBr.) from Koch-Light Laboratories, U.K. and hexamethylene diamine (HMD) from Hopkin and Williams, U.K.

Normal rabbit globulin (NRG) was prepared from rabbit serum by precipitation with 40% saturated ammonium sulphate twice, redissolving in phosphate buffered saline (PBS) and dialysing against PBS. Rabbit immune-globulin (RIg) was prepared by a similar technique from rabbit antiserum raised against mouse lymphoma cells (EL4), made specific by repeated absorption with normal mouse spleen cells [5].

Preparation of PDM-dextran

One gram of dextran was dissolved in 1 l distilled water and the pH raised to 11·0 by addition of 1 N NaOH. A solution of CNBr (3·3 ml) in acetonitrile at 250 mg/ml was added dropwise to the rapidly stirred dextran at room temperature. The pH was maintained between 10·8 and 11·0 by addition of NaOH. After addition of CNBr, the mixture was stirred with pH maintenance for a further 10 min. HMD (200 mg) dissolved in 5 ml water was then added and the pH lowered to 9·0 with 1 N HCl, and left stirring for 5 min. PDM (500 mg) dissolved in 10 ml ethanolic HCl, plus 40 ml 60% aqueous propylene glycol containing 1·2% w/v K_2HPO4 was then added dropwise, the pH being allowed to fall to 6·5 and there-

Accepted 26 October 1976.

after held at that pH by addition of NaOH. After stirring for 15 min at room temperature the mixture was cooled to 4°C and concentrated to 300 ml by hollow fibre ultrafiltration (Amicon Corp., model DC 2). The same apparatus was used to dialyse with distilled water till the dialysate was free of u.v. absorbing material. The preparation (PDM–DEX) was finally freeze-dried for storage.

Conjugation of PDM–DEX to globulins

Equal volumes of PDM–DEX at 30 mg/ml in water and globulin at 30 mg/ml in PBS were mixed at room temperature and glutaraldehyde gradually added to give a final concentration of 100 μg/ml. After mixing for 1 hr at room temperature the conjugate together with any remaining free globulin was precipitated from the solution by addition of an equal volume of 80% sat. ammonium sulphate. Unconjugated PDM–DEX remained in solution. The precipitate was centrifuged and washed with 40% sat. ammonium sulphate and finally redissolved in PBS. After dialysis the preparations PDM–DEX–NRG or PDM–DEX–RIg were stored at −70°C prior to injection or analysis.

Determination of alkylating activity

Since the conventional method [6] for measuring alkylating activity of drugs using nitrobenzyl pyridine (NBP) involves protein denaturation conditions, any alkylating protein formed by conjugation techniques becomes difficult to quantitate by spectrophotometry due to precipitation. The following modification was devised to retain solubility of the preparation during the assay. A sample of 0·3 ml was added to 0·6 ml acetone: propane-1,2-diol: 0·2 M acetate buffer pH 4·0 (8:16:9 by vol) and 0·15 ml 5% NBP in acetone added. The mixture was incubated at 80°C for 10 min, allowed to cool to room temperature and 0·5 ml acetone: propane 1,2-diol: 1 M potassium carbonate (1:2:3 by vol) added just before measuring absorbance at 600 nm. If the protein concentration of the sample does not exceed 10 mg/ml no loss of solubility occurs and the colour formed due to linked drug can be accurately measured by reference to a standard curve using free drug.

Measurement of in vivo *antitumour effects*

The method was as previously described [7] utilizing groups of mice of C57BL/6 strain inoculated with 5×10^4 live EL4 tumour cells intraperitoneally on day 0. Treatment with conjugates and control preparations was on days 1–4 and effectiveness determined by survival times of the mice.

RESULTS

The *in vivo* effect of dextran-linked PDM conjugates is shown in two separate experiments in Table 1. Different batches of PDM–DEX were used and different antisera served as the source of Ig. The results show that 450 μg PDM (alkylating activity), when conjugated to dextran, had virtually no antitumour effect. The Ig preparation alone (without drugs) increased mouse survival by 12–14 days and by 15 days when injected together with PDM–DEX ("drugged carrier") but unlinked to the Ig. The PDM–DEX–Ig conjugates, however, containing the same amounts of Ig and alkylating activity gave 100% long term survival in one experiment and 60% in the other.

Table 2 shows that the antitumour effect of the alkylating agent is related to potency of the antibody to which it is conjugated. Different immunoglobulin preparations were used ranging in protective antibody content from nil (normal rabbit globulin, NRG) to preparation R210/212 which gave the best protection when used alone.

Although the results shown in Table 1 support the idea that the effect is due to a conjugate and not to an additive or synergistic effect of PDM–DEX and Ig, physico-chemical analysis using gel-filtration has shown that free Ig is present in the materials injected. The possibility therefore must be considered that the preparation is a mixture of PDM–DEX–Ig and free Ig. The antibody activity may be diminished in the conjugate but retained in the free Ig with the result that a mixture could be effective by virtue of a synergism between free Ig and PDM–DEX–Ig. To test this hypothesis, PDM–DEX was conjugated to NRG and a mixture of PDM–DEX–NRG+Ig was compared for effectiveness with a PDM–DEX − Ig preparation. Table 3 shows the result. The conjugate remains the most effective preparation but a synergism between PDM–DEX–NRG and Ig is demonstrable.

DISCUSSION

The problems arising from the direct conjugation to antibody of high levels of hydrophobic anticancer agents have been overcome by the use of intermediate carriers [1]. These provide both multiple drug attachment sites and hydrophilic groups to give the conjugates water solubility. New problems arise, however,

Table 1. *Antitumour effects of PDM conjugates and immunoglobulin*

Treatment*	Dose per injection		Expt. No. RX 95		Expt. No. RX 104

PDM-DEX-NRG plus Ig	54	1/5
Ig alone	28	0/5

associated with conjugation of macromolecules; thus preparations contain free drug-carrier conjugates and free immunoglobulin in addition to the drug-carrier-Ig conjugate required. Variability in the preparations was a problem when polyglutamic acid was used as a carrier. The possibility exists of fractionating the preparations by gel filtration but the lability of the alkylating moiety in dilute solutions has made this of little practical value. In the present work, the use of dextran as a carrier has allowed ammonium sulphate precipitation to be used for fractionation. In this way the conjugates can be freed from unlinked PDM-dextran although they still contain free Ig.

The antitumour effectiveness of the preparations can be clearly demonstrated and shown to be an antibody-dependant phenomenon. What has not been proved is that the effect is due to "homing", i.e. selective transport of drug to tumour by specific antibody. The possibility that the observed effects are due to synergism between free Ig and conjugated Ig has been considered. Although the results suggest that this is not the cause, the limited numbers of animals tested in this way do not allow this to be ruled out unequivocally. However, since some loss of antibody activity occurs in conjugation, direct comparison of the two groups involved (PDM–DEX–NRG+Ig versus PDM–DEX–Ig) is not entirely fair since no allowance was made for this loss. This may add more weight to the view that the linked preparation is the most effective and may be working by a "homing" mechanism. Without further experiments, however, the detailed mechanism of action of these preparations must remain supposition.

Since the ultimate aim of the present study is to improve the therapeutic effectiveness of anti-cancer drugs it is valid to consider how the conjugates compare with unconjugated drug. Free PDM was not administered as a

control in the present experiments since when linked to a macromolecule it has totally different toxicological and pharmacological properties. However, we have in previous studies [8] shown that free PDM has very little anti-tumour effect in the EL4 test system and does not result in long-term survivors. Thus the drug-antibody conjugates appear to offer a true improvement in therapeutic index over drug alone.

Serum Prolactin Concentrations in Benign Breast Disease Throughout the Menstrual Cycle

E. N. COLE,* R. A. SELLWOOD,† P. C. ENGLAND† and K. GRIFFITHS

**Tenovus Institute for Cancer Research, Welsh National School of Medicine, Heath, Cardiff, CF4 4XX*

†Department of Surgery, University Hospital of South Manchester, Withington Hospital, Manchester, M20 8LR

Abstract—*Prolactin concentration has been estimated by homologous radioimmunoassay in morning serum samples taken daily throughout the menstrual cycle of normal women and women with benign breast disease. Whereas the median prolactin concentration in* 550 *sera from* 24 *normal cycles was* 0·10 *mu/ml, in* 19 *women with "fibroadenosis" the median of* 500 *values was* 0·15, *and was* 0·27 *mu/ml for* 337 *sera from* 12 *cycles of women who had had breast cysts aspirated. Abnormal daily or weekly prolactin profiles over the monthly cycle were found in benign breast disease, especially in women over* 30 *years old, and most marked in those with cystic disease. A significant positive correlation was present between age and prolactin in cystic disease, but not in the fibroadenosis or normal groups of women. The two benign breast diseases studied here would seem to be clinical conditions susceptible to treatment by prolactin-suppressive agents.*

INTRODUCTION

IT WOULD now appear to be well accepted that prolactin has many varied actions [1] some of which may be concerned in controlling the physiological activity of mammary tissue. Thus growth, interaction with steroid hormones and electrolyte movement are all aspects of prolactin action which justify the study of this hormone in relation to the breast and in particular to breast diseases. The role of prolactin throughout the various stages of the menstrual cycle is however poorly understood, and even the monthly pattern of the hormone's concentration in the blood has given rise to controversy [2]. Although the human breasts undergo cyclical changes in normally menstruating women, it is impossible at present to assess whether the cyclical nature of many benign breast complaints could be related to abnormal prolactin secretions. Furthermore, despite reports of normal concentrations in various benign breast diseases [3–5], these were based on single samples and do not exclude the possibility of abnormal prolactin profiles during some phases of the menstrual cycle.

The investigation now reported was undertaken to establish serum prolactin profiles over the complete menstrual cycle in two clinically different benign breast diseases in women from a wide range of age. Some patients were categorized as having "benign cystic disease of the breast" when breast discomfort or pain led to clinical examination that revealed a palpable lump containing fluid which could be aspirated. The term "fibroadenosis" was used here to denote a diffuse condition of painful, lumpy breasts [6]. These definitions were broad, and diseases of the mammary ducts, including nipple discharge, were excluded, as were solid lumps, whether benign adenomata or malignant cancer. Normal women were studied for comparison.

MATERIAL AND METHODS

Subjects and samples

The subjects were pre-menopausal women with benign disease of the breast. Eleven of them had had one or more cysts aspirated from one or both breasts, and a further 19 had painful lumpy breasts diagnosed clinically as

Accepted 26 October 1976.

having generalised fibroadenosis [6]. The existence of discrete fibroadenomata or microcysts cannot be excluded from the latter group. The range of age for women with cystic disease was 34–48 and for those with fibroadenosis, 24–49 years. These groups were sub-divided to include women in their 20s, 30s and 40s. Normal women aged 22–49 were also studied, but they are considered as one group because no age-related trends in serum prolactin were found in a detailed analysis of these 24 control cycles [7].

None of the subjects had a history of gynaecological disorders nor was taking drugs, hormone preparations or other agents known to affect prolactin, ovarian steroid, or gonadotrophin levels.

Samples of peripheral venous blood (10 ml) were obtained daily, or as often as possible, between 09.00 and 12.00 hr for at least one menstrual cycle. The blood was left to clot, centrifuged, and serum removed for storage at −20°C.

Measurement of prolactin, follicle stimulating hormone (FSH), oestradiol-17β and progesterone

Prolactin was measured by the radioimmunoassay established in these laboratories by Cole and Boyns [8]. Results are given as milliunits/ml M.R.C. Res. Std. A 71/222 where 1 mu = 50 ng prolactin by this assay system. Displacement of 5% of bound iodinated prolactin was achieved by 0·04 mu/ml. Serum samples were assayed in duplicate, all those for an individual subject being together in one of the 8 assays that were required. So far as was possible, each assay contained samples from normal, cystic and fibroadenosis groups, where age and the length of menstrual cycle were comparable for women of each group.

Measurements of FSH were limited to women over 40 yr old. The radioimmunoassay of Groom *et al.* [9] was used and the results served as a check on whether the women had normal cycles with a marked mid-cycle peak.

The results of oestradiol-17β and progesterone radioimmunoassays have been published for these subjects [1, 10].

Analysis of results

Prolactin concentrations were calculated from standard curves using the preferred equation of Taljedal and Wold [11]. Values of less than 0·01 were entered into subsequent calculations as 0·01 mu/ml.

Menstrual cycles varied greatly in length and so two reference points were used: the day of the mid-cycle peak of oestradiol-17β was designated Day 0, taking gonadotrophin and progesterone profiles into consideration; the day of appearance of menstrual bleeding was labelled M.

Serum prolactin concentrations approximated to a log-normal distribution and so Student's *t*-test was applied to mean logarithms for making planned comparisons [12]. Back transformation of mean logarithms yielded the geometric means which have been plotted for simplicity.

The experimental design supported planned comparisons between normal and each of the other groups, and also between benign disease groups within the same age range. Such comparisons would utilize all or similar portions of the prolactin profile over the menstrual cycle. For examining changes occurring within a cycle, the Student–Newman–Keuls procedure was applied as these were essentially unplanned comparisons. Significant effects were not found for any experimental group by this procedure because of inter-subject variation.

Correlation analysis was used for testing the presence of age-related trends of prolactin concentration.

RESULTS

When patients were grouped by diagnosis and age (Table 1), the expected age-distribution was apparent, with cystic disease tending to occur in later years than fibroadenosis. Cycle lengths tended to be more variable than normal for these breast disease patients although the median values were similar. However, the number of days from the mid-cycle oestradiol-17β peak to onset of menstruation was 16·4 ± 2·25 (S.D., 10 cycles) for patients with cystic disease, whereas the fibroadenosis and normal groups had shorter luteal phases (14·4 ± 2·48 and 14·9 ± 1·69 for 16 and 21 cycles respectively: $2P < 0{\cdot}05$ vs cystic group).

In Table 2, prolactin concentrations for each experimental group are given, using three statistics of location with their associated statistics of dispersion. The geometric mean lies closer to the median value than does the arithmetic mean in every case. Furthermore, the range which should contain 95% of the prolactin concentrations around the geometric mean corresponds quite well with the 2·5–97·5 percentiles of the raw data in every group, whereas the standard deviation of the arithmetic mean implies many negative values. Hence a logarithmic transformation was applied to prolactin concentrations, and back-transformation to give geometric means has been

Table 1. *Allocation of subjects to groups, their age and the duration of their menstrual cycle*

adopted for clarity of presentation. Mean logarithms were used for significance testing by Student's *t*-test. As detailed in Table 3, though apparent from Table 2, prolactin concentrations were higher than normal in benign breast disease, especially in women who had had cysts aspirated, and predominantly so in the 40s age group. This group of older cystic patients had higher prolactin levels than either the younger group or the comparable age of fibroadenosis patients. An age-related trend was established for all the cystic patients (Fig. 1) by correlation analysis, which showed that geometric mean prolactin concentration over the complete menstrual cycle was positively correlated with age (Spearman rank correlation coefficient = 0·57, linear correlation coefficient r = 0·749, 10 degrees of freedom). No such correlations were significant for the fibroadenosis group, whether as a whole or as subgroups, nor for the normal subjects.

The daily patterns of geometric mean prolactin concentration are shown in Fig. 2. A striking feature of the benign breast cases is the

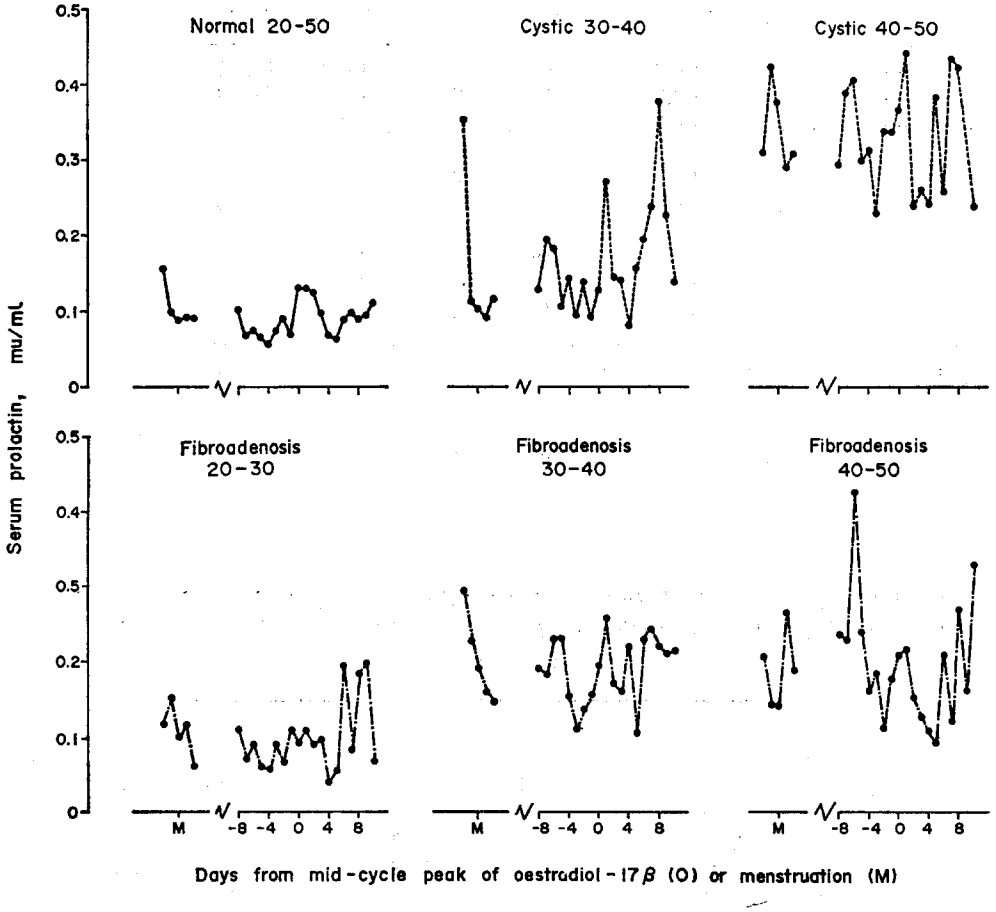

Fig. 2. Serum prolactin profiles of normal women ●——●, and patients with fibroadenosis ●—·—● or benign cystic disease of the breast ●– – –●. Geometric means are shown for days of the cycle aligned by reference to onset of menstrual bleeding (day M) and mid-cycle peak of oestradiol-17β (day 0).

wild fluctuation of serum prolactin level occurring over a few days. The small mid-cycle peak of the normal profile appears pronounced in the cystic breast disease groups and in all but the youngest fibroadenosis group. An abnormal follicular phase peak was similarly present. In the luteal phase, the gradual increase from about day +4 after the mid-cycle oestradiol-17β peak has become a sharp rise of prolactin concentration to a peak at about day +8. This is most clear for the group of women in their 30s in the cystic disease group because all five of them had similar luteal phases which differed by only 2 days.

Weekly patterns for serum prolactin are shown in Fig. 3. Day to day variations and errors due to misalignment of cycle days have been reduced by calculating mean levels over defined 5-day intervals in the menstrual, follicular, periovulatory and luteal phases. A clear pattern is found for normal subjects for whom luteal prolactin concentrations tend to be higher than in the follicular phase, and highest levels occur in the periovulatory phase (Fig. 3). In the benign breast disease patients, however, luteal phase prolactin concentrations were greater than in the periovulatory period, and follicular phase levels were higher than the normal pattern would predict in all but the youngest fibroadenosis group.

Significance levels are given in Table 4 for the planned comparisons that the data of Fig. 3 support. Prolactin concentrations of women with cystic disease were greater than in the normal women in the follicular and luteal phases, and for the remaining weeks in the older group. The cystic 30s group was significantly different from the cystic 40s, except in

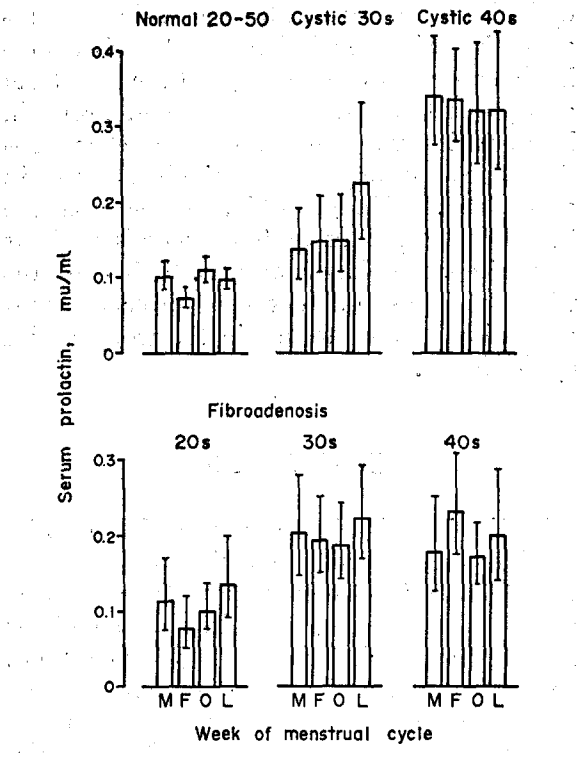

Fig. 3. Weekly patterns of serum prolactin in normal women and in patients with benign breast disease. Geometric means with their 95% confidence limits are shown for results which were pooled over 5-day intervals in the menstrual (M), follicular (F), periovulatory (O) or luteal (L) phases of the menstrual cycle.

the luteal phase, but no significant concentration differences were found when compared to the 30s group of fibroadenosis patients. Yet the older cystic group differed from the same age of fibroadenosis patients at all stages of the cycle. Both the 30s and the 40s group of fibroadenosis patients had significantly raised prolactin concentrations throughout the menstrual cycle, but the youngest group had prolactin levels which were above normal when considered overall and yet non-significantly so in each phase. Table 4 and Fig. 3 suggest that the 30s and 40s groups of fibroadenosis patients have similar prolactin profiles. This contrasts with the gross differences of prolactin concentrations related to age in the women with cystic disease.

DISCUSSION

Earlier investigations from these laboratories [3] indicated plasma prolactin concentrations were similar in benign breast disease, breast cancer at various stages and in control patients admitted to hospital for non-breast conditions. At least 2 other studies [4, 5] have also reported that prolactin levels in benign breast disease were within the normal range. These studies were based however upon single samples taken at random times in the menstrual cycle, which in association with rather imprecise terms like "benign breast disease" or "(poly)cystic mastitis", lessens the apparent discrepancy of previous results with the data now described. Furthermore, only one serum in every four had a prolactin concentration beyond the range found in normal menstrual cycles, even in the cystic 40s group (56/212 sera with more than 0·47 mu/ml). This illustrates the advantage of repeated sampling throughout the menstrual cycle.

The two benign breast diseases which were chosen for study were diagnosed by routine criteria, obtaining histological confirmation if practical. If a patient had a gross cyst from which fluid could be aspirated, then she was placed in the cystic disease group. If breasts had painful lumps, then such a condition was broadly termed fibroadenosis on exclusion of cancer, fibroadenoma, duct ectasia, inflammatory reactions, nipple discharge and many other distinctly defined breast complaints. It is obvious that the fibroadenosis group was much more heterogeneous than the cystic disease group and could obviously include microcysts and sub-clinical forms of other breast conditions.

Both cystic disease and fibroadenosis tend to become more severe in the few days before menstruation, and the symptoms disappear after the menopause [13] thus relating benign breast disease to ovarian function. As illustrated in Fig. 2, serum prolactin does not appear to follow oestrogens in a well defined monthly cycle [5, 7, 14–17], although it would seem that oestrogens play an important role in controlling secretion of human prolactin, and Vekemans and Robyn [17] have found a significant decline of prolactin concentration at the menopause in normal women blood donors. In a case of premenstrual syndrome associated with thirst and water retention, prolactin-suppressive therapy with bromocriptine has successfully relieved all symptoms for over a year [18]. Therefore, a cyclical variation of clinical symptoms may be linked to changes in serum prolactin concentration.

In the cystic disease group, there was a clear correlation between prolactin and age that was not present in the other groups. This correlation was in the opposite direction to that found by Vekemans and Robyn in their 86 normal women over their wider age range of 18–65 yr. Although cystic disease and raised prolactin may be associated, this does not prove that one causes the other nor does it exclude a common causative factor. However, the well established role of prolactin in water and electrolyte balance [1] has counterparts in humans as shown by the lowering of serum prolactin by water loading [19] or the relief of water retention by suppression of prolactin secretion [18]. Furthermore, a correlation has been demonstrated between the mean plasma prolactin concentration of male subjects and urinary Na/K excretion [20, 21]. The sign of this correlation became negative when diuretics were administered, which suggested that the diuretic response of an individual was a function of his prolactin set-point. As a working hypothesis then, serum prolactin concentration could control the movement of water and electrolytes into microcysts. A gross cyst would be formed as a consequence of localized fluid influx, and a more generalized swelling of microcysts may account for the cyclical pain in fibroadenosis. Normal breasts, which may also have microcysts [13], are in a prolactin environment that does not favour cyst enlargement.

The incidence of breast cancer in patients with gross cystic disease has been found to be 4 times higher than expected [13], but the raised prolactin levels in cystic disease cannot be given a role in carcinogenesis on the present

evidence since extrapolation is not possible from the 11 women of this study to the 1693 cases of cystic disease in the other study which included 72 that developed cancer [13]. Indeed, patients that have had mastectomy for breast cancer were found to have only minor abnormalities in their serum prolactin profiles throughout the menstrual cycle [7].

If the generally raised serum prolactin concentrations of these two benign breast conditions is a disease factor, then prolactin suppressive therapy would be effective. Such treatment is presently undergoing clinical trials which will be reported at a later date.

A Differential Interaction *In Vitro* of Mouse Macrophages with Normal Lymphocytes and Malignant Lymphoma Cells

AVRAHAM RAZ, MICHAEL INBAR and RACHEL GOLDMAN
Department of Membrane Research, The Weizmann Institute of Science, Rehovot, Israel

Abstract—In vitro *studies have shown that non-activated mouse peritoneal macrophages establish a differential interaction with mouse normal and malignant lymphocytes from syngeneic animals. The number of malignant lymphoma cells (YAC) bound to macrophages after 60 min of incubation at 37°C is 3–5 fold higher than that of normal lymphocytes. The binding of lymphoma cells to macrophages persists for at least 72 hr after cell–cell contact formation, whereas the normal lymphocytes detach from macrophages during the first 24 hr of incubation. Incubation of macrophage-lymphoma cell rosettes for 72 hr results in an extensive phagocytosis of about 50% of the bound lymphoma cells. However, replacement of the culture medium with fresh medium every 24 hr bolished the ingestion of the lymphoma cells without changing their attachment to rop ahages.*

INTRODUCTION

DIVERSE functions have been ascribed to mononuclear phagocytes. Among the most extensively studied are those involving phagocytosis of invading organisms and senescent self cells, killing of tumour cells, interaction with immunocompetent lymphocytes, elimination of cell debris in inflammation and secretion of various macromolecules [1–4]. There is no doubt that expression of several of these functions demands an intimate contact between the macrophages and the cell on which the function is exerted. Evidence is accumulating, however, of the release of soluble factors from macrophages, either under normal conditions or due to external nonspecific or immunologic stimulation that may replace the macrophage [5, 6].

A wide range of reports on macrophage cytotoxicity seems to establish contradictory concepts. According to the different experimental designs, cytotoxicity was found to be both non specific in some systems [7–10] and specific in others [11, 12]; killing was observed in some [9, 10, 13] whereas in others macrophages brought about cytostatic effects [7, 8, 14]. While several authors report on spontaneous nonspecific cytotoxicity towards tumour cells in "normal" macrophages derived from unstimulated animals [8, 15]. others report on development of such activities only in macrophages infected with bacteria and parasites [10, 16, 17]. Immunologically specific macrophage cytotoxicity depending on T-cell arming factors has also been extensively studied [18, 19] An unexpected observation of Nathan and Terry [20] adds to the already confused situation in that macrophages were shown to exert a differential stimulation of murine lymphoma cells.

Close contacts between guinea pig macrophages and lymphocytes have been shown to develop via an immunological species and strain specific mechanism as well as via a non immunological species but not strain specific mechanism [21–23], Lymphoma cell growth *in vitro* was shown to be inhibited by normal macrophages [15] and stable cell–cell contact between lymphoma cells and normal macrophages have also been described [24]. In both cases specific conditions could be found where immunological activated macrophages were more efficient.

The following study was undertaken to determine (a) whether there is a differential attachment of normal and malignant lympho-

Accepted 26 October 1976.

cytes to mouse peritoneal macrophages and (b) whether the attachment of the two cell types to macrophages is followed by phagocytic events.

MATERIAL AND METHODS

Media

Sterile phosphate buffered saline (PBS), Dulbecco's modified Eagle's medium (EM) supplemented with 100 u/l penicillin and 100 μg/l streptomycin and heat inactivated newborn calf serum (NCS) were obtained from Grand Island Biological Co. (N.Y.).

Cells

Peritoneal macrophages were aseptically collected from A and BALB/c strain mice (4–6 weeks old), following essentially the method of Cohn and Benson [25]. Peritoneal exudate cells suspended in medium were allowed to attach (1 hr, 37°C) on 25 mm diameter Corning cover-glasses, placed in Flacon plastic tissue culture dishes (35 × 10 mm, Falcon Plastics Div. Bioquest, Oxnard, Calif.). Peritoneal exudate cells containing about $0{\cdot}5 \times 10^6$ macrophages were applied in 0·2 ml medium to the cover-glasses. The attached cell monolayers were thoroughly rinsed with PBS in order to remove the nonadhering cells. The cultures were then cultivated for 24 hr at 37°C in 2 ml of 20% serum in medium, in a CO_2-incubator (5% CO_2–air mixture).

Thymus derived lymphocytes, splenocytes and lymph node cells of A mice were collected by teasing the respective organs apart. Tissue pieces and visible cell clumps that settle to the bottom of the tube by gravity were discarded.

Malignant lymphoma cells, an ascites form of a Moloney virus-induced lymphoma (YAC) [26] were grown in A strain mice by intraperitoneal inoculation of 10^5 cells per animal, and collected for experiments 11–14 days after inoculation.

For the experiments normal lymphocyte and malignant lymphoma cells were freshly collected from animals in PBS, washed twice and resuspended in medium before use.

Interaction of macrophages with normal and lymphoma cells

Macrophage monolayers were washed twice with PBS and exposed to 30×10^6 normal lymphocytes or lymphoma cells in 2 ml of medium for 60 min at 37°C. Culture plates were subsequently washed twice in PBS and were either fixed (2% glutaraldehyde 30 min, 4°C) or reincubated in 20% serum in medium for 72 hr and fixed. Culture plates were then stained (Giemsa) and cells attached per 100 macrophages were enumerated in tetraplicate cultures. Attached cells were readily distinguished from ingested cells by the colour changes and irregular contour of the latter. The stained cultures were examined and photographed with Karl Zeiss Ultraphot microscope.

RESULTS

Attachment of normal lymphocytes and malignant lymphoma cells to macrophages Thymus derived lymphocytes establish few stable cell–cell contacts with the macrophages (Fig. 1b) whereas lymphoma cells form stable rosettes at the periphery of the macrophages (Fig. 1c). Quantitation of the differential interaction of thymus derived lymphocytes and lymphoma cells with macrophages established a 3–5 fold higher interaction for the latter (Table 1). Macrophages are free of any interaction with extraneous cells unless incubated with thymus derived lymphocytes or lymphoma cells (Fig. 1a). Binding of YAC lymphoma cells to macrophages was not affected even by *in vitro* growing of the lymphoma cells for two passages.

*Macrophages were incubated with 30×10^6 lymphoma cells or thymus-derived normal lymphocytes in medium for 60 min at 37°C.

Macrophage–lymphocyte rosette formation following macrophage incubation with either lymph node lymphocytes or spleen cells was of the same extent as that established with thymus-derived lymphocytes.

Analysis of the distribution curve of lymphoma cells attached to macrophages indicate that 88% of macrophages establish stable contacts with lymphoma cells and the number of attached cells per macrophage appears to follow a Gaussian distribution. Thus the whole macrophage population is apparently capable

of forming cell–cell connections and the adherence phenomenon is not limited to a small subclass of macrophages (Fig. 2). A small subclass of macrophages incapable of binding of lymphoma cells is however not excluded.

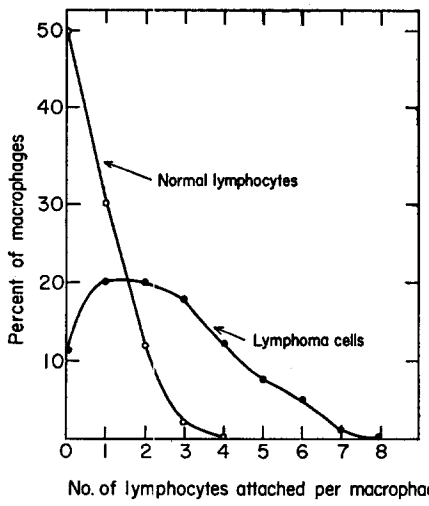

Fig. 2. Distribution curves of thymocyte and lymphoma cell attachment to macrophages. Based on experiments 1–3 *in Table* 1.

To assess whether the macrophage–lymphoma cell association is strain dependent, macrophages derived from BALB/c mice were cultivated and interacted with lymphoma cells under conditions comparable to the above. BALB/c macrophages were found to establish 10% of the cell–cell association observed with macrophages derived from A mice.

Ingestion of malignant lymphoma cells by macrophages

Most of the studies reporting nonimmunological cytotoxic effects of nonspecifically activated peritoneal macrophages on malignant target cells were carried out under conditions of prolonged incubation of the interacting cells. Destruction of target cells is readily observable at 60–72 hr of cell–cell interaction and does not involve phagocytic events though cell debris has been shown to be disposed of within the macrophages [24].

Incubation of lymphoma cell–macrophage rosettes for 72 hr in 20% serum–medium results in up to 50% interiorization of the attached lymphoma cells (Table 2). The total number of lymphoma cells associated with macrophages (ingested — attached) at 72 hr incubation is equivalent to the number associated with macrophages at the beginning of the incubation, namely after a 60 min incubation with lymphome cells and ×2 wash in PBS. It is worth mentioning at this point that thymus derived lymphocytes detach from the macrophages in the course of the first 24 hr of incubation and therefore no comparable studies with these cells could be carried out.

The light micrographs of macrophage–lymphoma cells cultured for 72 hr (Fig. 3a) suggest that normal macrophages are capable of both ingestion and digestion of lymphoma cells. The morphological observations further indicate that whole lymphoma cells are ingested and not just fragments of debris derived from degenerating cells. Instead of the strong homogeneous staining pattern of attached lymphoma cells, those ingested stain by Giemsa in a faded colour and non-homogeneously. Macrophage–lymphoma cell rosettes incubated for 24 hr show a very low index of phagocytosis (about 5% of attached lymphoma cells are ingested). Particles or cells that are phagocytozible by macrophages are usually ingested within a period of minutes of the time of their attachment.

Macrophage maturation in culture involves an increase in phagocytic capacity [27]. On the other hand continuous secretion of biologically active macromolecules including various enzymes from macrophages as well as from the lymphoma cells may modulate both the macrophage and the attached lymphoma cell plasma membrane and metabolism. In order to establish whether the maturation of macrophages *per se*, the aging of lymphoma cells or components accumulated in the culture medium within the 72 hr are detrimental in the delayed phagocytic response (most effective only after 48 hr incubation of rosettes) the following experimental procedure was adopted macrophage–lymphoma cell rosettes were incubated for 72 hr (37°C) in 20% serum–medium as above but culture medium was replaced by a fresh medium at 24 hr intervals. A striking difference in the fate of the lymphoma cells in indicated in Fig. 3(b). Practically no ingestion was detected under this condition, the cells remain adherent to macrophages and seem to form clusters over the entire area of the macrophage. Additional evidence to support the results obtained with the light microscopy techniques (Fig. 1, 3) was gathered by the aid of scanning and transmission electron microscopy (Fig. 4).

The differential interaction of macrophage–lymphoma cells with and without serum–medium replacement excludes the maturation of macrophages as the detrimental factor for the observed phagocytosis at 72 hr as opposed to lack of phagocytic activity at 24 hr. It should

be emphasized however that macrophages cultured for 72 hr with and without serum–medium replacement may differ to some extent in their metabolic activity and endocytic activities [27]. Figs 3c and 3d indicate a morphological difference under the two culturing conditions expressed in abundance of minute phase lucent vesicles in cultures incubated in serum–medium for 72 hr without replacement as compared to moderate vesicle formation in cells incubated with fresh serum–medium every 24 hr.

DISCUSSION

Normal macrophages have been shown to establish a differential interaction pattern with lymphocytes and malignant lymphoma cells. The interaction with lymphoma cells involves both a high degree of rosette formation (Table 1) and the development of stable cell–cell contacts; i.e., the number of attached lymphoma cells is not reduced with a 72 hr incubation period (Fig. 3b). The degree of rosette formation with normal lymphocytes derived from the thymus, spleen and lymph nodes is several times lower than that with lymphoma cells and the attached lymphocytes detach within the first 24 hr of incubation.

Viral induction of malignant transformation, changes various parameters of cell physiology. One of the most extensively studied parameters is that involving changes in plasma membrane composition, organization and function [28–29].

The high degree of macrophage interaction with lymphoma cells reported in the above could reflect a recognition by the macrophage of alterations in surface properties of the attached cell. It is of interest that this interaction depends on syngeneity of macrophages and lymphoma cells; namely macrophages from BALB/c mice that do not serve as hosts for YAC lymphoma cell transplantation do not form extensive interactions with the lymphoma cells. Activated mouse macrophages exhibit a cytotoxic effect on tumorigenic 3T12 and SV 40 3T3 transformed fibroblasts and are noncytotoxic to their nontransformed parental cell-line 3T3 fibroblasts [9]. Lipsky and Rosenthal [21] report however that two normal lymphoid cell populations, thymus and lymph node lymphocytes, were bound to syngeneic guinea pig macrophages in significantly larger numbers than L_2C leukemia cells. In the guinea pig macrophage–thymocyte interaction is exceptionally high, amounting to up to 300 thymocytes per 100 macrophages [21, 22, 30]. In the A mouse our results indicate a much lower degree of interaction of thymus-derived lymphocytes with macrophages.

Stable cell–cell associations of lymphocytes and macrophages have been frequently observed during *in vitro* cultivation of these cells [31–33], as well as in fixed preparations of lymphoid organs [34, 35]. Under *in vivo* conditions clusters of lymphocytes and blast cells around macrophages are formed in response to immunization procedures [34, 35]. Likewise the *in vitro* induction of primary antibody responses and antigen-mediated *in vitro* proliferation of immune lymphocytes [32, 33] has been shown to involve direct physical contact between lymphocytes and antigen-containing macrophages. Lymphocytes have also been found to adhere to macrophages both *in vivo* and *in vitro* in the absence of specific immunization [21, 22]. When macrophage–lymphocyte associations involve antigen [2] or lectin [6] presentation, the result of the association is lymphocyte proliferation. Very rarely have phagocytic events been observed.

The association of nonimmune and nonactivated peritoneal macrophages with a variety of lymphoma cells has been reported to result in inhibition of proliferation and (^{3}H)-thymidine uptake [15]. Many of the studies suggest the need for macrophage–lymphoma contact and indicate that though immune and nonspecifically activated macrophages are more efficient in their growth inhibition capacity, normal macrophages are also endowed with cytostatic as well as cytotoxic capacity [14, 24].

Most experimental systems studied use macrophage-target cell ratios of 100:1, 40:1, 10:1, 5:1 and rarely a ratio of 1:1 [7, 14, 17, 24]. The differential activity of activated vs normal macrophages is mostly evident under conditions of a low ratio of macrophage to target cell [14, 24].

In our studies we have used a ratio of 1:60 of macrophages to target cells. This ratio enabled the establishment of extensive interactions of macrophages and lymphoma cells; on the average 2.5 lymphoma cells were associated with each macrophage in the culture.

An incubation of macrophage–lymphoma cell rosettes for 72 hr without culture medium replacement results in an extensive phagocytosis of adherent lymphoma cells (Table 2). Up to 50% of macrophages were involved in phagocytosis of lymphoma cells and up to 50% of the adherent cells were ingested. In contra-distinction when culture medium was changed every 24 hr for fresh culture medium the macrophage adherent lymphoma cells preserved their stain-

ing characteristics with the Giemsa stain, and were all attached to macrophage surface.

Extensive ingestion of lymphoma cells has not been reported hitherto though Lejeune and Evans have observed engulfment by macrophages of lymphoma debris [24]. An early report by Bennett *et al.* [36] suggests that even peritoneal macrophages from immunized mice do not exhibit an inherent specific ability to phagocytose tumour cells *in vitro*, unless the medium contained a humoral antibody against the tumor.

The differential interaction of macrophage–lymphoma cells under conditions of culture medium replacement and continuous culture in the same medium is not fully understood. Several possible processes may be involved in the phenomenon, either of which can be the major responsible factor or they may exert synergistic effects.

During the extended incubation time of macrophage–lymphoma cell rosettes both cell types may undergo metabolic as well as surface changes. Recent studies in our laboratory indicate a continuous maturation process of macrophages in culture, during which the phagocytic activity increases and surface morphology changes [27]. The functional changes during maturation depend on whether or not the culture was incubated continuously in the same serum medium or whether culture medium was replaced every 24 hr. Figures 3(c) and 3(d) amply show the differential morphology of macrophages under the above-mentioned conditions. Moreover, macrophages release factors and various enyzmes to the medium [1, 37]. Their accumulation within 72 hr of incubation may act on both the macrophages as well as on the adherent lymphocytes and render them more susceptible to phagocytosis. Metabolic changes, cytostatic or cytotoxic effectors may serve as signals for macrophage scavenging capacity. Bennett *et al.* [36] have in fact shown that under certain conditions killed tumor cells are readily phagocytosed even without opsonization with isoantibody. If mediated by products released from macrophages, the fact that almost no phagocytosis is observed under conditions of culture–medium replacement means that a concentration factor for the product has to be involved. Either its secretion within 24 hr is not sufficient for triggering phagocytic events or the enriched aged medium enhances in itself product secretion. Macrophage challenge with tumor cells has been shown to cause rapid changes in lysosomal morphology and content [24]. It is not impossible that rosette formation serves in itself as a challenge for macrophage activation. That this would be more effective without culture medium replacement can stem from need of factors released by either macrophages, that upon activation release more enyzmes and biologically active products [28], or by lymphocytes. So that in addition to macrophage involvement in the phagocytic event, lymphocytes could mediate potentiation of macrophage function.

The various aspects of *in vitro* lymphoma cell interaction with macrophages and the phagocytic events that conclude it are currently under investigation. It is hoped that studies of the *in vitro* macrophage–lymphoma cell interaction would help to understand the *in vivo* situation where 10^3 lymphoma cells injected i.p. escape *in vivo* the resident peritoneal macrophage population ($1–2 \times 10^6$ cells), proliferate and kill the mouse within 20–25 days.

Protocol for a Cooperative Trial of Empirical Antibiotic Treatment and Early Granulocyte Transfusions in Febrile Neutropenic Patients

E.O.R.T.C.* INTERNATIONAL ANTIMICROBIAL THERAPY PROJECT GROUP†

**E.O.R.T.C.: European Organisation for Research on Treatment of Cancer*

†Chairman: H. Gaya, Bacteriology Department, St Mary's Hospital Medical School, London, Great Britain; Secretaries: J. Klastersky, Service de Medecine et Laboratoire d'Investigation Clinique, Institut Jules Bordet, Bruxelles, Belgium; S. C. Schimpff, Baltimore Cancer Research Center, Baltimore, Md, U.S.A.; M. H. N. Tattersall, Department of Oncology, Charing Cross Hospital, London, Great Britain; S. Zinner, Department of Medicine, Roger Williams General Hospital, Providence, R.I., U.S.A.

INTRODUCTION

THE RECENTLY completed E.O.R.T.C. trial [1] indicates that (a) empirical treatment with carbenicillin + gentamicin, carbenicillin + cephalothin and cephalothin + gentamicin cures respectively 69%, 45% and 62% of gram negative bacteremias in neutropenic patients; (b) significant nephrotoxicity occurs in 15% of the patients treated with cephalothin and gentamicin compared to those treated with cephalothin + carbenicillin (6%) and carbenicillin + gentamicin (2·4%).

Thus the "optimum" empirical antimicrobial regimen at present available (carbenicillin + gentamicin) still leaves ample room for improvement. This improvement may be obtained by adding to the carbenicillin + gentamicin combination a third drug (a cephalosporin) and/or by giving to the infected patient, early in the course of his infection, transfusions of granulocytes; the exact value of this treatment for infected neutropenic patients has still to be defined. It would be best however, for transfusions of granulocytes to be tested in a "poor risk" group of patients, defined by an analysis of the data from the last trial.

The "poor risk" group of patients will consist basically of those patients who are predicted to have gram negative septicemia and whose bone marrow is not expected to show any sign of recovery within 7 days following the start of therapy. The following are predictive of gram negative septicemia: (1) granulocyte count < 100/μl; (2) creatinine level > 1·0 mg%; (3) temperature > 39·0°C; (4) platelet count < 50,000/μl. All the patients eligible on these criteria for granulocyte transfusion will undergo a bone marrow aspiration (bone marrow aspirations performed between 48 hr before and 24 hr after onset of therapy are acceptable); retrospectively only patients with a hypocellular marrow (0 or + on a scale of 0 to + + + + where + + + is normal, as used by ALGB) will be considered to belong to the "poor risk group" provided they also present 3 out of 4 factors predictive of gram negative bacteremia mentioned above. Patients who are started on the protocol and who, retrospectively, do not have a hypocellular marrow will be considered as "protocol violations".

The patients should be followed in the protocol until discharge from the hospital or death.

Amikacin will be substituted for gentamicin because of its twice daily dosage and better *in vitro* activity against Klebsiella. Cefazolin will replace cephalothin as cephalosporin.

The study is designed to answer the following questions:

(1) Does the addition of cefazolin to amikacin + carbenicillin improve the response of infections in neutropenic patients? (Poor and good prognosis patients will be studied separately).

(2) Does a moderate dosage of cefazolin added to amikacin + carbenicillin carry a

Accepted 28 October 1976.

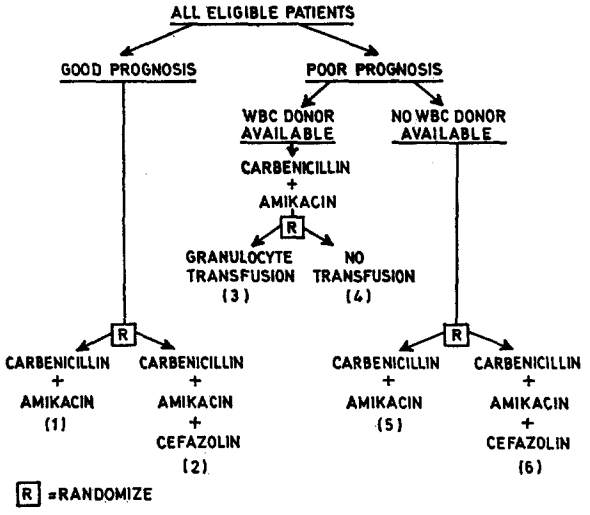

Fig. 1.

risk of nephrotoxicity similar to that found in the previous E.O.R.T.C. study?

(3) In poor-risk patients what is the value of early administered granulocyte transfusions?

(4) Do differently collected granulocytes affect the outcome of severe infection in neutropenic patients in a different way?

(5) What are the side effects of transfusions of granulocytes and can they be related to the mode of collection of the granulocytes and to other factors such as premedication of the donor and histocompatibility?

(6) What are the causes of death in infected neutropenic patients?

(7) Can gram negative bacteremia and the implied subsequent poor prognosis be predicted by the criteria given above?

EMPIRICAL ANTIBIOTIC/GRANULOCYTE TRIAL

RANDOMIZATION CARD

PATIENT NAME: _____ PATIENT-TRIAL NO: _____
HOSPITAL: _____ HOSPITAL NO: _____
INVESTIGATOR: _____ PATIENT AGE (YRS): _____
RANDOMIZED BY: _____ DATE OF RANDOMIZATION: _____

a) GRANULOCYTE COUNT: If < 100/μℓ enter 1; otherwise 0 ___
b) SERUM CREATININE: If > 1.0 mg % (88.4 mmol/L) enter 1, otherwise 0 ___
c) TEMPERATURE: If > 39.0°C (102.2°F) enter 1; otherwise 0. ___
d) PLATELET COUNT: If < 50,000/μℓ enter 1; otherwise 0. ___

TOTAL ___

If the TOTAL score = 0, 1 or 2 go to Section A (Good prognosis)
If the TOTAL score = 3 or 4 go to Section B (Poor prognosis)

A. GOOD PROGNOSIS PATIENTS
Allocated regimen is:-
1. CARBENICILLIN + AMIKACIN
2. CARBENICILLIN + AMIKACIN + CEFAZOLIN
GO TO SECTION E

B. POOR PROGNOSIS PATIENTS
Is there a granulocyte donor available? YES ___; NO ___
If YES go to Section C. If NO go to Section D

C. POOR PROGNOSIS, DONOR AVAILABLE
Allocated regimen is:-
3. CARBENICILLIN + AMIKACIN + GRANULOCYTES
4. CARBENICILLIN + AMIKACIN (NO GRANULOCYTES)
GO TO SECTION E

D. POOR PROGNOSIS, NO DONOR
Allocated regimen is:-
5. CARBENICILLIN + AMIKACIN
6. CARBENICILLIN + AMIKACIN + CEFAZOLIN
GO TO SECTION E

E. ALL PATIENTS: Enter number (1-6) of allocated regimen

Please complete and return this randomization card to the Statistical Center (Dr. H. Gaya) IMMEDIATELY
Retain the Clinical Report Form. Complete and return it to the Statistical Center within 4 weeks.

Fig. 2.

PROTOCOL (FIG. 1)

(A) *Eligibility*

Patients with neutropenia (< 1000 neutrophils/μl) and with fever (> 38·5°C) in the absence of obvious non-infective causes.

Patients are allocated to their treatment by drawing the next envelope from the stock supplied to each participating center. The required patient details must be entered immediately on the postcard provided (Fig. 2) and sent to the Statistical Center, even if the patient is subsequently excluded from the trial. Patients with known severe allergy to any of the anti-biotics in any of the regimens are excluded. Patients with any serum creatinine level are eligible; however, in patients with increased creatinine levels an adjustment of the dosage of amikacin should be made. The method proposed by Cutler and Orme (*J. Am. Med. Ass.* **209,** 539, 1969) can be used here: interval between 2 consecutive doses (in hours) = creatinine level in mg% × 9.

Patients may be included in the protocol more than once, provided there is an interval of 20 days between the two onsets of therapy and provided the patient has been off antimicrobial therapy for 5 days prior to the onset of the second treatment.

(B) *Investigations*

(a) *Before starting treatment:* (1) *Bacteriological.* Blood cultures (3 ×), swabs from relevant lesions, urine and sputum and pharyngeal swab or transtracheal aspirated material if feasible. All significant bacterial pathogens are tested by the Kirby–Bauer technique for susceptibility to carbenicillin (100 μg discs), cefazolin (30 μg discs) and amikacin (10 μg discs). Determination of the minimal inhibitory concentration is desirable but optional. (Use 10^5/ml inoculum and Mueller–Hinton broth.)

(2) *Virological and mycological.* Acute serum for virological screening (at least Herpes simplex and Cytomegalovirus) and for detection of antifungal antibodies (at least *Candida* and *Aspergillus*). Technique used should be specified.

(3) *Biochemical.* Serum creatinine, blood urea, uric acid, electrolytes (Na^+, K^+, intracellular K^+, Cl^-, HCO_3^-), transaminases (SGOT, SGPT), alkaline phosphatase.

(4) *Hematological.* Hematocrit, hemoglobin, total WCC, differential WCC, platelet count.

(5) *Immunological.* Take, separate and store serum from 10 ml blood in deep freeze.

(6) *Radiological.* Chest X-Ray.

(b) *During treatment:* (1) *Bacteriological.* Repeat after 72 hr, including 1 × blood culture, then twice weekly.

(2) *Virological and mycological.* Once weekly.

(3) *Biochemical.* Twice weekly.

(4) *Haematological.* Twice weekly.

(5) *Immunological.* Once weekly.

(6) *Radiological.* Repeat chest X-ray at 72 hr if initial X-ray was negative and no other site of infection found.

(7) *Control of antimicrobial therapy.* Serum for back-titration against the offending pathogen; to be obtained 1 hr and 6 hrs after the administration of antibiotics on the second day of treatment.

(c) *After treatment:* (1) *Bacteriological.* Once (without blood cultures).

(2) *Virological and mycological.* Once.

(3) *Biochemical.* Once.

(4) *Hematological.* Once.

(5) *Immunological.* Once.

(6) *Radiological.* Once.

Notes. Other investigations should be done when and where indicated.

For patients receiving granulocyte transfusion 1 hr and 12 hr post transfusion white counts are taken; the HLA-type of both patients and donors should be determined.

For patients dying during treatment or during the follow-up period a complete autopsy report (including histologic findings) and results of cultures of heart, blood, spleen and lungs (and relevant lesions) should be attached to the final report form.

Temperature should be recorded 6-hourly during the period of treatment. Photocopies of the patient's temperature chart must be attached to the final report form*.

Bacteriological evaluation. Microorganisms isolated from the blood (bacteremic patients) should be sent to the reference laboratory (Institut Jules Bordet) with samples of serum (5 ml) obtained 1 hr and 6 hr after the injection of amikacin plus carbenicillin (and cefazolin). *In vitro* synergism and minimum inhibitory concentrations for the antibiotics given to the patient from whom the microorganism has been isolated are deter-

*Official report forms are provided to the participating Centers along with the randomization cards.

mined along with the antimicrobial activity of the serum against that organism.

Clinical evaluation should be performed by the principal investigator at the center 4 days after start of therapy and at the end of the therapy. The notes should be brief but describe accurately the status of the patient and the opinion of the attending physicians.

(C) *Granulocyte transfusion trial*

(a) *Definition of the poor prognosis group.* The criteria for inclusion in the poor prognosis group are listed on the randomization card. These criteria include serum creatinine level, level of neutropenia and thrombocytopenia, and height of fever. They must be confirmed by a bone marrow examination, showing a hypocellular bone marrow as defined earlier.

(b) *Administration of granulocytes.* When demanded by randomization, granulocytes are started within 24 hr after the onset of therapy with amikacin + carbenicillin (see below). They are administered daily for at least 4 consecutive days. The daily administered dose must exceed 10^{10} cells/m^2. The method of collection of granulocytes is unimportant, but *should be consistent* in the same patient. The control patients should not receive granulocytes during the first 96 hr of therapy with antibiotics unless their clinical condition continues to deteriorate following initiation of the protocol antibiotics. Addition of granulocytes during that time would mean failure of antibiotics alone.

(D) *Antimicrobial therapy trial*

(a) *Dosage. Amikacin.* 15 mg/kg daily in 2 divided doses; for the average adult give 500 mg/12 hr.

Carbenicillin. 500 mg/kg daily in 4 divided doses; for the average adult give 10 g/6 hr. Ticarcillin may be used instead of carbenicillin at a dose of 250 mg/kg daily; for the average adult give 5 g/6 hr.

Cefazolin. 50 mg/kg daily in 4 divided doses; for the average adult give 1 g/6 hr.

(b) *Mode of administration.* All the antibiotics are given intravenously. The i.v. injection is given in 100 ml of water and administered over a 15 min period. The antibiotics should never be mixed together. Each dose of amikacin should be administered immediately following the carbenicillin (and cefazolin) injection(s). Pediatric doses of the antibiotics should be given in a proportionately reduced volume of water.

(c) *Duration of therapy.* Antibiotics should not be changed during the first 5 days of therapy unless there is microbiological evidence of inadequate coverage *associated with* an inadequate clinical response. The response to trial antibiotics should then be considered as a failure. After 5 days of treatment, inappropriate antibiotics, on the basis of susceptibility tests, may be discontinued. If pathogens resistant to the antibiotics in the trial regimen are isolated and considered as significant pathogens, addition of new antibiotics is allowed, as indicated by susceptibility tests. Adding new antibiotics means that the response to the trial antibiotics is a failure.

If no significant pathogen has been isolated, the trial regimen should be continued for at least 5 days after temperature has returned to normal. If no clinical response has occurred, other agents may be added to the regimen if clinically indicated, but the trial regimen must be continued until 5 days of treatment have been completed.

If the patient has no infection (infection doubted), stop all antibiotics at 5 days and observe. Antibiotics should be stopped even if the patient is still febrile provided no other evidence of infection is present on thorough repeated history, physical examinations, chest X-rays and laboratory investigations.

(E) *Optional additional measures*

These measures (oral antibiotics, isolation, vaccine, etc), if used, must be applied equally and without preference to each treatment group in the same way and for the same length of time.

(F) *Definitions*: (1) Documentation:

1 = Microbiologically documented. Signs and symptoms of infection present (i.e. primary site of infection recognised) and positive bacteriological cultures obtained from the suspected site, blood cultures, or histological sections.*

2 = Clinically documented. Site of infection identified and progress consistent with infection. Negative cultures from primary site and blood.*

3 = Possible infection. Signs, symptoms and progress are consistent with infection. Negative cultures and no site found despite complete re-examinations, history, X-rays and cultures at least every 3 days.

4 = Infection doubted. Infection improbable on review of clinical signs and progress.

*e.g., a pulmonary infiltrate is a pneumonia if consistent with proper signs and symptoms of infection—*clinically documented*—but is *microbiologically documented* if (1) blood cultures are positive, (2) sputum culture is positive with a clear preponderance of one organism, the specimen is of good quality (i.e., not saliva), etc., or (3), positive results are obtained from transtracheal puncture, biopsy, etc. . . . Pneumonia remains *clinically documented* if blood cultures are negative or no blood cultures were taken and sputum sample was of poor quality or had mixed flora.

(2) Response to therapy: (clinical evaluation at 4 days and after discontinuation of protocol).

1 = Improved.† Lasting return of temperature, signs and symptoms to normal or to pre-infectious state.

2 = Temporary improvement. As for "Improved" but with relapse in 3–6 days despite continuing antibiotic therapy.

3 = Failure. Infection persists or patient dies or is treated with other antibiotics.

4 = Not evaluable. Patient improves or remains unchanged but response cannot be related specifically to antibiotics or granulocyte therapy. Also if fungal or viral infection, or infection doubted.

†*EXAMPLES*

Pneumonia. Improvement requires patient to become afebrile, have resolution of pulmonary signs and symptoms and to show resolution of pulmonary infiltrate, although X-ray clearing may lag behind clinical response.

Urinary tract infection. Improvement requires resolution of fever, signs and symptoms and at least one negative culture after stopping antimicrobial therapy.

Bacteremia. Improvement requires at least one negative blood culture after cessation of antibiotics.

A superinfection (e.g., *Aspergillus* pneumonia on top of primary *E. coli* pneumonia) may make evaluation impossible by the above criteria. In such a case consider the *E. coli* pneumonia improved if signs and symptoms were improving, pulmonary infiltrate was clearing, blood cultures were negative, etc. . . ., when new pneumonia supervened.

RESULTS AND ASSESSMENTS

Clinical reports should be completed and sent to the Statistical Center within 2 weeks of completion of treatment.

PUBLICATIONS AND LECTURES

Nothing shall be published and no lectures shall be given by any of the participating members of the Group about either the work or the results of the trial without consent of the Group. However, each participant is free to publish data from his own patients and wards.

Encephalopathy Following Bone Marrow Transplantation

Abstract—*Increasing numbers of bone marrow transplants are now being attempted for the treatment of acute leukemia. A case of encephalopathy following syngeneic marrow transplantation is described in which the main causative factor was thought to be the total body irradiation given as part of the conditioning regimen prior to transplantation. The possible cumulative risk of encephalopathy and myelopathy in patients previously given cranial or craniospinal irradiation and intrathecal methotrexate is discussed.*

INTRODUCTION

Several hundred bone marrow transplants for the treatment of acute leukaemia are currently being performed each year [1]. A number of these patients, especially those with acute lymphoblastic leukemia (ALL), have previously received cranial or craniospinal irradiation and/or intrathecal (IT) methotrexate (MTX). Total body irradiation (TBI) is frequently employed in an attempt to eradicate residual leukaemia prior to marrow transplantation. Whilst encephalopathy due to cumulative doses of MTX [2, 3], cranial irradiation [4], and a combination of IT cytotoxic chemotherapy, cranial irradiation and central nervous system (CNS) leukaemia [5] is now well recognized in children receiving conventional therapy for ALL, its occurrence due to the additive effect of such factors and TBI in patients undergoing bone marrow transplantation has not been previously described [6], although the potential risk has caused concern.

MATERIAL AND METHODS

Case report

A boy aged $3\frac{1}{2}$ yr had ALL diagnosed in September 1974. He was a monozygotic twin and his sibling was not affected. His initial blood count was: haemoglobin 100 gm/l., white count 160×10^9/l., with 80% lymphoblasts, 14% lymphocytes and 10% neutrophils. His platelet count was $45 \times 10/^9$l. Chemotherapy with prednisone, vincristine and 6-mercaptopurine produced a partial remission with return of the peripheral blood to normal, but 4% blast cells remained in the bone marrow. It was felt that these blast cells were leukaemic. At this time the cerebrospinal fluid (CSF) was normal, and prophylactic cranial irradiation (2000 rad in $2\frac{1}{2}$ weeks) together with 5 IT injections of MTX (10 mg/m^2) was given. This course of radiation was given from a 230 kV machine using fractions of 400 rad twice weekly for $2\frac{1}{2}$ weeks, at a dose rate of 78 rad/min. A 2 mm Cu. H.V.L. filter was used; the focus skin distance was 50 cm, and the separation between the two fields was 15 cm. The course was started on October 25, 1974 and finished on November 8, 1974. Apart from some post-irradiation somnolence lasting 2 weeks, and occurring 5 weeks after the end of prophylactic cranial irradiation, he remained well, but a bone marrow aspirate in December 1974 showed relapse. Further chemotherapy with prednisone, vincristine, 6-mercaptopurine, MTX, daunorubicin, cytosine arabinoside and asparaginase failed to produce a remission. Re-examination of the CSF at this time (December, 1974) showed blast cells to be present and he received a further four injections of IT MTX. Because he had an identical

Accepted 19 November 1976.

Address Correspondence to: Kerry Atkinson, M.R.C.P. Fred Hutchinson Cancer Research Center, Division of Oncology, 1124 Columbia Street, Seattle, Washington 98104, U.S.A.

twin and was clearly doing badly it was decided to carry out a bone marrow transplantation. On February 10, 1975 after preparation with cyclophosphamide 60 mg/kg on two consecutive days followed three days later by TBI of 1000 rad in $3\frac{1}{2}$ hr from a ^{60}Co machine using a dose rate of 5 rad/min, he received bone marrow taken from his identical twin brother. He progressed satisfactorily, obtained a functioning graft, and bone marrow aspirate showed no evidence of leukaemia.

One month after bone marrow transplantation (March 1975), he gradually became drowsy and irritable, developed slurred speech and his gait was unsteady. Examination showed a right foot drop and increased tone in both legs but nothing else abnormal. The CSF, skull X-ray and brain scan were all normal, but the EEG showed grossly abnormal diffuse bilateral slow activity in all areas. Serum taken two months after the transplant contained no antibodies against measles or papovavirus; the titre against cytomegalovirus (CMV) was 1/32, against mycoplasma 1/32, and against influenza A 1/64. He became progressively more unresponsive, mute and, in addition to dementia, developed a spastic quadriplegia. This state persisted with little change for eight months. He also had occasional myoclonic jerks which coincided with bilateral spike and wave discharges on the EEG, apparently of subcortical origin.

Ten months after transplantation, with the bone marrow still in remission, he died with pneumonia, and at autopsy the brain showed macroscopic evidence of widespread leucoencephalopathy. This was confirmed by histological examination, which showed areas of demyelination and glial cell loss—changes similar to those described by Rubinstein [6]. Cultural and histological examination revealed no evidence of infection of the CNS by either bacterial, viral or protozoal agents.

DISCUSSION

There are several possible causes of the encephalopathy that he developed. IT MTX can produce subacute encephalopathy [2] manifested by somnolence, confusion, irritability, tremor, ataxia and fits. In this series by Kay *et al.* brain irradiation was not essential to produce the syndrome, which was associated with a partial improvement with folinic acid. In one autopsied case numerous small infarcts in the frontal, perietal and temporal lobes were present, together with necrosis of blood vessel walls. It is unlikely that IT MTX alone was the cause of encephalopathy in our patient, since, in Kay's series, all 7 patients had had massive amounts of oral, i.m. or i.v. MTX (944–4458 mg) prior to IT MTX. Our patient, apart from 60 mg IT MTX, received in addition a total of only 15 mg of oral MTX. Furthermore, encephalopathy in the reported cases developed during courses of IT injections. The neurotoxicity of IT MTX is associated with high CSF levels of MTX [7], and in the report by Bleyer *et al.* almost all cases of severe neurotoxicity occurred in patients with neuroleukaemia, suggesting that the latter may interfere with the egress of MTX from the CSF [8].

Cranial irradiation of 2400 rad by itself produces a transient encephalopathy, as in our own case, in a majority of children. This syndrome is characterized by somnolence, lethargy and anorexia [4]: recovery, however, is invariable. Combined IT cytotoxic therapy and irradiation in patients with neuroleukaemia or neurolymphoma can produce a subacute progressive encephalopathy [3, 5, 9] characterized by lethargy, irritability, dysphagia, dysphasia, spasticity and sometimes death.

A similar encephalopathy may occur as a consequence of measles during antileukaemic therapy, with or without a history of clinical measles, but with either a high antimeasles antibody titre or histological changes characteristic of disseminated measles infection [10]. This is an improbable cause in this case, although the role of the other viruses cannot be entirely excluded. The CMV titre is ambiguous but there was no other evidence of CMV infection.

The outstanding features that the majority of patients with such severe neurological complications share is (a) therapy with IT cytotoxic agents invariably including MTX, plus (b) whole brain irradiation, plus (c) malignant disease involving the CNS. Our own case was typical; not only did he receive IT MTX and have neuroleukaemia, but he underwent two courses of irradiation that included the brain—firstly, conventional prophylactic therapy (2000 rad in $2\frac{1}{2}$ weeks), and, 3 months later, 1000 rad in $3\frac{1}{2}$ hr. The biological equivalent of the large single dose is further complicated by the low dose rate at which it was delivered (5 rad/min) [11]. Reducing the dose rate to this level probably does reduce the degree of radiation damage in some normal tissues, particularly gastrointestinal mucosa [12]. Normal tissue sparing by reduction of radiation dose rate is more likely to occur in tissues which exhibit a marked capacity for

intracellular repair of sublethal radiation damage. Whether or not this might be the case in cerebral tissue is unknown. The timing in our case may have been important: radiation encephalopathy occurs several weeks to several months after irradiation, and it is possible that the large single dose may have been given during a critical period of the recovery of brain and vascular tissue from the first course of radiation. Age may also be important: our patient was $3\frac{1}{2}$ yr old, the ages of the children in Rubinstein's series [5] were $2–8\frac{1}{2}$. Younger children tended to have more severe symptoms in Freeman's series [4] of children given prophylactic cranial irradiation. The brain does not approach its adult weight until the age of 12: between the ages of 14 months and 12 yr there is an enormous increase in the weight of the brain (43%) and this is in part a reflection of myelin production [13]. The Seattle group have given 1000 rad TBI to 14 patients with acute leukaemia undergoing bone marrow transplantation, who have previously had cranial irradiation, and have had no cases of chemo-radiation encephalopathy [6]. Their youngest patient was 4 yr old.

The possible occurrence of this syndrome must be borne in mind when TBI of this nature is given to young marrow graft recipients who have had previous brain irradiation, IT cytotoxic chemotherapy and leukaemic involvement of the CNS.

Abstract—*Binding of concanavalin A to cell surface saccharides of rat glial cells, both normal and neoplastic, was investigated by two methods. Concanavalin A-mediated agglutination was demonstrated with tumor cells but not with normal newborn cells tested under the same conditions. Ultrastructural visualization of concanavalin A receptors by means of horseradish peroxidase revealed an essentially discontinuous type of staining on both tumor and normal cells alike, the distribution of the label being less evenly spread in the latter cells than in the former. Therefore, the observed difference in concanavalin A-induced agglutinability between normal and tumor glial cells did not correlate with whatever difference was detected by the cytochemical reaction in the distribution of concanavalin A binding sites between the two populations of rat glial cells. In conclusion, it seems reasonable to argue that the non-random distribution of cell-bound concanavalin A bears little or nothing upon the positive lectin-induced agglutination behaviour of the tumor cells, being apparently insufficient for or coincidentally related to it.*

INTRODUCTION

CONCANAVALIN A (Con A), a lectin with certain saccharide-binding specificities, has been widely applied as a molecular probe for the study of the cell surface (for literature see [1]). We used Con A for investigating the plasmalemma of normal and tumor glial cells of rat, in order to test whether any differences could be detected between these two cell populations and whether such differences could be correlated with the normal and neoplastic state. The results of our studies are reported in this communication; their significance is briefly discussed.

Accepted 19 November 1976.

†Presented at the joint meeting of German and Italian neuropathologists held in Pian di Mucini, Massa Marittima, Italy, June 3–4, 1976.

MATERIAL AND METHODS

Tumor cell cultures

Seven gliomas induced in rats by systemic application of methylnitrosourea [2] were dissected aseptically, rinsed in calcium- and magnesium-free phosphate buffered saline (PBS) solution, trimmed down to appropriately small fragments, explanted into Falcon plastic tissue culture vessels and grown routinely at 37°C in M-199 medium (Seromed, Munich, FRG) supplemented with 10% fetal bovine serum (Seromed, Munich, FRG). Primary cultures were subcultured many times. Passages 5, 7 and 9 of each cell line were used for agglutination and cytochemistry studies.

Normal cell cultures

The intracranial structures of newborn rats were exposed under aseptic conditions. Small

tissue fragments were excised from the cerebral hemispheres and cerebellum and rinsed with PBS. The fragments were seeded in plastic tissue culture vessels and grown routinely at 37°C in M-199 medium supplemented with10% fetal bovine serum. Ten primary cultures were established. They were subcultured several times. The morphology of the subcultures followed by light microscopy revealed that most of the cells had an epithelial aspect. Passages 5, 7 and 9 of each cell line were used for agglutination and cytochemical control studies

Agglutination test

Normal and tumor cells were detached after draining the medium and washing the cell layer with PBS. Following the third and last rinse the cells were flushed loose to a single-cell suspension with PBS pipetted gently against the bottom of the tissue culture vessel supporting the cell sheet. Cell viability by trypan exclusion test was more than 90%. Chemical methods of detachment employing proteolytic or chelating agents were discarded in view of the untoward effects on the cell membrane composition [3] and function [4] observed after using these substances. Equal volumes of cells suspended in PBS at a density of 10^6 cells/ml were mixed with equal volumes of PBS solutions of Con A (Serva, Heidelberg, FRG) of decreasing concentrations. These had been prepared prior to usage by diluting serially a 0·1% stock solution of Con A with PBS at dilution ratios ranging from 1:2 to 1:2048. The cell-Con A mixtures were finally incubated at 37°C for 30 min. The results were checked with the naked eye and then by placing a drop of the incubated mixture on a slide and examining it under the 16 mm objective of the microscope. Agglutination was scored using a semiquantitative scale ranging from ± to + + + +, the latter value indicating that all cells (100%) in the tested mixtures had been trapped into clumps.

Some cultures of normal and tumor cells were harvested as described above, exposed to 0·25% trypsin (Serva, Heidelberg, FRG) for 20 min and then incubated with Con A as the remaining cultures. The specificity of the phenomenon was checked by incubating additional cell cultures with a Con A solution containing 0·2 M of methyl-alpha-D-manopyranoside (MAM) (Sigma, Munich, FRG).

Cytochemical reaction

Con A staining of the cell surface was carried out on living cells *in situ* according to a slightly modified version of the original method described by Bernhard and Avrameas [5]. The medium was decanted and the cells, both normal and neoplastic, were first washed with PBS and then incubated with a 50 μg/ml PBS solution of Con A for 15 min at room temperature. Whereupon, the cells were rinsed again with PBS and incubated with a 50 μg/ml PBS solution of horseradish peroxidase (HRP) (Sigma, Munich, FRG) for 15 min at room temperature. Subsequently, the cells were washed with PBS and fixed for 15 min with a 2·5% PBS solution of glutaraldehyde. After renewed washing in PBS the cells were incubated for 15 min with a 500 μg/ml PBS solution of diaminobenzidine (Sigma, Munich, FRG) to which a few drops of a 0·1% solution of H_2O_2 had been added just prior to usage. Following rinsing with PBS the cells were postfixed for 1 hr with a 1% OsO4 solution, dehydrated in graded ethanol solutions and embedded in Durcupan. The plastic flasks were broken, the Durcupan layer was detached and appropriate areas of it were chosen under the microscope for further processing. Ultrathin sections were prepared with diamond knives, double stained with uranyl acetate and lead citrate and viewed with a Zeiss EM 9A electron microscope. The specificity of the reaction was controlled by adding 0·2 M of MAM to the Con A and HRP solutions of some cultures in each experiment. In addition, the effect of prefixation on Con A binding sites was tested by treating some cultures with 2·5% glutaraldehyde for 15 min prior to addition of Con A. The effect of trypsinization on the distribution of cell-bound Con A receptors demonstrable cytochemically was not tested

RESULTS

Agglutination test

All lines, regardless of their derivation from normal or neoplastic cells, were maximally agglutinated at the higher concentrations of Con A. Therefore, the data reported hereafter refer exclusively to results obtained under constant conditions of cell density, temperature, incubation time and Con A concentration, the latter corresponding namely to the 1:32 dilution.

Under the above-mentioned standard conditions, no agglutination was observed with untreated normal cells. Trypsinized normal cells showed a degree of agglutination corresponding to a 75% reduction or more in the number of single cells. A comparable + + +

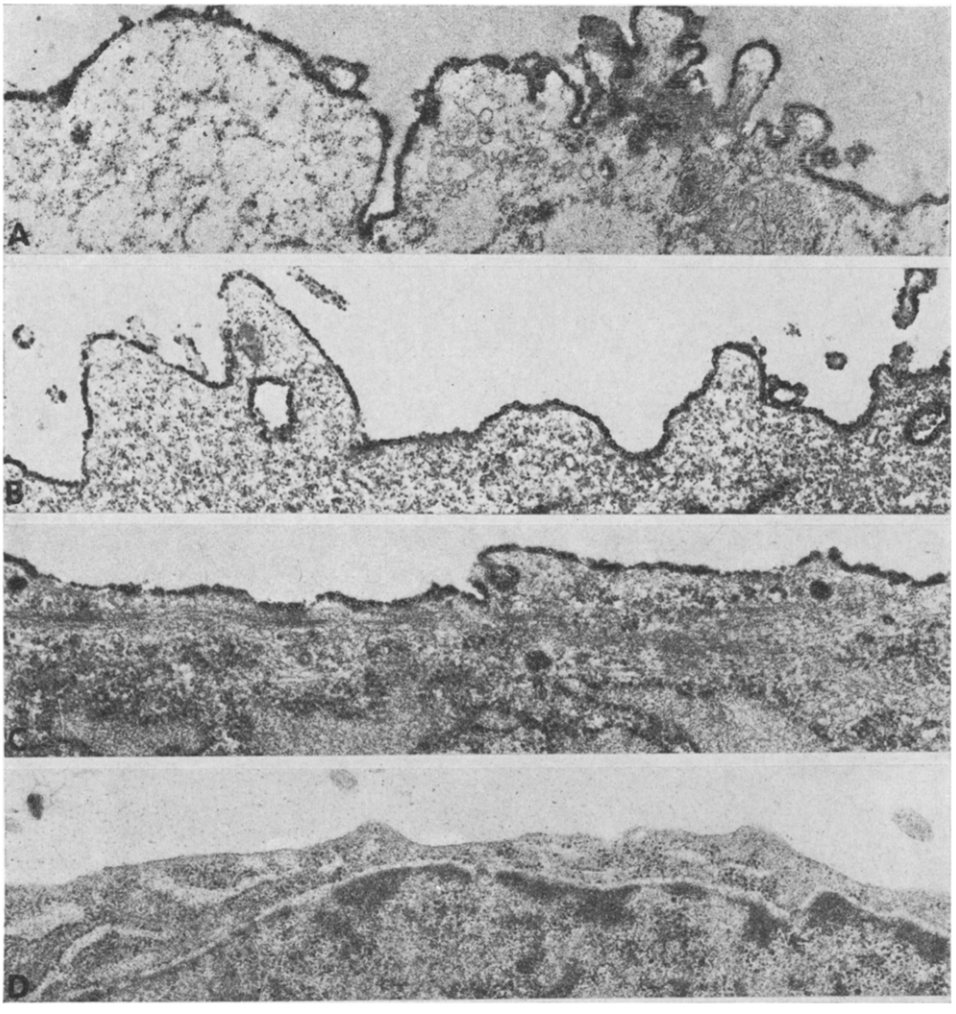

Fig. 1. *Rat glial cells stained with Con A-HRP either* in situ *and after glutaraldehyde fixation* (*A*) *or* in situ *and intra vitam before any such fixation* (*B, C, D*).

(*A*) *Segment of a tumor cell fixed* in situ *prior to incubation with Con A and HRP: the electron dense material forms almost a continuous ribbon decorating the cell surface* (× 21000).

(*B*) *Segment of a tumor cell stained intra vitam: a few isolated breaks interrupt the continuity of the surface label* (× 18000).

(*C*) *Segment of a normal cell stained intra vitam: solutions of continuity along the superficial band of reaction product are numerous and of varied extent* (× 24000).

(*D*) *Segment of a tumor cell stained intra vitam with Con A and HRP solutions to which MAM had been added: no surface staining* (× 21000).

agglutination was obtained with untreated tumor cells and trypsinized tumor cells alike. No agglutination was detected around the multinucleated giant cells occurring isolatedly in the cultures of experimental rat gliomas. Tumor cells, either untreated or trypsinized, and trypsinized normal cells did not agglutinate whenever MAM had been added to the lectin solution. No essential differences were detected between the different lines of normal cells and the different passages of the same cell line. Likewise, no essential differences were observed between the different lines of tumor cells and the different passages of the same cell line.

Cytochemical reaction

An almost continuous type of staining with few, small breaks thinly scattered along the ribbon of electron dense material was seen in the prefixed normal and tumor cells (Fig. 1A). Making allowances for a considerable degree of intercellular variation, untreated normal and tumor cells alike had less than a continuous distribution of the reaction product on their surfaces. Most of these cells showed lengths of continuous label following areas with a dotted or dot-and-dash type of label, and alternating with either bare spots or denuded patches of varied extent. In general, irregularities of the stained surface and discontinuities of all sizes were less numerous and extended over shorter stretches in tumor (Fig. 1B) than in normal (Fig. 1C) cells. Normal and neoplastic cells alike showed no surface staining (Fig. 1D) whenever MAM had been added to the Con A and HRP solutions. The results were essentially the same in the different cell lines and in the different passages of the same line.

DISCUSSION

We will discuss the results of the agglutination assay and cytochemical reaction in that order; at the end, we will briefly consider the two sets of findings taken together.

The results of our agglutination tests are in line with those of a large series of observations (for review see [1]). They are at variance, however, with those reported by Glimelius *et al.* [6] who also had been experimenting with cultures of normal and tumor glial cells. These authors found essentially no difference between normal and tumor cells, all cells being invariably agglutinated in presence of Con A at weaker concentrations and shorter incubation times than those used in our experiments. The reasons for the reported discrepancy between our results and those of the Scandinavian workers are not clear. It is possible that the difference pertaining to the animal species from which the tested cells had originated (rodent vs human) and that concerning the handling of the cells prior to incubation (PBS vs EDTA) might account entirely for the divergent results.

The essentially irregular distribution of the reaction product observed on the plasmalemma of our normal and tumor cells conforms to that reported by earlier observers in other pairs of normal cells and their modified counterparts [7–9]. It is at variance, however, with that reported by the same [7] or by other workers [10–12] in still other pairs of cells. In this connection it should be mentioned, however, that of all ultrastructural studies of this type none have dealt with glial cells of any kind, so that a meaningful comparison between the results yielded by rat glial cells in our hands and the results yielded by glial cells of either rat or another species in the hands of other authors is still awaiting. In the meanwhile, it is evident that an essentially discontinuous type of Con A labeling is neither characteristic of glioma cells nor inconsistent with normal newborn glial cells; whether also normal adult glial cells have a discontinuous type of labeling remains to be proven. For the time being it appears that rat glial cells, both normal and neoplastic, have an essentially similar type of labeling, and that staining is likewise irregular in both normal and tumor cells, being only less evenly spread in the former cells than in the latter. It seems further that the pattern we observed in our glial cell pair cannot be expected to have general validity nor to occur regularly, although it might be seen in other cell populations probed for binding sites with Con A or with another lectin.

Finally, if the distribution of the Con A receptors brought to light by the cytochemical method is largely similar in normal and tumor rat glial cells alike, then it shows no correlation with the negative and positive agglutination responses of these same normal and tumor glial cells, respectively, when incubated with a Con A solution of the appropriate concentration. Some authors [13, 14] investigating the Con A binding sites of other pairs of cells and getting essentially the same results as we did, concluded that unevenly distributed cell-bound Con A has little or no effect upon the lectin-induced agglutinability of the tested cells: a conclusion with which we would tend to agree, if we had to judge from the results of the work presented in this communication.

Perspectives in Cancer Research

Present and Future Clinical Relevance of Tumour Markers*

P. FRANCHIMONT and P. F. ZANGERLE†
Institut de Médecine, Laboratoire de Radioimmunologie, Université de Liège, Tour De Pathologie–Sart Tilman, 4000 Liège, Belgium

INTRODUCTION

THERE has been growing awareness, during the past 10 years, of the ability of neoplastic tissue to synthesize and release into the circulating blood, substances that are either lacking or are produced in extremely limited amounts by the original parent cells. The appearance of these substances, referred to as tumour markers or cancer-related antigens (due to their protein and polypeptide nature), is most often interpreted as being the result of derepression of silent genes during the processes of dedifferentiation and disorganization which accompany the malignant transformation.

These tumour markers have attracted considerable attention from biologists, biochemists, immunologists and clinicians for several reasons. In the first place, these antigens of cancerous origin may be expected to play an important role in the natural defense of the organism against the development of cancer. In fact, according to Currie [1] "It is clear that most, if not all, animal and human tumours possess cell membrane antigens which are immunogenic in the host".

They may be directly implicated in the rejection or the tolerance of the cancer by the host. Besides, these tumour antigens and the immunological reaction they elicit in the host may constitute one of the factors controlling the kinetics of multiplication of the cancer cells and thereby the growth of the tumour. Furthermore, the immunogenic character of these antigens and the localization on membranes of a good number of them can constitute the basis for specific active immunotherapy—indeed, they already do. Finally, the assay of the antigens in biological media such as blood, urine and the cerebrospinal fluid [2] serves as a useful method not only in the diagnosis but also in the determination of the extension of the cancer and in its therapeutic surveillance as well.

Our objective in this editorial is to: (1) list the principal cancer-related antigens and (2) define such properties and limitations of these markers as would be relevant to the clinician interested in their use for diagnostic purposes as well as for assessing tumour extension and the effectiveness of therapy.

We will conclude with an analysis of the directions of future research concerned with tumour markers.

1. CLASSIFICATION AND NATURE OF TUMOUR MARKERS

If one were to generalize on the properties of the various substances that have so far been used as tumour markers, one could state the following:

(a) Most tumour markers known to date are protein or polypeptide in nature since immunological methods have enabled their identification, purification and isolation. Nevertheless, it is equally possible that numerous other substances that are not protein in nature and that are more or less specific for cancer cells are also secreted. The polyamines constitute such an

*Supported by Grant No. 20.305 of "Fonds de la Recherche Scientifique Médicale (FRSM)" and by the "Fonds Cancerologique de la Caisse Générale d'Epargne et de Retraite", Belgium.

†Aspirant chercheur of the "Fonds National de la Recherche Scientifique (FNRS)", Belgium.

example—while they are not specific to the cancerous state, they are synthesized in large excess and released into the blood by growing tumours.

(b) They may belong to several parts of cancerous cells: sometimes to the nuclear, but most frequently to the cytoplasmic and membrane structures.

Their association with membranes confers a double interest: the antigen appears more readily in the blood and induces an immunological reaction which could be of great pathophysiological significance. Whether of cytoplasmic or nuclear origin release into the circulation and eventual induction of immunological reaction are equally feasible. Some substances which are sometimes used as tumour markers, belong to the normal tissue invaded by the neoplasms or by the metastases or are consequent upon the inflammatory reaction accompanying the tumour. Specificity of such markers is always very poor and only dependent on the quantitation of their assay.

(c) They can be biologically active and induce clinical symptoms as in ectopic hormone syndromes. However, the majority of tumour markers do not possess any biological activity; this does not exclude the possibility of a role in the tumour-host interaction, nor in the non-specific clinical manifestations such as cachexia nor in the modifications of the immunological defence, etc.

(d) On the basis of physico-chemical, immunochemical and biochemical analogies which exist between these tumour markers and substance normally found at particular times of life, one can offer a classification based on different categories:

Table 1. *Foetal and placental antigens*

Antigen	Foetal tissue of origin	Identified in blood of cancerous patients	Principal associated tumour
I. *Foetal antigens*			
Carcinoembryonic antigen (CEA)	G.I. tract	+	About 50% of all tumours
α Foetoprotein (αFP)	Serum, liver G.I. tract	+	Hepatocellular, teratomas
γ Foetoprotein (γFP)	Serum, G.I. tract spleen, thymus	+	11% various tumours
α_2H Ferroprotein (α_2HFP)	Liver	+	Leukaemias, Hodgkin's
Carcino-foetal glial antigen	Brain	After immunization	Gliomas
Foetal sulphoglycoprotein	G.I. tract	−	Gastric juice in stomach carcinoma
Melanoma-associated antigen	Melanoma	?	Melanoma and other various tumour
β Oncofoetal antigen	Fetal organs	+	All types of carcinomas, some cases of lymphomas
Leukaemias-associated antigen	Serum and various tissues	+	Leukaemias, Hodgkin' disease
II. *Placental antigens*			
Human chorionic gonadotrophin (HCG)	Trophoblast	+	Choriocarcinoma, teratomas, pancreatic cancer, 14% of various tumours
β Subunit of HCG (βHCG)	Trophoblast	+	16% of lung cancer, pancreas tumour
α Subunit of HCG (αHCG)	Trophoblast	+	Choriocarcinoma, teratomas 6% of digestive cancers 8% of lung cancers
Human placental lactogen (HPL)	Trophoblast	+	Teratomas, choriocarcinomas, various tumours
Placental alkaline phosphatase	Placenta	+	Various tumours Incidence: 1-12% in different series
Human chorionic thyrotrophin (HCT)	Trophoblast		Choriocarcinoma
Pyruvate kinase	Placenta	+	To be determined

1. *Foetal or embryonic antigens*

These substances are present in the tissues and serum of the foetus and either disappear or are drastically reduced in amount at the end of gestation or in the first weeks of extra-uterine life. Several foetal antigens are recognized (Table 1) but the two foetal antigens best characterized to date are carcinoembryonic antigen (CEA) and α foeto protein (AFP). CEA is a glycoprotein discovered by Gold and Freedman [3] in 1965 in the gastrointestinal tissues of the human foetus up to 6 months gestation and in adenocarcinomas derived from the gastrointestinal epithelium. The studies of Krupey *et al.* [4], Gold *et al.* [5] and von Kleist and Burtin [6], showed that it is a water-soluble membrane glycoprotein with a sedimentation coefficient of 7–8 S, electrophoretic mobility characteristic of β globulin and molecular weight of about 200,000 dalton. As shown by electronmicroscopy [7] CEA is present in the glycocalyx of the tumour cell. CEA displays a rich degree of polymorphism.

Human α foeto protein is made up of a single polypeptide chain with a molecular weight of about 70,000. It contains 4% carbohydrate and 2 mole of sialic acid per mole of protein [8]. It acts as a serum protein in the foetus since, synthesized by the foetal liver and by the yolk sac, it appears in the circulation from the 4th week of gestation. The serum concentration of AFP reaches its maximum levels, greater than 1 mg/ml, between the 12th and the 14th weeks of intra-uterine life. The total quantity of AFP in the foetus however increases up to 32 weeks and then falls [9]. Tatarinov [10] found AFP in the serum of a patient with a primary hepatoma and that finding has been confirmed subsequently on numerous occasions. The physico-chemical and immunochemical properties and the amino acid composition are identical for α foeto protein whether it be extracted from human foetal liver or from hepatoma.

Other foetal antigens have been described and are shown in Table 1. To this list should be added β-oncofoetal antigen and the melanoma cell membrane antigens. While these new antigens have been identified, we do not as yet have detailed information as to their frequency and specificity in relation to neoplasia and their presence in the circulating blood of cancer patients.

Beta oncofoetal antigen (BOFA) is a new antigen associated with several types of human cancer [11]. It was found to be different from AFP, CEA, ferritin and other previously described oncofoetal antigens. This new antigen seems to be present in many different types of human cancer at concentrations significantly higher than in normal adult tissues. A variety of new antigens expressed on the surface of melanoma cells have been described [12]. Some are tumour antigens and may be defined as re-expressed foetal antigens [13] whereas no clear conclusion can be drawn from the existing literature on the specific melanoma antigens as to whether they are common cross reacting antigens [14] or individually specific antigens [15].

2. *Placental antigens*

A second category of substances synthesized by the cancer cells are placental antigens which are normally present only in the serum of pregnant women. Amongst these are hormones such as human chorionic gonadotrophin (HCG) and its α and β subunits as well as human placental lactogen (HPL), all of which possess very specific antigenic determinants [16].

Enzymes constitute a group of non-hormonal placental antigens. Placental alkaline phosphatase has been investigated in depth but placental enzymes such as pyruvate-kinase appear to be of great potential interest in clinical and biological studies of cancers. In fact, immunological similarity exists between pyruvate-kinase from placental and from tumours of lung and stomach whereas no such similarity could be detected between pyruvate-kinase from placenta and several other normal human tissues.

Fottrell and Spellman [17] have demonstrated by immunological methods the appearance of placental pyruvate-kinase in the circulation of patients with tumours.

3. *Protein and polypeptide hormones*

Protein and polypeptide hormones constitute a third group of antigens produced by tumours. Numerous studies clearly demonstrate that various tumours are capable of secreting virtually all of the polypeptide hormones: ACTH, parathormone, calcitonin, ADH, etc. . . .

In principle, these ectopic endocrine secretions are of little interest in the diagnosis of tumours or the monitoring of tumour therapy because they are present under all physiological circumstances. They are not specific for the presence of tumour but there may be quantitative differences and it appears that the physico-chemical structures of ectopic hormones are different from those of hormones normally secreted by the relevant gland. Thus, a larger, more stable and more acidic form of ACTH which eludes before monomeric ACTH on gel

chromatography occurs consistently in tumour associated with the ectopic ACTH syndrome. In addition, this "big ACTH" is relatively resistant to suppression by steroid. Further characterization of the big ACTH molecule and the development of specific plasma assays would be of considerable clinical interest since it appears to be relatively abundant in patients with lung cancer [18]. Similar data were obtained with neurophysin [19]. The precancerous state might be capable of definition on the basis of the specific physico-chemical configurations characterizing such ectopic hormones. Certain antigenic groups could also be characterized by the ectopic hormone either following its unmasking or by an enhancement of its immunoreactivity in the new physico-chemical form. This may well be the case for calcitonin. Thus, with certain anti-sera and not others, it is possible to state that a majority of unselected breast carcinomas contained calcitonin as did some lung carcinomas [20, 21].

4. *Exocrine products*

A group of substances that have lately acquired relevance consists of exocrine secretion products. An example is casein, the phosphoprotein constituent of milk. This secretion of the breast is normally encountered only in pregnancy and lactation [22–24].

Lactoferrin and lactalbumin are also potential tumour markers, although recent investigations in clinical practice are unfortunately disappointing [25, 26].

5. *Normal cell constituents*

Different substances such as enzymes and polyamines are used as tumour markers. They are not specific in themselves but may acquire more significance because of their quantity. Tormey *et al.* [27] used N_2, N_2 dimethylguanosine associated with CEA and HCG in their study of breast cancer. In contrast putressin, spermidin, spermine, pseudouridine and I-methylinosine do not appear to be useful in the assessment of metastatic breast cancer or its treatment.

Gamma-glutamyl-transpeptidase in combination with CEA has been used by Cooper *et al.* [28] as a routine method of identifying hepatic metastases.

Other non-specific substances which have been proposed at some time or another as suitable markers to follow the evolution of cancer or suspected metastases include particularly haptoglobin, antitrypsin and acid glycoprotein [29].

2. CLINICAL RELEVANCE OF RADIOIMMUNOASSAY OF CANCER RELATED ANTIGENS

In order to draw conclusions in this field, five questions about the clinical value of the radioimmunoassays of tumour markers will be posed and answered.

1. *Are the cancer-related antigens specific for a particular type of tumour, or are they common to all neoplastic processes?*

Certain of these antigens are specific for a single organ and even for a single histological type of tumour. This is the case for α foetoprotein which is found almost exclusively in hepatoma and teratoma. Likewise, HCG and its α and β subunits are found in the serum of all the trophoblastic tumours and to a lesser degree embryonal tumours.

In contrast CEA has no specificity for any single type of tumour. It is found with approximately equal frequences in tumours developing from different sites: stomach, intestines, lung, breast, urinary tract, gonads, etc.

The frequency of kapa casein is greater in serum from patients with breast cancer particularly in the presence of metastases. This exocrine product appears to be a form of ectopic secretion of casein, as we have also found this substance in the serum of patients with cancers arising in the gastrointestinal tract and lungs.

2. *Is the radioimmunoassay of cancer-related antigens of value in early screening for cancer?*

At the present time the role of radioimmunoassays in the early diagnosis of cancer is impossible to assess. No epidemiological study has in fact been published.

From the biological point-of-view it is still not known at what stage of dedifferentiation of a tumour the antigens are secreted and how many cancer cells must be present before these antigens become detectable in the blood. From the practical point-of-view it must be established whether these substances occur in the blood earlier than clinically, radiologically and physically detectable morphological changes. The localization of the particular organ affected is obviously an important factor. In fact, if clinical investigations are difficult as in pancreatic carcinoma, biochemical diagnosis would be of greater importance than when the tumour commences in a tissue easily accessible to clinical investigation. It must be stressed that high risk factors for cancer are sometimes associated with cancer-related antigens, e.g. sera from

heavy smokers often contain CEA and big ACTH [30].

3. *Is the radioimmunoassay of these cancer-related antigens useful in making the diagnosis of neoplastic disorder?*

The usefulness of measuring these antigens in establishing the diagnosis of a neoplastic disorder merits discussion. If the quantitative nature of measurement is taken into consideration and if several markers are simultaneously assayed, we consider measurement of cancer-related antigens to be a useful diagnostic procedure, which, however, is neither absolute nor specific.

In a recent study [31] five tumour markers were measured simultaneously in serum by radioimmunoassay: CEA, AFP, HCG, β subunit of HCG and K-casein. Defining abnormal levels as those which were higher than maximun values detected in a population of 935 normal subjects, we confirmed that the incidence of positive findings for one of these antigens is 14.7% in non neoplastic disorders which limits the absolute specificity of these assays in establishing the diagnosis of cancer. It must, however, be recalled that the positive findings of these cancer associated antigens is particularly marked in liver disease and in acute pulmonary disorders [32–36], which can more readily be diagnosed by clinical examination and biochemical and radiological investigations. Thus, in the presence of pathological levels of these tumour markers, one must first of all exclude liver and acute pulmonary diseases of non-neoplastic origin before ascribing diagnostic significance to the results of the assays. False positivity may be partially controlled in this way.

Furthermore, the assay of these antigens is not always positive in cases of cancer at the beginning of the disease. Thus, the incidence of positivity of any one of these five cancer associated antigens was 72% in patients at the onset of the disorder, when clinical symptoms led the patients to consult for the first time, and in the absence of metastases. In fact, if CEA was considered alone its incidence was 53% in the general population of patients with cancer at the beginning of the disease. As shown in Fig. 1, the higher incidence is due to the additional estimation of casein and also of HCG and β HCG. Thus, the incidence of false negativity is decreased by the simultaneous measurement of several antigens.

It should be noted that AFP is only rarely found except in cases of liver disease, more particularly hepatoma. In these cases, it is always found together with CEA and/or β HCG. Thus, AFP would not appear to be an essential tumour marker in the screening of patients suspected to be suffering from cancer.

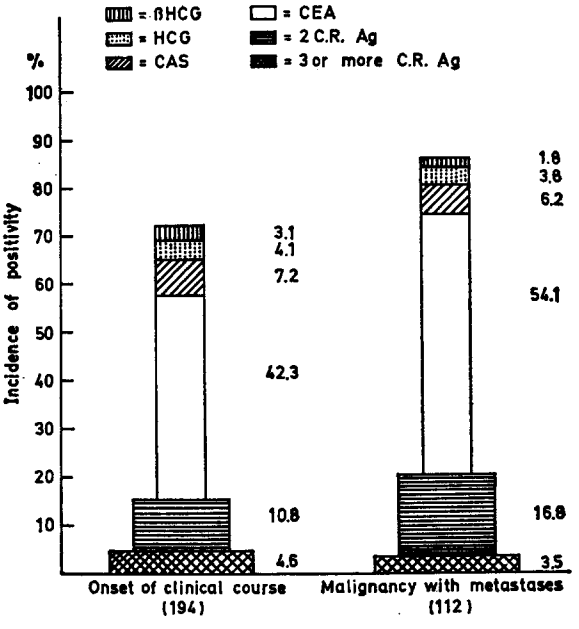

Fig. 1. Incidence of positivity of each cancer-related antigen in a sample of patients with malignancies at the onset of the clinical course, and with metastases. Horizontal bars indicate the incidence of positivity of 2 antigens and cross-hatched line the incidence of simultaneous positivity of 3 or more cancer-related antigens. Number represents the exact incidence.

As the detection of HCG and its two subunits is common to all trophoblastic tumours, the measurement of these substances is an important feature in the diagnosis of these tumours and may provide a means for early detection by screening. The ratio of α/β subunits is always lower than one as in early pregnancy but the quantity of HCG, β subunit is greatly increased in trophoblastic tumours [24]. The incidence of abnormal levels of HCG and its subunits is also high in embryonal tumours but only the levels of α subunit are invariably elevated.

In breast cancer, CEA and K-casein are most often increased and these associations may be of use in conjunction with other diagnostic investigations such as clinical examination, thermography and mammography.

Calcitonin may be of potential interest in breast cancer as it was shown with some selected antisera that the majority of unselected breast carcinomas contained this hormone [20]. Finally the combination of CEA and gamma-glutamy-transpeptidase (CGT) has been used as routine method for recognizing the presence

of hepatic metastases and for following their response to treatment by chemotherapy [28, 29].

4. *Does the concentration of cancer-related antigens provide information about extension of the neoplastic process?*

Here the reply is in the affirmative. Thus, when any cancer is complicated by metastasis the incidence of pathological levels and the absolute levels of some antigens such as CEA and kapa casein are higher than in those without metastasis. Furthermore, Laurence *et al.* [37] showed that the larger the primary tumour the higher is the level of CEA. The same relationship between the size of hepatoma and AFP levels was established by several authors [38]. Bagshawe [39] showed that the levels of production of HCG during the active phase of proliferation of trophoblastic tumour is characterised by exponential growth leading to doubling of the levels at intervals of 36 hr to 14 days depending on the individual patient and the nature of the tumour.

As an example, the levels of casein and CEA are higher in breast tumours complicated by metastasis or local recurrence than in such tumours when first diagnosed in the absence of metastasis (Figs. 2 and 3). Moreover, Chu and Nemoto [40] have established that the incidence of positivity and levels of tumour markers also varied according to the site of breast carcinoma metastases.

5. *Is the assay of cancer-related antigens useful in following the evolution of the tumour and the efficacy of therapy?*

The determination of the levels of these tumour markers provides a good criterion of the evolution of the neoplastic disorder and for following treatment. This was first demonstrated in gastrointestinal malignancy in which CEA is a useful index by which the completeness of surgical removal can be assessed: in cases of total ablation, CEA levels fall and remain undetectable. In cases of local recurrence or metastasis, CEA levels may fall to a greater or lesser degree but do not disappear. Ultimately, they increase sometimes several months before the metastases become clinically and radiologically evident [37].

Further, the usefulness of the measurements of certain antigens such as CEA, AFP and HCG in monitoring treatment has already been demonstrated by various authors [2, 33, 41–43]. The persistence of antigens in pathological concentrations appears to be correlated with the likelihood of recurrence. In our recent study on Breast Cancer [43] using 5 cancer-related antigens when the tumour had been removed at Stage N_0 the incidence of positivity of at least one antigen was only 10% whilst it reached 54% when the tumour had been removed but invasion of the regional lymph gland had already occurred (N^+). Further follow-up of the involved patients will be necessary to assess the values of the positivity as a precocious index of recurrence and/or metastases (Figs. 2 and 3). The estimation of CEA, HCG and N_2, N_2 dimethylguanosine in postoperative N^+ patients revealed one or more abnormalities in 67% [27]. Chu and Nemoto [40] also demonstrated in breast carcinoma that CEA levels after mastectomy were normal or transiently increased in 15 patients with no apparent metastases whereas increased values were detected in 4 out of 6 patients developing metastases during the follow-up.

In the group of patients treated by chemotherapy and radiotherapy the incidence of positivity of at least one cancer antigen is raised due to either local or general extension of the neoplastic process (which has led to the use of this therapy) or to the persistence of cancer cells which have escaped these varieties of treatment. It must be recalled that CEA levels fluctuate during chemotherapy, often in the same direction as the clinical course [41–44].

3. THE DIRECTION OF FUTURE RESEARCH

The study of tumour markers is still in its infancy. Only a few substances are known and even fewer are sufficiently pure to be suitable for radioimmunoassays. It is not unreasonable to postulate that there are other tumour markers, which are not necessarily proteins, which need to be identified, isolated and purified.

The limiting factor is without doubt the lack of specificity of known tumour markers. This lack of absolute specifity has several causes.

Firstly, methodology: in practice radioimmunological techniques are delicate and one must pay rigorous attention to fulfil the conditions necessary for their realisation, in particular to the purity of the tracer and its iodination, immunological specifity and the influence of non-specific proteins, etc. These technical qualities have not always been taken into consideration in certain studies and may account for anomalous results which are probably due to artefacts.

Secondly, biological factors: it is known that in practice repression of a gene is never complete. Thus, it is common to find traces of

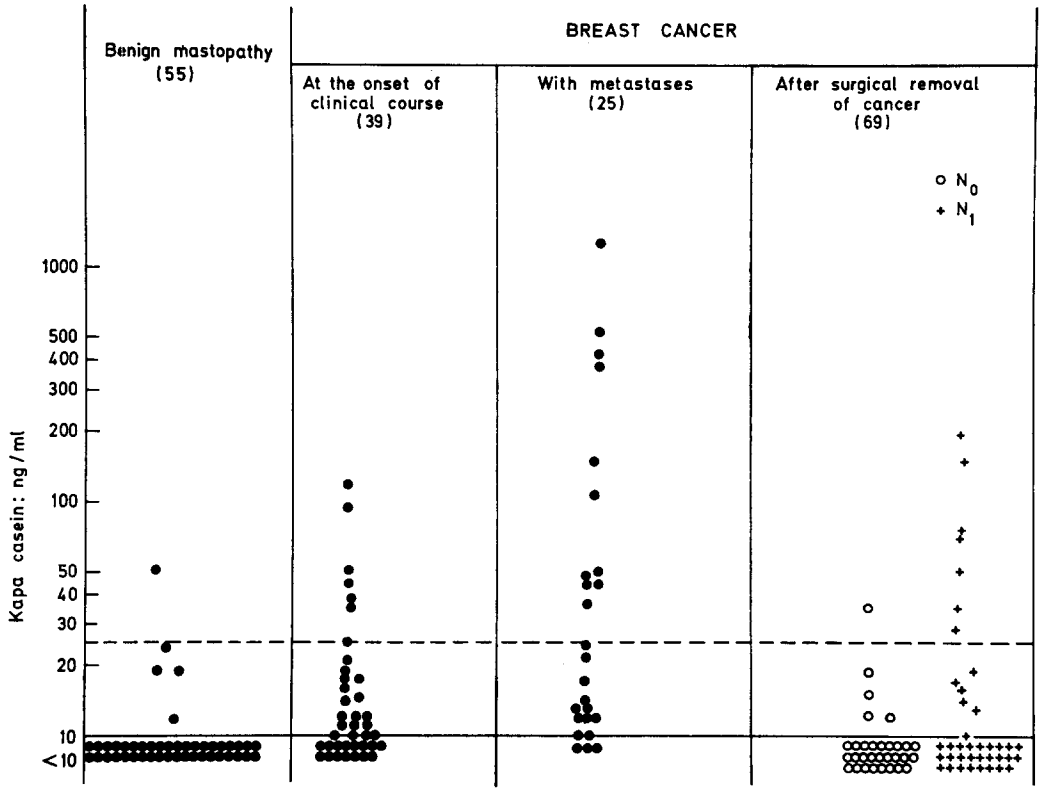

Fig. 2. Kapa casein levels expressed in ng/ml *in breast disease: benign mastopathy and breast cancer at different stages of evolution. embryonic antigens in several tissues [45] and sometimes in blood.

The specificity of the assays of cancer antigens could be improved in different ways. It is possible to select specific antigenic groups produced by the cancer cells, and to prepare corresponding antibodies. There appear to lie within the CEA molecule some common non specific antigenic groups belonging either to a glycoprotein to be found in the serum of normal subjects the NCA (non specific cross reacting antigens) isolated by von Kleist and Burtin [46], or to a glycoprotein secreted by the intestinal mucosa, found in meconium and also in the faeces of adults [47]. CEA produced by the cancer contains highly specific antigenic groups which should provide the basis for a specific radioimmunoassay of this embryonic antigen.

The recognition of hormonal exocrine forms relatively specific for neoplasia could lead to the development of specific plasma assays of exocrine and endocrine substance which would become much more interesting tumour markers than those available at present.

Another direction of research lies in the investigations of factors controlling the secretion of hormonal and exocrine products. Along these lines the use of dynamic tests provoking the liberation of tumour markers provides more useful information than that obtained by estimating only their basal levels. Furthermore it should be possible to study *in vivo* the hormone dependence of certain cancers by observing the rate of production of tumour markers under the modifying influence of hormones which exert an action on the normal tissue from which the tumour derives.

Finally, whilst the use of a histopathological classification of cancers deriving from a particular organ is generally very satisfactory, nevertheless there are large numbers of unclassified tumours which it should be possible to define by their functional activities and in particular by their production of tumour markers.

Nuclear Labelling of Leukaemic Blast Cells with Tritiated Thymidine Triphosphate after Daunomycin*

GUNHILD LANGE WANTZIN and SVEN-AAGE KILLMANN
Division of Haematology, Department of Medicine A, Rigshospitalet, University Hospital of Copenhagen, Copenhagen, Denmark

Abstract—*The incorporation of ^{3}H-thymidine-5-triphosphate (^{3}H-TTP) into nuclei of leukaemic blast cells (LBC) was studied. Such labelling presupposes that the LBC contain replicative DNA polymerase and primer-template DNA. Besides, various other cytokinetic parameters were followed. In 8 cases of acute myeloid leukaemia the ^{3}H-TTP labelling index (^{3}H-TTP LI) was about three to ten times higher than the fraction in DNA synthesis. After a single i.v. bolus injection of daunomycin (DMC) an initial decrease was usually apparent after 6 hr. The nadir was reached at widely different intervals (6–56 hr) after DMC. A late rise in the ^{3}H-TTP LI took place and reached pretreatment values except in 2 instances. The ^{3}H-TTP LI in the blood was definitely lower than in the marrow. In 1 patient the ^{3}H-TTP LI of blood LBC was studied sequentially and closely followed the ^{3}H-TTP LI in the marrow. The present method cannot distinguish whether the action of DMC is on the primer-template DNA or on the activity of DNA polymerase. The data suggest that a high fraction of ^{3}H-TTP labelled cells is necessary for a normal flux into S. A moderate decrease in ^{3}H-TDR LI was seen late, i.e., 24–96 hr after DMC.*

INTRODUCTION

DURING the last years daunomycin has proved to be an effective drug in the treatment of acute leukaemia [1–3].

Daunomycin is known to inhibit DNA and RNA synthesis [4–7] by forming complexes with double stranded DNA [8, 9]. An inhibitory effect on RNA and DNA polymerase is also observed in cell-free systems [7]. Thus, Zunino *et al.* [10] demonstrated an inhibitory effect on the DNA-directed activities of DNA polymerase from murine sarcoma virus, rat liver, *Escherichia coli* and *Micrococcus luteus*. Inhibition of DNA polymerase by DMC has also been shown by other authors [11].

Accepted 10 November 1976.

Previous studies of the effect of DMC on leukaemic blast cells in human acute leukaemia have demonstrated a general direct killing effect on leukaemic cells [12–14] and an inhibiting action on the progression of cells through G_2 phase [12, 14]. Besides, long-lasting depressions of mitotic index (MI), ^{3}H-TDR LI and leucine incorporation by the leukaemic blast cells has been observed [14].

The purpose of the present paper was to study the effect of a single dose of DMC on the nuclear ^{3}H-TTP labelling of single LBC. As will be discussed later, the ^{3}H-TTP LI depends on cell content of nuclear DNA polymerase activity and primer-template DNA. At the same time, various other cytokinetic parameters were followed.

MATERIAL AND METHODS

Eight adult patients with acute myeloid leukaemia (AML) were studied. All patients, except 1, were previously untreated. Pertinent data of the patients are given in Table 1. Bone marrow (BM) and blood (B) samples were obtained at the time of diagnosis before DMC

Table 1. *Clinical and therapeutical data on patients. All patients were previously untreated except patient ALN who received* 20 *mg prednisone daily before and during the study period*

Patient	Sex/Age (yr)	BW	Treatment during study
AJE	M 65	68·8	DMC 105 mg after first BM
NMS	M 53	73·0	DMC 110 mg after first BM
AS	F 70	56·4	DMC 100 mg after first BM
ML	M 57	52·0	DMC 100 mg after first BM
HP	M 61	70·8	DMC 100 mg after first BM
ALN	M 66	58·0	DMC 100 mg after first BM, repeated after 36·5 hr
MO	M 77	61·0	DMC 100 mg after first BM
KM	F 74	73·4	DMC 100 mg after first BM, repeated after 24 hr

and at various intervals after DMC which was given as a single i.v. bolus injection as indicated in Table 2.

Smears of BM and B were performed without delay directly and stained with May–Grünwald–Giemsa. The percentage of blast cells in mitosis from late prophase to telophase (mitotic index, MI) was determined from a count of 3000–9000 blast cells in each sample. The total number of blast cells per μl of venous blood was determined from blood leukocyte counts and a differential count of 200 cells.

Part of the sample was incubated with ^{3}H-TDR (specific activity 2·0 Ci/mM, final concentration 1 μCi/ml BM or B) for 1 hr at 37°C. The percentage of ^{3}H-TDR labelled cells (^{3}H-TDR LI) was determined from autoradiographs (Kodak NTB-2, exposure time 7 days), counting at least 1000 cells.

Part of the remaining aliquot was smeared without delay on rinsed glass slides and fixed as described by Darzynkiewicz [15]. The incubation procedure was done as reported by Nelson and Schiffer [16] with a few modifications. Incubation chambers were made by attaching 24 mm glass rings to the slides. The incubation mixture consisted of 20 mM Tris ph = 7·8, 0·135 mM of 2′-deoxyadenosine-5′-triphosphate (dATP), 2′-deoxycytidine-5′-triphosphate (dCTP) and 2′-deoxyguanosine-5′-triphosphate (dGTP) respectively, and 5 mmol $MgCl_2$; final volume in each chamber was 0·5 ml; to this was added 10 μCi ^{3}H-TTP (Schwarz/Mann, Orangeburg, New York, USA, specific activity 40 Ci/mmole). Ficoll was added to the incubation mixture to make a concentration of 40 g/100 ml. The slides were incubated for 1 hr at 37°C. After fixation with formaldehyde, autoradiograms were done using Kodak NTB-2 liquid emulsion with an exposure time of two weeks. One thousand-five hundred to 3000 cell *nuclei* were counted to determine the percentage of nuclei labelled with ^{3}H-TTP (^{3}H-TTP labelling index = ^{3}H-TTP LI).

Counting TTP-labelled cells is often more difficult than counting ^{3}H-TDR labelled cells because the former labelling method requires a certain damage of the cytoplasm which sometimes is lost altogether. Photomicrographs of well preserved and less well preserved cells are shown in Figs. 1 and 2. In the first case, labelled cells can be counted directly. In the second case, all cells are counted and a correction for non-blastic cells made from a differential count (400 cells) of the direct smears. It should be mentioned that in these cases, non-blastic cells represent a very definite minority so that the possible error introduced in the ^{3}H-TTP LI count anyhow would have been small in case no correction had been made. This is to emphasize that populationwise, MI, ^{3}H-TDR LI, and ^{3}H-TTP LI can be directly compared.

RESULTS

(1) *^{3}H-TTP labelling index of marrow and blood blast cells Table* 2

Pretreatment ^{3}H-TTP in BM varied from 22·5% to 96%. In all eight patients the ^{3}H-TTP LI exceeded the ^{3}H-TDR LI by a factor 2·4–8·8. Without exception a decrease in the ^{3}H-TTP LI of LBC was seen after DMC. An initial decrease was usually apparent after 6 hr (except in KM). The nadir was reached at widely different intervals (6–

56 hr) after DMC but in 6 of the patients the nadir was observed as late as 32–56 hr after DMC. After the nadir, a late rise in the ^{3}H-TTP LI took place and reached pretreatment values except in two instances. Values higher than the baseline was observed only in one patient (KM) who received DMC twice, namely 12 hr after the first dose and 60 hr after the second dose.

The pretreatment ^{3}H-TTP LI in blood varied from 10·3 to 22·1% in the three patients studied (Table 2). The ^{3}H-TTP LI in the blood was definitely lower than in the marrow. In one patient (ML), the ^{3}H-TTP LI of blood LBC was studied sequentially and closely followed the ^{3}H-TTP LI in the marrow although the initial decrease in the blood ^{3}H-TTP LI was somewhat more pronounced (Fig. 3).

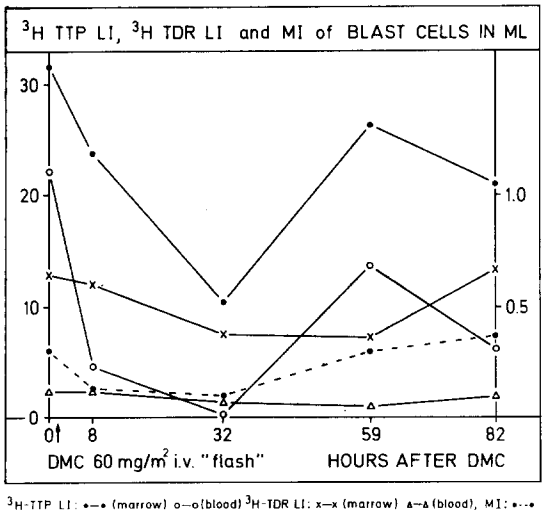

Fig. 3. An example of variations in ^{3}H-TTP LI, ^{3}H-TDR LI and MI of bone marrow and blood during treatment with daunomycin (Patient ML).

(2) *^{3}H-TDR labelling index and mitotic index Table 2*

Pretreatment ^{3}H-TDR LI in the BM varied from 6·0 to 15·5% and in the blood from 0·5 to 7·0% (Table 2). Except for patient MO, a moderate decrease in the ^{3}H-TDR LI of LBC was seen. The nadir was seen late, i.e., 24–96 hr after DMC. In four of the patients studied for a long period ($\geqq$ 84 hr), the ^{3}H-TDR LI was below pretreatment level 60–96 hr after DMC. It is interesting to note that the decrease in ^{3}H-TDR LI was relatively smaller than the drop in ^{3}H-TTP LI and took place later.

The initial MI value varied from 0·10 to 1·27%. Without exception an initial decrease in the MI was observed (6–24 hr). In four of the 7 patients studied for more than 24 hr, pretreatment values were reached 24–59 hr after DMC; in the remaining 3 patients the MI remained below baseline value 60–85, 5 hr after DMC.

DISCUSSION

1. *^{3}H-TTP LI before treatment*

The ^{3}H-TTP LI in LBC before treatment can be considered as a measure of the presence of nuclear DNA polymerase which is needed for replicative DNA synthesis. This is based on the following observations: Nelson and Schiffer [16] have demonstrated that with the present method one obtains in Sarcoma-180 mouse ascites tumors an estimate of nuclear DNA polymerase. It has been shown that both leukaemic blast cells [17] and lymphocytes [18] exhibit DNA repair after irradiation with u.v. light. However, non-treated lymphocytes do not exhibit observable repair synthesis and are negative when assayed for DNA polymerase by the TTP method. However, if the lymphocytes are stimulated to grow by phytohaemagglutinin they become ^{3}H-TTP positive [19]. Based on these studies it is reasonable to assume that any cell labelled with ^{3}H-TTP contains DNA polymerase for DNA-*replication* (and primer–template DNA). The range of the ^{3}H-TTP LI in this series is quite large, from 22·5% to 96·0%. Possibly, some of the lower figures may be underestimates since the assay is rather crude. However, in this case, one would expect to find a rather high fraction of cells with grains near the threshold. In the present study, a threshold of 5 grains has been used when counting in areas with very low background. By this approach there has been no doubt whether cells were labelled or not. We have tried to increase the threshold moderately to score a cell as "labelled" but this did not affect the LI markedly. The typical grain count of ^{3}H-TTP labelled cells is in the order of 10–20 grains. Moreover, extending exposure time up to 8 weeks did not increase the ^{3}H-TTP LI. Thus, the labelling with ^{3}H-TTP obtained in this study probably distinguishes quite well between cells with a high content and with no (or very low) content of DNA polymerase. Apart from this, the method is reproducible [20], and therefore can be used for comparative purposes which is the topic of this paper.

What then is the fate of cells which do not

label with ^{3}H-TTP? Probably, a fair fraction of these cells will not divide again but sooner or later die. It is very difficult to demonstrate death of leukaemic cells (and also normal haemopoietic cells). However, if one considers that the growth fraction of leukaemic cells is in the order of 15–35% and LBC have a cycle time of about 50–60 hr [21], one may compute that it would not last more than a few weeks before a patient with acute leukaemia would be transformed into a huge mass of leukaemic cells of the same weight as the patient. This obviously does not happen and is the best indication that there is considerable death among leukaemic cells. This is not to say that cells which will label with ^{3}H-TTP may not die. In fact, the maximum ^{3}H-TTP LI in this series was 96% and some of these cells must be expected to die. However, in general we believe that cells which do not label with ^{3}H-TTP are the most likely candidates for being end-cells.

The presence of DNA polymerase in the cell suggests that the cell has the capacity of DNA synthesis and cell division. This does not imply any particular model of the growth of leukaemic cells: the labelling indices observed here would be compatible both with a stem cell growth pattern, a stem cell growth pattern connected to one multiplicative compartment, or a stem cell compartment connected to subsequent serially connected multiplicative leukaemic cell compartments. It is interesting to note that the DNA polymerase containing cells are about three to ten-fold more frequent than cells in S-phase as measured by the ^{3}H-TDR LI. This demonstrates that the nuclear DNA polymerase is present not only during DNA synthesis but also in a large fraction of non-S-cells. Thus, DNA polymerase must be present in a large fraction of G_1 cells. Whether it is present in G_0 cells or not is a moot point and hard to answer because G_0 cells have not yet been formally identified in a human leukaemic cell population. However, if G_0 cells exist, there is a fair chance that they may label with ^{3}H-TTP. Our reason for believing this is a recent observation which indicates that liver cell nuclei all contain nuclear DNA polymerase [22], while it is well known that liver cells are very rarely in DNA synthesis or in mitosis unless the liver is damaged [23, 24].

2. *^{3}H-TTP labelling index after daunomycin*

As shown in Table 2 there was a definite effect of DMC on the fraction of cell nuclei labelled with ^{3}H-TTP. The response was variable but a definite alteration was observed in all patients. The general trend is an initial decrease in the fraction of ^{3}H-TTP labelled LBC by 6–12 hr; this may be followed by a further decline; the nadir is reached between 6 and 56 hr, and in some patients the ^{3}H-TTP LI returned to pretreatment values within the study period lasting up to 96 hr. In patient ML (Fig. 3) where both bone marrow and blood were studied, the pattern observed in the blood was equal to the changes in the bone marrow. It may be noted, in Table 2 and from Fig. 3, that the percentage of LBC labelled with ^{3}H-TTP in some instances came close to the number of cells in S-phase; however, the ^{3}H-TTP LI never got significantly below the ^{3}H-TDR LI. The effect of DMC on the fraction of cells in DNA synthesis as indicated by the ^{3}H-TDR LI was moderate and occurred late, as also described previously [14]. It holds true for all cases that the decrease in ^{3}H-TTP LI was considerably larger than the variations in the ^{3}H-TDR LI; even if the fraction of cells in DNA synthesis had fallen to zero (which did not occur, as indicated by the ^{3}H-TDR LI) such a decrease could numerically far from account for the fall in ^{3}H-TTP LI. The presence of thymidine-labelled and mitotic cells show that there still was a certain flux through S and M. However, the flux might be more impeded than the actual figures indicate, namely if the duration of S and M were prolonged due to damage inflicted upon the cells by DMC (e.g. it may be noted that mitotic time is prolonged after intensive treatment with cytosine arabinoside [25].

What is the explanation of the marked decline in the ^{3}H-TTP LI after DMC? There are two possibilities: (1) that DMC acts on the primer-template DNA of the LBC, and (2) an effect on the DNA polymerase activity of the LBC. From the data obtained both possibilities remain open. If DMC acts primarily on the enzyme it may be that the enzyme activity per cell exposed to DMC is reduced to the same extent in all cells. In this way many cells will fall below the grain count threshold to consider a cell "labelled". Another possibility would be that at least a fraction of cells containing DNA polymerase are more sensitive to the drug than cells with no detectable DNA polymerase. This cannot be decided. On the other hand, the data would be compatible with the notion that TTP-positive cells in late G_1 and S may be rather resistant, at least as judged from the initial stability of the ^{3}H-TDR LI, which suggests that for some time after DMC, cell flux from G_1 to S may not be particularly impaired. At later time intervals, the ^{3}H-TTP

LI rises whereas the ^{3}H-TDR LI tends to decrease. From this one may speculate that a rather large pool of DNA polymerase and primer-template DNA containing non-S cells is necessary to assure a constant influx of LBC into S-phase; in this respects, cells in late G_1 may be particularly important. As shown, a sudden decrease in the ^{3}H-TTP LI does not affect the ^{3}H-TDR LI immediately but apparently impairs flux into S at a later stage (Table 2). Such a delayed action on the flux into S may also explain that the ^{3}H-TTP LI rises later in the study period (in early G_1 cells?) without a simultaneous increase of the ^{3}H-TDR LI.

The late rise in the ^{3}H-TTP LI may either stem from originally TTP-negative cells, or from TTP-positive cells which temporarily became negative after daunomycin. That such repair is possible in principle is demonstrated by patient ALN who before DMC had a ^{3}H-TTP LI of 96% which dropped to 38·5% but later reached 100%. Here, at least, no visible ^{3}H-TTP LI negative cells could account for the full recovery of the ^{3}H-TTP LI 85·5 hr after DMC.

Combination Chemo-Immunotherapy with Adriamycin in Experimental Tumor Systems*

A. TAGLIABUE, N. POLENTARUTTI, A. VECCHI, A. MANTOVANI† and F. SPREAFICO

Laboratory of Tumor Immunology and Chemotherapy Istituto di Ricerche Farmacologiche "Mario Negri" Via Eritrea, 62–20157 Milano, Italy

Abstract—*The possibility of integrating adriamycin (Adria) in combined chemo-immunotherapeutic treatments with non-specific immunomodulators was investigated. With an appropriate choice of treatment conditions clear synergistic effects were observed in the L1210 Ha leukemia when Adria was followed by treatment with* Corynebacterium parvum (C. parvum), *BCG and levamisole; however the Adria-*C. parvum *combination was found to be the most active.* C. parvum *appeared additionally to exert better antitumoral activity in this system when associated with Adria than with other antitumorals given in equiactive doses. The high therapeutic activity of the Adria-*C. parvum *combination was confirmed in three other leukemia systems (P388, LSTRA, L1210 Cr) even in conditions where chemotherapy with Adria alone was ineffective. Clear beneficial effects were additionally seen with this combination in the solid spontaneously metastatizing Lewis lung carcinoma, a system in which the triple therapeutic approach surgery-Adria-*C. parvum *was more effective than either of the binary combinations. The potential clinical implications of these results and the possible mechanisms at the basis of the synergism between Adria and* C. parvum *are discussed.*

INTRODUCTION

IN RECENT years a number of reports has accumulated indicating the effectiveness of immunotherapy in experimental tumors, and increasing evidence has appeared on its value in at least certain human neoplastic conditions [1, 2]. In the majority of clinical tumors, immunotherapy employed in the form of non specific immunomodulators such as BCG or *Corynebacterium parvum* (*C. parvum*) is preceded by chemotherapy [3–6]. Adriamycin (Adria) is an antitumoral drug on which much interest has lately focused because of its remarkable activity on a wide range of human malignancies [7]. Since a paucity of data appear to exist on the use of this agent in combined chemo-immunotherapeutic treatments, it was considered of interest to investigate in experimental systems the antitumoral potential of the association of this antibiotic with three immunomodulators (BCG, *C. parvum* and levamisole) chosen among those more frequently employed in the clinic [3–6, 8, 9].

MATERIAL AND METHODS

Animals

Mice of both sexes of the following strains were used: C57Bl/6, Balb/c, $CD2F_1$ (Balb/c × DBA/2). The animals were obtained from Charles River Italy S.p.A. (Calco, Italy) and weighed 21 ± 1 g at the start of the experiments. Gross autopsy was performed on all animals and those found to be tumor-free 90 days after tumor transplant were considered cured.

Drugs

Adria and daunomycin (Dauno), obtained from Farmitalia (Milan, Italy), were freshly dissolved in sterile saline as done for 5-fluorouracil (5-FU) and cyclophosphamide (Cy) which were supplied by Dr. H. J. Wood

(DR & DT, NCI, Bethesda, Md.). Suspensions of formalin-killed *C. parvum* (lots PX 374 and 086 P, Wellcome Research Laboratories, Beckenham, England) were diluted with saline and injected i.v. in the dose of 0·7 mg/mouse. Fresh BCG preparations supplied by the Pasteur Institute (Paris, France) were injected i.v. in the dose of 1 mg/mouse; the standard dose of levamisole (Leva, Janssen Pharmaceutica, Beerse, Belgium) was 3 mg/kg i.p.

Tumors

The Lewis Lung (3LL) carcinoma was maintained and transplanted i.m. in syngeneic C57Bl/6 mice, the standard inoculum being 2×10^5 viable cells. Removal of the primary tumor was performed by disarticulation of the femural head of the tumor-bearing limb and measurement of metastatic dissemination to the lungs was carried out as previously described [10]. The L1210 and P388 leukemias were maintained by weekly i.p. passages in DBA/2 hosts, and transplanted in compatible $CD2F_1$ mice. Two different sublines of the L1210 leukemia were used in these experiments; the first, designated Ha, has previously been described as being immunogenic in compatible hosts [11]; the L1210 Cr subline was obtained from Dr. I. Wodinsky, A. D. Little Inc., Cambridge, Mass. and is currently employed in the antitumoral drugs screening program of the National Cancer Institute, N.I.H., Bethesda, Md. In immunosuppressed $CD2F_1$ hosts as well as *in vitro*, no differences were seen between the two sublines in their sensitivity to Adria and other antitumorals. The Moloney virus-induced LSTRA leukemia was maintained and transplanted i.p. in syngeneic Balb/c mice.

The number of tumor cells in the peritoneal cavity was determined as previously detailed [12] employing at least 5 animals per group. Results shown are net leukemic cell values subtracted of phagocytic-adherent cells whose proportion in the total ascitic population was determined as described [13], exploiting their capacity to adhere to glass surfaces and to phagocytize colloidal carbon particles.

Statistical analysis

Results presented are representative of at least three experiments performed employing 10 mice per experimental group. Statistical significance of the differences in survival was analysed by the Mann–Whitney U-test, by Fisher's exact test for the proportion of cures and by Duncan's new multiple range test for the evaluation of metastatic dissemination.

RESULTS

In preliminary experiments the chemotherapeutic activity of different i.v. doses of Adria given 1 day after implantation of 10^5 L1210 Ha leukemia cells was investigated. The greatest percentage of increases in lifespan (% ILS), without lethal toxicity, were seen with 10 mg/kg. This dose was therefore considered optimal in these conditions and employed for the subsequent tests.

Table 1 shows that single i.v. injections of 1 mg BCG on day 3, 6 or 8 after leukemia transplant did not significantly affect survival of the tumor-bearing mice; similarly ineffective were treatments on day 2, 4, 5 or 7 (data not shown). Significant increases in survival over that induced by Adria alone were seen when this BCG dose was administered 5 days after chemotherapy, this treatment also producing occasional cures (10–20% in 2 out of 6 experiments). This schedule was found to be the most effective in these conditions since the use of shorter (1, 2 or 3 days) or longer (6 or 7 days) intervals between Adria and BCG resulted in significantly lower % ILS or in results not different from those seen with Adria alone. Superimposable results were seen when the BCG dose employed was 2 mg.

Table 1. Antitumoral effects of adriamycin combined with BCG and levamisole on i.p. L1210 Ha leukemia

Day of administration of			
Adria	BCG	Leva	% ILS

10^5 L1210 Ha cells were transplanted i.p. in $CD2F_1$ mice on day 0; the Adria, BCG and Leva doses were 10 mg/kg i.v., 1 mg/mouse i.v. and 3 mg/kg i.p. respectively.

*$P < 0.05$ vs Adria alone.

When a 4 day course of Leva, *per se* not influencing survival, was given after an optimal Adria dose on day 1, a significant extra antileukemic effect was found when treatment with this adjuvant was initiated 5 days after chemotherapy (Table 1), the effectiveness of this

treatment being somewhat inferior to that seen with the most active Adria–BCG schedule since no cures were ever obtained. The use of other intervals (2 or 7 days) between Adria and the start of Leva treatment resulted in % ILS values not higher than seen with chemotherapy alone.

Table 2 shows that, whereas *C. parvum* alone was ineffective, significant schedule-dependent advantage was consistently found even with Adria dose (7·5 mg/kg) by itself giving only borderline ILS.

The kinetics of L1210 Ha leukemia cell growth and regression in the peritoneal cavity after chemo-immunotherapy with an optimal treatment of Adria–*C. parvum* is presented in Fig. 1. Treatment with the combined therapy resulted in a significant retardation of tumor

*$P < 0.05$; †$P < 0.01$; ‡$P < 0.001$ vs Adria alone.

prolongations in survival were seen when this agent was combined with Adria. In fact, while 2 days intervals between the two treatments resulted in only a modest, although significant, extra increase in survival, a very clear synergism was found with an interval of 5 days as evidenced by the finding of 80% cures (range 70–90% in 10 experiments) of mice transplanted with 10^5 L1210 Ha cells. In contrast, results not better than found with Adria alone were observed when an 8 days interval was allowed between the treatments.

In view of the higher effectiveness of the Adria–*C. parvum* combination, this association was submitted to more extensive investigation in this and other neoplastic systems. In the L1210 Ha system, and employing the optimal 5-day-interval, this combination proved synergistic also when 10^6 or 10^7 leukemia cell inocula were used (Table 2).

When a range of Adria doses was given in combination with *C. parvum* (Table 3), the best results were obtained when the 10 mg/kg dose was employed; however, a clear therapeutic growth detectable already 2 days after *C. parvum* injection (i.e., day 8) so that on day 12 the peritoneal leukemia cell number of mice given chemotherapy alone was more than double in comparison to that present in hosts injected with both agents. At later times, in contrast to the additional increase in cell numbers observed in Adria-treated mice, a linearly progressive fall in leukemia cell counts occurred in animals submitted to combined treatment so that neoplastic cells were no longer detectable in the peritoneal cavity by day 19–20.

The potential of the Adria–*C. parvum* combination was confirmed in three other murine leukemia models as shown in Table 4. In addition to the trebling in survival given by the combination over that of Adria alone in the i.p. P388 leukemia, of special interest was the finding that this combination proved clearly effective in both the i.p. LSTRA and i.v. L1210 Cr leukemias, i.e., in systems where the highest tolerated Adria doses (7·5 and 10 mg/kg, respectively) were incapable of statistically prolonging survival.

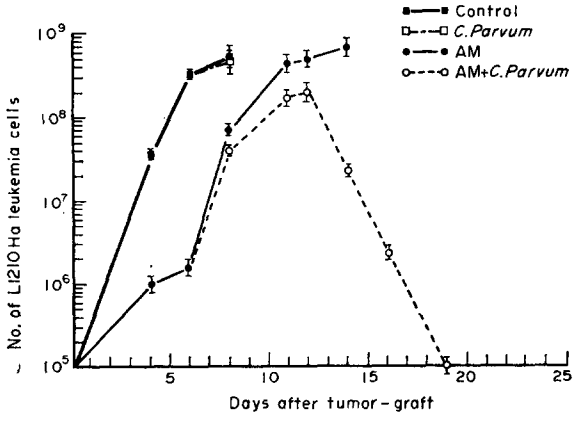

*Fig. 1. Kinetics of the leukemia cell numbers in the peritoneal cavity of mice given the Adria–*C. parvum *combination. Adria (10 mg/kg i.v.) was given on day 1 and* C. parvum *(0·7 mg/i.v.) on day 6 after the i.p. transplant of 10^5 L1210 Ha leukemia cells.*

The Adria–*C. parvum* combination was also investigated in the spontaneously metastasizing i.m. 3LL carcinoma, a model in which the effects of previous surgical removal of the primary tumor on the efficacy of subsequent chemo-immunotherapy with these agents could additionally be explored.

As shown in Table 5 by representative results of 3 such experiments, chemo-immunotherapy with Adria (10 mg/kg i.v. on day 11 when the primary tumor weight was 0·7–0·9 g) and *C. parvum* (0·7 mg on day 15) resulted in a better antineoplastic activity than either of the single treatments in terms of life-span increase, proportion of mice with metastases, weight of lung nodules. When surgery on day 9, which by itself significantly prolonged survival, was followed by Adria–*C. parvum*, this triple therapeutic approach was more effective than either of the binary combinations, both in terms of increase in median survival time and of the percentage of mice with lung metastases at sacrifice on day 23 (range 20–30% in 3 experiments). Moreover, surgery followed by this chemo-immunotherapeutic protocol resulted in a low (20–30%), but consistent, proportion of cured animals.

In view of the high activity of the Adria–*C. parvum* combination, it was considered of interest to examine in the L1210 Ha system, the effects of this immunomodulator when given after the injection of other antitumorals. When combined with *C. parvum*, doses of Cy equiactive with Adria in terms of %ILS produced a percentage of cures which, although remarkably high (between 20 and 50% in 3 experiments), was however significantly lower than that seen with Adria–*C. parvum* (Table 6). The 5-day-interval between Cy and the adjuvant appeared to be the most effective in these conditions since both shorter (3 days) and longer (7 days) intervals resulted in significantly lower % ILS values and proportions of cures (data not shown). As judged by the % ILS values, no added antitumoral effects were seen when *C. parvum* followed an

injection of 200 mg/kg 5FU, i.e., a dose equiactive with 10 mg/kg Adria in terms of prolongation of survival. Preliminary experiments have also revealed no extra antitumoral activity when *C. parvum* followed by 5 days an injection of 10 mg/kg Dauno, a dose which shows maximal antileukemic activity in these conditions and is equiactive with 7·5 mg/kg Adria.

DISCUSSION

The first conclusion emerging from these results is that Adria, a drug at present widely employed in the treatment of various human malignancies [7], can successfully be associated with a series of non specific immunostimulators chosen among those in current larger clinical use. Clear synergistic effects were in fact observed in the L1210 Ha leukemia system when this chemotherapeutic agent was combined with each of the 3 adjuvants investigated, as evidenced by the obtaienmnt of increases in lifespan and/or cures in proportions not seen with chemotherapy employed alone, immunotherapy *per se*, in this model, being ineffective in the conditions investigated. An increased antitumoral effect of chemo-immunotherapy with Adria was not restricted to this system nor only to leukemias as shown by our findings with Adria–*C. parvum* in the 3LL tumor model. These data thus extend recent results of Houchens *et al.* [14] who have described enhanced therapeutic effects when Adria was given with *C. parvum*; the combination of this chemotherapeutic agent with other immunostimulants was, however, not examined in their study. More generally these findings are a further indication of the potential of chemo-immunotherapeutic approaches at least in animal systems and confirm a series of previous conclusions regarding the best conditions for the expression of this potential, such as the importance of the tumor burden at the start of therapy and of the time interval between the two treatments [15–20]. In this study, in which to conform with the more frequent clinical practice [3–6] immunotherapy was applied only after chemotherapy, an interval of 4–5 days between Adria and the administration of BCG, *C. parvum* or Leva was found to be optimal in the L1210 Ha system and was therefore used in our subsequent studies with Adria–*C. parvum* in other neoplasms. Although this schedule proved active, whether this interval was still the best in these additional systems was not investigated, nor conclusions can be advanced on whether the stringent interval dependency of the therapeutic efficacy of this combination observed in L1210 Ha also applied to the other models.

Significant antitumoral effects were seen with Adria–*C. parvum* in the LSTRA and i.v. L1210 Cr leukemia models in conditions where the highest tolerated doses of Adria alone did not produce significant increases in lifespan. If confirmed in other systems, this type of finding would suggest that to obtain significant therapeutic effects with an effective chemo-immunotherapeutic combination, a high tumor sensitivity to chemotherapy is not a strict requirement.

Considering that, in the conditions employed, i.e., metastatic dissemination already present at the time of surgery of the primary, the 3LL

tumor can be regarded as representative of a frequently encountered clinical occurrence, the significant effectiveness in this system of chemo-immunotherapy with an active combination such as Adria–*C. parvum* could have clinical implications, not only for the possible obtainment of better therapeutic results, but also for the possible use of lower doses of toxic chemotherapy to obtain the same antitumoral response. The latter aspect has here been directly demonstrated in the L1210 Ha system and is of special importance for a drug such as Adria for which cumulative cardiotoxicity is known to be limiting [7]. Also of possible clinical significance is the demonstration that the triple combination surgery–chemotherapy–immunotherapy was more effective than either of the binary combinations when effective chemoimmunotherapeutic combinations are employed. These results thus confirm previous data in this [21] and other systems [22] employing different cytoxic and immunostimulatory agents.

A further finding which may have direct practical implications for the most effective application of chemoimmunotherapy, consists in the marked variation in therapeutic activity seen when optimal Adria doses were combined with different immunoadjuvants. Adria–*C. parvum* was found in fact to be the most effective combination in the L1210 Ha leukemia when compared to optimal schedules of Adria in association with BCG or Leva. It is suggestive that in preliminary experiments Adria–*C. parvum* appeared more active than Adria–BCG also in the 3LL. It may be noted that also in a mouse mammary carcinoma system *C. parvum* proved more effective than BCG when given after chemotherapy with Cy [16]. Although not totally excludable, the possibility that the use of suboptimal doses of BCG and Leva could have played a role in this differential therapeutic efficacy in respect to *C. parvum*, seems unlikely. No greater effects were in fact seen when the BCG dose was doubled from 1 mg which has repeatedly been found as optimal in murine neoplastic systems [17]; an increase in the dose of Leva to 10 mg/kg was not followed by greater antitumoral activity when this agent was combined with Methyl-CCNU in the 3LL tumor [10]. Differences in the intrinsic immunostimulatory potency of the adjuvants tested could obviously represent an important factor in explaining this differential therapeutic efficacy; comparisons between these agents conducted in a representative series of experimental neoplasms are still lacking.

The fact that, despite the use of apparently chemotherapeutically equiactive doses, lower antitumoral activities were seen when *C. parvum* was combined with Cy, 5FU or Dauno than with Adria, leads to the conclusion that differences between these cytotoxic agents in activities other than direct tumor cell killing play a crucial role in this finding. Although no direct comparisons between these agents appear to exist, such a factor is presumably represented by their differential qualitative and/or quantitative capacity to interact with host immunity. In support of this contention is the now ample evidence that Dauno is significantly more immunosuppressive than Adria employed at equitoxic doses [13, 23, 24]. It would thus appear that an appropriate choice of both components of the chemo-immunotherapeutic association can be of great importance for rationalized treatments of this type. Studies are in progress to further analyse this aspect employing a larger number of such combinations in various experimental tumors.

The mechanisms at the basis of the observed synergism between Adria and *C. parvum* are a matter of discussion. Adria has been shown to relatively spare macrophages [13, 25] which are known to be a major target in the complex antitumoral effects of *C. parvum* [26] and are credited with an important role in antineoplastic resistance and especially metastasis formation [27, 28]. A complementary interaction of the 2 agents at this and possibly other levels could thus have been expected. No direct data on this point are given by this study; results to be reported elsewhere show that the *in vitro* non-specific cytoxic activity against tumor cells of macrophages recovered after treatment with Adria–*C. parvum* is as high as that seen after *C. parvum* alone. Both Leva [29] and especially BCG are known to stimulate macrophages [30], it is possible that quantitative differences in this capacity may be important in this context and/or that a complementation between Adria and *C. parvum* rests also at other levels. It is suggestive that in preliminary experiments it has been seen that the activity of the effector cells of antibody-dependent cellular cytotoxicity was as high in Adria–*C. parvum* treated mice as in those given the immunostimulant alone; these cells are known to be an important target of *C. parvum* immunostimulation [31].

Whatever the mechanisms, the clear activity of the Adria–*C. parvum* combination observed in this study appears to provide an experimental rationale to current clinical trials employing Adria with non specific immunostimulation; the preliminary results in this direction appear encouraging [32].

Analysis of the Biotransformation of Benzo[a]pyrene in Human Fetal and Placental Tissues with High-Pressure Liquid Chromatography*

DAVID L. BERRY,† PRINCE K. ZACHARIAH, THOMAS J. SLAGA† and MONT R. JUCHAU‡

Departments of Pharmacology and Anesthesiology, School of Medicine, University of Washington, Seattle, WA 98195, *U.S.A.*

Abstract—*The biotransformation of benzo[a]pyrene (BP) was studied* in vitro *in the presence of microsomal fractions of placental and fetal tissues from humans and monkeys* (Macaca nemestrina). *Metabolites formed in the incubation flasks were extracted and separated by means of high-pressure liquid chromatography utilizing a microparticulate column. In general, the formation of diols and quinones in fetal and placental homogenates was undetectable following* 15-*min incubations. The formation of phenolic metabolites, however, was easily measurable in fetal liver and lung and in the placenta but not in fetal spleen, kidney, pancreas or adrenal gland. The latter observation contrasted with high specific activities measured in the fetal adrenal gland with the fluorometric assay for aryl hydrocarbon hydroxylase activity. In placentas from cigarette smokers, relatively large quantities of an unidentified metabolite(s) appeared in metabolic profiles. This metabolite(s) did not co-chromatograph with any of the standard metabolites and the retention time was between those of the* 9,10- *and* 4,5-*diols. The same placental tissues catalyzed the covalent binding of BP to DNA and were far more active in this regard than any of the other fetal tissues investigated. The data indicated a correlation between metabolic profiles and capacity for catalyzing covalent binding to DNA for fetal/placental tissues.*

INTRODUCTION

IT NOW is widely accepted that environmental factors play a highly significant etiologic role as determinants of the incidence of malignant tumors in human populations. Most authorities estimate that such environmental factors are responsible for 70–90% of all malignancies and that chemicals constitute the major source of environmental carcinogens [1–3]. Tissue monooxygenases appear to play a key role in the initiation of chemically-induced tumors since they catalyze the conversion of inactive procarcinogens to highly reactive electrophilic intermediates capable of binding covalently to DNA and producing mutations in bacterial cells [4]. The oxidized intermediates presumably are the proximate or ultimate carcinogenic species.

The occurrence of vaginal clear-cell adenocarcinomas in human females (aged 7–29 years) whose mothers had ingested quantities of diethylstilbestrol during pregnancy [5–7] has focused attention on observations that chemicals can initiate tumors transplacentally. Investigations indicating that polycyclic aromatic hydrocarbons (PAH[4]) are capable of eliciting tumors transplacentally in rodents [8–10] create concern as to whether these chemicals could produce the same effects in humans, especially in view of recent reports of mixed-function oxidations of PAH in fetal tissues of humans and sub-human primates [11–13]. The high susceptibility of rapidly differentiating or developing tissues to initiation of tumorigenesis by chemicals [14] likewise focuses attention upon these problems. In the

case of procarcinogens it may be expected that increased susceptibility of rapidly differentiating tissues to initiation of tumors could be compensated partially by low levels of monooxygenases in the same tissues. On theoretical grounds, however, the incidence of tumor initiation should be related to tissue concentrations of the reactive intermediate(s). These concentrations, in turn, may depend upon the activities of several different enzymes present in the tissues. High-pressure liquid chromatography (HPLC) allows a more critical evaluation of the overall metabolism of PAH in fetal tissues than previously utilized methods. Therefore, we have investigated a number of fetal and placental tissues of humans and pigtail monkeys with this technique. The rare opportunity to perform studies on fresh fetal tissues from the third trimester of human pregnancy provides considerable added interest and importance to this report.

MATERIAL AND METHODS

Chemicals

Glucose-6-phosphate, glucose 6-phosphate dehydrogenase (torula yeast), NADPH, NADH, calf thymus DNA (type I) and ATP were purchased from Sigma Chemical Company, St. Louis, MO. Benzo[a]pyrene (BP) was obtained from Eastman Chemical Co., Rochester, NY and recrystallized from benzene and methanol. N-2-fluorenylacetamide (FAA) was obtained from Mann Research Laboratories, New York, NY and recrystallized from methanol. BP-7,10-^{14}C (sp. act. 18·6 μCi/μmole) and BP-G-^{3}H (sp. act. 1600 μCi/μmole) were obtained from Amersham-Searle Corp., Arlington Heights, IL, and FAA-9-^{14}C (sp. act. 6·7 μCi/μmole from New England Nuclear Corp., Boston, MA. 1-, 3-, N-, 5- and 7-hydroxy-FAA were kindly provided as standards by Dr. E. K. Weisburger at the National Cancer Institute. The 3-hydroxy, 9-hydroxy, 3,6-quinone, 1,6-quinone, 6,12-quinone, 9,10-diol, 7,8-diol and 4,5-oxide metabolites of BP were obtained from Dr. H. V. Gelboin of the National Cancer Institute. The 4,5-diol, 4,5-quinone and 4,5-oxide also were synthesized in our laboratories according to methods described in the literature [15, 16]. All other reagents and chemicals utilized were of the highest purity commercially available.

Tissues

Human fetal and placental tissues (9–28 weeks gestation) were obtained from the Central Embryology Laboratory in the University Hospital, Seattle, WA. Tissues of one live-born fetus (at 28-week gestation) were obtained following a spontaneous abortion. Clinical details of this case are described below. Other human fetal tissues were obtained following routing terminations of pregnancies by hysterotomy, hysterectomy or dilatation and curettage. Gestational ages were between 9 and 16 weeks and were estimated from measurements of crownrump and foot lengths. Human placentas delivered at term were obtained from the delivery rooms of the University Hospital, University of Washington, and the Group Health Hospital, Seattle, WA. Fetal and placental pigtail monkey (*Macaca nemestrina*) tissues were obtained from the Regional Primate Center via the Central Embryology Laboratory. Two adult male rhesus monkeys were made available to us from the Department of Anesthesiology and results from those experiments are included for comparative purposes. One adult monkey was treated with 40 mg/kg of 3-methylcholanthrene via intraperitoneal injection 48 hr before sacrifice and removal of the various organs for assay. The fresh tissues were homogenized in 0·1 M potassium phosphate buffer (pH 7·4) in a polytron homogenizer. The other was treated with an equal volume of corn oil only. The homogenates were centrifuged at 8000 × *g* for 15 min and microsomal fractions were prepared by centrifuging the 8000 × *g* supernatant at 104,000 × *g* for 1 hr.

Clinical data from the spontaneous abortion of a 26-week, live-born fetus

A premature male caucasian infant born at 9.25 a.m. expired at 2.30 p.m. the same day. The infant weighed 860 g, was 13·25 in long, had no grossly observable abnormalities other than somewhat underdeveloped genitalia. The infant had been given 1 mg of phytonadione intramuscularly and 2 drops of silver nitrate solution (1%) in each eye following a facile spontaneous vaginal (vertex) delivery. One and five minute Apgar scores were both 2. The mother was 28 years of age, Rh negative (O), had one previous pregnancy in which a normal infant was delivered at term by Cesarean section and her nutritional status was rated as good. She had taken a prenatal vitamin preparation with iron during her pregnancy. She smoked 10–15 cigarettes per day, drank moderately and consumed 2–4 cups of coffee per day. After admission she received alcohol by i.v. infusion (2 courses) in an attempt to

delay parturition, and 100 mg of pentobarbital orally. She was known to be allergic to sulfa drugs. No other unusual history or clinical findings were noted with respect to either the mother or infant. Tissues were obtained from the Central Embryology Laboratory at 4.00 p.m. on the same day. Crown-rump and foot lengths were found to be 236 and 47 mm respectively. Liver, lungs, kidneys, pancreas, adrenal glands and spleen were placed on ice, taken to the laboratory and homogenized in ice-cold potassium phosphate buffer as described above. Unfortunately the placenta was not available for this study. Fractions were prepared in the evening, stored anaerobically overnight at −85°C and assayed the following morning. Tissues were maintained at 0–4°C throughout the procedure. Preliminary studies with monkey tissues indicated no significant differences in the enzymatic activities investigated between those incubated immediately and those stored overnight at −85°C.

Assays

Rates of 3-hydroxylation of BP (fluorometric assay) and of conversion of FAA to 7-, 5-, N-, 3-, and 1-hydroxylated metabolites in fetal and placental tissues were measured according to previously described procedures with equivalent incubation conditions [17]. Incubation flasks utilized in measurements of the metabolism of BP with HPLC contained BP-7,10-^{14}C (0·5 μCi/flask), 0·2 μmole BP, 120 μmole potassium phosphate buffer (pH 7·4), 3 μmole $MgCl_2$, 2·3 μmole NADPH, 10 μmole glucose-6-phosphate, 2 units of glucose-6-phosphate dehydrogenase and 0·5 ml of microsomal suspension in a total volume of 2·0 ml. The reactions were carried out at 37°C in total darkness in an atmosphere of 100% O_2 for 15 min. One gram of NaCl then was added, and the reaction mixture was extracted twice with 7 ml of ethylacetate: acetone (2.5: 1, v/v). The pooled extracts were evaporated to dryness under air in the dark. The metabolites were redissolved in 4·0 ml methanol which then was evaporated to near dryness and reconstituted to exactly 1·0 ml in methanol. Eight microliters were injected into a high-pressure liquid chromatograph (Micromeritics Model 7000–0111) for analyses. The metabolites were separated with a 2·1 mm × 8·0 cm permaphase ODS (DuPont) precolumn connected to a 4·1 mm × 25 cm Partisil ODS microparticulate column (Whatman, 10 μm) operated at ambient temperature with a constant flow rate of 1·0 ml/min and a 30–100% methanol–water gradient. Individual fractions were collected at 20 sec intervals directly into scintillation-counting vials beginning 3 min after the injection. Samples were collected for 30 min. Scintillation fluors (12 g omnifluor in 1 l of Triton X-100 and 2 l of toluene) were added and the samples were counted in a Packard Tri-Carb scintillation counter. Sufficient counts were accumulated to provide for 95% confidence intervals. Retention times of the radioactive metabolites were compared with the standard BP compounds listed above and are given in Table 1. Low quantities of impurities in the ^{14}C–BP obtained from Amersham-Searle did not co-chromatograph with any of the standard metabolites and appeared between the peaks containing BP and 3-hydroxy-BP. Heat-inactivated (100°C, 10 min) controls were run and the low values appearing in the resultant profiles were subtracted from the profiles of the test samples. Metabolites were tentatively identified on the basis of HPLC retention times. Standards were run several times during the course of these investigations in order to verify that retention times had not changed significantly. However, the very low activity of most of the tissues investigated as well as the unavailability of several known (hepatic) metabolites precluded further verification of peak identities.

Determinations of covalent binding of BP-^{3}H to DNA were based on the tissue-homogenate-mediated system originally described by Gelbon [18] and Grover and Sims [19]. Incubation flasks contained the following components in a final volume of 3 ml: 50 μmole sodium phosphate, pH 7·4, 100 μmole EDTA, 2 mg calf thymus DNA, 0·5 mg NADPH and 40 μg of BP-^{3}H in 25 μl ethanol (80 μCi). The reaction was started by the addition of hydro-

Table 1. *HPLC retention times for the standard compounds (BP and metabolites) utilized in the described experiments*

Compound	Retention Time	Fraction number
9,10-diol	11.30	35–36
4,5-diol	17.00	50–51
7,8-diol	18.05	53–54
1,6-quinone	19.00	56–57
3,6 and 4,5 quinones	20.40	61–62
6,12 quinone	22.00	64–65
9-OH	23.00	68–69
3-OH	24.00	71–72
Commercial contaminants*	24.30–25.30	74–77
BP	27.00–29.00	79–84

*Quantities of these radioactive contaminants, appearing in profiles of heat-inactivated (100°C, 10 min) tissue preparations, were subtracted from profiles of test samples.

carbon substrate and the mixture was incubated for 15 min at 37°C in the dark. The reaction was terminated by addition of 3 ml of a solution containing 2% SDS, 0·03 M NaCl, and 0·03 M NaCitrate at pH 7·0. The mixture was extracted twice with 1 volume of SDS-saturated phenol solution and the nucleic acids were precipitated from the aqueous phase by the addition of 3 vol of ice-cold 95% ethanol. The pellet was dissolved in H_2O and 0·3 ml of 2 M $MgCl_2$ was added, followed by 3 vol 95% ethanol. Subsequent centrifugation at 2000 × *g* for 20 min yielded a pellet that was washed twice more with 95% ethanol followed by one ether wash. The resulting nucleic acid pellet was hydrolyzed in 0·5 N PCA at 90°C for 20 min and aliquots taken for determination of DNA by the diphenylamine reaction [20] and radioactivity by liquid scintillation counting. The specific activities represent average values from 2 determinations with appropriate controls. Protein concentrations were estimated by the method of Lowry *et al.* [21].

RESULTS

An HPLC profile for the human fetal liver at 26 weeks gestation is presented in Fig. 1A. Essentially all of the metabolites appeared in fractions that co-eluted with 3-hydroxy- and 9-hydroxy-BP. Profiles from two livers at earlier stages of gestation were qualitatively similar but showed quantitatively lesser amounts of metabolites formed per unit protein in agreement with previous results obtained with fluorometric assays [22]. The profile for a fetal monkey liver is presented for comparison in Fig. 1B. This profile also exhibited some similarities to those obtained with human fetal livers but the ratio of quantities of metabolites in the 3-hydroxy-BP fraction to those in the 9-hydroxy-BP fraction were considerably lower in the fetal monkey liver (160 days gestation). By contrast, the profile of the MC-pretreated adult (rhesus) monkey liver exhibited large peaks coinciding with retention times of 3-hydroxy and 1,6-quinone standards, smaller peaks coinciding with retention times of 9-hydroxy, 6,12-quinone and 7,8-diol standards, and a large unidentified peak with a retention time between those of the 9,10 and 4,5-diols. No other metabolites were detectable. The adult monkey exhibited very low metabolism with most of the radioactivity coinciding with the 3-hydroxy standard small amounts coinciding with 9-hydroxy, 7,8-diol and the aforementioned unidentified peak also were detected.

An HPLC profile for human fetal adrenal glands (26-week gestation) is presented in Fig. 2A. In view of the high activity observed with the fluorometric assay (Table 2), the activity observed was surprisingly low. Nevertheless, the AHH activities obtained with the fluorometric assay were generally proportional to the capacities exhibited by the various tissues to catalyze the hydroxylation of FAA (Table 2). The metabolic profiles observed with fetal adrenal tissue were not markedly different from those obtained with heat-inactivated tissues except that the peak coinciding with 3-hydroxy-BP was slightly higher. Subsequent assays of monkey adrenal glands (fetal or adult) and a human adrenal gland from early gestation (14 weeks) likewise all exhibited very low activity by the HPLC method. The profiles obtained with human fetal kidney, spleen and pancreas (26 weeks gestation) were essentially identical to those

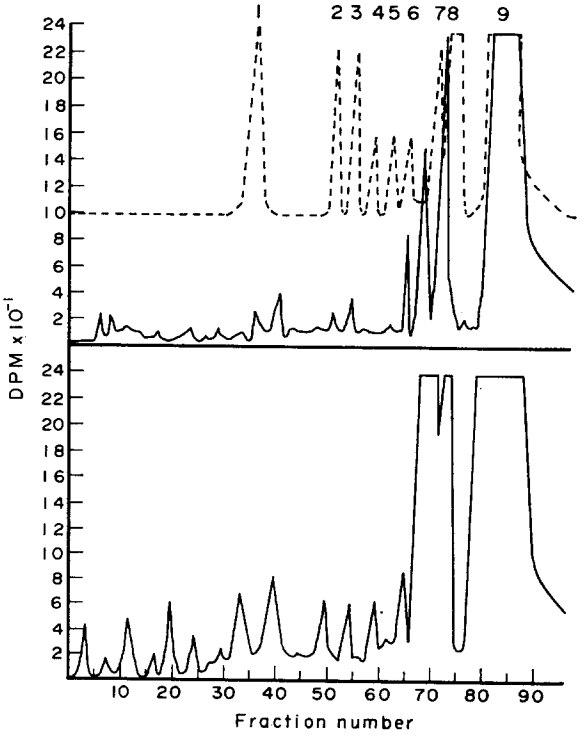

Fig. 1. *HPLC profiles of* ^{14}*C-BP metabolites formed in incubation flasks containing microsomal fractions of fetal livers of* (*upper*) *human* (26 *weeks gestation*) *and* (*lower*) *monkey* (22 *weeks gestation*). *Elution of standard BP metabolites is indicated by the numbers at the top of Fig.* 1*A:* 1. 9,10-*diol*, 2. 4,5-*diol*, 3. 7,8-*diol*, 4. 1,6-*quinone*, 5. 3,6- and 4,5-*quinones*, 6. 6.12-*quinone*, 7. 9-*hydroxy*, 8. 3-*hydroxy, and* 9. *BP. Fig. 2. HPLC profiles of ^{14}C-BP metabolites formed in incubation flasks containing microsomal fractions of human fetal (upper) adrenal glands and (lower) lungs. Both tissues were at 26 weeks gestation. Final protein concentrations in reaction flasks were (A) 0·6 mg/ml and (B) 2·1 mg/ml.

of the heat-inactivated controls. The HPLC profile obtained with fetal lung (Fig. 2B) tissue (26 weeks gestation) indicated considerably more activity than the adrenal glands with clearly distinguishable peaks coinciding with those of 3- and 9-hydroxy-BP and some very small peaks coinciding with the 6,12-quinone, 7,8-diol and 4,5-diol. Lungs from earlier gestation (12 and 14 weeks) however, exhibited profiles similar to those of the heat-inactivated controls. On the other hand, the profile obtained from the lung of the MC-pretreated adult rhesus monkey exhibited slightly less activity than the human fetal lung at 26 weeks gestation.

Typical profiles from human and monkey placentas obtained at term are illustrated in Fig. 3. The monkey placenta (Fig. 3A) consistently yielded profiles that were difficult to distinguish from heat-inactivated controls. Human placental microsomes yielded widely varying profiles—Fig. 3C illustrates a typical profile from a placenta with low to negligible AHH activity as measured with the fluorometric assay and Fig. 3B is a typical profile from a smoker's placenta that exhibited very high hydroxylase activity by the same assay. The largest peak coincided with the elution of the 3-hydroxy-BP. A relatively large peak coincided with the elution of the 1,6-quinone and another comparatively large peak eluted between the 9,10- and 4,5-diols as also was observed with the MC-pretreated adult (rhesus) monkey liver. Very small peaks coincided with elution of 6,12-quinone, 7,8-diol and 4,5-diol. The qualitative aspects of the profile were quite reproducible in placentas of 3 smokers but differed somewhat quantitatively as expected.

Other biochemical data from human fetal (26 weeks) and placental (term) tissues are given in Table 2. Interestingly, the data obtained with the fluorometric assay for measurements of rates of formation of 3-hydroxy-BP did not correlate well with data obtained with HPLC in some instances. This was particularly noticeable with the adrenal gland, pancreas and lung. However, the quantities of microsomes recovered from the adrenal

Table 2. Formation of hydroxylated products (pmole/mg protein/hr) from N-2-fluorenylacetamide and benzo[a]pyrene in microsomal fractions of human fetal (26 weeks) and placental (term) tissues as assayed with thin-layer chromatography and fluorescence spectroscopy respectively (see Methods)

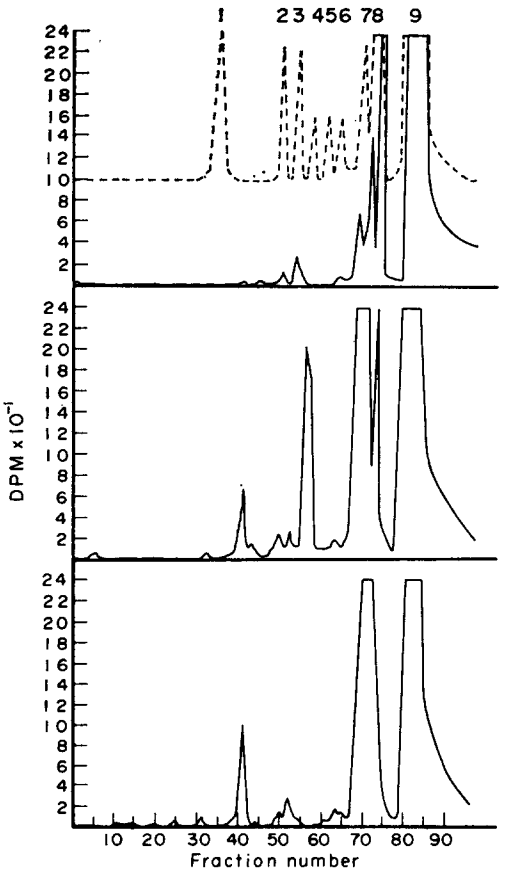

Fig. 3. HPLC profiles of ^{14}C-BP metabolites formed in incubation flasks containing microsomal fractions of placental homogenates at term from (upper) pigtail (middle) human (smoker) and (lower) human (nonsmoker). Final protein concentrations in reaction flasks were (A) 2·8 mg/ml, (B) 3·1 mg/ml and (C) 2·6 mg/ml.

gland and pancreas were quite low and, since the fluorometric assay is considerably more sensitive than the HPLC assay, it possibly reflects a more accurate measurement of the hydroxylating activity in the various tissues. Better correlations were observed with placenta, liver and kidney where much higher concentrations of microsomal proteins could be incubated.

The capacities of various human fetal (26-week gestation) and placental (term) tissues to catalyze the covalent binding of ^{3}H-BP to calf thymus DNA are given in Table 3. Of the tissues assayed, the placenta with the highest AHH activity likewise exhibited the greatest capacity to catalyze covalent binding to DNA. The lung also was comparatively active but the liver, kidney and spleen exhibited very low activities. The appearance of the metabolic profiles observed with the various tissues thus tended to correlate with the capacity of tissue enzymes to catalyze covalent binding to DNA. Unfortunately, there were insufficient microsomes from the adrenal gland and spleen to perform DNA-binding assays on those tissues.

Table 3. Covalent binding of ^{3}H-BP to DNA in the presence of microsomal fractions of human fetal (26 weeks) and placental (term) homogenates. Microsomes from the skin of methylcholanthrene pretreated (40 mg/kg, i.p. 48 hr before sacrifice) mice are included for comparison

DISCUSSION

Interest in the utilization of high-pressure liquid chromatography for analyses of the metabolism of polynuclear aromatic hydrocarbons has increased markedly in recent years due to a number of advantages of the method, particularly when employed in conjunction with ^{14}C-labelled substrates. The older fluorometric assay is extremely sensitive and measures primarily the 3-hydroxylated metabolite (although other phenolic metabolites may contribute varying amounts of fluorescence [23]) but does not measure non-phenolic metabolites. A more recent assay procedure that employs ^{3}H-BP as substrate [24] is somewhat unsatisfactory due to the complications of the NIH shift [25]. The advantages of HPLC include simplicity, rapidity (chromatography can be completed in 30 min in our system without sacrificing resolution), good separation of phenols, quinones and diols and separations can be effected at ambient temperatures—the principal advantage over gas–liquid chromatography. Present techniques of HPLC, however, do not allow separation of all the known and possible metabolites although considerable improvement in the separation of phenolic metabolites now seems feasible through recycling [26]. The use of microparticulate columns in these studies enabled good separation of the 9- and 3-phenols and of the various standard quinones and diols. The quantities of 7- and 1-phenols in the peak containing the 3-phenol however, are unknown and will

require further investigation. Also, current techniques with HPLC do not provide the sensitivity of the fluorometric assay.

The present investigation illustrates the potential usefulness of HPLC in studying the metabolism of PAH in primate fetal tissues. Since by virtue of their high lipid solubility these ubiquitous environmental contaminants would be expected to pass readily from the maternal to the fetal blood, the desirability of obtaining these metabolic data is immediately obvious. This is particularly pertinent in view of observations that such chemicals act as carcinogens transplacentally in experimental animals [8–10] and that human fetal tissues contain the necessary enzymes for bioactivation via mixed-function oxidation [11–13].

The lack of correlation of enzymatic activities as assessed with various techniques for measuring BP metabolism also has been noted by other researchers [27–29]. In this study, the lack of correlation between activities measured with the fluorometric assay vs the HPLC assay were particularly noticeable in assays with fetal adrenal glands. Although much less adrenal microsomal protein was present in incubation flasks as compared with liver, lung, and placenta, this did not appear to entirely account for the apparent discrepancy. Specific activities calculated for the adrenal gland on the basis of the HPLC assay were much lower in relationship to the liver than when calculated on the basis of the fluorometric assay. Further research will be required to resolve this question.

Of interest was the observation that placental microsomes with high AHH activity (from smokers) were more active in catalyzing covalent binding to DNA than any of the other fetal tissues investigated. Previous studies [30] have shown that epoxide hydratase activities in human fetal placental microsomes are very low regardless of the hydroxylase activity detectable in the same preparation. Human fetal liver, lung, kidney and adrenal gland, however, exhibited activities comparable to those observed in adult rat livers. Thus, the data obtained with respect to DNA binding in this study are in agreement with that expected on theoretical grounds based upon the metabolic data. Since other studies [31, 32] have indicated that human placental AHH activity is localized in the endoplasmic reticulum of syncitial cells, it would be of interest to determine whether the incidence of choriocarcinoma in humans is in any way related to the exposure of women to polycyclic hydrocarbons.

A study of the biotransformation of BP in adult human tissues (liver and lymphocytes) with HPLC has been reported very recently [33]. It is of interest to note that the investigators likewise detected metabolites that did not co-chromatograph with any of the known standards. Whether or not the formation of these metabolites is peculiar to primate tissues remains an interesting question for future investigations.

Serum Prolactin Concentrations Throughout the Menstrual Cycle of Normal Women and Patients with Recent Breast Cancer*

E. N. COLE,‡ P. C. ENGLAND,† R. A. SELLWOOD‡ and K. GRIFFITHS†

†*Tenovus Institute for Cancer Research, Heath, Cardiff, CF4 4XX.*
‡*Department of Surgery, University Hospital of South Manchester, Withington Hospital, Manchester, M20 8LR, Great Britain*

Abstract—*Prolactin concentration has been estimated by radioimmunoassay of serum samples taken daily throughout the menstrual cycle of* 11 *patients who had undergone mastectomy for primary breast cancer and* 32 *normal women. Although there were no marked cyclical changes in prolactin level, concentrations were lowest in the follicular phase. Hence, comparison of normal and cancer subjects required detailed statistical analysis of results from comparable stages of the monthly cycle. Mid-cycle peaks of oestradiol and follicle stimulating hormone and the onset of menstrual bleeding were used as reference points. Prolactin concentrations were very similar in samples from normal and cancer groups, although at certain stages of the cycle some significant differences were found: on the fifth day preceding the mid-cycle oestradiol peak; during the follicular and periovulatory phases; and among the highest mid-cycle levels. At these stages of the cycle, samples from the breast cancer patients had a greater prolactin concentration than normal controls, although levels were within the normal range. The physiological relevance of these higher prolactin concentrations is uncertain and, in general, this detailed study clearly indicates little difference between serum levels of prolactin in normal women and in patients with breast cancer whose primary tumour had been removed more than three months previously.*

INTRODUCTION

ALTHOUGH the mammotrophic–lactogenic and luteolytic–luteotrophic effects of prolactin are well established in experimental animals [1, 2], the physiological role of prolactin during the human menstrual cycle is not so well understood. Apart from generally higher plasma levels in the luteal phase, and a possible increase near mid cycle, no consistent patterns of prolactin concentration have been found from daily blood sampling [3–8]. Indeed, such studies have emphasized the marked variations in prolactin concentration which occur not only between individuals but also from day to day within subjects. Furthermore, because cycles of differing lengths are usually aligned for periovulatory events, prolactin concentrations at the time of menstruation have been given much less attention [9].

The effects of prolactin on experimental mammary tumours are well documented, and their relevance to human breast cancer has been reviewed recently [10]. Whereas basal plasma prolactin concentrations were correlated with differing susceptibility to chemical induction of mammary tumours in 3 strains of female rats [11], a finding which also appears true for male rats [12], our studies of human breast cancer patients have shown similar basal prolactin levels at various stages of the disease and in control subjects [13, 14]. These and other studies [15–17] indicate that if there are abnormal prolactin concentrations in breast cancer patients then the differences will be small. However, elevated prolactin concentrations in breast cancer patients have been found

using a heterologous radioimmunoassay [18] and also using a bioassay [19].

In this detailed study, basal prolactin concentrations throughout the menstrual cycle have been compared in normal women and in breast cancer patients, to examine the possibility that there may be differences at some stages of the cycle only. As it would be unethical to delay mastectomy for more than a month while collecting the daily blood samples, patients were studied at least three months after removal of the primary tumour, when they had resumed regular cycles. Such patients may still be considered to have breast cancer, though occult, since breast carcinoma is regarded by many as a systemic disease [20, 21].

MATERIAL AND METHODS

Subjects and samples

Samples of peripheral venous blood (10 ml) were obtained daily, or as often as possible, between 09.00 and 12.00 hr for at least one menstrual cycle. The blood was allowed to clot, centrifuged and serum removed to be stored at −20°C. The subjects were 32 normal women, and 11 women who had undergone mastectomy for primary carcinoma of the breast but had since resumed regular menstrual cycles. None of the subjects had a history of gynaecological disorders nor was taking drugs, hormone preparations or other agents known to affect prolactin, ovarian steroid or gonadotrophin levels.

Of the normal women, 11 were selected to be matched controls for the group of cancer patients on the basis of cycle length, age and completeness of sampling. The normal women, including matched controls, were placed into 3 subgroups by age for data analysis.

Measurement of prolactin, follicle stimulating hormone (FSH), oestradiol-17β and progesterone

Prolactin was measured by the radioimmunoassay established in these laboratories by Cole and Boyns [22]. Results are given as milliunits/ml M.R.C. Res. Std. A 71/222 where 1 mu = 50 ng prolactin by this assay system. Serum samples were assayed in duplicate, all those for an individual subject being together in one of the 8 assays that were required. Each cancer patient was paired with her matched control and their samples also included within the same assays. Displacement of 5% of bound iodinated prolactin was achieved by 0·04 mu/ml prolactin.

Measurements of FSH were limited to women over 40 years old. The radioimmunoassay of Groom *et al.* [23] was used and the results served to check whether subjects had normal cycles with a marked mid-cycle peak.

Oestradiol-17β and progesterone were determined by radioimmunoassays and the results for these subjects have been reported [24, 25].

Analysis of results

Prolactin concentrations were calculated from radioimmunoassay standard curves by the preferred equation of Taljedal and Wold [26]. Values of less than 0·01 were entered into subsequent calculations as 0·01 mu/ml.

Menstrual cycles varied greatly in length and so two preference points were used: the day of the mid-cycle peak of oestradiol-17β was designated Day 0, taking gonadotrophin and progesterone profiles into consideration; the day of appearance of menstrual bleeding was labelled M.

Prolactin concentrations were first examined to assess whether they met the assumptions inherent in parametric tests of statistical significance [27]. A logarithmic transformation was found necessary. Back-transformation yielded geometric means, but the logarithmic values were tested for significant differences.

As Student's *t*-test should be reserved for planned comparisons [27], for which the experimental design allowed relatively few, the Student–Newman–Keuls (SNK) procedure was applied to transformed daily prolactin values from the cancer, matched control, and normal 40s groups. The range of values in the cancer group was not wide enough to hold significant differences, but prolactin levels on days −5 and +1 in the other two groups lay beyond the maximum non-significant ranges at the 5% level. Planned comparisons were therefore made in the remaining groups using data from days −5 and +1.

The experimental design could support the use of Student's *t*-test for the following planned comparisons:

(a) test for homogeneity of normal subgroups and whether the cancer group is different.
(b) test highest periovulatory prolactin levels in cancer vs matched control groups.

Additionally, planned comparisons were made using samples taken during defined 5-day intervals which were evenly spaced over 4 consecutive weeks: days −1, 0, +1, 2, 3 (periovulatory phase); days −8 to −4 (fol-

licular phase); days +6 to +10 (luteal phase), and the period 2 days before and after Day M. By pooling the data in this way, the resulting prolactin levels should be less sensitive to misalignment of cycles. Values for the follicular phase were then compared with the periovulatory phase, and also the 5 days around menstruation, within all groups; the follicular phase prolactin in the cancer group was compared with matched controls and combined normals.

RESULTS

Mid-cycle peaks of oestradiol-17β or FSH could be located in 25 normal cycles and in all the 11 cycles from the patients with breast cancer. Two of the normal subjects (aged 53 and 46) were menopausal, having generally elevated FSH levels; critical samples were unavailable for a further 6 subjects and these were therefore omitted from detailed data analysis. One other cycle was rejected because of low FSH levels in an abnormally long luteal phase.

The remaining 24 normal cycles were placed in 3 age groups (Table 1). Distribution of ages within each group was essentially random, and cycle lengths were variable with no age-related trend. Table 1 also shows median value with range of both age and cycle length for the breast cancer group, matched control group and the combined normal group. The 30-year-old in the matched control group was chosen for her 22 day cycle to pair with the 23 day cycle of a 45-year-old cancer patient.

Prolactin concentrations did not follow a Gaussian distribution but approximated to a log-normal distribution. This is evident from Table 2 where for each group the median value from raw data is compared with the calculated arithmetic and geometric means. In a normal distribution, median and mean values coincide: in Table 2, the geometric mean is the closer to the median. Furthermore,

Table 1. *Allocation of subjects to groups, their age and the duration of their menstrual cycle*

Group	Age (years) Median	Range	Cycle length (days) Median	Range	Number of cycles
Normal 20s	25	22–29	30	26–32	8
Normal 30s	34	30–39	26	22–32	7
Normal 40s	44	40–49	27	25–32	9
Breast cancer	44	38–48	27	23–33	11
Matched control	41	30–49	27	22–32	11
Combined normal	35	22–49	28	22–32	24

Menstrual cycles of 23 normal women have been grouped by age and additionally by matching to the 11 cancer patients on the basis of cycle length and age. Note that 2 cycles were studied from one 22 year old subject.

Table 2. *Comparison of serum prolactin concentrations between groups of subjects using statistics of location and dispersion that are derived from raw data (median with 2·5–97·5 percentiles) and by arithmetic (mean, S.D.) or logarithmic (geometric mean ± 1·96 S.D. range) computation*

Group	Number of samples	Median value	2·5–97·5 percentiles	Arithmetic Mean	Arithmetic S.D.	Geometric Mean	± 1·96 S.D. range
Normal 20s	187	0·10	0·01–0·45	0·15	0·133	0·085	0·01–0·81
Normal 30s	147	0·09	0·01–0·33	0·12	0·090	0·083	0·01–0·53
Normal 40s	226	0·10	0·03–0·28	0·12	0·101	0·101	0·03–0·31
Breast cancer	292	0·11	0·02–0·44	0·15	0·112	0·114	0·02–0·53
Matched control	262	0·10	0·02–0·29	0,12	0·069	0·097	0·03–0·35
Combined normal	550	0·10	0·01–0·38	0·13	0·111	0·091	0·01–0·53

Serum prolactin concentrations in mu/ml MRC Res. Std. A 71/222 are given for menstrual cycles from subjects grouped as in Table 1. The median and 2·5–97·5 percentiles were found by inspection; arithmetic mean and standard deviation (S.D.) were calculated in the usual way; geometric mean ± 1·96 S.D. range are back transformations of the logarithmic mean ± 1·96 S.D., where 1·96 = t (approximately) at the 5% probability level for the appropriate degrees of freedom.

95% of raw data lie within the 2·5–97·5 percentiles by definition, and within ±1·96 S.D. of the mean of a normal distribution. These limits can be compared in Table 2 for each group of women, and it is obvious that a logarithmic transformation of prolactin values is reasonable.

Prolactin concentrations were similar in all groups of normal subjects and in the group of cancer patients (Table 2). The range of geometric mean prolactin for those individuals who were rejected from the normal group was 0·02–0·19, and this is similar to the ranges for normal subjects in their 20s, 30s and 40s or the range for breast cancer patients: 0·02–0·25; 0·02–0·21; 0·06–0·14; and 0·05–0·23 mu/ml respectively. There was no evidence for any trend in serum prolactin concentration with age (Fig. 1), and it can be seen that the geometric means for the cancer patients are within the range for the normal women.

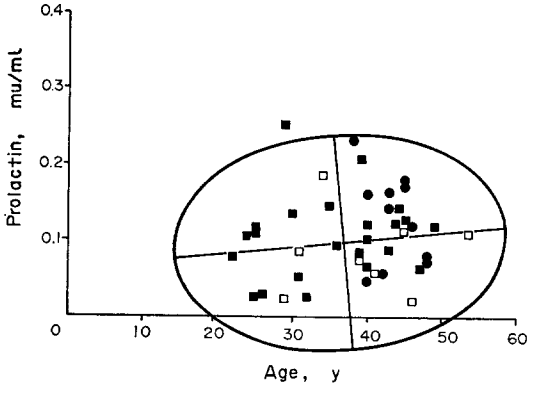

Fig. 1. Relationship between serum prolactin (geometric mean of daily samples over the menstrual cycle) and age. The ellipse was calculated to include 95% of data points from normal women. ■ Normal group; □ normal subjects whose prolactin concentrations were rejected from detailed analysis; ● breast cancer patients.

Daily prolactin concentrations for the follicular, periovulatory and luteal phases and the period of menstruation showed fluctuations of the geometric mean which were small compared with the range of the values for each day. Figure 2 illustrates this for the combined normal group. Nevertheless, prolactin levels were generally higher in the luteal phase than in the follicular phase, and an elevation at mid-cycle was present ($2P < 0{\cdot}025$ for day +1 vs −5 relative to the oestradiol-17β peak). A decline in serum prolactin occurred during the 2 days before onset of menstrual bleeding in 21 women out of 27 who were sampled on these days (significant at 1% level by a sign test).

When daily prolactin concentrations in breast cancer patients and matched controls were compared, a significant difference was found on day −5 in the follicular phase ($2P < 0{\cdot}01$) but not for day +1. A mid-cycle elevation of serum prolactin in the cancer group could not be shown ($2P > 0{\cdot}10$) whereas the significance level was 0·001 for day −5 vs +1 in the matched control group (Fig. 3). However, by using a paired comparison of the mean values shown in Fig. 3, Wilcoxon's matched-pairs signed-rank test indicated an overall difference between the 2 groups at the 2% probability level. This statistical method takes no account of the considerable range of prolactin concentrations associated with each mean (Fig. 2).

As the differences in mean prolactin levels within 5-day intervals were generally non-

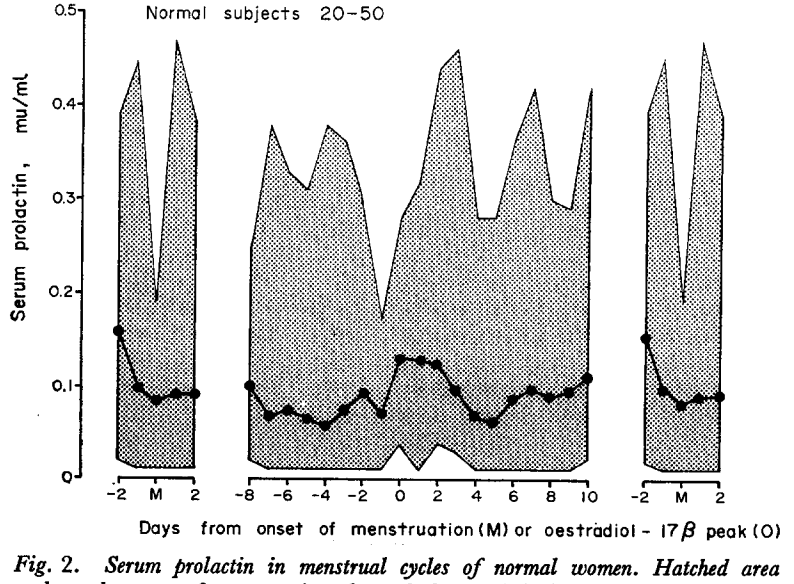

Fig. 2. Serum prolactin in menstrual cycles of normal women. Hatched area encloses the range of concentrations for each day, and the line denotes the geometric mean for 24 cycles.

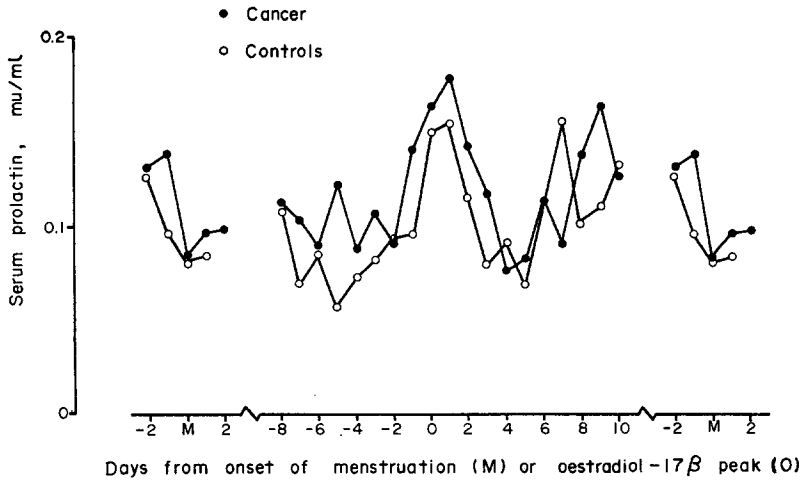

Fig. 3. Comparison of daily prolactin concentrations in breast cancer patients and matched controls. Values are geometric means for 11 *cancer patients* (●) *and* 11 *controls* (○).

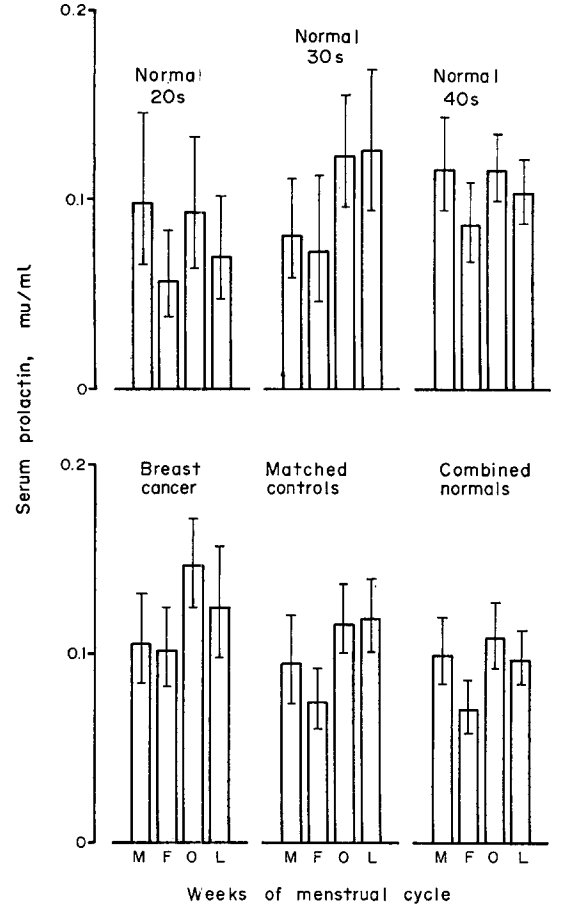

Fig. 4. Weekly patterns of serum prolactin in normal subjects, grouped according to age or selected as matched controls, and in breast cancer patients. Geometric mean with 95% *confidence limits are shown for prolactin concentrations over* 5*-day intervals in the weeks of menstruation* (M) *and ovulation* (O) *or within the follicular* (F) *and luteal* (L) *phases.*

significant, pooled values were calculated to represent the pattern of prolactin concentration week by week (Fig. 4). In each group, serum prolactin was lowest in the follicular phase and was significantly higher in the periovulatory phase ($2P < 0{\cdot}1$, 20s; $< 0{\cdot}05$, 30s; $< 0{\cdot}05$, 40s; $< 0{\cdot}01$, combined normal age groups; $< 0{\cdot}01$, cancer group; $< 0{\cdot}01$, matched controls). In all the groups of normal women, prolactin was higher in the week of menstruation than in the following week, significant at $2P < 0{\cdot}01$ for the combined group.

The weekly pattern of prolactin in serum from the cancer patients differs from normal (Fig. 4). Prolactin remained at the level of the menstrual phase during the follicular phase and was higher for the next 2 weeks. Consequently, there was a difference ($2P < 0{\cdot}05$) in the follicular phase serum prolactin concentration between 55 samples from 11 breast cancer patients and either 100 samples from 23 normal women or 49 from the matched controls. Similarly, these cancer patients have higher prolactin concentrations than normal in the periovulatory phase. In addition, by taking the highest values in the periovulatory phase, the geometric mean prolactin for the cancer patients (0·29) is greater than for the matched controls (0·20; $2P < 0{\cdot}025$).

DISCUSSION

Using samples taken throughout the menstrual cycle, only small differences could be found in serum prolactin concentrations between normal women and a group of patients that had undergone mastectomy for primary breast cancer. Indeed, to show any significant differences in prolactin levels, both the design

of the radioimmunoassays and the statistical treatment of results required very careful consideration. The physiological relevance of the differences is obviously uncertain.

The *a priori* selection of control subjects was intended to minimize possible sources of error due to interassay variation, age-related trends and bias arising from, for example, a prolonged follicular phase which would tend to lower an individual's mean prolactin level. In practice, however, the major variance components arose from within and between subjects. Hence, geometric mean prolactin values over the four 5-day intervals were within 2% of those given in Table 2 for which sets of results over the whole cycle were taken into consideration.

Several statistical treatments of the data were possible. Thus, prolactin concentrations could be normalized to reduce inter-subject variation and then tested for consistent cyclical changes. Alternatively, areas under the prolactin–time curve could be taken for the comparison of cancer and normal groups. Instead, the familiar Student's *t*-test has been applied to data which have undergone transformation in order that the assumptions of parametric significance testing were better met.

Prolactin concentrations approximated quite closely to a log-normal distribution, and a slight skewness may be accounted for by less than 0·01 mu/ml prolactin in the "prolactin-free" plasma that was used in constructing the radioimmunoassay standard curve. This skewness is a likely cause of the over-estimation of standard deviation terms which is indicated by the $\pm 1{\cdot}96$ S.D. limits being wider than the 2·5–97·5 percentiles (Table 2). The significance levels for differences between means are likely to be conservative estimates in consequence.

Daily serum prolactin concentrations were variable and there were no consistent patterns from one person to another during the menstrual cycle. This is in agreement with similar studies from other centres [3–7]. However, by pooling the results from the defined 5-day periods, a clear pattern of serum prolactin emerged. This pattern throughout the menstrual cycle was consistent insofar as follicular phase prolactin was lower than in the periovulatory or menstrual phases for the combined group of 24 normal cycles and in the subgroups of 8, 7 or 9 cycles by age, or the matched control cycles. However, the pattern for the breast cancer group differed because prolactin in the follicular phase remained at the level of the preceding week before increasing in the periovulatory and luteal phases (Fig. 4).

Comparison of patterns of serum prolactin week-by-week has advantages over the simple comparison of mean concentrations from one group of subjects with another. In addition to smoothing out daily fluctuations, assay and alignment errors should be minimal, and the errors due to the selection of patients and matched controls reduced. Thus, neither worry related to the mastectomy nor residual post-operative stress are likely to affect the pattern of prolactin levels over the month, whereas it could be argued that a single sample might well be affected.

The breast cancer patients for this study had undergone mastectomy for primary breast cancer and had since resumed normal cyclical activity. It is, of course, virtually impossible to obtain daily blood samples for a month from a woman with known or suspected breast cancer; it would be unethical to withhold treatment for this time, and hormone concentrations would be of doubtful value in a woman giving informed consent under such distressing circumstances.

The abnormal prolactin pattern in our patients may indicate some relationship between prolactin and carcinogenesis. The occurrence of significantly greater prolactin concentrations in the cancer patients during the periovulatory phase and the possible prolonged elevation at this stage (Fig. 3) certainly provide further evidence that the endocrinology of these women still differs if only minimally from the 23 normal subjects. Just as the disease persists in occult metastatic foci even after mastectomy [20, 21], so there may remain an abnormal prolactin balance in the breast cancer patients. However loss of breast tissue may itself affect prolactin secretion or utilization, although such a feedback mechanism from prolactin target tissue remains to be clarified. Mastectomy could result in neural stimulation of prolactin release, which might explain the generally elevated levels, but is unlikely to account for the observed difference in the weekly pattern.

Although differences in serum prolactin concentration were found, their interpretation requires care as it is probably unwise to generalize from a sample of only 11 premenopausal breast cancer patients. The differences between cancer and control levels are very small and their relationship to the disease is still uncertain.

Effects of Prolactin and Suppression of Prolactin Secretion on Experimental Tumours of Lung and Muscle in Mice

RASHIDA A. KARMALI* and D. F. HORROBIN*

Department of Physiology, University of Newcastle upon Tyne, NE1 7RU, England

Abstract—*Prolactin is established as a growth factor for a number of animal mammary tumours. Yet prolactin at the appropriate time may inhibit mammary tumour development. We have tested the possibility that these actions may be systemic rather than organ related by investigating the effects of prolactin treatment and of suppression of prolactin secretion using 2 Br α-ergocryptine (bromocriptine) on two tumours of organs not thought at present to be prolactin dependent. Prolactin appeared to inhibit the growth but not the induction of urethane-induced pulmonary adenomas in mice and to reduce tumour growth and increase survival in mice injected with the Moloney sarcoma virus. Bromocriptine had no significant actions on pulmonary adenoma growth but when given over the period of urethane injection it dramatically reduced thymic uptake of tritiated thymidine. Bromocriptine reduced survival and increased tumour growth in animals treated with the Moloney virus: prolactin given with the bromocriptine prevented these effects.*

INTRODUCTION

THE MAMMARY gland is the best established target organ for prolactin. There are many examples in the literature of experimental mammary tumours whose growth is enhanced by elevation of plasma prolactin levels and slowed or abolished by reduction of prolactin levels [1–5]. However, there is also a considerable amount of evidence that if prolactin levels are elevated before and during the administration of a carcinogenic agent such as dimethylbenz-α-anthracene then the development and growth of mammary tumours may be prevented or slowed [6–10]. There is no adequate explanation for these conflicting findings. When prolactin stimulates tumour growth a proposed explanation is that the prolactin-dependent tumour tissue is able to outgrow the prolactin-dependent normal tissue. When prolactin inhibits tumour growth it is assumed that in some undefined way activation of normal mammary tissue may prevent tumour development.

One possible but uninvestigated explanation for these conflicting results lies outside the mammary gland. This is that some of the effects of prolactin on mammary tumour growth may be unrelated to the fact that the mammary gland is a target organ for prolactin. If prolactin had general effects on the inflammatory response or on the immune system then this in itself would have an effect on tumour growth which would interact with the target organ dependent effects. That this is not impossible is indicated by the inhibition of human lymphocyte responsiveness to phytohaemagglutinin produced by prolactin [11] and human placental lactogen [12].

We have therefore investigated in mice the effects of prolactin on two tumours of tissues not at present thought to be prolactin-dependent, the urethane-induced pulmonary adenoma [13] and the Moloney virus-induced rhabdomyosarcoma [14].

Accepted 22 November 1976.

This work was supported by the North of England Cancer Campaign and by the National Cancer Institute of Canada. We thank Professor A. G. Heppleston, Professor J. J. T. Owen, Dr. Paul Dyson and Dr. W. A. Aherne for much advice, encouragement and help. Professor E. Fluckiger of Sandoz, Basel, kindly supplied the bromocriptine.

MATERIAL AND METHODS

Urethane-induced pulmonary adenoma

Random bred mature male A2G mice were used. In each of two experiments four groups of 10 animals were used. The animals were

distributed among the groups in a way which ensured that the mean starting weight of each group was the same. The groups were treated daily as shown. All injections were given subcutaneously in the afternoon in a volume of 0·1 ml.

(1) Control: 0·9%.
(2) Ovine prolactin (Ferring, Malmo, Sweden): 50 μg.
(3) Ovine prolactin 250 μg.
(4) 2 Br α-ergocryptine (bromocriptine): 100 μg. Bromocriptine is a long acting dopamine agonist and a potent inhibitor of prolactin secretion [4, 5, 15].

The prolactin was not contaminated by LH, FSH, ACTH or TSH as shown by radioimmunoassay. Growth hormone contamination was less than 2%. It contained less than 10 ng/mg of arginine vasopressin (W. B. Malarkey, personal communication).

Urethane was given i.p. to all animals in a dose of 1 mg/g body weight. In the first experiment the various treatments began 2 weeks before the urethane and continued for 4 weeks afterwards. In the second experiment the treatment began 8 weeks after the urethane and continued for a further 8 weeks. Each experiment thus lasted for 16 weeks. One hour before death each animal was given 0·5 μCi/g of tritiated thymidine i.p. After death the thymus and the lungs were removed. The thymus was weighed and its radioactivity counted. The lungs were fixed in Carnoy's solution. Tumours on the surfaces of both lungs were counted and measured using a dissecting microscope. The sum of the products of the horizontal and vertical widths of each tumour gave the area index. From the left lung 5 μm thick paraffin sections were prepared for autoradiography using a stripping film technique. The labelling index in the tumours was estimated by counting the number of labelled nuclei at a ×1000 magnification in different fields that contained a total of 3000 labelled and unlabelled nuclei. The index was equal to the number of labelled nuclei counted/total number of nuclei scanned multiplied by 100.

All parameters in the treated groups were compared with the control groups using Student's *t*-test.

Moloney virus-induced rhabdomyosarcoma

The experiments were carried out in male Balb/c mice. At 25 days of age each animal was injected in the mid-left thigh with 0·2 ml of crude tumour homogenate (20% of tumour by weight in Earle's saline) kindly provided by Professor J. J. T. Owen. Tumour growth was monitored for the next 14 days by measurement on alternate days of the thigh width at the point of injection. Seven experimental groups of 10 mice and one control group of 20 mice were used and were given daily the treatments shown by subcutaneous injection. Each treatment began 3 days before the virus inoculation and was continued until the end of the experiment.

(1) 0·9% saline.
(2) 50 μg ovine prolactin.
(3) 250 μg ovine prolactin.
(4) 500 μg ovine prolactin.
(5) 250 μg bromocriptine.
(6) 500 μg bromocriptine.
(7) 50 μg prolactin + 250 μg bromocriptine.
(8) 500 μg prolactin + 500 μg bromocriptine.

For each animal, its thigh width on day 0 was taken as 100% and subsequent changes in thigh width were first expressed as percentages of this. The mean percentage change in the control group on each day was then estimated. The percentage change in each experimental animal was then expressed as a percentage of the mean percentage change in the control group. The results in each group were finally expressed as a mean percentage deviation from control, with the mean control value on each day being taken as 100%. The experimental groups were compared with the control groups by an analysis of variance.

RESULTS

Urethane-induced pulmonary adenoma

The results are summarised in Fig. 1. When the treatments were given over the period when the urethane was injected only two significant findings were observed but these were very striking. The thymus uptake of tritiated thymidine and the tumour labelling index were both dramatically reduced ($P < 0·001$) in the group of animals given bromocriptine. The weight changes in the various groups are shown in Table 1.

When the treatments were started 8 weeks after the urethane by which time the tumours would have been established and begun to grow the only obvious effects were a reduction in the number of visible tumours and the total area index of the tumours in both the prolactin-treated groups. The effect of the lower dose of prolactin was more marked than that of the

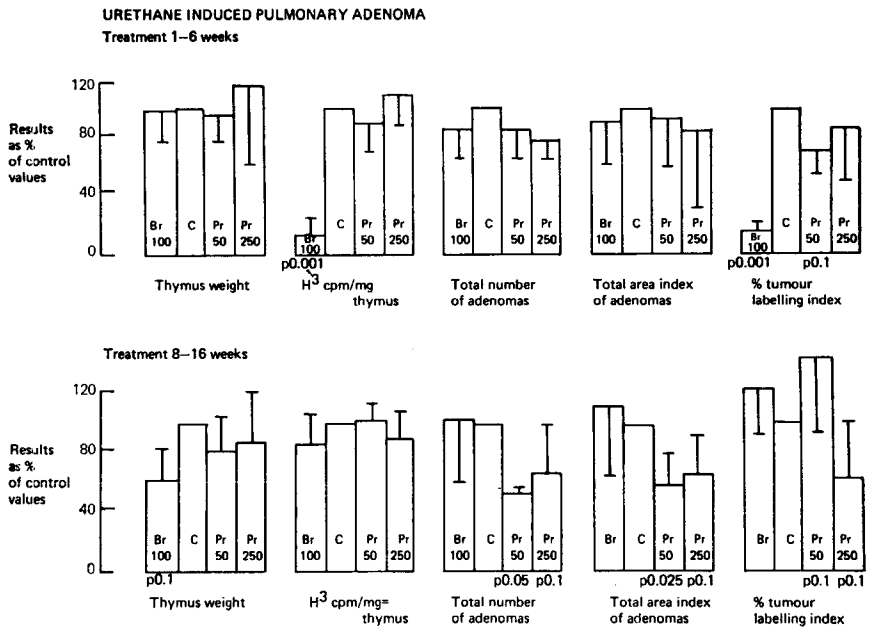

Fig. 1. *The effects of treatment with prolactin and bromocriptine on the development and growth of urethane-induced pulmonary adenomas in mice and on thymus weight and thymus uptake of tritiated thymidine. Detailed experimental protocols as described in the text. C, control: Br*100, *bromocriptine* 100 *μg/day: Pr* 50, *prolactin* 50 *μg/day: Pr* 250, *prolactin* 250 *μg/day. For each parameter the mean value in the control group was noted: each result in the other groups was then expressed as a percentage of this mean control value. The bars indicate the mean percentages of control* ± *S.E.M.*

Table 1. *Weights in g at* 16 *weeks in the various groups of animals given urethane. Initially the animals were distributed so that the mean weight in all the groups on starting the experiment was* 26·6 g. *All figures represent means* ± *standard deviation*

Animals treated from 0–6 weeks after receiving urethane		
Control		33·6 ± 2·30
Prolactin	50 μg/day	32·9 ± 3·11
Prolactin	250 μg/day	32·9 ± 4·63
Bromocriptine	100 μg/day	33·3 ± 2·29
Animals treated from 8–16 weeks after receiving urethane		
Control		32·6 ± 3·75
Prolactin	50 μg/day	32·3 ± 2·93
Prolactin	250 μg/day	33·0 ± 2·62
Bromocriptine	100 μg/day	33·5 ± 3·34

higher dose. The mean surface area of each tumour did not differ between the groups.

Moloney virus-induced rhabdomyosarcoma

The tumours developed at the site of inoculation approximately 5–7 days after virus administration, reached a maximum size by 9 days and thereafter regressed. The growth pattern in the control group is shown in Fig. 2a: mean thigh width on day 0 was 8·02 mm ±2·10 (S.D.) and on day 5, 13·86 mm ±2·53. In Figs. 2b and 3 the growth patterns in the other groups are expressed as deviations from the control. Differences between the groups were studied by analysis of variance.

The most striking results concerned survival at 14 days after injection of the virus (Table 2). One in twenty control animals, 0/30 prolactin treated animals and 10/20 bromocriptine treated animals died ($P < 0{\cdot}001$). The administration of exogenous prolactin largely prevented deaths associated with bromocriptine treatment: only 1/20 of the animals which received both treatments died.

With regard to tumour size, 50 μg/day prolactin consistently inhibited tumour growth ($P < 0{\cdot}005$). The two higher doses had inconsistent effects: tumour size was just significantly greater than control in the 250 μg/day group ($P < 0{\cdot}05$) from the 8th to the 12th day. Tumour size in the group which received 250 μg/day bromocriptine was significantly greater than control from the 6th to the 10th days ($P < 0{\cdot}05$) while results with the 500 μg/day group showed no consistent differences from control. When prolactin and bromocriptine were given together the tumour growth pattern was extremely close to that of the controls.

Table 2. *Survival data for animals injected with the Moloney sarcoma virus homogenate and treated in various ways*

	Total	Alive	Dead
Control	20	19	1
Prolactin (50, 250 or 500 μg/day)	30	30	0
Bromocriptine (250 or 500 μg/day)	20	10	10
Bromocriptine + prolactin	20	19	1

DISCUSSION

Urethane-induced pulmonary adenoma

This tumour was first described in 1943 [13] and has been the subject of many subsequent reports [16–21]. The urethane is believed to have both a direct local carcinogenic effect [22] and a systemic effect [23] in lowering the resistance of adenoma development.

The results of the present experiments show that none of the treatments given to cover the time at which urethane was administered had any effect on the tumour development at 18 weeks. This suggests that the treatments did not have any effect on the actual numbers of tumours induced and possibly did not have any important action on their growth in the early stages. The most striking finding in this part of the experiment was the dramatic reduction in thymus uptake given bromocriptine at the time of urethane administration. No such interference with thymidine uptake took place when the bromocriptine was given from 8–16 weeks.

We would be inclined to dismiss this as an unexplained artifact but for our finding that in mice of the Bar Harbor 129 strain bromocriptine has a similar profound action on thymidine uptake by the thymus [24]. It has been suggested that urethane may be toxic to the thymus [25] and this study indicates that in the absence of prolactin the toxic effect may be markedly enhanced. The Bar Harbor 129 mice seem to have some abnormality of thymus development and in this case again bromocriptine appeared to exaggerate this.

We have no satisfactory explanation for the dramatic decrease in tumour labelling index in the same group of animals which showed the sharp fall in thymidine uptake by the thymus. The labelling index theoretically should be a measure of the mitotic activity of the tumour. If this is so then tumours with a low labelling index should be smaller than others but there was no evidence that this was so. The same tumour size might be attained with a low labelling index if cell loss from the tumour were sharply reduced and this could be correlated with a failure of the immune response to the tumour. However there appeared to be little if any lymphocytic infiltration of the tumours in any group with no differences between the groups.

When the treatments were given from the 8th to 16th weeks prolactin clearly reduced the numbers of the visible adenomas. Since prolactin had no apparent effect on induction this must mean that some of the tumours stopped growing in the very early stages or disappeared altogether. The sizes of the individual tumours that were left as shown by the mean area indices were not significantly different from the sizes of the tumours in the other groups. This suggests that there may be two populations of tumours, one unaffected by prolactin and one susceptible to suppression in its presence. Variations in the antigens carried by the tumours might account for this.

Moloney virus-induced rhabdomyosarcoma

The tumours induced by inoculation of Moloney sarcoma virus into mouse muscle have been classified as rhabdomyosarcomas [14]. The nature of the sarcoma varies according to the animal strain inoculated, the age of the animals and the virus dose. Tumours induced in immunologically hyporesponsive hosts grow progressively and kill while those induced in more reactive hosts grow rapidly at first but then regress [26]. The regression is probably mediated by an immunological reaction against tumour specific transplantation antigens (TSTA) [27–29] which this tumour possesses. Reaction against TSTAs primarily depends on lymphocytes [30–33] but cytotoxic humoral antibodies may also be involved [34–36]. Two mechanisms of *in vitro* growth inhibition in the Moloney system have been suggested [37], the first non-specific and probably mediated by macrophages and the second specific and probably mediated by non-adherent cells. Macrophages, of course, could interact with lymphocytes and the armed macrophages and sensitized lymphocytes could recognize the TSTAs in tumour cells [38, 39].

Our experiments left no doubt that animals in which prolactin secretion was suppressed by bromocriptine were frequently killed by the Moloney virus inoculations. Bromocriptine is a long acting dopamine agonist [15] and could have many actions in the body apart from suppression of prolactin secretion. However, the relationship of the prolactin suppression to the deaths is strongly suggested by the reduction of deaths to one only out of the 20 animals which received exogenous prolactin in addition to the bromocriptine. Presumably actions of bromocriptine unrelated to prolactin suppression would have continued to be operative in this situation. If death due to the Moloney virus is related to hyporeactivity of the immune response then this may indicate that prolactin has a key role to play in the maintenance of a healthy immune system.

The lowest of the three doses of prolactin seemed to be the most effective in maintaining the animals in a healthy state and containing tumour growth. The higher doses may even have enhanced growth slightly. These observations are consistent with the effects of prolactin in other systems where repeatedly it has been observed that a low to moderate amount of prolactin has one effect which may be lost or even reversed when higher amounts are used [4, 5, 15].

GENERAL COMMENTS

These experiments are provocative in three main ways. First they are relevant to the interpretation of studies on the effects of prolactin on mammary tumours. Such studies to date have almost invariably been interpreted in the light of the concept that the mammary gland is a target organ for prolactin. Our findings using organs which at present are not thought to be prolactin target organs indicate that the

hormone can have a clear action in inhibiting tumour growth. The inhibition of mammary tumour growth by prolactin which has repeatedly been observed may in part therefore be dependent on the systemic effects of the hormone.

Second the experiments show that prolactin may have important actions on the growth of a variety of tumours. They therefore indicate that endocrine effects on tumour growth, even in tissues not thought to be hormone dependent, are worthy of further study. The fact that prolactin is now known to be present in both sexes and that in both its secretion rises dramatically in response to such stresses as emotional disturbance, exercise and surgery [40] may have both theoretical and practical implications in cancer treatment.

Third the experiments suggest that prolactin may have actions on the immune system. The effects of bromocriptine on the thymus uptake of labelled thymidine and on survival of the animals treated with the Moloney virus homogenate indicate that normal levels of circulating prolactin may be involved in the maintenance of the normal function of the immune system.

Abstract—*Epstein-Barr virus (EBV) DNA (82 genome equivalents/cell) and EBNA (EBV determined nuclear antigen) were found in tumor tissue from an Israeli Arab child with Burkitt's lymphoma. A lymphoma cell line (LB-132) carrying the EBV genome was established from tumor tissue from this patient. This line resembled other previously established and characterised Burkitt's lymphoma lines. Our results suggest that EBV—carrying lymphoma which occurs endemically in Africa occurs sporadically throughout the world.*

INTRODUCTION

THE EPSTEIN–BARR virus (EBV) has been found to be associated with two human malignant diseases: African Burkitt's lymphoma (BL) and nasopharyngeal carcinoma [1–3]. About 97% of the African Burkitt's lymphoma biopsies tested contained the EBV genome, with 38 genome equivalents per cell, on the average [1–3]. It has also been shown that the African Burkitt's lymphoma represents the proliferation of an EBV-genome carrying clone, in the vast majority of the cases [4]. The relatively few non-African BL cases so far studied were EBV–DNA negative [5–7], although occasional EBV-positive cases have now been found [8, 9]. Serological evidence on a larger number of cases also failed to show the uniform anti-EBV positivity, and the approximately tenfold elevation of mean titers characteristic for the African BL. In the African BL material examined, two cases were found that lacked detectable EBV-DNA and EBNA although the patients had high serum anti EBV titers [1, 2]. The permanent lymphoid cell lines that were established from these tumors were also EBV-negative, but they could be converted to permanent EBV-DNA and EBNA positivity by *in vitro* EBV-infection [10–12]. It might be speculated that these two cases represent the same disease as the majority of the non-African Burkitt's. Since lymphomas with BL-like histology and cytology are spread throughout the world (although their clinical manifestations are slightly different from the African disease) it is conceivable that the EBV genome-negative and positive lymphomas represent etiologically different entities [5]. It may be added that only the African form shows high endemic time–space clustering. We have recently isolated and established in continuous culture a new type of lymphoid cell line from an EBV genome-negative lymphoma [13]. This line is unique because although it has B cell characteristics (surface IgM-kappa) it is devoid of EBV genome and EBV surface receptors, and thus cannot be infected *in vitro*. This line has been described in detail elsewhere [14]. It resembles, however, very closely the Su-Am-B-1 line recently isolated from an EBV genome negative lymphoma in North America [8].

The present report describes a case of an EBV-genome positive lymphoma in an Israeli Arab child, and the establishment of the lymphoma cells in continuous culture. The presence of the EBV genome was demonstrated by nucleic acid hybridization and staining by the EBV-determined nuclear antigen (EBNA).

MATERIAL AND METHODS

Case history

A four year-old Arab boy (G.A.H.) from the Gaza strip was first seen in the Tel Hashomer clinic on February 3, 1975. During a course of one week he developed four tumours in the mandibules and maxillae, on both sides. On examination, a huge abdominal mass was palpated. No enlargement of the peripheral lymph nodes, nor liver or spleen was detected. A biopsy of the mandibular tumor revealed a classical histologic picture of Burkitt's lymphoma, of uniform cell infiltrate consisting of lymphoreticular cells, probably lymphoblasts, confirmed by cytochemical staining of imprints. Lymphoblasts were PAS negative and Sudan III positive. The blood count and bone marrow were normal except for an eosinophilia of 15%.

The patient was given cytoxan 40 mg/kg, after proper hydration and allopurinol therapy. The tumors greatly diminished in size after 48 hr and could not be seen or palpated after a week. The same dose of cytoxan was given every three weeks. Three months later (in May, 1975) an enlargement was palpated in the right testis, which suddenly grew in size two months later. On 3 August, a right orchidectomy was performed and the diagnosis of Burkitt's tumor was again confirmed.

After the operation, therapy by cytoxan was resumed. In November, 1975, the cytophosphan therapy was postponed for five weeks, and again a huge tumoral mass appeared in the right inguinal and testicular region. The administration of cytoxan, 40 mg/kg once again brought about a prompt disappearance of the tumor. It was, however, decided to add adriamycine, 60 mg/kg every three weeks for a total dose of 300 mg/m^2. The child is at present in complete remission.

Handling of the biopsies and isolation of the cell line

The biopsy material from the mandibular tumor was excised aseptically and cut into small pieces in RPMI 1640 medium containing 10% fetal calf serum and antibiotics. The cell suspension was washed several times in the medium, and partly used for the various assays (detection of EBV-DNA—by nucleic and hybridization; EBNA, Concanavalin A tests and determination of B and T cell surface markers) and in part for cell culturing. The biopsy from the tumor of the testis was handled in a similar manner.

Cultures of jaw biopsy cells were incubated in glass tubes (150 × 15 mm) in 2 ml of medium, RPMI 1640 + 30% fetal calf serum (GIBCO) at 37°C, 5% CO_2 in air and 80–95% relative humidity. The medium was changed every 4–6 days until growth was established and passages of the cell line were begun [13].

At that time, the fetal calf serum concentration was reduced to 20%.

EBV-DNA Assay

Preparation of cellular DNA and the details of the procedures used for hybridization of the DNA with precalibrated ^{32}p-labeled EBV complementary RNA (cRNA) were performed as described elsewhere [1]. The hybridizations were corrected to 10 μg DNA per filter and for ^{32}p decay. To estimate the number of EBV genome equivalents per cell the molecular weight of EBV-DNA was taken as 1×10^8 and that of the cellular DNA as 4×10^{12}. EBV DNA positive (Raji DNA) and negative (Molt-4 DNA) controls were included in all experiments. All determinations were performed at least twice.

EBNA Assay

EBNA was assayed by anticomplement immunofluorescence as described by Reedman and Klein [15]. EBNA tests were performed on the tumor biopsy cells and on the permanent cell line. Before testing, the cultures were put on a Ficoll-Hypaque gradient [16] to remove dead cells. Smears were prepared and fixed by acetone–methanol as described. The Hyland goat antiserum to human β1C/β1A reagent was used to stain EBNA at a dilution 1:40. The smears were counter stained with Evans blue (100 μg/liter) for 10 min.

Surface receptors

Rosette formation with sheep erythrocytes (E) was performed according to Jondal *et al.* [17].

Rosette formation with antibody coated sheep erythrocytes (EA) for detection of Fc receptors was performed according to Yoshida and Andersson [18].

Immunoglobulins and β2-microglobulin

Viable cells were exposed to rabbit sera with specificity for human gamma and mu heavy chains, light chains and β2-microglobulin. After washing antibody attachment was tested by incubation with FITC conjugated goat anti-rabbit immunoglobulin serum (Hyland laboratories, U.S.A.). The procedure

for surface fluorescence test was described before [19].

Assay for binding of fluorescent Con. A

Fluorescein-isothiocyanate-conjugated ConA (F-Con.A) was prepared by Miles Yeda (Rehovot, Israel). For the experiments, cells were incubated with 100 μg/ml F-Con.A for 15 min at 37°C. The cells were washed with phosphate-buffered-saline (PBS) and the fluorescence was determined on a drop of cells with a Zeiss ultraviolet microscope. Five hundred cells were counted for each point and only single cells and very small clumps (2–5 cells) were counted for the percentage of caps [13].

Assay for agglutination

Concanavalin A was obtained from Miles-Yeda. 0·5 ml Con.A at different concentrations diluted in PBS was mixed with 0·5 ml of cell suspension to give a final concentration of 2×10^6 cells/ml in a 35 mm petri dish. The density and size of aggregates was scored in a scale from − to + + + + after 30 min incubation at 24°C [13].

RESULTS

Characterization of the cells from the biopsy material

Cells obtained from the primary mandibular tumor were examined for various properties after Ficoll–Hypaque gradient centrifugation [16] to remove dead cells. Cell viability as determined by trypan blue exclusion was 95%. The cell morphology, using Wright's stain, revealed a predominance of small immature lymphocytes with large nuclei and frequent lipid droplets in the cytoplasm. The cells were tested for EBNA and found to be positive (50–60%). Examination of surface immunoglobulin showed presence of Ig-M-kappa on about 60% of the cells.

The cells were strongly agglutinated by 10 μg/ml Con.A even at low cell concentration (10^6/ml) and had low cap forming ability (10–12%) with fluorescent Con.A [13, 20].

A second tumor biopsy was obtained from the same patient six months later. This was a highly infiltrated peritesticular tumor with numerous lymphocytes. Cell preparations of this tumor were tested for EBNA and about 60% of the cells were found positive. The tumor specimen was found to contain 82 EBV genome equivalents per cell by DNA–cRNA hydridization experiments.

Establishment in culture and characterization of the cell line LB-132

After a lag phase of about 8 weeks, the mandibular biopsy cells began to divide. Subsequently the cultures grew rapidly. A cell was established, growing in loose free floating clumps. The cells were small (10–15 μ) rounded and with irregular surface. Morphologically they resembled small immature lymphoid cells, similar to other lines established by us from African EBV carrying BL [20, 21]. The cells doubling time was 24–30 hr, and the saturation density was about 2×10^6 cells/ml. The line was designated LB-132.

The LB-132 cells were EBNA positive at the earliest passage examined (4th–6th), 1–3% of the cells were also VCA positive. The cells were strongly agglutinated by Con.A even at a concentration of 1 μg/ml and at a low cell density of 10^6/ml. Cap forming ability with fluorescent Con.A was low (about 6%) and remained low in subsequent passages. Cells carried surface bound IgM and kappa, β2-microglobulin and formed EAC but no E rosettes.

Table 1 summarizes the main characteristics of the line, compared with the original biopsy cells.

DISCUSSION

While the vast majority (approximately 97%) of African BL cases represent the malignant proliferation of an EBV-genome carrying cell clone (4), the majority of lymphomas that have been diagnosed as BL outside Africa were EBV-genome negative (5–7, 22) although a few EBV positive cases were found [8, 9]. This paper reports a case of EBV-DNA and EBNA positive lymphoma in a Israeli Arab child. In view of the fact that the viral genome was found in the tumor biopsy itself, and also in the derived line, that resembled other lymphoma lines in its morphological features [21], there can be little doubt that this is a genuine EBV-carrying BL.

As argued elsewhere [22] it is unlikely that EBV-carrying lymphomas have picked-up the virus as passenger. It is relevant in this connection that EBV-negative lymphomas have been found in EBV-seropositive patients, were established as lymphoma-representative, EBV-negative lines *in vitro*, and were susceptible to EBV induced *in vitro* conversion to EBV-genome positivity [12, 23]. This demonstrates the actual absence of virus pick-up *in vivo* under otherwise favourable conditions [11, 22]. In

Table 1. *Properties of the biopsy cells and the derived cell line LB*-132

Characteristics	Biopsy	Line*
Cell morphology	Uniform, round, highly pyrominophilic, with long, multiple, basophilic nuclei. Starry sky pattern prominent.	Small immature lymphoid cells, grow readily in suspension with much clumping. No uropods, immature nuclei, prominent cytoplasmic fat droplets.
EBNA	positive	positive
EBV-DNA	positive 82 EBV-genome equivalents per cell	N.T.
VCA	N.T.	1–3%
Rosette formation E	negative	negative
Rosette formation EAC	negative	positive
Surface IgM kappa	positive	positive
Interaction with Con.A		
Cap forming ability	low (12%)	low (6%)
Agglutinability	very strong (+ + + +)	very strong (+ + + +)

*Derived from mandibular tumor.

addition, this is also unlikely in view of the high virus neutralizing antibody titers in EBV-seropositive individuals. In all likelihood, EBV-positive lymphomas originate from an EBV-carrying cell.

It is known that EBV can convert normal B-lymphocytes with a limited life span into "immortalized" lymphoid lines, capable of continuous proliferation *in vitro*. It is likely that these cells are not yet fully fledged lymphoma cells, since chromosomal [24–26] and other morphological [21] differences were regularly found between EBV-carrying lymphoid lines of non-malignant derivation and EBV-positive lymphoma lines. However, they are at least neoplastic, as suggested by the ability of the virus to induce neoplasia in non human primate hosts [27–29] and the ability of the EBV-converted normal lymphocytes to grow progressively in nude mice and in one experimental series [30] in autologous squirrel monkey hosts. In view of the excellent rejection of EBV-carrying B-blasts in infectious mononucleosis [31] immune restrictions may be expected to play a role in limiting the proliferation of EBV-converted preneoplastic cells as well [22]. Against the background of this reasoning, the development of an EBV-carrying malignant lymphoma probably involves, in addition to the original EBV-convertion at the inception, a certain degree of immunosuppression, and in addition a subsequent cytogenetic evolution of the EBV-carrying clone to fully autonomous neoplasia.

In Africa, EBV-positive Burkitt's lymphomas occurs endemically with a pronounced time-space clustering, suggesting that some environmental factor(s) play an important role in precipitating the malignant disease. Chronic holoendemic malaria has been postulated as a possible horizontally-transmitted co-factor [32]. The non-African, EBV-positive Burkitt s lymphomas show no such clustering, as far as known, and one must therefore envisage a variety of precipitating factors, probably different in the individual cases.

In all likelihood, EBV-negative and EBV-positive lymphomas represent different etiological entities [8, 14, 22]. Their similar histology, cytology and most importantly, cytogenetics suggest that their final evolution to autonomous neoplasia may be similar, although the original "transformation" event may have been caused by different viruses in the two cases.
