Leukocyte Adherence Inhibition and Immunoreactivity in Prostatic Cancer

I. Identification of Anti-Tumour Cell-Mediated Immunity and "Blocking" Factor

RICHARD J. ABLIN,*† RASHID A. BHATTI, GAILON R. BRUNS and PATRICK D. GUINAN

Divisions of Immunology and Urology, Cook County Hospital, Chicago, Illinois* 60612, *U.S.A.*

Abstract—*Modification of the recently described leukocyte adherence inhibition (LAI) test was utilized for the evaluation of anti-tumour cell-mediated immunity and the identification of "blocking" factor in* 20 *patients with prostatic cancer. Evidence of cross-reactivity of the observed anti-tumour immunity with extracts prepared from tumours of the same type and the specificity of "blocking" of the reactions for autologous sensitized lymphocytes and tumour* only *have similarly been demonstrated employing the LAI test. While the observed cross-reactivity between individual tumours, within each tumour type is in keeping with observations of anti-tumour immunity in patients with other tumours, e.g., colon, breast and melanoma, observations suggestive of a specificity of "blocking" for autologous tumour* only *is perhaps somewhat unique, of which further studies will be needed to confirm.*

INTRODUCTION

ENHANCED suppression of the proliferative response of peripheral blood lymphocytes (PBL) to the non-specific mitogen phytohaemagglutinin [1–5] and inhibition of the migration of leukocytes [6] in patients with prostatic cancer have been observed in association with autologous and allogeneic serum. The suggested presence of a serum inhibitory factor, migrating in the α_2-globulin fraction, and recent observations of the concomitant reduction of the suppressive properties of this factor in association with a favorable clinical response following cryoprostatectomy [5], have prompted study of anti-tumour cell-mediated immunity and the possible interference ("blocking") of this immunity.

MATERIAL AND METHODS

Tumour extracts

Extracts of malignant prostatic tissue were prepared by solubilization of autologous and allogeneic tissue in hypertonic (3M) KCl employing a modification of the method of Meltzer [7] and Brannen *et al.* [8]. Finely minced prostatic tissue, trimmed of extraneous material, was washed in phosphate buffered saline (PBS) pH 7·2 and lyophilized. The resulting lyophilizate was pulverized with mortar and pestle, resuspended in 10 ml of 3M KCl in 0·005 M potassium phosphate buffer, pH 7·4, per gram wet weight of original tissue, and left overnight at 4°C with intermittent agitation. The KCl tissue suspension was then centrifuged at 40,000 *g* for 60 min, after which the supernate was dialyzed overnight at 4°C against deionized water. The supernate was then re-centrifuged at 40,000 *g* for 15 min to remove the gelatinous precipitate formed during dialysis and passed through a 0·45 mμ Nalgene filter into a sterile Nalgene filter flask. The filtrate was lyophilized and reconstituted to one tenth of its original volume in sterile PBS.

The protein concentration of extracts so prepared as determined by the Lowry method [9] ranged from 1·0 to 3·8 mg/ml.

Cells and serum

Peripheral blood lymphocytes were obtained from each patient by centrifugation of the leukocyte-rich plasma of heparinized blood on

Accepted 24 November 1976.

a Ficoll–Isopaque gradient. Following washing in minimum essential medium, PBL were resuspended in RPMI 1640 medium containing 100 units/ml penicillin G and 100 μg/ml streptomycine at a concentration of 2×10^7 cells/ml.

Serum was obtained concomitantly from each patient.

Leucocyte adherence inhibition test

Employing a modification of the LAI test [10] three cultures consisting of equal volumes (0·1 ml) of the patient's PBL *plus:*

(i) Normal human serum (homologous serum) of a blood type identical to that of the patient under evaluation. This was the CONTROL and contained *no tumour extract*, permitting establishment of a baseline of normal adherence. Tumour extract (as a source of antigen), employed in (ii) and (iii) described below, was replaced by the same volume of medium.
(ii) Tumour extract and homologous serum.
(iii) Tumour extract and patient's serum (autologous serum).

were incubated at 37°C for 30 min with intermittent shaking. Each culture was then introduced independently into the chambers of Standard Neubauer haemocytometers, i.e., one culture/haemocytometer, using both chambers, and incubated at 37°C for 60 min in a humid atmosphere. The total number of cells in each chamber were then counted microscopically at a magnification of 400 × in predetermined areas. In the present study, 8 squares (0·2 mm × 0·2 mm) were counted in each chamber of the haemocytometer. Cover slips were floated off, each haemocytometer gently immersed in Hanks' balanced salt solution (HBSS) at 37°C, slowly withdrawn, and again immersed and withdrawn. Each chamber of the haemocytometer then received one drop of HBSS and was covered with a clean coverslip. The number of remaining "adherent" cells were counted in the same haemocytometer squares examined previously and the mean % of adherent cells for each culture was then determined.

RESULTS

In accordance with the description of the LAI test a representative example illustrating the application of this method for the evaluation of anti-tumour immunity and the identification of serum inhibition ("blocking") of the interaction of antigen and sensitized lymphocytes in patients with prostatic cancer is presented in Table 1.

For the evaluation of each patient, a baseline of normal % adherence as a control value was initially determined by culturing the patient's (W.H.) PBL in homologous serum in the absence of tumour extract. The patient's PBL were then cultured with autologous tumour extract and homologous serum. As shown in the example, the 17% adherence obtained in such cultures was reduced when compared to the normal % adherence of 66% obtained in the absence of tumour extract, suggesting that

Table 1. *Representative example illustrating application of the leukocyte adherence inhibition test for the detection of anti-tumour cell-mediated immunity, serum "blocking" factor, antigenic cross-reactivity and specificity of serum "blocking" factor in patient with prostatic cancer*

Source of:				
Peripheral blood lymphocytes	Tumour extract	Serum	% Adherence (mean)	Explanation
W.H.	(None)	Homologous	66	Normal adherence (control)
	Autologous*	Homologous	17	Cells reactive with autologous extract indicating immunity.
	Autologous	Autologous	72	Serum "blocking"
	Allogeneic (J.T.)*	Autologous	5	Cells reactive with allogeneic extract indicating cross-reactive immunity but absence of "blocking" by serum from W.H. demonstrating specificity of serum blocking factor for autologous tumour.

*Autologous and allogeneic designate the relationship of tumour extract and serum to the source of peripheral blood lymphocytes used.

an interaction of extract (antigen) with presumably sensitized PBL had occurred. In contrast to this the addition of autologous serum resulted, as shown in Table 1, in a return of the % adherence to a level (72%) slightly exceeding that obtained in the absence of extract, thus, suggesting the absence of interaction of antigen and cells. Absence of a detectable reaction between tumour extract and autologous PBL, presumed to be sensitized on the basis of their observed interaction with extract in absence of the patient's serum, was most likely due to the presence of a serum factor preventing ("blocking") this interaction.

Application of the LAI test as employed, in evaluating the specificity of serum mediated inhibition ("blocking") of the reaction of sensitized PBL with tumour extract is further illustrated in Table 1.

As shown, when PBL's from W.H. were reacted with an allogeneic extract from a prostatic cancer patient (J.T.), of the same tumour type, and cultured in the presence of W.H.'s serum, reactivity, i.e., interaction of cells and extract, as indicated by the low % adherence compared with that in the control, i.e., 5% vs 66%, was observed. This cross-reactivity suggested that the patient's PBL were also sensitized to antigens apparently shared in common within tumours of the same type. Observation of a lower % adherence when the tumour extract was allogeneic with respect to the patient's PBL rather than autologous, 5% vs 17%, suggested that cross-reactive immunity to allogeneic tumour was greater. However, in contrast to the high % adherence observed when PBL's from W.H. were reacted with and cultured in autologous tumour extract and serum, respectively, i.e., 72%, indicating the absence of an interaction of antigen and cells and the presence of "blocking", a low % adherence, i.e., 5%, was observed when the tumour extract was allogeneic with respect to cells and serum, indicating the absence of "blocking" and the apparent specificity of the serum "blocking" factor for autologous PBL and tumour extract.

Following this representative example illustrating the application of the LAI test and interpretation of the results, the presence of anti-tumour immunity, serum "blocking" factor, antigeneic cross-reactivity of this immunity, and specificity of "blocking" factor were evaluated in 20 patients with prostatic cancer. The results of this evaluation are summarized in Table 2.

In accord with the explanation for the results illustrated in Table 1, significantly ($P < 0{\cdot}05$) reduced percentages of adherence obtained in the absence of tumour extract, i.e., in the control, were observed when PBL cultured in homologous serum were reacted with autologous and allogeneic tumour extracts, i.e., 18 and 22% vs 56% (Table 2). This reactivity suggested the presence of sensitization of the patients' PBL to autologous and allogeneic extracts and anti-tumour immunity.

When PBL from these patients were cultured in autologous serum and reacted with autologous and allogeneic tumour extracts, a significant reduction in the per cent of adherence from the control was observed with allogeneic, but not with autologous extract, i.e., 25 and 50 vs 57% (Table 2). Absence of reactivity when the tumour extract was autologous with respect to the patient's' PBL and serum and the significant difference in the reactivity of the patients' PBL with autologous extract when cultured in homologous vs that obtained in autologous serum, i.e., 18 vs 50% are consistent with the interpretation illustrated in Table 1, of the presence of inhibition ("blocking") of the interaction of extract and sensitized PBL by autologous serum and of the suggested specificity of the latter.

DISCUSSION

In the present study employment of the LAI test has provided further evidence suggestive of anti-tumour cell-mediated immunity in prostatic cancer observed previously by inhibition of leukocyte migration [11]. In addition,

Table 2. Reactivity of lymphocytes from 20 patients with prostatic cancer with autologous and allogeneic extracts of malignant prostatic tissue as evaluated by leukocyte adherence inhibition

Tumour extract	Mean ± S.D. percentage of adherence when patients lymphocytes cultured in:	
	Homologous serum	Autologous serum
(None)	56 ± 14	57 ± 23
Autologous	18 ± 12	50 ± 24
Allogeneic	22 ± 8	25 ± 20

the presence of a factor in the serum of the patients evaluated inhibiting ("blocking") the interaction of autologous antigen and sensitized PBL has been observed. Lymphocytes reactive with extract preparations of autologous tumour were also observed to react with allogeneic extracts prepared from tissue of the same tumour type indicating a cross-reactive antigenicity and immunity. In contrast to this cross-reactivity, the observed "blocking" effect of the serum appeared to be specific for interference of the interaction of sensitized PBL and autologous tumour, but not when the tumour extract was allogeneic with respect to the sensitized PBL.

It has been suggested [10] that the reactions observed in the LAI test, preliminary to some extent in view of the limited experimental [12] and clinical [10] trials evaluated thus far, may be related to the interaction of antigen with sensitized PBL as, e.g. in inhibition of macrophage or leukocyte migration is related to the liberation of "lymphokines", which in turn alter the adhering properties ("stickiness") of indicator macrophages [13]. We may envisage that PBL, including indicator macrophages, cultured in the presence of homologous serum and absence of antigen, maintain their adhesive properties and stick to the glass surface of the haemocytometer. Re-encounter of sensitized PBL with specific antigen, i.e., in cultures of cells, tumour extract and homologous serum, leads to the liberation of "lymphokines", altering their adhesive properties such that cells reacting with antigen no longer stick to the glass surface. However, when sensitized cells and specific antigen are cultured in the presence of serum possessing "blocking" factor, interaction of antigen with sensitized cells and the subsequent liberation of "lymphokines" is prevented. The cells thus, maintain their adhesive properties sticking to the glass surface as indicated by the high % adherence observed.

Contrary to the above suggested mechanism, recent studies [14] suggest that interaction of sensitized PBL with tumour antigen leads to cell surface alterations inhibiting attachment of the cells to glass.

While cross-reactivity between individual tumours, within each tumour type observed is in keeping with observations employing LAI in evaluation of patients with other tumours, e.g. colon, breast and melanoma [10], results suggesting that the specificity of "blocking" factor for autologous tumour in prostatic cancer patients is somewhat unique.

Studies are presently in progress to elucidate the immunochemical nature of the observed serum "blocking" factor, i.e., is it circulating antigen and/or antigen-antibody complexes? Alterations of its reactivity as related to tumour stage and the patients' clinical responsiveness, and evaluation of the tissue-specificity of the observed responsiveness of sensitized PBL from prostatic cancer patients are also being examined. It will be interesting to evaluate and compare the antigenic diversity of the extracts of carcinomatous prostatic tissue (previous studies of which have suggested malignant tissue to be antigenically deficient with respect to normal [15]) and the sensitivity of autologous and allogeneic PBL with their reactivity to extracts of normal and benign prostatic tissue. Pending the outcome of such studies, the identification of a prostatic tumour-specific or tumour-associated antigen is a possibility in view of the present preliminary observations.

Presence of Splenic Suppressor Cells in Mice Bearing Regressively Growing Moloney Sarcomas and their Absence in Progressor Mice

EMILIE WEILAND and MANFRED MUSSGAY

Federal Research Institute for Animal Virus Diseases, Tübingen, Federal Republic of Germany, West-Germany

Abstract—*Cultured spleen cells prepared from mice bearing Moloney sarcoma at the stage of peak tumor size did not show induction of blastogenesis by Concanavalin A and phytohemagglutinin as measured by ^{3}H-thymidine uptake. Moreover, in such cultures the spontaneous ^{3}H-thymidine uptake was markedly depressed in the presence of the mitogens, especially of phytohemagglutinin. However the concomitantly assessed activity of these spleen cells in a ^{3}H-proline microcytotoxicity assay was strong. The depression of the mitogen response was restricted to the peak tumor size phase of the Moloney sarcoma and could not be observed during development and regression of the tumor. Spleen cells of mice bearing a non-regressing tumor with a development comparable with that of the Moloney sarcoma in the stage of progression did not show a depression of mitogen response and had no cytotoxic activity. Therefore the absence of detectable cytotoxic effector cells was not due to the activity of suppressor cells, and the growth rate of a tumor seems without influence on the development of suppressor cells.*

INTRODUCTION

IT HAS previously been shown [1–4] that spleen cells from mice carrying Moloney sarcoma virus (MSV-M) induced tumors have a depressed response to phytohemagglutinin (PHA) and/or Concanavalin A (Con A). Evidence has been obtained that these suppressive effects in cultures of MSV-M spleens are due to suppressor cells. The precise nature of these suppressor cells is not known. They are discussed as cells of the monocyte/macrophage series [2] and of B lymphocytes [1, 5], respectively. Gorczynski [1] found that these suppressor cells nonspecifically inhibited the PHA response of normal cells and the response of immune T cells to tumor associated antigen as measured by inhibition of migration and stimulation of protein synthesis. However, Kirchner *et al.* [4] comparing the cytotoxic activity of MSV-M spleen cells using a Chromium release assay with their mitogenic responsiveness observed coincidence between the peak of suppressor cell activity and that of specific cytotoxic effector cells, i.e., at the peak tumor phase. It was demonstrated, that the suppressor cells are *in vitro* without effect on the effector phase of specific cytotoxicity and evidence was presented suggesting that the suppressor cell activity inhibits proliferation dependent lymphocyte functions [4]. It was suggested that the suppressor cells may have the potential of interfering with the generation of cytotoxic effector cells, and it was assumed that in the MSV-M system effector cells may be generated before a significant number of suppressor cells have been developed [4]. In contrast to this assumption the present study demonstrates that in mice bearing progressively growing tumors the absence of cytoxic effector cells as measured in a ^{3}H-proline-microcytotoxicity assay is neither due to the presence of suppressor cells nor to the growth rate of the tumor. Furthermore, it is shown that unfractionated spleen cells from mice carrying regressing Moloney sarcomas in the stage of peak tumor size not only exhibited a depression of mitogen responsiveness but the mitogens even caused a decrease of spon-

Accepted 30 November 1976.

taneously occurring ^{3}H-thymidine (^{3}H-TdR) uptake; these spleen cells had a strong cytotoxicity.

MATERIAL AND METHODS

Animals and tumor cells

The STU-inbred mice and the Moloney sarcoma virus (MSV-M) producing ascitic tumor (asc-MSV-M) cells used are the same as those in preceding studies [6–8]. In addition, a progressively growing tumor was used which originated in a mouse after the regression of a MSV-M induced tumor at the site of the primary tumor and is designated "secondary tumor" (ST). This tumor obviously does not release C-type particles but contains rescuable sarcoma virus genom. As revealed in transplantation protection studies the ST cells did not induce a significant immunity against ST and asc-MSV-M cells. But in asc-MSV-M regressing mice the development of ST tumors was prevented if a small number of ST cells was used for tumor induction (to be published).

Tumor induction, spleen cell preparation, ^{3}H-proline-microcytotoxicity assay (MA)

Tumors were induced by asc-MSV-M or ST by intramuscularly (i.m.) inoculation of 10^5 and 10^6 cells, respectively, in 0·1 ml PBS into a thigh. The asc-MSV-M cell induced tumors reached their peak size during the 9th–13th day post transplantation (p.t.) and regressed thereafter. ST cell induced tumors were palpable about one week p.t. and exhibited progressive growth.

The preparation of lymphoid spleen cell suspensions as well as the ^{3}H-proline-MA have been described previously [6, 7]. The following cells were used as target cells:

(a) A cell line derived from asc-MSV-M cells; these cells produce in relatively high amounts Moloney helper virus [7].
(b) A cell line originating from ascitic ST cells; cells of this line do not produce C-type particles and grow progressively in mice after i.m. inoculation. It was demonstrated that in these cells the MSV-M genome could be rescued by infection with Moloney helper virus (to be published).

Mitogens

Phytohemagglutinin-M (PHA-M, Difco Laboratories, Detroit, Michigan, USA) was reconstituted to a 5 ml stock solution as proposed by the manufacturer. The reconstituted solution was stored in small samples at −20°C. For comparison PHA-P (Difco Laboratories, Detroit, Michigan, USA) was also used. Concanavalin A (Con A, Serva, Heidelberg, Germany) was dissolved in Eagle's minimum essential medium (MEM) to prepare solutions containing 100 μg/100 μl and was stored in small samples at −20°C until use and further dilution. Preliminary titration studies in spleen cell cultures of normal STU-mice revealed that Con A concentrations of 2–5 μg/culture and PHA-M dilutions of the stock solution between 1:2·5–1:10 were optimal with regard to a mitogenic response.

Determination of mitogen induced proliferative response in vitro

For the investigation of the mitogenic response, lymphoid spleen cells were cultured in 10 × 75 mm round bottom glass tubes at 2×10^6 nuclear cells (cells of two spleens were pooled) in 0·5 ml of MEM supplemented with 10% heat inactivated calf serum (one serum pool was used for the whole study), 100 i.u./ml penicillin and 50 μg/ml streptomycin. Mitogens or culture medium as control were added in a volume of 0·1 ml to each culture. Triplicate or quadruplicate cultures were incubated at 37°C in a stationary upright position after gassing with 5% CO_2 in air and closed with silicone rubbers. After 26–28 hr, usually 1 μCi ^{3}H-thymidine (^{3}H-TdR, 6-^{3}H-thymidine; specific activity 22·3 Ci/m mole; Radiochemical Centre, Amersham, England) was added to each tube and cultures were incubated for an additional 20 hr. The cultures were harvested onto glass fiber filters (2·5 cm GF/C; Whatman, London, England), washed three times with PBS and precipitated with 10% TCA and 5% TCA. The glass fiber filters with precipitates were placed in vials and treated by soluene 350 (Packard, Frankfurt, Germany), and assayed by liquid scintillation spectrophotometry (TRICARB model 3375, Packard, Frankfurt, Germany). The arithmetical mean of each set of three respectively four cultures was determined and expressed as counts/min.

RESULTS

Mitogen response of spleen cells derived from STU-mice during different phases of asc-MSV-M induced tumor development

The responsiveness to PHA-M and Con A of lymphoid spleen cells from STU-mice at the beginning of asc-MSV-M tumor development

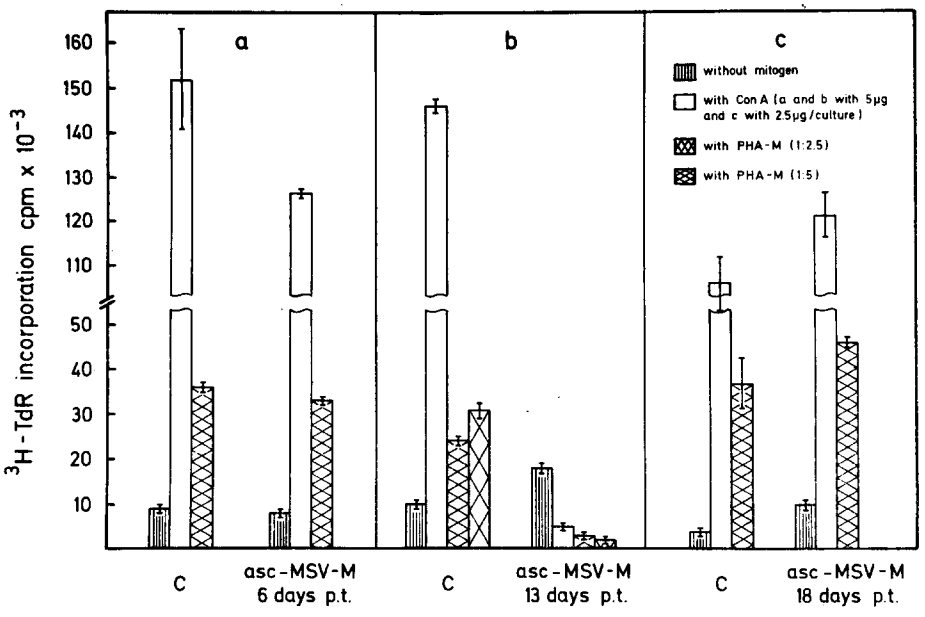

Fig. 1. Comparison of mitogen response during various stages of tumor development. Spleen cells were taken 6 days (tumor already measurable), 13 days (peak tumor phase) and 18 days (tumor in regression) after transplantation (p.t.) of ascitic MSV-M tumor cells. C: spleen cell cultures of age matched control mice. Values are mean ± standard error.

(6 days p.t.), the peak phase (13 days p.t.) and the regression period (18 days p.t.) was compared with the responsiveness of lymphoid spleen cells of age matched control mice (Fig. 1). Six and 18 days after tumor cell transplantation the mitogen response as measured by the incorporation of ^{3}H-TdR was nearly the same in spleen cells from both tumor and control mice. However, spleen cells of the peak tumor phase had a new pattern of reactivity: they did not respond to Con A or PHA-M with stimulation but with a reduction of the spontaneous ^{3}H-TdR uptake in the presence of the mitogens. When the PHA-P was used, the stimulation of spleen cells from control mice was not as high as in the case of PHA-M but there was also a depression of baseline proliferation in spleen cell preparations obtained at the peak tumor phase. The marked effect of PHA-M was the reason to use PHA-M throughout the following experiments.

Treatment of spleen cells from normal mice and mice bearing asc-MSV-M tumors at the stage of peak size with varying concentrations of PHA-M

Because spleen cells prepared from mice at the stage of peak tumor size did not show stimulation of ^{3}H-TdR uptake in the presence of mitogens in concentrations that caused a considerable stimulation in control spleen cells, an analysis was undertaken to determine whether this effect also occurs with varying amounts of PHA-M. Figure 2 shows the results.

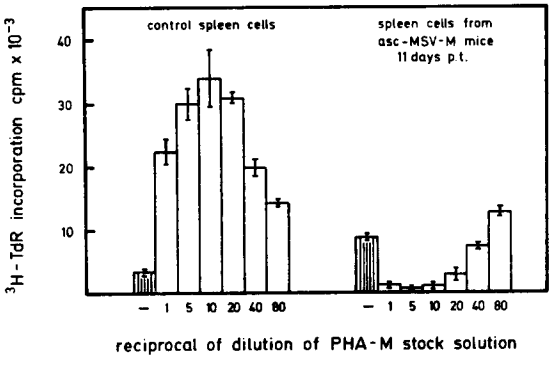

Fig. 2. Pattern of response after adding varying concentrations of PHA-M to spleen cell cultures of control mice and mice with Moloney sarcoma in its peak phase. Values are mean ± standard error.

It can be seen that PHA-M concentrations that induce optimal stimulation of ^{3}H-TdR uptake by spleen cells from control mice reduce the spontaneous ^{3}H-TdR uptake by spleen cells from peak tumor mice. Only the lowest tested PHA-M concentration (1:80 dilution of the stock solution) that caused a weak stimulation in control cultures induced a slight increase of the spontaneously occurring ^{3}H-TdR uptake in cultures of spleen cells from asc-MSV-M peak tumor mice.

Replacement of spleen cell culture fluid before addition of ^{3}H-TdR

To exclude factors that might compete with the uptake of ^{3}H-TdR and therefore could

mask a DNA-synthesis in the cultures of spleen cells from peak tumor mice, the medium was replaced before addition of ^{3}H-TdR. The spleen cell cultures were incubated for 42 hr in the presence of PHA-M, then the culture fluid was replaced by a fresh medium and 2 μCi ^{3}H-TdR was added, and the cultures were again incubated, however only for 6 hr in order to prevent a possible production of new competing factors. Under these conditions, again no mitogenic stimulation but a repression of spontaneous uptake of ^{3}H-TdR was detected in cultures of spleen cells from asc-MSV-M peak tumor mice (Fig. 3). The replacement of the culture medium caused in control cultures with or without mitogen as well as in cultures

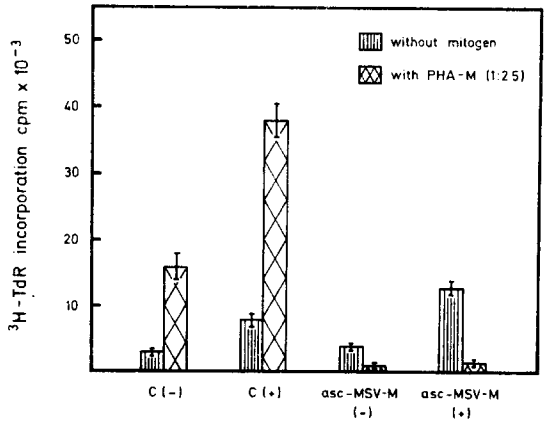

Fig. 3. Replacement of culture fluid before addition of ^{3}H-TdR. Influence on the isotope uptake of spleen cell cultures of asc-MSV-M peak tumor mice (11 days p.t.) and control mice (C) cultivated in the presence or absence of PHA-M for 42 hours. Values are mean ± standard error. (—): without change of culture medium before addition of ^{3}H-TdR (2 μCi/culture for six hours); (+): addition of ^{3}H-TdR after replacement of culture fluid by fresh medium.

of spleen cells from peak tumor mice cultured without PHA-M an increased uptake of ^{3}H-TdR.

Mitogen response of mixtures of spleen cells from peak tumor mice and syngeneic control mice

It was then of interest to determine whether spleen cells from peak tumor mice could suppress the Con A and PHA-M response of spleen cells from normal mice. Thus, 1×10^6 spleen cells from peak tumor mice in 0·25 ml culture medium and 1×10^6 normal spleen cells in 0·25 ml medium were mixed and the response to the two mitogens was compared with the response of 2×10^6 normal spleen cells in 0·5 ml and 2×10^6 peak tumor spleen cells in 0·5 ml medium. In the mixed cultures the spontaneous ^{3}H-TdR uptake (Fig. 4) was nearly as high as

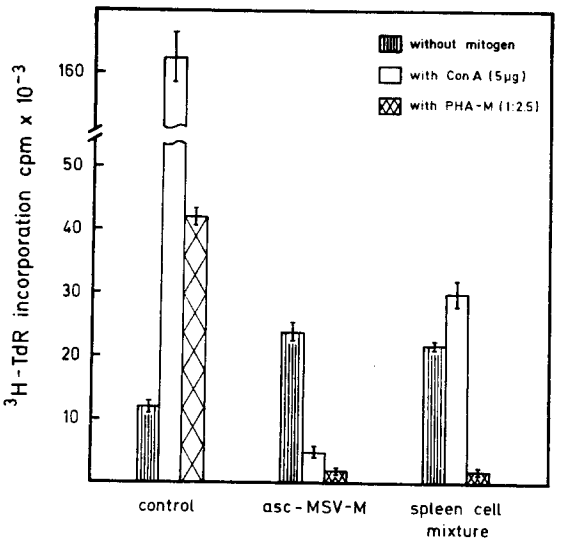

Fig. 4. Effect of mixing spleen cell suspensions of asc-MSV-M peak tumor mice (11 days p.t.) and of syngeneic control mice (C) on the mitogen response. The cell mixture consisted of equal parts of each suspension. Values are mean ± standard error.

in the cultures of the peak tumor spleen cells alone, and the PHA-M induced suppression of the uptake of ^{3}H-TdR was comparably strong in cultures of both groups. Only Con A induced a small increase of ^{3}H-TdR uptake in the mixed cultures but with a rate far below to that determined in the control cultures.

Comparison of mitogen response and cytotoxic activity of spleen cells from mice bearing asc-MSV-M cell and ST cell induced tumors in comparable stages

To see whether spleen cells from mice with a progressively growing tumor (ST) also exhibit a depressed uptake of ^{3}H-TdR after mitogen stimulation, the following experiment was conducted: Spleen cells from STU-mice bearing ST tumors with a diameter of about 1·3 cm were tested 14 days p.t. and compared with spleen cells of asc-MSV-M mice 13 days p.t. that beared tumors with diameters of about 1·15 cm. In contrast to the spleen cell cultures from mice with asc-MSV-M cell induced tumors the mitogen response of spleen cells derived from mice with ST tumors was similar to that of control cultures (Fig. 5, lower part). The concomitantly assessed cytotoxic activity in the ^{3}H-proline-MA [7] using the asc-MSV-M-derived cell line revealed a strong reduction of the number of attached target cells by spleen cells from asc-MSV-M bearers whereas such an effect was not observed after exposing these target cells to spleen cells from ST bearing mice (Fig. 5, upper part). Also there was no cytotoxic activity of spleen cells from mice

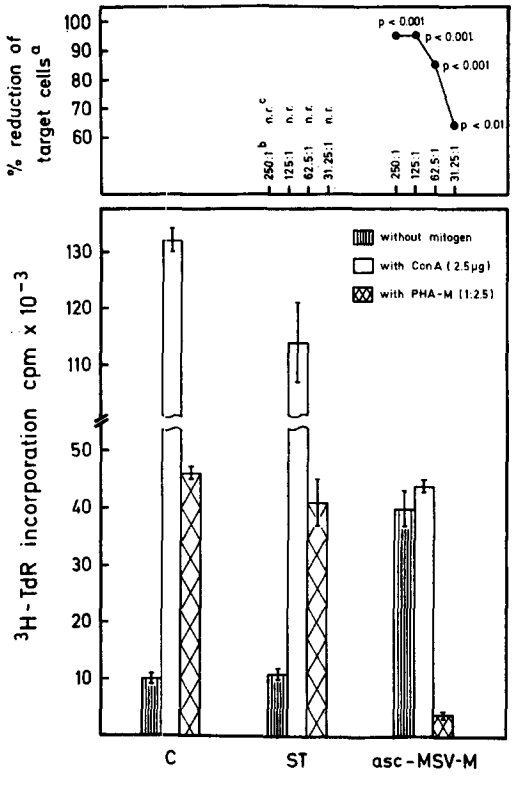

Fig. 5. Comparison of the mitogen response and the cytotoxic activity in the ^{3}H-proline microcytotoxicity assay of spleen cells from mice either carrying ST (14 days after transplantation, tumor diameter 1·3 cm) or asc-MSV-M (13 days after transplantation, tumor diameter 1·15 cm) tumors. Asc-MSV-M-derived cells were used in this experiment as target cells.

(a) % Reduction of target cells was measured by determination of the ^{3}H-proline radioactivity taking as 100% the mean radioactivity of control cultures which had received identical numbers of spleen cells from normal mice (C).

(b) Ratio of nuclear spleen cells to target cells.

(c) No reduction of target cell radioactivity in comparison to normal spleen cells.

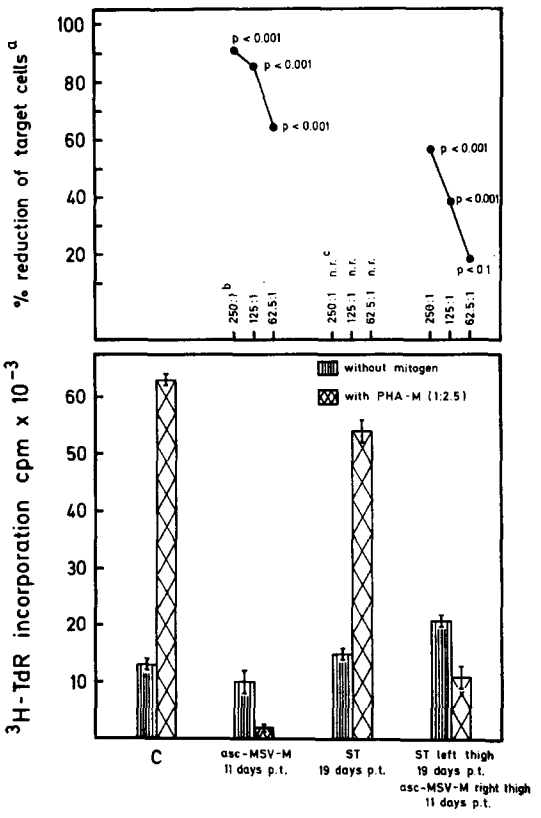

Fig. 6. Cytotoxic activity and loss of mitogen response of spleen cells from mice in which both ST tumor and 8 days later asc-MSV-M tumor have been induced (a, b and c), see legend to Fig. 5.

bearing ST tumors when a cell line derived from ascitic ST cells was used as target cells.

After these results the question arose whether the ST tumor prevents the appearance of spleen cells with cytotoxic activity and depressed mitogen response after inoculation with asc-MSV-M cells. Mice were inoculated with ST cells in the left thigh and received asc-MSV-M cells eight days later in the right thigh. Mice without inoculations and mice receiving either ST cells or asc-MSV-M cells alone served as controls. Eleven days p.t. of asc-MSV-M cells the tumors had developed at the site of inoculation (Fig. 6); at this time spleen cells were taken from mice of the four groups and assayed for PHA-M response and cytoxic activity in the ^{3}H-proline-MA. As Fig. 6 shows, asc-MSV-M tumor development induced in ST tumor bearers and non-bearers both loss of mitogen responsiveness of spleen cell cultures and spleen cells with cytotoxic activity in the ^{3}H-proline-MA.

DISCUSSION

The present studies confirm the observations of Kirchner *et al.* [3] that spleen cell cultures of mice bearing primary MSV-M-induced tumors show a marked depression of PHA and Con A reactivity. As in the investigation of Kirchner *et al.* [2, 3], we also found a parallelism between the depression of the mitogen response and the development of the tumor, and a coincidence between the peak of suppression of mitogen reactivity and that of cytotoxic effector cells. The frequently used assessment of lymphocyte stimulation by mitogen(s) as an indication of cellular immune potential is not in agreement with these results, at least with regard to the peak tumor phase. Moreover, instead of reflecting a state of immunological deficiency the PHA unresponsiveness seems to reflect evidence of an intense immune response. The spleen cell preparations of MSV-M-induced tumor bearers were able to inhibit mitogen response of normal spleen cells; this observation is in accordance with

that of Gorczynski [1] and Kirchner *et al.* [2] and indicates a lack of immunologic specificity of the mitogen suppression phenomenon.

In contrast to the findings of Kirchner *et al.* [2, 3] we observed not only a depression of mitogen reactivity in the MSV-M spleen cell cultures but the mitogens even reduced the "spontaneous" (mitogen-independent) ^{3}H-TdR uptake in such cultures. This discrepancy may be due to the different inbred mice strains used.

We found that relatively high doses of PHA inducing maximal stimulation of normal spleen cell cultures caused in MSV-M spleen cell cultures a decrease of the spontaneous ^{3}H-TdR uptake whereas low concentrations induced a slight mitogen response. These results indicate that a mitogen consuming process is not operative in the phenomenon of unresponsiveness of MSV-M spleen cell cultures to PHA.

To exclude factors in the supernatant of spleen cell cultures that may compete with ^{3}H-TdR and cause failure of ^{3}H-TdR uptake in spite of the presence of DNA stimulation [9], the influence of replacing the culture medium before addition of ^{3}H-TdR was investigated. This procedure did not increase the ^{3}H-TdR uptake in spleen cell cultures of MSV-M peak tumor mice cultivated in the presence of PHA. However, spleen cell cultures of MSV-M peak tumor mice cultivated in the absence of PHA and that of normal mice cultivated with or without PHA showed an increased ^{3}H-TdR uptake.

Kirchner *et al.* [2] reported that spleen cells of both MSV-M progressors and regressors exhibited specific cytotoxicity and a suppressed PHA response. In spleens from mice carrying a Rauscher leukemia virus-induced ascitic tumor, the PHA response was also strongly suppressed, but there was only low cytotoxic activity [2]. Furthermore, in spleen cells from rats injected with cells from the Gross leukemia virus induced lymphoma (C 58 NT) D suppression of mitogen response was only found if the cells were taken from progressors; these cells were unresponsive in the mixed leukocyte tumor cell interaction (MLTI), but became responsive in the MLTI and to mitogen after passage over rayon adherence columns or pretreatment with an iron/magnet technique [10]. Based on these results it was assumed [4] that the suppressor cells may interfere with the immune response against some tumors by inhibiting the proliferation of effector cells. The demonstration of suppressor cells in MSV-M regressor mice does not fit in this picture, and for an explanation it was pointed out [10] that in the MSV-M system tumors reach a large size before regression starts, while regressing (C 58 NT) D tumors are quite small in relation to the body weight of the rats. This explanation is based on the assumption that activation of suppressor cells may be mediated by substances released from the tumor, which only reach sufficient levels after the tumor has attained a certain size.

However, neither the assumption of an interfering activity of suppressor cells on the generation of effector cells nor the influence of tumor growth rate and size on the development of suppressor cells were confirmed in our experiments. We found no cytotoxic effector cell activity in the spleen cell cultures from mice with a non-regressing tumor (ST) in spite of the absence of suppressor cells, and the development of this ST tumor in size was comparable with that of MSV-M induced tumors during the stage of progression which was accompanied by the appearance of suppressor cells.

This ST tumor developed at the site of a primarily regressed MSV-M induced tumor possibly after immune selection of nonproducer tumor cells that may originate besides C-type particles producing tumor cells after infection with murine sarcoma virus [11]. Nonproducer tumor cells may exhibit no demonstrable immunity [12] or only weak antigenicity after repeated immunizations [13]. The failure of ST tumor cells to induce a demonstrable immune reaction may be also the cause of the failure to induce suppressor cells. Spleen cell cultures from mice bearing at one site a MSV-M regressing tumor and at the other site a progressing tumor showed a suppressed mitogen response. This indicates that the progressively growing tumor did neither prevent the phenomenon of depressed mitogen response and of reduction of the spontaneous ^{3}H-TdR uptake in the presence of mitogens nor the induction of cytotoxic effector cells. The function of the suppressor cells *in vivo* and their precise nature remains to be determined.

‡*Institut de Cancérologie et d'Immunogénétique, Villejuif, France and* §*Institut Pasteur, Paris, France*

Abstract—*We examined the effects of the heteropolyanion* 5-*tungsto*-2-*antimoniate on* Herpes virus saimiri, *Epstein–Barr virus, purified murine and avian viral reverse transcriptases, and on highly purified DNA polymerases α and β from lymphoblastoid cells producing Epstein–Barr virus or* Herpes virus saimiri. 5-*tungsto*-2-*antimoniate enhanced the replication and cytopathic effect of* Herpes virus saimiri *when the virus was present prior to treatment with the compound. Moreover, a rhesus cell line chronically infected with* Herpes virus saimiri *showed enhancement of cytopathic effect, early and late viral antigens and virus production. In contrast, the compound had no effect on EBV replication or antigen production in lymphoblastoid cell lines, whether the EBV was transforming or nontransforming. Highly purified Rauscher leukemia virus and avian myeloblastosis virus reverse transcriptases were inhibited to different degrees with a greater effect on the mammalian enzyme. The great susceptibility of the murine reverse transcriptase may explain the inhibition of* de novo *infection, with murine oncornavirus, of cells in medium containing the compound. Highly purified DNA polymerases α and β from P3HR–1 and MLC–1 cells also showed differential inhibition with a greater effect on the β enzymes. The different effects of this compound on oncogenic DNA and RNA virus systems suggest a complex mechanism of action and require further study. In the case of HVS, TA may interfere with the synthesis or action of a cellular product inhibitory for virus replication.*

INTRODUCTION

THE HETEROPOLYANION 5-tungsto-2-antimoniate (TA) is an antiviral agent which inhibits murine leukemia and sarcoma viruses, both *in vitro* (Sinoussi *et al.*, in preparation) and *in vivo* [1]. It protected mice against Friend- and plasma variant-induced leukemias, and delayed the appearance of tumors in newborn mice inoculated with Moloney murine sarcoma virus [1]. TA is an inhibitor of murine reverse transcriptase [2]. In addition, TA acts against many DNA and RNA nononcogenic viruses both *in vitro* and *in vivo* [3,4].

In the present experiments, we studied the effects of TA on two oncogenic agents, *Herpes virus saimiri* (HVS) [5,6] and Epstein–Barr virus (EBV) [7]. We also studied the effects of TA on highly purified Rauscher leukemia virus (RLV) and avian myeloblastosis virus (AMV) reverse transcriptases, and on cellular DNA-dependent polymerases α and β from primate cell systems.

MATERIAL AND METHODS

5-*Tungsto*-2-*antimoniate*

The ammonium salt of this compound was prepared according to the method described in [1] and [8]. We used TA dissolved in buffered saline, as this did not differ in biologic effects, in experiments with HVS and EBV, from TA dissolved in water. TA was dissolved in water for DNA polymerase inhibition studies.

Cell cultures

We used continuous owl monkey (*Aotus trivirgatus*) kidney cells kindly supplied by Dr. L. V. Meléndez; MEST–HVS, spontaneously transformed rhesus monkey (*Macaca mulatta*) embryo cells chronically infected with HVS [9,10]; and Vero, a continuous line of African green (*Cercopithecus aethiops*) monkey kidney cells. We also used Raji [11], an EBV-nonproducer lymphoblastoid cell line which contains the EBV genome; HK–LY 28 [12] and P3HR–1, EBV lymphoblastoid cell lines which produce transforming and nontransforming virus, respectively; and MLC–1, a lymphoblastoid cell line derived from a lymph node of a marmoset monkey (*Saguinus oedipus*), infected with HVS [13,10]. About 47 genome equivalents of HVS are present in each MLC–1 cell and 12–15 genome equivalents have also been detected in MEST–HVS cell cultures. (Ablashi, D. V., Fleckenstein, B. and zur Hausen, H., unpublished observations.)

Adherent cells were maintained in Eagle's Minimal Essential Medium (Grand Island Biological Co., Grand Island, New York) containing 100 units per ml of penicillin, 100 μg/ml streptomycin, and 2% heat-treated (56°C for 0·5 hr) fetal calf serum. Lymphoblastoid cells were maintained in medium RPMI–1640 containing penicillin, streptomycin and 20% heat-treated fetal calf serum. All cells were incubated at 37°C.

HVS

HVS, originally supplied by Dr. L. V. Meléndez, was plaque-purified three times and repeatedly passaged in our laboratory. A virus pool, having a titer of $10^{5\cdot5-6\cdot0}$ 50% tissue culture infective doses ($TCID_{50}$) per ml, was prepared in owl monkey kidney (OMK) cells and used in these experiments. One ml of this virus pool induced malignant lymphoma and lymphocytic leukemia in an adult owl monkey. HVS early antigen (EA) and late antigen (LA) were assayed by standard indirect immunofluorescent techniques [14].

EBV

EBV preparations were titrated by induction of EBV early antigen in Raji cells [15] or by induction of nuclear antigen in lymphocytes from human umbilical cords [16]. These antigens, as well as viral capsid antigen [17] were assayed by standard immunofluorescent techniques.

Determination of drug toxicity and effect on virus

Confluent tube cultures of OMK or Vero cells were employed. In toxicity studies, four cultures were incubated with a given concentration of compound, and observed for 14 days. Assays of the effect of TA on HVS replication were performed with cell cultures inoculated with 0·2 ml of ten-fold dilutions of the virus pool. Compound was added to all cultures, under the conditions specified for each experiment. Four cultures were used for each dilution of virus, and $TCID_{50}$ were calculated by the method of Reed and Muench [18]. The final reading for HVS cytopathic effect (CPE) was made 14 days after virus inoculation. Experiments with lymphoblastoid cells were performed in 75 cm^2 plastic Falcon flasks containing 35 ml of medium.

DNA polymerase assays

Assays for DNA-dependent and RNA-dependent DNA polymerases were as previously described [19, 20]. The procedures for purification of these enzymes have been described [21–24].

RESULTS

Toxicity of TA

TA had a borderline toxicity at a concentration of 40 μg/ml for Vero and OMK cells; greater concentrations caused cell rounding, refractility and death. We therefore used TA in concentrations of 10 and 20 μg/ml. For Raji, P3HR–1 and HK–LY 28 cells, borderline toxicity occurred at 25 μg/ml and cell degeneration and death occurred at greater concentrations.

Lack of effect of TA on HVS itself or on its absorption

In these experiments virus dilutions were made in medium containing 10 or 20 μg/ml TA, and were kept at 4°C for 24 or 48 hr. Aliquots of 0·2 ml were then added to Vero or OMK cell cultures for virus absorption for 2 hr. The cells were then washed three times, and fresh medium, not containing TA, was added. Cell cultures were observed for up to 14 days, with medium changes twice weekly. These experiments were repeated three times, and all experimental and control titrations yielded values of $10^{6\cdot0}$ $TCID_{50}$/ml. These results suggest that TA had no effect on HVS itself, or on its absorption or penetration.

Enhancement of HVS infectivity in OMK and Vero cells by TA

Table 1 shows that titration of HVS in the presence of TA yields titers which are thirty-fold higher than in the absence of TA. Pretreatment of the cells for 48 hr with TA, followed by titration of HVS in the presence of TA, gave similar results (Table 2). Pretreatment with TA of the cells used in the titrations thus seemed to have no additional effect (Table 2). HVS from the end-points of the TA titrations could be used to infect other cell cultures productively.

Table 1. *Enhancement of HVS replication by treatment of cells with TA after HVS absorption*

TA concentration (μg/ml)	HVS titer (log $TCID_{50}$/ml)
0	5·5
10	7·0
20	7·0

In these experiments, either Vero or OMK cell cultures were used for HVS titrations. TA was added to the cell cultures immediately after the 2-hr period for the absorption of HVS and kept on the cells for the duration of the titration. All experiments were repeated three times. Cells incubated solely with TA showed no CPE or toxicity. Cell cultures were observed for up to 14 days, with medium changes twice weekly.

Table 2. *Enhancement of HVS replication by pre-treatment and post-treatment of cells with TA*

TA concentration (μg/ml)	HVS titer (log $TCID_{50}$/ml)
0	5·5
10	7·0
20	7·0

In these experiments, cell cultures were incubated with TA for 48 hr at 37°C, washed three times, and used for HVS titrations. TA was added again to cell cultures immediately after the 2-hr period for the absorption of HVS and kept on the cells for the duration of the titration. Cell cultures were observed for up to 14 days for HVS CPE, with medium changes twice weekly. These experiments were repeated three times, using either Vero or OMK cells. Cells incubated solely with TA showed no CPE or toxicity. The results do not differ from those presented in Table 1.

Enhancement of HVS replication in MEST–HVS cells by TA

Table 3 shows that TA had an enhancing effect on HVS replication in a cell line (MEST–HVS) chronically infected with HVS. There was an increase in the percentage of cells showing CPE, an increase in the percentage of cells showing HVS antigens by immunofluorescence, and a thirty-fold increase in the amount of infectious HVS produced. The equilibrium between cellular resistance and viral replication was thus shifted in favor of the virus.

Table 3. *Enhancement of HVS replication and antigen production (HVS–EA and LA) by TA in a chronically infected cell line (MEST–HVS)*

TA concentration (μg/ml)	Cytopathic effect	HVS antigen production (% of cells)	Titer of HVS (log $TCID_{50}$/ml)
0	1+	5–7	0·5
10	3+	25–30	2·0
20	3+	25–30	2·0

Cells were maintained for 5 days at 37°C in the presence of TA. 1+ = 5–25% of cell sheet involved; 3+ = 50–75% of cell sheet involved. The HVS antigens (LA and HVS–EA) were assayed by immunofluorescence. LA was predominant. For the determination of virus titer, cells were removed from the surface of the containing flask, rapidly frozen and thawed three times with their supernates and titrated in owl monkey kidney cells. Cell cultures were observed for up to 14 days for HVS CPE, with medium changes twice weekly. These experiments were repeated twice.

Lack of effect of TA on EBV replication

Treatment of Raji, P3HR–1, or HK–LY 28 cells with TA failed to induce changes in the production of EBV or its antigens. However, treatment of P3HR–1 cells caused an increase in the size of the giant cells which occur in P3HR–1 cultures (Figs. 1–4).

Inhibition of DNA polymerases by TA

Figure 5 shows that RLV RNA-dependent DNA polymerase was inhibited 50% at a concentration of 2 μg TA per ml of reaction mixture, whereas the AMV enzyme required 100 μg TA per ml for 50% inhibition. At concentrations of 10 μg TA per ml and above, the RLV enzyme was completely inhibited. Evidence for the reversibility of the inhibition of the murine reverse transcriptase has been found by J.-C. Chermann *et al.* [2]. The nuclear (β) and cytoplasmic (α) DNA dependent DNA polymerases from P3HR–1 cells were also differentially inhibited. Fifty percent inhibition was seen at 2·5 and 5·0 μg TA per ml of reaction mixture, respectively. Thus, cellular as well as viral enzymes were affected by this compound. However, in contrast to its effect on the RLV enzyme, TA did not completely

inhibit the cellular enzymes, even at relatively high concentrations of the compound.

We also found that the nuclear and cytoplasmic DNA dependent DNA polymerases of MLC–1 cells were differentially inhibited. This inhibition was almost identical to that for the polymerases derived from P3HR–1 cells.

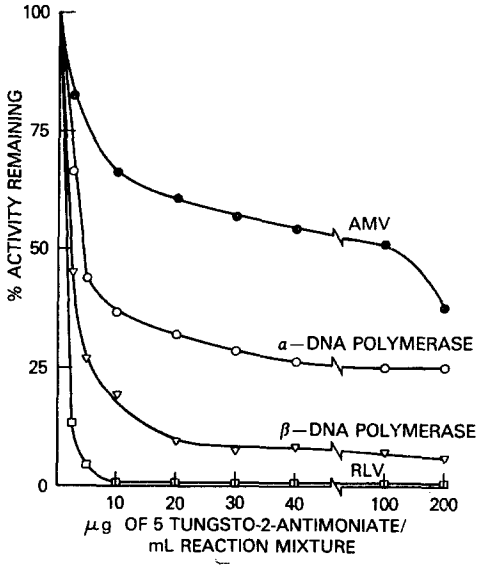

Fig. 5. Reaction mixtures (100 μl) containing the indicated amounts of TA were initiated by the addition of enzyme and incubated for 30 min at 37° and the incorporation of ^{3}[H]thymidine monophosphate (TMP) into acid insoluble material was determined. Specific activities for the enzymes were 65 pmole TMP/ng/hr for avian myeloblastosis virus reverse transcriptase, 40 pmole TMP/ng/hr for Rauscher leukemia virus reverse transcriptase, and 16 pmole TMP/ng/hr for the α DNA polymerase of P3HR–1 cells. Similar results were seen for DNA-dependent DNA polymerases β and α from P3HR–1 cells using either 20 μg activated DNA or 5 μg d(AT) per ml of reaction mixture as template. RNA-dependent DNA polymerase from AMV and RLV were assayed using $rA{\cdot}dT_{10-12}$ (2·5 μg/reaction) as template. A similar inhibition was also seen using rC·dG as template.

DISCUSSION

The results of the HVS titrations in the presence and absence of TA indicate that potentially infectious doses of HVS are present beyond the normal end-point of an HVS titration. It was also found that TA had no demonstrable effect on HVS itself, or on its absorption or penetration. These results could possibly be explained by the presence of an inhibitor, the action of which is overcome by relatively large doses of HVS, and which is sensitive to the presence of TA.

It had been previously found [25] that pretreatment of human embryonic lung cells with IUdR enhanced the replication of human cytomegalovirus. Virus genome in drug-treated cells exhibited a shorter eclipse period and the cells produced more infectious virus sooner than did untreated cells. In experiments in which the multiplicity of infection was varied, it was found that there was a hundred-fold increase in the sensitivity of cultures for virus detection when the cells had been previously exposed to IUdR. The authors felt that IUdR interfered with the synthesis of a cellular product inhibitory for cytomegalovirus replication, and that this product probably was not interferon. Such inhibitors have been described [26]. We feel that TA may have an effect on HVS replication similar to that of IUdR on the replication of cytomegalovirus.

Additional evidence for the presence of an inhibitor was provided in another communication [10], in which it was found that MEST–HVS cells are super-infectible with HVS and yielded thirty-fold more infectious virus than control cells. This suggests that a viral inhibitor is present in MEST–HVS cells, and that the action of this inhibitor is overcome by a relatively large dose of HVS.

In contrast to its effect on HVS, TA had no effect on the replication of, or antigen production by, either transforming EBV (HK–LY 28 cells) or nontransforming EBV (P3HR–1 cells). We have no explanation for the different results in the EBV and HVS cell systems in view of the fact that HVS otherwise is an excellent model for EBV. We also have no explanation for the larger size of the giant cells in the P3HR–1 cultures treated with TA. We do not know if the larger giant cells formed as a result of cell agglutination; dextran sulfate has caused trypsin-dispersed HeLa cells to form clumps [27]. In contrast to the results with TA, phosphonoacetic acid, another viral inhibitor, has been found to inhibit the replication of both EBV and HVS [28].

The inhibition by TA of the RNA-dependent DNA polymerase of RLV confirms the work of Chermann *et al.* [2], who also found that TA inhibited *E. coli* DNA polymerase and RNA polymerase. Reverse transcriptase is needed for oncornavirus replication during the primary infection of cells. The great susceptibility of the murine reverse transcriptase to TA may explain the important inhibition of *de novo* infection, with murine oncornavirus, of cells in a medium containing TA at relatively low concentrations (Sinoussi *et al.*, in preparation). The marked inhibition of the murine reverse transcriptase may thus be related to the profound *in vitro* and *in vivo* inhibition of certain murine oncornaviruses.

The finding that TA partially inhibits the α

and β DNA polymerases of primate cells provides evidence that this compound, in what seems to be nontoxic concentrations, may interfere with the nucleic acid metabolism of these cells. Other investigators [29] found that treatment with IUdR greatly reduced cellular DNA synthesis, and felt that this effect may have played an important role in the facilitation of viral replication in cells pretreated with this compound. Perhaps a similar effect, which may lead to interference with the production or action of viral inhibitors, is operative in the case of TA and HVS.

Cross-reaction between Antigens of Human Myelogenous Leukemia and Mason–Pfizer Monkey Virus*

BYUNG S. KIM†
La Rabida-University of Chicago Institute, East 65th Street at Lake Michigan, Chicago, IL 60649, U.S.A.

Abstract—*An antigen similar to a major protein of Mason–Pfizer monkey virus (MPMV) was found in breast cancers of 2 out of 9 women and in splenic tissue or peripheral leukocytes from 12 of 12 patients with myelogenous leukemias. Such antigen was not detected in other tumors or normal tissues. The cross-reactivity was detected using inhibition of the indirect quantitative radioimmunoprecipitation of ^{125}I-labeled purified MPMV p25 and anti-MPMV antiserum. Particles banding in a density region of 1·15 to 1·17 g/ml, the density characteristic of the known animal leukemia viruses, were used as inhibitors for the precipitation. An antigen isolated from a spleen of a patient with myelogenous leukemia using anti-p25 immunoabsorbent column was similar in net electrical charge and molecular weight to MPMV p25. These results suggest that a virus-like particle bearing some antigenic relatedness to MPMV may be potentially important in the pathogenesis of human myelogenous leukemia.*

INTRODUCTION

THE MASON–PFIZER monkey virus (MPMV), isolated from a spontaneous mammary carcinoma occurring in a Rhesus monkey [1], possesses morphological, biochemical and biophysical characteristics of known RNA tumor viruses [2–4]. The virus has been successfully propagated by cocultivation of the original mammary tumor with monkey embryo cells and by infection of chimpanzee and human cells [5,6]. MPMV-like particles have been identified in human cell lines derived from patients with leukemia or other malignancies [7, 8, 9] and in lines derived from normal cells which have spontaneously transformed [10, 11]. I report here that an antigen can be isolated from spleen cells of patients with myelogenous leukemia (ML). The antigen cross-reacts with and has very similar net electrical charge and molecular weight to MPMV p25. The results are consistent with the possibility that a MPMV-like virus may be involved in the etiology and/or pathogenesis of human myelogenous leukemia, a possibility strengthened by the demonstration of antibody to MPMV p25 in plasma from patients with ML [12].

MATERIAL AND METHODS

Viruses

The MPMV was propagated in either normal human lymphoblastoid cell line NC37 or the original monkey mammary tumor cell line, MT. A preparation purified by sucrose density gradient centrifugations was obtained from the J. L. Smith Memorial for Cancer Research, Pfizer, Inc. The virus was further purified by centrifugation through a 5-ml column of 30% sucrose in TNE buffer (0·01 M Tris–HCl, pH 8·3, 0·15 M NaCl, 0·002 M ethylenediamine tetra-acetate) at 40,000 rev/min for 4 hr.

Antisera

Anti-MPMV antiserum was obtained from a rabbit injected multiple times with Nonidet P-40-disrupted MPMV grown in the NC37 cell line. About 100 μg protein in complete

Freund's adjuvant was administered s.c. into hind foot pads and back. The rabbit was boosted by monthly injections of the protein (50 μg) in incomplete Freund's adjuvant (Difco Laboratories, Detroit, Michigan). Goat anti-rabbit antiserum used for the indirect reagent was obtained from Miles Laboratories.

Preparation of tumor extracts and particulates banding in the viral density region from human leukemic cells and tumor tissues

Leukemic leukocytes and leukemic spleens were disrupted with a Silverson homogenizer. In both cases two volumes of TNE buffer were used for suspending the material. After removal of nuclei and mitochondria by low speed centrifugation (1500 ×*g* and 10,000 ×*g* 10 min each), the supernatant was used as a tumor extract and centrifuged again for further fractionation at 98,000 ×*g* on a 12-ml 20% glycerol column in TNE buffer for 1 hr. The pellet was suspended and subjected to isopycnic separation by centrifugation at 98,000 ×*g* for 16 hr through a 20–45% continuous sucrose gradient. The material in the density region between 1·15–1·17 g/ml was collected, and the particles were recovered by centrifugation at 98,000 ×*g* for 1 hr. The pellet was resuspended in 1-ml TNE buffer and used for radioimmunoassay. Protein concentrations were estimated by the Lowry method [13] based on bovine serum albumin standard.

Radioimmune precipitations

A major protein of MPMV having a molecular weight of 25,000 daltons (p25) was purified by a combination of agarose gel filtration and DEAE-cellulose column chromatography as described previously [12]. The isolated p25 was more than 95% pure as estimated by sodium dodecyl sulphate (SDS)-polyacrylamide gel electrophoresis. The p25 was iodinated with ^{125}I (New England Nuclear) by the chloramine-T procedure [14]. The reaction was carried for 2–3 min at room temperature in 50 μl of 0·1 M sodium phosphate buffer at pH 7·5 containing 1 mCi ^{125}I, 5 μg protein and 5 μg chloramine-T. The reaction was stopped by addition of 8 μg (in 8 μl) of sodium metabisulfite. Free iodine was separated by passage through Sephadex G50 equilibrated with 0·1 M phosphate-buffered saline and/or dialysis against three changes of 500 ml saline at 5–10 hr intervals. The specific activity of the iodinated protein ranged from 1000–10,000 counts/min/ng.

For inhibition of indirect precipitation, the method of Kim and Dray [15] was used. The iodine-labeled p25 protein was precipitated with varying amounts of the anti-MPMV by the indirect precipitation procedure. A maximum of 72% precipitation was obtained with 0·02 μl of the antiserum. To optimize the sensitivity, the amounts of antiserum added for inhibitions of indirect precipitation were chosen to give 30–40% precipitation in the absence of inhibitor. Antibody and inhibitors were mixed and incubated for 1 hr at 37°C. In order to keep the inhibitor soluble and to prevent nonspecific adsorption of the iodinated antigen, a final concentration of 0·5% triton X-100 (Fisher Scientific Co.) was maintained for the first incubation. Iodine-labeled antigen (p25) was added then to the mixture and incubated for an additional 50 min at 37°C. The cold carrier, normal rabbit IgG (30 μg of a 14% Na_2SO_4 precipitate) and the indirect reagent, goat anti-rabbit IgG, were added sequentially. After another incubation at 37°C for 1 hr, the tubes were placed at 4°C for 16–18 hr. The precipitates were washed three times with 0·2% bovine serum albumin and 0·02% NP-40 in saline by centrifugation at 2000 rev/min for 10 min. The washed precipitates and the supernatants were counted in a Searle automatic gamma counter. The percent inhibition was normalized based on 100% precipitation without inhibitor (32–40% before normalization) and 0% precipitation without antibody.

Partial purification of cross-reactive leukemia antigen

Method for isolation of MPMV p25 [12] was applied. The viral band was prepared from human CML spleen as described in Material and Methods. After resuspension in TNE, the homogenous suspension was brought to 1% of Triton X-100 and kept in ice for 1–2 hr. Insoluble material was removed by 1 hr centrifugation at 100,000 ×*g*. The supernatant (10 ml) was loaded on a 2·5 × 70 cm agarose 0·5 M column and eluted with TNE containing 0·01% triton X-100. The third peak was pooled, diluted with water, and loaded on DE52 column equilibrated with 0·02 M phosphate pH 7·5. The fractions eluting between 0·08 M and 0·2 M NaCl were pooled, dialyzed against 2000 volume of H_2O and lyophilized to dryness.

Affinity chromatography

Monospecific antibody to MPMV p25 was coupled to CNBr activated Sepharose 4B [16]. Particles in the viral density region from 50 gm of spleen obtained from a patient with chronic ML was treated with Triton X-100 at a final concentration of 1% for 1 hr. The detergent

treated fraction was applied to the anti-p25-Sepharose column. After extensive washings (30 × volume) with TNE buffer, the protein bound to the antibody column was eluted with 0·1 M glycine-HCl buffer, pH 2·2. The eluent was dialyzed against phosphate buffered saline, then H_2O and concentrated by lyophilization.

RESULTS

Viral origin of the protein

In the initial experiments the antigen and the antiserum were prepared from virus grown in the human lymphoid cell line (NC37). It was necessary to ascertain whether the p25 antigen was derived from the virus or from the host cell. MPMV grown in NC37 and in the original Rhesus monkey mammary tumor cell line cocultivated with monkey embryo cells were compared for their ability to block the iodinated p25 protein. The viruses were both

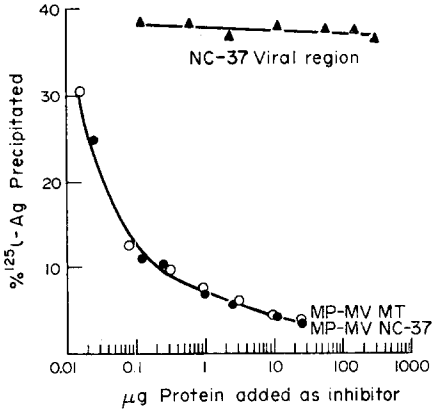

Fig. 1. Comparison of the inhibition of indirect precipitation reactions between ^{125}I-labeled MPMV p25, and anti-MPMV by MPMV grown in different hosts. The MPMV-MT (○) was grown in the original Rhesus monkey mammary tumor cells cocultivated with monkey embryo cells and the MPMV-NC37 (●) was grown in a normal human lymphocyte line, NC37. Uninfected NC37 cells were disrupted and a density region (1·15–1·19 g/ml in 20–45% sucrose density gradient) (▲) was taken for control. There was always less than a 2% difference in duplicate precipitations, and the average was recorded.

purified to the same extent and ruptured as described in Material and Methods. It is evident from Fig. 1 that the virus preparations from human and simian cell lines both yielded the same degree of inhibition through the concentration curve. As a further check, the crude extract (800 μg) and the proteins from uninfected NC37 cells, which accumulate in the viral density region (1·15–1·17 g/ml) in a sucrose gradient, were also examined. These failed to exhibit any detectable blocking ability. These results are in agreement with the studies done by others [17,18] and indicate that the labeled p25 antigen was a viral protein and not a membrane component of the host cell, NC37.

Particulate localization of cross-reacting proteins

The supernatants resulting from two successive low speed centrifugations (1500 × *g* and 10,000 × *g*, 10 min each) were tested for serological cross-reaction with p25 by inhibition of radioprecipitation. The supernatants from a variety of normal and malignant tissues including cancers of the lung, colon, rectum and breast were examined for inhibition. Only supernatants prepared from spleens and peripheral blood leukocytes (PBL) of patients with ML (acute and chronic) gave significant inhibition (> 15%) (Table 1).

Table 1. The inhibition of indirect precipitation reaction between ^{125}I-labeled MPMV p25 and anti-MPMV by post-mitochondrial supernatants of tumor tissues

Inhibitors		Protein added (μg)	Pptd. (%)	Inhibited (%)

		830	100	0

The major cross-reactivity of the supernatant was found to be in the density of known RNA tumor viruses although this density region is not exclusive for the viral particles. This was demonstrated using the supernatant from PBL of a patient with chronic ML. The supernatant was fractionated by centrifugation through a 20–45% continuous sucrose density gradient. The fraction banding isopycnically between 1·15 and 1·17 g/ml inhibited precipitation to the greatest extent (Fig. 2). Materials in 3 other fractions showed appreciable inhibition. This may be due to the formation of the aggregation of antigens or the formation of viral core-like

particles in the high density region (> 1·20 g/ml) and the release of free or small membrane bound antigens in the lighter density regions (< 1·15 g/ml).

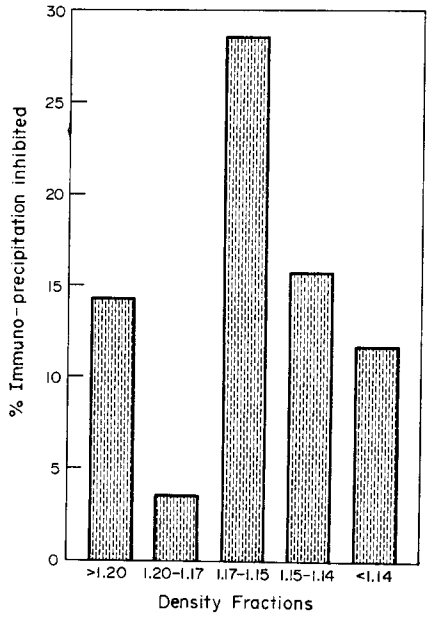

Fig. 2. Inhibition of indirect precipitation of ^{125}I-MPMV p25 by different density fractions of leukemia cell extract. The extract of WBC (500 mg) from a patient with chronic myelogenous leukemia was separated into 5 different density fractions by 20–45% sucrose density gradient centrifugation. Each fraction was pelleted by another centrifugation at 40,000 rev/min for 50 min and resuspended in 100 µl of 1% NP-40 in TNE buffer. For the inhibition of precipitation, 20 µl of each density fraction was used as an inhibitor.

Specific inhibition by antigens of myelogenous leukemia

Figure 3 illustrates some of the representative inhibition reactions of the proteins in 1·15–1·17 g/ml density region of human leukemic cells or spleen. As little as 2 µg of a preparation of this "viral density fraction" (VDF) produced 50% inhibition of precipitation. The slope of the inhibition curve obtained with VDF was similar to the curve obtained with MPMV suggesting that the leukemic tissue may contain a protein similar to MPMV p25. This very active inhibition was the highest observed, but other VDF preparations, though having less inhibitory activity, nevertheless produced similar inhibition curves.

VDF were prepared from malignant or normal tissues. Each VDF was assayed for inhibition using six different amounts ranging from 1–1000 µg. One thousand micrograms of VDF from some non-leukemic tissues inhibited by 20–25% presumably due to "non-specific interference" of the precipitin reaction caused by extremely high concentrations of proteins. However, at the 250 µg level, inhibition was only 10–15% for these tissues and, therefore, this amount of protein was used to assess the inhibition, except for VDF from PBL of patients with chronic ML, in which 120 µg were used. The results obtained with VDF prepared from 42 individuals are plotted in Fig. 4. VDF from

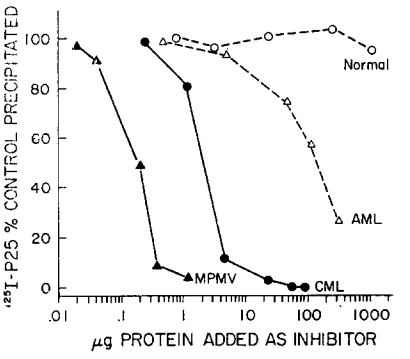

Fig. 3. Inhibition curve of immunoprecipitation of ^{125}I-MPMV p25 by various concentrations of density fractions derived from PBL of normal individuals or patients with ML. The material in the density region between 1·15–1·17 g/ml was collected, and the particles were then recovered by centrifugation at 98,000 × g for 1 hr. The pellet was resuspended in 1 ml of TNE buffer and used for radioimmunoassay. In the VDF, 80–500 µg of proteins were obtained from 1 g of starting materials.

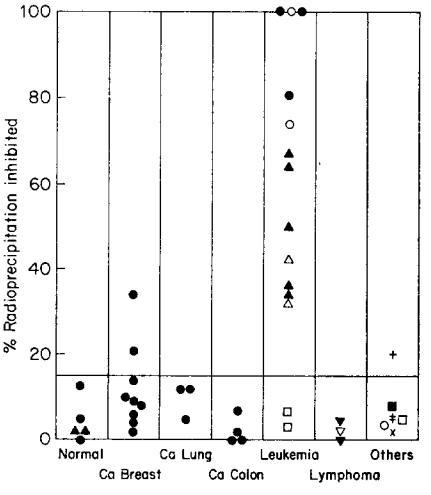

Fig. 4. Inhibition of immune precipitation of ^{125}I-p25 by proteins accumulated in the VDF of malignant or non-malignant tissues. Proteins banding on a sucrose gradient in the density region of 1·15–1·17 g/ml for ML and 1·15–1·19 for others were used for the assay. The degree of inhibition was determined at a point corresponding to 250 µg of protein. The line drawn at 15% is arbitrary to stress the significant level of the reaction. Normal PBL (●) and normal spleen (▲) for normal tissues; acute ML PBL (○), chronic ML PBL (●), acute ML spleen (△) and chronic ML spleen (▲), chronic lymphatic leukemia PBL (□) for leukemic tissues; African Burkitt's lymphoma (▼) and lymphosarcoma (▽) for lymphomas; carcinoma of the stomach (+), liposarcoma (□), Ca. pancreas (≠), Ca. bladder (○), Ca. kidney (■), and fibroadenoma (×) for others. Clinical materials from autopsies or biopsies were selected without regard to age, sex, stage or type of the malignancy or therapy.

12 of 12 patients with ML inhibited the precipitation most significantly; VDF from their PBL inhibited by 74–100%, while VDF prepared from their spleens inhibited by 32–69%. VDF obtained from two breast cancers also inhibited the precipitation significantly. None of the VDF prepared from seven other patients with breast cancer or from 20 other individuals who were either normal or had other malignancies inhibited precipitation.

Possibilities of non-specific interference by the proteins from CML leukocytes

Leukocytes from patients with ML might contain proteolytic enzymes which digest ^{125}I-p25 and cause nonspecific interference of immune precipitation by ^{125}I-p25. Experiments were done to rule out this possibility. Radiolabelled p25 was incubated for 1 hr under the same conditions used for the radioimmunoassay with 1 mg of the VDF from PBL of a patient with chronic ML. Fragmentation of ^{125}I-p25 was estimated by an electrophoresis of the mixture in 1% SDS-7·5% polyacrylamide and precipitability in 10% trichloroacetic acid. Insignificant levels of the radioactivity over background of free ^{125}I (10%) were observed either in the low molecular weight region of SDS gel or in the supernatant of 10% trichloroacetic acid solution. In addition, the same leukemic materials which were inhibitory to the precipitation of ^{125}I-p25 were not inhibitory to the precipitations of ^{125}I-Rauscher leukemia virus p30, ^{125}I-mouse mammary tumor virus gp52 and ^{125}I-Avian myeloblastosis virus p27. A representative result is shown in Fig. 5. Since no immunological cross-reaction is detectable among MPMV p25, Rauscher leukemia virus p30 and mouse mammary tumor virus gp52 [10,17], it was concluded that the inhibition is immunologically specific. Taken together, these results indicate that significant proteolysis has not occurred, and the inhibition is specific to p25.

Partial purification and characterization of the leukemia antigen

To investigate the nature of the cross-reaction between MPMV p25 and an antigen from human ML, partial purification and characterization of the leukemic antigen were performed. The VDF from PBL of a patient with chronic ML was partially purified by agarose-gel filtration. The enriched antigen was further separated by disc-gel electrophoresis in Tris-glycine buffer, pH 8·4, to determine relative net electrical charge to p25. The degree of cross-reactivity was estimated by inhibition of the radioimmune precipitation of ^{125}I-p25 with the eluent proteins from 3 mm sections of the gel. The peak of the cross-reactivity was found in the gel fractions to be in the same positions as MPMV p25, indicating similar net electrical charge to p25 (Fig. 6A). The peak of reactivity was relatively broad. This could be explained by overloading the gels with the sample (1–2 mg/gel of 6 mm diameter). Overloading was necessary due to the low efficiency of elution and the minor population of cross-reacting protein in the sample. However, this does not exclude the possibility of the presence of more than one cross-reacting protein with similar net electrical charges.

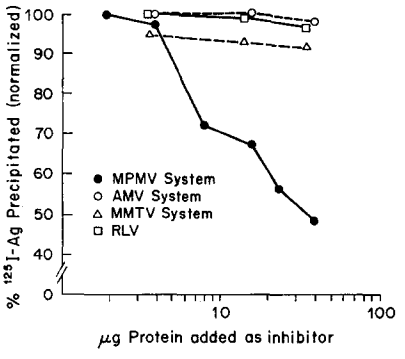

Fig. 5. Immunological specific inhibition of MPMV p25 anti-MPMV by partially purified human protein. Partially purified leukemia antigen was applied to 4 different radioimmuno-precipitation systems. The ^{125}I-labeled antigen–antibody systems used were: (a) AMV p27 (100,000 counts/min/ng) and anti-AMV p27 giving 32% precipitation; (b) RLV p30 (10,000 counts/min/ng) and anti-RLV p30 giving 47% precipitation; (c) ^{125}I-MMTV GP52 (8000 counts/min/ng) and anti-MMTV giving 37% precipitation, and (d) ^{125}I-MPMV-p25 (20,000 counts/min/ng) and anti-MPMV giving 51% precipitation. One μg of AMV, RLV, MMTV or MPMV inhibited completely homologous radioimmunoassay systems respectively. Increasing amounts of human leukemic protein were added to each of the assays. The data were normalized to 100% precipitation without inhibitors with the fixed amount of antiserum.

Furthermore, the cross-reacting protein was partially isolated using an immunoabsorbent column of rabbit anti-MPMV p25 (Fig. 6B). The eluate showed a major peak of molecular weight 26,000 daltons in SDS gel electrophoresis which is very close to MPMV p25 (Fig. 6B). As a minor peak, a protein with molecular weight 12,000 daltons was also found in the eluate. It might be due to dual specificity of the antibodies coupled to the Sepharose although the antiserum gave a single precipitin line against NP-40-disrupted MPMV in agar gel double diffusion. This possibility is supported by the electrophoresis pattern of eluate from

the column which had been applied with NP-40 disrupted MPMV. This result may suggest the presence of another antigen, p12, in human leukemic materials which is cross-reactive to MPMV p12. The purified human protein retained partial inhibitory activity for the radioimmune precipitation (10 μg was required for the 50% inhibition) of MPMV system. However, it did not inhibit the other radioimmune precipitation systems of viral proteins such as RLV p30-anti-p30. The failure to obtain 100% recovery of the activity may be due to the extensive manipulation and acid treatment of the material. When the leukemic material was applied to a column of Sepharose 4B coupled with normal rabbit IgG, no detectable protein was recovered in the eluate.

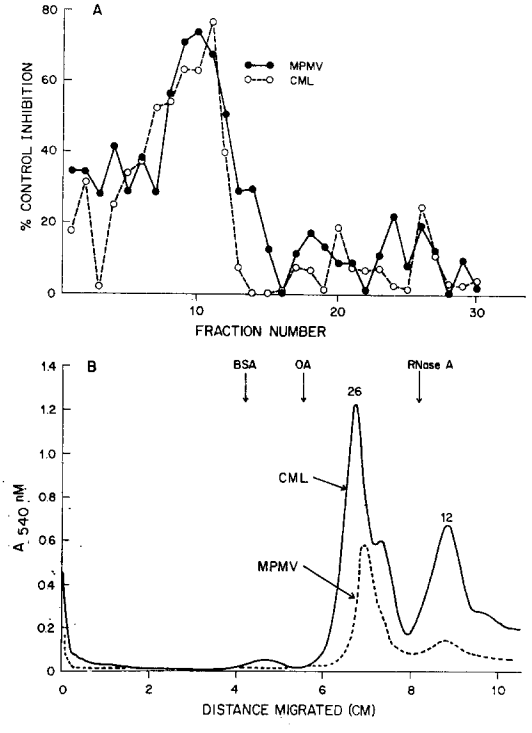

Fig. 6. Characterization of the human myelogenous leukemia antigen.

A. Similar net electrical charge to MPMV p25.

The particles from CML spleen which accumulated in the 1·16 g/ml region of a sucrose density gradient were disrupted with 1% Triton X-100 for 1 hr. The detergent-disrupted particles were fractionated by gel filtration on an agarose (A 0·5 M), and fractions showing greatest inhibition in the radioimmunoassay were pooled, desalted and concentrated. This preparation was further separated by disc-gel electrophoresis in Tris-glycine buffer, pH 8·4. The gel was cut into 3 mm fractions which were ground to 400 μl of TNE buffer, 200 μl of the resulting supernatant was used for inhibition of the radio-precipitation. This same procedure was applied to MPMV for a control reference.

B. Similar molecular weight to MPMV p25.

The detergent disrupted particles (prepared as above) were applied to the anti-p25-Sepharose column. After extensive washings (30 × volume) with TNE buffer, the protein bound to the antibody-column was eluted with 0·1 M glycine-HCl buffer, pH 2·2. The eluate was dialyzed extensively against phosphate buffered saline and H_2O, and then lyophilized. The concentrated material was analyzed by 1% SDS-7·5% polyacrylamide gel electrophoresis. Bovine serum albumin, ovalbumin and RNase A were used as references for molecular weights.

DISCUSSION

In the present studies, the existence of a cross-reacting antigen in the leukocytes of patients with myelogenous leukemia to the major protein (p25) of MPMV has been demonstrated. It is a striking fact that 12 out of 12 of the myelogenous tissues (PBL and spleens) were positive for the blocking protein. It is of interest that an antigen similar to the MPMV p27 (or p25) has been found in some human malignant breast tumors [19], and this may account for the two positive samples out of 9 viral density fractions of malignant breast tissues. Although its relation to the disease is unknown, MPMV apparently originated from a mammary tumor in a monkey [1].

Under the circumstances, it is surprising that an antigenic relationship was found between the p25 of MPMV and an antigen found in the human myelogenous leukemias. However, MPMV-like particles have been identified in human cell lines derived from patients with leukemia or other malignancies [7–9]. Relatively high levels of antibodies to the MPMV p25 were found in plasmas from some normal individuals and most patients with myelogenous leukemia [12]. Therefore, infection with the same or similar virus might be widespread and be associated with both leukemia and carcinoma of the breast.

No significant precipitation of ^{125}I-p25 was observed either by anti-gs3 (RLV) or by anti-MMTV (unpublished data). These results agree with the observations that MPMV does not cross-react serologically with other mammalian B- or C-type viral proteins [3, 10, 17]. Thus, the absence of interactions between MPMV-p25 and Rauscher leukemia virus or simian sarcoma virus makes it unlikely that we are dealing with antigens previously reported in normal and some human tumor tissues [20–23].

A number of experiments were done to exclude the possibilities of proteolysis which might interfere with immune precipitations nonspecifically. It is very unlikely that the inhibition of radioimmune precipitation had occurred by proteolysis for the following reasons: (1) no detectable fragmentation of ^{125}I-p25 was found by an active VDF (SDS

gel electrophoresis and 10% trichloroacetic acid precipitation); (2) the leukemic material which gave positive reaction did not inhibit the radioimmune precipitations of other RNA tumor viral proteins; (3) the leukemia antigen purified by specific immunoabsorbent column retained the inhibitory activity for the immune precipitation of ^{125}I-p25; (4) the net electrical charge and molecular weight of the leukemia antigen are very similar to those of MPMV p25.

On the basis of the present studies, it appears that the cross-reacting antigen obtained from cells from patients with ML is very similar to an antigen of the MPMV p25. The presence of antibody to the MPMV p25 in the plasmas of patients with myelogenous leukemia strongly supports this possibility [12]. Using protease inhibitors to rule out the possibility of protease is not appropriate for an immunological system. In most cases, the protease inhibitors modify active sites of enzymes and the use of such inhibitors might affect antigenicity and create uninterpretable artifacts. Although it is extremely unlikely, a possibility of a protease specific for MPMV p25 is not completely excluded. Even if it is assumed that proteolysis occurs, it would be most remarkable that the proteolysis is so specific for an enzyme present exclusively in VDF of ML materials. The inhibition appears to be so specific to myelogenous leukemia that it might provide valuable clinical information. For example, it is of interest that in preliminary studies leukocytes obtained from two patients in remission from myelogenous leukemia showed no detectable inhibition. Thus, the assay may be useful for following the course or determining the prognosis of myelogenous leukemia.

Inhibition of Chemical Carcinogenesis: Increased Activity of Soluble RNA Polymerase in the Liver of Rats Protected Against 3'MeDAB Hepatocarcinogenesis by Dietary Chloramphenicol*

W. A. PHILLIPS and JILL M. BLUNCK
Department of Pathology, University of Melbourne, Parkville, Victoria 3052, Australia

Abstract—*Soluble RNA polymerases (nucleotidyl transferases, EC 2.7.7.6) were isolated from liver nuclei of rats that had been pair-fed diets containing the hepatocarcinogen 3'methyl-4-dimethylaminoazobenzene (3'MeDAB, 0·06%) either alone or in combination with chloramphenicol (CAP, 2%), an inhibitor of azo dye carcinogenesis. DEAE Sephadex A-25 chromatography of crude nuclear extracts (fraction IV protein) revealed 2 major peaks of enzyme activity which were equated with RNA polymerases I and II on the basis of order of elution and sensitivity to α-amanitin. The specific activities of both enzymes, in particular RNA polymerase I, were significantly increased after 4 days on diets containing CAP or both 3'MeDAB and CAP. Rats protected from 3'MeDAB carcinogenesis by CAP showed the greatest increase, which exceeded that in the group fed dye alone by 292% for polymerase I and 116% for polymerase II. Increases in both RNA polymerase activities were probably not a consequence of altered affinity for the substrate UTP. RNA polymerase activity was not altered by feeding the 3'MeDAB diet for 4 days, but after 10 days there was a 340% increase in the specific activity of enzyme I and a 14% increase in the specific activity of enzyme II relative to levels in control rats. The total nuclear protein content was significantly increased in rats fed 3'MeDAB or both 3'MeDAB and CAP for 4 days. Crude polymerase extracts contained 4–6% of the total nuclear protein and 83–87% of the RNA polymerase activity present in isolated nuclei. There was a significant increase in the amount of nuclear sap protein extracted after feeding 3'MeDAB for 4 days. Differences in nuclear RNA synthesis between experimental groups were insensitive to presacrifice starvation and altered feeding and lighting schedules; neither were they due to differential losses of RNA polymerases during the nuclear isolation procedure or to preferential extraction of these enzymes from isolated nuclei in the various groups. We conclude that the differences in liver nuclear RNA synthesis between 3'MeDAB-fed rats and rats protected against 3'MeDAB-induced hepatocarcinogenesis by concurrent CAP administration are at least partly due to differences in the activity and/or amount of soluble RNA polymerases.*

INTRODUCTION

CHLORAMPHENICOL (CAP) inhibits azo dye hepatocarcinogenesis in the rat [1, 2]. The liver RNA/DNA ratio of protected rats is normal, in contrast with that of rats fed an azo dye, in which the ratio is significantly depressed [3]. This effect of CAP could be relevant to the protective action, for similar levels of protein-bound carcinogen were found in the livers of both dye-fed and CAP-protected rats [3], indicating that CAP administration probably

Accepted 3 December 1976

does not significantly affect the amount of carcinogen reaching the target tissue. The difference in liver RNA/DNA ratio between azo dye-fed and CAP-protected rats is due to differences in the amount of liver RNA [3]. Furthermore, there is evidence that this effect is a consequence of an increased rate of nuclear RNA synthesis, rather than slower degradation of total liver RNA [4, 5]. Alterations in nuclear RNA synthesis can be due to changes in the template activity of DNA and chromatin or in the activity and amount of the RNA polymerases (nucleotidyl transferases, EC 2.7.7.6). Methods describing the isolation of these RNA polymerases in high yield are now available [6–8] and in the present report, we describe some properties of purified RNA polymerases from the livers of rats which had been fed diets containing the azo dye 3′methyl-4-dimethylaminoazobenzene (3′MeDAB) either alone or in combination with CAP. The specific activities of both RNA polymerases I and II, especially the former, were found to be significantly increased in CAP-protected rats as compared with rats fed only 3′MeDAB.

The differences in soluble RNA polymerase activity between carcinogen-fed and CAP-protected rats described here have been shown not to be due to differences in the efficiency of extraction of soluble polymerase from isolated nuclei. Neither are they due to differential leaching of the enzyme activity from nuclei during the isolation procedure. Altered feeding and lighting schedules did not affect the pattern of our previous results [4], where administration of a diet containing 3′MeDAB and CAP caused a significant increase in RNA synthesis in isolated rat liver nuclei as compared with rats pair-fed a diet containing only 3′MeDAB.

MATERIAL AND METHODS

Animals and diets

Male Sprague–Dawley rats (a total of 96 of approx wt 145 g) random bred from local departmental stock were used in all experiments. They were housed in individual cages and pair-fed either a control diet or diets containing 2% CAP, 0·06% 3′MeDAB and 0·06% 3′MeDAB plus 2% CAP for 4 or 10 days as indicated in the Table and Figure legends.

Details of the diet preparation and pair-feeding procedure have been described previously [3]. Except where specified otherwise, the rats had continuous access to the diets until the time of sacrifice. At the conclusion of each experiment, the rats were killed by exsanguination under light ether anaesthesia between 09.00 and 10.00 hr.

Source of materials

The following reagents were purchased from the Sigma Chemical Co., St. Louis, MO: ATP (disodium salt), CTP (disodium salt), GTP (trisodium salt), UTP (tetrasodium salt), spermine diphosphate, dithioerythritol (DTE), dithiothreitol (DTT), ribonuclease A (type 1A, from bovine pancreas), protease (type VI, from *S. griseus*) and calf thymus DNA (type 1, highly polymerized). Uridine-4-^{14}C-5′-triphosphate (specific activity 43 mCi/m-mole) and uridine-5,6-^{3}H-5′-triphosphate (48 Ci/m-mole) were obtained from the Radiochemical Centre, Amersham, Bucks. and were periodically checked for radiopurity by paper chromatography [9]. α-Amanitin was purchased from Calbiochem, San Diego, Cal. and manufactured by C. H. Boehringer Ingelheim. Eastman Kodak Co., Rochester, N.Y. supplied the N, N-methylene bisacrylamide and N, N, N′, N′- tetramethylethylenediamine (TEMED) while cellulose casing dialysis tubing, size 18/32, was obtained from the Visking Co., Chicago, Ill. Crystalline bovine serum albumin (BSA), Cohn fraction V, was purchased from the Commonwealth Serum Laboratories, Melbourne and DEAE Sephadex A-25 from Pharmacia, Uppsala. 3′MeDAB (m.p. 119° C) was synthesized as described by Giese *et al.* [10] and CAP (D(–) *threo* isomer) was a gift from Parke, Davis and Co., Caringbah. Coomassie brilliant blue FF (1434) was obtained from E. Gurr, Ltd., Bucks. All other chemicals used were of analytical reagent grade and solutions were prepared with metal-distilled water which had been passed through an Elgastat deionizer.

Rat liver histone was prepared according to the recommendations of Hnilica [11]. The histone content of our preparation was determined by the method of Mirsky and Pollister [12] as described by Hnilica [11] and the

$$E\,\frac{354\text{ nm}}{1\text{ mg/ml}}$$

was found to be 0·785 as compared with a literature value of 0·800 [11].

The procedure followed for the preparation of rat liver DNA was basically that of Marmur [13] and has been described elsewhere [14]. The DNA obtained was dissolved in phosphate-citrate buffer (0·01 M phosphate/0·001 M citrate, pH 7·5) at a final concentration of 1·462 mg/ml and stored at −20° C prior to use. Analytical ultracentrifugation of a sample of

this preparation revealed a single polydisperse peak with a sedimentation coefficient of 21·3 ± 2·6 (S.D.). In contrast with the findings of a recent report [15], there was no detectable DNA nuclease activity in the commercial ribonuclease and protease preparations used during the isolation of the DNA. Furthermore, the buoyant density in CsCl [16] of a sample of commercial calf thymus DNA was unaltered if it was subjected to the DNA isolation procedure. Calf thymus DNA also showed a lack of hyperchromicity [17] in the presence of either the ribonuclease and/or the protease. DNA nuclease activity was determined by the procedure recommended by the Sigma Chemical Co., St. Louis, MO after heating the ribonuclease at 90° C for 10 min and autodigesting the protease at 37° C for 2 hr.

Isolation of nuclei

The basic technique of Blobel and Potter [18] was routinely used for isolating nuclei prior to solubilization of the DNA-dependent RNA polymerases.

When studies were made of the nuclear protein composition and also in the controlled feeding experiments, nuclei were isolated by a modification [4] of the method of Widnell and Tata [19], for more liver samples could be processed by using this procedure. The recovery of liver DNA in these nuclear preparations varied between 43 and 47%. The large scale nuclear isolation procedure of Read and Mauritzen [20] was used when nuclei were required for the preparation of rat liver histone standard.

When estimations were made of the amount of "free" RNA polymerase activity present in nuclear preparations, a comparison was made of nuclei isolated by the Blobel and Potter technique with those isolated by using the procedure of Yu [21] which we modified by omitting the perfusion step and substituting $MgCl_2$ for $CaCl_2$ in the homogenizing medium. The nuclei obtained had an RNA/DNA ratio of 0·199 as compared with a value of 0·184 for nuclei prepared from an identical liver sample by the Blobel and Potter procedure. Nuclei isolated by either the Blobel and Potter technique described above or the modified Widnell and Tata procedure were comparable with respect to percent recovery of total homogenate DNA, RNA/DNA ratio and capacity for RNA synthesis. Total homogenate DNA and RNA were determined using the procedure described by Munro and Fleck [22], while nuclear DNA and RNA were estimated as described by Blobel and Potter [23]. All nuclear pellets were resuspended in 4 ml of 0·25 M sucrose containing 1 mM $MgCl_2$.

Solubilization of RNA polymerases

Aliquots of the respective nuclear suspensions were taken for the estimation of RNA synthesis, then the residual portions were centrifuged at 750 g for 10 min to pellet the nuclei prior to extraction of the RNA polymerase. In our experience, the method of Jacob *et al.* [8] was found to give high yields of active enzyme and was used routinely. The dialysed protein preparation (fraction IV protein) did not require clarification by centrifugation as no precipitate was evident. A portion of the fraction IV protein was immediately assayed for DNA-dependent RNA polymerase activity and the remainder subjected to ion exchange chromatography within 5 hr of dialysis.

Ion exchange chromatography

DEAE Sephadex A-25 was prepared as described by Saunders *et al.* [24]. Fraction IV protein from the various rats (1–8 mg in 2·5–5·5 ml) was applied to columns (0·9 × 12 cm) and was washed into the gel with 0·05 M $(NH_4)_2SO_4$ in a solution comprising 0·05 M Tris-HCl (pH 7·9), 25% (v/v) glycerol, 5 mM $MgCl_2$, 0·1 mM ethylenediaminetetraacetate (EDTA) and 0·5 mM dithiothreitol (TGMED, 20 ml). The enzymes were then eluted with a linear gradient of 0·05–1·2 M $(NH_4)_2SO_4$ in TGMED (70 + 70 ml). A total of 110 fractions (1 ml) were collected, commencing at the time of sample application. The flow rates of the columns were *ca* 35 ml/hr.

The concentration of $(NH_4)_2SO_4$ in the individual fractions was determined by either the phenol-hypochlorite reaction for ammonia [25] or by measurement of the conductivity (Philips conductivity-measuring bridge PR 9500) or resistance (Avo multimeter) of the solution. The phenol–hypochlorite method required that aliquots (100 µl) of the fractions be diluted (1 part in 20,000 parts of water) prior to analysis, while conductivity or resistance measurements were made on undiluted eluate. The $(NH_4)_2SO_4$ concentration of the respective samples was estimated from a graph of standard values obtained by analysis of solutions of known concentrations of $(NH_4)_2SO_4$ in TGMED. Assays of RNA polymerase activity in the fractions were always performed within 12 hr of chromatography.

Assay of RNA synthesis

Nuclear RNA synthesis was estimated by the method of Widnell and Tata [26] as detailed

in a previous report [4]. RNA polymerase activity in fraction IV protein was routinely determined by the method of Jacob *et al.* [8]. The fractions obtained after DEAE Sephadex chromatography were also assayed for RNA polymerase activity by the method described by Jacob *et al.* [8] for the Mg^{2+}-dependent activity of fraction IV protein, except that $MnCl_2$ (1·5 μmole) was also included in the incubation medium, the amount of unlabelled UTP used was 0·015 μmole and ^{3}H-UTP (1 μCi) was used as the radioactive precursor. In a pilot study, α-amanitin (0·08μg in 50μl) was added to the media immediately prior to initiation in RNA synthesis assays on samples representative of the various preparations.

The various incubations were routinely terminated by the addition of ice-cold 0·3 M $HClO_4$ (1 ml) and the precipitates collected by centrifugation. They were then washed either twice (^{14}C-UTP incubations) or five times (^{3}H-UTP incubations) with 0·2 M $HClO_4$ (3 ml) and hydrolyzed for 15 min at 37°C with 0·3 M KOH (1 ml). The volume was made up to 2·9 ml with deionized water and a portion (1 ml) of this solution neutralized with conc. HCl (100 μl); an aliquot (7·5 ml) of scintillation mixture comprising 2:1 toluene/Triton X-100 containing 4 g PPO/l. was then added and the radioactivity of the samples determined.

The above-mentioned procedure for estimating incorporation of radioactivity into RNA gave results which were comparable with those of the Blobel and Potter procedure [23]. All radioactivity measurements were made with a Packard model 3314 liquid scintillation spectrometer. Addition of ^{14}C-toluene or ^{3}H-toluene internal standards revealed that the counting efficiency was 80% for ^{14}C and 29% for ^{3}H.

Polyacrylamide gel electrophoresis

Chromatographic fractions which contained peaks of RNA polymerase activity were pooled, stored at −70° C for 3 months and then lyophilized. Each sample was resuspended in 50 μl of a buffer (identical except for the omission of sodium dodecyl sulphate (SDS) with that described by Weaver *et al.* [27]); 10–15 μl of the resulting solutions were then layered over 5% acrylamide gels (pH 8·5). The gels were prepared by the method of Shapiro *et al.* [28] except that once again, SDS was omitted. Electrophoresis was performed under nondenaturing conditions for 3 hr at a constant current of 8 mA/gel in a Quickfit polyacrylamide gel electrophoresis apparatus, type DO 95270/1. The separated proteins were stained with Coomassie brilliant blue FF (1434) as described by Weber and Osborn [29].

Extraction of nuclear proteins

The protein composition of nuclear preparations was determined both before and after solubilization of the DNA-dependent RNA polymerases. The basic procedure used for the fractionation of the nuclear proteins was that of Teng *et al.* [30] but the sap proteins and acidic proteins were extracted by the methods of Hnilica [11] and Elgin and Bonner [31] respectively.

Protein estimation

Total nuclear protein was determined by the microbiuret method of Itzhaki and Gill [32] and the protein content of the homogenate by the biuret method as described by Cleland and Slater [33]. The protein content of fraction IV protein was determined by measuring A_{260nm}/A_{280nm} [34], while that of the nuclear protein fractions and the column effluent was determined by measuring A_{215nm}/A_{225nm} [35, 36]. The histone content of the column effluent was measured by the method of Mirsky and Pollister [12] as described by Hnilica [11].

Statistical analysis

Statistical analysis was performed with the two-tailed Student's *t*-test unless otherwise indicated; a *P* value of less than 0·05 was taken as being significant.

RESULTS

Effects of controlled food access and lighting on RNA synthesis in isolated nuclei

In agreement with the results of a previous study [4] rats protected against 3′MeDAB-induced hepatocarcinogenesis by the inclusion of CAP in the diet, exhibited a significantly increased level of nuclear RNA synthesis as compared with rats fed 3′MeDAB alone (results not shown). The effect was apparent within 4 days of commencing the diets and was most pronounced in the Mg^{2+}-stimulated assay, which predominantly measures ribosomal RNA synthesis [37].

There are recent reports, however, that both Mg^{2+}-stimulated and $Mn^{2+}/(NH_4)_2SO_4$-stimulated nuclear RNA synthetic activities exhibit a diurnal rhythm [38, 39] and that these periodic fluctuations in activity are related to food intake [38]. The CAP-containing

diets are unpalatable and furthermore, there is evidence that the feeding pattern of rats is altered by the administration of a hepatocarcinogen in the diet [40]. The differences in nuclear RNA synthesis between dye-fed and CAP-protected rats might therefore be an artifact. This could arise from different feeding patterns in rats eating the respective diets, for the animals, although pair-fed, were allowed continuous access to the food. RNA synthesis in isolated liver nuclei was therefore compared in rats pair-fed diets containing azo dye and/or CAP by the conventional procedure [3], in rats pair-fed and starved 16 hr prior to sacrifice, and in rats subjected to the "8 + 16" feeding and "12 + 12" inverted and displaced lighting schedules of Potter *et al.* [41] as described by Barbiroli *et al.* [38]. These rats were also starved for 16 hr before sacrifice. The results of this experiment indicated that the differences in nuclear RNA synthesis between dye-fed and CAP-protected rats were not a consequence of altered feeding patterns induced by the diets.

Comparison of methods for extraction of RNA polymerase activity

Initially, the procedures described by Roeder and Rutter [6] and Jacob *et al.* [8] for the solubilization of rat liver RNA polymerases were compared with respect to the yield of active enzyme obtained. There are several difficulties involved in quantitating this parameter, perhaps the most serious being that the enzyme present in isolated nuclei reads from an endogenous chromatin template, while the solubilized enzyme is routinely assayed with free DNA, usually of a relatively low mol. wt. We therefore measured both the extracted activity and the residual activity in the nucleus after the extraction procedure, as recommended by Jacob [42]. The results showed that the amount of activity extracted agreed quite well with the level of activity remaining in the nucleus after extraction; on this basis 82·6% of the Mg^{2+}-stimulated activity and 86·6% of the $Mn^{2+}/(NH_4)_2SO_4$-stimulated activity were extracted. The procedure advocated by Jacob *et al.* [8] was also, in our hands, found to be more efficient than that of Roeder and Rutter [6] for solubilizing rat liver RNA polymerases. This finding could be due in part to the absence of a sonication step in the method of Jacob *et al.* [8], for sonication has been shown by others to decrease the yield of active enzyme [21, 43]. Furthermore, the procedure of Jacob *et al.* [8] requires that the dissociated polymerases be separated from the chromatin by centrifugation at 10° C, this temperature presumably being necessary to prevent reaggregation of enzyme and template [44]. In contrast, in the method described by Roeder and Rutter [6], the centrifugation step is performed at 0–4° C. These conditions might permit reaggregation to occur with a consequent decrease in the yield of soluble RNA polymerases.

Effects of diets containing 3′MeDAB and/or CAP on extractable RNA polymerase activity

Rats protected against 3′MeDAB-induced carcinogenesis by concurrent administration of CAP possessed significantly greater ($P < 0{\cdot}01$) total amounts of crude liver RNA polymerase activity, as estimated in fraction IV protein preparations, than rats fed 3′MeDAB alone (Table 1). However, there were increases in the amounts of total crude RNA polymerase activity extractable from the livers of all rats fed the experimental diets (CAP, 3′MeDAB, or both 3′MeDAB plus CAP). The same pattern of results was apparent for both the Mg^{2+}-stimulated and the $Mn^{2+}/(NH_4)_2SO_4$-stimulated assays, but were more pronounced in the former. When RNA polymerases I and II were estimated separately following DEAE Sephadex chromatography of fraction IV protein preparations, the alterations in the activity of these enzymes that had been noted in the crude preparations were confirmed. In particular, the protected rats, which had been fed both 3′MeDAB plus CAP, had much more extractable RNA polymerase I and II activity than those fed 3′MeDAB alone ($P < 0{\cdot}05$).

After 10 days on the diets, rats pair-fed the diet containing 3′MeDAB still showed an increase in extractable enzyme activity (Table 1). It is interesting to note that greater levels of enzyme activity were extracted from both control and 3′MeDAB-treated rats after 10 days of pair feeding than after only 4 days. These results are in contrast with data on the RNA synthetic activity in whole nuclei in these rats, which in general decreases rather than increases during this time interval [4]. The state of semi-starvation induced by the pair feeding regimens might result in altered nuclear structure and facilitate extraction of the enzyme activity; alternatively, there could be absolute increases in the amount of enzyme protein. The decreased levels of nuclear RNA synthesis, despite an increase in the amount of extractable enzyme, might be due to restriction of the chromatin template in semistarved rats [45].

Table 1. Effect of pair feeding a control diet and diets containing 2% CAP, 0·06% 3′MeDAB and 0·06% 3′MeDAB plus 2% CAP to rats for 4 or 10 days on the total amount of extractable RNA polymerase activity in the livers

Diet	4 days on diet				10 days on diet

The results are expressed as pmole UTP incorporated/liver/100 g body wt and represent the mean ± S.D. of estimations on the number of rats shown in parentheses. A total of 28 rats (mean wt ± S.D.; 147 ± 8 g) were used in these experiments. The data shown for the column-purified enzymes (polymerases I and II) represent the areas under the peaks (I and II) that were obtained on DEAE Sephadex A-25 chromatography. These values have been corrected for losses occurring prior to and during chromatography by using the percent recovery data given in Table 7. The corresponding data for the protein content of these fractions are given in Table 4.

*Significantly different from the respective control group ($P < 0·01$).

Effects of diets containing 3'MeDAB and/or CAP on loss of RNA polymerase during nuclear isolation and on efficiency of extraction of the enzymes from isolated nuclei

Differences in the amount of RNA polymerase solubilized from liver nuclei such as those shown in Table 1 could be a result of differential enzyme extraction from nuclei of rats fed the various experimental diets. To test this hypothesis, the residual RNA synthetic activity was measured in nuclei isolated from rats pair-fed the control and experimental diets. Levels of residual activity as measured by both the Mg^{2+}-stimulated and $Mn^{2+}/(NH_4)_2SO_4$-stimulated assays were roughly similar. This finding suggests that the differences observed between the groups in the amounts of extractable RNA polymerase activity are not due to altered solubilization of these enzymes from the nuclei of the experimental rats.

Selective leaching of RNA polymerases during the nuclear isolation procedure could also account for differences in the amounts of enzyme activity extractable from nuclei of the livers of rats fed the control and experimental diets. Yu [21] has recently reported that as much as 50% of the total nuclear RNA polymerase activity in normal rat liver may exist in the form of 'free' enzyme which is easily lost when the isolation procedure involves the use of an isotonic buffer medium. We therefore compared nuclei isolated directly in hypertonic sucrose [21] with those isolated by the Blobel and Potter procedure [18]. Levels of Mg^{2+}-stimulated RNA synthesis were roughly comparable in nuclei isolated by either procedure from rats fed the control or experimental diets. However, when exogenous DNA was added, a much greater increase in measurable enzyme activity was noted in nuclei isolated in hypertonic sucrose (Fig. 1). These findings indicated that, in agreement with Yu [21], there is measurable 'free' RNA polymerase activity in rat liver nuclei and that there is more of this 'free' enzyme if the nuclei are isolated in hypertonic sucrose. However, the relative differences in Mg^{2+}-stimulated RNA synthetic activity between nuclei isolated from rats fed the control and experimental diets were even more pronounced when measurements were made on nuclei isolated in hypertonic sucrose and in the presence of exogenous DNA. These findings exclude the selective leaching of RNA polymerase activity during nuclear isolation as an explanation of the differences in extractable RNA polymerase I activity in the variously-treated rats.

A basically similar pattern of results to those obtained for the Mg^{2+}-stimulated activity was observed if $Mn^{2+}/(NH_4)_2SO_4$-stimulated RNA synthesis was measured in nuclei isolated by the Yu [21] and Blobel and Potter [18] procedures. However in this instance, a greater amount of 'free' enzyme activity was noted

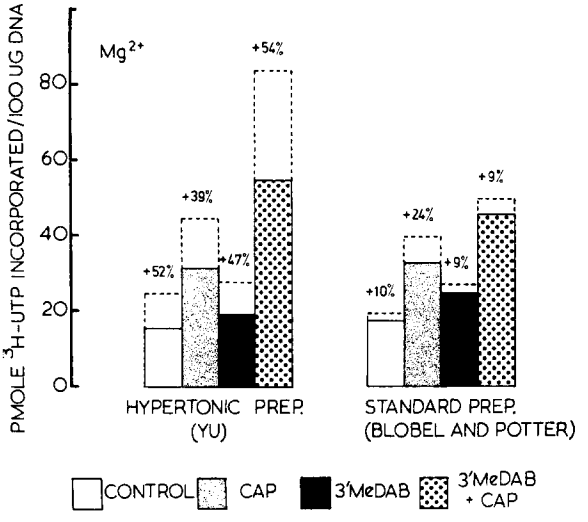

Fig. 1. Effect of the nuclear isolation procedure used on the level of Mg^{2+}-stimulated RNA synthesis in isolated liver nuclei from rats pair-fed either a control diet or diets containing 2% CAP, 0·06% 3'MeDAB or both 0·06% 3'MeDAB plus 2% CAP for 4 days. Pooled liver samples from 4 rats in each group were divided into two equal portions and nuclei were isolated from each of these according to procedures described by Yu [21] or Blobel and Potter [18] and outlined in 'Material and Methods'. A total of 16 rats (mean wt ± S.D.; 134 ± 11 g) were used. The percentage increases in incorporation indicated by the dotted lines were observed if exogenous rat liver DNA (84 μg) was added prior to the incubation; these increases represent the amount of 'free' RNA polymerase activity present in the nuclei. All incubations were performed in triplicate.

in the nuclei isolated in isotonic medium (Fig. 2), and the level of 'free' enzyme activity measured was similar regardless of the procedure used for nuclear isolation. These results indicate that the $Mn^{2+}/(NH_4)_2SO_4$-stimulated activity is more resistant to leaching during the isolation of nuclei. The relative differences in $Mn^{2+}/(NH_4)_2SO_4$-stimulated RNA synthetic activity between nuclei isolated from rats fed the control and experimental diets were, as in the instance of the Mg^{2+}-stimulated activity, more pronounced when exogenous DNA was added to the assays. Selective leaching of RNA polymerase activity during nuclear isolation therefore could also not explain differences in extractable RNA polymerase II activity in the variously-treated rats.

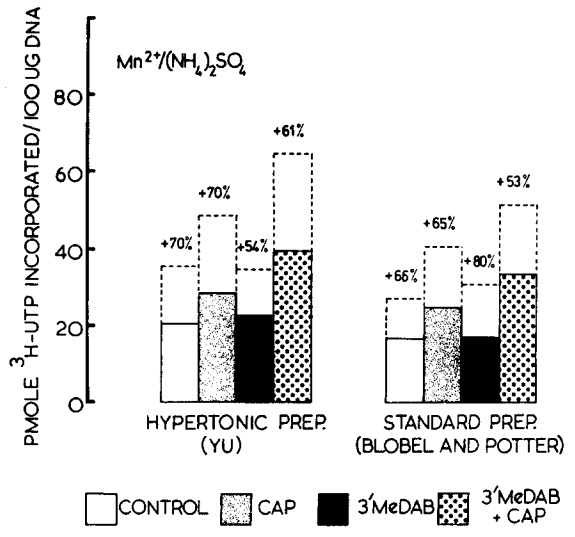

Fig. 2. Effect of the nuclear isolation procedure used on the level of $Mn^{2+}/(NH_4)_2SO_4$-stimulated RNA synthesis in isolated liver nuclei from rats pair-fed either a control diet or diets containing 2% CAP, 0·06% 3'MeDAB or both 0·06% 3'MeDAB plus 2% CAP for 4 days. Pooled liver samples from 4 rats in each group were divided into two equal portions and nuclei were isolated from each of these according to procedures described by Yu [21] or Blobel and Potter [18] and outlined in 'Material and Methods'. A total of 16 rats (mean wt ± S.D.; 134 ± 11 g) were used. The percentage increases in incorporation indicated by the dotted lines were observed if exogenous rat liver DNA (84 μg) was added prior to the incubation; these increases represent the amount of 'free' RNA polymerase activity present in the nuclei. All incubations were performed in triplicate.

Characteristics of nuclear proteins extracted with the RNA polymerases

There were increases in total liver nuclear DNA, RNA and protein in rats pair-fed the experimental diets for 4 days (Table 2). The increases were significant for DNA in rats fed both 3'MeDAB-containing diets, for RNA in all treated groups (the smallest increase being in the group fed 3'MeDAB) and for protein in the group fed 3'MeDAB. Further analysis of the increases in total nuclear protein induced by pair feeding the experimental diets revealed that there were minor increases in nuclear sap proteins, histones and acidic nuclear proteins (Table 3). The increases were significant in the instances of nuclear sap proteins in rats fed both of the 3'MeDAB-containing diets, histones in rats fed the 3'MeDAB diet and acidic nuclear proteins in rats fed the diet containing both 3'MeDAB plus CAP.

The amount of protein in the crude enzyme extracts (fraction IV protein) was significantly increased after 4 days of pair feeding diets containing 3'MeDAB when results were expressed either as protein extracted/4 g liver (Fig. 3) or as protein extracted/liver/100 g body wt (Table 4). Estimation of total nuclear protein both before and after the extraction procedure showed that only 4–6% of the total nuclear proteins were extracted; this experiment also confirmed the increased extraction of protein from the nuclei of rats fed 3'MeDAB (results not shown). More detailed analysis of

Table 2. Effect of 4 days of pair-feeding a control diet and diets containing 2% CAP, 0·06% 3'MeDAB and 0·06% 3'MeDAB plus 2% CAP on the DNA, RNA and protein content of rat liver nuclei

Diet	DNA	RNA	Protein
Control	5·45 ± 0·04 (−)	1·03 ± 0·03 (−)	21·44 ± 0·87 (−)

the protein content of nuclei that had been subjected to extraction suggested a selective extraction of nuclear sap proteins in rats fed 3'MeDAB and possibly acidic nuclear proteins in rats administered both 3'MeDAB plus CAP as compared with control rats (Table 3).

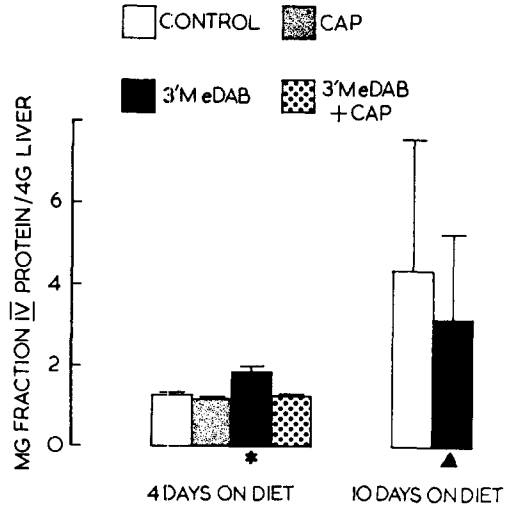

Fig. 3. Comparison of amounts of fraction IV protein extracted from the livers of rats which were pair-fed the various diets for 4 or 10 days. Each bar represents the mean ± S.D. of data derived from 3–8 rats; a total of 28 rats in all (mean wt ± S.D.; 147 ± 8 g) were used. The asterisk indicates a value that is significantly different from that of the control group ($P < 0·01$). The black triangle indicates a value that is significantly different from that of the control group only if the results are expressed as a percentage of the control value ($P < 0·01$. one-tailed t-test).

Characteristics of RNA synthesis catalyzed by fraction IV protein

The fraction IV protein samples were tested against standard rat liver DNA templates for their ability to catalyze RNA synthesis. In preliminary studies using a fraction IV protein preparation from a control rat, the amount of product formed increased with incubation time for 20 min. The reaction rate was determined by the amount of RNA polymerase present (DNA excess) when ≥ 15 μg of DNA and ≤ 250 μg of protein were used/assayed and under these conditions there was a linear increase in the amount of product formed when increasing amounts of fraction IV protein were added.

Rats pair-fed the diets containing CAP and 3'MeDAB plus CAP for 4 days showed a significant increase in the RNA polymerase specific activity (pmole ^{14}C-UTP incorporated/mg protein) of fraction IV protein preparations (Fig. 4). Although there was also a significant increase in the RNA polymerase activity of fraction IV protein preparations from rats fed 3'MeDAB alone for 4 days (Table 1), greater amounts of protein were extracted from the nuclei of these rats as compared with those receiving the other experimental diets (Table 4). Consequently, the specific activity of the RNA polymerase in the fraction IV protein from the rats fed 3'MeDAB for 4 days did not significantly differ from that of the control group (Fig. 4). However, if rats were fed the

Table 4. Effect of pair-feeding a control diet and diets containing 2% CAP, 0·06% 3'MeDAB and 0·06% 3'MeDAB plus 2% CAP to rats for either 4 or 10 days on the protein content of the nuclear extract

Diet	4 days on diet			10 days on diet

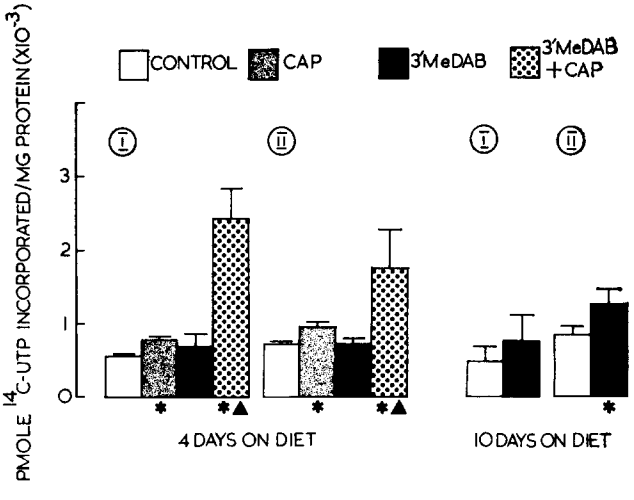

Fig. 4. Comparison of specific activity of RNA synthesis by fraction IV proteins isolated from the livers of rats that were pair-fed one of the various diets for either 4 or 10 days. The proteins were extracted from the liver nuclei by the method of Jacob et al. [8] *and aliquots (0·1 ml, ca 20–35 μg protein) were assayed against a standard rat liver DNA template (14·6 μg). The Mg^{2+}-stimulated and $Mn^{2+}/(NH_4)_2SO_4$-stimulated activities are shown beneath the symbols I and II respectively. Each bar represents the mean ± S.D. of data derived from 3–8 rats. A total of 28 rats (mean wt ± S.D.; 147 ± 8 g) were used in these experiments. The asterisks indicate values that are significantly different from those of the control group ($P < 0·01$). The black triangles indicate a significant difference between the group fed the 3'MeDAB-containing diet and that fed both 3'MeDAB plus CAP ($P < 0·01$). The values for the total RNA polymerase activity of these preparations are given in Table 1.*

3'MeDAB-containing diet for 10 days, there was a significant increase (relative to the control group) in the specific activity of the $Mn^{2+}/(NH_4)_2SO_4$-stimulated RNA polymerase activity, for greater amounts of enzyme activity were recovered from the nuclei of these 3'MeDAB-fed rats while the amount of protein extracted was similar to that in the respective control group (Tables 1 and 4). Differences in RNA polymerase activity in fraction IV protein preparations from rats fed the control and experimental diets were probably not due to an altered affinity of the enzymes for the substrate UTP. The K_m, determined by regression analysis [46], was virtually unchanged following any of the dietary regimens (Table 5).

Chromatography of fraction IV proteins on DEAE Sephadex A-25

When fraction IV protein from a control rat was applied to a column of DEAE Sephadex A-25, there was a large flow through peak of protein that eluted with the void volume. Two distinct peaks of RNA polymerase activity eluted at 0·14 M $(NH_4)_2SO_4$ and 0·26 M $(NH_4)_2SO_4$ respectively. Feeding the rats on the various diets had no significant effect on either the elution profile or the molarity of $(NH_4)_2SO_4$ at which the peaks of enzyme activity were eluted. The first and second

Table 5. Effect of pair-feeding a control diet and diets containing 2% CAP, 0·06% 3′MeDAB and 0·06% 3′MeDAB plus 2% CAP to rats for 4 days on kinetic parameters of RNA polymerase activity present in crude enzyme (fraction IV protein) preparations

Diet	Polymerase I			Polymerase II

Determinations were made using fraction IV protein preparations derived from 4 rats (mean wt ± S.D.; 165 ± 7 g); one rat in each dietary group. Incubations were performed as described by Jacob *et al.* [8]; Mg^{2+}-stimulated activity is designated as RNA polymerase I and $Mn^{2+}/(NH_4)_2SO_4$-stimulated activity as RNA polymerase II. Each assay tube contained 47·9 μg DNA and 3 μCi of ^{3}H-UTP and varying amounts of unlabelled UTP (0·05, 0·07, 0·09, 0·10, 0·11 and 0·13 μmole) were included in the incubation mixtures. At the conclusion of the incubations, the $HClO_4$ precipitates were processed according to the modification of the Blobel and Potter [23] procedure described in "Material and Methods". The data shown represent the means ± S.E. determined by regression analysis [46].

Table. 6. *Effect of α-amanitin on the incorporation of UTP into RNA by whole nuclei, fraction IV protein and purified RNA polymerases from normal rat liver*

Tissue fraction	Assay conditions	% Inhibition of UTP incorporation by α-amanitin
Nuclei	Mg^{2+}(pH 8·5), 6 min	22·8
	$Mn^{2+}/(NH_4)_2SO_4$(pH 7·5), 15 min	83·1
Fraction IV protein	Mg^{2+}(pH 8·0), 20 min	17·7
	$Mn^{2+}/(NH_4)_2SO_4$(pH 8·0), 20 min	86·4
DEAE Sephadex A-25 Peak I	Mg^{2+}/Mn^{2+}(pH 8·0), 20 min	8·0
DEAE Sephadex A-25 Peak II	Mg^{2+}/Mn^{2+}(pH 8·0), 20 min	96·5

α-Amanitin (0·08 μg in 50 μl deionized water) was added to the media just prior to initiation. The results shown are the mean of duplicate estimations. Nuclei were isolated by the method of Blobel and Potter [18] from the liver of a normal male Sprague–Dawley rat (156 g).

peaks of enzyme activity were equated with RNA polymerases I and II of Roeder and Rutter [6] (or A and B of Chambon *et al.* [47]) on the basis of their order of elution from DEAE Sephadex and relative sensitivities to the fungal toxin α-amanitin (Table 6). In agreement with others [48, 49], we found that RNA polymerase I activity was more labile than that of RNA polymerase II (Table 7). Accordingly, the total amounts of extractable RNA polymerase activity (Table 1) and the total amounts of fraction IV and enzyme-

Table 7. *Recovery of protein and RNA polymerase activity following DEAE Sephadex A-25 chromatography of fraction IV protein preparations from rats pair-fed a control diet and diets containing* 2% *CAP*, 0·06% *3′MeDAB and both* 0·06% *3′MeDAB plus* 2% *CAP for* 4 *or* 10 *days*

Control	96·3 ± 6·1 (5)	98·2 ± 4·0 (3)	81·2 ± 10·1 (5)	96·4 ± 4·2 (5)	70·8 ± 16·0 (3)	89·1 ± 5·8 (3)
CAP	102·2 ± 5·7 (3)	—	83·1 ± 13·8 (3)	92·6 ± 7·1 (3)	—	—
3′MeDAB	97·5 ± 10·2 (5)	95·7 ± 2·7 (3)	82·5 ± 15·7 (5)	94·2 ± 13·3 (5)	66·2 ± 9·6 (3)	86·0 ± 13·5 (3)
3′MeDAB plus CAP	101·3 ± 9·6 (3)	—	72·2 ± 16·3 (3)	98·7 ± 9·3 (3)	—	—

Each value shown represents the mean ± S.D. of estimations made following DEAE Sephadex chromatography of fraction IV proteins from the number of individual rats shown in parentheses. In each instance, no statistically significant differences were noted between the values obtained from rats fed the various experimental diets and the rats fed the control diet. Polymerase I and II activities refer to the pooled activities of the first and second enzyme peaks that eluted from the columns. The corresponding data for RNA polymerase activity and protein content of these preparations are given in Tables 1 and 4 respectively.

*The original amounts of protein were those contained in the various fraction IV protein samples that were subjected to chromatography. The original amounts of RNA polymerase activity refer to the amounts of Mg^{2+}-stimulated activity (in the instance of polymerase I) and $Mn^{2+}/(NH_4)_2SO_4$-stimulated activity (in the instance of polymerase II) in the same samples.

associated protein (Table 4) have been corrected for any losses that occurred before or during chromatography.

Determination of the specific activity of RNA polymerases purified by DEAE Sephadex chromatography is subject to two major sources of error. The first is that of contamination of the enzyme peaks with other proteins that lack polymerase activity [50]. This source of error can be at least partly overcome by further purification procedures, but the lability of RNA polymerase I activity makes such attempts impracticable. The second problem, which has been stressed by Jacob [42], is to find a very sensitive method of protein analysis that is not affected by components of the elution buffer. The procedure described by Murphy and Kies [36] fulfilled these requirements and was routinely used for the protein analysis of the column effluents in the present study.

Both polymerases I and II, when partially purified by chromatography, exhibited a significantly increased specific activity in rats that were fed CAP or 3'MeDAB plus CAP for 4 days (Fig. 5). In particular, the specific

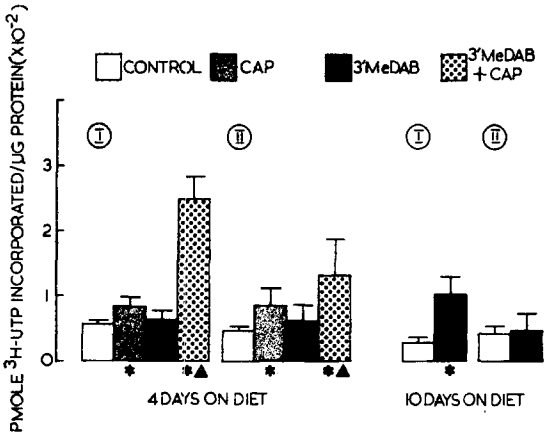

Fig. 5. Comparison of specific activity of RNA synthesis by soluble RNA polymerases I and II isolated from the livers of rats that were pair-fed one of the various diets for either 4 or 10 days. Samples of fraction IV *protein were chromatographed on DEAE Sephadex A-25 as described in 'Material and Methods' and fractions collected and assayed for RNA polymerase activity against a standard rat liver DNA template* (14·6 µg). *The values obtained for the respective peak fractions containing the enzyme activities were pooled. The symbols* I *and* II *refer to polymerases* I *and* II *respectively, the enzymes being distinguished by their order of elution and relative sensitivity to the toxin α-amanitin. Each bar represents the mean ± S.D. of data derived from* 3–5 *rats; a total of* 22 *rats (mean wt ± S.D.;* 147 ± 9 *g) were used. The asterisks indicate values that are significantly different from those of the control group* ($P < 0·05$). *The black triangles indicate a significant difference between the group fed the 3'MeDAB-containing diet and that fed both 3'MeDAB plus CAP* ($P < 0·05$). *The values for the total RNA polymerase activity of these preparations are given in Table* 1.

activity of these enzymes was much greater in rats fed the diet containing both 3'MeDAB and CAP (which protects against 3'MeDAB hepatocarcinogenesis) than in rats fed only 3'MeDAB. This effect was most pronounced in the case of RNA polymerase I activity. The specific activities of RNA polymerases I and II were not significantly different from the control values after 4 days of feeding only 3'MeDAB, but there was a significant increase in the case of RNA polymerase I if the diet was fed for 10 days. Changes in the specific activities of the RNA polymerases were mostly due to alterations in enzyme activities (Table 1) as opposed to alterations in the amounts of protein that chromatographed with each enzyme peak (Table 4). The proteins from the pooled peak fractions of polymerase activity were subjected to electrophoresis in polyacrylamide gels under non-denaturating conditions. Polymerases I and II both comprised two prominent bands of protein, a finding which is in agreement with earlier reports of their heterogeneity [50, 51]. The experimental diets did not significantly influence either the mobility or the staining intensity of the bands (results not shown).

The nature of the protein eluted in the flow-through peak was investigated. This peak comprised 69–83% of histone as determined by the method of Mirsky and Pollister [12] and these values are probably underestimated because of the limits of sensitivity of the reaction. A comparison of the histone contents of fraction IV protein samples from control and 3'MeDAB-fed rats revealed that they were almost identical (47% and 50% respectively).

DISCUSSION

The present study was undertaken with the aim of investigating the increase in nuclear RNA synthesis that takes place in the livers of rats that are protected against the hepatocarcinogenic azo dye 3'MeDAB by the antibiotic CAP. Nuclei from the livers of the protected rats showed early marked increases in both Mg^{2+}- and $Mn^{2+}/(NH_4)_2SO_4$-stimulated RNA synthetic activities (especially the former) when compared with those from rats fed the carcinogen alone for a similar period, in which the level of activity was little different from that of the controls [4]. The results presented in this report confirm those findings and suggest that the increases in nuclear RNA synthesis are at least in part the result of increases in soluble RNA polymerase activity, the most pronounced increase taking place in the activity of RNA polymerase I. Furthermore,

kinetic studies indicate that the increases in both RNA polymerase I and II activities are probably not due to an altered affinity for the substrate UTP. Caution is however necessary for the unequivocal interpretation of experiments where relatively crude polymerase preparations, such as those used in this study, are incubated with DNA. Several nuclease activities are present in similar preparations and have led to misinterpretation of the significance of altered levels of precursor incorporation into RNA catalyzed by those preparations [52]. Nicking enzymes, by creating artificial promoter sites in the DNA, increase incorporation [53], while other nucleases may degrade the reaction product [4] and/or inactivate the template [53].

Inhibition of azo dye-induced hepatocarcinogenesis has been shown to be accompanied, in the instances of the inhibitors CAP [4] and nitrofuran [54, 55], by an increase in Mg^{2+}-stimulated nuclear RNA synthesis. With the proviso mentioned above regarding possible nuclease contamination of the polymerase preparations, the findings of the present study suggest that with CAP, this increase is at least partly a consequence of increased polymerase I activity.

A rapid increase in the activity of hepatic RNA polymerase I has likewise been shown to follow partial hepatectomy [56–58] and the administration of certain hormones [59–62] and there is evidence suggesting that some of these alterations are due to allosteric changes rather than increased enzyme synthesis [59]. RNA polymerase molecules appear to have extended half-life periods and represent a fairly stable population [63], which is further evidence in support of the concept of modulation of RNA polymerase activity by allosteric change.

There are several reports in the literature concerning the effects of chemical carcinogens on soluble RNA polymerase activities in target organs. Thus the hepatocarcinogens aflatoxin B_1 [24], ethionine [64] and N-hydroxy AAF [65, 66] have all been shown to decrease the activity of either one or both of the soluble polymerases extractable from rat liver nuclei and the reports indicate that there is a tendency for polymerase II activity to be selectively decreased. Akinrimisi *et al.* [67] were able to show that the effects of aflatoxin administration *in vivo* on RNA polymerase II were mimicked by a metabolite of aflatoxin that was generated by an *in vitro* microsomal system. In contrast, Wu and Smuckler [68], who used the method of Cunningham *et al.* [69] to isolate the soluble nuclear polymerase, reported that the azo dyes, when given p.o., did not significantly affect RNA polymerase activity. Nevertheless, the synthetic ester N-benzoyloxy MAB, which is chemically related to postulated azo dye metabolites [70], was shown by them to inhibit the enzyme. The enzyme isolated by Cunningham *et al.* [69] was probably RNA polymerase II because of its stability and its salt optima. In all of these reports of the effects of carcinogens on polymerase activity, the carcinogens were administered in large single or repeated doses. Such experimental conditions are quite different from those routinely employed in tumour induction experiments and in the present study, where the carcinogen was incorporated in the diet at a low dosage level and fed continuously for weeks or months.

Continuous administration of a diet containing 0·06% 3′MeDAB was shown by us to have no significant effect on either RNA polymerase I or II activity if it was fed for only 4 days, a similar result to that obtained by Wu and Smuckler [68] when they administered azo dyes p.o. in acute doses. If a diet containing CAP was fed for 4 days, increases in the activity of soluble RNA polymerases I and II were observed, but these were significantly less than those in the rats fed both 3′MeDAB and CAP. The contribution made by CAP to the increase in polymerase activity therefore could not fully account for the increases noted in the protected rats after only 4 days on the diet. These findings led us to suspect that although RNA polymerase activity was not actually decreased by 3′MeDAB in our experiments, the increase in enzyme activity that might be expected to take place in response to cellular injury could be delayed in the livers of rats fed this carcinogen. If this is so, there should be an increase in RNA polymerase activity in the livers of rats fed 3′MeDAB for periods of longer than 4 days. In agreement with our hypothesis, when the diet containing the dye was fed for 10 days, an increase in both polymerase I and II activity was noted; this increase was less marked than that seen in the protected rats after only 4 days on the diet.

Total liver DNA increases to a similar extent in 3′MeDAB-fed rats and in rats protected from hepatocarcinogenesis by concurrent CAP administration [3], the decreased RNA/DNA ratio in rats fed 3′MeDAB [1, 3] being the result of a lag in production of liver RNA. The protected rats, in contrast, show no such lag, the liver RNA and DNA contents increasing in synchrony and the liver RNA/DNA ratio remaining at control levels [1, 3]. Previous

work indicates that alterations in RNA polymerase I activity are closely associated with alterations in ribosomal RNA synthesis [71]. The increase in RNA polymerase I activity in the livers of the protected rats is therefore probably largely responsible for the increase in liver RNA content and for restoring the RNA/DNA ratio to normality in these rats.

The enhanced activity of RNA polymerase I in the protected rats may ensure that ribosomes are available for the synthesis of the new protein that would be required following cellular damage. The situation would be somewhat analagous to the increase in polymerase I activity in liver that occurs prior to the mitotic response that follows partial hepatectomy [56–58]. The concomitant increase in the protected rats in the activity of RNA polymerase II, which is localized in the nucleoplasm and implicated in the synthesis of messenger-like RNA [6], might ensure that new m-RNAs are produced to direct the synthesis of these new proteins. The increases in RNA polymerase I and II activities in the protected rats could therefore be ultimately related to the normal mitotic response in these animals, for they might ensure, for example, that the spindle proteins would be coded for and produced at the appropriate time.

Some provisos, however, must be made regarding the interpretation of our findings. The first concerns the extrapolation of results obtained using extracts of nuclei to the intact liver. The extent to which the isolated nuclei represent the total nuclear population in the liver was discussed in our earlier report on the effects of 3'MeDAB and CAP on rat liver nuclear RNA synthesis [4]. A second problem is that only a few of the cells present in a tissue are at risk of transformation to tumour cells [72]. Furthermore, possible toxic effects of 3'MeDAB and CAP must be discriminated from pre-carcinogenic effects and effects necessary for the inhibition of carcinogenesis.

An increase in the amount of protein in the crude enzyme extract (fraction IV protein) obtained from liver nuclei after only 4 days of feeding the carcinogen was prevented by concurrent administration of CAP in the diet. As there were only minor effects of these diets on the total amount of nuclear protein and on the relative amounts of the major subclasses, the increase in extractable protein could be related to an early structural change within the nucleus induced by the carcinogen and prevented by CAP. There is evidence of nucleolar segregation and occasional nucleoli with condensations of the fibrillar component following 3'MeDAB administration [73] and these changes have been reported to be reversed by another inhibitor of carcinogenesis [74]. In addition, an increase in the nuclear sap proteins was noted in rats fed 3'MeDAB for 4 days. This increase, as well as the increased protein content of the crude enzyme extract, could be a consequence of 3'MeDAB-induced nuclear membrane alterations. Administration of the related hepatocarcinogen N-hydroxy AAF to rats is known to produce alterations in the nuclear membrane [75].

We did not find any direct evidence in these experiments for the presence of RNA polymerase III and there are several possible explanations of this observation. First, there are reports that polymerase III (or C) is located predominantly in the cytoplasm [76, 77] and our soluble RNA polymerase preparations were extracts of isolated liver nuclei. Furthermore, there is evidence that RNA polymerases I and III may be selectively lost during isolation of a crude nuclear pellet in isotonic buffer solutions [21]. In addition, RNA polymerase III is not adequately separated from RNA polymerase II by chromatography on DEAE Sephadex [76, 78] and has an intermediate sensitivity to α-amanitin [76–78]. Trace amounts of RNA polymerase III could therefore have cochromatographed with RNA polymerase II in the present study. Evidence that supports this notion is our finding that the second major peak of enzyme activity that elutes from the DEAE Sephadex column (which we have called RNA polymerase II) was not completely inhibited by α-amanitin.

Why is there little alteration in liver RNA polymerase activity (especially in RNA polymerase I activity) in the early stages of feeding the carcinogenic azo dye 3'MeDAB? When an increase finally takes place, it is concomitant with, rather than preceding the significant increase in liver DNA [3]. This sequence of events is at variance with that in the liver following partial hepatectomy [79] and suggests to us that some regulatory mechanism of RNA polymerase activity may be defective in the livers of rats fed the azo dye. RNA polymerases belong to the class of acid nuclear proteins [80], which have been strongly implicated in the regulation of gene activity [81]. It is therefore of some interest that the carcinogenic azo dyes DAB and 3'MeDAB have been shown to interact to a greater extent with acidic nuclear proteins than with histones [82, 83]. Whether 3'MeDAB or its metabolites interact

with the polymerases or with other protein regulatory factors and what such reactions, if demonstrated, would imply in terms of the regulation of cellular activities will require much further investigation.

Acknowledgements—We wish to thank Parke, Davis and Co. for a gift of chloramphenicol powder and Dr. Cyril Curtain of the C.S.I.R.O. Division of Animal Health, Parkville, for determining the sedimentation coefficient of a sample of our rat liver DNA.

Correlation Between Urinary Steroids and Estrogen Receptor Content in Women with Early Breast Cancer*

Y. J. ABUL HAJJ
College of Pharmacy, University of Minnesota, Minneapolis, MN 55455, *U.S.A.*

Abstract—*The urinary levels of* 11-*deoxy*-17-*ketosteroids and estrogen receptor content in tumor tissues were determined in* 76 *patients with early breast cancer. Twenty-six postmenopausal and* 16 *premenopausal patients with estrogen receptor negative tumors were found to excrete subnormal amounts of* 11-*deoxy*-17-*ketosteroids while* 22 *postmenopausal and* 12 *premenopausal patients with estrogen receptor containing tumors excrete near normal levels of urinary* 11-*deoxy*-17-*ketosteroids.*

INTRODUCTION

ENDOCRINE responsive tumors in women with metastatic breast cancer constitute only 20–40% of patients treated by surgical ablation or by pharmacologic hormone therapy. A number of clinical, pathologic, and biochemical criteria have been used in an attempt to predict the clinical course of patients with breast cancer after therapy [1].

Various studies have indicated a possible association between abnormal levels of androgen and corticosteroid metabolites in urine and plasma and the occurrence of breast cancer. The most convincing endocrine abnormality in patients with breast cancer has been found to be a subnormal excretion of 11-deoxy-17-ketosteroids (11-DOKS) [2–5] which can predict with considerable accuracy, either alone or in combination with urinary excretion of corticosteroids, the response to endocrine ablation therapy in patients with breast cancer. While these results have been supported by several investigators [4–7] others have disagreed with these findings [8–10]. The balance of evidence indicates that some steroid metabolites are present in abnormal concentrations in the urine and plasma of women, with breast cancer.

Accepted 7 December 1976.

†This work was supported in part by a grant from the Graduate School, University of Minnesota. Part of this work was conducted at the American University of Beirut, Lebanon while on sabbatical leave from the University of Minnesota.

Estrogen receptors (ER) have been demonstrated in approximately 70% of human breast cancer [11, 12]. The absence of ER almost always indicates that the tumor will be resistant to endocrine therapy while their presence is associated with a remission of advanced breast cancer in about 55% of cases [13].

In view of the fact that both an abnormality in urinary excretion of steroid metabolites and ER content in mammary tumors have been shown to be predictors of hormone responsiveness, the present study was undertaken to determine whether there is any correlation between the ER content in human breast cancer and the urinary excretion of 11-deoxy-17-ketosteroids.

MATERIAL AND METHODS

Control and cancer patients

The subjects were patients admitted to the American University of Beirut Hospital and came from various countries of the Middle East. Eighty-eight per cent of the patients were Lebanese. The rest came from Syria and Jordan. A total of 76 patients with primary breast cancer were included in this study (28 premenopausal, mean age 44·6 ± 4·4 years; and 46 postmenopausal, mean age 64·7 ± 6·3 years). The controls were 27 healthy premenopausal (mean age 43·3 ± 4·7 years) and 36 postmenopausal (mean age 62·4 ± 4·6 years) women, none of whom were taking any form of steroid preparations. The urine from control subjects was collected at home from normal

healthy women, but in 9 instances, the urine was obtained from patients in a geriatric ward.

Urine collection and analysis

Urine was collected from all patients 48 hr before operation. Urine analysis was done on 24-hr specimens stored at −20°C without preservative. The techniques used for the determination of 11-deoxy-17-ketosteroids (etiocholanolone + androsterone + dehydroepiandrosterone) were based on that described by Thomas *et al.* [14].

Estrogen receptor determination

Estrogen receptor content of the tumor samples was carried out using the dextran-charcoal coated technique as determined previously [15].

Expression and evaluation of results

The levels of urinary 11-deoxy-17-ketosteroids were calculated and expressed as means ± S.D. in mg/24 hr urine. Results were evaluated statistically by use of the *t*-test. Differences between means were considered statistically significant at $P < 0{\cdot}05$.

RESULTS

The urinary excretion of 11-DOKS has been estimated in normal women and patients with primary breast cancer. The mean excretion of 11-DOKS (Fig. 1) in the normal postmenopausal group was found to be 1·66 ± 0·88 mg/24 hr, 1·44 ± 0·54 mg/24 hr in the postmenopausal ER positive group and 0·75 ± 0·28 mg/24 hr in the postmenopausal ER negative group. There was no significant difference between the control group and the ER positive groups, $P < 0{\cdot}30$, while the difference between the control group and the ER negative group was found to be very significant, $P < 0{\cdot}001$.

Figure 2 shows the distribution and the means of urinary 11-DOKS in normal premenopausal women and patients with ER positive and ER negative primary breast cancer. The mean excretion was found to be 4·18 ± 0·47, 3·91 ± 0·42, and 3·66 ± 0·55 mg/24 hr, for the normal group, the ER positive group and the ER negative group, respectively. The results show that there was no significant difference between the control group and the ER positive group ($P < 0{\cdot}20$), but that there was a significant difference between the control group and the ER negative group ($P < 0{\cdot}005$).

The results show also that there is a significant difference between the mean levels of 11-DOKS in the pre- and postmenopausal control and cancer patients, there being a substantial reduction in 11-DOKS excretion after the menopause.

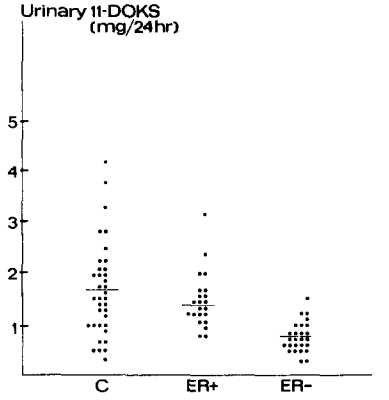

Fig. 1. Urinary 11-deoxy-17-ketosteroids (11-DOKS) by postmenopausal women in control subjects (C) and breast cancer patients with estrogen receptor positive (ER+) and estrogen receptor negative (ER−) tumors. The horizontal bars show the means.

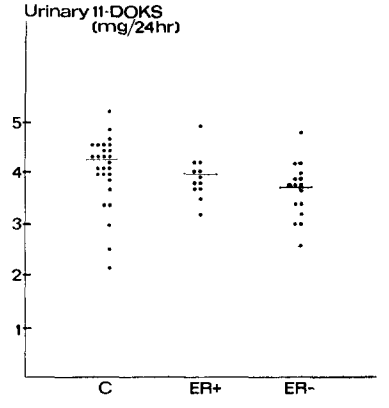

Fig. 2. Urinary 11-deoxy-17-ketosteroids (11-DOKS) by premenopausal women in control subjects (C) and breast cancer patients with estrogen receptor positive (ER+) and estrogen receptor negative (ER−) tumors. The horizontal bars show the means.

DISCUSSION

Abnormalities in urinary excretion of steroid metabolites have been observed by Bulbrook and his colleagues in women with both primary [3] and advanced [4] cancer of the breast and have been related to the prognosis and outcome of endocrine surgery. These observations were supported by several groups of investigators [6, 7] while others have presented evidence [8–10] in variance with that presented by

Bulbrook and his coworkers. However, it is generally accepted that significantly low levels of androgen metabolites are associated with poor prognosis in patients with advanced breast cancer.

The initial results of Jensen [16] on the use of ER content in breast tumor tissues for predicting response to endocrine therapy has been confirmed by other investigators [13]. The presence of ER in tumors of patients with advanced breast cancer increases the likelihood of response to endocrine therapy from about 25 to 55–60%. A favorable prediction based on ER alone will, therefore, prove incorrect in approximately 40% of cases. But, in ER negative tumors the chances of regression in response to endocrine therapy are minimal, and so selection based on the ER assay alone will still save many patients from profitless major endocrine surgery.

If in fact the low levels of urinary 11-DOKS excretion and the absence of ER are both predictors of hormone unresponsiveness, then they should correlate well in the same group of patients. On the other hand, cases in which hormone dependence has not been lost, one might expect to have a near normal level of urinary 11-DOKS as well as the presence of ER in the same group of patients. The results obtained from this study show that there is good correlation between the absence of ER and low levels of 11-DOKS in both pre- and postmenopausal patients, though the significance levels are different. Also, there was a good correlation between the presence of ER and the near normal values for 11-DOKS in both the pre- and postmenopausal group. There was no significant difference between the means for 11-DOKS in patients with ER positive tumors and the control groups, yet one observes a slight decrease in the means for 11-DOKS in both the pre- and postmenopausal group with mean differences of 0·27 and 0·22 mg/24 hr, respectively. This slight decrease in the mean level of urinary 11-DOKS in patients with ER positive tumors might be due to the contribution of the lower urinary 11-DOKS in those patients that do not respond to endocrine therapy, even though ER are present in the tumors of these patients.

Whilst it is now well established that absence of ER in a breast tumor almost invariably indicates that the tumor will be resistant to endocrine therapy [13], the situation regarding the urinary levels of androgen metabolites remains equivocal. However, the fact that a good correlation was obtained between the absence of ER, and the low levels of 11-deoxy-17-ketosteroids, suggests that patients unresponsive to endocrine therapy excrete subnormal amounts of 11-deoxy-17-ketosteroids. Furthermore, our results show that responsive patients, as determined by the presence of ER, excrete near normal values of 11-deoxy-17-ketosteroids even though about 40% of patients with ER positive tumors are endocrine resistant. The findings obtained from this study may imply that only those tumors growing in a normal environment respond to the alterations in the environment brought about by the treatment and it remains to be seen whether patients with ER positive tumors that do not respond to endocrine therapy have in fact a significantly lower level of urinary 11-deoxy-17-ketosteroids than patients with ER positive tumors that do respond to endocrine therapy.

Radiofrequency Heating of Tumours in Rodents*

J. A. DICKSON, S. K. CALDERWOOD and M. L. JASIEWICZ

Cancer Research Unit, University Department of Clinical Biochemistry, Royal Victoria Infirmary, Newcastle upon Tyne, Great Britain

Abstract—*This paper describes the results of treating* 170 *tumours in rodents at temperatures up to* 50°C *by radiofrequency (RF) heating. The apparatus used operates at a crystal-controlled frequency of* 13·56 *MHz* (22 *m wavelength*) *and the tumour is included in the output circuit by capacitive coupling between the electrodes. The paddle electrodes are applied directly to opposite sides of the tumour mass. The circuitry of the equipment incorporates special stabilising features which enable homogeneous tumour heating to be achieved easily and controllably.*

Two syngeneic tumours in the rat (D23 carcinoma amd MC7 sarcoma), and an allogeneic rat tumour (Yoshida sarcoma) growing subcutaneously in the foot or flank were heated at 45°C *intratumour temperature for* 15 *min. Ehrlich ascites tumours in mice were heated at* 42°C/1 *hr*, 43°C/30 *min or* 44°C/15 *min.*

Skin temperature over the rat tumours remained at 4–5°C *below that in the tumours. With the MC7 and Yoshida tumours treated at a volume of* 1–1·5 *ml, a* 100% *regression rate was obtained. With large* (6–12 *ml*) *Yoshida tumours in the leg muscles heated at* 45°C *for* 30 *min or* 50°C *for* 15 *min, all rats died soon after treatment. The D23 carcinoma* (0·7–1·5 *ml*) *was not cured by hyperthermia up to* 45°C *for* 15 *min. All tumour-bearing mice, and also a series of normal mice, died during or immediately after heating.*

When the normal leg of the rat was heated in the same RF field as the intramuscular Yoshida tumour, the tumour maintained a temperature 2–3°C *below that in the muscle. The electrical resistance of the heated tissue was not altered by the presence of the tumour. The results suggest that in the case of this tumour blood flow is greater than in adjacent normal tissue. This therefore places an upper limit on the temperature/time regimen that can be used to destroy the tumour.*

INTRODUCTION

THERE is growing interest in the use of hyperthermia (42°C and above) for the treatment of cancer. The approach exploits a fundamental difference in the thermal sensitivity of normal and malignant cells. There is evidence for this, both *in vitro*, where the metabolism of several types of cancer cell is irreversibly inhibited at 42°C [1–3], and *in vivo* where the selective heat destruction of a wide spectrum of tumours in animals [2, 4–8] and in man [1, 9–10] has been demonstrated.

There is also evidence of a potentiating effect of hyperthermia in the destruction of malignant cells by radiotherapy [11–13], chemotherapy [14–16] and cell specific antiserum [17].

Accepted 17 January 1977.

*This work was supported by the North of England Council of the Cancer Research Campaign.

The destruction of tumour cells by hyperthermia is a complex process not yet fully understood. Response to heat in animals is governed by tumour volume, temperature and the duration of heating [18]. Cytokinetic studies *in vitro* and *in vivo* have shown a slow death of heated cell populations, involving competing processes of cell loss and repopulation [19, 20]. At the biochemical level, hyperthermic cell killing appears to be at least a two-stage process requiring the conversion of sublethal to lethal damage [14, 19]. Host factors also appear to be involved, as indicated by the regression of metastases in animals [2, 8] and in man [1] following curative local hyperthermia, increased tumour dissemination after inadequate tumour heating [18, 21] and apparent immunosuppression caused by total body hyperthermia in mice [22] and in rabbits [23].

Using presently available heating techniques for the treatment of cancer in humans, thera-

pists have been largely restricted to a temperature range of 41–43°C by considerations of host tolerance [1, 9, 24]. The general findings of this work have been initial regression of tumours followed by recurrence. In addition, human tumours *in vitro* have been shown to be less sensitive than animal tumours to 42°C [3]. The use of temperatures above 42°C offers a possible solution to this problem, although such temperatures involve the loss of the differential sensitivity between normal and malignant tissue, and the effectiveness of any such technique will depend on the degree to which adjacent normal tissues can be protected from heat damage. This report describes the destruction of rodent tumours by single short exposure to a low power radiofrequency field. The specially-designed radiofrequency machine enabled intra-tumour temperatures of up to 50°C to be achieved rapidly and controllably without damage to surrounding tissue.

MATERIAL AND METHODS

Tumours

Three chemically induced transplantable tumours of the rat were studied. The Yoshida tumour had a multifocal origin in the genital omentum, pelvic peritoneum and liver, following administration of O-aminoazotoluol to an albino rat and painting of the skin with potassium arsenite. It is classed as an undifferentiated tumour [25]. The tumour was maintained by periodic transfer of 0·1 ml (100 mg) tumour homogenate by trocar into the hind leg muscles of outbred Wistar rats. The D23 tumour is a syngeneic hepatocellular carcinoma that was produced by feeding young male rats a low protein diet containing 4-dimethylaminoazobenzene [26]. Sarcoma MC7 was the result of s.c. injection of 3 methylcholanthrene in trioctanoin into inbred female Wistar rats [27]. The D23 and MC7 tumours were passaged by serial transfer of 0·1 ml (100 mg) tumour homogenate s.c. into the flank of inbred Wistar rats.

For the present work, the Yoshida and MC7 tumours (100 mg) were transplanted into the dorsum of one hind foot of the rats. The Yoshida tumour was also treated at the implantation site in the leg muscles, and the D23 and MC7 tumours after s.c. transplantation into the flank, the initial inoculum in each case being 100 mg. At the time of implantation all rats weighed 200–250 g. From these various sites the untreated tumours metastasized to kill the host within 60 days.

The Ehrlich ascites tumour was maintained by serial passage of 10^7 cells in Tuck outbred (TO) adult white mice. Following this i.p. inoculation, the mice died in 10–14 days.

Tumour volumes were calculated from caliper measurements made in the antero-posterior, lateral and vertical planes. Allowance was made for the host's normal tissues on the basis of measurements made on each animal before inoculation of tumour.

Tumour heating

The apparatus for heating tumours by radiofrequency (RF) currents is shown in Figs. 1 and 2, and is available from Critical Systems Inc., Palo Alto, California. It consists of tuned oscillator and resonator circuits with refinements developed as a result of experiments using phantoms of isotonic NaCl gel as heating models. The generator has an output of 320 W at a crystal-controlled frequency of 13·56 MHz

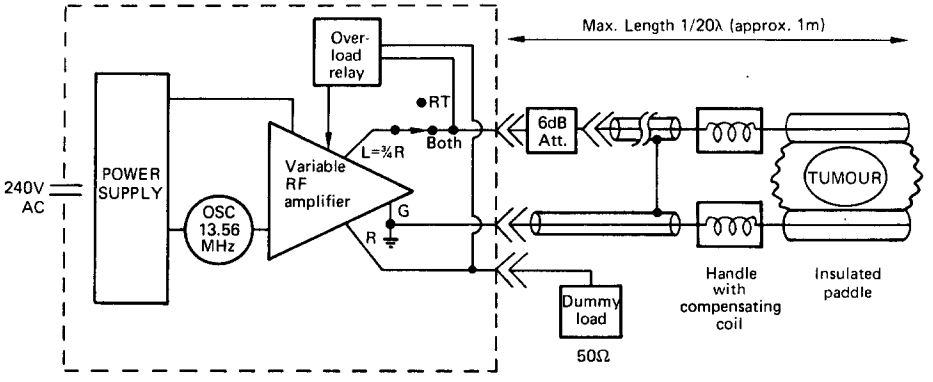

Fig. 1. Block diagram of RF heating system electronics. The broken square indicates the basic oscillator and output circuits which are contained in the portable RF machine (A) shown in Fig. 2. The tumour constitutes part of the dielectric of the capacitor formed by the heating paddles, and is coupled to the machine via two coaxial cables. The option switch shows both outputs of the machine driven, the L channel heating the tumour via the 6dB attenuator, and the R channel being directed into a 50Ω dummy load.

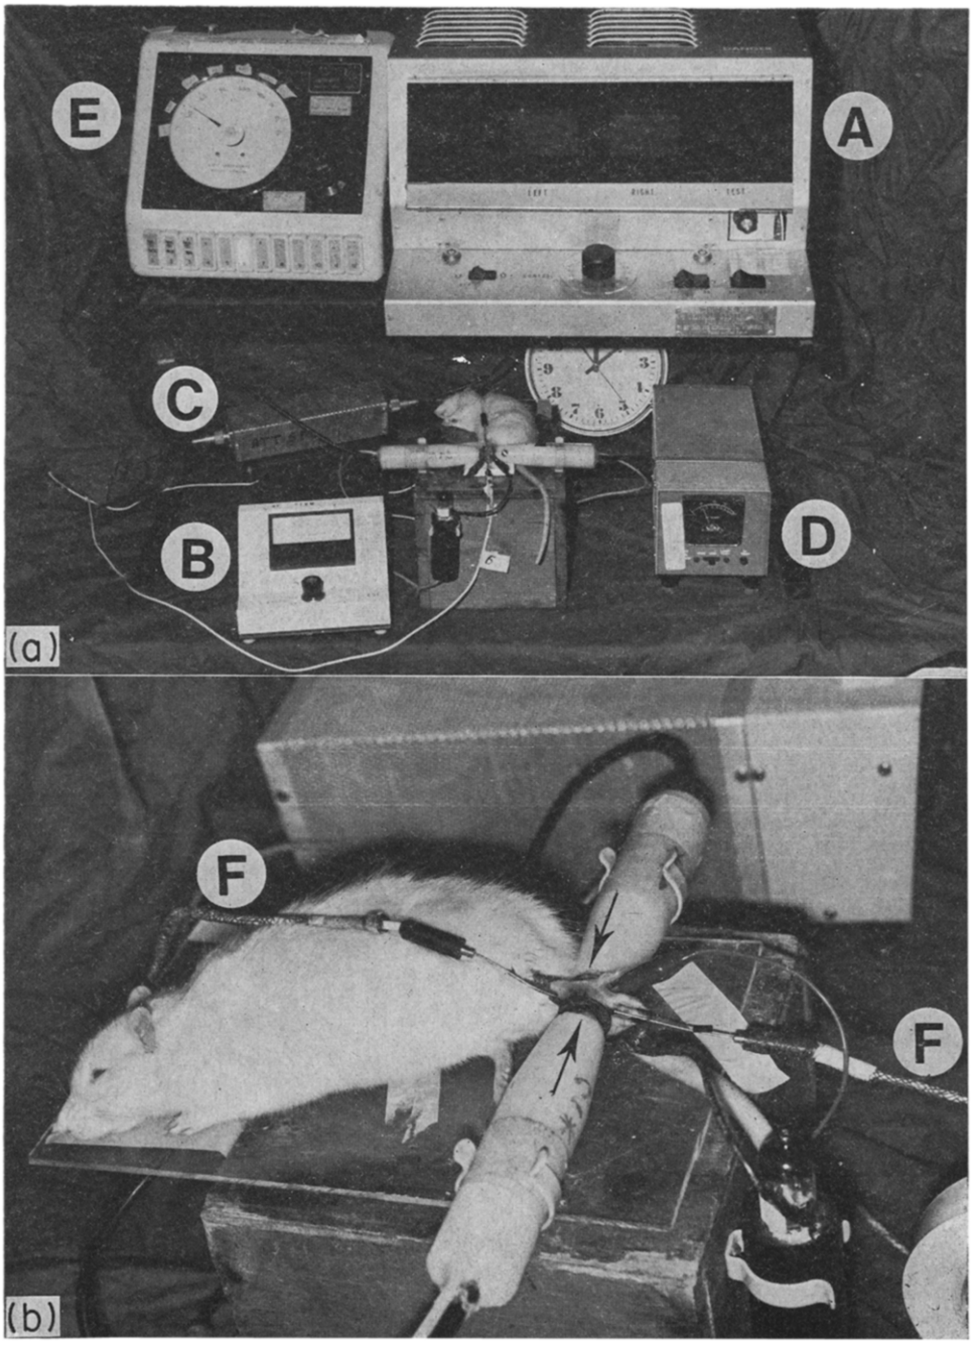

Fig. 2. Experimental arrangement for RF heating of rat foot tumour (a), and close-up of electrode configuration (b).

The high frequency current generated by the RF machine (A), and measured as amperes, is applied to the tumour via two heating paddles (arrows) with insulating handles. Potential drop across the tumour is measured by a valve voltmeter (B) attached to the electrodes. Low currents are obtained by inserting a resistance (attenuator, C) between the RF machine and the live paddle. The machine output channel not in use is fed into the 50 Ω dummy load (D).

Temperatures in the tumour and host are continuously monitored by direct readout on the 12 channel electric thermometer (E), coupled to multiple sensors (F) inserted at right angles to the RF field.

The RF current is transmitted from the amplifier to the tumour via an impedance matching circuit and two coaxial cables that terminate in flat paddle electrodes. When these electrodes are placed on diametrically opposite sides of the tumour mass, a condenser or electrostatic field is achieved, and the tissue becomes part of the dielectric of a capacitor. The paddles may be of various shapes and sizes depending on the dimensions of the tumour being heated, and are coated with a thin film of low-loss dielectric. This minimizes heating of the paddles, and in addition provides a high capacitive reactance minimizing the possibility of electric shock from low frequency switching transients. Tuned compensating inductance coils are contained in the insulating paddle handles to neutralize the capacitive reactance between the electrodes and the tissue, and thus maximize the heating component of the current in the tissue. An additional improvement in coupling the tissue to the electrodes was achieved by connecting the outer sheaths of the coaxial paddle cables through a "jumper" lead. This provides for optimum current flow between the heating paddles, and ensures that the ends of the cable sheaths are grounded with respect to RF voltage. The length of the coaxial cables from the generator to the electrodes was kept well below 1/10 of a wavelength (22 m), taking into account the velocity of propagation in coaxial cable (typically 60–70% of that in free space). This avoids the necessity of adding adjustable tuning controls to the equipment, and provides for accurate RF current measurements using panel meters.

The generator has a 2 channel output. When the L channel is used, the R channel is fed into a 50 Ω dummy load. Low currents are obtained by incorporating a 6dB attenuator into the L channel output. RF power is measured in amperes, and the potential drop across the tissue (V) by a high impedance vacuum tube voltmeter across the paddles. To provide high stability of the power control and to ensure a constant current for variations in spacing between electrodes, a d.c. inverse feedback loop was developed to inter-connect the output RF and the master crystal oscillator. An overload relay automatically shuts off the generator output at an RF current of 2·2 A, providing a necessary safety factor.

Temperature measurement

Temperatures were monitored by thermistor probes and a 12 channel direct reading electric thermometer (Model 3GID, Light Laboratories, Brighton, England) with a scale range of 36–56°C and an accuracy of ± 0·1°C. For intra-tumour, intra-abdominal or subcutaneous temperature measurement, the probes used were 3 or 5 cm long needle type IH 0·8 mm in dia, recording temperature change only at the needle tip; polythene-covered type IMR sensors were used for rectal recordings. The probes were individually earthed to the light meter and the cables were shielded to minimize interference from the RF field. The thermometers were standardized against a mercury-in-glass thermometer of the British Standards Institution, and the probes and meters were checked for "drift" before each days experiments.

At the low power outputs (< 6 W) used in the present work, the thermistor probes were unaffected by the RF field. That the sensors gave a valid measure of tumour temperature was confirmed by inserting thermistors into tumours immediately after the RF field was switched off. Tissue temperatures within the field were also checked by means of needle-type copper–constantan thermocouples.

Heating procedure

Anaesthesia was induced in the rats and mice with i.p. Sagatal, 0·1 ml of a 1:5 dilution per 50 g body weight (Sagatal Veterinary, 60 mg pentobarbitone sodium per ml: May and Baker) and maintained by additional small doses of the barbiturate as required.

All experiments were performed in a temperature-controlled room (25°C) and, where necessary, an i.r. lamp was used to minimize the initial fall in body temperature of the anaesthetized animals while they were prepared and the equipment positioned.

The animals were shaved with electric clippers or razor and final traces of hair were removed by a 5-min application of hair remover cream. The probes were then inserted. The tumour needles were placed in the proximal and distal poles, or centre of the mass, and the intra-abdominal sensor was introduced under the liver in a right paramedian position. Skin temperature was measured by a needle introduced s.c. between the tumour and heating paddle. All probes were positioned at right-angles to the RF field ensuring that there was no contact between paddle and needle. One surface of each paddle was coated lightly with conducting electrode jelly (Cam Creme, Kent Cambridge Medical Ltd.) and the two paddles applied to diametrically opposite sides of the tumour. The tumour was heated as part of a cylinder of tissue, the cylinder ends being the paddles, the paddle size selected and the cylin-

der volume heated being governed by the tumour size. Limb tumours and flank tumours were treated with the animal lying on its side (paddles applied to the medial and lateral aspects of the tumour); for the foot tumours, heat was applied by paddles held against the dorsum of the foot and the footpad. Flank tumours were also heated by "coning". A small heating paddle covered the tumour and formed the apex of the RF cone, while a larger ground paddle was applied to the opposite side of the animal abdomen constituting the base of the RF cone. Ascitic tumours in mice were treated by the cylinder technique, circular paddles being applied to opposite sides of the abdomen with the mouse lying on its back.

RESULTS

Figure 3 illustrates the temperature profiles and required RF power when Yoshida foot tumours of 1·0–1·5 ml vol were heated at 45°C

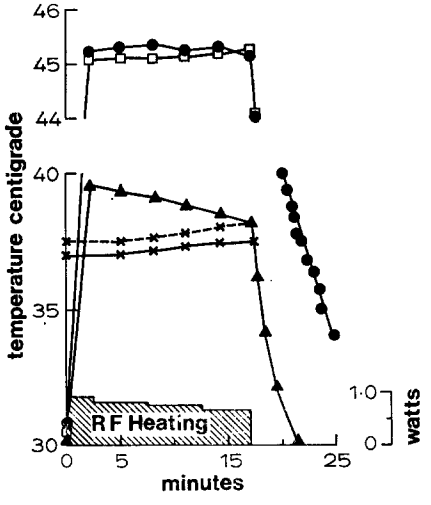

Fig. 3. Simultaneously recorded intra-tumour (● proximal pole of mass, □ distal pole), skin over tumour (▲), intra-abdominal (× – – – ×), and rectal (×——×) temperatures for a rat with a Yoshida tumour implanted on the dorsum of the left hind foot. The 1·2 ml tumour was treated by RF heating (intra-tumour temperature 45°C) for 15 min. Heating paddles were 1·5 cm in dia with a separation distance of 1·2 cm.

for 15 min. With an applied power of less than one Watt, the intra-tumour temperature increased rapidly to 45°C within 2–3 min. Homogeneous heating was maintained easily and controllably with a very low applied current (0·15–0·25 A). Skin temperature over the tumour did not exceed 40°C, and abdominal and rectal temperatures did not increase significantly. A cure rate of 100% has been obtained with 34 foot tumours 0·8–1·5 ml in volume treated at 45°C for 15 min. Eighteen Yoshida foot tumours of similar volume heated at 42°C for 1 hr were also cured. Tumour regression took place within 14 (45°C treated) or 22 (42°C treated) days. Four rats with bilateral 1·0–1·5 ml tumours were given RF treatment to one foot only (45°C for 15 min.) Both tumours regressed within 6 weeks in these animals.

MC7 sarcomas (1·0–1·5 ml vol) situated on the dorsum of the foot or on the flank were treated by RF cylinder heating using paddles applied above and below the foot, or paddles applied to each side of the tumour. A regression rate of 100% was achieved in both situations (12 foot, 16 flank tumours) following a 15 min heating session at 45°C intra-tumour temperature. Flank tumours of this volume were also cured by "coning" using a 2·5 cm dia paddle over the tumour and a 4·5 cm dia paddle applied to the opposite side of the abdomen. With this geometric cone, the animals intra-abdominal temperature remained below 40°C. When the 4·5 cm abdominal paddle was replaced by a 2·5 cm dia paddle, and the subcutaneous tumour heated at 45°C as part of an abdominal cylinder, all rats died soon after treatment. The temperature of the abdomen within the RF cylinder was 44–45°C.

A series of experiments were performed to investigate the pattern of heating of tumour and normal tissues exposed to the same RF field. The results are illustrated in Fig. 4.

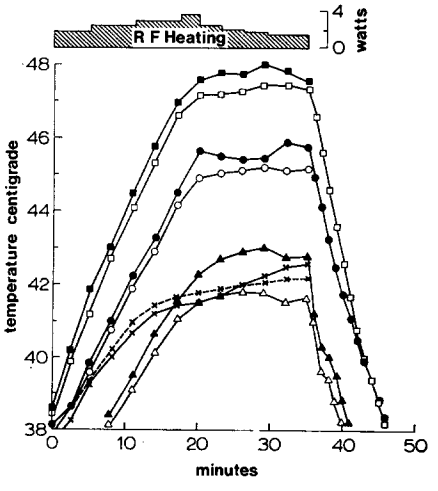

Fig. 4. Temperature profiles and cooling curves for RF heating of the two rear legs of a rat, one leg bearing a 6 ml intramuscular Yoshida tumour. A tissue cylinder was formed between the heating paddles by strapping the limbs together loosely at the ankles. Three cm diameter paddles were used at a separation distance of 2·7 cm. Tumour temperature (●, ○) was maintained at 45°C for 15 min. Concomitant temperatures achieved in normal muscle of the opposite leg (■, □), skin over the tumour (△), and skin over the normal muscle (▲), as well as rectal (× – – – ×) and intra-abdominal (×——×) temperatures are indicated.

Intramuscular Yoshida tumours of 5–10 ml in the rat were used. The tumour-bearing limb and the animal's normal limb were lightly strapped together at the ankle. A cylinder of tissue of diameter adequate to cover the tumour was heated, with one paddle applied to the tumour and the other to the lateral side of the normal leg. Passage of the current between the legs was facilitated by coating the apposed skin surfaces in the field with conducting jelly.

When the Yoshida tumour was heated at 45°C, the normal muscle of the rat maintained a temperature that was consistently 2–3°C higher than the tumour (Fig. 4). The heating and cooling curves for tumour and muscle were similar. There was little difference in skin temperatures under the paddles, both remaining below 43°C. Rectal and intra-abdominal temperatures increased progressively, and were in excess of 42°C during the latter part of the 15 min heating period. Seven rats were treated by this procedure. All animals survived the heating, but died within a further 48 hr.

Table 1 records the detailed electrical measurements obtained with RF heating of normal legs and tumour-bearing limbs in experiments similar to that depicted in Fig. 4. The tissues were brought to 45°C and maintained at this temperature for 15 min. From the mean amperage (I) and mean potential difference (V) across the tissue cylinder during the 15 min heating period, the tissue resistance (V/I) was calculated. The geometry of the heated tissues is indicated by the diameter and separation of the paddles, and the range of amperes and volts required to maintain these cylinders of different volume at temperature is given. The presence of tumour in the muscle did not significantly alter the electrical resistance of the leg(s). The resistance of rat leg muscle at 48°C (the temperature achieved in Fig. 4) was similar to the resistance at 45°C.

Unsuccessful treatment

Large Yoshida tumours (6–12 ml vol) situated in the leg muscles were treated at 45°C for 30 min (17 rats) or 50°C for 15 min (16 rats). To maintain these temperatures, the applied RF power did not exceed 5 W (10 V at 0·5 A) and usually less than 3·5 W sufficed. Rectal temperatures reached 41°C in 4 of the 45°C treated rats, but remained below 40°C in the others and in the 50°C treated animals throughout the heating; skin temperature over the tumours was consistently 4–6°C below intra-tumour temperature. All rats died within 72 hr of heating. At autopsy, no macroscopic lesion was observed that might have led to death of the host, and the tumour showed no gross lysis.

D23 tumours (0·7–1·5 ml vol) on the flank of rats were subjected to RF treatment regimens of 42°C/1 hr, 43°C/30 min, or 45°C/15 min. Cylinder heating by paddles applied to opposite sides of the tumour was employed. No regression occurred in a series of 20 tumours treated.

A series of mice bearing Ehrlich ascites tumour were treated 7 days after intraperitoneal inoculation of 10^7 cells. RF heating was by a cylinder using 2·0 or 2·5 cm paddles applied to opposite sides of the abdomen. An intra-abdominal temperature of 42, 43 or 44°C was maintained for 60, 30 or 15 min respectively (6 mice at each temperature), the applied power being less than 2 W. All mice died during or immediately after heating. At post-mortem there was acute haemorrhagic necrosis of the small intestine. Normal mice treated by RF (intra-abdominal temperature 42°C/60 min, 43°C/30 min, 44°C/15 minutes, 6

Table 1. *Protocol for maintaining normal and tumour-bearing limbs of the rat at* 45°C *by RF heating for* 15 *min*

	Volts (V)	Amps (I)	Resistance $\left(\Omega = \frac{V}{I}\right)$	Paddle diameter (cm)	Paddle separation (cm)
One leg (4)	3–6	0·1 –0·25	25·4 ± 4·0	1·5	1·0–1·3
Both legs (4)	6·4–10·1	0·2 –0·35	28·0 ± 3·9	2·0 or 2·5	2·0–2·7
One leg with tumour (6)	8–13	0·35–0·50	26·3 ± 4·7	2·5 or 3·0	2·5–3·2
Both legs, one with tumour (7)	5·2–10·5	0·2 –0·42	26·7 ± 2·0	3·0 or 3·5	2·7–3·8

The tissue was heated as a cylinder between two paddles of equal diameter applied to opposite sides of the leg(s). Paddle diameter was chosen to be greater than or equal to the thickness of the limb(s); with tumour-bearing legs, the paddle diameter was always greater than the tumour diameter measured in the same plane. The tumours ranged in volume from 4 to 10 ml. Resistance values are given ± S.D., and the figures in brackets represent the number of different animals examined in each group.

animals at each temperature) also died immediately after treatment. Acute necrosis of the small intestine was also present in these mice at autopsy.

DISCUSSION

Electrical approaches to the local heating of animal tumours are not new. Diathermy techniques have occupied most attention, and over the years wavelengths ranging from 500 m [28] to microwaves at 10 cm [29], have been employed. Most workers have been unable to obtain high percentage cure rates. In recent years, workers have concentrated on achieving intra-tumour temperatures of 42–44°C [6, 30], since at higher temperatures damage to normal tissues becomes a limiting factor.

The older literature contains reports on the electrical heating of animal tumours at temperatures in the region of 50°C. Overgaard and Okkels [28] treated Crocker sarcomas (approx. 0·1 ml vol) on the tail of mice with radiofrequency currents of wavelength 500, 20–30 or 5–7 m. Temperatures of up to 46°C were maintained for 15–60 min. A cure rate of less than 20% was obtained in a large series of tumours. Westermark [31] treated Flexner–Jobling and Jensen tumours growing s.c. in the flanks of rats. He used electrodes of unequal size (15–20 cm^2 probe applied to the tumour, and a ground electrode of 100 cm^2 on the opposite side of the animal body) and a current of 0·1–0·4 A, but unspecified frequency. Westermark obtained superficial to deep skin damage at tumour temperatures over 46°C. Johnson [32] gripped Walker 256 and Jensen tumours between two electrodes, and subjected them to short radio waves (λ3·4 m) at temperatures of 47°C for up to 45 min, or 50°C for 4 min. Damage to healthy skin occurred at temperatures in excess of 47°C. As found by Westermark, a considerable number of tumours treated at each temperature were unrestrained or regressed only temporarily after treatment. Cater *et al.* [29] achieved 45–47°C for 10 min in intramuscular hepatoma 223 tumours in the thigh of rats, using microwave heating at 10 cm wavelength. No tumour cures were obtained, and at 47°C oedema of the foot and areas of thrombosis in the tumour and overlying tissue occurred. Heating periods of over 10 min at 47°C incurred the danger of limb destruction.

The theory and use of radiofrequency currents in the short wave diathermy range (λ30–3 m) have been reviewed in detail [33–35], and the problems associated with obtaining selective heating of tumours by this means have been discussed by previous workers [6, 31, 32]. It has been repeatedly demonstrated that the depth of penetration of the heating effect, and the temperature distribution within the tissue, is critically dependent upon the relationship between the heated part and the electrodes, and on the geometry of the electrodes, as well as the current frequency employed [33, 34, 36]. In the present work, efficient contact between the paddles and skin was crucial. All traces of hair must be removed from the skin, thus decreasing greatly the high electrical resistance of this barrier. The distance between the paddles should not greatly exceed the paddle diameter, since the power compensation for varying plate separations takes place over a range of ± 20% approximately, where 100% represent plate diameter. Other important contributory factors in the readily-controlled and uniform tumour heating may be: (1) the use of the longest wavelength (22 m) approved by the Federal Communications Commission for medical use, with its greater depth of penetration in tissue and less heat generation in fat than shorter wave lengths [34, 37]; (2) employment of the electrostatic (condenser) field technique whereby the tissue becomes part of the resonator circuit, instead of the more commonly used inductive (electromagnetic) field method in which the tissues are not in the circuit but within the magnetic field of a coil; (3) the incorporation of tuned compensating coils in the paddle handles; and (4) the stabilising influence of the d.c. inverse feedback loop in the circuit.

LeVeen *et al.* [38] have recently reported results obtained from heating tumours in animals and humans with an RF apparatus operating at 13·56 MHz, and seemingly resembling the currently described machine in construction. Extensive necrosis and regression was obtained in a series of 21 solid human tumours of the lung, colon, kidney and in cancers of the head and neck following treatment at 46–50°C for 30 min. The heating was usually repeated for up to as many as 9 sessions. Tumour temperature was 8–10°C higher than that of normal adjacent tissue in 3 patients in whom this could be measured. The blood flow through 6 human tumours (4 colon, 1 lung, 1 kidney), measured *in vitro*, was only 1–15% of that through the adjacent normal organ. These authors believe the selective RF heating of tumours can be accounted for in terms of decreased blood flow, which would inhibit rapid heat dissipation. The present results with large intramuscular Yoshida tumours and normal leg muscle exposed to the same RF field (Fig. 4, Table 1) do not support this view.

It is known that the resistance offered to the passage of an electric current by a composite electrolyte-dielectric like a living body cannot be explained merely by Ohm's Law [31, 33, 34]. Nevertheless, tissue resistance is a major factor in high frequency heating, which in general follows the ordinary laws of electric heating [31, 33, 34]. Since the tissue resistance, as measured under standardized conditions, was not significantly affected by the presence of the tumour (Table 1), the differential heating of tumour and muscle may reflect a better blood flow through the tumour and a greater ability to contend with the increased heat load.

LeVeen *et al.* [38] also treated Brown–Pearce tumours in rabbits and an unspecified ascites carcinoma in mice by RF heating, but details of the work are totally lacking. It is stated that the temperature was raised to "7–9°C above that of the surrounding tissue" and "these tumours were rapidly and completely necrosed". We have been unable to confirm the results of LeVeen *et al.* in relation to ascites carcinoma in mice. All normal mice heated to an intra-abdominal temperature of 42, 43 or 44°C died rapidly, with haemorrhagic necrosis of the small bowel, and there was no evidence that tumour-bearing animals had increased tolerance to the elevated temperature. The Ehrlich ascites cells were sensitive *in vitro* to the temperatures used, there being a total inhibition of respiration after 4 hr in Warburg flasks at 42°C, or after 2 hr at 43°C; anaerobic glycolysis was not affected at these temperatures (the technique of Warburg manometry and the buffers used were as detailed in [39]). Fifty years ago, Westermark [31] reported extensive coagulation of the abdominal viscera in rats following high-frequency heating of tumours at temperatures over 45°C, and with the electrodes placed on opposite sides of the animal body. The present results with the MC7 sarcoma show that it is feasible to heat superficial tumours to 45°C with electrodes of unequal size "coning", provided the choice of electrode size is such as to selectively heat the tumour and yet prevent the body temperature rising to 42°C by effective dissipation of the current deep to the tumour.

The present method is the best technique of local hyperthermia we have yet tested for tumours in animals. It is easy to perform, and high temperatures with homogeneous tumour heating can be achieved in a reliable and controlled manner, enabling a 100% regression rate to be obtained in heat sensitive tumours. The generated heat seems to act in a manner similar to other forms of heating, e.g. waterbath immersion, since tumour regression after curative heating at a given temperature follows a similar time course [2], and regression of a heated tumour is accompanied by disappearance of tumour elsewhere in the host (the so-called "abscopal" response [40]).

We previously reported rapid death from elevated body temperature in rats bearing 10 ml intramuscular Yoshida tumours heated at 42°C for 1 hr [21]. The animal deaths following heating of large leg tumours at 45°C for 30 min or 50°C for 15 min, and in which the intra-abdominal temperature usually remained below 40°C, remain unexplained. It is presently believed that radiofrequency currents produce their effects solely by heat production within the tissues, and that any damage produced has a purely thermal basis [34, 36].

In relation to the failure to cure the D23 tumour at temperatures up to 45°C, it is of note that this carcinoma is only weakly antigenic [26], while both the Yoshida tumour [41] and the MC7 sarcoma (27) elicit a marked immunological response on the part of the host. As far back as 1927, Westermark [31] believed a host immune response to be involved in tumour cure after local hyperthermia, and Johnson [32] suggested that the Jensen sarcoma was more sensitive to heat than the Walker tumour because it could induce immunity in rats. More recent workers have also adduced circumstantial evidence that tumour regression and host cure following local heating may imply participation of the immune system [1, 2, 8, 22, 23, 42].

Acknowledgements—We are particularly grateful to Mr. Wilfrid Whalley, designer of the RF machine, and to Mr. David Waggott, President, Critical Systems Inc., for in depth discussions on the technology and operation of the machine, and for their continuing enthusiastic support in its application. We are indebted to Mrs. J. Hogg and Mr. R. McCoy, Cancer Research Unit, and to Mr. R. Bridgett, Medical Electronics, for expert technical help.

1. BACKGROUND AND INTRODUCTION

UNTIL recently chemotherapy in metastatic soft tissue sarcoma has given poor results. Since a few years adriamycin (ADM) as a single agent in these tumors has given higher remission rates than obtained with any other drug [1, 2].

Gottlieb's results [3–6] and those of others [7], with combination therapy in soft tissue sarcoma are encouraging. In broad phase II studies during 1970–1971 adriamycin and 5-(3,3-dimethyl-l-triazeno)imidazole-4-carboxamide (NSC-45338) both proved to have definite activity when given as single agents in soft tissue sarcoma [1, 2, 8]. These effects were obtained despite extensive previous therapy with surgery, radiotherapy and the commonly used chemotherapeutic agents vincristine (VCR), actinomycin D (ACD) and cyclophosphamide (CPA). The remission rates for ADM and NSC-45338 (DIC) in these studies were 29 and 15% respectively. His studies also show that ADM is the most active single drug agent and that it can be combined well with other agents. Regression rates of single and combination therapy in soft tissue sarcoma are shown in Table 1. It can be seen that the effects of ADM and DIC are additive [5], while this has been shown in experimental data as well [9]. The two drugs can be given together with little increase in toxicity. Addition of VCR appears to act independently at essentially the same level as DIC. The median duration of remission of combination treatment has been significantly longer (16 months for ADM + DIC).

In a pilot study performed in 1974–1975 within the Soft Tissue Sarcoma Working Party ACD has been introduced instead of VCR. However, toxicity of this 4-drug combination was unacceptable.

Actinomycin D had been introduced in the combination treatment because this drug is effective in single drug treatment of soft tissue sarcoma. Because of the toxicity the schedule has been changed. A single dose treatment with the 4-drug CYVADIC combination described by Gottlieb will be compared with a cycling schedule. With the alternating administration ADM can be given for a longer period of time, while resistance might be built up less rapidly.

2. PURPOSE OF STUDY

The purpose of this trial is to investigate the remission rate and duration of remission and survival of two schedules of 4-drug treatment in soft tissue sarcoma, a single dose schedule and a cycling schedule. The proposed alternating schedule has not been studied before in soft tissue sarcoma, but the four drug combination has been studied previously [4]. The second objective of this study will be to verify these results.

3. SELECTION OF PATIENTS

3.1 *Conditions of patient eligibility*

1. Eligible patients must have confirmed residual or metastatic soft tissue sarcoma.

The cell types which are included are summarized in Section 10.

2. All patients should have measurable and evolutive disease. Osseous lesions and pleural effusions are not considered as measurable lesions. Progression must be proved within a period of 2 months before the beginning of the treatment, but if it has been proven in a shorter period of time, the patient can enter on study.

3. All patients previously treated by radiation with progressive and measurable growth outside the field of radiation may be accepted for the present study.

4. The patient must be inoperable without other definitive therapy available.

3.2 *Conditions for patient exclusion*

1. Patients 14 years old or younger.
2. Patients above 75 years of age.
3. Patients with overt psychoses or marked senility.
4. Performance status according to Karnofsky under 50 (see Table 2).
5. Active second tumor or serious concomitant disease.
6. Acute intercurrent complications such as infection or post surgical complication.
7. Previous treatment with ADM, DTIC, VCR or CPA.
8. Congestive heart failure.
9. Central nervous lesions including metastases.
10. Unfavourable haematologic status: leukocytes < 4000 per mm^3, thrombocytes $< 100{,}000$ per mm^3.

4. DESIGN OF TRIAL

4.1 Patients will be randomized to receive either the S_1 single dose schedule or the S_2 cycling schedule. Patients will be stratified according to cell type since there are differences in remission rates between the histologic subtypes and also according to age (15–59 years, 60–75 years). No stratification for histologic grading will be done (Table 3).

4.2 Treatment should be administered, if possible, for a minimum of 8 weeks. In responders or in patients with static disease, the dose schedule should be continued for at least 2 years. Patients go off study upon progression and should be followed until death whenever possible.

5. THERAPEUTIC REGIMENS

5.1 For patients between 15 and 59 years of age, the schedule will be

S_1: ADM 50 mg/m^2, Day 1
DTIC 250 mg/m^2/day, Days 1–5
CPA: 500 mg/m^2, Day 1
VCR: 1·5 mg/m^2 (top dose 2 mg), Day 1
This course is repeated every 4 weeks.

S_2: ADM: 50 mg/m^2, Day 1 plus
DTIC 250 mg/m^2/day, Days 1–5;
CPA: 1200 mg/m^2, Day 1 plus
VCR 1·5 mg/m^2 (top dose 2 mg),
Day 1
Cycled dose: every 4 weeks, alternating (ADM + DTIC) and (CPA + VCR).

5.2 For patients between 60 and 75 years of age, the schedule will be

S_1: ADM: 35 mg/m^2, Day 1
DTIC: 170 mg/m^2/day, Days 1–5
CPA: 330 mg/m^2, Day 1
VCR: 1·0 mg/m^2, Day 1
This course is repeated every 4 weeks.

S_2: ADM: 35 mg/m^2, Day 1 plus
DTIC, 170 mg/m^2/day, Days 1–5
CPA: 800 mg/m^2, Day 1 plus
VCR, 1·0 mg/m^2, Day 1.
Cycled dose: every 4 weeks, alternating (ADM + DTIC) and (CPA + VCR).

Table 2. Dose modifications in case of leukopenia and/or thrombocytopenia

	Thrombocytes		
	≧ 100,000	75,000–100,000	≦ 75,000
Leukocytes ≧ 4000	100%	50%	—
2000–4000	50%	50%	—
≦ 2000	—	—	—

Table 3. Drug schedule

		Age	
		15–59	60–75
S_1:	Adriamycin, Day 1	50 mg/m²	35 mg/m²
	DTIC, Days 1–5	250 mg/m²/day	170 mg/m²/day
	Cyclophosphamide, Day 1	500 mg/m²	330 mg/m²
	Vincristine, Day 1	1·5 mg/m² (top dose 2 mg)	1·0 mg/m²
	This course is repeated every 3 weeks.		
S_2:	Adriamycin, Day 1 plus	50 mg/m²	35 mg/m²
	DTIC, Days 1–5	250 mg/m²/day	170 mg/m²/day
	Cyclophosphamide, Day 1 plus	1200 mg/m²	800 mg/m²
	Vincristine, Day 1	1·5 mg/m² (top dose 2 mg)	1·0 mg/m²
	Cycled Dose: every 3 weeks, alternating (ADM+DTIC) and (CPA+VCR).		

Table 4. Dose modifications of ADM in hepatic dysfunction

Bilirubin	BSP-retention	% of normal dose
< 2·0 mg/100 ml	< 12%	100%
2–3 mg/100 ml	12–18%	50%
> 3 mg/100 ml	> 18%	25%

5.3 *Duration of therapy*

ADM will be administered to a total dosage of 550 mg/m². After reaching this dosage, therapy will be continued with DTIC, VCR and CPA at the same doses. No dose escalation is permitted. In patients still showing disease progression after a treatment period of 6 weeks, therapy has to be discontinued. In responders or in patients with static disease the dose schedule will be continued for at least two years. Treatment for patients going off study due to progression will be determined individually by each institution. However, it is recommended that patients failing in S_2 will be crossed over to S_1. It is suggested to treat patients failing on S_1 by doubling the S_1 doses (if facilities for isolation of patients are available).

5.4 *Drug formulation and procurements*

5.4.1 *Supplied.* ADM: vials containing 10 mg; DTIC: vials containing 100 and 200 mg; VCR: vials containing 1 mg; CPA: vials containing 100, 200, 500 or 1000 mg as a powder.

5.4.2 *Storage.* ADM: refrigerator 4°C; DTIC: deep freeze −20°C; VCR: refrigerator 4°C; CPA: refrigerator, keep dry.

5.4.3 *Methods of administration.* All four drugs should be introduced i.v. (pushdose).

5.5 *Supportive therapy*

No radiotherapy should be given to patients in the trial, except for palliative treatment of lesions of the skeleton.

5.6 *Nausea and vomiting*

Phenothiazine should be administered before giving medicaments.

6. TOXICITY AND DOSE MODIFICATIONS

6.1 Dose modifications of adriamycin should take place with hepatic dysfunction according to Table 4. This dose

should also be applied with development of liver dysfunction after start of treatment. Dose modifications of adriamycin should not be applied with renal dysfunction.

6.2 If at 4 weeks the leukocytes are between 2000 and 4000 and/or the thrombocytes between 75,000 and 100,000 the dose will be adjusted according to Table 2. If at 4 weeks leukopenia and/or thrombocytopenia persist below these levels, treatment will be postponed a maximum of 3 weeks. If a cycle has to be postponed more than 3 weeks, the patient should be dropped from the trial. At the moment (within 4–6 weeks from the beginning of the last cycle) that the leukocytes and thrombocytes have recovered to levels above 2000 and 75,000 respectively, treatment can be recontinued at 50% of the initial dose. In this case the dosage of subsequent cycles will be maintained at 50% of the initial dose even if leukocytes and thrombocytes recover to normal levels within 3 weeks.

7. PRETREATMENT STUDIES

7.1 *History*

a. Age
b. Sex
c. Date and nature of first symptoms
d. Date of initial diagnosis and how made
e. Prior treatment (dates, methods, nature and duration of response).

7.2 *Physical examination*

a. Ambulatory status using Karnofsky's criteria
b. Height, weight and surface area
c. Description and measurements of soft part metastases with a suitable caliper
d. Photographs of the soft tissue lesions. (optional),

7.3 *Laboratory studies*

a. Complete blood count
b. Serum creatinine, Na, K, Ca
c. Serum uric acid
d. Bilirubin, alkaline phosphatase, transaminases, serum proteins and electrophoresis
e. Urinalysis.

7.4 *X-thorax*

7.5 *Bone*

Skeletal X-ray survey including following bones: skull lateral and AP views, pelvis AP view, lumbar, dorsal, cervical spine lateral and AP views.

7.6 *Isotopic scintigraphy*

Liver scan; skeletal scan: skull, spine and pelvis.

7.7 *Electrocardiogram*

8. FOLLOW-UP STUDIES

8.1 Every week during the first 8 weeks and then every 5 weeks thereafter: 7.3a.

8.2 Every 4 weeks: 7.2a, 7.2b, 7.2c, 7.2d.

8.3 Every 8 weeks: 7.3b, 7.3c, 7.3d, 7.3e, 7.4.

8.4 Every 6 months: 7.5, 7.6, unless indicated earlier either on a medical indication or for determination of a complete remission.

8.5 In case of objective tumor response: pre-treatment studies except 7.1.

8.6 In case of toxicity: follow-up of the toxicity until complete recovery.

8.7 Every side-effect of therapy has to be recorded: anorexia, nausea, vomiting, mouth ulcerations, alopecia, haemorrhagic cystitis, hepatic dysfunction.

8.8 Complementary studies may be performed provided they do not interfere with or bias the results of the studies required by the protocol. Immunological studies are optional.

9. DEFINITION OF RESPONSE

Only objective tumor response criteria are used in these studies. These are the following:

9.1 A complete remission is defined as the disappearance of all symptoms and signs of soft tissue sarcoma for a minimum of 4 weeks.

9.2 A partial remission is defined as a significant decrease in size in at least 50% of all lesions for a minimum of 4 weeks while the remainder are static. In the case of accurately measurable lesions, such a decrease is defined as a reduction by 50% of the product of the two largest tumor diameters. For lesions that do not lend themselves to accurate measurement, the reduction should be at least three-fourths of the estimated volume. Changes in body chemistry and improvement in hemodoiesis cannot be construed as criteria of objective remission.

9.3 No change is recorded for a patient when no new lesions appear and no lesions increase in size; decreases in lesion size, if any, are not sufficient to indicate a partial remission.

9.4 Progression occurs when any lesion increases in size or any new lesions appear, regardless of what the response of the other lesions may have been.

10. REGISTRATION AND RANDOMIZATION OF PATIENTS

A patient is registered and randomized after the local pathology review by telephoning to the E.O.R.T.C. Data Center (tel: Brussels 538.65. 33) from 9.00 a.m. to 5.00 p.m., Monday through Friday. The date of registration is the date of making this telephone call. At this time the following information is requested:

1. Protocol number (62761).
2. Patient's age (15–59 or 60–75 yr).
3. Cell type (see below).
4. Patient's name.
5. Institution's name.
6. Physician's name.
7. Caller's name.

The treatment assigned by randomization will then be given.

If registration by telephone is not possible, patients may also be registered by telex: 22773, or by mail:

E.O.R.T.C. Data Center,
Institut Jules Bordet,
1, rue Héger-Bordet,
1000 Bruxelles, Belgium,

by including the information requested above. Stratification will take place on the patient's age (15–59 or 60–75 yr) and on the following cell types:

1. Angiosarcoma (haemangioendotheliosarcoma + haemangiopericytoma)
2. Fibrosarcoma
3. Leiomyosarcoma
4. Liposarcoma
5. Neurofibrosarcoma
6. Rhabdomyosarcoma
7. Synovial cell sarcoma
8. Undifferentiated sarcoma
9. Mesothelioma
10. Unclassified or miscellaneous.

Thus, Kaposi's sarcoma, chondrosarcoma, and osteosarcoma, will be excluded. No stratification will be done on extent of disease or anatomic staging.

11. CENTRAL PATHOLOGY REVIEW

There will be a central pathology review with grading of the histology by the Department of Pathology, University Hospital, Utrecht, The Netherlands. The following material and information is requested:

11.1 Clinical data: age, sex, localization of tumor, number of samples taken for histopathological exam, original macro and micro report.

11.2 Six unstained sections of each sample (or paraffin blocks, by preference tumor tissue in fixation fluid).

11.3 The central Pathology Review would be very grateful to receive tumor tissue, fixed or embedded, for electronmicroscopy. It can be processed and studied by the University Hospital in Utrecht.

11.4 If additional biopsies during the course of the study are done or if an autopsy is performed, the Central Pathology Review would be very interested to study this material as well.

12. SUBMISSION OF FORMS

All forms are to be sent in duplicate to the E.O.R.T.C. Data Center, Institut Jules Bordet, 1, rue Héger-Bordet, 1000 Bruxelles, Belgium.

The schedule for submission of forms is as follows:

1. *On-study form (Form II)*

Send within one week of the patient's entry on study (randomization).

2. *Chemotherapy form (Form V)*

Send after completion of each 4 week cycle of chemotherapy.

3. *Flow sheet (Form VII)*

The first flow sheet should be filled out prior to the first cycle of chemotherapy and sent with the on-study form. It should also be filled out at 8 weeks, 4 months, and then every 3 months thereafter.

4. *Measurement form (Form VIII)*

The schedule is the same as for the flow sheet. The first measurement form should be filled out prior to the first cycle of chemotherapy

and sent with the on-study form. It should also be filled out at 8 weeks, 4 months, and then every 3 months thereafter. The location of the lesion is identified by the grid on page 2 of the measurement form. The location of any lesion is identified by a letter (horizontal axis) followed by a 2 digit number (vertical axis). Initially the coordinates relating to the center of the lesion should be used. When following a lesion, the same coordinates must always be used to identify the lesion even if the lesion changes in size and shape. In the case of multiple lesions in one area, the largest lesion should be indicated on the form.

5. *Summary form (Form IX)*

To be sent in whenever the patient goes off study for any reason.

Patients who go off study while still alive should be followed until death whenever possible and the Data Center notified of the date of death, cause of death, and localization of disease if the cause of death is malignant disease, upon the death of the patient.

13. STATISTICAL CONSIDERATIONS

Three hundred patients will be entered on study and randomized to receive either the single S_1 or cyclic S_2 dose schedule. While a remission rate of approximately 50% is expected on each arm, 150 patients on each arm is sufficient to detect a difference of 15% in the two response rates. ($\alpha = 0{\cdot}05$, $\beta = 0{\cdot}20$). If the remission rate is approximately 50% then 75 responding patients on each arm is sufficient to detect a ratio of 1·5:1 in the mean (or median) length of the time to progression of the two treatments if all responding patients are followed until progression ($\alpha = 0{\cdot}05, \beta = 0{\cdot}20$) This assumes that the time to progression follows an exponential distribution.

The expected duration of the trial depends on the number of (responding) patients entered each year and the distribution of the time to recurrence. If 100 evaluable patients are entered each year and 50% respond, then it will take 3 years to enter the required number of patients. However, to do an analysis at the error rates given above, the length of the trial will depend on the length of the longest time to progression. If the median length of remission is one year on S_1, then in order to detect a median length of remission of 1·5 years on S_2, the shortest duration of the trial will occur if patients are entered for 4·7 years. After this time a definitive analysis can be made.

14. ADMINISTRATIVE RESPONSIBILITIES

This study is a joint effort between the E.O.R.T.C. Soft Tissue Sarcoma Cooperative Group:

Nederlands Kanker Instituut, Amsterdam: Dr. R. Somers.
Rotterdamsch Radiotherapeutisch Instituut, Rotterdam: Dr. R. Treurniet, Dr. J. H. Mulder.
Academisch Ziekenhuis, Leiden: Dr. A. T. van Oosterom.
Academisch Ziekenhuis, Utrecht: Dr. H. M. Pinedo.
Radboud Ziekenhuis, Nijmegen: Dr. Th. Wagener.
Ziekenhuis Westeinde, 's-Gravenhage: Dr. G. Booy.
Institut de Cancérologie et d'Immunogénétique, Hôpital Paul-Brousse, Villejuif, France 94800: Prof. C. Jasmin.
Istituto Nazionale per lo Studio e la Cura Dei Tumori, Milano, Italy: Dr. G. Bonadonna.
Innere Klinik und Poliklinik (Tumorforschung) der Ruhruniversität Essen, Germany: Prof. Dr. C. G. Schmidt.
Zentrum für Innere Medizin, Robert Bosch-Krankenhaus, Stuttgart, Germany: Prof. Dr. W. Wilmanns.
Christie Hospital, Cancer Research Campaign, Manchester, United Kingdom: Prof. D. Crowther.
Institut Jules Bordet, 1000 Bruxelles, Belgium: Dr. Y. Kenis and Dr. M. Staquet.
Swiss Group for Clinical Cancer Research, 62 rue de Carouge, 1205 Genève: Dr. H. J. Senn.
University Hospital, 9000 Ghent, Belgium: Dr. A. De Schryver.

Study Coordinator

Mammalian mRNA Translation of the Liver Ribosome Subunits Isolated from Dimethylnitrosamine-Treated Mice

A. DELPINO and U. FERRINI

Regina Elena Institute for Cancer Research, Rome, Italy

THE CARCINOGENIC compound dimethylnitrosamine (DMN) displays strong hepatotoxic effects in several mammalian species when given in a single dose ranging from 30 to 100 mg/kg of body weight.

The main effect, within 2 hr after treatment, is a severe reduction of the liver protein synthesis, parallel to a progressive polysomal disaggregation and increase of 80 S monomer fraction.

A number of experimental evidences seems to indicate that this inhibition is caused by an impairment of the ribosome recycling and, therefore, of the initiation step of the protein synthesis. The mechanism of this effect, however, is still unknown.

DMN-generated monomers have been found to have many of the features typical of monomers of run-off type, rather than of monomers produced by the mRNA breakdown [1, 2]. Previous observations have also shown that these monomers and their constitutive subunits are fully competent for the poly-U directed polyphenylalanine synthesis [2, 3]. It is well known, however, that such an assay cannot be adopted as a test for controlling the ribosome capacity to synthetize proteins by means of the specific initiation mechanism, i.e., by the recognition of the initiation codon on natural eukaryotic messenger.

In order to clarify this point, we have tested purified subunits, isolated from the DMN-

Accepted 27 October 1976.

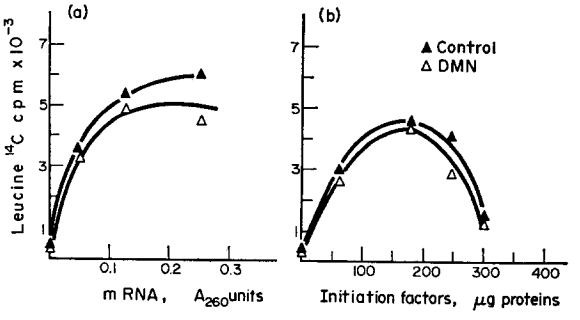

Fig. 1. Rabbit globin mRNA-directed protein synthesis with ribosomal subunits isolated from control (▲) and DMN-treated (△) animals.

Treated mice received an i.p. injection of 50 mg/kg b.w. of redistilled DMN 3 hr before killing.

Liver ribosome subunits were isolated by high salt (300 mM KCl and 3 mM $MgCl_2$) gradient centrifugation directly from detergent treated postmitochondrial supernatant.

Crude initiation factors and globin mRNA were prepared from rabbit reticulocyte ribosomes according to published methods (4, 8).

Incorporation was carried out in 0, 1 ml reaction mixture containing 0·16 A_{260} units of 40 S + 0·40 A_{260} units of 60 S ribosomal subunits; 30 μl of pH 5 enzyme (about 600 μg of protein); 0·1 μmole of ATP; 0·05 μmole of GTP; 2 μmole of creatine phosphate; 0·25 units of creatine kinase; 2 nmole of each L-amino acid (minus leucine); 0·25 μCi of ^{14}C-leucine (324 mCi/mM); 1·3 μmole of Tris–HCl (pH 7·6); 7 μmole of KCl; 0·45 μmole of $MgCl_2$; 0·65 μmole of β-mercaptoethanol. In panel A the amount of protein initiation factors was 150 μg and the amount of rabbit globin mRNA was made variable. In panel B the amount of mRNA was 0·15 A_{260} units and the amount of protein initiation factors was made variable. Incubation was carried out for 30′ at 37°C.

Reaction was stopped by the addition of 3 ml of 10% cold CCl_3COOH. Samples were heated 15′ at 90°C, then collected onto glass fibre filters and washed three times with cold 5% CCl_3COOH.

generated monomers, in an *in vitro* system programmed with rabbit globin mRNA and supplemented with heterologous initiation factors.

As shown in Fig. 1A and 1B, DMN-subunits are able to translate on natural mammalian mRNA with the same efficiency of the corresponding control subunits.

In the presence of a fixed amount of initiation factors (Panel A) both control and DMN-subunits are saturated by the same quantity of mRNA (0·15 A_{260} units of globin mRNA for 0·16 A_{260} units of 40 S and 0·40 A_{260} units of 60 S).

An identical behaviour between control and DMN-subunits is also evident when the synthetic capacity is tested by varying the concentration of initiation factors at fixed amount of globin mRNA (Panel B). The maximum activity for 0·5 A_{260} units of reconstituted ribosome couples is attained when 200 μg protein of unfractionated ribosome KCl wash are present; by increasing the amount of the KCl extract the protein synthesis progressively decreases, owing to the presence of inhibitory factors in such crude extract [4]. In the absence of ribosome KCl wash, the incorporation activity is strongly reduced, as expected for ribosome subunits which, after isolation in high salt gradients, are known to be completely devoid of their endogenous initiation factors.

On the basis of these results we can assume that, within the first 3 hr after DMN injection, the protein synthesis capacity of the subunits derived from DMN-generated monomers is unchanged and therefore the ribosomes *per se* do not play any significant role in the inhibition of the protein synthesis following a toxic dose of DMN.

Our results are in agreement with the data of Nygard and Hultin [5] which demonstrated that monomers prepared from DMN-treated rats are able to translate on heterologous mammalian mRNA, when supplemented with homologous unfractionated initiation factors.

Anyhow, the observation that these ribosomes retain a fully capacity to synthetize proteins badly correlates with the fact that, up to the first hours, their 18 and 28 S rRNAs are methylated at a very fast rate and with the highest activity among the various cellular components [6]. In this connection it is worthy to mention the fact that the mammalian ribosomes can support within certain limits a nucleolytic attack, without loosing their capacity to synthetize proteins [7]. It is possible, therefore, that the alkylation of the ribosome may produce a functional defect whenever the number and the distribution of alkyl groups on the nucleophylic centers attain a critical level.

According to this hypothesis, we have observed a constant slight reduction on the activity of the DMN-derived subunits [2]; this fact can be related to the presence of a number of a fully inactivated particles.

Letter to the Editor

Nuclear DNA Polymerase-α and Replicative Potential in Mammalian Cells*

P. G. BRAUNSCHWEIGER and L. M. SCHIFFER
Cancer Research Unit, Division of Raditaion Oncology, Allegheny General Hospital,
320 *East North Avenue, Pittsburgh, PA* 15212, *U.S.A.*

DNA POLYMERASE-α has been investigated as a potential marker to distinguish proliferative and nonproliferative cells [1]. This enzyme copies activated DNA at a high rate and comprises 80–90% of the total cellular polymerase. It has a sedimentation coefficient of 6–8S and a molecular weight of 110,000–220,000 daltons [2], although it has also been suggested that the enzyme may be composed of two or more subunits of 55,000–87,000 daltons [3]. The α-polymerase activity, unlike the β-polymerase, can be inhibited with agents that bind sulfhydryl groups, such as *p*-chloromecuribenzoate (*p*-CMB) and *n*-ethylmaleamide [4, 5]. Although the α-polymerase can be isolated from the cytosol of cells [1, 6, 7], its activity has also been demonstrated in the nucleus [7, 8]. Unlike β-polymerase, α-polymerase levels in the nucleus have been shown to correlate well with the proliferative status of the cell population [8–11].

Although most DNA polymerase assays utilize liquid scintillation counting techniques to detect ^{3}H-thymidine triphosphate (^{3}H-TTP) incorporation into activated primer-template, an autoradiographic, slide assay has been described in which DNA polymerase activity in isolated cell nuclei is measured utilizing the cells own DNA as primer-template [12]. Utilization of this technique (primer available, DNA polymerase or PDP assay) permits enumeration of the fraction of cells in which both DNA polymerase and endogenous available primer-template are present in the same nucleus. Other more recent studies have shown that the fraction of PDP labeled nuclei, for a variety of experimental tumors, gives a good estimation of the tumor growth fraction as measured by more classical methods [13]. In the present studies the PDP index and mean grain count were determined in the presence of the sulfhydryl binding agent (*p*-CMB) to determine if the enzyme component of the PDP assay is the DNA α-polymerase.

In these studies, touch imprint preparations of solid tumors and dry film smears from spleen cell suspensions were subjected to PDP assays as previously described [12, 13]. Briefly, the slide preparations were dipped in 0.25% agar (to remove cytoplasm, leaving nuclei adherent to the slide), air dried and fitted with a glass incubation chamber. The slides were incubated for 45 min at 37°C with a mixture containing the four nucleotide triphosphates, including 5μCi per chamber of ^{3}HTTP at specific activity 54Ci/mM.

The incubation mixture, optimized with respect to Mg^{2+}, was buffered with Tris-HCL (pH 7.4) and included ficoll as a stabilizing agent. In addition, duplicate slides for each tumor were treated in a similar manner except for addition of various concentrations of *p*-CMB to the reaction mixture at the beginning of the incubation period.

Following incubation the slides were rinsed thoroughly in tap water, then triple distilled water and air dried. The slides were subjected to autoradiography with Kodak NTB-2 liquid photographic emulsion as previously described

Accepted 23 February 1977.

*Supported by Breast Cancer Task Force Contract N01-CB-43899 and Clinical Radiation Therapy Research Center Grant CA-10438.

[14]. All exposure times were 7 days. Labeling indices were determined on at least 500 cells per tumor, and mean grain counts determined on at least 100 cells per sample. Background levels determined in adjacent acellular areas of each sample were consistently less than 2 gr per equivalent cell area and subtracted from the mean grain count. For ease of comparison, the mean grain counts in *p*-CMB samples were expressed as a percent of the untreated controls.

The PDP index, the ^{3}H-TdR labeling index, and the cell production rates were determined for a variety of experimental tumors, including spontaneous C3H/He mammary tumors, "fast" and "slow" line mammary tumors, the 13762 transplantable rat mammary tumor, a transplantable rat glioma, the T1699 transplantable mouse mammary tumor and the 2 day S-180 ascites tumor. The ^{3}H-thymidine labeling indices and DNA synthesis times were determined as described previously [14], and the cell production rate calculated by the method of Steel, $K_p = 0.693/(\lambda T_S/{}^3\text{HTdR LI})$ [15].

Figure 1 shows the results from studies with the 13762 tumor in which the PDP index was 69.1%, the T1699 tumor with a 47.6% PDP index and normal spleen cells from SJL/J mice with an average PDP index of 16.3%. The addition of various concentrations of *p*-CMB results in a quantitative inhibition of ^{3}HTTP incorporation. Regression lines fit by a linear least square method show that the 13762 tumor

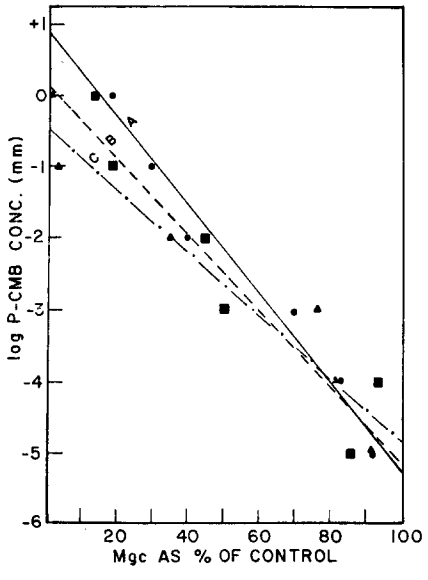

Fig. 1. The effect of increasing p-*CMB concentration on* ^{3}*H-TTP incorporation into isolated cell nuclei, as measured by the mean grain count (mgc) in autoradiograms. For ease of comparison the mgc's were normalized to % of controls untreated with* p-*CMB.* —●—, *13762 rat mammary tumor (A);* – – –■– – –, *T1699 mouse mammary tumor (B);* —·▲·—, *normal spleen cells (C).*

required the greatest concentration of *p*-CMB for complete inhibition, while spleen cells required the least. The concentration for 50% inhibition was calculated at 7.00×10^{-3}mM, 3.17×10^{-3}mM and 2.69×10^{-3}mM *p*-CMB for the 13762, T1699 and normal spleen cells respectively. The results suggest that the PDP assay measures the presence of DNA α-polymerase and that, on an individual basis, the average amount of α-polymerase per labeled cell is greatest in the 13762 tumor and lowest in normal spleen cells.

Table 1 shows the PDP and ^{3}HTdR labeling indices and the DNA synthesis times for the various tumors studied. Figure 2 shows the relationship between the PDP index and the ^{3}HTdR labeling index and the PDP index and the cell production rate (K_p) for the tumors

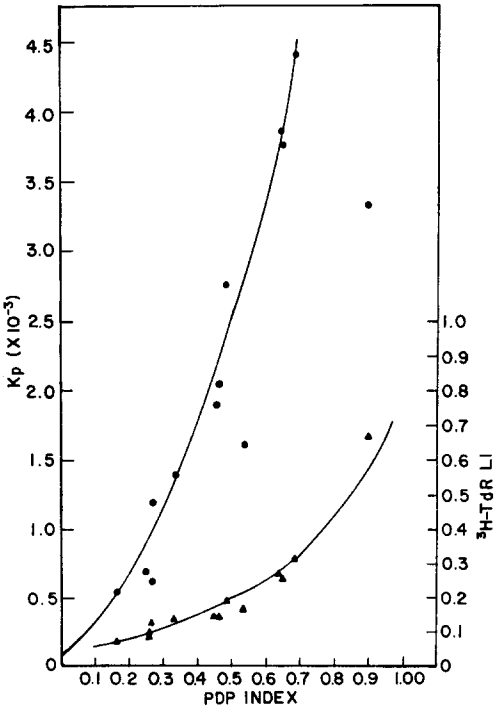

Fig. 2. The relationship between PDP index and cellular production rate (●) and the PDP index and ^{3}*HTdR labeling index (▲) for a variety of experimental tumours (see Table 1 for details).*

listed in Table 1. A line with the equation $y = x/-0.225x+0.333$ was fit by computer ($r = 0.932$) to the data for PDP and K_p, while a line with the equation $y = 4.317 \times 10^{-2}$ $e^{2.833x}$ was similarly fitted to the PDP and ^{3}HTdR LI data ($r = 0{\cdot}968$). The results show a high degree of correlation between the PDP index and both of the cell kinetic parameters reflective of cell proliferation.

In studies in which endogenous DNA was used as primer-template, nuclear DNA poly-

merase activity was shown to be increased during DNA synthesis [9]. In regenerating rat liver, DNA polymerase-α activity in the nucleus increased prior to increases in ^{3}H-thymidine incorporation [8, 10]. Although cytoplasmic polymerase-α activity may be an artifact of the isolation procedure [8], nonproliferating AKR lymphoma cells have low or nonexistent cytoplasmic α-polymerase activity. In unperturbed tumor systems the PDP index has been shown to be a good estimate of the fraction of proliferating tumor cells. Further, in studies with solid tumors [16] and human leukemia [17] the PDP index has been shown to be a responding modality to agents which inhibit DNA synthesis.

A number of studies have also indicated that proliferating and nonproliferating cells may have different levels of primer-template activity [18, 19] and suggest that in assessing proliferative status both endogenous primer-template activity as well as α-polymerase activity are crucial. This may be especially important in perturbed systems where α-polymerase levels alone determined on exogenous primer-template may be misleading in terms of cell proliferation [11].

The results from the present study and others in this laboratory [11, 12] have shown that the PDP assay measures the simultaneous presence of nuclear DNA polymerase and endogenous available primer-template. We now show that the nuclear DNA polymerase is sensitive to *p*-CMB and this suggests that the enzyme is probably DNA polymerase-α. The PDP index, i.e. the fraction of cells with both α-polymerase and endogenous primer-template, correlates strongly with, but is not equivalent to, the ^{3}HTdR labeling index and the cell production rate. Since the PDP index has been demonstrated to be a good estimate of tumor growth fraction [13] we suggest that it could be an important parameter for therapy decisions.

Announcements

The Czechoslovak Society for Oncology, commissioned by the Czechoslovak Medical Society J. E. Purkyne is organizing the:

3rd CZECHOSLOVAK CONGRESS OF ONCOLOGY
WITH INTERNATIONAL PARTICIPATION

To be held in Bratislava from 26–29 October 1977.

The European Organization for Research on the Treatment of Cancer is in the process of compiling a directory of European statisticians working in the field of clinical trials in cancer. Statisticians working in this area in Europe are asked to please write to:

Richard Sylvester,
E.O.R.T.C. Data Center,
Institut Jules Bordet,
1 rue Heger-Bordet,
1000 Brussels, Belgium,

requesting information concerning this directory.

A Message from the Editor

The *European Journal of Cancer* was created in 1965, and the first issue appeared in June of the same year. The founder members are all members of the European Organization for Research on Treatment of Cancer. This is a European and not a national organization. Its objectives are to stimulate and coordinate therapeutic research on cancer in Western Europe. It is a non-governmental multinational body which is supported by private donations and can function effectively because of the support of the individual laboratories and hospitals which are members of the group, with the assistance of a grant from the National Cancer Institute, Bethesda, Maryland, U.S.A., and, more recently, with the contribution from the E.O.R.T.C. Foundation under the chairmanship of Mr. Ronald Grierson, London.

The *European Journal of Cancer* pursues the same objectives as the E.O.R.T.C. It has no restrictive policy as far as the geographical origin of the articles is concerned. However, it has been publishing a majority of manuscripts originating from Western Europe (Fig. 1, Table 1). Of a total number of 1131 published papers, 769 or 68% originate from the countries of the E.E.C. This fact is a justification for the name of the journal, but it is also a realization of the objectives the founder members assigned to the journal: to provide to scientists and clinicians doing cancer research, in this area of the world, a journal with high standards of publication.

Among the E.E.C. countries, the United Kingdom comes first, contributing two and one half the number of articles emanating from any other E.E.C. country.

TOTAL	2108	1131	8044

The Netherlands, France, Belgium and Italy, are at about the same level, despite the difference in size and population among them.

The United States of America represent an important contributor, coming second after the United Kingdom and preceding the other countries. This is a very welcomed contribution and goes a little way towards balancing the numerous publications in United States scientific journals of manuscripts from European Institutes.

Other countries have a smaller participation in the total number of publications, and it is not clear whether this is due to a lesser production or to a preference for national or American journals. The American scientific periodicals remain a formidable attractive force for manuscripts of good quality.

All in all, 35 countries are represented in our Tables of Content. The number of submitted articles has risen from 100 in 1965 to 308 in 1976. The curve (Fig. 2) is a continuous one without major breaks. The curve representing the accepted articles is parallel to the other, extending from 48 published papers in 1965 to 144 in 1976. In number of published pages, the progression is from 330 in 1965 to 1028 in 1976 (Table 2).

The *European Journal of Cancer* has published several symposia and proceedings of meetings. These have usually been published as supplements, and their content should be added to the total published material.

A scientific or medical journal is just as good as its contributors are. If the *European Journal of Cancer* has a good standing in the scientific community, it is due to the quality of the writers who chose to send their manuscripts to our editorial office. But it is also due, in no small measure, to the selfless assistance of the many referees who have accepted to review submitted articles, suggest corrections and improvements and assisted the Editorial Board in making a decision on the acceptability of manuscripts. The list of referees is found in this issue. The Editorial Board is to be thanked also. Finally, the Technical Editor, Miss Leroy, and the Pergamon Press have been the important instruments of our continued expansion.

In the future, the *European Journal of Cancer* will maintain and confirm its policy of publishing papers, the results of research of good quality representing the best that modern medical science can offer.

H. J. TAGNON, M.D.

Alkalotic Disequilibrium in Patients with Solid Tumors: Rediscovery of an Old Finding

S. HARGUINDEY,* W. A. SPEIR,† R. C. KOLBECK,‡ and E. D. BRANSOME,*
*Divisions of *Endocrinology, †Respiratory Disease, and ‡Cardiology, Department of Medicine, the Medical College of Georgia, Augusta, Georgia, 30901, U.S.A.*

Abstract—*Acid-base equilibrium in two groups of cancer patients, one with newly diagnosed bronchogenic cancer and one with various solid tumors, was compared to that of a group of normal volunteers and a group of hospitalized patients with diverse diseases. A consistent tendency toward alkalosis was found in both groups of cancer patients. Similar findings reported in the literature of 40–70 years ago are discussed and the possible biochemical implications of these findings considered. It is our hope that this report of findings obtained with modern technology will encourage studies of the effects of alkalinity in the pathogenesis and progression of cancer.*

INTRODUCTION

THERE are a number of reports in the medical literature of the first half of the twentieth century concerning an apparent association of malignant tumors with systemic alkalosis [1–5]. Furthermore, a few controversial reports suggest the possibility of inhibition of cancer growth by induced systemic acidosis [5–7, 8]. In 1906, Moore and Wilson [4] noted an increase in blood alkalinity in a large series of cancer patients as measured by titration techniques. They suggested that alkalinity was a cause rather than an effect of cancer because of its presence early in the course of the neoplastic process and its persistence after surgical removal of malignant tumors. Similar findings were reported in 1929 by Reding and Slosse [5, 9] using colorimetric methods and once again the suggestion was made that alkalosis might play an etiologic role in cancer. Interpretation of such findings is difficult nowadays not only because of the relatively crude laboratory methodology employed, but also because there is little information on the clinical condition of the patients studied, and no assurance that other causes of alkalosis had been considered.

In addition to studies alluding to systemic alterations in acid-base balance, there have been a wide variety of observations over the years suggesting an association between abnormalities of local pH and the development of cancer. Some gastrointestinal tumors appear to be both preceded and accompanied by micro-environmental conditions in which the local acid-base equilibrium has been temporarily shifted in the alkaline direction. Deficiencies of gastric acid secretion are associated with carcinoma of the stomach and also with other tumors [3, 10]. In the more distal parts of the gastrointestinal tract, cancers have developed at sites at which local alkalinity may have been induced by an excessive elimination of cations [11, 12]. In the Plummer–Vinson syndrome, development of esophageal cancer may be prevented by the administration of iron and hydrochloric acid [13]; although it is not known if hydrochloric acid alone would have the same preventive effect.

The present study was undertaken using current methods of determining clinical acid-base status to determine whether a tendency to systemic alkalosis is present in patients with solid tumors.

MATERIAL AND METHODS

Patient selection

Arterial blood gas analyses (ABG) were performed on 18 normal volunteers and on

Accepted 25 November 1976.

*Current address: Roswell Park Memorial Institute, Department of Medicine A, 666 Elm Street, Buffalo, New York 14263, U.S.A.

126 patients, hospitalized between 1970 and 1975 at the Medical College of Georgia.

Group 1 consisted of 18 healthy volunteers—eleven females and seven males (ages 21–34, mean 26). These individuals were on no medication, with the exception of five women who were taking oral contraceptive preparations. In this group of volunteers we were unable to detect sex related variations in arterial blood gas values.

Group 2 consisted of 83 consecutive patients studied regarding ABG who were hospitalized with a variety of acute and chronic medical and surgical problems. This group was divided into three subgroups: A, B and C, according to their age on admission: 2A: range 19–34, mean 26; 2B: range 35–53, mean 46; 2C: range 54–77, mean 61. Subgroups A and C were of approximately the same mean age as Groups 1 and 3 respectively. No separation was made regarding sex, diagnosis, severity of the patient's disease process, or medications.

Group 3 consisted of 32 patients—30 males and two females (ages 45–74, mean 61) in whom a diagnosis of lung cancer was clinically suspected and subsequently confirmed. The cell types and frequency of these tumors were as follows: squamous 19, bronchogenic 11, alveolar 1 and clear cell 1. Two patients in this group (Nos. 15 and 18)* complained of chest pain. Three patients (Nos. 17, 20, 26) had severe obstructive ventilatory impairment.

Three patients (Nos. 6, 10, 12) had mild to moderate obstructive ventilatory impairment. One patient (No. 31) had severe restrictive ventilatory impairment. Two patients (Nos. 9 and 15) had mild restrictive ventilatory impairment. Three patients (Nos. 13, 18, 24) had mild to moderate obstructive and restrictive ventilatory impairment. One patient (No. 21) had lobar atelectasis. The predicted normal values for pulmonary function tests were calculated from standard nomograms [14].

Group 4 consisted of 11 hospitalized patients with histologically diagnosed solid tumors of different tissue origin: 7 female and 4 males (ages 25–73, mean 53). Nine of the eleven fell into the age range of Groups 2C and 3, (ie., 48–73). Hospitalization was at various times after the initial diagnosis (0–6 years, mean 2·3 years). The original sites of the tumors are given in the appendix. Only one patient (No. 9) had recently received a course of chemotherapy (vincristine and cyclophosphamide). None of the other patients were receiving drugs. Two patients (Nos. 6, 9) complained of mild to moderate intermittent pain during the time of the study. No other conditions known to affect acid base balance were detected in this group. All patients in Groups 3 and 4 were studied during a symptomatic period of their disease. None of the patients in the two cancer groups had clinical or laboratory evidence of abnormal liver or renal function, serum glucose values which were suggestive of diabetes mellitus, hypercalcemia, hypocalcemia, hyper- or hypokalemia. Cancer patients receiving diuretics, corticosteroids, antacids, or other drugs known to affect acid-base balance were excluded from the study. There was no evidence of clinical dehydration, a history of recent vomiting in any of these patients, or suggestion of abnormal hormonal production known to happen with some tumors.

Methods

The collection and analysis of arterial blood samples were performed identically in all groups. Samples were collected in 10 ml heparinized plastic syringes, immediately immersed in ice and transported to the blood gas laboratory. Analysis was performed within ½ hr after collection, using an Instrumentation Laboratories Blood Gas System, Model 213. The measured pH values were tabulated and corrected to a PCO_2 of 40 mm Hg using the Sigaard–Andersen nomogram [15, 16]. This "corrected" pH is designated as the "metabolic" (met.) pH. Hydrogen ion concentrations were calculated from the measured pH by standard methods. Calculated bicarbonate values are listed in Table 1.

Student's "*t*" test was used to determine the significance of differences of group means. Duncan's multiple range test was employed for non-parametric comparisons of groups.

RESULTS

Data from the arterial blood gas studies of Group 1, 2, 3 and 4 are summarized in Table 1. The *P* values listed for each variable in Table 1 represent the results of Student "*t*" test of the differences between the mean value of that group as compared to that for the normal volunteers (Group 1). Figure 1(a) graphically shows the distribution of measured arterial blood gas values between the normal volunteers and the two cancer groups. Figure 1(b) shows the distribution of measured arterial blood gas values between the two cancer groups and the inpatient population. It is worth noting that none of the 144 individuals studied had a

Means, standard deviations and *P* values between the different groups according to the Student's "*t*" test.

Table 3. Duncan's Multiple Range Test. Means of groups that are not significantly different at the 0·01 level are underlined. The non-parametric comparison shows that both groups of cancer patients (3 and 4) are significantly different from the volunteers (1) and hospital patients of different ages (2A, 2B, and 2C)

	1	2A	2B	2C	3	4
pH	7·41	7·44	7·43	7·43	7·48	7·48
Metabolic pH	7·39	7·39	7·41	7·42	7·44	7·46

measured pH below 7·35. Table 2 shows the means, standard deviations and P values among the different groups. Table 3 shows the statistical differences at the 0·01 level according to the Duncan's Multiple Range Test. The measured arterial pH, (hydrogen ion concentration) and the corrected "metabolic" pH in the two groups of patients with solid tumors show a significant shift in the alkaline direction when compared to a control group of normal volunteers and to three subgroups of hospitalized patients with diverse diseases.

Although the differences between the pH values of the older consecutively hospitalized patients of Group 2C and the cancer patients of Groups 3 and 4 do not seem as impressive as those seen with the volunteers or the younger patients, there still is a clear separation between groups. Both pH and metabolic pH values are significantly higher in Groups 3 and 4 according to the Student "t" test ($P < 0·001$ and $P < 0·01$) and Duncan's multiple range test ($P < 0·01$) than in the older inpatient population (2C) (see Tables 2 and 3).

DISCUSSION

Our findings using modern techniques are in agreement with observations made by other investigators in decades past [4, 5, 9] and suggest that there is an unexplained tendency toward alkalosis in cancer patients with solid tumors which have not yet progressed to the terminal stage.

It is well known that pain, fear and anxiety may be accompanied by both acute and chronic hyperventilation with an associated respiratory alkalosis. Metabolic alkalosis in cancer patients has also been reported to be directly related to the severity of pain [17]. Neither of these situations seems to pertain to our study. No significant differences in arterial

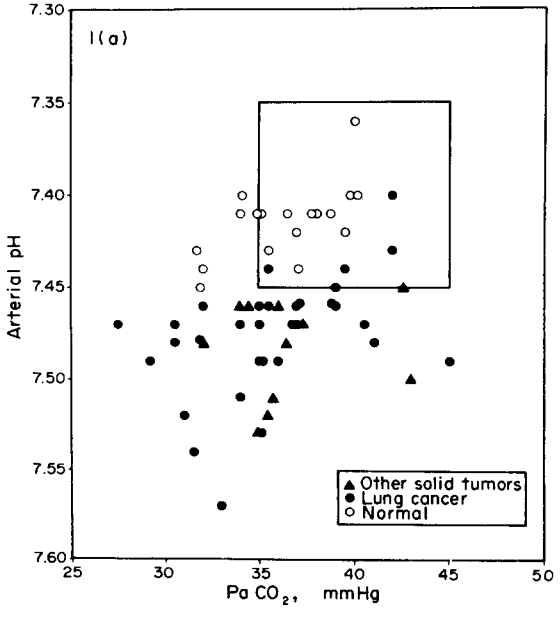

Fig. 1(a). Distribution of measured pH and $PaCO_2$ values in solid tumor groups (3 and 4) and normal volunteers (1). The smaller square indicates the normal range for arterial pH and $PaCO_2$.

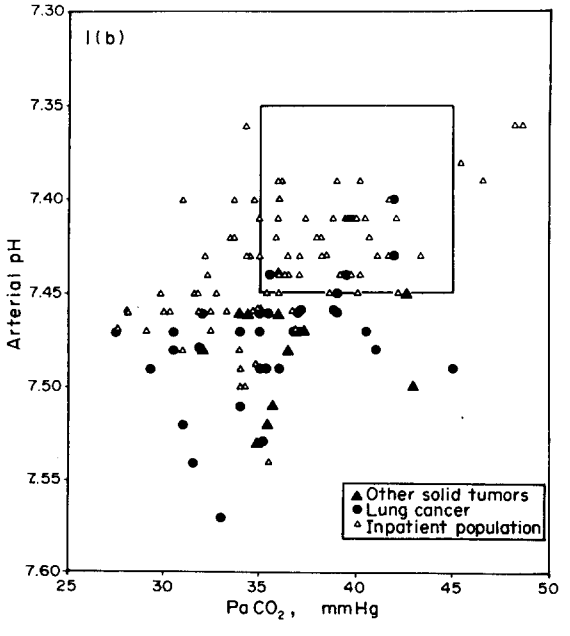

Fig. 1(b). Distribution of measured pH and $PaCO_2$ values in cancer groups (3 and 4) vs the consecutive inpatient population (group 2).

$PaCO_2$ exist between the cancer groups and the older subgroups of inpatients. Indeed a significantly lower mean value for arterial PCO_2 was found in the youngest subgroup of patients.

In addition to the increased rates of anaerobic and aerobic glycolysis and accumulation of lactic acid, a tendency toward decreased glucose levels in the venous effluent of tumors has been reported in association with cancer by some investigators [18–22]. These same three characteristics: an accumulation of lactic acid, increased glycolysis, and decreased glucose levels, can be produced experimentally by increasing the alkalinity of the blood [23–26]. Huckabee has shown in humans that hypoxia is not the only circumstance in which lactate production is increased [27]. He and others have documented that an elevation of pH, of *either* respiratory or metabolic origin accelerates the process of glycolysis and the formation of lactate [27–29]. This alkalosis mediated acceleration of glycolysis has been shown to be induced principally through stimulation of the phosphofructokinase enzyme reaction [29, 30]. Therefore, in many ways alkalosis, independent of the cause, seems to act on the physiology of the organism in a manner similar to hypoxia. It can thus be concluded that many of the abnormal metabolic characteristics of malignant cells and tissues can be induced in normal cells by stimulus of a higher than normal pH.

Reding and Slosse in 1929 [5, 9] reported that a tendency toward alkalinity in the blood exists at the time of the first clinical manifestations of cancer. Our findings, particularly in the lung cancer patients, Group 3, lend support to their contention.

The basis for the association between alkalosis and cancer from the time of its initial clinical manifestations has not been defined, nor obviously has the question of cause and effect been resolved. However, a possible primary role of acidosis in stimulating the immune response has been advanced [31, 32], and a recent report has described tumor inhibition following the induction of systemic acidosis in different animal malignancies [8]. Therefore, the possibility that local and systemic alterations in acid-base balance in the alkalotic direction play an important role in the genesis and/or propagation of cancer remains not only a viable but a vital issue at the present time.

Acknowledgement—The authors wish to express their appreciation to Dr. Edward S. Henderson, Chief of Medicine A, Roswell Park Memorial Institute, for useful advice and corrections of the manuscript as well as to the personnel of the Pulmonary Blood Gas Laboratory, Eugene Talmadge Memorial Hospital, Medical College of Georgia, for their technical assistance; R. Harp and M. McRae for their help with the statistical data; and to J. Campbell, J. Kelley and W. Kurk for their excellent secretarial help.

Insulin-induced Growth Hormone Response in Patients with Uterus Carcinoma. I. Endometrial Carcinoma*

S. MADAJEWICZ†, J. HARUPPA and J. KAMINSKA
Departments of Gynecology and Nuclear Medicine, Institute of Oncology, Warsaw, Poland

Abstract—*The insulin-induced GH responses were studied in 37 patients with endometrial carcinoma and 11 healthy obese women. Mean GH concentrations were significantly lower in the cancer patients. Quarter of patients showed abnormally low pituitary GH release. The GH responses in obese patients with endometrial carcinoma were significantly lower than those in thin.*

INTRODUCTION

GROWTH hormone has been shown to result in tumor development in laboratory animals [1, 2]; and there has also been some evidence that tumors develop more frequently in patients with acromegaly [3]. Benjamin found in patients with endometrial cancer increased GH secretion after insulin administration as well as paradoxical rises in its concentration following a glucose load [4, 5]. This paper represents the studies on disturbances in hypothalamo-pituitary axis regulation which are conducted in patients with endometrial carcinoma.

MATERIAL AND METHODS

Thirty-seven patients with endometrial cancer (e.c.) and 11 healthy obese women (h.o.w.) were studied. All patients had histologically proven carcinoma and were in good general condition. Patients with clinical diabetes were excluded.

In order to make our conclusions more precise, patients were divided due to stage of disease and weight. Out of patients with e.c 28 were in stage I and 9 in more advanced stages.

"Desirable" body weight was obtained from the Tables of Metropolitan Life Insurance Company [6]. For a given height the mean of the range for "medium frame" was considered 100% and the criterion of obesity was an actual weight greater than 115%. Twenty-three patients with e.c. were obese. The results of insulin-induced GH responses in obese patients with e.c. were compared to those in h.o.w. Because of J. Roth report that there is no difference in GH responsiveness to stimulation tests between the obese and thin [7], we considered our group of h.o.w. as a control group to thin patients with e.c. as well.

After overnight fasting, patients and control women each received intravenously 0·1 units of regular insulin/kg b.w. Blood samples for glucose and GH concentrations were obtained prior to and at the 30, 45, 60, 90, 120 and 180 min after the insulin injection. All patients and controls experienced at least a 50% fall in serum glucose concentrations with concomitant symptoms of neuroglycopaemia. Serum GH concentrations were measured by means of CEA-IRE-Sorin kit, and plasma glucose levels by the method of Asatoor–King [8].

Student-*t* test was used for statistical analysis.

RESULTS

Serum GH concentrations after the insulin stimulation are shown in Table 1 and in Fig. 1. Mean serum GH level rose from 1·1 ± 0·26 ng/ml (mean ± S.E.) to 14·4 ± 2·90 ng/ml in whole group of patients with e.c., and

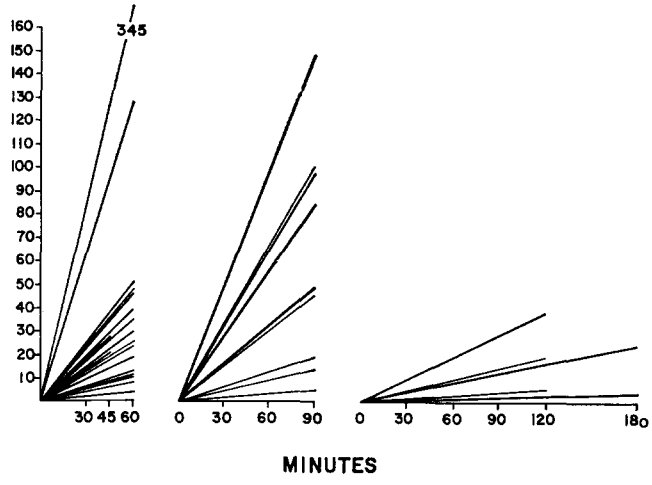

Fig. 2. *Multiplicity of maximum GH increments plotted against time in patients with endometrial carcinoma.*

from 0·9 ± 0·34 ng/ml to 32·4 ± 5·33 ng/ml in the controls. Mean GH concentrations following the insulin stimulation were significantly lower in patients with e.c. than in the controls. Nine patients (25% of total) showed less than 5 ng/ml increment of GH concentration; these patients were obese.

When responses to insulin stimulation were expressed as maximum multiplicity over the basal value of GH, 8 patients showed values below 10. Nine patients showed rise in GH concentrations at the 90th min; 5 of them were obese. Five patients showed rise in GH concentrations only after 120 min, and 3 did not any; all of them but one were obese (Fig. 2). Seventeen patients had the peak responses at or after the 90th min while only 3 out of 11 h.o.w. showed the peak at the 90th min and 2 had the value of multiplicity of increment less than 10 (Fig. 3).

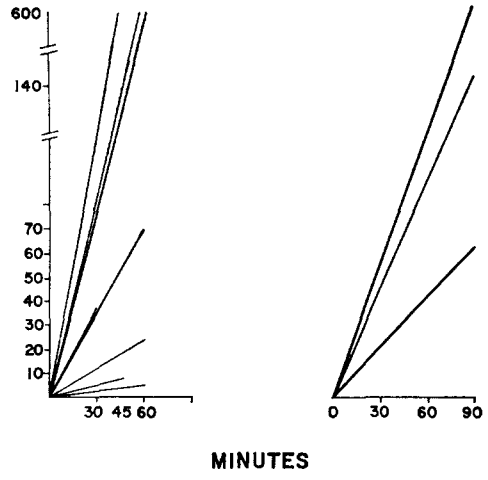

Fig. 3. Multiplicity of maximum GH increments plotted against time in control group.

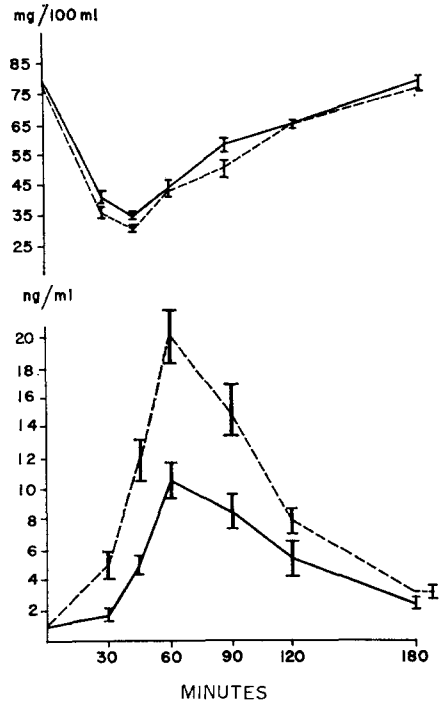

Fig. 4. Mean serum GH and glucose concentration following the insulin stimulation in thin (----) and obese (———) patients with endometrial carcinoma.

The GH responses to hypoglycemia were significantly lower in obese patients than in the thin (Table 1 and Fig. 4). We did not find any influence of stage of disease on the results.

DISCUSSION

Many authors have been unable to document any significant difference in GH release in men which could be related to age or sex [9, 10]. Johansen has given evidence that there is a decrease in the metabolic clearance rate of GH in diabetics, rather than increase in secretion [11]. Obesity decreases GH responsiveness to stimulation tests [12]; but some reports notify that there is no difference between the obese and thin [7]. We have found that survival rate after the cobalt-therapy was higher in obese patients with e.c. than in the thin ones. Does this fact depend upon the different hormonal environment?

We found serum GH concentrations after insulin injection significantly lower in patients with e.c. than in h.o.w.; this observation is in variance to that of Benjamin [4]. Eight out of 37 patients with e.c. reached a peak of GH response at the 120th min or later, and 5 of them had abnormally low GH responses (less than 5 ng/ml). It means that 13% of patients had GH deficiency and other 9% showed delayed pituitary release. All of them but one were obese. It might be useful to measure not only serum GH concentrations but also the amount or capacity of tissue receptors for this hormone. It is conceivable that despite of normal GH level the capacity of GH receptors may be increased as in some cases of breast cancer [13]. At the present time the role played by GH in endometrial carcinoma remains unclear.

Acknowledgements—The authors wish to thank Prof. L. Tarlowska, M.D. and Dr. J. Szymendera for their encouragement and helpful discussion. We are also grateful to Dr. J. Nauman for his cooperation and providing the control group.

Prognosis in Inoperable Stage III Carcinoma of the Breast

R. D. RUBENS,* P. ARMITAGE,† P. J. WINTER,‡ D. TONG‡ and J. L. HAYWARD*

**Imperial Cancer Research Fund, Breast Cancer Unit, Guy's Hospital, London. SE1 9RT, Great Britain*

†Department of Biomathematics, Oxford University, Pusey Street, Oxford, OX1 2JZ, Great Britain

‡Department of Radiotherapy, Guy's Hospital, London, SE1 9RT, Great Britain

Abstract—*One hundred and eighty-four patients with inoperable Stage III breast cancer presenting to the Guy's Hospital Breast Unit between* 1961–1973 *were treated initially by radiotherapy alone. The response rate was* 60% *but duration of response and survival were short. Seventy-two per cent of patients did not have prolonged control of local disease and* 63% *developed distant metastases.*

The association between certain prognostic variables and response to radiotherapy, subsequent development of metastases and survival was analysed statistically. The duration of response to radiotherapy showed no significant associations with any prognostic variable. Subsequent distant metastases occurred less often in patients responding to radiotherapy, having a subsequent mastectomy or if the duration of symptoms before presentation was long, but more frequently if the primary tumours were diffuse. Survival was shorter in patients who were early postmenopausal, had a short duration of symptoms or had diffuse primary tumours. Improved survival was associated with a good response to radiotherapy and, unexpectedly, with deep fixation of the primary tumour. Prognosis was not significantly associated with size of primary tumour or involvement of skin or lymph nodes. The effectiveness of combining variables in predicting prognosis is described.

A further group of 30 *patients, unsuitable for radiotherapy were treated primarily by additive endocrine therapy and had a median survival of* 14 *months.*

The clinical course of Stage III breast cancer is variable, there being two extremes: a slowly-growing, non-metastasising form and a more common, rapidly-growing, metastasising form. For prognosis to be improved, systemic therapy as part of the primary management of this disease may be necessary. Prognostic variables should be considered in the design and assessment of future clinical trials.

INTRODUCTION

THE FACTORS contributing to the inoperability of locally advanced breast carcinoma (Stage III) are large size of the primary tumour, involvement of the overlying skin, satellite skin nodules, peau d'orange, attachment to deep structures, matting or fixation of axillary lymph nodes and involvement of supraclavicular lymph nodes. Although these factors may not necessarily render operative removal technically impossible, the results of surgery for this type of disease are poor. There is a high incidence of relapse and survival is short [1], and the preferred conventional treatment for this type of breast cancer is radiotherapy. This usually gives satisfactory control of local disease in adequate dosage [2], but survival is still poor (median less than three years), and most patients relapse with distant metastases [3]. Seventeen per cent of patients with localised breast cancer presenting to the Guy's Hospital Breast Unit have inoperable disease.

In this paper we describe the clinical course of patients with locally advanced, inoperable breast cancer, classified as Stage III by the TNM classification [4], analyse factors which affect prognosis and speculate on the role of primary systemic treatment in this condition.

Accepted 1 December 1976.

MATERIAL AND METHODS

Radiotherapy

One hundred and eighty-four patients with Stage III breast cancer presenting at the Guy's

Hospital Breast Unit during the 13-year period 1961–1973 who were treated primarily by radiotherapy have been studied. Stage III is defined using the TNM classification [4] as: either $T_{3,4}$ any N, M_0 or any T, $N_{2,3}$, M_0. Included are 13 patients with T_{3a}, $N_{0,1}$, M_0 tumours who would normally have been treated by radical mastectomy at this Unit, but, because they were unfit for surgery, were treated primarily by radiotherapy. Each patient received 3600–4000 rad in 3–3½ weeks by tangential fields to the chest wall by a 4 MeV linear accelerator with skin bolus (15 fractions) followed by 3000 rad in two weeks to the ipsilateral local gland fields at 250 kV.

Before radiotherapy, all lesions in the breast and regional lymph glands were measured. These were used as a baseline on which to assess the response to radiotherapy. Full physical examination and chest and skeletal radiography was done to exclude the presence of detectable distant metastases to confirm the M_0 status.

The therapeutic response to radiotherapy was assessed as follows:

1. Complete regression (CR): complete disappearance of all visible and palpable disease.
2. Partial regression (PR): a decrease of 50% or more in the sum of the products of the largest perpendicular axes of the individual lesions.
3. No change (NC): less than 50% decrease or a less than 25% increase in the sum of the products of the largest perpendicular axes of the individual lesions.
4. Progressive disease (PD): a greater than 25% increase in the sum of the products of the largest perpendicular axes of the individual lesions, and/or the appearance of new local lesions or distant metastases.

The duration of response (for CR, PR and NC) is the time from the date of commencement of radiotherapy to the date of documentation of progressive disease. When progression of disease occurred after radiotherapy, patients received subsequent treatment as appropriate, including palliative simple mastectomy, further radiotherapy, oophorectomy, androgens, oestrogens, hypophysectomy, corticosteroids and cytotoxic chemotherapy. Sites of subsequent distant metastases were documented and the survival of patients from the time of diagnosis of Stage III breast cancer was recorded. Minimum follow-up for this series is 28 months.

Certain factors ("prognostic variables") were studied to determine whether significant associations existed between them and the therapeutic response to radiotherapy, development of distant metastases and survival as follows: (a) The year of first presentation, diagnosis and primary treatment (always the same calendar year); (b) Menopausal status at diagnosis (premenopausal, including those having a menstrual period in the previous year; postmenopausal 1–5 years, 6–10 years, >10 years); (c) Duration of symptoms; (d) Size of primary tumour (largest dimension); (e) Skin involvement (fungation, infiltration of skin overlying primary, satellite skin nodules over the breast, peau d'orange); (f) Fixation to deep structures; (g) Node involvement ($N_{0,1,2,3}$ according to the TNM classification [4]. The association between the response to radiotherapy and subsequent palliative mastectomy (in 25 patients) with the eventual development of distant metastases and survival was also analysed.

Statistical analyses

The aim of the statistical analyses has been to assess the extent to which the "response variables" (response to radiotherapy, development of metastases and survival) were associated with various factors or "prognostic variables". The method of analysis depended on the nature of the variable concerned. The development of metastases at any site was taken as a binary variable and analysed by logistic regression. In some analyses of response to radiotherapy this was also treated as a binary variable by counting CR or PR as a positive response; these analyses also used logistic regression. Other analyses of response to radiotherapy retained the four categories and used an extension of logistic regression for polytomous variables. Survival data was of the usual "censored" type, with some complete measurements of survival for patients who had died, and other incomplete observations for patients still alive. Cox's [5] method of analysis was used to assess the association with prognostic variables. The survival experience of the whole group, and of various subgroups, was analysed by standard life-table methods.

In the various analyses relating response variables to prognostic variables, various alternative combinations of the latter were used. Also, alternative methods of specifying variables were used: for instance, the year of the study was used both as a quantitative variable to see whether any smooth trend was apparent, and as a qualititative variable by using seven

time periods and distinguishing between them by dummy variables.

In statements of the results of significance tests $\chi^2_{(f)}$ means χ^2 on f degrees of freedom.

Endocrine therapy

A small group of 30 patients with Stage III carcinoma of the breast who presented during the same period, were unsuitable for radiotherapy, either because of old age and infirmity or because the disease was so extensive as to render local treatment technically impracticable. They were treated initially by additive hormones with either oestrogens (23 patients) or androgens (7 patients). The survival of these patients has also been analysed for comparison with those treated by radiotherapy, but, because of the small number, prognostic variables have not been studied.

RESULTS

Patients treated by radiotherapy

Table 1 shows the principal characteristics of these patients, separately for each of three time periods of 4–5 years. The distributions of the various characteristics did not change greatly during the 13 years, the most noteworthy change being perhaps a lengthening of the duration of symptoms.

3	6 (15)	12 (18)	6 (8)	24 (13)

Response to radiotherapy

Table 2 shows the number and duration of responses for patients in each of the response categories; the poorer responses being associated with lower durations. Of the 24 patients with PD, 17 failed to have regression of disease locally; the remaining 7 patients developing distant metastases before the completion of radiotherapy. A further 115 patients (in the CR, PR and NC categories) subsequently relapsed in the irradiated field. Thus a total of 132 patients (72%) failed to have prolonged control of local disease.

Table 2. Response to radiotherapy

Response	Number of patients (%)	Duration (months) Mean	Range
CR	34 (19)	17.26	3–56
PR	73 (41)	12.48	2–43
NC	49 (27)	7.59	2–18
PD	24 (13)	0.00	0–0
	180 (100)		
Incomplete information	4		
Total	184		

Table 4. Subsequent distant metastases: relation to response to radiotherapy

Response to radiotherapy	Number of patients With metastases	Without metastases
CR+PR	64	44
NC+PD	56	17
Unknown	1	2

$\chi^2_{(1)} = 5.2$; $P = 0.02$.

Subsequent distant metastases in patients treated by radiotherapy

Table 3 shows the numbers and proportions of patients who developed subsequent metastases at various sites.

Table 4 shows that the incidence of subsequent metastases at any site is lower for patients showing a response to radiotherapy than for those not responding ($\chi^2_{(1)} = 5.2$; $P = 0.02$) and that it is lower ($\chi^2_{(1)} = 3.2$; $P = 0.07$), although not significantly so, for those who had a palliative mastectomy than for those who did not (Table 5).

A logistic regression shows that the incidence of subsequent metastasis decreases with the duration of symptoms, the association being highly significant ($\chi^2_{(1)} = 9.1$; $P = 0.003$).

Table 3. Incidence of metastases at distant sites developing in patients treated by radiotherapy

	Bone	Pleura	Lung	Liver	Peritoneum (ascites)	Brain	Other	Any sites
Number	61	43	27	35	13	9	3	121
%	33	23	15	19	7	5	2	63

Analyses of response, either as a binary variable or as a 4-level variable, showed no significant overall association with prognostic variables. In the latter analysis, though, some of the individual regression coefficients reached significance, suggesting that more than 10 years postmenopausal, and a diffuse tumour were each detrimental.

The proportion of responses showed no clear trend during the 13-year period, but there were curious fluctuations from year to year; for example 13 responses in 27 patients in 1969, 16 in 16 in 1970 and 18 in 24 in 1971.

The duration of response, analysed by Cox's method, showed no significant associations with any prognostic variable.

Table 6 illustrates this association. When several prognostic variables were introduced simultaneously the effect of duration of symptoms remained significant ($\chi^2_{(1)} = 6.3$; $P = 0.01$), and a diffuse tumour was associated with a higher risk of subsequent metastases ($\chi^2_{(1)} = 5.2$; $P = 0.02$); the effect of year was not quite significant ($P = 0.08$), but suggested a reduction in the chance of metastases during the 13-year period. However, this may just reflect the shorter follow-up periods for patients presenting in more recent years.

Survival after radiotherapy

The survival pattern of the whole series, calculated by life-table methods, is shown in

Table 5. *Subsequent distant metastases: relation to palliative simple mastectomy after radiotherapy*

	Number of patients	
	With metastases	Without metastases
Palliative mastectomy	12	13
No mastectomy	109	50

$\chi^2_{(1)} = 3.2$; $P = 0.07$.

Table 6. *Subsequent distant metastases: relation to duration of symptoms*

	Number of patients	
	With metastases	Without metastases
Duration of symptoms		
Less than 6 months	80	39
6 or more months	41	33
Unknown	0	1

$\chi^2_{(1)} = 9.1$; $P = 0.003$.

Fig. 1. The median survival time after radiotherapy is estimated as 25 months. Twenty-eight per cent of patients survived more than 3 years, and 13% more than 5 years.

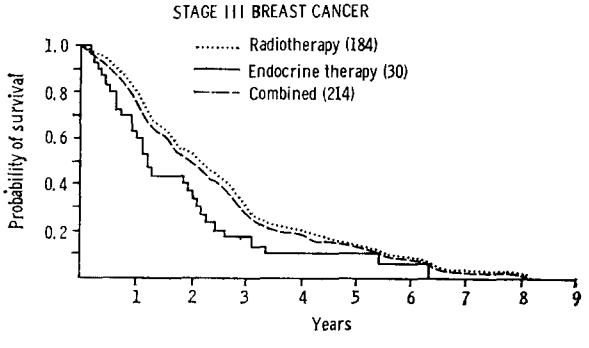

Fig. 1. *Survival curves for* 184 *patients treated by radiotherapy,* 30 *patients treated by endocrine therapy and the combined group* (214 *patients*).

The results of a Cox analysis, using five prognostic variables, are summarized in Table 7. The regression coefficients, shown in that table with their standard errors, measure the extent to which the natural logarithm of the force of mortality (the instantaneous death rate amongst those who have survived any given time) is affected by changes of one unit in each of the prognostic variables. The variables shown in Table 7 were chosen after a series of preliminary analyses using each of these factors, and several others, individually; those shown in Table 7 were the factors which, when used alone, were significantly associated with survival.

Table 7. *Analysis of survival by Cox's method*

Prognostic variable	Regression coefficient ± standard error
Year of diagnosis	−0.095 ± 0.027
Menopausal status (if 1–5 yrs postmenopausal)	0.41 ± 0·21
Log. duration of symptoms	−0.103 ± 0.074
Tumour (if diffuse)	0.44 ± 0.32
Deep fixation	−0.51 ± 0.18

The joint effect of all the variables shown in Table 7 is highly significant ($\chi^2_{(5)} = 35.7$; $P < 0.001$). Each variable shows a separate effect greater than its standard error, those for year and deep fixation being highly significant. The mortality rate declined during the 13-year period in a way that cannot be attributed to changes in other known prognostic variables; deep fixation is associated with *better* prognosis. Of the other three, less significant, variables, women 1–5 years postmenopausal had a rather shorter survival, and survival was longer for patients with a longer duration of symptoms and shorter for those with diffuse tumours.

Subsequent analyses, not reported in detail here, showed that the use of further information about the size of tumour, nodal grading and skin fixation made no appreciable difference to the prognosis, as judged by the χ^2 value. The addition of response to radiotherapy and of palliative mastectomy each made a highly significant improvement in prognostic effectiveness (survival being longer for patients showing positive response and for those having palliative mastectomy), but of course these are two variables which are not measurable at the start of treatment.

To confirm the effectiveness of prognosis based on the variables listed in Table 7, the patients were divided into five subgroups of approximately equal size, according to the value of the expression which predicts the mortality rate by appropriate weighting of these variables. The life-table for each subgroup was then calculated. The results are

shown in Fig. 2. There is a fairly clear gradation between the results, with groups 2 and 3 less clearly distinguished than the others. The contrast between the extreme groups corresponds to an approximate doubling of survival between groups 5 and 1.

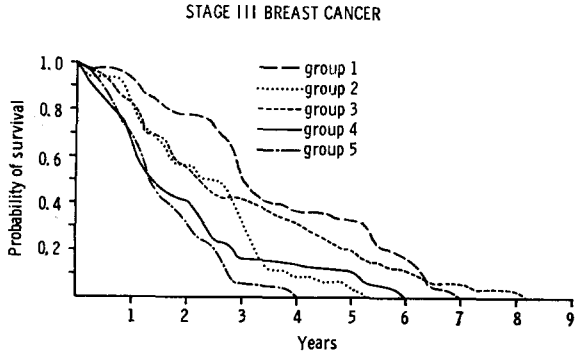

Fig. 2. Survival curves for five subgroups of patients treated by radiotherapy, distinguished by prognostic factors. Group 1 has the lowest risk, group 5 the highest.

This division into groups is influenced considerably by the effect of the "year" variable, which implies that prognosis is affected by unidentified factors which change gradually over the whole period.

Survival after endocrine therapy

The survival pattern after endocrine therapy calculated by life-table analysis is shown in Fig. 1; survival is on the whole worse than for the patients treated by radiotherapy.

The 23 patients treated by oestrogens were elderly (median age 71 years; range 56–90); 18 (78%) were over 70 and 10 (43%) were over 80, only one was under 60. The median survival for this group was 14 months, but 5 patients (22%) survived 3 years and 3 of them (13%) 5 years.

The 7 patients treated by androgens (median age 54 years, range 47–79) also had a median survival of 14 months, but none survived more than 29 months.

Figure 1 also shows the life-table survival for the whole group of 214 patients treated by either radiotherapy or endocrine therapy.

DISCUSSION

A proportion of patients with localized breast cancer (17% of those referred to this Unit) have inoperable disease, the preferred treatment being radiotherapy. Although the initial response rate to this form of treatment is high, more than half the patients have progressive disease within 18 months. In this study 72% of patients had progressive local disease and 63% had developed evidence of distant metastases within the minimum follow-up period of 28 months; survival was short (median 25 months). The radiotherapy in the doses used here, can, therefore, only be considered palliative, although similar results were reported by Zucali *et al.* [3] using considerably higher radiation doses. There was no definite association between the response to radiotherapy and any of the prognostic variables identifiable at the time of presentation. Distant metastases occurring after radiotherapy were less in patients having a good response (CR + PR) to radiotherapy (Table 4), a subsequent palliative mastectomy because local primary disease was not controlled (Table 5), and if the duration of symptoms before presentation had been long (Table 6). Diffuse primary tumours were associated with a high incidence of subsequent distant metastases.

Significant correlations were found between survival and certain of the prognostic variables. In particular, survival was poor in patients whose last menstrual period had occurred 1–5 years before presentation, had a short duration of symptoms before presentation (less than six months), and with diffuse primary tumours. Unexpectedly, deep fixation of the primary tumour was associated with improved survival and the explanation for this is obscure. Response to radiotherapy, (CR or PR) was also associated with better survival. The mortality rate throughout the 13-year period of the study showed a steady decline which cannot be attributed to changes in the other known prognostic variables. This implies that other unknown changes occurred during this period and cautions against the use of historical controls in therapeutic trials. The effectiveness of combining these variables has been clearly illustrated (Fig. 2). Although large size of primary tumour and extensive regional nodal involvement have been shown to be adversely associated with survival in other studies [3, 6], this was not found in this study, nor was there any significant correlation between skin involvement and prognosis.

This study shows that the clinical course of Stage III breast cancer is highly variable. At one extreme there is a slow growing, non-metastasizing form in which patients have a long duration of symptoms before presentation; at the other extreme is a more common, rapidly growing metastasizing form in which patients have a short history.

The small group of patients in this series treated primarily by additive hormone therapy

had a poorer survival than those treated by radiotherapy. This was to be expected as these patients were selected for systemic treatment because either their disease was too extensive to be treated locally or they were old and infirm. However, it is clear that the majority of patients with Stage III breast cancer eventually develop distant metastases which are present in an occult form at the time of presentation and that more radical local therapy does not improve the prognosis. It is, therefore, pertinent to consider the possibility of incorporating systemic therapy into the primary management of Stage III disease. Breast cancer is the one common tumour which is frequently sensitive to cytotoxic chemotherapy and study of the use of this form of treatment in Stage III disease has begun [7]. The outlook in Stage III breast cancer may well improve by combining local and systemic therapies, but the true place of any treatment (surgery, radiotherapy, chemotherapy, endocrine therapy, immunotherapy) will be known only after critical evaluation by controlled clinical trials. Information gained from the prognostic variables discussed here should be considered in both the design and assessment of such trials.

Effect of Progesterone and Estrogen on DNA Synthesis of Pregnancy-Dependent Mammary Tumors in GR/A Mice*

REIKO YANAI and HIROSHI NAGASAWA

Pharmacology Division, National Cancer Center Research Institute, Tsukiji 5-1-1, *Chuo-ku, Tokyo* 104, *Japan*

Abstract—*The effects of progesterone and estrogen on the growth and DNA synthesis of pregnancy dependent mammary tumors of GR/A mice were studied. One group of mice with palpable mammary tumors received daily subcutaneous injections of* 3*mg progesterone plus* 0.5*μg estradiol benzoate in combination during days* 14 *and* 19 *of pregnancy and ovariectomized bilaterally on day* 15. *Another group of mice was given only the unilateral ovariectomy on day* 15. *These treatments resulted in the increase in mammary tumor size and the prevention of decrease in DNA synthesis (estimated by the* in vivo *incorporation of* (^3H) *thymidine) of normal and neoplastic mammary glands on day* 19 *of pregnancy. On the other hand, mammary tumor size changed little and DNA synthesis of either gland was significantly decreased in ovariectomized mice receiving* 2*mg progesterone alone. Three mg progesterone increased DNA synthesis of mammary tumors, but not of normal glands as compared to* 2*mg progesterone. These results indicate that both progesterone and estrogen are essential for the growth of pregnancy-dependent mammary tumors and that there are some differences in responsiveness to progesterone between normal glands and pregnancy-dependent mammary tumors.*

INTRODUCTION

IN A PREVIOUS paper [1], progesterone was found to prevent the decrease in DNA synthesis of pregnancy-dependent mammary tumors after parturition in GR/A mice. On the other hand, estrogen had no such effect and the administration of estradiol benzoate in combination with progesterone did not stimulate the effect of progesterone on DNA synthesis. These findings indicate the importance of progesterone on the growth of this type of tumors during pregnancy. However, these results cannot exclude the possible participation of estrogen, since intact mice were used in the experiment [1] and therefore progesterone acted on the tumors in the presence of levels of endogenous estrogen in the circulation.

The present study was carried out to clarify more completely the relation between progesterone and estrogen on the growth of pregnancy-dependent mammary tumors in GR/A mice.

MATERIAL AND METHODS

Female mice of the highly inbred GR/A strain were mated with males at 60–70 days of age and were subjected to force-breeding without subsequent lactation. Only the animals with palpable mammary tumors during the 2nd and the 4th pregnancies were used. The day when the vaginal plug was found was designated as day 1 of pregnancy. Mice were divided into five groups; Group I received no treatment and served as the control. Groups II, III and IV were given daily subcutaneous injections of 2mg progesterone, 3mg progesterone and 3mg progesterone plus 0.5μg estradiol benzoate in combination, respectively, during days 14 and 19 of pregnancy and ovariectomized bilaterally on day 15. Group V received only unilateral

ovariectomy on day 15. On the afternoon (about 3:00 p.m.) of day 19 of pregnancy, each mouse was given a single intraperitoneal injection of 50μCi [^{3}H] thymidine (5Ci/mmole; The Radiochemical Centre, Amersham, England) and was killed 2 hr later. [^{3}H]thymidine incorporated into DNA of normal and neoplastic mammary tissues was determined as described previously [2] as the index of DNA synthesis.

Number of mammary tumors and mammary tumor size expressed in terms of the geometric mean of the major two diameters were recorded on days 15 and 19 of pregnancy.

RESULTS

Changes in mammary tumor size during days 15 and 19 of pregnancy in each group is presented in Table 1. The average tumor sizes significantly increased in mice ovariectomized and injected with progesterone plus estrogen (Group IV) and mice ovariectomized unilaterally (Group V) ($P<0.01$). On the other hand, no further growth of tumors was observed in mice ovariectomized and injected with either 2 or 3mg progesterone singly (Groups II or III).

There was slight difference between groups in the number of fetuses at autopsy and the number of tumors changed little during days 15 and 19 of pregnancy in all groups.

Figure 1 shows [^{3}H]thymidine incorporated into DNA of normal and neoplastic mammary glands in each group. [^{3}H]thymidine incorporation was significantly lower in Groups II and III than in Group I not only in normal glands but also in tumors ($P<0.01$). Groups IV and V were at the levels similar to Group I and were significantly higher than Groups II and III in both measures ($P<0.01$). The incorporation of [^{3}H]thymidine into mammary tumors was significantly increased by the injection of 3mg progesterone as compared to the injection of 2mg progesterone, but this difference was not observed in normal glands.

The correlations in DNA synthesis between normal and neoplastic mammary glands were statistically highly significant in Groups I, IV and V ($P<0.01$).

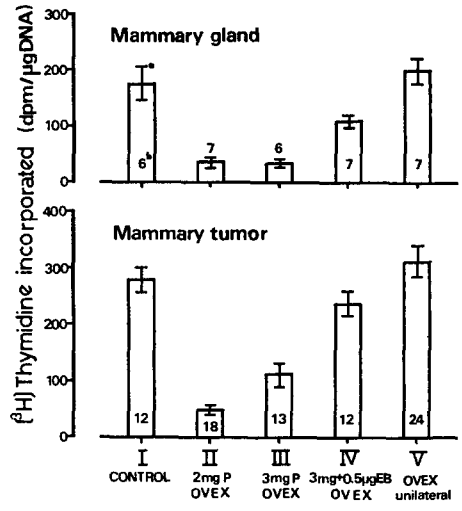

Fig. 1. *The* in vivo *incorporation of* [^{3}H] *thymidine into DNA of normal and neoplastic mammary glands on day* 19 *of pregnancy in each group. See Table* 1 *for details of treatments. Ovex: ovariectomy, P: progesterone, EB: estradiol benzoate. (a) Mean ± S.E.M. (b) Number of estimates. Significance of differences between groups are, Mammary gland:* I/II,III; II,III/IV,V; IV/V: $P<0.01$. *Mammary tumor:* I/II,III; II/III,IV,V; III/IV,V: $P<0.01$.

DISCUSSION

In the present study, DNA synthesis of normal and neoplastic mammary glands at the end of

§Means ± S.E.M.

pregnancy decreased significantly after bilateral ovariectomy despite the supplement with 2mg progesterone. Increase in the daily dose of progesterone to 3mg caused a significant increase in DNA synthesis in mammary tumors, but the values were still much lower than those of the controls. On the other hand, the administration of the same dose of progesterone (3mg) in combination with estrogen completely remedied the effect of ovariectomy on DNA synthesis, and raised levels to those of the controls. In accord with these results, progesterone combined with estrogen caused significant increases in mammary tumor size during the experiment as compared to the controls. In our previous study, estrogen was found to have no effect on DNA synthesis of mammary tumors in intact mice after parturition [1].

Sluyser and Van Nie [3] reported that the growth of transplanted mammary tumors elicited by progesterone and estrogen in castrated GR/A mice was stimulated by the treatment with progesterone and estrogen in combination, but it was much less sufficient by either hormone alone. These findings clearly indicate the permissive, but essential synergism of estrogen on progesterone in stimulating the growth of pregnancy-dependent or hormone-responsive mammary tumors in mice. There are indications that the synthesis of progesterone receptor in some tissues depends upon the presence of estrogen [4, 5]. Horwitz *et al.* [6] reported that 56% of human breast tumors which contained estrogen receptors also contained progesterone receptors, but progesterone receptors were absent in tumors which were devoid of estrogen receptors. Furthermore, Trams and Henning [7] found in carcinogen-induced rat mammary tumors that progesterone receptor concentration decreased very rapidly after ovariectomy. These data appear to suggest that in pregnancy dependent mammary tumors and in hormone-responsive mammary tumors estrogen induces the synthesis of progesterone receptor, thereby increasing the susceptibility of mammary tumor cells to progesterone.

Daily injections with 3mg progesterone to bilaterally ovariectomized mice enhanced DNA synthesis of mammary tumors, but not of normal glands. Addition of estrogen to progesterone increased significantly DNA synthesis in both normal and neoplastic glands. However, mice receiving progesterone plus estrogen had still significantly lower DNA synthesis in normal mammary glands than unilaterally ovariectomized mice, whereas there was no significant difference between these groups in the synthesis of mammary tumors. These observations have demonstrated the higher susceptibility to hormones in pregnancy-dependent mammary tumors than in normal glands.

Changes in mammary tumor size and changes in DNA synthesis in mammary tumors and normal glands were affected little by unilateral ovariectomy. This shows that the amount of ovarian hormones in the circulation is more than sufficient to stimulate the growth of normal or neoplastic glands.

Significant and positive correlations in DNA synthesis between normal and pregnancy-dependent mammary tumors in groups in which DNA synthesis of both glands was conspicuous support our previous hypothesis that this type of mammary tumors still retain more or less the intrinsic biological characteristics of normal mammary glands [1].

Melphalan vs Polymelphalanum in Ovarian Cancer Patients Resistant to Cyclophosphamide: A Tentative Statistical Approach to Balance Risks and Benefits*

L. MORASCA,† M. RECCHIA,† E. GRAMELLINI,‡ G. BOLIS‡ and C. MANGIONI‡

†*Mario Negri Institute for Pharmacological Research, Via Eritrea, 62—20157 Milan, Italy and*
‡*First Clinic of Obstetrics and Gynecology of the University, Via Commenda, 12—20100 Milan, Italy*

Abstract—*A randomized trial based on a sequential analysis plan was started to check the activity of melphalan vs polymelphalanum in ovarian cancer patients resistant to cyclophosphamide. The trial was however closed in advance after treating only seven pairs of patients because of polymelphalanum toxicity. This decision is explained on statistical grounds in an attempt to provide a quantitative basis for balancing the toxicity found against the hoped-for benefits during the early phases of a clinical trial.*

INTRODUCTION

CYCLOPHOSPHAMIDE and melphalan are at present the two compounds which give the best response in ovarian cancer [1]. About 50% of patients treated with either melphalan [2] or cyclophosphamide [3] respond to the treatment. Very little information, however, is available on how to treat patients who are resistant to the first cycle of therapy.

Actinomycin D, 5FU and cyclophosphamide polychemotherapy showed some activity [2] but this was not confirmed by other authors [4]. High doses of cyclophosphamide showed greater toxicity and very little activity [4].

Among the many analogues of melphalan studied in the past [5, 6] a mixture of oligopeptides containing metaphenylalanine mustard (polymelphalanum) [7] has recently been marketed in Italy, with the trade name Peptichemio^{R} [8]. This compound has been extensively studied on cancer patients [9–11] and in a phase I trial on ovarian cancer it induced responses in 7 out of 15 patients who had never been treated before, and in 8 out of 26 patients treated before with different compounds [11]. These trials were not, however, carried out in controlled conditions.

Data on plasma cell myeloma showing that melphalan-resistant patients may respond to high-dose cyclophosphamide [12] suggested it was unlikely that cross-resistance would appear between the two drugs.

A trial was then started with the following aims: First, to explore whether cyclophosphamide-resistant patients obtained any improvement after melphalan or polymelphalanum treatment, and second, to check whether polymelphalanum had any advantage over melphalan treatment. A sequential trial was designed to compare the two drugs, should their efficacy be confirmed.

MATERIAL AND METHODS

Experimental plan

Patients entering the protocol had Müllerian ovarian cancer, histologically confirmed, stages III or IV of the FIGO classification, or abdominal and pelvic persistances. Maximum age was 75 yr. Cyclophosphamide, 100 mg/day, orally [3], was given for at least 2 months before patients were withdrawn as non-responders. Patients responding to cyclophosphamide were treated until relapse occurred. A few patients recorded as non-responders were in

Accepted 5 January 1977.

*This work was supported by a grant from Mr. Mario Ratto.

fact treated for more than 2 months, because subjective improvement was reported.

Patients were divided into three groups on histological grounds, i.e. serous, mucinous or undifferentiated carcinomas. Pairs were randomized in each of these groups to enter a sequential analysis plan based on 35% mean efficacy of the two treatments, and a minimal discriminating efficacy of 30%, to be obtained with a maximum of 33 pairs of patients. Response was graded by measuring two perpendicular diameters of at least one measurable mass, either by clinical examination, X-rays or ultrasound scanning. Complete response (CR) involved the disappearance of every measurable tumour mass for at least two months; partial response (PR) was achieved when a reduction of more than 50% was measured in at least one of the tumoral masses for at least two months; objective improvement (OI) when the reduction was from 25 to 50% for the same period of time. Non-responders (NR) were patients either with progressive or unchanged tumour [3].

Patients entering the second course of therapy at random, were treated as follows:

Melphalan group: 1 mg/kg, total oral dose, divided over 5 days, repeated once every 4 weeks [2].

Polymelphalanum group: 25 mg/m^2, i.v. on day 1; 50 mg/m^2 i.v. on days 2 and 3; 50 mg/m^2 i.v. every 2 weeks [11].

After two months of treatment patients were evaluated as described, and NR were withdrawn from the protocol.

Toxicity was scored as follows: (1) Allergic reaction; (2) Vomiting, (3) Alopecia; (4) Phlebothrombosis; (5) Mild leuk or thrombocytopenia; (6) leuk/or thrombocytopenia (WBC <2000, PL $<75{,}000$).

RESULTS

Table 1 reports the data collected on the seven pairs of patients studied before the protocol was closed for toxicity. One complete response was observed after melphalan treatment; this patient is still in remission after 16 months of treatment. No other response was observed during the two months of treatment, after which all the non-responders were withdrawn from the protocol.

The evaluation of one complete response out of 14 treated patients shows that the mean efficacy was already lower than the expected 35%; $P = 0{\cdot}05$, fiducial limits from 0·18 to 33·87%.

The sequential plan was therefore designed on an uncorrect hypothesis.

In addition, the two failure frequencies of 7/7 polymelphalanum and 6/7 melphalan tested by the one-way chi-square test against a theoretical frequency of 1/2, gave a highly significant ($P<0{\cdot}01$) probability of failure.

Evaluation of toxicity in terms of the number and severity of toxic events gave significant evidence of the higher toxicity of polymelphalanum in comparison with melphalan (Table 2) at the tested doses, which are those recommended by previous investigators. The protocol was consequently closed.

*P = 0·05 from Table 3.
†P = 0·05 confidence limits from binomial distribution tables.

The decision to close a protocol for toxicity is always somewhat subjective and evades any strict evaluation of the balance between observed toxicity and hoped-for benefits. From the statistical point of view, the fiducial limits of a percentage increase as the percentage approaches zero or 100%. For the zero frequency of responses, no fiducial limits can be calculated. It is, however, possible to evaluate the probability of not achieving any "response" phenomenon in a known number of samples, from a population containing a theoretical proportion of responses.

The probability of not observing any response (R) in a sequence of patients N with the risk of β = 0·05 is: $(1-P)^N = 0{\cdot}05$.

For a given value β this equation gives the value of N as a function of P (see Table 3 showing the hypothesis of efficacy E nullified at the stated probability in a sample N in which no response occurs): when no response is recorded in N samples, the efficacy is lower than the value given.

In the case of polymelphalanum treatment, at a 0·05 risk, the probability of achieving benefit was less than 33% after 7 non-responders, but already after 4 non-responders, the efficacy of the treatment was less than 50%.

The risk of toxicity, judging from the actual frequency of toxic events, was defined by the fiducial limits obtained from binomial tables. The figures at P = 0·05 were in a range from 0·36 to 58% for allergic reactions, low grade thrombocytopenia and serious leukopenia; from 3·7 to 71% for serious thrombocytopenia, from 47 to 100% for phlebothrombosis. In this case, however, the figure obtained from binominal distribution tables can give only a rough approximation since 7/7 (100%) cases are involved. It would, perhaps, be statistically more precise to ask what probability these patients have to escape phlebothrombosis. This probability, as set out in Table 3, is less than 33%.

DISCUSSION

The present trial was closed because, at least for one of the drugs tested, toxicity appeared to be greater than expected benefits.

Analysis of the seven pairs of patients treated with melphalan or polymelphalanum led us to stop the trial when it was still too soon to draw any conclusions about the efficacy of melphalan.

The low toxicity of this treatment, and the one complete response obtained, suggested more patients might be admitted to the protocol to reach some conclusion in terms of efficacy.

The patients receiving polymelphalanum, however, were showing increasing cases of toxicity, while the hoped-for benefits did not appear.

Having calculated the probability of observing a benefit, which in fact was never observed in the present population, we could compare risks with benefits for polymelphalanum treated patients. The benefits expected, ie, objective improvement, partial or complete response lasting at least two months, were relatively small in relation to the toxicity risk, and an equally significant indication that treatment was not worth continuing could perhaps have been noted when with only four patients the probability of achieving benefits already fell below 50%.

In this trial the observation and treatment period was limited to two months, which was considered sufficient to detect treatment-induced responses and also to give some of the patients a chance for further treatment later.

Four patients withdrawn from the protocol but still eligible for chemotherapy were in fact treated with adriamycin, 40 mg/m^2, every three weeks. Three of these patients were from the polymelphalanum and one from the melphalan group. One partial response and one objective improvement were recorded.

In conclusion, the unsuccessful trial of polymelphalanum in ovarian cancer patients resistant to cyclophosphamide confirmed the utility of statistical probability tables to compare observed toxicity with expected benefits during the early phases of a trial, with a view to minimizing the risk for patients entering experimental protocols.

The Effects of 1-β-D Ribofuranosyl-1, 2, 4-Triazole-3-Carboxamide (Ribavirin) on the Transplanted Tumours of Animals

H. NEWMAN, LADA VODINELICH and C. W. POTTER
Department of Virology, University of Sheffield Medical School, Beech Hill Road, Sheffield S10 2RX, England

Abstract—*The effect of Ribavirin on the growth of three transplantable tumours was examined. At a concentration which was non-toxic to CBA mice, the compound reduced significantly the incidence of tumours in mice inoculated with transplanted adenovirus 12-induced tumours. Ribavirin was toxic for hamsters at a concentration of 100 mg/kg/day; at this concentration the compound reduced the tumour incidence of drug-treated animals inoculated with a transplanted SV40 virus-induced tumour, but the effect was less than that seen in mice. Studies in rats showed that Ribavirin had an inhibitory effect on tumour cell growth; however, drug-treated animals exhibited little or no lymphoreticular response to tumour growth, and this secondary immunosuppressive property of the compound had the collective effect of promoting tumour growth.*

INTRODUCTION

PREVIOUS studies have shown that several compounds, such as ethidium bromide, rifamycin and tilorone, inhibit the RNA dependent DNA polymerase essential for the replication of tumour viruses, and have an antitumour activity [1–4]; indeed, if the RNA viruses found in tumour cells are important in maintaining the cancerous properties of transformed cells, the two properties may be related. Thus, tilorone has a chemotherapeutic action against a wide range of viruses, and is an interferon inducer [5]; however, the antitumour activity of different analogues of this compound correlated more closely with the inhibitory activity on viral DNA polymerase, than with the ability to induce interferon [6]. From these observations, it is possible that some compounds active against RNA viruses may have antitumour activity.

The compound 1-β-D ribofuranosyl-1, 2, 4-triazole-3 carboxamide (Ribavirin) has been reported to inhibit the replication of both RNA and DNA viruses *in vitro* [7–9]. The compound acts by interfering with guanidine monophosphate formation and subsequent nucleic acid synthesis [10, 11]. In studies of influenza virus infection of chick cells, Ribavirin used at a concentration which completely inhibited influenza viral polypeptide production had no demonstrable effect on cellular protein synthesis [12]. In contrast, Ribavirin at a concentration which prevented influenza virus infection in ferrets suppressed the serum antibody response; the suppression of antibody formation was also demonstrated in guinea pigs immunized with influenza vaccine in Freund's adjuvant [13]. In the present studies, we report an investigation of the activity of Ribavirin against transplantable tumours, since the effect of this compound on either the RNA viruses of tumour cells or on the immune response of the host [14, 15] may initiate antitumour activity.

Accepted 16 December 1976.

MATERIAL AND METHODS

Ribavirin

Ribavirin was kindly supplied by Dr. R. W. Sidwell, ICN Nucleic Acid Research Institute, Irvine, California and by Lederle Labs., Gosport, Hants., and was stored at 4°C. The drug was weighed out freshly each day and dissolved in phosphate buffered saline, pH 7.2. For the treatment of animals, daily inoculations of 100 mg/kg were given subcutaneously to mice and hamsters, and daily inoculations of 12.5–100 mg/kg were given intraperitoneally to rats.

Tumour cells

Experiments were carried out in CBA mice, Syrian golden hamsters or in rats all of which

were obtained from closed, randomly-mated colonies at the University of Sheffield. The adenovirus 12-induced tumour of CBA mice [16], the SV40 virus induced tumour of hamsters [17], and the Rd3 tumour of rats [18] were maintained by transplanting tumour fragments at 2–3 week intervals into animals aged 4–5 weeks. To prepare tumour cell suspensions, subcutaneous tumours 10–15 mm in diameter were excised, freed from adhering fibrous tissue, minced to small fragments and treated with 0.25% trypsin to give a single cell suspension. The cells were washed with two changes of Eagle's minimal essential medium (MEM) containing 2% foetal calf serum and antibiotics (100 units/ml of penicillin and 100 μg/ml of streptomycin) and the cell concentrations adjusted to a measured number of viable cells/ml; the cells were used immediately to inoculate animals.

Toxicity of Ribavirin for animals

For toxicity studies, Ribavirin was inoculated into groups of 9–10 mice or hamsters at a concentration of 50, 100 or 150 mg/kg; the compound was prepared fresh each day, and given by the subcutaneous route. Mice received a dose of compound daily for 20 days, and hamsters received a daily dose for 15 days. Due to the limited supply of the compound, similar studies could not be performed in rats. The number of dead animals was recorded daily, and changes in body weight were measured twice weekly; in addition, the surviving animals were all killed at the end of the treatment period and the spleen weights recorded.

Experimental design

(1) *Adenovirus 12-induced tumours.* Groups of CBA mice were inoculated subcutaneously with 100 mg/kg/day of Ribavirin. Two hours after the second drug inoculation, these animals, together with a group of untreated mice, were each inoculated subcutaneously with 5×10^5 transplanted adenovirus 12-induced CBA mouse tumour cells in 0.1 ml of MEM; the tumour cell inoculum used represented ten (50%) tumour-induced doses [16]. Ribavirin was given to the treated mice for a further 20 days, and the incidence and size of tumours in the animals was recorded twice weekly for four weeks.

(2) *SV40 virus-induced tumours.* Groups of hamsters of 90–110 g weight were inoculated subcutaneously with 100 mg/kg/day of Ribavirin. After the second injection of Ribavirin, these animals and a control group of untreated hamsters were each inoculated with $10^{2.0}$ viable SV40 virus-induced tumour cells per hamster; this tumour cell inoculum had been shown by prior titration to correspond to ten (50%) tumour-inducing doses. The drug-treated hamsters received 15 daily doses of Ribavirin and the incidence and size of tumours were recorded for 21 days at which time the experiments were terminated.

(3) *Rd3 tumours.* Groups of male rats of 250–300 g weight were each inoculated in the footpad with 5×10^6 Rd3 cells in an 0.1 ml volume. One group of rats received 100 mg/kg/day Ribavirin by the intraperitoneal route daily from two days before tumour cell inoculation; a second group received the same dose of Ribavirin from the same day that the tumour cells were given; and a third and fourth group received Ribavirin from two and four days, respectively, after tumour cell inoculation. The drug was given daily for eight days after tumour cell inoculation. A number of animals from each of the treated groups, and from an untreated control group, were killed at four days or eight days after inoculation with tumour cells. From these rats, the footpad and popliteal lymph nodes were taken for histological examination, as described previously [18]. In a second experiment, groups of rats were inoculated daily by the intraperitoneal route with Ribavirin at different concentrations from two days before footpad inoculation with 5.0×10^6 Rd3 cells. Animals from each group were killed at 4 or 8 days after tumour cell inoculation and specimens taken for histological examination, as described above.

The size of the lymph nodes was measured at autopsy, and the presence and relative number of tumour cells in the lymph nodes was determined by microscopic examination; these latter results were graded according to the following scheme:

Grade 0	—	no tumour cells present.
Grade 1	—	tumour cells present in the subcapsular sinus only.
Grade 2	—	tumour cells in subcapsular sinus and radial sinusoids.
Grade 3	—	massive replacement of node with tumour cells.

In addition to the above observations, the size of the footpad tumours was measured using calipers, and these primary tumours were examined histologically. The presence of macrophages and lymphocytes in the tumours or metastases was recorded, as an indication of a cellular immune response; in control animals,

the presence of a lympho-reticular response was a marked feature of the primary tumour.

RESULTS

Toxicity studies

The toxic effect of Ribavirin was investigated in both CBA mice and hamsters. The results are shown in Table 1. At concentrations of 50, 100 and 150 mg/kg/day, Ribavirin did not cause death in any of the mice tested; however, 100 mg/kg/day and 3 out of 10 hamsters given 150 mg/kg/day died during the study period. The body and spleen weights of these two groups of treated hamsters fell significantly as a result of Ribavirin treatment (Table 1).

Effect of Ribavirin on an adenovirus 12-induced tumour of CBA mice

Two experiments were carried out which showed very similar findings; the results are given in Table 2. In both experiments, palpable

mice given 100 or 150 mg/kg/day failed to gain weight to the same extent as control animals, though the compound did not significantly affect spleen weight. None of the hamsters inoculated with Ribavirin at 50 mg/kg/day died during the three week treatment and observation period. The body weight of these animals increased by 11% of the initial weight and the spleen weights increased by 5%; these values compare with 22 and 6% respectively, for control hamsters. One out of ten hamsters given

tumours were first observed in untreated mice 14 days after inoculation with 5×10^5 viable tumour cells. At 26 days after tumour cell inoculation, a total of 15 of 16 (94%) mice in the two experiments had rapidly enlarging tumours; the animals were killed at this time, since previous experience had shown that these animals would die with massive growth within the following 5–7 days. In contrast, mice treated with 100 mg/kg/day of Ribavirin from one day before tumour cell inoculation developed

*No. mice with tumours/No. mice inoculated (mean tumour diameter in cm).

significantly fewer tumours than observed in control mice. Thus, at 14, 17 and 21 days, post-inoculation, tumours were palpable in 0, 1 and 4 Ribavirin-treated mice, respectively, whilst in control mice the incidence of tumours was 4, 8 and 10 at the above times. The results at 26 days, post-inoculation, showed that Ribavirin-treated mice had significantly less tumours than control animals ($X^2 = 4.218$, $P = <0.05$). In addition, at the end of the experiments, the tumours present in treated mice had a mean diameter of 0.5–0.7 cm, whilst at this time the tumours of control animals had a mean size of 1.4–1.5 cm. Thus, Ribavirin treatment inhibited tumour formation, and the growth of those tumours which did appear (Table 2).

Effect of Ribavirin on SV40 virus-induced tumours of hamsters

The effect of Ribavirin on the transplantability and growth of SV40 virus-induced tumours of hamsters is shown in Table 3. For control animals, palpable tumours were first observed at 12 days post-inoculation; all hamsters had recognisable tumours at 16 days which grew rapidly. In contrast, four of ten hamsters treated with 100 mg/kg/day had palpable tumours at 12 days post-inoculation, and only seven developed tumours during the observation period. In addition, the mean size of tumours at 20 and 23 days was less for treated hamsters than for control animals. The small number of animals used in this experiment precluded tests of significance on these results.

*No. of hamsters with tumours/No. of hamsters inoculated (mean tumour diameter in cm).

Effect of Ribavirin on Rd3 tumour cells of rats

(a) *Effect of dose of Ribavirin.* At four or eight days after Rd3 tumour cell inoculation and treatment with varying doses of Ribavirin, groups of rats were killed, and the local tumours and regional popliteal lymph nodes excised; sections from these tumours were stained by H and E for microscopic examination. The results are shown in Table 4. At four days after tumour cell inoculation, tumours were well established in the footpads of control rats and in animals treated with 25 mg/kg of Ribavirin, but only a few tumour cells were present in the footpads of rats treated with 100 mg/kg of the compound. Whereas the tumours of control rats showed a marked lympho-reticular response with extensive lymphocyte and macrophage infiltration in and around the tumours, the tumours of treated animals showed no evidence of a cellular immune response (Fig. 1). Metastasis of the Rd3 tumour cells to the popliteal lymph node was found to have occurred in both treated and untreated rats; evidence of a cellular immune response was seen in the nodes of control rats, but none was found in those of treated rats (Fig. 1).

At eight days after inoculation, the footpad tumours of control rats were very large, and histologically showed massive tumour cell growth with lymphocyte and macrophage infiltration (Table 4). The tumours of rats treated with 25 mg/kg/day of Ribavirin were similar in size but those of rats treated with 100 mg/kg/day of the drug were smaller; the tumours of all treated rats showed little or no histological evidence of a lympho-reticular response. Similar findings were seen in the popliteal lymph nodes of these animals. Thus, the tumour metastasised to the lymph nodes of rats treated with 100 mg/kg/day of Ribavirin and to the nodes of control animals; however, the number of tumour cells was less in treated than in control rats, and there was no demonstrable cellular immune response (Table 4).

(b) *Effect of time of treatment.* Since any alteration in the pattern of Rd3 tumour development in Ribavirin-treated rats was seen best in

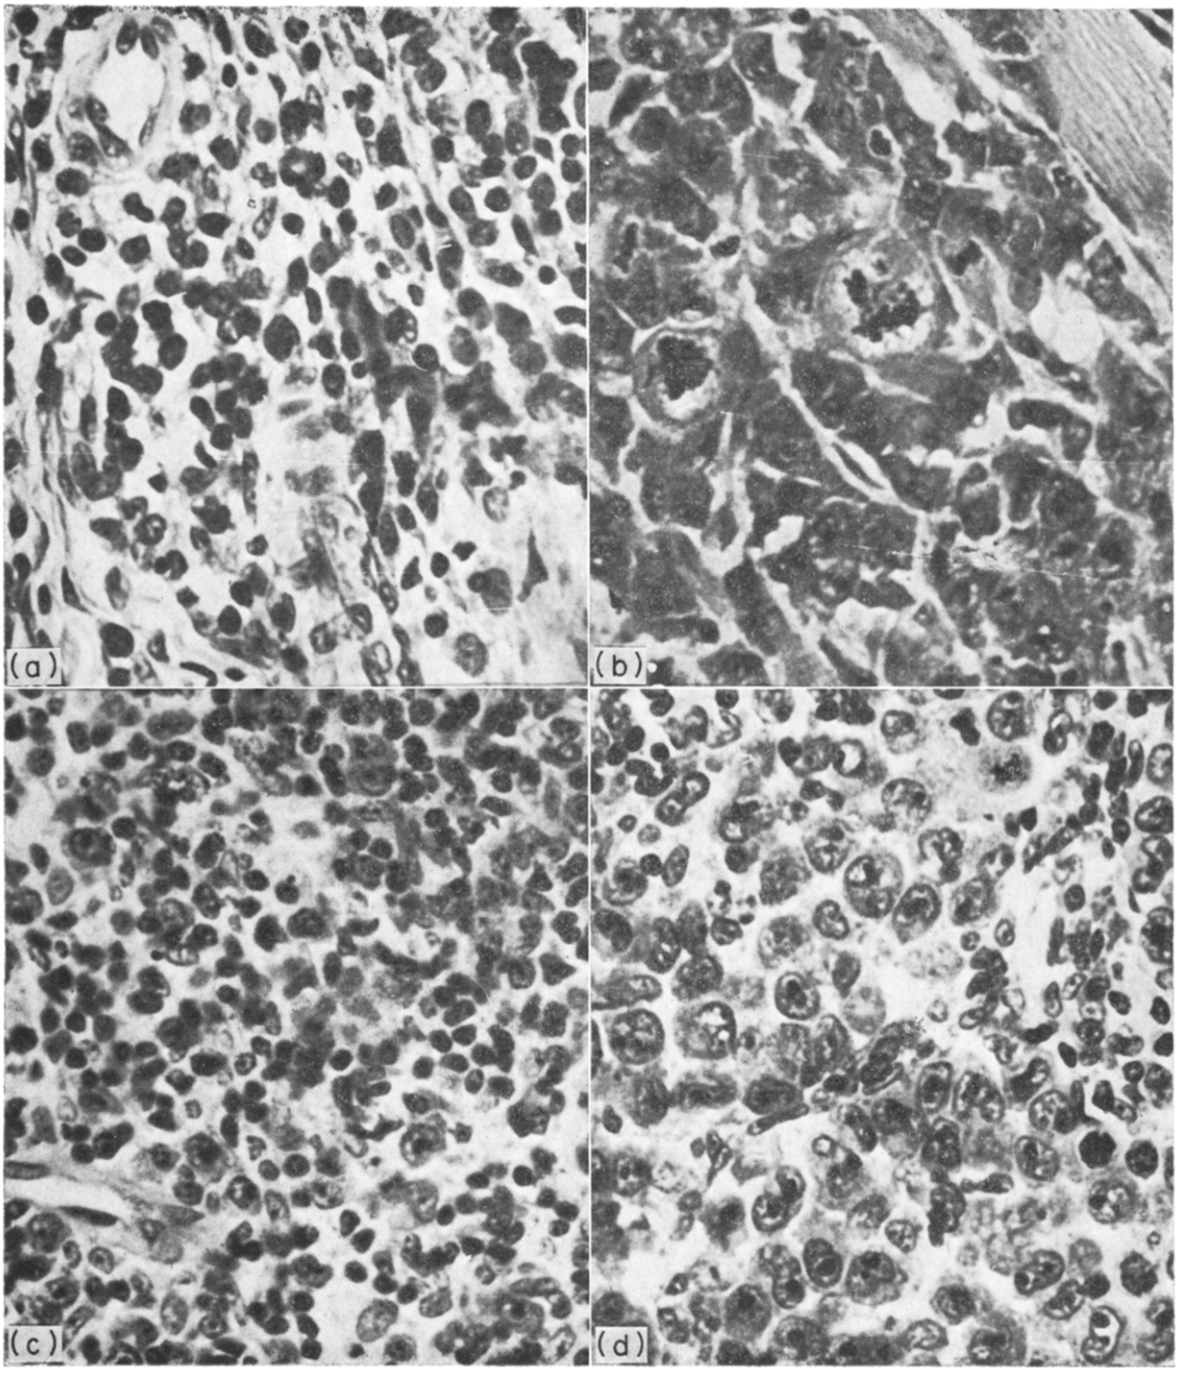

Fig. 1. *Histological appearance of Rd*3 *tumours in rats.* (*a*) *Tumour and lymphoid cell in primary tumour.* (*b*) *Tumour cells only in primary tumour of rat treated with* 100 mg/kg *Ribavrin.* (*c*) *Tumour metastasis in a regional popliteal node with tumour and lympho-reticular cells.* (*d*) *Tumour metastasis in popliteal node with tumour cells only.* (*Magnification* × 700).

animals treated with 100 mg/kg/day, this dose was given to five groups of rats. Tumour cells were inoculated into the footpad two days after treatment started (group 1), on the day treatment started (group 2) or two or four days before treatment with Ribavirin (groups 3 and 4). The results are shown in Table 5. At 4 days after tumour cell inoculation, the findings in control and drug-treated rats were very similar. Thus, tumours were established in the footpads, though less well in animals treated from two days before tumour cell inoculation, and metastases were seen to the lymph nodes. Animals treated with Ribavirin showed no evidence of a

lympho-reticular response in the popliteal lymph node, but the metastases of control rats showed macrophage infiltration in and about the tumours (Table 5).

At eight days after Rd3 tumour cell inoculation, the findings for control and drug-treated rats were quite distinct (Table 5). The footpads of control rats contained only a small number of live tumour cells, but the specimens showed an extensive lympho-reticular response; no tumour cells were found in the popliteal lymph nodes of these animals but again a marked macrophage infiltration was observed. Compared to the findings at four days, post-inoculation, these results clearly indicate that the tumour cells were being rejected. In contrast, the primary tumours of drug-treated rats were well established and showed little or no cellular immune response; by comparison with the results seen in control rats, the effect of Ribavirin treatment had been to inhibit the immune response and promote tumour development. The size of the popliteal lymph nodes at eight days after tumour cell inoculation differed markedly for the different groups. Thus, the nodes of control rats were very large but contained no recognisable tumour cells; histologically, the increase in size was due entirely to the lympho-reticular response. The popliteal nodes of treated rats all showed evidence of tumour cell metastasis. The nodes of rats treated with Ribavirin for the longest period of time showed no cellular immune response, whilst the nodes of other treated groups showed a minimal response. Thus, the node sizes were inversely related to the length of Ribavirin treatment (Table 5).

DISCUSSION

The demonstration that some antiviral compounds which are active against viruses present in tumour cells may also have antitumour activity [1, 2] has two important implications. Firstly, the finding suggests that the activities of tumour viruses are important in the maintenance of the neoplastic properties of tumour cells; compounds which interfered with the function of these oncornaviruses may act also on the tumour cells that contain them. Secondly, the possibility exists that in the lists of compounds which have known antiviral activity, there may be found drugs which have activity against tumours. For this reason, we have investigated the antitumour properties of Ribavirin. This compound has been shown to inhibit both RNA and DNA viruses *in vitro* [7, 9], and *in vivo* [8, 13].

The transplanted adenovirus 12-induced tumour of CBA mice is a rapidly growing, undifferentiated tumour [19]: the tumour is encapsulated, and shows no evidence of metastasis. The present results show that Ribavirin, at a concentration of 100 mg/kg/day inhibited the growth of this tumour; both the number of tumours which developed and the rate of tumour growth were significantly reduced by Ribavirin in two separate experiments. Although it has been shown that Ribavirin has an immuno-suppressive effect on the host at the concentration used. [13], and that mice bearing adenovirus 12-induced tumours exhibit a marked cell-mediated immune response [16, 20], the sum total effect of the compound was to limit but not totally inhibit tumour growth. This may be due in part to the tolerance of mice for Ribavirin, and the relatively minor effect of the compound on the immune response of this species (13); thus, at 100 mg/kg/day mice were not killed, and although body weight was reduced the spleen weights increased.

The results obtained for the effects of Ribavirin on a transplantable SV40-induced tumour of hamster was similar to those for the adenovirus 12-induced tumour. This tumour is a very rapidly growing anaplastic carcinoma, the cells of which did not metastasise when inoculated subcutaneously; however, metastasis to regional lymph nodes could be demonstrated following footpad inoculation [21]. Ribavirin at a concentration of 100 mg/kg had a marginal effect on the incidence and growth of transplanted SV40 virus-induced tumours of hamsters; at this concentration the compound was clearly toxic to hamsters causing death in some animals, and a reduction in both body and spleen weight. Since this tumour has been shown to be immunogenic [22], the relative failure of Ribavirin compared to the results obtained for adenovirus-induced tumours may be due to the greater effect of the compound on the immune mechanism of the host.

The Rd3 tumour of rats is a chemically-induced tumour which metastasises to the lymph nodes following footpad inoculation [18, 21]. Using different doses of Ribavirin to treat rats inoculated with Rd3 tumour cells, the results showed that all rats developed footpad tumours, but the size of the tumours and the lymph node metastasis were measurably reduced in rats given the compound at a concentration of 100 mg/kg/day; the reduction in size was probably due to the absence of a lympho-reticular response in the tumour mass. In a further experiment, the effect of Ribavirin

on the immune response is more clearly demonstrated; thus, the tumour cells inoculated into control rats were almost entirely rejected at eight days, post-inoculation. The number of cells necessary to produce a tumour with Rd3 cells is critical, and in this experiment the number used was probably too small. In contrast, treated animals given the same tumour cell dose had established tumours at eight days after inoculation; there was little or no demonstrable cellular immune response in those hamsters or in the metastasis which was probably the reason why the tumours were not rejected in the same manner as seen in untreated rats.

The present results indicate that Ribavirin was active against the cells of three transplantable tumours; however, the concentration of compound used to demonstrate this activity was also immunosuppressive. This latter activity was probably least important in the experiments in mice using the adenovirus 12-induced tumour, since this host was relatively tolerant to Ribavirin. In contrast, the antitumour effects of Ribavirin was less evident for the other two tumour systems investigated, where the effect of the compoud on the immune response of the host abrogated the effect of the compound on the tumour cells. The above experiments indicate that Ribavirin probably has no value in antitumour therapy, and may even have deleterious effects; however, antiviral compounds which do not affect the immune response may yet be of value, and these should be investigated.

A Fine Structural Study on the Therapeutic Effect on an Aromatic Retinoid on Chemically-Induced Skin Papillomas of the Mouse

A. MATTER and W. BOLLAG

Pharmaceutical Research Department, F. Hoffmann-La Roche & Co. Ltd., Basle, Switzerland

Abstract—*Skin papillomas induced by dimethylbenzanthracene and croton oil were treated systemically with a single injection of an aromatic new retinoid (Ro 10-9359). A marked regression of the tumors occurred within 7 days. The effects of this drug as seen with the electron microscope were (a) a marked enhancement of production of mucopolysaccharides and their secretion into the extracellular space, (b) a labilization of the plasma membrane resulting in vacuolization and loss of cytoplasmic constituents into the extracellular space, (c) an increase in lysosomal organelles, (d) formation of many necrotic cells. There were no clear-cut effects on either the nuclei, nucleoli or cytoplasmic constituents such as ribosomes and tonofibrils, nor was there any increase in the number of gap junctions as seen in keratoacanthomas after local retinoic acid treatment. Our interpretation favours the hypothesis that cell necrosis is mainly due to the labilization of the plasma membrane, but that other effects like the enhanced mucopolysaccharide production secreted into the extracellular space, might also play a role in the regression of the papillomas.*

INTRODUCTION

VITAMIN A is important for physiological functions such as growth, vision and fertility and for the differentiation of epithelial tissues. Possibly linked to this latter function vitamin A and its analogs (retinoids) also show the capacity to prevent and revert hyper- and metaplastic- changes *in vitro* [1–3] and even neoplastic lesions *in vivo* [4–13] induced either by vitamin A deficiency or by carcinogens. The mechanism of action is not known but several phenomena should be considered such as the labilization of lysosomal membranes by vitamin A [14], the fragmentation of the plasma membrane [15], the generation of gap junctions [16].

The model used in this study was the skin papilloma of the mouse induced by carcinogens [7]. It is a benign tumor with a potential malignant degeneration. It is characterized by hyperplastic and metaplastic changes. These papillomas decrease rapidly in size when treated systemically with a single injection of a new aromatic retinoic acid analog (Ro 10-9359).

Accepted 7 January 1977.

A previous study [17] had already shown that the mechanism of action for this analog was not to inhibit DNA synthesis but to induce necrosis. In the present study we used electron microscopy and histochemical staining procedures to define the cytological parameters accompanying the regression of these papillomas in order to gain more insight into the mechanism of action of these interesting compounds.

MATERIAL AND METHODS

1. *Animals*

Female Swiss albino mice of the Füllinsdorf random-bred strain were used. They were fed on the mouse diet Nafag 199, containing 2500 I.U. of vitamin A per kg of food.

2. *Tumors*

Skin papillomas were induced by skin painting with 7,12-dimethyl benzanthracene (DMBA) and croton oil according to the method described elsewhere [5, 7]. Twenty mice with 2–3 papillomas measuring between

3 and 8 mm in diameter were selected for the experiment.

3. *Treatment*

The retinoid, ethyl all-trans-9-(4-methoxy-2, 3, 6-trimethylphenyl) 3, 7-dimethyl-2, 4, 6, 8-nonatetraenoate (Ro 10-9359) was suspended in arachis oil (250 mg/ml) and given intraperitoneally to the animals in a single dose of 1000 mg/kg. In previous experiments this substance was shown to be highly effective in causing regression of papillomas [7]. In the present experiments the regression was determined by measuring the percentage decrease of the volume of the papillomas [6] from the time of injection until the time of sacrifice. Time intervals studied between treatment and sacrifice were 8 hr, 16 hr, 2 days, 3 days and 7 days. The total volume changes of the tumors were measured and expressed as percentage change of the volumes of the tumors per animal [6].

4. *Electron microscopy*

Animals were killed by cervical dislocation and small pieces of skin and papillomas were sampled and immersed for 24 hr in the following fixative: 1% glutaraldehyde (Serva, Heidelberg, Western Germany), 4% paraformaldehyde (Merck, Darmstadt, Western Germany) buffered with 0·1M phosphate buffer, pH 7·2. The blocks were rinsed overnight with phosphate buffer and postfixed for 2 hr with 2% osmium tetroxide in 0·1M cacodylate buffer, pH 7·2. Dehydration in a graded alcohol series was followed by epon embedding [18]. The sections were cut with diamonds on a Porter-Blum ultra-microtome MT-1 (Ivan Sorvall, Inc., Norwalk, Connecticut, USA) and stained with an aqueous 5% uranylacetate solution followed by lead citrate [19]. They were examined in a Philips EM 300 electron microscope (Philips, Eindhoven, The Netherlands).

5. *Histochemistry*

Acid mucopolysaccharides were stained on formalin fixed sections with the dialysed iron method according to Hale [20].

RESULTS

1. *The untreated papilloma*

Light microscopy. These tumors are mainly characterized by a thickening of all cell layers of the epidermis. The number of nuclear layers is increased from 1–3 in the normal skin to 7–12 in the papilloma. The histological features of normal skin are, however, fully preserved. The keratinization varies only slightly: The keratinized layer in most places is very thick but the cohesion of the cells appears to be lower. The dead cells defoliate easily retaining a spiny appearance. There are usually no signs of inflammation or necrosis, only the network of the many blood vessels and lymphatics in the subcutis beneath the papilloma is striking. Probably due to lack of space during the development the tumor acquires a deeply infolded, sometimes even convoluted aspect with keratin encapsulated by the epithelium.

Electron microscopy. Papillomas retain also at the ultrastructural level all features of normal skin. In addition the usual signs of a hyperplastic state are present: Big nuclei with euchromatin and huge nucleoli, large masses of polyribosomes in the cytoplasm with a usually well-developed Golgi apparatus.

2. *Papillomas treated with Ro* 10-9359, 8 *and* 16 *hr after injection*

Light microscopy. At these time intervals there are no appreciable changes with respect to the untreated papilloma. There is also practically no volume change of the tumors.

Electron microscopy. No conspicuous alterations were detected at either time interval.

3. *Papillomas treated with Ro* 10-9359, 2 *and* 3 *days after injection*

Light microscopy. At this stage tumors decreased in volume considerably in our experiments by 33, 33 and 46% at 48 hr, by 42, 45, 48, 48 and 80% at 72 hr. The effects of the treatment are distributed unevenly. Some regions of the papilloma are unaltered whereas others show distinct degenerative signs: large inclusion bodies, vacuolization, pyknosis and karyorrhexis.

Other regions form a homogeneous necrotic mass where no cytological features can be distinguished any more.

Electron microscopy. Necrotic cells are sharply distinguishable from the relatively intact cells. They are easily recognizable by their 'empty' cytoplasm (Fig. 6), the occasional large secondary lysosomes (Figs. 5 and 6), the nearly absent ribosomes, and in more advanced cases, by the fragmented or pyknotic nucleus. The rest of the cells shows more subtle alterations: there is a conspicuous widening of the intercellular cleft (Figs. 1–5), which is due to the presence of (a) a finely fibrillar mass, (b) many smooth vesicles and vacuoles (Figs. 2–5), (c) other cytoplasmic constituents such as ribosomes, tonofilaments,

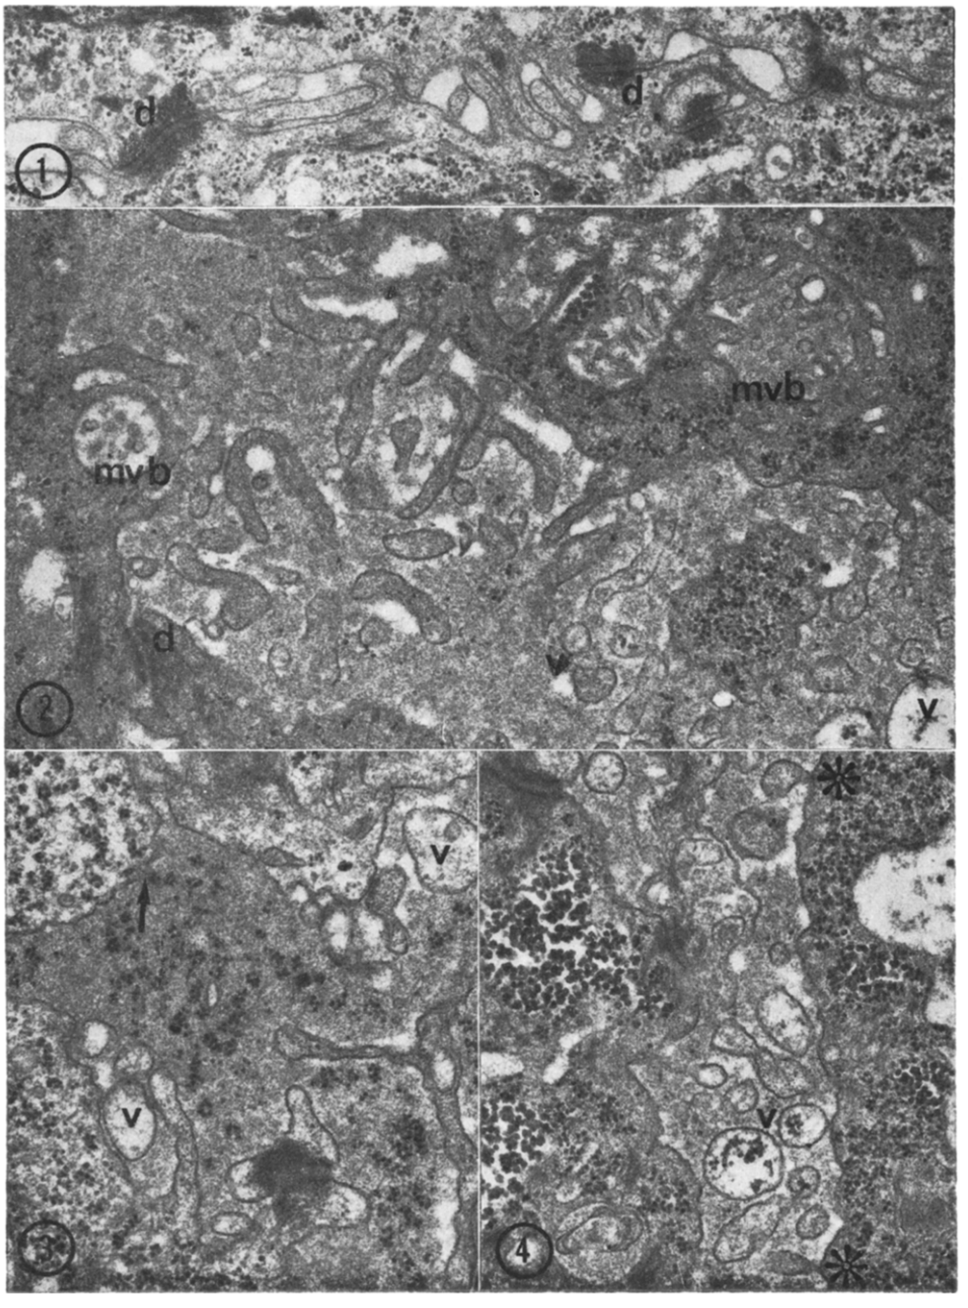

Fig. 1. *Intercellular cleft of the basal layer of a papilloma* 48 hr *after treatment. This part appears very similar to the untreated papilloma at the* 8 *and* 16 hr *interval after treatment. Fig. 6. *Same material as in Fig.* 5. *Degenerating cell containing huge secondary lysosomes. On either side of this cell degenerating cells are found with a swollen, 'empty' cytoplasm.* × 30,150.

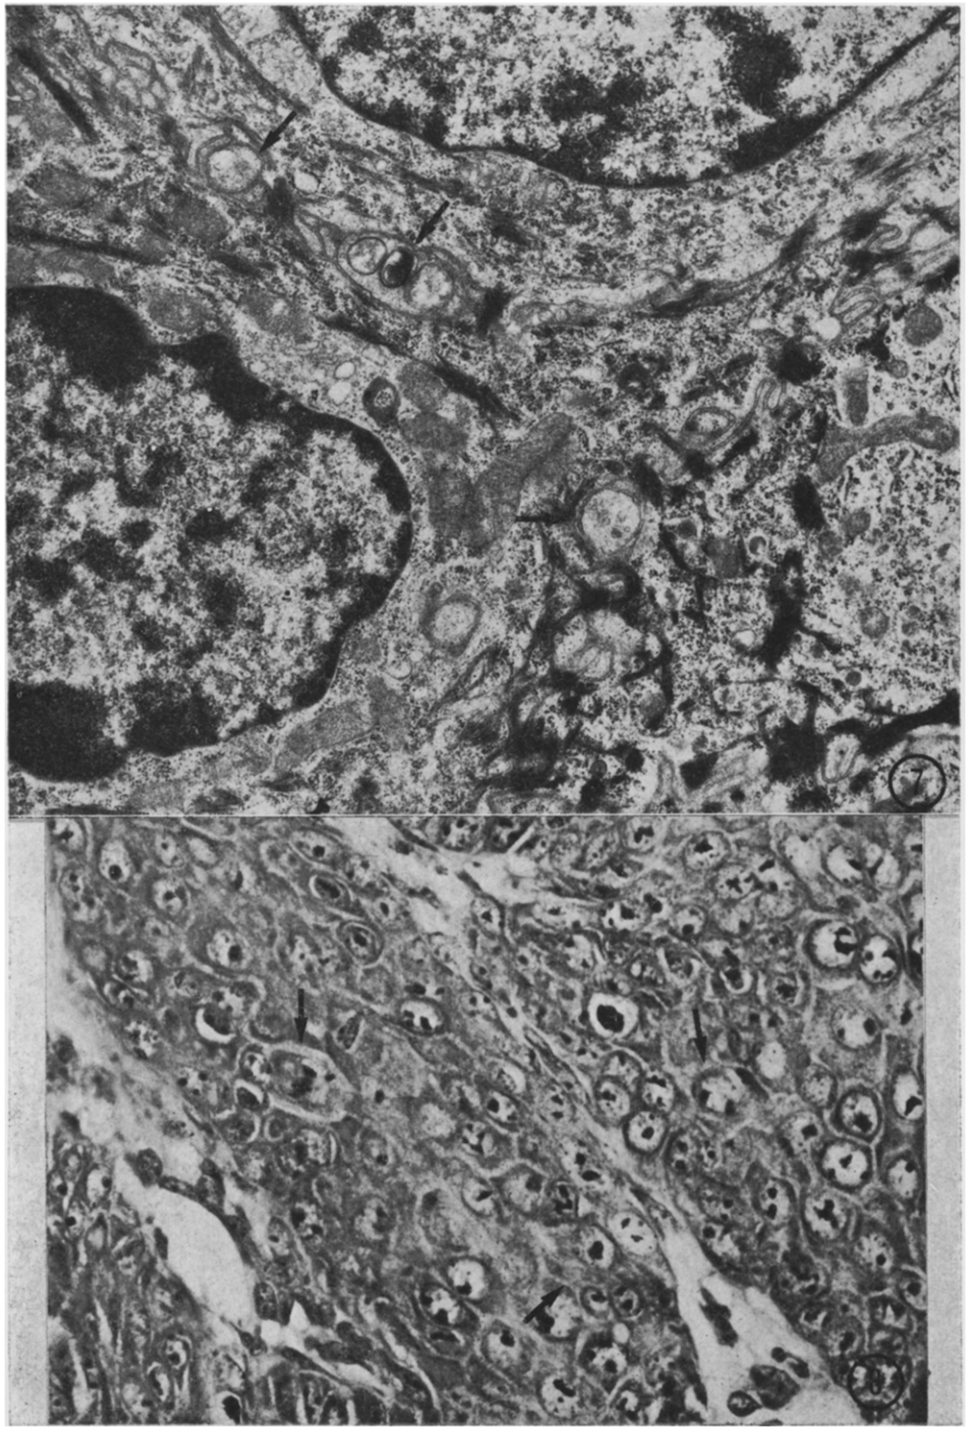

Fig. 7. Skin, basal layer, 72 hr *after retinoid treatment. The skin preserves its integrity throughout the treatment with Ro* 10-9359, *except that in few instances there are vacuoles containing cytoplasmic constituents in the intercellular cleft (arrows).* × 16,650.

Fig. 8. Basal layers of a skin papilloma, 72 hr *after treatment. Histochemical demonstration of acid mucopolysaccharides in the intercellular space (arrows) by means of the method of Hale* (20). × 576.

glycogen (Fig. 3), etc. The vacuoles seem to be formed by a pinching-off from protrusions of the plasma membrane (Figs. 2–4). Smooth and rough vesicles probably derived from the Golgi apparatus communicating with the extracellular space are involved in the secretion and possibly reabsorption of the extracellular mass. This latter mass consists of mucopolysaccharides as demonstrated by a positive reaction with dialysed iron according to Hale (Fig. 8). The presence of these mucopolysaccharides appears to lead to a rupture of many desmosomes (Fig. 5). It is noteworthy that there is no increase in the frequency of gap junctions as observed by Prutkin [16] in keratoacanthomas. The frequency actually decreases slightly from 1 in 7 cells to 1 in 10 cells, a frequency being maintained up to seven days after treatment with retinoids. Intracellularly, in the surviving cells a slight decrease of tonofilaments, polyribosomes and an increase in multivesicular bodies (Fig. 2) and vacuoles containing regular arrays of membraneous material (Fig. 5, inset), (possibly consisting of phospholipids), can be observed, but all these changes are difficult to quantify.

4. *Papillomas treated with Ro* 10-9359, 7 *days after injection*

Light microscopy. The volume of the tumor has shrunk to less than 1% of the original size. There are still a few areas showing hyperplastic epithelium but most parts show an epithelium not much thicker (3–5 nuclear layers) than normal skin. There is also widespread necrosis.

Electron microscopy. Intact cells have at this stage reverted to a practically normal appearance. Only in very few places alterations were detectable in the extracellular space that were so frequent at 48–72 hr. There was, however, one intriguing detail: In many instances mitochondria showed membrane-bound inclusion bodies filled with a homogeneous mass (fatty substances?), 0·1–0·3 μm in diameter. The significance of this observation remains unexplained.

5. *Skin, treated with Ro* 10-9359, 8 *hr to* 3 *days after injection*

No alterations comparable to those seen in papillomas were observed. At a few places only (Fig. 7) were there inclusions and some vacuoles in the extracellular space, the intracellular organelles being undistinguishable from those seen in normal skin.

DISCUSSION

This study was undertaken in order to gain morphological information useful for proving or disproving one of the following hypotheses. The mode of action of retinoids in reversing hyperplasia induced by carcinogens could be due to: (a) a lysosomal labilization leading to autolysis and necrosis, (b) a surfactant action on the plasma membrane resulting in a leaky membrane and consequently in necrosis, (c) an increased formation of gap junctions [16] possibly providing a signal for mitotic arrest, (d) an increased production and secretion of mucopolysaccharides into the extracellular space with an enlargement of this latter. This would lead to a loss of anchorage of the cells and, concomitantly, to a deprivation of nutrients. This hypothesis would be compatible with findings obtained in other systems [21, 22].

Hypothesis (c) can be eliminated easily for two reasons: Firstly, the frequency of gap junctions does not increase in our system during retinoid treatment, but rather decreases. Secondly, it is difficult to see how such junctions could induce necrosis since they are a normal constituent of a variety of normal cells, including epidermal cells.

Hypothesis (a) is in line with many earlier observations in different systems [14]. The activation of the lysosomes in the retinoid treated papillomas, however, is not striking. It is therefore doubtful whether much importance can be ascribed to this mechanism.

Hypothesis (d) is a very attractive one and would explain the formation of necrosis most easily. However, it must be remembered that many necrotic cells are not surrounded by a thick layer of mucopolysaccharides which casts a doubt on the importance of that mechanism.

Hypothesis (b) holds that the surfactant action on the plasma membrane is the cause of necrosis and cell loss. This is certainly the mechanism that is directly and most strikingly supported by our data and probably the most likely mechanism responsible for the effects of retinoid treatment.

It is likely, however, that all the aforementioned mechanisms do occur simultaneously and may act synergistically to produce the dramatic regression of the papillomas. It is important, however, to stress that the systemic treatment with Ro 10-9359 has little or no effects on normal skin. These findings are in contrast to those obtained with topical application of retinoic acid on normal skin [23], where similar phenomena were observed as those described in papillomas in the present study. This is most encouraging in view of the

badly needed specificity of retinoids for potential clinical use. Clinically useful retinoids must show a high degree of specificity, i.e. good anti-tumor activity with little toxic (A-hypervitaminotic) effects. Our study shows that this lies in the realm of possibility.

Breast Cancer: The Long Latent Interval

E. ALLAN

The Christie Hospital and Holt Radium Institute, Manchester 20, *United Kingdom*

Abstract—*A group of female patients who developed recurrence* 5 *yr or more after their initial treatment for carcinoma of the breast have been studied retrospectively. It is concluded that there is no justification for the concept of an immunological or hormonal control maintaining the cancer cells in a dormant state during the latent interval. The results of this study are consistent with the theory of constant growth rate of the tumours.*

INTRODUCTION

IT IS a well recognized fact that, in a small proportion of patients with breast cancer, there is a long latent interval between primary treatment and the first recurrence. The reasons for this are not obvious at first sight. Two conflicting theories have been proposed: that of slow but constant growth rate [1–5] and that of hormonal or immunological control, maintaining the cancer cells in a dormant state [6–10].

MATERIAL AND METHODS

In this paper, an attempt has been made to identify the correct theory by a retrospective analysis of 139 patients with breast cancer, who had a disease-free period of 5 yr or more. This comprised the total number of such patients registered at the Christie Hospital during the years 1956–1961 inclusive.

This group has been compared with groups of unselected patients with breast cancer. Details of these have been obtained from the literature, with the exception of the group with initial bone recurrence which has been assessed by the author. In addition the author's group of patients having a long latent interval has been subdivided, and the subgroups compared with each other. Also the relationship has been investigated between latent interval and survival after recurrence for those patients who had a long latent interval with initial chest wall recurrence.

Accepted 29 December 1976.

RESULTS

Comparison has been made with respect to age of patients at presentation (Fig. 1) [11], site of tumour in the breast (Table 1) [12], and metastatic pattern (Table 2) [13]. With the exception of a difference in primary metastatic pattern, the groups are similar. The greater incidence of local recurrence in the primary metastatic pattern of the author's group probably resulted from the fact that a smaller percentage of these had received post-operative X-ray therapy to the chest wall and glandular areas.

The duration of the latent interval in the author's group showed a random scatter throughout the age distribution (Fig. 2).

A semi log plot of the survival curve for the whole of the author's group has been compared with that constructed from data published by Campos [14] for 274 unselected patients dying from breast cancer (Fig. 3). It was found that the difference between the slopes is nowhere near statistically significant ($Z = -0.05$). This indicates a similar mortality rate for the two groups of patients.

Survivals in the author's group following initial recurrence on the chest wall have been compared with survivals after initial recurrence at this site in a group of patients with breast cancer having unselected latent intervals (Fig. 4) [13]. Both groups had initial chest wall recurrence alone or coincident recurrence at other sites. There is a statistically significant difference ($P < 0.005$).

Similarly, a comparison has been made between survivals after initial recurrence in bone, in the author's group of patients having a long latent interval, and a group of patients

L.I.Q.	11%	6.6%
Nipple area	15%	19%

recurring at this site initially, but having unselected latent intervals. There was a statistically significant difference (Table 3) ($P < 0.02$).

Insufficient numbers of patients developed initial recurrences at other sites for useful statistical analysis.

Patients developing initial chest wall recurrence alone, who did not have induction of the menopause or X-ray therapy to the chest wall as part of their initial treatment, have been selected from the author's group of patients

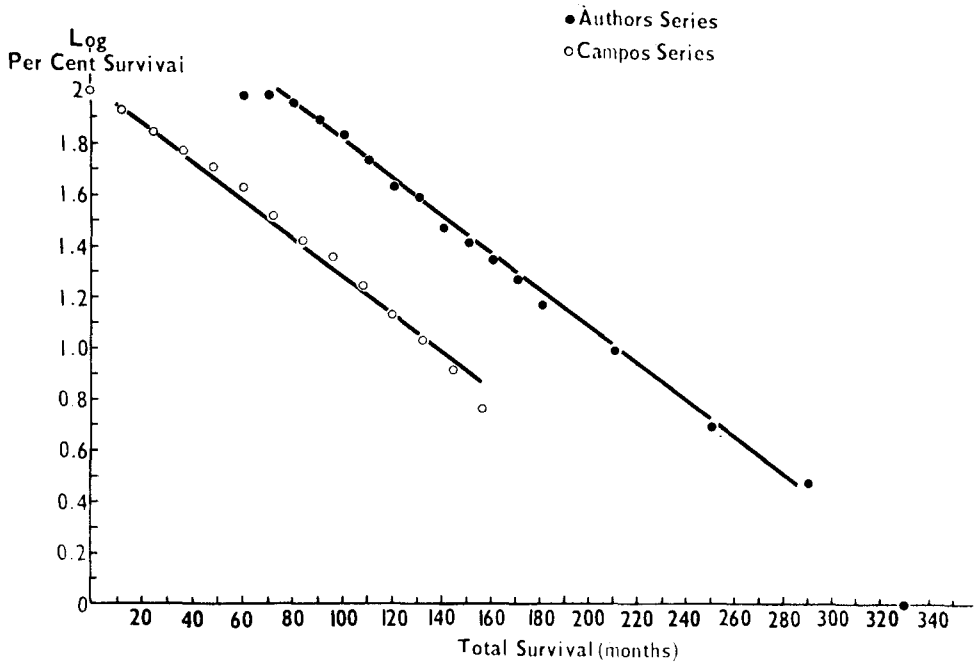

Fig. 3. Comparison of survival curve for all patients in this group with that obtained from Campos's figures.

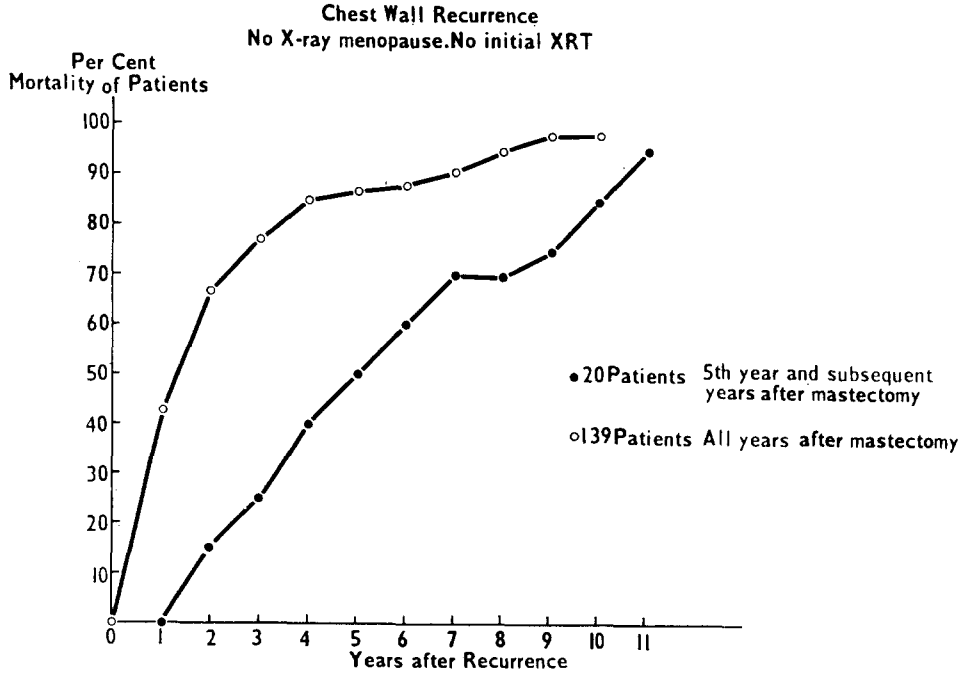

Fig. 4. Chest wall recurrence. Comparison of survival curves obtained for this group and Jackson's group.

having a long latent interval. For these patients the latent interval has been plotted against survival after recurrence. The correlation was highly significant ($P < 0.001$). However, as there were few patients with extreme values of duration of latent period 8 patients were added. These constituted the sum total of patients first registered during the years 1951–1955 inclusive at the Christie Hospital who fulfilled the above criteria for inclusion into the correlation. There is now no doubt concerning the highly significant correlation ($P < 0.001$) (Fig. 5).

From the author's group of patients having a long latent interval, subgroups have been selected by virtue of histologically involved axillary nodes, muscle fixation of primary tumour, poor differentiation or anaplasia and palpable but histologically negative axillary nodes or reactive hyperplasia. It was found that

Bone	19.3%	26%
Local	45%	34%
Subsequent metastatic pattern following local recurrence		
Lung	34%	35%
Bone	36%	28%
Liver	16%	18%

there is no significant difference in survivals from subgroups not displaying these features (Tables 4–6).

DISCUSSION

The patients in the author's group received a variety of treatments, both for the primary tumour and for recurrent disease. However, different modes of therapy seem to make little difference to the survival figures for patients with breast cancer [13, 15–18]. It is therefore reasonable to compare survivals in the author's group with survivals in unselected groups of patients with breast cancer. However, the ratio of latent interval to survival after recurrence may be altered by induction of the menopause or by local X-ray therapy to the chest wall, given as part of the initial treatment. Patients who received these treatments have been excluded from analysis when survival after recurrence is considered.

It has been demonstrated in this paper that the author's group of 139 patients, with a long latent interval, is similar to an unselected population of patients with breast cancer in all features investigated, with the exception of a longer survival after initial recurrence in bone and chest wall. When a tumour is clinically apparent it grows, in most cases, for most of the time in an exponential manner [1, 3, 4]. Also tumour growth rate is proportional to survival times [19]. Therefore, patients with breast cancer having long latent intervals are those with tumours which when clinically apparent exhibit a slow constant growth rate. It would seem reasonable to assume a similar slow constant growth rate giving rise to a long latent interval and it is unnecessary to postulate hormonal or immunological control to account for this phenomenon. This contention receives support from the highly significant correlation when latent interval is plotted against survival after recurrence on chest wall.

Table 3. Solitary bone recurrence—survival of this group compared with author's random group. No X-ray menopause as part of initial treatment. None alive

	Survival after recurrence	Dead after		No.
		6 months	12 months	
Author's group Long latent intervals	(2–108) Median 21 months	16%	31%	13
Author's group Unselected latent intervals	(0–106) Median 8 months	41%	60%	80

Table 4. Axillary nodes—comparison of survival times for negative nodes, positive nodes, and palpable nodes negative or nodes showing reactive hyperplasia

	No.	Survival after original treatment	Survival after recurrence
Nodes negative histologically	45	59–292 Median 107 months	0–130 Median 17
Nodes positive histollogically	48	71–213 Median 111.5 months	1–93 Median 15
Palpable nodes negative or reactive hyperplasia	9	78–147 Median 103 months	0–55 Median 11

Table 5. Muscle fixation—comparison of survival times for tumour fixed and not fixed to muscle

	No.	Survival after original treatment	Survival after recurrence
No fixation	41	49–334 Median 103 months	0–130 Median 18
Fixation present	16	70–139 Median 106.5 months	2–55 Median 10.5

Table 6. Histology of original tumour—survival times

	Survival after original treatment	Survival after recurrence
13 patients Poorly differentiated or anaplastic	88–179 Median 94 months	0–59 Median 18 months
126 patients Grade not stated	59–179 Median 106 months	0–144 Median 21.5 months

One of the main objections to the theory of constant growth rate is that some patients who present with apparently advanced or aggressive cancers have long disease free intervals following their initial treatment [13]. Examples of these tumours are those with muscle fixation, or where there is histological evidence of axillary node involvement, or where the tumour was poorly differentiated or anaplastic. It has been shown in this paper that survivals in groups of patients with these tumours is similar to those of patients having tumours without these features.

It has been suggested that palpable, but

histologically negative axillary nodes, or reactive hyperplasia is an indication of enhanced immunological host activity [20]. However, an analysis of the author's group of patients has shown that the survival times of patients having these features is similar to cases not exhibiting these phenomena.

Since survival is proportional to tumour growth rate, these results indicate that the whole of the author's group of patients is homogeneous in respect of tumour growth rate, and there is therefore no evidence of a separate immunological or hormonal control in the subgroups considered.

It is a clinically apparent fact, that in a few patients with breast cancer, endocrine manipulations may lead to prolonged remissions. However, long term remissions tend to occur in patients who have had long latent intervals [21]. These are therefore patients with slowly growing tumours. The induction of the menopause by irradiation, performed shortly after mastectomy delays the onset of clinical recurrence in a few patients for short periods, but does not significantly alter survival [22–24]. It is therefore suggested that remissions occur as a result of minor changes in tumour doubling time and that very little deviation from the exponential growth rate would be expected from alterations in the hormonal environment of the tumour during the latent intervals.

Acknowledgements—The idea for the study of the patients, forming the basis of this paper, was conceived by Dr. R. Gibb, consultant radiotherapist and deputy director at the Christie Hospital. I am grateful to him, and also to Dr. E. Sherrah-Davies, Dr. D. Deakin and Dr. R. Hunter for advice in its preparation.

I should like to thank Mr. M. Palmer, Miss L. P. Hunt and Mr. R. Swindell, statisticians at the Christie Hospital, for invaluable assistance with the statistical aspect of this paper.

I should also like to thank the staffs of the departments of Statistics and Medical Records at the Christie Hospital. I am indebted to the staff of the department of Medical Illustration for the production of the diagrams. I am grateful to Mrs. A. Hurst for the typing of the manuscript.

Effects of Inducers and Inhibitors of the Benzo(a)pyrene Hydroxylase of Isolated Rat Liver Nuclei and Nuclear Envelopes on the Binding of Benzo(a)pyrene to DNA*

K. ALEXANDROV

Institut de Recherches Scientifiques sur le Cancer, B.P. 8, 94800-*Villejuif, France*

Abstract—*Rat liver nuclei obtained from rats pretreated with different inducers of mixed function oxidases were incubated with* ^{3}*H-benzo(a)pyrene* (^{3}*H-BP*). *The binding of* ^{3}*H-BP to the DNA of these nuclei was found to increase only after induction by* 3-*methylcholanthrene* (3*MC*), *but not after pretreatment of rats with phenobarbital* (*PB*) *of pregnenolone* 16α-*carbonitrile.*

7, 8-*Benzoflavone* (7, 8-*BF*), *a known inhibitor of aryl hydrocarbon hydroxylase, inhibited to about* 80% *the binding of* ^{3}*H-BP to DNA if the nuclei were obtained from* 3*MC-pretreated rats, but not if they were from PB-pretreated or control rats.*

When 1, 1, 1-*trichoropropene*-2, 3-*oxide* (*TCPO*), *an inhibitor of BP epoxide hydratase, was added to the nuclei, the binding of* ^{3}*H-BP to DNA increased in the nuclei of both untreated and treated rats. Microsomes obtained from* 3*MC-pretreated rats when added to the nuclei increased the binding* 2–5 *times. A slight decrease in binding occurred when control microsomes were incubated with nuclei from* 3*MC-pretreated rats as compared to the same incubation without microsomes.*

When these experiments were carried out with denuded nuclei, the addition of nuclear membranes to the medium increased the binding only when the membranes were from 3*MC-pretreated rats. The effect of added* 7, 8-*BF or TCPO to the medium was similar to that observed with intact nuclei. These latter results show that the enzyme activity which activated BP to species that bind to DNA is localized in the nuclear envelope.*

INTRODUCTION

BENZO(A)PYRENE (BP), one of the most common carcinogenic hydrocarbons, is metabolized by aryl hydrocarbon hydroxylase (AHH), the microsomal NADPH-dependent mixed-function oxygenase which contains cytochromes P-448 or P-450 [1], and BP epoxide hydratase (EH) [2]. The action of the mixed-function oxygenases and the hydratase results in the conversion of BP to oxides, phenols, dihydrodiols, diolepoxides and quinones [1, 3].

Although the metabolic activation of BP is believed to take place chiefly in microsomes, such activation has recently been demonstrated with nuclei [4–7]. Increased binding of BP to nuclear DNA was observed in rat liver nuclei from 3-methylcholanthrene (3MC)-pretreated rats [4, 6, 8, 9]. The binding of ^{3}H-BP to DNA in isolated rat liver nuclei was very similar in nature to that which occurred when BP was added to calf thymus DNA in the presence of microsomes [5].

At least two forms of the BP hydroxylating enzyme system (AHH), which can be differentially induced *in vivo* by administration of phenobarbital (PB) or 3MC, have been found in rat tissues [10]. One, therefore, ought to be able to increase or decrease the ability of a potential carcinogen to bind to DNA by inhibiting or stimulating these drug metabolizing enzymes or by adding agents which

Accepted 20 January 1977.

selectively compete with DNA as a substrate for these carcinogens. 7, 8-Benzoflavone (7, 8-BF), an inhibitor of AHH, markedly inhibits this enzyme in hepatic microsomes from 3MC-pretreated rats but not from untreated rats [10]. 1, 1, 1-Trichloropropene-2, 3-oxide (TCPO), an inhibitor of hepatic epoxide hydratase (EH), increase BP binding to exogenous DNA in the presence of liver microsomes [3].

This paper describes studies on the effect of inducers and inhibitiors of AHH and EH on the binding of BP to DNA in rat liver nuclei *in vitro*.

MATERIAL AND METHODS

Chemicals

^{3}H-labelled BP (specific activity, 25 Ci/mmole) was purchased from the Radiochemical Centre, Amersham, England, and purified on 0.25-mm thick silica gel (Merck, Germany) with benzene. All other chemicals used were as previously noted [5].

Treatment of animals and preparation of nuclei and nuclear membranes

Sodium phenobarbital (0.1%) was placed in the drinking water of 120- to 150-g male Wistar rats (Wag strain) for 10 days; a micronized suspension of pregnenolone 16α-carbonitrile (PCN) in 2 ml water with a trace of Tween 80 was given *per os* to another group (50 mg/kg). The compound was administered at 8-hr intervals (twice daily for 2 days and once on the 3rd day); 3-methylcholanthrene in 0.5 ml corn oil was injected i.p. (25 mg/kg) daily for two days. Control animals received corn oil only. Decapitation was preceded by a 24-hr fast. Nuclei from rat liver were isolated as previously described [5] and were used immediately without storage. All preparations were routinely examined by light and electron microscopy. The nuclei appeared to be normal, intact and essentially free of contaminations from organelles such as microsomes [5]. The nuclear membranes were prepared according to Kay [11] using DNAse I.

Binding of ^{3}H-BP to nuclear DNA

The nuclear pellet was resuspended in 0.05 M Tris–HCl buffer (ph 7.5) containing 0.003 M $MgCl_2$ and NADPH (1.3×10^{-4}M). In 1 ml of medium were suspended the nuclei from about 2 g of liver, liver microsomes (1 or 2 mg of protein) and ^{3}H-BP at 80 nmole in 50 μl acetone. 7,8-BF was added at a concentration of 10^{-4}M and TCPO at 5×10^{-3}M. For the blanks, we used an incubation medium without nuclei. The mixture was incubated for 15 min at 37°C. Thereafter, the incubation medium was chilled to 4°C and the nuclei were sedimented at 1000 $\times$ **g** for 10 min. The nuclear pellet was suspended in 0.05 M Tris–HCl buffer, made 6% with sodium p-aminosalicylic acid (PAS) and 1% with sodium dodecylsulfate (SDS) and the solution was extracted with a phenol mixture [5]. The DNA was precipitated with two volumes of ethanol in the presence of 2% CH_3COONa, then washed with ethanol. The DNA was redissolved in 0.01 M phosphate buffer (pH 7.0) and the solution was incubated with 100 μm/ml of preheated RNAse (80°C for 10 min) at 37°C for 30 min and subsequently for 1 hr with 100 μg/ml preheated pronase (DNAse-free). The solution was adjusted to 1 N $NaClO_4$ and washed with $CHCl_3$- isoamyl-alcohol (24:1). The aqueous phase was washed with ether and the DNA was precipitated as above, washed with ethanol and ether and dried. The DNA was dissolved in water at a concentration of 0.05–0.08 mg/ml. One ml was added to 10 ml of a Triton X100-based scintillant and the radioactivity was measured in an Intertechnique Counter model LS30 with a 29% efficiency for ^{3}H. Samples (0.5 ml) were taken before and after incubation for the AHH enzyme assay as described elsewhere [5].

RESULTS

Effect of inducers on AHH activity and on the binding of ^{3}H-BP to nuclear DNA

The results show 10–16 times more enzymatic activity in the nuclei from MC-treated rats than in those from the control, PB- and PCN-pretreated animals (Table 1). The uninduced nuclei, however, activated BP which bound at low levels to DNA (0.8 μmole BP/mole P-DNA). The binding levels we observed in uninduced nuclei were about 2 times lower than those found by Rogan *et al.* using ^{14}C-BP [6, 8]. PB and PCN did not increase the binding of BP to DNA, whereas 3MC pretreatment increased the binding to the nuclei of the controls about 5 times. These results show that the increased binding level responded only to induction by MC which specifically induces cytochrome P-448 enzyme activity [1, 12] and did not respond after pretreatment of rats with PB or PCN which induce cytochrome P-450.

Table 1. Effect of various inducers of microsomal mixed-function oxidases on nuclear membrane-mediated binding of ^{3}H-BP to DNA of rat liver nuclei. Twenty-four hours prior to sacrifice, rats were given injections of 25 mg of 3-methylcholanthrene (3MC) in 0.5 ml corn oil; phenobarbital (PB) and pregnenolone 16α-carbonitrile (PCN) were administered as described in Materials and Methods. The liver nuclei were incubated for 15 min at 37°C and aliquots (0.5 ml) were removed for AHH determinations. The DNA of the nuclei was isolated as described in Material and Methods

Liver nuclei	AHH*	Enzymatic activity ratio to controls	Binding of ^{3}H-BP to DNA†	Binding ratio to controls
Control rats	100	1.0	0.8 ± 0.2	1.0
PB-treated rats	140	1.4	0.9 ± 0.4	1.1
PCN-treated rats	152	1.5	1.0 ± 0.5	1.3
3MC-treated rats	1604	16.0	3.8 ± 1.5	4.8

*The mean specific activity for the uninduced (control) rat liver nuclei based on more than three separate experiments is equal to 142 pmoles/30 min/mg protein.
†The binding of ^{3}H BP is expressed in μmoles BP/mole P-DNA.

Effect of inhibitors on the AHH and EH activities and on the binding of ^{3}H-BP to nuclear DNA

7, 8-Benzoflavone, a known inhibitor of AHH, exhibited a contrasting effect on the binding of carcinogen when added to the incubation medium at a concentration of 10^{-4}M (Table 2). With control nuclei and nuclei from BP-treated rats, 7, 8-BF had no effect on AHH and on the binding of ^{3}H-BP to DNA. With nuclei from 3MC-pretreated rats, about 80% inhibition of AHH was observed, and BP binding to DNA was inhibited to a level of 0.9 μmole of BP per mole P-DNA which correspond to that observed in nuclei from control and PB-pretreated rats.

When TCPO, a potent inhibitor of BP epoxide hydratase, was added to the nuclei at high concentrations (5×10^{-3}M), the AHH activity (mixed function oxidases) was inhibited. This was supposed to reduce epoxide formation which would reduce binding. However, the binding of ^{3}H-BP to DNA was increased in the nuclei of both untreated and treated rats

Table 2. Effect of 7, 8-BF and TCPO on the binding of benzo(a)pyrene to the DNA of rat liver nuclei. The table represents the average of values obtained in at least three separate experiments. The quantity of protein was 2.5–3 mg/ml of medium ^{3}H-BP (specific activity 1.25–2.5 Ci/m-mole) was incubated with the nuclei in the presence of 10^{-4}M 7, 8-BF and 5×10^{-3}M TCPO

Treatment of animals	Additions	Binding of ^{3}H-BP to DNA (μmole/mole-P)*	(% of controls)
Control	None	1.1	100
	7, 8-BF	1.2	109
	TCPO	2.8	254
Phenobarbital	None	1.0	100
	7, 8-BF	1.0	100
	TCPO	1.9	190
Methylcholanthrene	None	4.6	100
	7, 8-BF	0.9	20
	TCPO	7.4	161

*1 Unit = The fluorescence equivalent to 1 pmole 3-OH-BP formed in 30 min/mg of protein.

(Table 2) which must mean that the essential action of TCPO is inhibition of epoxide hydratase.

Effect of added liver microsomes on BP binding to DNA of liver nuclei

Liver microsomes at two different concentrations (1 and 2 mg of protein per ml) from untreated and 3MC-pretreated rats were added to the purified liver nuclei obtained from untreated and 3MC-pretreated animals (protein concentration 1–2 mg/ml) (Table 3). Slight inhibition (~ 25%) was observed only when microsomes from untreated (control) rats were added to the nuclei from 3MC-pretreated animals. A 5–8-fold greater binding occurred when microsomes from 3MC-pretreated animals were added to control nuclei. A lesser increase in binding (~ 2-fold) was observed when both microsomes and nuclei were obtained from 3MC-pretreated rats.

Table 3. The effect of added liver microsomes on ^{3}H-BP binding to the DNA of purified rat liver nuclei. ^{3}H-BP was incubated with nuclei from 3-methylcholanthrene (3MC)-pretreated rats or control nuclei in the presence of microsomes obtained from the liver of corn oil-treated (Control) or 3MC-pretreated rats. The ratio of binding was determined by dividing the binding results of each group by the results obtained without microsomes

Nuclei	Added microsomes	Protein of microsomes (mg/ml)	^{3}H-BP binding to DNA (μmole/mole-P)	Ratio of binding with to without microsomes
Control	None	0	1.1	1.0
	Control	1	1.2	1.1
	Control	2	1.0	0.9
	3MC	1	5.6	5.1
	3MC	2	9.2	8.4
3MC	None	0	5.5	1.0
	Control	1	3.9	0.7
	Control	2	4.2	0.8
	3MC	1	10.6	1.9
	3MC	2	12.1	2.2

Experiments with Triton X-100

The addition of Triton X-100 at concentrations between 0.5 and 2% to rat liver nuclei leads to complete inhibition of AHH activity in the envelope-denuded nuclei and of the binding of ^{3}H-BP to DNA in all three nuclear preparations from untreated animals and animals pretreated with PB and 3MC (Fig. 1). Treatment with Triton X-100 removed the nuclear envelope and the associated ribosomes leaving the nuclear contents morphologically intact. These results show that enzymes present in the nuclear envelope are capable of activating benzo(a)pyrene to species that react with DNA.

Addition of nuclear membranes to denuded nuclei and the effect of inhibitors on enzyme activity

The addition of nuclear membranes at concentrations of 0.4–0.6 mg of protein per ml of medium leads to the metabolism of BP and subsequently to its binding to DNA (Table 4). The binding increased only when nuclear membranes of liver nuclei from MC-pretreated rats were added to the medium. When 7, 8-BF (10^{-4}M) or TCPO (5×10^{-3}M) were added to the medium containing denuded nuclei and nuclear membranes from 3MC-pretreated rats, the effect was similar to that observed with intact nuclei and microsomes from 3MC-pretreated rats (Table 5). 7, 8-BF inhibited to about 80% the binding of ^{3}H-BP to DNA while TCPO increased it. These results show that the enzyme activity which activated BP to species that bind to DNA is localized in the nuclear envelope.

DISCUSSION

There are recent indications that differences exist between nuclei and microsomes for the metabolic activation of hydrocarbons and their

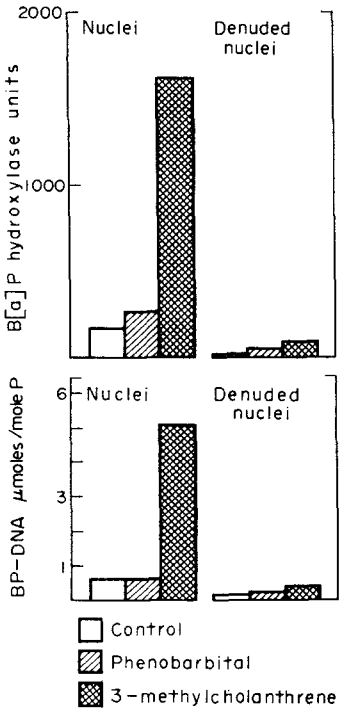

Fig 1. *The effect of Triton X-100 on the BP hydroxylase activity (AHH) and BP binding to DNA in rat liver nuclei.*

Denuded rat liver nuclei were obtained by adding 0.5% *Triton X-100 to isolated liver nuclei. The BP hydroxylase activity and BP binding to DNA in both denuded and intact nuclei were determined as described in Material and Methods.*

binding to DNA [6, 8]. In a previous study [5], we observed a similarity between BP-DNA binding catalyzed by the liver nuclei and liver microsomes from 3MC-pretreated rats.

The levels and induction of nuclear AHH activity that we observed were similar to those reported by others [6, 8, 13] for nuclei from control rats and those from 3MC- or PB-pretreated rats. Again 3MC had a much greater inductive effect than PB, which did not increase the level of nuclear AHH. The ratio of nuclear to microsomal AHH was two to four times higher in 3MC-pretreated rats than in PB-pretreated rats [5]. The effect of PB induction was greatest on the level of nuclear cytochrome P-450 [8].

The amount of hydrocarbon bound to DNA in nuclei from untreated rats was generally low (Table 1). We observed the same with nuclei from PB-pretreated rats while others [8] found that PB doubled the binding; 3MC induction increased the level of binding for all hydrocarbons studied. These data suggest that the potent carcinogen 3MC preferentially induces nuclear enzymes, possibly increasing the binding of hydrocarbons to DNA with the likelihood of tumor initiation.

The addition of TCPO increased the binding level of ^{3}H-BP to DNA in control nuclei and in

Table 4. *Binding of ^{3}H-BP to DNA in denuded rat liver nuclei in the presence of nuclear membranes from treated and untreated rats. The nuclear membranes from controls, phenobarbital (PB)-pretreated or 3-methylcholanthrene (3MC)-pretreated rats were added at a concentration of* 0.5–0.7 *mg/ml of protein to the incubation medium containing the denuded nuclei. nuclei from pretreated animals. TCPO at the concentration used [3] is known to inhibit completely the formation of BP diols and the AHH activity. At this concentration TCPO may also interfere with BP epoxide hydration. The increased ^{3}H-BP binding contributed to the increased quantity of BP oxides and perhaps BP dioxides whose hydrations were inhibited by TCPO. However, Jernström *et al.* [14], using a lower concentration of TCPO, did not observe inhibition of the formation of BP phenols nor of the binding to DNA. 7, 8-BF reduced the binding of ^{3}H-BP to DNA in the liver nuclei from 3MC-pretreated rats, but had no effect on the binding in nuclei from control and PB-pretreated rats. With nuclei from control and PB-pretreated rats, 7, 8-BF did not inhibit the formation of the BP phenol fraction (unpublished results), while with nuclei from 3MC-pretreated rats, 7, 8-BF strongly inhibited phenol formation to an extent similar to that observed with microsomes from 3MC-pretreated rats [10].

The washing of nuclei with Triton X-100 has been shown to remove the nuclear envelope [7, 8]. The simultaneous removal of binding and AHH activities clearly shows that the binding activity as well as the enzyme are associated with the nuclear envelope. The effect of 7, 8-BF and TCPO on the binding activity of nuclear membranes from the nuclei of 3MC-pretreated rats (Table 5) was similar to that observed with all nuclei (Table 2) and with the microsomes from 3MC-pretreated animals [3, 10]. This suggested that the 3MC-induced enzyme involved in the nuclei-dependent BP binding has the same response as that involved in the microsome-dependent BP binding to DNA [3, 15]. We observed a significant increase in the binding of ^{3}H-BP to DNA when the microsomes used were from 3MC-pretreated rats, and slight inhibition with microsomes from untreated animals only when they were incubated with nuclei from 3MC-pretreated rats. These results are in agreement with the results recently published by Pezzuto *et al.* [16] and Jernström *et al.* [14], but are in contrast with the findings of Vaught and Bresnick [9] who recently reported a reduction of BP binding to nuclear DNA when microsomes from untreated rats were added to the nuclear incubation systems, and no effect when microsomes from 3MC-pretreated rats were used. This difference may be due to the low concentration of ^{3}H-BP used in their study. The *in vitro* system used in this study (nuclei and microsomes) closely approximates the *in situ* condition. However, further studies are needed to clarify the role of microsomes in the binding of ^{3}H-BP to DNA in rat liver nuclei.

The manner in which BP is activated in the cell seems to be well established [17, 18]. Recent work shows differences between nuclei and microsomes in the metabolic activation of hydrocarbons and their binding to DNA [6]. We observed a similarity between BP-DNA binding catalyzed by the liver nuclei and liver microsomes from 3MC-pretreated rats [5].

Nagata *et al.* [19] have reported that the nucleus has an enzymatic activity capable of converting BP to the 6-oxo-BP radical. It has also been proposed [8] that cytochrome P-450 rather than other enzymes is involved in the hydrocarbon activation, the one-electron oxidation being the mechanism by which hydrocarbons bind to cellular components. Such oxidations of the substrate would produce a reactive intermediate radical cation capable of binding to cellular nucleophiles [8].

This study has shown that the activity observed with liver nuclei is identical with that of the microsomes from the same animals, and that it is possible to alter *in vitro* the binding of BP to nuclear DNA by adding inhibitors of AHH and EH.

Highly Cytotoxic Antisera Obtained in W/Fu Rats against a Syngeneic Gross Virus Induced Lymphoma*

DENIS GERLIER,† CATHERINE GUIBOUT‡ and JEAN-FRANÇOIS DORE§

Centre Léon Bérard, 28, rue Laënnec, 69373 Lyon Cedex 2 (D. G., J. F. D.) and Institut de Cancérologie et d'Immunogénétique (I.N.S.E.R.M.), 14–16, avenue Paul-Vaillant-Couturier, 94800 Villejuif, France (C.G.)

Abstract—*Antisera raised in W/Fu rats against the syngeneic (C58NT)D lymphoma induced by the Gross agent may provide specific antibodies for passive immunotherapy of Gross virus-induced murine leukaemia. Searching for high antibody activity towards tumour cells, which is highly desirable for passive immunotherapy, eight immunization schedules were assayed in 68 W/Fu rats: groups of five to thirteen adult rats received subcutaneously an injection of 100–700 × 10^6 viable (C58NT)D cells, followed after an interval of three to eight weeks, by weekly subcutaneous injections of 50–250 × 10^6 viable cells. The injection of 400 × 10^6 tumour cells followed four weeks later by five weekly injections of 200 × 10^6 cells gives highly cytotoxic antisera. However, kinetic studies of the antibody response show that if near maximal titers may be reached twenty days after a single inoculation, highly cytotoxic antisera were only reliably obtained after three booster injections. In repeatedly inoculated rats, blood could be drawn several times from the same animal, between the fourth and the twentieth day after the last injection without loss in cytotoxic activity.*

INTRODUCTION

ANTISERA raised in W/Fu rats against the syngeneic (C58NT)D lymphoma induced by the Gross agent have provided a new insight into the definition of cell surface antigens associated with murine leukaemia viruses [1]. These antisera, presently used as typing sera, appear to recognize at least three types of cell surface antigens induced by the Gross agent (GCSAa, GCSAb, G_{IX}) [1, 2], by other murine leukaemia viruses (GCSAb) [1, 3] or even expressed on some normal cells [4]. These antisera have also been used for passive immunotherapy of Gross virus induced murine leukaemia [5]. It is highly desirable that antisera used for passive immunotherapy should have a high activity towards tumour cells. Up to now, three immunization schedules have been used for the production of antisera to Gross virus associated cell surface antigens [1, 5, 6]; however, the cytotoxic titers of the antisera obtained were usually rather moderate and only a few animals occasionally produced high activity antibodies.

We tried different hyperimmunization schedules of adult W/Fu rats with (C58NT)D cells, searching for high antibody activity and reproducibility. The results of these attempts are presented here. The kinetics of the antibody response was followed on some rats.

MATERIAL AND METHODS

Animals

W/Fu rats were originally provided by Dr. J. C. Leclerc (INSERM, Hôpital Cochin, PARIS) and bred in the laboratory; 2.5–5-month-old rats were used for hyperimmunization. W/Fu rats used for the study of the kinetics of antibody production were purchased from Iffa-Credo (Les Oncins, St-Germain-sur-l'Arbresle, France). C57Bl/RhoIco mice were obtained from Iffa-Credo and bred in the laboratory.

Tumour cells

The W/Fu (C58NT)D lymphoma, a syngeneic Gross virus induced lymphoma of W/Fu rat [1] kindly provided by Dr. R. B. Herbermann (National Cancer Institute, Bethesda, U.S.A.) was used. This subline behaves differently from the French-NTD [7]: subcutaneous inoculation of $400–700 \times 10^6$ cells in adult rats produces a tumour which regresses in nearly all rats within 3–4 weeks, progressive growth being an extremely rare event. The lymphoma is serially transplanted as an ascites by intraperitoneal inoculation of 20×10^6 viable cells into weanling W/Fu rats. Cells used for immunization were harvested from the animals 7 days after transplantation, and washed three times in phosphate buffered saline pH 7.2 before use.

E♂G2 lymphoma, a Gross virus induced lymphoma of C57B1/6 mice [8] originally provided by Dr. E. A. Boyse (Sloan Kettering Institute, New-York, U.S.A.) was obtained from the Institut de Cancérologie et d'Immunogénétique. It is transplanted weekly into 6–7-week-old male C57B1/6 mice, by intraperitoneal injection of 5×10^6 viable tumour cells obtained by mincing the spleen. E♂G2 cells used as target in cytotoxicity assays were washed three times and finally suspended in Hank's balanced salt solution.

Antisera

Antisera to (C58NT)D lymphoma were raised in syngeneic adult W/Fu rats by subcutaneous injections of viable (C58NT)D cells. Eight different schedules were used; briefly, a first injection of a variable number of viable (C58NT)D cells was given on day 0 and followed 3–8 weeks later by several weekly injections of different numbers of viable tumour cells. The number of cells used, the number of booster injections and the duration of the interval between the first and the second injections are detailed in Table 1. Usually small tumours grow after the first injection but spontaneously regress within 3–4 weeks and sometime after the third or fourth injection with rapid regression in 8–10 days. Sera were collected by cardiac puncture under ether anesthesia 8–12 days after the last injection. For the kinetic study of antibody production, blood was collected from the tail.

Cytotoxicity test

The test has been previously described [9]. Rabbit complement, individually preselected for absence of natural cytotoxic activity against normal mouse cells, was used. The titer of an antiserum was expressed as the last dilution giving a cytotoxicity index [9] equal to 0.50. For each group of rats the geometric mean of the cytotoxicity titers of the antisera was calculated: $\text{gmt} = \sqrt[n]{t_1 \times t_2 \times \ldots t_n}$.

RESULTS

Comparison of the different immunization schedules

The cytotoxic activities against E♂G2 cells of the individual antisera obtained in the eight groups of rats are shown on Fig. 1. From these data it can be seen that four parameters appear to play a major role in the determination of the best immunization schedule: the number of (C58NT)D cells used for the first injection, the number of cells used for the booster injections, the time interval between the first and the

Table 1. *Immunization schedules of adults W/Fu rats by* (C58*NT*)*D lymphoma cells*

Group No.	Number of animals	Number of cells for 1st injection ($\times 10^6$)	Interval of time between 1st and 2nd injection (weeks)	Number of viable cells for weekly booster injections ($\times 10^6$)	Number of weekly booster injections
I	8	100	8	50	6
II	7	150	5	200	7
III	5	700	4	250	9
IV	7	450	8	250	9
V	6	300	3	150	7
VI	10	400	4	150	8
VII	13	400	4	200	6*
VIII	12	400	4	200	5

*The last injection was given two weeks after the fifth booster injection.

second injections and the number of booster injections.

The number of cells initially injected does not appear to be critical, but the use of 150×10^6 (group II, gmt = 540) or 400×10^6 viable cells (groups VI and VII, gmt = 500 and 890 respectively) yields better results than 700×10^6 cells (group III) which only gives a mean titer of 170.

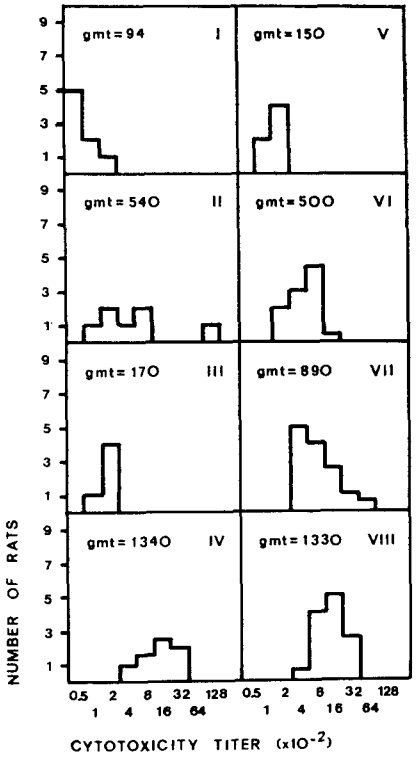

Fig. 1. Cytotoxic activity to E♂G2 lymphoma cells of W/Fu anti (C58NT)D rat sera. Distribution of individual cytotoxicity titers and geometric mean titer (gmt) are indicated for each group of immunized rats (see protocol on Table 1).

A time interval of 4 weeks or more between the first and the second injections yielded high activity antisera (groups IV, VI, VII and VIII). Poor results were obtained when a 3 weeks interval was used (group V, gmt = 150).

Booster injections of 50×10^6 (C58NT)D cells were found to be inefficient (group I, gmt = 94) and higher number of cells were required to produce antisera with high cytotoxicity titers: in group IV a mean titer of 1340 was obtained with booster injections of 250×10^6 cells.

The total number of injections also appears to be an important parameter in the obtention of high activity antisera. Animals in groups VI, VII and VIII received the same initial injection of 400×10^6 (C58NT)D cells, and, after a 4 weeks interval, booster injections of $150–200 \times 10^6$ cells. Antisera obtained in group VIII, after 6 injections, showed a mean titer of 1330, while antisera obtained after 9 injections in group VI showed a lesser activity (gmt = 500). Animals in group VII were immunized identically to animals in group VIII, but they received 2 weeks after the sixth injection an extra booster injection: the cytotoxic activity of antisera obtained in this group of rats was somewhat lesser (gmt = 890) than that of antisera raised in group VIII.

Kinetic studies of the cytotoxic antibody response during immunization

Five 10-week-old W/Fu rats were immunized identically to animals in group VIII (Table 1). Injections were given on days 0, 28, 35, 42, 49 and 56; blood was drawn from the tail of each rat during immunization at days 1, 7, 13, 20, 27, 35, 41, 48, 55, 60, 64, 67, 72, 76 and 79. The cytotoxic activity to E♂G2 cells of sera from individual rats is shown on Fig. 2. Cytotoxic antibodies rise between the 7th and the 13th days, and reach a peak value (256–1024) at day 20. Thereafter a slight diminution in titer was observed, just before the second injection. The second peak of maximal titer (1024) was already obtained 6 days after the third or the fourth immunization. The fifth and sixth injections only maintain the maximal titer which slightly declines (down to 512) 23 days after the last immunization.

In a control experiment where the rats were only given one injection of 400×10^6 cells, a single antibody peak of comparable magnitude was obtained at day 20, followed by a slow decrease in titer and by day 48, sera from the above mentioned rats showed a cytotoxic activity about 10 times lesser than that of repeatedly inoculated rats.

DISCUSSION

Immunologic studies of the response of syngeneic rats against the Gross virus induced lymphoma (C58NT)D have been performed by many investigators. However few studies provide information about the optimal methods of immunization to produce the highly cytotoxic antisera required for passive immunotherapy trials. Antisera have been either raised following repeated intraperitoneal inoculations of (C58NT)D cells [1] or harvested from animals developing a slowly growing tumour after a single subcutaneous inoculation [5, 6].

In our experiments, the use of an immunization schedule consisting in repeated subcutaneous injections appears to frequently give antisera with high activity against E♂G2 cells. The best immunization schedule appears to consist, as in group VIII, of an initial injection of 400×10^6 viable (C58NT)D cells, followed 4 weeks later by 5 weekly injections of 200×10^6 cells. Such a schedule yields highly cytotoxic antisera (gmt = 1330, with individual titers ranging from 400 to 3200) within a rather short time.

These results were confirmed by the kinetic study of the immune response which also showed that the number of booster injections must not be too high and can even be reduced to 2 or 3. This was further verified: when 22 rats were immunized according to protocol VIII and blood drawn 7 days after the second and the fifth booster injections, the antisera obtained showed identical titers. So, near maximal titers may be achieved 2–3 weeks after a single inoculation, but highly cytotoxic antisera were only reliably obtained after repeated inoculations. Previously reported kinetic studies showed a biphasic response to a single inoculation of (C58NT)D cells in 8 week-old W/Fu rats: a first 19S and a second 7S antibody peaks were evidenced respectively 10 and 30–50 days after the subcutaneous injection of 100×10^6 cells [6]. In the experiments reported here, a single antibody peak was observed. An explanation for these appatently conflicting results could be that two different targets cells were used in the tests, which could have revealed different cell surface antigens; likely, we cannot exclude a difference due to the source of rats or lymphoma cells, various sublines of the (C58-NT)D considerably varying in their ability to generate immune responses [7].

Enzyme treated (C58NT)D cells were also used in immunization of W/Fu rats [9] and gave a higher cytotoxic antiserum than untreated cells without detectable qualitative modification of antigens on (C58NT)D cells. But a modification of the capacity of the animals to recognize each of the different cell surface antigens cannot be excluded, eventually related to the immunization schedule used. Finally, it must be stressed that the antisera obtained in the studies reported here were assessed for their activity towards Gross virus-associated cell surface antigens. Data from other investigator [3] and preliminary results from our laboratory indicate that, using E♂G2 lymphoma cells as target, a complement dependent cytotoxicity assay detects almost exclusively antibodies to GCSAa. However, these sera would certainly also react with other antigens of the Gross agent, but it is not known whether such reactivity would parallel their cytotoxic activity.

The Difference Between "Selective Folinic Acid Protection" and "Folinic Acid Rescue" in L5178Y Cells Culture

BRIDGET T. HILL,*† L. A. PRICE,‡ S. I. HARRISON§ and J. H. GOLDIE§¶

The Imperial Cancer Research Fund Laboratories, Lincoln's Inn Fields, London WC2A 3PX, U.K.
‡The Institute of Cancer Research, Royal Marsden Hospital, London SW3 6JJ, U.K.
§St. Michael's Hospital and the University of Toronto, Canada

Abstract—*The separate concepts of "folinic acid protection" and "folinic acid rescue" have been investigated in two sublines of L5178Y lymphoblasts differing in their sensitivity to methotrexate (MTX). The effects on cell viability of both sublines have been studied using combinations of folinic acid (CF) with both MTX or DDMP (2, 4-diamino-5-3′, 4′-dichlorophenyl-6-methylpyrimidine).*

The use of CF protection (i.e. the simultaneous addition of CF) with MTX or DDMP produces different results in both cell lines. MTX-sensitive cells can be protected from the lethal effects of both MTX and DDMP by the simultaneous addition of CF. However, it is not possible to protect MTX-resistant cells in this way from the cytotoxic effect of either of these drugs. These results may partly be explained by transport studies which show that the simultaneous addition of CF has no effect on the efflux of both drugs from either cell line nor on MTX influx. Concurrent addition of CF does, however, reduce the influx of DDMP into MTX-sensitive cells but not into MTX-resistant cells.

Folinic acid rescue (i.e. the addition of CF some time after drug administration) rescues MTX-sensitive cells from the toxicity of MTX to a greater degree than MTX-resistant cells. However, rescue from DDMP toxicity occurs in both cell lines to a similar extent. The delayed addition of CF increases the efflux of MTX from MTX-sensitive cells, but not MTX-resistant cells. CF rescue does not alter DDMP efflux from either cell line.

These findings suggest that in treating neoplasms likely to be resistant to MTX selective folinic acid protection should be used, both with DDMP and/or MTX (i.e. CF should be given simultaneously with either or both drugs). This will prevent toxicity to cells likely to be sensitive to MTX (e.g. bone-marrow, gut) but will not prevent any tumouricidal effect of either agent on MTX-resistant cells. Conversely, in an MTX-sensitive tumour, the use of MTX plus a folinic acid rescue is more appropriate. Most of the therapeutic effect of DDMP will be lost by using CF rescue in treating either MTX-sensitive or MTX-resistant tumour cells.

INTRODUCTION

THE REVERSAL of methotrexate (MTX) toxicity by the addition of folinic acid (CF) is now a well established fact. This practice improves the therapeutic index of methotrexate and is widely used in the clinical management of various human malignancies including epidermoid carcinomas of the head and neck and acute leukaemia in children [1–7]. CF was first shown to prevent the toxic effects of MTX in mice [8–10] and then the concept of folinic acid rescue was demonstrated in mice bearing the L1210 leukaemia by Goldin *et al.* [11–13] and subsequently in man by Schoenbach *et al.* [14] and Burchenal and Kingsley-Pillers [15]. The logical extension of these earlier clinical and preclinical studies with folinic acid rescue enabled the use of very high doses of MTX over short periods of time

(i.e. less than 36 hr) [16] and subsequently in lung cancer [17] and childhood tumours [18, 19].

The original experimental studies of Goldin *et al.* [12, 13] showed in particular that delayed administration of CF following treatment with MTX rescued from the toxic effects of the MTX without significantly reducing therapeutic effects, whilst simultaneous addition of CF and MTX prevented toxicity but resulted in significant loss of therapeutic activity. We have investigated the apparent differential effects of these two processes in tissue culture, namely "folinic acid rescue" involving subsequent addition of folinic acid after MTX, and "folinic acid protection" where the drug and the antidote were added simultaneously. From these studies it would be possible to determine whether particular advantages could be gained by exploiting either or both these concepts selectively.

We have shown *in vitro* that in an MTX-sensitive line of L5178Y lymphoblasts the simultaneous addition of equimolar amounts of MTX and CF significantly reduces the lethal effect of MTX [20]. However, in an MTX-resistant line CF failed to prevent the cytotoxic effects of MTX. This "selective protection" with CF of cells sensitive to MTX has been demonstrated also using DDMP, a diaminopyrimidine (i) in experimental transport studies [21] and (ii) clinically, where the simultaneous administration of CF with DDMP protects the bone marrow from the toxic effects of the drug without impairing the therapeutic effects against the tumour [22–25].

In this study we have compared the effects of (i) delayed and (ii) simultaneous addition of equimolar folinic acid with either MTX or DDMP on the colony-forming ability of two sublines of L5178Y lymphoblasts, one sensitive and the other resistant to MTX. In addition, the effects of CF on the extent of uptake and efflux of isotopically labelled MTX and DDMP by both cell lines was measured. Our results have enabled us to distinguish between the effects of "protection" and "rescue" with CF and illustrate that "protection" appears more selective for MTX-sensitive cells than "rescue". It may be particularly advantageous, therefore, to try to exploit this phenomenon when attempting to eradicate cells resistant to MTX from mixed cell populations.

MATERIAL AND METHODS

Chemicals and reagents

DDMP and DDMP-2-^{14}C were kindly provided for these studies as gifts from Drs. A. H. Griffith and C. A. Nicol, The Wellcome Research Laboratories, Burroughs Wellcome Co., Beckenham, Kent, U.K. and Research Triangle Park, N.C., U.S.A. The radiochemical purity of DDMP-2-^{14}C (specific activity 13.8 mCi/m mole) was 98%, as checked by TLC in three systems and by isotopic dilution. MTX and folinic acid (CF), as calcium leucovorin, were obtained from Lederle Products Limited, Montreal, Quebec, Canada and thymidine was obtained from Sigma Chemical Co., Norbiton, Surrey, U.K. ^{3}H-MTX (specific activity 250 mCi/m mole) was purchased from Amersham Searle Corporation, Illinois, U.S.A. and checked for radiochemical purity by paper chromatography in (a) 0.5% sodium carbonate solution and (b) *n*-butanol: pyridine:water (1:1:1). Other chemicals were purchased from Fisher Scientific Co. Ltd., Don Mills, Ontario, Canada, Sigma Chemical Co., or British Drug Houses, Limited.

Cell cultures

Two sublines of L5178Y lymphoblasts were grown in suspension culture in Fischer's medium for leukaemic cells in mice (Grand Island Biological Supplies Ltd., N.Y.) supplemented with 10% foetal calf serum (Flow Laboratories Ltd.) as described previously [26, 27]. The growth of the MTX-sensitive line was inhibited by continuous exposure to 10^{-8}M MTX and that of the MTX-resistant line by 5×10^{-6}M MTX. The MTX-resistant line was shown to transport MTX less effectively than the parent sensitive line, with results comparable to those published earlier [20, 28].

The cells, in logarithmic growth, were incubated for varying times with drugs at a concentration of 5×10^{-5}M. This drug concentration was selected since it produced a significant cell kill even in the drug-resistant cell line [27]. The viability assays were performed according to the method of Chu and Fischer [29] with the modifications described previously [26, 27]. Under these conditions the cloning efficiency was 60–75%. Treated cultures were expressed as a percentage of the control (non-treated) cultures, which were given the value of 100%. The mean and standard deviation of the colony counts of 5 replicate cultures were computed to attain the survival curves which were produced by plotting the percentage surviving fraction against time on a semi-logarithmic scale.

(i) "*Folinic acid protection*". This procedure involved the simultaneous addition of equimolar CF with the drug to the cultures at the

commencement of the experiment, as described previously [20].

(ii) "*Folinic acid rescue*". This procedure involved the addition of drug (MTX or DDMP) at zero time followed by the subsequent addition of equimolar CF to individual cultures at 6, 24 and 48 hr after the experiment commenced. Prior to this addition of CF, the cells were removed from the drug-containing medium by centrifugation at 500 *g* and resuspended in fresh medium. At 24 hr after CF addition the viability assays were carried out, namely at 30, 48 or 72 hr after the original addition of MTX or DDMP. This procedure was an attempt to duplicate the *in vivo* conditions of rescue with CF.

(iii) *MTX reversal by thymidine.* This procedure involved the simultaneous addition of 4×10^{-6}M thymidine with the drug to the cultures at the commencement of the experiment.

Transport studies

Logarithmically-growing L5178Y cells were removed from suspension by centrifugation at 350 *g* at room temperature for 3 min. The cells were then counted and resuspended to a final concentration of 2×10^6/ml in Hank's balanced salt solution pH 7.4 (Grand Island Biologicals Ltd., N.Y.) and placed in a water bath at 37°C, as described previously [20, 21, 30]. Drugs were added to aliquots of these cell suspensions resulting in a final drug concentration of 5×10^{-5}M and a radio-isotope concentration of 0.625 μCi/ml and 2.5 μCi/ml of ^{14}C-DDMP and ^{3}H-MTX respectively. Incubations were carried out at 37°C in a water-bath with gentle shaking.

(i) *Influx.* At various times after drug addition (either drug alone or drug plus equimolar CF), aliquots of cell suspension were removed, washed with ice-cold Hank's solution and isotonic saline as described before [20, 21, 30]. The resultant cell pellets were solubilised in N. NaOH and mixed with 10 ml of Aquasol (NEN, Dorval, Quebec, Canada). Radioactivity was determined using a Nuclear Chicago Scintillation Counter Unilex II Model No. 6853 at 63% efficiency for ^{14}C and 40% efficiency for ^{3}H.

For long term incubations with DDMP alone or in combination with equimolar CF the drugs were added to cells growing in Fischer's medium supplemented with 10% foetal calf serum. Six hours later the incubation was terminated by rapid chilling and dilution with ice-cold Hank's solution as described above, and the ^{14}C content of the resultant cell pellets was estimated.

(ii) *Efflux.* Previous experiments had established that after a 30 min incubation a steady-state concentration of both DDMP and MTX was achieved in both cell lines [20, 21, 30]. Therefore, the rates of efflux of DDMP or MTX from the cells at 37°C were determined by incubating cells with the drug, using the conditions described above, for 30 min. The cells were then centrifuged at 350 *g* for 2 min at room temperature and resuspended to the same volume in fresh Hank's solution without drug at 37°C. In these experiments the rate of efflux of the drugs alone, previously established [20, 21], was confirmed and the effects of (a) the simultaneous addition of CF with the drugs at the commencement of the preincubation, or (b) the delayed addition of CF until the cells were resuspended in fresh drug-free medium after the initial 30 min incubation, on the rates and extents of drug efflux were determined. Aliquots of cell suspension were removed at subsequent time intervals, and treated as described above in order to determine their radioactivity content.

RESULTS

Cell viability assays demonstrating "folinic acid protection"

Figure 1 shows the effect of 5×10^{-5}M MTX in the presence and absence of simultaneously added equimolar folinic acid on the survival of MTX-sensitive (Fig. 1a) and MTX-resistant (Fig. 1b) L5178Y cells. These results confirm our earlier findings (i) that the simultaneous addition of folinic acid with the MTX had no effect on the response of resistant L5178Y cells to MTX, however (ii) the lethal effects of MTX on the sensitive cells were considerably reduced by exposure to the combination with only a 0.75 log kill after 48 hr [20].

This concept of selective folinic acid protection of MTX-sensitive cells is also illustrated by the results in Fig. 2. MTX-sensitive L5178Y cells were treated with 5×10^{-5}M DDMP alone or with the simultaneous addition of equimolar folinic acid (Fig. 2a). The combination almost abolished the reduction in cell viability seen with DDMP alone. In contrast in the MTX-resistant cells (Fig. 2b) no protection was afforded by CF.

These data indicate that there are significant differences in sensitivity to folinic acid protection in two sublines of L5178Y lymphoblasts. It is not possible to protect MTX-resistant cells from the toxicity of either MTX or DDMP by the simultaneous addition of

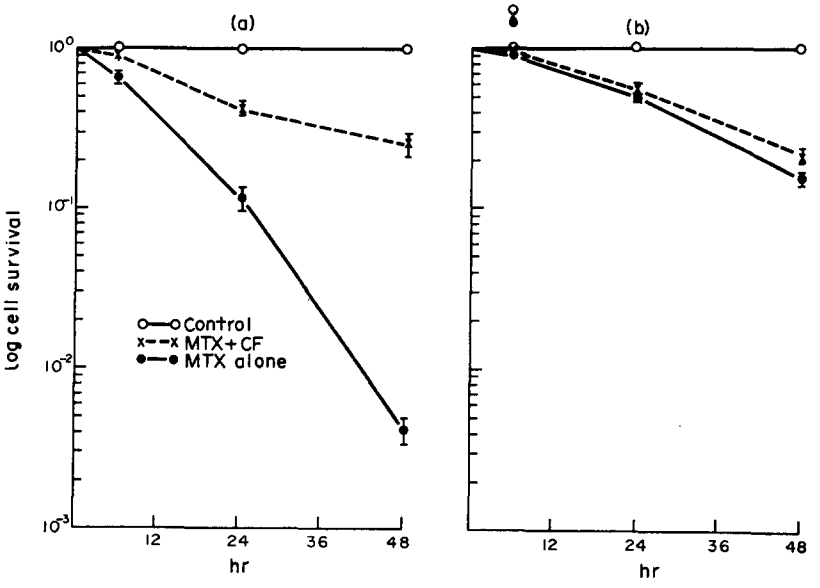

Fig. 1. The ability of CF to "protect" from MTX cytotoxicity. (a) MTX-sensitive cells; (b) MTX-resistant cells. Percentage surviving fraction plotted against duration of drug exposure. Each point represents the mean of 5 determinations.

equimolar CF. However, this inability to protect MTX-resistant cells should not be taken to imply that drug toxicity cannot be overcome in these cells, since Fig. 3 shows that the simultaneous addition of equimolar thymidine and MTX reverses the lethal effects of MTX not only in MTX-sensitive cells but also in the drug resistant cells.

Cell viability assays demonstrating "folinic acid rescue"

Figures 4 and 5 illustrate CF rescue from the lethal effects of MTX and DDMP respectively, using drug concentrations of 5×10^{-5}M. In these experiments, as described in Material and Methods folinic acid was administered 6, 24 and 48 hr after drug addition at zero time,

and the ability of cells to form colonies was tested 24 hr later after the addition of CF, i.e. at 30, 48 and 72 hr after the start of the experiment. Figure 4 (a) shows that MTX-sensitive cells can be rescued from the lethal effects of MTX, and Fig. 4 (b) shows that the subsequent addition of CF after MTX treatment of MTX-resistant cells does afford a slight rescue. The extent of rescue after 6 hr treatment with MTX is comparable in both sensitive and resistant cells (i.e., approx. 40%), but after 24 and 48 hr treatment the addition of CF rescues the sensitive cells more effectively than the drug resistant line (see Table 1).

The results with DDMP in Fig. 5 also show

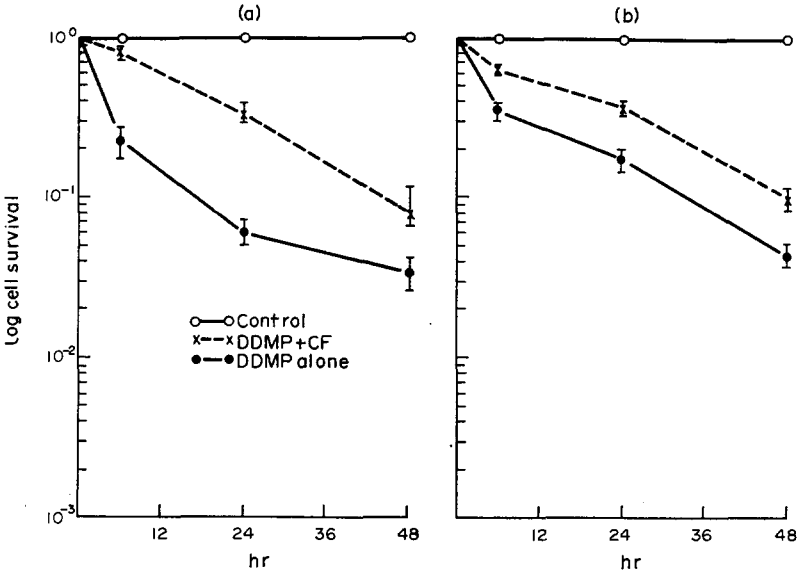

Fig. 5. The ability of CF to "rescue" from DDMP induced cytotoxicity. *Table 1. The differential effects on cell survival of "protection" and "rescue" with CF in combination with MTX or DDMP treatment**

	Percentage of cell survival* MTX-sensitive cells	MTX-resistant cells
MTX treatment		
With CF—rescue	44%	26%
With CF—protection	75%	11%
With added thymidine	96%	83%
DDMP treatment		
With CF—rescue	25%	26%
With CF—protection	78%	0%

*These numbers were calculated from the results illustrated graphically in Figs. 1–5, using the 48 hr points in all cases. They represent the percent increased survival after addition of CF or thymidine compared with survival from drug treatment alone.

that it is possible to rescue both cell lines to a degree from DDMP toxicity by the delayed addition of folinic acid. A better rescue is achieved in the sensitive cells when the rescue is commenced within 24 hr of DDMP treatment with 85% and 60% of the population being rescued when CF was added at 6 and 24 hr respectively. When rescue is delayed to 48 hr the extent of rescue is much less and both MTX-sensitive and MTX-resistant cells appear rescued to a similar degree (see Table 1).

These data indicate that in applying the principle of folinic acid rescue both cell types can be rescued to a certain extent from the toxicity of both DDMP and MTX. The sensitive cells are rescued to a greater degree than the resistant cells from both drugs unless the DDMP rescue is delayed until 48 hr when this differential is lost.

Transport studies

(i) *Influx of MTX and DDMP.* We have previously shown, in both cell lines, that the simultaneous addition of equimolar folinic acid is without effect on the steady-state level of MTX after a 30 min *in vitro* incubation [20]. Similarly, the uptake of DDMP into MTX-resistant cells was unaffected by the presence of CF [21]. However, during this short-term incubation the extent of influx of DDMP into the MTX-sensitive cells was markedly reduced by the simultaneous addition of folinic acid [21, 30]. In these present studies we have confirmed these latter observations after a 6 hr incubation with 5×10^{-5}M DDMP in the presence and absence of simultaneously added equimolar CF. The results in Table 2 demonstrate that the simultaneous addition of CF, under the conditions used for the cell viability assays described above, selectively reduces the

*Table 2. The effect of simultaneous addition of folinic acid on the level of DDMP in L5178Y lymphoblasts after a 6-hr incubation at 37°C**

Cell line	Extent of DDMP uptake†
MTX-sensitive	49% ± 5
MTX-resistant	88% ± 3

*Uptake of ^{14}C-DDMP was measured following a 6 hr exposure of logarithmically growing cells in standard culture conditions at a concentration of approximately 2×10^5 cells per ml (as described in Material and Methods) to 5×10^{-5}M DDMP, plus or minus equimolar folinic acid.

†The extent of uptake in the absence of added folinic acid = 100%.

amount of DDMP which enters MTX-sensitive cells without markedly influencing the uptake of the drug by the MTX-resistant cells.

These results are in agreement with our previous proposal that the inability of folinic acid to prevent DDMP influx into MTX-resistant cells may account possibly for the failure of folinic acid to protect this cell line from DDMP toxicity [21].

(ii) *Efflux of MTX and DDMP.* L5178Y lymphoblasts were preloaded with either MTX or DDMP by incubation for 30 min at 37°C with drug at a concentration of 5×10^{-5}M. In both cases more drug is taken up by MTX-sensitive cells than by the resistant cells, confirming previously reported observations [20, 21, 28]. The cells were then centrifuged, washed and resuspended either in fresh medium alone or medium containing 5×10^{-5}M CF at 37°C. Aliquots of cell suspension were removed at the time shown in Figs. 6 and 7 for MTX and DDMP respectively. The Figs. illustrate the extent of efflux of the drugs in the presence and absence of CF from the two cell types. In Fig. 6 it can be seen that the addition of CF markedly enhances both the initial rate and final extent of efflux of MTX from the MTX-sensitive cells. This is in contrast to the lack of effect that added CF has on drug efflux from MTX-resistant cells. Figure 7 shows that the addition of CF to cells preloaded with DDMP does not alter the efflux characteristics from either cell type. The addition of folinic acid prior to preloading the cells with either drug was without effect on the subsequent efflux of either DDMP or MTX in both cell lines of L5178Y cells [unpublished data, 20].

These results indicate that the original addition of folinic acid enhances the efflux from MTX-sensitive cells, but is without effect on MTX-resistant cells or on DDMP efflux from both cell types.

DISCUSSION

These studies were designed to answer the following questions about the reversal or prevention of MTX or DDMP toxicity:

(i) Is there a difference between the MTX-

sensitive and MTX-resistant cell lines in their response to MTX or DDMP using CF protection as opposed to CF rescue?
(ii) Is there any correlation between the biological viability assays and the transport phenomena seen when studying DDMP or MTX alone or in combination with CF?
(iii) If a distinction can be made between CF "rescue" and "protection" can it provide a basis for separate therapeutic strategies against varied tumour cell types?
(iv) From our experimental data, can we provide any insight into the clinical observations that have been made with DDMP?

Our data show that the effects on cell viability if CF is added simultaneously with MTX or DDMP (namely "CF protection") are very different from those observed following the delayed addition of CF (namely "CF rescue"). A summary of results is given in Table 1.

When treating cells with MTX a significantly greater proportion of MTX-sensitive cells can be protected for a given cell kill than can be rescued following delayed addition of CF. This protection of MTX-sensitive cells confirms our earlier results with MTX and pyrimethamine [20], those of Burchenal *et al.* with DDMP [31] and the work of Borsa and Whitmore [32]. In MTX-resistant cells, however, simultaneous addition of CF affords no protection whilst the delayed addition does rescue a small proportion of the cell population. An explanation for this latter finding may be that under conditions of rescue, the extracellular MTX is washed from the cells, preventing further cell kill, whilst for protection the MTX remains in contact with the cells for the duration of the experiment. The greater degree of protection afforded to MTX-sensitive cells with simultaneous CF may be related to the fact that the CF is either competing with, or attenuating the MTX toxicity throughout the experiment [21, 30]. The observed rescue of MTX-sensitive cells, confirming the now well documented phenomenon of leucovorin rescue [33–35], may be explained by the observation that delayed CF addition enhances the efflux of MTX. This latter finding was one of several mechanisms which have been implicated in the CF reversal of MTX toxicity [20, 33]. However, this efflux effect is not seen in the MTX-resistant cells and neither are they rescued to the same extent.

The effects of simultaneous addition of equimolar CF to DDMP treated cells are similar to those with MTX, with a higher degree of protection afforded to MTX- sensitive cells and negligible protection in MTX-resistant cells. In these sensitive cells, the simultaneous addition of CF must, as in the case of MTX, be reducing the toxicity of the

DDMP. In contrast, with the delayed addition of CF there is less selectivity and if rescue is delayed until after 24 hr both drug-sensitive and -resistant cells are rescued to approximately the same extent (see Table 1). The selective protection afforded to MTX-sensitive cells by simultaneous addition of CF may occur as a result of the competition for uptake seen between DDMP and CF in this cell line [21, 30]. This competition is not apparent in drug-resistant cells which are also not protected from the cytotoxicity of DDMP by simultaneous CF addition. In contrast the delayed addition of CF allows some degree of rescue in both cell lines. This effect cannot be explained in terms of altered efflux of DDMP. The observation that the extent of rescue with equimolar CF is not as great from DDMP as it is from MTX in MTX-sensitive cells, may be related to the fact that in this experimental system DDMP has a relatively poor ability to inhibit dihydrofolate reductase as compared with MTX [27].

In treating with MTX clinical neoplasms which are primarily composed of cells which are relatively resistant to MTX by virtue of similar mechanisms to those in these L5178Y cells, the simultaneous MTX-CF combinations would be expected to produce less cytotoxic effects against normal cell systems, i.e. bone marrow and gut, without loss of antitumour effect. In addition, MTX treatment could be given for longer than usual. Conversely, a clinical tumour that has properties akin to the sensitive-L5178Y cells and normal sensitive cell systems would be largely protected from MTX toxicity by simultaneous CF. In such tumours, delayed CF or CF rescue would be the appropriate therapy. Since the use of thymidine in combination with MTX reverses the toxicity in both MTX-sensitive and MTX-resistant cells to comparable extents (see Fig. 3 and Table 1), there would appear to be no selectivity and therefore no advantage in employing this combination.

Most of the therapeutic effect of DDMP will be lost if the drug is combined with the delayed addition of CF or CF rescue in either MTX-sensitive or -resistant cells. DDMP would be expected to be most effective against resistant-type cells in which CF protection (simultaneous addition of CF) is employed. This correlates well with our clinical experiences [22–25] and the original clinical observations of Murphy *et al.* [36].

CONCLUSION

The optimal MTX-CF combinations will be determined by whether the tumour being treated has properties more closely related to the MTX-resistant type or MTX-sensitive type cells. In the former case, CF protection strategy would be expected to be the most effective and in the latter case, the usual delayed rescue would be the most rational.

The optimal combination of DDMP and CF against MTX-resistant cells is the simultaneous addition of the two drugs. In this way, selective folinic acid protection of drug sensitive cells can be exploited. However, this selectivity is lost when DDMP is administered followed by a CF rescue.

Abstract—*Preliminary results are reported on the acute toxicity and antitumour effectiveness of prednimustine, a prednisolone ester of chlorambucil. Prednimustine was less toxic to the rat, but slightly more toxic to the mouse than chlorambucil. In both rodent species, the acute toxicity of binary combinations of chlorambucil and prednisolone could be reduced by giving the steroid 4 hr after the alkylating agent.*

Prednimustine was more effective than chlorambucil against a sensitive line of the Yoshida ascites sarcoma and killed 70% of cells from a strain which exhibited a 50-fold acquired resistance to chlorambucil. However, prednimustine was ineffective against the Ehrlich ascites tumour which is intrinsically resistant to alkylating agents.

The molecular mode of action of prednimustine appeared comparable to that of chlorambucil, though the former compound did exhibit corticosteroid-like properties, as evidenced by its cytotoxicity to a hormone-sensitive mouse lymphoma cell line.

INTRODUCTION

SINCE the initial recognition of the leukopoenic properties of nitrogen mustard and its utilisation for the treatment of leukaemia [1], many alkylating compounds have been synthesised in attempts to produce selective antitumour agents. Alkylating functions have been attached to biologically essential molecules, for example sugars or amino acids, in the hope that the resultant compounds might be transported selectively into proliferating cells [2, 3]. Such a rationale has provided many of the alkylating agents which currently find wide clinical application (e.g. myleran, melphalan, degranol, chlorambucil) [2–5]. More recently alkylating functions have been attached to various hormones by workers at the Leo Research Laboratories, Sweden [6]. One of these compounds, Estracyt, a 3-*N*-(bis(2-chloroethyl) carbamate of estradiol 17-phosphate, is useful in the treatment of prostatic carcinoma [7–9].

The present communication describes the results of animal and tissue culture studies with another steroid–cytostatic compound, prednimustine, a prednisolone-21 ester of chlorambucil [10, 11].

MATERIAL AND METHODS

Chemicals

Prednimustine (pregna-1, 4-diene-3, 20-dione, 11, 17-dihydroxy, 21-4-p(bis-(2-chloroethyl)-amino) phenylbutyrate was synthesised in the laboratories of Leo Research, Helsingborg, Sweden. Chlorambucil (Leukeran) ($ClCH_2$-$CH_2)_2N.\ _6H_4.\ (CH_2)_3COOH$ was synthesised in the Chester Beatty Research Institute, London and prednisolone (11β, 17α, 21-trihydroxy-1, 4-pregnadiene- 3, 20-dione) was obtained from the Sigma Chemical Company Ltd., Kingston-upon-Thames, England. It should be noted that the molecular weights of prednimustine, chlorambucil and prednisolone are respectively 646.7, 304.2 and 360.5: for

Accepted 20 January 1977.

rough comparative purposes, therefore, xg prednimustine contains $x/2$ g chlorambucil. Fischer's medium, foetal bovine serum and horse serum were obtained from Gibco-Biocult, Glasgow, Scotland. Benzyl penicillin (Na) BP and streptomycin sulphate BP were obtained from Glaxo Laboratories Ltd., Greenford, England. [6-^{3}H]-thymidine (25Ci/mmol), [6-^{3}H]-uridine (5Ci/mmol), L-[4, 5-^{3}H]-leucine (1Ci/mmol) and 2-deoxy-D-[1-^{3}H]-glucose (4.6Ci/mmol) were all obtained from the Radiochemical Center, Amersham, England All other chemicals were purchased from either Hopkin and Williams Ltd., Chadwell Heath, Essex, England or British Drug Houses Ltd., Poole, Dorset, England. AnalaR grades were used where available.

Cell lines

Two lines of the Yoshida ascites sarcoma, one sensitive to alkylating agents and the other exhibiting a 50-fold [12] increase in acquired resistance, were routinely passaged at weekly intervals by the intraperitoneal injection of 2×10^6 cells in female Wistar rats as previously described [13]. Ehrlich ascites tumour cells were also passaged weekly by an intraperitoneal injection of 2×10^6 cells in male BALB/C mice. Drugs were administered subcutaneously three days after tumour transplantation, dissolved in dimethyl sulphoxide (DMSO). Rats or mice were killed by cervical dislocation and the tumour aspirated in 0.9% saline.

Primary suspension cultures of both the sensitive and resistant Yoshida sarcoma cell lines could be maintained for up to 10 days *in vitro*. Growth was initiated with 5×10^4 cells/ml in Fischer's medium containing 20% foetal bovine serum, benzyl penicillin (60μg/ml) and streptomycin (100μg/ml). Drugs were added to suspension cultures 24 hr after initiation when the cells were in logarithmic growth.

Hormone-sensitive mouse lymphoma cells (S49) were maintained in logarithmic growth in suspension culture using Fischer's medium supplemented with 10% horse serum. Drugs were added 24 hr after initiation of new cultures as described for Yoshida cells.

Survival curves

The survival of female Wistar rats and male BALB/C mice from acute drug treatments was determined: all animals were weighed daily for at least 3 weeks. Drugs were administered subcutaneously.

Yoshida and Ehrlich ascites tumour cells were harvested from the peritoneal cavity of both drug-treated and control animals and counted using a Coulter Model ZF Electronic Particle Counter (Coulter Electronics, Harpenden, Herts, England). The surviving fraction was determined from the percentage of cells surviving in the treated animals compared with those present in untreated hosts.

Survival data for the S49 mouse lymphoma cells were determined by growth rate and trypan blue dye exclusion tests. Drugs were added to *in vitro* cultures in either ethanol or DMSO; the final concentrations of ethanol or DMSO were never more than 0.1%.

Isotope incorporation experiments

Yoshida ascites sarcoma cells were harvested from animals treated on the 4th day following tumour transplantation with either a single dose of chlorambucil (10 mg/kg), or prednisolone (10 mg/kg), or prednimustine (20 mg/kg). At various times after treatment animals were killed and aliquots of cells(10^6/ml) were incubated in Fischer's medium in the presence of ^{3}H-thymidine (1μCi/ml), ^{3}H-uridine (5μCi/ml) or ^{3}H-leucine (5μCi/ml) for 15 min at 37°C. At the end of the incubation the cell suspensions were cooled to 0°, centrifuged to remove medium and extracted twice with an equal volume of 0.2 N perchloric acid (PCA). The residual pellet was fractionated into RNA, DNA and protein by the method of Munro and Fleck [14]. The radioactivity in aliquots of the DNA, RNA and protein fractions was counted using a Multimat II Intertechnique liquid scintillation spectrometer. DNA was estimated colorimetrically by the method of Burton [15], RNA by the Orcinol technique [16] and protein according to Lowry *et al.* [17]. The packed cell volume of a constant number of cells at various times after treatment was determined using haematocrit tubes.

Measurement of glucose transport in Yoshida sarcoma cells

Tumour-bearing animals received prednimustine (20 mg/kg) or prednisolone (10 mg/kg). The tumour cells were harvested 3 hr later and incubated in Fischer's medium containing 1.0μCi/ml ^{3}H-2-deoxyglucose at 37°C. At various time intervals thereafter, aliquots of the cell suspension were cooled to 0°, centrifuged, washed with ice-cold Fischer's medium, and extracted with an equal volume 0.5 M perchloric acid. The radioactivity in aliquots of the supernatant was counted in a Multimat II Intertechnique liquid scintillation spectrometer.

Studies were also performed on Yoshida cells exposed *in vitro* to prednimustine (10^{-5}M) or prednisolone (10^{-5}M). ^{3}H-2-Deoxyglucose at a concentration of 0.1μCi/ml was added im-

mediately after the drug and the cells were incubated at 37°C. Aliquots of cell suspension were removed at measured time intervals, extracted with 0.5 N PCA and counted as above.

RESULTS

Acute toxicity of prednimustine

Prednimustine was less toxic to rats than chlorambucil, as shown in Table 1. For example, a dose of 32 mg/kg chlorambucil killed 3/10, whereas an equivalent dose of prednimustine (in terms of its chlorambucil content, 64 mg/kg) produced no deaths. The simultaneous administration of chlorambucil (32 mg/kg) and prednisolone (32 mg/kg) produced toxicity comparable to chlorambucil alone (32 mg/kg). However, when prednisolone (32 mg/kg) was given 4 hr after chlorambucil (32 mg/kg) the resultant toxicity was less than that produced either by chlorambucil alone (32 mg/kg) or by the simultaneous administration of chlorambucil (32 mg/kg) and prednisolone (32 mg/kg). Figure 1 shows selected body weight curves of rats following treatment with prednimustine, chlorambucil, or binary combinations of chlorambucil and prednisolone. Although the weight losses induced by high doses of prednimustine were less than those induced by chlorambucil, recovery was slower. At low drug doses there was little difference in the weight losses produced either by chlorambucil alone, or by prednimustine, or by combinations of the two agents.

BALB/C mice tolerated larger doses of both chlorambucil and prednimustine than did Wistar rats. However, as can be seen from Table 2, prednimustine (at doses equivalent to its chlorambucil content) was more toxic to the mouse than chlorambucil. Further, prednisolone (64 mg/kg) enhanced the toxicity of chlorambucil (64 mg/kg) when the two drugs were administered simultaneously, though when prednisolone (64 mg/kg) was given 4 hr after chlorambucil (64 mg/kg) the toxicity became comparable to that produced by chlorambucil (64 mg/kg) alone. From Fig. 2 it can be seen that prednimustine produced a larger fall in mouse body weight than did an equivalent dose of chlorambucil. The reduction in body weight produced by chlorambucil was enhanced by the simultaneous administration of prednisolone, and in addition recovery was delayed. The reduction in body weight resulting from binary combinations of chlorambucil and prednisolone was less extensive when the administration of the hormone was delayed by 4 hr.

schedule of administration was critical. Simultaneous administration of chlorambucil and prednisolone produced the same survival of both tumour cell types as resulted from the injection of chlorambucil alone. However, by exploiting the observation that sub-cellular binding of chlorambucil was maximal 4 hr after injection [18, 19], and giving prednisolone at this time, the surviving fractions corresponded

Antitumour effects of prednimustine

Dose–response curves for chlorambucil and prednimustine against alkylating agent-sensitive and resistant lines of the Yoshida ascites sarcoma in host rats are shown in Fig. 3. Prednimustine was more effective than chlorambucil against the sensitive tumour and killed a small but significant fraction of drug-resistant cells. Both tumour lines showed some sensitivity to prednisolone. The antitumour effects of prednimustine could be mimicked with combinations of prednisolone and chlorambucil, though the to those obtained with an equivalent dose of prednimustine. Thus at a dose of 10 mg/kg chlorambucil, followed 4 hr later by 10 mg/kg prednisolone, the surviving fraction of sensitive cells at 72 hr was 0.05, comparable to that obtained with prednimustine alone. More extensive data for the resistant line are shown in Fig. 3. Combination treatments were adopted in an attempt to enhance the antitumour effects of prednimustine against resistant cells. Injection of chlorambucil (30 mg/kg) 4 hr after prednimustine (60 mg/kg) resulted in the same

cell survival as prednimustine (60 mg/kg) alone, but when prednisolone (30 mg/kg) was given 4 hr after prednimustine (60 mg/kg) the surviving fraction was reduced significantly from 0.32 to 0.23.

Acquired resistance has been developed in the Yoshida tumour strain which fails to respond to alkylating agents [20]. On the other hand the Ehrlich tumour is intrinsically resistant to alkylating agents and was used in the present study to investigate whether prednimustine might be effective against neoplasms which are refractory to chemotherapy *ab initio*. Even toxic doses of prednimustine (128 mg/kg), chlorambucil (64 mg/kg) or combinations of chlorambucil (32 mg/kg) plus prednisolone (32 mg/kg) failed to suppress the growth of this tumour.

Effects of prednimustine on macromolecular synthesis

Table 3 shows the changes in cell volumes, DNA, RNA and protein contents of the sensitive Yoshida cell line following treatment of tumour-bearing animals with prednimustine or chlorambucil. Prednimustine induced both an increase in cell volume and imbalanced growth (as demonstrated by the enhanced RNA:DNA and protein:DNA ratios), typical of alkylating agents, though these changes were less than those resulting from chlorambucil treatment. The effects of prednimustine, prednisolone and chlorambucil on the rates of DNA, RNA and

protein synthesis are shown in Fig. 4. Prednisolone produced an initial fall in the rate of DNA synthesis which returned to the control level after 24 hr. Both prednimustine and chlorambucil induced similar decreases in the rates of synthesis of all the macromolecular species and in this respect prednimustine exhibited properties characteristic of a typical alkylating agent [13]. The incorporation of radioactivity into the acid soluble pools was not altered by prednimustine, prednisolone or chlorambucil, showing that these agents did not restrict the uptake of radiolabelled precursors into the cells.

Role of the prednisolone component of prednimustine

Glucocorticoid hormones are known to inhibit glucose transport [21] and it could be that the antitumour properties of prednimustine derive from such an effect. In order to explore this possibility we have investigated the effects of prednimustine and prednisolone on the transport of 2-deoxyglucose into Yoshida sarcoma cells. Table 4 shows the uptake of [^{3}H]-2-deoxyglucose by alkylating agent sensitive and resistant Yoshida tumour cells following their aspiration from host animals 3 hr after drug administration. It is apparent that neither prednisolone nor prednimustine markedly affected glucose transport into cells of either strain. These results were confirmed in an *in vitro* experiment where resistant strain Yoshida tumour cells were incubated with [^{3}H]-2-deoxyglucose in presence of either prednimustine or prednisolone. The results shown in Fig. 5 demonstrate that neither compound modified the uptake of carbohydrate. These results are perhaps not surprising since in other studies we have found that Yoshida cells contain very few glucocorticoid receptor bind-

ing sites (data not shown). Hence it seemed relevant to explore further the possibility that prednimustine possesses glucocorticoid-like properties. We examined the response of a known glucocorticoid-sensitive lymphoma cell line (S49) to prednimustine and to its individual components. The results are shown in Table 5. It can be seen that both prednimustine and prednisolone, each at similar low molar concentrations, induce comparable amounts of cell lysis. On the other hand the cells are highly refractory to much higher concentrations of chlorambucil.

Table 4. Uptake of 2-deoxyglucose by Yoshida sarcoma cells

Cultures containing 4×10^5 cells/ml were either untreated or exposed to various drug concentrations. The number of viable cells was counted 24 hr later.

DISCUSSION

Prednimustine was less toxic than chlorambucil to Wistar rats, while the simultaneous administration of chlorambucil and prednisolone resulted in toxicity comparable to that produced by chlorambucil alone. However, if the prednisolone component of the combination was given 4 hr after chlorambucil, then the resultant toxicity was significantly less than that produced by chlorambucil alone. BALB/C mice tolerated larger doses of both chlorambucil and prednimustine than did Wistar rats, though in the mouse the former drug proved less toxic than the latter. Unlike the situation with the rat, the simultaneous administration of chlorambucil and prednisolone resulted in greater toxicity than was produced by chlorambucil alone. However, comparable with the

rat, when prednisolone was given 4 hr after chlorambucil, the toxicity of the combination was reduced.

Prednimustine was more effective than chlorambucil in killing an alkylating agent-sensitive strain of the Yoshida tumour. However, it was possible to enhance the antitumour effects of chlorambucil with prednisolone given 4 hr after the alkylating agent, when the tumour cell kill became comparable to that obtained with prednimustine. Prednimustine exerted a significant cytotoxic effect against a Yoshida tumour line which exhibited a 50-fold (acquired) resistance to chlorambucil [12]. Again, however, a binary combination of chlorambucil and prednisolone (the latter given 4 hr after former) produced a tumour cell kill comparable to that of prednimustine. The rationale for the delayed administration of prednisolone derives from previous studies of this laboratory on the whole animal distribution and rates of subcellular binding of chlorambucil, the latter being maximal at about 4 hr [18, 19]. It proved possible to potentiate the antitumour effects of prednimustine with a subsequent dose of prednisolone, though no enhanced antitumour effect was achieved when chlorambucil was given following prednimustine. Hence, since toxicity is reduced and antitumour effects enhanced by delaying the administration of prednisolone when this steroid is used in combination with chlorambucil, it would seem logical to propose this sequence for the combination.

Unlike the two Yoshida tumour lines just discussed, the Ehrlich tumour, which is intrinsically resistant to alkylating agents, proved totally refractory to prednimustine, chlorambucil, or to binary combinations of chlorambucil and prednisolone.

Comparison of the inhibitory effects of prednimustine and chlorambucil on the levels of macromolecules and their rates of biosythesis in drug-sensitive Yoshida cells, indicated that both compounds produced an increase in cell volume and an imbalance in the proportions of RNA:DNA and protein:DNA. These effects are characteristic of alkylating agents, and in these respects prednimustine exerted effects typical of this class of compound [13, 20].

Since glucocorticoids inhibit the cellular transport of glucose [21], it might be argued that the molecular basis of the antitumour effects elicited by prednimustine is inhibition by its steroid component of glucose transport. However, glucose transport into Yoshida cells was insensitive to either prednisolone or to prednimustine. The very low number of specific glucocorticoid receptor binding sites in these cells could account for this result [unpublished observations]. On the other hand prednimustine exerts a cytotoxicity comparable with prednisolone in a steroid-sensitive lymphoma cell line (S49) which is resistant to chlorambucil. It is apparent therefore that prednimustine is capable of exerting a steroid-type function in cells which possess receptor-binding capacity, while not exhibiting such properties in cells possessing few binding receptors. Whether the alkylating and hormonal properties of prednimustine are dependent upon hydrolysis to its component moieties is the subject of present enquiry.

Abstract—*In view of contradictory reports regarding detrimental effects of regional lymph node removal in animal tumour models, studies were performed to evaluate this controversy. In the experiments it was investigated whether removal of regional lymph nodes (R.L.N.) at any stage of tumour growth had a favourable or unfavourable effect on survival after removal of primary tumours. Removal of tumours was performed also at a stage when early metastases had taken place; this implied leaving a low tumour burden which could possibly be influenced by the host's immunological system. In three tumour models which differed in antigenicity there was no significant effect of R.L.N. removal on survival. In two tumour models which consistently showed lymph node metastases if left untreated, a significant reduction in regional recurrences was noted when regional lymph nodes were removed. In the most appropriate model of the three, the non-antigenic mammary carcinoma, a very pronounced reduction in lymph node metastases was observed when adjuvant combination chemotherapy was given after tumour removal. This was even the case at a level of drug treatment which was ineffective in prolonging survival. In this combined approach, more or less extensive surgery had no discernable effect on survival. Results are discussed in relation to relevance for the clinical management of R.L.N. in breast cancer, with special emphasis on the hazards of regional recurrence.*

INTRODUCTION

THE CONTROVERSY existing regarding the best local treatment for breast cancer is, at least in part, the consequence of the changed concepts which resulted from new information relative to tumour biology. In the field of cancer dissemination, animal experimentation aims at a better understanding of the course of the disease in the human patient. At the present time, this has a particular bearing on the role of the regional lymph nodes draining a tumour. Some experimental studies [1–9] have shown that, at certain stages in the development of a tumour, the regional lymph nodes respond to it and that these early responses appear to be, at least temporarily, inimical to the tumour's progressive growth or resulting metastases. The implications of these observations may be important for the management of uninvolved regional lymph nodes in patients with breast cancer and discussion continues on the merits of retaining or ablating the draining nodes at certain stages in the development of cancer of the breast. In this controversy, one essential condition for valid experimental research is the use of a model which shows similar essential characteristics to the human cancer to which it refers. Even if there is no perfect animal tumour model for any human cancer, certain principles do carry over. The essential characteristics needed for our study include: staging, metastasizing pattern, i.e. lymphogenous and haematogenous spread, similarities in response to therapy and low antigenicity, as expected for

Accepted 24 January 1977.

*A major part of these studies was supported by the "Koningin Wilhelmina Fonds" of the National Cancer League.

spontaneous tumours [10]. For the experiments a rodent mammary carcinoma (2661) which shows these characteristics, was selected [11]. Although this model was shown to have essential metastasizing and therapy-response characteristics, a single animal tumour model can only serve as a model for a certain class of tumours found within a disease. Therefore, two additional tumours were evaluated in a similar way. Since most of the tumour models explored to evaluate an effect of removal of regional lymph nodes were antigenic tumours [1–3, 5–9, 12–19] one moderately and one highly antigenic tumour were additionally used.

In our experimental design, we wanted to evaluate whether there was at any stage before or after inoculation of the tumours a favourable or unfavourable effect of regional lymphadenectomy on survival and tumour growth in the area of the regional lymph node. Tumours were removed at a stage when early metastasis had taken place. This meant leaving a low tumour burden which could be influenced by the host's immunological system. The implications of variations in surgery for breast cancer treatment cannot be judged without taking into account the effect of adjuvant chemotherapy. This led us to study also the effect of combinations of adjuvant chemotherapy with more or less extensive surgery in the most appropriate model, i.e. the 2661 mammary carcinoma model.

MATERIAL AND METHODS

Tumour–host systems

Three different tumour–host systems were used in the present study:

1. Mammary adenocarcinoma 2661 was selected from a trial testing tumours on lymph node and lung metastases. Only this particular tumour, which had originated spontaneously in a CBA/Rij mouse, consistently showed metastatic growth in popliteal, inguinal, paraaortic, renal and axillary lymph nodes as well as lethal haematogenous metastases in the lungs, if inoculated via the foot pad. Following subcutaneous and intravenous immunity challenge tests it was found to be nonantigenic [11]. For each of the experiments 2×10^5 tumour cells were inoculated into the foot pad of female CBA/Rij mice weighing approx. 20 g.

2. Lewis lung carcinoma, a widely used experimental tumour, arose spontaneously in the lung of a C57BL mouse in 1951 [20]. After foot pad inoculation, it always metastasizes to the lungs but only rarely to lymph nodes. Following similar immunity challenge tests as those described for the mammary carcinoma system it was shown that this tumour is antigenic in its host [21]. For each of the experiments 2.5×10^5 tumour cells were inoculated into the foot pad of female C57BL/Ka mice weighing approx. 20 g.

3. The RD/3 tumour was obtained from Dr. Carr* in 1975, together with the inbred strain of albino rats, in which it was originally induced by injection of dibenzanthracene. This tumour model has been described as a valid experimental model for lymphatic metastases after foot pad inoculation [22–24]. According to results of the migration inhibition test and growth curves in immunized and nonimmunized hosts, this tumour was found to be antigenic [25]. Immunization with 10×10^6 viable tumour cells in the flanks and subsequent removal of tumours resulted in the regression of all growing tumours (after 5×10^6 tumour cells) whereas non immunized sham operated control animals showed exponential growth of the tumour (unpublished observations). Accordingly, this tumour may be described as a highly antigenic neoplasm. For the experiments with this tumour, 5×10^6 tumour cells were inoculated into the foot pad of rats weighing approx. 200 g.

Tumour cell suspensions were prepared by the trypsinization method described by Reinhold [26].

Technique of regional lymphadenectomy and tumour removal

In a previous publication it was described that following Patent Blue Violet injection in a manner similar to tumour cell inoculation, the mouse foot pad's lymphatic drainage is to the popliteal lymph node [11]. In rats a similar observation was made. Removal of the regional, popliteal lymph node was carried out under pentobarbital (60 mg/kg i.p.) anaesthesia after shaving and cleaning the popliteal skin area with alcohol. Control groups always underwent a sham lymphadenectomy designed to mimic the trauma of lymph node excision. This procedure consisted of a similar skin incision in the popliteal area without exposure of the node. Incisions were closed with metal clips, which were removed 10 days later.

Experimental design

*For putting this tumour at our disposal, our thanks are due to Dr. I. Carr, Department of Pathology, University and Weston Park Hospital, Sheffield, England.

otherwise indicated tumours were removed by amputation 14 days after inoculation. This interval was chosen intentionally, since it provided a number of deaths from recurrent disease as well as long-term tumour free survivors. The time of regional lymph node removal or sham lymphadenectomy was used as a variable in order to investigate whether presence or absence of R.L.N. before and at any stage after tumour cell inoculation had any discernible effect. In different studies R.L.N. removal was performed 4 days before, 4 or 8 days after tumour inoculation; simultaneously with tumour removal or 6 days later as a secondary procedure. Our major endpoint for evaluation was survival, plotted as the percentage of mice surviving. At autopsy the extent of metastatic spread was recorded and special attention was given to tumour growth in the popliteal area.

Lewis lung carcinoma

Tumour removal was performed 18 days after inoculation. Times of R.L.N. removal or sham lymphadenectomy were, respectively, 4 days before and 4 and 8 days after tumour inoculation and finally simultaneously with amputation. Secondary removal of R.L.N. was not performed for several reasons: 1. in the other models R.L.N. were already infiltrated by tumour at that time and the main purpose was to evaluate if extent of tumour removal showed an effect on survival at that stage. 2. For the role of the R.L.N. this time in the Lewis Lung system would be of no relevance: systemic immunity would be present at that time as haematogenous spread had already taken place.

RD/3 tumour

Time of removal of tumours and treatment of R.L.N. was somewhat different in this system. Amputation was performed 5 days after inoculation and R.L.N treatment was done 3 days before, 1 day after and 3 days after inoculation. Secondary R.L.N. removal was done 8 days after inoculation. These times were chosen earlier than in the other systems because R.L.N. were almost completely replaced by tumour at day 5. This is similar to data described by Carr and McGinty [22].

Chemotherapy as an adjunct to surgery

This study was carried out only in CBA/Rij mice. A similar combination of drugs as described in an earlier publication [11] was used both on established flank tumours and in the adjuvant situation. When given as full dosage the mice received each week:

100 mg/m^2 cyclophosphamide	day 1, 2, 3	i.p.
20 mg/m^2 methotrexate	day 1	s.c.
300 mg/m^2 5-fluorouracil	day 1	i.v.

This schedule was adapted from the clinically used dosages of Bonadonna *et al.* [27–29] on the basis of equal dose per 4 weeks per m^2 body surface [30] and was continued for 4 weeks. Variations in drug doses were used in order to find a level of drug treatment which had an effect on flank tumours comparable to that of C.M.F. in established recurrences in human mammary carcinoma. Subsequently the full and the half dose schedules were employed in the adjuvant situation to determine the effect of these levels of chemotherapy, with and without surgical removal of R.L.N. at the time of amputation.

RESULTS

All mice that died after treatment in the mammary carcinoma model showed almost total replacement of the lungs by metastatic tumour and in addition lymph node metastases in various sites. Other sites of metastatic spread were observed only very rarely (1 ovarian metastasis, 1 brain metastasis and 2 adrenal gland metastases). Evaluation of experiments was done after a long observation period, since late deaths due to recurrent disease were to be expected. Long-term survivors never showed macroscopic or microscopic evidence of tumour, nor was any benign regrowth of removed lymph nodes observed.

Figure 1 shows the survival curves of animals which had their R.L.N. removed or underwent a sham procedure prior to inoculation of the non-antigenic mammary carcinoma. There is no significant difference in percentage surviving animals ($P = 0.89$). It appears however that animals which had their R.L.N. removed have a somewhat longer delay before death. This difference is not significant and can possibly be explained from autopsy records: all sham lymphadenectomized animals always showed large masses of tumour in the popliteal area (sometimes even over 1 g) which could have affected the ultimate date of death. A similar difference is found in most of the groups to be presented. In a separate experiment estimation of lung weights and ^{125}I-(5)-iodo-(2′)-deoxyuridine (0.5 μCi/g of body weight i.p.)—activity in the lungs of similarly treated animals, simultaneously killed, revealed no differences between lymphadenectomy and sham operated animals,

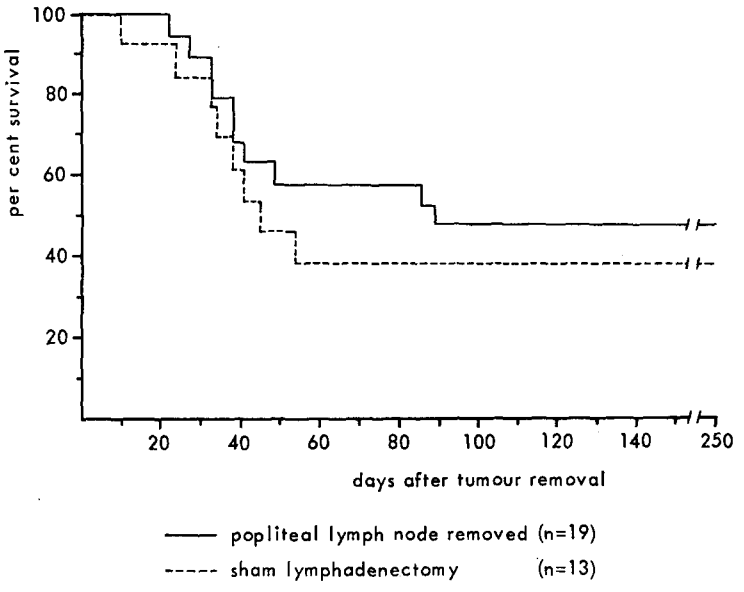

Fig. 1. 2661 *mammary carcinoma. Survival of mice after removal of the primary growth: popliteal lymph node removal or sham lymphadenectomy before inoculation.*

although these parameters seem to be valid indications of the degree of metastatic tumour growth in the lung as shown by much higher lung weights and ^{125}IUdR activity (unpublished observations). If R.L.N. are important in the initiation of immunity it could have been that this specific function, after removal of the R.L.N. prior to inoculation was taken over by other lymph nodes non regional to the foot pad. At days 4 and 8 after inoculation R.L.N. are never infiltrated by metastatic tumour. They are however enlarged due to a reaction to the growing tumour, which has been morphologically interpreted as a sequential combination of a cellular and a humoral immune response [21]. It was shown that an 'early' response consisted mainly of an increase in thymus dependent areas in the lymph node associated with the cellular response. A 'late' response was associated with an increase of the thymus independent humoral response areas. If in the R.L.N. thymus dependent cellular responses are relevant to the rejection of tumour [31] and humoral responses may result in enhancement [32], there should be a difference in 'early' (day 4) or 'late' R.L.N. removal (day 8). Figure 2 shows shows the pooled data of these experiments. Evaluation of the single experiments showed similar results: survival was similar whether treatment of R.L.N. took place at 4 or at 8 days ($P = 1.0$ and $P = 0.74$, respectively).

Removal of R.L.N. at the time of tumour removal could theoretically influence tumour spread, since R.L.N. in most cases contain tumour at this time (14 days after inoculation. Figure 3 shows the survival curves which indicate no difference ($P = 1$) dependent on treatment. It appears that the extent of surgery has no effect on development of blood borne metastases. This finding is similar to that of secondary (tumour containing) lymph node removal at day 20 (Fig. 4). Removal of metastastic lymph nodes independent of whether one (popliteal) or two (also inguinal) lymph nodes were grossly metastatic on palpation at that time after tumour removal had no discernible effect on survival. Nevertheless, the number of palpable metastatic nodes at that time appeared to be a crude index for survival.

As mammary carcinoma 2661 was found to be non-antigenic it could be that findings with tumours which clearly demonstrate antigenicity by influencing tumour cell survival, would differ.

The Lewis lung carcinoma spreads primarily via the blood stream so that this model is less adequate for evaluating recurrence of tumours in lymph nodes. Figure 5 shows the pooled data of experiments similar to those performed in the mammary carcinoma model. Evaluation of experimental groups in which R.L.N. were treated at different times showed no difference; for that reason results were pooled. The surviving fraction of mice is very small in these studies, as a consequence of an earlier haematogenous spread to the lungs. Survival curves run parallel for both groups evaluated.

The RD/3-tumour is a highly antigenic

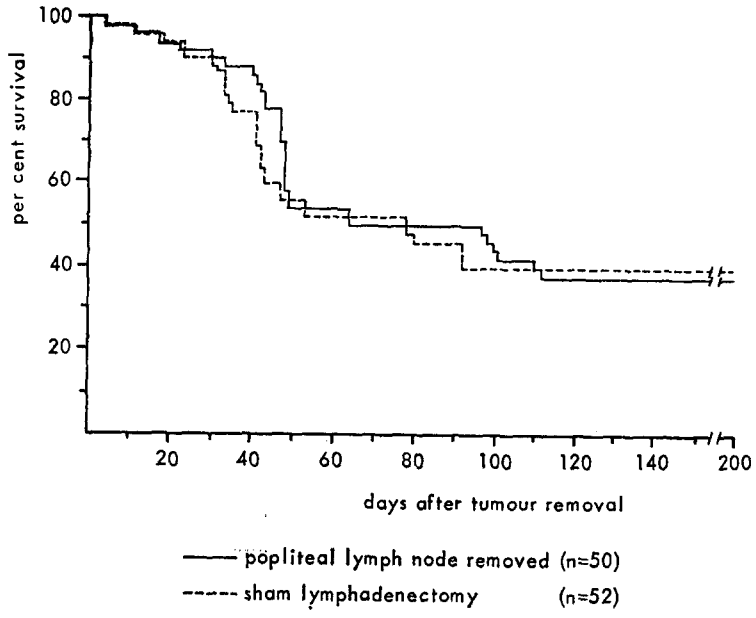

Fig. 2. 2661 *mammary carcinoma. Pooled data on survival after popliteal lymph node removal or sham lymphadenectomy before tumour removal.*

tumour which metastasizes mainly through R.L.N. In contrast to the findings of Carr and McGinty [22] our rats always died as a result of extensive lymph node metastases in the abdomen. Paraaortic lymph nodes almost completely replaced the abdomen in the absence of any macroscopic or microscopic evidence of tumour cells in the lungs. The reason for this different finding is not clear. The time of R.L.N. treatment differed from that used in the other two models since very early lymph node replacement by tumour was observed, similar to findings of Carr and McGinty [22]. Treatment of R.L.N. was performed before, and 1 and 3 days after tumour inoculation of 5×10^6 tumour cells. A smaller number of 10^6 cells usually produced temporary enlargement of the foot pad which regressed afterwards. For similar reasons as for the Lewis lung carcinoma data were pooled and Fig. 6 shows the results.

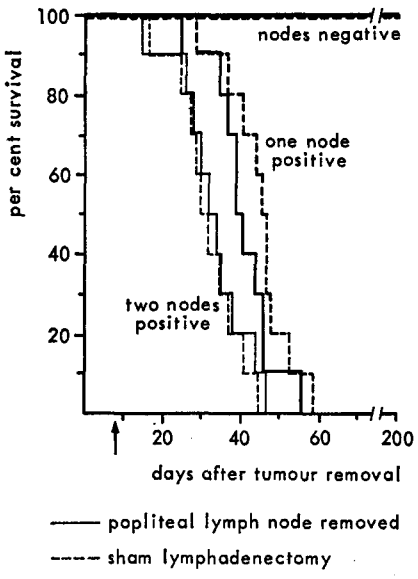

Fig. 4. 2661 mammary carcinoma. Survival of mice dependent on node status and treatment: secondary lymph node removal.

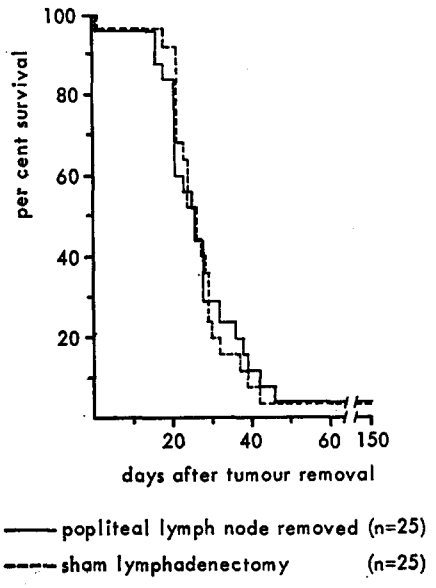

Fig. 5. Lewis Lung carcinoma. Pooled data of experiments comparing removal of the popliteal lymph node with sham lymphadenectomy on survival.

The difference in surviving fraction is not significant ($P = 0{\cdot}46$). A similar phenomenon as found for the mouse mammary carcinoma is observed in the survival curves: i.e. sham-operated animals have a somewhat shorter survival probably due to large tumour masses in the popliteal area.

untreated significant differences were recorded for the incidence of recurrent disease in the popliteal area as shown in Table 2. Recurrent disease was also seen, but in a lower frequency, in animals which had their R.L.N. removed, possibly as a result of spread by lymphatics cut at surgery.

Table 1. *Absence effect of lymphadenectomy on survival**

Time of treatment of R.L.N. 2661 mammary carcinoma	Percentage of mortality from tumour Lymphadenectomy	*P*-values	Sham
Before inoculation	52.6	0.89	61.5
4 days after inoculation	61.3	1	63.6
8 days after inoculation	63.2	0.74	52.6
At amputation	57.1	1	61.5

producing an objective regression, whereas reduction of dosages resulted in resumption of tumour regrowth during therapy.

Since the size of the primary growth was shown to be a crude index for survival [11] a large tumour was chosen for the adjuvant treatment to determine whether cures could be achieved. Chemotherapy was given at the full and at the half dose level. Surgical removal of the primary tumour with or without simultaneous lymph node ablation took place at 18 days after tumour inoculation; lymph node metastases were already established at this stage. Figure 8 shows the survival curves for treated and untreated animals.

Animals treated by adjuvant chemotherapy consisted of four groups in order to evaluate whether variation in the extent of the removal of tumour mass (i.e. with and without regional nodes) and degree of adjuvant chemotherapy would result in differences in survival. As shown, the full dose schedule results in a significant prolongation of survival ($P < 0.05$). This was not significantly dependent on the extent of surgery. Reduction of the chemotherapy schedule to half dose abolished the effect: survival was similar to controls. The extent of surgery also failed to affect survival significa n this group. A similar difference in the sites of metastases as found earlier (11) was found in the groups treated with adjuvant chemotherapy (Table 3). All animals treated by surgery alone, showed extensive lymph node metastases in addition to lung metastases at autopsy. A significant reduction in numbers of lymph node metastases occurred in the treated groups, in contrast to the much less noticeable effect on the massive lung metastases from which the animals apparently had died.

Even though there was no polongation of survival in the animals receiving only half the dosage, the difference in numbers of lymph

node metastases was highly significant. Only in the full dose regimen, a significant difference in the number of lymph node metastases was found between mice treated with lymphadenectomy or not. It must be pointed out, however, that data presented here are expressed as percentages of four nodal areas.

DISCUSSION

In challenging the classical concept of en bloc resection of the primary tumour along with its regional lymphatics for cancer of the breast, Crile's choice of simple mastectomy (i.e. with preservation of R.L.N.) was based on his experimental findings that retention of R.L.N. uninvolved by tumour could be important in maintaining a degree of systemic immunity against growth of metastatic microfoci. Results of his early clinical survival studies seemed to confirm this hypothesis [2, 33–36].

Since then, in addition to the clinical studies, devoted to this controversy, many investigators have developed various experimental models for evaluating the role of R.L.N. in cancer. When reviewing the literature on these studies, differences are noted in tumour models explored, endpoints evaluated and final conclusions. In the present studies, one model, the 2661 mammary carcinoma model, is more fully described, since this is the first model in which an effect on the two modes of spread, i.e. lymphogenous and haematogenous spread, could be evaluated. On the basis of our findings, in both this non-antigenic tumour model and in two additional antigenic tumour models, we must express serious doubts of the unique role ascribed to R.L.N. in antitumour immunity at any stage of tumour growth. On the other hand, relative to the possible barrier function of R.L.N. to tumour cells [37–39] no favourable effect of the removal of R.L.N. which contain tumour was observed in contrast with findings of Sato [12]. An important finding in two models was a significant reduction of tumour growth in the popliteal area. This reduction was observed after R.L.N. removal at any stage. These results indicate that the lymph node itself may present a privileged site in the outgrowth of metastasis. Some experimental data even show that the number of cells necessary to give a 'take' in the lymph node is much smaller than for successful inoculation at other sites [40]. In our studies the large tumour masses in the popliteal area may have influenced survival to a small extent;

similar recurrences in the clinical situation would probably have been treated by radiotherapy and/or chemotherapy, so that this influence would be minimal.

What is the value of these findings among the large list of contradictory reports of experimental studies? Are these models appropriate for conclusions that R.L.N. removal cannot affect ultimate survival?

The presence or absence of some degree of immunological reactivity of the host against its tumour is a controversial condition,regarding the relevance to spontaneous cancer in man of a transplanted animal tumour system. When using quantitative morphometric analysis of draining lymph nodes of the nonantigenic mammary carcinoma and the antigenic Lewis Lung carcinoma we could not find a clear difference in response [21]. It is, however, reasonable to have some doubt about animal tumour systems as models for clinical cancer if they elicit forms of resistance which are clearly attributable to laboratory artefacts associated with their induction. Most of the tumour models previously used for study of the effect of R.L.N. removal involved either highly antigenic, chemically induced, or allogenic tumours. Results from these studies are contradictory: some described a detrimental effect of R.L.N. removal [1–9], whereas others did not find such an effect [13–19, 41] independent of the endpoint evaluated.

Tumours of spontaneous origin were used in only three of the studies: two of them revealed no effect [18, 41], but one showed a detrimental effect of R.L.N. removal in both the initiation [4] as well as in the maintenance of immunity [5]. In these latter studies secondary challenge of tumour was used as an endpoint for the existence of R.L.N. dependent immunity. A reduction in percentage tumours arising at secondary challenge was described in both experimental groups (with and without R.L.N. removal) compared to the first challenge in nonpretreated control animals. This clearly suggests growth affecting antigenicity.

Nevertheless in the present studies antigenicity of the tumour was shown to be of no relevance for the effect of R.L.N. removal. In these studies however we used survival as an endpoint. Many survival curves in the various experiments show 'breaks' before reaching the horizontal level. Skipper [42] observed these breaks in many animal tumour models as well as in human survival curves after surgical treatment. He related these breaks in the slopes of survival curves to the presence of a tumour load of a few or even one tumour cell. If this relation is justified R.L.N. dependent immunity would certainly be expected to have influenced the outcome of an experiment dependent on the survival of such small tumour cell numbers.

From present studies we can qualify R.L.N. only in their properties as part of the reticuloendothelial system's response to tumours. A morphometric analysis of the immune response supports this assumption since it was shown that the reaction of R.L.N. was quantitatively but not qualitatively different from 'distant' lymph nodes evaluated. As a result we cannot support the hypothesis of Crile based on his experimental findings.

The clinical trials comparing simple with radical mastectomy do not confirm Crile's clinical studies. Most of the preliminary reports show no difference in survival [43–45]. This could also be interpreted as evidence that less extensive surgery is equally good. From an emotional and aesthetic point of view, this would be a major improvement. Great caution however must be exercised in this regard: preliminary reports of an international multicenter trial comparing simple mastectomy with radiotherapy to simple mastectomy alone, did show, independent of survival, a significant increase in axillary nodal metastases when left untreated [46]. The 10 years report of a clinical trial comparing radical mastectomy with wide excision showed a similar difference in patients with uninvolved axillary nodes; when axillary nodes were involved, local recurrence and survival were both significantly worse in the latter regimen [47]. Bonadonna noted that local recurrences were decreased by adjuvant chemotherapy [28]. Therefore, we applied this combination of drugs at different levels. Since many experimental studies have shown that there is a inverse relationship between the number of viable tumour cells present at initiation of chemotherapy and curability [48, 49], the comparison of more or less extensive surgery was included. Our findings showed however that there was no relation between extensiveness of surgery and survival. This could be due to the fact that the stage at which amputation was performed was too late. There was apparently a large tumour cell load. A significant reduction in lymph node metastases in contrast to haemotogenous metastases was observed after chemotherapy. This was even the case at a level of drug treatment which was ineffective in prolonging survival. Van Putten *et al.* [50] observed a similar specific decrease of lymph node metastases after cytotoxic drug treatment, associated with an

increase in the number of lung metastases. It is presently not clear whether our finding is due to a difference in cell kill in metastases existing at the time of treatment or to a different localization of regrowth and spread of recurring tumours. The possibility that the lymph bed is a poorer area for regrowth after damage of the lymphatic system by drug treatment cannot be excluded.

Before the general application of less extensive surgery in breast cancer patients is justified by an effect of adjuvant chemotherapy, the presently running trials on adjuvant treatment must be evaluated more fully. Similarly its effectiveness in combination with different surgical approaches should be tested in view of the present findings. Experimental models may share mechanisms and responses to treatment with certain aspects of clinical cancer. In this way employment of suitable models may have a predictive mode and guide the clinician. If experimental results are translatable to man, even if only broadly, it would appear that using such tumour models, the experimentalist is in a position to indicate possibly useful approaches to surgery, adjuvant chemotherapy and the combination of these. Of course such approaches will have to be subjected to the final test of usefulness, the controlled clinical trial. In the evaluation of the results in which survival is the major endpoint, the quality of life closely associated with the incidence of regional recurrences must not be forgotten.

Letter to the Editor

Cell Killing Effectiveness of Hycanthone*

PETER LELIEVELD
Radiobiological Institute TNO, 151 Lange Kleiweg, Rijswijk, The Netherlands

IN ADDITION to possessing antischistosomal activity, lucanthone and its metabolite hycanthone [1] have been found to be active against a variety of tumours [2, 3]. These findings made it interesting to determine the activity of hycanthone in our experimental systems consisting of normal haemopoietic stem cells, either resting or in rapid proliferation, an osteosarcoma and leukemia L1210 cells, all in mice.

Hycanthone, as the methanesulfonate salt, was a gift from the Sterling Winthrop Research Institute, Rensselaer, NY. The drug was dissolved in a NaCl solution and injected subcutaneously.

Survival after hycanthone treatment of normal haemopoietic stem cells was determined using the spleen colony assay of Till and McCulloch [4]. Briefly, hycanthone was injected into groups of 5 mice. Sixteen hours later the mice were killed and from their femurs a bone marrow suspension was prepared. The cell suspension was diluted and injected intravenously into groups of lethally irradiated (950 rad of ^{137}Cs γ-rays) mice. Nine days later, these recipients were killed and their spleens fixed in Telleyesniczky's solution. Spleen colonies (each colony arising from one surviving stem cell) were counted. The results were expressed as the number of colony forming units (CFU) per donor femur. CFU survival after treatment was calculated by comparison with the number of femoral CFU from an untreated group. Rapidly proliferating stem cells were obtained by injection of a standard amount of bone marrow cells into lethally irradiated mice. Seven days later their spleens contained sufficient numbers of rapidly proliferating CFU to permit an assay analogous to the method described above.

For the determination of the activity against tumour cells we used the transplantable osteosarcoma C22LR and leukemia L1210 cells, both available in our laboratory in compatible host strains. Drug effectiveness against the solid osteosarcoma was determined by its influence on the relative tumour volume, defined as the product of caliper measurements in three dimensions of the subcutaneously growing tumour [5]. Drug effectiveness against the L1210 leukemia was determined by colony formation *in vitro* after treatment *in vivo* [6]. This was performed by injecting mice intravenously with 10^4 L1210 cells from an *in vitro* culture. After 6 days, groups of 5 of these leukemic mice were treated. Sixteen hours later a femoral bone marrow suspension, containing leukemic cells, was prepared. From this suspension a dilution was made and plated in 35 mm petri dishes with a mixture of Dulbecco's tissue culture medium, 20% serum, 0.3% agar, and 2-mercaptoethanol as a stimulating agent in a final concentration of 60 μmol/l. The dishes were incubated at 37°C in an atmosphere of 10% CO_2 and 100% humidity for 7 days. Colonies consisting of 50 or more cells were counted and the number of leukemic CFU per femur as well as the surviving fraction were calculated by comparison with the untreated control.

Spleen colony assays and osteosarcoma volume measurements were carried out with (C57BL/Rij × CBA/Rij)F_1 male hybrid mice. Survival of leukemia L1210 cells was determined using (C57BL/Rij × DBA_2)F_1 male hybrid mice.

The toxicity of hycanthone in (C57BL/Rij × CBA/Rij)F_1 male mice was determined. A dose of 400 mg/kg caused death within 30 min.

Accepted 17 February 1977.

*This work was supported in part by the "Koningin Wilhelmina Fonds" of the National Cancer League.

Two-hundred mg/kg produced immediate morbidity, though the mice recovered soon thereafter, and survived for 30 days. In the assay for normal CFU survival 250 mg/kg appeared to be the highest tolerated dose.

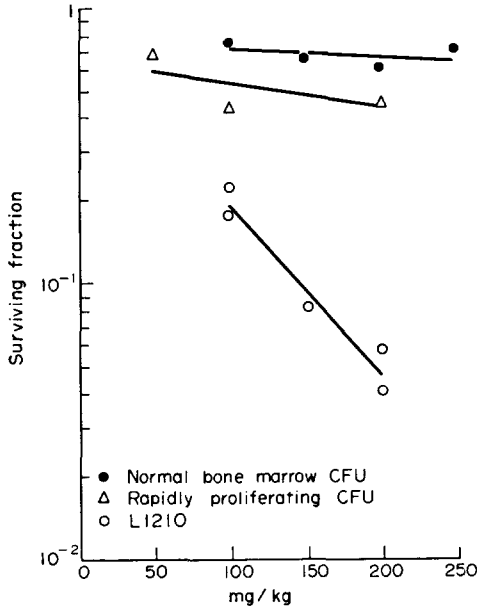

Fig. 1. Dose–effect curves for the survival of resting and rapidly proliferating spleen colony forming haemopoietic stem cells (CFU) and L1210 leukemia cells after subcutaneous administration of hycanthone to mice.

Dose–effect curves for normal resting and proliferating haemopoietic stem cells are presented in Fig. 1. Even at the highest tolerated dose hycanthone was not effective in killing resting stem cells; rapidly proliferating stem cells were more sensitive, but to a minor degree. As a consequence of the ineffectiveness of hycanthone in killing haemopoietic stem cells, no recruitment will take place of resting stem cells into the cell cycle, by which they otherwise should become more sensitive to drug treatment [7]. Since this implies that after prolonged treatment no bone marrow damage will occur, the drug might be suitable for daily administration.

For the osteosarcoma, the tumour volume reduction ratio (TVR) was calculated as the relative volume of the treated over control tumours 4 days after treatment, and a correction was made for differences in tumour volume at the time of treatment. Doses of 125 and 250 mg/kg resulted in TVR values of 0.86 and 0.76 respectively. Earlier observations [5] had made clear that ratio's of 0.5 and higher indicate only temporary arrest of tumour growth. For the osteosarcoma hycanthone clearly belongs to this category.

The dose–survival curve for L1210 cells is presented in Fig. 1. A linear dose–effect relationship was obtained within the dose range tested resulting in a surviving fraction of 5×10^{-2} at the maximum tolerated dose.

The observed absence of bone marrow toxicity of hycanthone and its activity against L1210 cells make it attractive to evaluate effectiveness of hycanthone in combination with other chemotherapeutic agents. However, as hycanthone itself is hepatotoxic [8], combinations with other hepatotoxic drugs must be avoided.

Acknowledgments—The technical assistance of Wil Akkerman is gratefully acknowledged.

Perspectives in Cancer Research

Application of the Phenomenon of Changes in the Structuredness of Cytoplasmic Matrix (SCM) in the Diagnosis of Malignant Disorders: a Review*

LEA CERCEK and B. CERCEK

Paterson Laboratories, Christie Hospital and Holt Radium Institute, Manchester M20 9BX, U.K.

Abstract—*A new approach in the detection of human cancer and leukaemias in which changes in the SCM of lymphocytes induced by cancer basic protein (CaBP), phytohaemagglutinin (PHA) and tumour tissue associated antigens are measured with the technique of fluorescence polarization is described. In this review a special emphasis is given to the outline of the effects of experimental conditions on the results of the "SCM test". Normal human lymphocytes* (266/270) *and those from patients with non-malignant disorders* (30/30) *responded to PHA with a decrease in the SCM and gave no response to CaBP, whereas lymphocytes from patients with cancer* (269/272) *responded to CaBP with a decrease in the SCM and gave no response to PHA. The SCM test becomes tumour specific if specific tumour tissues are used for the stimulation of lymphocytes. After successful surgery the lymphocyte responses obtain characteristics of those from healthy donors. Lymphocytes from patients with leukaemia have a subnormal SCM value and gave either an increase or no SCM response to PHA stimulations.*

INTRODUCTION

THE TERM "structuredness of the cytoplasmic matrix" (SCM) is used to describe the physical state of organization of the cytoplasmic matrix at the molecular level. The SCM reflects the forces of interaction between macromolecules, such as proteins and small molecules, such as water molecules, ions, ATP, cyclic-AMP and other cardinal adsorbants [1–3]. Perturbations of these interactions result in changes in the SCM. The SCM is measured with the technique of fluorescence polarization [1]. Fluorescein molecules are introduced into living cells by intracellular hydrolysis of the non-fluorescing fluorescein-diacetate (FDA) and the degree of polarization of the fluorescein fluorescence is determined. The degree of fluorescence polarization is a measure of the SCM. If the degree of fluorescence polarization is high, SCM is high and vice versa.

The "SCM test" for the detection of cancer is based on the phenomenon that the SCM changes during the cell cycle [1]. When cells progress from the resting phase (Go or G1) into the cell cycle the SCM decreases. Responses of human peripheral lymphocytes, which are normally in the Go or G1 phase of their cell cycle, to mitogens and antigens can, therefore, be detected by a decrease in the SCM [4, 5]. We have reported that lymphocytes from healthy donors and donors with non-malignant diseases can be differentiated from lymphocytes of patients with malignant disorders on the basis of changes in the SCM induced by phytohaemagglutinin (PHA), cancer basic proteins (CaBP) and specific tumour tissue associated antigens [4–7]. We are now presenting an up-to-date summary of the results of the "SCM test" obtained on 679 cases. In this review a special emphasis is given to the outline of the effects of experimental conditions on the results of the "SCM test". Details of the preparation and treatment of lymphocytes as well as of the technical aspects in the measurements of fluorescence polarization in living cells are discussed.

MATERIAL AND METHODS

1. *Preparation of lymphocytes*

1.1. *Collection of blood samples.* Human lymphocytes are prepared from blood collected either in Searle-LH/10 lithium heparin-containing vials or Vacutainer sodium heparin tubes. The heparin concentration should not be less than 300 i.u. per 10 ml of blood. Heparinized blood samples can be stored for up to 24 hr at room temperature without deleterious effects on the SCM responses of lymphocytes.

1.2 *Isolation of SCM-responding lymphocytes.* Ten millilitre samples of blood are transferred into glass vials containing 0.1 g of carbonyl iron powder Type SF (GAF, Great Britain Ltd.) or 8365 w 99.5% iron powder (Koch-Light Laboratories Ltd.) and rotated at 37°C at 20–30 rev/min for 30 min. Vials are then placed on a magnet for 10 min. Lymphocytes are separated by the Ficoll–Triosil gradient technique [8], but using a modified gradient. The gradient is prepared by mixing 24 vol of 9% (by weight) of Ficoll (Pharmacia AB) solution (filtered through a Millipore paper, 0.22 μ), and 10 vol of 35.6% (by weight) of Triosil 440 (Nyegaard and Co. AS, Oslo). The Ficoll–Triosil solution can be prepared in larger amounts, e.g. 1000 ml and stored in a dark bottle at 4°C for up to 2 months. The density of the Ficoll–Triosil solution should be 1.081 g/cm^3 at 25°C and its osmolality 0.320 Osm/kg. The solutions are prepared by using sterile water for injections without preservatives (Phoenix Pharmaceuticals Ltd., Cardiff, Wales, U.K.). Five millilitre aliquots of blood, cooled to 25°C are layered on 5 ml of the Ficoll–Triosil solution equilibrated to 25°C, in 16 mm o.d. centrifuge tubes which are kept in a water bath at 25°C. The centrifuge tubes are wiped dry and centrifuged in a thermostatically controlled centrifuge at 25°C for 20 min at 550 ***g*** (calculated for the interphase position). Only lymphocytes which float on the Ficoll–Triosil solution are collected with a sterile Pasteur pipette, avoiding excess of the blood plasma. None of the lymphocytes which separate inside the Ficoll–Triosil solution should be collected. The latter are SCM-non-responding lymphocytes. Lymphocytes from two gradients of the same donor are pooled into a round-bottom 10 ml glass centrifuge tube and washed twice by adding 6–7 ml of 0.9% preservative-free sodium chloride solution for injections (Phoenix Pharmaceuticals Ltd., Cardiff, Wales, U.K.). Cells are washed by gently drawing them in and out with a clean, sterile Pasteur pipette. Between washes cells are centrifuged at 400 ***g*** for 6 min and the supernatant is decanted. Then lymphocytes are washed once or twice in the same way with complete Dulbecco's [9] phosphate buffered saline (PBS). Lymphocytes from the same donor are pooled and resuspended in PBS in a sterile glass tube at the concentration of not more than 6×10^6 lymphocytes per ml. The suspension is kept in an incubator at 37°C.

The differential cell counts showed that the cell suspensions are over 90% pure lymphocytes. The largest contaminant represent erythrocytes with negligible amounts of granulocytes or platelets. About 25% of the total lymphocyte population is isolated.

1.3 *Stimulation of lymphocytes.* Aliquots of lymphocyte suspensions are incubated at 37°C in sterile glass tubes with phytohaemagglutinin (PHA), cancer basic protein (CaBP) or other antigens for 30–60 min. One tenth of a millilitre of the reconstituted and five times diluted Reagent Grade PHA (Wellcome Ltd.) is added with a 1 ml syringe per ml of lymphocyte suspension mixed by syringing 2–3 times and placed into the incubator. Within the range of undiluted to 20 times diluted PHA the effect is the same. However, we noticed that for some batches of PHA the decrease in the SCM response is not as fast as initially reported [5] and up to 45 min of incubation may be needed to reach the full response. Similarly, the concentration of CaBP is adjusted so that again 0.1 ml is added to 1 ml of cell suspension. Each batch of CaBP has to be assessed for its activity. The CaBP exhibits a sigmoidal dose–response curve, i.e., when full stimulation has been obtained further increase in the concentration of CaBP does not increase the response. For the stimulation of lymphocytes with histologically defined biopsies of tumours, tissues are used either fresh or after storage in dry ice or liquid nitrogen. Before use the frozen pieces of tissue are quickly warmed up to room temperature, washed well in PBS and kept until used for stimulation. Aliquots of 0.5 to 1 ml of lymphocyte suspensions are incubated with tumour tissues, pieces of about 10 mm^3, for 10–15 min at 37°C. To achieve frequent contact between lymphocytes and the tissue, the suspension is gently mixed 2–3 times during the incubation.

In the preparation and incubation of lymphocytes great care should be taken that lymphocyte suspensions of different donors are not cross-contaminated as this will result in a decrease in the control value of the SCM induced by mixed lymphocyte reactions [10] and any further stimulations with PHA or CaBP will be either abrogated or diminished.

2. *Measurement of the SCM*

2.1. *Preparation of the FDA solution.* The fluoresceindiacetate (FDA) is only slightly soluble in water. Therefore, the FDA is first dissolved in acetone. A stock solution is prepared by dissolving 25 mg of FDA* (Koch–Light Ltd.) in 5 ml of spectroscopic grade acetone (Eastman-Kodak). This solution is stored at 4°C and should be prepared fresh weekly. The 2.5 μM FDA substrate solution is prepared by injecting 0.02 ml of the FDA stock solution into 100 ml of sterile, complete PBS (Gibco, Cat. No. 404). Immediately after injection the solution should be well agitated to prevent flocculation. The pH of the PBS must be 7.4 and its osmolality 0.330 Osm/kg; each new batch of PBS should be checked and if necessary its pH and osmolality corrected. Slow thermal hydrolysis occurs in the FDA substrate solution at room temperature. If during the experiment the fluorescence background of the FDA substrate solution should increase to over 20% of the recorder span, a fresh substrate solution must be prepared: even so it can be electronically subtracted on the MPF-4 fluorescence spectrophotometer. As can be seen from Fig. 2 the fluorescence background of the FDA substrate solution is normally about 1% of the recorder span.

2.2. *Equipment.* Measurements of the SCM in living cells are carried out on cell suspensions in a fluorescence spectrophotometer equipped with the polarization accessory. A schematic presentation of the experimental set up is shown in Fig. 1. The bulk concentration of the fluorescein in the SCM measurements is of the order of $10^{-9}-10^{-10}$ M and the increase of the intensity of polarized fluorescence is recorded as a function of time. Therefore, only fluorescence spectrophotometers of sufficiently high sensitivity and stability, i.e., which compensate for fluctuations in the intensity of the exciting light, are suitable. Furthermore, as fluorescein excitation and emission polarization spectra in lymphocytes show that changes in the SCM on mitogen or antigen stimulations can be detected only within a narrow wavelength region [11], broad band filter instruments cannot be used in the SCM measurements. In our laboratory we are currently using a grating type Perkin–Elmer MPF-4 fluorescence spectrophotometer of high stability and wavelength resolution. The degree of fluorescein fluorescence polarization in living cells changes by 3%/°C. A thermostatically controlled cuvette-holder is, therefore, essential. The excitation and emission polarizers used in the SCM measurements must have high precision optical surfaces with negligible light scatter and a polarization defect of less than 0.01.

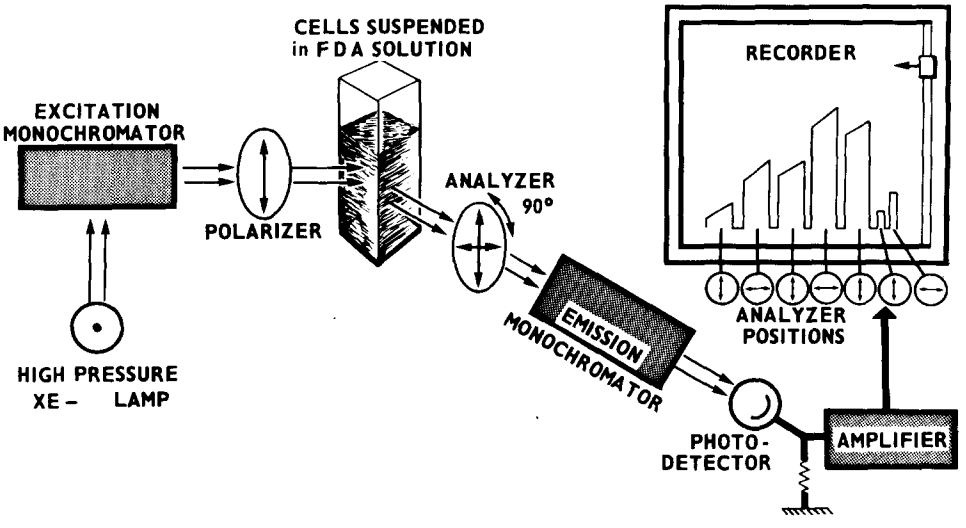

Fig. 1. Diagram of the fluorescence polarisation spectrophotometer arrangement used in the measurements of the SCM on cell suspensions.

*We have noticed that recent batches of acetone, used in the preparation of FDA stock solutions, contain impurities which decrease the SCM of lymphocytes and diminish, or abrogate, mitogenic and antigenic SCM responses. To obviate these effects, the FDA stock solution should be prepared in Aristar grade (BDH) glacial acetic acid. Dissolve 50 mg of FDA in 5 ml of acetic acid by gentle heating, if necessary. This stock solution is stored at room temperature. The FDA substrate solution is prepared as follows: dissolve 0.37 g of $Na_2HPO_4.12H_2O$ in 100 ml of complete, sterile PBS to compensate for the decrease in pH caused by the subsequent addition of acetic acid. The solution must be agitated until all the solid is dissolved to prevent precipitation of calcium phosphates. Inject 0.01 ml of the FDA stock solution into this PBS, shake well and immediately subdilute by injecting 25 ml of this FDA–PBS solution into 75 ml of complete, sterile PBS. The pH of the final substrate solution must be 7.4 and its osmolality 0.330 Osm/kg.

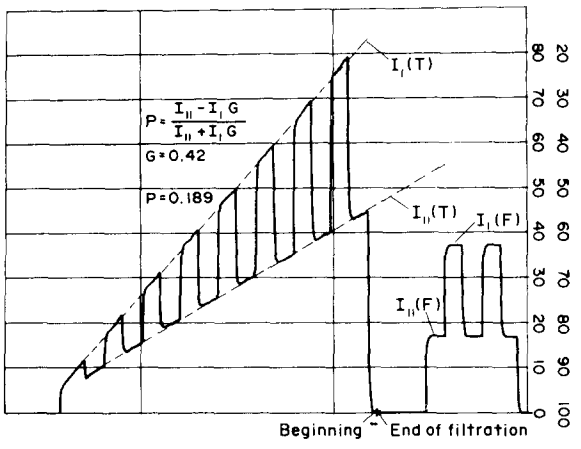

Fig. 2. An example of the SCM recording obtained with a Perkin–Elmer, type MPF-4, fluorescence spectrophotometer.

The polarization defect is defined as $k_2/(k_1+k_2)$, where k_1 is the fractional transmission for polarized light in the pass-axis and k_2 that in the direction perpendicular to the pass-axis [12]. A further requirement is that the polarizers have a low obliquity dependence of the polarization defect, i.e., the polarization defect should not change for incident light angles of up to 30°, and the extinction of light with crossed polarizers should be better than 1%. *In all our experiments we have been using "Polacoat" sheet-polarizers, type 105 u.v. mounted between fused quartz discs (supplied by Perkin–Elmer, U.K.). It is advisable to equip the emission polarizer (analyzer) with an automatic changer of the position as frequent manual changing of the analyzer is tedious and may also result in perturbations of the temperature equilibrium in the cell suspension. Fluorescence polarization measurements on cell suspensions can be affected by artefacts caused by scattered light. This occurs if there is insufficient resolution of the exciting and fluorescent light by the gratings or filters used. It is, therefore, necessary to check the level of scattered light before the equipment is used in SCM measurements. For this purpose 0.2 ml of lymphocytic suspension (6×10^6 cells/ml) is injected into 3 ml of PBS. Using the same settings on the fluorescence spectrophotometer as in the experiment the difference between the signals obtained with parallel polarizers on the lymphocyte suspension and on the PBS solution without cells should be less than 0.5% of the full-scale deflection on the recorder.

2.3. *Experimental procedure.* Aliquots of 0.2 ml of control or stimulated lymphocyte suspensions are slowly injected with a 1 ml syringe into a 10 ml beaker containing 3 ml of the 2.5 μM FDA substrate solution. This suspension is gently swirled and rapidly transferred into a 1 cm quartz cuvette and put into the thermostated cuvette holder of the Perkin–Elmer fluorescence spectrophotometer MPF-4 fitted with the polarization accessory. Measurements are made at 27°C. The excitation monochromator is set at 470 nm (maximum spectral slit-width 20 nm) and the emission monochromator at 510 nm (maximum spectral slit-width 10 nm). At the moment when cells are suspended in the FDA solution, the recorder of the fluorescence spectrophotometer is started. The intensities of the emissions parallel, $I_{\parallel}(T)$ and perpendicular, $I_{\perp}(T)$, to the vertically exciting light beam are recorded alternately (with an automatic polarizer changer) for about 6 min or until $I_{\perp}(T)$ reaches 80–90% of the full scale deflection (see Fig. 2). To correct for the leakage of the fluorescein from the cells and for any fluorescence background in the substrate solution cells are quickly filtered away on Millipore paper (0.22 μ pore size) mounted in a Millipore filter head (Swinex 25 mm dia). The filtration is performed by suction, applying not more than 40 cm of Hg vacuum, using a hand vacuum pump (Mityval Neward Die and MFG, California). The filtrate is collected into a glass tube with a side arm for the vacuum line. Details of the filtration set-up are illustrated in Fig. 3. The times of the beginning and the end of filtration are marked on the chart of the recorder and the fluorescence intensities of the components $I_{\parallel}(F)$ and $I_{\perp}(F)$ in the filtrate (F) are measured (Fig. 2), using the same, meticulously washed, cuvette and orientation of the cuvette as during cell suspension measurements. The fluorescence intensities $I_{\parallel}$ and $I_{\perp}$ emitted from cells are obtained by subtracting values for the filtrate from the total fluorescence intensities $I_{\parallel}(T)$ and $I_{\perp}(T)$ extrapolated to the half-time of filtration. Polarization values, P, are calculated from the relationship: $P=(I_{\parallel}-GI_{\perp})/(I_{\parallel}+GI_{\perp})$, where $I_{\parallel}$ and $I_{\perp}$ denote the corrected components of the fluorescence intensities and G the correction factor for unequal transmission of the two components of polarized light. The value of G is calculated from the parallel, $i_{\parallel}$, and antiparallel, $i_{\perp}$, fluorescence intensities emitted from a filtrate solution or 10^{-7}M fluorescein solution in PBS, excited with horizontally polarized light, i.e. $G=i_{\perp}/i_{\parallel}$. For our Perkin–Elmer MPF-4 type instrument $G=0.42$. The reproducibility of polarization values, P, within a series of experiments is better than ±2.5%.

Non-viable cells do not retain fluorescein [13].

*A further requirement is that the polarizers do not exhibit intrinsic fluorescence. For this reason, "Polaroid" visible polarizers cannot be used in the SCM measurements.

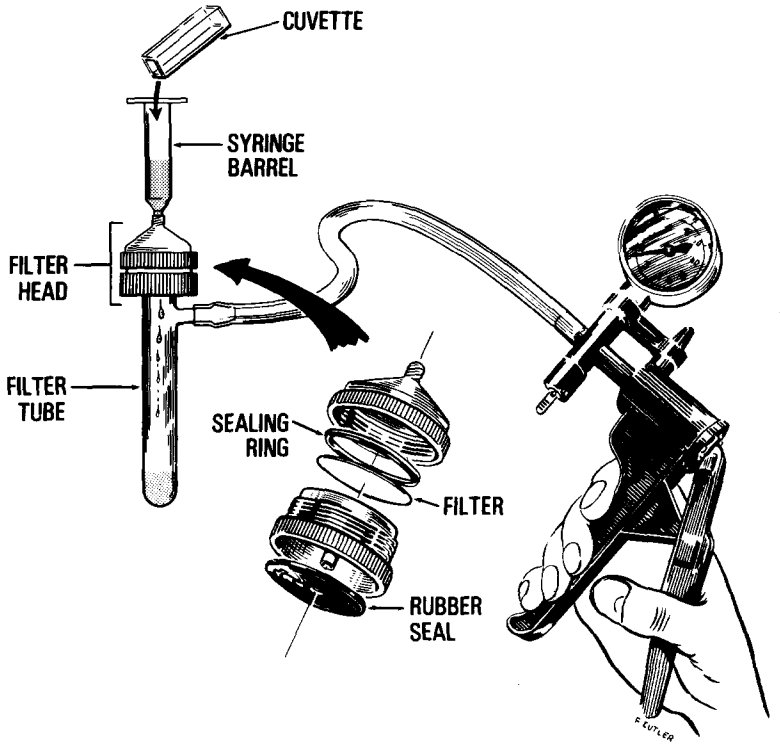

Fig. 3. Details of the filtration set-up.

The contribution of non-viable lymphocytes to the fluorescence intensities $I_{\parallel}$ and $I_{\perp}$ emitted from cells is negligible. The SCM measurements therefore exclude non-viable lymphocytes.

2.4. *Treatment of glassware.* SCM measurements are a high precision microassay which require meticulous control of the fluorescence background. Contamination of filtrates, glassware and cuvettes by fluorescent residues is the most frequent single cause of interference in SCM measurements. Therefore, all the glassware which comes into contact with FDA solutions should be first rinsed with hot tap water, soaked in 50% nitric acid for at least 2 hr, rinsed 10 times in hot tap-water, soaked in double distilled water for at least 4 hr and finally rinsed 10 times in double distilled water before drying in an oven at 110°C. Glassware which was in contact with cell suspensions is after rinsing with hot tap water soaked for 12 hr in 4% "Extran" (B.D.H.) or other surface active agents which do not contain active chlorine. After rinsing 10 times with hot tap water the same washing procedure as that outlined for glassware which was in contact with FDA solutions is followed.

RESULTS AND DISCUSSION

1. *Effects of the experimental conditions*

1.1. *Density of the gradient.* Lymphocytes which respond to PHA and CaBP stimulations in the SCM test are isolated over a narrow range of the Ficoll–Triosil solutions of densities from 1.080 to 1.086 g/cm^3 (Fig. 4). However, our recent results suggest that there is a narrow window at a density of 1.081 g/cm^3 where an enriched SCM-responding lymphocyte population is isolated which on stimulation decrease the polarization to as low as 50% of control values. The density of the Ficoll–Triosil solution, ρ, decreases with increasing temperature according to the following relationship:

$$\rho_T = \rho_{18} - 3.43 \times 10^{-4} \times (T^\circ - 18^\circ), \{g/cm^3\}$$

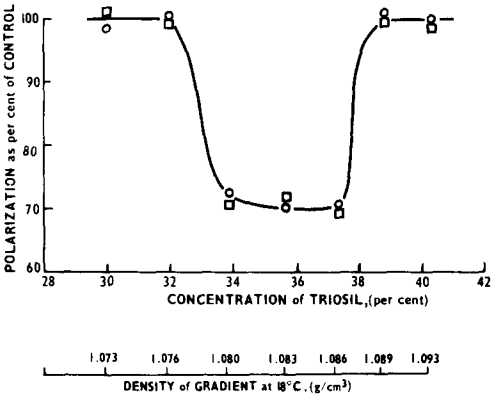

Fig. 4. Effect of the Ficoll–Triosil gradient density on the SCM responses of isolated lymphocytes to PHA (circles) or CaBP (squares).

where ρ_T and ρ_{18} denote densities at T°C and 18°C, respectively. This equation can be used to find the exact temperature at which a Ficoll–Triosil solution will have the density required for the isolation of an enriched SCM-responding lymphocyte population.

SCM-responding lymphocytes are those which float on the Ficoll–Triosil solution. Lymphocytes which band out inside the Ficoll–Triosil solution are SCM non-responding cells which are characterized by a 20% lower SCM value than that of the SCM responders. Dilution of the SCM-responding lymphocytes with non-responders results in progressively lower SCM values and smaller responses on stimulation.

1.2. *The FDA substrate solution.* The SCM values and in part the responses of lymphocytes to stimulation depend on the hydrogen ion concentration (pH), calcium ion concentration, osmolality and temperature of the FDA–PBS substrate solution. The effect of the pH of the substrate solution on the SCM value of lymphocytes and responses to PHA (or CaBP) is shown in Fig. 5. It can be seen that at pH below

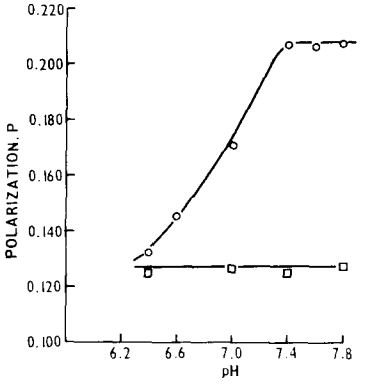

Fig. 5. Effect of the pH of the FDA substrate solution on the SCM values (circles) and PHA (or CaBP) responses (squares) of lymphocytes.

7.4 the fluorescence polarization value, P, (i.e. SCM value) progressively decreases with decreasing pH of the PBS. Since the SCM value of stimulated lymphocytes is pH independent the response to stimulation measured as per cent of the control SCM value decreases. Similarly, when the concentration of calcium ions decreases from 2×10^{-3}M to no calcium ions in the PBS the SCM value of unstimulated lymphocytes sigmoidally decreases by 20% and thereby decreases the per cent of SCM responses to stimulation [3].

The reproducibility of the SCM values depends on the osmolality and temperature of the FDA–PBS substrate solution. With increasing osmolality of the substrate solution the SCM value progressively increases from $P=0.118$ at 0.104 Osm/kg to $P=0.244$ at 0.587 Osm/kg [3]. The osmolality of the PBS should be 0.330 Osm/kg. Variations in the osmolality of up to $\pm 10\%$ will affect the control values of the SCM but not the magnitude of the per cent of SCM changes on stimulation.

As shown in Fig. 6 the temperature of the substrate solution during the SCM measurements affects equally the SCM values of control and stimulated lymphocytes by 3%/°C. We measure the SCM at 27°C. This temperature was selected as a compromise between the rate of FDA hydrolysis and the rate of permeation of the fluorescein from inside cells so that on the average about 80% of the fluorescein is retained in the cells.

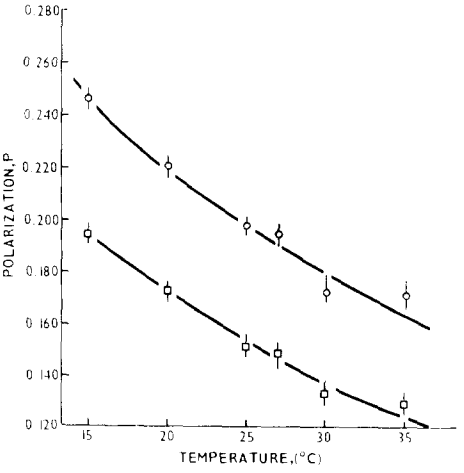

Fig. 6. Effect of the temperature during SCM measurements on SCM values, P, of controls (circles) and stimulated lymphocytes (squares).

1.3. *Wavelength dependence of the SCM changes.* Significant changes in the SCM of lymphocytes in response to stimulations with PHA or CaBP occur in the fluorescein emission polarization spectrum only at 510 nm (Fig. 7). Because of the sharp peak at 510 nm in unstimulated lym-

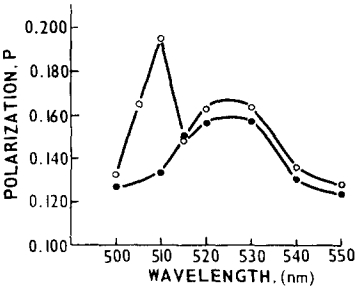

Fig. 7. Fluorescein emission polarization spectra in lymphocytes. Excitation wavelength 470 nm. Controls (open circles), PHA or CaBP stimulated lymphocytes (full circles).

phocytes the spectral slit-width of the emission monochromators, or the wavelength band-width in filter instruments, must not exceed 10 nm. An increase of the spectral slit (or band) width beyond 10 nm will result in a decrease in the control SCM value and increase in the SCM value after stimulation, resulting in a decrease in the magnitude of the SCM responses. As shown in Fig. 8 the degree of fluorescence polarization as measured at 510 nm also depends on the excitation wavelength. The optimal conditions are obtained if the excitation wavelength is set at 470 nm and the spectral slit width (or spectral band width in filter instruments) is 20 nm.

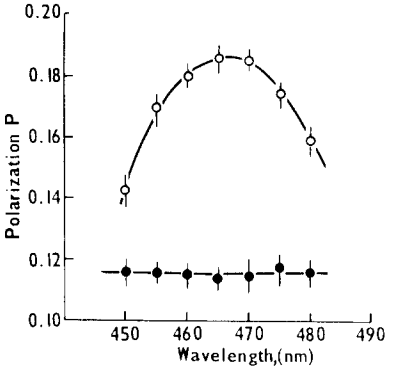

Fig. 8. Fluorescein excitation polarisation spectra in lymphocytes. Emission wavelength 510 nm. Controls (open circles) and PHA stimulated (full circles).

1.4. *Spectrum of the exciting light source.* The cytoplasmic matrix is a heterogeneous and polyphasic system in which the physico-chemical properties, such as pH, dielectric constants and polarity, differ between the micro-domains. Because of this the fluorescein molecule in the cytoplasmic matrix can be in its neutral, cationic and/or anionic molecular structure. These molecular structures have different excitation and emission spectra as well as life-times of the excited state [14]. The fluorescein molecules in the living cells therefore represent an ensemble of different fluorophores, subgroups of which emit photons of the same degree of fluorescence polarization. In this case the average degree of fluorescence polarization measured depends on the fraction of light contributed by each subgroup of fluorophores emitting photons of the same polarization [15]. In the SCM measurements the fluorescein fluorescence is excited with light of 20 nm band-width. The spectral distribution of photons within this band-width can therefore modify the degree of fluorescein fluorescence. Thus, the preferential excitation of fluorescein molecules, which probe domains in which on stimulation changes in the SCM occur, will increase the observed effects. The fluorescein excitation polarization spectrum exhibits a maximal change after stimulations at 470 nm (Fig. 8). The spectrum of the high pressure Xenon light source has a sharp peak at 469 nm and is, therefore, an excellent light source for the SCM measurements. For example, we find that with a tungsten light source the average degree of fluorescence polarization of unstimulated lymphocytes is 80% and the decrease in the SCM observed after stimulation is about half of that obtained with a high pressure Xenon light source.

2. *Summary of the SCM tests*

2.1. *Responses to PHA and CaBP.* The mean value of the SCM of lymphocytes from 270 healthy donors (174 males and 96 females, ages 18–75 yr) is $P=0.196\pm0.004$ (S.E.). The mean SCM value of lymphocytes from 272 patients with malignant diseases is $P=0.195\pm0.003$ (150 females and 122 males, ages 16–90 yr) and that of lymphocytes of 30 patients with non-malignant disorders is $P=0.190\pm0.002$ (15 females and 15 males, ages 18–84 yr). Lymphocytes from healthy donors and patients with non-malignant disorders responded to PHA stimulation with a decrease in the SCM from 20 to 50% of the control value. Stimulation with CaBP resulted in maximal changes of less than 5% in the SCM [5, 6]. In contrast, lymphocytes from donors with cancer did not respond with a significant decrease in the SCM to PHA stimulation. For up to 180 min of incubation, maximal changes in the SCM did not exceed 5% of control values. However, on stimulation with CaBP the SCM decreased from 10 to 50% of the control value [5, 6].

To express the response of the lymphocytes to CaBP and PHA stimulation as a single parameter and to increase the resolution of the SCM test the "SCM response ratio" (RR_{SCM}) is calculated. The RR_{SCM} value is the ratio of the degree of fluorescence polarization obtained after CaBP stimulation, P_{CaBP} over that after PHA stimulation, P_{PHA}, both measured at comparable times after 30–100 min of incubation:

$$RR_{SCM}=P_{CaBP}/P_{PHA}$$

The summary of the results of 621 cases in Table 1 shows that lymphocytes from patients with malignant diseases can be differentiated from the lymphocytes of other donors on the basis of the RR_{SCM} parameter. For healthy donors the mean RR_{SCM} value is 1.46 as compared to 0.76 for patients with malignant disorders.

Table 1. RR_{SCM} values for healthy donors, patients with malignant and non-malignant diseases

Diagnosis	No. of cases	Fraction of cases in RR_{SCM} intervals 0.5–0.9	0.9–1.0	1.0–1.1	1.1–1.9	Mean value RR_{SCM}
Healthy Donors	270	1/270	1/270	2/210	266/270	1.46
"Non-malignant" conditions:						
Sarcoidosis	2				2/2	1.26
Psoriasis	1				1/1	1.30
Thyrotoxicosis	2				2/2	1.26
Rheumatoid arthritis	2				2/2	1.32
Chronic bronchitis	4				4/4	1.33
Cirrhosis of liver	2				2/2	1.50
Crohn's disease	2				2/2	1.34
Infective hepatitis	1				1/1	1.30
Ulcerative colitis	1				1/1	1.36
Gastric ulcer	1				1/1	1.36
Gallstones	2				2/2	1.31
Multiple sclerosis	5				5/5	1.35
Pregnancy (24–35 weeks)	4				4/4	1.50
Diabetes	1				1/1	1.54
"Benign" conditions:						
Thyroid adenoma	1				1/1	1.25
Verrucae vulgaris	2				2/2	1.32
Lypoma	5				5/5	1.41
Pituitary tumour	2				2/2	1.33
Prostate enlargement	2		1/2		1/2	1.12
Displasia cervix uteri	14	1/14	7/14	6/14		1.00
Histologically benign breast growths	21	8/21	5/21	8/21		0.96
"Pre-malignant" conditions:						
Polyposis coli (familial cancer)	1	1/1				0.78
Hyperkeratosis	1			1/1		1.05
"Malignant" conditions:						
Carcinoma of breast	33	31/33	2/33			0.78
Carcinoma of bladder	13	12/13	1/13			0.77
Carcinoma of tongue	9	8/9	1/9			0.78
Carcinoma of larynx	25	24/25	1/25			0.77
Carcinoma of skin	19	18/19	1/19			0.71
Carcinoma of cervix	31	30/31	1/31			0.78
Carcinoma of lung	26	25/26	1/26			0.79
Carcinoma of uterus	10	10/10				0.78
Carcinoma of colon and rectum	12	11/12	1/12			0.72
Carcinoma of pharynx	3	3/3				0.81
Carcinoma of ovary	23	22/23	1/23			0.78
Carcinoma of kidney	3	3/3				0.69
Carcinoma of oesophagus	8	8/8				0.75
Carcinoma of thyroid	3	3/3				0.76
Carcinoma of pyriform fossa	2	2/2				0.80
Carcinoma of epiglottis	2	2/2				0.85
Carcinoma of prostate	2	2/2				0.79
Carcinoma of tonsils	2	2/2				0.76
Carcinoma of stomach	2	2/2				0.72
Carcinoma of ear	1	1/1				0.76
Carcinoma of mouth	7	6/7	1/7			0.80
Carcinoma of alveolus	4	4/4				0.81
Carcinoma of parotis	1	1/1				0.75
Carcinoma of ethmoid sinus	3	3/3				0.74
Carcinoma of penis	2	1/2			1/2*	*1.26, 0.85
Carcinoma of vulva	1	1/1			post biopsy	0.80
Brain tumours	7	6/7	1/7			0.78
Secondary tumour of neck	1	1/1				0.76
Seminoma	1	1/1				0.85
Bone Ewing's tumour	2	2/2				0.74
Malignant melanoma	4	3/4	1/4			0.76
Osteogenic sarcoma	2	2/2				0.72
Reticulum cell sarcoma	1	1/1				0.75
Myosarcoma (Leiomyosarcoma)	1	1/1				0.80
Fibrosarcoma	2	1/2			1/2	1.17
Mesothelioma (?no histology)	1				1/1	1.10

To illustrate the extent of separation or any overlap between the RR_{SCM} values of cancer patients, healthy donors and patients with non-malignant disorders the RR_{SCM} values are divided into two intervals of 0.1 in the RR_{SCM} region of 1.0 and two further intervals encompassing the maximal spread of the RR_{SCM} values above 1.1 and below 0.9. The results obtained on 270 healthy donors and 30 donors with non-malignant disorders which in other tests for the diagnosis of human cancer gave false positive results [16–18] show that 98% of these cases responded on PHA stimulation with an average decrease of 30% in the SCM value and did not respond to CaBP stimulation, resulting in an average RR_{SCM} of 1.46. Between the healthy donors we found four exceptions. Two cases responded to CaBP with a decrease in the SCM of 23 and 16% and to PHA stimulation with a 19% decrease and no response, respectively, resulting in RR_{SCM} values of 0.96 and 0.84. In further 2 cases the unstimulated lymphocytes had a low SCM value of $P=0.150$ and responded in the first case both to PHA and CaBP with an increase of 30% in the SCM and in the second case no responses to PHA and CaBP were observed. The results of the latter 2 cases are similar to those obtained on lymphocytes from patients with chronic lymphocytic leukaemia and pre-leukaemia, respectively (Table 3). The former case also had a ribosomal RNA molecular weight profile characteristic of chronic lymphocytic leukaemia lymphocytes [20].

Between 272 cancer cases studied are 37 groups of different sites of malignancies. Most of the groups include early, intermediate, and late stages of the disease with metastases (Table 1). 93.4% of all cases responded to CaBP stimulation with an average SCM decrease of 25% and no response to PHA stimulation resulting in an average RR_{SCM} of 0.76. A further 5.9% of the cases responded to CaBP with only a 5–10% decrease in the SCM and no response to PHA. We found 3/272 cases of cancer (1.1%) which gave an RR_{SCM} characteristic for non-malignant disorders, i.e., >1.1. In two cases, i.e., cancer of the penis (post biopsy) and fibrosarcoma the SCM tests were not repeated. Therefore, we do not know if they represent "true false negatives" or can be ascribed to a technical error. In the case of mesothelioma no histology report was available.

In the progression from the normal to "pre-malignant" to malignant state the RR_{SCM} value appears to decrease from values greater than 1 to smaller than 1. For example, in a case of hyperkeratosis of skin lymphocytes responded to PHA and CaBP stimulation with a 15% and 10% decrease in the SCM, respectively, resulting in RR_{SCM} values of 1.05, but fully developed cancers of the skin gave RR_{SCM} values from 0.63 to 0.79. In a case of the familial condition, polyposis coli, the lymphocytes responded to CaBP stimulation with a small (9%) decrease in the SCM; however, on stimulation with PHA the response was a 17% increase, resulting in the RR_{SCM} value of 0.78 (Table 1).

In the group of patients with benign growths, i.e., benign pituitary tumours, lypomas, verrucae vulgaris and thyroid adenoma gave RR_{SCM} values characteristic for non-malignant conditions (Table 1). In 2 cases of enlargement of prostate one gave repetitively a 9% response to CaBP and no response to PHA ($RR_{SCM}=0.91$). No histological data were available for this case. The second case gave a normal RR_{SCM} value of 1.34. In cases of histologically diagnosed displasias of the cervix uteri 1/14 gave a RR_{SCM} value of 0.84, 7/14 gave a border-line (−5%) response to CaBP and no response to PHA and 6/14 gave no response to CaBP, but had a diminished response to PHA. The RR_{SCM} values are similar to those in "pre-malignant" conditions (Table 1). In contrast to displasias, 5/5 cases of cancer *in situ* of the cervix uteri show full responses to CaBP and no responses to PHA with RR_{SCM} values of 0.82. Cases of histologically declared benign growths in the breast gave a distribution of RR_{SCM} values similar to that in displasias of the cervix uteri. As shown in Table 1, in 8/21 cases no response to CaBP and a diminished response to PHA was observed (RR_{SCM} values of 1.0–1.1) and 5/21 cases gave an insignificant response to CaBP (<5%) and no response to PHA (RR_{SCM} 0.9–1.0). These two groups consisted of seven fibroadenomas, four lypomas and one case of an abscess under the nipple. However, in 8/21 cases the RR_{SCM} values were typical for malignant conditions (RR_{SCM} 0.5–0.9). This group consisted of 4 cases of cystic fibroadenoses, three intraduct and duct papillomatas (with or without nipple discharge) and one case of a lypoma consisting of a partly encapsulated adipose tissue. The recovery pattern after operation was in 6/8 of these cases the same as in histologically declared malignant growth [19]. One could therefore, argue that sensitisation of lymphocytes to CaBP may precede histological changes, and that the sensitization to CaBP could indicate cases which may be committed to become histologically recognisable malignancies if the growths were left *in situ*.

From the magnitude, mode and time dependence of the SCM response of lymphocytes to PHA and CaBP we inferred that the same size and type of the lymphocyte population may be

Table 2. Changes in the SCM of lymphocytes induced by tumour and normal tissues

Diagnosis of blood donors	Average SCM as percentage of control and fraction of cases responding to tissues

Table 3. SCM values and PHA responses of lymphocytes from donors with pre-leukaemic and leukaemic conditions

Diagnosis	Number of cases	Mean SCM value P	Fraction of cases responding to PHA stimulation as SCM		
			Decrease	Increase	No response
Refractory cytopenia	7	0.203	7/7		
(RC)	3	0.156		2/3	1/3
Refractory cytopenia with an excess of marrow	1	0.221	1/1		
myeloblasts (RCEM)	8	0.153		1/8	7/8
Chronic myelomonocytic leukaemia	5	0.148		2/5	3/5
Chronic myeloblastic leukaemia	3	0.125			3/3
Acute myeloblastic leukaemia	9	0.128			9/9
Chronic lymphocytic leukaemia	22	0.139		22/22	

involved [5, 6]. Our study on single cells [21] confirmed that indeed a large fraction of the isolated lymphocyte populations respond to both PHA and CaBP. In healthy donors about 50% of the isolated lymphocyte population decreases the SCM on PHA stimulation, and in cancer patients about 40% of the isolated lymphocyte population responds to CaBP stimulation. The SCM measurements on single cells also revealed that in healthy donors about 4% of the isolated lymphocytes changes the SCM on CaBP stimulation and in cancer patients about 20% of the isolated cell population responds to PHA. However, changes in the SCM of individual lymphocytes are less than 10% and mean values of the SCM obtained either from single cell measurements or SCM measurement on cell suspensions do not show significant changes to stimulation by CaBP in healthy donors and to that by PHA in cancer patients [21].

2.2. *Specificity of the SCM test.* Cancer basic proteins (CaBP) extracted from a general pool of cancer tissues are recognised by lymphocytes from all patients with different malignant diseases [5, 6, 18]. To reveal the type or site of the tumour, lymphocytes from healthy donors and from donors with different malignant disorders were stimulated with histologically defined biopsies of tumour or normal tissues [7]. In these tests lymphocytes from donors with different malignant diseases decreased the SCM only when brought into contact or "baited" with tumour cells similar to those which they have encountered in the body of the donor. The largest decrease in the SCM was observed when the lymphocytes were stimulated with the autologous tumour tissue. Lymphocytes from healthy donors did not respond to any normal or malignant tissue after up to 60 min of incubation. A summary of the up-to-date results is presented in Table 2.

2.3. *Changes in the RR_{SCM} after surgery and radiotherapy.* Studies on changes in the RR_{SCM} after surgical removal of malignant tissues showed [19] that within 2 weeks after successful surgery the lymphocytes did not respond any longer to CaBP (8/8 cases) and in 7/8 cases responded again to PHA stimulation with a decrease in the SCM, resulting in RR_{SCM} values greater than 1.20. The same change in the RR_{SCM} value was found in a case of an *in situ* cancer of the cervix after coning: the RR_{SCM} value changed from 0.83 before to 1.31 after coning. In 18 cases with residual or recurrent disease the RR_{SCM} values were typical for malignant conditions.

In 11 cases of cancer of the larynx, ST1, there was no significant change in the RR_{SCM} values up to 7 months after radiotherapy. However, more than 2 yr after radiotherapy 1/3 cases did not respond to CaBP and also not to PHA stimulation, resulting in the RR_{SCM} value of 1.00. In 2/3 cases the RR_{SCM} value was greater than 1.20, i.e., indicating SCM responses characteristic of healthy donors.

2.4. *SCM values and PHA responses in leukaemic lymphocytes.* As shown in Section 2.1, normal human lymphocytes have a mean SCM value of $P=0.196$ and they respond to PHA stimulation with a decrease in the SCM. In contrast, lymphocytes from patients with chronic lymphocytic leukaemia have a low SCM value of $P=0.139$ and respond to PHA stimulation by an immediate and with time of incubation progressive increase in the SCM to values similar to those of normal, resting state lymphocytes [4]. Still lower SCM values were found in lymphocytes from patients with chronic—or acute—myeloblastic leukaemias (Table 3). In these cases lymphocytes did not respond to PHA stimulation. Chronic myelomonocytic leukaemias showed also a lowish value of the SCM and on PHA stimulation lymphocytes in some of

the cases (2/5) responded with an increase in the SCM or in others (3/5) with no change in the SCM (Table 3). The SCM values and responses to PHA stimulation were also studied in a group of patients with refractory cytopenia (RC) of one or more cell lines with no other abnormal characteristics of the marrow or blood picture. These patients can have either a benign course of the disease, or if characterized by a modest excess of marrow myeloblasts (RCEM), are regarded as "preleukaemic" or "smouldering leukaemias" [22]. The results in Table 3 show that between the RC cases studied 3/10 had a subnormal SCM value and abnormal PHA responses, the other 7/10 cases had normal SCM values and gave also a normal response on PHA stimulation. In 9 patients with refractory cytopenia, characterized by a modest excess of marrow myeloblasts (RCEM), 1/9 patients had a normal SCM value and a normal response to PHA. In the other 8/9 cases the SCM values were subnormal and either an increase (1/8 cases) or no SCM response (7/8 cases) was observed on PHA stimulation (Table 3). The clinical course in the RC and RCEM group is often indistinguishable until the evolution of overt leukaemia permits a retrospective diagnosis. Therefore, the SCM measurements might be useful in recognition of potentially leukaemic cases [22].

In order to ascertain that the lymphocyte population obtained on the density gradient is the same as that from normal donors, the ratio of T- and B-cell lymphocytes was assessed using the rosetting techniques. A case of the chronic myelomonocytic leukaemia which gave a subnormal SCM value and no responses to PHA stimulation had 67.7% T-cells and 17.2% B-cells and a case from the RC group with a normal SCM value and normal responses to PHA had 63.4% T-cells and 20% B-cells, i.e. both were in the normal range of T- and B-cell populations. The abnormal SCM values and responses seem to be, therefore, a genuine reflection of the disease in the peripheral lymphocytes.

The SCM measurements on at least one third of the 679 cases summarised in this study were performed in a single or double bind way, i.e., the diagnosis was available after the results of the SCM test were known.

In conclusion, the successful accomplishment of the SCM-test and the reproducibility of the results mainly depends: *First*, on the isolation of the SCM-responding lymphocyte population. *Second*, on the technical characteristics of the fluorescence spectrophotometer and of the polarization accessory. These should meet the requirements of the SCM measurements in terms of sensitivity, stability, wavelength resolution, light source, and polarization defect of polarizers. *Third*, on the strict control of the pH, calcium ion concentration and osmolality of the substrate.

The results indicate that the SCM test could become useful as a clinical aid in the detection and prognosis of human cancer and leukaemias. With the present "laboratory technique" two technicians can carry out at most 4 complete SCM tests per day. However, the SCM measurements can be fully automated by adapting the flow-fluorometer technique to fluorescence polarization measurements on single cells. This would increase at least ten times the number of complete tests which could be performed in a day.

Abstract—*Transfer factor produced* in vitro *by a lymphoblastoid cell line, subsequent to induction with specific TFd obtained from patients with transitional cell carcinoma of the bladder (TCCB) or hypernephroma was used for injection of TCCB or hypernephroma patients. Four patients thus injected showed an increase in their reactivity to allogeneic and/or autologous tumour cells in the leucocyte migration test (LMT). E-rosette counts and Con-A and PHA stimulations were also increased following TFdL injections. The specificity of these reactions, as well as the possible clinical effects and the use of* in vitro *produced transfer factor for cancer therapy, are considered.*

INTRODUCTION

WE HAVE recently reported the *in vitro* replication of specific dialysable Transfer Factor (TFd) for transitional cell carcinoma of the bladder (TCCB) by lymphoblastoid cell lines [1, 2]. The Transfer Factor produced by such a lymphoblastoid cell line (TFdL) was induced with TFd obtained from patients whose leucocytes were found reactive to tumour cells. The leucocyte migration test (LMT) was used in these experiments to assess *in vitro* transfer of reactivity following incubation of unreactive leucocytes with TFdL.

Since several reports have already shown that TFd can be used with beneficial effect for treatment of cancer patients [3–6], we undertook the study of the effect of TFdL injections in four such patients.

We present here further evidence that specific TFd from patients reactive to tumour cells (TCCB and hypernephroma) can be reproduced *in vitro* by our lymphoblastoid cell lines and that it transfers reactivity when it is injected into non-reactive patients. Four patients were thus injected with TFdL and the state of their immune system was followed during 7–11 months. They all responded to the TFdL injections, but the reactivity of their leucocytes varied during the course of this study. Our central experimental criterium in these studies was the acquisition, or the increase, of the reactivity (i.e. inhibition) of the patients' leucocytes in the LMT in presence of tumour cells.

MATERIAL AND METHODS

Two patients with TCCB stage T2, one patient with hypernephroma and pulmonary metastases, and one patient with TCCB and hypernephroma were studied. Prior and subsequent to each TFdL injection, the patients were tested in the LMT against TCCB or hypernephroma formalin-treated cells [1, 2], depending upon the tumour under study, which were obtained from allogeneic, and, in some instances, the autologous tumours after surgical excision. Lymphocyte counts, E-rosettes and PHA and Con-A stimulations were also studied during this period. E-rosettes were evaluated using the method of Jondal *et al.* [7]. PHA-P was used at 1 μg/ml for 10^6/ml lymphocytes distributed in microplates, each well containing 0.2 ml. Con-A was used at 30 μg/ml under the same conditions.

Patients were injected for the first time with

TFdL from 10^8 or 2×10^8 cells and tested 3 days later. Injections were repeated if necessary until patients became positive in the LMT. They were retested every month and reinjected with various amounts of TFdL (multiples of 10^8 cells) as soon as they became unreactive in the LMT (see Figs. 1–4).

The *in vitro* replication of TFd has been described elsewhere [1, 2, 8]. Briefly, TFd from patients found positive to TCCB formalin-treated cells in the LMT were used for induction of one of our lymphoblastoid cell lines. Sterile TFd from 5×10^6 lymphocytes was added to 100 ml of tissue culture containing 2×10^5 lymphoblastoid cells per ml. The culture was grown to approximately 4 l. by addition of fresh medium as required, and samples of approximately 3×10^9 cells were harvested every week. Dialysates were prepared by the same technique as that used to prepare TFd [9]. The TFdL thus produced was tested, prior to its *in vivo* use, for its pyrogenicity in the limulus test [10]. It should be noted that some preparations, which were found pyrogenic *in vitro*, did not elicit any febrile reaction when injected *in vivo*.

The activity of the TFdL was checked in the LMT in the presence of the tumour cells from the patients to be injected [1, 2]. It is worth noting here that the TFdL used for injection of patients were induced by allogeneic TFd obtained from reactive TCCB patients. TFdL induced using autologous TFd has not yet been injected. TFdL from 10^8 to 6×10^8 cells was used for each injection (Figs. 1–4).

RESULTS

Case reports

Case 1. (*Fig.* 1). Patient BA is a 63-yr-old female. She was tested in the LMT using her autologous tumour cells one week after surgical removal of her TCCB (stage T2), and she was found negative. She was retested 59 days later with the same result. She received her first injection of TCCB—immune TFdL (10^8 cells) on day 62. Her LMT was still negative on day 65; she then received another injection of TFdL (10^8 cells) on day 66. Conversion of the LMT was observed three days later (d. 69). LMT performed on days 72 and 102 were also found positive. During this period she received one further TFdL injection (2×10^8 cells) on day 69. The patient was found negative when tested 137 days after the last TFdL injection and this coincided with a relapse of the tumour (of 1 mm dia), which was removed. On day 207 she received a TFdL injection from 4×10^8 cells. Three days later she was still negative. A second injection of TFdL (5×10^8) was administered on day 211. Conversion of the LMT was observed 2 days later.

When she was retested $1\frac{1}{2}$ months after this last TFdL injection she was again found to be negative. However, a new administration (2×10^8 cells) converted the LMT within two days and the patient's LMT test remains positive 5 months later.

During the course of the TFdL injections, peripheral blood lymphocytes and E-rosettes were counted and an increase of both was noticed up to day 210, i.e. until the fourth injection of TFdL. The percentage of E-rosettes has remained constant although a decrease has since been noticed in the total number of lymphocytes.

PHA and Con-A stimulations were similarly found to be increased on day 72, i.e. after a total injection of TFdL from 4×10^8 cells. A decrease was subsequently observed, followed by a moderate and transient increase after the TFdL injections. These results are shown in Fig. 1.

Case 2. Patient CR is a 54-yr-old male with TCCB (stage T2) whose reactivity in the LMT against his autologous cells became positive 6 days after the first TFdL injection (2×10^8 cells) administered 20 days after tumour removal. His LMT test remained positive for 5 months, although he received only one more injection of TFdL (2×10^8 cells) on day 27. When the LMT test was found to be negative on day 208, the patient was given TFdL (5×10 cells) on day 209 and his test was found to be positive 2 days later. The LMT remains positive to date, i.e. 150 days after the last injection and 359 days after his operation.

Lymphocyte counts and E-rosettes steadily increased until day 156. Then they decreased. An increase was again observed 2 days after the last TFdL injection on day 209.

PHA and Con-A stimulation increased after the second TFdL injection, but they subsequently fell to the initial values after 2 months. A slight increase was observed after the 3rd TFdL injection (Fig. 2).

Case 3. (*Fig.* 3). Patient PC is a 65-yr-old male. This patient had a double localization of primitive tumours: kidney and bladder. Both his tumours were surgically removed, the TCCB was at stage T2, the hypernephroma at stage T3. The patient was injected using TFdL (2×10^8 cells), specific for TCCB, 15 days after the surgical removal of the bladder tumour. Two days after this injection the patient's cells became positive in the LMT in presence of allogeneic TCCB cells, whereas the reactivity to his autologous TCCB remained positive. A further injection of TFdL (2×10^8 cells) was given 19 days after surgery. The LMT remained positive with both autologous and allogeneic TCCB cells until day 120 when it became negative for both. He then received TFdL from 4×10^8 cells and the LMT was found to be positive 6 days later, but it again became negative after a further $2\frac{1}{2}$ months. At this time a bladder relapse was noted and the tumour was removed. Five days after the tumour resection he again received TFdL (4×10^8 cells). His leucocytes then became reactive for both allogeneic and autologous TCCB cells in the LMT, and this reactivity lasted for 3 weeks. A new injection of TFdL (10^8 cells) again produced a positive result in the LMT with allogeneic tumour cells. It is worth noting that the LMT showed reactivity for allogeneic and autologous tumour cells derived from both the primitive tumour and the relapse. Only a 'one-way' specificity of TFdL was shown in that the TCCB reactivity was transferred but not the hypernephroma re-

activity and this may be considered as being very suggestive evidence for specificity of TFdL.

Lymphocyte counts and E-rosettes increased until the 4th month after surgery and then decreased. This decrease coincided with the relapse. However, they again increased after the 4th TFdL injection given on day 215.

Both PHA and Con-A stimulation increased during the first three months of TFdL injections, but there was a dissociation afterwards, PHA stimulation being restored to a high level whereas Con-A stimulation fluctuated (Fig. 3).

Case 4. (*Fig.* 4). Patient RG is a 38-yr-old male. He had a hypernephroma at stage T2 with two pulmonary metastases of approximately 1 cm dia. Before surgery the patient's cells were reactive in the LMT against allogeneic hypernephroma cells. However, he was afterwards repeatedly tested against the autologous tumour cells and was constantly found negative, and he also lost his reactivity to allogeneic tumour cells 7 months after the operation. During this period he received 4 injections of TFdL, produced with the TFd obtained from another hypernephroma patient, as follows: 1st injection: 3×10^8 cells, 2 months after the operation; 2nd injection: 6×10^8 cells at $2\frac{1}{2}$ months; 3rd injection: 5×10^8 cells at 3 months and the 4th injection of 4×10^8 cells was administered one week after the 3rd injection. *In vitro* tests [7, 10] of the TFdL D_{26}* used for these injections had shown the failure of this TFdL to sensitize the patient's or allogeneic leucocytes to the patient's tumour cells, whereas it was capable of transferring sensitivity towards allogeneic hypernephroma tumour cells, thus strongly suggesting the presence of more than one tumour antigenic specificity in hypernephromas.

E-rosettes increased spontaneously after surgery, whereas lymphocyte counts were not affected. E-rosettes were further increased from 30 to 65% one week after the first TFdL injection, given 2 months after surgery. This increase remained until $3\frac{1}{2}$ months after surgery, i.e. 2 days after the last TFdL injection.

PHA and Con-A responses before TFdL injections were at quite high levels for a cancer patient and no further increase was observed after the TFdL injections.

Since no sensitization to autologous tumour cells in the LMT nor diminution of pulmonary metastases was observed during the TFdL therapy, TFdL injections were discontinued and hormonal therapy was administered (Medroxi-Progesterone-Acetate (M.A.P.) at 1.5 g/day for 30 days). During this therapy the E-rosette counts showed a marked decrease with an increase of the B lymphocytes and the EAC rosettes. The PHA and Con-A responses were also diminished. Two months after the end of the hormonal therapy, E-rosettes, PHA and Con-A resumed their previous values (Fig. 4).

DISCUSSION

For the first time, *in vitro* produced Transfer Factor was injected into cancer patients (TCCB and hypernephroma) who 2 months before the beginning and during the course of the immunotherapy did not receive any other treatment. No side effects whatsoever were noticed during these TFdL injections.

The specificity of the TFdL used was tested *in vitro* in the LMT prior to its injection. Autologous and allogeneic tumour cells were used for these tests. [1, 2]. The TFdL used was always induced by a TFd capable of sensitizing for the patients' tumour cells when tested in the LMT. The TFdL thus derived and injected was, with two exceptions, always active *in vitro* for the patients' tumour cells.

TFdL D_{28} used for the last injection of patients CR and PC (cases 2 and 3) had not shown any activity *in vitro*, but it did show activity when injected, whereas TFdL D_{26}, injected into patient RG (case 4), failed to transfer *in vivo* thus confirming its *in vitro* unreactivity. It was also observed that TFdL A_{12} has a lower activity for *in vitro* transfer and larger doses were needed to obtain an effect *in vivo*, this effect is less marked than with TFdL D_{24} (Table 1) [1, 2]. Since A_{12} and D_{24} are two different batches of TFdL obtained by the induction of two different lymphoblastoid lines using the same inducing TFd, it seems that the various lymphoblastoid cell lines do not respond in the same way to TFd induction. This is now under active investigation.

Specificity of TFdL is clearly suggested in two instances: patient PC who received TFdL specific for TCCB remained unreactive to his hypernephroma cells, whereas he showed a transfer of reactivity to allogeneic TCCB cells. Similarly, patient RG, who received TFdL D_{26}, which never transferred reactivity to his tumour cells *in vitro*, remained unreactive to his tumour cells, whereas he developed

*D_{26} is a batch obtained after a single induction of a lymphoblastoid cell line with a hypernephroma reactive TFd.

Table 1. Leucocyte migration tests (LMT) for patient BA (TCCB). Reactivity of patient BA between d 206 and d 212, i.e. 171 and 177 days after the first TFdL injection. On d 206 the patient did not react to autologous tumour cells (BA) or two allogenic tumour cells (TG and CR), but he did react to the allogenic tumour cells PC. After injection of TFdL from 4×10^8 cells (batch A_{12}) on d 207, no change in the pattern of his reactivity was seen on d 210. The injection of TFdL from 5×10^8 cells, from batch D_{24}, on d 211 resulted in a change of his reactivity when he was tested on d 212. He became reactive to the autologous and allogeneic cells to which he was previously unreactive, and his reactivity to PC tumour cells was increased. Significant LMT inhibitions are underlined. It is worth noting that the patient's leucocytes remained unreactive to tumour cells from two melanoma cell lines (IGR_1 and MEL SK_1). This argues again in favour of the specificity of the TFdL

reactivity to allogeneic tumour cells, thus suggesting the existence of more than one tumour antigenic specificity for hypernephroma tumours. It should be noted here that a possible polymorphism of hypernephroma tumour antigens is consistent with our findings in TCCB [1, 2] and leukaemias [11]. Furthermore, the TFdL injections which induced patient PC's reactivity to allogeneic TCCB cells, never converted his leucocytes to react to his own hypernephroma cells, thus also suggesting specificity of the TFdL and antigenic polymorphism. Also in favour of TFdL specificity is the non-reactivity of patient BA, after TFdL injections, to melanoma tumour cells (Table 1).

TFdL injected into TCCB cancer patients transferred reactivity for their autologous tumour cells in patients BA and CR and for allogeneic tumour TCCB cells in patient PC. In patients BA and CR the reactivity to tumour cells in the LMT transferred with TFdL from 4×10^8 cells was maintained for 4 and 6 months respectively. These data again imply tumour antigenic polymorphism for TCCB, and specificity of the TFdL.

The data obtained by the *in vivo* use of TFdL confirm that TFdL induction is not always successful and also that the activity of the TFdL batches varies from one induction to another. Similarly, a TFdL batch may be capable of transferring reactivity to some antigenic specificities, but not to others, despite their presence in the inducing TFd molecule. It seems that the inducing TFd recruits a population of cells among the cell line for a given specificity, and it is conceivable that the recruitment for another specificity fails or is low in a given experiment.

There are non-specific effects of the TFdL: the increase in the number of T cells and the response to Con-A and PHA, but these effects seem independent of the transfer of reactivity to tumour antigenic specificities. Indeed, they may be obtained when a TFdL induced by TFd from non-cancer patients, is injected into cancer patients with low T cell

counts (Boucheix and Viza unpublished). This non-specific effect of the TFdL on the E-rosettes and the PHA and Con-A stimulations may be compared to an adjuvant effect and it is possibly carried by a different molecule. This is best illustrated by the E-rosette counts of patient RG, which doubled spontaneously within 2 months after operation, and doubled again within one week after the first TFdL injection, whereas his reactivity in the LMT remained low. The increase in the number of lymphocytes and T cells was general for the 3 other patients after TFdL injections, which also induced an increase of the stimulation with Con-A and PHA. However, the increase of the E-rosettes after TFdL injection takes longer to develop than the increase of the response to the mitogens, but the latter is always more transient than the former. Indeed the Con-A and PHA stimulations resumed the low figures within a few weeks, whereas the E-rosettes remained high for longer periods. It should be noted here that preliminary data show that incubation of leucocytes with TFdL *in vitro* does not increase their response to the mitogens. On the other hand, no explanation can be offered for the dissociation between Con-A, PHA stimulations and E-rosette counts observed for patient PC, 7 months after surgery.

For the time being no conclusion can be drawn from these observations showing an *in vitro* increase of reactivity after TFdL injections, as to the value of the use of TFdL in cancer therapy. Only a long-term (5 yr) clinical trial on a large group of patients could prove the clinical efficacy of TFdL.

Acknowledgements—We would like to thank Dr. Diana Spina for performing the pyrogenicity tests and John Phillips for the graphic designs and fruitful suggestions in preparing the manuscript. The skilful technical assistance of Madame Chantal Sartorio is greatly appreciated.

Departments of †Pathology, ‡Microbiology and §Surgery, Dalhousie University, Halifax, Nova Scotia, Canada

Abstract—*Injections of appropriate numbers of irradiated, but not iodoacetate treated, EL4 lymphoma cells into C57BL/6J mice were effective in immunoprophylaxis against* 10^6 *EL4 cells and in immunotherapy against* 10^2 *EL4 cells per mouse. The addition of BCG injections made immunotherapy with irradiated EL4 cells effective against a load of* 10^4 *EL4 cells/mouse. Though inoculation of BCG into BALB/c mice inhibited the growth of the allogeneic Ehrlich carcinoma, immunoprophylaxis with BCG only was ineffective against EL4 in C57BL/6J mice. Coating irradiated EL4 cells with concanavalin A did not increase their immunogenicity. Immunotherapy with vibrio cholera neuraminidase and mitomycin treated EL4 cells or with sensitized syngeneic lymphoid cells did not protect EL4 inoculated C57BL/6J mice. However, injections of several rabbit anti-EL4 globulins completely suppressed EL4 lymphoma in a proportion of mice even when treatment was started* 120 hr *after i.p. inoculation of* 10^4 *EL4 cells per mouse. When administered within* 72 hr *of tumour inoculation* ^{131}I *or chlorambucil noncovalently bound to nontumour inhibitory anti-EL4 globulins were at least as effective tumour inhibitors as the inhibitory anti-EL4 globulins.*

INTRODUCTION

INHIBITION of the chemically induced EL4 lymphoma in allogeneic BALB/c and A mice after passive immunotherapy with xenogeneic and allogeneic antisera, enabled Gorer [1] to unequivocally demonstrate specific antigens (i.e. X antigens) on tumour cells. Since then, this tumour has been widely used as a model to assess the effectiveness of various methods of immunoprophylaxis and immunotherapy[2–7].

In an attempt to evaluate the effectiveness of different methods of immunotherapy in this model we have first investigated the lethality of intraperitoneal (i.p.), intravenous (i.v.) or subcutaneous (s.c.) inoculation of varying numbers of viable EL4 cells in the syngeneic C57BL/6J mice and have then re-examined the efficacy of such reported methods of immunoprophylaxis against EL4 lymphoma as peritoneal tapping of ascites tumour bearing mice [3], intradermal inoculation of viable tumour cell [8] and preimmunization with attenuated [9, 10] and antigenically altered EL4 cells [2, 4]. Further, the usefulness of injections of BCG and/or irradiated EL4 cells for immunoprophylaxis was investigated and compared with the results of similar immunomanipulation in an allogeneic tumour model, i.e. Ehrlich ascites carcinoma (EAC) in BALB/c mice, in which the effectiveness of immunoprophylaxis with BCG was initially reported [11]. Finally, the therapeutic response of this tumour to active and adoptive immunotherapy has been compared with the results of immunotherapy with xenogeneic antibody bound to ^{131}I or chlorambucil. Serotherapy with appropriate xenogeneic antitumour globulins (ATG) or ATG bound to cytotoxic agents [5, 7] appears to be more effective in suppressing EL4 lymphoma than the methods of active immunotherapy tested.

Accepted 19 January 1977.

MATERIAL AND METHODS

Tumours

The EL4 lymphoma, which originated in 1945 in a C57BL/6J mouse treated by Gorer [1] with dimethylbenz[a]anthracene, has been maintained since 1946 at The Chester Beatty Research Institute, London, from where we obtained the tumour in 1969 and have main-

tained it by serial i.p. passage in C57BL/6J mice.

Despite the presence of at least three well-defined tumour associated antigens (X, L and E antigens) [6], this tumour is reported to be unhibited by immunoprophylaxis with 'unmodified' or X-irradiated EL4 cells, though allogeneic antibody against the X antigen could protect C57BL/6J mice against inocula of EL4 cells [1].

The Ehrlich Lettre hyperdiploid ascites carcinoma was maintained by serial passage in 12–16 week-old BALB/c mice. Intraperitoneal inoculation of even about 25 viable EAC cells led to solid intraperitoneal tumour formation and subsequent death of tumour inoculated mice. However, 2.5×10^5 viable EAC cells constitute the 'critical inoculum' for the production of ascites in 100% of the mice: the presence of less than this number of viable EAC cells in the peritoneal cavity of mice tends to give rise to solid intraperitoneal tumours [12]. The survival of EAC inoculated BALB/c mice varied inversely with the size of the tumour inoculum. After transplantation into BALB/c mice, EAC grows progressively, invades various organs, forms metastases and kills all tumour inoculated mice in spite of the probable antigeneic differences between EAC cells and the allogeneic host BALB/c mice [12, 13].

Tumour cell and BCG preparations for immunization

Freshly obtained tumour cell suspensions (10^8 cells/ml), after being washed in phosphate buffered saline (PBS, 0.01 M, pH 7.1), were exposed under sterile conditions to 15,000 rad of Y rays from a Gamma Cell 220 ^{60}Co Irradiation Unit (Atomic Energy of Canada Ltd., Ottawa, Ontario, Canada) [7, 12]. Viable BCG organisms (Connaught Medical Research Laboratories, Toronto, Ontario, Canada) were inoculated (10^7 BCG cells/mouse) by various routes as stated in the different experiments.

Neuraminidase treated tumour cells were prepared for immunotherapy following the method of Rios and Simmons [14]. Aliquots of 2×10^6 EL4 cells were incubated with 50 units/ml of vibrio cholera neuraminidase (VCN, General Biochemicals, Chargin Falls, OH, U.S.A.) for 1 hr at 37°C, were washed 3 times with M199 and then reincubated for 1 hr with 50 μg/ml of mitomycin C (Sigma Chemical Co., St. Louis, MO, U.S.A.). The cells were again washed 3 times with M199 and the viability of the cells was confirmed by trypan blue exclusion [5] before injection. Comparison groups of mice were vaccinated with EL4 cells exposed to VCN only, mitomycin C only and M199 only.

The binding of Con A to EL4 cells was verified by autoradiography of EL4 cells [7] incubated with Con A containing tracer doses of ^{3}H Con A (New England Nuclear, Dorval, Quebec, Canada). To coat tumour cells with Con A (Calbiochem, Los Angeles, CA, U.S.A.), 10^7 tumour cells/ml were reacted with 25 μg Con A/ml for 30 min, at 37°C.

Spleen and peritoneal cells for adoptive transfer

Peritoneal cells were collected by washing the peritoneal cavity with Hank's balanced solution (HBSS). Splenic cells were dissociated with 0.2% ethylenediaminotetraacetic acid in PBS and erythrocytes were lysed with 0.83% NH_4Cl. The nucleated spleen cells and peritoneal cells were washed 3 times with sterile HBSS, thei r viability was assessed by trypan blue exclusion and the cells were then suspended in HBSS at the desired concentration.

Anti-EL4 sera

The details of the methods of production and purification of rabbit anti-EL4 sera, the tests to establish their specificity and the method of fractionation to obtain the ATG have been described recently [7, 15]. In brief, groups of female New Zealand white rabbits were intramuscularly injected twice with 4×10^8 EL4 cells mixed with Freund's complete adjuvant (Difco Laboratories, Detroit, MI, U.S.A.) followed by repeated intramuscular injections of 10^8 EL4 cells/rabbit without any adjuvant. The immune sera were rendered tumour specific by repeated absorptions with homogenates of organs from adult C57BL/6J mice until the sera reacted as assayed by immunofluorescence, only with EL4 cells and neither with cryostat sections of normal C57BL/6J mouse tissues nor with suspensions or smears of C57BL/6J lymphoid cells from lymph nodes, spleen and thymus, B16 melanoma cells from C57BL/6J mice and EAC cells. The three batches of EL4 inhibitory rabbit sera were obtained after a total of 12, 22 and 35 injections of EL4 cells. Normal rabbit sera and the anti-EL4 sera after being rendered tumour specific after absorptions with homogenates of normal C57BL/6J mouse tissues were fractionated with 33% saturated ammonium sulphate. The methods of binding chlorambucil [16] and ^{131}I [7, 15] to rabbit globulins have been recently described in detail.

Detection of tumour antibodies

Cytoplasmic and membrane immunofluorescence of mouse tumour cells and other control preparations were carried out by the sand-

wich method using as appropriate fluoresceinated goat antirabbit or rabbit antimouse 7S globulin (Hyland Laboratories, Los Angeles, CA, U.S.A.) [5, 7, 15].

For detection of agglutinating and complement dependent cytotoxic antibodies tumour cells were incubated *in vitro* with immune rabbit or other test sera with and without the the addition of eight times diluted fresh rabbit serum, guinea-pig serum or C57BL/6J mouse serum which were not cytotoxic by themselves and which were assessed for their hemolytic complement activity by the method described by Cinader *et al.* [17]. At the end of the incubation period, the cells were examined for agglutination, morphological changes and permeability to trypan blue [5] and were then injected into syngeneic mice. To detect tumour suppression or enhancement by these antibodies the mean survival of these test mice was compared with that of control groups inoculated with aliquots containing identical numbers of tumour cells incubated with normal rabbit serum or HBBS.

Mice

C57BL/Icrf mice were donated by the Imperial Cancer Research Fund Laboratories, London, U.K. All other inbred mice were purchased from the Jackson Laboratory, Bar Harbor, MN. When not stated otherwise, experimental groups consisted of at least ten 12–16-week-old female mice.

Statistical evaluation

The significance of the difference in mean survival between groups was assessed by Student's *t*-test and the significance of the difference in the numbers of tumour free survivors between groups was evaluated by the fourfold table method of X^2 test.

RESULTS

Survival of C57BL/6J mice inoculated with varying numbers of EL4 lymphoma cells

Table 1 shows that i.p. inoculation of even about 10 EL4 cells leads to progressive tumour formation and subsequent death of tumour inoculated C57BL/6J mice. All the C57BL/6J mice inoculated i.v. or s.c. with 10^3 EL4 cells died approximately at the same time as the mice inoculated i.p. with comparable numbers of EL4 cells. With inocula of 10^7 EL4 cells/mouse, the mice injected i.v. died earlier (survival 9.0 ± 0.7 days) than the mice inoculated i.p. (survival 12.4 ± 0.89 days) or s.c. (survival 12.8 ± 1.1 days). None of the mice inoculated i.v. with EL4 cells had ascites. In the mice inoculated with EL4 cells s.c., ascites was seen only in those mice in which the s.c. tumour had penetrated into the peritoneal cavity. A few of the mice inoculated i.v. with 10^3 or 10^4 EL4 cells had bilateral pleural effusion containing EL4 c

At autopsy, the C57BL/6J mice inoculated i.v. with EL4 cells revealed enlargement of spleen and lymph nodes. With inocula of 10^7 EL4 cells/mouse, the range of splenic weight in the mice inoculated i.v. was 402–508 mg (median, 442 mg), whereas in the groups inoculated with 10^7 cells i.p. or s.c. the range of spleen weights was 65–140 mg (median, 68 mg). The mean spleen weights of 13 normal female C57BL/6J mice of a comparable age group was 70.72 ± 6.25 mg. Immunofluorescence assay using xenogeneic anti-EL4 serum [9] revealed dense accumulation of EL4 cells in the enlarged spleen and lymph nodes from the C57-BL/6J mice inoculated i.v. with EL4 cells. In the C57BL/6J mice inoculated i.p. with 10^8,

Table 1. *Survival of C57BL/J mice inoculated i.p. with varying numbers of EL4 lymphoma cells*

Number of EL4 cells inoculated	Survival (days ± S.D.[a]) After i.p. inoculation
1	—[b]
10	26.6 ± 6.84
10^2	23.4 ± 2.60
10^3	20.0 ± 1.0 21.3 ± 2.91* 20.7 ± 1.2†
10^4	18.4 ± 0.55 18.8 ± 1.64* 19.8 ± 1.48†
10^5	15.6 ± 1.81
10^6	12.8 ± +0.83
10^7	12.4 ± 0.89 9.0 ± 0.71* 12.8 ± 1.1†
10^8	10.0 ± 0.0

[a]Each group contained at least 15 adult female mice.
[b]Only 4 of 42 C57BL/6J mice inoculated i.p. with a single EL4 cell developed tumour.
*Figures represent survival of groups inoculated i.v. with EL4 cells.
†Figures represent survival of groups inoculated s.c. with EL4 cells.

10^7 or 10^6 EL4 cells, the weight of the spleens varied between 60 to 140 mg (median, 71 mg) in contrast to the groups inoculated with 10^5 cells (range of spleen weight 90–230 mg, median 145 mg); 10^4 cells (range of spleen weight 150–240 mg, median 190 mg); 10^3 cells (range of spleen weight 165–190 mg, median 182 mg); 10^2 cells (range of spleen weight 140–310 mg, median 185 mg). It is interesting to note that the volume of ascites fluid at the time of death in the mice inoculated i.p. with $\geqslant 10^6$ EL4 cells was $\geqslant$ 7 ml per mouse, wheras the volume of ascites fluid per mouse in the mice inoculated i.p. with $\leqslant 10^5$ EL4 cells/mouse, did not exceed 4 ml per mouse. The splenic weight of the mice with subcutaneous tumours varied widely and was influenced by the ulceration and infection of the tumours.

Irrespective of the route of tumour inoculation, survival of the tumour inoculated C57BL/6J mice was inversely related to the size of the tumour inocula and histological examination of tissues obtained at autopsy revealed widespread infiltration of EL4 cells into all internal organs.

Effect of peritoneal tapping on the growth of i.p. inoculated EL4 cells in C57BL/6J mice.

There was no difference in the survival between groups of C57BL/6J mice which had their peritoneal cavity aspirated daily for 4 days beginning 24 hr (survival 11.80 ± 1.30 days), 72 hr (survival 12.4 ± 0.54 days) or 10 days (survival 14.6 ± 4.92 days) after i.p. inoculation of 2×10^6 cells/mouse. The survival of comparison groups inoculated i.p. with 2×10^6 EL4 cells/mouse without any treatment or sham aspirated daily for 4 days beginning 24 hr after i.p. inoculation of 2×10^6 cells were 13.00 ± 1.80 and 14.0 ± 4.47 days respectively.

Effect of intradermal inoculation of EL4 lymphoma cells in C57BL/6J mice

The survival of groups of C57BL/6J mice intradermally inoculated with 10^5 (survival of 16.20 ± 1.64) or 10^3 (survival 22.6 ± 0.89 days) EL4 cells/mouse was not different from the survival of groups of mice inoculated with 10^5 or 10^3 EL4 cells i.p. (survival 15.6 ± 1.81, 20.0 ± 1.0 days respectively). The experiments were repeated several times, with comparable results.

'Immunogenicity' and growth of EL4 cells pretreated in vitro *with iodoacetate in PBS for* 1 hr *at* 37°C

Table 2 shows the results of inoculation of 10^7 EL4 cells pretreated with various concentrations of iodoacetate *in vitro*. Pretreatment of EL4 cells even with 0.01 M iodoacetate did not prevent tumour development in the tumour inoculated mice, though the appearance of tumour in these mice was considerably delayed. There was no tumour in comparison groups of mice inoculated with normal syngeneic spleen cells pretreated *in vitro* with 0.005 M or 0.01 M iodoacetate.

Table 2. Survival of C57BL/6J mice inoculated i.p. with 10^7 EL4 cells exposed to various concentrations of oidoacetate in PBS for 1 hr *at* 37°C

Inoculation of 10^7 EL4 cells pretreated with:	Survival (days ± S.D.)
Nil	12.4 ± 0.89
0.001 M Iodoacetate	17.0 ± 0
0.001 M Iodoacetate	32.8 ± 1.30
0.005 M Iodoacetate	39.2 ± 2.05
0.01 M Iodoacetate	94.4 ± 2.97

Immunoprophylaxis with Con A-modified tumour cells

Every member of groups of fifteen mice was injected i.p. with 5×10^5 of either X-irradiated tumour cells or X-irradiated tumour cells coated with Con A, following the method of Martin and Wunderlich [4]. After 4 weeks each mouse received i.p. 5×10^7 tumour, cells prepared as in the first injection. However, consistant with our previous report [7] and that of Johnson *et al.* [10], i.p. inoculation of 10^6 EL4 cells exposed to 1500 rad in C57BL/6J or C57BL/Icrf mice, i.e. a substrain derived from Gorer's colony of C57BL/6 mice in which the EL4 lymphoma originated [1], did not prevent the development of tumour in all tumour inoculated mice irrespective of whether the tumour cells were coated with Con A. Complete tumour suppression could be obtained after exposure of EL4 cells to 2000 rad which was, therefore, the irradiation dose used in this experiment. None of the C57BL mice challenged with 10^4 EL4 cells 10 days after the completion of immunization survived longer than the control group of C57BL mice immunized with irradiated EL4 cells not coated with Con A (survival 18.4 ± 3.5 and 19.2 ± 2.1 days respectively).

Since Martin and Wunderlich, in their experiments with induction of immunity with Con A coated EL4 cells used C57BL/6N mice, i.e. another substrain of C57BL/6 mice maintained for long in the National Institute of Health, U.S.A. [8, 18], the emergence of histoincompatibility between the long transplanted EL4 lymphoma and C57BL/6N mice was thought to be a possibility explaining the complete suppression in this substrain of EL4 cells exposed to 1500 rad and the induction of im

munity by injections of Con A coated EL4 cells [4, 18]. We, therefore, investigated the effectiveness of Con A coated tumour cells in inducing tumour resistance in an allogeneic model, i.e. the EAC in BALB/c mice.

BALB/c mice immunized with Con A modified EAC cells died earlier (i.e. within 10–16 days of challenge) compared to the survival of BALB/c mice immunized with irradiated tumour cells alone (survival 23–31 days). Prior sensitization of groups of C57BL and BALB/c mice to Con A by a method described by Wong *et al.* [19] did not prolong the survival of these mice when challenged as appropriate with Con A coated 10^4 viable EL4 or 2.5×10^6 viable EAC cells.

Immunoprophylaxis against EL4 lymphoma with irradiated tumour cells

Immunoprophylaxis could be consistently induced in C57BL/6J mice using irradiated EL4 cells provided that the number of irradiated EL4 cells per injection and the number of immunizing injections were adequate. Injections containing 10^6, 10^7 or 10^8 irradiated EL4 cells (but not comparable numbers of irradiated syngeneic nucleated spleen cells) given i.p. once a week at least for 3 consecutive weeks, consistently protected varying proportions of mice when they were challenged i.p. with either 10^3 or 10^4 viable EL4 cells/mouse 1 week after the completion of immunization. No such protection could be observed when the number of irradiated EL4 cells per injection was less than 3. The protection increased with increasing numbers of injections and increasing numbers of irradiated EL4 cells per injection. However, immunization with 10^8 irradiated tumour cells (or 10^8 irradiated nucleated spleen cells) i.p. caused ascites and an occasional death due to peritonitis. EL4 specific antibody could be detected in the serum and ascites fluid of the C57BL mice immunized with 10^8 irradiated EL4 cells/mouse but not in mice immunized with comparable numbers of irradiated spleen cells. These anti-EL4 sera were not cytotoxic to EL4 cells *in vitro* and they neither inhibited nor enhanced EL4 lymphoma when injected into tumour-bearing mice [9].

Figure 1 shows that i.p. immunization with 10^7 irradiated EL4 cells/mouse offered better protection against challenge inocula containing 10^3 EL4 cells/mouse than inocula containing 10^4 EL4 cells/mouse, and, also that four i.p. injections of 10^7 irradiated EL4 cells were more protective than four s.c. injections or three i.p. injections followed by one intrasplenic injection of 10^7 irradiated EL4 cells.

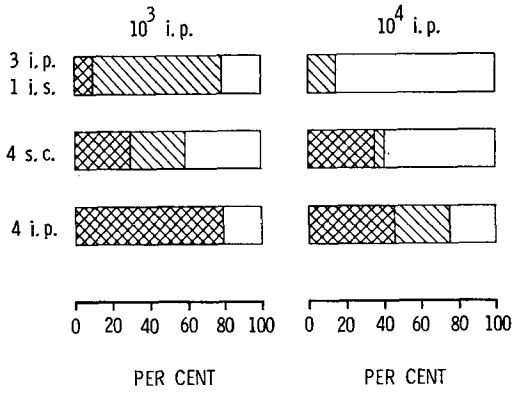

Fig. 1. *Survival of C57BL mice immunized with injections of* 10^7 *X-irradiated EL4 cells/mouse once a week for* 4 *weeks and challenged* 1 *week after the last injection with either* 10^3 *or* 10^4 *viable EL4 cells i.p. Empty space represents per cent of mice dead of tumour within* 30 *days of challenge. Diagonally hatched space represents per cent of mice dead of tumour from days* 31 *to* 200 *post tumour challenge. Cross-hatched space represents per cent of mice surviving tumour-free for* 200 *days.*

The immune C57BL/6J mice that survived a challenge inoculum of 10^4 EL4 cells/mouse were resistant 60 days after the first challenge to further i.p. challenges with 10^5 and 10^6 EL4 cells, but not to a challenge i.p. with 10^7 EL4 cells. However, these immune mice (i.e. those surviving tumour free 60 days after being challenged with 10^4 EL4 cells) had a mean survival of 22.2 ± 2.7 days when rechallenged with 10^4 syngeneic B16 melanoma cells compared to the survival of 22.4 ± 1.9 days of previously untreated C57BL/6J mice inoculated with 10^4 B16 melanoma cells.

Tumour resistance in immunized C57BL/6J mice (not challenged with viable EL4 cells) declined rapidly and was undetectable 16 weeks after immunization as assessed by their survival after i.p. challenge with 10^3 EL4 cells (Table 3). Immunoprophylaxis against EL4 lymphoma with irradiated tumour cells and/or BCG.

Figure 2 shows the survival of C57BL/6J mice challenged i.p. with 10^4 tumour cells after immunoprophylaxis with irradiated EL4 cells and/or BCG. In another experiment the results of different methods of immunoprophylaxis in C57BL/6J mice against the syngeneic EL4 lymphoma was compared with the results of identical methods of immunoprophylaxis against the allogeneic EAC in BALB/ mice (Fig. 3). In immunization protocols 3 and 8, BCG and irradiated tumour cells were incubated together for 10 min at 37°C immediately before injection. The s.c. injections during immunization protocols 5–10 were given at separate sites along the dorsal midline starting

Table 3. Survival of C57BL/6J mice challenged i.p. with 10^3 viable EL4 cells 1, 4, 8 and 12 weeks after completion of immunization with irradiated EL4 cells

Interval between immunization* challenge† (week)	Survivor > 200 days tumour free	Died of tumour between 30 and 200 days post challenge‡	Died of tumour within 30 days (postchallenge)
1	17/21	4/16	4/21
4	6/16	5/14	6/16
8	2/14	5/13	8/13
16	0/14	0/14	14/14§ (All died of ascites tumour between 14 and 18 days after challenge.)

*Immunized with 10^7 irradiated EL4 cells i.p. once a week for 4 weeks.
†Challenged with 10^3 viable EL4 cells per mouse.
‡The majority of the mice in this group did not develop ascites. Autopsy of these mice revealed large spleen and widespread infiltration of internal organs with EL4 lymphoma cells.
§A comparison group of previously untreated C57BL mice challenged with 10^3 EL4 cell died between 17 and 22 days after challenge.

from the caudal end on week 1 and finishing over the neck on week 4. Immunoprophylaxis with BCG alone administered either i.p. (protocol 1) or s.c. (protocol 6) did not protect C57BL mice against challenge with EL4 cells, but both these protocols of immunization offered varying degrees of protection to BALB/c mice against the allogeneic EAC. However, in terms of tumour free survival for more than 200 days in C57BL/6J mice, the protection resulting from i.p. immunization with irradiated tumour cells alone (protocol 2) was increased ($P<0.01$) when the mice were simultaneously immunized with BCG s.c. (protocol 5). As immunization with i.p. injections of only irradiated EAC cells offered complete protection to the BALB/c mice (protocol 2) any additive effect of BCG injections in protocols 3, 4 and 5 could not be elucidated. BCG given i.p. lowered the protection (i.e. tumour free survival > 200 days) produced by s.c. injection of irradiated EL4 cells alone (protocols 7 and 10) in C57BL mice ($P<0.01$), but did not significantly alter the protection offered by s.c. injections of irradiated EAC cells in BALB/c mice. Injections of BCG s.c. at the opposite side (protocol 9) did not increase the protection (i.e. tumour free survival > 200 days) resulting from s.c. injections of irradiated EL4 cells or EAC cells alone (protocol 7). Incubation of irradiated EL4 or EAC cells with BCG prior to subcutaneous injection appears to lower the protection provided by immunization with irradiated EL4 or EAC cells alone (protocol 8).

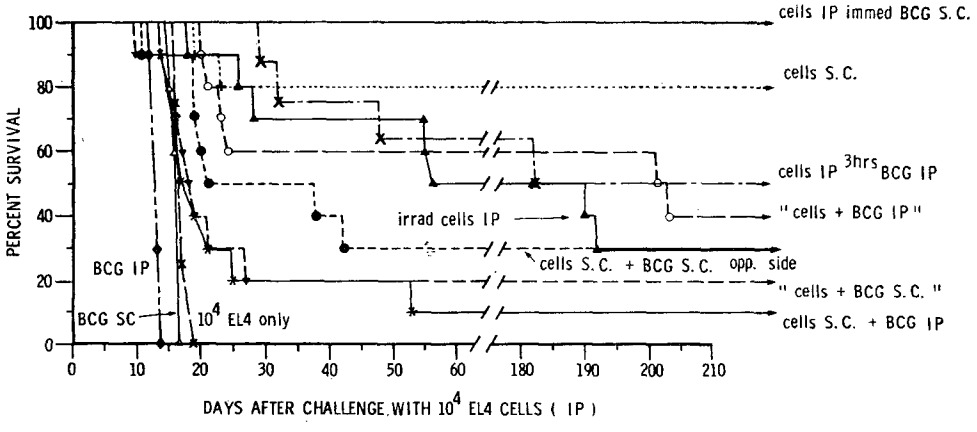

Fig. 2. Survival of C57BL/6J mice challenged with 10^4 EL4 lymphoma cells/mouse 1 week after immunization with injections of 10^7 irradiated tumour cells and/or 10^7 viable BCG once weekly for 4 weeks. 'Cells + BCG' i.p. represents groups of mice inoculated with irradiated EL4 cells incubated with BCG before injection.

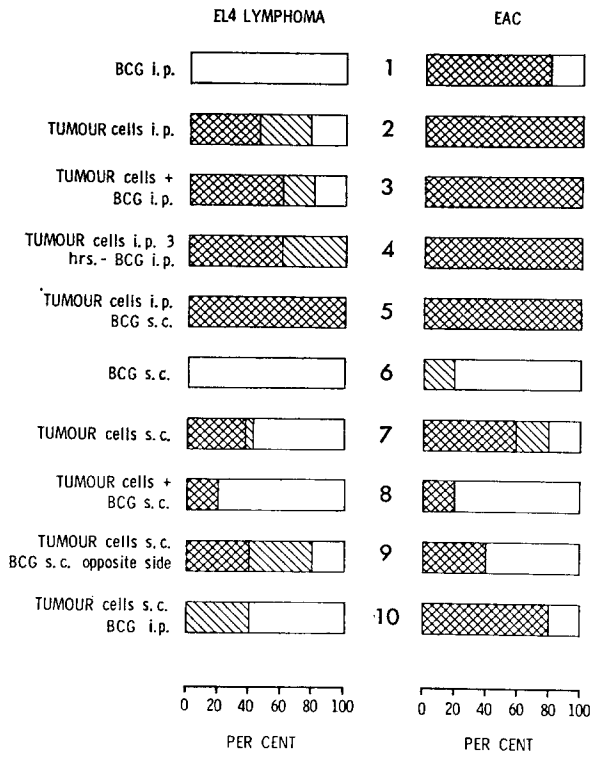

Fig. 3. Comparison of the survival of C57BL and BALB/c mice challenged respectively with 10^4 *EL4 lymphoma and* 2.5×10^6 *EAC cells per mouse 1 week after immunization with injections of* 10^7 *irradiated tumour cells and/or* 10^7 *viable BCG once a week for 4 weeks as explained in the left hand column. For convenience of reference each protocol of immunization has been assigned a number presented in the third column.*

Immunotherapy of EL4 lymphoma with irradiated tumour cells only or irradiated tumour cells and BCG

After i.p. inoculation of 10^2–10^6 viable EL4 cells/mouse, three i.p. injections of 10^8 irradiated EL4 cells were given 2, 48 and 168 hr later. Nine of 10 mice inoculated with 10^2 cells and 1 of 10 mice from groups inoculated with 10^3 and 10^4 EL4 cells/mouse survived tumour-free for 300 days. None of the mice given 10^5 or 10^6 cells before immunotherapy or treated with 3 i.p. injections of irradiated syngeneic nucleated spleen cells survived longer than did the untreated controls. Injection of irradiated tumour cells i.p. followed by BCG s.c., i.e. protocol 5 (Fig. 3), the most potent protocol for immunoprophylaxis, was also used in a modified form for immunotherapy. Two hours after i.p. inoculation of 10^4, 10^5 or 10^6 EL4 cells, each C57BL/6J mouse received injections of 10^8 irradiated EL4 cells i.p. and 10^6 BCG cells s.c. The injections of irradiated EL4 cells and BCG were repeated on days 3 and 7 after tumour inoculation. The survival times of the treated mice receiving 10^5 and 10^6 EL4 cells (14.20 ± 3.19 and 11.25 ± 0.5 days, respectively) were not different from those of untreated controls (15.20 ± 2.28 and 11.40 ± 2.60 days, respectively). However, immunotherapy with BCG and irradiated tumour cells resulted in the survival of two out of twenty mice given 10^4 EL4 cells i.p.

Immunotherapy of EL4 lymphoma with 'adoptive' transfer of syngeneic immune splenic and peritoneal exudate cells

Spleen and peritoneal cells from tumour-free immune C57BL/6J mice 60 days after challenge with 10^3 viable EL4 cells inhibited EL4 cells. This was established by the longer survival i.e. (24.4 ± 3.64 days for splenic cells and 27.6 ± 4.51 days for peritoneal cells) of mice inoculated i.p. with 10^6 EL4 cells mixed with either 10^7 immune nucleated splenic or peritoneal cells compared to the survival of groups of C57BL/6J mice inoculated with 10^6 EL4 cells mixed with splenic or peritoneal cells from previously untreated mice (survival 14.4 ± 1.05 days and 14.4 ± 1.34 days respectively). For immunotherapy, C57BL/6J mice were first given 10^4 viable EL4 cells i.p. and were then treated 1 or 2 hr later with 10^5 immune spleen or peritoneal cells. Survival was slightly prolonged (22 days) in 1 of 10 mice inoculated i.p. with immune spleen cells and 2 of 10 mice (23 and 24 days) given immune peritoneal cells 1 hr after tumour inoculation. The survival times of all other mice in these groups did not differ from the survival of 10 mice inoculated i.p. with 10^4 EL4 cells only (16–19 days).

Active Immunotherapy of EL4 lymphoma with neuraminidase treated tumour cells

Groups of C57BL mice were treated 2 hr after receiving 10^4 EL4 cells/mouse with i.p. injections of either 10^7 EL4 cells exposed *in vitro* to both VCN and mitomycin, mitomycin only or Ml99 only. The mice injected i.p. with VCN and mitomycin treated EL4 cells (survival 15.2 ± 0.44 days) or only mitomycin treated (survival 17.0 ± 1.87 days) or only VCN treated tumour cells (survival 17.2 ± 1.92 days) did not survive longer than the control group of mice which after receiving 10^4 EL4 cells/mouse were injected i.p. with PBS only (survival 17.2 ± 1.92 days). The group of mice, which after receiving 10^4 EL4 cells i.p. were injected with 10^7 EL4 cells exposed to Ml99 only died earlier (survival 11.0 ± 0 days).

Passive immunotherapy of EL4 lymphoma

While examing the biological properties of more than fifty batches rabbit and goat anti-

EL4 sera, 3 batches of rabbit anti-EL4 sera were found to consistently inhibit tumour growth in C57BL mice preinoculated with EL4 cells even though these anti-sera did not render EL4 cells permeable to trypan blue after exposure *in vitro* to these ATG preparations and complement. Table 4 shows the survival of groups of C57BL/6J mice which were tested with 5 injections of 2 mg ATG/mouse/day, either 2, 24 or 120 hr after i.p. inoculation of 10^3, 10^4, 10^5 ATG preparations (Table 4). However, when treatment was started at 120 hr after i.p. inoculation of 10^3 or 10^4 cells/mouse, daily injections of 2 mg ATG (TI)/mouse for 5 days completely suppressed the EL4 lymphoma in a proportion of these mice. Comparison groups of EL4 inoculated C57BL mice treated with 0.1 mg of chlorambucil or 2 mg ATG (NTI) per mouse daily for 5 or 9 days died between 18 and 22 days after tumour inoculation [5, 15].

Table 4. Survival of C57BL/6J mice treated either with tumour inhibitory anti-tumour globulin (ATG) (A) or non-tumour inhibitory ATG bound to chlorambucil (B) or ^{131}I (C) 2, 24, 72 and 120 hr after i.p. inoculation of various numbers of EL4 cells. Each group contained at least 10 mice

No. of EL4 cells inoculated (per mouse) i.p.	Interval—(hr) between tumour inoculation and beginning of treatment and per cent survival after the 3 modalities of treatment, i.e. A, B and C*			
	2	24	72	120
10^3	A—80 B—100 C—100 (400μCi)	A—80 B—100 C—100 (400μCi)	A—80 B—80	A—80 B—0 (P.S.)†
10^4	A—40 B—100 C—100 (540μCi)	A—60 B—90 C—80 (500μCi)	A—50 B—60	A—50 B—0 (P.S.)†
10^5	A—20 B—100			
10^6	A—0 B—60			
10^7	A—0 B—0			

*A—Treated with tumour inhibitory anti-EL4 globulin (2 mg daily for 5 days).
B—Treated with nontumour-inhibitory anti-EL4 globulin bound to chlorambucil (2 mg globulin + 0.1 mg chlorambucil daily for 5 days).
C—Treated with nontumour inhibitory anti-EL4 globulin bound to ^{131}I (approximate activity of ^{131}I in parenthesis).
All injections were intraperitoneal.
†Prolonged survival only, no cure.

or 10^6 EL4 cells/mouse. Eighty per cent of the mice inoculated with 10^3 EL4 cells/mouse and approx 50% of the mice inoculated with 10^4 EL4 cells/mouse survived tumour-free irrespective of the interval between tumour inoculation and treatment.

Immunochemotherapy of EL4 lymphoma with ATG noncovalently bound to chlorambucil

When administered within 72 hr of tumour inoculation, chlorambucil noncovalently bound to a xenogeneic ATG (non tumour inhibitory, NTI) was a better or at least equally effective tumour inhibitor as the tumour inhibitory (TI)

Immuno-radiotherapy of EL4 lymphoma

Xenogeneic ATG (not tumour inhibitory, NTI) when bound to ^{131}I could suppress the growth of EL4 lymphoma in mice preinoculated with 10^4 cells provided that adequate amounts of radio-iodinated ATG was administered within 72 hr of tumour inoculation (Table 4). For tumour inhibition in mice preinoculated with 10^4 EL4 cells/mouse longer than 72 hr it was necessary to administer more than 1 mCi of ^{131}I/mouse, which causes severe bone marrow depression and diarrhaea in these mice. The details and survival of appropriate comparison groups of mice have been described elsewhere [7, 14].

DISCUSSION

The localization of large numbers of i.v. inoculated EL4 cells into the spleen and lymph nodes of C57BL/6J mice is similar to the lymphoid tissue specific localization of i.v. inoculated lymphoma cells in AKR mice [20, 21]. The decreased volume of ascites tumour and increased spleen weight in the C57BL/6J mice inoculated i.p. with $\leqslant 10^5$ EL4 cells compared to the mice receiving $\geqslant 10^6$ EL4 cells i.p. might indicate either localization of EL4 cells in the spleen in preference to the peritoneal cavity in these mice or the ability of these mice to offer effective resistance only against inocula containing $\leqslant 10^5$ EL4 cells.

Increased splenic cellularity and organ weight has been postulated to be associated with tumour resistance in mice bearing syngeneic tumours [22] including lymphomas [23]. It is interesting to note that splenic enlargement, decreased volume (or absence) of ascites and disseminated tumour were also seen at autopsy in those C57BL/6J mice which after immunotherapy or immunoprophylaxis against i.p. inoculated EL4 lymphoma survived longer than tumour inoculated untreated control mice.

Contrary to the report of Rubin [8] that viable EL4 cells after intradermal injection into C57BL/6J mice do not proliferate and induce immunity against further challenges with EL4 the results presented here demonstrate that inoculation of as few as 10^3 EL4 cells into C57BL/6J mice leads to the death with widely disseminated tumour in all tumour inoculated mice irrespective of i.v., i.p., s.c. or intradermal routes of tumour inoculation. This discrepancy might be due to minor degrees of histoincompatibility between the EL4 lymphoma and the C57BL/6N mice, the evidence for which has already been discussed.

In our laboratory, intraperitoneal injection of blood into C57BL/6J mice from mice preinoculated i.p. 24 hr ago with as few as 10^5 EL4 cells/mouse led to the development of EL4 lymphoma in the recipient mice, thus demonstrating the presence of EL4 tumour cells in the circulation of C57BL/6J mice 24 hr after i.p. inoculation of 10^5 EL4 cells/mouse. Further, histological examination of internal organs of C57BL/6J mice inoculated i.p. with 10^6 EL4 cells/mouse had revealed small foci of tumour cells in the lungs 72 hr after tumour inoculation and also definite invasion of the liver and kidney 120 hr after tumour inoculation [7, 15].

Using the 'Pondville subline of C57BL mice', Apffel and Arnason [2] have reported the induction of immunity against EL4 lymphoma after injections of EL4 cells 'inactivated' with 10^{-2}, 10^{-3} and 10^{-4}M iodoacetate. They also reported in this subline of C57BL mice the complete suppression of EL4 lymphoma followed by the development of tumour immunity after serial peritoneal tapping beginning 7–14 days after i.p. inoculation of 2.5×10^6 EL4 cells [3].

However, the suppression of EL4 lymphoma after serial peritoneal tapping [3] and after immunoprophylaxis with iodoacetate treated cells can be explained on the basis of genetic heterogeneity of the C57BL mice used, i.e. a tumour indigenous in the 'C57BL/6 Pondville mice' was rejected by another substrain of C57BL/6 mice used by these investigators [2]. Consistent with our observation, iodoacetate treated tumour cells have been reported to be not very effective in tumour immunotherapy [24] and VCN and mitomycin treated tumour cells are therapeutically effective mostly in tumour models with relatively long survival of tumour inoculated mice [14] compared to the survival of EL4 inoculated C57BL/6J mice.

Studies on immunoprophylaxis and immunotherapy using tumours of long transplantation history like the EL4 lymphoma are complicated by the possibility of viral contamination and the emergence of histoincompatibility between the various tumour sublines and the substrains of mice evolving from the strain of origin of the primary tumour. Our results confirm the effectiveness of immunoprophylaxis with BCG and/or irradiated tumour cells in allogeneic tumours like the EAC [11] or the S91 melanoma in BALB/c mice [25]. On the other hand, immunoprophylaxis with BCG and/or irradiated tumour cells failed in our laboratory to inhibit in AKR mice the syngeneic L2 lymphoma which has a much shorter transplantation history [9]. It is, therefore, not certain that the immunity induced in C57BL/6J mice with injections of irradiated EL4 cells by us and others [9, 10] is truly tumour specific.

The superiority of tumour inhibition by ATG linked cytotoxic agents over tumour inhibition by ATG or cytotoxic agents by themselves is now well established [7, 15, 26–30]. However, although the therapy of malignant tumours with xenogeneic and allogeneic antisera has been generally disappointing [31], more recently there have been reports on the prolongation of survival by a few days, but not 'cell cure' of EL4 bearing C57BL mice [32] and rats bearing a syngeneic lymphoma [33] after injections of appropriate rabbit antitumour sera. The ATG preparations obtained by us appear to be more potent as cell cure could be obtained

in a proportion of mice preinoculated with 10^5 EL4 cells (i.e. 10^4 times more than the minimum number of EL4 cells necessary for 100% tumour take). The complete tumour suppression in a proportion of mice, even when passive immunotherapy was instituted 120 hr after i.p. inoculation with EL4 cells, is especially interesting because there is definite evidence of tumour dissemination 120 hr after i.p. inoculation of EL4 cells and even chlorambucil bound ATG only prolonged the survival and failed to produce any 'cell cure' when treatment was initiated 120 hr after tumour inoculation. We have so far failed to detect tumour inhibition by several goat anti-mouse lymphomas including goat anti-EL4 sera. Further, more than 50 different batches of rabbit and goat antisera against the L2 lymphoma have consistently failed to cause any tumour inhibition. This lack of universality of tumour inhibition by xenogeneic antisera at present limits the usefulness of passive immunotherapy of cancer.

Water Soluble Derivatives and Bifunctional Analogs of the Anticancer Agent 1, 3-bis(2-chloroethyl)-1-nitrosourea (BCNU)

H. H. FIEBIG,* G. EISENBRAND, W. J. ZELLER and T. DEUTSCH-WENZEL

Institute for Toxicology and Chemotherapy of the German Cancer Research Center, Heidelberg, West Germany

Abstract—*Three water soluble and 6 bifunctional newly synthesized analogs of 1,3-bis(2-chloroethyl)-1-nitrosourea* (BCNU) *were screened for anticancer activity against subcutaneously and intracerebrally inoculated Walker carcinosarcoma 256 and 7,12-dimethylbenz(a)anthracene* (DMBA) *induced mammary cancer of the rat. The water soluble 1-(2-hydroxyethyl)-3-(2-chloroethyl)-3-nitrosourea showed a higher activity than BCNU in s.c. inoculated Walker carcinosarcoma 256 in several experiments. Treatment of i.c. inoculated Walker carcinosarcoma 256 with the bifunctional analogs and 1-(2-hydroxyethyl)-3-(2-chloroethyl)-3-nitrosourea resulted in a marked increase in lifespan over untreated rats. However, statistically no differences were found in comparison to the treatment with BCNU. Against the DMBA induced mammary cancer of the rat, only 2 new analogs were examined; they produced a smaller tumor weight inhibition than BCNU. Further investigations are under work to examine the activity of the new compounds against chemically induced brain tumors.*

INTRODUCTION

THE NITROSOUREAS BCNU, 1-2(chloroethyl)-3-cyclohexyl-1-nitrosourea (CCNU) and methyl-CCNU are active in a number of experimental and human tumours. They produce cures in L 1210 leukemia and L 5222 leukemia after intraperitoneal or intracerebral inoculation [1–3] and also cause a marked inhibition of tumor weight or cures in the solid tumor systems B 16 melanoma and Lewis lung carcinoma [4]. In human tumors they have a broad spectrum of activity. BCNU, CCNU and MeCCNU are effective in advanced brain tumors, Hodgkin's disease, non-Hodgkin's lymphomas and melanomas [4–6]. Furthermore BCNU shows some activity against breast cancer [4], and CCNU against lung cancer [6]. In combination therapy they have not yet been investigated adequately [7]. The nitrosoureas are potent alkylators of nucleic acids [8–10]. They are cell cycle nonspecific in their mode of action and also active in slowly proliferating tumors.

BCNU, CCNU and MeCCNU have qualitatively similar toxic effects. Clinically, the main toxic effects observed are acute nausea and vomiting and delayed, dose-limiting myelosuppression [7].

The bifunctional nitrosoureas described here were synthesized to study the influence of bifunctional carbamoylating activity on chemotherapeutic effectiveness [11]. Water soluble compounds were prepared following a suggestion by Hansch *et al.* [12] that the synthesis of more hydrophilic nitrosoureas might uncover less toxic and chemotherapeutically more potent compounds [12].

MATERIAL AND METHODS

Animals. All investigations were carried out with Sprague–Dawley rats kept under conventional conditions. They received Altromin® pellets and water *ad lib.*

Toxicological investigations. For determination of the LD_{50}, at least 4 logarithmically spaced doses were given to 5 male and 5 female rats (3–5 month old) respectively (total number of rats at least 40 for each compound tested). The observation period for the determination of the LD_{50} was 60 days; values were calculated

Accepted 6 December 1976.

*Supported by the Deutsche Forschungsgemeinschaft.

according to the method described by Spearmen and Kärber [13]. All rats were dissected, and the organs with pathological alterations were examined histologically. Early toxicities within 14 day observation period were also given (Table 1).

induced by 7,12-dimethyl-benz(a)anthracene (DMBA). Female Sprague–Dawley rats (50–55 days old) received 3 intravenous injections of DMBA in a total dose of 4 mg per rat within 1 week. The rats were checked weekly for palpable mammary tumors. Estimates of tumor

Tumors. Male Sprague–Dawley rats (5–7 weeks old) were inoculated subcutaneously with 4×10^6 Walker ascites cells on day 0. Treatment started on day 4, when the tumor had reached approx 0.8 g. On day 8, all rats were killed with ether and the tumors were excised and weighed.

Intracerebral inoculation of Walker 256 ascites cells was carried out according to the method described by Valzelli [14]. A needle (No. 20) with a glass sleeve limiting its penetration to 11 mm was inserted into the petrotympanic-fissure. The rats were anesthesized with ether. Ascites cells (2×10^4 in 25 μl) were implanted into the thalamic area. Pathological examination of randomly selected rats showed that the tumor was growing in a solid form practically exclusively in the target area of the brain (Fig. 1); in rare cases, some tumor cells could be detected additionally within the meninges. Tumor take was 100%.

The autochthonous mammary cancer was size were made by palpation and comparison with plastilin models which had been copied from representative original tumors [15].

The tumors developed multicentrically along the milk-groin. The total tumor mass per rat which was obtained by addition of estimated weights of individual tumors, was taken for evaluation. The first palpable tumors appeared 3 weeks after the application of DMBA. The median induction period until beginning of treatment was 63 days ranging from 42 to 84 days.

Tumors with a longer induction period were not used for chemotherapeutic experiments. The antitumor activity was expressed as tumor weight inhibition,

$$\left[\frac{\text{control-treated}}{\text{control}} \times 100\right],$$

and mean number of tumors per rat. Mortality and changes of body weight were taken as a

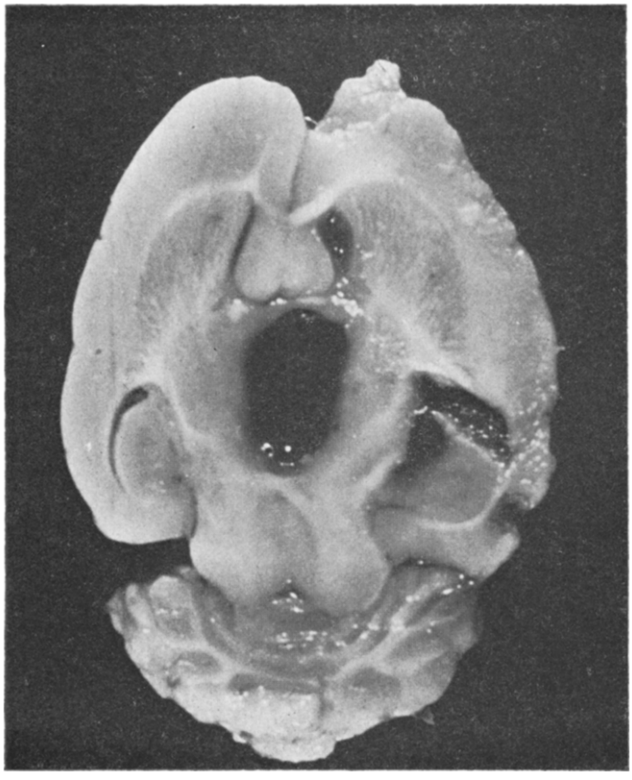

Fig. 1. *Intracerebral growth of Walker* 256. *Untreated rats died* 6 days *after intracerebral inoculation of* 2×10^4 *cells.*

measure for toxic effects. At the beginning of chemotherapy the mean total tumor mass was 3.6 ± 0.6 g and the mean number of tumors was 4.0 ± 1.3 per rat. Each rat had at least one tumor exceeding a weight of 1 g. The rats were randomly assigned into different groups of treatment. All rats were killed 42 days after the beginning of chemotherapy and the tumors were excised and weighed. The tumors from the 18 control rats were examined histologically. Out of 131 tumors, 124 were classified as carcinomas, 5 as preneoplasms, and only 2 as adenomas.

Compounds

Preparation of the compounds and chemical properties have been described elsewhere [11]. Nitrosoureas, not soluble in water, were first dissolved in a mixture of absolute ethanol and Cremophor®-EL* and then made to volume with 0.9% saline solution (Table 1). All substances were given intraperitoneally, except for compound 9 which was given intravenously.

Statistics

Tumor mass or survival time were statistically evaluated by the Kruskal–Wallis test, followed by multiple comparisons [16]. For the evaluation of BCNU against compound 6 the Wilcoxon rank sum test was used (Table 3).

RESULTS

Toxicological investigation

All 9 nitrosoureas showed qualitatively similar toxic effects. Bleedings of the stomach and intestines, lung oedema and a depression of the bone-marrow and lymphoid tissue were observed in animals which died 3–14 days after a single i.p. injection. A marked loss of body weight and moderate leucopenia was observed 40–60 days after the substances had been given. Rats which died of late toxicity showed pronounced liver necrosis and bleedings of the stomach and intestines. Liver-necrosis was not observed after i.v. injection.

The LD_{50} values were determined after an observation period of 60 days to take care of late toxicity of the nitrosoureas. The hydroxylated substances 6–8 and BCNU all had LD_{50} values of 25 mg/kg; LD_{50} values for the bifunctional analogs 1–5 were around 35 mg/kg with a range of 32–40 mg/kg. The aromatic compound 9 was more toxic with a LD_{50} of about 13 mg/kg after i.v. application; (after i.p. application compound 9 produced a peritonite and was therefore given i. v.). LD_{10} values were approximately 20% smaller than LD_{50} values. The early toxicities of the 10 nitrosoureas (observation period of 14 days) are given in Table 1. For all compounds toxicities were similar in both sexes.

Anticancer activity

Tables 2 and 3 summarize the anticancer activity of BCNU analogs in s.c. inoculated Walker 256. BCNU and cyclophosphamide served as reference compounds.

The bifunctional compounds 1–5 showed smaller chemotherapeutic effects than those of BCNU in the 2 schedules tested. One single dose (approx 80% of the LD_{10}) given 4 days after transplantation was more effective than the fractionated schedule given on days 4–7. Single dose application however produced a reduction in body weight, which is a rough parameter of toxicity. The water soluble compounds 6–8 showed striking differences in their activities. Compound 6 was slightly more effective than BCNU in three dose-levels tested; in further experiments, the differences were statistically significant (Table 3). Compounds 7 and 8, however, were practically inactive, although their toxicities were equal to that of 6. The aromatic nitrosourea 9 showed a moderate tumor weight inhibition.

Nitrosoureas used for clinical purposes are known to cross the blood–brain–barrier [17]. Therefore, the newly synthesized nitrosoureas were also tested against i.c. inoculated Walker 256. Control rats died 6–7 days after transplantations of 2×10^4 ascites cells. Treatment with BCNU and the newly synthesized nitrosoureas, listed in Table 4, caused a significant increase in lifespan. However, differences in survival time between BCNU and the new compounds 1–6 were statistically not significant.

In addition to transplantation tumors we used the DMBA-induced mammary cancer of the rat as a tumor model for screening experiments. Table 5 summarizes the results obtained by the treatment with BCNU and the new compounds 3 and 6. In this experiment the new analogs showed an activity which was somewhat smaller than that of BCNU. Schedules with repeated injections were more effective than those with one single injection; they were, however, also more toxic, causing a considerable loss of body weight and increase of mortality.

*A non-ionic solubilizing agent and surfactant based on polyethoxylated ricinus oil (BASF-Ludwigshafen, W. Germany).

DISCUSSION

Screening for anticancer activity of BCNU and 9 newly synthesized analogs in the s.c. Walker 256 revealed one analog which produced a statistically higher tumor inhibition than BCNU. This was compound 6, 1-(2-hydroxyethyl)-3-(2-chloroethyl)-3-nitrosourea which is a water soluble analog of BCNU. The lipophilic compounds 1–5, however, were somewhat less active than BCNU. No relationship could be found between the length of the polymethylene bridges and antitumor or toxic effects of these bifunctional congeners of BCNU. The introduction of bifunctional carbamoylating activity into the nitrosourea molecule therefore does not influence its biological properties significantly.

Treatment of i.c. inoculated Walker 256 with BCNU, the bifunctional lipophilic analogs 1–5 and compound 6 showed no statistical differences in survival time: all compounds displayed equal activities. However, compounds 1–5 were somewhat less active against s.c. implanted Walker 256 than BCNU. The relatively better chemotherapeutic effectiveness of the latter compounds against i.c. inoculated tumor cells might be attributed to an increased ability to cross the blood brain barrier.

Further investigations using slower growing models of brain tumors which better reflect the characteristics of human neoplasm are in progress.

Acknowledgements—We thank Prof. Dr. K. Goerttler (Institute for exp. Pathologie, Deutsches Krebsforschungszentrum Heidelberg) for carrying out the histological examinations. We are greatly indebted to Mrs. B. Strobel and Mrs. A. Pohl for excellent technical assistance and to Mr. Paul E. Schurr for supplying 7,12-Dimethylbenz(a)anthracen.

Proteases During the Growth of Ehrlich Ascites Tumor. III. Effect of *e*-Aminocaproic Acid (EACA) and Heparin*

NATHAN BACK† and PIERRE P. LEBLANC‡

Department of Biochemical Pharmacology, School of Pharmacy, State University of New York, Buffalo, N.Y. 14207, U.S.A.

Abstract—*The effect of heparin and e-aminocaproic acid (EACA) on the* in vivo *growth of Ehrlich ascites tumors was studied. The drugs were administered intraperitoneally every* 8 hr *for* 8 *consecutive* days *beginning* 16 hr *after transplant of* 10 *million tumor cells. Heparin doses studied ranged from* 50 *to* 800 units/kg *and EACA doses were* 125–2000 mg/kg. *Criteria for therapeutic effect included measurement of total ascites volume (TAV) and total packed cell volume (TPCV) determined* 16 hr *after the last drug injection. Both heparin and EACA exerted a dose-dependent chemotherapeutic effect. Heparin, at the highest dose of* 800 units/kg *significantly reduced TAV by an average of* 46.9% ($P<0.01-<0.005$) *and reduced the TPCV by an average of* 46.1% ($P<0.01-<0.005$). *At the lowest heparin dose of* 50 units/kg *a biphasic inhibitory response was obtained reflected by a decrease in both TAV* (26.1%, $P<0.025-<0.01$) *and TPCV* (26.3%, $P<0.05-<0.005$). *EACA, at the highest dose of* 2000 mg/kg, *inhibited TAV by* 56.3% ($P<0.001$) *and TPCV by* 48.1% ($P<0.001$).

INTRODUCTION

WITHIN recent years, attention once again has focused on the possible relationship between protease activity in malignant tissue and *in vitro* transformed cells and tumor growth and development [1–6]. Moreover, both tumors and transformed cells have been reported to be affected adversely by protease inhibitors studied *in vitro* [3, 7–11] and *in vivo* [4, 12–16], as well as by heparin [17].

Studies in our laboratory have explored the possible role of proteases in certain phases of tumor growth [5, 16, 18]. This investigation was designed to study the potential chemotherapeutic effect of *e*-aminocaproic acid (EACA) and heparin on the *in vivo* growth of the Ehrlich ascites tumor.

MATERIAL AND METHODS

Tumor transplantation

Ehrlich ascites tumor, provided by Dr. P. Hebborn of our department, was maintained by weekly intraperitoneal transplant in male albino Swiss mice, ranging in weight from 20 to 25 g. Tumor transplant was carried out as described previously [5]. On the 7th or 8th day after maintenance transplant, donor mice were killed by cervical fracture and the ascites fluid drained from the abdominal cavity into sodium citrate, 3.8%, in a ratio of 1 ml/10 ml ascitic fluid. The tumor cell number was estimated by microscopic cell count and the tumor cell viability confirmed with lissamine green [19]. The tumor cell suspension was diluted with physiologic saline to a concentration of 20 million cells per ml and 10 million cells (0.5 ml suspension) were transplanted into the lower quadrant of the peritoneal cavity of experimental recipient mice.

Treatment

Sixteen hours after tumor transplant, therapy was stated every 8 hr for 8 consecutive days. The drugs studied included heparin (Pan-Heparin, Abbott Labs., North Chicago, Ill) at doses of

50, 100, 200, 400 and 800 units/kg, and *e*-aminocaproic acid (EACA; Lederle Labs., Pearl River, N.Y.) at 125, 250, 500, 1000 and 2000 mg/kg doses. A volume of 0.2 ml of the drug or saline (control) solution was injected into the lower abdominal quadrant opposite the implantation site. Every 2 days a contralaterial injection site was used. Twenty mice constituted the saline control groups and 10 mice for each drug treatment group.

Evaluation of therapeutic effect

The ascites tumors were harvested 16 hr after the last injection of drug. The carcass weights of the animals in each group were recorded and compared to the initial pre-treatment weights as an indication of general drug-induced toxic effect. As an index of tumor inhibition [20], the total packed cell volume (TPCV = ascites volume in a mouse × percentage of packed cell measured in an IEC model MB (Boston, Mass.) micro-capillary centrifuge) was determined. Total ascites volume (TAV) also was recorded as an indication of the extent of fluid effusion into the peritoneal cavity. The means of the TAV and TPCV of the drug-treated and control groups were compared (±S.E. of mean) and levels of significance calculated using the *t* test method.

RESULTS

Table 1 summarizes the effect of heparin on the total ascites volume (TAV) and total packed cell volume (TPCV) in 2 individual experiments. While the control means of both the TAV and TPCV varied between the 2 experiments, the relative effects of the respective heparin doses were similar. At the lowest dose of 50 units/kg, heparin reduced the TAV by 21.9% ($P<0.001$) and 30.2% ($P<0.025$) respectively with an average of 26.1%. At that low dose, heparin inhibited tumor growth (TPCV) by 18.2% ($P<0.05$) and 34.3% ($P<0.005$) with an average of 26.3%. This inhibitory effect was exceeded only at the highest heparin dose studied, 800 units/kg, where TAV was decreased by 36.0% ($P<0.005$) and 57.7% ($P<0.001$) and TPCV inhibited by 44.2% ($P<0.005$) and 48.0% ($P<0.01$). Exclusive of the lowest dose of heparin studied, a dose–response relationship obtained relative to the two parameters measured. No significant differences between the initial weight and carcass weight were noted in mice receiving saline and those receiving heparin up to 400 units/kg. The mean weight increase (carcass weight minus initial weight) in the mice treated with 800 units/kg heparin was 0.1 g ± 0.15 while in all other treatment and control groups the mean weight increase ranged from 1.6 to 2.8 g.

The effect of EACA on the TAV and TPCV of the Ehrilich ascites tumor is summarized in Table 2. EACA inhibited the accumulation of the ascites fluid (TAV) in a dose-related manner. At the lowest dose, 125 mg/kg, EACA inhibited the TAV 19.0%. As the dose was increased, less ascites fluid accumulated. The highest dose of EACA studied, 2000 mg/kg, resulted in an inhibition of TAV by 56.3% ($P<0.001$). The 53.2% inhibition at the 1000 mg/kg dose was significant at the 0.001 level. EACA also inhibited the tumor growth at all dose levels. The highest percent of TPCV inhibition was obtained at the 1000 mg (53.5% $P<0.001$) and 2000 mg/kg (48.1%, $P<0.001$) doses. Mean weight increases in mice receiving 1000–2000 mg/kg EACA during the 8-day treatment period was 0.3 ± 0.15 g compared to the mean weight increases of 1.8–2.6 g for the control and other experimental groups.

DISCUSSION

The results reported here demonstrate that, in appropriate doses, both EACA and heparin significantly inhibit Ehrlich ascites tumor growth. Component levels of both the fibrinolysis [5, 21] and the vasopeptide kinin systems [18, 22], present in the ascites tumor fluid, were reported in dynamic change during various phases of tumor growth, suggesting that these systems are active during the tumor growth process. This suggestion receives further support from the results obtained with EACA, a known inhibitor of plasmin and plasminogen activation. In addition, EACA was found to be a weak inhibitor of plasma and urinary kallikrein [23], and a moderate inhibitor of pancreatic kallikrein [23] and rodent plasma and tumor tissue kallikrein [24]. Thus, the tumor chemotherapeutic effect of EACA may relate to its action on vascular-tumor protease systems possibly active during tumorigenesis [4].

In this study, heparin also was shown to decrease the growth of the Ehrlich ascites tumor. A recent review has summarized previously published reports on the tumor-inhibitory effect of heparin [17]. The actions of heparin are complex and its tumor-inhibitory mechanism not clear. Heparin was found to be a mitotic inhibitor of ascites tumor cells *in vivo* [25], an activity not expressed in the absence of a plasma coagulum [26]. Heparin was found to inhibit trypsin [27], thrombin [28] and, at high concentrations, the kinin-forming activity of plasma and tissue kallikrein [29]. Heparin did inhibit the growth of solid rodent tumors without exerting influence on the tumor vasopeptide kinin protease system [16]. The possible antitumor potential of heparin also has been viewed in terms of its anticoagulant action [17]. The reported *in vitro* inhibition of plasma fibrinolytic activity by heparin [30] may be of importance, if indeed there is a link between fibrinolysis and tumor growth, an area recommended for further study by Reich [2]. The biphasic inhibitory effect of heparin noted in this study may relate to findings that heparin enhances fibrinolysis in low concentrations but exerts an inhibitory effect in higher concentrations [31].

Abstract—*A group of sixteen patients with untreated hypernephroma were shown to have significantly reduced PHA induced cytotoxicity and antibody dependent cellular cytotoxicity compared with the same patients* 10–14 days *post nephrectomy, or with normal controls. The T cell and non T (K) cell function improved following nephrectomy and values were reached not significantly different from the normal controls. The influence of tumour burden was also investigated. Six patients had demonstrable distant metastatic disease preoperatively and ten patients were without clinically evident metastases and were apparently "tumour free" following operation. No significant differences were found between these two groups of patients. The known occurrence of "spontaneous" regression in metastatic tumour after palliative nephrectomy raises speculation as to the* in vivo *significance of the increase in cytotoxicity described in this* in vitro *investigation of immune function.*

INTRODUCTION

HYPERNEPHROMA is one malignant neoplasm in which an effective host defence mechanism is clinically manifest. This is illustrated by occasional indolent activity, with slow growth of the primary tumour and the development of metastases after prolonged latent periods [1]. The rare spontaneous regression of these tumours, particularly of pulmonary metastases, is also well documented [2]. The regression of metastases has been particularly evident following ablation of large primary tumours and provides good evidence for host resistance to this neoplasm [3].

Laboratory investigation of leucocyte function using different assay systems has given support for an immune reaction directed towards the renal carcinoma [4–7]. However, little information is available concerning the correlation of these immune responses to the clinical status of the tumor and to the effects of therapy used. One report has described a higher leucocyte reactivity in the blood of patients with early stage as compared with late stage disease [7], but other reports have not confirmed this relationship [4, 5].

The present investigation was undertaken to determine the influence of nephrectomy on lymphoid cell effector function, in localized disease where operation removed all known tumour and in metastatic disease where tumour remained behind after nephrectomy. This investigation would also be interesting in the light of the rare metastatic regressions occurring after nephrectomy for hypernephroma.

The tests chosen were of antibody dependent cellular cytotoxicity (ADCC), phytohaemagglutinin stimulated cytotoxicity (PCC) and direct cellular cytotoxicity (DCC), against a Chang target cell. Different subpopulations of blood lymphocytes are thought to be involved with these effector functions and provide a useful assessment of changes in immune reactivity *in vitro*.

Antibody dependent cellular cytotoxicity is a function of "non-T cells" [8], but the effector cell ("K" cell) is separate from the B cells which are precursors of antibody forming cells [9]. The PHA stimulated cytotoxicity would appear to reside mainly in the T cell subpopulation [10, 11]. The identity of the human effector cell responsible for spontaneous, non-specific cytotoxicity is unclear. It has been reported to bear Fc receptors [12, 13] and is found in the non T cell population [14, 15].

MATERIAL AND METHODS

Patients

The details of sixteen patients with hypernephroma are summarized in Table 1a. No patient had received previous radiotherapy, chemotherapy or hormone therapy. Ten patients were classed "non-metastatic" as having no distant metastases at time of investigation. These patients were, apparently, tumour free following nephrectomy (Table 1a). The "metastatic" group comprised 6 patients with multiple deposits involving lung, liver and bone (Table 1a). Although these patients had a nephrectomy, no further attempt at reduction of tumour volume, e.g. resection of metastases, was made at this time. Blood transfusions were given post operatively as shown (Table 1a). The mean age of the patients was 55.3 yr (range 33–76). The normal controls were 14 individuals employed in the hospital service and seven relatives of patients (Table 1b). The mean age of the controls was 46.9 yr (range 32–68).

Lymphocyte preparations

The patient blood samples were obtained on the day of operation prior to premedication and at 11–14 days after operation. The blood samples were tested on the same day as collection. Lymphocyte suspensions for cytotoxic assays were prepared from defibrinated peripheral blood after incubation with finely divided iron and sedimentation with a magnet at 37°C in 1% methylcellulose. The lymphocyte-rich supernatant was washed three times in minimal essential medium (MEM) and the concentration adjusted to 3×10^5 cells/ml in MEM supplemented with 10% heat inactivated foetal calf serum, 2mM glutamine, 100 I.U./ml streptomycin, 200 I.U./ml penicillin and $NaHCO_3$ buffer. The lymphoid cells comprised 97% or more of the leucocytes present in these suspensions.

Cytotoxic assay

Chang cells labelled with ^{51}Cr sodium chromate (100–350 mCi/mM, Amersham, Bucks.), were washed and diluted to give a final concentration of 10^4 cells/ml in supplemented MEM. The ^{51}Cr release assay of non-specific cytotoxicity against antibody sensitized Chang target cells [16, 17] and the phytohaemag-

glutinin stimulated lymphocytotoxicity against the labelled Chang cell [18, 19] were performed as follows. The cultures were set up in triplicate, containing 1 ml of lymphocytes and 1 ml of Chang cells. The test was divided into three sections. Chang cells were reacted with lymphocytes alone—DCC; with lymphocytes and rabbit anti-Chang serum diluted $1:10^5$—ADCC; and lymphocytes with phytohaemagglutinin, PHA (Wellcome Reagents Ltd.); 3 μg/ml—PCC. Control tubes were set up with each experiment containing Chang cells alone, with antibody or with PHA, but without lymphocytes. These tubes gave the spontaneous ^{51}Cr release. Maximal ^{51}Cr release was obtained by lysis with distilled water. After standing at 37°C in a 5% $C0_2$ incubator for 20 hr the tubes were centrifuged and 0.5 ml supernatant transferred to empty tubes and counted on a gamma counter. The counts/min were printed onto a punch tape which was processed by a digital computer.

The ^{51}Cr percentage release was computed for each tube from

$$\frac{\text{supernatant counts/min} \times 4}{\text{total counts/min (pellet and supernatant)}} \times 100.$$

The maximal release varied between 82–90% and the spontaneous release between 20–34%.

Results were expressed as the mean corrected percentage ^{51}Cr release (M.C.R.) of the triplicates, and obtained from

$$\frac{\text{experimental } ^{51}Cr \text{ percentage release} - \text{spontaneous } ^{51}Cr \text{ percentage release}}{\text{maximal } ^{51}Cr \text{ percentage release} - \text{spontaneous } ^{51}Cr \text{ percentage release}} \times 100.$$

The S.D. between triplicates was ± 3.8.

RESULTS

The test values before nephrectomy of the "non-metastatic" and "metastatic" patient groups were compared. No statistically significant difference was found, although the DCC, median 5.5, was lower whilst the PCC, median 36.5, was higher in the "metastatic group" compared with the "non-metastatic" values of 11.0 and 25.3 respectively (Table 2a).

The changes following nephrectomy were also compared for the two patient groups (Table 2a). Again no significant difference was found between these changes in "non-metastatic" patients and the changes in "metastatic" patients. However, the change in ADCC values was smaller for the "metastatic" patients (median 3.6) than the change for "non-metastatic" patients (median 13.3).

Since the prenephrectomy values for the "metastatic" and "non-metastatic" groups showed no significant difference and there was no significant difference in the changes with nephrectomy between the two patient groups, it was concluded that there was no statistically significant difference between the post nephrectomy "metastatic" and "non-metastatic" patient groups. The values of the "metastatic" and "non-metastatic" groups could, therefore, be combined for the remainder of the analysis.

The prenephrectomy results for all patients were accordingly compared with the post nephrectomy results (Table 2b). The prenephrectomy, ADCC values (median 27.0) and PCC values (median 29.9) were significantly lower ($P<0.02$, $P<0.01$ respectively) than the post nephrectomy values (median ADCC 46.1, median PCC 43.0). The DCC test values were also lower (median 7.4) prenephrectomy, compared with the post nephrectomy values (median 10.3), but this difference was not significant ($P>0.19$). The prenephrectomy values for the ADCC and PCC tests were also significantly less ($P<0.031$ and $P<0.05$ respectively) than the corresponding values for normal controls (Table 2b). The prenephrectomy DCC test value when compared with normals showed a similar trend, but again the difference was not significant ($P>0.1$). No significant difference was found between the post nephrectomy test values and the normal control values.

DISCUSSION

Non-specific cytotoxicity mediated by T cells, (PCC) [10, 11] and non T, K cells, (ADCC) [8, 9] was found to be significantly depressed in patients before nephrectomy, compared with the same patients after nephrectomy or with normal controls. A similar depression was also seen in the DCC test, another non T cell function [14, 15], but this was not statistically significant. Other tests of T cell function, e.g. PHA lymphocyte blastogenesis have shown depressed values in cancer patients [20], but non T cell function has received less attention. The depression in ADCC values of unresected hypernephroma patients is supported by another study using lysis of antibody coated normal lymphocytes by lymphocytes from patients with a variety of tumour types [21].

After nephrectomy, the depression in T cell and non T cell function was abrogated and the

post operative tests were not significantly different from those of the normal controls. The increase in post operative cytotoxicity could not be explained by blood transfusion sensitization as only 3 patients were transfused during the test period and in these 3 the rise in cytotoxicity (particularly ADCC) was modest. Few reports are available demonstrating an increase in nonspecific cytotoxicity following operation, but such an increase has been described in bronchogenic carcinoma [22].

An allied situation concerns the relationship of tumour burden or tumour stage and various *in vitro* assays of immune function. This remains an area of considerable controversy. A more profound decrease in nonspecific lymphocytotoxicity has been noted for late stage compared with early stage disease in bronchogenic carcinoma [22], various cancers [21] and in hypernephroma [7], but only the latter report demonstrated statistically significant differences. Other tests such as PHA blastogenesis using "sub-optimal" PHA concentrations have also demonstrated a depressed responsiveness which increased in severity with the extent of malignant melanoma [23] and several authors have described a diminution in "tumour specific" cellular immunity with increasing dissemination of this tumour [24, 25]. Similar observations have also been made with bladder carcinoma: low stage tumour patients had cytotoxic lymphocytes in almost all cases, but the frequency of positive cases was significantly less when tumour growth was extensive [26]. In contrast to these reports the present study of hypernephroma did not demonstrate a significant difference between the preoperative tests of the "metastatic" and "non-metastatic" patient groups, and no significant difference in the changes of cytotoxicity from pre to post nephrectomy for the two groups. This lack of correlation of *in vitro* cytotoxicity with tumour stage agrees with other studies in hypernephroma [4, 5] and investigations of other tumours [27]. Although in the latter study a reduction in cellular immunity was recorded in tumour bearing patients if lower lymphocyte concentrations were used.

The increase in cytotoxicity following operation noted in this present study might be a reflection of the removal of tumour derived material with inhibiting properties on cytotoxicity, thereby allowing normal levels of nonspecific cytotoxicity to be expressed. An alternative explanation would be that the lymphocytes were "activated" by the operation by a mechanism apart from actual removal of tumour or the tumour itself might remove "activated" leucocytes and thus prevent their participation in cytotoxic reactions. Nevertheless, the increase in T cell and non T cell cytotoxicity seen in this study indicates that the immunodepression in cancer patients need not be a permanent feature and that even a palliative operation is capable of increasing cytotoxic immune function in metastatic patients. Any relationship between this non-specific increase in cytotoxicity and the "spontaneous" regressions described in hypernephroma remains conjectural.

Abstract—*The concentration of plasma testosterone in peripheral venous plasma was measured before operation in* 109 *female patients undergoing surgery for a breast lump. The results showed that the levels were not significantly different in those patients with early breast cancer compared with those with benign breast disease. In addition, the values were similar before and after the menopause.*

INTRODUCTION

MUCH work has been reported on the androgen status of women with breast cancer. In particular the levels of androsterone and aetiocholanolone in urine have been found to be subnormal in those women who subsequently develop breast cancer [1]. The abnormality of urinary androgen excretion was present at all ages and was also found in women with advanced breast cancer; it was claimed that those who excreted low amounts of androsterone and aetiocholanolone respond less well to endocrine ablation [2], and that excretion of small amounts of androgen metabolites is associated with a poor prognosis [3]. However, Japanese women excrete less androgen metabolites, but have a lower incidence of breast cancer compared with British women [4].

The sebaceous glands are known to be highly sensitive to androgenic stimulation, and women with breast cancer have been shown to produce increased amounts of sebum [5–7].

The results of the investigations of urinary metabolites do not necessarily conflict with those of sebum production. The urinary metabolites, aetiocholanolone and androsterone, mainly originate from precursors secreted by the adrenalcortices and it is not known which androgens are involved in the stimulation of sebaceous glands. In view of these findings it is perhaps surprising that circulating levels of plasma testosterone have been measured previously in only a small number of patients.

Accepted 8 December 1976.

MATERIAL AND METHODS

Patients

One hundred and nine patients aged between 25 and 70 yr who had been admitted for breast surgery were studied. All gave their informed consent. Blood sampling was performed between 9.00 and 10.00 a.m., as there is evidence of a diurnal rhythm in the level of circulating testosterone [8]. However, the time of the menstrual cycle was not taken into consideration in women who still had menses because the fluctuations are small and the pattern is variable [8]. None of the women were ovariectomized.

The patients were subsequently divided into two groups, those with benign and malignant disease, according to the histology of the breast tissue removed. Only patients with cancer stages I and II of the Manchester classification [9] were included in the group with malignant tumours. The patients were then categorised as being either pre- or postmenopausal, depending on whether 6 months had elapsed since the last menstrual period. The menopausal status of every subject was checked 2 yr later, and if any doubt existed about their original classification these patients were excluded from the study. We regarded the postmenopausal group as being homogeneous as data on plasma testosterone concentrations after the menopause is relatively scarce. It has been shown, however, that there is no significant fall in plasma testosterone concentrations at the menopause [10], and that the ovary continues to secrete significant amounts of testosterone [11], in addition to continuing adrenal production of the hormone [12].

All patients on drugs likely to affect the

concentrations of testosterone in plasma were excluded from analysis. In both pre- and postmenopausal groups the plasma testosterone concentrations of patients with benign breast disease and those with cancer were compared. The levels of plasma testosterone in the premenopausal group were then compared with those in the postmenopausal group.

Plasma testosterone was measured in a liquid phase radioimmunoassay system comprising tritiated testosterone as labelled antigen, and an antiserum raised against testosterone-3-carboxymethyloxime-bovine serum albumen. A mixture of ammonium and calcium sulphates was used to separate the antibody-bound fraction [13]. Under these conditions the cross reaction with 5α-dihydrostestosterone was less than 5%, and the inter-assay variation was within 12%, according to the method of Snedecor [14].

RESULTS

The frequency with which the concentration of testosterone appeared in each group was studied and it was concluded that in general the distribution was best described by the arithmetric mean and range. The values are shown in Table 1. An analysis with Students' *t*-test showed that there was no significant difference between any of the groups.

DISCUSSION

There were no significant differences in plasma testosterone concentrations between patients with benign breast disease and patients with early breast cancer. Our results agree with those of others using an alternative method [15]. Furthermore, Horn and Gordan also found no significant difference in plasma testosterone levels when studying a group with advanced breast cancer [16]. There has been a recent report of significantly raised plasma testosterone levels on sequential sampling in six patients with breast cancer [17]. However, only two of them had early disease and in view of the small numbers involved these results must be viewed with caution.

There was no significant difference between premenopausal and postmenopausal plasma testosterone concentrations. This finding supports the results of others [10, 11], who suggest that the postmenopausal ovary continues to secrete significant amounts of androgens.

Our results do not conflict with the reported findings of reduced levels of androsterone and aetiocholanolone in urine from women with breast cancer, as the metabolites are derived from many precursors in the blood other than testosterone [18]. From our results it is difficult to comment further on the findings of increased sebum production in breast cancer patients, as the role which circulating androgens play in stimulation of the sebaceous glands is not understood. Matters are further complicated by extensive interconversion of circulating androgens in peripheral and growth responsive tissues [19].

Much more must be learned of the androgen status of women with breast cancer, and the physiological role of the different androgens, before reported discrepancies can be explained and their endocrine role in breast cancer understood.

Acknowledgements—We would like to thank an anonymous American donor for financial support.

Catechol-O-Methyltransferase in Human Breast Cancers*

M. ASSICOT, G. CONTESSO and C. BOHUON

Laboratoire de Biologie Clinique et Expérimentale, Institut Gustave-Roussy, 94800 Villejuif, France

Abstract — *Catechol-O-methyltransferase (EC 2-1-1-6) was identified in human breast tissue. The methyltransferase activity of 78 primary carcinomas and 18 benign tumors was determined. Large variations were observed among the examined normal and pathological breast samples. The relationships between enzyme levels and various pathological aspects of breast tumors were investigated. A statistically significant increase in the enzyme activity was observed in the majority of primary carcinoma samples of higher malignancy, according to Bloom grading. No correlation was found between the catechol-O-methyltransferase activity and the levels of estrogen receptors. Furthermore, enzyme levels were not related to tumoral size, histological type and metastatic involvement. The physiological role of breast catechol-O-methyltransferase, specially in the metabolism of estrogens, is discussed.*

INTRODUCTION

IT IS well established that 2-hydroxylation is an important pathway of estrogen metabolism in both animals [1, 2] and man [3–6]. While 2-hydroxylated estrogens, or catecholestrogens formed fail to exhibit significant uterotrophic activity, it has been recently demonstrated *in vitro* that these compounds have a considerable affinity for the cytosol estrogen receptors from rat pituitary, anterior hypothalamus [7] and rat uterus [8]. These observations suggest that a possible physiological role of these estradiol metabolites might be to function as antiestrogens [8]. In our laboratory a similar interaction of 2-hydroxyestradiol and 2-hydroxyestrone with cytosol estrogen receptors from human breast cancers has been observed (unpublished results). The 2 or 3-methylated derivatives of catecholestrogens do not bind significantly to receptors [8]. 2-methoxy-estrone has been identified as a by product after incubation of either estrone or estradiol with breast tumor supernatant [9–11]. These data lead to conclude that the catechol-O-methyltransferase, enzyme responsible for the O-methylation of catecholestrogens [12], if present in human breast tumor tissues, might be involved in estrogen action on these tissues. We report here unequivocal evidence for the presence of catechol-O-methyltransferase in breast tissue and the relationship between enzyme levels and various pathological aspects of the breast tumors.

Accepted 27 January 1977.

*Part of this investigation was presented at the Xth meeting on the mammary cancer in experimental animals and man. Kobe, Japan, 29–31 March, 1976.

MATERIAL AND METHODS

Reagents

6,7-^{3}H 17 β-Estradiol (specific activity 51 Ci/mmole) and S-adenosyl-L-(methyl-^{14}C)-methionine (specific activity 50 mCi/mmole) were obtained from New England Nuclear Corporation. 6,7-^{3}H-R 5020 (17–21 dimethyl-19 nor pregne 4–9 diene 3–20 dione, specific activity 51 Ci/mmole) was a gift from Roussel-Uclaf. Non radioactive estrogens were purchased from Steraloids, Pauling, NY. The purity of estrogens was checked by thin-layer chromatography just before use.

Tissue preparation

Most tumors examined were obtained from patients subjected to mastectomy. During the operation, samples from the primary tumor and sometimes from axillary lymph metastases and from non neoplastic breast tissue were taken for histological classification and chemical analysis. Within 15 min of excision, all tissues were dissected free of fat, weighed, minced, homogeneized with a Potter and Elvehjem glass-on-teflon homogenizer in 5 vol of ice cold 0.01 M Tris buffer (pH 7.4) containing 12 mM dithiothreitol and 10% of glycerol. The homogenate was immediately centrifuged at 105,000 × ***g*** for 60 min. Aliquots of the supernatant were analysed for progestin and estrogen receptor pro-

teins, catechol-O-methyltransferase activity and protein concentration.

Catechol-O-methyltransferase assay

Catechol-O-methyltransferase activity was determined by measuring the amount of metanephrine from epinephrine and S-adenosyl-(methyl-^{14}C) methionine. Portions of enzyme preparations (100–400 μg protein) were incubated at 37°C for 20 min with 10 μmole of sodium phosphate buffer (pH 7.8), 1 μmole of $MgCl_2$, 0.15 μ mole of epinephrine and 3.6 nmole of S-adenosyl-(methyl-^{14}C) methionine in a final volume of 0.15 ml. The reaction was stopped by the addition of 0.5 ml of 0.13 M borate buffer (pH 10). A blank containing enzyme preparation but no catechol substrate was treated simultaneously for each tissue sample. The formed metanephrine was extracted into 5 ml of ethylacetate. After shaking for 5 min the tubes were centrifuged at 600 ***g*** for 5 min and 2 ml of the organic layer was added to 10 ml of fluid scintillation and assayed for radioactivity.

When 2-hydroxyestradiol was used as the substrate, appropriate concentrations of 2-hydroxyestradiol in 5 μl of ethanol was added to the incubation mixture.

Assay for estrogen and progestin receptors

The presence of oestrogen and progestin receptors were assayed by radioexchange using the method described previously [13].

Assay for protein

Protein concentration was determined according to the method of Lowry *et al.* [14] using crystalline bovine serum albumine as standard.

RESULTS

Catechol-O-methyltransferase activity in breast tissue

Evidence for the identity of the breast tissue O-methyltransferase was obtained by incubating the enzymatic preparations in various conditions (Table 1). The enzymatic activity showed an absolute requirement of Mg^{2+} and was inhibited by tropolone, a potent inhibitor of the catechol-O-methyltransferase [15]. When monophenols or related compounds were used as substrates, no O-methylated products were detected.

To establish the identity of the enzymatically formed product, the radioactive metabolite was extracted into ethylacetate at pH 10 and was evaporated until dryness under nitrogen. The residue dissolved in ethanol was subjected to chromatography:

(1) With epinephrine as substrate, the radioactive product was found to chromatography with metanephrine in paper chromatographic system (butanol-acetic acid–water (4:1:1), *Rf* 0.52).

(2) With 2-hydroxyestradiol the formed methylated product behaved identically with 2-methoxyestradiol on thin-layer chromatography (silica gel-60, chloroform–ethylacetate (3:2), *Rf* 0.63).

Additional evidence for the identity of the breast O-methyltransferase was obtained by using specific antibodies to rat liver purified COMT [16]. The breast enzymatic activity was almost completely inhibited by preincubation with the antiserum (Fig. 1).

Table 1. *Catechol-O-methyltransferase in human breast tissue*

Conditions	Total (cpm)
Blank	620*
Test	13,180
Mg^{2+} omitted	1200
Tropolone, 10^{-4}, added	4190
Substrate:	
Octopamine	0
Tyramine	0
Serotonine	0
O-phosphoethanolanine	0
Histamine	0

50 μl of enzyme preparation were incubated for 20 min with epinephrine or other substrates as indicated. The ^{14}C O-methylated product was extracted in ethylacetate and the radioactivity measured.

*These counts have been subtracted from all of the other results in this table.

These observations indicated that the O-methylating enzyme in human breast tumor is catechol-O-methyltransferase. In order to determine whether the breast tissue catechol-O-methyltransferase could be distinguished from the liver enzyme, some biochemical properties of both enzymes were compared. Both enzyme preparations had similar pH optima (7.8–8.3) and an optimal concentration of Mg^{2+} (1 mM). The apparent K_m values determined by double reciprocal Lineweaver–Burk plots were similar for both enzymes: 2.2×10^{-4} M and 1×10^{-5} M respectively for the substrates, epinephrine and 2-hydroxyestradiol (Fig. 2). The low K_m value found for 2-hydroxyestradiol is of the same magnitude as values reported by Ball *et al.* for human liver catechol-O-methyltransferase ($K_m = 1.4 \times 10^{-5}$ M) [17].

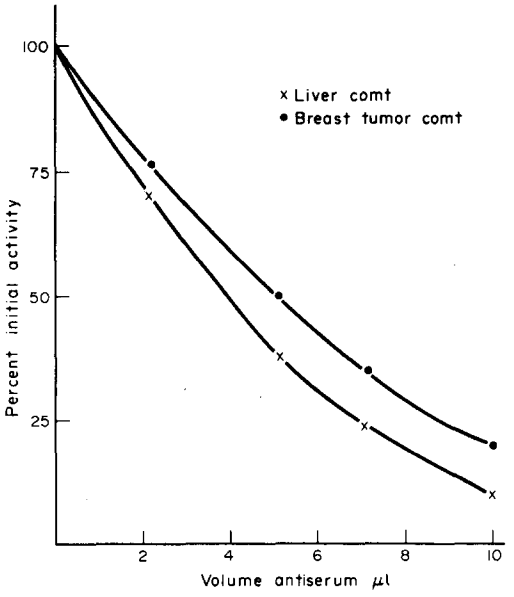

Fig. 1. Inhibition of catechol-O-methyltransferase from human liver and breast tumor by rabbit antiserum to rat liver enzyme. Catechol-O-methyltransferase in primary and metastatic breast cancer

The catechol-O-methyltransferase activity was found to be quite variable in human breast tissue. The standard error of the mean was in the order of 20–25% of the mean in "normal" tissues as well as in diseased tissues of 32 cases where normal tissue and malignant tumor were obtained from the same patient: 27 (84%) showed a 2–30 fold increase for catechol-O-methyltransferase activity in carcinoma samples when compared to "normal" tissues. In 5 cases, levels were found similar.

The mean values for enzyme activity in normal breast tissue and benign and malignant tumors are given in Table 2. The histologically "benign" tumors consisted of 10 fibroadenomas and 8 cystosarcoma phyllodes. No significant difference was observed between normal breast tissue and benign tumors. For carcinomas, the catechol-O-methyltransferase activity was compared to the histologic grade of the tumor using the grade I–III system of Bloom and Richardson [18]. Activity in grade I tumors was not significantly different from that obtained in normal tissue (Table 2). On the contrary, a statistically significant increase of catechol-O-methyltransferase was found to exist in grade II and III lesions.

Table 2. Catechol-O-methyltransferase activity in normal and abnormal human breast tissues

Tissue	No. samples	COMT activity (mean ± S.E.M.)
Normal breast	32	344 ± 83
Benign tumor	18	570 ± 155*
Carcinoma (Grade I)	13	555 ± 152*
Carcinoma (Grade II)	32	1538 ± 328†
Carcinoma (Grade III)	33	1716 ± 450‡

COMT activity is expressed as pmole of radioactive metanephrine formed per 20 min per mg of cytosol protein.
*Not significantly different ($P < 0.02$—Student's *t*-test) compared with normal breast.
†Significantly different ($P < 10^{-9}$—ε test) compared with normal breast.
‡Significantly different ($P < 10^{-8}$—ε test) compared with normal breast.

Sixty-six malignant tumors were analyzed for a possible correlation between catechol-O-methyltransferase activity and estrogen and progestin-binding capacity. The results are summarized in Fig. 3. There was no relationship between the enzyme activity and the presence or absence of receptors (< 100 fmole/g tissue). In addition, no difference in levels of catechol-O-methyltransferase was observed in relation to size of primary tumor, hystological type of carcinoma (colloid, medullary, lobular, tubular), and number of metastatic lymph nodes. Finally, there was no influence of menopausal status of patients on the catechol-O-methyltransferase activity in breast malignant tissue.

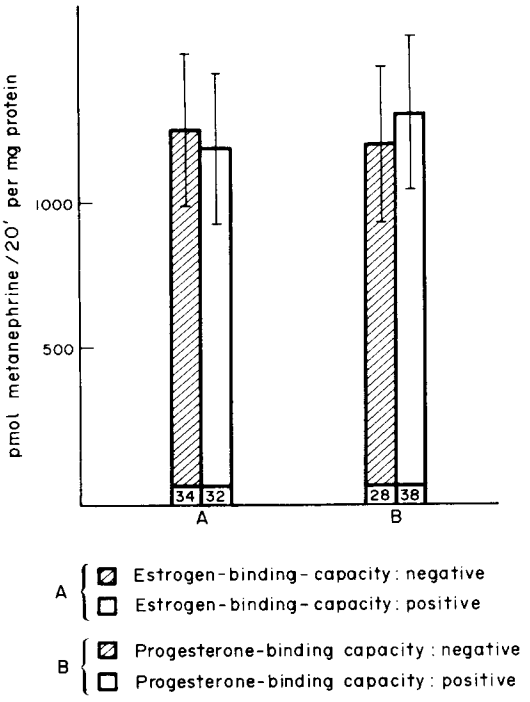

Fig. 3. Relationship between estrogen and progesterone binding capacity of breast tumors and catechol-O-methyltransferase activity. Values are presented as mean ± S.E.M. Number of samples examined is shown at the base of each bar.

The results of the lymph nodes examinations are presented in Table 3. In all cases examined, catechol-O-methyltransferase activity was higher in lymph nodes containing metastases compared to "normal" lymph nodes. Table 4 lists data obtained in normal and invaded lymph nodes from the same patient. There was a relationship between the enzymatic activity and the degree of metastatic involvement. A similar increase was observed in breast carcinoma compared to "normal" tissue and benign tumor (cystosarcoma phyllodes) from the opposite breast in the same woman (Table 4).

DISCUSSION

The experiments described in this report show the presence of catechol-O-methyltransferase in human breast tissue. In contrast, other methyltransferase enzymes (phenol-O-methyltransferase enzymes (phenol-O-methyltransferase, non specific N-methyltransferases, histamine N-methyltransferase) could not be detected in this tissue. The cathechol-O-methyltransferase activity was found to be very variable among the examined breast samples. Similar variations in levels of different enzyme activities in human breast tissue have been reported [19]. Moreover, an important aspect of studies on the estrogen binding capacity of breast carcinomas relates to considerable tumor to tumor variations in extrogen receptor levels. In spite of this great variability in the catechol-O-methyltransferase activity and although the values extended over a broad range, a significant increase in the activity of this enzyme was observed in the majority of primary carcinoma samples of higher malignancy (grade II and III). The mean value was approximately 5 fold that found in normal breast tissue. In contrast, statistical analysis failed to disclose a significant difference in grade I tumors and benign lesions when compared to normal tissues. We must emphasize the fact that the enzyme activity was expressed per mg cytosol protein. Although there was essentially no difference in protein content among the tissues examined, it is obvious that the expression of enzyme activity per mg DNA would normalize any difference in enzyme activity that would be due to difference in cell number. The DNA content have been reported

to be significantly increased in fibroadenoma and infiltrating ductal carcinoma, when compared to normal breast [19]. However, it appears doubtful that as high as 30 fold increases for catechol-O-methyltransferase could be due only to cellularity increase. So, the cellular pleomorphism of many carcinomas may be responsible for large variations in the catechol-O-methyltransferase content of breast tissue. Cytological studies with fluorescent labeled antibodies should provide an answer to this problem.

The question arises, what can be the physiological significance of the presence of catechol-O-methyltransferase in breast tissue? 2-Methoxyestrone has been identified on column chromatography and on thin-layer chromatography after incubation of either estrone or estradiol with human breast tumor supernatants [11]. This finding strongly suggests that breast tissue catechol-O-methyltransferase is involved in estrogen metabolism. As postulated by Martucci and Fishman [8], its possible physiological role in breast tumor might be to abolish the catechol-estrogen binding ability to tumor cytosol estrogen-receptors. However, data reported here demonstrate the lack of correlation between the levels of catechol-O-methyltransferase activity and the estrogen binding ability of breast tumors. Furthermore, unlike earlier observations [11], attempts for carrying out a complete identification of methylation products after incubation of human breast tumor with estrone or estradiol have been unsuccessful. Therefore, further studies are required to bring a direct evidence to the presence of a 2-hydroxylase activity in breast tissues. By now, preliminary results suggests that catecholestrogens formation, if present in breast tumors, is in no way related to the apparent capacity of O-methylation in these tissues.

Comparison of Soluble Oestrogen and Progestin Receptor Content of Primary Breast Tumours from Japan and Britain

R. J. B. KING,* J. L. HAYWARD,† S. KUMAOKA‡ and H. YAMAMOTO‡

**Hormone Biochemistry Department, Imperial Cancer Research Fund, Lincoln's Inn Fields, London, WC2A 3PX, Great Britain, †Imperial Cancer Research Fund Breast Cancer Unit, Guy's Hospital, St. Thomas Street, London, SE1 9RT, Great Britain and ‡National Cancer Center Hospital, Tsukiji 5-Chome, Chuo-ku, Tokyo, Japan*

Abstract — *Soluble oestrogen (R_E) and progesterone (R_P) receptors have been measured in primary breast tumours from English and Japanese women. The only difference between the two groups of patients was that the Japanese had a higher proportion (31%) of R_E negative tumours than the English group (19%).*

INTRODUCTION

THE PROGNOSTIC significance of oestrogen receptor (R_E) measurements in breast tumours is of increasing interest in relation to hormone therapy [1, 2]. All of the reports published thus far have been concerned with R_E measurements in tumours from countries with a high incidence of breast cancer. In view of the low incidence of breast cancer in Japanese women it was of interest to see if the R_E content of their tumours differed from that of tumours from British women. We have carried out such a comparison on tumours from the National Cancer Center Hospital in Tokyo and from the Breast Unit at Guy's Hospital, London. Progesterone receptors (R_p) were also assayed.

MATERIAL AND METHODS

Tumours from Tokyo were stored in liquid nitrogen for a maximum of 8 weeks and dispatched to London by air in an insulated container with solid carbon dioxide. They were then stored in liquid nitrogen for a maximum of 2 weeks prior to assay. Four separate batches of tumours were processed in this way. The London tumours were transported in solid carbon dioxide from the operating theatre to the laboratory and were stored in liquid nitrogen for a maximum of 2 weeks prior to assay.

A known weight of tumour slices was pulverized in a microdismembrator (Braun Instruments, Melsungen) using teflon containers pre-cooled in liquid nitrogen. The tumour powder was stirred in 8 vol of 5 mM sodium phosphate, 10% v/v glycerol, 1 mM thioglycerol pH 7.4 [3] for 10 min at 4°C and centrifuged for 10 min at 1500 ***g***. The supernatant was separated from the pellet and any fat at the surface and used for the R_E and R_p assays. Aliquots were taken for protein estimation [4].

R_E assay

All tubes contained 200 µl supernatant plus 20 µl 10^{-8} M 2, 4, 6, 7^3H oestradiol (82 Ci/m mole, Radiochemical Centre, Amersham). Duplicate tubes contained 20 µl 10^{-5} M diethylstilboestrol whilst control tubes contained the same volume of buffer. After overnight equilibrium at 4°C, 240 µl of dextran/charcoal suspension (D/C 0.25% charcoal, 0.0025% Dextran T20 in 10 m M Tris: 1 mM EDTA, ph 7.4) was added and, after mixing, was allowed to stand at 4°C for 90 min [5]. After centrifugation at 10^3 ***g*** for 10 min, 300 µl of the clear supernatant were added to 5 ml phosphor (5 g diphenyloxazole/l toluene). The mixture was shaken, stood at room temperature for at least 1 hr, cooled to 4°C and counted in a Packard Tricarb Scintillation counter. Quenching was corrected for by external standardization. Specific binding was measured as the difference between the control and diethylstilboestrol-treated samples.

R_p assay

All tubes contained 200 µl supernatant plus 20 µl 10^{-7} M 1, 2, 6, 7^3H progesterone (84 Ci/mmole, Radiochemical Centre, Amersham) plus 20 µl 10^{-5} M cortisol. Triplicate

Accepted 6 January 1977.

tubes contained 20 μl 10^{-5}M norethisterone whilst control tubes contained the same volume of buffer. The samples were processed as described for R_E except that D/C treatment was limited to 10 min. Specific binding was calculated as the difference between the control and norethisterone-treated samples.

With both R_E and R_P assays, the lower limit of assay sensitivity was 3 fmole/mg protein: tumours with less than this value were classified as negative. All results were obtained with primary tumours.

RESULTS

A comparison of R_E levels in Japanese and British patients is shown in Fig. 1(a). The

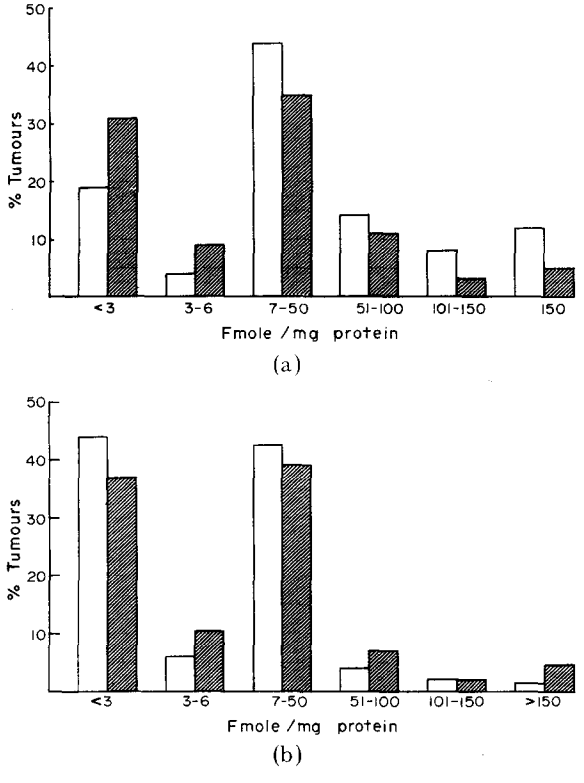

Fig. 1. Percentage of tumours containing different levels of R_E (Fig. 1a) and R_P (Fig. 1b). Unshaded columns: British tumours, total number R_E 136; R_P 87. Shaded columns: Japanese tumours, total number R_E 65, R_P 47.

Japanese group contain a higher proportion of negative tumours than the British group (χ^2 test, $P<0.001$). In other respects, the two populations are similar. Four separate batches of Japanese tumours were analysed and the proportion of R_E negative tumours was similar in each batch (range 29–35%). Five separate batches of British tumours gave a range of 12–32% negative tumours. The slightly higher proportion of negative Japanese tumours could be due to different storage conditions. R_E content of tumour tissue is stable for months in liquid nitrogen and for several weeks in solid carbon dioxide. Hence, storage alone is unlikely to be a cause but it is impossible to eliminate unknown accidents occurring during transit. However, such a hypothetical accident would have had to happen to all four batches of Japanese tumours; also, one batch of tumours had the same proportion of R_p negative tumours as the British tumours. If storage conditions do not provide the explanation it would be tempting to speculate that the Japanese might have fewer unresponsive but R_E positive tumours; clinical correlations would be required to answer that possibility.

Only two batches of Japanese tumours were analysed for R_p content but the profiles of R_p content were similar in Japanese and British tumours (Fig. 1b).

The distribution of R_E and R_p levels in tumours from patients of different ages is shown in Figs. 2(a) and 2(b) respectively. With one exception, no significant differences are evident between the Japanese and British tumours. The exception is in the R_E levels in the 60–69 yr-old group in which the British tumours exhibit a higher R_E content than the Japanese (Mann–Whitney U test, $P<0.005$). No explanation can be offered for this result. The small number of tumours from Japanese patients in the higher age range conforms with the known incidence pattern in Japan.

The number of combined R_p and R_E measurements made on Japanese tumours is small but comparison of tumours containing the various combinations of R_p and R_E (Table 1) indicates that, with the possible exception of the small group of R_E-, R_p+ tumours, no difference exists between the tumours from the two countries. With the possible exception of the small number of R_E-, R_p+ tumours, the percentage of British tumours in the groups shown in Table 1 is similar to that reported for

Table 1. Combined oestrogen (R_E) and progestin (R_p) assays on breast tumours

	(%) Tumours	
	British	Japanese
R_E+, R_p+	40	37
R_E+, R_p-	25	24
R_E-, R_p-	24	20
R_E-, R_p+	10	20

These data are based on 87 British and 46 Japanese tumours. Tumours containing < 3 fmole/mg protein have been classified as −; all others are +.

●, *British patients;* ○, *Japanese patients.*
The dashed line is the mean value for the positive (> 3 fmole/mg *protein) tumours within any one age group. There were* 13 R_p *negative Japanese tumours in the* 40–49 yr-*old group. These are represented as an open rectangle.*

American tumours by McGuire [6]. Of the R_E+, R_p+ tumours, no difference in R_p:R_E ratios was detected between the Japanese and British tumours.

DISCUSSION

The only major difference in R_E and R_p content of primary Japanese and British breast tumours was that the former had a slightly higher proportion of R_E negative tumours than the latter group. This might be due to different storage conditions of the two groups of tumours but it could also have clinical significance.

It is not known whether the response rates to the endocrine treatment of advanced breast cancer differs in Japanese and British patients although, as far as adrenalectomy and oophorectomy are concerned, the results look very similar between Japan and the West [7]. A prospective study is being undertaken to compare the response of British and Japanese women with advanced breast cancer to castration, androgen or oestrogen therapy.

Analysis of Dehydroepiandrosterone and Androstenediol in Human Breast Tissue Using High Resolution Gas Chromatography–Mass Spectrometry

P. V. MAYNARD, A. W. PIKE, A. WESTON and K. GRIFFITHS

Tenovus Institute for Cancer Research, Welsh National School of Medicine, Heath Park, Cardiff, CF4 4XX, Wales, U.K.

Abstract—*Dehydroepiandrosterone (DHA) and 5-androstenediol have been measured in human breast tissue by a method consisting of extraction and purification with final analysis by gas chromatography–mass spectrometry. The method has been shown to be specific and reproducible, measuring only free DHA and not its sulphate. Preliminary results indicate that levels of DHA are in the range* 15–200 ng/g *tumour whereas in fibroadenomata the amounts are much higher* (200–1000 ng/g). *Androstenediol is present in tumours and benign tissues in similar amounts* (10–200 ng/g).

INTRODUCTION

THE RELATIONSHIP of C_{19}-steroids to the responsiveness of breast tumours to endocrine therapy has been the subject of many studies and a number of groups have reported that the estimation of 11-deoxy-17-oxosteroids in urine samples from their patients with breast cancer has been of value in discriminating between those who will and those who will not benefit from adrenalectomy or hypophysectomy [1–3]. Although similar investigations from our laboratories [4] supported the view that steroid excretion in many patients with breast cancer differed from the normal population, the results did not agree completely with those previous reports, abnormalities being found only in patients with advanced cancer of the breast.

Further studies from these laboratories [5, 6] and from others [7] were directed to the paraendocrine behaviour of breast tumour tissue and its capacity to metabolise plasma C_{19}-steroids, particularly dehydroepiandrosterone sulphate (DHA sulphate) and DHA, to compounds such as testosterone, androst-5-en-3β,17β-diol (androstenediol), 17β-hydroxy-5α-androstan-3-one and oestrone. Obviously, the C_{19}-steroid concentration in the breast tumour may well play a role in regulating the oestrogenic stimulation of this tissue and Poortman, Prenen, Schwarz and Thijssen [8] have reported that androstenediol will displace oestradiol-17β from the cytoplasmic receptor in breast tumours. Concurrent studies from this Institute indicate that a 50-fold excess of androstenediol will result in approximately 50% displacement of oestradiol-17β [Powell-Jones, submitted for publication].

As part of this investigation into the role of C_{19}-steroids in breast cancer, the present communication deals with the assay of DHA and androstenediol in breast tissue. The procedure is based on a simple extraction and purification with quantitation by gas chromatography–mass spectrometry using high resolution selected ion detection and internal standards to monitor losses during extraction.

Accepted 28 January 1977.

MATERIAL AND METHODS

Chemicals

DHA and androstenediol were obtained from Sigma Chemical Co., London; 3α-hydroxy-5-androsten-17-one and 5α-androstanediol (5α-androstane-3α,17α-diol) from Steraloids Inc., U.S.A. Bis (N, O) trimethylsilyl acetamide (BSA) was purchased from Jones Chromatography, Llanbradach, Mid-Glam., U.K. and polyfluorokerosene from Koch-Light Ltd., England. All solvents were of analar grade and were distilled before use.

Tissues

Breast tissue, received from a number of centres, was homogenised by powdering in a Thermovac automatic frozen tissue pulveriser (Telcolab Corpn., N.Y.) and then suspended as a 15% (w/v) homogenate in 10 mM Tris-HCl buffer pH 7.4 containing EDTA (1 mM) and sodium azide (3 mM), using a glass–glass homogeniser. Portions of the homogenate were stored at −20°C until extracted.

Extraction of steroids

Internal standards, 3α-hydroxy-5-androsten-17-one (20 ng) and 5α-androstanediol (5 ng), in ethanol, were added to a stoppered glass tube followed by 0.5–2.0 ml of homogenate. After mixing vigorously the tubes were left at 4°C overnight.

Lipid material was extracted twice with ethanol/acetone (1:1, v/v) (5 ml) by agitation for 2 min on a vortex mixer, and the combined extracts evaporated to dryness under a stream of nitrogen in a water bath at 40°C. Most of the non-steroidal lipid was then removed using a modification of the method of Ismail, Love and McKinney [9]. Ethyl acetate (50 μl) was added to the residue followed by 1% aqueous $CaCl_2$ solution (5 ml) and the tubes placed in a water bath at 50°C for 10 min without shaking. The tubes were then carefully removed, placed in ice for a further 10 min and then slowly filtered through a scintered glass funnel (porosity 1). The funnels were washed with ice-cold $CaCl_2$ solution (1 ml).

The filtrate was extracted twice with diethyl ether (5 ml) and the solvent evaporated to dryness under nitrogen. Residues were transferred in a small volume of ethanol to tubes for derivative formation.

Derivative formation

Trimethylsilyl ethers of the steroids were prepared by drying the tubes *in vacuo* over phosphorus pentoxide for 1 hr and adding BSA (20 μl) to the residue. The tubes were tightly stoppered, left at room-temperature overnight and the derivatised extracts analysed within 48 hr.

High resolution molecular ion monitoring

Details of the procedure by these laboratories for selected ion monitoring at high resolution have been described [10, 11]. A Varian 2700 gas chromatograph fitted with a 2 m × 2 mm i.d. helical glass column containing 3% OV-17 on Gaschrom Q (100–120 mesh) was interfaced to a Varian MAT 731 mass spectrometer by a two stage Watson–Biemann type separator followed by a glass lined probe. The ion source temperature was 150°C and the gas chromatograph injector, separator and probe temperatures were 275°C, 250°C and 245°C respectively. The electron beam energy was 70 eV with the resolving power at 8500–10,000 (10% valley) at the mass to be monitored, which was located with the aid of the reference compound polyfluorokerosene. In all cases the most intense peak was the molecular ion of the steroid derivative, and this was the ion monitored. The steroid extract (1–2 μl) was injected using BSA as solvent.

Determination of results

The output of the mass spectrometric detector was displayed on a potentiometric recorder and the respective peak heights of the steroid and internal standard were measured and compared with a standard curve for quantitation. DHA and androstenediol were assayed in the same extract in two separate injections.

RESULTS AND DISCUSSION

In order to show that there was little likelihood of any endogenous material interfering with the peak associated with the internal standards selected, a number of breast tissues (normal, benign and neoplastic) were extracted with no steroids added. In no case was there found a significant peak with the same ion mass nor a gas chromatograph retention time identical with the derivative of 3α-hydroxy-5-androsten-17-one or 5α-androstanediol. For the assay of DHA the ion mass monitored was 360.24845 and a typical trace of one standard is shown in Fig. 1(a), demonstrating an adequate gas chromatographic separation of the two compounds. In the majority of tissue extracts a peak of unknown material with this mass was found, but this had a very much shorter retention time on the column (Fig. 1b).

For the androstenediol assay it was necessary to monitor at an ion mass of 436.3192 and then at 434.30364 for, respectively, 5α-androstanediol and androstenediol derivatives. Figure 2 shows typical traces of a standard (Fig. 2a) and of a tissue extract (Fig. 2b).

Standard curves were set up with every group of tissues extracted and a linear relationship was found between the ratio of steroid to internal standard and the amount of steroid, both for DHA (Fig. 3) and androstenediol (Fig. 4). Although the between-assay variation in stan-

dard curves was small, it was considered necessary to include a curve with each extraction batch.

A number of experiments were performed to test the efficiency of extraction of DHA and androstenediol from tissues. No differences were found between the steroid content of extracts of tissue prepared as described or when tissue was extensively homogenised with the acetone/ethanol mixture. Furthermore, the efficiency of the extraction procedure did not depend upon the amount of tissue present up to 300 mg (2 ml of homogenate) as shown in Table 1.

Table 1. Endogenous DHA and androstenediol in different quantities of 15% homogenate of a primary breast tumour

Amount of homogenate (ml)	Steroid content (ng) DHA	Androstenediol
2.0	18.5	3.5
1.5	14.5	2.4
1.0	10.0	1.8
0.5	5.5	—*
0.0	0.0	0.0

*Derivatised extract hydrolysed before analysis completed.

Because of the high levels of DHA sulphate in plasma, it is possible that some of the DHA detected could have come from contaminating plasma, following hydrolysis of the sulphate during processing. Table 2 shows the DHA measured in samples of tissue from two fibroadenomata, generally more vascular than malignant tissue, following the addition of 35 ng of either DHA or its sulphate before extraction. It can be seen that whereas recovery following the addition of the free steroid is good, the sulphate contributed nothing to the measurement. Therefore the method estimates only the free steroid content.

Table 2. DHA measured in 1 ml portions of a 15% homogenate of two fibroadenomata either alone or following addition of free DHA (35 ng) or of its sulphate (35 ng)

Additions	Dehydroepiandrosterone (ng)	
	Fibroadenoma 1	Fibroadenoma 2
None	3.5	18.5
DHA (35 ng)	35.0	53.8
DHA sulphate (35 ng)	4.0	17.5

The reproducibility of the assay obviously will depend largely upon the homogeneity of the prepared sample, and breast tissue is well known to be difficult to homogenise. Table 3 shows the values obtained following the extraction of five 1 ml aliquots of a 15% homogenate of a fibroadenoma. The one sample with low levels of both steroids probably demonstrates the heterogeneity of the homogenised preparation before extraction.

Table 3. DHA and androstenediol in replicate 1 ml portions of a 15% homogenate of a fibroadenoma

	DHA	Androstenediol
	(ng)	(ng)
	52.7	8.0
	56.2	8.5
	34.5	7.8
	51.7	9.0
	52.3	8.0
Mean	49.5	8.3
Coefficient of variation	17	6

In this pilot study on the amount of DHA and androstenediol in breast tissues, a small number of malignant tumours and fibroadenomata have been assayed. As shown in Table 4, the concentration of these steroids is sufficiently high to be accurately determined in both types of tissue. Although the levels of DHA in the benign condition appear to be considerably higher than in the malignant tumours, it should be pointed out that these results are not corrected for cellularity, either by protein or by DNA estimation. Further work is necessary to determine whether such analyses can be related to subsequent development of the disease or to its clinical management.

Combined Therapy of the Spontaneous Mouse Mammary Tumour: Methotrexate and Hyperbaric Oxygen Irradiation

JENNIFER SHEWELL† and R. W. DAVIES‡

†*Department of Radiobiology and* ‡*Department of Physics, Medical College of St. Bartholomew's Hospital, Charterhouse Square, London EC1M 6BQ, Great Britain*

Abstract—*The response of spontaneous mammary adenocarcinoma of female C_3H/Bts mice to combinations of methotrexate administration and irradiation with* 14 MeV *electrons under hyperbaric oxygen* (3 *ata*) *was measured. The wide variation in doubling times of these tumours was taken into account by making up experimental groups to contain equal numbers of faster- and slower-growing tumours. A standard dose of* 80 mg/kg *methotrexate injected into the tumour, followed by citrovorum rescue* 24 hr *afterwards, produces a small but significant tumour response. There was no effect on the response of tumours of* 1000 rad *under HPO when methotrexate was given* 7 days *before irradiation, but a significant increase in response, which was essentially additive, when the drug was given as a* 24 hr *pretreatment. Oxygen concentration measurements showed there to be no essential difference in rate or degree of oxygenation between pretreatment and control groups.*

A dose of 3000 rad *under HPO was followed* 7 days *later by methotrexate administration, and gave an increased effect on the tumours which was more than additive. Early skin reactions were essentially the same for groups given combined treatment or irradiation only.*

Possible mechanisms involved, long term survival of the mice and metastatic spread from the primary tumour are discussed.

INTRODUCTION

THE EFFECTIVENESS of combined radiotherapy and chemotherapy compared with that of radiotherapy alone is still a subject of clinical trial. Combined therapy appears to produce better results than radiotherapy alone in the treatment of childhood leukaemias [1], bronchogenic carcinoma [2], oat cell carcinoma of the lung [3], lymphomas [4] and perhaps in some solid tumours of the head and neck [5, 6]. There are many questions outstanding, not least that of the risk of increasing the incidence of toxic side effects [7] with combined therapy. The work described here uses an animal tumour system as a model to investigate the effectiveness of combining the antifolate agent, methotrexate, with irradiation in different time relationships.

A dose of 1000 rad under hyperbaric oxygen (HPO) was used as a test dose for combination therapy with methotrexate, where the drug was given *before* irradiation. The drug was administered at a dosage of 80 mg/kg, 7 days or 24 hr pre-irradiation. The initial choice of this test dose of radiation was made in the expectation that it would not be a tumour "cure" or "control" dose, but that it would produce a marked tumour response, since synergistic or additive effects cannot be demonstrated on maximal response.

In further experiments where the effect of administering the drug *after* the radiation treatment was to be studied, it was decided to use a larger standard dose of irradiation—3000 rad under HPO. Although this was still not a "cure" dose, it would make it possible to evaluate the effects of the combined treatments on two endpoints rather than one, namely both tumour and skin responses.

As the irradiations were carried out under hyperbaric oxygenation, it was necessary to establish whether or not methotrexate pretreatment could alter the degree of oxygenation of the tumour. A series of investigations was made using oxygen cathode electrodes to measure directly tumour oxygen concentrations in

mice treated with methotrexate, but not irradiated.

MATERIAL AND METHODS

1. *Tumour response*

The tumour used was the spontaneously arising mammary tumour of the female C_3H mouse. Mice bearing mammary tumours in the thoracic region were withdrawn from the C_3H/Bts stock colony and caged 8 to a box; they were fed Dixons CDDM diet with water *ad libitum*. Tumour diameters were measured three times a week, and the relative tumour volume (the product of 3 orthogonal dia) plotted on a semilogarithmic plot against time. From this the volume doubling time can be calculated, and the response of the tumour to either drug or radiation treatment measured by the formula for assessing radiation response described by Cheshire and Lindop [8], where tumour response =

$$\frac{\text{time taken to regrow to volume at treatment}}{\text{post treatment doubling time}}$$

The variable doubling time of the spontaneous C_3H mammary tumours make the use of this type of assessment essential [9].

After treatment each mouse was caged separately. They were examined daily and tumour measurements were continued until the death of the animal. Since the C_3H mouse often produces more than one mammary tumour, it was sometimes necessary to kill an animal if second or subsequent tumours caused great discomfort. The ages of the mice at irradiation ranged from 11 months to 26 months old with a mean age of 20 months.

2. *Irradiation*

Tumours were irradiated with a single dose of electrons of 14 MeV mean energy from the linear accelerator in the Department of Radiotherapy, St. Bartholomew's Hospital. Irradiations were carried out under 3 ata oxygen, in a pressure tank designed [10] to allow the pressurization of 4 mice simultaneously with consecutive irradiation of each mouse in turn. The beam of electrons was collimated outside the tank by a 11.5 cm Dural applicator and internally by a 5 cm thick lead collimator with a hole 2.2 cm dia. Mice were anaesthetized with 65 mg/kg sodium pentobarbitone solution i.p. and placed on a Perspex platform fitted beneath the internal collimator. The platform was adjusted so that the tumour lay concentrically with the collimator hole. A strip of 35 mm photographic film (Ilford Fine Grain Safety Positive) in black polythene was placed under each tumour, to check that the tumour was central in the field during irradiation, and a LiF capsule was fixed in the field adjacent to the tumour. An ionization chamber in the beam outside the pressure tank was calibrated against a 0.2 cm^3 Baldwin Farmer Sub-Standard Dose Meter in the position of the tumour, and the chamber voltage produced by the required dose determined. During the exposure of the mice the ion chamber voltage was fed to a trigger-comparator unit which stopped the machine when this set value was reached.

3. *Hyperbaric oxygenation*

Anaesthetized mice were compressed to 3 ata—30 lbf in^{-2} gauge pressure (207 kPa) in the pressure tank at 30°C. Humidifiers were placed in each mouse compartment, and CO_2 build-up prevented by the 6 l/min O_2 leak. The pressure in the tank was raised by 5 lbf in^{-2} (34.5 kPa) increments over 2 min and the mice maintained at 30 lbf in^{-2} (207 kPa) for 4 min before irradiation for washout. (The timing for equilibration at different pressures was confirmed by oxygen cathode electrode studies, see below.) After the 4 mice had been irradiated consecutively, the tank was decompressed over a period of 1.5–2 min. The total time spent under pressure therefore did not exceed 16 min. No mice died as a result of compression, except for 2 in the first experiment which were shown at *post mortem* examination to have substantial pulmonary metastatic deposits of mammary tumour cells.

4. *Methotrexate administration*

A single dose of 80 mg/kg methotrexate (Methotrexate sodium, Lederle) injected directly into the C_3H mammary tumour will produce a small but positive tumour response [9]. This dose of methotrexate followed 24 hr later by 200 mg/kg citrovorum factor (Calcium leucovorin, Lederle) s.c. was shown to be the optimum dose for tumour response to methotrexate at a level of toxicity where all the mice could be saved by citrovorum. Intratumour injection of methotrexate produced a more consistent effect on the tumour, with a satisfactory dose–response relationship over a range of doses from 20 mg/kg to 80 mg/kg without citrovorum rescue [9]. When methotrexate was injected intraperitoneally without citrovorum there was no dose–response relationship, with high mortality at the higher doses. Control mice were given equal volumes of sterile saline solution, injected into the tumour.

5. *O_2 Concentration measurements in tumours*

Oxygen concentration was measured using 200 μm gold oxygen cathode electrodes of the "open" type, insulated with an araldite mixture except at the tip. A reference voltage of 0.6 V was applied via a silver/silver chloride electrode. Currents proportional to oxygen concentration were amplified and recorded on a multi-channel apparatus [11]. Absolute values of oxygen concentration and electrode drift were determined by pre- and post-calibration in aerated saline at 37°C.

Female C_3H/Bts mice with spontaneous mammary tumours arising in abdominal or inguinal sites and not therefore suitable for irradiation experiments were used for the oxygen concentration measurements. (The histopathology of tumours arising on the abdominal milk crest does not differ from that of tumours arising in the thoracic region, and there is no reason to suppose that the site of the mammary tumour along the milk crest alters its response to irradiation or oxygenation. The similarity of response to oxygenation of both axillary and inguinal mammary tumours has been demonstrated in experiments carried out in this laboratory.) The tumour volumes were comparable with those irradiated, i.e., about 1000 mm^3.

The mice, anaesthetized with 65 mg/kg body wt sodium pentobarbitone as for the irradiation experiments, were lightly tethered to a Perspex platform. One or two calibrated oxygen cathodes were inserted into the tumours, a hypodermic needle being used to facilitate their entry through the skin. The reference electrode was placed in the rectum. After measurements started, time was allowed for the animal to equilibrate in air and a steady base line to be obtained. The platform was then placed in the Vickers Small Animal Chamber, through which oxygen passed at a flow rate of 4 l/min. After steady readings had been reached in 100% oxygen, the pressure was incrementally increased to a maximum of 45 lbfin^{-2} (310 kPa) absolute chamber pressure. Time was allowed at each pressure for measurements to reach equilibrium values. The tank was then decompressed to 100% oxygen at atmospheric pressure and the animal was removed and allowed to breathe air.

After the experiment the mouse was killed with an overdose of anaesthetic. With the electrodes fixed in position, the tumour was dissected from the animal. The positions of the electrodes were marked using ink (Pelikan, black) after dissection of the tumour. The position of the electrodes could be determined with some accuracy from histological sections when the tumour was fixed with the electrode *in situ*, and this was done in a few instances. The histological structure of the tumour was determined, and results from mammary adenocarcinoma only were included. 95% of the mammary tumours in the C_3H/Bts colony are adenocarcinoma [9].

6. *Assessment of skin damage*

The skin damage scale used is set out in Table 1. It does not differ much from that used by other workers in assessing damage to mouse skin in other sites [12], but is slightly easier to apply to pigmented C_3H skin over a tumour. All reactions were judged separately by two independent observers, and the mice were coded so that treatment details were not known to the observer. (This also applied to all tumour measurements.)

Table 1. *Skin reaction over tumour—(plucked skin)*

Very tiny skin flakes	$\frac{1}{4}$
Cracking in skin folds	$\frac{1}{2}$
Marked cracking	1
Scaling	2
Dry scab formed	3
Dampness	$3\frac{1}{2}$
Wet scab formed	4
Bad wet scab	$4\frac{1}{2}$
Ulcer	5

7. *Post-mortem examination*

All mice, control or treated, were examined *post-mortem*, and histological preparations made of all tumours, irradiated or not. If a mouse died before substantial post-irradiation tumour regrowth had occurred the irradiation site was examined for viable tumour cells.

The incidence of pulmonary metastatic deposits in these mice was recorded at *post mortem* examination, and extended with histological observations. If arterial emboli of mammary tumour cells were unequivocally visible on sections of lung tissue, the mouse was scored as positive for pulmonary metastatic deposits despite no gross lesion having been found at macroscopic examination.

RESULTS

(A) *A thousand rad in HPO combined with pretreatment with methotrexate* 7 days *before irradiation*

Groups of mice bearing tumours in the thoracic region only were allocated to four different treatment groups:

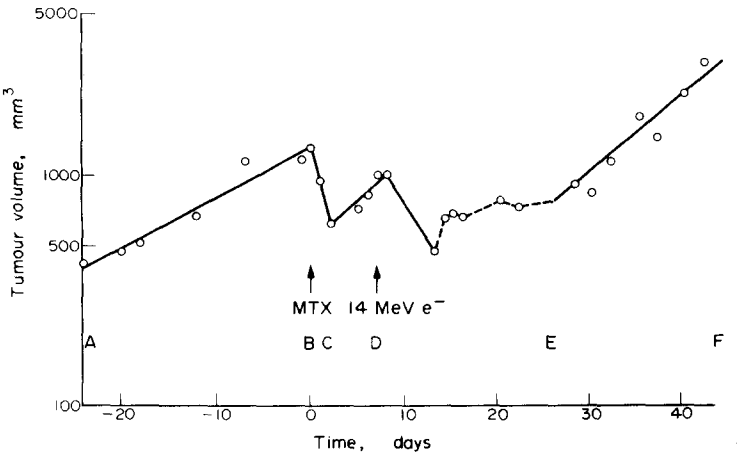

Fig. 1. Tumour volume changes in a spontaneous mouse mammary tumour. AB—pretreatment volume doubling time calculated (12.4 days). *At B,* 80 mg/kg *methotrexate injected into the tumour results in decreased tumour volume. C–D regrowth after methotrexate treatment—(volume doubling time* 9.0 days). *Response to methotrexate* = 0.36. *At D,* 1000 rad 14 MeV *electrons in HPO, with again decrease in tumour volume. D–E irregular volume changes due to oedema, etc. E–F regrowth after irradiation—volume doubling time* 8.8 days. *Response to* 1000 rad *HPO* = 0.72.

(1) 1000 rad in HPO (2) 80 mg/kg methotrexate intratumour + anaesthesia and HPO (3) 80 mg/kg methotrexate intratumour 7 days before 1000 rad in HPO (4) control mice subjected to anaesthesia and HPO treatment only.

As the supply of mice bearing mammary tumours on the thorax is about 4–8 mice/week from the C_3H/Bts colony, experimental groups of 8–12 mice at a time were accumulated over a period of 2–3 weeks. During this time the volume doubling times of the tumours were calculated, and treatment groups made up to contain equal numbers of faster and slower growing tumours. The range of volume doubling times of tumours used was 4.6–47.3 days, with a mean of 14.3 days. Tumours were irradiated at a relative volume of 1000–1200 mm^3. Exceptionally 24 mice at once were available for experiment, and altogether 56 mice were used in 4 experiments. One mouse from each treatment group was included in each group of 4 pressurized mice.

After injection of methotrexate into the tumour, the tumour stopped growing and decreased in volume. After 4–5 days growth started again, so that when irradiation was carried out 7 days after methotrexate injection the relative volume of the injected tumour had often but not always regained its pre-injection volume at the time of irradiation. (Figure 1 shows a typical growth curve for a tumour treated in this way, to illustrate the time relationships.) In this treatment group it is therefore possible to calculate the response of the same tumour first to methotrexate and then to 1000 rad HPO. It can be seen (Fig. 2a) that the tumour response of mice given methotrexate only, 0.22 ± 0.04, agrees well with the response, 0.23 ± 0.06, of the tumour in mice given methotrexate 7 days before irradiation. This response also agrees with the value of 0.20 ± 0.02 obtained from a larger group of 32 mice, neither anaesthetized nor subjected to HPO given this

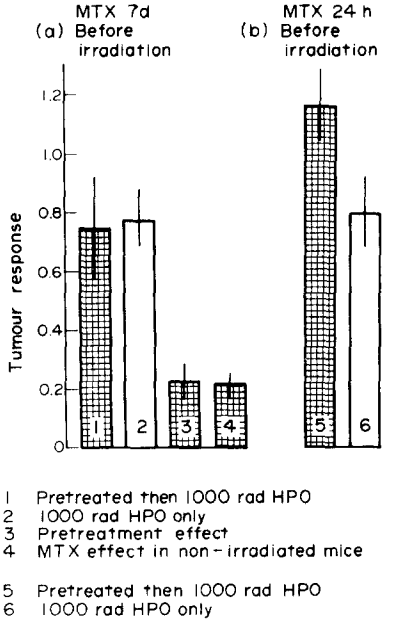

Fig. 2(a). Effect of 80 mg/kg *methotrexate given* 7 days *before* 1000 rad *in HPO.*

dose of methotrexate in a dose–response assay [9]. Mice given 1000 rad HPO showed a tumour response of 0.78 ± 0.09, and this does not differ from the response to 1000 rad after methotrexate pretreatment, which was 0.75 ± 0.17.

The growth of tumours on mice subjected only to anaesthesia and compression was not affected.

(B) *A thousand rad in HPO combined with pretreatment with methotrexate* 24 hr *before irradiation*

A further 24 mice were used in 2 experiments where the interval between methotrexate pretreatment and 1000 rad HPO was reduced to 24 hr. As the response obtained to the standard dose of methotrexate was so reproducible the methotrexate only and procedural control groups were omitted. Each batch of 4 mice irradiated was made up of 2 pretreated and 2 non-pretreated mice. Figure 2(b) shows the result obtained. The mean tumour response to 1000 rad HPO, 0.80 ± 0.12, agrees well with the response to the same dose of irradiation, 0.78 ± 0.09, in the first 4 experiments. The response of the pretreated tumours is 1.16 ± 0.12 which is significantly greater than that of the non-pretreated tumours at the 0.05% level. The increase in response is approximately equivalent to the effect that 80 mg/kg methotrexate produces on its own. A combined methotrexate treatment and hyperbaric irradiation within a 24-hr period therefore produced an additive effect.

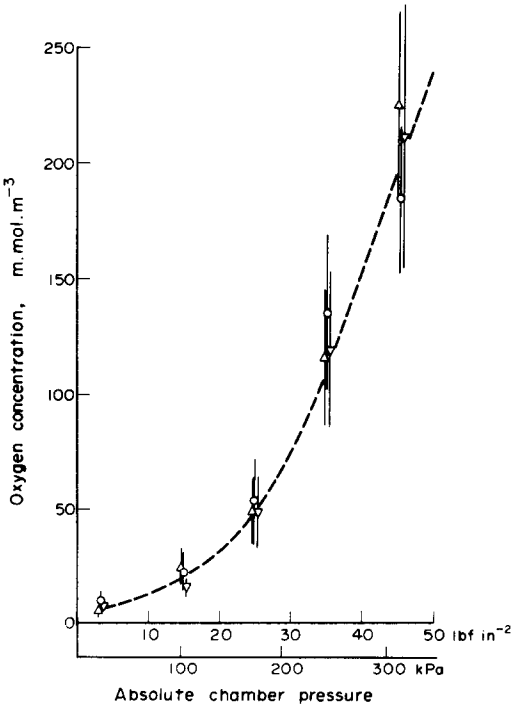

Fig. 3. Relationship between oxygen concentration in mmol m^{-3} *and absolute chamber pressure in* lbf in^{-2} *and* kPa *for mice treated with methotrexate* 24 hr *and* 7 days *before measurement and control, untreated mice. Circles represent mean values from untreated mice. Triangles represent* 24 hr *pretreatment, and inverted triangles* 7 day *pretreatment. Vertical bars represent* $\pm$ *one S.E.M.*

(C) *Oxygen concentration measurements in tumours*

The mice were divided into three groups to mimic the time intervals used in the irradiation experiment, i.e. (i) tumours pretreated with methotrexate 24 hr before oxygen measurements. (ii) tumours treated with methotrexate 7 days before measurement. (iii) untreated control group.

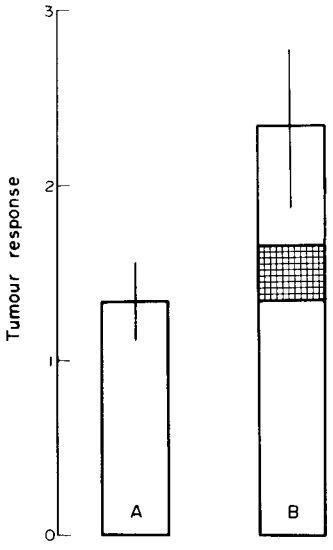
Figure 3 shows the relationship between oxygen cathode readings expressed as oxygen concentration in m mole m^{-3} against absolute chamber pressure lbf in^{-2} and kPa. The same line may be fitted to the mean response of tumours from untreated mice, and mice treated with methotrexate either 24 hr or 7 days beforehand, showing that there was no essential difference in rate or degree of oxygenation between the three treatment groups.

(D) *Three thousand rad in HPO combined with methotrexate given after irradiation*

In the remaining 3 experiments 32 mice were used. Skin over the tumours was plucked 24 hr before irradiation. All mice were irradiated with 3000 rad in HPO to the tumour, and 7 days later 16 mice were given 80 mg/kg methotrexate into the tumour. This group was then given citrovorum 200 mg/kg 24 hr after methotrexate. Both tumour response and the response to irradiation of the epilated skin over the tumour were assessed.

Tumour response

During the 300 day period of follow-up after treatment, 6 mice, 3 in each group, died or were killed before the treated tumour started to regrow. In three cases no cells recognizable as viable tumour cells were found in histological examination of the irradiation site, but in all cases it was assumed that regrowth would have taken place at the pretreatment rate starting the day after death, and regrowth curves were constructed accordingly. Figure 4 shows the mean response of the tumours to 3000 rad in HPO, and to 3000 rad in HPO followed by the standard dose of methotrexate (1.43 ± 0.21 and 2.43 ± 0.44 respectively). The hatched portion of the histogram indicates the contribution made by this dose of methotrexate injected into a tumour that has not been irradiated, and it can be seen that an additive effect is not, here, enough to account for the enhanced response.



A 3000 rad HPO

Fig. 4. Tumour response to 3000 rad *in HPO with or without* 80 mg/kg *methotrexate given* 7 days *after irradiation. The hatched portion on col B represents the mean tumour response to* 80 mg/kg *methotrexate in non-irradiated tumours. Vertical bars represent* ± *one S.E.M.*

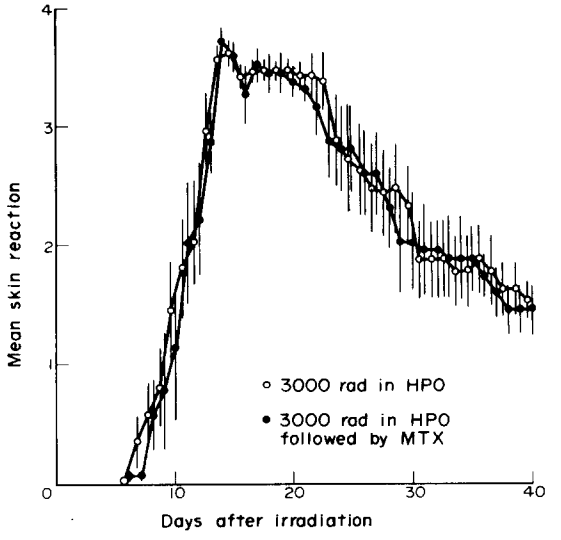

Fig. 5. Skin response to 3000 rad *in HPO, alone or followed by methotrexate administration. Vertical bars represent* ± *one S.E.M.*

Skin response

(a) *Early skin reactions.* Since methotrexate is not a specific "anti-tumour" agent, but will block cell division in the basal layer of the epidermis also, it would not have been altogether surprising if the skin reaction to 3000 rad in HPO had been more severe, or had followed a different time course, in mice which were given 80 mg/kg methotrexate intratumour 7 days after irradiation. The mean 6–30 day skin reaction was 2.4 ± 0.46 in the combined treatment group and 2.3 ± 0.41 in the irradiated only group. Figure 5 shows that the time of onset of skin damage was the same in both groups, and that the rate of repair to 40 days was substantially the same. The injection of methotrexate at a time after irradiation, just before irradiation-induced skin damage became apparent, did not delay healing.

(b) *Late skin reactions.* These were recorded in the 16 mice surviving more than 50 days after irradiation, 8 from each treatment group. Six out of 8 mice (75%) given methotrexate and irradiation showed some form of late damage at the irradiation site—2 out of 8 developed papillomas, in one mouse the skin became scarred and fibrosed and in 3 more there was late skin breakdown at 92, 114 and 128 days after irradiation respectively. Mice given irradiation alone showed the same incidence of papilloma formation, 2 out of 8, but only one late skin breakdown, at 98 days. Since these numbers are so small it is not possible to draw any firm conclusion from them.

Survival and lung metastases in all experiments

Survival data in these experiments are not clearcut, as it was necessary to kill 24 mice out of 112 because secondary mammary tumours were causing what was judged to be excessive discomfort to the mouse, including bleeding or ulceration of the tumour or obstruction of the anus. Despite this, certain points may be made. Table 2 shows the mean survival times after 1000 rad and 3000 rad for the different combinations of treatment and for methotrexate treatment alone. Mice given combined methotrexate and 1000 rad showed no increased survival compared to those given 1000 rad only, but the combined treatment had a slight beneficial effect on survival after 3000 rad. Survival after 3000 rad to the tumour, as might be expected, was longer than after the lower dose of irradiation.

The tumours of both methotrexate-treated and non-methotrexate-induced mice would be expected to suffer a certain degree of mechanical disruption following injection, with a concomitant increase in the incidence of pulmonary metastatic deposits [13]. The usual incidence in untreated C_3H/Bts mice is around 30%, and the incidence in combined and 1000 HPO irradiation only treated groups in these experiments was 39 and 45% respectively, increasing to 60% in both 3000 rad groups in which survival was longer. There is therefore no evidence that methotrexate administration altered the degree of metastatic spread from the treated tumours.

Table 2. Mean survival time after treatment

		Days ± S.E.
experiments 1–4	No treatment	43.1 ± 9.8
	Methotrexate 80 mg/kg	48.7 ± 7.3

	3000 rad + methotrexate 7 days later	139.0 ± 17.4

DISCUSSION

The combination of methotrexate pretreatment and radiation has been claimed to be more efficacious than radiation alone, although clinical trials of this point present at the moment conflicting evidence. In the present animal experiments, a comparison was made between hyperbaric irradiation alone and hyperbaric irradiation combined with a single large dose of methotrexate at different time intervals. The spontaneous mammary tumour of the C_3H mouse is a relatively well oxygenated tumour, with a hypoxic cell population of perhaps 1% [14]. Nonetheless, irradiation under hyperbaric oxygenation produces a better tumour response to irradiation than under eubaric aerobic conditions, and it was decided to use hyperbaric irradiation in order to obtain the most favourable conditions for radiation damage. (Methotrexate therapy is used by some radiotherapists routinely in combination with hyperbaric irradiation.)

The administration of methotrexate 7 days before irradiation had no effect on the response of the tumour to 1000 rad. When the interval between methotrexate pretreatment and 1000 rad was shortened to 24 hr, a significantly increased radiation response was obtained. The amount of increase in response was such that we consider that this was essentially an additive effect of two submaximal killing agents upon the tumour cells.

Since the 1000 rad doses were given under hyperbaric conditions, it is theoretically possible that any increase in radiation response after methotrexate treatment might have resulted from increased effectiveness of tumour oxygenation under HPO. For example, loss of tumour volume might have allowed better distribution of oxygen to hypoxic cells, or damaged cells might have exhibited reduced oxygen utilization. The fact that we observed no difference in response to hyperbaric oxygenation for untreated tumours, tumours 7 days after methotrexate and tumours 24 hr after methotrexate indicates that the increased radiation response of tumours in the 24 hr pretreatment group is not caused by alterations in tumour oxygenation.

It is also possible that the modes of action of methotrexate and radiation may be independent of each other. If different targets are damaged by the two agents, then when radiation is given 7 days after methotrexate, repopulation of methotrexate-killed cells may have occurred, with the result that overall tumour response does not increase as it does with an interval of only 24 hr between the two agents. Friedman, de Narvaes and Daly [15] believe that methotrexate and radiation have their own specific modality in affecting tumour cells, in that methotrexate given before irradiation does not specifically enhance the effect of irradiation on the cells.

Berry, on the other hand, suggested that methotrexate might act by potentiating the effect of radiation upon the anoxic or hypoxic cells in a tumour more than on the well-oxygenated cells of normal tissues; he observed a reduction in OER from 2.6 to 1.8 for tumour cells surviving high drug doses [16].

The increased efficacy of methotrexate given 7 days after the higher dose of irradiation is believed to be more than additive, although, of course, synergistic effects cannot be proved at only one dose point. A possible explanation for this increase may be that phase-specific methotrexate may be more effective when irradiation has reduced the degree of asynchrony among the tumour cell population.

Acknowledgements—We are grateful to Professor Patricia Lindop for constructive advice and discussion, and to Professor Arthur Jones for access to the 14 MeV Mullard accelerator in St. Bartholomew's Hospital. We also thank Mr. W. S. Hall and Miss Linda Barbrook for help with the irradiations, Mrs. Margaret Jones and Mrs. Susan Scott, M.Sc. for tumour measurements and care of the mice, and Mrs. Janet Hartfree for histology.

†*Medical Department Tumor Research, University of Essen, Essen, Germany and*
‡*Jan Swammerdam Institute, University of Amsterdam, Amsterdam, The Netherlands*

Abstract—*The course of secretion of immunoglobulin (Ig) μ-chain secretion by cultured peripheral blood lymphocytes in a case of heavy chain disease has been studied. It has been found that μ-chain protein is secreted primarily as a monomer. Dimers and polymers of μ-chain protein found in the serum of this patient are of secondary i.e. post-synthetic origin. By comparison of cytoplasmic and culture supernatant protein it has been found that metabolically inert deposits of μ-chain protein in aggregated form are present within the cultured cells. By ultrastructure studies these cells were classified as small lymphoid cells. The cells associated with μ-chain secretion in this patient exhibit distinct functional and ultrastructural features and possibly are arrested at a differentiation stage at which surface Ig synthesis is initiated.*

INTRODUCTION

BIOCHEMICAL studies with μ-chain protein (μCP) from three patients have shown that μCP in its monomeric form has a mol. wt in the range of 56,000 daltons [1–4] resp. 35,000 daltons [5]. All these patients had μCP of polymer type in the serum, showing the strong tendency of these abnormal proteins to aggregate.

By analysis of the cell sap of a μ-chain secreting tumor molecules of a mol. wt in the range of 10,000–350,000 have been observed [6] and it has been proposed on the grounds of ultrastructure studies that μCP is released by a process of limited cytolysis from enlarged cytoplasmic sacs or vacuoles visible in the cells [7].

We observed a 52 yr old female patient (Be.) with μCD. The finding of a high percentage of PBL staining positive for surface Ig of μ chain specificity and regrowing of these membrane-bound molecules after trypsination prompted us to perform short time cultures of PBL of this patient. My chains could be found regularly in the supernatant of such cultures. We used this approach to answer the following questions: 1. Is the μCP detected in the serum of patient Be. of heterogeneous type and what is the size of the monomer? If heterogeneous, i.e. if polymeric μCP is present, a second question should be answered. 2. Is this type of heterogeneity also found in culture supernatant of PBL of this patient? If μCP of high mol. wt is found in culture supernatant a third question has to be answered. 3. Does the comparison of cytoplasmic and secreted internally labelled μCP provide an answer to the question if synthesis and secretion of μCP of different mol. wt show a different time course?

MATERIAL AND METHODS

The diagnosis of μCD has been made in a 52 yr old female patient on the grounds of an Ig μ-chain related protein which has been detected by a combination method of starch gel electrophoresis and immunodiffusion [8]. Main symptoms of the patient were generalized lymphadenopathy, enlargement of the liver and the spleen and hemorrhagic complications. Details of this case are reported elsewhere [9]. Isolation of PBL was performed by density gradient centrifugation [10] in Ficoll–Isopaque (Lymphoprep®, Nyegaard & Co., Oslo). Venous blood was drawn in heparin (Liquemin®, Roche) 0.4 ml/20/ml blood. For culture the cells were washed three times in HBSS.

Accepted 4 January 1977.

*Supported by the Deutsche Forschungsgemeinschaft, Bad Godesberg.

Immunoelectrophoresis [11] and Ouchterlony analyses have been done using anti human serum from the rabbit (Medac/Hamburg) and μ-chain specific antisera (Behring-Werke AG, Marburg) in agar pur. (Behring-Werke AG./Marburg). Isolation of μCP has been performed by immunoadsorption on polyacrylamide particles [12] coated with μ-chain antibodies (Medac/Hamburg). SDS–PAGE [13, 14] has been done in a Multiphor apparatus (LKB-Producter AB/Bromma, Sweden) using Combithek® (Boehringer/Mannheim), an Ig light chain protein of kappa type and a reduced alkylated macroglobulin of Waldenström type as marker proteins. Densitometric tracings of gels after staining with Coomassie Brilliant Blue (0.05%) were done in the DD2 apparatus (Kipp and Zonen, Delft/Netherlands).

L-[U-^{14}C] leucine (324 mCi/mmol, RadioAmersham, G.B.) has been used for radiolabelling of μCP in cell cultures. Radioactivity in gels has been measured (Packard Tricarb.) using solubilizer TS-1 (Koch-Light Lab. LTD, G.B.) after dissection of the gel in slices of 1 mm thickness. Anti μ-chain antibodies (Medac/Hamburg) have been labelled with ^{125}I using the Bolton–Hunter reagent (NEN/Boston, U.S.A.). For the detection of μCP after gel electrophoresis Whatman 3 mm paper soaked with antiserum was layered on to the gel for 24 hr in a humid chamber. Radioactivity in slices of the gel was measured after washing the gel in saline for 24 hr.

Short time cultures have been done in TC Medium 199 (Difco Lab./Detroit, USA) with 50 $\times 10^6$ PBL/ml. A total of 250×10^6 cells was used and 10 μCi/ml of ^{14}C-leucine was added. Culture supernatant has been collected at various days of culture and dialyzed exhaustively against PBS. For the study of the time course of secretion of μCP 4×10^6 cell/ml were used. A total of 40 $\times 10^6$ cell in the presence of 5 μCi/ml ^{14}C-leucine were used.

For reduction and alkylation of μCP and IgM protein 0.75 m mercaptoethanol [15] (Merck/Darmstadt) and iodoacetamide (Merch/Darmstadt) or dithiotreitol [5] (Calbiochem, San Diego, USA) and iodoacetamide has been used.

For SDS–PAGE cytoplasmic proteins of cultured cells (day 5 of culture) after ultrasonication (Biosonik III, Bronwill Scientific, Rochester, U.S.A.) were prepared by centrifugation (18,000 ***g***, 10 min) in PBS.

For electron microscopy PBL together with other mononuclear leucocytes and platelets were isolated [10], washed three times in SBSS, fixed in suspension with 2% glutaraldehyde (in 1/15 m Sørensen buffer, pH 7.4, 2.55 mM $MgCl_2$, 500 mOSM), the isolation and fixation were carried out between 0° and 4°C; pellets of fixed cells were postfixed in 1% OsO_4 and 1% uranyl acetate solution, embedded in Epon 812, cut into ultrathin sections with a LKB Ultratom and examined with a Philips EM 300 electron microscope at 60 kV.

RESULTS

Figure 1 shows the result of SDS–PAGE of isolated μCP from the serum of the patient Be. (A). Three components of 65,000, 84,000 and 220,000 daltons are visible. After reduction and alkylation using mercaptoethanol as reducing agent a main component of 38,000 daltons is observed (B). Smaller components of 18,000 and 65,000 daltons are present. Using dithiotreitol for reduction a main component of 42,000 daltons is observed; minor components of 66,000 and 93,000 daltons are present.

In an earlier experiment with mercaptoethanol 5 components of 16,000, 32,000, 69,000, 93,000 and 182,000 daltons have been found, the component of 32,000 daltons being the main fraction.

With supernatant of PBL cultured for 4 days (Fig. 1, C) four components of 18,000, 41,000, 65,000 and 142,000 daltons are observed in SDS–PAGE. Reduced and alkylated monoclonal IgM protein shows five components of 11,000, 20,000, 33,000, 65,000 and 95,000 daltons.

Radiolabelled protein after SDS–PAGE of culture supernatant collected at day 1, 3 and 5 and of cytoplasmic protein (CP) after ^{14}C-leucine incorporation is shown in Fig. 2. From the start of electrophoresis (left side) radioactivity decreases to a level of about 0.5×10^2 counts/min and rises to a major peak at 30,000 daltons and a minor peak at 12,000 daltons on day 1. On day 3 a zone of radiolabelled protein appears in the region of 20,000–68,000 daltons. On day 5 a sharp peak of 15×10^2 counts/min arises at 30,000 daltons.

Radiolabelled cytoplasmic proteins (CP) appear in a more heterogeneous distribution in a region of 20,000–68,000 daltons with maximum activity of about 100×10^2 counts/min. Localization of μCP within the gel is shown in Fig. 3. Again, the peak maximum of internally labelled protein is seen at a position of about 30,000 daltons (Fig. 3, upper part).

Binding of ^{125}I-labelled μ-chain antibodies (Fig. 3, lower part) obviously corresponds to the distribution of radiolabel with a peak at 30,000 daltons. A second minor peak of ^{14}C-leucine

Lower part: result of binding of ^{125}J *labelled μ chain antibodies* (○——○).

labelled protein corresponding to 78,000 daltons without significant binding of μ-chain antibodies has been observed in this experiment.

A comparison between the size distribution of internally radiolabelled cytoplasmic μCP and "cold" cytoplasmic μCP is shown in Fig. 4. Cytoplasmic protein of cultured PBL after a period of 5 days (from the experiment shown by Fig. 2) were used. The maximum binding (20 $\times 10^3$ counts/min) of ^{125}I-labelled antibodies (Fig. 4, lower part) is observed in a region of 160,000 and 110,000 daltons. In contrast to internally labelled μCP (Fig. 4, upper part) "cold" μCP resides at a position in the gel which corresponds to a significantly lower mol. wt. Virtually no ^{14}C-leucine radioactivity has been observed in the region of maximum binding of labelled μ-chain antibodies.

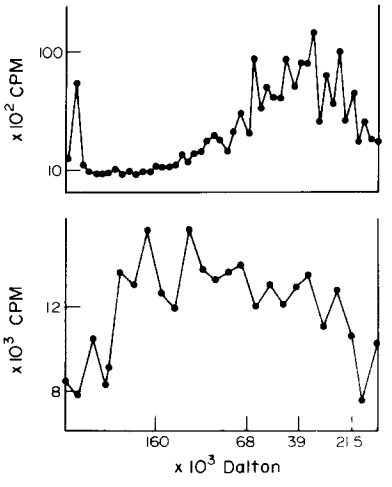

Fig. 4. Comparison of SDS–PAGE of cytoplasmic μCP after 5 days *of culture in presence of* ^{14}C*-leucine. Internally labelled μCP (upper part) and "cold" μCP (lower part).*

The results of SDS–PAGE of isolated serum μCP, reduced and alkylated serum μCP and culture supernatant μCP are shown in Table 1. Some variation of the numbers due to preparation and methodological hazards is obvious. It follows from these figures that culture supernatant proteins show a greater heterogeneity than μCP from the serum, especially in the region below 65,000 daltons. A strong "new" component of 372,000 resp. 355,000 daltons has been observed.

Figure 5 shows the result of ultrastructural analysis of PBL of the patient by transmission electron microscopy. The predominant cell type (80 out of 100 sections of cells studied) is a small lymphoid cell, showing some striking differences with the usual type of circulating small lymphocyte. First, whereas in normal PBL essentially no ER is present, patients PBL show a considerable number of smaller (smooth and rough) ER-cisternae; moreover, the Golgi stacks in these cells are invariably extended. Second, in contrast with the conformation of the mitochondria in normal PBL the mitochondria in patients PBL are all in the condensed state [16]. Third, the nucleocytoplasmic ratio of patients PBL appeared to be considerably lower than in normal PBL. No nuclear or nucleolar alterations were observed.

Table 1. Results of SDS–PAGE of μCP under various conditions. Main components as judged by densitometer tracings are underlined

Isolated serum μCP, untreated		Reduced and alkylated serum μCP			Culture supernatant μCP, untreated		
1	2	1*	2*	3†	Day 1	Day 3	Day 5
		18,000	16,000		17,000	18,000	15,000
					26,000	25,000	23,000
	38,000	38,000	32,000		32,000	33,000

*Reduction by mercaptoethanol
†Reduction by dithiotreitol

DISCUSSION

Heterogeneity of μCP has been shown to result from intracellular synthesis in the first and hitherto only report [6] on biosynthesis of μCP. It has been also shown by these authors [6] that almost all of the secreted μCP is of a greater size than 350,000 daltons. In contrast to this observation the majority of μCP secreted by cultured PBL of the patient Be. described here is of considerably smaller size and is of the same order of size as the monomer of serum μCP (about 40,000 daltons). Cultured PBL of the patient Be. secrete μCP of low mol. wt which has not been found in the serum using immunoadsorption on antibody coated polyacrylamide beads. It seems possible, therefore, that polymer type μCP results in part from the isolation procedure as it has been discussed by the above cited authors [1]. Another factor, which may play a role as to electrophoretic behavior is storage of μCP. We observed changes of the pattern of μCP components in SDS–PAGE occurring after 4 and 7 days storage at 4°C with μCP of culture supernatant (unpublished results). From the comparison of the mol. wt of secreted μCP and cytoplasmic μCP (Fig. 4) follows that the major part of cytoplasmic μCP of a higher mol. wt than 100,000 daltons remains unlabelled after 5 days of culture in the presence of ^{14}C-leucine. The internally radiolabelled cytoplasmic μCP shows the same mol. wt as the secreted μCP. This finding and the time course of secretion (Fig. 2) clearly indicates that monomer is the form of μCP which is primarily synthesized and does not originate from intracellular or extracellular degradation. From the fact that a large amount of μCP remains unlabelled within the cells and virtually no radiolabelled molecules of more than 70,000 daltons are released into supernatant we conclude that μCP of higher mol. wt cannot be exteriorized properly by the cells and form a sort of metabolically inert deposits within the cell. The mechanism by which these aggregates are discharged by the cells is unknown. In order to evaluate the possibility that this material originates from cell disintegration the viability of cultured cells and radioactivity in the supernatant after ^{14}C-leucine incorporation over a period of 13 days has been measured. A strong resemblance of the course of cell number and supernatant radioactivity has been observed indicating that labelled protein is the product of functional intact cells (unpublished results). It has been suggested on the grounds of ultrastructure studies that μCP is released by a process of limited cytolysis from vacuoles visible in bone marrow cells of plasma cell type of a patient with μCD [7]. The presence of numerous cytoplasmic vacuoles is a common ultrastructural feature of the cells of the above mentioned case [7] and our patient. Cytoplasmic vacuoles of plasma cells have been found in another case [17] of μCD by light microscopy. These vacuoles have not been found in cells associated with the production of free γ or α heavy chains or free light chains [18]. Considering the obvious ultrastructural differences between the two types of μCP producing cells discussed here the observation of these vacuoles may indicate a common basic defect and it can be speculated that the cells represent different maturation steps of the lymphoplasmacytoid B-series. The fact that in our case small lymphoid cells were associated with μCP production and that a significant percentage of these cells showed S.Ig of μ-chain specificity by immunofluorescence techniques [9] as well as the failure of mitogenic stimulation by PHA and

Con A and response by PWM [9] is compatible with this assumption. With respect to the origin of the cytoplasmic vacuoles of μCP producing cells it is of interest to note the swollen Golgi stacks (Fig. 5). A similar observation has been made by the cited authors [7]. This correspondence supports the view that the vacuoles originate from the Golgi complex. The presence of a minor component of 18,000 daltons after reduction and alkylation of μCP using mercaptoethanol (Fig. 1) has to be discussed. A component of about this mol. wt has been observed in the culture supernatant as well. Isolated μCP from the serum of the patient Be. and culture supernatant, therefore, has been tested for the presence of J chains which are of about this mol. wt [19, 20] and which have been found in a case of μCD [5]. By the analysis in Ouchterlony plates using an antiserum against J chains kindly supplied by Dr. Brandtzaeg/Oslo no precipitation line has been detected. Reduced and alkylated monoclonal IgM protein has been used as a control. The nature of this component remains obscure for the moment. The fact that a component of this mol. wt has not been seen using dithiotreitol for reduction of μCP does not support the view that it represents the monomer unit of μCP.

Acknowledgements—The very capable assistance of Mrs. M. Kuppe in preparing the manuscript and of Miss T. Hogenes in preparing the material for electron microscopical investigation is highly appreciated.

Demonstration of a Wilms' Tumour Associated Antigen Using Xenogenic Antiserum (Preliminary Communication)*

MADHAV WAGHE† and SHANT KUMAR

Clinical Research Laboratories, Christie Hospital, Withington, Manchester M20 9BX, England

Abstract—*In this report we describe the preparation and partial characterization of a mono-specific anti-Wilms' antiserum raised in rabbits which had previously been injected normal kidney extracts* in utero. *The tumour associated antigen in Wilms' tumour does not appear to be oncofoetal antigen and it has also failed to react with feutin. It is possible that both our antiserum and that of Burtin and Gendron may be directed against a similar cell component.*

INTRODUCTION

WILMS' tumour, a primary neoplasm of the kidney, is one of the common malignancies of early childhood [1]. Immune responses against tumour associated antigens (TAA) of Wilms' tumour have been investigated by a variety of techniques. Lymphocyte-recognised antigens have been demonstrated by tumour cell killing techniques [2–5] and cytoplasmic and membrane antigens by immunofluorescence [6, 7]. Other evidence for the presence of tumour associated substance in Wilms' tumour is provided by the work of Allerton *et al.* and Wise *et al.* who demonstrated an abnormal component in the serum, urine and tumour extracts of these patients [8, 9]. Xeno-antisera have also been used to demonstrate specific antigens in Wilms' tumour extracts [10]. In this report we describe the preparation and partial characterisation of a monospecific anti-Wilms' antiserum.

MATERIAL AND METHODS

Tissues were either fresh surgical biopsies or those stored in a liquid nitrogen bank [11].

Accepted 17 February 1977.

*This work was partly financed by the Wigan and District Cancer Research Committee and the British Cancer Research Campaign.

†Present address: Department of Safety of Medicine, I.C.I. Ltd., Pharmaceutical Division, Mereside, Alderley Park, Macclesfield, Cheshire SK10 4TG.

(A) *Tissue homogenates*

The kidney extracts used to tolerize rabbit foetuses (see below) were obtained by homogenizing aliquots of tissue fragments (10% w/v; Silverson Homogenizer), from three normal kidneys in 0.1 M phosphate buffered saline (pH 7.2) for 2 min at 0–4°C.

Tissue extracts used for raising the antiserum, immunochemical and absorption studies were obtained by homogenizing tissue (10% w/v) in EDTA by the method of Allerton *et al.* [8]. Protein estimations were carried out according to Lowry *et al.* [12].

(B) *Antiserum*

Attempts to tolerize the rabbits which were to be used for raising the antiserum against Wilms' tumour were made by injecting 2 week old foetuses *in utero* with 0.2 ml of normal kidney extract. These rabbits (4 litter mates) when 6 months old were inoculated intradermally with 0.5 ml of "pooled" EDTA extract of 6 Wilms' tumours. Six injections without adjuvant were given at fortnightly intervals and a week after the last injection the rabbits were bled and the sera separated and pooled.

(C) *Tissue culture*

Cell cultures were established in a similar way to that described in our previous study [5]. Briefly, blood clot and necrosed areas were removed from the tissue fragments which were washed in medium 199, and macerated with scalpels and scissors. The resulting suspension

was grown either in roller bottles or in tissue culture flasks (Falcon Plastic). Cultures were usually confluent within 2 weeks of initiation. Morphologically two different types of cells were seen in culture: (a) fusiforms which resemble fibroblasts and (b) polygonal cells (25–35 μm in diameter) lying either by themselves or in epithelial-like sheets. Because the cells from a Wilms' tumour have a certain mesenchymal appearance in their nuclear and cytoplasmic pattern it is impossible to distinguish with certainty the stromal from neoplastic elements. However, there is a considerable variation in nuclear size suggesting that the outgrowth did contain neoplastic cells. Cells were harvested by a brief treatment with trypsin (0.25% Difco) and were either grown as a monolayer on glass coverslips in the wells of Leighton tubes for immunofluorescence or were homogenized for gel diffusion, absorption studies etc.

(D) *Gel diffusion and immunoelectrophoresis*

Gel diffusion plates were prepared by using 1% agar (Difco, Noble agar) in 0.85% saline. Immunoelectrophoresis was carried out at 4°C using 1% agarose in 0.05 M Barbitone buffer at pH 8.2 [13].

(E) *Immunofluorescence ("IF")*

Tissue cultured cells and cryostat sections were fixed in acetone and the indirect "IF" technique was carried out as described previously [6].

(F) *Absorptions*

The pooled antiserum was successively absorbed with freeze dried extracts (100–200 mg/ml) of pooled foetal kidney (12, 25, 31 and 37 weeks), neonatal and adult kidneys, liver, thymus, spleen, tissue cultured Chang cells, neuroblastoma, mammary carcinoma and pooled human sera. Absorptions with each of these absorbants was carried out individually at 4°C for 24 hr. After each absorption the precipitate was removed by centrifugation at 30,000 rev/min for 1 hr at 4°C.

RESULTS

The antiserum in gel diffusion produced several precipitation lines against extracts of Wilms' tumour, hypernephroma and kidneys obtained from 4 foetuses (12, 25, 31 and 37 weeks), 2 neonates (4 and 8 weeks), 2 adult and 5 normal-looking kidneys from Wilms' patients which were attached to the tumour mass but had no gross or microscopic evidence of tumour infiltration (Fig. 1a). The number of precipitation lines were the same against all ages of kidney and a reaction of complete identity was observed in all of them. The presence of an extra line against Wilms' tumour extract (Fig. 1a) indicated that although we may have succeeded in obtaining antibody against TAA, obviously our attempt to tolerize rabbits to normal renal antigens *in utero* were not successful. Therefore the pooled antiserum was absorbed with several tissue extracts, normal human serum etc. (see Methods). The absorbed antiserum produced a single precipitation line in gel diffusion against 4 Wilms' tumours (Fig. 1b and Table 1). An extract of hypernephroma also reacted with the antiserum while its tissue culture homogenate failed to produce any precipitation line. A complete reaction of identity was observed between extracts of Wilms' tumours, Wilms' tumour cell lines and hypernephroma. Control extract of normal human kidney, non-renal solid tumours including their cell cultures, serum samples from normal donors and patients with Wilms' tumour did not produce any precipitation line (Table 1).

Immunoelectrophoresis of Wilms' tumour extract against absorbed antiserum showed a single anodic band with α-mobility (Fig. 2).

Indirect immunofluorescence using absorbed antiserum (1:20 dilution) produced a strong diffuse intra-cytoplasmic staining of 4 Wilms' tumour and cultured cells derived from 2 Wilms' tumours and 1 hypernephroma (Table 1 and Fig. 3). By using class specific Ig (Wellcome, Beckenham, Kent, England) the type of antibody involved was identified as IgG. Similarly treated 5 non-renal tumours, 4 foetal kidneys, 2 neonatal kidneys, 2 adult and 4 normal looking kidneys were negative.

DISCUSSION

The antigenic substance associated with Wilms' tumour has been demonstrated using anti-Wilms' serum raised in rabbits. The TAA detected in Wilms' tumour does not appear to be an onco-foetal antigen as the absorbed antibody failed to react (both in gel diffusion and immunoelectrophoresis) with foetal kidney and liver from 4 foetuses (12, 25, 31 and 37 weeks), thymus, α-foeteprotein, carcinoembryonic antigen. Similarly, cryostat sections of foetal kidney, liver and thymus when tested by indirect "IF" were not stained by the absorbed antiserum. It is realised that more stringent testing would be necessary before our antiserum's reaction against onco-foetal antigen can be completely excluded.

Unlike Wise *et al.* [11] we failed to detect any

cross-reactivity of Wilms' antigen with fetuin present in foetal and newborn calf serum, using geldiffusion and immunoelectrophoresis. Absorption of our antiserum with foetal calf serum did not influence its "IF" staining of cryostat sections of Wilms' tumours. Thus far we have not absorbed the antiserum with purified fetuin. It is possible that both our antiserum and that of Burtin and Gendron [10] may be directed against a similar cell component as both antigens had the similar electrophoretic mobility. Both antisera also cross-reacted with hypernephroma. The presence of a common antigenic determinant in Wilms' tumour and hypernephroma supports our earlier lymphocytotoxicity results [5]. The antigen shared by the two tumour types was not a normal renal antigen as the antiserum neither produced immunofluorescence nor a precipitation line in gel diffusion against normal kidneys. We are very grateful to Dr. P. Burtin who has recently tested our antiserum and has confirmed its specific reactivity against Wilms' tumour extracts by gel diffusion and immunoelectrophoresis. He also found that the antiserum did not react with normal kidney.

Further studies are in progress to characterize TAA in Wilms' tumour extracts.

Tumor-Related Blocking of Anti-Fetal Immunity*

C. H. GRANATEK,† E. M. HERSH, J. U. GUTTERMAN and G. M. MAVLIGIT

Department of Developmental Therapeutics, The University of Texas System Cancer Center, M. D. Anderson Hospital and Tumor Institute, 6723 Bertner Avenue, Houston, Texas 77030, U.S.A.

Abstract—*A modified spleen colony assay was employed to evaluate the effect of various tumor-related factors upon the* in vivo *effectiveness of anti-fetal immunity. Reduction of fetal liver (hemopoietic) colony formation by* in vitro *incubation of fetal liver cells with lymph node cells sensitized to syngeneic fetal liver or plasma cell tumor was blocked by* (1) *solubilized fetal antigen,* (2) *serum from mice recently immunized with syngeneic fetal liver and* (3) *serum from patients with metastatic colon cancer. In the latter, the degree of blocking correlated with plasma C.E.A levels.*

Both humoral and cell-mediated mechanisms of anti-fetal immunity were blocked in plasma cell tumor-bearing mice, suggesting in vivo *suppression of the immune response via circulating tumor-associated fetal antigen.*

INTRODUCTION

IMMUNIZATION with fetal cells confers modest protection against subsequent tumor challenge in some [1–6], but not all [7–13], animal systems. Conversely, immunization with methylcholanthrene (MCA)-induced tumor cells effected the resorption of developing mouse fetuses in a subsequent pregnancy [14], and the administration of antiserum to alpha-fetoprotein during pregnancy has caused abortion [15] or developmental abnormalities [16] in mice and rats. Castro *et al.* [11] have shown that embryoma development was more successful in thymectomized than in normal syngeneic recipients. Furthermore, the development of mouse fetal liver (hemopoietic) colonies in the spleens of irradiated syngeneic mouse recipients can be suppressed by preimmunization with various animal [17–19] or human [20, 21] tumor cells, including malignant melanoma, colon carcinoma, and myelogenous or lymphocytic leukemia. The evidence generated from such studies suggests that tumor-associated fetal antigens may indeed elicit transplantation-type immunity, and that they could play a critical role in tumor-host interactions.

Numerous factors have been suggested to account for the failure to obtain tumor protection via fetal immunity in some systems. Coggin and Anderson [22] have delineated several requirements for a successful fetal vaccine in the SV40 hamster tumor. Girardi *et al.* [3] correlated the parity status of hamsters with the appearance of serum blocking factors that can abrogate the cytotoxicity of lymphocytes from tumor-bearing animals against SV40 transformed cells. The Hellströms have noted the blocking activity of serum from pregnant or MCA-tumor-bearing (TB) mice in a microcytotoxicity assay of lymph node cells (LNC) from multiparous (MP) mice on cultivated syngeneic tumor cells [23] and unblocking by a rabbit antiserum to BALB/c embryonic tissues [24]. Studies with solubilized embryonic antigens and their corresponding antisera have suggested that only antigen–antibody complexes block efficiently at the target-cell level [25]. Baldwin *et al.* have also noted MP and TB serum blocking of the effects of MP-LNC cytotoxicity on a variety of chemically induced rat tumors. However, these investigators emphasized that MP serum could not block the tumor-specific cytotoxicity of TB-LNC [26]. Similarly, this group showed that blocking at the effector level with solubilized tumor-associated fetal antigen was only successful when MP-LNC, rather than TB-LNC were employed against cultured tumor target cells [27].

†To whom reprint requests should be sent.

These findings reflect the multiplicity of tumor-associated neoantigens that are susceptible to immunologic attack. Therefore, in attempting to define factors responsible for the failure of anti-fetal immunity, we have sought to reduce the complexity of the situation by avoiding the use of tumor cells as targets. Rather, we have examined the effect of various factors from the tumor setting in an *in vivo* assay of anti-fetal immunity.

MATERIAL AND METHODS

Colony-forming cells

Single cell suspensions were prepared from the liver of 15-day BALB/c fetuses (from primipara) and from adult femoral bone marrow by several passages of the tissue through an 18-gauge needle with Hank's balanced salt solution (HBSS).

Lymph node cells

Sensitized lymph node cells (LNC) were collected from mice which had been immunized with syngeneic 15-day fetal liver or plasma cell tumor (PCT). Mice were immunized 5 times i.p. over a 2 week period with 10^7 viable, irradiated cells (5000 rad ^{137}Cs). Non-immunized controls were injected with HBSS. LNC were collected one week after the last immunization.

The BALB/c PCT, originally induced with mineral oil, was passaged in males in ascites form. Fetal immunization has been shown to offer weak protection against this tumor [2]. An inoculum of 10^6 cells kills the host in approximately 2 weeks. LNC from tumor bearers were collected at day 7 or day 14.

The axial, brachial, inguinal and mesenteric lymph nodes were dissected aseptically and disrupted in a ground glass tissue homogenizer with HBSS. Single cells were recovered after passage through a 50-mesh screen and diluted to an appropriate concentration without further washes, or washed 6 times with HBSS.

Sera and antigens

Antigen was solubilized from BALB/c fetal or adult liver cells with 3M KCl by the procedure of Reisfeld *et al.* [28]. The extracts were stored at −70°C.

Serum was obtained from individual colonic carcinoma patients or pooled from normal male blood donors. Plasma CEA levels were determined by radioimmunoassay using zirconyl phosphate gel [29]. Human sera were heat-inactivated (56°C for 30 min) and absorbed *in vivo* (0.4 ml injected i.v. into 15–20 g male mice and collected by exsanguination 2 hr later) or *in vitro* v/v against normal BALB/c tissue (heart, lung, kidney, spleen and liver) for 1 hr at 37°C and overnight at 4°C.

Spleen-colony assay

The assay for development of fetal colony-forming units (FCFU) has been described in detail elsewhere [30, 17–20]. Briefly, the assay quantitates fetal liver (FCFU) or bone marrow (CFU) hemopoietic colonies that have developed in the spleens of lethally irradiated (750 rad) male recipients 8 days after i.v. challenge with the stem cell inoculum. The challenge inoculum is generally 5×10^5 fetal liver or 10^5 bone marrow cells to normalize the numbers of hemopoietic stem cells in the experimental and control groups. The irradiated recipients are either previously immunized with fetal or tumor cells or transfused with sensitized LNC or immune serum.

Lymph node cell transfer

In these experiments non-immunized mice were used for the colony-forming assay. Prior to inoculation, the fetal liver (FLC) or bone marrow (BM) cells were incubated with normal or sensitized LNC to allow cytotoxic killing of susceptible stem cells. Sensitized LNC were obtained from FLC- or PCT-immune donors. A 10:1 ratio of effector to target cells was used in a 60 min incubation in heparinized vials gently agitated on a platform rocker in a 37°C (5% CO_2) incubator. The LNC's have a negligible colony-forming capacity (as opposed to spleen cells, which cannot be used as effector cells in this assay). Thus the colonies on the spleens of the irradiated recipients reflect the progeny of the remaining viable challenge FLC or BM.

A 20 min preincubation of the LNC's with either adult vs fetal liver antigen or normal vs cancer patient serum was conducted to test for blocking of cell-mediated antifetal immunity; 6×10^7 LNC were incubated with 500 μg of antigen or 0.5 ml of serum prior to their admixture with the target colony-forming cells. No corrections for viability were made in any of the samples after incubation; the colony-forming inoculum was calculated on the basis of an initial equivalent number of viable cells in each group.

RESULTS

Cell-mediated reduction of fetal colony-forming units (FCFU) by lymph node cells (LNC) sensitized to fetal liver or to a BALB/c plasma cell tumor has previously been reported by Salinas *et al.* [18]. We attempted to block this effect by preincubating the effector LNC with fetal antigen before they were mixed with target stem cells and adoptively transferred to non-

*Only significant P values are shown. Challenge with LNC alone induced negligible colony formation, the mean number of colonies, regardless of preincubation, being only 0.7 ± 0.3 colonies per spleen. Ten mice per challenge group.

†Controls with no preincubation of LNC had the following values: No LNC, 16.3 ± 0.9; Normal LNC, 18.3 ± 1.9; Anti-fetal LNC, 8.8 ± 2.0 ($P < 0.005$).

immunized recipients. The data from these experiments is presented in Table 1.

There was no effect on bone marrow CFU in any of these experiments. Lymph node cells alone were shown to have negligible colony-forming capacity (Table 1, footnote *). However, both FCFU and CFU were often higher after incubation with normal LNC than in groups receiving no transfer of LNC. Enhancement of bone marrow colony formation by LNC has previously been noted, both *in vivo* [31] and *in vitro* [32]. Therefore, the statistical analysis was made between the groups receiving normal LNC (Hank's immunized) vs anti-FLC LNC (vertical comparisons in Table 1). Horizontal comparisons are included for the "No LNC" groups, showing that the fetal antigen or patient serum was not acting (at the target cell level) on the colony-forming FLC.

In the first experiment, preincubation of the anti-FLC LNC with solubilized fetal liver antigen abolished the reduction in FCFU (from 12.0 to 7.2 colonies) achieved in the presence of antigen solubilized from adult mouse liver.

Similarly, in the second experiment, preincubation of the sensitized LNC with BALB/c serum collected 24 hr after 2 daily fetal cell immunizations abrogated the reduction in FCFU (from 19.1 to 13.9 colonies) observed in the treatment with normal syngeneic serum. Controls with no pretreatment of LNC (Table 1, footnote †) showed that LNC enhancement of FCFU was independent of antigen effects, and that the preincubation of LNC with normal antigen or serum used in these experiments did not compromise the 50% reduction of FCFU achieved by sensitized LNC alone.

Since we had previously demonstrated the cross-reactive fetal antigen in human colonic carcinoma [21], serum from such a patient containing a known circulating fetal antigen was tested in experiment 3 for blocking activity against FLC-sensitized lymphocytes. The serum from a colonic cancer patient with a CEA level of 114 ng/ml (diluted 1:4 by *in vivo* absorption) was compared to normal human serum (also absorbed). The cancer patient's serum suppressed the cytotoxic action of the sensitized lymphocytes. Calculating the percent reduction in FCFU from the normal LNC control values (39% in normal serum vs 22% in patient serum), this represents a 44% blocking effect. While the reduction of FCFU by the sensitized LNC was statistically significant, the blocking effect of this patient's serum was marginal ($P<0.07$).

Therefore, a dose–response study was conducted testing sera from colonic cancer patients with varying levels of plasma CEA. Table 2 summarizes the data collated from these experiments. An inverse correlation was found between serum CEA concentration and the percent of reduction in FCFU in each experiment. Since the reduction in FCFU achieved by LNC preincubated with normal human serum in these experiments was 48–50% (data in footnote ¶), we have calculated blocking on a scale of 0–100% relative to these controls. Thus, in our assay serum containing less than 20 ng/ml of CEA was not blocking. There was a steep linear increase in blocking between 20 and

Table 2. Blocking of cell-mediated anti-fetal immunity by absorbed, heat-inactivated colonic cancer patient sera

§Lymph node cells (LNC) were sensitized to BALB/c 15-day fetal liver cells, except for experiments D and E, in which LNC were sensitized to a syngeneic plasmacytoma known to express fetal antigen.

‖The level of statistical significance as determined by Student's *t*-test is indicated as *, $P<0.05$; **, $P<0.005$; *** $P<0.001$.

¶The % blocking was calculated relative to reductions in FCFU by the LNC treated with normal human serum. The spleen colony counts with normal or anti-fetal LNC in these controls were (A + B) 10.2 ± 1.0, 6.4 ± 1.1*; (C) 16.1 ± 2.2, 9.9 ± 1.1*; (D + E) 5.8 ± 1.0, 3.1 ± 0.8*; and (F + G) 10.2 ± 1.0, 5.7 ± 0.8***.

40 ng/ml, which thereafter appeared to level off. Two patients' sera (F and G) were studied at a tenfold dilution (A and B) showing that blocking could be reduced concurrent with dilution of CEA. Dilution of the pooled normal serum (controls, footnote ¶) did not alter the percent reduction of FCFU by sensitized LNC.

To check that the blocking of cell-mediated anti-fetal immunity by patients' sera was not a toxic effect, LNC incubated with each of the human sera were tested for their ability to carry on an unrelated biological function: the graft-vs-host reaction. In either the Boranic spleen colony assay [33] or the Simonsen assay [34], none of the sera impaired the ability of either BALB/c normal or sensitized LNC to mount a GVHR in C57 mice or their BALB/c F1 hybrids. Furthermore, none of the sera reduced FCFU at the target cell level in the absence of LNC.

Reduction of fetal colony formation by the adoptively transferred LNC was equally effective whether syngeneic fetal liver or plasma cell tumor (PCT) was used to immunize the LNC donors (see controls in Table 2). In an analogous fashion, blocking of anti-fetal immunity by colon cancer patients' sera also occurred regardless of whether the effector LNC had been sensitized to tumor or fetal tissue.

In contrast to the anti-fetal capability of LNC from mice immunized with irradiated PCT, LNC from PCT tumor-bearing mice were unable to reduce fetal colony-formation (Table 3). Tumor-bearing mice were given an inoculum of PCT that causes death of the host in 15 days. LNC were obtained from these animals at either day 7 (experiments 1 and 2) or day 14 (experiment 3). In all of these experiments the tumor-bearer LNC failed to reduce FCFU while the anti-PCT^{irr} LNC consistently gave 50% reductions in fetal colonies compared to controls using normal LNC. Experiment 1 shows that after 6 washes the anti-PCT^{TB} LNC caused a 77% reduction in FCFU. This is attributed to the removal of blocking factor, since similar washing of normal LNC did not affect fetal colony formation.

An interesting observation in these experiments was that normal bone marrow colony formation was abrogated or significantly reduced when the stem cells were incubated with anti-PCT TB LNC. Since the anti-PCT^{irr} LNC did not reduce CFU, it is unlikely that this phenomenon was due to LNC sensitization to a PCT-BM cross-reactive antigen.

These experiments were conducted without any *in vitro* incubations of the LNC with blocking factors, suggesting that the anti-fetal capacity of the LNC had effectively been blocked *in vivo* in the tumor-bearing donor.

Indeed, when tumor-bearing mice were used as the recipients for the colony-forming assay (Table 4), there was no reduction in FCFU. PCT-immunized recipients again showed a 50% reduction in fetal colony formation relative to the normal controls. It must be emphasized that in this experimental setting we are detecting an antibody-mediated reduction of colonies, since the cellular immune mechanisms have been paralyzed by the lethal whole-body irradiation used to halt endogenous hematopoiesis prior to

‡PCT, plasma cell tumor; BM, bone marrow; FLC, fetal liver cells; stem cell recipients were either non-immunized, immunized with irradiated PCT or FLC, or tumor-bearing mice at day 7 after PCT inoculation.

challenge with the hemopoietic colony-forming cells.

In these experiments there was no antibody-mediated reduction in CFU in either the PCT-immunized or tumor-bearing animals. Furthermore, BM from tumor-bearers showed enhanced colony-forming capacity when transferred to normal recipients. These findings suggest that the CFU suppression in Table 3 may have been due to a radiosensitive suppressor cell, and that the existence of such a phenomenon is unrelated to anti-fetal immunity.

The failure of antibody-mediated anti-fetal immunity in the tumor-bearing mice in Table 4 is in contrast to the significant reduction of FCFU in both PCT- and FLC-immunized animals. The absence of blocking in the latter groups (7 days after immunization), as opposed to the serum blocking seen in Table 1 24 hr after fetal immunization, suggests the clearance of antigen following lysis of the immunizing cells. This process takes about 3 days after a s.c. tumor inoculation [35] and is probably faster by the peritoneal route used here. Since solubilized fetal antigen and cancer patients' sera were shown to be blocking in Tables 1 and 2, the mechanism most likely to account for the failure of both antibody-mediated and cell-mediated anti-fetal immunity in the tumor-bearing host is the persistance and release of fetal antigen by the growing tumor.

DISCUSSION

We have investigated the effect of various tumor-related factors upon the *in vivo* effectiveness of anti-fetal immunity. These experiments demonstrate blocking of cell-mediated reduction of fetal colony formation by (1) solubilized fetal antigen, (2) serum from recently immunized mice, and (3) serum from colonic cancer patients with metastatic disease. Furthermore, unwashed lymph node cells from plasmacytoma (PCT) tumor-bearing mice were shown to be ineffective mediators of cellular anti-fetal immunity, and antibody-mediated immunity was also shown to be blocked in these animals. These data are consistent with an antigen-shedding mechanism of immune-escape as proposed by Alexander [36].

Blocking of cell-mediated cytotoxicity at the effector level has been shown *in vitro* by tumor-associated [36–38] and embryonic [27, 39] antigens in animal tumor models. Poupon *et al.* [40] detected free circulating tumor antigen in the sera of plasmacytoma-bearing BALB/c mice. These sera could independently provoke a migration inhibition of immune spleen cells or block the reaction initiated by extraneous antigen. While sera from tumor-immunized mice were also blocking in their system, in the spleen-colony assay, adoptive transfer of LNC from PCT-immunized mice effectively reduced FCFU, whereas LNC from tumor bearers did not. This discrepancy could be due to route and timing of immunization, since we did observe blocking by serum of FLC-immunized mice 24 hr after immunization.

These observations become important in the current controversy of whether tumor-associated fetal antigens are involved in anti-tumor immunity. The evidence is conflicting in different animal models. Immunization with fetal cells has been reported to offer the host some protection against SV40, adenovirus, Rauscher virus, and methylcholanthrene (MCA) induced tumors [1–5]. However, transplantation resistance could not be induced in this way against

a mouse polyoma tumor or rat MCA sarcoma [7–13] except in the case of an MCA lung metastasis model [6]. In some MCA tumor systems [11, 13] fetal immunization has actually enhanced tumor growth. In the latter study, tumor enhancement also resulted when immunity was induced by embryo or tumor tissues grown in implanted diffusion chambers, suggesting a role of soluble embryonic and tumor antigens.

Various requirements have been delineated for successful anti-tumor fetal vaccination, including sex of recipients, route and timing of immunizations, irradiation, and choice of immunogen relative to parity and gestational phasing of the expression of onco-fetal gene products [22]. Given these considerations, we would suggest that it is important to determine that one has established effective *in vivo* anti-fetal immunity when evaluating the anti-tumor efficacy of a fetal vaccination regimen.

The FCFU assay has demonstrated cross reactivity between the BALB/c fetal liver hemopoietic stem cell and various animal tumors including BALB/c PCT, MSV-BALB/3T3, C57 BL/6 EL4, hamster SV40 [18], and BALB/c P 1798 [19], as well as several human tumors [20, 21]. A fetal immunization regimen that successfully reduced fetal colony formation in the FCFU assay has previously been shown to induce protection against the same BALB/c PCT tumor [2].

Reductions of FCFU by LNC sensitized to either syngeneic FLC or PCT were equally inhibited by human colonic cancer patients' sera with elevated CEA levels. The degree of blocking was correlated with CEA levels in the sera, and increased from 0 to 80% in the range of 20–40 ng CEA/ml of serum. It has not been conclusively established in these experiments that CEA or fetal antigen alone is responsible for the observed blocking, since immune complexes or unrelated active substances could be present in the sera. Data on the partial purification and characterization of the fetal liver–human tumor cross-reactive antigen have been reported elsewhere [20]. The relevant point regarding CEA is that in clinical screening studies [41], except for primary colonic or pancreatic carcinoma, Roche-CEA titers above 20 ng/ml were associated with metastatic disease, since blocking in the FCFU assay rapidly progressed above this level. In contrast, Baldwin *et al.* [42] found no correlation with CEA levels in the blocking of patients' lymphocyte cytotoxicity for human colonic carcinoma by papain-solubilized tumor antigen. This is not unexpected, since their assay system incorporated aspects of both anti-fetal and tumor-specific immunity.

Fetal colony reduction by LNC from FLC- or PCT-immunized mice could be abrogated by *in vitro* incubation of the effector cells with fetal antigen extract or with serum containing fetal antigens. Furthermore, neither antibody nor LNC from PCT tumor-bearers successfully reduced FCFU, but after 6 washes, PCT^{TB} LNC achieved the most potent anti-fetal activity seen in these experiments. These results suggested that both humoral and cell-mediated anti-fetal immunity may be blocked *in vivo* by circulating tumor-associated fetal antigen. If this anti-fetal immunity is important in host defense against cancer, then a mechanism by which the tumor would suppress the immune response might be the release of fetal antigen.

Abstract—*Flow cytometric analysis of the cellular DNA content and high pressure liquid chromatographic analysis of the cellular concentration of the polyamines putrescine, spermidine and spermine have been performed on exponentially growing populations of rat brain tumor cells following treatment with methylglyoxal-bis(guanylhydrazone) (MeGAG). This drug has previously been found to be a potent inhibitor of S-adenosyl-L-methionine decarboxylase, the enzyme that catalyzes the initial step in spermidine and spermine biosynthesis.*

MeGAG was found to inhibit cell proliferation within one generation time. During this time it produced an increase in the fraction of cells with a 2C DNA content (cells in the G_1 phase of the cell cycle). Continued accumulation of cells in the G_1 phase occurred with sustained treatment. Drug treatment also resulted in a marked decrease in the cellular spermidine and spermine concentrations. Cells did not emerge from their G_1-arrest after the addition of spermidine or fresh medium and apparently had become irreversibly blocked by the drug.

We suggest that (1) growth inhibition by MeGAG was due to depletion of the cellular pools of spermidine and spermine, and that (2) the cells accumulated in the G_1 phase of the cell cycle because of a possible requirement for spermidine and spermine during the subsequent phases (S, G_2 and M), the period during which polyamine biosynthesis and accumulation take place in continuously dividing mammalian cells.

INTRODUCTION

METHYLGLYOXAL-BIS(GUANYLHYDRAZONE, 1,1′-[(methylethanediylidene)dinitrilo]-diguanidine (MeGAG), is a synthetic compound that possesses a significant antiproliferative capacity. In a pharmacological study of this substance, Mihich [1] observed that its inhibitory effect on cell proliferation could be prevented by concurrent administration of spermidine. This fact suggested that the effect of MeGAG might be due to interference with the metabolism of the polyamines, putrescine, spermidine and spermine. The subsequent finding by Williams-Ashman and Schenone [2], that MeGAG was a very potent inhibitor of mammalian putrescine-activated S-adenosyl-L-methionine decarboxylase (EC 4.1.1.50), the rate-limiting enzyme in the synthesis of spermidine (and spermine) [3, 4] further substantiated this idea and opened a new avenue for obtaining information concerning the physiological role(s) of the polyamines.

The inhibition of putrescine-activated S-adenosyl-L-methionine decarboxylase activity in

Accepted 23 February 1977.

extracts of rat ventral prostate and yeast by MeGAG [2] has since been confirmed with enzyme preparations from many other tissues [5–10]. Some information has also been obtained regarding the effect of MeGAG *in vivo*. Thus, when studying the concentrations of the polyamines in spleens of leukemic mice as affected by treatment with various antineoplastic agents, it was observed that all the drugs tested, except MeGAG, caused decreases in the concentrations of putrescine, spermidine and spermine [11]. MeGAG-treatment resulted in decreased spermidine and spermine concentrations but in an increased putrescine concentration [9, 11]. The accumulation of putrescine was due to increased L-ornithine decarboxylase (EC 4.1.1.17) activity, i.e., increased putrescine synthesis, as well as decreased S-adenosyl-L-methionine decarboxylase activity, i.e. decreased utilization of putrescine for spermidine (and spermine) synthesis [9, 12]. Similar results were obtained from other laboratories for different experimental systems [6, 8, 13].

There is considerable evidence to suggest that the polyamines are involved in the regulation of cellular growth. The biosynthesis and the intracellular levels of the polyamines increase markedly following treatment with various growth stimuli [14–16] and then decline as the cells approach a stationary phase of growth [11, 17–19]. In fact, during the growth of a rat brain tumor cell line, polyamine biosynthesis as well as the spermidine content showed high positive correlations with the cellular growth rate [19]. Furthermore, it has been found that virus-transformed cells have a higher putrescine content than their normal non-infected counterparts despite the fact that both have similar growth rates [20].

The rate of polyamine synthesis in mammalian cells changes during the cell cycle [21, 22] and the cellular polyamine content increases markedly during the S, G_2 and M phases [23–25]. As a means of studying whether spermidine and spermine are essential for progression through these cell cycle phases we have analyzed the effect of MeGAG-treatment, i.e. spermidine and spermine synthesis inhibition, on cell cycle traverse of exponentially growing populations of rat brain tumor cells *in vitro*. The distribution of the cells among the G_1, S and G_2M phases of the cell cycle, determined by means of flow cytometry at the time when population growth had ceased due to drug-treatment, showed that the majority of the cells had accumulated in the G_1 phase of the cell cycle.

MATERIAL AND METHODS

Cell culture

Rat brain tumor cells were obtained from W. H. Sweet, P. T. Kornblith, J. R. Messer and B. O. Whitman of the Massachusetts General Hospital, Boston, Massachusetts. The brain tumor was induced in CD Fisher rats by weekly i.v. injections of N-methylnitrosourea. Cell culture and preservation methods have been described by Benda *et al.* [26]. Upon receipt, the frozen brain tumor cells were thawed and suspended in Eagle's basal medium (BME) supplemented with L-glutamine (398 mg/l), fetal calf serum (10%), and antibiotics (penicillin, 80.5 I.U./ml; streptomycin, 80.5 I.U./ml), and grown in monolayer culture according to the method for continuous cell culture described by Barker, Hoshino and Wilson [27].

Growth experiments were performed in 75 cm^2 Falcon flasks as previously described by Heby *et al.* [19]. Each flask initially contained 1.0×10^6 cells in 15 ml of BME with Earle's balanced salt solution supplemented with L-glutamine (292 mg/l), fetal calf serum (10%), BME vitamin mixture (1%), BME essential amino acid mixture (1%), and penicillin–streptomycin mixture (1%). The cell cultures were incubated at 37°C in a humidified atmosphere containing 5% CO_2.

MeGAG, dissolved in Ca^{2+}- and Mg^{2+}-free Hank's balanced salt solution (HBSS) immediately prior to the experiment, was added to cultures in exponential growth. At various times after addition of the drug, cells were harvested by trypsinization (0.25% trypsin and 0.02% Na_2EDTA in Ca^{2+}- and Mg^{2+}-free HBSS for 5 min at 37°C) and suspended in phosphate-buffered saline (PBS). To determine the number of cells per Falcon flask, an aliquot of the dispersed cell suspension was counted in a hemocytometer. Samples were then taken for flow cytometric analysis as well as for polyamine analysis.

Flow cytometric analysis

To determine the distribution of cells in the cell cycle, samples containing $1–4 \times 10^6$ cells were washed with ice-cold PBS and fixed in PBS containing 10% formalin overnight. The cells were then Feulgen-stained with the fluorescent dye acriflavine which is specific to DNA according to the method described by Gill and Jotz [28] and analyzed on the Livermore bicolor flow cytometer [29–31]. In this device the stained cells are hydrodynamically focused so that they flow at uniform velocities in single file, at rates of up to 1000 cells/sec, through an intense beam of

exciting light from an argon ion laser. The acriflavine in each cell is stimulated to fluoresce; the intensity of fluorescence is proportional to the amount of dye in the cell and is a measure of the cellular DNA content. The fluorescent light pulse from each cell is detected by a photomultiplier and converted into an electrical pulse, whose amplitude is digitized and stored in the memory of a multichannel analyzer, so that after analysis of a large number (10^6) of cells, the contents of the analyzer represents the DNA distribution of the population.

The distribution of cells among the G_1, S and G_2M phases of the cell cycle were calculated from the DNA distributions utilizing a computer-based mathematical technique [32]. The duration of each phase of the cycle could then be measured from the doubling time of the exponentially growing culture whose growth fraction was unity, assuming that the doubling time equaled the generation time and that the population age distribution decreased exponentially with age [33].

Polyamine analysis

To determine the concentration of the polyamines, the cells were sedimented by centrifugation at 500 × ***g*** for 5 min at 4°C and the cell pellet was sonicated in 10% trichloroacetic acid (approximately 200 μl per 10^6 cells). The homogenate was kept on ice for 1 hr, centrifuged at 8000 × ***g*** for 5 min, and 50 μl of the supernatant was analyzed for its polyamine content utilizing a Durrum D-500 amino acid analyzer as previously described [19]. Protein was determined according to the method described by Lowry *et al.* [34].

Chemicals

Methylglyoxal-bis(guanylhydrazone) dihydrochloride monohydrate (MeGAG) was purchased from Aldrich Chemical Co., Milwaukee, Wisconsin, and cell culture media and salt solutions were purchased from Microbiological Associates, Bethesda, Maryland and from GIBCO, Santa Clara, California.

RESULTS

Inhibition of cell proliferation by MeGAG

Rat brain tumor cells in exponential, i.e. asynchronous, growth were treated with 40 or 400 μM MeGAG and the cell number was measured as a function of time (Fig. 1). The untreated control cells grew with a population doubling time of approximately 23 hr. After the addition of MeGAG the cell number continued to increase at a rate similar to that of the control

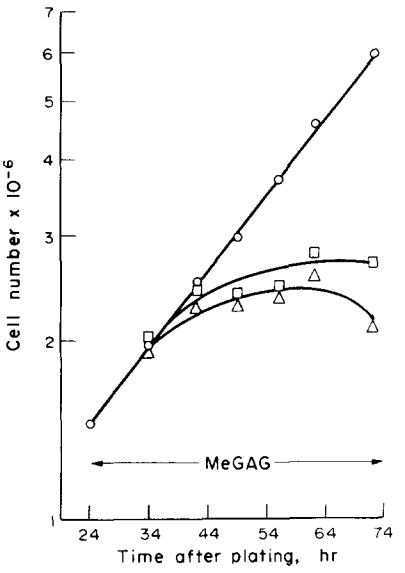

Fig. 1. Effect of methylglyoxal-bis(guanylhydrazone) on proliferation of rat brain tumor cells in vitro. *Methylglyoxal-bis(guanylhydrazone) (MeGAG) was added to exponentially growing cells, i.e.* 24 hr *after plating of* 1.0×10^6 *cells;* (○) *untreated cells;* (□) *cells treated with* 40 μM *MeGAG;* (△) *cells treated with* 400 μM *MeGAG.*

cells for about 18 hr, after which time it became almost constant. Drug concentrations lower than 40 μM reduced, but did not stop, cell proliferation after a lag of about one cell generation time (not shown). At a 400 μM concentration the drug caused a marked cell death after 48 hr.

After 24 hr of treatment most of the cells were permanently blocked from progressing through the cell cycle; cell proliferation did not resume upon resuspension in fresh growth medium or in fresh medium containing 2 mM spermidine. In the latter experiment, the cells were grown in a medium supplemented with 10% horse serum instead of fetal calf serum to avoid possible oxidation of the added spermidine. Amine oxidases which are present in bovine sera, but not in horse serum, may convert extracellular polyamines into toxic aldehyde derivatives, which may have an adverse effect on growth [35].

Accumulation of cells in the G_1 phase of the cell cycle after treatment with MeGAG

To reveal any possible cell cycle phase specificity of MeGAG, we analyzed the cellular DNA content in populations of rat brain tumor cells growing *in vitro* at various times after drug-treatment. Exponentially growing cells were treated with 40 μM MeGAG for 20, 30 and 45 hr. The cellular DNA content was determined utilizing a flow cytometric technique

[29] and the distribution of the cells among the G_1, S and G_2M phases of the cell cycle was estimated by computer analysis according to the method of Dean and Jett [32].

Figure 2 shows the fraction of cells in the G_1 phase of the cell cycle at various times after the addition of the drug. After 20 hr of treatment, the cell cycle distribution differed significantly from that of the untreated control cultures; the G_1 fraction had increased by 15%. The G_1 fraction increased continuously during the 45-hr treatment-period studied; by 30 hr it was 31% and by 45 hr 42% greater than in untreated control populations. In parallel with the increase in the fraction of cells in G_1 there was a decrease in the fraction of cells in S and G_2M. During the experimental period studied, the fraction of cells in G_1 decreased slightly in the untreated control populations.

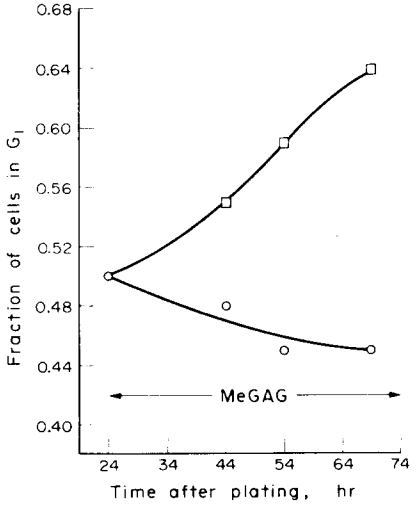

Fig. 2. Kinetics of the perturbation in cell cycle distribution following methylglyoxal-bis(guanylhydrazone)-treatment. Methylglyoxal-bis(guanylhydrazone) (MeGAG) was added to exponentially growing cells and flow cytometric analysis of the cellular DNA content was performed at various times after the addition. The distribution of cells among the G_1, S and G_2M phases of the cell cycle was calculated from the DNA distributions utilizing a computer-based mathematical technique [32]; (○) untreated cells; (□) cells treated with 40 μM MeGAG.

To study whether the cells blocked in G_1 would be able to enter the S phase upon removal of the drug, fresh medium (with and without 2 mM spermidine) was added to brain tumor cells treated for 20 hr with 40 μM MeGAG and the composition of the cell population was followed every second hour by flow cytometric analysis. No progression of cells into the S and G_2M phases was observed and it may be concluded that when cell proliferation has ceased due to MeGAG-treatment a permanent block, mainly in the G_1 phase, is imposed on the cells.

Assuming that the rat brain tumor cells, whose growth fraction was unity, had a population doubling time (23 hr) that was identical with the cell cycle time, the phase durations of untreated control cells were approximately 9.5, 9.4 and 4.1 hr, respectively, for G_1, S and G_2M (see experimental procedures). These phase durations are similar to those obtained by analysis of fraction of labeled mitoses curves derived from cells grown under the same conditions.

Accumulation of putrescine and depletion of spermidine and spermine in cells treated with MeGAG

Immediately following the addition of MeGAG, the putrescine concentration increased; by 10 hr it was maximal and twice that of untreated control cells (Fig. 3). Shortly thereafter the putrescine concentration decreased and approximately 25 hr after the addition of the drug it was below the control level.

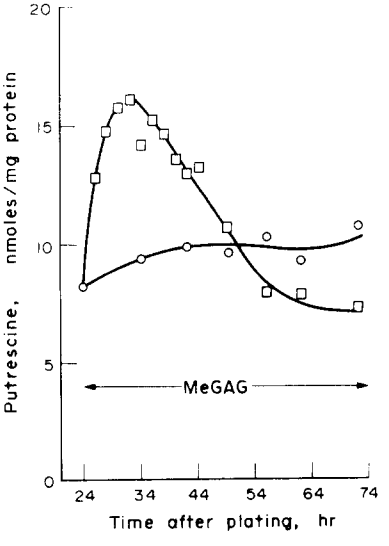

Fig. 3. Effect of methylglyoxal-bis(guanylhydrazone) on putrescine concentration in rat brain tumor cells. Methylglyoxal-bis(guanylhydrazone) (MeGAG) was added to exponentially growing cells and high-pressure liquid chromatographic analysis of the cellular polyamine concentration was performed at various times after the addition: (○) untreated cells; (□) cells treated with 40 μM MeGAG.

In contrast to the increase in putrescine concentration, there was a decrease in the cellular spermidine and spermine concentrations (Fig. 4). The spermidine and spermine concentrations started to decrease immediately following the addition of MeGAG, which shows that the drug rapidly passed the cell membrane. About 18 hr after the addition of the

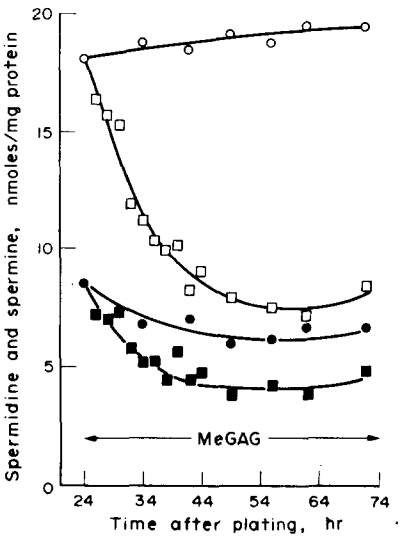

Fig. 4. Effect of methylglyoxal-bis(guanylhydrazone) on spermidine and spermine concentration in rat brain tumor cells. Methylglyoxal-bis(guanylhydrazone) (MeGAG) was added to exponentially growing cells and high-pressure liquid chromatographic analysis of the cellular polyamine concentrations was performed at various times after the addition: (○, ●) untreated cells; (□, ■) cells treated with 40 μM MeGAG. (Top) Spermidine; (Bottom) Spermine.

drug the cellular spermidine concentration had decreased by 50% and that of spermine by 35% relative to their controls. The lowest concentrations obtained were only 35 and 57% of the control levels for spermidine and spermine, respectively.

DISCUSSION

MeGAG inhibits growth of many experimental tumors, e.g. L1210 lymphoid leukemia [1, 11, 36–38] and sarcoma 180 ascites tumor [37]. It also has clinical activity against acute myelocytic leukemia [39–44] and various other cancer forms [39, 41, 42, 45–47]. However, these effects have only been established through survival studies on tumor-bearing mice and on patients treated with MeGAG. Thus far there have been no reports in the literature concerning the time required before population growth is arrested by treatment with this drug. To determine the duration of this possible lag period, we studied the proliferation of exponentially growing rat brain tumor cells following treatment with MeGAG.

The rat brain tumor cells used, which have a cycle time of 23 hr, ceased to divide about 18 hr after the addition of the drug, i.e. before the entire population had doubled (Fig. 1). In view of the fact that MeGAG affects the metabolism of the polyamines within 2 hr (Figs. 3 and 4) we consider it unlikely that the lag time is the result of a slow rate of uptake of the drug. Furthermore, MeGAG has been found to accumulate rapidly in a large variety of cells [48, 49].

The fact that the growth curve showed no effect of MeGAG for 18 hr does not necessarily imply that the cells took this long to respond to the drug. Flow cytometric data show that there is almost an immediate effect on cell cycle traverse; cells begin to accumulate in the G_1 phase of the cell cycle. This suggests at least a partial block in the G_1 phase, and the cells which have passed this stage will complete the cycle and eventually become blocked in G_1 of the subsequent cycle. Thus, the growth curve will not reflect the block for many hours (18 hr) but the fraction of cells in G_1 will respond immediately.

These results are at variance with those obtained by Fillingame, Jorstad and Morris [50] on concanavalin A-stimulated lymphocytes. Their data suggest that cells progress normally from G_0 through G_1 and into S, but that there is a prolongation of the S phase in the presence of MeGAG. Possibly, the fact that only a partial block (60% inhibition of DNA synthesis and cell division) was obtained and that the total polyamine content was unchanged in the lymphocyte cultures may explain their different kinetic behavior. However, no satisfactory explanation for these discrepancies can be given at the present time.

At the time when the rat brain tumor cells had ceased to divide due to MeGAG-treatment there was a residual S and G_2M population (Fig. 2). The presence of these cells, not blocked in G_1, might be explained by the following possibilities: (1) they may have escaped from the G_1 block and this could be an infrequent but regular phenomenon, (2) they may represent a subclass that is drug-resistant, (3) they may be dying, and/or (4) they may be subject to a secondary block in another part of the cell cycle. None of these possibilities can be definitely excluded at the present time, however. The fact that cells which had been subject to 24 hr drug exposure were unable to cycle normally upon resuspension in fresh growth medium suggests that the majority of the cells were irreversibly blocked and that these cells might eventually die. In contrast to this, the effect of MeGAG on phytohemagglutinin-stimulated lymphocytes could be reversed by washing the cultures free of the drug. However, this reversal took place only during the first 24 hr following its addition, the time during which the lymphocytes had not yet replicated their DNA [7].

During the first 20 hr of treatment with MeGAG the spermidine and spermine concentrations decreased by 65 and 43%, re-

spectively, whereas the putrescine concentration showed a 100% increase and a subsequent decline to the control level (Figs. 3 and 4). Inasmuch as low concentrations of MeGAG appear to exert no direct inhibitory effect on events such as DNA, RNA and protein synthesis [13, 51] but rather specifically inhibit spermidine and spermine synthesis, it seems likely that the marked decrease in spermidine and spermine concentration (as a result of the drug treatment) is the direct cause of the cell cycle arrest. Thus, the intracellular concentration of these compounds may be critical for cell cycle traverse. Since the ensuing G_1 block was irreversible, the spermidine and spermine deficiency appears to have introduced errors in the reproductive apparatus. In fact, during polyamine-starvation of polyamine-deficient mutants of *E. coli* apparent aberrations in chromosome replication [52] and in phage DNA synthesis [53] have been observed.

We have previously shown that polyamine synthesis increases markedly during two discrete phases of the cell cycle; immediately before DNA replication and before division [22, 25]. This finding indicates the phase(s) of the cell cycle during which the polyamines may exert their effect(s). Our present observation that the polyamine-depleted rat brain tumor cells are primarily blocked in the G_1 phase of the cell cycle suggests that DNA replication in particular may require spermidine and spermine. The possible requirement of polyamines for DNA synthesis is also indicated by other reports. Kay and Pegg [7], Fillingame and Morris [13], Otani *et al.* [54] and Fillingame *et al.* [50] observed that when MeGAG was added to lymphocyte cultures at the same time as the transforming agent (phytohemagglutinin or concanavalin A) the stimulation of DNA synthesis some 48 hr later (incorporation of ^{3}H-thymidine into DNA) was almost completely inhibited. However, the drug had less of an inhibitory effect when added at a later time, and when added during the DNA synthetic period the drug did not have any effect on DNA replication [50, 54]. These observations could be partly due to drug-interference with the transforming agent. However, in view of the present findings it seems likely that the effects observed are due to polyamine depletion.

Even though MeGAG can effectively inhibit DNA polymerase *in vitro* at mM concentrations [51] it does not seem likely that DNA synthesis proper is affected by the concentrations used in most studies. RNA and protein synthesis also appear to proceed unabated in the presence of the drug. In concanavalin A-stimulated lymphocytes, the RNA that accumulated in the presence of MeGAG (in the absence of spermidine and spermine accumulation) was qualitatively and quantitatively indistinguishable from that obtained in the absence of the drug (in the presence of spermidine and spermine accumulation) [13]. The reduced rate of ^{3}H-uridine and of ^{14}C-phenylalanine incorporation into RNA and protein observed by Kay and Pegg [7] in transforming lymphocytes was probably due to secondary, pharmacological effects of the high doses used, since Fillingame and Morris [13], who used much lower doses of MeGAG, observed a normal accumulation of RNA and protein in the absence of spermidine and spermine accumulation.

In view of these findings, it seems likely that depletion of the cellular spermidine and spermine content was the direct cause of the inhibition of DNA replication and cell division. The present work demonstrates through kinetic analysis that cells exhibiting exponential growth (continuously dividing) at the time of addition of MeGAG lose their capacity to synthesize DNA and to divide. As previously mentioned it was not possible to reverse the effect by washing out the drug with fresh growth medium when the rat brain tumor cells had ceased to divide as a result of treatment with MeGAG, nor was it possible to reverse the effect of the drug by adding spermidine. In experiments in which spermidine or spermine was added at the same time as MeGAG [1, 7, 54] or within 24 hr, i.e. before DNA synthesis [50], drug action was found to be completely reversible, but the later the addition of spermidine the less pronounced was its effect [54].

The inhibitory effect of a single injection of MeGAG on spermidine synthesis has been shown to persist for maximally 20 hr in the liver and kidney of the rat. This period was not sufficient to produce a large decrease in the tissue spermidine concentration [6, 8]. In fact, only a minor decrease in spermidine concentration can be expected to occur within this time period even after complete inhibition of spermidine formation since spermidine is catabolized very slowly (half-life of 4–5 days in the liver). Within the same time period in a proliferating cell system, represented by the exponentially growing rat brain tumor cell culture, the spermidine and spermine concentrations decreased by 50 and 35%, respectively (Fig. 4). This is the first occasion where a marked decrease has been observed in these parameters upon MeGAG-treatment. This decrease is due mainly to the fact that a large number of cells were able to go through one division in the absence of spermidine and spermine synthesis, thus decreasing

the cellular concentrations of these polyamines accordingly. The difference in rate of decrease between spermidine and spermine may be related to the fact that spermine is catabolized more slowly than spermidine. If the half-lives of the polyamines are as long as previously indicated one would expect that after the cells had stopped dividing the spermidine and spermine concentrations would be almost constant. Indeed this was the case in the studies we have described.

In a recent publication, Mamont *et al.* [55] reported that (DL)-α-methyl ornithine, a potent competitive inhibitor of L-ornithine decarboxylase, blocks DNA synthesis and cell proliferation of rat hepatoma cells in culture. This finding lends further support to the concept that polyamines play an essential role in the traverse of the cell cycle.

Therapeutic Controlled Trial in Ewing's Sarcoma

Report on the Results of a Trial by the Clinical Cooperative Group on Radio- and Chemotherapy of the E.O.R.T.C.

J. M. ZUCKER* and M. HENRY-AMAR†

**Institut Gustave-Roussy—94800 Villejuif, and*
†Unité de Recherches Statistiques—94800 Villejuif, France

Abstract—*Sixty-five patients, 1–25 yr old, have been included between 1965 and 1972 in a therapeutic controlled trial comparing radiotherapy alone, to radiotherapy plus a chemotherapy giving one course of phenylalanine mustard, followed by continual administration of small doses of cyclophosphamide for at least 2 yr.*

The disease-free survival, chosen as criterion, was the same in both arms. No statistical significant difference was found in the prognosis, according to age, pathological subtype or localisation.

A much more aggressive chemotherapy is now being tested in Ewing's sarcoma with promising early results.

INTRODUCTION

In spite of its good local curability, Ewing's sarcoma keeps a bad prognosis, due to early dissemination in lungs and bones [1, 2]. The trial described below was an early tentative to evaluate the effect of chemotherapy, in addition to local radiotherapy for these patients.

The trial, sponsored by the E.O.R.T.C. (radiotherapy and chemotherapy group) has been run between June 1965 and June 1972 for inclusion of patients.

Three Centers participated:

—Institut Gustave-Roussy, Villejuif/Paris (Coordinator: Dr. O. Schweisguth).

—Rotterdam Radiotherapeutisch Institut, Rotterdam/The Netherlands (Coordinator: Prof. B. Van der Werf Messing).

—Antoni Van Leeuwenhoek Ziekenhuis, Netherlands Cancer Institute, Amsterdam/The Netherlands (Coordinator: Prof. K. Breur).

MATERIAL AND METHODS

1. Criteria for inclusion in the trial were the following:

—localized Ewing's sarcoma in any site (primary in the rib with pleural effusion were excluded).

—absence of contra-indication, by clinical, geographical or haematological status, to long term chemotherapy.

—Pretreatment evaluation including:

X-rays of primary tumor, skeleton and lungs.

Bone marrow examination.

Complete blood count and sedimentation rate.

VMA and HVA urinary excretion.

—Histopathological diagnosis, reviewed by a board of pathologists*.

Included diagnoses were typical Ewing's sarcoma, atypical or uncertain Ewing's sarcoma, reticulum cell sarcoma of bone. Five "other" cases, which the board did not consider to belong to one of these groups, were still included, because they were considered as Ewing or reticulum cell sarcoma by the local pathologist.

Accepted 22 February 1977.

*Dr. R. Van der Heul and Dr. R. Blaché.

2. Local treatment was the same in both arms of the trial: radiotherapy with a cobalt Unit to the whole of the involved bone, including soft tissue tumor and, if necessary, the adjacent joint. The given dose was 6000 rads in 6 weeks and 30 fractions, to the long bones. To short and flat bones, a dose of 4000–4500 rad was delivered to the whole of the bone with a boost of 1000–2000 rad on a smaller vol including the tumor itself. Doses for all patients are shown in Fig. 1.

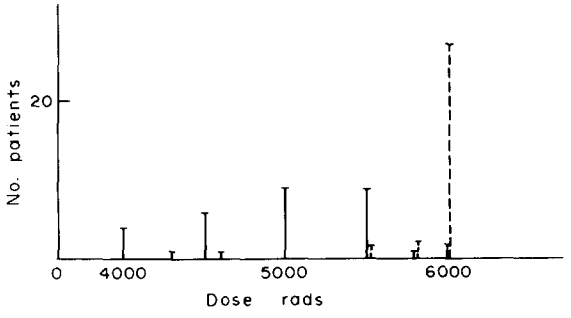

Fig. 1. Radiotherapy of the primary tumor. Doses in rad. ——— *34 flat and short bones (1 dose unknown).* – – – – *31 long bones (1 dose unknown).*

Randomization into 2 groups took place half way during the course of radiotherapy of the primary, so after 3000 rad: 1—no chemotherapy (C−) 2—adjuvant chemotherapy (C+).

Chemotherapy consisted of a course of 0.2 mg/kg/day for 10 days of phenylalanyl mustard. After recovery of haematological depression, cyclophosphamide, 2 mg/kg every other day, was given in the long run for at least 2 yr, or until relapse, without serious toxicity.

Clinical and radiological work-up were done at 2, 4, 6, 9, 12, 18 and 24 months after randomization, then every six months.

Recurrence-free survival was chosen as the comparative criterion.

3. Seventy-four patients, 1–25 yr old, were randomized during this 7 yr study (Table 1). Nine cases were excluded afterwards: in 6, metastases occurred during the course of radiotherapy (3 in each arm); in 3 there was pleural effusion complicating a rib tumor (C-arm).

Table 2 shows the repartition of patients by Center, and Table 3 by site of the primary tumor. Sex ratio, and mean age at diagnosis did not differ in both arms: the mean age in group C− was 11 yr and in group C+ 13 yr.

Nevertheless, there were more patients younger than 10 in the (C−) arm, than in the (C+) arm ($P<0.05$) (Table 4). No explanation could be detected for this difference, nor any cause for selection found.

Table 1. Distribution of the 65 patients

	Rx	Rx+C	Total
No. of randomized patients	36	38	74

Rx+C	8 (36%)	24 (62%)	3	35
Total	22	39	4	65

Histopathological repartition is given in Table 5. Diagnosis in Ewing's sarcoma can be difficult, specially if biopsy material is not technically perfect which happens if patients are referred to the Centers after biopsy. In our previous experience in children, as well as in others [3, 4] natural history of the disease as well as prognosis is similar in reticulum cell sarcoma and in Ewing's tumor. In this trial, different types are evenly distributed in both arms. Two out of three of cases are reported as typical Ewing's sarcoma.

Table 5. *Distribution of the patients by histopathology*

	Typical Ewing	Atypical Ewing	Uncertain Ewing	RS	Other	Total
Rx	17 (41%)	4	2	3	3	29 (45%)
Rx+C	24 (59%)	2	1	6	2	35 (55%)
Total	41	6	3	9	5	64
						Unknown = 1

RESULTS

Seventeen out of sixty-five patients remain in first remission after 3–10 yr.*

As shown in Fig. 2, recurrences are evenly distributed in both arms of the trial and the disease free survival curve is the same. Table 6 gives the site of recurrence, known in 43/48 cases.

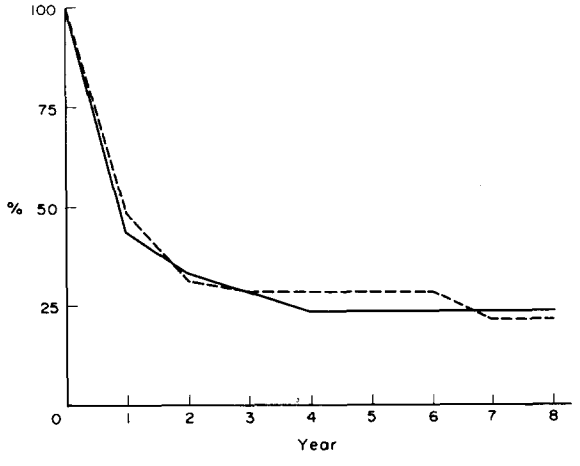

Fig. 2. *Disease-free survival.* ——— *Without chemotherapy* (30 *cases*) – – – – – *With chemotherapy* (35 *cases*).

Local relapse occurred in 6 children. Table 7 shows in these cases the site of primary tumor and the dose of radiation to the tumor. It must be noticed that only two long bone tumors relapsed despite a 6000 rad dose. Other cases were located in ribs, iliac bone and vertebra, where radiotherapy to high dose is more difficult to achieve.

Table 6. *Site of the* 48 *recurrences*

	Rx	Rx+C	Total

M. Pierre	$15\frac{1}{2}$	Humerus	6000	20
H. Julie	19	Pelvis	4000	4

Fifty-five percent of the metastases were detected in the 1st yr, 68% into 2 yr, the longest interval in the group being 33 months.*

Figures 3, 4 and 5, indicate the survival rates according to age, site and pathological type, neither of them showing significant differences.

As shown in Fig. 6, comparing disease-free survival and survival, death occurs rather rapidly after relapse in most of the cases. Metastatic patients have been treated with more powerful chemotherapies without a significant prolongation of life.

DISCUSSION

The clinical trial as performed by our cooperactive group, indicates that an adjuvant chemotherapy regimen with phenylalanyl mustard and cyclophosphamide in the time and dose schedule as described, failed to improve prog-

*Since the writing of this paper two other patients have relapsed:
1 local recurrence at 57 months (C–),
1 mediastinal nodes metastases at 38 months (C+),
2 have disclosed an osteogenic sarcoma in an irradiated area after 10 and 11 yr (2 C+).

nosis of patients suffering from clinically localized forms of Ewing and reticulum cell sarcomas.

This trial was designed 12 yr ago. With our present knowledge, it is obvious that this form of chemotherapy is inadequate, both with regard to dose and choice of the drugs.

Since 1972 it has become general practice to administer more active multiple drug chemotherapy to these patients [5–9].

The small number of cases included in 7 yr with 3 active Centers shows the difficulty, in that sort of very rare tumor, to gather a sufficient number of patients to carry through a randomized trial in a few years.

Regarding the local treatment, the type of radiotherapy given to our patients with an homogeneous protocol, shows its efficacy in 90% of the cases (6/65 local relapses). It has also given an apparent cure in 25% of the children. The price is an important growth disturbance in these patients, most of them being children in active stage of growth.

In this group of young patients, we can also confirm that there is no evolutive difference between the distinctive patterns of Ewing's Sarcoma and the so called reticulum cell sarcoma of bone.

The whole group of the patients in this trial has been treated locally in a very homogeneous and satisfactory way, and we don't expect to change local treatment [10, 11]. Since a few years, pilot studies were performed by members of our group applying for these cases cyclic multiple drug chemotherapy (Vincristine, Cyclophosphamide, Adriamycin and Procarbazine) in high dosage during 18 months, following the same local treatment with radiation. In view of

the rarity of these tumors, it seems admissible to use the data of this trial as a historic series for matched comparison. Thirty children have already been included in this current historical trial since March 1973. In June 1976, 18 of them (60%) had no evidence of disease 3–38 months after the beginning of treatment (median: 25 months). These early results seem to be promising [12] since the difference between disease free survival curves of the two series is significant up to 30 months.

Relationship Between Tumour Growth Rate and Proteic Variations in Interstitial Subcutaneous Fluid and Serum: Possible Thymic Control*

D. VAILLIER, J. VAILLIER and P. BISCHOFF

Unit of Experimental Cancerology, INSERM—U. 95, Plateau de Brabois, 54500, Vandoeuvre, France

Abstract—*Some murine tumours stimulate the proliferation of target cells in diffusion chambers implanted subcutaneously near the tumour. The growth of tumours with or without the property to stimulate the proliferation of target cells was studied in relation to the proteic variations in interstitial subcutaneous fluid and serum in normal hosts and thymectomized or thymus-deprived hosts.*

"Stimulating" tumours were found to exhibit a much faster growth than "non stimulating" tumours, in normal hosts. A significant protein decrease was observed in interstitial fluid of mice bearing "stimulating" tumours as compared to control mice.

In contrast, the analysis of interstitial fluid and serum of mice bearing "non stimulating" tumours revealed a significant proteic increase.

The study of the growth behaviour of these tumours in T-cell deprived mice revealed a deceleration of the "stimulating" tumours, and a heavy acceleration for the "non stimulating" tumours. No proteic variation as compared to control mice was found in interstitial fluid and serum of tumour bearing T-cell deprived mice.

The hypothesis was formulated that some relationship exists between tumour growth rate and proteic variations in interstitial subcutaneous fluid and serum which might be under thymic control.

INTRODUCTION

In a previous work, it was found that tumour cells in diffusion chambers implanted close to some chemio-induced tumours of mean size proliferated more rapidly than in control mice. Other tumours do not show this stimulation phenomenon [1]. The analysis of interstitial fluid near these "stimulating" tumours has shown a proteic decrease, but no notable variation in the serum nor in the interstitial fluid of "non stimulating" tumours [2].

It seems of interest to correlate "stimulating" or "non-stimulating" tumours with their growth *in vivo* and with proteic variations in interstitial fluid and serum, extending the previous study to the larger tumours.

Furthermore, several investigators have reported that most of the tumours grow significantly faster in normal mice than those in thymus-deprived mice [3, 4]. This was demonstrated to be due to the lack of normal T cell function in these animals and it may be concluded that T cells are required for an optimal growth of the tumours. Existence of T-lymphocyte inhibitors has been found in the serum of tumour-bearing mice [5].

In this paper, we study the growth of two "stimulating" and two "non-stimulating" tumours in normal and T cell-deficient mice according to proteic variations in interstitial subcutaneous fluid and serum.

MATERIAL AND METHODS

Animals

C3H/He and CBA mice were obtained from breeding colonies in our laboratory, as were the nu/nu mice of Balb/c background.

Accepted 24 February 1977.
*This work was supported by a grant from INSERM (ATP 11-74-32).

C3H/He and CBA mice were used when 2 or 3 months old, nu/nu mice when 4 or 6 weeks old.

ATXBM mice (adult, thymectomized, irradiated, bone-marrow reconstituted mice) were also used. They were thymectomized when 1 month old, lethally irradiated (850 R) 1 month later, and reconstituted by i.v. injection of 10^7 bone–marrow cells; they were used 1 month later.

Tumours

The tumours were rhabdomyosarcomas induced by intramuscular injection of methylcholanthrene. RV2 and VMM2 tumours, induced in C3H males, were respectively used from graft-passage 100 to graft-passage 115 and from graft-passage 42 to graft-passage 55. MC2 and MC3 tumours, respectively induced in CBA males and CBA females were used from graft-passage 16 to graft-passage 26.

Growth of the tumours

Comparison of the tumour growth was made after a s.c. injection of 10^5 tumour-cells, or of 1 mm^3 of calibrated tumour-fragment, varying with the experiments, in groups of 10 mice. The tumours developed in 100% of the animals. Tumour size was measured with a vernier caliper. The largest diameter and the diameter perpendicular to the largest one were determined and the average was recorded. The measurements were stopped when the first animal of each group died.

Collection of interstitial s.c. fluid and serum

The interstitial s.c. fluid was collected by means of diffusion chambers which were constituted by a plexiglass ring limited by two Millipore filters of 0.1 μ porosity. The diffusion chambers were impermeable to cellular penetration. In our experiments, they were filled with culture medium and were s.c. inserted into the back, close to the tumour of mean dia 25 mm also into the backs of the normal mice. Five days later, the chambers were removed and liquids were collected. Blood was collected from the retro-orbital sinus of normal and tumour-bearing mice. It was allowed to clot overnight at 4°C; serum was then separated and centrifuged.

Determination of the protein amounts

Total protein content of the interstitial fluid and the serum was determined according to Lowry's method [6] using crystalline bovine serum albumin as a standard.

Polyacrylamide gel electrophoresis

Serum and interstitial fluid were subjected to electrophoresis on gradient gel slabs. The electrophoresis was performed with a Uniscil Electrophoresis Apparatus UE4 from Universal Scientific Ltd., London, U.K., loaded with four Gradipore polyacrylamide gradient gels (2.5–28%) from Gradient Pty, Ltd., Sydney, Australia. The gel slabs were prerun for 15 min at 125 V (constant voltage) to remove any excess catalyst. After the application of the samples (5 μl mixture made of 10 μl serum or interstitial fluid in 25 μl sucrose), six samples per gel slab, the gels were run first at 70 V during 20 min and then at 130 V for 15 hr. The buffer temperature was maintained at 14–15°C. The gel slabs were then stained during 30 min in 0.7% Amidoblack 10B in 7% acetic acid and destained in a Uniscil destainer apparatus UDSI. The gel slabs were scanned with a Vernon photometer integrator (42, rue des Haies, 75020 Paris, France).

Protein identification

Albumin was localized in regard to the position of the mouse albumin-purified protein. To identify the transferrin after electrophoresis, the gel slab was sliced into two parts. One part was stained and then juxtaposed the other part. The supposed transferrin fraction was sliced with a razor blade and elution from the gel section was made by electrophoresis. After concentration, the protein was identified by immunoelectrophoresis against a rabbit antimouse transferrin specific anti-serum from Cappel Laboratories.

RESULTS

Comparison of the growth-curves of "stimulating" and "non stimulating" tumours

The growth of tumours which do or do not possess a stimulating action on target cells put in diffusion chambers has been studied. Groups of 10 mice were inoculated s.c. with 10^5 syngeneic tumour-cells. Four host–tumour systems were studied: C3H male-RV2 tumour, C3H male-VMM2 tumour, CBA male-MC2 tumour and CBA female-MC3 tumour. The mean diameter of tumours of 10 mice of each group $\pm$ S.E. is given in Fig. 1 according to the number of days after the graft.

A significant difference exists between the growth-rate of RV2 and MC3 with respect to that of MC2 and VMM2. RV2 and MC3 which are "stimulating" tumours have a faster growth-rate than MC2 and VMM2 tumours which are "non stimulating" tumours.

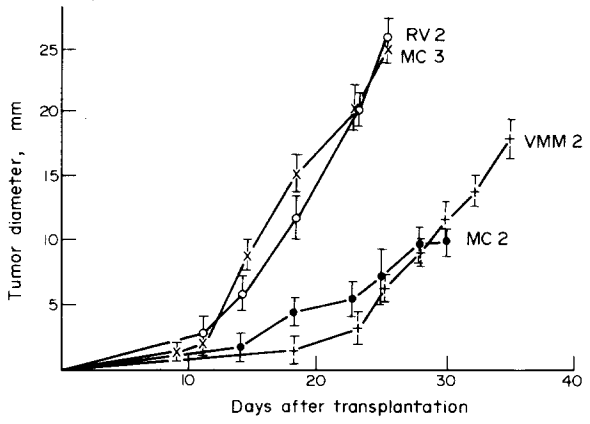

Fig. 1. Growth curve of the tumours MC2 ●, MC3 ☆, VMM2 ★, RV2 ○ in syngeneic system after a subcutaneous injection of 10^5 tumor cells. Each point represents the mean tumor diameter for a group of 10 mice ± S.E.

Variation of protein quantities in interstitial s.c. fluid and in serum of normal and tumour-bearing mice

The 4 host-tumour systems previously described have been tested. For each experiment, electrophoresis of interstitial fluid of 3 normal mice and 3 mice bearing tumours (of mean diameter 25 mm) were made on the same polyacrylamide gradient gel slab. Four experiments gave similar results. Figure 2 reproduces the curves obtained after scanning of the gel slabs of interstitial fluid of a normal CBA and of MC2- and MC3-tumour-bearing CBA's. Four main zones were noted. Zone C contained predominantly transferrin followed by α-globulins. Zone D contained albumin and pre-albumin. For the MC2 tumour, a large increase was observed in zones A and C. Similar results were found for the VMM2 tumour. By contrast, for the MC3 tumour, a decrease of proteins in the same zones was observed with similar results for the RV2 tumour.

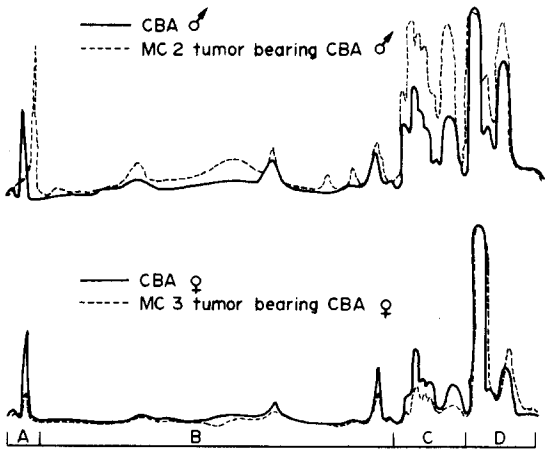

Fig. 2. Superimposed curves of polyacrylamide gradient gel electrophoresis of the interstitial fluid of normal mice and tumour-bearing mice: diameter 25 mm.

Identical work was performed with the serum. An increase of proteins was found for MC2 and VMM2 tumours and a decrease for RV2 and MC3 tumours. Figure 3 reproduces the curves obtained after scanning of the gel slab of serum of normal CBA and of MC2- and MC3-tumour-bearing CBA's.

It can be seen that the changes are more considerable in interstitial fluid than in serum. Indeed, for serum, in all experiments, no notable variation was found for zone A but only for zone C.

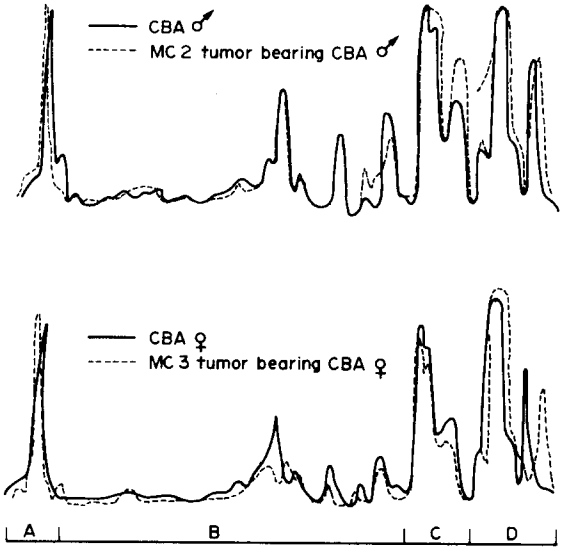

Fig. 3. Superimposed curves of polyacrylamide gradient gel electrophoresis of the serum of normal mice and tumour-bearing mice: diameter 25 mm.

As it was difficult to quantify these observed differences with the electrophoresis technique, an estimate of total proteins in the serum and interstitial liquid of all tested systems has been made according to Lowry's method [6]. Protein amounts of groups of 6 control mice and 6 tumour-bearing mice having mean tumour dia 25 mm have been calculated according to Lowry's method [6]. The mean quantity of proteins in g/100 ml ± S.E. has been recorded for each group of 6 mice and Student's *t*-test has been made to compare results obtained on control and tumour-bearing mice. Results are given in Table 1 and they show good correlation with those found with the electrophoresis method. In interstitial fluid of RV2 and MC3 tumour-bearing mice, there was a significant decrease of proteins with respect to control mice and an increase for MC2 and RV2 tumour systems. Differences were also observed for serum but they were only significant in serum of "non stimulating" tumour-bearing mice.

These results corroborate those previously

*Mean amount of proteins in g/100 ml ± S.D. contained in interstitial fluid and serum of 6 normal mice and 6 tumour-bearing mice (mean tumour diameter 25 mm).
†Statistical differences between normal mice group and tumour-bearing mice group are evaluated by Student's *t*-test.
‡NS: not significant.

published [2], i.e. a decrease of proteins in interstitial fluid of mice bearing "stimulating" tumours. Extending the investigations to large tumours, a significant increase of proteins in interstitial fluid and serum is revealed in "non stimulating" tumours.

Influence of "stimulating" and "non stimulating" tumours on the tumour growth in vivo

To demonstrate a direct relationship between tumour growth and proteic variations in interstitial fluid, we wanted to see first whether the growth of "stimulating" tumours was influenced when they were implanted in mice bearing a "non stimulating" tumour, and second, whether the growth of "non stimulating" tumours was also influenced by their implantation in animals bearing "stimulating" tumours. For this purpose, the following experiments were carried out. A ten CBA ♀ mice group was subcutaneously grafted with a 1 mm^3 fragment of MC3 tumour in the tail direction. When the mean tumour diameter reached 10 mm, a 1 mm^3 fragment of MC2 tumour was injected in the head direction in the same mouse and in the 10 control mice. Similar experiments were performed with MC3 tumour grafted in MC2 tumour-bearing mice and control mice. The growth curves of MC2 and MC3 tumours in normal and MC3 and MC2 tumour-bearing mice respectively, are recorded in Fig. 4. When mice carried the MC3 tumour, the growth of the MC2 tumour was significantly accelerated as compared to that of the control ($0.05<P<0.001$). On the contrary, when mice carried the MC2 tumour, the growth of the MC3 tumour was slowed down ($0.05<P<0.01$).

It is possible to hypothesize that the protein

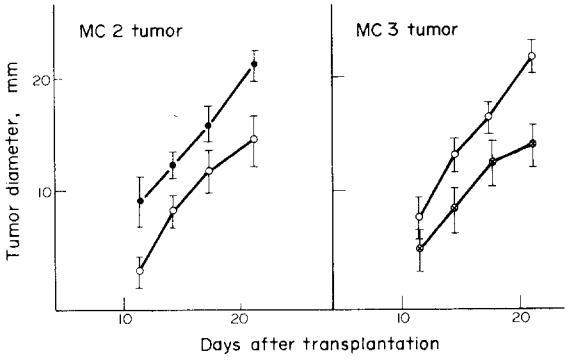

Fig. 4. Growth of MC2 and MC3 tumours grafted in normal CBA mice (○), and respectively in MC3 (●), and MC2 (⊗) tumour-bearing mice.

decrease in interstitial fluid of MC3 tumour-bearing mice may induce an acceleration of MC2 growth; the increase of proteins in the interstitial fluid of MC2 tumour bearing mice may induce a slowing down of MC3 tumour growth.

Tumour growth in normal and T cell deprived mice

Groups of 10 mice were s.c. inoculated with a 1 mm^3 calibrated fragment of tumour. Each previously described tumour was grafted in 3 animal groups, syngeneic control animals, thymectomized reconstituted syngeneic animals and nu/nu mice.

The mean diameter of the tumours of each group is given in Fig. 5 as a function of the number of days after the graft. The Student's *t*-test has shown a significant slowing down for MC3 and RV2 tumour growth in T cell of deprived mice with respect to that of normal animals after a 15-day post-graft period ($0.05<P<0.001$).

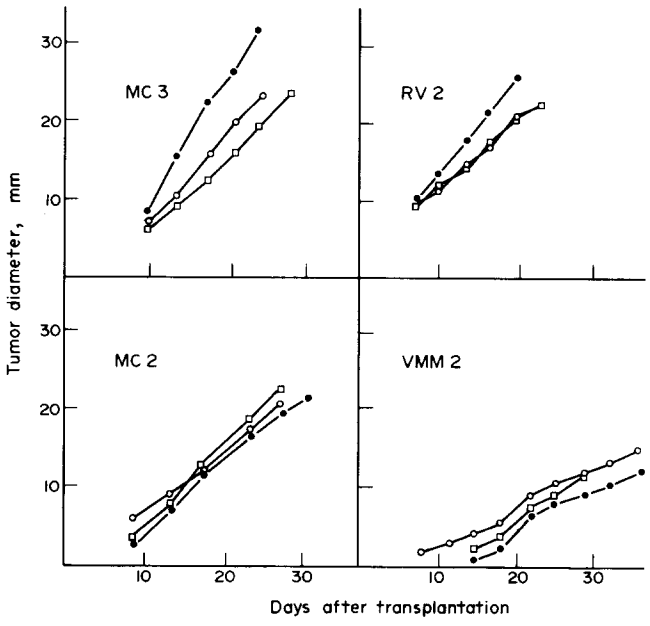

Fig. 5. Growth of MC3, RV2, MC2 and VMM2 tumours in syngeneic mice ●, thymectomized, bone marrow reconstituted syngeneic mice □, nu/nu mice ○.

The results shown in Table 2 indicate no significant variations between thymectomized-reconstituted mice and nu/nu mice bearing MC2 and MC3 tumours and on control mice.

The electrophoresis of the interstitial fluid of three control and three tumour-bearing mice was performed on the same slab. Four experiments gave similar results. Figures 6 and 7 reproduce the curves obtained after scanning of the gel slabs of interstitial fluid of control and MC2 and MC3 tumour-bearing mice. In particular, the increase observed in zones A and C for MC2 tumour in the normal system is not found in the T cell deprived system. For MC3 tumour-bearing mice, the decrease observed in zone C in the normal system is not found, but the decrease in zone A remains.

DISCUSSION

In preceding papers [1, 2], we have shown the existence of "stimulating" or "non stimulating"

Table 2. Estimation of total proteins of interstitial fluid and serum of control and tumour-bearing mice in T-cell-deprived mice according to Lowry's method

*TXB Thymectomized irradiated bone–marrow reconstituted.
†Mean amounts of proteins in g/100 ml ± S.D. contained in interstitial fluid and serum of 6 control mice and 6 tumor-bearing mice (mean diameter of the tumor: 25 mm).
‡Statistical differences between the control mice group and the tumor-bearing mice group are evaluated by Student's *t*-test.
NS: not significant.

On the other hand, for the MC2 tumour, there was no significant difference of growth between normal and T-cell deprived mice, and for the VMM2 tumour there was an acceleration of growth which was significant ($P < 0.05$) in nu/nu mice.

Study of proteins in interstitial fluid and serum in T cell deprived mice (control and tumour-bearing mice)

Protein amounts in the interstitial fluid and the serum of groups of 6 mice bearing MC2 and MC3 tumours (dia 25 mm) and of the control mice have been recorded according to Lowry's method [6] in thymectomized-reconstituted CBA and nu/nu mice.

tumours on the proliferation of target cells cultured in diffusion chambers implanted s.c. near these tumours: the study of the interstitial liquid removed from near these tumours of median size, showed a decrease of proteins for the "stimulating" tumours and no variations for "non stimulating" tumours.

In this paper, we have shown that the "stimulating" tumour has a faster *in vivo* growth rate than the "non stimulating" tumour. Study of the proteins in the interstitial liquid and the serum has been extended to larger tumours. The proteic decrease found in the interstitial liquid of mice bearing the "stimulating" tumours has also been found for large tumours. However, for

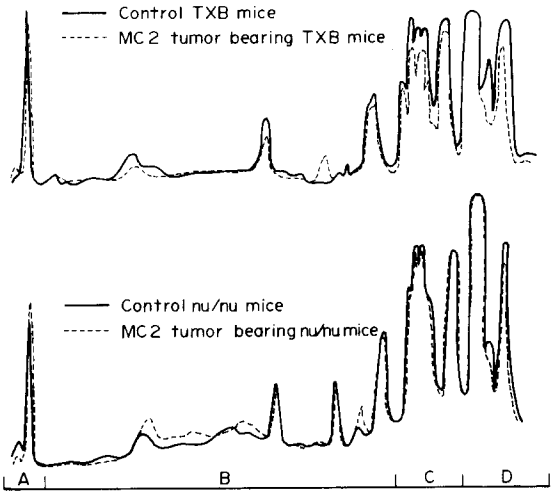

Fig. 6. Superimposed curves of polyacrylamide gradient gel electrophoresis of the interstitial fluid of control and MC2 tumour-bearing mice in TXB (thymectomized, irradiated, bone-marrow reconstituted) mice and nu/nu mice.

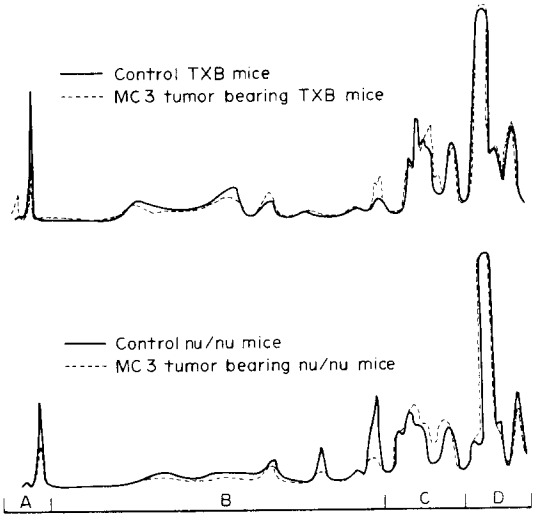

Fig. 7. Superimposed curves of polyacrylamide gradient gel electrophoresis of the interstitial fluid of control and MC3 tumour-bearing mice in TXB (thymectomized, irradiated, bone-marrow reconstituted) mice and nu/nu mice.

"non stimulating" tumours the absence of variations found for median size tumours has not been found; on the contrary a significant increase has been found in the interstitial liquid, a smaller increase was found for the serum.

The fact that the protein amount in the interstitial fluid decreases for the faster growth tumour and increases for the slower growth tumour provided an additional basis for speculation as to a possible relation between proteic variations and tumour growth rate. *In vivo*, an acceleration of the "non stimulating" tumour growth was found when it was grafted in an animal bearing a "stimulating" tumour and vice versa. This supports the hypothesis on the role of the interstitial fluid in tumour growth: indeed an interstitial fluid with less proteins would provoke an acceleration of growth; to the contrary an interstitial fluid with more proteins would provoke a slowing down of growth.

Experiments in progress show a stimulating action of the interstitial fluid of mice bearing "stimulating" tumours on the proliferation of tumour target cells in microtests.

The much more important changes noticed in the interstitial subcutaneous fluid than in the serum led us to believe that the tumour was responsible. In fact, the origin of these variations may depend either on neoplastic cells or other cells infesting the tumour.

The decrease observed in the interstitial fluid of mice bearing tumours with the faster growth may be explained simply by the nutritive requirement of some growing tumours. Also, the rapidly proliferating tissue has been shown to have a higher affinity to iron than other tissues [7]. The decrease observed for transferrin in fast growing tumours may be explained by a degradation of transferrin by tumour cells.

Different hypotheses may be made to explain the proteic increase in interstitial fluid of "non stimulating" tumour bearing mice. The simplest hypothesis may be a local increase of serum proteins due to the vascularization increase in some large tumours. Protein increase may also be explained by the synthesis of proteins by neoplasic cells. Some neoplasic human cells growing *in vitro* have been shown to synthesize ferritins [8].

The observed proteic variations may be related in part to an immunological phenomenon. Indeed, there is accumulating evidence that macrophages are numerous in tumours and that they exert a modulating effect on the tumour growth [9]. On the other hand, the presence and the quantity of lymphocytes in tumours play a role in immunostimulation or inhibition of tumour growth, the phenomenon depending on a direct lymphocyte-to-cells interaction [10, 11].

Numerous reports have shown that a variety of animals and human tumours of connective and epithelial tissue contain a large number of cells with receptors from the Fc part of immunoglobulins. These cells corresponded to infiltrating host cells, especially macrophages and antigen-activated T cells [12, 13]. Proteic increase has been observed for proteins migrating at the level of transferrin and α-globulins. Macrophages have been shown to synthesize transferrin *in vitro* [14]. Moreover, a lymphocyte growth-promoting protein indistinguishable from transferrin was isolated from human serum [15].

The high levels of α-globulins in sera from tumour-bearing hosts have been found in many instances [16–18]. These increases of α-globulins play an important role in immune tolerance. Indeed, the existence of an immunoregulatory α-globulin, which is an effective inhibitor of the immune response, has been demonstrated [19, 20]. It was hypothesized that macrophages may be the origin of this immunoregulatory substance [21].

Some works [22, 23] have shown the existence of factors produced by sensitized thymus-dependent cells which would have the property to make macrophages specifically cytotoxic for tumour cells. The molecular weight of these factors are of the same order as those of the α-globulins.

The immunological origin of these variations would be confirmed because the graft of "stimulating" and "non stimulating" tumours in T cell-deprived mice does not induce notable variations of protein amounts in interstitial fluid and serum. The hypothesis of a relationship between the proteic variations in interstitial liquid and the tumour growth is equally corroborated by the fact that tumour growth is affected in thymectomized animals and also that the proteic variations observed in a normal system no longer take place. In a normal system, for the tumour with a fast growth, the growth was accompanied by a decrease of proteins in the interstitial liquid; in an athymic system, the tumour growth was decelerated and the proteic decrease was not observed. For the tumour with a slower growth, the growth was accompanied by an increase of proteins in the normal system; in the athymic system, the tumour growth was accelerated and the proteic variation was no longer observed.

Increased Sensitivity of Chronic Lymphocytic Leukemia Lymphocytes to Alkylating Agents due to a Deficient DNA Repair Mechanism*

P. A. MAURICE and C. LEDERREY

Division of Onco-Hematology, Department of Medicine, Hôpital Cantonal, 1211 Genève, Switzerland

Abstract—*DNA damage was produced in suspensions of human blood lymphocytes by nitrogen mustard (HN2) and the resulting unscheduled DNA synthesis (U.S.) was determined by non-S phase labeling with tritiated thymidine. Lymphocyte samples from 20 healthy donors and 12 patients with untreated chronic lymphocytic leukemia (CLL) were tested. Maximal U.S. was induced by a 30-min exposure to 10 μM of HN2 in both cell varieties. Thymidine uptake, stimulated by this drug concentration, was higher in normal cells (270% of the control values ± 13 = S.E.M.) than in the leukemic cells (212% ± 14). In order to correlate these findings with their functional consequences normal and CLL lymphocytes pretreated with various doses of HN2 were subsequently stimulated for semi-conservative DNA synthesis with phytohemagglutinin (PHA). The dose–response curves of the HN2 induced inhibition of replicative synthesis, together with the U.S. data, suggest a deficient repair mechanism in CLL lymphocytes. The possibility that this result might be the consequence of the differing proportions of T and B lymphocytes among leukemic and normal cell suspensions was envisaged. Therefore, T-cell depleted samples of normal lymphocytes were compared to unfractionated CLL suspensions in respect to U.S. and PHA response after HN2 treatment. Results indicate that the repair deficiency observed in CLL cells is not due to the prevalence of B lymphocytes in this disease.*

INTRODUCTION

ALKYLATING agents are widely used in the treatment of lymphoproliferative diseases like chronic lymphocytic leukemia (CLL). Clinical observations suggest that in the majority of the cases of previously untreated CLL, the leukemic blood lymphocytes are particularly sensitive to several of these agents and that clinical remissions may therefore be obtained without excessive toxicity to the normal lymphocyte population. Cell sensitivity to an alkylating agent like nitrogen mustard (HN2) depends on many factors including those related to cell cycle or to drug uptake mechanisms; it also depends on the presence or absence in the cell of enzymes involved in the repair of DNA damaged by alkylation. In the particular case of normal and leukemic lymphocytes, cell sensitivity differences due to cell cycle factors can be excluded because both cell varieties represent an almost non-dividing population; furthermore no significant difference in drug uptake has been detected in these two lymphocyte varieties [1] suggesting that this particular factor may also be of little importance in this respect. The possibility therefore that differences in cell sensitivity to alkylating agents could depend on cell ability to repair damaged DNA was considered.

Repair of sublethal DNA damage produced by alkylation in mammalian cells was first suggested by Crathorn and Roberts [2] who observed that HeLa cells treated *in vitro* with varying doses of mustard gas exhibited a dose–survival curve with a shoulder suggesting that repair of alkylated DNA had occurred. De Wys and Knight [3] came to similar conclusions on the basis of the dose–response curve obtained in treating leukemia L1210 in mice with cyclophosphamide, another alkylating agent. Exposure of various mammalian cells to HN2 was further shown [4] to stimulate incorporation of labeled precursors into their DNA, as had been previously observed with u.v. light or ionizing radiations. This non-S phase labeling, representing a non-semi-conservative synthesis process, was termed unscheduled DNA synthesis and was shown to follow the excision of damaged regions

Accepted 24 February 1977.

in a DNA strand. Unscheduled DNA synthesis, which has been shown to occur also in human peripheral blood lymphocytes [5] (a practically non-dividing cell population), is generally determined by the amount of thymidine taken up by lymphocytes cultured in presence of hydroxyurea an agent known to selectively suppress semi-conservative DNA synthesis in the few dividing cells of this population [6]. In an attempt to detect eventual differences in repair ability between normal and CLL lymphocytes which could account for differences in sensitivity to HN2, we first measured unscheduled DNA synthesis in these cells after damaging *in vitro* their DNA with this drug. Furthermore, we tried to correlate these data with some parameter indicative of repair. One way of assessing the functional significance of a repair process that correlates with cell survival is to determine the ability of repaired DNA to undergo semi-conservative replication. Because most of the blood lymphocytes are normally in a resting stage semi-conservative DNA synthesis had to be stimulated with a mitogen in order to determine the proliferative response in relation to a previous alkylation.

MATERIAL AND METHODS

Lymphocyte cultures

Human peripheral blood lymphocytes were prepared under sterile conditions by the Ficoll–Metrizoate method of Böyum [7] using heparinized whole blood samples collected from 20 healthy donors and 12 patients with untreated CLL. The white blood cells in such preparations were approximately 95% lymphocytes as judged by their morphology. After two washings with Hank's TC medium the lymphocytes were suspended at a concentration of 10^6 per ml in TC 199 (Difco) buffered with 0.04 M Hepes (H-2-hydroxyethylpiperazine-N'-2-ethane sulfonic acid, pH 7.6) and with 20% autologous serum. All work unless otherwise indicated was performed at 20°C.

Unscheduled DNA synthesis

One milliliter aliquots of cell suspensions were then incubated in screw capped plastic tubes with various concentrations of HN2 (Mustargen, Merck Sharp & Dohme) ranging from 1 to 10^3 μM. After 30 min the cultures were centrifuged (1000 rev/min for 10 min in a Christ Heraeus 11 KS centrifuge at 4°C) and the suspending medium replaced with fresh medium. Unscheduled DNA synthesis was determined in the lymphocyte suspensions by measuring DNA thymidine (TdR) uptake in the presence of 5 mM hydroxyurea (HU, Calbiochem). One μCi of (^{3}H) TdR (labeled in the methyl group, Radiochemical Center, Amersham, England) was added to culture samples which were then incubated for 12 hr at 37°C. The reaction was stopped by cooling the culture tubes in an ice-bath, and after extraction the radioactivity of the TCA insoluble material was determined by a standard technique [8], using a Packard Tri-carb liquid scintillation spectrometer (Model 3380). All experiments were performed on cultures in triplicate with one additional set of cultures for cell counting and viability tests as described below.

Semi-conservative DNA synthesis

HN2-damaged lymphocytes as well as undamaged controls were tested for their ability to perform semi-conservative DNA synthesis upon stimulation with a mitogen. For this purpose the cell suspensions were first treated as for unscheduled synthesis measurements and exposed during 30 min to varying concentrations of HN2 as previously mentioned except that HU and (^{3}H) TdR were omitted. After medium renewal the cells were kept at 37°C for a 12-hr period, in order to allow for DNA repair, and then cultured for 72 hr at 37°C in the presence of PHA-M (phytohemagglutinin-M Difco, 0.05 ml of the commercial solution per culture). The lymphocytes were then labeled for the last 12 hr of the culture with (^{3}H) TdR (1 μCi per culture) and the acid insoluble radioactivity was determined [8].

Cell counting and control of cell viability

Lymphocytes cultured in a special set of tubes (without PHA-M) were counted in an hemocytometer at the beginning and at the end of the incubation period. At the same time the lymphocytes were also examined for their ability to exclude Trypan blue. Cells were resuspended at a concentration of 3×10^6 per ml and two drops of culture were mixed with two drops of 0.2% Trypan blue. A total of 400 cells per series were examined and the results were expressed as a percentage of cells taking up the dye.

B-cell enrichment of normal lymphocyte suspensions

When comparing the effects of chemically induced DNA damages in lymphocytes collected from normal and from leukemic donors, the possibility that some differences may have resulted from the differing proportions of T and B cells among CLL and normal lymphocyte populations had to be considered, and adjustments were made through B-cell enrichment. For this purpose T-cell rosettes were produced in

the suspensions of normal lymphocytes by adding sheep red cells according to the method of Haegert *et al.* [9]. The cell mixture was then centrifuged on a layer of Ficoll–Metrizoate in order to sediment the rosettes and to keep the B lymphocytes at the interface layer from where they were collected washed and resuspended in TC 199 medium. The resulting cell suspensions were shown to contain from 5 to 20% rosetting cells whereas 5–28% of these cells were found in untreated suspensions of leukemic lymphocytes.

RESULTS

Unscheduled DNA synthesis

The kinetics of (^{3}H) TdR uptake by normal and CLL lymphocytes previously exposed to 5 and 10 μM HN2 concentrations and incubated in the presence of HU are presented in Fig. 1(a)

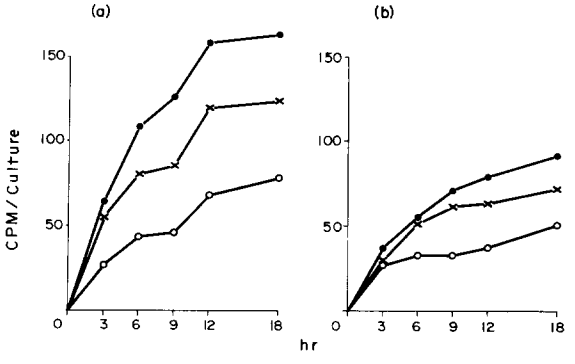

Fig. 1. The kinetics of HN2 stimulated incorporation of (^{3}H) *TdR into normal lymphocytes (a) and CLL lymphocytes (b). After a previous* 30-min *exposure to* 5 (×) *and* 10 μM *of HN2* (●) *the lymphocyte suspensions were incubated for various periods of time and the radioactivity of the TCA insoluble material determined. Control curves without HN2* (○).

(normal lymphocytes) and 1(b) (CLL lymphocytes). During the first 12 hr of incubation there is a progressive increase in DNA radioactivity with a relative flattening of the curve thereafter. The lower level of incorporation observed in unalkylated lymphocytes represents semi-conservative DNA synthesis not suppressed by HU [10, 11]. HN2 stimulated synthesis, which corresponds to the difference between these two values, remains approximately unchanged after the 12 hr-incubation so that this particular incubation time was selected for further experiments.

Dose–response curves obtained on the same lymphocyte suspensions with various concentrations of HN2 are shown in Fig. 2(a) (normal lymphocytes) and 2(b) (CLL lymphocytes). In the presence of HU, which suppresses semi-conservative DNA synthesis, there is an increasing stimulation of (^{3}H) TdR

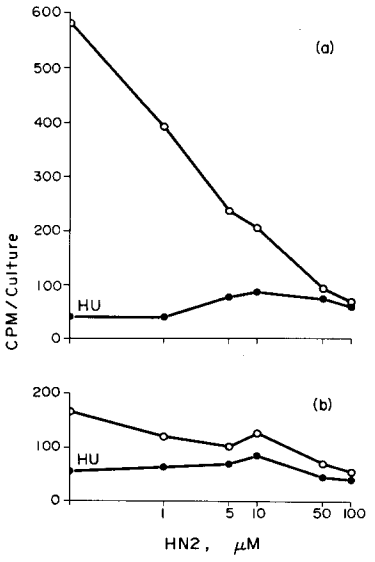

Fig. 2. (^{3}H) *TdR uptake into the DNA of normal (a) and CLL lymphocytes (b) previously exposed to increasing concentrations of HN2 and incubated for* 12 hr *thereafter. Incubation in the presence of HU* (●), *in the absence of HU* (○).

incorporation reaching its maximum in cultures preincubated with 10 μM of HN2, and followed by a decline at higher drug concentrations. When the same experiment is performed without HU there is a progressive fall in (^{3}H) TdR incorporation with increasing HN2 concentrations. This fall which occurs already in cultures preexposed to 1 μM of the damaging drug, represents selective inhibition of the semi-conservative DNA synthesis in an occasional dividing lymphocyte.

The mean values of (^{3}H)TdR uptake determined on normal and CLL lymphocytes after HN2 damage and incubation in the presence of HU, are given as percentages of control values in Fig. 3. Maximal (^{3}H) TdR uptake is again

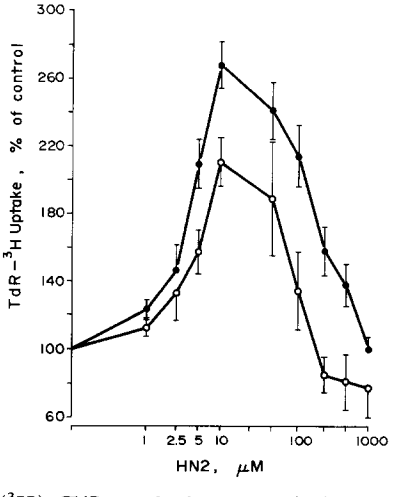

Fig. 3. (^{3}H) *TdR uptake by normal* (●) *and CLL* (○) *lymphocytes previously exposed to increasing concentrations of HN2 and incubated thereafter in the presence of HU. Results given in percentage of controls (mean values ± S.E.M.).*

observed in cultures exposed to 10 μM of HN2, but the peak values (expressed as a percentage of the control) appear to be significantly less ($2P < 0.05$) for leukemic cells (212% ± 14 = mean ± S.E.M.) than for normal lymphocytes (270% ± 13). Mean values (± S.E.M.) of (^{3}H) TdR uptake in the absence of HN2 were 55 counts/min ± 6.9 for normal lymphocytes and 40 counts/min ± 7.1 for leukemic lymphocytes, a finding which rules out the possibility that the decreased repair synthesis observed in leukemic cells could have resulted from an insufficient suppression of semi-conservative DNA synthesis by HU in these particular cells. The progressive inhibition (declining slope), which occurs at HN2 concentrations exceeding 10 μM, implies an inhibitory effect on repair synthesis which occurs at higher concentration of the drug. This inhibition which is more pronounced for CLL than for normal cells probably also affects the residual semi-conservative synthesis. Cell counts performed at the end of these experiments gave similar results in normal and leukemic cell suspensions indicating no cell loss; the Trypan blue test, however, showed a two to three times higher mortality rate among CLL cells than among normal cells (Table 1).

Effect of DNA alkylation on semi-conservative synthesis in stimulated lymphocytes

The dose–response curves of HN2 pretreated lymphocytes upon PHA-M stimulation are presented in Fig. 4 which relates (^{3}H) TdR uptake to the incremental HN2 doses. Clearly at drug concentrations ranging from 0.5 to 10 μM the resulting effect is very different depending on whether normal or leukemic lymphocytes were tested. It appears that DNA synthesis is fully maintained in the former even after an incubation with 5 μM of HN2 whereas leukemic lymphocytes exhibit a definite impairment in synthesis at a ten times lower drug concentration. Thus the dose–response curve obtained with normal cells shows a shoulder which

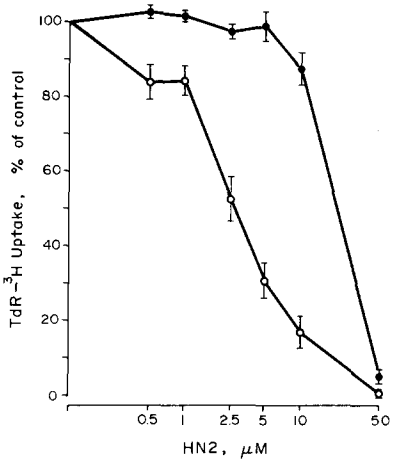

Fig. 4. *PHA induced* (^{3}H) *TdR uptake in normal* (●) *and CLL* (○) *lymphocytes previously exposed to increasing concentrations of HN2 and incubated for* 72 hr *thereafter with PHA. Results given in percentage of controls unexposed to HN2* (*mean values* ± *S.E.M.*).

is almost lacking in the case of leukemic cells. These differences could not be explained by an excessive cell loss in CLL cultures as controlled by cell counts. Furthermore cell viability averaged 74 and 65% respectively in normal and leukemic lymphocytes preexposed to a 10 μM concentration of HN2 and incubated thereafter for 72 hr.

Table 2 gives the percentages of rosetting cells determined in suspensions of lymphocytes ob-

Table 2. *Percentage of "rosette-forming" lymphocytes in various lymphocyte suspensions*

Lymphocyte suspension	Number of experiments	Rosette-forming cells (%)

tained (a) from normal donors, (b) from CLL patients and (c) in suspensions of normal lymphocytes submitted to the T-cell depleting procedure described above. The results of the PHA stimulation test performed in these various lymphocyte suspensions after previous exposure to HN2 are shown in Fig. 5. T-cell depleted and unfractionated suspensions of normal lymphocytes exhibit approximately the same type of response which differs significantly from that of the leukemic lymphocytes. Finally the ability to perform unscheduled DNA synthesis was tested in T-cell depleted and in unfractionated suspen-

sions collected from the same donors. As can be seen from Fig. 6 higher values (expressed as a percentage of the control) were observed in the first mentioned suspensions ($390 \pm 14 =$ mean $\pm$S.E.M.) than in the second ones (286 ± 20), a

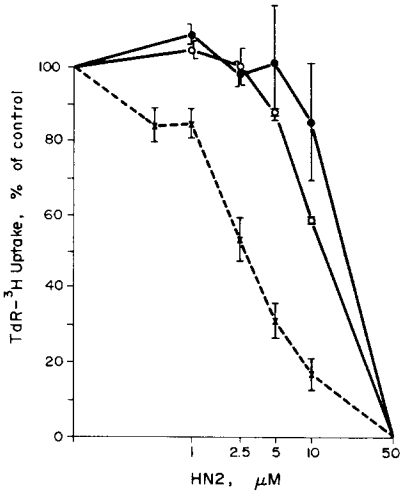

Fig. 5. PHA induced (^{3}H) TdR uptake in unfractionated suspensions of normal lymphocytes (●), T-cell depleted suspensions of normal lymphocytes (○) and unmodified suspensions of CLL lymphocytes (×). The lymphocytes were treated as in Fig. 4, and the results represent mean values ± S.E.M.

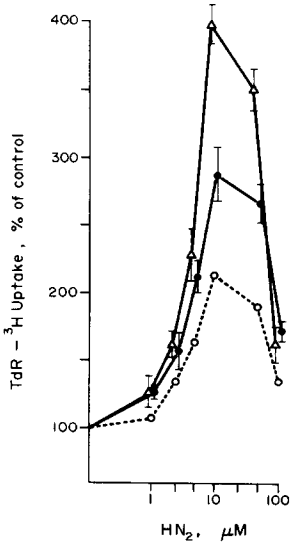

Fig. 6. HN2 stimulated (^{3}H) TdR uptake by unfractionated (●) and by T-cell depleted (△) suspensions of normal lymphocytes. The curve obtained with CLL lymphocytes and shown in Fig. 3 is indicated for comparison (○). The lymphocytes were treated as in Fig. 3 and the results represent mean values ± S.E.M.

finding which excludes the possibility of a reduced unscheduled synthesis in normal B lymphocytes.

DISCUSSION

DNA repair was first compared in normal and CLL lymphocytes by measuring unscheduled DNA synthesis following alkylation. HN2 stimulated (^{3}H) TdR uptake was found to be significantly lower in leukemic than in normal cells. This result could not be explained on the basis of thymidine pool size differences in these two varieties of lymphocytes which have been shown by others [12] not to differ in this respect. Furthermore it was also shown that the differing proportions of T and B cells in normal and leukemic lymphocyte populations could not account for the reduced level of unscheduled synthesis observed in CLL because T-cell depleted suspensions of normal lymphocytes exhibited higher unscheduled synthesis values than unfractionated suspensions from the same donor. Thus the generally reduced level of labeling observed in leukemic cells, which, nevertheless, showed a maximal (^{3}H) TdR uptake at the same HN2 concentration as normal cells, suggests a deficiency in some repair mechanism.

A second possibility of detecting differences in repair mechanisms between normal and leukemic cells was explored in looking for some biological consequence of the DNA damage, namely its ability to perform semi-conservative synthesis. This functional test was performed by stimulating the lymphocytes with PHA and observing the effect of a previous alkylation on the proliferative response. Our results show that the dose–response curves obtained in HN2 pretreated lymphocytes obtained from normal and from leukemic donors are very different: whereas DNA synthesis appears to be fully maintained up to a concentration of 5 μM of HN2 in normal cells, synthesis impairment is observed already at a 10 times lower concentration of the drug in lymphocytes collected from leukemic blood samples, a finding which suggests that functional repair is somewhat deficient in CLL. The assessment of repair ability in these two varieties of lymphocytes by comparing their response to PHA could raise some objections because of the well known observation that PHA stimulation of DNA synthesis is a weaker and slower process in leukemic than in normal cells. These differences, however, cannot explain the dissimilar behavior of these cells as observed in our system where the curves represent percentages of the control values obtained with undamaged lymphocytes. The reported data indicate only that, after incubation with given concentrations of HN2 (^{3}H) TdR uptake is relatively more depressed in lymphocytes obtained from leukemic than from normal blood.

As the PHA response may also depend on the percentage of T lymphocytes in a cell pop-

ulation, the HN2 stimulated repair process of leukemic cells was compared to that of a population of normal lymphocytes in which the proportion of T cells had been lowered to the level observed in leukemic samples. The results obtained with both normal and leukemic cell suspensions containing less than 20% rosetting lymphocytes showed that the T-cell depleted normal lymphocyte samples behaved after alkylation like unfractionated normal lymphocytes when stimulated with PHA.

Thus, even after T-cell adjustment, PHA stimulated semi-conservative DNA synthesis appears to be very much more sensitive to alkylation in the case of CLL than in normal controls. These results however have to be interpreted with caution because PHA is generally considered to be a specific T-cell stimulant [13]. If only T cells were activated by this mitogen then our data would imply a T-lymphocyte deficiency in patients with CLL, a disease known however to involve B lymphocytes. If on the contrary one admits, as proposed by several authors [14, 15] that leukemic B-cells may also participate in the PHA stimulation process, then a deficient repair mechanism in these particular cells is conceivable. Activation of leukemic lymphocytes is indeed suggested by DNA synthesis studies in cell suspensions cultured with PHA for periods longer than 3 days: whereas normal controls show a peak response after 3 days and reduced values of (^{3}H) TdR uptake after 5 days, maximal response occurs between the 5th and the 7th day in the case of CLL.

Since normal lymphocytes synthesize less DNA after a 5-day incubation period, it appears that those cells which take up increasing amounts of (^{3}H) TdR after a 5-day incubation period are mainly the leukemic ones [14, 15]. We have confirmed these data on 3 and 5 day-cultures of normal and leukemic lymphocyte suspensions stimulated with PHA (results not shown). Furthermore, when the effect of a previous alkylation was examined on these 5-day cultures the same difference between the normal and the leukemic dose–response curves as reported in 3-day cultures, was again observed. This finding as well as the reduced level of unscheduled DNA synthesis demonstrated in leukemic lymphocytes following an exposure to HN2 suggests that these cells are deficient in some DNA repair mechanism.

Further studies will be needed to confirm these observations by more direct techniques designed to detect the nature of the differences in DNA fragmentation and repair processes occurring in normal and leukemic lymphocytes.

Studies on the Effects of the Mammary Carcinogen 7,12-Dimethylbenz(a)anthracene on Release and Synthesis of Prolactin by Rat Pituitaries *In Vitro**

P. M. INGLETON

Department of Zoology, The University, Western Bank, Sheffield S10, 2TN, U.K.

Abstract — *These* in vitro *experiments have shown that 7,12-dimethylbenz(a)anthracene (DMBA) at concentrations of* 5 μg *and* 50 μg/ml *can inhibit release of prolactin by female rat pituitaries and that the pituitary at pro-oestrus is more sensitive than at other stages of the oestrous cycle. The use of specific adrenergic blocking agents has shown that the inhibitory reaction occurs through binding of the carcinogen at α- and β-receptor sites. A chemically related non-carcinogenic hydrocarbon phenanthrene, did not inhibit prolactin release. Synthesis of prolactin was inhibited by the higher concentration of DMBA but the adrenergic blocking agents did not ameliorate this effect. The release and synthesis of prolactin by male rat pituitaries was also inhibited by DMBA. The release of growth hormone by these pituitaries* in vitro *was not inhibited by the carcinogen.*

INTRODUCTION

THE ROLE of prolactin in 7,12-dimethylbenz(a)-anthracene (DMBA) induced mammary cancer in the rat has been shown to be a complex one. Clemens *et al.* [1] showed that lesions of the median eminence prior to a single intravenous injection of DMBA significantly reduced tumour incidence whereas similar lesions made at 75 days after DMBA administration stimulated tumour growth. Release of prolactin is known to be mainly under inhibitory hypothalamic control, probably by dopamine [2], and lesions in the hypothalamus would presumably destroy the inhibitory effects. It would appear then that increased prolactin release at the time of carcinogen administration is inhibitory of tumour induction but that prolactin stimulates growth of established tumours.

It has been reported that following a single intravenous injection of DMBA in female Sprague–Dawley rats there was a massive release of prolactin into the plasma which was not followed by compensatory hormone synthesis [3]. It would seem that the carcinogen may inhibit release of a prolactin inhibitory factor (PIF) by acting on the hypothalamus, but it is also possible that the carcinogen can directly affect synthesis and release of prolactin by the pituitary. To see if this was happening a series of experiments has been made on rat pituitaries *in vitro* to determine if DMBA could have a direct and specific effect on prolactin release and synthesis.

Accepted 1 March 1977.

*This work was supported by the Yorkshire Cancer Research Campaign.

MATERIAL AND METHODS

The animals used in these experiments were eight week old female Wistar rats bred in the Zoology Department, Sheffield University. Rats were killed by decapitation and the pituitary immediately removed and placed in a drop of TC199 culture medium. Each pituitary was bisected sagittally, one half serving as the control for its opposite half. Hemi-pituitaries were pre-incubated for 30 min in 200 μl TC199 at 37°C. After pre-incubation each half pituitary was incubated for 5 hr at 37°C in small tubes held in a Dubnoff shaker with a constant atmosphere of 95% O_2 in CO_2. Each tube contained 100 μl TC199 with 10 μCi/ml 4.5 ^{3}H-leucine so that hormone synthesis as well as release could be measured. Appropriate drugs were added to both pre-incubation and incubation media. Prolactin and growth hormone content of both pituitary and medium were measured by densitometry after polyacrylamide gel elec-

trophoresis (PAGE), at the end of the incubation period.

Polyacrylamide gel electrophoresis (PAGE)

The system of Davis [4] was used to separate the hormones except that the samples were not incorporated into gels. Identification of rat growth hormone and prolactin after separation by this system has been made by Jones *et al.* [5] and Yanai and Nagasawa [6]. At the end of the incubation period the total volume of medium was layered onto a single gel, the pituitary weighed and homogenised in Tris/glycine buffer pH 8.3. After solubilisation in ice for 30 min the equivalent of 0.25 mg wet weight of pituitary was layered onto a gel. At the end of the electrophoresis run gels were stained overnight in Coomassie Blue (0.1% in water:methanol:acetic acid, 8:1:1) and destained in the dye solvent until the background cleared.

The amount of hormone in each stained band was quantified by densitometry using a Joyce-Loebl "Chromoscan". A standard curve for rat prolactin run on similar gels was constructed by running various amounts of rat prolactin, in duplicate, and staining the gels with Coomassie Blue (Fig. 1). Thus experimental results could be expressed as μg prolactin. Radioactivity in the separated hormones was measured by the method of Tishler and Epstein [7], a piece of gel from beyond the ion front was used as background control.

For the sake of clarity the procedure for each experiment will be described separately together with the results.

1. *Action of DMBA on release of prolactin by female rat pituitaries*

DMBA (Light & Co.) was recrystallised from ethanol and tested for its effect on release and synthesis of prolactin by female rat pituitaries *in vitro* as follows. The carcinogen was dissolved in absolute ethanol and added to the incubation medium at three dose levels, 50 μg/ml, 5 μg/ml and 0.5 μg/ml, each time dissolved in 10 μl ethanol. Ten microlitres of ethanol was added to the control hemipituitaries.

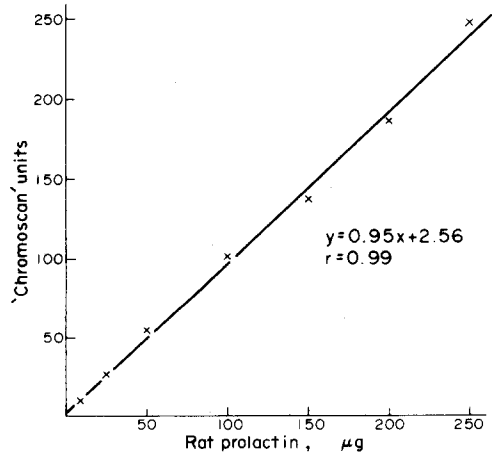

Fig. 1. Standard curve for the estimation of rat prolactin stained with Coomassie blue after polyacrylamide gel electrophoresis. Measurements were made by densitometry on a Joyce-Loebl "Chromoscan".

The results of these experiments are shown in Fig. 2, in which the amount of hormone in the medium is expressed as μg/mg pituitary. It can be seen that there was a significant reduction in the release of prolactin in the presence of 50 μg and 5 μg/ml DMBA but that 0.5 μg/ml had no significant effect (Student's *t*-test). There was also a significant reduction in the release of hormone by male rate pituitaries as shown in the final pair of columns in Fig. 2.

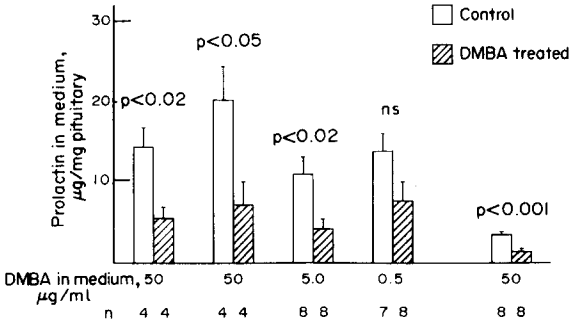

Fig. 2. Effect of various concentrations of DMBA on the release of prolactin by rat pituitaries in vitro. *The first four pairs of columns are female and the final pair are male rat pituitaries.*

These results showed that DMBA could inhibit release of prolactin *in vitro*. To see if this action was specific and not simply a toxic reaction several experiments were performed as follows.

2. *Action of adrenergic blocking agents on DMBA-mediated inhibition of prolactin release*

It has been shown by Shaar and Clemens [2] in an elegant series of experiments that dopamine is the agent in hypothalamic extracts which inhibits prolactin release by rat pituitaries *in vitro*, suggesting that this is probably the *in vivo* inhibitory agent. MacLeod and Lehmeyer [8] have demonstrated by the use of specific blocking agents in an *in vitro* system that dopamine acts via the α-adrenergic receptor and the dopamine receptor site. These experiments have formed the basis for examining the specificity of DMBA-mediated inhibition of prolactin release. All the blocking agents were made up in 0.01 N HCl containing 10 μg/ml ascorbic acid and added to the incubation medium as 10 μl

aliquots to give the final desired concentration. All controls received the solvent only.

(a) *Haloperidol (Serenace, G. D. Searle & Co. Ltd.).* Haloperidol has been shown to block the dopamine receptor in pituitary prolactin cells [8].

Control pituitary halves were treated with 5 μg/ml DMBA whilst their opposite halves were incubated with 5 μg/ml DMBA together with 0.7 μg/ml haloperidol. It can be seen from the results (Fig. 3) that haloperidol did not significantly increase the release of prolactin in the presence of DMBA. Therefore the carcinogen is not acting via the dopamine receptor.

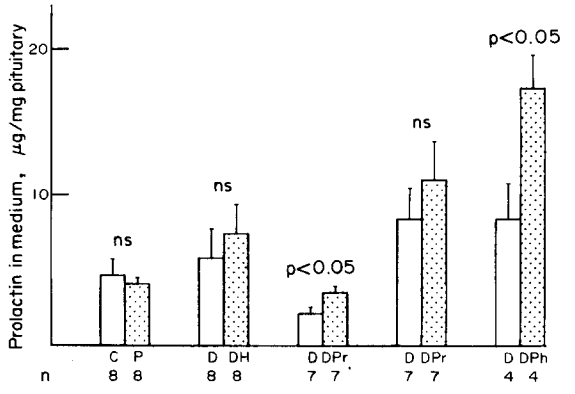

Fig. 3. Results of experiments on the effects of various drugs on the specificity of DMBA-mediated inhibition of prolactin release. C.-ethanol only (10 μl/min). *P.-phenanthrene* (35 μg/ml). *D.-DMBA* (50 μg/ml). *DH.-DMBA* (5 μg/ml) + *haloperidol* (0.7 μg/ml), *DPr.-DMBA* (50 μg/ml) + *propranolol* (4×10^{-5} M), *DPh.-DMBA* (50 μg/ml) + *phentolamine* (4×10^{-5} M).

(b) *Phentolamine (Phentolamine mesylate. CIBA).* Phentolamine, which is an α-adrenergic receptor blocking agent, was tested for its effect on DMBA-mediated inhibition of prolactin release by adding 14.9 μg/ml (4×10^{-5} M) phentolamine to incubations containing 50 μg/ml DMBA. The result in Fig. 3 shows that phentolamine blocked the action of the carcinogen and significantly increased the release of prolactin. DMBA is therefore acting as the α-adrenergic receptor.

(c) *Propranolol (D-L propranolol hydrochloride. Sigma).* Four times 10^{-5} M concentration of propranolol significantly increased the release of prolactin by rat pituitaries incubated with 50 μg/ml DMBA as compared with controls treated with DMBA alone in one experiment but not in a second (Fig. 3). However, the prolactin in the medium expressed as a percentage of the total in medium plus pituitary combined did give a significant result in both experiments (Table 1). This shows that the carcinogen may act via the β-adrenergic receptor site as well as the α receptor, but as propranolol may have slight blocking effects at the α receptor too this could contribute to the reduced inhibition by DMBA.

Table 1. Effect of specific blocking agents on 7,12-dimethylbenz(a)anthracene (DMBA) mediated inhibition of prolactin release by rat pituitaries in vitro

Treatment	*n*	Prolactin in medium $\frac{M \times 100}{M+P}$
DMBA (5 μg/ml)	7	7.13 ± 2.07 NS
DMBA (5 μg/ml) + Haloperidol (0.7 μg/ml)	7	10.48 ± 2.62
DMBA (50 μg/ml)	8	3.40 ± 1.04 $P<0.05$
DMBA (50 μg/ml) + Propranolol (4×10^{-5} M)	6	7.10 ± 1.21
DMBA (50 μg/ml)	8	6.07 ± 1.32 $P<0.05$
DMBA (50 μg/ml) + Propranolol (4×10^{-5} M)	8	14.36 ± 2.07
DMBA (50 μg/ml)	4	5.5 ± 1.27 $P<0.01$
DMBA (50 μg/ml) + Phentolamine (4×10^{-5} M)	4	14.67 ± 2.07

3. *Effect of a related non-carcinogenic hydrocarbon on release of prolactin by rat pituitaries*

To test if the inhibition of prolactin release by DMBA had any significance for the carcinogenic potency of DMBA a structurally related non-carcinogenic hydrocarbon phenanthrene was tested in the *in vitro* system. Phenanthrene was recrystallised from ethanol and added to the incubation medium to give a final concentration of 35 μg/ml (2×10^{-4} M), equimolar with 50 μg/ml DMBA. Phenanthrene did not inhibit prolactin release (Fig. 3).

4. *Effect of DMBA on release of growth hormone by rat pituitaries* in vitro

During the experiments the release of growth hormone was also measured to see if the action of the carcinogen was specific to prolactin. It can be seen in Table 2 that none of the three dose levels of DMBA used had a significant effect on the release of growth hormone, indicating that the carcinogen had a specific interaction with the prolactin cells.

5. *Oestrous cycle and inhibition of prolactin release by DMBA*

In a number of these experiments the results were variable between individual pituitaries

Table 2. Effect of 7,12-dimethylbenz(a)anthracene (DMBA) on release of growth hormone by rat pituitaries in vitro

Treatment	*n*	Growth hormone in medium* $\frac{M \times 100}{M+P}$
Control (Ethanol only)	7	3.17 ± 0.46 NS
DMBA (50 μg/ml) (2×10^{-4}M)	8	3.67 ± 0.91
Control (Ethanol only)	8	3.67 ± 0.62 NS
DMBA (5 μg/ml) (2×10^{-5}M)	8	5.87 ± 1.55
Control (Ethanol only)	6	3.39 ± 0.51 NS
DMBA (0.5 μg/ml) (2×10^{-6}M)	8	2.90 ± 0.57

*Chromoscan readings.

leading to large standard errors. The secretion of prolactin by rat pituitaries varies during the normal oestrous cycle and both pituitary prolactin content and *in vitro* secretion are higher during pro-oestrous and oestrus than dioestrus [9]. To see if the stage of the oestrous cycle had any effect on the degree of prolactin inhibition by DMBA the following experiment was performed.

Vaginal smears were taken from 8 week old rats and groups of 4 in each stage of proestrus, oestrus, metoestrus or dioestrus were used to measure the effect of 50 μg/ml DMBA on prolactin release as previously described. The results are shown in Fig. 4 in which it can be seen that there is variation in the degree of inhibition of prolactin release at different stages of the cycle with the least inhibition at dioestrus. Figure 5 shows that the amount of prolactin in the medium of the DMBA treated pituitary halves as a percentage of the controls was lowest at pro-oestrus. This indicates that the pituitary at pro-oestrus is most sensitive to DMBA-mediated inhibition of prolactin release.

6. *Effect of various drugs on rat prolactin* in vitro

The various drugs added to the incubation media may have had a direct effect of preserving or destroying prolactin in the medium or of interfering with the electrophoretic separation of the hormones. To check this possibility pituitaries from 13 young mature female rats were each cut into three parts and incubated in 4.5 ml TC199 at 37°C for 2 hr. The pituitaries and loose cells were spun down and the supernatant collected. Eight 0.5 ml aliquots were taken and

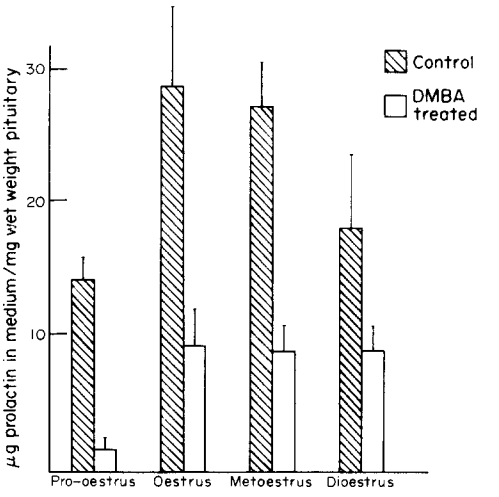

Fig. 4. Inhibitory action of DMBA (50 μg/ml) on prolactin release by female rat pituitaries at different stages of the oestrous cycle.

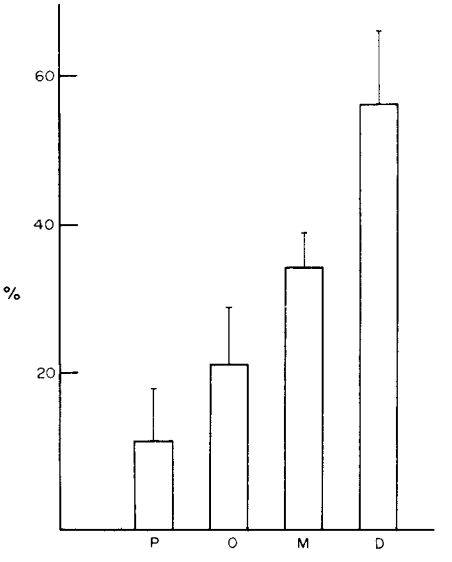

Fig. 5. Prolactin in the medium of DMBA (50 μg/ml) treated hemipituitaries as a percentage of that secreted by their control hemipituitaries.

to an aliquot was added one of the following drugs: (a) phentolamine (4×10^{-5}M) (b) propranolol (4×10^{-5}M) (c) haloperidol (0.7 μg/ml) (d) DMBA (50 μg/ml) (e) ethanol (10 μl/ml) (f) ascorbic acid in 0.01N HCl (10 μg/ml), one aliquot received no additions and a further one was not incubated. Thus all but one of the aliquots contained one of the drugs used in the incubation experiments at the specified concentration.

Four 100 μl samples were taken from each of the aliquots and incubated separately for a further 4 hr at 37°C. It can be seen from Table 3 that there was no significant difference in the prolactin content of any of the incubated tubes whether or not a drug was added. The experiment does demonstrate however that there is

Table 3. Effect of various drugs on rat prolactin secreted in vitro

Treatment	*n*	μg Prolactin per 100 μl incubation medium
Phentolamine (4×10^{-5}M	4	22.31 ± 1.0
Propranolol (4×10^{-5}M)	3	24.33 ± 2.81
Haloperidol (0.7 μg/ml)	4	22.83 ± 0.90
DMBA (50 μg/ml)	4	21.52 ± 1.77
Ethanol (10 μl/ml)	4	23.10 ± 1.10
Ascorbic acid (10 μg/ml in 0.01 N HCl)	4	23.10 ± 0.30
No additions	4	22.57 ± 0.61
No additions + No incubation	3	29.94 ± 0.61

some loss of prolactin during incubation and shows that readings of prolactin content in media after several hours incubation represents a balance between secretion and breakdown and therefore the apparent rate of secretion is an underestimate.

7. *Effect of DMBA on synthesis of prolactin by rat pituitaries* (in vitro)

Synthesis of prolactin by both male and female rat pituitaries was significantly reduced by 50 μg/ml DMBA (Table 4). The inhibition of synthesis however was not ameliorated by either phentolamine or propranolol (Table 4), suggesting that inhibition of synthesis is caused by interaction of the carcinogen at intracellular sites different from the adrenergic receptors.

Table 4. Effect of 7,12-dimethylbenz(a)anthracene (DMBA) on 4.5 ^{3}H-leucine incorporation into rat prolactin in vitro *and its modification by adrenergic blocking agents*

DMBA (50 μg/ml)	8	89.0 ± 15.3

DISCUSSION

Support for the view that the stimulated rat mammary gland is refractory to tumour development has been provided by a number of different experiments. Dao and Sunderland [10] observed that pregnant rats treated with the carcinogenic hydrocarbon 3-methylcholanthrene (3-MC) failed to develop mammary tumour and Dao, Bock and Greiner [11] showed that lactating rats were also refractory to tumour induction by 3-MC. Treatments known to raise the circulating levels of prolactin, lesions in the median eminence [1, 12, 13], administration of reserpine [14], combined treatment with norethynodrel and mestranol [15] and grafting of additional pituitaries beneath the kidney capsule [16] all reduced the incidence of mammary tumours in rats subsequently treated with DMBA. Thus if DMBA can inhibit release of prolactin, as demonstrated in these *in vitro* experiments, it can clearly enhance its own ability to induce mammary tumours. It may be that a temporary reduction in circulating prolactin leaves binding sites free in the mammary gland with which DMBA may interact. However Dao and Sinha [3] showed that within a few hours there was a massive increase in circulating levels of prolactin after a single intravenous injection of DMBA, which would stimulate the mammary gland. In contrast to these results recent experiments by Valero *et al.* [17] have shown that up to 30 hr after intragastric instillation of DMBA into female rats there is a reduced level of plasma prolactin when given at any stage of the oestrous cycle together with elevated pituitary prolactin content. The divergence of these results may be due to the different routes of administration of the carcinogen and different dose levels used, nevertheless both treatments are commonly used to induce mammary tumours and clearly much more investigation is needed.

The results of Dao and Sinha [3] also suggest that the carcinogen acts at the hypothalamic level as well as the pituitary to produce opposite effects, one to increase and the other to decrease the release of prolactin. Not only does DMBA act at these sites and the mammary gland it also causes considerable damage to the adrenal

cortex shortly after injection [18] which may influence metabolism of the carcinogen and prolong its presence in the body. Thus DMBA administered systemically has many actions in various tissues some or all of which may influence the ultimate development of mammary tumours.

In these *in vitro* experiments the concentration of carcinogen used in the incubation medium is comparable with or less than those used *in vivo* to induce mammary tumours. Huggins *et al.* [19] used various doses of DMBA to induce mammary tumours of which 1, 2.5 and 5 mg per rat given intravenously produced tumours in 80–100% of the animals without toxic effects. The average weight of such rats is about 140 g and if the blood represents 8% of body weight then the lowest dose of 1 mg would give a concentration of 89.2 μg/ml. The highest dose, 5 mg, is the most commonly used one for mammary tumour induction and therefore gives a much higher blood concentration.

The inhibition of prolactin synthesis by DMBA *in vitro* would explain the *in vivo* observations of Dao and Sinha [3] that prolactin secreted from the pituitary during the first few hours after a single intravenous injection of DMBA was not replaced, but these results again conflict with those of Valero *et al.* [17] who found an increase in pituitary prolactin content. The *in vitro* inhibition did not appear to be ameliorated by either phentolamine or propranolol since there was no significant difference between the control and test groups. The absence of a blocking effect suggests that DMBA may affect prolactin synthesis via a different mechanism from that concerned in inhibition of release. DMBA can combine with DNA and RNA as well as protein [20, 21] and it may be that such an interaction causes reduced synthesis of prolactin. To clarify this and reduce the variability between pituitaries, experiments with pools of dispersed cells would be most valuable. Yanai and Nagasawa [22] noted that in female rats bearing DMBA-induced mammary tumours the pituitary content and concentration of both growth hormone and prolactin were significantly lower than in controls. This could be due to the actively growing tumours or to a permanent effect of the single instillation of the carcinogen.

Mammary cancer can be induced in a low percentage of male rats by a pulse dose of DMBA [23], but Dao and Greiner [24] were able to induce mammary tumours in male rats only after ovarian implantation. This shows that oestrogenic hormones may be important in tumour initiation. It has been shown recently that oestrogen administered *in vivo* to lactating rats can inhibit prolactin binding to specific receptors in the mammary gland [25] which again suggests that the effect of oestrogens in mammary cancer induction may be related to reduced prolactin binding in the mammary gland at the initiation stage.

The action of DMBA at the α and possibly the β-receptor sites differs from that of dopamine which has been shown to inhibit prolactin release via the α-receptor and the dopamine receptor [8]. However in a teleost fish (*Poecilia latipinna*) dopamine appears to inhibit prolactin release by interaction at both adrenergic receptor sites as well as the dopamine receptor [26]. The nature of adrenergic receptors in pituitary cells is unknown but Cuatrecasas *et al.* [27] using labelled catecholamines has shown binding to membrane proteins in a variety of tissues in the rat. What determines the site of binding is however not clear but it has been suggested [27] that it may be governed by the presence of the catechol-o-methyl transferase enzyme. The pathway by which the adrenergic agents ultimately produce their effects is still not known.

The results of these *in vitro* experiments show that more studies must be made on pituitary hormone synthesis and release and on mammary tissue receptors during the first few hours after carcinogen administration *in vivo*. More work must also be done with pituitary tissue *in vitro* for prolonged periods to determine the longer-term effects of the carcinogenic hydrocarbons.

I. INTRODUCTION

IMPROVEMENTS in early diagnosis and supportive care are major problems in cancer research. Progress achieved in oncological surgery and radiotherapy as well as improved chemotherapy programs can significantly alter the natural history and have led to an increasingly better prognosis for patients with malignant diseases. Morbidity and mortality is in many cases determined not only by the primary disease but also by overwhelming fatal or non-fatal complications. Beside infections, thromboembolic and hemorrhagic phenomena are of significant importance. During the last decade characteristic laboratory and morphological data could be correlated to the clinical symptoms. This paper is intended to give a summary of the present knowledge and to demonstrate possibilities for their diagnostic and therapeutic use in clinical practice.

II. CLINICAL SIGNS

Thromboembolic complications such as venous thromboses, phlegmasia coerulea et alba dolens, thrombophlebitis migrans and pulmonary embolism as well as hemorrhagic diathesis and paradoxically sometimes both of them, are often primary symptoms and typical complications in the course of neoplastic diseases. The incidence in solid tumors varies between 10 and 30% [1–4]. In particular malignant adeno-carcinomas are associated with non-bacterial thrombotic endocarditis appearing in about 1–5% of all cases [5–6]. Vascular accidents can be detected in about 50% of patients with polycythemia vera [7]. In acute promyelocytic leukemia wide-spread intravascular coagulation involving the microcirculation and combined with a severe bleeding tendency is a very common finding [8–10]. In contrast, most malignant hematological diseases associated with thrombocytopenia are characterised in their history by a generalised tendency to bleed. Interestingly enough, however, even in these cases thromboembolic complications, fulminant pulmonary embolism and cardiac infarctions can occur [11–13].

Statistical data concerning the causes of death in patients with cancer [14–16] and malignant hematological diseases [17–19] demonstrate the high incidence of fatal bacterial infections. Next to these complications thromboembolic events are the main cause of death in solid tumors, while in malignant blood diseases a generalised bleeding tendency is a predominant finding at autopsy.

III. LABORATORY FINDINGS

In systematic studies hemostatic abnormalities are detectable in about 95% of patients with malignancies, with or without there being any clinical evidence of a thromboembolic or hemorrhagic tendency. According to Sun *et al.* [20] 82% of the cases under investigation had increased fibrin degradation products, 57% had prolonged prothrombin time, 55% had hyperfibrinogenemia, 55% had a positive ethanol gelation test indicating elevated levels of fibrin monomers, 47% had prolonged thrombin time and 28% had prolonged or shortened partial thromboplastin time. Thrombocytopenia was present in only 30% and hypo-fibrinogenemia in 11%. In a series of 50 patients with inoperable lung cancer [21] fibrinogen was increased in 82%, prothrombin time was prolonged in 62%, fibrin split products were increased in 38%, thrombocytosis was present in 30% and the ethanol-gelation test was positive in 11% of the

*Own investigations supported by grants from the Deutsche Forschungsgemeinschaft (SFB 112).

cases. A reduced activity of factor XIII and defects of fibrin stabilization can be detected in about 65% of the patients with acute leukemia at the time of hospitalisation [22]. In this chapter typical results in various forms of malignant diseases will be considered in detail.

1. *Platelets*

An elevated platelet count is a characteristic finding in myeloproliferative disorders. In addition, in polycythemia vera there is an increase in blood viscosity due to erythrocytosis. A nonspecific, and in the first instance inexplicable rise in the platelet count, is to be seen in the initial phase and in the course of several solid tumors and malignant lymphomas [23–27]. It should be mentioned that in a small number of cases of acute leukemia an enhanced proliferation of megakaryocytes (Fig. 1) and thrombocytosis occur [28, 29]. However, thrombocytopenia is the characteristic symptom in patients with acute leukemia. It can also appear in the course of other malignant diseases in which cases it is necessary to examine whether it is due to neoplastic bone marrow infiltration, bone marrow depression following cytostatic chemo- or radiotherapy or enhanced peripheral consumption. It should be mentioned that idiopathic thrombocytopenic purpura complicating chronic lymphocytic leukemia was described [30]. Impairment of platelet function, particularly disturbances of ADP- and collagen-induced platelet aggregation, have been demonstrated in patients with preleukemia, acute leukemia, myeloproliferative diseases and dysproteinemias [31–39]. The cause and mechanism of the platelet defect are not completely understood.

2. *General tests of hemostatic function*

Prolonged bleeding time is to be found in patients with thrombocytopenia and/or platelet dysfunction. In about 50% of patients with solid tumors there is a significant shortening of whole blood clotting time, a highly significant reduction of plasma recalcification time, a shortening of siliconised glass clotting time, decreased partial thromboplastin time, accelerated thromboplastin generation and a decreased heparin tolerance, while prothrombin time and thrombin time are slightly prolonged [40–45].

Surprisingly, the tendency of the blood to clot is distinctly higher also in patients with acute leukemia compared to normal control groups [46–49]. In 1952 Tagnon *et al.* [50] described enhanced blood fibrinolytic activity in patients suffering from metastatic cancer of the prostate. Studies involving general tests of the fibrinolytic enzyme system (whole blood clot lysis test, plasma dilution clot lysis test, euglobulin clot lysis test) which have been carried out in a systematic way in other types of malignancy gave controversy results and have demonstrated clinically relevant enhanced fibrinolysis in only a few cases [51–57]. Widespread pathological changes of hemostatic functions as have been shown by means of such tests as those quoted above are very common in cases of malignant diseases with severe liver dysfunction and with disseminated intravascular coagulation.

3. *Determination of clotting factors*

Patients suffering from malignant diseases, without any complications, regularly exhibit an increased activity in the plasmatic blood clotting factors. The fibrinogen level is clearly raised in about 30–50% of the cases with solid tumors as well as in patients with acute leukemia [2, 41, 49, 58]. Among the clotting factors II–XII the most marked increases in activity can be seen in factor VIII/anti-hemophilic globulin [59–61]. The immunologically identified antigen associated with factor VIII is elevated also (Fig. 2).

In contrast to the clotting factors quoted above the fibrin stabilizing factor (blood clotting factor XIII, plasma transglutaminase) frequently has a reduced biological activity, particularly in patients with acute leukemia [22] and in disseminated cancer [62, 63]. There are contradictory results concerning the determination of fibrinolytic factors. Ogston *et al.* [54] found reduced plasminogen levels in 14 out of 43 patients with leukemia. Studying a group of 100 unselected patients with disseminated malignancies Soong and Miller [56] found plasminogen levels within the normal range. In a series of 179 unselected cancer patients Thornes *et al.* [64] found a definite increase in the anti-plasmin levels. The mean value for the inhibitors was approximately twice that of the normal.

In a few cases of patients with acute leukemia an isolated and clinically relevant decrease in the blood clotting activity of factors V and X has been described, without, however, any evidence of the participation of other clotting factors being mentioned. The pathogenesis of this abnormality is not clear [65]. Acquired factor VIII inhibitors have been described in a few patients with malignant lymphomas [66] and dysproteinemias [67]. In macroglobulinemia the most frequently observed inhibitor is one that interferes with fibrin monomer aggregation [68, 69]. Dysfibrinogenemia was described in some patients with primary hepatoma [70, 71].

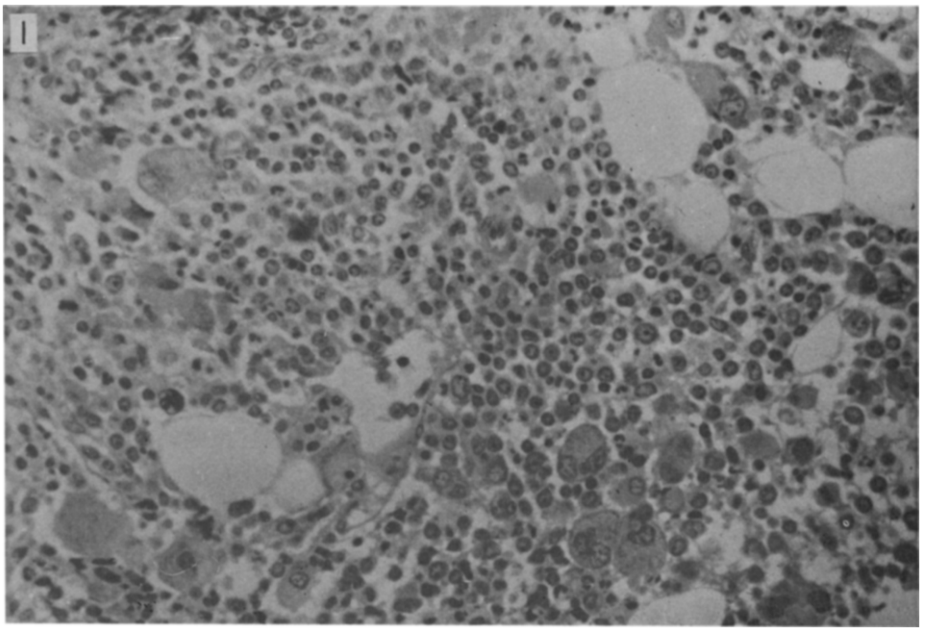

Fig. 1. Unusual case of acute myeloblastic leukemia with high number of megacaryocytes, abnormal "microcaryocytes" and thrombocytosis (1·6 million platelets/μl blood).

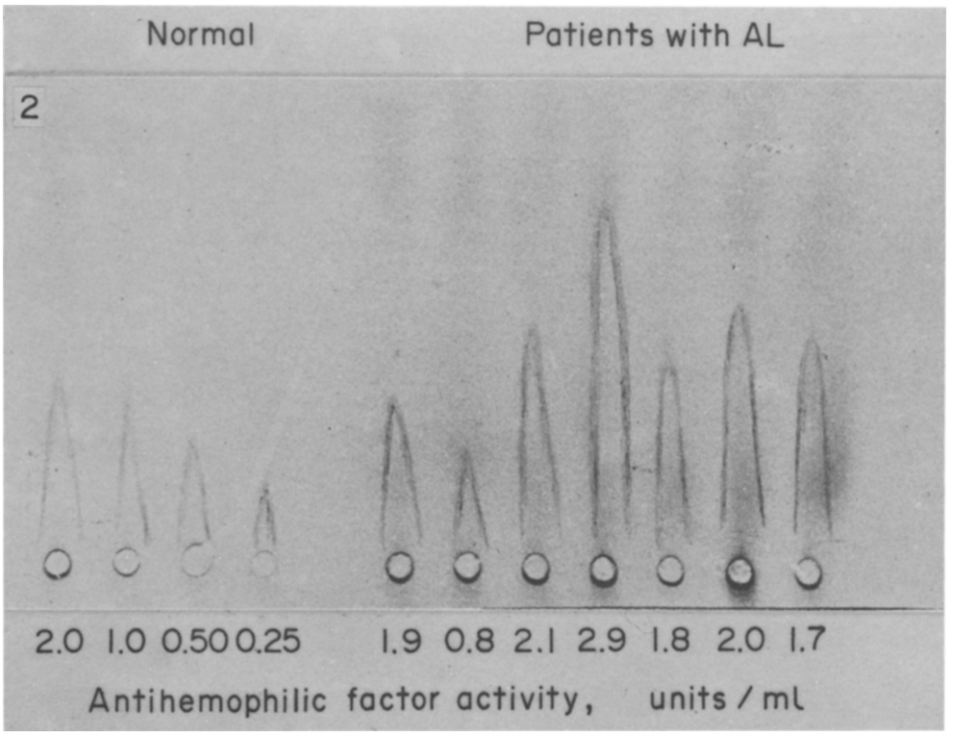

Fig. 2. Clotting factor VIII *activity (units/ml) and factor* VIII *associated antigen (immuno diffusion electrophoresis) in seven patients with acute leukemia (AL). As a control a normal factor* VIII *concentrate in various dilutions is demonstrated.*

4. *Fibrinogen and fibrin derivatives*

It has been demonstrated clearly that malignancy is a disease entity in which the levels of soluble fibrin complexes and fibrinogen/fibrin degradation products are elevated in an extremely large number of cases. They can be detected by means of laboratory tests even in patients not showing any clinical evidence of hemorrhagic or thromboembolic diathesis (Fig. 3). In a study of 61 patients with various malignancies the value of the serum fibrinolytic split products were increased in 82% and the fibrin monomer tests were positive in 55% of the cases [20]. In the light of these data and the confirming results of other investigators [72] the determination of fibrinogen and fibrin derivatives would seem to be an important diagnostic method for clinical practice.

nogen as the underlying disease progressed. The main findings of these results were confirmed by the studies of other investigators [27, 74–76].

IV. PATHOGENESIS

The tendency for thromboembolic complications to develop can be correlated in patients with malignant diseases with various non-specific factors such as age, sex, cachexia, physical immobilisation, exsiccosis, cardiac insufficiency, treatment with corticosteroids and diuretics. The decrease in megacaryocytopoiesis in the bone marrow arising in malignant blood diseases or as a result of aggressive chemotherapy with the ensuming thrombocytopenia would alone offer a sufficient explanation of a serious bleeding tendency. A depression of fibrinogen

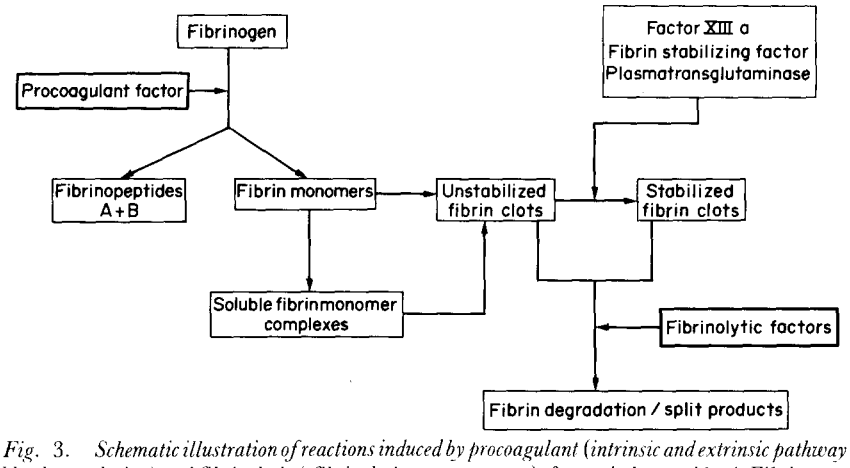

Fig. 3. Schematic illustration of reactions induced by procoagulant (intrinsic and extrinsic pathway of blood coagulation) and fibrinolytic (fibrinolytic enzyme system) factors in human blood. Fibrinogen as well as intermediates of fibrin formation (fibrin monomers and soluble fibrin monomer complexes) and fibrin degradation/split products are often elevated in patients with malignant diseases and can be estimated by simple laboratory tests.

5. *Platelet and clotting factor survival studies*

According to the studies of Slichter and Harker [73] the survival of labelled platelets and fibrinogen decrease parallel to one another in cancer patients. Grouping the data according to disease categories revealed a progressively shorter survival of the labelled components in chronic leukemias, metastatic solid tumors, lymphomas and sarcomas, carcinoma of the prostate and acute leukemias. In those patients, who died within 2 weeks of the study, platelet and fibrinogen survivals averaged 1 day, regardless of their disease classification, compared with the normal values of 9.5 ± 0.6 and 5.1 ± 0.3 days, respectively. In 5 out of 8 patients for whom there was objective evidence of response to chemotherapy or radiotherapy, there was a significantly prolonged survival of platelets and fibrinogen towards normal values. In contrast 5 patients with unresponsive disease showed an increased consumption of platelets and fibrinogen as the underlying disease progressed.

synthesis in the liver can be expected in the course of L-asparaginase therapy [77–79].

1. *Intravascular coagulation and fibrinolysis (ICF) syndromes*

Malignant diseases tend to be associated with a hypercoagulable state ("chronic disseminated intravascular coagulation") together with clinical and subclinical abnormalities of the hemostatic system, e.g. thrombocytosis, elevated levels of fibrinogen and other clotting factors, shortening of platelet and fibrinogen survival, elevated levels of fibrin monomers and soluble fibrin monomer complexes. At the same time fibrinogen/fibrin split products are elevated too, indicating a low grade activation of the fibrinolytic enzyme system. Wide-spread intravascular fibrin deposits are not detectable at autopsy. The term "intravascular coagulation with fibrinolysis (ICF)" was introduced to stress the close relationship between accelerated intravascular

coagulation and activated fibrinolytic mechanisms [80]. Diagnostically the most confusing cases of the ICF-syndrome are those with milder abnormalities and little or no bleeding. In many cases, however, the diagnosis can be established by the combination of characteristic laboratory findings.

Malignant tumors are thought to release procoagulant and fibrinolytic factors which are assumed to be the trigger mechanism responsible for the enhancement of the pathological process (Fig. 3). Procoagulant and fibrinolytic materials have been demonstrated in solid tumors as well as in leukemic cells [81–89]. At the present it must remain undecided however, whether this is the only trigger mechanism or whether others, which are primarily independent from clotting mechanisms, are not of importance as well. A possible limited or enhanced clearance function of the reticuloendothelial system for intermediates of the clotting process has to be taken into account. Interestingly enough, in some patients with acute leukemia an increased fibrinogen catabolism has been demonstrated without there being any clinical or laboratory evidence of intravascular coagulation [74].

2. *Disseminated intravascular coagulation and consumption coagulopathy*

The state of blood hypercoagulability and the intravascular coagulation–fibrinolysis syndrome in malignant diseases can develop to such a point that it gives rise to disseminated intravascular coagulation and consumption coagulopathy. Particularly characteristic for such a state are thrombotic and bleeding manifestations and thrombocytopenia as well as the reduced activity of most clotting factors. In most patients respiratory and renal insufficiency as well as symptoms of prolonged shock are apparent due to fibrin deposits in the microcirculation. This dangerous complication is not frequent, however, it is a constant finding in acute promyelocytic leukemia [8, 9, 90–95]. In other forms of acute leukemia the syndrome is rarer. There are only casuistic reports of acute disseminated intravascular coagulation and consumption coagulopathy in solid tumors describing in particular carcinomas of the prostate and pancreas. It is not fully understood, why some patients with malignant diseases develop the severe complication of acute disseminated intravascular coagulation and consumption coagulopathy while others do not [96]. It has been suggested that besides febrile episodes and endotoxaenemia particularly cytostatic chemotherapy could be an important accelerating factor in leukemias [97–99]. This seems not to be true, however, for patients with solid tumors [100].

3. *Microangiopathic hemolytic anemia*

The syndrome is characterized by elevated levels of plasma hemoglobin and erythrocyte fragments (schistocytes) in the peripheral blood smears. It is associated with thrombocytopenia and other irregularities in the blood clotting mechanism. Microangiopathic hemolytic anaemia is obviously a rare complication in metastasing carcinomas [101–103]. Carcinomas of the breast and stomach were the most frequent primary tumors, but single cases of metastatic carcinomas of colon, gall-bladder, pancreas, lung and prostate as well as malignant hemangioendotheliomas, have been known to be complicated by a microangiopathic hemolytic anemia.

Experimental data suggest that schistocytosis and hemolysis in microangiopathic hemolytic anemia is the result of mechanical erythrocyte fragmentation in diseased small blood vessels [104]. Pathological changes of small blood vessels in metastatic carcinoma due to intravascular tumor cell aggregates and fibrin deposits have been described [105].

Normally, microangiopathic hemolytic anemia is a late and fatal complication of metastatic carcinoma. However, quite often this type of anemia is inherent in the underlying tumor.

V. DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS

Venous thromboembolism, lung embolism and the appearance of bleeding tendency may be the first clinical symptom indicating the presence of a malignancy in patients not suffering from other predisposing diseases. The following tests should be included in a laboratory program with hemostatic parameters for early cancer diagnosis: evaluation of schistocytosis in peripheral blood smears, platelet counts, fibrinogen level, thrombin time, thromboplastin time and partial thromboplastin time, simple tests for detection and estimation of fibrin monomers and soluble fibrin monomer complexes (ethanol gelation test: Godal and Abildgaard [106]; protamine sulphate test: Lipinski and Worowski [107]; Niewiarowski and Gurewich [108]) as well as fibrin degradation products (hemagglutination inhibition test: Merskey *et al.* [109]). It should be pointed out that none of these tests giving pathological results in cancer patients is pathognomonic of such a disease as they may be seen also in non-malignant diseases. However,

they can be used as an additional diagnostic information. It has been clearly demonstrated that the regular control of hemostatic laboratory tests is helpful in estimating the course and prognosis of malignant diseases. It is important to be able to predict fatal complications such as acute consumption coagulopathy or microangiopathic hemolytic anemia. Laboratory evidence of intravascular coagulation and fibrinolysis syndromes disappears, when tumor regression is achieved.

Cancer patients with thromboembolic complications are treated according to the common rules of internal medicine. In patients with thrombocytopenia alone due to bone marrow insufficiency platelet transfusions will be able to get a bleeding tendency under control.

The therapy of intravascular coagulation and fibrinolysis syndromes should always be directed towards the primary disease, and measures should be taken to correct anything that exaggerates the coagulopathy, such as sepsis, shock or acidosis. Experience clearly indicates that no specific therapy other than supportive measures need be undertaken when the intravascular clotting is so minor and short lived that it does not contribute to either morbidity or mortality. However, the administration of heparin should be considered in cases where a thrombotic or bleeding tendency presents an immediate threat to the patient's life and where it is not possible to reverse the underlying mechanism triggering the intravascular clotting. The use of other agents such as blood transfusions, cryoprecipitates, platelet concentrates and antifibrinolytic drugs must be decided anew in each individual case [110]. The use of oral anticoagulants or antiplatelet agents (acetylsalicylic acid, dipyridamol) has not yet proved successful with these indications.

The adequate treatment of acute disseminated intravascular coagulation with consumption coagulopathy presents big therapeutic problems. Some authors have suggested the use of fibrinolytic agents such as streptokinase or urokinase, but as yet not much experience has been acquired in the field. The experiences with heparin therapy are conflicting [96, 111]. They include success with short term heparin therapy combined with specific treatment of the underlying disease, favorable laboratory response but clinical failure as well as both clinical and laboratory failure. It should be given, however, in cases of acute promyelocytic leukemia [112] and should be combined with fibrinogen, platelet concentrates and plasma fractions.

Heparin therapy is not appropriate for cancer patients with microangiopathic hemolytic anemia, unless there is laboratory evidence of disseminated intravascular coagulation and bleeding tendency. When trying to gain control over hemolysis and thrombocytopenia, only chemotherapy supported by platelet and erythrocyte transfusions seems to be beneficial. The use of antiplatelet drugs is still under discussion.

VI. CONCLUSIONS

From the clinical and laboratory data summarized in this review it becomes evident that the evaluation of the hemostatic system in patients with malignant diseases is important. A hypercoagulable state of the blood is a constant finding and can be diagnosed by laboratory procedures. Malignancy is associated with an increased consumption of platelets and fibrinogen and the turnover rate of these factors is related to the type and extent of the disease. From a pathogenetic point of view this seems to be due to an intravascular coagulation and fibrinolysis syndrome. Acute disseminated intravascular coagulation and consumption coagulopathy is a common complication in acute promyelocytic leukemia, but it is rare in other forms of malignancies. A hemostatic disorder is most effectively treated with antitumor therapy in order to reduce or remove the underlying lesion. Antithrombotic drugs such as heparin may prevent thromboembolic disorders. In the actively bleeding patient, transfusion therapy presents a better method of getting the bleeding under control in the first instance, than a manipulation of the hemostatic system. In general, it can be said that the pathogenesis, diagnosis, prevention and treatment of hemostatic abnormalities in cancer patients certainly deserves further clinical and basic studies. The laboratory techniques used to identify a hemorrhagic or thrombotic tendency as well as the therapeutic regimens used to correct such a tendency are not effective in all patients. Investigations are required to understand the mechanism and significance of impaired platelet function in many cases of malignant diseases. The reason for isolated coagulation factor deficiencies in acute leukemia (factors I, V, X, XIII) is not yet fully understood. The question must be clarified as to whether a reduced or enhanced clearance function of the reticuloendothelial system contributes to the coagulation disorders in malignancy by more or less eliminating the precursors and intermediates of the coagulation and fibrinolytic enzyme system. From a clinical point of view it would be important to know whether there is a correlation

between elevated levels of soluble fibrin monomer complexes in blood and the clinical incidence of thrombosis.

In the present paper, experimental results concerning the local involvement of hemostatic mechanisms in the formation of metastasis were not considered. Preliminary studies in man using anticoagulant drugs in cancer chemotherapy were excluded also. Both topics have been discussed in detail elsewhere [113–124].

Furthermore, recent animal model systems for studying the mechanisms of hemorrhagic and thrombotic tendencies in malignant diseases [125–126] were not reviewed.

Plasma Levels and Biotransformation of Infused Daunorubicin and Daunorubicin–DNA Complex in Rabbits: A Preliminary Report

R. HULHOVEN,*† J. P. DESAGER,* G. SOKAL‡ and C. HARVENGT*

**Laboratoire de Pharmacothérapie, U.C.L. 53.49 and*
‡Service d' Hématologie, Université Catholique de Louvain, 1200, Bruxelles, Belgium

Abstract—*Plasma levels and biotransformation of daunorubicin and daunorubicin–DNA complex were studied in rabbits after an i.v. bolus injection and during and after a* 4 hr *infusion period. The administered dose was* 5 mg/kg *expressed as the free drug.*

The levels of daunorubicin (DNR) and its active metabolite, daunorubicinol (DNR-ol), were determined on plasma extracts by high-pressure liquid chromatography.

The results demonstrated a slower disposition of the complex. In addition, a five-fold higher DNR-ol plasma level was achieved at the end of the infusion of the complex as compared with the free DNR infusion.

Incubations of DNR and DNR–DNA complex with whole rabbit blood indicated also a slower disposition of the complex.

Cell DNR-reductase activity in the rabbit was intense. Indeed, DNR-ol appeared rapidly during infusion of free drug and complex and during in vitro *incubation with whole rabbit blood.*

INTRODUCTION

DAUNORUBICIN (DNR), an anthracyclinic cytostatic antibiotic produced by *Streptomyces peucetius*, is very active in the treatment of several hematologic malignancies.

A lysosomotropic complex of DNR with DNA, extracted from calf thymus (Sigma, type V) or from herring sperm (Sigma, type VIII), has been prepared by Trouet. The complex injected into leukaemic mice was more active than the free drug [1].

The disposition of the complex in mice has recently been described. However, the authors measured the total plasma levels by fluorescence and did not attempt to separate the parent drug from its active metabolite, daunorubicinol (DNR-ol) [2].

Recently we described a fast, easy, and sensitive, method for the determination of DNR and DNR-ol in plasma by high-pressure liquid chromatography [3].

Accepted 24 February 1977.

†Aspirant du Fonds National de la Recherche Scientifique de Belgique.

The aim of this work was to estimate the plasma levels of DNR and its metabolite, DNR-ol, in normal rabbits during and after a 5 mg/kg i.v. infusion of either DNR as free drug or complexed with DNA.

A four-hour infusion period was preferred, since fast i.v. injection of the same dose of the complex required a too large volume (12.5 ml/kg), which resulted in an acute heart failure.

Studies on the *in vitro* metabolism of DNR and its complex in the whole rabbit blood were also performed.

MATERIAL AND METHODS

Normal F_1 rabbits, males and females, weighing about 3 kg, were used. No sex linked difference was observed for the measured parameters.

Pure reference samples of DNR and DNR-ol were obtained as the hydrochlorides from Rhône-Poulenc (France). Commercial daunorubicin-HCl (Cerubidine, Spécia, France) was administered to the rabbits.

For the preparation of the complex, a solution of DNA (4.68 mg/ml in NaCl 0.9%) from

herring sperm was used.* The solution was autoclaved for 15 min at 120°C and slowly cooled down. After cooling, appropriate amounts of DNR were added in order to obtain a molar ratio of 20 [1].

In vivo *studies*

In some experiments, uncomplexed DNR was injected i.v. (5 mg/kg in NaCl 0.9%) as a bolus. Intravenous fast injection (4 min) of the DNR–DNA complex was performed in 5 animals.

Slow i.v. infusions, at a constant rate of 12 ml/hr, were given by means of a Braun-Unita-I infusion pump. The 5 mg/kg DNR and DNR–DNA complex solutions were adjusted to a final volume of 48 ml by addition of NaCl 0.9%. Injections and infusions were made into the lateral vein of the ear.

Blood samples (5 ml) were collected, from a polyethylene catheter inserted in the carotid artery, in tubes containing EDTA di-K as anticoagulant and immediately centrifuged at 0°C. The plasma was removed and stored at −20°C until analyzed.

Electrocardiogram, blood pressure and rectal temperature of the treated rabbits, were monitored during the whole infusion period (Hewlett-Packard 7754 A-7803 B).

Chromatographic analysis

The extraction procedure and the high-pressure liquid chromatography have previously been reported [3].

One millilitre plasma samples containing adriamycin as internal standard were extracted with a mixture of methylenechloride and isopropanol (92:8 v/v).

The extracts were injected on a 5 μm silica microsphere column, eluted at 4500 psi (flow-rate 0.9 ml/min) with a quaternary solvent mixture (methylenechloride/methanol/25% ammonia/water 90:9:0.1:0.8 v/v). The absorbance of the eluates was monitored at 490 nm (Du Pont 848–837). Results were calculated from a calibration curve. Each extraction and each determination were done in duplicate.

With this method, plasma levels as low as 10 ng/ml of DNR or DNR-ol could be detected. The recovery from rabbit plasma was 90 ± 3% for both compounds.

For some controls, thin-layer chromatography on silica gel plates was performed, according to Bachur [4].

In vitro *studies*

Fifty millilitres of fresh heparinized whole rabbit blood were incubated with 100 μg DNR or DNR–DNA complex in a shaking and heating water bath (Lab Line Instruments, model 3564) under O_2/CO_2 (93.5/6.5 v/v) at 39 ± 0.5°C.

Five millilitre aliquots were drawn at various times (1, 5, 15, 30, 60 and 120 min), and DNR and its metabolite levels determined as described above.

The Student's *t*-test for independent means was utilized for all statistical analyses.

RESULTS

Infusion of pure DNA solution, free DNR or DNR–DNA complex, did not induce any significant change in the electrocardiogram, the blood pressure or the rectal temperature.

In contrast, fast i.v. injection of the DNR–DNA complex (about 40 ml in 4 min) induced acute cardiac failure in 2 of 5 rabbits. A more concentrate DNA solution could not be injected because of its high viscosity. Moreover, a dosage reduction would not allow any comparison with the other experimental data.

Plasma levels

(a) Intravenous bolus injection of 5 mg/kg free DNR in 4 rabbits (Fig. 1).

A high DNR-ol plasma level was achieved at the fifth minute. Thereafter, plasma levels of the parent drug and its metabolite declined rapidly. The plasma levels of the metabolite remained always higher than the levels of the parent drug. The clearance curve could apparently be fitted to the sum of three exponential terms. The half-life of DNR at the elimination phase (γ-phase) was about 300 min. Because of the lack of enough time points during the α and β phases, half-lives could not be calculated for these phases.

(b) Fast i.v. injection of DNR–DNA complex (5 mg/kg DNR) in 5 rabbits.

Because the severe side effects (acute heart failure and premature death) induced by the fast injection, the dispersion of the data was too large and did not allow evaluation of the results in this group.

(c) Free DNR 4 hr infusion (5 mg/kg) in 4 rabbits (Fig. 2).

During infusion, the DNR-ol plasma levels increased steadily, exceeding the DNR plasma level after 2 hr. The plasma decay of DNR was fast after discontinuation of the infusion. The decay of DNR-ol was slower.

(d) DNR–DNA complex 4 hr infusion (5 mg/kg DNR) in 7 rabbits (Fig. 3).

A progressive increase in the plasma levels of the 2 compounds was obtained; the DNR-ol concentration reached the level of 2/3 of the

DNR concentration at the end of the infusion. Thereafter, the plasma decay of DNR and DNR-ol was similar to that observed after uncomplexed DNR infusion.

Statistical analysis of the data obtained during infusion of free DNR and DNR–DNA complex revealed a significant increase ($P \leqq 0.05$) at each time point for both DNR and DNR-ol plasma levels during infusion of the complex. After the end of the infusion, a significant increase in DNR levels was only observed at 15 and 30 min, while statistical significance was lost for the DNR-ol levels.

In vitro *studies*

Incubation of free DNR and DNR–DNA complex with whole rabbit blood (3 experiments, Table 1).

A fast decay of DNR from the plasma was observed during the incubations. However, the initial levels were higher with the complex. DNR-ol appeared rapidly in both cases. No significant difference could be observed between the DNR-ol levels, except at the last time point. The decay of both DNR and the complex was bi-exponential. The half-lives were 6 min 30 (α-phase) and 160 min (β-phase) for the free drug, 10 min (α-phase) and 70 min (β-phase) for the complex.

No further metabolite than DNR-ol was detected as controlled by thin-layer chromatography [4].

DISCUSSION

The plasma levels obtained after bolus injection of DNR are consistent with those previously reported [4]. However, a high plasma level of the metabolite DNR-ol was observed during the initial period (5 and 15 min). No explanation for this phenomenon can be put forward from our present data.

The plasma levels of both DNR and DNR-ol were significantly higher during infusion of the complex than during infusion of the free drug. This indicates that the disposition of the complex is slower and probably occurs by endocytosis [1]. If the disposition of the complex is indeed due to endocytosis, this process must be very active in the rabbit, since the plasma decay of the complex was very fast upon termination of the infusion: only the DNR plasma levels obtained at 15 or 30 min after infusion were significantly increased as compared to the free DNR infusion experiments.

The higher DNR-ol plasma levels observed during infusion of the complex are probably due to the binding of this compound by circulating DNA, since the binding sites of the DNR–DNA complex used in our experiments are not completely saturated [5].

Further experiments are needed to examine a possible slower biliary or urinary elimination of the complexed drug and to calculate the distribution volumes.

During the incubation of DNR and DNR–DNA complex with the whole rabbit blood, the half-lives of DNR plasma levels were different. In the case of the complex the α phase was slower whereas the β phase was markedly faster. In addition, the level calculated for the zero point was definitely lower in the free DNR incubation. This might indicate a stronger binding of the free drug to the blood cell membranes.

The plasma levels of the metabolite were similar during the whole incubation period, except at the last time point. As in humans [6], blood cell DNR reductase activity of the rabbit is probably highest in leukocytes. If the complex is taken up by endocytosis in these cells, this might explain its slower disposition during the initial phase as well as the similar plasma levels of DNR-ol found with the free drug and the complex.

In conclusion, the aim of this work was to compare plasma levels and biotransformation of DNR during a 4 hr infusion of DNR–DNA complex and of free DNR. It was found that the disposition of the complex was slower and that a five-fold higher DNR-ol plasma concentration was obtained with the complex. The slower disposition of DNR and the higher plasma levels of its active metabolite, DNR-ol, during infusion of the complex might explain the experimentally more sustained cytostatic activity of the complex.

Studies of the Mechanism of Carcass Fat Depletion in Experimental Cancer

RAYMOND C. KRALOVIC, E. ANDREW ZEPP and RICHARD J. CENEDELLA*

Department of Biochemistry, Kirksville College of Osteopathic Medicine, Kirksville, MO 63501, *U.S.A.*

Abstract—*Loss of body fat is commonly associated with both experimental and human cancers. A direct effect of cancer upon free fatty acid mobilization from host adipose tissue could potentially explain this lipid depletion. Rates of free fatty acid (FFA) production were measured in epididymal adipose tissue removed from normal-control rats and rats bearing the Walker* 256 *carcinoma either intramuscularly (i.m.) or intraperitoneally (i.p.). By the* 4th *day after i.p. transplantation and by the time the i.m. tumor mass reached* 4% *of body weight (b.w.), basal lipolytic rates were* 2–3 *times higher in adipose tissue from tumor bearing than age matched control rats. Body neutral lipids were not yet significantly reduced at this early time. The high rates of adipose tissue lipolysis were maintained as the cancer progressed and body neutral lipids became significantly reduced once the i.m. tumor attained* 6–7% *of b.w.*

The mechanism by which cancer causes this increased fatty acid mobilization is yet unclear. The Walker 256 *tumor might produce a lipolytic factor which directly stimulates adipose tissue lipolysis, since ascites serum from i.p. tumor bearing rats could stimulate adipose tissue lipolysis* in vitro. *However, blood serum from tumor bearing rats did not seem to stimulate adipose tissue lipolysis* in vitro *more than blood serum from control rats. Severe chronic stress seems an unlikely explanation for the early stimulated lipolysis in cancer, particularly the i.p. tumor. However, rats with even small i.m. tumors, although appearing stress free, possessed enlarged adrenal glands and somewhat atrophied thymus glands, classic markers for the presence of a stress situation. The cancer, in some unknown manner, might induce some special stress reaction.*

INTRODUCTION

Body lipids become progressively depleted in rats with the Walker 256 carcinoma [1–6], in mice bearing the Krebs-2 tumor [7] and in patients with various neoplasms [8, 9]. This depletion could be related to the growth of the tumor and could contribute to the debilitation of the host. Hyperlipidemia, consisting mainly of elevation of triglyceride-rich very low density lipo-proteins (VLDL), also occurs in experimental animals [3, 4, 10–14] and man [15, 16] with cancer. The decrease in body fat and increase in plasma lipid concentration could be secondary to increased mobilization of free fatty acids (FFA) from adipose tissue and subsequent conversion of these FFA to VLDL-triglyceride by the liver. VLDL-triglyceride derived from the host plasma could be an important source of the fatty acid for tumors. Brenneman *et al.* [12] recently reported that the ascites plasma formed with the Ehrlich ascites tumor contains large amounts of triglyceride-rich VLDL which are probably derived from the host's blood plasma and the Ehrlich cells can readily incorporate this triglyceride fatty acid [17]. Brenneman *et al.* suggest that "triglyceride-rich VLDL may serve as a transport vehicle for delivery of free fatty acids to the tumor" [12].

The mechanism by which the cancer leads to depletion of the host's body fat and to hyperlipidemia is unknown. It could be due to a cancer mediated stimulation of FFA release from host adipose tissue; however, this possibility has not been directly investigated. Others have speculated that the cancer might cause the host to produce lipolytic hormones [18, 19] and that the cancer itself might secrete lipolytic factors [7, 20, 21]. The present study examines the relationship between cancer and depletion of host body lipids by directly measuring *in vitro* production of FFA by epididymal adipose tissue from normal-control rats and from rats bearing the Walker 256 carcinoma, either intraperitoneally (i.p.) or intramuscularly (i.m.), at various stages of tumor growth. In addition, the ability of blood serum from normal and tumor bearing rats and of cell-free ascites serum

to stimulate adipose tissue lipolysis was measured.

MATERIAL AND METHODS

Tumor maintenance

The Walker 256 carcinoma, obtained from the Arthur D. Little Co., Inc., Cambridge, MA, was maintained by weekly passage of 0.5–2×10^5 cells into the peritoneal cavity of male Wistar rats (50–100 g, Hilltop Lab Animals, Inc., Scottdale, PA) fed Purina rat chow. Groups of age and weight matched male rats were equally divided into control and test groups. Rats inoculated intraperitoneally (i.p.) with $1–2 \times 10^5$ cells died 7–8 days later and then possessed a tumor load of more than 10^9 cells. The tumor load on day 6 was about 0.5×10^9 ascites cells. Intramuscular (i.m.) tumors were maintained by injecting $0.5–5 \times 10^6$ ascites cells into the right thigh. These animals survived 4–5 weeks and possessed a tumor mass often exceeding 20% of total body weight.

Measurement of body neutral lipids

Quantitation of total body neutral lipids (mainly triglycerides) involved sacrificing age matched control and tumor bearing rats by decapitation, skinning the rats, mincing the hide, and putting the combined carcass plus minced hide through a meat grinder. The ground rat was quantitatively recovered by washing with one percent NaCl containing 2mM EDTA (Sigma Chem. Co., St. Louis, MO.), transferred to a large beaker and thoroughly homogenized in a polytron (Kinematica GMBH, Luzern, Switzerland) at low speed. Tumors were removed from the cancer bearing rats prior to grinding and homogenization. The homogenized rat mixture was transferred to a 1 liter volumetric, brought to volume with the NaCl solution, and a 10 ml aliquot was extracted into 200 ml of 2:1 chloroform:methanol (Spectroanalyzed, Fisher Scientific Co., Fair Lawn, NJ). The lipids were recovered essentially as described before [22]. Phospholipids were removed with silicic acid and the recovered neutral lipids were measured gravimetrically. Serum triglycerides were measured by the method of Lofland [23] and plasma FFA were quantitated as described below.

Measurement of adipose tissue lipolysis

Epididymal adipose tissue, immediately removed from decapitated rats, was incubated for 1 hr at 37°C in Krebs phosphate buffer (pH 7.4, no calcium, 2.5% fatty acid poor bovine serum albumin). Incubated systems contained 50–70 mg of minced adipose tissue pooled from 2 or more rats/ml. Samples of the incubation medium were taken for measurement of FFA by automated titration [24] after 6 min of equilibration at 37°C and after 60 additional min of incubation. Net lipolytic rate was expressed as μEq of FFA produced/g tissue (wet wt)/hr.

The effects of adding to the buffer either norepinephrine (Winthrop Labs, NY, NY), prostaglandin E_1 (Upjohn Co., Kalamazoo, MI), propranolol (Sigma Chem. Co., St. Louis, MO.), ascites serum or blood serum upon adipose tissue lipolysis were measured. Ascites serum is the cell-free fluid which accompanies the ascites cells isolated from the peritoneal cavity. Significant volumes of ascites serum (>2 ml) were collectable usually only after 6 days post-transplantation.

Measurement of triglyceride lipase activity

Lipase activity of ascites and blood serum was measured by a modification of the method of Guder *et al.* [5]. One ml of fresh serum was incubated for 1 hr at 37°C with 0.5 ml of buffer [pH 5–7, sodium cacodylate (0.1 M); pH 7–9.5, Tris-HCl (0.1 M), Fisher Scientific Co., Fair Lawn, NJ] and with either 0.5 ml of a 40% acqueous emulsion of purified triolein (Nutritional Biochem. Co., Cleveland, Ohio) or 0.5 ml of isotonic saline. Net lipolysis of triolein was calculated by subtracting the endogenous FFA production measured at each pH and expressed as μEq of FFA produced/ml of serum or liter of buffered-medium/hr.

Measurement of ascites or blood serum lipolytic activity

When blood or ascites serum was added to adipose tissue incubated *in vitro*, FFA production was increased. Since ascites serum was subsequently shown to contain lipase activity (Table 5 and Fig. 3), some or all of the apparent stimulation of lipolysis could be due to lipase attack of triglyceride normally present in ascites serum or to attack of triglyceride droplets dislodged from the adipose tissue pieces during incubation. Ascites serum from the Walker tumor contains about 70 mg % triglyceride [26] that is assumed present as VLDL-triglyceride [12]. In order to separate increased FFA production due to lipase activities from that due to stimulation of adipose tissue lipolysis, epididymal adipose tissue pieces, pooled from several normal rats, were incubated in either the plain Krebs phosphate buffer described above, or in this buffer containing ascites or blood serum at 33% or less by volume; respectively, called systems A and B (see Table 6). Adipose tissue-free medium recovered after incubation of the adipose tissue in buffer alone, system A, was centrifuged ($100{,}000 \times g$ for 45 min) to con-

centrate medium lipids, the bottom one-third volume or less was replaced with serum, and the mixture, now system C, was reincubated for 1 hr at 37°C. The concentration of triglyceride in system C (a tissue free incubation) is assumed to approximate the concentration present when adipose tissue and ascites serum were incubated together (system B). That is, system C is assumed to contain the same amount of medium lipids upon which ascites or blood serum lipases could act as was present in system B. Lipolytic activity of serum (the increased FFA production by adipose tissue due to stimulation by factors in serum) should therefore equal the total FFA produced when adipose tissue and ascites serum were incubated together (system B) *minus* the *sum* of the FFA produced as a consequence of basal lipolysis (estimated in system A) *plus* the FFA produced through the action of serum lipase (estimated in system C). That is, the lipolytic activity of serum should equal B − (A + C); see Table 6. This value might be somewhat high because of possible under estimation of the total ascites serum lipase activity. This might have occurred if ascites serum caused release from adipose tissue of lipase activating factors, tissue lipases, or triglyceride substrate. Such effects would have been missed with the current methods.

RESULTS

Effect of the Walker tumor on host total body neutral lipids and blood lipids

As compared with age and weight matched controls, rats bearing the Walker 256 tumor intramuscularly progressively lost body neutral lipids after the tumor reached about 6–7% of the total body weight (Table 1). When the tumor comprised 10% or more of the body weight, total neutral lipids fell to about one-half the level found in the age matched controls. Also, plasma FFA concentrations were increased in rats with large i.m. tumors (Table 2). In contrast, body lipids were not decreased in rats bearing the tumor intraperitoneally in ascites form (data not shown); although, plasma FFA levels were increased by day 4 of this tumor (Table 2). The ascites form of the tumor was almost always fatal at day 7 after transplantation; whereas, rats with the i.m. tumor survived 4–5 weeks. Circulating levels of triglycerides of control and tumor bearing rat groups ranged from means of about 80 to 120 mg/100 ml and were not statistically different.

Effect of the tumor on host adipose tissue lipolysis

Once the intramuscular tumor reached 4% of total body weight, basal lipolytic rates of epididymal adipose tissue removed from tumor bearing rats were 2–3 times higher than those from matched controls (Fig. 1). Also, as compared with controls, basal lipolytic rates were significantly elevated in rats with the i.p. tumor starting at day 4 after transplantation and continued elevated until day 7, the usual time of death (Fig. 1). Elevation of adipose tissue lipolysis for only 3–4 days prior to death is apparently insufficient time to result in the major loss of body fat in these i.p. tumor-bearing rats.

Bars are the means ± S.E.M. of the net lipolytic rates determined for the underlined number of individual control rats, ▨, or tumor bearing rats, □. Epididymal fat pads from rats were minced and incubated for 1 hr at 37°C in Krebs phosphate buffer (pH 7.4, no calcium) containing 2.5% bovine-serum albumin (fatty acid poor). Incubation flasks contained 50–70 mg of tissue/ml. P(t) of difference from control activity are < 0.025 for a and < 0.001 for b.

Indices of stress in tumor-bearing rats: food consumption and weights of adrenals and thymus

Rats with the Walker 256 tumor growing intraperitoneally consumed the same amount of food as matched controls until the 24 hr immediately prior to death; i.e. day 6–7 (data not shown), and had adrenal and thymus gland weights similar to those of control animals (Table 3). Also, rats with large i.m. tumors (about 17% of body weight) demonstrated no gross signs of anorexia; however, rats with even small i.m. tumors possessed significantly larger adrenal and smaller thymus gland weights than controls (Table 3). In stress adrenal weight can increase and thymus weight decrease [27].

Search for lipolytic factors in cell-free ascites serum

The possibility that the Walker 256 tumor secretes lipolytic factors was investigated initially by incubating epididymal adipose tissue from normal rats in buffer containing varying concentrations of fresh cell-free ascites serum obtained from rats bearing a 7 day i.p. tumor. Addition of ascites serum to the incubation medium resulted in a dose-related increase in FFA production (Table 4). Since we subsequently observed that ascites serum also contains appreciable lipase enzyme activity (Table 5), some or all of the apparent stimulation of lipolysis could be due to lipase hydrolysis of lipids normally present in ascites

serum or to hydrolysis of lipid droplets released from the adipose tissue pieces during incubation. Lipase activities in ascites serum did indeed account for some of the increased FFA production seen upon incubation of adipose tissue with ascites serum; however, it is unlikely that it accounted for all of the increase (Table 6). The apparent lipolytic activity in ascites serum was unaffected by concentrations of prostaglandin E_1 and propranolol which clearly blocked the lipolytic response to norepinephrine (Fig. 2).

late lipolysis of control rat adipose tissue. Since blood serum from both control and tumor rats contained significant lipase enzyme activity at pH 7.4 (Fig. 3), it was necessary to conduct the "balance type" experiment described before (see Methods) for ascites serum in order to separate blood serum lipolytic activity from lipase activity. Blood serum from normal rats stimulated lipolysis in a dose-related manner, producing a maximum 3–4 fold increase above basal levels (Table 7). Rather surprisingly, blood serum from rats with ascites or intramuscular tumors did not stimulate adipose tissue lipolysis more than that from control rats. Serum from the i.m. tumor bearing rats actually seemed to be less active.

DISCUSSION

The present study demonstrates that rats bearing the Walker 256 carcinoma either intraperitoneally or intramuscularly begin to mobilize adipose tissue FFA early in the development of the tumor. This increased mobilization precedes or parallels the depletion of carcass neutral lipid in rats with the i.m. tumor and is seen to occur when the tumor mass is still small and before the tumor is life-threatening. Body neutral lipids were not significantly decreased in rats with the i.p. tumor apparently because of the short period during which FFA mobilization was elevated. Increased adipose tissue lipolytic rates were first recognized on day 4 after i.p. transplantation of the tumor; however, the animals died on day 7–8. Many different mechanisms could theoretically explain this cancer-related early stimulation of fat mobilization.

The cancer could secrete factors which directly stimulate lipolysis or which cause the host to produce more circulating lipolytic hormones. Recently Farron and Lightholder [28] reported that the Walker 256 carcinoma cultured *in vivo* along with foetal liver explants produces a diffusable factor(s) which directly inhibits the accumulation of certain embryonic liver enzymes. In the present study, cell-free ascites serum recovered from rats bearing this tumor intraperitoneally did stimulate adipose tissue lipolysis. And, this apparent lipolytic factor(s) in ascites serum is probably not a catecholamine or a hormone which stimulates lipolysis through activation of adenylate cyclase, since neither propranolol nor prostaglandin E_1 antagonized the lipolytic activity of ascites serum at doses

Table 7. Stimulation of lipolysis by blood serum from control and tumor-bearing rats

Serum source	No. samples tested*	% Serum (v/v)	Stimulation of basal lipolysis (%)†‡
Control rats	2	6.6	39.1 (30.8 and 47.4)
	12	16.7	278 ± 53
	8	33.3	347 ± 46
I.P. Tumor rats (day 6)	2	6.6	71.4 (55.6 and 87.2)
	2	16.7	214 (259 and 168)
	9	33.3	400 ± 69
I.M. Tumor rats (tumor = 13.9 ± 2.2% b.w.)	12	16.7	120 ± 37§

*Serum samples from individual rats.

†The values are means and means ± S.E.M. Correction for serum lipase activity was done as described for the experiments reported in Table 6.

‡Adipose tissue basal lipolysis in the absence of added serum was an average 1.19 ± 0.05 μEq FFA/g/hr.

§$P(t)$ of difference from control serum at 16.7% serum is < 0.005.

which clearly block the lipolytic response to norepinephrine (Fig. 2). Propranolol specifically blocks the beta-receptor mediated catecholamine stimulation of adipose tissue lipolysis [29] and prostaglandin E_1 is a general antagonist of substances which increase lipolysis by activation of adenylate cyclase [30]. Whether this ascites factor enters the systemic circulation *in vivo* is unclear, since blood serum from both i.p. and i.m. tumor bearing rats failed to stimulate adipose tissue lipolysis *in vitro* more than that from normal rats. These findings could suggest that the Walker tumor neither secretes quantitatively significant amounts of lypolytic factors into the circulation nor causes the host to produce more circulating lipolytic hormones. However, the activity of certain lipolytic factors in blood serum could have been missed with the present methods. For example, labile substances with a short biological half-life could have been lost prior to start of the incubations. On the other hand, the activities of some lipolytic factors could have been overlooked because our incubations were too short. For example, the lipolytic activity of pituitary diabetogenic protein is independent of cAMP and requires more than 1 hr incubation with adipose tissue *in vitro* to be expressed [31–33]. Pituitary diabetogenic protein secretion is greatly increased in patients with lipoatrophic diabetes [34], a disease strikingly similar to advanced cancer in that both conditions can result in generalized subcutaneous lipoatrophy and hyperlipidemia.

The general mechanisms of relative caloric deficiency or stress would appear inadequate alone to explain the observed increased adipose tissue lipolysis and depletion of carcass neutral lipid in cancer. The loss of body lipids is reduced but not prevented in both animals [35] and humans [36] bearing cancer by increasing caloric intake through force feeding. In the present study anorexia was not evident in rats with i.p. tumors until just 24 hr prior to death and there was no great difference in food consumption between groups of normal rats and ones bearing large i.m. tumors. Baldwin *et al.* [37] also observed no decrease in food intake or weight gain of rats bearing large subcutaneous Walker 256 tumors (4–6 cm dia). Tumor growth is probably more dependent upon the host than host growth upon tumor activity. For example, glucose utilization *in vivo* by the Walker tumor is dependent upon the host's plasma glucose concentration [38]. Our finding of an increase in adrenal gland and decrease in thymus gland weights in rats with even small i.m. tumors indicates the presence of some stress at early stages of tumor growth. Whether this stress is resulting in the increased fatty acid mobilization, perhaps secondary to increasing the tone of sympathetic fibers innervating adipose tissue, must yet be determined.

In conclusion, the results of the present study indicate that the loss of body lipid in cancer results from a primary effect on mobilization of free fatty acid from the host's adipose tissue and that this increased mobilization begins early in the growth of the tumor. The mechanism by which the cancer causes this fatty acid mobilization is still unknown. It possibly could involve tumor production of a lipolytic factor which directly affects adipose tissue lipolysis and (or) induction, in some unknown manner, of a special stress reaction. Understanding how cancer leads to excessive lipid mobilization in the host opens the possibility of preventing this action and this could be potentially important for retarding tumor growth and improving the well-being of the patient.

DNA Synthesis Inhibition by Dimethylnitrosamine in Regenerating Rat Liver*

ROSE GOL-WINKLER and ROLAND GOUTIER

Laboratoire de Biochimie Appliquée, Université de Liège, 32, boulevard de la Constitution, 4020 Liège, Belgium

Abstract—*The DNA synthesis was measured in regenerating liver of rats injected with various doses of dimethylnitrosamine at different times after partial hepatectomy, and sacrificed from* 20 *to* 264 hr *after surgery* (1 hr *after* [^3H]-*thymidine injection*).

DMNA (9 mg/kg) *given* 30 min *after partial hepatectomy deeply inhibits the first two DNA synthesis waves, significant incorporation of* ^3H-*thymidine being observed only* 56 hr *after surgery.*

When administered 24 hr *after partial hepatectomy* (*at the peak of DNA synthesis in control animals*), *the same dose of DMNA quickly inhibits the* [^3H]-*thymidine incorporation, which only starts again with an overshoot above control values*, 96 hr *after surgery.*

Doses of 2, 4, 9 *and* 18 mg/kg*DMNA were given* 30 min *or* 24 hr *after partial hepatectomy, and the DNA specific activity was measured at* 28 hr *after surgery* (1 hr *after injection of* [^3H]-*thymidine*). *The DNA synthesis inhibition was usually proportional to the dose, but very similar when the drug was injected* 0.5 *or* 24 hr *after surgery. From this observation, it may be concluded that DNA synthesis inhibition by DMNA administered after partial hepatectomy originates more from template alteration than from delay in enzyme synthesis.*

INTRODUCTION

DIMETHYLNITROSAMINE (DMNA) is a powerful carcinogen inducing liver tumours in the rat if administered chronically over a long period of time [1], or as a single dose if given during liver regeneration following partial hepatectomy [2–5].

The most striking biochemical effect of this drug is nucleic acids alkylation, mainly in the liver, which is the site of the DMNA metabolism [1]. Quantitatively, the main alkylation site is the N7 position of guanine [6]. This alteration, however, does not seem to be related to carcinogenesis [7]. Loveless [8] pointed out that alkylation of O^6 position of guanine might be an important carcinogenic event since it induces mutations in viruses. Gershman and Ludlum [9] did show, since then, that a synthetic polymer of poly C and O^6 methyl guanine induces misincorporation by RNA polymerase.

DMNA induces other important lesions in hepatocytes, mainly protein synthesis inhibition [10], polyribosome disaggregation [11]. RNA polymerase activity is inhibited as well [12].

DNA synthesis is a moment of high sensitivity to carcinogenic effect of DMNA since one single dose of 9 mg/kg of the drug administered during that period induces liver tumours [2].

However, the lesion(s) responsible for the development of cancer is still unclear as is the relationship between the effect of DMNA on DNA synthesis and the other biochemical lesions brought about in the regenerating liver.

Given during the prereplicative period (6 hr after partial hepatectomy) DMNA prevents the increase of the DNA polymerase α activity. [13], and the first DNA synthesis wave [14]. On the other hand, the same dose administered during replicative period (20 hr after partial hepatectomy), only slightly inhibits DNA polymerase α activity [13] while deeply altering DNA synthesis [14].

However, these experiments were not carried out beyond the first replication wave, when regeneration is far from being completed. Little

is known on how long DNA synthesis is inhibited.

We investigated the effect of 9 mg/kg DMNA given either soon after partial hepatectomy (30 min) or 24 hr thereafter, on DNA synthesis during the first 2 weeks after operation. Moreover, we compared the DMNA-dose dependence of DNA synthesis inhibition when 4 different doses of the drug were administered 30 min or 24 hr after partial hepatectomy.

Our results indicate that DNA synthesis starts to resume only 56 hr after partial hepatectomy when 9 mg/kg DMNA are given immediately after partial hepatectomy, and 96 hr thereafter if the drug is administered 24 hr after surgery. During 168 hr of investigation, DNA synthesis never reaches the peak control values.

On the other hand, 2, 4, 9 or 18 mg/kg DMNA inhibits DNA synthesis to a similar extent whether given 30 min or 24 hr after partial hepatectomy, suggesting thus the preponderance of template alteration on direct effect on the enzymes in the observed inhibition.

MATERIAL AND METHODS

Chemicals

Dimethylnitrosamine was purchased from Merck (Darmstadt) and kept at −20°C in the dark. Dilutions are made with 0.15 M NaCl immediately before use. Thymidine-6[^{3}H] (specific activity 10 Ci/mmole) was purchased from IRE (Belgium).

Treatment of animals

Female Wistar rats weighing 150–170 g at the time of treatment were used.

Experiments summarized in Fig. 1 were performed with animals from our breeding colony. All the other experiments were made with animals from the same strain, but purchased from Janssen Pharmaceutica (Belgium). Partial hepatectomies, according to the technique of Higgins and Anderson [15] were performed by the same investigator between 9 and 12 a.m. At the moment of surgery, animals were starved since 18 hr. Each experimental group was made of 3–8 rats and treated in parallel to a control group of a similar size. The rats were injected i.p. with 20 μCi ^{3}H-thymidine and sacrificed 1 hr later by stunning and bleeding. The times of sacrifice are mentioned in the text.

Extraction of DNA

The livers, perfused *in situ* with 40 ml ice-cold 0.25 M sucrose through the portal vein, were quickly excised, minced with scissors and homogenized in 7 volumes 0.25 M sucrose 1.8 mM $CaCl_2$ in a Potter tube. Nuclei were collected in the pellet after a 600 × ***g***, centrifugation (10 min) at 4°C and purified by spinning in 2.2 M sucrose 1.8 mM $CaCl_2$ according to the method of Chauveau *et al.* [16].

DNA was extracted by the Schmidt–Tannhauser method [17]. The radioactivity was measured in a Nuclear–Chicago Mark II liquid

(values ± S.E.).

scintillation counter with Instagel (Packard) ready-made scintillation cocktail. Quench corrections were made by external standard method. DNA concentration was estimated by the Burton's modification of the Dische colorimetric reaction [18].

Estimation of acid-soluble radioactivity

A 10-ml aliquot of the first low-speed centrifugation supernatant was precipitated with perchloric acid (final concentration 0.5 N). After allowing the supernatant to stand for 30 min in the cold, it was then collected by centrifugation. The pellet was washed once with 5 ml 0.5 N perchloric acid, and centrifuged. Both supernatants were combined and radioactivity counted as above.

Statistical analyses

Student's *t*-test and standard deviation were calculated with the Hewlett Packard 25 program.

RESULTS

The effects of 9 mg/kg DMNA administered 30 min or 24 hr after partial hepatectomy are summarized in Figs. 1 and 2.

In both sets of experiments, 3 DNA synthesis peaks can be clearly seen in control animals. The relative importance of these peaks is different owing probably to the different origin of the rats (see Material and Methods).

This is consistent with other published data. For instance, Hwang *et al.* [19] found that DNA is synthesized in two waves until the 50th hr after partial hepatectomy. In our case, however, the first peak is somewhat delayed (28 hr after surgery) compared with Hwang's (20 hr).

Given soon after partial hepatectomy, 9 mg/kg DMNA dramatically inhibits the first two DNA synthesis waves (Fig. 1). Tritiated thymidine is not incorporated to an important extent in liver DNA before the 56th hr following surgery. The overall regeneration process is delayed since 120 hr after surgery exogenous thymidine incorporation is much higher in DMNA treated rats while in control rats it reaches values close to those of unoperated animals.

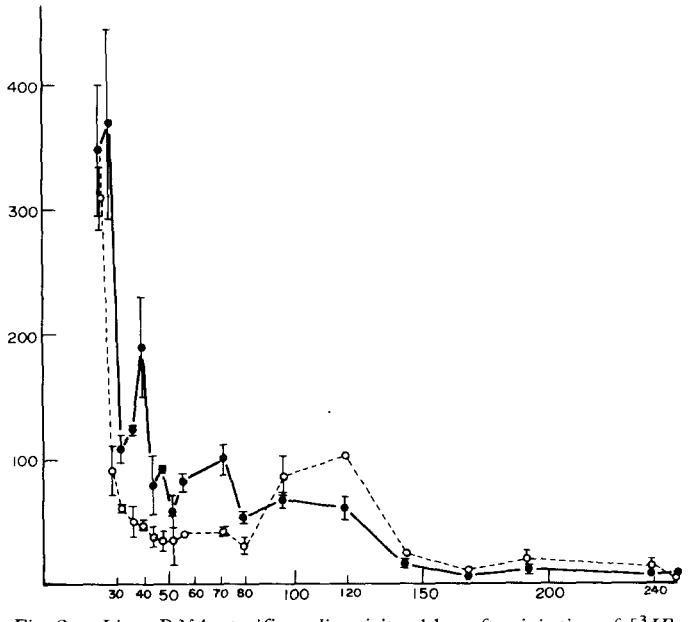

Fig. 2. Liver DNA specific radioactivity, 1 hr *after injection of* [^3H]-*thymidine, in rats injected with* 9 mg/kg *DMNA* 24 hr *after partial hepatectomy.*

Abscissa: time of sacrifice after partial hepatectomy.
Ordinate: specific radioactivity in 10^3 dis/min/mg *DNA.*
(*values* $\pm$ *S.E.*)

Administered 24 hr after partial hepatectomy, 9 mg/kg DMNA quickly inhibits DNA synthesis, which resumes only 96 hr after operation (72 hr after administration of the drug) (Fig. 2).

Our results are in good agreement with those of Craddock [14] with regard to both the deep inhibition of DNA synthesis when the drug is administered early after partial hepatectomy, and the speed of this inhibition when DMNA is administered during S phase. Moreover our results show that in both experimental schemes, DNA inhibition is a long lasting phenomenon, disturbing the whole liver regeneration.

Recently, Herzog and Farber [12] showed that DMNA inhibits RNA synthesis by acting

directly on RNA polymerase rather than on the DNA itself.

In order to see whether inhibition of DNA synthesis also results from enzyme inhibition, we compared the effect of 4 different doses of DMNA (2, 4, 9, 18 mg/kg) but given 0.5 or 24 hr after partial hepatectomy, on DNA specific activity 28 hr after surgery.

We chose this moment since, in both experimental conditions, this is the point of maximal difference between DMNA-treated and control animals.

The reason why we decided to check the inhibition mechanism by this rather indirect way is the following. The enzymes necessary for DNA synthesis are present at a very low level in normal adult rat liver. During regeneration following partial hepatectomy, their activity increases at well determined moments [19].

By giving the carcinogen at 0.5 hr after partial hepatectomy, we avoid direct interaction of the drug with the enzyme molecules, while such an action is produced when the drug is administered 24 hr after partial hepatectomy.

On the other hand, DNA alkylation extent in N7 position of guanine increases linearly with DMNA dose at least in normal liver [20]. Moreover, guanine is alkylated in N7 position in regenerating liver DNA to a similar extent whether DMNA is given 6 or 24 hr after partial hepatectomy [14]. Alkylation in N7 position of guanine is simply indicative of the actual DMNA metabolism.

Thus, if DNA synthesis is inhibited because of direct action on proteins involved in this process, DMNA should be more effective when given 24 hr after surgery when the enzyme is present in high concentration [19].

Results summarized in Fig. 3 show that in fact the drug inhibits thymidine incorporation in DNA to a similar extent when given immediately after partial hepatectomy or 24 hr thereafter. The only exception is the 2 mg/kg DMNA dose, which is effective only if given immediately after surgery. This is the only point where the difference between the two timings is statistically significant (Table 1).

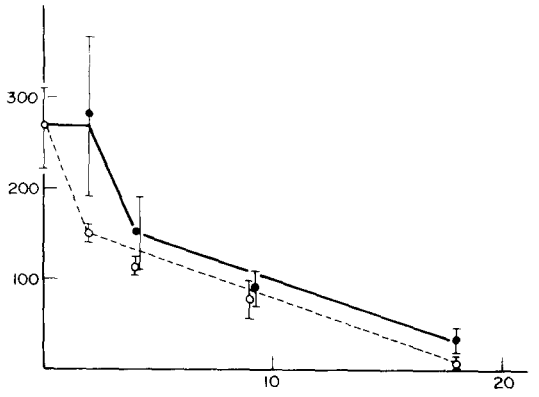

Fig. 3. Liver DNA specific radioactivity, 1 hr after injection of [^3H]-thymidine, in rats injected with different doses of DMNA either 30 min or 24 hr after partial hepatectomy and killed 28 hr after surgery.

Abscissa: dose of DMNA injected.

Dotted line: DMNA injected at 30 min.

DNA synthesis inhibition is not linked linearly to the DMNA dose. Clearly it is a double component function. Neither direct effect on template nor on enzymes alone can account for such a graph (Fig. 3). [^{3}H]-thymidine incorporation in DNA does not seem to be impaired by a mere unavailability of the radioactive precursor since acid-soluble radioactivity accumulates in supernatant while DNA specific activity decreases (Fig. 4). Here again, there is no statistical difference between acid-soluble radioactivity in supernatant when DMNA is given shortly or 24 hr after surgery (Table 2).

The coincidence between the results of Tables 1 and 2 cannot be understood by assuming that DMNA at 0.5 hr would inhibit enzyme synthesis while at 24 hr it would alter the enzyme molecules already present in the cell.

Table 1. DNA specific radioactivity in rats injected with different doses of DMNA 30 min or 24 hr after partial hepatectomy and sacrificed 28 hr after surgery

DMNA dose injected	Time of DMNA administration		*t*-test			
	30 min	24 hr	*t*	Degrees of freedom	*P*	Commentary
2 mg/kg	147 ± 11	223 ± 18	5.78	2	$0.02 < P < 0.05$	Significant
4 mg/kg	115 ± 11	147 ± 40	1.38	4	$0.2 < P < 0.3$	Non significant

when the same dose of DMNA was given 0.5 hr after partial hepatectomy.

It should be pointed out that thymidine kinase activity cannot be the limiting factor in exogenous [^{3}H]-thymidine incorporation into DNA. Indeed, we calculated that the lowest level of enzyme activity, measured *in vitro* after DMNA administration is still sufficient to produce at least 50 times more TMP than is actually incorporated into DNA. DNA-polymerase [13], but not thymidine–kinase [21], could be the limiting factor in [^{3}H]-thymidine incorporation in DNA when the carcinogen is administered during the early replication period (0.5 hr). On the contrary, even the highest DMNA dose (18 mg/kg) given 24 hr after partial hepatectomy failed to inhibit thymidine kinase activity measured 24 hr later [21]. DNA-polymerase activity was not inhibited by 9 mg/kg DMNA administered 24 hr after surgery [22]; at that moment, however, [^{3}H]-thymidine incorporation in regenerating liver DNA is inhibited by the same DMNA dose.

Nevertheless, in carcinogen-treated animals, [^{3}H]-thymidine incorporation into regenerating liver DNA is always at least 20 times higher than in normal, unoperated animals.

Table 2. Acid-soluble radioactivity of liver supernatants from rats injected with different doses of DMNA 30 min *or* 24 hr *after partial hepatectomy and sacrificed* 28 hr *after surgery*

DMNA dose injected	Time of DMNA administration		*t*-test			
	30 min	24 hr	*t*	Degrees of freedom	*P*	Commentary
2 mg/kg	531 ± 23	497 ± 27	1.47	3	$0.2 < P < 0.3$	Non significant
4 mg/kg	726 ± 284	627 ± 22	0.47	4	$0.5 < P < 0.9$	Non significant

Controls	336 ± 71					

[^{3}H]-thymidine is injected 1 hr before sacrifice. Values in 10^3 dis/min/g liver ± S.E.

DISCUSSION

Exogenous thymidine incorporation into DNA after partial hepatectomy depends on the increase in thymidine—and thymidylic kinase and in DNA polymerase activities. Clearly, DMNA can affect both enzymes activities.

Salisbury and O'Connor [13] showed that DNA polymerase activity measured 24 hr after partial hepatectomy is inhibited when 9 mg/kg DMNA are given 6 or 12 hr after surgery, but the inhibition is much less important when the same dose is administered 20 hr after operation.

Similarly, Gol-Winkler and Goutier [21] found that thymidine kinase activity is inhibited

It is not yet clear whether some particular cell types keep incorporating [^{3}H]-thymidine into liver DNA and what type of replication pattern might be assigned to this residual incorporation.

Lee and Spencer [23] reported that, after [^{3}H]-DMNA administration to pregnant rats, liver RNA is methylated to different extents in the different liver lobes. Thus, some cells might undergo less damage and keep on synthesizing their DNA.

This hypothesis, however, is not confirmed by other experimental results. Ord [24] showed that after treatment with methylnitrosourea, [^{3}H]-

thymidine incorporation into Amoeba proteus DNA continues after low alkylating doses. Recently, De Paermentier *et al.* [25] reported that after DMNA administration to rats 24 hr after partial hepatectomy, DNA synthesis seemed to continue in nuclei which were in S phase at the time of treatment, but that no new nuclei entered the S phase. Rajalakshmi and Sarma [26] showed that, in regenerating rat liver, [^{3}H]-thymidine could be incorporated in replicating DNA, when the parental strands were alkylated.

On the other hand, the residual [^{3}H]-thymidine incorporation in DNA might reflect "repair synthesis". It has been claimed that, after treatment of rats or cultured HeLa cells with alkylating agents, [^{3}H]-thymidine incorporation into DNA could be accounted for by repair replication.

It appears, therefore, that DMNA-induced inhibition of [^{3}H]-thymidine incorporation in DNA is a complex phenomenon. When the drug is administered during the early prereplicative stages, the persistence of lesions in DNA as well as impairment of enzymes induction necessary for DNA replication could account for the observed inhibition.

When the drug is given during DNA replication, enzymes such as thymidine kinase [21] and DNA-polymerase [22] are not affected. The possibility remains, however, that other enzymes involved in DNA replication (enzymes for purine and pyrimidine nucleotides synthesis, DNA ligase) or proteins adapting DNA structure to replication process be damaged by the carcinogens.

Abstract — *The effect of A-43818 [D-leu^6 (des-gly-NH$_2^{10}$, pro-ethylamide^9)]-gonadotropin releasing hormone (GnRH) was investigated on rats bearing 7,12-dimethylbenz(a)anthracene (DMBA)-induced mammary tumors. Tumor growth was significantly inhibited by the s.c. administration of 10 μg A-43818, twice daily, for six weeks. A dose of 25 μg seemed less effective. Controls and experimental groups were subjected to radioimmunoassays (RIA) of serum luteinizing hormone (LH), follicle-stimulating hormone (FSH) and prolactin (PRL), and to histological examination of pituitaries and ovaries. Treatment with A-43818 resulted in atrophy of pituitary lactotropes and decreased prolactin concentration in plasma. Plasma LH levels were enhanced whereas FSH levels remained unchanged. The endocrine mechanisms of inhibition of tumor growth are discussed in the light of the well-known hormone dependance of DMBA-induced mammary tumors.*

INTRODUCTION

PURIFICATION and synthesis of the decapeptide gonadotrophin-releasing hormone (GnRH) led to the discovery of a single neurohormone endowed with the ability to promote synthesis and release of both follicle-stimulating hormone (FSH) and luteinizing hormone (LH) [1–4]. Attempts were then made to synthesize analogues of this molecule, in order to obtain more potent stimulators of gonadotrophin production [5–10] or, conversely, competition antagonists [11–13]. A-43818 is one of these analogues. Depending on experimental circumstances, it is able to stimulate [5, 6, 9, 10] or to inhibit [12] gonadotrophin functions. This component is devoid of toxic side-effects and its action is reversible on cessation of treatment [12].

Accepted 7 March 1977.

*This work was supported in part by Grant NO1-CM-57040 from the National Cancer Institute, Bethesda, MA 20014, U.S.A.

Investigation of its potential effect on hormone-dependent tumors was therefore of interest. The present paper describes the inhibitory effect of A-43818 on growth of DMBA-induced mammary tumors and studies the underlying endocrine mechanisms. The anti-tumor effect of A-43818 in the rat has previously been reported as short notes independently by us [14] and by others [15, 16].

MATERIAL AND METHODS

Animals and carcinogen

Mammary tumors were induced in Sprague–Dawley female rats, bred in our laboratory, by a single feeding of 20 mg of DMBA (Eastman Organic chemicals, Rochester, N.Y.) dissolved in sesame oil, at 50 days of age [17].

Tumor size was measured by means of a caliper and expressed as "surface" by multiplying 2 perpendicular diameters. Total tumor surface per rat designates the sum of the surfaces of individual tumors [18].

Fifty-two tumor-bearing rats were housed in colony cages in a temperature – (25 ± 1°C) and light-controlled room (14 hr of light and 10 hr of dark). They had received the carcinogenic dose of DMBA 3 months earlier. They were block-randomized into 4 equal groups, the blocks being made up on the basis of equal number and size of the tumors. Group A served as control. Group B was subjected to ovariectomy. Groups A and B received subcutaneous (s.c.) injections of drug-free solvent. Groups C and D were given 2 injections daily of respectively 10 μg and 25 μg of A-43818 dissolved in 0.5 ml of solvent (0.1% bovine serum albumine–0.9% sodium chloride in water) at 9 a.m. and 5 p.m. Treatments were continued for 6 weeks. Body weights were recorded weekly and vaginal smears were taken daily. Tumors were measured every 2 weeks. Statistical analysis was carried out by the Wilcoxon test on paired differences.

At the end of a 6-week period of treatment, the animals were killed by decapitation with a guillotine (Harvard apparatus, Co. Dover, Mass., U.S.A.). Blood was collected and allowed to clot at room temperature. It was kept in the refrigerator (4°C) overnight and then centrifuged at 3000 rev/min for 15 min, at 4°C. The serum was collected and stored in the frozen state (—20°C) until assayed for hormone levels.

Histological procedures

Pituitaries, mammary glands, tumors and ovaries were fixed in Bouin–Hollande sublimate for at least one week. Mammary glands, tumors and ovaries were stained by hematoxylin, eosin and safran.

The microscopical identification of prolactin cells was performed in immunofluorescence using antibodies to ovine prolactin of well-known specificity [19, 20]. The same paraffin sections were processed for immunofluorescence and then for differential staining by Herlant's tetrachrome method [21] as previously described [19, 20].

Radioimmunoassay (RIA)

Serum levels of FSH, LH and PRL were assayed with the RIA kits supplied by NIAMDD and the results were expressed in ng NIAMDD-Rat-FSH-RP 1, ng NIAMDD-Rat-LH RP 1 and ng NIAMDD-Rat-PRL-RP1 standards/ml.

The numerical results were processed for analysis of variance using Fisher F test [22].

RESULTS

The results given in Table 1 show that A-43818 significantly increased the body weight as compared to the control group and that it induced a significant inhibition of tumor growth either after 4 and 6 weeks. Likewise, ovariectomy produced the expected increase in body weight and tumor regression. The latter was significantly more complete than in the A-43818 treated groups (Table 1). The response to treatment was also evaluated on the basis of individual tumors. Table 2 shows the results of such an analysis and that in the A-43818 treatment groups, as in the ovariectomy group, many of the regressions were complete in 6 weeks.

The results, summarized in Table 3, show that A-43818 significantly increased LH blood levels as compared to the controls. Furthermore, in group C, A-43818 induced a significant inhibition of prolactin release. No effect of A-43818 on plasma FSH was recorded under the experimental conditions investigated in this work. As expected, ovariectomy provoked a sharp rise in FSH and LH plasma values. Vaginal smears taken daily showed that the control rats (group A) had normal oestrus cycles while those receiving A-43818 (groups C and D) had prolonged and irregular cycles.

In control animals (group A), the pituitary glands processed for immunofluorescence and Herlant's tetrachrome staining allowed distinct observation of numerous prolactin cells and gonadotropes of normal size. Each ovary contained follicles at different stages of maturation and two or three normal corpora lutea.

In the ovariectomized animals (group B), the expected hypertrophy of gonadotrophic cells was observed, resulting in typical castration cells with prominent Golgi apparatus. The immunofluorescence technique using antiprolactin serum showed no detectable change of prolactin cells.

In group C, A-43818, 10 μg twice daily provoked some hyperplasia of gonadotrophic cells, but to a lesser extent than that observed in the ovariectomized animals. In immunofluorescence prolactin cells were still detectable but were atrophic, with shrunken cytoplasm. In the same animals, the ovaries contained very small and scanty follicles but numerous young corpora lutea (10–15/ovary) with vacuolated luteal cells.

In group C, A-43818, 10 μg twice daily conditions of pituitary and ovaries were comparable to that of the animals of group C, although their differences with the controls (group A) were less evident.

Table 1. Response of tumor-bearing rats to ovariectomy or treatment with A-43818

Treatments	Mean weight of rats (g)			Mean total tumor "surface" per rat (mm^2)

B vs D	$P<0.001$	$P<0.001$	n.s.
C vs D	n.s.	n.s.	$P<0.1$
C vs B, D	$P<0.001$	$P<0.001$	n.s.

All the tumors studied in this work were subjected to histological controls and proved to be adenocarcinomas.

DISCUSSION

GnRH analogues containing both the D-aminoacid[6] and C-terminal ethylamide modifications are known to produce a powerful and prolonged release of gonadotropins [5, 7] with resultant gonadotropin agonist activity. In contrast, under certain circumstances, inhibitory effects on reproductive functions have been reported [12, 13]. This apparent paradox is probably due to differences in experimental methods with respect to dose ranges and frequencies of administration. On the basis of the known inhibitory effects of A-43818 on the ovaries, it was suggested that its effects on mammary tumors were the results of a temporary "chemical" ovariectomy [16]. Such a simple explanation is not sufficient to account for the inhibition of tumor growth observed in the experiments reported here.

In the conditions of the present work, A-43818 was found to increase LH secretion, to inhibit prolactin cells, and to be apparently devoid of effect on FSH production. Oestrogen secretion was certainly not suppressed for oestrous cycles were still present. The ovariectomized controls differed from the animals treated with A-43818 on production of at least two hormones that could be instrumental in controlling tumor growth: oestradiol and prolactin. Oestrogen production is practically suppressed by removal of the ovaries. On the other hand in the same animals, pituitary lactotropes and serum prolactin levels were not significantly impaired. Normal prolactin levels are sufficient to promote growth of DMBA-induced rat mammary tumors, and tumor regression after ovariectomy may be ascribed to decrease of prolactin secretion as well as to deprivation of ovarian hormones [23]. Therefore it is of interest to notice that the more complete inhibition of prolactin secretion observed in the animals treated with A-43818 resulted in lesser suppression of tumor growth than in the ovariectomized animals. Clearly a direct action of ovarian steroids on tumor tissue should account for the difference. Such view is in good agreement with recent *in vitro* experiments [24].

The reason why A-43818 depresses prolactin production remains to be determined. It is not only by suppression of ovarian hormones that act as physiological stimulators of prolactin production. Indeed, the complete removal of the ovaries resulted in much lesser effect on prolactin cells. It seems thus that A-43818 is endowed with a specific prolactin-inhibiting activity, either by direct action on the anterior pituitary or by an effect through the hypothalamic regulatory mechanism. Such prolactin-suppressing activity is apparently the means by which A-43818 inhibits growth of DMBA-induced rat mammary tumors.

Acknowledgements—We are indebted to Prof. P. Franchimont for the measurement of plasma FSH, LH and PRL; to C. Nuyens for skilful technical assistance and to P. Miroir for secretarial help. Our thanks are due to Abbott Laboratories, North Chicago, IL 60064 (U.S.A.) who provided their new component A-43818 and financial support.

Interspersion of Cyclophosphamide and BCG in the Treatment of L1210 Leukaemia and Lewis Tumour

G. MATHÉ, O. HALLE-PANNENKO and C. BOURUT

Institut de Cancérologie et d'Immunogénétique (INSERM)
Hôpital Paul-Brousse, 94800–*Villejuif, France*

Abstract – *The therapeutic value of interspersing cyclophosphamide (CPM) chemotherapy and BCG immunotherapy was investigated in two tumour models: L1210 leukemia and Lewis solid tumour (LLT). In the case of L1210 leukemia, the antileukemic effect of CPM was enhanced by subsequent BCG administration where a single cycle of combined treatment was applied; treatment by repeated doses of CPM interspersed with BCG was no more effective than CPM chemotherapy alone. In the case of LLT tumour, the effect of one cycle of combined CPM–BCG treatment was not different from CPM administered alone but treatment by repeated doses of CPM interspersed with BCG immunotherapy was less effective than CPM chemotherapy alone. These results indicate that, while the effect of BCG immunotherapy may be favourable or nil when BCG is applied after cell-reducing chemotherapy, it may be nil or unfavourable when applied repeatedly in interspersed chemoimmunotherapy treatments.*

INTRODUCTION

OUR FIRST experiments on active immunotherapy of L1210 murine leukaemia revealed the efficacy of this form of treatment in eradicating the disease only when a small number ($\leqq 10^5$) of neoplastic cells were present [1]. However, subsequent experiments [2] demonstrated that, even when this necessary condition is fulfilled, individuals may respond in three different ways: (a) complete tumor regression; (b) a "plateau" in tumour growth (lasting as long as 60 days) followed by relapse with a new phase of rapid tumour growth; and (c) no perceptible alteration of tumour growth. A cell kinetic study of the "plateau phenomenon" suggested that the number of "new" cells being produced by the tumour is, in this case, equal to the number of cells being destroyed by immunotherapy, so that an equilibrium is maintained [3]. We wondered if, in such cases, chemotherapy interspersed with immunotherapy might reduce the volume of the tumour enough to enable immunotherapy to eradicate the tumour.

Interspersion of chemotherapy and immunotherapy represents a tempting strategy for tumour therapy. Such interspersion has already been used in clinical trials [7]. We are, nevertheless, reluctant to intersperse chemotherapy and immunotherapy, as we previously showed that, while BCG applied after cyclophosphamide (CPM) is able to cure mice carrying L1210 leukaemia not cured by CPM alone, BCG applied before CPM adversely affects the antineoplastic action of the latter, and induces a strong immunodepression, demonstrated by allogeneic skin graft experiments [6]. Thus the experiments reported here were devoted to an investigation of the value of interspersing chemo- and immunotherapy.

Accepted 7 March 1977.

MATERIAL AND METHODS

(a) In experiments using "L1210 leukaemia", the mice were inoculated i.v. with 10^3 live leukaemia cells on day 0. BCG was injected i.v. at the optimal immunostimulating dose of 1 mg/mouse [7]; and CPM was injected i.p. at the suboptimal dose of 80 mg/kg [5]. Mice were given 1, 2 or 3 cycles of CPM–BCG therapy, one cycle essentially being defined as a single treatment with CPM followed 5 days later by a single injection of BCG. Thus CPM was admin-

istered either on day + 1 only, or on days + 1 and + 21, or on days + 1, + 21, and + 41. Similarly, BCG was administered either on day + 6 only, or on days + 6 and + 26 only, or on days + 6, + 26 and + 46.

(b) In experiments using the "Lewis lung tumour (LLT)", which grows as a solid tumour with lung metastases, 2×10^6 live LLT cells were injected intramuscularly (i.m.) on day 0. BCG and CPM treatments were identical with the protocol used for the L1210 experiments, except that mice were given only 1 or 2 cycles of CPM–BCG therapy.

Mortality was recorded daily and autopsies were made. Differences between groups in the same experiment were analysed either by the χ^2 test (L1210 leukaemia) or by Wilcoxon's assigned-rank non-parametric test (LLT). Each group contained 16–20 mice.

RESULTS

The results are presented in Figs. 1 and 2. In the treatment of L1210 leukaemia (Fig. 1), CPM–BCG combination therapy is more efficient than CPM alone only when the leukaemic mice were given a single cycle of treatment. When the animals receive 2 or 3 cycles of combined therapy, their survival does not differ significantly from that of control mice treated with CPM alone.

While one or two injections of CPM are effective in prolonging survival of animals carrying the Lewis tumor (Fig. 2), one or two cycles of combined CPM–BCG therapy are not effective.

DISCUSSION

These observations confirm (a) the effectiveness of BCG applied as an immunotherapy agent

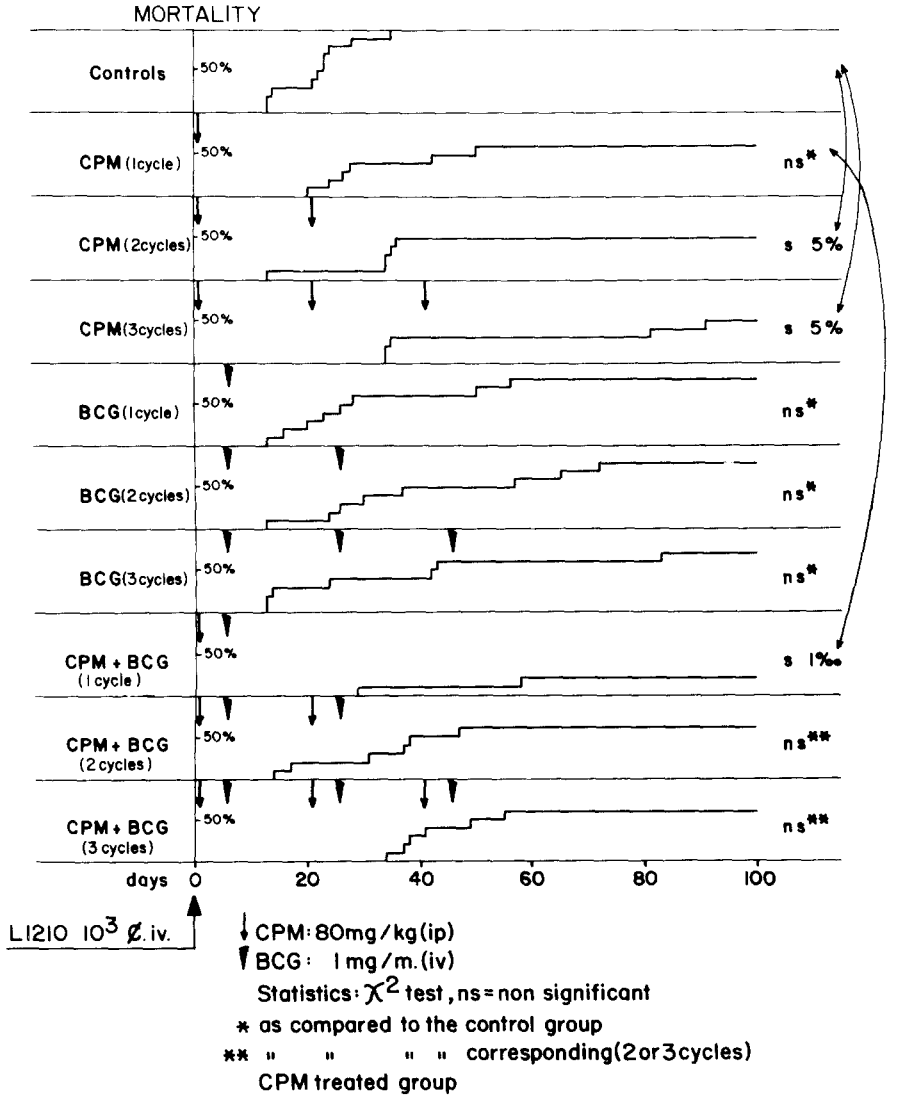

Fig. 1. Interspersion of cyclophosphamide (CPM) and BCG for treatment of L1210 leukaemia: when their sequential combination is given 2–3 times, the effect is poorer than that obtained by one injection of CPM followed by one administration of BCG.

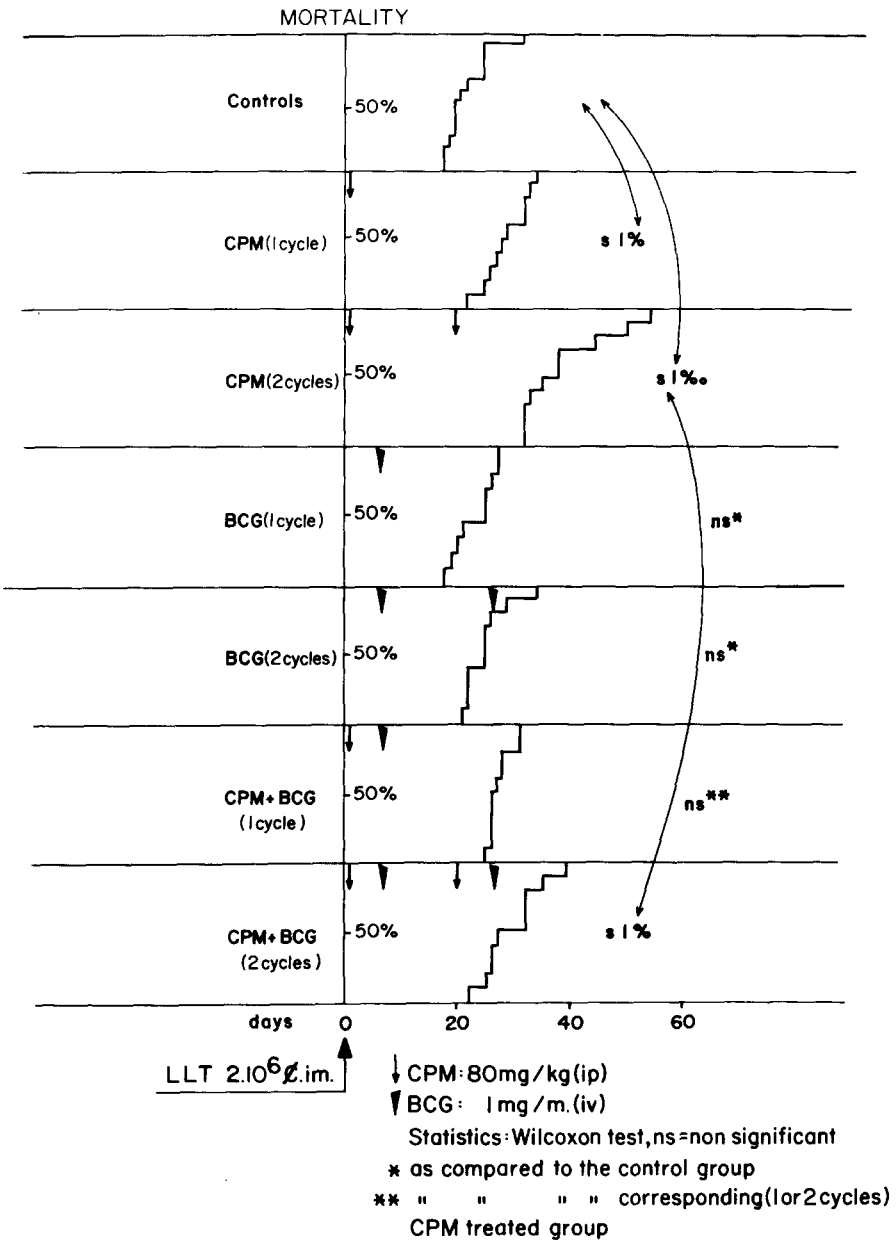

Fig. 2. Interspersion of cyclophosphamide (CPM) and BCG for treatment of Lewis tumour: BCG given after CPM does not improve its effect. When applied twice and interspersed with two injections of CPM, it weakens their effect.

in the treatment of L1210 leukaemia and (b) that BCG is more efficient against this disease when applied after CPM chemotherapy than alone [5], at least with an interval of 5 days.

However, the experiment clearly demonstrates that two or three CPM–BCG sequential combinations are much less effective than one such combination.

As BCG induces a powerful antileukaemic effect when applied after CPM chemotherapy given only once, one is tempted to wonder if the reduced effect of the repeated administrations of both agents is not due to the deteriorative effect of the interspersed sequence: CPM–BCG–CPM. Indeed, we previously showed that the sequence BCG–CPM, when given once, is less effective than BCG or CPM alone [5]. Moreover, we demonstrated that this sequence is a powerful means of inducing immunosuppression as demonstrated by allogeneic skin graft experiments [6].

The effects observed on solid Lewis tumors are more complex to explain. A single application of BCG given after a single injection of CPM is no more active than CPM alone; more interesting is the fact that the mice submitted to two sequences of combined CPM–BCG treatment have a significantly shorter survival than those treated

by two injections of CPM. This may be due either to the same phenomenon as that observed in L1210 leukaemia, namely that BCG applied before CPM adversely affects the effect of the CPM, or to a possible growth enhancing effect of BCG on this tumour, which we have already observed [7].

It should be emphasized that such a result, observed when using an immunosuppressive drug such as CPM, may not be found when using a non-immunosuppressive drug: a later paper will confirm this hypothesis, reporting on an experiment in which the non-immunosuppressive RFCNU [(chloro-2-ethyl)-1-ribofuranosyl-2′-3′ paranitrobenzoate-5′)-3 nitrosourea)] (not published) was used.

Effect of Synchronization on Chemotherapy of Solid Transplanted Tumours

MANFRED VOLM, LIESELOTTE KRIEG, JÜRGEN MATTERN and KLAUS WAYSS

German Cancer Research Centre, Department of Experimental Pathology, Im Neuenheimer Feld 280, 6900 *Heidelberg, Federal Republic of Germany*

Abstract—*A partial synchronization can be induced in the rapidly growing Walker carcinosarcoma and the slowly growing neurosarcoma of the rat by* 6 *applications of hydroxyurea* (50 mg/kg *of body weight) at intervals of* 1.5 hr. *When the block is removed, an increase in the rate of DNA synthesis is observed after* 3–5 hr (^3H-*thymidine incorporation, labelling index*), *which is followed by an increase in the mitotic rate. In order to test whether the effect of therapy with cytostatic agents can be increased by synchronization, different cytostatics were applied at various times after partial synchronization. The times of application were chosen in such a manner that different cell cycle phases were exposed to the action of the cytostatics* (*G*1, *S*, *M*). *The influence of treatment on tumour size, tumour growth and survival time was measured. A strong dose-dependent reduction in tumour growth after cyclophosphamide treatment was similar for both synchronized and non-synchronized animals. Also the growth inhibiting activity of adriamycin was not increased by partial synchronization. This lack of any improvement in the results of therapy using cyclophosphamide and adriamycin is explained by the non-specificity in the mode of action of these substances with regard to the various cell cycle phases. If hydroxyurea, which acts specifically during the S-phase, is used as a therapeutic agent, an improvement in the results of the therapy is obtained by prior synchronization* (1, 3 *and* 4 hr *after partial synchronization*). *Analogous results were obtained with cytosine arabinoside and vincristine, substances which also act predominantly on the S-phase cells.*

INTRODUCTION

THE ACTIVITY of most cytostatic agents varies during the different phases of the cell cycle [1, 2]. In order to improve the effectiveness of the treatment with cytostatics, attempts have been made to increase the proportion of tumour cells in a particularly chemosensitive phase [3–8]. This is achieved by the use of specific inhibitors of macromolecular synthesis. The cells are "collected" at a particular part of the cycle, and after removal of the block reach the sensitive phase synchronously.

Despite promising results obtained after synchronization of both animal and human tumours [4–6, 8–11], it is not yet completely clear whether or not the better therapeutic results really were due to synchronization of the tumour cells [5, 12–18]. In particular, it is difficult to understand why favourable therapeutic results should be obtained after partial synchronization with a substance which does not act specifically during a particular cell cycle phase.

We have now investigated this problem, using rapidly and slowly growing transplanted tumours synchronized with hydroxyurea. Animals were then treated with cytostatic agents cyclophosphamide, adriamycin, hydroxyurea, cytosine arabinoside and vincristine in order to see whether better therapeutic results could be obtained after synchronization.

Accepted 17 February 1977.

We gladly dedicate this paper to Professor Dr. V. Schwartz in celebration of his 70th birthday.

MATERIAL AND METHODS

Animals and tumours

Sprague–Dawley rats (♂, weighing 200 g at the time of tumour transplantation) were maintained under standard conditions (individually in macrolon cages, 25°C, 65% humidity, water and standard diet Altromin^R—from Altrogge, Lage/Lippe—available *ad libitum*). The Walker carcinosarcoma 256 and a solid neurosarcoma were transplanted s.c. in the backs of the animals. The primary tumour of the neurosarcoma was a peripheral tumour of the trigeminus induced transplacentally on the 18th day of

pregnancy by treatment with ethylnitrosourea [19]. Without treatment, animals with the Walker carcinoma survive for 10–12 days, and those with the neurosarcoma *ca.* 10 weeks. In Table 1, data on the cell kinetic parameters of both tumours are presented. The data were calculated from the mitotic indices, labelling indices and percentage of labelled mitoses.

Chemicals

Cyclophosphamide (Endoxan^R, Asta, Brackwede), adriamycin (Adriblastin^R, Farmitalia, Freiburg/Br.), hydroxyurea (HU, m.p. 139°C—we are indebted to Dr. M. Wiessler, Institute for Toxicology and Chemotherapy, German Cancer Research Centre, for the preparation of HU—), cytosine arabinoside (Alexan^R, Mack, Illertissen), vincristine (Vincristin, Lilly, Giessen), ^{3}H-methylthymidine (Fa, NEN, spez. Akt. 20 mCi/mmole).

Toluene scintillator: 34 ml Scintol 3 (Koch–Light Laboratories Ltd., to 1 l toluene.

Chemicals for the preparation of autoradiograms were obtained from Ilford, Essex, England. Other materials were obtained from Merck (Darmstadt).

Synchronization with hydroxyurea

Hydroxyurea (HU) reduces the rate of DNA synthesis to about 5% of the control value at a concentration of 50 mg/kg body weight in both the Walker carcinosarcoma and the neurosarcoma (Fig. 1a). The blockage of DNA-synthesis is carried out by repeated application of HU since the concentration of the reagent in the body rapidly decreases. After the first application, the blockage lasts only 1 hr and after each subsequent application 1.5 hr (Fig. 1b). The following scheme was therefore used: first HU application at 23:30, 2nd application at 0:30 and further applications at intervals of 1.5 hr. In order to determine the maximum possible synchronization with HU, the DNA synthesis was blocked for different times in different groups of animals. Three groups were treated

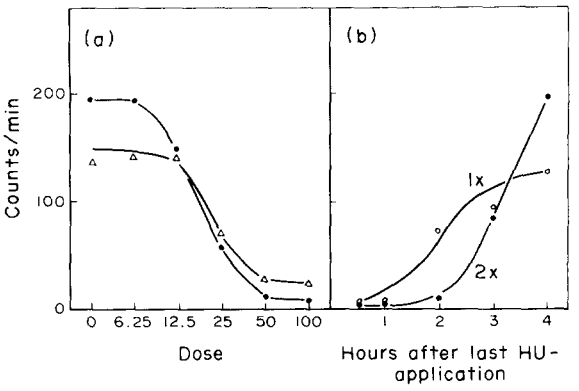

Fig. 1a. Dose–response curve for treatment of the neurosarcoma (△) *and the Walker-carcinosarcoma* (●) *with HU. HU-application (i.p.) at the time* 0. ^{3}*H-thymidine* (0.5 μCi/g *rat, i.p.) was injected* 50 min *later and the animals killed after further* 20 min. *Average values from* 5 *rats* ($n = 60$ *rats*).

Fig. 1b. Comparison of the inhibition in ^{3}*H-thymidine incorporation after* 1 (*time* $t = 0$) *or* 2 (*times* $t = -1$ *and* 0) *injections of HU* (50 mg/kg *body weight*). ^{3}*H-thymidine was injected for a pulse time of* 20 min *and thereafter the animals were killed. Average values from* 6 *rats* ($n = 60$ *rats*).

Ordinates: ^{3}*H-thymidine incorporation per* mg *tumour* (*wet weight*), (△ × 5).

Abscissae: dose (mg HU/kg *body weight*).

with HU either 3, 6 or 9 times, corresponding to a blockage of DNA synthesis for 4, 8.5 or 13 hr respectively. From Fig. 2 it can be seen that the treatment 6 times with HU is sufficient to obtain a good synchronization. The maximal rates of DNA synthesis for the tumour and for normal tissues (duodenum, liver) are reached about 4–6 hr after the last treatment with HU. In all subsequent investigations, synchronization was carried out by 6 successive applications of HU.

Application of cytostatic agents

As soon as the tumours become palpable (Walker-carcinosarcoma, 3–4 days, neurosarcoma, 2–3 weeks), the animals were randomly distributed into groups. After synchronization, the cytostatics were applied i.p. at different cell cycle phases: (1) at the G_1/S border (1 hr after last HU-application), (2) at the maximum in

DNA synthesis (4 hr after last HU application) and (3) after the decrease in DNA synthesis and entry of the tumour cells into M-phase (8 hr after the last HU application). Non-synchronized groups of animals were also treated with cytostatic agents. Tumour size was determined before and after treatment, using a moveable gauge (two diameters, for the Walker carcinoma every day for 4 days; for the neurosarcoma every 2nd day for 7 days) [18, 20]. In addition to increases in tumour size the survival times were also determined. Different doses (prepared in a geometrical series of dilutions) were used in all experiments, the highest concentration (dose V) corresponding to 4/5 LD_{50}. Six to eight animals were used at each time point and for each concentration.

Liquid scintillation counting

Rates of DNA synthesis were determined by injection of ^{3}H-methylthymidine 20 min prior to killing the rats. After killing, the organs were removed, packed in labelled plastic bags, frozen in liquid nitrogen and stored until further use. After thawing, samples were homogenized (ultraturrax) in distilled ice cold water (1:20). Aliquots (3 × 100 μl) of each sample were pipetted on to round filter paper discs (Whatman, 3 MM, 2.3 cm) which were fixed on polistyrol^R sheets with stainless steel pins. Immediately after pipetting the aliquots, the filter papers were dried in a stream of warm air (60 sec) and extracted in ice cold 5% trichloroacetic acid (TCA) (100 filters in 1 l TCA) twice for 30 min. The filters were then washed with ether/ethanol (1:1, 500 ml, 2 × 30 min), ether (250 ml, 10 min), dried and the acid insoluble radioactivity measured by scintillation counting [21, 22].

Autoradiography

Autoradiograms were prepared according to the method of Schultze [23]. Stripping film (Kodak AR 10) was exposed for a period of 3 weeks. The developed sections were stained with HE and 1000 cells were counted by 2 observers for each tumour. For the determination of labelling index (LI) only cells were counted which had more than 5 grains.

Determination of the mitotic index (MI)

Histological sections were stained with acid haemalaun and 2 persons counted at least 1000 cells each to determine mitotic index.

Statistical analysis

Experimental animals were distributed into individual groups using random numbers. Each group contained 6–8 animals. Days on which measurements were to be made were determined before commencing the experiment. Evaluation of results was carried out by two way variance analysis.

We are very grateful in Professor Dr. H. Immich, Department of Medical Documentation and Statistics, University of Heidelberg, and Professor Dr. E. Weber, Institute for Documentation, Information and Statistics, German Cancer Research Centre, Heidelberg,

for discussions on the statistical evaluation of experimental results.

RESULTS

Synchronization

The degree of synchronization obtained by blockage of DNA synthesis in the Walker-carcinosarcoma and neurosarcoma with HU for 8.5 hr is shown in Figs 3 and 4. When treatment with HU is stopped, a peak in DNA synthesis is observed (^{3}H-thymidine incorporation) which is followed by an increase in mitotic rate. The curves then return to control values. The HU applied during synchronization had no effect on the growth (tumour size) of either tumour.

Therapy

Both the solid Walker-carcinosarcoma and the solid neurosarcoma respond to treatment with cytostatics (Fig. 5). Cyclophosphamide has a very pronounced, dose-dependent inhibitory effect on the growth of the Walker-carcinosarcoma, whereas the effect on the slowly growing neurosarcoma is not so evident. In the following experiments, the tumour size was measured on different days after application of cytostatic agents and the average daily increase was taken as a measure of the success of therapy.

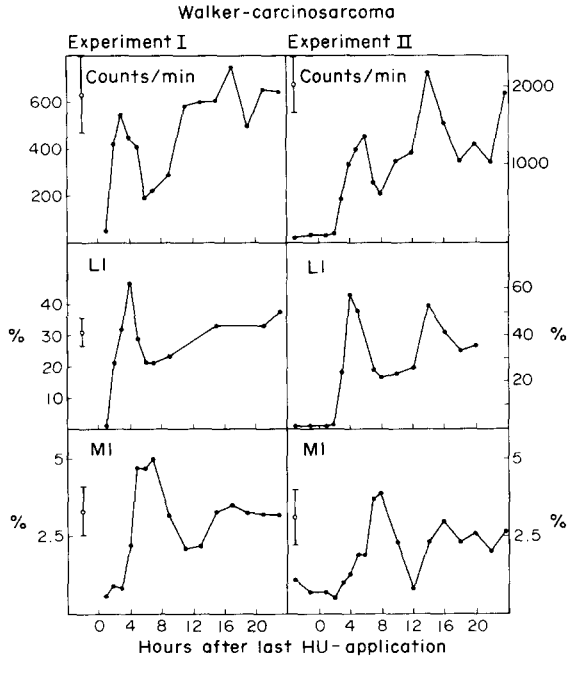

Fig. 3. Effect of 6 applications of HU on solid Walker-carcinosarcoma in two independent experiments on ^{3}H-thymidine incorporation (top, counts/min*), labelling index (middle, LI), and mitotic index (bottom, MI). At each point, 3 (exp. I) or 6 (exp. II) synchronized animals and the same number of non-synchronized control animals were used ($n=278$ rats). At the times shown (abscissa) the animals were killed. ^{3}H-thymidine (exp. I, 0.5 μCi/kg; exp. II: 1 μCi/kg body weight) was injected i.p. 20min (exp. I) or 60 min (exp. II) prior to killing. Each tumour was removed and cut into two parts, one of which was fixed in formalin and used for the determination of LI and MI and the other frozen in liquid nitrogen for measurement of ^{3}H-thymidine incorporation* (counts/min/mg *wet weight). The form of the curves after synchronization is statistically significant in all cases ($P=0.05$). The shape of the curve obtained for the control values was not significant and is therefore presented as one point (with S.D.).*

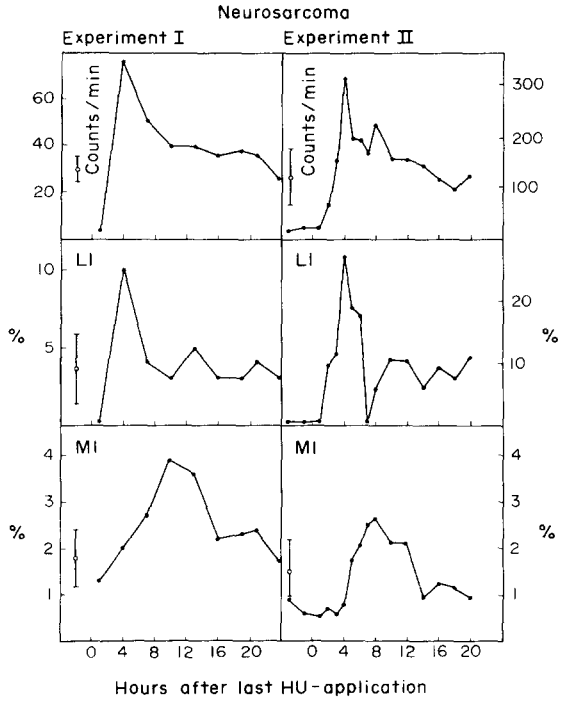

Fig. 4. Partial synchronization of solid neurosarcoma after 6 applications of HU in 2 independant experiments. At each time point, 3 (exp. I) or 7 (exp. II) synchronized animals and the same number of non-synchronized animals were used ($n=306$ rats). For details, see Fig. 3. The form of the curves after synchronization is statistically significant ($P=0.05$). The shape of the curve obtained for the control values was not significant and is therefore presented as one point (with S.D.).

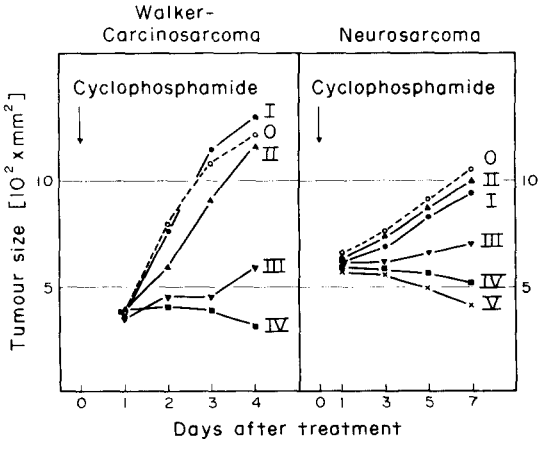

Fig. 5. Growth curve (tumour size in mm^2*) for the Walker-carcinosarcoma and the neurosarcoma without treatment (○) and after application of different doses of cyclophosphamide* (mg/kg: I $=9.5$; II $=19$; III $=38$; IV $=76$; V $=152=4/5$ LD$_{50}$). *Days of application are indicated by arrows. Average values from 6 tumours at each point ($n=66$ rats).*

In order to test whether the efficiency of therapy could be increased by prior synchronization with HU, cytostatics were applied to groups of animals at different times after synchronization with HU. The times of application were chosen in such a way that cells in different phases of the cell cycle were exposed to the cytostatic agents (late G_1, S, mitosis).

The data obtained on the effects of cyclophosphamide on the synchronized and non-synchronized Walker-carcinosarcoma are presented in Table 2 (tumour size, increase in tumour size and survival time). Although a clear dose-dependent reduction in tumour growth and a lengthening of survival times of the animals is obvious in all cyclophosphamide-treated groups, no differences could be observed between the effects on synchronized and non-synchronized animals. The time of application of cyclophosphamide with respect to the last HU treatment did not influence the results.

Analogous results were obtained for the neurosarcoma, in which similar dose-dependent inhibitions of tumour growth were observed for the synchronized and non-synchronized animals (Table 3). The results of therapy were also similar for both cases, and independent of the time of application of cyclophosphamide.

The cytostatic agent adriamycin exerts a much smaller effect than cyclophosphamide on the growth of the neurosarcoma. In contrast to the non-specific action of cyclophosphamide, adriamycin is presumed to affect proliferating cells in the S-, G_2- or M-phases of the cell cycle [1]. For this reason, the possibility of increasing the activity of adriamycin by prior synchronization of the cells was investigated. Adriamycin was injected 1, 4 and 8 hr after the last application of HU. Table 4 shows that the activity is not increased at any time by this procedure.

Other authors reported that cyclophosphamide and adriamycin preferentially affect cells in S-phase [4–6]. We therefore carried out an experiment in which the synthesis of DNA was blocked with HU, cyclophosphamide, or adriamycin, were applied and the block in DNA synthesis maintained for a further 5 hr. A reduction in the effect of the therapy owing to the block in DNA synthesis, which would be expected if the opinion of these authors is correct, was not observed (Table 5).

The lack of an improvement in therapeutic results, using cyclophosphamide and adriamycin after partial synchronization can be explained by the relatively unspecific action of these substances during the cell cycle. In the subsequent experiments, substances were used which have a more specific mode of action [1, 24]. An improvement in the success of therapy was indeed observed with HU when applied during the maximum in DNA synthesis (3 and 4

hr after the last application of HU) for the purposes of synchronization (Fig. 6).

In order to determine whether the improved results with HU can only be obtained when the substance is applied during the maximum in DNA synthesis, therapy was carried out at different times after synchronization. Figure 7 shows that an increased effect is only obtained by injection of HU at 1, 3 and 4 hr after the last HU application. After injection at 8 and 16 hr, no difference could be observed between tumour growth in synchronized and non-synchronized animals.

With this experimental system it can not be said, that the improved therapeutic results are really due to the synchronization or that the pretreatment with HU for synchronization could render the cells more susceptible to a subsequent therapeutic dose following soon after. For this reason, other substances were tested—cytosine arabinoside and vincristine—which have specific prints of attach during the cell cycle. Cytosine arabinoside and vincristine preferentially attack S-phase cells [1, 2] (low doses of vincristine hold cells up in mitosis, whilst 10 times the concentration favours cell kill in the S-phase). The times of application of the cytostatics after synchronization were chosen such that the tumour cells were exposed during the different cell cycle phases. Whereas the asynchronous tumours reacted only weakly or not at all to both substances, synchronized tumours responded clearly to therapy, the major effect being observed after the first two times of application (1 hr = G1-S-phase; 3.5 hr = S-phase) (Fig. 8).

DISCUSSION

In order to study the question whether the success of tumour therapy can be improved by partial synchronization of the tumour cells, experiments were carried out with the solid Walker-carcinosarcoma and neurosarcoma. The tumours were synchronized with HU, a substance which blocks the passage of cells through the S phase but allows cells in G_2, M or G_1 to continue through the cycle until they reach the G_1/S boundary [1, 24, 25]. Using 6 individual applications of HU the synthesis of DNA could be blocked for *ca.* 8.5 hr. With this dose, which corresponds to 1/3 of that used by Rajewsky [24], both tumours could clearly be synchronized. The dose used was chosen so that a total block could be induced in the synthesis of DNA without there being any detectable inhibitory effect on tumour growth.

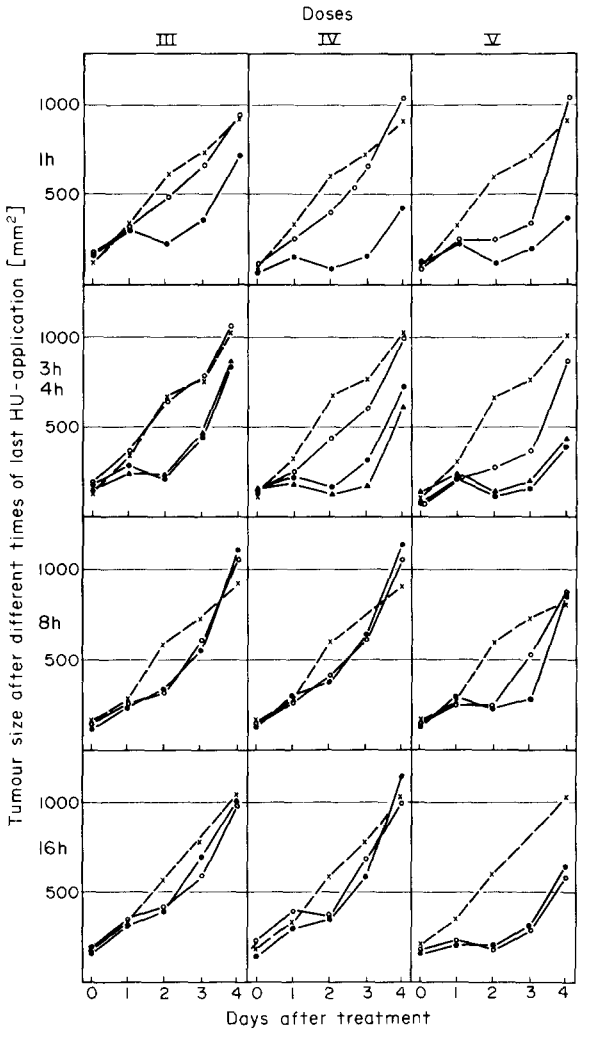

Fig. 7. Tumour size of the Walker-carcinosarcoma on different days after synchronization and treatment with HU. Doses: (mg/kg/20 ml *saline*)*:* III (1400), IV (2800), V (5600). *The therapeutic dose of HU was applied at* 1, 3 *or* 4, 8 *and* 16 hr *after the last synchronizing dose of HU* (*see Table* 1).

In addition to the blockage induced by HU at the G_1/S boundary, it has been reported that HU has cytotoxic effects on cells in the S-phase [1, 24, 25]. The length of the cell cycle for the Walker-carcinosarcoma is relatively short (9 hr). More than half of the cells are in the S-phase at any particular time and can therefore be eliminated by treatment with HU. This explains the fact that in the DNA synthesis peak observed after removal of the block, the control values are not reached. For the slowly growing neurosarcoma (cell cycle duration 22 hr), only 1/4 of the proliferating cells are found in the S-phase and are thus susceptible to the action of HU. When the block is lifted, a maximum in DNA synthesis is reached with values twice as high as in the controls.

Over the past few years, a "synchronization therapy" has been carried out in various clinics. It was hoped that by "collection" of cells in a cell cycle phase which is particularly sensitive to the action of certain cytostatics, the tumour cells could be selectively eliminated.

Various studies have reported favourable therapeutic results with cyclophosphamide after partial synchronization with vincristine [4–6]. This positive effect was interpreted on the basis

of an S-phase specific activity for cyclophosphamide. An apparent contradiction exists here, since other workers have reported that cyclophosphamide has an unspecific effect on all cells [1, 16, 17]. In order to resolve this problem, cyclophosphamide therapy was carried out on two different rapidly growing solid transplanted tumours after partial synchronization. The times of application were chosen such that the cells were exposed to the drug at different phases of the cell cycle (late G_1, S and M). Partial synchronization was carried out with HU rather than vincristine, since using the latter substance, a synchronous passage of the cells through the S-phase can not always be induced [12, 14]. With the tumours used here, dose-dependent increases in the effects of therapy were obtained which were, however, independent of the degree of synchronization (Tables 2, 3, 5). Similarly, at other times after synchronization (3 and 6 hr before last HU-application), no differences were observed. According to these results, cyclophosphamide is not active specifically during one phase of the cell cycle. The improved therapeutic results obtained by other authors using cyclophosphamide after pre-treatment with vincristine could be explained on the basis of a combination therapy with particularly favourable timing of the application of the substances. The pre-treatment with vincristine might lead to a fascilitated drug entry into cells.

Also with adriamycin, which reacts mainly with S/G_2 and M-phase cells, no improvement in results was obtained after synchronization. The results of therapy were the same for synchronized and non-synchronized animals with both the neurosarcoma (Table 4) and the Walker carcinosarcoma (unpublished results). These results do not exclude the possibility that an improvement in the results of therapy would be obtained using an appropriate combination of vincristine and adriamycin [6]. The results do, however, show that no improvement can be obtained after synchronization with adriamycin. This is perhaps not surprising, since the biological half life of adriamycin is about 24 hr [26], and during this time all of the cells can pass through the sensitive cell cycle phases.

If HU is used both as a synchronizing agent and, in higher doses, as a cytostatic substance, a clear increase in the effect of therapy is observed (Fig. 6, 7). This improvement is only obtained if the cytostatic dose of HU is applied at the G_1/S boundary or during the S-phase (1, 3 and 4 hr after partial synchronization). Since the combination of synchronization and therapy, using HU could represent an exceptional case, a further experiment was carried out using cytosine arabinoside and vincristine, which affect predominantly S-phase cells as does HU. The results of this experiment are similar to those obtained using HU. The increased effects of therapy using HU, cytosine arabinoside and vincristine after a synchronization step could be explained by the short biological half lives of these substances which would ensure that each cell cycle phase is exposed invididually to the drug. So, the "synchronization therapy" can improve the effectiveness of tumour therapy with cytostatics.

The Relationship of Plasma Prolactin to 17-B Oestradiol in Women with Tumours of the Breast

M. K. JONES,* I. D. RAMSAY,† W. P. COLLINS† and GAIL I. DYER*

**Faith Courtauld Unit for Human Studies in Cancer, King's College Hospital Medical School, London, †North Middlesex Hospital, London and ‡Department of Obstetrics & Gynaecology, King's College Hospital, London, United Kingdom*

Abstract – *The concentrations of plasma prolactin and 17-B oestradiol in peripheral venous plasma were measured in 94 female patients previously admitted for breast surgery. The results showed that the levels were not significantly different in those patients with early breast cancer compared with those with benign breast disease. In addition, there was no direct correlation between the circulating levels of oestrogen and prolactin. The levels of prolactin, however, were shown to be significantly lower after the menopause.*

INTRODUCTION

OESTROGEN is thought to be the most important factor regulating the secretion of prolactin in the female rat [1]. This relationship may well be true in women. Friesen and Hwang raised basal prolactin concentrations [2] using pharmacological doses but Jaffe *et al.* were unable to repeat this finding [3]. There seems little doubt that oestrogen potentiates the prolactin response to drug stimulation [4, 5] and more recently it has been shown that relatively low doses of oestrogen are effective in stimulating prolactin secretion [6].

At a more physiological level, the literature is again conflicting. Prolactin levels increase progressively during pregnancy [7] and are elevated in the middle of the menstrual cycle and during the luteal phase [8]. Both these reports suggest that the changes are oestrogen related. However, Hwang *et al.* [9] and Friesen *et al.* [10] found no change in prolactin levels during the menstrual cycle. More recently, Vekemans and Robyn [11] observed that plasma prolactin levels decreased with age and concluded that the fall was due to the declining level of oestrogen. Boyns *et al.* [12] reported a similar finding in patients with breast cancer.

It is well recognised that hormones are involved in the growth and development of breast cancer. Much work has been done on the endocrine status of these patients. In animal work oestrogen, progesterone, cortisol, prolactin and growth hormone have been shown to be necessary for mammary growth and development [13]. However, in women with malignant breast disease, although the plasma concentrations of oestrogen and prolactin have been measured separately, nothing is known about their inter-relationship. The purpose of our study was to investigate this relationship in women with benign and malignant breast disease, by correlating the changes in prolactin with changes in 17-B oestradiol concentration measured on the same sample of blood. We also set out to study the effect of menopausal status on circulating prolactin concentrations in these women.

MATERIAL AND METHODS

Ninety-four patients aged between 25 and 70 yr, who had been admitted for breast surgery were studied. All gave their informed consent. The patients were subsequently divided into two groups: those with benign and malignant disease, according to the histology of the breast tissue removed. Only patients with cancer Stages I and II of the Manchester Classification [14] were included in the group with malignant tumours. Patients were then categorised as being pre- or post-menopausal, depending on whether 6 months had lapsed since the menses had ceased. The menopausal status of these patients was checked 2 yr later, and if any doubt existed about their original classification these patients were excluded from the study. Patients taking drugs

Accepted 16 March 1977.

that might affect oestrogen or prolactin concentrations were also excluded from analysis.

As physical and psychological stress have been implicated in raising prolactin concentrations [15] venepuncture was performed on a visit to the hospital 3 months after surgery. The sample was collected between 9.00 a.m. and 10.00 a.m., because there is evidence of a sleep-mediated 24-hr pattern of prolactin secretion [16]. Plasma was separated by centrifuging at 1000 rev/min for 15 min and immediately stored at −20°C. Prolactin and 17-B oestradiol concentrations were analysed on the same blood sample.

17-B oestradiol was separated on a column of Sephadex LH20 and determined by radioimmunoassay in a system containing the tritiated antigen, and an antiserum to oestradiol-6-carboxymethyloxime-bovine serum albumin [17].

Prolactin was measured by a specific double antibody radioimmunoassay using an anti-human prolactin antiserum raised in rabbits and purified human pituitary prolactin as standard and for iodinisation [18].

RESULTS

The frequency with which the concentrations of prolactin and 17-B oestradiol appeared in each group was studied and it was concluded that in general the distribution was best described by geometric mean and range. The values are shown in Tables 1 and 2. The prolactin results are expressed in micro units of the human pituitary prolactin research standard MRC71/222. An analysis with Students' *t*-test on the log data showed that there were no significant differences in the levels between patients with benign breast disease and those with early breast cancer (Table 1). On application of the Bravais–Pearson coefficient of linear correlation there was no significant tendency to a straight line. The concentrations of prolactin ($P<0.025$) and 17-B oestradiol ($P<0.001$) were significantly higher in the premenopausal, compared with the postmenopausal groups (Table 2).

DISCUSSION

There were no significant differences in plasma 17-B oestradiol and prolactin concentrations between patients with benign breast disease and those with early breast cancer. Data on plasma oestradiol and prolactin concentrations after the menopause is relatively scarce. It is known, however, that plasma 17-B oestradiol production from the ovary ceases abruptly at the menopause [19, 20], and that peripheral venous blood concentrations fall to approximately 80% of their premenopausal values. When comparing prolactin and 17-B oestradiol concentrations in the benign and cancer patients we therefore regarded the postmenopausal group as being homogeneous.

Table 1. *The concentrations of plasma oestradiol and prolactin in patients with benign and malignant disease of the breast*

Plasma oestradiol						
Menopausal status	Diagnosis	Number of patients	Mean (log)	Geometric mean (pmole/l)	Standard deviation (log)	Range (pmole/l)
Premenopausal	Benign	42	2.4159	260.6	0.323	43.1–876.6
	Cancer	16	2.3072	202.9	0.390	34.2–893.9
Postmenopausal	Benign	11	2.0829	121.0	0.370	22.1–293.3
	Cancer	25	2.1128	129.7	0.176	57.0–243.2
Plasma prolactin				(mu/l)		(mu/l)
Premenopausal	Benign	40	2.4128	258.7	0.133	144.0–478.0
	Cancer	14	2.4073	255.5	0.176	132.0–540.0
Postmenopausal	Benign	10	2.2948	197.2	0.200	94.0–372.0
	Cancer	19	2.3439	220.7	0.132	124.0–370.0

Our results agree with other groups who have studied serum prolactin levels in breast cancer [12, 21–24]. However, some of these studies must be interpreted with caution: blood samples were not always taken at a uniform time of day, a variety of control groups was used and data on patients' use of drugs was omitted. Operative stress may also, in some cases, have affected results. Kwa *et al.* [25] suggest that although they found no difference in plasma prolactin concentrations between patients with breast cancer and matched hospital controls, it may be a factor in certain high risk populations.

Owing to the great individual variation in 17-B oestradiol during the menstrual cycle, it is not

Table 2. The concentration of plasma oestradiol and prolactin in pre- and postmenopausal patients with breast disease

Menopausal status	Number of patients	Mean (log)	Geometric mean (pmole/l)	Standard deviation (log)	Range (pmole/l)	*t*. Value	Degrees of freedom	2-tailed probability
Plasma oestradiol								
Premenopausal	58	2.3859	243.2	0.343	43.1–893.9	4.63	90	$P<0.001$
Postmenopausal	36	2.1037	127.0	0.246	22.1–293.3

Plasma prolactin								
Premenopausal	54	2.4114	257.9	0.144	132.0–540.0	2.47	81	$P<0.025$
Postmenopausal	29	2.3269	212.3	0.157	94.0–372.0			

justified to comment on our premenopausal data on this hormone. However, postmenopausally there was no significant difference in 17-B oestradiol concentrations between patients with benign breast disease and those with early breast cancer. The only other study we are aware of measuring postmenopausal 17-B oestradiol concentrations in women with breast cancer [26] reported raised concentrations which is in conflict with our results.

Our results show that both prolactin ($P<0.025$) and 17-B oestradiol ($P<0.001$) concentrations were significantly lower in the postmenopausal compared with the premenopausal groups, but there was no correlation between prolactin and 17-B oestradiol concentrations in the same blood sample in either group. In the premenopausal group it could be said that no correlation was shown as 17-B oestradiol concentrations fluctuate greatly throughout the menstrual cycle. However the same cannot be said postmenopausally, when oestrogen levels are relatively constant [20].

We have shown that prolactin levels fall as women with breast disease pass through the menopause, and our results agree with those of Vekemans and Robyn [11] who studied a normal population. However, at physiological levels, in our patients, it would seem that there is no definite direct relationship between prolactin and 17-B oestradiol. This could mean that patients with breast disease differ in the way that prolactin secretion is controlled from "normal" women, or that they form one population in this respect, and prolactin levels in normal women although related to menopausal status or advancing age, are not related to circulating plasma 17-B oestradiol. It must be said that although 17-B oestradiol is the most potent oestrogen and oestriol is only present in much reduced levels, oestrone may well have a greater affinity for hypothalamic receptor sites than 17-B oestradiol and play the major role in control of prolactin secretion. Further investigation into the "prolactin–oestrogen" relationship is obviously required before the role played by oestrogens in prolactin secretion is understood.

Acknowledgements – We would like to thank Dr. A. S. McNeilly and Dr. Lesley Rees of St. Bartholomew's Hospital, London, for measuring plasma prolactin concentrations; we are grateful to an anonymous American donor for financial support for Dr. M. K. Jones.

Serum Kappa-Casein in Breast Cancer

R. L. WOODS,* F. SEARLE,† P. WILSON,† K. D. BAGSHAWE† and E. H. COOPER‡

†*Department of Medical Oncology, Charing Cross Hospital, London, W6 8RF, Great Britain and*
‡*Department of Experimental Pathology and Cancer Research, University of Leeds, Leeds, Great Britain*

Abstract—*Kappa-casein concentrations were measured by radioimmunoassay in serum samples from patients with breast diseases, and from controls, who were healthy volunteers and patients with various non-malignant diseases. Seventeen of three hundred and sixty-one* (4.7%) *samples from controls gave values of greater than* 60 ng/ml. *Sixty-two samples from lactating women gave values ranging from* 136 ng/ml *to* 1700 ng/ml. *Forty-nine of eighty-eight* (55.6%) *samples from patients with metastatic breast cancer and* 21 *of* 53 (39.6%) *samples from patients with cancer localized in the breast and its regional nodes had K-casein concentrations greater than* 60 ng/ml. *Twelve of forty-nine* (19.7%) *patients with treated breast cancer who were clinically tumour-free at the time of sampling, and* 10 *of* 76 (15.2%) *samples from patients with histologically established benign breast disease had increased serum concentrations of Kappa-casein. No correlation was found between casein levels and age, parity and endocrine status.*

INTRODUCTION

SEVERAL workers have suggested that mammary tumours may produce casein. Turkington [1] reported the presence of a casein-like fluid in a rat mammary carcinoma cultured *in vitro*, whilst Young [2] also demonstrated a milk protein in mammary tumours grown *in vitro*, although the antisera he used were not specifically raised to the casein fraction of the milk proteins.

Radioimmunoassay of alpha-lactalbumin has been performed and various reports [3] indicate that this protein is not elevated in the serum of patients with breast cancer. Hendrick and Franchimont [4] however, have reported that a significant number of patients with breast cancer have elevated concentrations of circulating casein. A radioimmunoassay for casein was, therefore, developed to assess the possible value of this protein as a marker of tumour activity in the management of breast cancer patients.

Normal production of casein in lactating women is known to be dependent on circulating prolactin levels [5], but attempts to induce casein production in cultured mouse mammary tumours by increasing the prolactin concentration in the cultured medium have been only partially successful [6]. Prolactin secretion is not constant throughout the day, and single assays of this are of only limited value. Tests involving stimulation of the pituitary gland to maximal or near maximal secretion of prolactin and other anterior pituitary hormones reflect the endocrine status of the patient more accurately than do random assays of the individual hormones. These tests were, therefore, performed on a small number of patients with elevated concentrations of K-casein in their peripheral blood.

MATERIAL AND METHODS

Preparation of casein

Human milk was obtained from the Human Milk Bureau (South Birmingham HMC), and whole casein was prepared by the method of Malpress and Seid-Akhavan [7].

In view of the instability of whole casein after iodination, this was fractionated by the method of Malpress [7] to yield Kappa-casein, and this fraction was used throughout the study for standards, for labelled antigen and for antiserum production. This was stored at 20°C.

Production of antiserum

One milligram of Kappa-casein was injected into 30 intradermal sites on two rabbits, followed by booster injections after 40 days. A further booster injection was made after 4 months. The

Accepted 14 March 1977.

antiserum was absorbed with 20 mg/ml of freeze-dried normal human plasma. The antiserum gave a single line of precipitation when tested on Ouchterlony double diffusion plates against whole casein and Kappa-casein.

Iodination procedure

Iodination was carried out by modification of the standard chloramine T procedure [8]. Ten micrograms of Kappa-casein in 10 μl of 0.05 molar phosphate buffer (pH 7.5) were added to 1 mCi of ^{125}I in 10 μl of 0.05 M phosphate buffer. Twenty-five microliters of a 1 mg/ml solution of chloramine T in 0.05 M phosphate buffer were added to the solution and mixing was allowed to proceed for 30 sec before 100 μl of 0.05 M phosphate buffer containing 120 μg of sodium metabisulphite was added and allowed to mix for 30 sec. Two hundred microliters of a solution containing 20 mg/ml of bovine albumin and 2 mg/ml of potassium iodide were added to the solution and allowed to mix for one minute before separation of the iodinated protein fraction on a 25 cm × 1.5 cm column of sephadex G 150.

Treatment with iodoacetamide [9] before iodination decreased the immunological damage encountered on iodination; and when prepared in this manner, the ^{125}I Kappa-casein was usable for 7 days.

Assay method

Radioimmunoassay was performed by a double antibody method by means of an automatic, dispensing, filtering and counting apparatus, with computer calculation of results [10].

One hundred microlitres of normal serum and 100 μl of 0.05 M phosphate buffer containing known amounts of K-casein were added to polystyrene tubes for calibration standards. One hundred microliters of sample serum and 100 μl of 0.05 M phosphate buffer were dispensed into other tubes. Fifty microlitres of diluted antiserum were added. The antiserum was diluted into phosphate buffer containing 400 mg/ml of ethylene diaminotetracetic acid (EDTA). The initial dilution of antiserum used was one part in 12,500 giving a final dilution of 1 in 87,500. This mixture was incubated at 37°C for 2 hr.

Fifty microlitres of ^{125}I K-casein diluted in 0.05 M phosphate buffer were then added and incubation was allowed to proceed for a further 2 hr at 37°C.

Fifty microlitres of sheep anti-rabbit globulin antiserum were added and incubation continued for 16 hr at 5°C. Separation was by glass fibre discs on an automatic filtration machine described elsewhere [10].

Quality control

Aliquoted pools of sera with known high and low casein concentrations were stored at −20°C and those were incorporated in each assay as quality controls. The within assay coefficient of variation was 2.5%. The between assay coefficient of variation was 18%.

Samples

Serum was collected from patients with known breast diseases, both benign and malignant, at various stages in the course of the disease. Samples, were also obtained from healthy volunteers, from hospital patients with various non-malignant diseases and from lactating women. The serum was separated and stored at −20°C until assayed for K-casein.

Pituitary stimulation test

The patients selected for this test were all under the age of 60 without any cardiovascular abnormality. Samples of blood were collected for assay of glucose, adrenocorticotrophic hormone (ACTH), growth hormone (GH), cortisol, thyroid-stimulating hormone (TSH), prolactin and K-casein. Soluble insulin (0.15 units/kg), 200 μg of thyrotrophin-releasing hormone (TRH) and 100 μg of luteinizing-hormone-releasing hormone (LHRH) were then injected intravenously. Further samples were collected at 15, 30, 45, 60, 90 and 120 min for estimation of glucose, ACTH, GH, cortisol, TSH, prolactin and casein.

RESULTS

The limit of sensitivity of the assay was 300 pg of K-casein per tube (30 ng/ml). Values were not affected by thawing and freezing samples up to five times, nor by the addition of EDTA to the collecting tubes. Since the inhibition curve obtained with our K-casein and antiserum was almost super-imposable upon that obtained by using our K-casein and Hendrick and Franchimont's anti-whole-casein serum, it was concluded that our antiserum was directed against the same determinants. (We are indebted to Professor Franchimont and Dr. Hendrick for the above result.)

Assay of 361 control samples (72 normal subjects and 289 patients with non-malignant diseases) gave 17 results greater than 60 ng/ml. Assay of 62 samples from lactating women gave values in the range 136 ng/ml to 1700 ng/ml.

Of 76 patients with histologically established benign breast diseases, 10 had values in excess of 60 ng/ml. (Fig. 1). Samples from 53 patients with

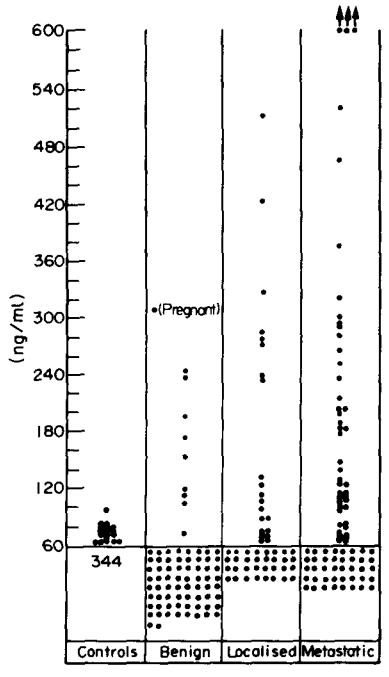

Fig. 1. Distribution of K-casein concentrations in normal subjects, patients with benign breast diseases and patients with breast cancer.

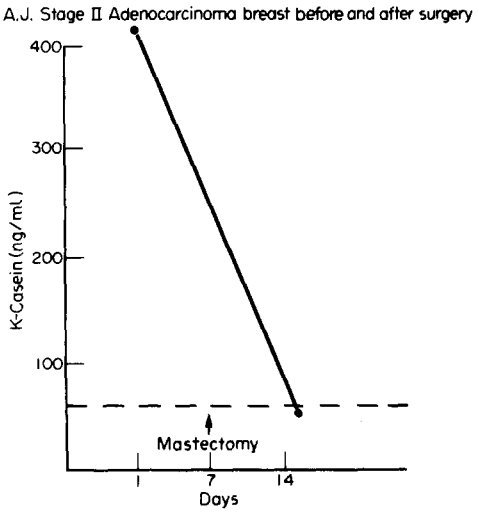
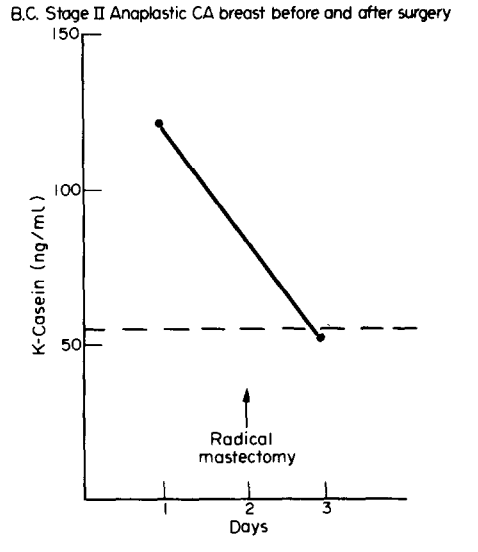
tumours localized to the breast or ipsilateral axillary nodes were assayed. Twenty-one of these (39.6%) had concentrations of K-casein greater than 60 ng/ml whereas 49 of 88 (55.6%) samples from patients with metastatic breast cancer gave results greater than 60 ng/ml (Fig. 1).

No abnormalities were found in glucose, adrenocorticotrophic hormone, growth hormone, cortisol, thyroid-stimulating hormone or prolactin values of six patients with elevated casein values before and after stimulation with insulin, thyrotrophin-releasing hormone, and luteinizing-hormone releasing-hormone. Casein concentrations did not alter following pituitary stimulation.

There was no correlation between casein concentration and age, menstrual status, parity, family history of breast cancer, number of breast-fed children, history of hormone administration, or, in advanced disease, site of metastases. Studies of a possible correlation between K-casein concentrations and the histological type of tumour are in progress.

Serial measurements of K-casein concentrations were performed in a small number of patients (Figs. 2–5). In two patients, K-casein values fell following mastectomy (Figs. 2 and 3). Clinical remissions and relapses correlated with falls and elevations of casein concentration (Figs. 4 and 5), but it is not yet clear whether changes in casein concentrations are sufficiently sensitive to give advance warning of changes in the clinical condition.





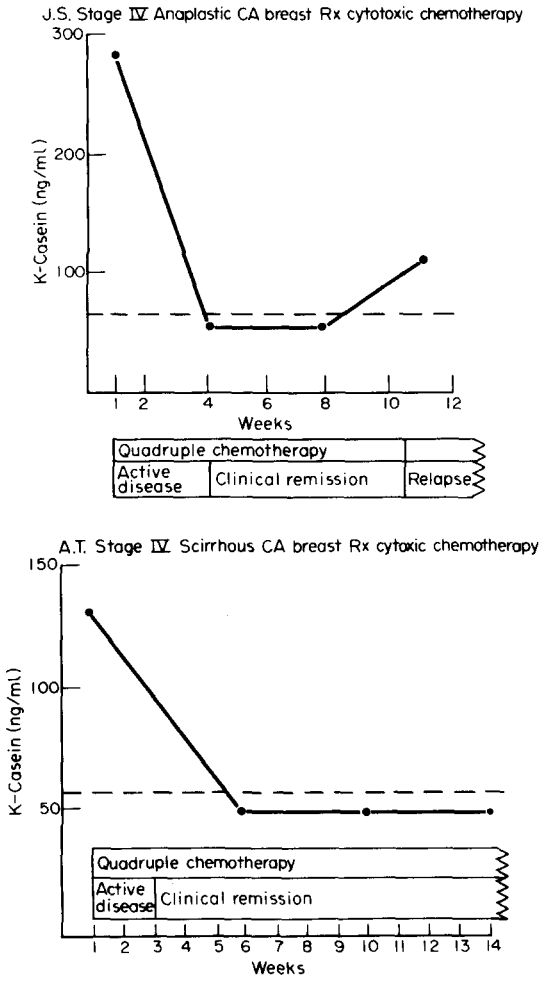
Figs. 2 and 3. K-casein concentrations in two patients before and after mastectomy.

DISCUSSION

Apart from any information which studies of tumour products may yield about the cell kinetics of various cancers, they may be of value in their clinical management. Tumour products already aid screening, diagnosis, treatment monitoring, follow-up and prognosis of various malignant diseases.

Breast cancer is the commonest tumour of women. Current clinical problems include early detection, adequacy of initial therapy, detection and treatment of occult metastatic disease, and treatment of overt metastatic disease. A suitable tumour marker might help solve these difficulties.

The ideal tumour index substance would have several properties: it should be soluble, detectable in peripheral blood, and preferably have a short half-life so that changes in plasma con-



Figs. 4 and 5. K-casein concentrations in 2 patients receiving cytotoxic chemotherapy, showing correlations between these concentrations and clinical conditions.

centrations would accurately and quickly reflect growth or regression of the tumour producing it. K-casein fulfils these criteria although clearly it is not detectable in the serum of all patients with breast cancer and is not unique to breast cancer. Studies to determine the exact half-life of K-casein are in progress but changes in casein concentrations have been noted within 48 hr of removal of tumours by mastectomy.

Many tumour markers are hormones and suffer from the disadvantage of requiring differentiation from the normal hormone concentrations. We have found elevated circulating casein concentrations to be common in benign and malignant breast diseases, other malignancies, and in pregnant and lactating women (Fig. 1), whereas the incidence of positivity in the control samples is low (4.7%) and this degree of specificity may be acceptable for clinical purposes. We have no evidence that casein concentrations are affected by any secondary factors such as physiological variations in the lactogenic hormones.

It seems, however, that any role which K-casein may have as a screening agent for breast cancer may be limited by the relatively high number of positive values in patients with histologically proven benign breast diseases, and by the high number of negative results found in patients subsequently shown to have breast cancer.

Many of tumour-associated antigens are enzymes or hormones found in foetal or placental tissue, and thought to be produced by the tumour as a result of genetic derepression. It seems probable that the mechanism of secretion of this exocrine product may be a similar response to changes in cellular genetic control, induced by the onset of malignancy. The cells most sensitive to such a change would be those already associated with production of the normal product. Thus it may be that mammary gland cells require less "transformation" to produce milk proteins than cells from other organs and this may account for the high incidence in breast cancers. This is similar to the situation with other tumour markers, such as human chorionic gonadotrophin, which is produced by many tumour types, but which is particularly common in the tumours of the placenta and testis.

Immunofluorescent studies are in progress to ascertain whether production of K-casein is directly from the tumour, or whether it is produced by the normal breast tissue as a response to malignancy.

Relative Importance of Genotype and Type of Mammary Tumor Virus on Mammary Tumorigenesis in Mice*

HIROSHI NAGASAWA,† SOTOKICHI MORII,‡ AIRO TSUBURA‡ and REIKO YANAI†

†*Pharmacology Division, National Cancer Center Research Institute, Tsukiji* 5-1-1, *Chuo-ku, Tokyo* 104, *and*
‡*Department of Pathology, Kansai Medical University, Fumizono-cho* 1, *Moriguchi-shi, Osaka* 570, *Japan*

Abstract—*Relative importance of genotype and type of mammary tumor virus (MTV) on determining the biological and morphological characteristics of mammary tumors appearing during reproductive states was studied in mice. Females of GR/A§, SHN, their reciprocal F1 hybrids [(GR × SHN)F1 and (SHN × GR)F1, GR/A fosternursed by SHN lactators (GR/SHN) and SHN fosternursed by GR/A lactators (SHN/fGR) were subjected to force breeding until the* 3rd *to the* 5th *pregnancy beginning* 60 days *of age. In GR/A, both F1-hybrids and GR/fSHN, mammary tumor incidence by the* 3rd *pregnancy was* 88–100%, *all tumors were pregnancy-dependent and almost all of them were diagnosed as plaques or mammary tumor type p. On the other hand, in SHN and SHN/fGR, mammary tumor incidence and percentage of pregnancy-dependent tumors were very low and most of the tumors were adenocarcinoma. Numbers of tumors per mouse were* 2.2–3.2 *and about* 1 *in the former four and in the latter two groups, respectively. Taking into consideration of the genotype(s) and type(s) of MTV of each group of mice, these results indicate that the relative importance as factors for determining the characteristics of mammary tumors during the reproductive states in mice is in the order of GR-genotype, SHN-genotype, GR type of MTV and SHN type of MTV.*

INTRODUCTION

GR/A§ MICE [1] is unique in that the growth of mammary tumors is pregnancy-dependent and mammary tumor virus (MTV) is transmitted not only by females but also by males. Genetical control of the transmission of this type of MTV [2–4] and the growth pattern of this type of mammary tumors [5] have been studied. On the other hand, in SHN mice established recently in our laboratory [6], the growth of mammary tumors is autonomous and MTV is transmitted only through milk quite similarly to most high mammary tumor mouse strains [7, 8], although this strain has been established with no relation to the other high mammary tumor strains.

The primary objective of this paper is to evaluate the relative importance of genotype and type of MTV in determining the biological and morphological characteristics of mammary tumors using these two strains with special reference to the tumors which appear during the reproductive states.

MATERIAL AND METHODS

GR/A and SHN strains maintained in the senior author's laboratory were used at F69–70 and F28–29 of brother × sister mating, respectively. Six groups were set up: Group I, GR/A; Group II, SHN; Group III, Fl-hybrid between GR/A females and SHN males [(GR × SHN)Fl]; Group IV, Fl-hybrid between SHN females and GR/A males [(SHN × GR)Fl]; Group V, GR/A fosternursed by SHN [GR/fSHN]; Group VI, SHN fosternursed by GR/A [SHN/fGR]. In Groups V and VI, new born females were removed from their own mothers within 8 hr, mostly immediately after birth, and groups of 6–7 were fosternursed by females of another strain that had began to lactate 2–4 days earlier. At about 60 days of age, every female in Groups I–IV was mated with

Accepted 18 March 1977.

*This work was supported partly by the grants-in-aid-for Cancer Research from the Ministry of Education, Science and Culture, Japan (Nos. 001043 and 001080).

§The name was recently changed to GRS/A (J. Staats, Standard nomenclature for inbred strains of mice: Sixth listing. *Cancer Res.* **36,** 4333, 1976).

one male of corresponding genotype; each female in Groups V and VI was mated with an SHN male. Three to five consecutive pregnancies without subsequent lactation were obtained by removing the young soon after parturition (force-breeding). Each mouse was checked for palpable mammary tumors every day for a few days before and after parturition and every 2 or 3 days during the other period. Number of tumors and tumor size expressed in terms of the geometric mean of the major 2 diameters were recorded. On the day of parturition, some mice in each group were killed by decapitation and mammary tumors were removed and prepared for histologic observation. Pieces of tumors were fixed in Bouin's solution, embedded in paraffin, cut at 6 μm and stained with hematoxylin-cosin. Histologic type of tumors was classified according to the following criteria:

Adenocarcinoma;

Type A = Mammary tumors of basic acinar structure, which are composed mostly of microtubular adenocarcinoma.

Type B = Mammary tumors of basic papillary structure, which are composed of papillary cystadenocarcinoma and pierced by capillaries and blood extravasations.

Type AB = Mammary tumors mixed with Types A and B.

Type C = Fibroadenomatous or adenofibromatous tumors.

Adenoacantoma = Squamous or keratinizing mammary tumors.

Pale-cell or large-cell carcinoma = Solid masses of the large pale cells with enlarged and vesicular nuclei, which reveal more or less cellular atypia [9].

Special forms;

Mammary tumor type p = Mammary tumor is composed of imperfect plaques and small atypical tubuloalveolar or papillomatous hyperplasia, the cells of which are larger than those of the surrounding normal mammary tissue. Some tumors of type p lack organoid structure of plaques but are usually bound together by varying amounts of connective tissue. Type p is usually more clearly demarcated than adenocarcinoma, but the proliferating elements radiate into the tissue of the fat pad [10].

Plaque = Plaque is characterized by abundant overgrowth of tubules. In perfect plaques these systems of branching tubules are symmetrically arranged and form an organoid structure with a loose medulla and a more compact cortex of radially disposed branching tubules. Many variants of this simple arrangement are present (multilobular, giant, irregular comple, etc.) [11].

Throughout the experiment, each couple of mice was kept in a teflon cage (15 × 30 × 12 cm) with wood shavings, maintained in an animal room air-conditioned (24 ± 0.5°C and 65–70% in relative humidity) and artificially illuminated (14 hr light from 5:00 A.M. to 7:00 P.M.) and provided with a commercial diet (CA-1: CLEA Japan Inc. Tokyo, Japan) and tap water *ad libitum*.

RESULTS

Genotype, type of MTV carried and results of mammary tumorigenesis at the 3rd pregnancy in each group are illustrated in Table 1. Most mice had mammary tumors by the 3rd pregnancy (4 months of age) in Groups I, III, IV and V. Meanwhile, only 20 and 35% of mice had tumors in Groups II and VI, respectively. Furthermore, growth of almost all tumors was pregnancy-dependent in the former four groups, but none and only 20% of tumors were pregnancy-dependent in Groups II and VI, respectively. Number of tumors per tumor-bearing mouse in Group II or VI was about half or less than half of those of the other groups. The differences in all parameters were statistically significant between Groups II and VI and the other groups ($P < 0.05$ or 0.01).

Growth curves of mammary tumors in each group expressed in terms of the percentage of the size against that on the day of parturition are presented in Fig. 1. In Groups I, III, IV and V, mammary tumors increased in size during the latter half of pregnancy, peaked approximately on the day of parturition and regressed thereafter. No difference was observed in the pattern of growth between the 2nd and the 3rd pregnancies. On the other hand, mammary tumors in Group II continued to grow after appearance without being influenced by pregnancy. While the growths of 8 out of 10 tumors in Group VI were slightly influenced by pregnancy and parturition, 2 tumors regressed temporarily after parturition. Thus, the average size of tumors in this group showed a temporary reduction after parturition followed by regrowth. However, the pattern of growth curve of tumors in Group VI was rather like that in Group II than in the other groups. These findings in the pattern of mammary tumor growth reflected well with the

percentage of pregnancy-dependent mammary tumors in each group (Table 1).

The results of the histologic type of mammary tumors in each group are illustrated in Table 2. As observed in the biological characteristics, there was similarity in the histologic type of tumors between Groups I, III, IV and V and between Groups II and VI, respectively. More than 74% of tumors belonged to mammary tumor type p and plaques in Groups I, III, IV and V. On the other hand, 100 and 90% of tumors examined were diagnosed as adenocarcinoma type A, B or AB in Groups II and VI, respectively.

DISCUSSION

This study shows that (GR × SHN)F1, (SHN × GR)F1 and GR/fSHN are quite similar to GR/A in the pattern of mammary tumor growth, mammary tumor incidence and number of tumors per mouse. Moreover, more than 74% of tumors were diagnosed as tumor type p and plaques and the percentage of adenocarcinoma were less than 13% in these groups. In this respect, van Nie [10] described that less than half of the pregnancy responsive mammary tumors arose as plaques, the remainder arising as aggregated foci of adenosis and epitheliosis, and that the pregnancy unresponsive tumors had the structure of adenocarcinoma types A and B, the latter being more frequent. Van Ebbenhorst Tengbergen [12] also reported that genetical factors exert an influence on mammary tumor types. GR/A, both F1-hybrids and GR/fSHN have both GR-genotype and GR type of MTV and some groups further contain SHN-genotype and/or SHN type of MTV. Thus, the results infer that both GR-genotype and GR type of MTV would play the limiting roles in determin-

ing the biological and morphological characteristics of mammary tumors in mice. However, the superiority of SHN-genotype to GR type of MTV in this process has been proved by the subsequent results that several characteristics of SHN/fGR with SHN-genotype were mostly the same as those of SHN, despite its carrying GR type of MTV. While (GR × SHN)Fl and (SHN × GR)Fl females are heterozygous for genotypes of GR/A and SHN, both behaved as GR/A in all characteristics examined. Finally, it may be concluded from the present results that the relative importance of factors determining the characteristics of mammary tumors which appear during the reproductive states is in the order of GR-genotype, SHN-genotype, GR type of MTV and SHN type of MTV.

It seems that GR type of MTV induces some degree of hormone-dependency on mammary tumors of SHN/fGR in view of the temporary reduction in size of some tumors after parturition in this group, which was not observed in SHN.

Schedule Dependent Effectiveness of CCNU and 5-Fluorouracil in Experimental Chemotherapy*

J. H. MULDER,†‡ T. SMINK† and L. M. VAN PUTTEN†

†*Radiobiological Institute TNO, Rijswijk, The Netherlands, and*
‡*Department of Internal Medicine, Rotterdam Radiotherapeutic Institute, Rotterdam, The Netherlands*

Abstract—*The effect of combination chemotherapy with CCNU and 5-FU given either simultaneously or with a time interval of* 24 hr *was studied in the Lewis lung carcinoma and in the mouse osteosarcoma C22LR. Tumour growth delay, number of lung metastases and lung colonies as well as the survival time of mice with and without surgical removal of the primary tumour were used as parameters. Treatment with CCNU followed by 5-FU was the least effective schedule in both tumour lines.*

In order to evaluate therapeutic gain, we also investigated the cell killing effect of both drugs in different schedules on resting and on rapidly proliferating bone marrow stem cells: CCNU followed by 5-FU was the most toxic treatment sequence. Consequently, the therapeutic effect (the ratio between effect on tumour and effect on normal tissues) must be low when this sequence is given.

If a combination of CCNU and 5-FU is considered for the clinical treatment of gastrointestinal cancer, the most frequently used scheme is a nitrosourea on the first day of a 5-*day course of* 5-*FU. Based on our preclinical studies, we suggest a schedule in which* 5-*FU is followed within a short time interval by CCNU.*

INTRODUCTION

THE MODE of treatment of malignant diseases with cytostatic drugs is strongly influenced by different theories and concepts. Originally, single drugs were given preferably daily, and in low dosages. Later, sequential courses with a different agent were alternated at intervals of a few weeks.

Drugs were increasingly used in combination and, instead of a daily single drug treatment, high dose-intermittent polychemotherapy schedules were gradually applied: many drugs were given together on the same day, and the scheme was usually repeated every 3 or 4 weeks, depending on the bone marrow recovery.

The use of cytostatic drugs in sequences with short time intervals of hours instead of days or weeks is based on various assumptions. The design of treatment schedules is influenced by data from cell kinetics, pharmacokinetics and enzyme kinetics. Tumour cell synchronization in order to increase the cell killing effect of a second drug was recently reviewed [1–3]. The enhancement of the cellular transport of methotrexate by pretreatment with vincristine is an example of sequential treatment based on pharmacokinetic data [4]. The concepts of concurrent and sequential enzyme inhibition of metabolic pathways have a great impact on the drug schedule design [5]. The use of leucovorin after methotrexate treatment is another example of sequential treatment [6]. This short interval sequential treatment is the subject of our study and the selection of the drug combination was based on knowledge of cellular kinetics.

The growth of solid tumours is characterized by a decreasing growth fraction. This will result in a less effective treatment with cell cycle specific drugs such as cytosine arabinoside, methotrexate and 5-FU. Recruitment of cells after tumour cell kill by cytostatic treatment may increase the sensitivity of the tumour to cell cycle specific drugs [7]. Based on this concept, Schabel suggested a sequential treatment with cell cycle non-specific drugs such as CCNU followed by cell cycle specific drugs [8].

We investigated the effect of the sequential

treatment with CCNU and 5-FU on two different solid tumour lines and, in order to evaluate therapeutic gain, also on critical normal tissue.

The effect of combination chemotherapy with CCNU and 5-FU given either simultaneously or with a time interval of 24 hr on the Lewis lung carcinoma, the mouse osteosarcoma C22LR, and on haemopoietic stem cells, was therefore studied.

MATERIAL AND METHODS

Tumours

The Lewis lung carcinoma, a transplantable poorly differentiated epidermoid carcinoma, arose spontaneously in the lung of a C57BL mouse in 1951 [9]. Our tumour line was obtained from the "Mario Negri" Institute, Milan, Italy, in 1973. Since then, it has been passaged in C57BL/Ka/Rij male mice by bi-weekly s.c. injection of an inoculum of about 10^6 viable tumour cells into both flanks. From a single passage, multiple ampoules of tumour cells were stored in liquid nitrogen. Not more than 8 passages from each ampoule were derived for use in experiments. For the experimental work, the (C57BL/Rij × CBA/Rij)F_1 hybrid male mouse (BCBA) was used. Lewis lung cells, 10^6 cells per 0.1 ml Hanks' balanced salt solution, were injected s.c. into the flank. In order to increase the number of spontaneous lung metastases, Lewis lung cells were injected into the gastrocnemius muscle or into the foot pad of the right hind leg of the recipient mouse. The length and width of tumours in mm were obtained by caliper measurements and converted to volume using the formula: $V = (a \times b^2)/2$ where $b < a$. Volume measurements between 200–800 mm^3 of s.c. and i.m. inoculated Lewis lung cells resulted in a doubling time of 2.5 days. For the assessment of the effect of treatment on artificial lung colonies produced by i.v. injected Lewis lung tumour cells, lungs were removed about 2 weeks after injection and fixed in Bouin's fluid. The lobes were separated and the total number of macroscopic tumour nodules on the lung surface was counted using a dissecting microscope. The effect of treatment on spontaneous lung metastases was assessed by counting the number of lung metastases after a specified time period. After amputation of the leg with the tumour in the foot pad, the mice die of lung metastases. The survival time of mice after post-operative chemotherapy therefore correlates with the effect of treatment on lung metastases.

The strontium-90 induced C22LR mouse osteosarcoma originated in our institute in a mouse in 1957 and was serially transplanted in similar mice or stored in liquid nitrogen [10]. All studies were performed with tumour of passages 78–84 from frozen samples of passage 77. Osteosarcoma cells, 10^6 cells per 0.1 ml Hanks' balanced salt solution, were injected bilaterally s.c. into BCBA male mice and the volume in mm^3 was obtained by caliper measurements. The doubling time, measured between 200–800 mm^3, is 2.5 days. In both solid tumour lines, volume measurements were done at least twice a week. The median tumour volume in mm^3 was calculated from data of at least 4 tumours per treatment group. For the assessment of the effect of treatment on s.c. or i.m. inoculated tumours, groups of 5 mice were selected randomly from a large group of tumour bearing mice.

Preparation of tumour cell separations

The s.c. tumours were excised under aseptic conditions and minced with scissors. A suspension of single cells was prepared by a combined mechanical and enzymatic technique [11]. Fragments of tumour were trypsinized at room temperature in 150 ml Hanks' balanced salt solution containing 0.05% trypsin and a small quantity (~5 mg) of DNase. Mechanical dispersion was accomplished by a rotating razor blade for 10 min. Cells were filtered through 6 layers of nylon gauze under gravity and trypsin activity was halted by cooling and the addition of foetal calf serum. After centrifugation at 4°C and 500 ***g*** for 10 mins, the pellet was resuspended and diluted in Hanks' balanced salt solution with 5% (v/v) foetal calf serum. Viability was checked by eosine staining. It usually exceeded 75%.

Haemopoietic stem cell systems

For the determinations of the activity of drugs against normal cells, we used the haemopoietic stem cells from the mouse, since bone marrow is often the tissue that defines the tolerance to cytostatic treatment. The survival of haemopoietic stem cells was determined by the spleen colony technique of Till and McCulloch [12]. Groups of 5 BCBA male mice were treated by i.p. injection of drugs. CCNU was given in a dose of 15 mg/kg and 5-FU in a dose of 50 mg/kg. Sixteen hours after the last treatment, the bone marrow was flushed from the femurs with cold Hanks' balanced salt solution. After filtration through nylon gauze, suitable dilutions of the pooled femurs marrow were injected i.v. into groups of 10 lethally irradiated isogenic male mice (950 rad of gamma rays from a 611 Ci ^{137}Cs source at an exposure rate of 122 rad/min 1–2 hr earlier). Nine days later, the spleens of these

recipients were fixed in Tellyesniczky solution. The spleen colonies with a dia of 0.25 mm or more were counted under a dissecting microscope. The results were expressed as the number of colony forming units (CFU) per donor femur. These results were compared with the results of a simultaneous assay in a group of untreated donor mice to determine the relative CFU survival.

After treatment with a cytostatic drug, the normally resting haemopoietic stem cells will be recruited into cycle and this may result in increased drug sensitivity. Therefore, we also looked into the effect of treatment on recruited, rapidly proliferating normal bone marrow stem cells. Lethally irradiated male mice (950 rad) received i.v. injections of a standard amount of bone marrow (one quarter of a femur content). Six days later, their spleens contained a large number of colony forming stem cells in a phase of rapid proliferation [13]. CCNU was given in a dose of 20 mg/kg and 5-FU in a dose of 25 mg/kg. Drugs were administered i.p. to groups of 5 mice.

Sixteen hours after the last treatment spleen cell suspensions were prepared and assayed for the number of CFU as described above. The survival of rapidly proliferating CFU was calculated at the ratio of the mean number of CFU per spleen of treated to that of simultaneously assayed control mice.

Chemicals

CCNU, NSC-79037; CAS reg. No. 13010–47–4; 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea was kindly supplied by the Division of Cancer Treatment, National Cancer Institute, Bethesda, MD. The drug was injected i.p. as a finely divided suspension in 2% carboxymethylcellulose; the mixture was homogenized before being injected. The particles were fine enough to pass easily through a 25 gauge needle. 5-Fluorouracil, NSC-19893; CAS reg. No. 51–21–8; 5-FU was kindly supplied by Hoffman La Roche, Basel, Switzerland.

Treatment schedule

The drug sequences we tested were 5-FU and CCNU given simultaneously, 5-FU was given 24 hr before (5-FU→CCNU) or 24 hr after CCNU (CCNU→5-FU), Since we kept this interval constant in all experiments, no information was obtained on a time response relationship. For each solid tumour experiment, the day of CCNU treatment was kept constant; the day of 5-FU treatment was varied. In the stem cell experiments, the time of the last drug treatment and of assay were kept constant.

Endpoints and statistical evaluation

The end-point of treatment of both solid tumour lines is the growth delay in days; the displacement in time between the growth curve of the tumours in the control group and the growth curve of the tumours recurring after treatment. The displacement between the growth curves is chosen at a point, usually close to the original tumour volume, where the growth curves for treated and control animals are again parallel [14]. If no original tumour volume is known (e.g., for tumour inocula exposed to treatment before a tumour is palpable), the delay in comparison with the control group to reach an arbitrary volume between 400–800 mm^3 is estimated. The endpoint of the lung assay is the number of artificial lung colonies or number of spontaneous lung metastases per mouse. Survival experiment results are expressed in median survival time in days. The end-point of the effect of treatment of resting and rapidly proliferating haemopoietic stem cells is the surviving cell fraction. The Student's *t*-test is used for the evaluation of the results of treatment with the different sequential combinations.

RESULTS

Table 1 shows the effects for the combination CCNU and 5-FU on Lewis lung carcinoma if administered to the mice before tumours are palpable; 5-FU given 24 hr before or simultaneously with CCNU seems to enhance the effect of CCNU. The sequence CCNU→5-FU is the least effective. The effects of the single agents and their combinations in the treatment of palpable tumours using both tumour volume and the number of spontaneous lung metastases were then investigated. As shown in Table 2, there is no effect of CCNU or 5-FU alone on tumour volume, but the number of visible spontaneous lung metastases in these groups is very low in comparison with the control group, Note that the average number of lung metastases in the fourth group is unexpectedly high. To increase the number of spontaneous lung metastases, Lewis lung tumour cells were inoculated i.m. instead of s.c. in the subsequent experiments. In Table 3, the influence of the sequence of drug treatment on primary tumour growth and lung metastases is clearly seen. The effect of treatment on the number of artificially induced lung colonies is shown in Table 4. A similar pattern emerges as is seen in Tables 1, 2 and 3. The effect of treatment on mouse survival time was followed in order to see whether this was

Table 1. The effect of sequential treatment on tumour volume in Lewis lung carcinoma

Treatment schedule	Tumour volume day 13 (mm^3) Median (range)	Mice with tumour on day 13/ total number of mice
Control	900 (1624–720)	5/5
5-FU	637 (1062–450)	5/5
CCNU	320 (598–100)	5/5
CCNU→5-FU	90 (315– 12)	5/5
CCNU+5-FU	0 (315– 12)	0/5
5-FU→CCNU	0	0/5

Groups of 5 C57BL/Ka male mice (20 g) were inoculated s.c. with 10^6 Lewis lung tumour cells on day 0. CCNU 20 mg/kg i.p. was given on day 3. A dose of 100 mg/kg 5-FU i.p. was given either simultaneously, 24 hr before or 24 hr after CCNU.

Table 2. The effect of sequential treatment on tumour volume and on spontaneous lung metastases in Lewis lung carcinoma

Treatment schedule*	Tumour volume day 21 (mm^3) Median (range)	Growth delay (days) Mean ± S.E.	Number of lung metastases per mouse Mean ± S.E.
Control	2737 (3496–1012)	0 ± 0.5	16.2 ± 3.9
CCNU	2352 2572–1450)	0 ± 0.5	1.2 ± 0.4

Groups of 5 BCBA male mice (20 g) were inoculated i.m. with 10^6 Lewis lung carcinoma cells. CCNU was given on day 3 and 5-FU was given either simultaneously, 24 hr before or 24 hr after CCNU. Lung metastases were counted on day 32.
*Growth delay in days. Mean with S.E.; (a) $P<0.01$; (c) not significant.
†Number of lung metastases per mouse. Mean with S.E.; (b) $P<0.0025$; (d) $P<0.0005$; (e) $P<0.05$.

similarly affected as was tumour growth delay. Table 5 shows the median life span of mice with Lewis lung tumour. The more than additive effect of the combination and the influence of drug sequence on the median life span are in agreement with the data obtained by volume measurements. Figure 1 shows the results of experiment II in Table 5 in detail: CCNU→5-FU treatment results in a number of early toxic deaths, presumably caused by bone marrow failure. On the other hand, when 5-FU is followed by CCNU, 2 out of 10 animals were without evidence of disease 82 days after inoculation. The effect of adjuvant chemotherapy is shown in Table 6.

In order to investigate whether treatment of another tumour system with CCNU and 5-FU shows similar responses to different sequences, we treated s.c. transplanted osteosarcoma in BCBA mice. Table 7 shows the effects of a single

Table 4. The effect of sequential treatment on number of lung colonies in Lewis lung carcinoma

Treatment schedule	Number of lung colonies per mouse Mean ± S.E.	
Control*	86.7 ± 8.8	
5-FU	92.0 ± 8.0	
CCNU	20.6 ± 6.4	
CCNU → 5-FU	9.8 ± 3.0	$P < 0.01$
CCNU + 5-FU	1.5 ± 0.5	
5-FU → CCNU	1.5 ± 0.5	

One million Lewis lung tumour cells in 0.5 ml Hanks' balanced salt solution were injected into one of the tail veins of C57Bl/Ka male mice. Lung colonies were counted on day 17.

*Two out of 5 animals of the control group died on day 17 as a result of lung disease. Treatment schedule as in Table 1; CCNU was given on day 3.

drug treatment and the influence of the drug sequence: CCNU → 5-FU seems to be the least effective treatment schedule. The effects of sequential treatment on haemopoietic stem cells are shown in Table 8.

DISCUSSION

The results indicate that, for haemopoietic stem cells, either in a resting or in a rapid proliferation state, CCNU → 5-FU gives the lowest survival fraction in comparison with the other treatment schedules. The combination of 5-FU and CCNU shows schedule dependency: CCNU → 5-FU is the most toxic sequence for the normal tissue as represented by bone marrow stem cells. This same sequence, CCNU → 5-FU, however, seems to be the least effective sequence

Table 5. The effect of sequential treatment on life span of mice with Lewis lung carcinoma

Treatment schedule	Median survival time and range of death (days) Experiment I	Experiment II
Control	35 (26–38)	34 (23–42)
5-FU	39 (27–42)	35 (30–41)
CCNU	44 (34–49)	35 (33–50)
CCNU → 5-FU	47 (14–73)	28 (13–44)†
CCNU + 5-FU	52.5 (40–)*	36 (34–48)
5-FU → CCNU	61 (40–)*	45 (36–)*

Groups of 10 BCBA male mice (20 g) were inoculated i.m. with 10^6 Lewis lung tumour cells on day 0. CCNU 20 mg/kg i.p. was given on day 4 in experiment I and on day 6 in experiment II. 5-FU in a dosage of 100 mg/kg i.p. in experiment I and of 50 mg/kg i.p. in experiment II was given simultaneously, 24 hr before or 24 hr after CCNU.

*Two out of ten mice had no apparent tumour growth at the implantation site at the end of the experiments (82 days).

†The wide ranges were due to early toxic deaths.

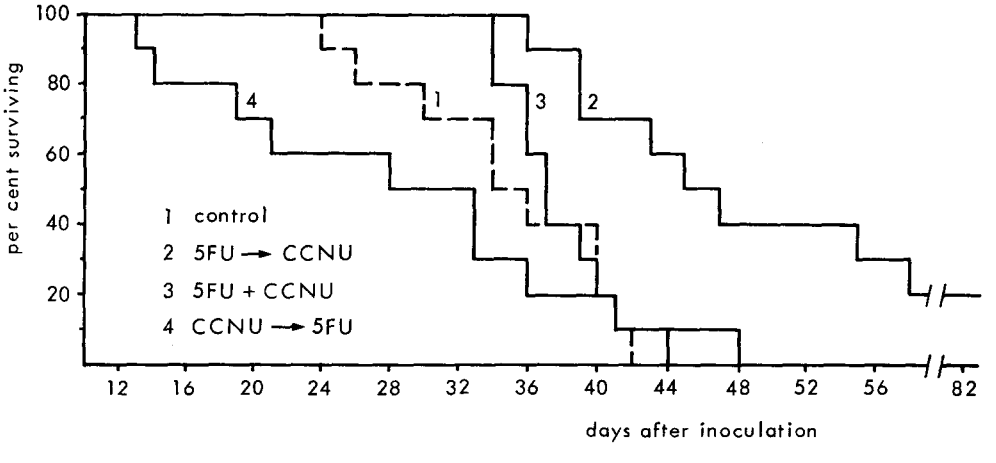

Fig. 1. Groups of ten BCBA mice were inoculated i.m. with one million cells. Six days later treatment was given. Dose: 5-FU, 50 mg/kg i.p. and CCNU, 20 mg/kg i.p.

Table 6. The effect of adjuvant chemotherapy with different drug sequences on the life span of mice with Lewis lung carcinoma

Treatment schedule	Median survival time and range of death (days) Experiment I	Experiment II
Control	44 (21–69)	71 (33–88)*
5-FU	54 (33–57)	71 (34–82)
CCNU	58 (33–59)	74 (44–88)
CCNU→5-FU	53 (45–59)	75 (37–86)
CCNU+5-FU	59 (47–69)	75 (32–90)
5-FU→CCNU	88 (59–)*	82 (32–90)

In experiment I. BCBA male mice were inoculated into the foot pad with 5×10^5 Lewis lung tumour cells in 0.02 ml Hanks' balanced salt solution on day 0. Tumour volume at the time of amputation on day 18 was approximately 500 mm^3. On the seventh post-operative day, groups of 8 mice were treated with CCNU 10 mg/kg i.p. A dose of 100 mg/kg 5-FU i.p. was given either simultaneously, 24 hr before or 24 hr after CCNU. Animals died of lung metastases. In experiment II, C57BL/ka male mice were used; the treatment procedure was as in experiment I.

*Four out of 8 animals had no evidence of disease on day 120.

†The last 2 mice in each treatment group were sacrificed for macroscopic lung investigation: all animals showed multiple, mostly large, lung metastases.

Table 7. The effect of sequential treatment in osteosarcoma

Treatment schedule	Mean growth delay and standard errors (days) Experiment I		Experiment II	
Control	0±0.3		0±0.3	
5-FU	4.5±0.3		3.3±0.1	
CCNU	9.0±0.7		3.5±0.1	
CCNU→5-FU	12.0±0.8	$P<0.025$	5.0±0.2	$P<0.0005$
CCNU+5-FU	13.5±1.2		7.5±0.4	
5-FU→CCNU	17.0±0.7		7.0±0.2	

One million osteosarcoma cells were injected bilaterally s.c. into groups of 5 BCBA male mice (23 g) on day 0. CCNU 20 mg/kg i.p. was given on day 3. A dose of 100 mg/kg i.p. 5-FU was given either simultaneously, 24 hr before or 24 hr after CCNU.

Table 8. Percentage of surviving cells per femur and repopulating spleen in comparison with untreated control mice

Treatment schedule	Resting stem cells Exp. I	Exp. II	Proliferating stem cells Exp. I	Exp. II	Exp. III
CCNU→5-FU	1.69	7.83	0.70	2.38	0.21
CCNU+5-FU	13.50	13.30	2.33	3.46	5.78
5-FU→CCNU	17.50	25.82	4.13	10.91	9.48

in both solid tumour lines investigated. Consequently, the therapeutic effect (the ratio between the effect on the tumour and the effect on normal tissues) must be low when this sequence is given. Based on the concept of growth fraction, recruitment and increased sensitivity to cell cycle specific drugs, Schabel suggested sequential treatment for solid tumours with first an alkylating agent (in our experiments CCNU) followed by an anti-metabolite (in our experiments 5-FU). The data shows that CCNU →5-FU is most effective against the bone marrow, but least effective on the 2 malignant solid tumour lines, making this sequence pro-

bably unsuitable for clinical practice. We would like to suggest that the optimal treatment schedule is 5-FU→CCNU. In our assay system, this sequence is least toxic for haemopoietic stem cells and the results with the 2 solid tumour lines indicate that 5-FU→CCNU may be preferable to simultaneous administration.

Why is CCNU→5-FU the most toxic sequence for bone marrow? CCNU, an alkylating agent, kills resting and proliferating tumour cells with equal effectiveness [15]. After CCNU treatment, recruitment will take place in the resting stem cell model and, because 5-FU is more effective on proliferating than on resting cells [16], an enhanced effect of 5-FU may be anticipated. However, increased sensitivity to 5-FU due to recruitment cannot play an important role in the maximally recruited proliferating stem cell situation [13].

Why is CCNU→5-FU the least effective sequence for the two solid tumour lines? Earlier, we showed the competition between a nucleoside analogue and different nucleosides at the uptake level of tumour cells [17]. As a result of effective treatment, cells will lyse and nucleosides and possibly nucleotides may be released. The concentration of these metabolites, especially with solid tumours, may become high enough to inhibit the effect of a nucleoside analogue such as 5-FU. This could explain the relative ineffectiveness of CCNU→5-FU treatment of Lewis lung carcinoma and osteosarcoma. This hypothesis is tentative in character; a conclusive explanation for the different schedule dependency of 5-FU and CCNU in bone marrow, on the one hand, and the 2 solid tumour lines, on the other, cannot be made.

Is there a synergism between 5-FU and CCNU? The combination of Me-CCNU and 5-FU has been claimed to be modestly potentiating against the experimental colon carcinoma No. 38 and the P388 leukemia [18]. Similarly, a synergistic effect on AKR lymphoma with 5-FU administered 4 hr before BCNU has been described [19]. Our results of treatment of Lewis lung carcinoma suggest a more than additive effect for a particular drug sequence. Since the dose–effect curve for growth delay is usually not linear, the identification of synergism is uncertain. For this reason, we have mainly emphasized the differences in effect seen when sequences are varied, without drawing conclusions on synergism.

What may be the clinical relevance of our study? We tested different drug sequences on resting and recruited bone marrow cells and found the sequence CCNU→5-FU to be the most toxic. In two different solid tumour lines as well as in one of our experimental colon tumour lines [20], the same sequence was shown to be least effective. The ultimate proof of which therapeutic regimen is the best can only be obtained by doing a clinical trial; nevertheless, preclinical research may give leads to which treatment is worthwhile testing. The extrapolation of data on model tumours to clinical treatment is uncertain; however, there is more agreement on effects on normal tissues. Since, in this respect, the sequence under discussion also points to the disadvantage of giving 5-FU after CCNU, it seems reasonable to test other sequences.

For the treatment of gastrointestinal tumours, one of the nitrosoureas such as CCNU, BCNU or Me-CCNU is usually given on the first day of a 5-day course of 5-FU with or without a third drug such as vincristine [21–30]. Drug dosages and schedules as well as the length of the 5-FU course are based on the results of Phase-II studies and most probably based on historical grounds as well. From our broad spectrum analysis, we would like to suggest a treatment schedule starting with a short course on 5-FU followed by CCNU.

Two Methods for Measurement of Oestradiol-17β and Progesterone Receptors in Human Breast Cancer and Correlation with Response to Treatment*

DIANA M. BARNES,† G. G. RIBEIRO‡ and L. G. SKINNER†

†*Clinical Research Laboratories and* ‡*Department of Radiotherapy, Christie Hospital and Holt Radium Institute, Manchester M20 9BX, United Kingdom*

Abstract—*Two simple quantitative methods, one employing a dextran-charcoal (DCC) procedure, the other using gel filtration on Sephadex LH-20 for separation of bound from free radioactive steroid, have been developed for measurement of specific oestradiol-17β receptor (E_2R) and progestin receptor (PgR) activities in the same tumour cytosol. The synthetic progestin ^3H R5020 (Roussel-UCLAF), was used in the PgR assays. Good agreement was observed between the estimations obtained from the methods for either receptor activity. Either method had a sensitivity level of* 5 fmole/mg *cytosol protein for E_2R and* 15 fmole/mg *for PgR. Dissociation constants obtained by Scatchard analyses from DCC and LH-20 assays were respectively* 2.2 ± 0.2 *(S.E.M.)* $\times 10^{-10}$ *M and* $2.6 \pm 0.3 \times 10^{-10}$ *M for E_2R,* $7.7 \pm 0.7 \times 10^{-10}$ *M and* $7.6 \pm 0.7 \times 10^{-10}$ *M for PgR.*

Of 71 *primary and* 43 *metastatic human breast tumours examined* 62 *and* 51% *respectively were found to have E_2R+ activity. Approximately* 63% *of all tumours with E_2R+ activity were also PgR+. In no instance was PgR+ activity found in a tumour which was E_2R-. Of* 30 *patients with advanced metastatic breast cancer,* 62% *of those with E_2R+ tumours had a clinical response to endocrine therapy. Our present data suggest that the presence of both E_2R and PgR in a tumour may represent a much more accurate indication of a tumour's responsiveness to hormone therapy than the presence of E_2R alone.*

No linear correlation existed between concentrations of E_2R and PgR in primary or in metastatic tumours, nor did the PgR concentration (in contrast to that of E_2R) bear any relationship to the patient's age.

INTRODUCTION

THE SUGGESTION was made by Jensen *et al.* [1] that the presence or absence of oestradiol receptor sites in human breast cancer tissue might be used to predict which tumours were likely to respond to endocrine therapy. In approximately one-third of patients with metastatic breast cancer, the tumour responds favourably to either additive or ablative forms of endocrine therapy. It would be especially desirable to select patients for ablative procedures, such as adrenalectomy or hypophysectomy, as accurately as possible, as these patients are often quite ill and should perhaps be spared these procedures if there was little or no likelihood of success.

Pooled data from several centres has indicated that 55–60% of patients with positive oestradiol receptor (E_2R) activity in their tumour show objective remission to some form of endocrine manipulation [2] whereas less than 10% of those lacking E_2R in their tumour show any response. The fact that 40% of E_2R+ tumours fail to respond indicates the necessity for additional marker(s) to identify the responsive tumour.

The first evidence of specific progesterone-binding components in human mammary carcinoma was provided by Terenius [3]. Horwitz *et al.* [4] proposed that since in oestrogen target tissue, synthesis of progesterone receptor (PgR) is dependent upon oestrogen action [5], the

Accepted 29 March 1977.

presence of PgR in addition to E_2R in malignant cells would indicate that the tumour was capable of synthesizing at least one end product under oestrogen regulation and should therefore be expected to remain endocrine responsive.

In this report we describe two simple quantitative methods, one based on the dextran–charcoal procedure of Korenman and Dukes [6] and the other using gel filtration on Sephadex LH-20 as suggested by Ginsburg *et al.* [7] which we have used, with satisfactory agreement between estimations, to determine both E_2R and PgR activity in the same tumour cytosol. Since progesterone, in addition to binding to its own receptor, binds also to glucocorticoid receptors and to corticosteroid binding globulin the use of ^{3}H-progesterone to assess specific PgR presents difficulties. For assay of PgR sites, we have therefore used the synthetic progestin, R5020 (17, 21-dimethyl-19-nor-4, 9-pregnadiene-3, 20-dione), which has been found to bind specifically to PgR in immature rat and mouse uteri [8].

The methods have been employed to assess the relative frequency of occurence of E_2R and PgR in both primary and metastatic tumours. In a small group of patients with advanced metastatic breast cancer, clinical response to hormone therapy has been correlated with receptor activity.

MATERIAL AND METHODS

Material

[2, 4, 6, 7-^{3}H] Oestradiol-17β [^{3}H-E_2] (spec. act. 100 Ci/mmole) was obtained from the Radiochemical Centre, Amersham. Diethylstilboestrol (DES) was purchased from Koch-Light. [6, 7-^{3}H] 17, 21-dimethyl-19-nor-pregna-4, 9-diene-3, 20-dione [^{3}H-R5020] (spec. act. 50 Ci/mmole) and radio-inert R5020 were a gift from Dr. J.-P. Raynaud (Roussel-UCLAF).

Dextran T-70 and Sephadex LH-20 were purchased from Pharmacia Ltd.; gelatin from the Sterling Gelatine Co. Ltd. and Norit-A-charcoal from Sigma Ltd. Scintillator Grade xylene and PCS liquid scintillation cocktail were supplied by Hopkin and Williams, Chadwell Heath, Essex.

All other reagents used were of Analar grade.

Buffer solutions

The following buffers were used as indicated:

Buffer A for oestradiol receptor (E_2R) measurement: 10 mM Tris-HCl, pH 7.4 containing 1 mM EDTA, 3 mM sodium azide and 0.5 mM dithiothreitol.

Buffer B homogenisation medium for preparation of cytosols for measurement of both E_2R and progesterone receptors (PgR): 10 mM Tris-HCl, pH 7.4 containing 1 mM EDTA, 12 mM thioglycerol, 3 mM sodium azide and 30% (v/v) glycerol.

Buffer C for PgR measurement: as buffer B with 10% (v/v) glycerol in place of 30%.

Steroid solutions

The labelled steroids were stored in convenient sealed aliquots (100 μl) at -20°C as received from the manufacturers: ^{3}H-E_2 in benzene–ethanol 95:5; ^{3}H-R5020 in toluene–methanol 9:1.

Stock solutions. The solvents were evaporated off from an aliquot under a stream of nitrogen and the residue dissolved in ethanol and stored at -20°C in sealed 200 μl aliquots at concentrations of 100 pmole/ml for ^{3}H-E_2 and 200 pmole/ml for ^{3}H-R5020.

Working solutions. ^{3}H-E_2 stock solution was diluted with buffer A to a concentration of 3 pmole/ml and each day from this working solution there were prepared a range of concentrations of from 1.5 to 0.25 or 0.125 pmole ^{3}H-E_2/ml buffer A. ^{3}H-R5020 stock solution was diluted with buffer C to a concentration of 8 pmole/ml and each day a range of concentrations of from 4.0 to 0.375 pmole ^{3}H-R5020/ml buffer C was prepared.

Non-radioactive compounds. Stock solutions (1 mM) of DES and R5020 in ethanol were stored at 0°C and diluted directly with buffers A and C, respectively, to give working solutions of 2×10^{-7} M DES and 8×10^{-7} M R5020.

Dextran-coated charcoal (DCC) suspension

DCC suspension (0.5% charcoal, 0.05% dextran, 0.1% gelatin) was prepared by dissolving 1 g gelatin in 200 ml 10 mM Tris buffer pH 7.4; 40 ml of this 0.5% gelatin solution were used to dissolve 100 mg dextran T70, 1 g charcoal was added with stirring, the volume made up to 200 ml with Tris buffer and the DCC suspension stirred for 1 hr at 4°C. The ice-cold suspension was stirred continuously during subsequent sampling.

Preparation of cytosol

Samples of primary breast tumour tissue were obtained at the time of mastectomy. Biopsies from metastatic skin deposits were taken under local anaesthetic. The samples were freed from surrounding fat and connective tissue, cut to

convenient size and placed immediately in vials in liquid nitrogen. In our experience tumours stored in liquid nitrogen retain oestradiol receptor activity for more than a year. Five hundred milligrams of tumour tissue was obtained: the assay procedure may be carried out with as little as 100 mg but in such cases the cytosol will have a low protein concentration which may lead to less reliable results.

Homogenization was carried out using a "microdismembrator" (Braun, Melsungen, Germany) as recommended by the E.O.R.T.C. Breast Cancer Cooperative Group [9]. The frozen tissue was placed on the wall of a 7 ml Teflon vial, free of a 10 mm tungsten carbide ball at the bottom. The lid was sealed in position with adhesive tape and the vial placed in a flask of liquid nitrogen for 10 min. The Teflon vial was then fixed in the instrument and vibrated for 30 sec at maximum frequency. The frozen powder was transferred rapidly to a 10 ml glass beaker and dispersed in about 4 vol buffer B by stirring for 10 min at 4°C with a magnetic stirrer. The homogenate was transferred by Pasteur pipette to 2.5 ml cellulose nitrate reduction tubes and centrifuged for 60 min at 100,000 × ***g*** and 4°C. The clear cytosol supernatant was removed with a Pasteur pipette, care being taken to leave behind the upper fatty layer.

Wherever possible, E_2R and PgR assays were carried out immediately after preparation of the cytosol. Whereas buffer A may be used in place of buffer B for preparation and storage of cytosols for E_2R measurement alone, it is preferable to use buffer B where the cytosol is required for both E_2R and PgR assay, since glycerol markedly increases PgR stability. Cytosols with protein concentrations in the range 1.0–2.5 mg/ml were found to give satisfactorily reproducible saturation curves for E_2R and PgR in both assay methods used and to retain activity on storage in liquid nitrogen for at least 3 weeks in respect of PgR and up to 10 weeks for E_2R. It is essential to ensure that the cytosol is kept at 0–4°C at all times during its preparation to preserve the activity of the receptors.

Oestradiol-17β receptor (E_2R) *assay*

One hundred microlitres of cytosol were incubated with the same volume of a range of concentrations of ^{3}H-oestradiol-17β in a final volume of 300 μl for 30 min at 30°C or overnight at 4°C, control experiments having shown that comparable binding equilibrium was attained under either condition. A minimum of 8 concentrations of oestradiol were normally used. A second set of tubes contained a 60 × excess of DES. Diethylstilboestrol was preferred to unlabelled E_2 as competitor for specific receptor sites since it is less susceptible to surface adsorption [7].

The bound and unbound E_2 fractions after incubation of cytosol with E_2 were separated by one of the following techniques:

(a) *Dextran-coated charcoal method.* This procedure was based on the method of Korenman and Dukes [6].

Five hundred microlitres of ice-cold DCC solution was added to each incubation tube. The contents of the tubes were well mixed and the tubes left to stand in ice for 10 min before centrifugation at 2000 × ***g*** for 15 min at 4°C. Unbound ^{3}H-E_2 was removed by the charcoal. Five hundred microlitres of the supernatant fluid, containing the bound ^{3}H-E_2 was used to measure the radioactivity.

A duplicate reagent blank was prepared for each concentration of ^{3}H-E_2 used, in which buffer replaced the cytosol. Reagent blanks were incubated and submitted to the same procedure as tubes containing cytosol. The total amount of radioactivity available at each concentration was determined from a series of tubes prepared as for the reagent blanks except that 500 μl buffer was added in place of DCC suspension.

(b) *Gel filtration on Sephadex LH-20.* The method followed was based on that described by Ginsburg *et al.* [7] for the study of high-affinity oestradiol binding in brain and pituitary. Small glass columns (Pasteur pipettes) internal dia 0.5 mm equipped with glass wool plugs were loaded with sephadex LH-20 pre-equilibrated in buffer A (for E_2R) or C (for PgR), to a bed height of 6 cm. The columns were mounted in sets of 24 in rubber bungs fitted into a perspex stand which was provided with a well underneath each column to hold a scintillation vial. When column effluents were not being collected in vials, as, for example, during regeneration, they were allowed to drip into a common basement tray. Columns were maintained in a chamber at 0–4°C during use to minimize dissociation of high affinity bound complexes. Flow through columns was stopped simply by allowing the eluant level above the column to fall to the surface of the gel, capillary action preventing entry of air into the bed.

After use, the LH-20 was regenerated by washing with ethanol (2 ml) followed by buffer (2 ml) which effectively freed the beds of residual radioactivity. Air bubbles were eliminated from the bed during regeneration. The LH-20 could then be re-used without detectable change in its properties over a period of at least 12 months. When not in use, columns were left with a few cm

of buffer above the surface and sealed with small rubber bungs.

Two hundred microlitre aliquots of incubates were applied to the columns and washed in with 100 μl buffer. Flow was allowed to stop for 30 min in order to permit maximum reduction of low affinity, high capacity non-specific bound steroid by differential dissociation as recommended by Ginsburg *et al.* [7], without appreciably affecting the specific high affinity binding. The receptor bound hormone was eluted directly into a scintillation vial by passage of 700 μl buffer, that volume of buffer previously determined as necessary to ensure elution of the complete bound hormone peak without breakthrough of free steroid.

Progesterone receptor (PgR) *assay*

The procedures followed were the same as those used in the measurement of oestrogen receptor, except that ^{3}H-R5020 and radio-inert R5020 were used in place of ^{3}H-oestradiol-17β and DES; buffer C replaced buffer A. Incubation was carried out for 2.5–3 hr at 4°C or overnight as convenient. Comparative assays with tumour cytosol have shown that binding of ^{3}H-R5020 was essentially complete after 2.5 hr and that the concentration bound remained constant over 18 hr.

Measurement of radioactivity

Five hundred microlitres of supernatant fluid following DCC treatment or 700 μl eluate from the sephadex LH-20 column were dispersed in 10 ml of a 1:1 dilution with Scintillator Grade xylene of PCS–liquid scintillation cocktail and counted for 2 min in a Nuclear Chicago Isocap/300 liquid scintillation system using Programme 1B. Counting efficiency was approximately 38%. In the LH-20 method, total counts available at each concentration of radioactive steroid were determined by incubating 300 μl buffer C with the appropriate concentration of radioactive steroid and adding 200 μl of this incubate with a further 500 μl buffer to the scintillation fluid.

Protein determination

The protein content of the cytosol was determined by the method of Lowry *et al.* [10] with bovine serum albumin as standard. Correction was made for the effect of glycerol on the colour reaction when the cytosol was prepared in buffer B.

Analysis of data

Bound steroid was estimated by subtracting the radioactivity present in those tubes containing unlabelled competitor (non-specific binding) from the total bound radioactivity in the tubes without competitor with correction for reagent blanks. The data were then analysed according to Scatchard [11]. Counts/min were expressed as pmole/steroid bound/ml cytosol and plotted against the ratio of bound to free steroid (B/F). Where a single binding component is present the plot gives a straight line the reciprocal of whose slope represents the dissociation constant, K_d. The intercept with the abscissa represents the number of receptor sites in pmole/ml cytosol.

Results were expressed in terms of fmole/mg cytosol protein and were only considered as indicating the presence of positive receptors where a satisfactory Scatchard straight line plot was obtained with K_d values in the range 0.5–5.0 $\times 10^{-10}$ for E_2R and 2.0–14.0 $\times 10^{-10}$ for PgR.

RESULTS

Comparison of results obtained by DCC and Sephadex LH-20 methods

(a) *Oestradiol-17β receptors* (E_2R). Figure 1(a) shows a representative ^{3}H-E_2 binding curve obtained for typical oestradiol receptor positive (E_2R+) tumour cytosol. The Scatchard plot, Fig. 1(b), of the high affinity binding appeared rectilinear, indicating the presence of a single class of high affinity receptor.

A comparison was made between the estimates of specific oestradiol binding capacity obtained by the two methods for 17 tumour cytosols with E_2R+ values ranging from 5 to 250 fmole/mg cytosol protein. In each case, the estimation by the DCC method was made at the time of preparation of the cytosol whereas the LH-20 assay on 75% of the samples was carried out after the cytosol had been preserved from 1–10 weeks in liquid nitrogen. There was no significant difference between the estimates obtained from the two methods. The correlation coefficient was statistically highly significant: $r = 0.91$, $P \ll 0.001$. The regression line equation was $\log(E_2R - \text{LH-20}) = 1.03 \log(E_2R - \text{DCC}) - 0.09$. Storage time of the cytosol did not significantly affect the LH-20 estimate (partial correlation coefficient, $r = -0.04$).

All tumour cytosols found to be E_2R negative when assayed by one method were also found to be E_2R negative by the other method and in no case to date have the methods failed to agree as to whether a cytosol was E_2R positive or negative, although in one instance where the DCC method gave an E_2R value of 10 fmole/mg, the gel

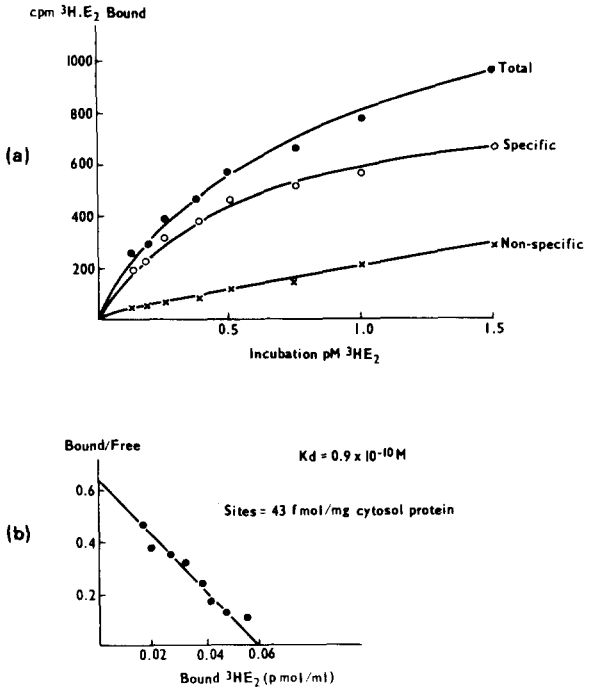

Fig. 1. (*a*) *Binding of* $^3H.E_2$ *by receptor + ve breast tumour cytosol, determined by DCC method.*
(*b*) *Scatchard analysis of data*

filtration method estimate was inconclusive. The mean dissociation constant (K_d) of the complex for 65 tumour cytosols determined by the DCC method was 2.2 ± 0.2 (S.E.M.) $\times 10^{-10}$ M. All except 2 values (8.3 and 8.7×10^{-10} M respectively) fell in the range $0.5–5.0 \times 10^{-10}$ M. The mean K_d for 24 E_2R+ tumour cytosols determined by the LH-20 method was 2.6 ± 0.3 (S.E.M.) $\times 10^{-10}$ M and all values lay in the range $0.5–5.0 \times 10^{-10}$ M. Provided that the experimental data yield a satisfactory Scatchard plot, it appears that either method has a sensitivity level of 5 fmole/mg cytosol protein.

Preliminary tests with rat uterus cytosol (subsequently confirmed with human breast tumour cytosol) indicated that the cytosol could be stored in liquid nitrogen for 2–3 weeks without appreciable loss of receptor activity provided the protein concentration was not less than 1 mg/ml protein and that a sulphydryl group preservative reagent was included in the buffer. At first, cytosols for E_2R estimation were prepared in buffer A (containing dithiothreitol). When both E_2R and PgR were measured in the same cytosol, the presence of glycerol was found to be necessary to preserve PgR stability and buffer B (containing thioglycerol) was used in preparation of the tumour cytosol. Either buffer may be used for preparation of cytosol for E_2R measurement with reproducible results.

When a cytosol which had been stored in liquid nitrogen was allowed to thaw and subsequently re-frozen in liquid nitrogen, it was found that on thawing for a second time, receptor activity was completely lost. On the other hand, a freshly prepared cytosol stored for 24 hr at 0–4°C suffered no loss of oestrogen receptor activity.

Table 1 illustrates the reproducibility of E_2R data obtained from four primary tumours by either method. The data indicate that the tumour tissue appeared to be homogeneous with regard to receptor sites and that the receptor sites were not appreciably affected by storage of the tissue in liquid nitrogen for several months or by storage of the cytosol for up to 2 weeks.

(b) *Progesterone receptors* (*PgR*). Difficulty was experienced in our early trials with ^3H-progesterone in demonstrating the presence of specific high affinity progesterone receptor in tumour cytosols since, in addition to low-affinity, high capacity non-specific binding such as is observed with oestradiol-17β, progesterone also binds to corticosteroid binding globulin (CBG) and cytoplasmic glucocorticoid receptors. The synthetic progestin R5020, used by Philibert and Raynaud [8] to identify progesterone receptor in immature rat and mouse uteri was employed by Horwitz and McGuire [12] and by Raynaud *et al.* [13] to assay progesterone binding sites in breast tumour tissue. We have used ^3H-R5020 successfully in both our assay procedures for estimation of PgR in tumour cytosols with excess non-radioactive R5020 as competitor to discriminate specific binding.

Figure 2(a) shows a representative ^3H-R5020 binding curve for a typical PgR+ cytosol. Scatchard analysis, Fig. 2(b), indicated the presence of a single class of high affinity receptor. A comparison was made between estimates of PgR activity obtained by the DCC and LH-20 methods for 15 tumour cytosols with PgR+ values ranging from 25 to 1200 fmole/mg cytosol protein. In each case, estimation by the DCC method was made on freshly prepared cytosol, that by the LH-20 method on two-thirds of the samples was made after periods of from 0.5 to 4 weeks' storage of the cytosol in liquid nitrogen. Agreement was very good. The correlation coefficient was statistically highly significant, $r = 0.93$, $P \ll 0.001$. However, it was found that the LH-20 estimate decreased with increasing storage time (partial correlation coefficient, $r = -0.65$) and taking this into consideration the coefficient of multiple correlation is $R = 0.96$, $P \ll 0.001$. The regression equation, log(PgR −LH-20) = 0.89 log(PgR − DCC) − 0.09 in-

*Stored in liquid N_2.

terval (weeks) + 0.28, represents this relationship.

All tumour cytosols found to be lacking in PgR when assayed by the DCC method were also found to be PgR − when the LH-20 technique was employed and in only one instance was an inconclusive result obtained by the LH-20 method where the DCC procedure estimate was positive, a result possibly accounted for by the very high ambient temperature on the day of the LH-20 assay.

The mean dissociation constant (K^d) of the PgR complex for 27 tumour cytosols determined by the DCC method was 7.7 ± 0.7 (S.E.M.) $\times 10^{-10}$ M. Only one value, 16.6×10^{-10} M, fell outside the range $2.0–14.0 \times 10^{-10}$ M. The mean K_d for 18 cytosols determined by the LH-20 method was $7.5 \pm 0.7 \times 10^{-10}$ M and again only one value, 15.3×10^{-10} M, lay outside the range $2.0–14.0 \times 10^{-10}$ M. Given a satisfactory Scatchard analysis, either method could detect progesterone receptor down to a level of 15 fmole/mg cytosol protein.

Available data on the stability of progesterone receptor in cytosol stored in liquid nitrogen is at present insufficient and inconclusive. On the other hand, we have evidence which suggests there is no appreciable loss of progesterone receptor activity in tumour tissue stored in liquid nitrogen for up to 4 months.

Cytosols stored in liquid nitrogen, allowed to thaw and re-frozen in liquid nitrogen were found to have lost all progesterone receptor activity on subsequent thawing.

Incidence of E_2R+ and PgR+ in primary and metastatic tumours

Of 71 primary mammary tumours examined for oestrogen receptor activity, 44 were found to be E_2R+ (62.0%), amounts of E_2 bound ranging

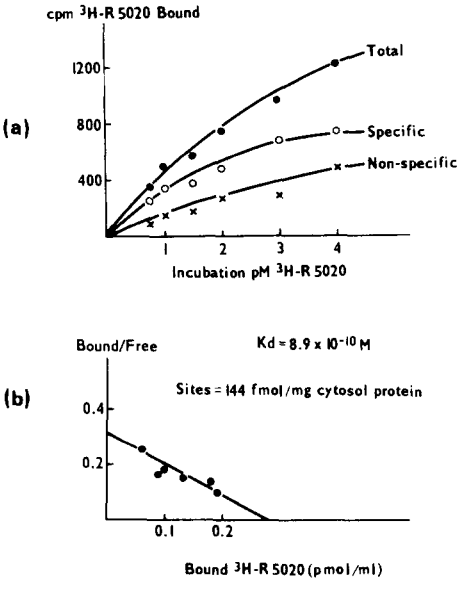

Fig. 2. (a) Binding of progestin ^3H.R5020 by receptor + ve breast tumour cytosol, determined by DCC method.

(b) Scatchard analysis of data.

from 8 to 650 fmole/mg cytosol protein. Progesterone receptor assay was also performed on 54 of these samples, 22 of which were found to be PgR + (40.7%) with amounts of R5020 bound varying from 17 to 1200 fmole/mg cytosol protein. Twenty-two out of thirty-five (62.8%) of tumours which were E_2R + were also PgR +. In no instance was PgR + activity found in a tumour which was E_2R −.

Of 43 secondary tumours, 22 (51.2%) were found to have E_2R + activity with a range of bound oestradiol from 5 to 372 fmole/mg cytosol protein. Progesterone receptor estimation was carried out on 12 of these samples, 5 of which (41.7%) were found to have PgR + activity within a steroid-binding range of 17–145 fmole/mg protein. Seven of these twelve tumours were E_2R + so that 71.4% (5/7) were positive for both activities. In no instance was PgR + activity found in a tumour which was E_2R −.

The results obtained for these tumours which were both E_2R + and PgR + are shown in Fig. 3. It is apparent that the two receptors are not found in constant proportions. In five of the primary tumours, a higher concentration of oestradiol receptor was present, in the remaining 17 a higher proportion of progesterone receptor was found. Of the 5 metastases which contained both receptors, the oestradiol receptor content was the higher in two cases, with the progesterone receptor content prevailing in the other three samples.

In Fig. 4, E_2R binding capacity determined in tumours is related to patients' ages. The mean value in premenopausal women was found to be considerably less than in postmenopausal subjects, and the proportion of E_2R + to E_2R − in the tumours of the former (40%) was less than in those of the latter group (67.1%). The scatter diagram indicates a trend towards higher E_2R binding capacity with increasing age. The correlation coefficient is statistically significant: $r = 0.37$, $P < 0.01$. PgR binding capacity in tumours does not appear to correlate with the patient's age (Fig. 5. $r = -0.08$).

Correlation of clinical response with oestrogen receptors

Thirty patients with metastatic breast cancer have been treated with various forms of hormone therapy. The minimum follow-up has been 7 months and the longest 1 yr.

Before starting therapy, accessible metastatic lesions were biopsied. Half of the material was sent for histological examination and the re-

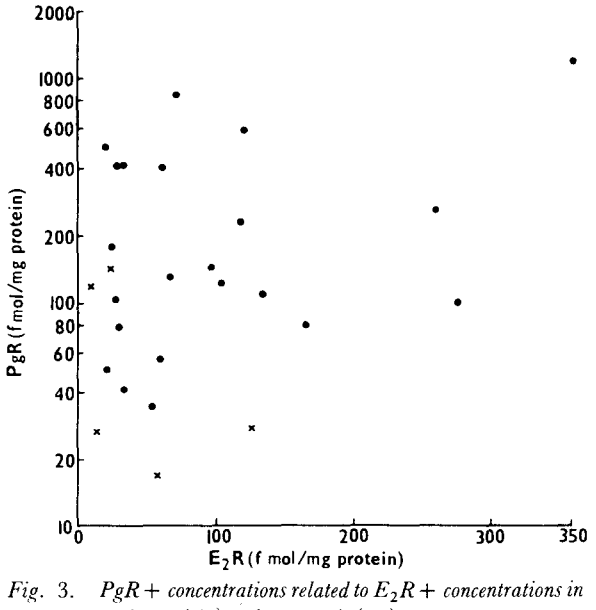

Fig. 3. PgR + concentrations related to E_2R + concentrations in primary (●) and metastatic (×) tumours.

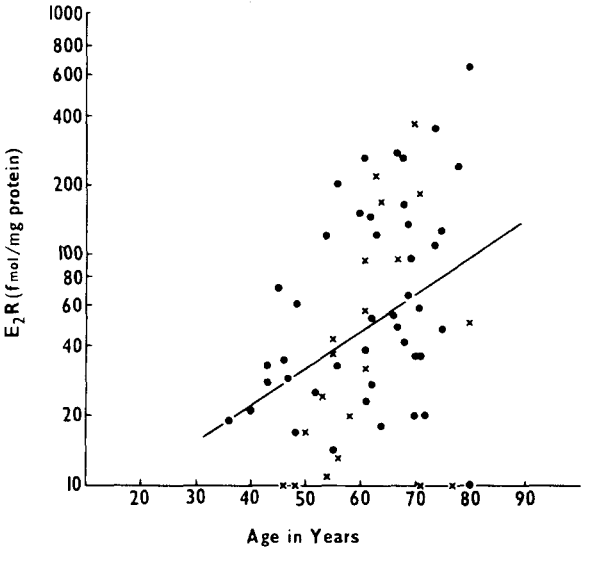

Fig. 4. E_2R + concentrations in primary (●) and metastatic (×) tumours related to patients' ages.

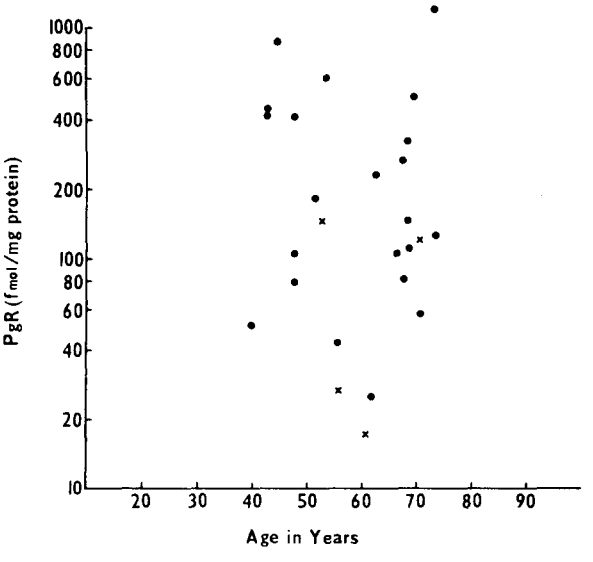

Fig. 5. PgR + concentrations in primary (●) and metastatic (×) tumours related to patients' ages.

mainder used for receptor assay. Careful clinical examinations were made and each patient had accurate measurements of visible and palpable lesions. Clinical photographs were taken. A full blood count and biochemical profile was done and plasma 17β oestradiol assay was also carried out on patients before additive hormone therapy was given. A chest X-ray and X-rays of the major portions of the skeleton were carried out and whenever possible a whole body TC99 scan.

Assessment of response. The criteria laid down by the British Breast Group [14] have been followed. Assessment was made at 6 months from the start of therapy.

Table 2 shows the correlation of response to hormone therapy for 17 patients with metastatic breast tumour classed as being E_2R+.

Table 2. E_2R+ metastatic tumours

Type of therapy	Objective	Response Partial	Failure
Tamoxifen	5/11	4/11	2/11
Diethyl stilboestrol	1/5	1/5	3/5
Prednisolone	0/1	0/1	1/1
Total	6/17	5/17	6/17

Using the criteria above, 6 patients had an objective response and 5 a partial response. There were 6 failures. The total response was approximately 62%. Of the 6 failures, 3 patients had more than one form of therapy followed by cytotoxic drugs but still no response was obtained. These 3 patients are listed in the Table under the first hormone used. The patients were all postmenopausal, ranging from 6 months to more than 10 yr postmenopausal. Where the disease responded objectively, in all cases it was soft tissue disease that regressed, i.e. disease in the operative flaps and regional nodes. The plasma 17β oestradiol in all the patients was so low as to be virtually undetectable.

In Table 3 is shown the response to therapy in 13 patients with E_2R- metastatic tumours. Only 1 patient has had the disease on the chest wall and lung metastases static for 6 months. This is classed as a partial response, since the disease was progressing prior to hormone therapy. Again the patients were all postmenopausal. Two patients did not respond to other hormones or to cytotoxic drugs.

Table 3. E_2R- metastatic tumours

Type of therapy	Objective	Response Partial	Failure
Tamoxifen	0/6	1/6	5/6
Androgens	0/2	0/2	2/2
Prednisolone	0/2	0/2	2/2
Progestogen	0/1	0/1	1/1
Bilat. oophorectomy	0/2	0/2	2/2
Total	0/13	1/13	12/13

DISCUSSION

Two simple quantitative methods, one based on the dextran–charcoal procedure of Korenman and Dukes [6] and the other using gel filtration on Sephadex KH-20 as originally described by Ginsburg *et al.* [7] for measurement of oestradiol receptors in brain and pituitary, have been used to estimate both E_2R and PgR activity in the same tumour cytosol. Where adequate control over experimental parameters (especially temperature) and storage conditions was exercised, agreement between the assay estimations of either receptor activity was remarkably good and in no instance did the methods fail to agree on whether a tumour cytosol was positive or negative in respect of either receptor. The K_d values observed provide good evidence for the specificity and identity of the individual receptors measured by either method. Either procedure has a sensitivity level of 5 fmole/mg cytosol protein for E_2R and 15 fmole/mg cytosol protein for PgR, and these levels have therefore been regarded as the cut-off points for determining whether a tumour was receptor positive, subject to a satisfactory Scatchard analysis being obtained. Use of either method would permit 15–20 assays of both receptors to be carried out in a normal working week by a single operator.

Addition of glycerol and thioglycerol to the homogenisation buffer (Jänne *et al.* [15]; Horwitz and McGuire [12]) greatly increased the stability of the progesterone receptor and did not affect subsequent estimation of E_2R so that the same tumour cytosol prepared in 30% glycerol may be used for assay of both activities.

Under the assay conditions described, the E_2R assay measures predominantly free, unoccupied receptors [16]. As shown by Sakai and Saez [17], however, binding sites in all tumours are undersaturated by oestradiol *in vivo* and the absolute number of receptors occupied by endogenous oestradiol (which rarely exceeds 15% in postmenopausal or 20% in premenopausal women) is partly dependent on the total numbers of receptors available. Because of its greater affinity for the progesterone receptor, ^{3}H-5020 as used in the PgR assay measures not

only unoccupied sites but also occupied sites from which it displaces progesterone [13].

Various authors have reported positive E_2R values in proportions ranging from 50 to 80% of primary tumours assayed and there is general agreement that there is a lower incidence of E_2R+ in metastatic specimens [2]. In our series to date, we have found an incidence of 62% positive results in primary, 51% in metastatic tumours. The proportion of E_2R+ in the tumours of premenopausal women (40%) was markedly less than in those of postmenopausal subjects (67%), and we also found the mean number of sites in the younger women with E_2R+ to be lower than in the older age groups, in keeping with the data reported by other groups on the relationship between E_2R+ tumours and patient's age and menopausal status (see McGuire *et al.* [2]).

In the group of 30 postmenopausal patients with metastatic breast cancer studied we found 62% of 17 E_2R+ cases responded to hormone manipulation, whereas 12 out of the 13 E_2R- cases failed to respond and in the remaining patient the disease remained static. Our data therefore agree with the collective experience of several centres reported by McGuire *et al.* [2]: patients with breast cancer who lack oestrogen receptors in their tumour tissue have a minimal prospect of responding to endocrine therapy, but some 40% of these with E_2R+ tumours fail to respond to hormone manipulation. This would suggest that although the cells in this latter group of tumours are capable of the initial step of binding oestrogens, there is a lesion at some later stage in the chain of hormone action which prevents them from responding to changes in the hormonal environment. To identify the hormone responsive tumours more precisely therefore requires measurement of some later product of oestrogen action in the cell.

Freifeld *et al.* [18] and Reel and Shih [5] demonstrated the induction of progesterone receptor activity in uterine tissue following oestradiol administration. Horwitz *et al.* [4] have postulated that the presence of PgR in a tumour would therefore indicate that the tumour was capable of synthesizing at least one end product under oestrogen regulation and hence might be expected to be responsive to hormone therapy.

Only a few reports have so far appeared in the literature of the incidence of PgR in human breast cancer (Terenius [3]; Horwitz *et al.* [12], Raynaud *et al.* [13], Liskowski *et al.* [19]). This probably stems from the difficulty of identification of specific PgR in the presence of corticosteroid-binding globulin and cytoplasmic glucocorticoid receptors for which progesterone has marked affinity and from the unstable nature of the PgR complex. This difficulty has been overcome by the use of the radioactive synthetic progestin R5020 which was used by Philibert and Raynaud [8] with immature rat and mouse uteri and by Horwitz and McGuire [12] with human mammary carcinoma to demonstrate the presence of specific PgR.

McGuire's hypothesis [4] requires that PgR should be rare in tumours where E_2R is absent. All E_2R- tumours which we have examined to date (19 primary, 5 metastatic) have been found to have no PgR activity. Forty-one to forty-two percent of all tumours (primary and metastatic) on which PgR estimation was carried out were found to have PgR+ activity. These results are in marked contrast to the data published by Liskowski *et al.* [19] who report PgR+ in 85% of all tumours assayed and 40% of these classified as E_2R- (i.e. <10 fmole E_2 bound/mg cytosol protein). This would suggest that the type of assay used by these workers which employs ^3H progesterone at a single concentration is failing to discriminate specific PgR activity effectively. Sixty-three to sixty-four percent of all tumours (primary and secondary) on which we have carried out both receptor measurements and which have been found to be E_2R+ have also PgR+ activity, which accords well with McGuire's hypothesis that possession of PgR+ activity should indicate which of approximately 60% of tumours with E_2R+ have retained hormone dependence and might therefore be expected to respond to hormone therapy. Although our data on the clinical response of patients with metastatic breast cancer is at present limited to 30 patients whose tumour E_2R activity was estimated prior to treatment, the overall response rate (62%) is consistent with the percentage of all E_2R+ tumours in which we have also found PgR+ activity. Of seven patients whose tumour PgR was also estimated, three with PgR+ had a remission, four with PgR− failed to respond.

In agreement with Liskowski *et al.* [19] we found no linear correlation between estimated values for E_2R and PgR in primary and metastatic breast tumours. Unlike oestradiol binding capacity, which shows a trend towards higher levels with increasing age and change in menopausal status, progesterone binding capacity does not appear to bear any relationship to the patient's age.

In our experience, limited to response in menopausal patients with metastatic breast cancer, there does not appear to be any direct relationship between the absolute value for tumour E_2R and the percentage response. In

selecting suitable standardized assay systems for estimating both E_2R and PgR in tumours, it seemed to us more important that each assay should have a clearly defined threshold value which distinguished between positive and negative binding and that from the data in each individual assay it should be possible to demonstrate that the cytosol contained only one class of binding sites whose dissociation constant conformed to that expected for the specific tissue receptor assayed. When these criteria are observed, we conclude that an accurate picture of the tumour's responsiveness to hormones should be obtained. We await data which it is hoped will provide direct correlation between clinical response and presence or absence of PgR, but our present evidence would appear to support the hypothesis of Horwitz *et al.* [4] that the presence of both PgR and E_2R would indicate a tumour whose endocrine regulatory mechanism was largely intact and which might therefore be more confidently predicted to respond to endocrine therapy. If this were indeed the case, estimation of E_2R and PgR in primary tumours at time of mastectomy might serve as a useful guide to predict response to hormone therapy when metastases appear at a later time, (often in inaccessible sites), as suggested by Jensen *et al.* [20]. This is at present under investigation in our laboratory.

Acknowledgements—We are grateful to Dr. J.-P. Raynaud (Roussel-UCLAF) for generous gifts of radioactive and radio-inert R5020. Primary tumour samples were provided by Professor R. A. Sellwood, Dept. of Surgery, University Hospital of South Manchester, and his staff, and by Mr. L. Turner, Christie Hospital, Manchester. Technical assistance was provided by Mrs. Elizabeth Hayward and statistical analysis was carried out by Mr. Michael Palmer.

Cell Surface Charge, Sialic Acid Content and Metabolic Behaviour of Two Tumour Sublines. A Comparative Study*

B. BOHN, C. THIES and R. BROSSMER

Institut für Biochemie II (Med. Fakultät) der Universität Heidelberg, Im Neuenheimer Feld 328, *D*-6900 *Heidelberg, Federal Republic of Germany*

Abstract—*Two sublines of the Ehrlich-Lettré mouse ascites tumour, the glycogen-storing and the glycogen-free strains, were compared with respect to their respiratory and glycolytic activities, their electrophoretic mobility and the cell surface sialic acid content. An attempt to correlate differences in these parameters with the growth behaviour of the two cell types showed some deviations from "classical" malignancy criteria. Although the two cell lines exhibited differences in their surface sialic acid content we did not find similar differences in reduction of electrophoretic mobility after neuraminidase treatment.*

INTRODUCTION

THERE has been considerable interest in the electrical charge of the cell surface, especially with respect to malignancy, ever since Ambrose *et al.* [1] advanced the hypothesis that malignant transformation is associated with elevated net negative cell surface charge. It has been proposed that neuraminic acids may mask cell surface antigens [2–5]. Much significance is attributed to the surface charge for phenomena like invasiveness, metastasis and contact inhibition of growth [6]. On the other hand, attempts to correlate membrane sialic acid content directly with anodic electrophoretic mobility have met with little success [7–9]. In addition to sialic acids, membrane-associated ribonucleic acids [10, 11], sulphate and thiol groups [12] are believed by some authors to contribute to the net negative surface charge. In the present study we compared closely related tumour sublines with different biochemical and growth characteristics with special regard to surface charge and sialic acid content. We chose two strains of the hyperdiploid Ehrlich–Lettré ascites tumour (EAT) which have developed spontaneously from the same original tumour: one subline (G+) stores glycogen, especially in the nucleus, whereas the other one (G∅) is essentially free of glycogen deposits [13]. The two variants differ in several biological, biochemical and pharmacological properties. For example, the G+ strain exhibits a faster growth rate; glucose is primarily utilized for glycogen synthesis (with the G∅ strain for lipid biosynthesis); the G+ cells are partially resistant against antitubulins such as colchicine and vinca alkaloids [14, 15]. Since such dissimilarities point to a possible involvement of the cell surface it seemed promising to compare the two sublines in terms of their surface charge and sialic acid content, as well as their metabolic characteristics, and to try to correlate these parameters with the growth behaviour. Preliminary results have already been reported [16].

Accepted 17 March 1977.

*Our investigations were sponsored by the Deutsche Forschungsgemeinschaft, SFB136 (Cancer Research).

MATERIAL AND METHODS

(*a*) *Cells*

The glycogen-free (G∅) and glycogen-storing (G+) sublines [14] of the hyperdiploid Ehrlich-Lettré mouse ascites tumour (EAT) were grown in male NMRI mice weighing about 30 g. The cells were harvested 7 days after inoculation, suspended in cold Hank's solution, centrifuged 10 min at 120 × ***g***, and, depending on the nature of the subsequent experiment, washed again in the same way up to 3 times, or resuspended immediately in an appropriate buffer system.

(*b*) *Metabolic assays*

The determination of global metabolic parameters, i.e. respiratory and glycolytic rates, with and without exogenous substrates (10 mM glucose) was carried out with four independent

methods as described earlier [17, 18]: 1. classical Warburg manometry; 2. enzymatic determination of lactate production; 3. autotitration in pH-stat systems under anaerobic conditions (N_2); 4. continuous automatic measurement of oxygen consumption under constant oxygen pressure using a combined polarographic–titrimetric method. As we did in previous studies [17, 18], we compared these methods for each experimental condition. Again we found a high degree of congruence between the different methods.

(*c*) *Determination of electrophoretic mobility of cells*

We used the cytopherometer from Zeiss, Oberkochen (Germany), developed by Ruhenstroth-Bauer and Fuhrmann [19]. The measuring chamber is connected to a Zeiss phase contrast microscope, and the electrophoretic mobility of cells is expressed in (μ/s)/(V/cm). All mobility measurements were carried out at 25 $\pm$0.5°C and repeated with reversed polarity. In each experiment, the mobility of at least 40 cells was determined. We used the following composition for the measuring fluid: 7.5 ml isotonic sucrose solution, 2.0 ml phosphate buffer, pH 7.18, 300 mOsM made up to 10.0 ml with 0.5 ml cell suspension, the latter being diluted 1:4 with physiological saline. We chose this composition as a "compromise", following an advice given by Fuhrmann (Fuhrmann, personal communication): on the one hand the medium should possess a relatively high buoyant density in order to facilitate mobility measurements, on the other hand the percentage of ion-free liquid should not exceed 80% since the properties of the cell surface may be altered (cf. [20]). The final cell concentration was about 3×10^4/ml.

(*d*) *Neuraminidase treatment of cells and sialic acid determination*

Washed cells were subjected to treatment with *Vibrio cholerae* neuraminidase (glycoprotein N-acylneuraminyl hydrolase, E.C. 3.2.1.18.) from Behringwerke, Marburg. The optimum enzyme concentration and incubation time had to be found for our purposes in order to release sufficiently high amounts of sialic acid with incubation times during which the cells do not lose their functional integrity. We compared incubation times from 15 min to 6 hr, with enzyme concentrations of 25, 50 and 100 U*/ml cell suspension and 6×10^6 cells/ml. We found that 50 U/ml for 60 min yielded the best results. Using this procedure, more than 90% of sialic acids liberated with 100 U/ml within 6 hr are released. Similar results have been obtained by Kojima and Maekawa [9]. Unless stated otherwise, this protocol was applied for electrophoretic studies as well as for the determination of cell surface sialic acid. The following buffer system was used throughout: 25 ml maleic acid in Tris (24.23 g Tris hydroxyaminomethane plus 23.21 g sodium maleate per liter of twice distilled water); 17.9 ml 0.2 N NaOH; 100 mg $CaCl_2$, made up to 100 ml with twice distilled water. The osmolarity was adjusted to 290 mOsM; the pH was 6.5. Nine-tenths of a millilitre of this maleate buffer was mixed with 1.0 ml of washed cells and 0.1 ml of neuraminidase, containing 100 U. The incubation was carried out at 37°C while the cells were gently shaking in Warburg flasks. After incubation, the cells were centrifuged at $120 \times g$ for 15 min and resuspended to the original volume in physiologic saline containing 10^{-2} M EDTA. Omission of the latter sometimes resulted in aggregation of cells which made cytophoretic studies impossible. The supernatants were used for the determination of sialic acid according to the method of Warren [21] (acidic oxidation of free sialic acids and colorimetric determination of the coloured complex produced with 2-thiobarbituric acid).

(*e*) *Assessment of membrane integrity of treated cells*

Prior to cytophoretic examination, neuraminidase-treated cells were routinely examined in the phase-contrast microscope. In some cases, electron micrographs were kindly made by Prof. Forssmann (Dept. of Anatomy). Furthermore, leakage of cytoplasmic lactate dehydrogenase (E.C. 1.1.1.27.), as determined photometrically, and of potassium ions, measured with an atomic absorption spectrophotometer (Pye-Unicam SP 90), as well as the trypan-blue exclusion test were used for the assessment of membrane integrity. Cell "viability" was determined with a laser flow cytofluorometer, with fluorescein diacetate as "fluorogenic substrate", cf. [22], for intact cells and erythrosine B as fluorescent counterstain for damaged cells. With 50 U neuraminidase/ml for 60 min at 37°C, about 90% of the cells were functionally "intact" as judged by these criteria.

RESULTS

(*a*) *Metabolism*

As can be seen from Fig. 1, left side, the

*1U is defined as the amount of neuraminidase which releases 1 μg of N-acetylneuraminic acid from human α-acid glycoprotein in 15 min at 37°C, in a sodium acetate buffer solution 0.05 M, pH 5.5, containing 9 mg NaCl/ml and 1 mg $CaCl_2$/ml (producer's specification).

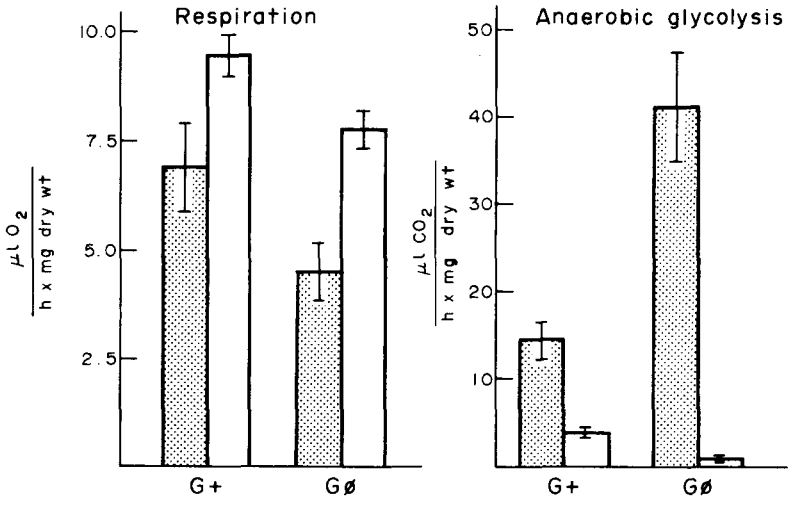

Fig. 1. Metabolic rates of glycogen-storing (G+) and glycogen-free (GØ) Ehrlich–Lettré mouse ascites tumour cells. Left side: respiratory activity after addition of 10 mM *glucose (dark columns). Right side: anaerobic glycolysis with* 10 mM *glucose (dark columns) and without exogeneous substrate (light columns). Respiratory activity is expressed in* µl O_2 *consumption per* hr *and* mg *cell dry mass, anaerobic lactate production in* µl CO_2 *liberated from the bicarbonate buffer system per* hr *and* mg *cell dry mass.* $n = 14$.

glycogen-storing cells (G+) show a considerably higher O_2-consumption than the GØ cells when exogeneous substrate (10 mM glucose) is supplied. Without the addition of glucose, both cell types exhibit increased respiratory activity when the determination is carried out within 90 min after aspiration of the cells from the peritoneal cavity. It also can be seen that the impairment of respiration in the presence of glucose, a phenomenon known as "Crabtree effect" [23], is more pronounced with the GØ strain. In contrast, the glycolytic activity under anaerobic conditions is considerably higher with the GØ cells (Fig. 1, right side). Interestingly, the glycogen-storing cells show the ability to perform anaerobic glycolysis to some extent even in the absence of exogenous glucose for about one hour.

(*b*) *Electrophoretic mobility*

Figure 2 (left side) shows that the electrophoretic mobility of the G+ cells is higher. This finding applies, however, only to cells which have been washed once immediately after aspiration. When the cells were subjected to shaking in Warburg flasks for 60 min, this difference in electrophoretic mobility disappeared.

(*c*) *Cell surface sialic acid content*

Figure 2 (right panel) depicts the amount of

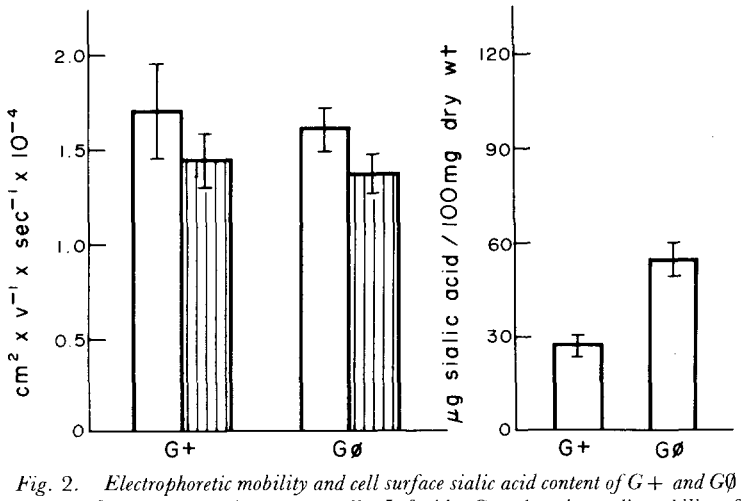

Fig. 2. Electrophoretic mobility and cell surface sialic acid content of G+ and GØ Ehrlich–Lettré mouse ascites tumour cells. Left side: Cytophoretic anodic mobility of native cells (light columns) and of cells treated with 50 U Vibrio cholerae *neuraminidase/*ml *for* 60 min *at* 37 °C *(dark columns). The mobility is expressed in* (µ/s)/(V/cm). *Right side: Sialic acid content, as determined by the thiobarbituric acid assay.*

sialic acids removable by neuraminidase from the two cell types. It seems of particular interest that the GØ cells contain much more, i.e. almost twice as much, sialic acid susceptible to ketosidic cleavage by neuraminidase than the glycogen-storing ones, although the cytophoretic behaviour (left panel) might rather suggest the contrary.

(d) Electrophoretic mobility after neuraminidase treatment

After neuraminidase treatment (50 U/ml, 60 min, 37°C), the electrophoretic mobility for GØ cells was found to be:

$1.37 \pm 0.09 \frac{\mu/s}{V/cm}$, as compared to

$1.61 \pm 0.12 \frac{\mu/s}{V/cm}$ for untreated cells.

For G+ cells the corresponding values were:

$1.45 \pm 0.14 \frac{\mu/s}{V/cm}$ (treated) and

$1.80 \pm 0.26 \frac{\mu/s}{V/cm}$ (untreated) (Fig. 2, left panel). This means a decrease in electrophoretic mobility by 15% for GØ, and 19% for G+ cells, respectively. These values are considerably lower than those reported in the literature for Ehrlich and other ascites cells [7–9, 24]. The puzzling inconsistency with the values for neuraminidase-liberated sialic acids (right panel in Fig. 2) remains to be discussed.

DISCUSSION

It always has been a problem to establish "malignancy criteria" other than growth rate, invasiveness or degree of dedifferentiation of specialized cells. With the data of this comparative study on two tumour sublines no definite correlation can be obtained between known differences in growth rate [14], "classical" matabolic malignancy criteria [23, 25], "malignant" electrokinetic behaviour [1] and sialic acid content of the cell surface.

The faster-growing glycogen-storing cells exhibit a higher respiratory activity, with and without addition of exogenous glucose, and a considerably lower glycolytic rate under anaerobic conditions (Fig. 2). In addition, reduction of respiratory activity in the presence of glucose, the so-called "Crabtree effect" [23], is more pronounced with the glycogen-free cells (dark columns in Fig. 2, left panel). The decrease in O_2-consumption is parallelled by a rise in aerobic lactate production (not shown on the graph). All these findings would suggest that the GØ strain is "more malignant", according to "classical" metabolic criteria. On the other hand, we were able to demonstrate that the glycogen-storing cells are capable to maintain about 30% of their anaerobic glycolytic rate for about 1 hr in the absence of glucose, an ability lacking with GØ cells. Apparently the stored glycogen can be mobilized at times of nutritional deficiency, and in fact, microscopical examination of such cells revealed the disappearance of most of the cytoplasmic and many of the intranuclear glycogen grana as compared with control cells maintained under the same conditions with exogeneous glucose. One might speculate that this possibility offers an advantage for the *in vivo* growth of G+ cells which makes these cells, at least temporarily, independent of exogenous substrates, especially when they are remote from adequate oxygen and substrate supply.

The interpretation of cytophoretic mobility is quite intricate, some of the difficulties have been reviewed recently [26]. Yet we think that cytophoresis is a useful means to estimate cell surfaces-charge properties for comparative purposes. Although other charge carriers are being discussed, we believe that for cells growing in suspension the bulk of ionogenic groups that generate the net negative cell surface charge is contributed by sialic acids, in spite of the controversial findings discussed below. It has been demonstrated by others that sialic acids are responsible for electrostatic repulsion between cells, cf. [27]. Moreover, there is evidence for the existence of membrane-associated "ecto-sialidases" [28, 29], a finding that might be of great importance for cell–cell interactions and tumour biology. If Ambrose's [1] hypothesis is applied to our cells, the G+ strain with its greater anodic electrophoretic mobility (Fig. 2) ought to be the "more malignant" one. On the other hand, it has been found with normal and proliferating liver cells that the latter exhibit an increase in electrophoretic mobility to about the same extent as malignant liver cells [19]. Thus it has been proposed that higher negative surface charge relates to faster growth. This is consistent with the higher growth rate of G+ cells, as compared with the GØ strain [14], whether this means "greater malignancy" or not. It should be pointed out that we found electrophoretic mobilities for both cell types that are higher than those reported earlier for Ehrlich cells by Hoelzl Wallach *et al.* [7, 8] and Mayhew [24]. On the other hand, the reduction in electrophoretic mobility after neuraminidase treatment was markedly smaller (19% for G+ cells) than

reported by Hoelzl Wallach (72%). The inverse relationship between electrokinetic behaviour and amount of enzyme-removable Warren-positive material is not unique. Similar discrepancies have been encountered by other investigators, cf. [7, 8]. Possible explanations may relate to different spatial arrangements of sialic acid molecules within the membrane. Since the zeta-potential is supposed to comprise only those ionogenic groups that do not extend more than 10 Å from the hydrodynamic plane of shear, sialic acid residues located farther away from this plane would not be detected; yet they may be accessible to neuraminidase. We are currently investigating this possibility with the aid of a new preparative isoelectric focussing technique. With such a technique it should be possible to detect charge changes which occur farther away than 10 Å from the hydrodynamic plane of shear. Indeed, preliminary findings indicate that comparative studies with the two techniques allow for this conclusion [30]. On the other hand, removal of sialic acids may lead to a conformational change within the membrane, giving rise to the appearance or disappearance of positive or negative ionogenic groups, with different results for different cell types. It has been pointed out in "results" that the differences in electrokinetic behaviour between the two cell types disappear after shaking for 60 min. This raises the possibility that even mechanical events may lead to membrane conformational changes with subsequent rearrangement of ionogenic groups. Alternatively, the possibility must be considered that substituted sialic acids may be present other than N-acetyl-D-neuraminic acid which may not be substrates for *Vibrio cholerae* neuraminidase. Any one or all of these possibilities may reconcile the apparent contradiction between the amount of sialic acids liberated and the reduction in electrophoretic mobility, especially with the G+ cells.

Acknowledgements—We wish to express our gratitude to Prof. W.-G. Forssmann (Department of Anatomy) who kindly made a series of electron micrographs. Furthermore, the skilful technical assistance of Mrs. A. Sauer is gratefully acknowledged.

Modification of Tumour Cells by Covalent Attachment of *N*-Acetyl-D-Neuraminic Acid to the Cell Surface*

R. BROSSMER, B. BOHN and C. THIES

Institut für Biochemie II (*Med. Fakultät*) *der Universität Heidelberg, Im Neuenheimer Feld* 328, *D*-6900 *Heidelberg, Federal Republic of Germany*

Abstract—*Two sublines of the Ehrlich-Lettré mouse ascites tumour were compared with respect to their ability to covalently bind the 4′-diazobenzyl-α-ketoside of N-acetyl-D-neuraminic acid* per viam *azo linkages. The increase in anodic mobility of the cells was correlated with their content in neuraminidase-removable sialic acid before and after the coupling procedure.*

INTRODUCTION

TWO SUBLINES of the Ehrlich-Lettré mouse ascites tumour, glycogen-storing (G+), and glycogen-free (GØ) were compared with respect to their "responsiveness" to accept "artificially grafted" sialyl residues, which, as diazonium salts, are covalently attached chiefly to tyrosyl and histidyl residues.

To our knowledge, chemical attachment of sialic acids to the surfaces of viable cells has not been performed before. Preliminary results have already been reported [1]. In addition, we performed similar attachment reactions under mild conditions with erythrocytes [2, 3] and with proteins, having defined biological activity [4].

Although such additional negatively charged groups are located on protein moieties rather than on the oligosaccharide chains of the cell surface, such "grafting" experiments seem quite attractive. They might tell us something about the relationships between cell-surface sialic acids and the specific requirements for their location with respect to the electrokinetic behaviour and growth characteristics of such cells.

MATERIAL AND METHODS

Details on the cell strains used, on the methodology for metabolic assays, cytophoresis, sialic acid determination and "viability" tests are given in the preceding article [5].

The 4′-aminobenzyl-α-ketoside of *N*-acetyl-D-neuraminic acid was prepared by Koenigs–Knorr glycoside synthesis. A similar approach has been used by Gielen and Uhlenbruck [6], but our method [7, 8], which yields the pure α-anomeric form, showed some major deviations from their procedure. For the preparation of the 4′-diazobenzyl derivative, the 4′-aminobenzyl compound was diazotized with sodium nitrite.

After neuralization (pH electrode) the solution was brought into Tris-HCl buffer, pH 8.2, containing about 5×10^6 cells/ml, to yield a final concentration of 3.8×10^{-3} M diazo compound. Although no unreacted nitrite could be detected nitrite under the conditions employed, we prophylactically added small amounts of urea to the neuralized solution. The reaction with the cells was carried out for 30 min at 20°C, while the cells were shaken with an amplitude of 5 cm at a frequency of 100/min. Unreacted ketoside was largely removed by washing the cells twice in PBS. Nevertheless, for the determination of neuraminidase-sensitive material, we used controls treated with the 4′-aminobenzyl-α-ketoside in order to eliminate non-covalent adsorption from the evaluation.

Treatment of the cells under the conditions described did not significantly impair their metabolic activity (respiration, glycolysis) or their "viability", as determined cytofluorometrically with fluorescein diacetate or erythrosine B, cf. [9].

RESULTS

Figure 1 summarizes the effects on glycogen-storing (G+) and glycogen-free (GØ) Ehrlich–

Accepted 17 March 1977.

*Our investigations were sponsored by the Deutsche Forschungsgemeinschaft, SFB 136 (Cancer Research).

Lettré mouse ascites tumour cells brought about by covalent attachment of the 4′-diazobenzyl-α-ketoside of *N*-acetyl-D-neuraminic acid, both with and without neuraminidase treatment. The left panel shows the electrophoretic mobilities, as determined by cell electrophoresis. It can be seen that the relative increase in anodic mobility is greater with the G+ subline (15%), as compared to 7% with the GØ cells. Untreated GØ cells possess a slightly lesser mobility before and after incubation with neuraminidase as compared with G+ cells. Unfortunately it could not be demonstrated whether neuraminidase treatment after azo coupling reduces the increased anodic mobility, since cells subjected to both procedures were partially damaged and not suited for cytophoretic studies.

charged sialyl residues to the cell surfaces brings about a parallel increase in both electrophoretic mobility and in neuraminidase-removable sialic acids with the two cell strains. This probably means that the "artificially" attached sialyl residues are located in membrane portions which—in contrast to their physiologically located counterparts—contribute rather uniformly to the zeta-potential, with concomitantly uniform accessibility to the enzyme.

The differences between the two cell types in the number of additionally attached sialyl residues may relate to the fact that one of the predominant factors for the "responsiveness" of the cells to our coupling reagent must be the availability of tyrosyl and histidyl residues. In other words, it seems reasonable to assume that

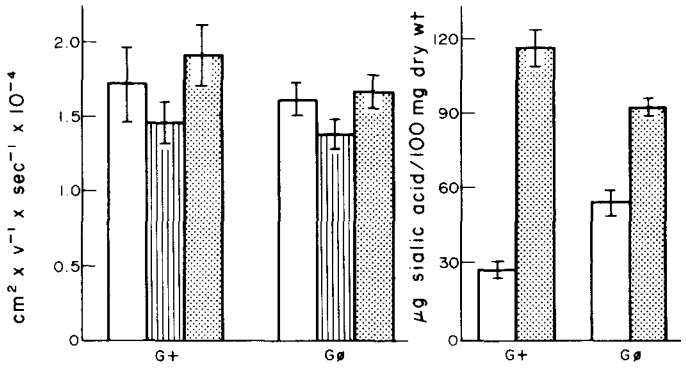

Fig. 1. Electrophoretic mobility and cell surface sialic acid content of glycogen-storing (G+) and glycogen-free (GØ) Ehrlich–Lettré mouse ascites tumour cells. Left side: Cytophoretic anodic mobility of native cells (light columns), cells treated with 50 U/ml Vibrio cholerae *neuraminidase for* 60 min *at* 37°C *(dark columns), and of cells treated with* 3.8×10^{-3} M 4′-*diazo-benzyl-α-ketoside of N-acetyl-D-neuraminic acid for* 30 min *at* 20°C, pH 8.2 *(dotted columns).* $n = 14$. *Right side: Sialic acid content, as determined by the thiobarbituric acid assay after incubation with neuraminidase* (50 U/ml, 60 min *at* 37°C). *Light columns: native cells; dotted columns: cells pretreated with* 3.8×10^{-3} M 4′-*diazobenzyl-α-ketoside as described above.* $n = 14$.

The right panel in Fig. 1 depicts the amount of neuraminidase-removable Warren-positive material: the increase after treatment with the diazobenzyl compound is considerably higher with the G+ than with the GØ subline whereas the content of neuraminidase-removable material with native cells is inversely related to the amount of additionally "grafted" sialic acid residues.

DISCUSSION

The discrepancy between the relative net negative cell surface charge and the amount of neuraminidase-sensitive material of native ascites tumour cell sublines has been one of the subjects of the preceding article [5]. On the other hand, "grafting" of additional negatively differences in covalent binding of the compound to cell surfaces may reflect different protein dispositions of the cells. Preliminary experiments with similar diazo compounds of neutral sugars and their effects on lectin binding [10] favour this view since GØ cells are, here too, less "responsive".

Since the electrokinetic behaviour of cells as revealed by cell electrophoresis is supposed to reflect ionogenic groups within only about 10 Å from the hydrodynamic plane of shear, we are currently comparing the results presented here with those obtained with a special technique for preparative isoelectric focussing of intact cells. In fact, some apparent contradictions may be resolved by using both methods [11]. Furthermore, it seems of interest to follow the electrokinetic behaviour of the cells (with either

method) when they have been subjected to neuraminidase treatment prior to coupling with the diazonium compound.

We feel that cell surface modifications with "artificially grafted", but otherwise "physiological" molecules; especially when cells of different growth behaviour are compared, may contribute to the understanding of different cell surface arrangements of whole cells. Furthermore, reimplantation experiments or similar studies with cultured cells might reveal more aspects on mutual relationships between cell surface charge and growth behaviour.

One might speculate that such reimplanted or cultured cells will repair this surface alteration brought about by the local change of negative charge. In this context it should be especially interesting to study the effect of "grafted" *N*-acetyl-L-neuraminic acid, which has not been found in nature so far. The L-isomer was synthesized in this laboratory [12–13] and found to be completely resistant to the action of neuraminidase and aldolase (*N*-acetylneuraminate pyruvate-lyase, E.C. 4.1.3.3) [13, 14]. With such L-neuraminic acid residues attached to the cell surface, a specific repair should be much more difficult. As a consequence, a modified cell would keep its higher negative charge in cell culture and after reimplantation.

The Clinical and Histopathological Significance of Feulgen DNA-Values in Transitional Cell Carcinoma of the Human Urinary Bladder*

S. D. FOSSÅ,†‡ O. KAALHUS§ and O. SCOTT-KNUDSEN||

†*General Department and* ||*Department of Pathology, The Norwegian Radium Hospital, Oslo, Norway, and Departments of* ‡ *Tissue Culture and* §*Biophysics, Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway*

Abstract—*Scanning absorption cytophotometric measurements were performed in Feulgen-stained cell nuclei in imprints from 123 biopsy specimens from human transitional cell carcinoma (TCC). The results were correlated with the histopathological grade and the clinical stage of the tumour. Nearly all histologically well differentiated bladder carcinomas and tumours of clinical stage I had diploid DNA-stemlines, while non-diploid DNA-stemlines were found in most of the dedifferentiated carcinomas and in most of the advanced cases.*

Increasing clinical stage and decreasing histological differentiation were correlated with low numbers of DNA-stemline values.

Within the group of locally advanced carcinomas, patients with non-diploid tumours had a worse prognosis than those with diploid TCC.

Distant metastases in 3 patients showed non-diploid DNA-stemlines. In some tumours the DNA-histogram showed regional differences.

INTRODUCTION

In 1948 Boivin *et al.* [1] found that the nuclear DNA-content was usually constant in cells from different tissues in the same species. A few years later it became evident that the variations in the nuclear DNA-content which can be observed in certain tissues may be explained as a result of nuclear polyploidy and by nuclear DNA-synthesis [2].

The DNA-content in carcinoma cell nuclei may differ from that of normal cells [3]. Many studies have dealt with the relationship between the nuclear DNA-content and the histopathology in human tumours. In addition, some authors have considered nuclear DNA-content in relation to clinical aspects suggesting that measurement of the nuclear DNA-content might be of prognostic value in patients with a malignant disease [4].

In this study we correlated histopathological and clinical aspects of transitional cell carcinoma (TCC) of the human urinary bladder with the results of cytophotometric DNA-measurements of individual Feulgen-stained cell nuclei in imprints from bladder tumour biopsies.

MATERIAL AND METHODS

Imprints were made from biopsies of histologically proven transitional cell carcinoma from 123 patients admitted to the Norwegian Radium Hospital during the year 1974 and from 1st October 1975 to 31st March 1976. The biopsy material ("actual biopsy") was taken from areas thought to be representative of the whole tumour, either by transurethral resection or by cystotomy. A single biopsy was taken in 118 patients, whereas both a central and a peripheral tumour area were biopsied in the remaining 5 patients (Fig. 2). In the latter the results from the

Accepted 31 March 1977.

● *octoploid*

peripheral biopsy were used in the sampled material of 123 patients (Tables 2–5 and Fig. 1). In 3 patients biopsies were also taken from distant metastases (Fig. 3).

A control group consisted of 32 specimens of macroscopically normal bladder mucosa. These were collected from patients with benign disorders of the lower urinary tract (mostly benign prostatic hyperplasia) or were taken immediately after death from patients who died without urological disorders.

The age distribution in the TCC group and the control group was similar.

In 20 patients the bladder carcinoma was

○ *tetraploid* } *DNA-value.*
● *octoploid*

when the actual biopsy was taken, regardless of previous surgical intervention. As it was often impossible to distinguish between stage II and stage III in previously operated patients these stages were grouped together. This stage II–III was defined by the presence of a firm mobile induration of any size in the bladder wall, or of a tumour with histologically proven infiltration of the muscular layer of the bladder wall.

Chest X-rays were performed in all patients. Pedal lymphography was done in 29 patients. Only patients with unquestionable evidence of disseminated disease were considered to have metastases.

Table 1 shows the treatment of the patients, following the actual biopsy. Preparation, fixation, staining and mounting of the imprints were done as described previously [6].

The total extinction (*te*) of a Feulgen-stained cell nucleus, here defined as Feulgen DNA-value, was measured by means of a scanning microscope photometer SMP05 (Zeiss, Oberkochen, W. Germany) [6].

A total of 100 round or elipsoid cell nuclei with reticular chromatin pattern was measured in randomly selected regions of the imprints. The mean DNA-value of 30 polymorphonuclear leukocytes in each imprint was used as a reference to the actual specimen's diploid DNA-value (internal standard) [3].

Table 1. Treatment in 123 patients with bladder carcinoma

Clinical stage	Treatment—number of patients					
	Radical surgery	Non-radical surgery	Radical surgery + local chemo-therapy	Non-radical surgery + external irradiation	General chemo-therapy	Total
Stage I	47		14		2	63
Stage II–III	2	5		17	2	26
Stage IV		1		27	6	34

Local chemotherapy: 30 mg Thiotepa intravesically for 30 min after transurethral resection.
External irradiation: 60 Gy/6 weeks to the pelvis by a betatron 33 mV.
General chemotherapy: 5-fluorouracil intravenously 12 mg/kg/week.

verified histologically by the actual biopsy, while 103 patients were admitted with tumour recurrence after surgery in other hospitals. In these patients information was not available to determine the clinical stage of the bladder carcinoma when the initial diagnosis was made. The TNM-system, used for staging of the bladder tumour [5] in all patients, was therefore slightly adjusted in the present study: The terms, stages I–IV, were here used to describe the clinical extent of the bladder tumour at the time

The frequency distribution of 100 Feulgen DNA-values in each specimen (DNA-histogram) was drawn using the following definitions:

The diploid region was defined as the diploid DNA-value ± 25%. The tetraploid and octoploid regions were 2-fold and 4-fold the diploid DNA-value respectively, ± 25%. The diploid, tetraploid and octoploid regions were each

subdivided into 5 intervals, each comprising 10% of the diploid, tetraploid and octoploid figure respectively. The definition of a DNA-stemline has been described elsewhere [6]. DNA-values within the DNA-stemline region were called DNA-stemline values. The mean of the DNA-stemline values yielded the modal DNA-value [4].

Following imprint preparation the tissue fragments were fixed in formalin and embedded in paraffin.

Grading of the histological haematoxylin-eosin-stained sections was done according to Mostofi [7] denominating all epithelial bladder tumours with cellular anaplasia as carcinomas, regardless whether infiltrative growth was demonstrated or not.

Statistical evaluation

The actuarial survival of patients was calculated from the date of the actual biopsy using the life table method [8]. Differences between survival rates at a definite point of time were tested by the Student's *t* test.

Differences between survival curves for different groups of patients were also tested by the logrank test [9]. The original test is not directly applicable for data grouped in time. The scheme was therefore modified making all possible rankings within each group equally probable when evaluating the estimator (e) for the logarithm of the survival curve. The numbers for death expectancy E_j obtained by cumulating the e-values for the j'th group of patients, were compared to the number of deaths 0_j by the χ^2 test.

RESULTS

In each of the control specimens a diploid DNA-stemline was found. The control group comprised, on the average, 2.4% tetraploid and 0.1% octoploid DNA-values. In 6 individual control specimens a frequency of 8–10% polyploid DNA-values was found.

Table 2 shows the distribution of DNA-stemlines in relation to histological grade and clinical stage. Sixty-three specimens showed a diploid DNA-stemline, while in 60 the stemline was non-diploid. Of the latter, 35 were tetraploid and 6 showed bimodality (diploid and tetraploid DNA-stemline).

The relative frequency of non-diploid tumours increased with decreasing histological differentiation and increasing clinical stage.

In Table 3 the mean percentage of DNA-stemline values is shown for diploid and non-diploid tumours. Within the same histological grade the number of DNA-stemline values tended to decrease with increasing clinical stage, most clearly demonstrated when comparing stage I with more advanced tumours. Especially in diploid tumours increasing clinical stage and decreasing histological differentiation were correlated with low numbers of DNA-stemline values. Non-diploid tumours showed no such clear correlation, but the DNA-stemlines in non-diploid tumours generally comprised less DNA-stemline values than observed in diploid tumours.

Table 4 shows the relationship between the DNA-stemline ploidy and the number of patients with obvious metastases found either at the time of the actual biopsy or during follow-up. Metastases were twice as often associated with non-diploid tumours as with diploid carcinomas. A particularly high frequency of metastases was noted in non-diploid stage IV tumours.

The actuarial survival of patients with diploid TCC was compared to that of patients with non-diploid tumours (Fig. 1a). After 24 months more patients with diploid tumours than with non-diploid tumours were alive ($P<0.05$). The logrank test showed a statistically significant difference between the survival curves. One obvious reason for this is that 43 of 63 diploid carcinomas were at stage I. Therefore, in Fig. 1(b) and 1(c) the survival curves were given separately for patients with stage I disease and with advanced stages (stages II–III and stage IV). Patients with advanced diploid tumours had a higher cumulative survival rate at 18 months than those with non-diploid tumours

Table 4. *Correlation between clinical stage and tumour's DNA-stemline ploidy in* 27 *patients with metastasizing bladder carcinoma*

Clinical stage		Stage I	Stage II–III	Stage IV	Total
Diploid tumours	Number of patients	3(43)	2(8)	4(12)	9(63)
Non-diploid tumours	Number of patients	3(20)	2(18)	13(22)	18(60)

Figures in brackets refer to the total number of patients within each subgroup.

Table 5. Number of patients with poorly differentiated and undifferentiated locally advanced bladder carcinoma surviving 18 months related to the tumour's DNA-stemline ploidy

DNA-stemline ploidy	Number of patients		
	Total	Alive	Dead
Diploid	10	6	4
Non-diploid	30	10	20
Total	40	16	24

($P \simeq 0.10$). After 24 months the survival rate was the same for patients with diploid and non-diploid advanced bladder tumours. No significant difference was observed in the survival regarding patients with stage I disease.

Table 5 shows the number of patients with poorly differentiated and undifferentiated locally advanced bladder carcinoma (grade III and grade IV, stages II–III and stage IV) surviving 18 months. Patients with diploid tumours seem to do better than those with non-diploid tumours.

In 3 of the 5 patients with two biopsy specimens from the same tumour, different modal DNA-values could be demonstrated in the central and peripheral tumour area, demonstrated both in stage I tumours (Figs. 2c and 2d) and in a stages II–III tumour (Fig. 2e).

Comparison of the DNA-histogram from a bladder tumour with that of a distant metastasis was made in each of 3 patients (Fig. 3). The metastases in these patients had non-diploid DNA-stemlines, even in the patient with a diploid bladder tumour (Fig. 3a).

DISCUSSION

We have based our control group on specimens taken from patients with benign urological disease or from deceased individuals without urological disease. As the bladder mucosa often shows inflammatory reactions in patients with urological disease it was necessary to accept the presence of a slight degree of inflammation in some of the first-mentioned controls.

We found a low mean percentage (2.4%) of tetraploid DNA-values in our control group while some individual control specimens showed between 8 and 10% polyploid cell nuclei.

Levi *et al.* [10] found about 25% polyploid cell nuclei in human urothelium. Tribukait *et al.* [11] and Freni *et al.* [12] examined bladder washings and urine from patients with benign urothelial disorders by flow-cytometry. They found an almost pure diploid DNA-stemline with only few polyploid DNA-values. Freni *et al.* [12] observed about 10% non-diploid DNA-values in urothelial cells obtained by scraping normal bladder mucosa.

Some of the discrepancies found in the frequency of polyploid cells in the bladder mucosa in different studies may be explained by different techniques in obtaining the specimens and by different methods in selection of cell nuclei to be measured.

Based on our own studies and Freni's *et al.* [12] observations we assume that normal urothelium does not contain more than 15% non-diploid DNA-values, most of them in the tetraploid range.

Sixty-three bladder carcinomas were characterized as diploid and 60 as non-diploid. These results were based on DNA-measurements in a single tumour biopsy. However, intratumoural variations of the DNA-stemline ploidy may occur (Fig. 2). This limitation of the method, used in this study, should be regarded when evaluating the present results.

In this study the cytophotometric results were correlated with clinical stage and histological grade of the bladder tumour, though the clinical stage according to the TNM-system [5] does not always describe the real extent of the disease [13]. However, no other clinical classification system is available which can easily be used in all patients with bladder carcinoma.

The preponderance of non-diploid tumours found in clinically advanced and histologically dedifferentiated carcinomas is in agreement with the results of others [10, 14–17]. We found, however, that 5 out of 10 undifferentiated bladder tumours had diploid DNA-stemlines. Contrary to what is observed in well differentiated tumours, these undifferentiated diploid bladder carcinomas had "weak" DNA-stemlines with low numbers of DNA-stemline values.

The number of DNA-values outside the DNA-stemline increased with decreasing histological differentiation. In dedifferentiated bladder tumours an increased uptake of ^{3}H-thymidine has been observed as compared to well differentiated carcinomas [18, 19]. The raised numbers of non-DNA-stemline values may therefore indicate an increased growth fraction in dedifferentiated tumours as compared to well differentiated ones. In addition, the increased frequency of non-DNA-stemline values in dedifferentiated bladder carcinomas may also reflect that such tumours have lost the relative homogeneity of the normal urothelium and that aneuploid and polyploid cell clones are developing as a result of chromosomal changes.

In the 3 patients with metastasizing bladder

carcinoma a weak DNA-stemline and numerous non-diploid cells were observed in the primary tumour. Non-diploid tumour cells may have selective advantages leading to the predominance of these cells in metastases, even in those from diploid bladder tumours. The observation that DNA-stemlines in metastases may show a higher degree of ploidization than those in the corresponding primary tumours, has also been made by Avtandilov *et al.* [20] and Rabotti [21].

From the literature, only limited information is available about the prognostic significance of cytophotometric DNA-measurements in human bladder carcinoma [22].

In the present study the survival of patients was calculated from the date when the actual biopsy was taken, as only at this time comparable results of the clinical, histological and cytophotometric examination could be obtained,

In our series of 123 patients those with diploid carcinomas had a higher survival rate than those with non-diploid tumours (Fig. 1a). However, the prognostic significance of cytophotometric DNA-studies can only be proven when comparing patients with the same clinical stage and with the same histological grade. In this study the prognostic value of DNA-measurements was indicated by the observation that patients with diploid locally advanced dedifferentiated tumours had a better prognosis than those with non-diploid carcinomas.

Clinically, non-diploid bladder carcinomas seemed to be more aggressive than diploid tumours, by more extensive local growth, by metastasizing more frequently and by leading to the patient's death within a shorter period of time.

Another possible explanation of the observed differences between the survival curves might be that diploid bladder carcinomas corresponded differently to treatment than non-diploid ones. Of 16 patients with advanced diploid bladder tumours treated by non-radical surgery and radiotherapy, 6 were without tumour after 18 months whereas only 4 of 26 likewisely treated patients with non-diploid carcinomas were tumour-free.

Whatever the explanation may be for the better survival of patients with diploid bladder carcinomas the present study indicates that cytophotometric DNA-measurements have clinical and histopathological significance which may be valuable in determining the prognosis in patients with TCC.

Cytophotometric DNA-studies in imprints from solid tumours are time-consuming. Only a limited number of cell nuclei can be evaluated in each specimen. More rapid DNA-determination by pulse-cytophotometry may therefore offer some advantages, but this method's role in studies of human bladder carcinoma needs further investigation [11, 12].

Abstract—*Scanning absorption cytophotometric measurements were performed in Feulgen-stained cell nuclei in imprints from 123 biopsy specimens from human transitional cell carcinoma (TCC). The results were correlated with the histopathological grade and the clinical stage of the tumour. Nearly all histologically well differentiated bladder carcinomas and tumours of clinical stage I had diploid DNA-stemlines, while non-diploid DNA-stemlines were found in most of the dedifferentiated carcinomas and in most of the advanced cases.*

Increasing clinical stage and decreasing histological differentiation were correlated with low numbers of DNA-stemline values.

Within the group of locally advanced carcinomas, patients with non-diploid tumours had a worse prognosis than those with diploid TCC.

Distant metastases in 3 patients showed non-diploid DNA-stemlines. In some tumours the DNA-histogram showed regional differences.

INTRODUCTION

In 1948 Boivin *et al.* [1] found that the nuclear DNA-content was usually constant in cells from different tissues in the same species. A few years later it became evident that the variations in the nuclear DNA-content which can be observed in certain tissues may be explained as a result of nuclear polyploidy and by nuclear DNA-synthesis [2].

The DNA-content in carcinoma cell nuclei may differ from that of normal cells [3]. Many studies have dealt with the relationship between the nuclear DNA-content and the histopathology in human tumours. In addition, some authors have considered nuclear DNA-content in relation to clinical aspects suggesting that measurement of the nuclear DNA-content might be of prognostic value in patients with a malignant disease [4].

In this study we correlated histopathological and clinical aspects of transitional cell carcinoma (TCC) of the human urinary bladder with the results of cytophotometric DNA-measurements of individual Feulgen-stained cell nuclei in imprints from bladder tumour biopsies.

MATERIAL AND METHODS

Imprints were made from biopsies of histologically proven transitional cell carcinoma from 123 patients admitted to the Norwegian Radium Hospital during the year 1974 and from 1st October 1975 to 31st March 1976. The biopsy material ("actual biopsy") was taken from areas thought to be representative of the whole tumour, either by transurethral resection or by cystotomy. A single biopsy was taken in 118 patients, whereas both a central and a peripheral tumour area were biopsied in the remaining 5 patients (Fig. 2). In the latter the results from the

Accepted 31 March 1977.

● *octoploid*

peripheral biopsy were used in the sampled material of 123 patients (Tables 2–5 and Fig. 1). In 3 patients biopsies were also taken from distant metastases (Fig. 3).

A control group consisted of 32 specimens of macroscopically normal bladder mucosa. These were collected from patients with benign disorders of the lower urinary tract (mostly benign prostatic hyperplasia) or were taken immediately after death from patients who died without urological disorders.

The age distribution in the TCC group and the control group was similar.

In 20 patients the bladder carcinoma was

○ *tetraploid* } *DNA-value.*
● *octoploid*

when the actual biopsy was taken, regardless of previous surgical intervention. As it was often impossible to distinguish between stage II and stage III in previously operated patients these stages were grouped together. This stage II–III was defined by the presence of a firm mobile induration of any size in the bladder wall, or of a tumour with histologically proven infiltration of the muscular layer of the bladder wall.

Chest X-rays were performed in all patients. Pedal lymphography was done in 29 patients. Only patients with unquestionable evidence of disseminated disease were considered to have metastases.

Table 1 shows the treatment of the patients, following the actual biopsy. Preparation, fixation, staining and mounting of the imprints were done as described previously [6].

The total extinction (*te*) of a Feulgen-stained cell nucleus, here defined as Feulgen DNA-value, was measured by means of a scanning microscope photometer SMP05 (Zeiss, Oberkochen, W. Germany) [6].

A total of 100 round or elipsoid cell nuclei with reticular chromatin pattern was measured in randomly selected regions of the imprints. The mean DNA-value of 30 polymorphonuclear leukocytes in each imprint was used as a reference to the actual specimen's diploid DNA-value (internal standard) [3].

Table 1. Treatment in 123 patients with bladder carcinoma

Clinical stage	Treatment—number of patients					
	Radical surgery	Non-radical surgery	Radical surgery + local chemo-therapy	Non-radical surgery + external irradiation	General chemo-therapy	Total
Stage I	47		14		2	63
Stage II–III	2	5		17	2	26
Stage IV		1		27	6	34

Local chemotherapy: 30 mg Thiotepa intravesically for 30 min after transurethral resection.
External irradiation: 60 Gy/6 weeks to the pelvis by a betatron 33 mV.
General chemotherapy: 5-fluorouracil intravenously 12 mg/kg/week.

verified histologically by the actual biopsy, while 103 patients were admitted with tumour recurrence after surgery in other hospitals. In these patients information was not available to determine the clinical stage of the bladder carcinoma when the initial diagnosis was made. The TNM-system, used for staging of the bladder tumour [5] in all patients, was therefore slightly adjusted in the present study: The terms, stages I–IV, were here used to describe the clinical extent of the bladder tumour at the time

The frequency distribution of 100 Feulgen DNA-values in each specimen (DNA-histogram) was drawn using the following definitions:

The diploid region was defined as the diploid DNA-value ± 25%. The tetraploid and octoploid regions were 2-fold and 4-fold the diploid DNA-value respectively, ± 25%. The diploid, tetraploid and octoploid regions were each

subdivided into 5 intervals, each comprising 10% of the diploid, tetraploid and octoploid figure respectively. The definition of a DNA-stemline has been described elsewhere [6]. DNA-values within the DNA-stemline region were called DNA-stemline values. The mean of the DNA-stemline values yielded the modal DNA-value [4].

Following imprint preparation the tissue fragments were fixed in formalin and embedded in paraffin.

Grading of the histological haematoxylin-eosin-stained sections was done according to Mostofi [7] denominating all epithelial bladder tumours with cellular anaplasia as carcinomas, regardless whether infiltrative growth was demonstrated or not.

Statistical evaluation

The actuarial survival of patients was calculated from the date of the actual biopsy using the life table method [8]. Differences between survival rates at a definite point of time were tested by the Student's *t* test.

Differences between survival curves for different groups of patients were also tested by the logrank test [9]. The original test is not directly applicable for data grouped in time. The scheme was therefore modified making all possible rankings within each group equally probable when evaluating the estimator (e) for the logarithm of the survival curve. The numbers for death expectancy E_j obtained by cumulating the e-values for the j'th group of patients, were compared to the number of deaths 0_j by the χ^2 test.

RESULTS

In each of the control specimens a diploid DNA-stemline was found. The control group comprised, on the average, 2.4% tetraploid and 0.1% octoploid DNA-values. In 6 individual control specimens a frequency of 8–10% polyploid DNA-values was found.

Table 2 shows the distribution of DNA-stemlines in relation to histological grade and clinical stage. Sixty-three specimens showed a diploid DNA-stemline, while in 60 the stemline was non-diploid. Of the latter, 35 were tetraploid and 6 showed bimodality (diploid and tetraploid DNA-stemline).

The relative frequency of non-diploid tumours increased with decreasing histological differentiation and increasing clinical stage.

In Table 3 the mean percentage of DNA-stemline values is shown for diploid and non-diploid tumours. Within the same histological grade the number of DNA-stemline values tended to decrease with increasing clinical stage, most clearly demonstrated when comparing stage I with more advanced tumours. Especially in diploid tumours increasing clinical stage and decreasing histological differentiation were correlated with low numbers of DNA-stemline values. Non-diploid tumours showed no such clear correlation, but the DNA-stemlines in non-diploid tumours generally comprised less DNA-stemline values than observed in diploid tumours.

Table 4 shows the relationship between the DNA-stemline ploidy and the number of patients with obvious metastases found either at the time of the actual biopsy or during follow-up. Metastases were twice as often associated with non-diploid tumours as with diploid carcinomas. A particularly high frequency of metastases was noted in non-diploid stage IV tumours.

The actuarial survival of patients with diploid TCC was compared to that of patients with non-diploid tumours (Fig. 1a). After 24 months more patients with diploid tumours than with non-diploid tumours were alive ($P<0.05$). The logrank test showed a statistically significant difference between the survival curves. One obvious reason for this is that 43 of 63 diploid carcinomas were at stage I. Therefore, in Fig. 1(b) and 1(c) the survival curves were given separately for patients with stage I disease and with advanced stages (stages II–III and stage IV). Patients with advanced diploid tumours had a higher cumulative survival rate at 18 months than those with non-diploid tumours

Table 4. *Correlation between clinical stage and tumour's DNA-stemline ploidy in* 27 *patients with metastasizing bladder carcinoma*

Clinical stage		Stage I	Stage II–III	Stage IV	Total
Diploid tumours	Number of patients	3(43)	2(8)	4(12)	9(63)
Non-diploid tumours	Number of patients	3(20)	2(18)	13(22)	18(60)

Figures in brackets refer to the total number of patients within each subgroup.

Table 5. Number of patients with poorly differentiated and undifferentiated locally advanced bladder carcinoma surviving 18 months related to the tumour's DNA-stemline ploidy

DNA-stemline ploidy	Number of patients		
	Total	Alive	Dead
Diploid	10	6	4
Non-diploid	30	10	20
Total	40	16	24

($P \simeq 0.10$). After 24 months the survival rate was the same for patients with diploid and non-diploid advanced bladder tumours. No significant difference was observed in the survival regarding patients with stage I disease.

Table 5 shows the number of patients with poorly differentiated and undifferentiated locally advanced bladder carcinoma (grade III and grade IV, stages II–III and stage IV) surviving 18 months. Patients with diploid tumours seem to do better than those with non-diploid tumours.

In 3 of the 5 patients with two biopsy specimens from the same tumour, different modal DNA-values could be demonstrated in the central and peripheral tumour area, demonstrated both in stage I tumours (Figs. 2c and 2d) and in a stages II–III tumour (Fig. 2e).

Comparison of the DNA-histogram from a bladder tumour with that of a distant metastasis was made in each of 3 patients (Fig. 3). The metastases in these patients had non-diploid DNA-stemlines, even in the patient with a diploid bladder tumour (Fig. 3a).

DISCUSSION

We have based our control group on specimens taken from patients with benign urological disease or from deceased individuals without urological disease. As the bladder mucosa often shows inflammatory reactions in patients with urological disease it was necessary to accept the presence of a slight degree of inflammation in some of the first-mentioned controls.

We found a low mean percentage (2.4%) of tetraploid DNA-values in our control group while some individual control specimens showed between 8 and 10% polyploid cell nuclei.

Levi *et al.* [10] found about 25% polyploid cell nuclei in human urothelium. Tribukait *et al.* [11] and Freni *et al.* [12] examined bladder washings and urine from patients with benign urothelial disorders by flow-cytometry. They found an almost pure diploid DNA-stemline with only few polyploid DNA-values. Freni *et al.* [12] observed about 10% non-diploid DNA-values in urothelial cells obtained by scraping normal bladder mucosa.

Some of the discrepancies found in the frequency of polyploid cells in the bladder mucosa in different studies may be explained by different techniques in obtaining the specimens and by different methods in selection of cell nuclei to be measured.

Based on our own studies and Freni's *et al.* [12] observations we assume that normal urothelium does not contain more than 15% non-diploid DNA-values, most of them in the tetraploid range.

Sixty-three bladder carcinomas were characterized as diploid and 60 as non-diploid. These results were based on DNA-measurements in a single tumour biopsy. However, intratumoural variations of the DNA-stemline ploidy may occur (Fig. 2). This limitation of the method, used in this study, should be regarded when evaluating the present results.

In this study the cytophotometric results were correlated with clinical stage and histological grade of the bladder tumour, though the clinical stage according to the TNM-system [5] does not always describe the real extent of the disease [13]. However, no other clinical classification system is available which can easily be used in all patients with bladder carcinoma.

The preponderance of non-diploid tumours found in clinically advanced and histologically dedifferentiated carcinomas is in agreement with the results of others [10, 14–17]. We found, however, that 5 out of 10 undifferentiated bladder tumours had diploid DNA-stemlines. Contrary to what is observed in well differentiated tumours, these undifferentiated diploid bladder carcinomas had "weak" DNA-stemlines with low numbers of DNA-stemline values.

The number of DNA-values outside the DNA-stemline increased with decreasing histological differentiation. In dedifferentiated bladder tumours an increased uptake of ^{3}H-thymidine has been observed as compared to well differentiated carcinomas [18, 19]. The raised numbers of non-DNA-stemline values may therefore indicate an increased growth fraction in dedifferentiated tumours as compared to well differentiated ones. In addition, the increased frequency of non-DNA-stemline values in dedifferentiated bladder carcinomas may also reflect that such tumours have lost the relative homogeneity of the normal urothelium and that aneuploid and polyploid cell clones are developing as a result of chromosomal changes.

In the 3 patients with metastasizing bladder

Tumour Regression and Survival of Patients with Disseminated Malignant Melanoma Treated with Chemotherapy and Specific Active Immunotherapy*

D. W. HEDLEY, T. J. McELWAIN and G. A. CURRIE

Departments of Tumour Immunology and Medicine, Royal Marsden Hospital and Chester Beatty Research Institute, Belmont, Sutton, Surrey, United Kingdom

Abstract—*We have treated 59 patients with disseminated or inoperable malignant melanoma with a combination of chemotherapy (D.T.I.C.) and immunotherapy (comprising irradiated allogeneic melanoma cells plus BCG) and have followed their progress for a minimum of ten months.*

Objective tumour regression was observed in 44% of the patients but most of these patients relapsed despite continued treatment, the longest complete regression lasting 21 months. Patients with disease confined to the skin, lymph nodes or lungs had a higher regression rate (19/34 as against 7/25) and survived longer than those with visceral, osseous or cerebral metastases. Complete regressions were commoner in women but the overall regression rate was the same in both sexes.

By comparison of these results with literature controls and from the inexorable decline in the survival curves we conclude that despite its apparent effect on objective regression rate this form of combination immunotherapy–chemotherapy has little or no worthwhile effect on survival.

INTRODUCTION

THE OVERALL results of cytotoxic chemotherapy in the treatment of the "final common pathway" of malignant melanoma are disappointing. At present DTIC (5, 3, 3-dimethyl-1-triazeno imidazole 4-carboxamide) is the most active single agent providing objective regression in about 20% of treated patients [1] but with little or no effect on survival. Drug combinations, some including DTIC, have so far proved to be disappointing since they produce more side effects than DTIC alone but no significant increase in overall regression rate [1–4]. Immunotherapy is being evaluated in many centres [5], but so far is of little or no proven value. Our own studies have indicated [6–8] that immunization with irradiated melanoma cells admixed with BCG can lead to predictable changes in some measurable parameters of host responses to malignant melanoma, i.e., can evoke the appearance of tumour-directed cytotoxic lymphocytes and the disappearance of inhibitory factors from the serum. This form of immunization was tested in a group of patients receiving cytotoxic chemotherapy in an uncontrolled study and we noted an objective regression rate higher than that anticipated from historical and literature controls [8].

We have extended these observations and here report a study of 59 patients which indicates that, while the objective regression rate remains high, there appears to be no significant effect on survival and that some patients relapse while on treatment. We also describe several features of the patients which seem to have prognostic significance.

Accepted 29 April 1977.

MATERIAL AND METHODS

Patients

Between May 1973 and October 1975 a total

of 66 patients referred to the Royal Marsden Hospital, Sutton, with disseminated or inoperable malignant melanoma were treated with the combined chemo-immunotherapy protocol. Seven started this treatment at a very advanced stage of their disease and either died before completing the first course or were too ill to attend for further treatment. The remaining 59 patients were treated for a minimum of 6 weeks, none were withdrawn before 6 weeks since regression often occurred after 2 or 3 courses. There were 26 men with a mean age of 45.9 and 33 women with a mean age of 48.2 yr. Patients varied considerably in the amount of tumour present and the sites of overt dissemination at the start of medical treatment, but could be divided into two broad groups: those with disease confined to skin, lymph nodes or lungs (34 cases—lung disease was included in this group since it was our earlier experience that disease confined to the lungs regressed as frequently as nodal or cutaneous metastases) and those with visceral, cerebral or bone metastases (25 cases), since prognosis is known to be particularly bad in the latter group [4]. All patients have been followed up to death or for a minimum of 10 months, and we present data on the regression rate, duration of regression and survival from the start of chemo-immunotherapy. Since this was an extended pilot study there were no concurrent control patients, the shape of the survival curve leading us to abandon a formal controlled trial. Our regression and survival data were compared to those obtained in recently published studies from other centres [2, 4]. Furthermore our own historical survival data are similar to those reported by Einhorn and colleages [2].

Treatment Protocol

(a) *Chemotherapy.* All patients received DTIC every 4 weeks. Initially the dose used was 2.5 mg/kg intravenously daily for five consecutive days combined with Vincristine 1.4 mg/m^2 intravenously on the first day. Because of some cases of neurotoxicity and lack of evidence of any clear cut benefit from the addition of vincristine [9] this agent was not used in the last 27 patients and the dose of DTIC was increased to 250 mg/m^2 for 5 days. There were few serious adverse reactions and no deaths attributed to the DTIC, although vomiting for a few hr after the injection was common. One patient developed thrombocytopenic purpura on DTIC 250 mg/m^2 but tolerated a reduced dose.

(b) *Immunotherapy.* This consisted of 2×10^7 irradiated allogeneic malignant melanoma cells plus 50 μg of percutaneous Glaxo BCG by intradermal injection as previously described [8]. This "immunotherapy" was given midway between chemotherapy courses.

Alternating chemotherapy and immunotherapy was continued either until it was obvious that the disease was unresponsive or until the patient had been in complete remission for at least 6 months.

RESULTS

The clinical effect of treatment was judged to be (a) no response; (b) partial regression or (c) complete regression. Partial regression is defined as a decrease in the mean diameter of measurable lesions of 50% for at least 30 days in the absence of disease progression elsewhere or the presence of static disease elsewhere. Patients with less than 50% regression or whose disease remained static were included amongst the non-responders. Furthermore, patients who showed more than 50% regression of some lesions while other lesions were progressing were regarded as non-responders. Using these criteria 33 (56%) of the 59 evaluable cases did not respond to treatment. Of the 25 responders 6 went into complete regression and 20 had partial regressions (i.e., overall regression rate = 44%).

Regression rate according to extent of metastases

Although the overall response rate (of evaluable cases) in males and females was similar (males 11/26, females 15/33) only 1 male patient achieved complete regression compared to 5 females. This difference was not related to the extent of the disease since regression of visceral and even bone metastases were seen in the women whereas many men with skin and nodal involvement did not achieve complete regression.

Regression rate according to extent of metastases

In patients with disease confined to skin, lymph nodes or lungs, the regression rate was 56% (19/34). This is exactly twice that of patients with visceral disease, 28% (7/25), in whom there was only one complete regression. Table 1 lists the sites of overt metastasis at the start of chemo-immunotherapy and the number of patients in whom disease regression took place. In several patients disease regressed at some sites while remaining static at others. Table 2 summarises the regression rates according to sex and the presence or absence of visceral metastases.

Table 1. Sites of metastasis at the start of chemoimmunotherapy and the number of patients in whom regression was seen

Site	Number of patients with involvement	Number of patients with disease regression
Skin	37	18 (49%)
Lymph nodes	27	14 (52%)
Lungs	21	9 (43%)
Bone	10	2 (20%)
Liver	16	5 (31%)
Brain	6	1
Bowel	3	0
Nasal mucosa	1	0
Salivary gland	2	1
Adrenal	1	0

Table 2. Regression rates according to sex and the presence or absence of visceral metastases

	All sites	Visceral disease	Disease confined to skin, lymph nodes or lungs
Men and women	26/59 (44%)	7/25 (28%)	19/34 (56%)
Men	11/26	3/12	8/14
Women	15/33	4/13	11/20

Regression rate according to duration of history

The interval between primary excision and the start of chemo-immunotherapy for surgically incurable disease ranged from 2 to 300 months, the median being 47 months in patients who showed disease regression and 28 months in those who did not. A test for the mean (log) duration of history showed no significant difference—$t=0.72$, degrees of freedom (d.f.) 53, $P<0.5$.

Regression rate according to age

The mean age of all patients was 47 yr, of regressors 54 yr and of non-regressors 42 yr. These results were tested by Chi square analysis which showed that the difference was significant

$$(\chi^2=9.6, \text{d.f.}=3, P<0.05)$$

This difference in mean age between regressors and non-regressors was almost exactly the same in the men as in the women.

Interval from start of treatment to start of regression

All but two regressions had become clinically detectable by the third month of treatment, 9 of these occurring within the first 4 weeks. There was no significant correlation between the speed with which a regression became evident and its duration, except that the 2 regressions noted after 3 months were only of short duration.

Duration of regression

All patients who achieved complete regression have since relapsed, with a median regression length of 12 months. Three patients relapsed while still on treatment.

The 20 patients achieving partial regression have now all relapsed despite continuing on the full treatment protocol. Partial regressions were sustained for a shorter period (median 3 months) than complete regressions.

In patients with visceral, cerebral or bone disease the median duration of regression was 3 months whereas in those with nodal, pulmonary or cutaneous deposits it was 6.5 months.

Survival from the start of chemo-immunotherapy

Patients showing disease regression lived longer than those who did not (Fig. 1). None of the non-responders survived for more than 9 months from the start of chemo-immunotherapy, whereas 6 out of the 26 remitters are still alive 10, 14, 18, 18, 25 and 28 months after the start of treatment. Figures 2 and 3 divide the patients into those with visceral, cerebral or bone involvement and those with disease confined to skin, lymph nodes or lung. The survival curves for patients with visceral disease show a very poor prognosis which is improved only slightly in those with disease regression. This group includes one complete regression, a patient who had multiple osteolytic bone deposits in addition to lung, skin and regional and distant lymph node involvement. Those patients with metastases confined to skin, lymph node or lung showed longer median survival in those achieving disease regression (15 months) compared to 6 months in non-remitters. The pronounced shoulder in the survival curve

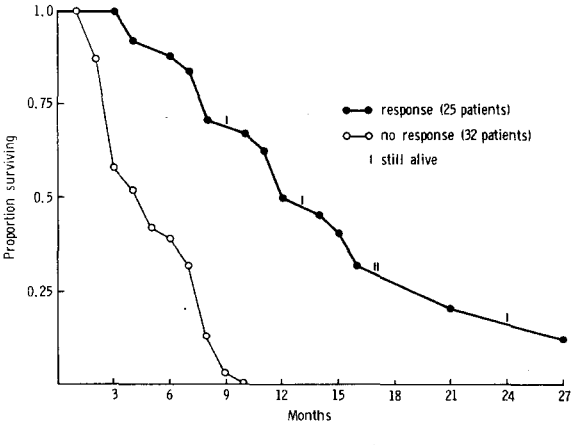

Fig. 1. Survival curves (life table) for all patients.

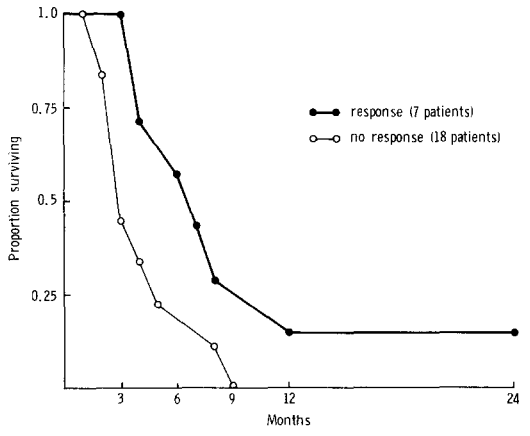

Fig. 2. Survival curves (life tables) for patients with overt visceral, osseous or cerebral metastases.

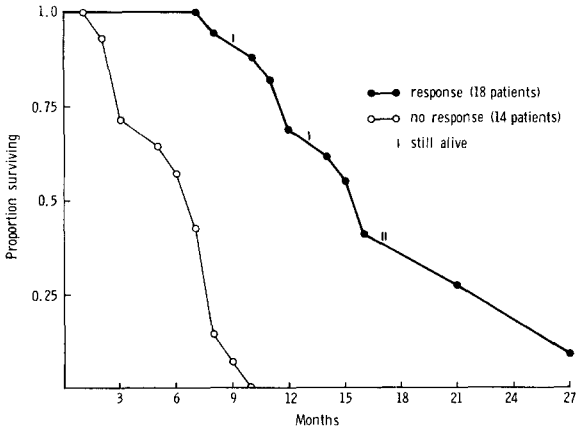

Fig. 3. Survival curves (life table) for patients with disease limited to skin, lymph nodes or lung.

of responders in this group (Fig. 3) is the main difference between its shape and that of all responders (Fig. 1), and this plus the absence of a tail of survivors suggests that the improved survival of patients with disease limited to skin, node or lung may be a function of the disease rather than the treatment, i.e., treatment was started earlier because metastases at these sites are more easily detected.

DISCUSSION

Despite widespread enthusiasm for immunotherapy as a form of cancer treatment, there is little convincing clinical evidence of its effectiveness and the rationale behind many of the forms of treatment in current use remains poorly defined.

This extended pilot study confirms our earlier findings [8] which suggested that specific active immunotherapy increases the overall objective regression rate, but the shape of the survival curves, with the complete absence of any tail, shows that this treatment is incapable of significantly improving survival in patients with advanced disease. The median survival times achieved are very similar to those described by other authors [2, 4] and closely resemble the figures published by De Vita and Fisher [10]. Indeed, all of the patients who had partial objective regressions relapsed while continuing treatment with alternating immunotherapy and chemotherapy. Such results are reminiscent of the effects of unsuccessful cytotoxic chemotherapy in other tumours such as colorectal cancer where objective regressions can be achieved but are not associated with significant prolongation of life.

The overall regression rate of 44% is about twice that achieved in most large series using chemotherapy alone and was obtained with a relatively non-toxic regime. Although regressions were seen most frequently in patients with disease confined to the skin, lymph nodes or the lungs, we do not believe that the selection of patients alone can account for the high regression rate since we obtained a rate of 19/34 (56%) in this group and 7/25 (28%) in those with visceral, cerebral and bone metastases, both figures being substantially higher than those reported for the effects of chemotherapy alone in such patients [1, 2].

Newlands and his colleagues [11] have reported a study in which specific active immunotherapy combined with chemotherapy was compared with chemotherapy alone in similar patients to our own. Their results clearly demonstrated the absence of any effect on survival despite showing an effect of immunotherapy on the regression rate, which was 4 out of 17 (23%) in patients receiving chemotherapy alone and 9 out of 19 (47%) in patients receiving chemotherapy plus immunotherapy.

In our hands the combined treatment induced 56% regressions in patients with skin, lymph node and lung disease. The fact that the chemo-immunotherapy protocol can produce such regressions of overt disease at least raises the hope that it might be of value as an adjunct to surgery and prevent or delay the appearance of subclinical metastases. Such a trial is currently in progress.

Yolk Sac Derived Teratomas and Carcinomas in Hamsters*

H. SOBIS and M. VANDEPUTTE
Rega Institute, University of Leuven, B-3000 *Leuven, Belgium*

Abstract—*The induction as well as the histology of visceral yolk sac derived benign teratomas in hamsters is described. The teratomas are characterized by the presence of adult well-differentiated tissues derived from all three germ layers. In these teratomas malignant transformation to yolk sac carcinoma was occasionally observed. The histogenesis of this malignant tumor is described and its origin discussed in relation to viral induced yolk sac carcinoma.*

INTRODUCTION

WE HAVE previously described the development of teratomas from displaced yolk sac in rats [1, 2]. These tumors were composed of various adult well-differentiated tissues derived from all 3 germ layers. No marked difference was recorded in the kind of tissues found at 3 weeks after the surgical procedure and those observed 6–9 weeks later. The much greater differentiation potential of the ectopic visceral yolk sac in our system compared to the limited differentiation obtained by Payne and Payne [3] who implanted the visceral yolk sac in the peritoneum may be explained by the continuity of the extra-uterine part of the visceral yolk sac with the intra-uterine one until the extension of the placenta.

The present experiments were performed in order to verify whether the differentiation of visceral yolk sac outside the uterus after fetectomy occurs in rats only, or whether it is a general phenomenon common to other species of rodents such as the hamster. We also wanted to extend the observation period until 4 months after the operation to explore the possibility of degenerative or malignant changes in the teratomas. Moreover, in order to determine if later extension of the placenta from the uterus can influence the differentiation potential of the yolk sac, we treated one group of hamsters with progesterone. This hormone is known to prolong the retention of the placenta in the uterus after fetectomy [4].

Accepted 28 April 1977.

*This work was supported by a grant from the Belgian A.S.L.K.-Cancer Fund (Algemene Spaar- en Lijfrentekas), and by the N.F.W.O. (Nationaal Fonds voor Wetenschappelijk Onderzoek).

MATERIAL AND METHODS

Hamsters of the inbred ALB/Mey Pfd strain were used. Nine days after mating, laparatomy was performed on pregnant primiparous hamsters. In both uterine horns the fetuses were removed together with the amnion and the yolk sac was gently pulled through the incision and left outside the uterus. In each place of incision two sutures were put in the uterine wall. All placentas were left *in situ* [1].

Half of the hamsters were treated with medroxyprogesterone acetate (Depoprovera, Upjohn). An injection of 25 mg was given subcutaneously on the day of fetectomy and 14 and 28 days afterwards.

Two to four months after operation the animals were killed by cardiac puncture under ether anaesthesia, and autopsy was performed.

For histological studies the uterine horns and in some cases other organs were routinely fixed in formaldehyde, embedded in paraffin and stained with erythrosine-hematoxylin and PAS. From each tumor observed 6–8 sections were prepared for histological examination.

For ultrastructural studies small pieces of any tumors were fixed in glutaraldehyde with osmium post-fixation, stained with uranyl acetate, dehydrated and embedded in araldite. Thin sections were cut on OMU-2 Reichert ultramicrotome, stained with lead hydroxide and examined with a Zeiss 9S electron microscope. A few one micron thick sections were cut from each block and stained with methyl blue and safranin.

RESULTS

Macroscopic appearance

Fifty-nine out of 60 operated hamsters developed extra-uterine tumors attached to the

uterine horns. The number of tumors varied from 1 to 5 per uterus, a total of 197 tumors being recorded among 50 operated animals. The size of the tumors varied from 0.2 to 2 cm dia. They were well encapsulated, had a smooth surface and remained attached to the uterine wall (Fig. 1). After incision many tumors displayed several cysts containing yellow mucinous fluid. No detectable lesions were observed in the other organs of these tumor-bearing hamsters.

However, in 7 cases ascites was found during autopsy. The ascitic fluid was hazy and the peritoneum was covered with small yellow to reddish tumors (Fig. 2).

Histological appearance

Histologically, the tumors were characterized by the presence of a variety of differentiated tissues (Fig. 3). Most frequently epidermal and endodermal cysts were observed. The epidermal cysts contained keratin and were lined with a well-differentiated squamous epithelium consisting of all the structural layers commonly present in mature skin (Fig. 4). In the subadjacent connective or adiposal tissue layer, skin appendages, such as hair follicles and sebaceous glands, were frequently observed.

The endodermal cysts contained mucin and were lined with a columnar epithelium which often formed folds similar to intestinal villi, with a central core of connective tissue. Smooth muscle was regularly seen around these endodermal cysts.

In many tumors cartilage and bone with bone marrow were found (Fig. 5). Striated muscular tissue was often observed. Less frequently the tumor also contained lymphoid tissues, nervous tissues, pancreas, salivary glands and thyroid (Fig. 6).

The number of different tissues present in examined tumors is summarized in Table 1. Their histological and ultrastructural appearance was identical to that previously described in the rat yolk sac derived teratomas [1].

The presence of all the described well-differentiated tissues was not dependent upon the time of tumor development (from $2\frac{1}{2}$ to 4 months), nor upon the treatment or not with progesterone.

However, during the whole observation period from $2\frac{1}{2}$ until 4 months we observed, in 24 tumors out of a total of 197, the presence of proliferating parietal yolk sac cells and their histological evolution from an *in situ* proliferation to disseminated yolk sac carcinoma.

In the histological sections made from 8 tumors which had developed for $2\frac{1}{2}$ months, small foci of epithelial cells secreting eosinophilic substance were seen inside endodermal cysts of the teratomas (Figs. 7 and 8). This eosinophilic substance was also shown to be PAS-positive and diastase-resistant.

Table 1. Presence of different tissues in yolk sac derived teratomas developing during $2\frac{1}{2}$ to 4 months

	Months after fetectomy				Total number
	$2\frac{1}{2}$	3	$3\frac{1}{2}$	4	
Number of tumours examined	36	41	63	57	197
Various tissues observed					
Epidermal cyst	31	37	56	49	173
Skin appendages	21	26	33	21	101
Endodermal cyst	22	26	48	34	130
Muscle	17	24	41	31	103
Cartilage	11	17	29	18	75
Bone	9	13	20	14	56

Pancreas	1	1	3	1	6
Salivary gland	3	5	5	4	17
Thyroid	1	1	2	—	4
Parietal yolk sac proliferation	8	—	—	—	8
Yolk sac carcinoma *in situ*	—	9	—	—	9
Yolk sac carcinoma with metastases	—	—	3	4	7

In 9 tumors examined after 3 months these foci were found to be larger and frequently similar in structure to the ascitic form of yolk sac carcinoma. They were composed of endodermal cells which surrounded a hyalin substance. In some cases these foci consisted of large aggregates of polygonal cells with one, or occasionally two, pleomorphic nuclei and cytoplasm containing PAS-positive droplets. The same PAS-positive material was found between the cells. These foci were present only inside the teratomas (Fig. 9), but never in the uterine wall.

In 7 cases, killed $3\frac{1}{2}$ or 4 months after fetectomy, numerous metastases were found in the peritoneum, lymph nodes, lungs and under the liver, or kidney capsule. Also, at that later stage malignant cells were never observed in the uterus itself. The structure of these malignant neoplasms as well as their metastases was identical to the previously described yolk sac carcinoma in rats (Fig. 10) [5].

Electron microscopy

The ultrastructural studies of metastatic tumors from 2 hamsters showed the presence of endodermal cells embedded in lamellar substance-hyalin. The cytoplasm of the cells was

Fig. 11. Numerous "spoked" particles with centrally placed nucleoid attached to the bilaminar membrane by rays.

rich in rough-surfaced endoplasmic reticulum and free ribosomes were often seen (Fig. 11). Many cells contained endoplasmic cisternae filled with a grey substance. The structure of these tumors was very similar to the previously described yolk sac carcinoma in the rat.

However, in many cells we found intracytoplasmic virus-like particles. These particles were enclosed, either singly or in groups, within small vacuoles, which often had ribosomes on their membranes and were, presumably, part of the granular endoplasmic reticulum (Fig. 11). The particles had a mean outer diameter of approximately 100 mμ and were limited by a bilaminar membrane to which a centrally placed nucleoid was attached by a number of characteristic rays or spokes (Fig. 12).

Tumor transplantation and tissue culture

In 5 cases, we attempted to transplant the encapsulated tumors or metastatic tumors into young adult hamsters by subcutaneous trocar implantation. Three encapsulated tumors, which proved afterwards to be teratomas devoid of malignant parietal yolk sac cells, did not grow out after transplantation. The metastatic tumors were successfully transplanted in this way and were kept as continuous transplantable lines in syngeneic hamsters. Their microscopic appearance after transplantation was identical to that of the metastatic tumors, which were diagnosed as yolk sac carcinoma.

DISCUSSION

The results described indicate that the displaced visceral yolk sac in hamsters possesses the same capacity of differentiation as in rats and, as we have recently described, in mice [6]. This membrane, placed outside the uterus after fetectomy, gives rise to teratomas containing various well-differentiated tissues, derivatives of all 3 germ layers. Other teratomas which also contain derivatives of all 3 germ layers are the testicular teratomas, described by Stevens [7–9], derived from primordial germ cells and the ovarian teratomas derived from parthenogenetically activated ovarian eggs [10]. In these tumors, the stem cell of the teratoma is a totipotential germ cell. Such multipotential cells (primary germ cells) are formed in the visceral yolk sac during embryogenesis and migrate to the genital ridges. Thus, one has to bear in mind the possibility that some of these cells do not leave the yolk sac until the day of fetectomy and therefore may be responsible for the development of the teratomas we have described.

In our previous papers [1, 2] we gave the arguments against germ cell origin of the yolk sac derived teratomas. However, definite proof was obtained by treating pregnant rats with busulphan. This drug, which is known to destroy the germ cells during their migratory phase, led to the complete absence of these cells in the gonads [11–13]. However, busulphan did not influence the number or the morphology of the yolk sac derived teratomas. Therefore, it can be concluded that these teratomas do not arise from germ cells [14].

The presence of derivatives of all three germ layers in teratomas is observed only when the operation is performed early enough: in rats at day 12 and in mice at day 11 [6]. The same differentiation potentiality of the visceral yolk sac in hamsters is observed at day 9 of pregnancy.

As indicated by our results, the capacity of differentiation does not depend upon the time of expulsion of the placenta from the uterus, which is delayed by hormonal treatment. Indeed, no difference was found in the development or structure of teratomas in the hamsters treated or not with progesterone. This proves that 7 days connection of the yolk sac with the placenta (the period of gestation in hamsters being 16 days) is sufficient to start the differentiation which will lead to the development of various well-differentiated tissues. This is in agreement with the findings of our previous studies where we observed the first steps of differentiation as early as 4 days after fetectomy [2].

Moreover, we did not find any difference in quality or quantity of differentiated tissues in teratomas which had developed for $2\frac{1}{2}$, 3, $3\frac{1}{2}$ or 4 months, with the exception of parietal yolk sac proliferation. In the teratomas of hamsters sacrificed $2\frac{1}{2}$ and 3 months after fetectomy we observed, respectively, proliferation of parietal yolk sac and yolk sac carcinoma *in situ*. In seven out of 26 hamsters killed $3\frac{1}{2}$ or 4 months after operation we found disseminated yolk sac carcinoma. However, it was very difficult to find a primary tumor, only microscopic examination of teratomas showed the presence of malignant proliferation in endodermal cysts. Therefore, it can be concluded that in the cysts of teratomas in which endodermal proliferation occurs in some cases the proliferating cells are hyalin-secreting parietal yolk sac cells. This seems likely if one bears in mind that the endoderm of visceral yolk sac can also differentiate into various other types of epithelium such as intestinal, bronchiolar and transitional epithelium. All these epithelia although characteristic for embryo proper, differentiate in these teratomas from visceral yolk sac. As it was demonstrated that transplantation of embryo proper under the kidney capsule may

give rise to yolk sac carcinoma [15], it is probable that embryonal parts can differentiate into extra-embryonal ones and that, conversely, the fetal membranes can give rise to tissues which usually develop in the fetus. Moreover, these yolk sac derived endodermal cysts in teratomas can proliferate and form a structure similar to parietal yolk sac and after that yolk sac carcinoma.

Until now it was thought that yolk sac carcinoma in rodents differentiates from teratocarcinoma. Such differentiation was observed *in vivo* as well as *in vitro* in spontaneous or induced teratocarcinoma in mice [7, 8, 16–19] or by MSV inoculation in placentas of fetectomized rats [5, 20]. Comparing our last and present experiments one can argue that yolk sac carcinoma can develop in the uterus of fetectomized animals without virus inoculation. Such a conclusion was reached by Sakashita and Hirai [21]. It seems, however, that the origin of the yolk sac carcinoma in the case of virus inoculation into placenta after removal of the fetus as well as the free part of the visceral yolk sac which does not adhere to the placenta is different from those cases where the fetal membranes are left outside the uterus without virus inoculation.

The MSV induced yolk sac started to proliferate in the uterus itself and developed from parts of the yolk sac which adhered to the placenta. In some cases we could even observe embryonal carcinoma which differentiated into yolk sac carcinoma [22]. All these tumors metastasized 2–3 months after fetectomy.

The yolk sac carcinomas described in the present experiment start as proliferations in endodermal cysts in teratomas and the metastases appear not earlier than $3\frac{1}{2}$–4 months after operation. Moreover, we never found tumoral structures in the uterus itself which proves that these tumors develop in differentiated teratomas. The teratoma-derived yolk sac carcinomas can be compared to human malformation teratomas which may become cancerous, and MSV-induced yolk sac carcinomas to human tumoral teratomas which arise from multipotential cells [23].

In the cytoplasm of the yolk sac carcinomas described here, we found virus-like particles of unusual "spoked" morphology. Similar particles have been observed in hamster tumors and in tumor lines cultured *in vitro*, but the significance of these viruses is not known [24]. The localisation of these particles is very similar to intracisternal A-type particles which have been described in mouse teratocarcinoma and mouse yolk sac carcinoma [25, 26] as well as in mouse embryo [27]. They are thought to play a role similar to that of fetal antigen [28].

Preliminary results indicate that the intracisternal "spoked" virus is present not only in tumors but also in hamster embryos but is absent in the normal tissues of the adult hamster. The role of these particles seems worth further investigation.

Pulmotropic Carcinogenic Activity of *N*-Methyl-*N*-Nitrosopropionamide*

JURIJ STEKAR†

Forschergruppe Praeventivmedizin‡ am Max-Planck-Institut für Immunbiologie, Freiburg i.Br, Federal Republic of Germany

Abstract—*N-Methyl-N-nitrosopropionamide applied intravenously (i.v.) to BD-rats in small weekly repeated doses selectively induced lung cancer in a high yield. Moreover, like the well-known pulmonary carcinogen N-methyl-N-nitrosourethane, N-methyl-N-nitrosopropionamide avidly reacts with cysteine, whereby elementary nitrogen is evolved. On the other hand, N-methyl-N-nitrosourea, a powerful neurotropic carcinogen, does neither react with cysteine nor induce lung cancer. It has been, therefore, concluded that reaction with cysteine under concomitant N_2-liberation might be a characteristic feature of lung cancer-inducing nitrosamides; accordingly all nitrosamides which display this reaction should on i.v. application produce lung cancer and vice versa. To check this hypothesis, N-methyl-N'-nitro-N-nitrosoguanidine was chosen. A report on these experiments, which yielded a high percentage of malignant lung tumours, will be given later.*

INTRODUCTION

IN THE large class of *N*-nitroso compounds the carcinogenic activity of which was extensively investigated in rats by Druckrey and his school [1–3] beside numerous nitrosated derivatives of carbonic acid (nitrosoureas and nitroso carbamic esters) some nitrosocarboxylamides were also studied [1, 2]. Upon oral administration they induced cancer of the forestomach [1, 2]. The same effect was achieved with some orally applied nitrosoureas and nitroso carbamic esters, e.g. *N*-methyl-*N*-nitrosourethane (MNUT) and *N*-methyl-*N*-nitrosourea (MNU). However, in spite of having this property in common, MNUT and MNU given intravenously in small weekly doses strikingly differ in their specific organotropic properties: they induce selectively lung cancer and brain tumours respectively [1]. It interested, therefore, whether or not organotropic effects and of what kind would be found after i.v. application of nitrosocarboxylamides. *N*-Methyl-*N*-nitrosopropionamide (MNPA) was chosen for this purpose.

The reactivity of *N*-nitroso compounds and their derivatives with cysteine has interested us for some years [2, 4]. As the first preliminary experiments have shown a very rapid gas liberation and decomposition of MNPA upon addition of cysteine, it was decided to investigate this reaction in some detail.

MATERIAL AND METHODS

N-Methyl-N-nitrosopropionamide

MNPA was first synthesized by R. Preussmann by nitrosation of *N*-methylpropionamide [5]; we have later modified the synthesis in a few details.

The readily water-soluble methylpropionamide (prepared by adding propionyl chloride dropwise to a cooled alkaline solution of methylamine hydrochloride) was isolated from the reaction mixture by adding excess of solid potassium carbonate; it then appeared as a white layer and could be separated, dried and distilled. Nitrosation was performed by slowly adding of H_2SO_4 to a cooled aqueous solution of the amide and nitrite.

By using fluorescent thin layer plate (TLC Aluminium sheets, Silica gel 60 F 254 precoated, layer thickness 0.25 mm; E. Merck, Darmstadt; as solvent benzene was used) and exposing the chromatogram briefly to N_2O_3 and its dissociation products [6] it was possible to show in u.v.-light that MNPA thus obtained was still contaminated with un-nitrosated methylpropionamide (besides containing other impurities). On a silica gel column (Silica gel 60, 70–230 mesh ASTM, E. Merck, Darmstadt; ben-

‡Dissolved in 1973: the reported experiments were performed in 1970–1973.

zene was used as eluent), however, the substance could be purified; after vacuum distillation only a single spot appeared on the thin layer chromatogram.

Elementary analysis was in accordance with the formula assumed for the substance. (Found: C, 42.00; H, 6.90; N, 24.40%. Calc. for $C_4H_8N_2O_2$: C, 41.37; H, 6.94; N, 24.13%).

MNPA is a yellow–red fluid (b.p. 43.5°C/11 mm Hg). It is soluble in organic solvents but only moderately in water (1.1%). In the visible region the absorption spectrum in methanol has the maximum at 402 nm ($\varepsilon_{max} = 114$); for the u.v. range, λ_{max} at 238 nm ($\varepsilon_{max} = 9300$) was observed.

The volume of the gas liberated in the course of reaction between MNPA and cysteine at 27°C was measured in the Warburg apparatus. In the main compartment of the Warburg flask 2.8 ml of a 0.04 M cysteine solution in M/15 phosphate buffer (KH_2PO_4–Na_2HPO_4) were added (pH = 6.0); 0.2 ml of MNPA solution (0.02 M) in the same buffer were put into the side arm of the vessel which thus contained 4 μmole of MNPA. To prevent the autoxydation of cysteine the air had to be displaced by flushing the flask for 10 min with a stream of N_2 from a steel cylinder. After temperature equilibration, the content of the side arm was tipped into the main compartment and manometer readings recorded at regular time intervals, taking into account thermobarometer corrections. To detect any possible evolution of CO_2, the reaction between cysteine and MNPA was allowed in some experiments to proceed in the presence of 10% KOH, put into the center well of the flask together with strips of filter paper. Simultaneously, the decomposition of MNPA in absence of cysteine was registered.

In experiments aimed at testing the inhibition of the reaction between cysteine and MNPA by inhibitors of SH-groups, the solution in the main compartment besides cysteine (0.04 M) contained also iodoacetamide (0.1 M) and N-ethylmaleimide (0.08 M) respectively.

Experimental animals

For animal experiments female and male BD X-rats [7] were used. Age: 3 months, average body weight 220 and 350 g for females and males respectively. Standard food was alternating Altromin maintenance diet 1320 and Latz biscuits; water ad libitum. Characteristic for BD-rats is a low spontaneous tumour rate; at the age of 2 yr the incidence of benign and malignant tumours is about 2 and 2% respectively [7]. Spontaneous lung tumours are hardly ever observed.

Determination of LD_{50} was performed on several groups of 6 rats; MNPA was dissolved in normal saline and injected intravenously (0.5%). As the BD-rats are very homogeneous, the lethality regression lines display a high slope; the LD_{50} could be, therefore, determined graphically.

To test the carcinogenic activity of MNPA, 24 rats of both sexes were given i.v. 2 mg/kg weekly, as 0.2% solution in normal saline. After 31 weeks the treatment was discontinued. The total dose given thus amounted to 62 mg/kg body weight.

The experimental animals were subjected to complete autopsy immediately after natural death; some were sacrificed in the final stage with chloroform. Removed organs were fixed in 10% formalin. Organ slices were stained with hematoxylin and eosin for microscopic examination.

For quantitative evaluation of the carcinogenesis experiment the method of Miescher *et al.* [8] for the calculation of the cumulative percentage mortality was used.

RESULTS

Toxicity

The value of LD_{50} determined for MNPA by the i.v. route was 15 mg/kg. At the autopsy of the animals, which died after administration of the median lethal dose, severe haemorrhagic pulmonary oedema was regularly observed; pathological alterations of other organs were only slightly indicated or absent. The median survival time was 7 days.

Carcinogenesis experiments

In animals treated intravenously with 2 mg/kg MNPA (13.3% of LD_{50}) per week, lung tumours were found in a high yield (84%). Tumours of other organs—especially of the brain—were not observed.

Before the occurrence of the first tumour 5 rats died of pneumonia. Of the surviving 19 animals 13 developed lung cancer; 6 rats died intercurrently of lung infections. Using logarithmic probability paper a linear regression with high slope was obtained after plotting cumulative percentage mortality against individual survival times of rats with tumours (Fig. 1). Evidently, the individual survival times are lognormally distributed. The mean survival time was 420 days, standard deviation ± 100 days. Since lung tumours spontaneously hardly ever occur in BD-rats, these findings evidence a specific pulmotropic carcinogenic action of MNPA.

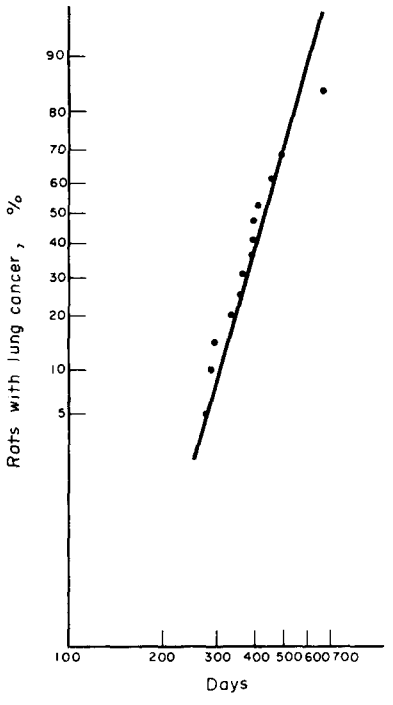

Fig. 1. Survival times of rats with lung cancer. Each point represents an animal, which died of a tumour. Ordinate: cumulative percentage mortality. Abscissa: individual survival time, days.

Either multilocular tumour growth or solitary nodes were found at the autopsy (Fig. 2); metastases of the mediastinal lymph nodes were frequently observed. On microscopic examination all tumours proved to be carcinomas, but of different histological types. Squamous cell carcinomas (with and without cornification) were encountered in 7 cases; in 5 cases alveolar-cell carcinomas were found. Finally, an anaplastic carcinoma was registered. Pronounced pleomorphism and anaplasia were always detectable at least in some parts of the tumours.

Decomposition of MNPA in the presence of cysteine

By using specific absorption reagents (10% NaOH; 10% $Na_2S_2O_4$ in 10% NaOH; CuCl in ammoniacal NH_4Cl-solution i.e. Winkler's reagent) the gas evolved in the reaction between MNPA and cysteine was shown not to be either CO_2, O_2 or CO; since it was insoluble in ethyl ether, it could not have been diazomethane, CH_2N_2. Furthermore, no precipitate of cystine was formed during the reaction; the possibility of N_2O formation seems thus to be excluded [9]. Considering the structural formula of MNPA, the conclusion that N_2 is liberated seems to be justified.

In the Warburg apparatus the volume of N_2 evolved could be exactly measured. At pH 6.0 solution of MNPA in phosphate buffer slowly decomposes under gas liberation. Upon addition of cysteine, however, a very rapid gas evolution takes place (Fig. 3). The volume of N_2 given off amounted to 85% of that which would be expected if the whole N of MNPA molecule had been liberated as N_2 (i.e. 89.6 μl N_2 at STP, corresponding to 4 μmole MNPA).

No concomitant evolution of CO_2 could be detected. A clear dependence of decomposition rate on pH was observed; both in the presence and in the absence of cysteine liberation of N_2 proceeded at pH 7.2 substantially faster than at pH 6.0. Reduction of cysteine concentration to 0.01 M retards the disintegration of MNPA. Decomposition products have not been identified yet.

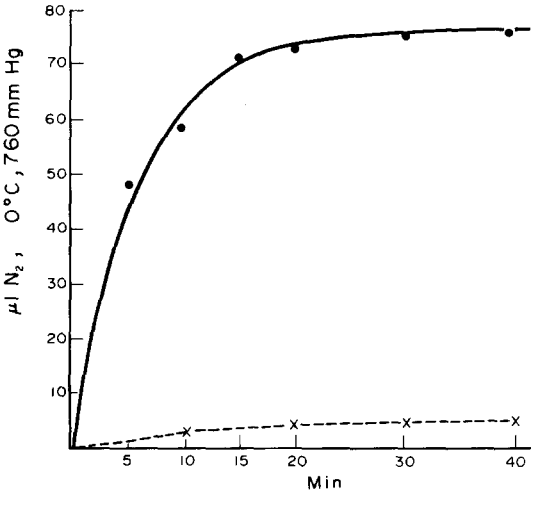

Fig. 3. Time course of evolution of N_2 from MNPA in the presence or absence of cysteine. The solid line was calculated by the method of least-squares.
Points: manometer readings.
The reaction mixtures contained 4 μmole MNPA and 112 μmole cysteine in $M/_{15}$ phosphate buffer ($KH_2PO_4 - Na_2HPO_4$), pH 6.0, at 27°C.
Broken line: decomposition of MNPA (4 μmole) in the same phosphate buffer without cysteine; pH 6.0, 27°C.

By the method of integration [10] it could be shown that the gas evolution of MNPA in the presence of cysteine represents a first-order reaction. It seems that because of the 28-fold molar excess of cysteine over MNPA the reaction is pseudounimolecular and, therefore, obeys the first-order kinetics. Calculated by the method of least squares the best value of the rate constant was found to be $k=0.17$ min^{-1}. By using inhibitors of SH-groups it was possible to show that the thiol group of cysteine was essential for the reaction with MNPA. Iodoacetamide (0.1 M) or *N*-ethyl-maleimide (0.08 M) was able to suppress the evolution of N_2 entirely. Obviously the free thiol groups are indispensable for liberation of N_2.

DISCUSSION

The results presented clearly point out two characteristic properties of MNPA: its specific pulmotropic carcinogenic action on i.v. application and its high reactivity with cysteine. In connection with these facts it seems to be important that MNUT beside inducing lung cancer also avidly reacts with cysteine with liberation of N_2 [11]. MNU, on the other hand, which given intravenously selectively induced brain tumours but never lung cancer, does in neutral aqueous media not react with cysteine [2, 12]. Considering these 3 substances, a parallelism between the pulmotropic cancerogenic action and reactivity with cysteine seems to exist. This parallelism may be purely accidental or it may be indicative of a causal relationship between the two phenomena. The latter possibility seems to be more probable. Schoental [13] has shown that *in vitro* cysteine substantially enhances the alkylation of DNA by MNUT. Like cysteine *in vitro*, tissue SH-groups in the lung may enhance alkylation of DNA by MNUT and MNPA respectively, thus triggering the process of carcinogenesis. It is, therefore, tentatively assumed that the reaction with SH-groups *in vivo* represents in the system: lung tissue—nitrosamide an essential prerequisite for induction of tumours. The failure of MNU to induce lung cancer would thus be due to its inability to react with SH-groups.

For haemodynamical reasons, the intravenously injected MNPA may be largely retained and decomposed by the lung tissue and probably only a fraction of the applied dose should reach other organs. This unequal distribution of MNPA would at least partly account for its selective pulmotropic carcinogenic activity upon i.v. application.

Moreover, there is ample experimental evidence that alkylation of DNA does not necessarily mean cancerisation [14]. For the malignant transformation of a cell by an alkylating agent much more than a merely random alkylation of the genetic material seems to be required. We have, therefore, to assume that some relevant segments of DNA—"Duplikanten" according to Druckrey [15]—must be alkylated if a normal cell is to become a cancer cell. In the lungs presumably the spatial arrangement of SH-groups (e.g. that of the non-histone nuclear protein) might be such as to enable the carbonium ions, originating from the reaction between MNPA and sulfhydryl groups, to approach and attack the relevant segments of the double helix. In the organs other than lungs a different situation may be present and even if some reaction between MNPA and SH-groups should take place, the malignant transformation cannot occur.

The fact that no lung cancer can be induced following chronical oral administration of either MNPUT or MNPA seems to indicate that under the conditions of the chronical experiment (carcinogen administered in the drinking water) both substances might be largely destroyed in the intestine, before entering the circulation; thus lung cancer cannot be induced. This presumption is supported by the fact that the LD_{50} determined by the oral route is substantially higher than LD_{50} i.v. [1], which holds true for both substances. MNU, on the other hand, being well absorbed when given orally—as evidenced by the fact that LD_{50} oral equals to LD_{50} i.v. [1]—induces in rats brain tumours also upon administration in drinking water [1].

Upon chronical oral application, however, all 3 nitrosamides induced cancer of the forestomach; thus the specific organotropic carcinogenic activity, so well pronounced upon i.v. administration of these substances, gets lost when they are allowed to act directly upon the epithelial cells of the forestomach. Whether or not the biochemical mechanism underlying the induction of the cancer of the forestomach resembles that involved in the carcinogenesis following the i.v. application of the respective nitrosamide, must at present remain unclear.

If the hypothesis outlined above should hold true, the reaction *in vitro* with cysteine under concomitant liberation of N_2 would be characteristic for all nitrosamides which would induce lung cancer following i.v. administration, thus offering a method of finding new pulmonary carcinogens in the group of nitrosamides by means of a test *in vitro*. On the other hand, the hypothesis can be checked by animal experiments. According to a suggestion of H. Druckrey and G. Eisenbrandt, *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG) was chosen for this purpose. This nitrosamide is known to react avidly with cysteine with liberation of N_2 [9, 16]. According to the above hypothesis it should on i.v. application induce lung cancer.

A report on experiments with MNNG (performed together with J. Gimmy) which in fact yielded a high percentage of lung cancer (about 70%), will be given later.

Acknowledgements—I thank Prof. Druckrey for numerous fruitful discussions. The expert technical assistance of Mrs. Sigrid Mücke and Mr. W. Mössner is gratefully acknowledged.

The Effect of Temperature During the Diethylnitrosamine Treatment on Liver Tumorigenesis in the Fish, *Oryzias latipes*

YORIKO KYONO and NOBUO EGAMI
Zoological Institute, Faculty of Science, University of Tokyo, Tokyo 113, *Japan*

AFTER the first observation on hepatic carcinoma in hatchery-reared rainbow trout in the United States [1], experimental liver carcinogenesis in salmonid fish with several carcinogens have been studied extensively [2, 3]. However, the experiment with these fish require much space and special facilities, so small aquarium fish have been used for experimental carcinogenesis. Stanton first succeeded in the induction of liver neoplasia in the small aquarium fish, *Brachydanio rerio* [4], and after that, liver tumors in guppy have been reported [5, 6]. Recently hepatomas induced by diethylnitrosamine in the medaka (*Oryzias latipes*) has been reported by Ishikawa *et al.* [7].

Since body temperature can be controlled in fish, a series of experiments to ascertain the temperature effects on tumorigenesis at various stages has been carried out. The results of the first experiment will be reported here.

One hundred and eighty fish of both sexes of medaka (orange–red variety), about 1 yr old, 2.0–3.0 cm in body length and fed on Tetramin (Tetra Werke, West Germany), were divided into 2 groups, and each group was divided again into 3 subgroups. The first group (G1) was kept at room temperature (25 ± 2°C), and the other group (G2), at a low temperature (8 ± 2°C), during the treatment period of diethylnitrosamine (DENA, Tokyo Kasei Co., Ltd., Tokyo). DENA was added to the water in both groups at the concentrations of 100, 50 and 0 ppm for 8 weeks. After the DENA treatment at high or low temperatures, all fish were transferred to normal water and kept at 25 ± 2°C. The glass containers were set under the fluorescent light. The water was changed once a week and not aired throughout the experiment. Twelve weeks after the beginning of the experiment, the surviving fish (in G1, 19/30, 22/30 and 20/30 at the concentrations of 100, 50 and 0 ppm of DENA, and in G2, 10/30, 11/30 and 16/30 respectively) were killed and fixed in Bouin's solution. After the samples were transferred into 70% alcohol, the ratios of liver weight to body weight were examined (Fig. 1). Histological serial sections of the liver were made by a routine procedure and stained with hematoxylin and eosin.

A marked enlargement of the liver was observed macroscopically in all fish (13 fish were observed) in the high-temperature group (G1) treated with 100 ppm of DENA. The ratios of

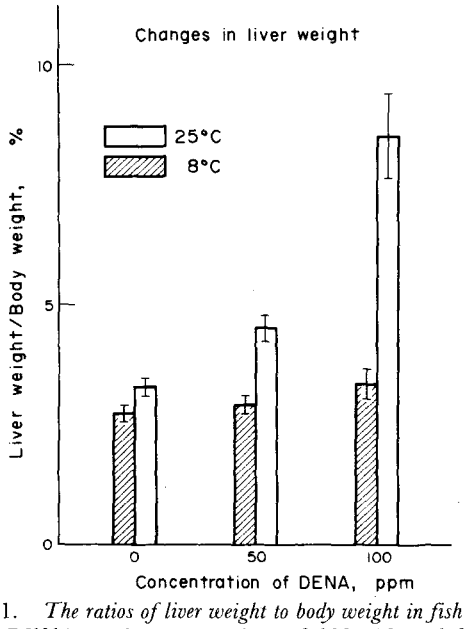

Fig. 1. *The ratios of liver weight to body weight in fish treated with DENA at the concentrations of* 100, 50 *and* 0 ppm *respectively. The ratio of fish treated at* 25 ± 2°C (*G*1) *was significantly higher* ($P < 0.001$) *than that of fish treated at* 8 ± 2°C (*G*2). *After the DENA treatment, fish of both groups were kept at* 25 ± 2°C *for* 4 weeks.

Accepted 10 March 1977.

liver weight to body weight in G1 was significantly higher ($P<0.001$) than that in G2. Many large or small tumor nodules were found through microscopic observation in all these fish (Figs. 2, 3). These tumor nodules consisted of hyperbasophilic cells with round to oval nuclei of various sizes, all containing a single prominent nucleolus. The cell density was very high in these nodules. Mitotic figures were noted frequently (Figs. 4 and 5). Some nodules appeared to be "trabecular hepatoma" and "liver cell carcinoma", and some were poorly differentiated nodules. Although the half of fish treated with 50 ppm of DENA in G1 did not have such hyperbasophilic nodules (12 fish were observed), they showed the livers associated with hyperplastic foci and the disarrangement of parenchymal cells. The infiltrating cells which were similar to lymphatic cells and/or the cells of connective tissue were also observed.

In the low-temperature group (G2), however, the majority of fish had no nodules even if 100 ppm of DENA was administered. A widely spread necroses and the infiltration of the cells mentioned above were observed frequently. However, the residual part of these livers seemed to be normal (Fig. 6). Only one fish treated with 100 ppm of DENA at low temperature had a very small hyperbasophilic cell mass (diameter $=70\ \mu m$) which was very different in size from the nodules in G1 (Fig. 7).

From these results, it is considered that the histological changes observed in fish treated with DENA at a low temperature are induced by the toxicity of the drug, and that the step to tumorigenesis is a different event from this phenomenon. In liver of fish, nitrosamine may be metabolized to some degree as Montesano *et al.* reported [8], and the various damages produced by DENA, perhaps induced by the alkylation of macromolecules as the case of mammals [9], might be relevant to cytotoxic or lethal effects on cells at low temperatures, and the step to tumorigenesis seems to require an appropriate high temperatures. In order to ascertain the cause of the difference in tumor formation between the two temperature groups, further studies are in progress.

Acknowledgements—We would like to thank Dr. T. Ishikawa and Dr. S. Takayama, Cancer Institute, Tokyo, for their kind instruction in histological observations. The study was supported in part by a Grant from the Ministry of Education, Science and Culture in Japan.

Inhibition of DNA Synthesis by a Factor from Ascites Tumor Cells*

K. ROTHBARTH, G. MAIER, E. SCHÖPF and D. WERNER

Institut für Zellforschung, Deutsches Krebsforschungszentrum, Heidelberg, and Hautklinik der Universität Heidelberg, Heidelberg, Federal Republic of Germany

OUR PREVIOUS studies [1–3] have demonstrated that Ehrlich ascites tumor (EAT) cells release an inhibition factor for protein and DNA synthesis during incubation in an isotonic but non nutritive environment (Hank's balanced salt solution, HBSS). This synthesis inhibition factor (SIF) may be involved in the autoregulation of ascites tumor growth. Furthermore, SIF could also be directed against immunocompetent cells. Factors released by tumor cells which may allow tumor cells to by-pass the host immunological system have been described recently by other authors [4, 5]. In order to understand the possible biological significance of SIF we have investigated its effect on stimulated lymphocytes.

SIF was purified from cell-free HBSS which had been used for incubation of EAT cells. This was freeze-dried, extracted with ethanol–acetone 1:1 (v/v), and chromatographed on Biogel P2 in water. The inhibitory activity which eluted in front of the conductivity peak was used. Further purification of SIF can be achieved by paper electrophoresis in an acidic system (acetic acid–formic acid–water, 4:1:36). The gel chromatography and ultrafiltration experiments on Amicon UM2 and UM05 membranes have shown that SIF has a mol. wt in the range of 500–1000. As an assay for SIF activity we measured the depression of incorporation of radioactively labelled amino acids and thymidine into cold acid insoluble material by cells. Human lymphocytes were prepared as described elsewhere [6], cultured in medium 199 (Fa. Gibco) supplemented with 20% calf serum at a density of 2×10^6 cells/ml and stimulated by pokeweed mitogen. Seventy-two hours after addition of the mitogen, the cells were sedimented, resuspended in fresh medium and incubated for 30 min with 20 μCi/ml ^{3}H-thymidine (20 Ci/mmole). SIF was added in HBSS, the controls were supplemented by the same volume of HBSS. Incorporation of radioactivity into acid insoluble material was measured in aliquots taken at times indicated in Fig. 1. DNA synthesis in stimulated human lymphocytes is strongly inhibited by SIF. This inhibition persists throughout the observation period of 240 min. When the same experiment was carried out with EAT

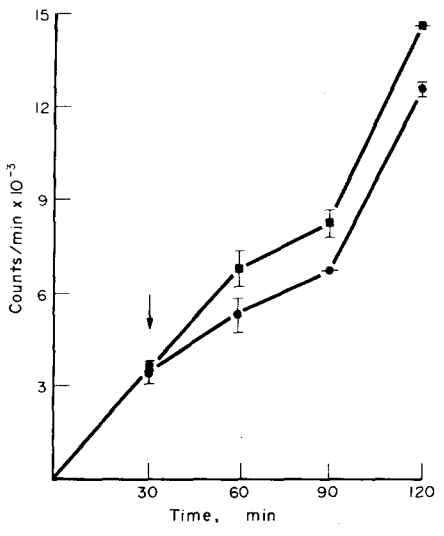

Fig. 2. Incorporation of ^{3}H-thymidine into the cold acid insoluble material of cultured EAT cells. Incubates contained, per ml medium: 5.5×10^5 cells, 2 μCi ^{3}H-thymidine (20 Ci/mmole). Mean values and standard deviations of 3 aliquots taken at the times indicated are given. The arrow indicates time of addition of SIF. (●——●) SIF treated cells, (■——■) controls.

cells which were cultured as described elsewhere [7] (Fig. 2), DNA synthesis is less affected. The same level of SIF causes an inhibition period which lasts only 30 min, after which the rate of incorporation of ^{3}H-thymidine into the treated cells recovers and parallels the control incorporation rate.

Thus, it appears that DNA synthesis is more sensitive to SIF inhibition in stimulated lymphocytes than in EAT cells. We would suggest that during the early stages of tumor development, when the number of tumor cells and, therefore, the release of SIF is low, SIF may affect primarily the immune competent cells. This is in agreement with data presented by Fauve *et al.* [4] who described factors released by tumor cells which allow tumor cells to by-pass the surveillance of the host immunological system. In a later stage of tumor development with high numbers of tumor cells, the consequently higher concentrations of SIF may act on the tumor cells themselves causing the autoregulation typical for the growth of ascites tumors [8].

Presence of Herpes Simplex Virus-Specific Antigens in Exfoliated Cervical Cells of Virgins and Sexually Active Women*

A. S. PACSA,†‡ B. PEJTSIK,§ G. DORSITS§ and L. KUMMERLÄNDER§
Institute of Microbiology, University Medical School‡ and
Departments of Oncology and Obstetrics, County Hospital,§ Pécs, 7643, Hungary

SINCE the evidence for the association between cervical anaplasia and Herpes simplex virus (HSV) type 2 had been published [1], a number of investigations was devoted to clarify the role of HSV-2 in the development of cervical cancer. However, the way how the virus might be linked with the tumour remained unanswered [2].

By the indirect immunofluorescence technique the Herpes virus-specific antigens in the cervical cells can be localized [3]. As exfoliated cells are easily accessible, this method provides a feasible approach to investigate the relationship between HSV-2 and cervical cancer.

Our previous work on the presence of HSV antigen in exfoliated cervical cells revealed: (a) not only anaplastic cells, but also apparently normal cells containing the antigen [4], (b) gradual increase of the prevalence of antigens from normal to cancerous stage [5]. These studies concerned sexually active women. The question therefore emerged whether cervical cells of virgins contain the antigens or not. In this report we present our recent data on the prevalence of HSV antigens in cervical cells in the following groups of women.

Virgins. They were selected from those girls seen and examined at the Outpatient Department of Children Gynecology, Health Centre, Pécs. Their age was between 10 and 18 yr. Only the girls were involved in the study (106 in number) whose virginity was approved unequivocally by physical examinations. Patients visited the Department because of dysfunctional bleeding, vaginal fluor, uncertain origin of abdominal pain and hormonal disorders. Imprints were taken between periods.

Sexually active women. This group includes: (a) 710 women who were selected by the on-going screening programme as part of our Herpes virus–cervical cancer project. They had normal cervical epithelium by pelvic examination, Papanicolaou test and colposcopy; (b) 205 women with bland disorders. This term covers ectopium, iodine-negative areas, erosions, inflammations seen by colposcopy and histological diagnosis like keratitis, hyperplasia, metaplasia, basal activity according to definitions described previously [6], (c) sixty-two patients with cervical dysplasia diagnosed histologically and (d) 49 patients with invasive cervical carcinoma confirmed histologically.

Cervical imprints were obtained by a piece of sponge impressed to the surface of the cervical portion, atypic lesion or tumour. From each person six imprints were made on coded slides. They were fixed in cold acetone for 5 min and kept at −20°C until processed.

The presence of HSV-specific antigens in cervical cells was determined by the indirect immunofluorescence method. Imprints were treated with rabbit antiserum to HSV-2 and then with fluorescein-conjugated sheep anti-rabbit IgG from the Human Sera and Vaccine

Accepted 1 April 1977.

Table 1. Incidence of HSV antigens in exfoliated cervical cells of virgins and sexually active women

Group	No. tested	No. of positives	(%)
1. Virgins	106	None	—
2. Women with normal cervical epithelium	710	64	9.1
3. Women with bland disorders	205	79	38.0
4. Patients with cervical dysplasia	62	35	56.4
5. Patients with invasive cervical carcinoma	49	45	91.8

Institute, Budapest, Hungary. The preparation of anti-HSV-2 rabbit immune serum, and the particulars of conjugated IgG were described earlier [7]. Slides mounted with 90% glycerol were examined in a Zeiss fluorescence microscope. The test was specific for HSV antigens, as antiserum was prepared by immunizing rabbits with HSV-2 propagated in primary chick embryonic fibroblast cultures; serum used in the test was absorbed with a cell culture derived from human carcinoma of the larynx (HEp-2), HEF and HeLa cells. The serum did not show fluorescence when checked with non-infected HEP-2, HeLa, and cytomegalovirus-infected (strain AD-169) HEF cells. Absorption of the immune serum with HSV-2-infected HEp-2 cells removed almost entirely its staining capacity to HSV antigen, leaving a faint fluorescence not higher than in dilution of 1 in 5. For staining imprints a working dilution of 1 in 50 was applied. For detecting HSV-specific antigens in the cervical cells, the following staining pattern was used. Two impressions of cervical cells were treated with HSV-2 immune serum, 2 others with normal rabbit serum, and the remaining 2 with 0.1 M phosphate-buffered saline (pH 7.2). Samples were considered positive for HSV antigens when cervical cells had shown characteristic fluorescence with HSV-2 immune serum only. Evaluation was done by a technologist not aware of the code.

By this procedure we could detect antigens in none of the samples from the 106 virgins examined so far. In contrast to this, in exfoliated cervical cells of sexually active women with apparently normal, healthy cervical epithelium, HSV-specific antigens were present in 9%. Comparison of the prevalence of antigens by groups with different cervical disorders reveals that antigen positivity increases from normal to cancerous stage (Table 1). A follow-up study of selected groups of women indicated that the HSV antigen, when once acquired, remains in the cervical cells for at least 1 yr [5]. These facts may support the initiating role of Herpes virus genitalis in the development of anaplastic changes. The fact that none of the samples from virgins contained the antigens does strengthen further the hypothesis that Herpes virus infection precedes neoplastic changes of the cervical epithelium. Moreover it underlines that sexual activity is indispensable for acquiring HSV antigens.

Since non-cytopathogenic, cell-associated virus is capable of transforming cells *in vitro* [8], we suppose that healthy women with herpes virus antigens in their cervical cells stand a certain risk of developing cervical cancer. We suggest that in addition to the conventional Papanicolaou test, detection of viral antigens in cervical cells would be desirable by at least two reasons: (1) establishing risk population and (2) helping to solve the actiological background of the neoplastic changes of the cervix uteri.

Letter to the Editor

A Proposal for Assessment of Hormone Sensitivity and Consequent Endocrine Therapy of Breast Cancer

P. W. JUNGBLUT, A. HUGHES, W. SIERRALTA and R. K. WAGNER

Max-Planck-Institut für Zellbiologie, 2940 *Wilhelmshaven*, *Postfach* 1009, *Germany*

THE OESTRADIOL receptor content of breast cancer specimens is now widely used as an indicator for hormone sensitivity which is a prerequisite for endocrine therapy. Although positive correlations between receptor content and response to endocrine measures have been reported, a comparative evaluation of these data remains difficult. This is, to some extent, due to the different assay techniques and reference parameters employed, but probably more so to ovarian-independent fluctuations in the oestradiol receptor levels. We recently described such ovarian-independent fluctuations for several mammalian tissues [1] including human breast cancer: 1. An apparent circadian rhythm influences the uterine oestrogen receptor concentration of ovariectomised rats. 2. A seasonal variation was found in uteri of immature calves and ovariectomised pigs and in breast cancer biopsies from postmenopausal women. 3. A fluctuation with a periodicity of 9–12 days was observed in the uteri of ovariectomised/hypophysectomised rats. Circadian and seasonal fluctuations might be attributed to the release of adrenal steroids which are peripherally aromatized. In contrast, the fluctuating pattern of uterine oestrogen receptor concentration in ovariectomised/hypophysectomised rats points to a steroid-independent turnover of "receptor" [2].

The non-existence of "normal base-line" values considerably reduces the value placed on the quantitative oestrogen receptor assay as the sole indicator for hormone-sensitivity. Therefore, this assay should be complemented by further criteria. 1. The assessment of nuclear-bound oestradiol is both a logical choice and an easy task. The presence of the hormone would demonstrate that the receptor is still susceptible to steroid-facilitated conformational change, dimerisation and translocation into the nucleus. 2. Intact transcription-enhancing capability could be deduced from the presence of a specific transcription/translation product, such as the progestin receptor, the synthesis of which apparently depends on oestrogen receptor action [3].

Together, these 3 parameters should provide a reliable indication for hormone sensitivity, as demonstrated by the presence, in 10 normal human uteri, of substantial amounts of oestrogen receptor, oestradiol in the nuclear fraction and progestin receptor.

In mammary cancers, quite diverse patterns were observed: 3 out of 35 cancers so far investigated contained neither receptor nor nuclear oestradiol, indicating a failure in steroid binding, receptor "activation" and translocation. Six carcinomas contained oestrogen receptor and oestradiol in the nuclear fraction but no progestin receptor, pointing to a failure in the transcription-enhancing events. Two cancers, exceptionally, contained no oestrogen receptor, but both nuclear oestradiol and progestin receptor were present. This could be explained either by experimental error, or by the presence of trace (undetectable) amounts of oestradiol receptor, and underlines the importance of having more than one parameter for assessing hormone sensitivity. The remaining 24 cancers showed a pattern similar to that seen in normal human uterus.

Most of the postmenopausal cancers examined contained surprisingly high nuclear oestradiol concentrations. Since oestrogen production of the ovaries declines rapidly after menopause, this oestradiol must mainly orig-

Accepted 2 May 1977.

inate from peripherally aromatised adrenal precursors.

An ablative endocrine treatment of patients, whose mammary cancers fulfill all 3 criteria for hormone sensitivity, should therefore ideally comprise ovariectomy and adrenalectomy, since ovariectomy alone obviously does not secure hormone-withdrawal.

However, in view of our latest results, it must be doubted that even the complete withdrawal of hormones is fully effective. Besides the already mentioned turnover of the oestradiol receptor in the uteri of ovariectomised/hypophysectomised rats, the receptor content of purified nuclei isolated from uteri of chronically castrated pigs was found to be about 5 times higher than the corresponding oestradiol content. This discrepancy could be explained either by a separate release of oestradiol and receptor which had originally entered the nucleus jointly, or by a steroid-independent entrance of the "receptor", which in itself possesses transcription-enhancing activity. The latter possibility is the more probable one and consequently receptor-"poisoning" in addition to hormone withdrawal must be envisaged as a therapeutic requirement. The experiments of Lippmann *et al.* [4] on human mammary cancer cell lines, the growth rates of which are enhanced by oestradiol and decreased by antioestrogens, lend support to this concept.

I. INTRODUCTION

SINCE the original observation by Beatson [1] who reported in 1896, 2 regressions of mammary carcinomas following ovariectomy, endocrine therapy of advanced breast cancer has been widely applied. Two main modalities are used to this effect: on one hand, endocrine surgery (ovariectomy, adrenalectomy or hypophysectomy) and radiocastration; on the other hand, administration of different steroid hormones or their antagonists. The remission rate obtained with these treatments varies somewhat but is in the neighbourhood of 30%. The problem of selecting patients who will respond favorably to therapy has always preoccupied the clinician, in order to avoid unnecessary interventions and loss of time which is sometimes irretrievable. Radiobiological measurements of urinary or plasma steroid hormones, steroid sulfatation by tumor extracts as well as response to hormone in organ cultures have been proposed as prognostic tests. The validity of such tests has, however, never been established. In contrast, the study of the mode of action of sex steroids hormones has introduced another selecting test which seems valuable for assessing the probability of responding to endocrine therapies.

The capacity to concentrate steroid hormones is a characteristic of their target organs (i.e. estrogens and progestins for uterus and vagina, androgens for prostate, testis). This phenomenon is due to the presence in the tissues of these organs of specific cytoplasmic steroid–hormone binding proteins. These proteins, called "receptors", are assumed to play an essential part in the mechanism of action of these hormones. After their entrance into the target tissue cells, steroid hormones bind to their own specific receptors and convert them to an "activated form" [2]. The activated steroid–receptor complexes are then translocated into the nucleus where they bind to the chromatin. This interaction results in a nuclear retention of the hormones. An immediate increase in the ability of the chromatin to bind ^{3}H-actinomycin D [3, 4] and to synthesize RNA [2] seems also to derive from the interaction. These changes in transcriptional properties are followed by increased protein synthesis. Although the functions of these various metabolic processes remain unsettled, it is likely that some of them are related to the growth and/or differentiating effects of the steroid hormones.

With regard to human breast cancer Folca *et al.* [5] observed in 1961 that the uptake of administered ^{3}H-hexestrol by cancer tissues was higher in 4 patients who responded to adrenalectomy than in 6 others who did not respond to the operation. On the basis of this observation, the presence of estrogen receptors (ER) was searched for in samples from primary and metastatic mammary tumors. Their presence was demonstrated around 1970 by Korenman and Dukes [6] as well as by Jensen *et al.* [7]. Furthermore, in a clinical study of patients with advanced breast cancers, Jensen *et al.* [7] reported that most patients with "ER-positive" tumor biopsies obtained an objective remission with adrenalectomy while those who were "ER-

†This service is a member of the European Organization for Research on Treatment of Cancer (E.O.R.T.C.).

negative", usually failed to respond to therapy. These studies on biochemical-clinical correlations were repeated in several centers and extended to androgen (AR) [8, 9] and progesterone (PgR) [10] receptors as well as to other forms of endocrine treatments. It is the purpose of the forthcoming paragraphs to describe the various assays used for the detection of the receptors and to analyse the therapeutic significance of the receptors in the treatment of breast cancer.

II. METHODS FOR STEROID HORMONE RECEPTORS ASSAY IN NEOPLASTIC TISSUES

Numerous methods have been developed to measure with accuracy the receptors concentrations in neoplastic human mammary tissues [11]. Assays are usually restricted to cytoplasmic receptors which are measurable in extracts from fresh or frozen tissues.

Homogenization of the tissue specimen is the first step of the assay. The addition of a sulfhydryl reagent (β-mercaptoethanol or dithiothreitol) to the homogenization buffer increases the sensitivity of the method [12]. The homogenate is then centrifuged to obtain the cytosol fraction. The demonstration of labeled steroid specifically bound to this fraction permits the detection of receptors in the tissue samples; ^{3}H-estradiol-17β is used for the detection of ER, ^{3}H-dihydrotestosterone for AR, ^{3}H-R-5020* (a progestin) for PgR. R-5020 is usually used instead of progesterone because unlike the latter hormone, it does not bind to the plasma contaminant CBG [13–15]. Specific ^{3}H-steroid complexes may be distinguished from unspecific binding by one of the following two methods.

(i) Two cytosol fractions are incubated with nearly saturating amounts of ^{3}H-steroid. A large excess of unlabeled steroid is added to one fraction in order to distinguish specific from unspecific binding.

(ii) Aliquots of the cytosol fraction are incubated with increasing amounts of ^{3}H-steroids. The specificity of the binding reaction is determined by the graphical method of Scatchard [16].

After incubation, unbound steroid is removed to detect labeled steroid receptors complexes. Of the methods most frequently used, the *sucrose density gradient* has the unique advantage of evaluating the molecular shape of these complexes [7, 11]. In dilute buffer, without added salt they migrate as aggregates of which the sedimentation coefficients are close to 8 S. In some cases, 4 S complexes are also observed. In presence of high amounts of contaminating serum proteins in the cytosol fractions, the identification of these 4 S forms may be quite difficult because most contaminating serum binding proteins sediment in the 3–5 S region of the gradient. This difficulty does not exist with *agar-gel electrophoresis* [17] in which all specific tritiated molecular forms migrate as a single peak that can more easily be distinguished from the contaminating serum binding proteins. Both sucrose density gradient sedimentation and agar-gel electrophoresis require expensive equipment. This is not the case for the *dextran-coated charcoal* (*DCC*) method [18], which has the additional advantage of being easy, fast and more sensitive. This method, which is used in our laboratory [19], is based on an adsorption procedure: the addition of a dextran-coated charcoal suspension to the ^{3}H-steroid containing cytosol preparation rapidly removes most unbound and unspecifically bound labeled hormones while it has no significant effect on the amount of specifically bound radioactivity. *Protamine sulfate precipitation* [20] is another simple method which was recently introduced. It is based on the observation that receptors precipitated from the cytosols by protamine sulfate are still able to bind labeled steroids. It has the advantage of easily measuring total receptors binding sites, free as well as occupied by endogenous hormones. It should be stressed that, among all these methods, dextran-coated charcoal cannot be used for measuring AR because the charcoal treatment fails to remove ^{3}H-dihydrotestosterone bound to the plasma contaminant SHBG. In contrast, agar gel electrophoresis [21] and protamine sulfate precipitation [22] were shown to be especially accurate for the study of AR.

The binding capacity of the cytosols is generally expressed in fmole (10^{-15} mole) per mg *total* cytosol protein or *tissue* protein after correction for contaminating serum proteins. For assessing tissue protein, serum albumin is measured by a radioimmunodiffusion assay and the following formula is used [18]:

$$\text{tissue protein} = \text{total protein} - \text{serum albumin} \times \frac{100}{60}$$

*R-5020: 17, 21-dimethyl-19-nor-pregna-4, 9-diene-3, 20-dione.

III. OCCURRENCE AND CONCENTRATION OF SEX-STEROID HORMONE RECEPTORS IN HUMAN BREAST CANCERS

1. *Estrogen receptors*

In *female* breast cancers, the proportion of ER-positive tumors varies from laboratory to laboratory (range: ~35–85%). In some of them, including ours [23], the proportion steadily increased as the study progressed. Such progressive changes may probably be ascribed to technical improvements. Our present-day results indicate that about 85% of primary and metastatic breast cancers contain ER [24]. In the receptor-positive lesions, receptor concentrations were found to be extremely variable from tumor to tumor [23]. They varied over a wide range of values from about 5 to 2000 fmole/mg of tissue protein. Within this range the distribution of tumors appeared continuous with a progressive increase in proportion towards the lower values. Besides differences in sensitivity of methods, it is likely that the reported disagreements in the proportion of ER-positive tumors result from the criteria used to define positivity. Many investigators use, for that purpose, an arbitrary minimal concentration of binding sites. The continuous distribution of ER concentrations together with a very small proportion of "negative" tumors in our series is not in favor of the existence of two classes of breast cancers on the basis of *presence* or *absence* of ER. It is our feeling that most, if not all, do contain receptors although some in too low concentration to be detected by the current assays.

It is now established that the mean ER concentration is lower in women before than after the menopause [25]. Whether this difference is due to physiological changes or to partial saturation of receptors sites by endogenous estrogens is not established. Recent preliminary data suggest, however, that low concentrations of ER found in premenopausal patients cannot be explained by partial saturation of sites [26].

In *male* breast cancers, the presence of ER was also detected in primary and metastatic tumors. A recent report from our laboratory gives the more complete investigation on this matter [27]. ER were found in a large majority of primary (6/7) as well as in 1 out of 3 metastatic tumors. Receptor concentrations varied from tumor to tumor. Finally, no difference was detected between estrogen binding specificity of cytosol preparations from a male and a female breast cancer. All these data suggest a great similarity between estrogen receptivity of male and female mammary neoplastic tissues.

2. *Progesterone receptors*

The presence of PgR in some *female* breast cancers was first reported by Terenius [28] using ^{3}H-progesterone as labeled hormone. This observation was confirmed by Horwitz and McGuire [15] using the tritiated progestin R-5020 (see Section II). Later on, presence of PgR was reported in *male* breast cancer [24, 29].

In our laboratory, PgR was detected in 59% of primary and 47% of metastatic tumors [24]. These proportions are within the range reported by others (~35–60%) [30]. It is likely that the difference in proportions of receptor-positive lesions are partially due to the criteria used to define positivity. In contrast, there is a general agreement that the presence of PgR is essentially restricted to ER-positive cancers. Furthermore, data from our laboratory indicate that lesions positive for both ER and PgR are more frequent in primary than in metastatic lesions suggesting a loss of progesterone receptivity during the metastatic process [24].

Our investigations indicate that in PgR-positive cancers, receptor concentrations varied over a wide range of values from about 5 to 5000 fmole/mg tissue protein [24]. Within this range, the tumors were distributed in a continuous manner, with a progressive increase in proportion from the higher towards the lower values. This pattern was the same as for ER (see above). Furthermore, in cancers containing both ER and PgR, receptor concentrations were significantly correlated. Absence of PgR in ER-positive tumors was, however, associated with ER concentrations distributed along the whole scale. Similar observations were reported by other investigators [30].

Mean PgR concentration was found to be higher in pre- than in post-menopausal women. This difference might be explained by the higher level of circulating estrogens in the former patients.

3. *Androgen receptors*

Wagner *et al.* [31] first detected the presence of AR in some primary and metastatic *female* breast cancers. This observation was confirmed by Engelsman *et al.* [32] as well as by Maass *et al.* [33]. Whereas the two latter groups reported a quite low rate of receptor-positive tumors (~20%) Wagner and Jungblut [21] found AR in about half the cases. Differences in receptor assays seem unlikely to explain this discrepancy since all authors used the same

†Adrenalectomy, castration and hypophysectomy.
‡Androgens, estrogens and glucocorticoids.

technique (agar-gel electrophoresis). AR concentrations were found variable from tumor to tumor. On the average, they are largely lower than ER concentrations [21].

IV. ABSENCE OF RELATIONSHIP BETWEEN ESTROGEN RECEPTORS AND PATHOLOGICAL FINDINGS

Consistent correlation studies between sex-steroid hormones receptors and pathological findings are only available in the case of ER.

Most investigators found no correlation between the presence of ER in a tumor and its histological type [25]. Rosen *et al.* [34] reported, however, a higher frequency of ER-positive tumors in the invasive lobular carcinomas than in the typical ductal ones. The same authors also reported that receptors were less frequent in tumors with a prominent local lymphocyte reaction. Finally, no correlation was found between ER concentrations and the epithelial cell density of the tumors.

A well-established fact is that the presence as well as the concentrations of ER in a primary breast cancer bears no relationship with the presence or absence of invaded axillary nodes [25]. This suggests that the estrogen receptivity of a primary tumor is of little or no prognostic value since the axillary nodal status is the factor of greatest prognostic significance for survival [35].

V. SEX-STEROID RECEPTORS AS A GUIDE FOR ENDOCRINE THERAPY IN ADVANCED BREAST CANCER

1. *Estrogen receptors*

Qualitative assessment of estrogen receptors for endocrine therapy. In 1974, an international workshop was held for evaluating the relationship between presence of ER in tumor of patients with advanced breast cancer and response to endocrine therapy [25]. A total of 436 treatment trials from various centers were reviewed by two independent oncologists.§ It was found that 55% of the patients with ER-positive cancers responded to ablative endocrine procedures (Table 1). In the same way, 60% of the positive patients had a remission after administration of pharmacological doses of androgens, estrogens or glucocorticoids. A somewhat lower proportion (43%) was obtained after administration of a variety of other additive therapies including antiestrogens, aminogluthetimide, etc. On the other hand, in ER-negative patients, only 8–16% responded to these various treatments.

These results led to the conclusion that the detection of ER in advanced breast cancer was helpful in predicting response to endocrine therapies. Nevertheless, they were also disappointing because the predictive value of the receptors test was much weaker than in Jensen's initial report [7]. The question then arose why many ER-positive cases failed to be clinical responders.

Quantitative assessment of estrogen receptors for endocrine therapy. In a large series of 123 women, Jensen [36] observed that patients without an arbitrary minimal ER concentration had virtually no chance of responding to any kind of endocrine therapy. This minimal receptor concentration in the tumors appeared to be lower in pre- than in postmenopausal women. Above this minimal concentration, about 65% of the patients were found to respond to various endocrine therapies. In this range there was, however, no significant correlation between ER level and the likelihood of a remission. This

§Dr. M. E. Sears and G. C. Escher.

approach simply increased the proportion of responders in the arbitrary-defined ER-positive patients as compared to the whole ER-positive group.

Search for a quantitative relationship between the likelihood of obtaining a remission and ER concentration was performed at our Institute in a series of 34 patients using a linear logistic regression model [37]. Eleven additional clinical variables of possible relevance to response [35] were included in the analysis (age, menopausal status, postmenopausal yr, presence or absence of a free interval, duration of free interval, primary treatment vs secondary treatment, soft tissue involvement, bone involvement, lung involvement, liver and abdomen involvement, performance status). It was found that ER concentration was significantly correlated with the probability of obtaining a response to endocrine therapies and that among the 12 variables it was the most significant in this regard ($P=0.016$). Furthermore computation yielded a formula that served to construct a curve estimating the probability of response as a function of receptor concentrations (Fig. 1). Inclusion of 2 other significant variables (bone involvement, age) in addition to receptor concentration yielded a second curve which better fitted the experimental data.

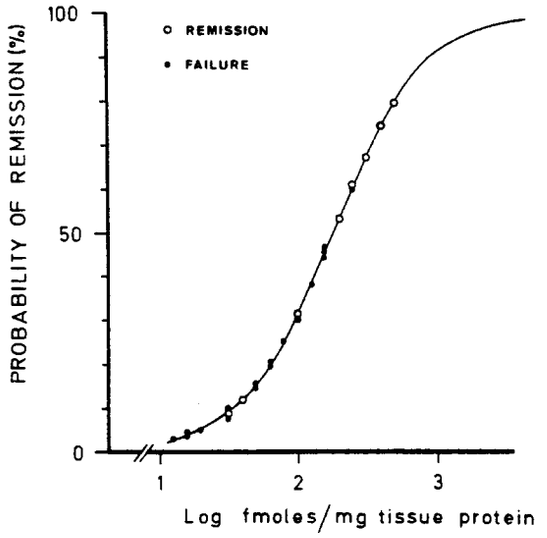

Fig. 1. Relationship between estrogen receptor concentrations and the probability of response to endocrine therapy. Experimental data were analysed by using the linear logistic regression model. The curve is a graphical representation of the statistical model.

Relationship between the sedimentation characteristics of estrogen receptors and response to endocrine therapy. At low ionic strength cytoplasmic ER sediments as a 8 S or/and 4 S components on linear sucrose density gradients (see Section II). Wittliff *et al.* [38] reported that patients having only 4 S binding components never respond to endocrine therapy. Although these data need confirmation, they suggest that the clinical usefulness of assays which do not distinguish sedimentation characteristics may be limited.

2. *Progesterone receptors*

Because in the uterus the synthesis of PgR is induced by estrogens and therefore requires an intact estrogen receptive machinery, Horwitz *et al.* [10] proposed that PgR might be an improved predictor of hormone dependency. This theory found support in the observation that PgR is absent in almost all ER-negative tumors but is present in about half the ER-positive ones (see Section III, 2).

With regard to clinical application, a preliminary correlation study by McGuire's group [10] suggested that the theory might be valid since, in a series of 9 patients, response occurred only in those with tumours containing both ER and PgR (3 cases). At a recent workshop on PgR [30] (Table 2), Bloom *et al.* [39] reported data in perfect agreement with those of this preliminary study. Present-day results from Horwitz and McGuire [40] indicated that among ER-positive tumors, remissions occurred in both Pg-positive and -negative cases with a higher rate of remission in the tumors containing both receptors. In contrast, in our own cases, no relationship was found between response and presence or concentration of PgR (Table 3). Remissions were, however, observed in cancers containing the highest levels of ER as in our previous study (Section V, 1). Differences in receptors assays might be responsible for the disagreement between the two former groups and ours. Further studies are needed to assess this point and to evaluate the exact predictive value of PgR. Nevertheless, it already appears that PgR is not an entirely reliable predictor of hormone dependency.

3. *Androgen receptors*

Only few data are available on the predictive value of AR for endocrine therapy. In a small series of patients, Maass [8] reported a higher rate of remissions in the receptor-positive (4/5) than in the receptor-negative cancers (6/20). In another small series, Persijn *et al.* [9] found a significant relationship between the presence of the receptors and the response to castration (AR-positive: 4/6; AR-negative 0/13; $P=0.004$). In contrast, they observed that the presence of AR had no significant predictive value for response to ethinylestradiol.

*Table 2. Relationship between presence of estrogen and progesterone receptors and response to endocrine therapy**

		(No. remission/No. total)

VI. ANTIESTROGENS IN THE TREATMENT OF ADVANCED BREAST CANCER

A wide range of synthetic compounds are able to inhibit the growth-promoting effects of estrogens in the rodent's uterus. Although the mode of action of these *antiestrogens* is still largely unknown, evidence was reported indicating that some of them operate by interfering with the action of ER. These facts suggested that antiestrogens could inhibit growth of ER-positive breast cancers. As yet, the antitumor efficacy of 3 compounds *nafoxidine* (U-11, 100A)‡ (41, 42), *tamoxifen* (ICI-46, 474)§ (43–47) and *CI*-628‖ (43, 48) has been demonstrated in dimethylbenz(a)-anthracene-induced rat mammary tumors. Furthermore, in this experimental system, data were reported supporting the hypothesis that the action of antiestrogens is dependent upon the presence of ER in the tumors [43, 46]. Finally, in human breast cancer, *nafoxidine*, *tamoxifen* and *clomiphene*¶ proved to be therapeutically active.

In 1972, the E.O.R.T.C. Breast Cancer Cooperative Group reported a 35% objective remission rate in a series of 23 patients treated with *nafoxidine* [49]. This rate of remission is almost identical to that reported in another trial by Bloom and Boesen (37% in 48 patients) [50]. These exploratory studies were followed by a randomized trial comparing nafoxidine with ethinylestradiol [51]. Objective remissions occurred in 31% (15/49) and 14% (7/49) of the patients respectively. Although nafoxidine yielded a distinctly higher remission rate than ethinylestradiol, the difference was not significant at the 0.05 level ($\chi^2 = 2.872$; $0.05 < P < 0.10$). Recently, in a series of 24 patients, Sasaki *et al.* [52] reported that nafoxidine produces remissions only in ER-positive cancers, suggesting that its action in man is also mediated through these receptors. Furthermore, they found that it is effective only in the treatment of cutaneous metastases. Patients with lesions in other sites uniformly failed, for unknown reasons, to respond to therapy. Finally, nafoxidine was found to produce specific toxic reactions on skin and hair [50, 51] that limits its practical usefulness.

Tamoxifen and *clomiphene* have been reported to be therapeutically active without the major side-effects of nafoxidine. In 1971, Cole *et al.* [53] reported 10 objective remissions in 46 women treated with tamoxifen (22%). This rate was comparable to that obtained in two historical control groups, one treated with diethylstilbestrol (16 remissions out of 64 patients), the other with androstenediol (10 remissions out of 60 patients). The antitumor efficacy of the drug was confirmed by Ward [54] who observed objective tumor regression by more than 50% in

¶Clomiphene: *cis*-isomer of 1-[p-(β-diethylaminoethoxy)phenyl]-1, 2-diphenyl-2-chloroethylene.

26 out of 68 patients. Clomiphene was investigated by Hecker *et al.* [55] in 50 women and 1 male. Objective remissions were found in 39% of patients (19 women, 1 male).

VII. STEROID HORMONES LINKED WITH CYTOXIC AGENTS IN THE TREATMENT OF ADVANCED BREAST CANCER

The potential interest of using steroid hormones or related compounds linked with cytotoxic agents is based on the principle that such molecules would specifically concentrate into the target tissues including breast cancer provided certain conditions are fulfilled. Among them, the drug should have a significant affinity for the receptors and should not be easily metabolized outside the target tissues into its two main moieties, cytotoxic agent and hormone. Subject to these provisions, the use of such molecules might increase the specificity of action and decrease the systemic toxicity of chemotherapy. Along this line, *estramustine phosphate* (*Estracyt*, Leo 299),* a phenolic N-bis (β chloroethyl carbamate of estradiol-17β phosphate) and *predmustine* (Leo 1031),† a chlorambucil ester of prednisolone, have been tested in clinical trials on patients with advanced breast cancer. The latter compound is not a sex-steroid hormone derivative, but its apparent therapeutic efficacy justifies its inclusion in this section.

In 1969, the E.O.R.T.C. Breast Cancer Cooperative Group [56] reported negative results in a series of 34 patients treated with *estramustine phosphate*. Only two remissions were obtained after daily i.v. administration of 60 mg of the drug. Since this rate of remission was lower than that expected from the use of either estrogen alone or cytotoxic agent, Estramustine phosphate was considered of no therapeutic value. This drug was recently studied *in vitro* in our laboratory [57]. Its affinity for ER was found extremely low. Moreover, it rapidly degraded into compounds of higher binding affinity in blood and in cytosol preparations from liver, uterus and mammary tumors. Evidence was given that estradiol-17β might be one of these degradation compounds. These observations may easily explain the therapeutic failure of estramustine phosphate in breast cancer.

The therapeutic efficacy of *predmustine* was investigated by Könyves *et al.* [58] in a series of 15 patients. After a daily oral administration of 20–100 mg of the compound, 2 complete and 5 partial remissions were recorded. Whether these remissions were induced by the drug itself or prednisolone and/or chlorambucil produced from its degradation, is unknown.

Other molecules are available [47, 59, 60]. Some of them are currently subjected to *in vitro* studies [47, 61] and animal experimentation in our laboratory.

VIII. CONCLUSIONS

The demonstration of the presence of sex-steroid hormone receptors in human breast cancer has fostered progresses in the therapy of the disease. First, the presence of ER, PgR and AR in tumor biopsies proved helpful in predicting the probability of a patient responding to endocrine therapy. Secondly, they allowed a legitimate hope of obtaining highly efficient and specific new treatments based on the use of drugs interfering with the mode of action of these receptors.

With regard to the first point, although the results are encouraging, it is already known that some cancers, even with high amounts of receptors, are clinically refractory to endocrine treatments. The reason for these therapeutic failures is unknown. Alterations in the receptor machinery (Section I) were proposed to be responsible. Thus, lack of transfer of ER from the cytosol to the nucleus [62, 63] and deficiency in ER-induced RNA synthesis [64] have been described in experimental models. These considerations are probably undue oversimplifications since tumors regress after a variety of endocrine treatments not necessarily involving steroid-related mechanisms. In this context, preliminary data suggest that tumors might be composed of several populations of cells in respect to sex-steroid receptors [65, 66]. According to this multiclonal theory, therapeutic failures may be due to selective hormone-dependent cell kill leading to preponderant growth of hormone-independent cells. Finally, it is obvious that steroid receptivity is only a part of a complex system regulating tumor growth in which polypeptide hormones could also play key roles. Thus, evidence was reported suggesting that prolactine controls the level of ER in dimethylbenz(a)anthracene induced rat mammary tumors and thereby modulates estrogen receptivity [67–69]. Refinements in sex-steroid

*Estramustine phosphate (Estracyt, Leo 299): estradiol-3N [bis-3(2 chloroethyl)carbamate-17β-dihydrogenophosphate.

†Predmustine (Leo 1031): pregna-1, 4-diene-3, 20-dione, 11β, 17α, 21-trihydroxy-21-4-p [bis(2 chloroethyl)amino] phenyl-butyrate.

and polypeptide hormone receptor assays seems therefore to be needed to improve knowledge in this matter and thereby increase the accuracy of testing hormone dependency. Unfortunately, such sophisticated assays will not be very convenient for use in clinical laboratories so that search for simple techniques should also be developed.

The clinician is now facing an alternative. Either he decides to follow a traditional therapeutic approach, i.e. endocrine treatment followed as a last resort by cytotoxic chemotherapy. If he selects this option, receptor assays may serve as a guide to his initial decision: in such a case, ER concentration will inform him on the probability of response to endocrine treatments (Fig. 1). Additional assays of PgR and AR will probably improve the predictive value of the test. Nevertheless, it remains that endocrine treatments will never exceed a success rate of 30%. The clinician may therefore adopt a distinctly different approach. Knowing that most breast cancers are hormone receptive at least to some extent and thereby more or less hormone-dependent, he should resort to endocrine treatments in *all* cases. He does not expect to *recognize* objective remissions in each, but he may assume that some beneficial effect has nevertheless been obtained. In this perspective, endocrine treatment should be complemented by cytotoxic chemotherapy in a majority of cases. Search is needed to define the optimal means of combining these two modalities.

In Vitro Arming and Blocking Activity of Sera from BALB/c Mice Bearing a Spontaneous Transplantable Adenocarcinoma*

SANTO LANDOLFO,† MIRELLA GIOVARELLI and GUIDO FORNI

Department of Microbiology, University of Turin, Torino, 10126, Italy

Abstract—*The kinetics of the immune response of BALB/c mice to a syngeneic spontaneous adenocarcinoma (ADK-1t) were analyzed in vitro during the various stages of tumor growth. Cell-mediated cytotoxicity, as measured by a colony inhibition assay, was first detected 5 days after tumor inoculation, reached a peak at about 13 days, and then declined to low but significant levels by day 21.*

A peak of complement-dependent serum cytotoxicity was observed at 10 days when the tumor size was about 5 mm. Moreover, sera from animals bearing tumors of 1.5–10 mm dia were able to arm lymphocytes from normal BALB/c mice and enhance the cytotoxic activity of lymphocytes from tumor-bearing mice. On the other hand, no blocking activity was observed when the ADK-1t target cells were preincubated with the same sera. When cytotoxic lymphocytes were pretreated with sera from mice bearing tumors larger than 10 mm in size, inhibition of cell-mediated cytotoxicity was observed.

These findings show that the interaction of serum factors on cellular reactivity is of a complex, evolving nature, directly related to the tumor size.

INTRODUCTION

SPECIFIC cellular cytotoxicity against autochthonous or syngeneic tumors may be demonstrated in human patients and tumor-bearing animals by different *in vitro* assays. However, sera from patients and animals bearing tumors contain factors that strongly modify cellular reactivity. "Blocking factors" have been demonstrated in several host-tumor systems [for a review see 1]. The blocking activity seems to be mediated by 7S immunoglobulins [2], antigens shed from cell membrane [3, 4] or tumor-specific antigen–antibody complexes [5, 8]. On the other hand, "potentiating" [9] and "arming" [10, 11] serum activities have also been described.

However, the temporal evolution of the cellular reactivity and the influence of humoral factors have been studied mostly in particular systems, i.e. virus-induced tumors or in chemically induced neoplasms of particular antigenicity [12, 15].

In the present studies we analyzed the kinetics of the immune response of BALB/c mice against a syngeneic spontaneous mammary adenocarcinoma. Moreover, we defined the interaction of humoral factors from tumor-bearing animals with the cell-mediated cytotoxicity during the tumor growth.

MATERIAL AND METHODS

Mice and tumors

Inbred BALB/c mice, 6–8 weeks old, from our colony, were used. The syngeneic tumor studied was a mammary adenocarcinoma (ADK-1t) that arose spontaneously in our BALB/c colony. It was maintained for 20 generations by serial s.c. inoculations of 1×10^6 living cells, suspended in 0.2 ml of Hanks' basal salt solution (HBSS). The injection site was palpated for the presence of a tumor every two days and growth rates were measured with a caliper. Two sarcomas (Sa I and Sa II) arisen spontaneously in our colony were used as specificity controls.

Target cell cultures

ADK-1t, Sa I and Sa II monolayers were obtained *in vitro* as previously described in detail

Accepted 28 February 1977.

[16]. After treatment of the excised tumors with a 0.25% trypsin solution supplemented with 1000 U of deoxyribonuclease/ml (DNase I, Sigma) the cells were washed twice, layered on 3 ml of Lymphoprep (Nyegaard & Co., AS., Oslo, Norway) and centrifuged at $400 \times g$ for 40 min 4°C. The cells were subcultured *in vitro* for 2–3 passages before use. The cell lines obtained were constantly tested for tumorigenicity.

One hundred percent of syngeneic animals injected s.c. with 5×10^5 cultured tumor cells developed tumors resembling the primary tumors in their growth pattern and histological characteristics.

Sera from immune and tumor-bearing mice

Different groups of tumor-bearing mice, injected with 1×10^6 ADK-1t cells, were bled on the 3rd, 5th, 8th, 10th, 13th, 15th, 21st, 26th and 34th day after the transplant. ADK-1t hyperimmune sera were obtained from BALB/c mice injected 4 times at weekly intervals with 5×10^5 tumor cells pretreated with 40 μg/ml of mitomycin C (Sigma, St. Louis, Mo., USA) for 45 min at 37°C in a humidified atmosphere of 5% CO_2 and 95% air. All the sera were heat inactivated at 56°C for 30 min and stored in separate vials at −20°C until required. They were diluted 1:5 with Eagle's MEM and filtered through 0.22 μ Millipore filters immediately before use.

Lymphocytes

Lymphocytes from normal and tumor-bearing mice were obtained from cervical, axillary and mesenteric lymph nodes, minced with forceps, and passed through a 100-gauge stainless-steel screen. The cells were washed twice in HBSS, suspended in Eagle's MEM supplemented with 15% fetal calf serum (FCS), and incubated 18 hr in tissue culture dishes (No. 3001: Falcon Plastics, Oxnard, Calif., U.S.A.) at 37°C in a humidified atmosphere of 5% CO_2 and 95% air as described by de Landazuri and Herberman [17]. Then the nonadherent cells were collected, washed twice in HBSS, and suspended in Eagle's MEM at a concentration of 15×10^6 viable cells/ml. Cellular viability (determined by Trypan blue exclusion) was greater than 90% in all experiments.

Lymphocyte cytotoxicity

The colony inhibition (CI) test was performed as described by Hellström [18]. The CI test and the complement-dependent cytotoxicity assay (see below) were performed at 37°C in a humidified atmosphere of 5% CO_2 and 95% air, using Eagle's MEM supplemented with 10% FCS. Eight hundred-thousand cultured ADK-1t, Sa I and Sa II tumor cells were seeded into each well (35 mm ϕ) of macroplates (Funke–Gerber, Munich, W. Germany). After 18 hr the medium was removed and 7.5×10^6 lymphoid cells in 0.5 ml of medium were added to the effector: target cell ratio of 10,000:1. After 45 min incubation, 2 ml of fresh medium were added. The plates were then incubated for 3 days, after which nonadhering cells were removed by repeated washing in HBSS. The cytotoxic assays testing the influence of sera from normal, immune or tumor-bearing mice on the cell-mediated immune response were performed in two ways. First, tumor target cells were incubated for 60 min at 37°C with 0.2 ml of 1:5 diluted sera and then washed twice before the addition of lymphoid cells. Second, lymphocytes (6×10^7) were incubated with 0.2 ml of 1:5 diluted sera for 60 min at 37°C, washed twice and then added to the target cells. After 3 days incubation the cells were fixed, stained with Giemsa, and the colonies were counted under low-power microscopy. Specificity controls were always performed on Sa I and Sa II target cells. Six macrowells were always set from each combination tested. The percentage of cytotoxicity obtained in the different test combinations was quantitated as follows:

$$\% \text{ destruction} = \frac{(\text{mean number of colonies in control conditions} - \text{mean number of colonies in test conditions})}{\text{mean number of colonies in control conditions}} \times 100$$

$$\% \text{ blocking} = \frac{(\% \text{ destruction with normal serum} - \% \text{ destruction with test sera})}{\% \text{ destruction with normal serum}}$$

Cytotoxic antibody test

The cytotoxic activity of sera from immune or tumor-bearing mice was assayed as described by Hellström [18] with some modifications. One hundred and fifty to two hundred cultured tumor cells in 0.2 ml of medium were distributed in 96 well microplates II (No. 3040; Falcon Plastics). After 18 hr the medium was removed and 0.1 ml of 1:5 diluted test or control sera was added.

After 45 min the sera were removed and 0.1 ml of fresh guinea pig serum as complement (C) source absorbed with mouse red cells was added

to each plate, except to the controls. The plates were reincubated 24 hr and washed twice with HBSS. Cell viability was determined by adding to each culture 0.1 ml of 1:500 dilution of fluorescein diacetate (FDA, Sigma) in HBSS [19]. After 10 min at room temperature, the FDA was removed, the wells gently rinsed 3 times and observed with a fluorescent microscope (Leitz Ortholux, Leitz, W. Germany) equipped with a vertical illuminator, BG 38 and BG 12 exciting filters and a TK 580 suppression filter. The brightly fluorescent living cells were counted and the percentage of cytotoxicity was quantitated as follows:

$$\%\ \text{cytotoxicity} = 100 - \frac{\text{number of cells in presence of test serum} + \text{C}}{\text{number of cells in presence of control serum} + \text{C}} \times 100$$

Immunofluorescence test

To perform the indirect immunofluorescence experiments viable ADK-1t cells were distributed on macroplates (Funke–Gerber).

After 24 hr of incubation to allow attachment, the cells were washed 3 times with HBSS and incubated for 30 min at 4°C with 1:5 diluted serum (5th, 10th, 21st and 34th day after the transplant). After 3 washings with HBSS solution, 0.1 ml of various dilutions of fluorescein-conjugated goat antiserum to mouse gammaglobulin (Hyland Laboratories, Los Angeles, Calif., USA) was added to each well and the cells were incubated for 30 min at 4°C. They were then washed 3 times with HBSS solution and observed with a Leitz microscope. The highest goat antiserum dilution to give fluorescence was selected as the serum titer.

RESULTS

Temporal evolution of cellular cytotoxicity

The cytotoxic response of lymphocytes removed at various times after tumor injection was tested *in vitro* against ADK-1t, Sa I and Sa II cultured target cells (Fig. 1).

A cytotoxic activity of about 25% against ADK-1t cells was first detected 5 days after tumor inoculation, when the neoplastic mass was not yet palpable, reached its maximum at 2 weeks when the mass was about 11 mm dia, and then gradually decreased to low but significant levels. By contrast, no activity was observed on Sa I and Sa II target cells.

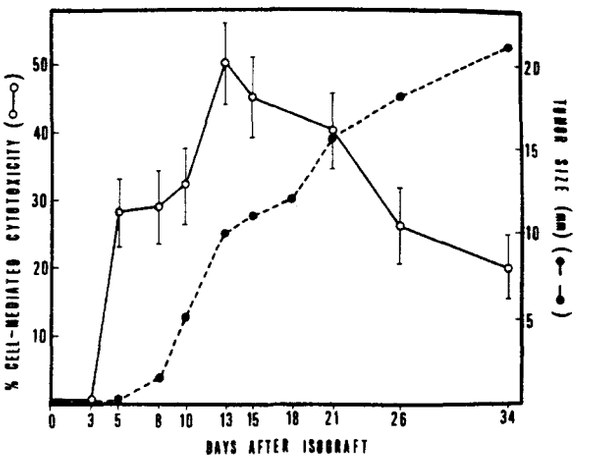

Fig. 1. Temporal evolution of cell-mediated cytotoxicity against ADK-1t cells. Lymphocytes were taken from tumor-bearing mice at progressive periods during tumor growth. Each point represents the mean of 6 separate determinations. Vertical bars: ± S.E.

Temporal development of anti-ADK-1t antibody

Sera from ADK-1t-bearing mice were collected at progressive times after tumor injection and tested for antibody activity by indirect immunofluorescence and C-dependent cytotoxicity (Fig. 2). Fluorescent antibodies against ADK-1t were first detected 10 days after challenge with a titer of 1:40. Later sera resulted in lower titers. In comparison, isoimmune serum produced fluorescence down to a dilution of 1:160. An increase of C-dependent cytotoxicity against ADK-1t cells was found at 8 days, with a tumor size of less than 3 mm dia, reached a peak of 20% two days later and decreased thereafter.

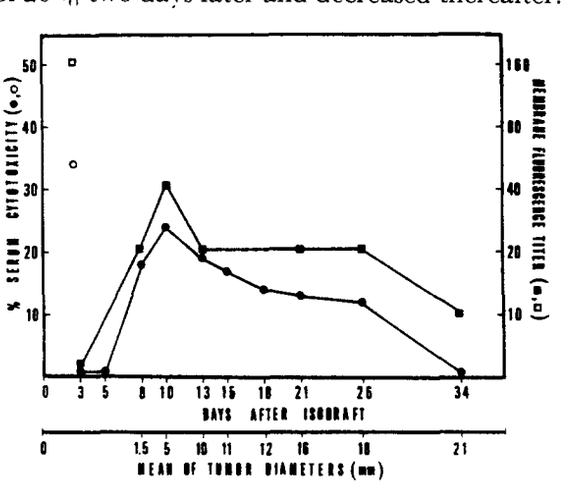

Fig. 2. Temporal evolution of complement-dependent cytotoxicity and membrane fluorescence titer of sera from ADK-1t-bearing and immune mice against ADK-1t cells. ●, ■: sera collected from tumor-bearing animals at progressive times during tumor growth and tested in presence of guinea pig complement ($P < 0.01$ from 8th to 13th day) or mouse gammaglobulin. ○, □: sera from animals immunized four times with ADK-1t mitomycin-C treated cells, tested in presence of fluorescein-conjugated goat antiserum to mouse gammaglobulin. The final dilution of all sera was 1:5. Each point represents the mean of 6 separate determinations.

A value of 34% was observed with isoimmune sera at the same dilution. In contrast, no cytotoxicity was observed on Sa I and Sa II control cells.

Temporal development of arming and potentiating activities of tumor-bearer sera

Lymphocytes from normal animals or from animals injected 2 weeks earlier with ADK-1t were added to target cells previously preincubated with different heat-inactivated sera as shown in Fig. 3. Normal lymphocytes were strongly activated when the target cells were pretreated with early sera obtained from tumor-bearing animals. This arming activity was first evident when ADK-1t cells were preincubated with sera obtained when no tumor mass was still evident, reached a peak with sera from animals bearing tumors of 2–5 mm dia, and decreased progressively during the tumor growth. Neither a potentiating nor a blocking activity was observed when cytotoxic lymphocytes were employed as effector cells. However, the preincubation of target cells with isoimmune antisera strongly armed normal lymphocytes and potentiated cytotoxic lymphocytes. The heat-inactivated sera alone did not show any cytotoxicity to target cells.

Moreover, control experiments with Sa I and Sa II target cells showed that the arming and potentiating activity of the sera were specific for ADK-1t cells only.

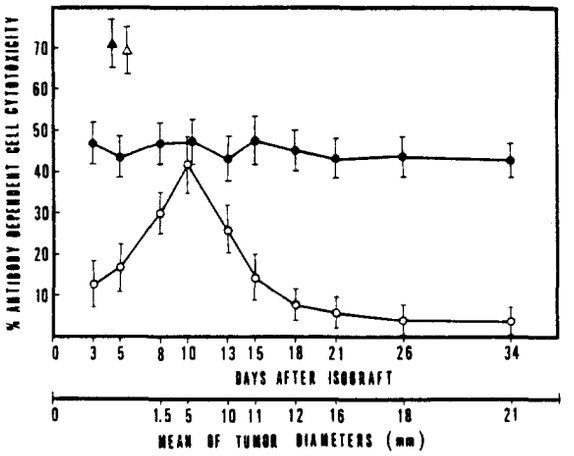

Fig. 3. Temporal evolution of arming activity of sera from ADK-1t-bearing mice against ADK-1t cells detected by CI. After preincubation of target cells with isoimmune sera and sera collected at progressive periods during tumor growth, normal or cytotoxic lymphocytes were added. ○: normal lymphocyte arming activity of sera from animals bearing progressively growing tumors. △: Normal lymphocyte arming activity of isoimmune sera. ●: cytotoxic lymphocyte activity in presence of sera from animals bearing progressively growing tumors. No potentiating or blocking effect was evident. ▲: cytotoxic lymphocyte potentiating activity of isoimmune sera. Each point represents the mean of 6 separate determinations. Vertical bars: ±S.E.

Temporal development of blocking activity of tumor-bearer sera

Immune lymphocytes from mice transplanted 2 weeks before with ADK-1t were preincubated with sera from ADK-1t-bearing mice removed at progressive periods after tumor injection and tested on untreated target cells (Fig. 4).

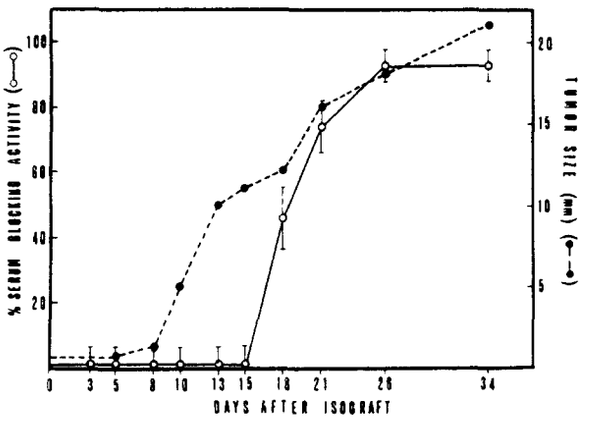

Fig. 4. Temporal evolution of blocking activity of sera from ADK-1t-bearing mice detected by CI. Cytotoxic lymphocytes were preincubated with sera collected at progressive times during tumor growth. Each point represents the mean of 6 separate determinations. Vertical bars: ±S.E.

When the immune lymphocytes were preincubated with sera from animals with tumors not yet palpable or with tumors not exceeding 10 mm dia, no blocking activity was observed. However, when the effector cells were preincubated with sera from animals with larger tumors, a sudden and rapidly increasing inhibition of cytotoxic activity was evident.

It should be noted that the serum blocking activity observed appears not to be directly related to the time factor but to the tumor size. When tumors were obtained either later or earlier than in the standard protocol by injecting different tumor cell numbers as previously described [20], the serum inhibitory activity always correlated with the tumor size and not with the time (Table 1).

Table 1. Correlation between tumor size and serum blocking activity

Number of ADK-1t cells injected	Days after injection	Tumor size (mm)	Serum blocking activity %
1×10^7	7	12±2	38±8
1×10^7	10	18±1.5	86±4
1×10^5	20	7±3	−2±5
1×10^5	29	15±3	75±7

The preincubation of normal lymphocytes with isoimmune, early or late sera did not stimulate cytotoxicity.

DISCUSSION

The ADK-1t mammary adenocarcinoma used in these studies is a tumor of moderate antigenicity [21] which presents several antigenic and structural membrane features that are not to be found in the normal cells [22, 23]. Previous work has also indicated that the growth rate of this tumor is influenced by spontaneous or artificially produced changes in the host immune reactivity, suggesting that its growth in a syngeneic host is hindered by a self-induced immunological mechanism [20].

In this host-tumor system, a marked level of cellular and humoral immunity was observed during the earlier phases of tumor growth before the appearance of a palpable neoplastic mass. Cytotoxic antibodies can be detected 8 days after the inoculation of 1×10^6 ADK-1t living cells. Similarly the cellular reactivity increased progressively and reached a peak about 2 weeks after inoculation in mice with a tumor size of 10 mm dia and then progressively decreased. It must be noted that animals with greater tumor diameters still had cytotoxic effector cells although at low, but significant, levels. These findings are in contrast to the data of Le Francois *et al.* [24] who found that cell-mediated cytotoxicity disappeared entirely after 21 days in a similar mammary tumor system. The discrepancy between our and Le Francois's findings could be ascribed to the preincubation of effector cells for 18 hr before cytotoxicity testing.

This development and decline of cellular cytotoxicity are similar to those reported in several host-tumor combinations in which a cytotoxic peak was detectable about 15 days after challenge [9, 14, 15, 25, 26, 27].

While in some host-tumor systems the evolution of cellular reactivity seems directly related to tumor size [25, 28], it is quite possible that this peak of cellular reactivity is mainly related to a general pattern of cytotoxic lymphocyte activation. In fact, a peak of cytotoxicity can be seen in several animal systems about 10 days after immunization with allogeneic or heterologous cells or with non cellular antigens [29].

In contrast, the different interfering serum activities sequentially observed in our ADK-1t-BALB/c system appear to be directly related to tumor size. A normal lymphocyte arming activity was detectable only with early sera from mice with a tumor size of 10 mm. Beyond this critical size there was a rapid decrease of the sera arming ability. At the same time a blocking activity of cytotoxic lymphocytes emerged and sharply increased. Therefore, the tumor size and not the time factor appears to be the critical determinant for the switch from the arming to the blocking activities. The appearance of the blocking activity may be related to an increase of free or antibody-complexed membrane antigens shed by growing tumors [7, 8, 30]. This may gradually become excessive and so block the arming antibody activity [31]. Relatively small variations in tumor size can therefore determine a rapid inversion of serum activity. A similar blocking activity *in vitro* within a narrow range of antigen and antibody concentrations has been reported by Baldwin [6].

The failure to affect the ADK-1t growth rate *in vivo* by passive administration of blocking serum and/or solubilized membrane antigens [32] may also be related to the use of doses lying outside a critical concentration range.

In agreement with Blair and Lane [33], the method used to demonstrate *in vitro* serum activity may well be of importance. Not a blocking but an arming activity is detectable after preincubating target cells with sera from ADK-1t-bearing mice. Otherwise, not a recruitment of normal lymphocytes but a block of cytotoxic lymphocytes is obtained after preincubating directly lymphoid cells with sera from tumor-bearing mice.

In conclusion, these data indicate that the tumor size-dependent evolution of serum activities may play a central role in modulating the magnitude of the cellular reactivity to ADK-1t detectable *in vitro* by colony inhibition technique. After an initial arming and potentiating influence the latter sera switch off the specific cytotoxicity of lymphoid cells. In contrast, the strong arming and potentiating activities of isoimmune sera appear to be an important cooperative factor *in vitro*. The ability of isoimmune sera to increase the initial host resistance and to overcome the blocking serum activity *in vivo* is presently under investigation.

Influence of Altered Lysosomal Enzyme Activities on the Regression of DMBA-Induced Rat Mammary Tumours*

R. I. NICHOLSON

Tenovus Institute for Cancer Research, Welsh National School of Medicine, Heath, Cardiff, CF4 4XX, United Kingdom

Abstract—*The activities of two lysosomal acid hydrolases and one pyridine nucleotide-linked dehydrogenase were studied in relation to the regression of the hormone dependent DMBA-induced rat mammary tumour. Tumour regression was characterized by an elevated activity of p-nitrophenylphosphatase and β-glucuronidase whereas the activity of glucose-6-phosphate dehydrogenase plus 6-phosphogluconate dehydrogenase decreased. Administration of cycloheximide to ovariectomized animals reduced [^3H]-leucine incorporation into tumour proteins, inhibited the elevated activities of the lysosomal enzymes studied and reduced the decrease in tumour mass resulting from the operation.*

INTRODUCTION

IN RECENT years there has been a great deal of evidence to indicate that lysosomal enzyme levels are increased during the processes of tissue disruption, degradation or reabsorption [1, 2]. Several reports have linked the activity of lysosomal enzymes to changes which take place during tumour regression [3–7]. The precise relationship between these parameters has not, however, been established.

The present study has examined early changes in the activity of various lysosomal enzymes during the enforced regression of dimethylbenzanthracene-induced mammary tumours under different experimental conditions.

MATERIAL AND METHODS

Animals

Mammary tumours were induced in virgin female Sprague–Dawley rats (50 ± 2 days old) by intubation with a single dose of 20 mg dimethylbenzanthracene (DMBA) in 1 ml sesame oil. Animals were housed in groups of 4 and fed diet and water *ad libitum*. After 5 weeks, the rats were palpated for tumours at weekly intervals and the size recorded as the mean of two perpendicular diameters, one measured across the greatest width. No tumour was used in experimentation which did not attain an approximate size of 20 mm mean dia in the 23-week period following carcinogen administration.

Chemicals

DMBA and cycloheximide were purchased from Sigma Chemical Company Ltd., London. [L-4,5-^{3}H] Leucine (specific radioactivity 50 Ci/mmole) was obtained from the Radiochemical Centre, Amersham, Bucks, U.K. Tissue culture media 199 was purchased from Flow Laboratories Ltd., Ayr, Scotland.

METHODS

Removal of tissue biopsies. Small biopsies of tumour tissue were removed aseptically, under ether anaesthesia using a sterile trocar.

Experimental. Four experiments were undertaken:

(i) Homogeneity of tumour samples. Fifteen samples (*ca.* 50 mg each) from a normal, growing tumour, and also from a tumour removed from a 7 day ovariectomized animal, were subjected to replicate analysis with respect to enzyme content and [^{3}H]-leucine uptake.

(ii) Effect of ovariectomy on enzyme levels. Eight tumours were biopsied daily for 5 days and then on days 7, 14 and 21 after operation. Approximately 50 mg of tissue was removed with

Accepted 17 March 1977.

*The generous financial support of the Tenovus organisation is gratefully acknowledged.

each biopsy. The biopsy removed at day 7 was sectioned and classified histologically as having characteristics indicative of either tumour growth or regression [7].

(iii) Effect of ovariectomy and cycloheximide treatment on enzyme levels and protein synthesis. Groups of animals were ovariectomized and given a single intramuscular injection of cycloheximide (0.5 mg/kg body weight, in 0.15 M NaCl) within 10 min of the operation. Control animals underwent the sham operation. Tumour tissue was biopsied at the time of the operation (prior to cycloheximide treatment) and on 5 subsequent days. Approximately 100 mg of tissue was removed with each biopsy and examined for changes in enzyme activity and [^{3}H]-leucine uptake.

(iv) Effect of ovariectomy and cycloheximide treatment on subsequent growth patterns of tumours. Groups of animals were ovariectomized and given a single intramuscular injection of cycloheximide (0.5 mg/kg body weight in 0.15 M NaCl) within 10 min of the operation. Control animals underwent the sham operation. Tumour size was measured weekly as the mean of two diameters. Biopsy samples were taken on day 7 from both groups and the tissue histologically classified as "growing" or "regressing".

Incorporation of [^{3}H]-leucine into tumour protein. Slices of mammary tumour (approximately 1 mm × 5 mm, 20 mg) were washed in 0.15 M NaCl and incubated for 4 hr at 37°C with 2 μCi [^{3}H]-leucine/ml tissue culture medium 199 (1 ml). The tissue was then washed twice in 0.15 M NaCl. All subsequent procedures were carried out at 4°C. Tissue slices were homogenized in 2 ml 50 mM Tris–HCl buffer pH 7.4, containing 1 mM EDTA, using a Sorvall-Omnimixer (5 × 15 sec at full speed with 1 min intervals. A sample of homogenate (0.5 ml) was stored at −20°C for enzyme and protein estimations and the remaining homogenate was mixed with an equal volume of a solution containing bovine serum albumin (1 mg) and leucine (0.1 mg). After 2 min, an equal volume of 10% (w/v) TCA was added. The contents of the tube were mixed and centrifuged at 1000 ***g*** for 15 min at 4°C. The pellet was separated from the supernatant and washed twice in ice-cold 5% (w/v) TCA. Washings and the original supernatant, containing TCA soluble radioactivity, were stored at 4°C. The pellet was then hydrolyzed in 0.4 M perchloric acid (PCA) (2 ml) for 60 min at 80°C, centrifuged, the supernatant collected, and the washing procedure repeated. The supernatants were combined. Aliquots (0.5 ml) of this supernatant and also of the TCA soluble fraction were added to 10 ml scintillator fluid (1 l. toluene containing 4 g, 2,5-diphenyloxazole, 0.1 g 1,4-di [2-(5-phenyloxazolyl)] benzene) and radioactivity measured using a Nuclear Chicago Mark 1 Scintillation counter. Results were expressed as counts/min/mg protein.

Enzyme assays

The procedures for the estimation of *p*-nitrophenylphosphatase and β-glucurondase activity, together with the method of protein determination, have been previously described [6]. The combined activity of glucose-6-phosphate dehydrogenase plus 6-phosphogluconate dehydrogenase was assayed at 25°C by the method of Kornberg and Horecker [8]. One unit of enzyme activity was defined as the amount of enzyme which will convert 1 μmole of substrate per min at its optimal conditions.

RESULTS

Tumour homogeneity with regard to biochemical characteristics

A major consideration in studies involving the removal of sequential samples from one tumour must be the homogeneity of the tissue with respect to the end point investigated. Analysis of acid hydrolase and pyridine nucleotide-linked dehydrogenase activities (units/g protein) in 15 tissue samples (approximately 50 mg each) removed from a growing tumour indicated that all values were within 5% of the mean. A similar analysis of a tumour removed 7 days post-ovariectomy showed an 8% variation.

Effect of ovariectomy on enzyme activities of mammary tumours

Of the 8 tumours studied, 2 were histologically classified as "growing" at day 7. These showed no variations in enzyme activity over the subsequent 21-day period (Fig. 1). Marked changes were, however, observed in the 6 "regressing" tumours. These tumours showed elevated *p*-nitrophenylphosphatase and β-glucuronidase activities, with maxima at day 5. The enzymes have been previously shown to be associated with a sedimentable fraction following differential centrifugation at 330,000 × ***g*** min and display the phenomena of structural latency [9]. These features are characteristic of lysosomal acid hydrolases in other tissues [10–12]. The non-lysosomal enzymes, glucose-6-phosphate dehydrogenase plus 6-phosphogluconate dehydrogenase slowly declined in activity over the 21 day experimental period (Fig. 1).

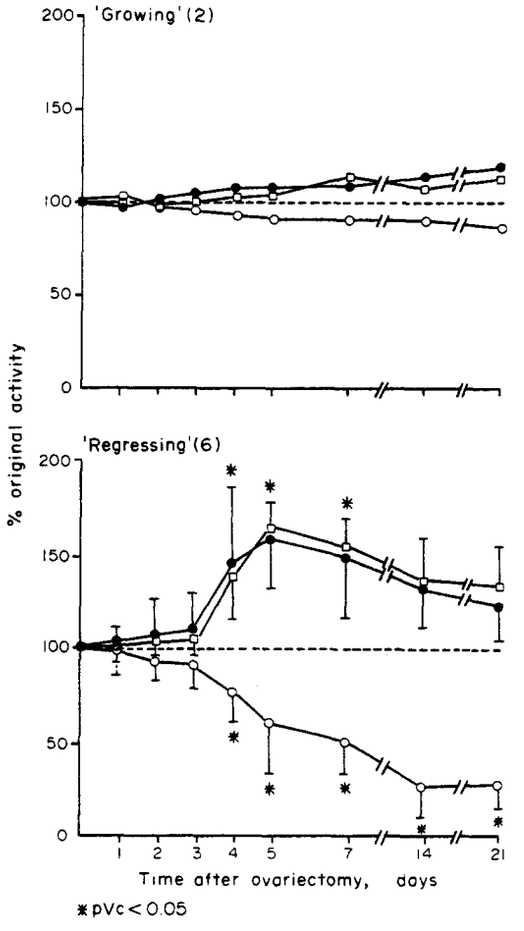

Fig. 1. Effect of ovariectomy on enzyme activities of mammary tumours. Tumour tissue was biopsied daily for 5 days *and then on* days 7, 14 *and* 21. *Tumours were classified histologically at* day 7 *as "growing" or "regressing". Results are expressed as a percentage of the original activity present within the tissue ± S.D. Activity was determined as units/g protein. Groups of animals were ovariectomized and given a single i.m. injection of cycloheximide (0.5 mg/kg *body weight) within* 10 min *of the operation. Control animals were sham operated. Tumour tissue was biopsied at the time of the operation (prior to cycloheximide treatment) and on* 5 *subsequent days. Slices of tissue were incubated with [^3H]-leucine. Results show the mean of* 5 *tumours per group and are expressed as counts/min/mg protein ± S.D. Statistics (Students 't'-test for independent means) were performed by comparison of* (i) *the incorporation data determined on* days 1–5 *with the values determined at time* 0 (*$pVc < 0.05$) *and* (ii) *the incorporation data determined on corresponding days in ovariectomized animals with and without cycloheximide* (†, $pVO < 0.05$).

Effect of ovariectomy and cycloheximide treatment on the incorporation of [^3H]-leucine into tumour protein and on enzyme levels

[^{3}H]-Leucine incorporation into DMBA-induced rat mammary tumour protein was significantly reduced in tumours by day 2 after ovariectomy (Fig. 2). The levels of protein synthesis remained low during the remaining experimental period. Cycloheximide (0.5 mg/kg body weight) administered 10 min after ovariectomy further reduced [^{3}H]-leucine uptake into tumour protein as measured on day 1 or 2. Administration of cycloheximide to sham operated animals resulted in a marked decrease in the level of protein synthesis measured on days 1 and 2. The effectiveness of cycloheximide treatment was not however maintained over the remaining experimental period when levels returned to pre-injection values. The radioactivity found in the TCA soluble fraction was unaltered by any of the treatments.

Figure 3 presents data obtained from measurements of enzyme activity in these tumours. Cycloheximide treatment inhibited the ovariectomised-induced elevation of *p*-nitrophenyphosphatase and β-glucuronidase but did not affect the decrease in glucose-6-phosphate dehydrogenase/6-phosphogluconate dehydrogenase activity. Administration of cycloheximide to sham operated animals had no appreciable effect on any of the enzymes studied.

Effect of ovariectomy and cycloheximide treatment on subsequent growth patterns of DMBA-induced mammary tumours

Administration of cycloheximide within 10 min of ovariectomy did not prevent the histologically classified [7] "regression process" observed at day 7, postovariectomy. Cycloheximide did however prevent to some degree, the reduction in tumour mass measured 3 weeks later (Fig. 4). No altered tumour growth patterns were seen following the administration of cycloheximide to intact animals.

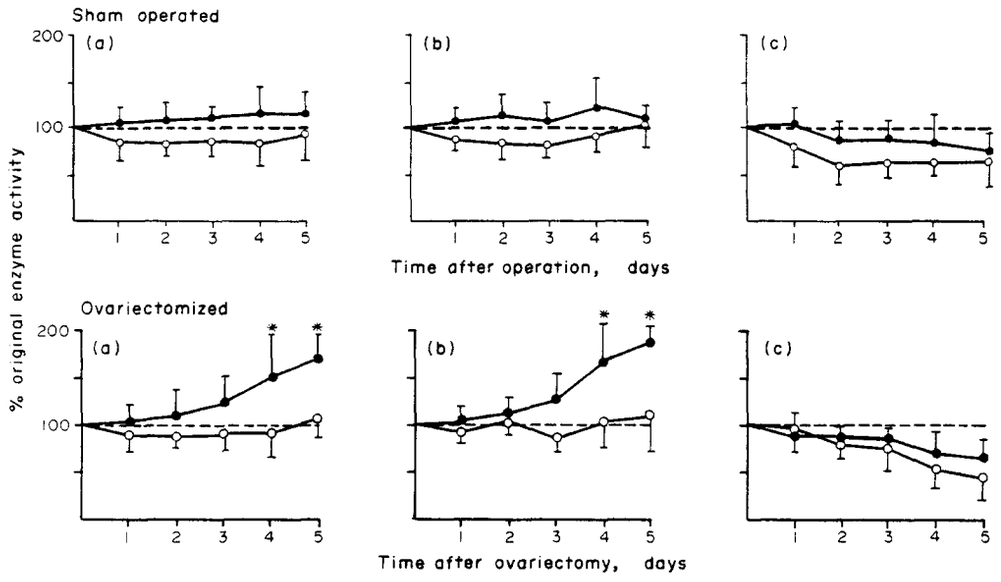

Fig. 3. Effect of ovariectomy and cycloheximide treatment on enzyme activities present within mammary tumours. Groups of animals were ovariectomized and given a single i.m. injection of cycloheximide (0.5 mg/kg *body weight*) *within* 10 min *of the operation. Control animals were sham operated. Tumour tissue was biopsied at the time of the operation (prior to cycloheximide treatment) and on* 5 *subsequent days. Approximately* 100 mg *of tissue was removed with each biopsy and portions homogenized and assayed for (a) p-nitrophenylphosphatase, (b) β-glucuronidase and (c) glucose-6-phosphate dehydrogenase plus 6-phosphogluconate dehydrogenase. DISCUSSION

One of the most important features of the DMBA-induced rat mammary carcinoma is that the majority of these tumours regress after either ovariectomy [13] or hypophysectomy [14]. The results now described clearly show that after ovariectomy the activities of the various enzymes studied in "regressing" DMBA-induced mammary tumours were found to be different from values determined in "growing" or autonomous tumours. Such enzyme assays, therefore, offer a means by which tumour regression could be monitored and reflect also the hormone dependency of the tissue. The histologically recognized "regression" in ovariectomized animals was characterized by increased specific activities for the enzymes *p*-nitrophenylphosphatase and β-glucuronidase. These enzymes showed elevated activities 5 days after ovariectomy in spite of reduced levels of protein synthesis occurring within the tumour tissue at this time. The time sequence between the increase in lysosomal enzyme activity and the regression of tumour mass would suggest that these enzymes were concerned in the process. This was further emphasized by studies with cycloheximide, an inhibitor of protein synthesis [15–17]. Administration of the inhibitor to ovariectomized animals within 10 min of the

operation, decreased [^{3}H]-leucine incorporation *in vitro* into tumour protein, inhibited the elevated activities of the lysosomal enzymes studied and reduced the decrease in tumour mass resulting from the operation. These results indicate that the processes which govern the elevation of acid hydrolase synthesis are initiated on day 1 postovariectomy and that the levels obtained relate to the regression produced. Since changes in lysosomal enzyme activity were not observed until approximately 3 days post-ovariectomy, it is possible that the triggering events are not initially directed towards acid hydrolase synthesis, rather they operate through an intermediary process.

Weekly palpatation of the hormone-dependent tumours showed that no significant decrease in tumour size occurred until the third week after ovariectomy, at which time tumour size had decreased 40%. The result is in agreement with Hilf *et al.* [18]. Recent studies by Gullino *et al.* [19–22] have failed to show any marked lysosomal enzyme activity alterations prior to changes in tumour size. They have also been unable to affect tumour regression by administration of actinomycin D, cycloheximide and puromycin [22]. In those studies, however, physical regression, to about 50% the original size, was observed after 72 hr. Clearly the results indicate considerable variations in the rates and the responses of tumour regressions to those described here. The differences may reflect the hormone environment of tumours in animals from different laboratories. Such a difference with respect to plasma prolactin concentrations has been postulated to effect the incidence of DMBA-induced mammary tumours in varying strains of rats [23].

It seems likely, from the present data, that the elevation of acid hydrolase activity involves at least some *de novo* synthesis of enzyme protein and is not totally mediated through alterations in the chemical properties of the enzymes [9]. The evidence of Lanserotti and Gullino [21] supports these results. They demonstrated that the increased activity of the lysosomal enzymes RNAase, β-glucuronidase, β-galactosidase and acid phosphatase seen during the regression of the transplantable MTW9 mammary tumour and also the DMBA-induced mammary tumour coincided with an increased quantity of enzyme as measured by a radial diffusion immunoelectrophoresis technique.

Tumour regression following ovariectomy was also characterized by an apparent decrease in the activity of enzymes related to carbohydrate metabolism. Reduced activity of the enzymes glucose-6-phosphate dehydrogenase plus 6-phosphogluconate dehydrogenase was demonstrated by day 5 postovariectomy. Unlike the lysosomal acid hydrolase response to ovariectomy where activities determined in "regressing" tissue approached normal levels after approximately 3 weeks, the pyridine nucleotide-linked dehydrogenase levels continued to decrease over the experimental period. Similar results have been observed in the DMBA-induced mammary tumour by Hilf *et al.* [18] and in the 3-methylcholanthene-induced mammary tumour by Rees and Huggins [24] following ovariectomy. Administration of cycloheximide did not prevent the decrease of the pyridine nucleotide-linked dehydrogenases caused by ovariectomy. The results may indicate therefore that lysosomal enzymes are not directly involved in the process by which the activity of these enzymes are reduced, although cathepsin B_1, an enzyme of probable lysosomal origin in the DMBA-induced tumour [25], has been shown to inactivate certain pyridine nucleotide-linked dehydrogenases [26].

Further studies are now in progress to examine more closely the role of these enzymes in the regression process of mammary tumours. It is hoped that a greater understanding of the molecular events leading to alterations in tumour mass will be useful in therapeutic approaches to human breast cancer.

Abstract—*Lymphocytes isolated from the peripheral blood of* 32 *patients with acute lymphatic leukemia (ALL),* 4 *patients with non-leukemia malignant disorders and from* 12 *normal healthy donors were studied for fluidity of membrane lipids. The degree of fluidity of cellular membranes was determined by fluorescence polarization analysis using the fluorescent probe* 1,6-*diphenyl* 1,3,5-*hexatriene (DPH), when embedded in membrane lipid region of intact cells. Based on the fluorescence polarization* (P) *analysis the degree of membrane microviscosity* ($\bar{\eta}$) *was determined. Results have shown that lymphocytes isolated from untreated ALL patients have a more fluid lipid layer in their cellular membrane (average of* 17 *patients* $\bar{\eta} = 2.65$ *poise at* 25°C) *than lymphocytes isolated from normal donors (average of* 12 *donors* $\bar{\eta} = 3.91$ *poise at* 25°C). *The results also showed that the degree of membrane lipid microviscosity of lymphocytes isolated from ALL patients in partial or complete clinical remission is similar to that of normal lymphocyte (average of* 15 *patients* $\bar{\eta} = 3.89$ *poise at* 25°C). *Lymphocytes isolated from patients with non-leukemic malignant disorders showed a similar characteristic to normal lymphocytes. These results which confirmed our previous observations with other leukemias are in line with the suggestion that fluorescence polarization analysis of DPH labelled lymphocytes can serve as a quantitative clinical tool for human acute lymphatic leukemia.*

INTRODUCTION

IT SEEMS to be generally agreed that analysis of differences in the dynamic structural organization [1, 2] of membrane components in normal and malignant cells is an important tool in the study of leukemogenesis and carcinogenesis [3–5]. Among the membrane changes that are associated with malignant transformation of normal cells, dynamic characteristics, such as the degree of mobility of membrane protein receptors [6] or the degree of fluidity of membrane lipids [7], can be quantitatively evaluated by fluorescence polarization analysis [8]. Study of these changes, therefore, can be of value for the development of quantitative methods for distinguishing between normal and malignant cells.

Previous studies have led to the development of a quantitative techniqie for the determination of the degree of fluidity of membrane lipids in normal and leukemic lymphocytes [7, 9, 10] and in normal and transformed fibroblasts [11–13], both on a population level and on a single cell level [14]. This method is based on fluorescence polarization analysis of the fluorescent probe, 1,6-diphenyl 1,3,5-hexatriene (DPH) when embedded in the hydrophobic core of membrane lipids of intact cells. With the aid of this method it has been shown that the development of leukemia both in experimental animals and humans is accompanied by a marked increase in the degree of fluidity of membrane lipids in the leukemic cells as compared to normal lymphocytes [15, 16]. The difference in the degree of lipid fluidity between normal and leukemic lymphocytes is determined to a large extent by a difference in the lipid composition of their cellular membranes [17].

The main issue of our present experiments was to determine the degree of membrane lipid fluidity of human normal and leukemic lymphocytes in order to establish a reliable and quantitative tool for the detection and prognosis of human acute lymphatic leukemia.

Accepted 5 April 1977.

MATERIAL AND METHODS

Patients. Blood samples for these studies were obtained from hospitalized patients with acute lymphatic leukemia (ALL) at the IGR and at I.C.I.G. Villejuif, France. Samples of peripheral blood were obtained from ALL patients, patients with non-leukemic malignant disorders and from normal donors, including treated and untreated cases.

Isolation of cells. Nucleated cells were isolated from the blood samples by the Ficoll–Hypaque gradient centrifugation. For isolation a Ficoll–Hypaque solution was prepared by mixing 24 ml of a 9% Ficoll-400 (Pharmacia, Sweden) solution in distilled water with 6.8 ml Hypaque sodium 50%, brand sodium diatrizoate (Winthrop Co., U.S.A.) with 3.2 ml distilled water. Fresh blood was diluted 1:1 or 1:2 with phosphate-buffered saline (PBS) (pH 7.2) and a volume of 10 ml diluted blood was layered on 3 ml of the Ficoll–Hypaque solution. The samples were centrifuged for 20 min at 500 x *g* at 25°C and the isolated lymphocytes were washed twice with PBS and diluted with PBS to the appropriate concentration. Blood samples and isolated cells were kept at 4°C.

Labelling of cells with DPH. The fluorescent hydrocarbon 1,6-diphenyl 1,3,5-hexatriene (DPH) was used in the present study as a fluorescence probe for monitoring the degree of fluidity in the cellular membrane lipids. Labelling of cells was performed with a 2×10^{-6} M DPH dispersion in PBS obtained by injection of 0.1 ml of 2×10^{-3} M DPH in tetrahydrofuran into 100 ml PBS which has been vigorously stirred. This DPH dispersion is practically clear and void of fluorescence [7]. A volume of 2 ml cell suspension in PBS at a concentration of 4×10^6 cells/ml was incubated with 2 ml DPH dispersion for 60 min at 25°C. The labelled cells were then washed twice with PBS, resuspended in PBS at a concentration of 2×10^6 cells/ml and immediately used for the fluorescence studies. Similar results were obtained when cells were labelled with a DPH dispersion where the 0.1 ml tetrahydrofuran was evaporated by nitrogen.

Fluorescence polarization analysis. The degree of lipid fluidity was quantitatively determined by fluorescence polarization, *P*, analysis of the DPH labelled cells. Experiments were carried out with the Elscint Microviscosimeter, Model MV-1 (Elscint Ltd., Haifa, Israel). Excitation was performed with a polarized 365 nm band generated from a 200 W mercury arc, and the emitted light was detected in two independent cross-polarized channels equipped with cut-off filters for wavelengths below 390 nm. The degree of fluorescence polarization, *P*, and the fluorescence anisotropy, *r*, were obtained according to the following equations:

$$P = \frac{I_v - I_h}{I_v + I_h} \qquad \text{(a)}$$

$$r = \frac{I_v - I_h}{I_v + 2I_h}, \qquad \text{(b)}$$

where I_v and I_h are the emission intensities polarized vertical and horizontal to the direction of polarization of the exciting light, respectively. High *P* values represent low lipid fluidity, whereas low *P* values represent high lipid fluidity [7]. All fluorescence measurements with DPH in the present study were carried out at 25°C. The accuracy of the *P* values obtained with the microviscosimeter was $P = \pm 0.005$. The method employed in the present study for the evaluation of membrane microviscosities is based on the fluorescence polarization properties of a fluorescence probe as described by the Perrin equation:

$$\frac{r_0}{r} = 1 + C(r)\frac{T \cdot \tau}{\bar{\eta}}, \qquad \text{(c)}$$

where *r* and r_0 are the measured and the limiting fluorescence anisotropies, T is the absolute temperature, τ is the excited state lifetime of DPH and $\bar{\eta}$ is the microviscosity of the medium where the DPH molecules are embedded [7]. High *P* values correspond to high $\bar{\eta}$ values and indicate a low lipid fluidity and vice versa. The fluorescence lifetime, τ, of DPH in human normal and leukemic lymphocytes at 25°C was 10.0 ± 0.7 nsec as determined with the aid of an Ortec photon-counting fluorescence instrument. These values are in good agreement with those described for mouse normal and leukemic lymphocytes [17].

RESULTS

The degree of fluidity of membrane lipids of cells isolated from human peripheral blood was quantitatively determined by monitoring the degree of fluorescence polarization, *P*, of DPH embedded in lipid regions of intact cells. Based on the *P* values which were obtained by a direct measurement the degree of membrane micro-

viscosity, $\bar{\eta}$ was calculated. High P or $\bar{\eta}$ values indicate a low lipid fluidity and vice versa. The present studies were carried out with cells isolated from untreated and treated acute lymphatic leukemic (ALL) patients, patients with non-leukemic malignant disorders, and normal healthy donors. The results indicate (Table 1 and Fig. 1) that blood cells isolated from untreated ALL patients or ALL patients in relapse exhibit low P values: range $P=0.224$–0.265; average $P=0.250$ (Table 1). These low P values correspond to low microviscosity, $\bar{\eta}$, values (high lipid fluidity): range $\bar{\eta}=2.00$–3.05 poise; average $\bar{\eta}=2.65$ poise. The low P and $\bar{\eta}$ values of cells isolated from untreated ALL patients increases in lymphocytes isolated from ALL patients undergoing clinical remission (Table 2 and Fig. 1). The P values of cells obtained from ALL patients in remission (no blasts in the peripheral blood and less than 5% blasts in the bone marrow) were: range $P=0.275$–0.309; average $P=0.288$ (Table 2) which correspond to the following $\bar{\eta}$ values: range $\bar{\eta}=3.37$–4.80 poise; average $\bar{\eta}=3.89$ poise (Fig. 1). These results have indicated that the mean degree of membrane lipid fluidity decreases in blood cells isolated from ALL patients undergoing clinical remission as compared to cells obtained from untreated ALL patients and from ALL patients in relapse. It is of great interest to point out that blood cells isolated from ALL patients in partial remission (more than 5% blasts in the bone marrow) exhibit membrane fluidity values in between those which are characteristic for cells isolated from untreated ALL patients and from ALL patients in complete remission (Table 1 and Table 2).

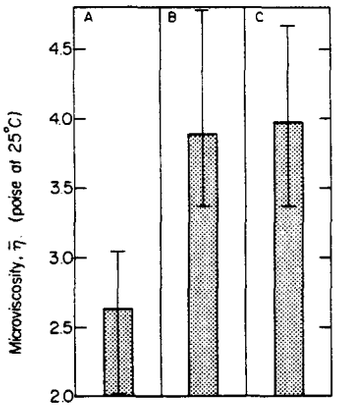

Fig. 1. The range and the average membrane microviscosity of lymphocytes isolated from the peripheral blood of: A—untreated ALL patients (Table 1); B—ALL patients in remission (Table 2); C—normal donors (Table 3) and patients with non-leukemic malignant disorders (Table 4).

Lymphocytes isolated from normal donors (Table 3) or from patients with non-leukemic malignant disorders (Table 4) exhibit P and $\bar{\eta}$ values similar to those obtained with cells isolated from ALL patients who undergo complete clinical remission. The average membrane microviscosity, $\bar{\eta}$, values were 2.65; 3.89 and 3.91 poise at 25°C for untreated ALL patients (17 patients); ALL patients in clinical remission (15 patients); and normal donors (12 donors), respectively (Fig. 1). It is of importance to notice that the upper limit of $\bar{\eta}$ values in blood cells isolated from untreated ALL patients is below the lower limit of the $\bar{\eta}$ value of lymphocytes

obtained from ALL patients in remission, normal donors and patients with non-leukemic malignant diseases (Fig. 1).

Some of the patients in the present study were followed for periods of up to 4 weeks and their cells examined on several occasions using DPH. The results summarized in Fig. 2 indicate that the degree of fluorescence polarization of DPH

obtained from different samples of blood cells from the same patient was generally in good agreement and corresponded well with the steady state of the disease.

DISCUSSION

In the present study we have employed fluorescence polarization analysis in order to establish a quantitative method for the prognosis of human acute lymphatic leukemia (ALL). The results of our studies clearly indicate that cells isolated from peripheral blood of untreated ALL patients or from ALL patients in relapse can be characterized by an increase in the degree of fluidity of the membrane lipids (decrease in membrane microviscosity) as compared to cells isolated from ALL patients undergoing clinical remission or from normal donors. These results are in line with previous studies where it has been shown that the increase in membrane lipid fluidity of leukemic cells both from experimental animals and humans is apparently mainly due to a decrease in the mole ratio of cholesterol to phospholipids in membranes of the leukemic cells as compared to normal lymphocytes [7, 9, 10, 14, 16, 17]. Further studies will include a detailed cytological analysis of the blood cells.

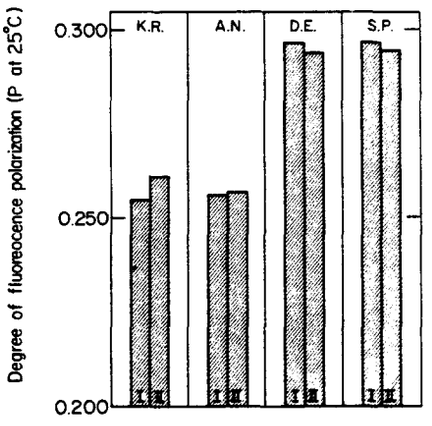

Fig. 2. Degree of fluorescence polarization, P, *of DPH labelled lymphocytes isolated at different periods (I,II) from the same patient.*

The results of previous and present studies in human leukemia indicate that one of the basic parameters that changes in leukemic cells as compared to normal lymphocytes is the lipid composition of cellular membranes, mainly the cell surface membrane [15, 17]. These changes in the lipid composition of the cell membrane determine to a large extent its dynamic behavior. The major dynamic change induced by changes in the lipid composition of the cellular lipid layers is on the fluidity/rigidity nature of the surface membrane lipid core [17]. One of the most sensitive methods now available to determine the degree of membrane lipid fluidity in mammalian cells is fluorescence polarization analysis of DPH labelled intact cells [7]. By using this method, the fluidity/rigidity behavior of cellular membrane lipids can be quantitatively monitored [7, 10, 11, 13, 14]. Based on our present results, which confirmed previous observations, it is suggested that fluorescence polarization analysis of DPH labelled normal and leukemic cells can serve as a quantitative clinical tool for the prognosis of human acute lymphatic leukemia.

Moreover, studies attempting to elucidate the biological and clinical significance of membrane lipid fluidity and of the cholesterol to phospholipids (C/PL) ratio in cellular membranes showed that the reduction of membrane fluidity of mouse leukemic cells induced by an *in vitro* introduction of exogenous cholesterol into the surface membrane resulted in a marked inhibition of their tumorigenicity *in vivo* [18, 19]. It has also been suggested that in human leukemia cholesterol, but not phospholipids, in cellular membranes is exchangeable with cholesterol in the serum lipoproteins and therefore concomitant to the cellular reduction in C/PL, the C/PL average in the blood serum of leukemic patients is below the average normal C/PL ratio [15]. Experimental evidence to support this hypothesis have been recently obtained by *in vitro* incubation of human leukemic cells in normal serum [16]. The results of these experiments have shown that there is a rapid translocation of cholesterol from the normal serum to the leukemic cells that changes the membrane fluidity from the leukemic behavior to that characteristic for normal lymphocytes [16]. Based on these observations, it is now suggested to test the possibility of whether or not increase in the C/PL molar ratio both in the blood serum of leukemic patients and in the leukemic cell membranes up to the normal C/PL ratio will result in a clinical remission. The interrelationships between membrane lipid fluidity, C/PL ratio in the cell membrane and in the blood serum and the normal and malignant behavior of human normal lymphocytes and leukemic cells is as yet hypothetical in many respects and requires further investigation. Research along some of these lines is presently being carried out by our groups.

Abstract—*From* 1963–1974, 62 *cases of malignant lymphoma were treated:* 24 *patients with Hodgkin's lymphoma (HL) and* 38 *with non-Hodgkin's lymphoma (NHL). Relapse rate in children with HD before* 1971 *(pre-laparotomy data) was significantly higher than in the group after* 1971, *when explorative laparotomy, splenectomy and more aggressive radio- and chemotherapy were applied* (10/15 *vs* 2/9). *Since* 1970 *all children with NHL were entered in a modified leukaemia protocol combining radiotherapy to the primary site, prophylactic C.N.S.-irradiation and aggressive multiple drug chemotherapy. In this group* 23/26 *patients achieved complete remission vs* 7/12 *before* 1970, *when therapy consisted of low dose irradiation to the primary site, and/or single agent chemotherapy. Median survival in the group before* 1970 *was* 5 *months compared with* 34+ *months after* 1970. *Only* 1 *patient receiving prophylactic C.N.S.-irradiation developed C.N.S.-leukaemia vs* 5/12 *in the group before* 1970.

INTRODUCTION

WITH the introduction of explorative laparotomy and splenectomy in 1969 the diagnostic approach to Hodgkin's disease changed considerably [1]. More aggressive radiotherapy in the early stages and the use of multiple drug combinations since the late 1960's have revolutionized treatment programmes [2, 3]. Whereas Hodgkin's lymphoma (HL) with its distinct histological features has a similar biological behaviour in adults and children, non-Hodgkin's lymphoma (NHL) in childhood differs from lymphomas in adults in its pattern of spread, following the course of acute lymphoblastic leukaemia. This provided the rationale for treatment programmes successful in the latter disease.

This retrospective analysis was undertaken to compare the results of different treatment programmes in children with malignant lymphoma.

Accepted 25 February 1977.

MATERIAL AND METHODS

Between 1 January, 1963 and 31 December, 1974, 62 patients with malignant lymphoma were diagnosed at Children's Hospital, University of Munich: 24 had HL and 38 had NHL.

Hodgkin's disease

Among the 24 patients 18 were male and 6 female. The youngest patient was 2 yr 6 months, the oldest 15 yr. Half of the patients were under 10 yr. Histological classification yielded lymphocytic predominance (3), nodular sclerosis (4), mixed cellularity (12), lymphocytic depletion (1), and lymphogranulomatosis without any further specification (4).

Non-Hodgkin's lymphoma

Among the 38 patients, 28 were male and nearly half of the children were under 10 years. Initially our lymphomas were classified as lymphosarcomas and reticulum cell sarcomas. Retrospective analysis using the "Kiel Classification" [4, 5] showed, that all lymphomata were of high grade malignancy. In the group before 1970 6 children had lymphoblastic and one immunoblastic lymphoma. In 5 patients a

retrospective histologic classification was not possible. In the group after 1970 18 children had lymphoblastic and 4 immunoblastic lymphoma, in 4 patients no retrospective classification could be carried out.

Clinical staging was done retrospectively, according to the staging system by Wollner *et al.* [6], which is a modification of the Ann Arbor classification [7]. None of our patients had lymphangiograms, staging laparotomy or radioactive isotope scans. Bone marrow aspirates, however, no marrow biopsies, were performed in all children. In case of bone marrow involvement, criteria for diagnosis of non-Hodgkin's lymphoma versus acute lymphoblastic leukaemia was the demonstration of either a bulky primary tumor in a nodal or an extranodal site. Since 1970 spinal taps were performed regularly at the time of diagnosis.

The distribution by stage was as follows: Stage I (8), stage II (6), stage III (10), stage IV (14).

TREATMENT

Hodgkin's disease

In 1971 explorative laparotomy and splenectomy were incorporated in the diagnostic and therapeutic programme. Before 1971 the diagnosis of abdominal involvement could only rely on physical findings and lymphangiograms. Since then the extent of disease was defined more precisely by splenectomy, liver and lymphnode biopsies. In addition radiation was changed from involved field therapy to extended field therapy, the extent depending on the pathological stage. Also single agent chemotherapy was abandoned in favour for combination chemotherapy with cyclophosphamide, vinblastine, procarbazine and prednisone.

Non-Hodgkin's lymphoma

Between January 1964 to December 1969 all patients were treated with low dose irradiation to the primary and single agent chemotherapy in most cases. No consequent maintenance therapy followed remission. Since January 1970 all children with non-Hodgkin's lymphoma, regardless of stage and histology, were entered in a modified leukaemia protocol, using intensive induction therapy with vincristine, prednisone and cyclophosphamide, concurrent with megavoltage therapy to the primary with 3000–4000 rad Co^{60}. As soon as clinical remission was obtained, C.N.S.-irradiation with 2400 rad to the cranium and intrathecal methotrexate were given in most cases. Simultaneously oral therapy with 6-mercaptopurine daily and cyclophosphamide weekly was started. After C.N.S.-prophylaxis, methotrexate p.o. was added. According to protocol $2\frac{1}{2}$ yr of chemotherapy are given.

RESULTS

Hodgkin's disease

Out of 15 children before 1971, 11 achieved complete and four partial remission. In 10 patients the disease recurred. Five children of the total group are still living in their first remission, off therapy (median 78+ months). In the group of 9 patients since 1971, 8 entered complete remission. Two children relapsed. No patient had complications which could be solely attributed to splenectomy. Also, we did not encounter a higher incidence of infections or of severe complications with aggressive therapy than in the first group without aggressive therapy.

Non-Hodgkin's lymphoma

Seven of twelve patients before 1970 achieved complete remission. Five children developed C.N.S.-leukaemia. Median survival for all patients was 5 months. No patient survived (Table 1). In the group since 1970, 23/26 patients showed complete remission. Thirteen patients (50%) are alive with no evidence of disease with a median survival of 34+ months. Eight of these children are still in their first complete remission and 5 in their second complete remission. Four children are off therapy from 22 to 48 months (Table 2). Only one patient with C.N.S.-prophylaxis developed C.N.S.-leukaemia. All patients with the primary site in the mediastinum relapsed, but one.

Table 1. Non-Hodgkin's lymphoma (NHL)—patients before 1970

Stage	Patients achieving complete remission	Patients surviving
I	2/2	0/2
II	0/0	0/0
III	2/3	0/3
IV	3/7	0/7
All patients	7/12	0/12 Median survival 5 months

DISCUSSION

In agreement with data of other centres, our patients with Hodgkin's disease were pre-

Table 2. Non-Hodgkin's lymphoma (NHL)—patients 1970

Stage	Patients achieving complete remission	Patients surviving (NED) median survival (range) in months	Patients in first remission median (range) in months

All patients	23/26	13/26 34^+ ($16 - 63^+$)	8/26

NED = no evidence of disease.
* = one lost to follow up.

dominantly male. Also mixed cellularity was the most frequent histological subgroup. Though Hodgkin's disease is rare below the age of five, it should not be omitted from differential diagnosis in this age group. At time of diagnosis 3 of our 24 patients were $2\frac{1}{2}$, 4 and $4\frac{1}{2}$ yr respectively.

Poor results in the group of patients before 1971 with only one third remaining in their first remission, led to a more aggressive approach. Staging laparotomy and splenectomy in our experience were not followed by more serious side-effects. However, it seems to be difficult to evaluate accurately whether infectious complications after splenectomy in Hodgkin's disease are due to the missing spleen, chemotherapy or to immunologic alterations inherent to the disease [8].

Though the disease is potentially curable with radiotherapy in the early stages, patients of stage I and II with unfavourable localization, histology, and systemic symptoms have a high risk of extranodal relapse ranging between 20–60% [9, 10]. Apart from these considerations rationale for chemotherapy even in early stages was based on the possibility, that microfoci below the diaphragm may be overlooked in spite of laparotomy. With this approach, the relapse rate of 10/15 patients before 1971 could be reduced to 2/9 patients after 1971. However, because of the small number of patients and the short period of observation, definite conclusions cannot be drawn.

Non-Hodgkin's lymphoma in childhood is known for its propensity to involve bone marrow and to spread to the meninges, a biological behaviour known with acute lymphoblastic leukaemia [11, 12]. Half of the patients can be expected to manifest leukaemic transformation within the first year followed by C.N.S.-disease. Thus survival rates in non-Hodgkin's lymphoma in childhood reported by several investigators in the 1960's were very discouraging [12–14].

In agreement with recent reports [15, 16] most of our patients in both groups had lymphoblastic lymphoma (24/29), which according to Lennert and the "Kiel classification" of malignant lymphomas includes acute lymphoblastic leukaemia (ALL) [4]. The small number of cases with immunoblastic lymphoma does not allow conclusions regarding the influence of histology on prognosis.

At present the best results in ALL are achieved with vincristine and prednisone induction, maintenance combination chemotherapy, and C.N.S.-prophylaxis mostly in the form of cranial irradiation and intrathecal methotrexate [17]. It consequently seems obvious to employ these principles for the treatment of all NHL in children [15, 18]. Our present results justify this aggressive approach: 88% of the patients treated in this manner achieved complete remission compared with 50% before 1970. Whereas all patients with a less aggressive treatment died, 50% of our patients in the second group are alive with no evidence of disease. These data compare favourably with results of other centres employing combined treatment programmes in childhood non-Hodgkin's lymphoma.

Total Body Irradiation in Advanced Non-Hodgkin's Lymphoma

A. Y. ROSTOM and M. J. PECKHAM

Institute of Cancer Research, The Royal Marsden Hospital, Downs Road, Sutton, Surrey, United Kingdom

Abstract—*Twenty-four patients with Stage* III *and* IV *non-Hodgkin's lymphoma were treated by total body irradiation (TBI). Complete clinical and radiological regression of disease (CR) was achieved in* 13 *patients* (54.2%). *The duration of complete remission ranged from* 3.5 *to* 26 *months (mean* 9.7 *months), including five patients disease-free at the time of reporting. On the basis of these preliminary observations a regime employing repeated courses of TBI is being evaluated.*

INTRODUCTION

RECOGNITION of the widespread nature of many forms of human malignant disease led naturally to the concept of TBI early in the history of radiation therapy. Dessauer [1] for example employed this approach within 12 yr of the discovery of X-rays. Heublein [2] designed a special unit for the purpose in which a 135 kV X-ray machine was in continuous operation. Medinger and Craver [3] treated more than 200 patients with a variety of tumours and reported responses in lymphoma patients. Systemic radiotherapy was explored and utilized in the 1940's and 1950's by Osgood [4] for the treatment of the chronic leukaemias. More recently the study of low dose rate TBI has been in progress at Oak Ridge [5]. Renewed interest in TBI for malignant lymphomas is due to the recent published work of Johnson [6–9] who has reported that small fractions of megavoltage radiation to the whole body may induce complete remissions in both lymphocytic lymphoma and chronic lymphocytic leukaemia.

This paper reports our experience with TBI in 24 patients with Stage III and IV non-Hodgkin's lymphoma.

MATERIAL AND METHODS

1. *Histological classification*

The Rappaport classification (1966) [10] was employed.

Lymphocytic lymphoma. Well-differentiated nodular—WDLN. Well differentiated diffuse—WDLD.

Lymphocytic lymphoma. Poorly differentiated nodular—PDLN; Poorly differentiated diffuse—PDLD. Mixed lymphocytic/histiocytic, nodular—NMX, diffuse—DMX. Histiocytic nodular—NH; Histiocytic diffuse—DH; Diffuse undifferentiated—DU.

2.

Staging was according to the Ann Arbor system [11].

3. *Patients*

Twenty-four patients were treated. Details of sex, age, stage and his ology are shown in Tables 1–3.

There were 11 Stage III patients and 13 Stage IV. Sixteen patients had lymphocytic lymphoma (seven nodular, seven diffuse), three patients had diffuse undifferentiated lymphoma and five nodular mixed lymphoma. Three of the Stage IV patients had extensive skin lymphoma.

4. *Patient investigation*

This included lymphography, i.v. urography, chest radiograph, marrow aspirate and trephine biopsy and liver function tests.

5. *Criterion for therapy*

Following patient assessment no therapy was instituted in cases of nodular lymphoma until there was definite evidence of tumour progression (usually nodal enlargement on the abdominal film).

6. *Treatment protocol*

Radiation therapy was covered by Allopurinol (300 mg/day) to prevent uric acid nephropathy. Three irradiation regimes were employed and these are summarized in Table 4.

Accepted 31 March 1977.

Table 1. Hemibody irradiation Cr 4/8 (Range 4.5–26 months)

Table 4. Total body irradiation protocols

1. *Total Body Irradiation* (TBI)
   Mid plan dose 150 rad given in 10 fractions over 12 days.

2. *Protracted TBI* (PTBI)
   Mid plan dose 150 rad given in 10 fractions twice weekly over 5 weeks.

3. *Hemibody Irradiation* (HBI)
   300 rad mid plan dose given to one half of the body in 10 fractions over 12 days.
   6–8 weeks later the remaining half is treated in the same way.

Patients were irradiated in the sitting position with arms crossed in front of the chest and knees flexed with tissue equivalent rubber between the legs to approximate leg thickness to that of the body. No part of the body was shielded. Because of the difference of the head and neck thickness to that of the body, the mid-plane cranial dose was 15–25% higher than that of the mid-pelvis. Doses were checked in all cases using lithium fluoride thermoluminescent dosimetry. Both sides of the body were treated at each treatment session. Six or eight MeV X-rays or ^{60}Cobalt γ-rays were used. When hemibody irradiation (HBI) was given the most affected half of the

body was irradiated first and no skin gaps were left between the upper and lower half of the body.

RESULTS

TBI was well tolerated and symptomatic side effects when they occurred were minimal. In the HBI group transient salivary gland swelling occurred in one patient, mild hair loss in three patients, subungual melanotic striae in one patient and nail fragility in one patient. White count and platelet nadirs are summarized in Fig. 1. Nadir values were reached at 4–5 weeks following the end of irradiation in the majority of patients and somewhat sooner (2–3½ weeks) for patients with bone marrow infiltration. There was little change in haemoglobin levels. As expected the most important single factor in determining the degree of neutropenia and thrombocytopenia was the initial pre-irradiation counts and it is clear that the technique may be hazardous in those patients with compromized marrow function. In two patients with positive marrows there was no evidence of infiltration after irradiation. Post-mortem examination in one and repeat bone marrow biopsy in the second failed to demonstrate lymphoma.

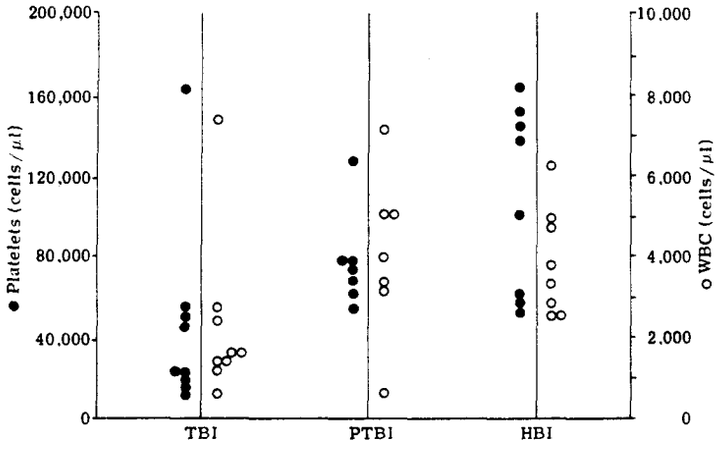

Fig. 1. Nadirs for platelets and white cells.

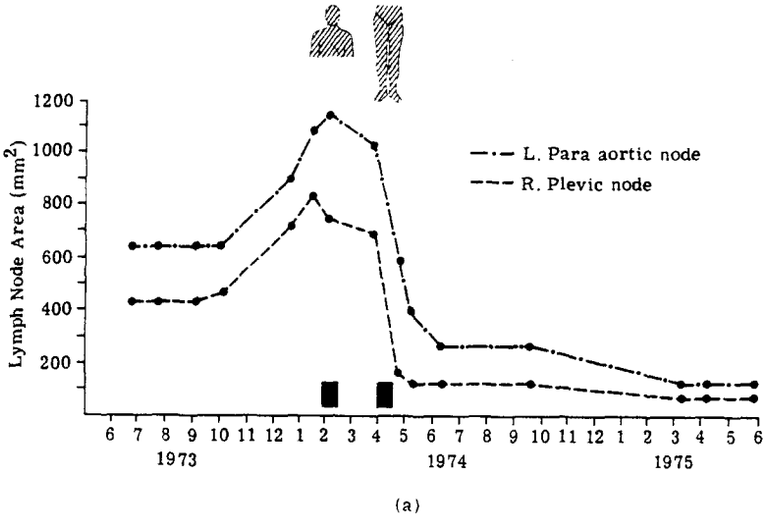
Effect on skin infiltration

Three patients had generalized skin infiltration in addition to lymph node involvement. Following TBI there was relief of pruritus and complete regression of the nodal disease in two. The majority of skin infiltrates resolved (Fig. 2), the remaining one or two patches in each patient becoming flattened and paler. One patient relapsed soon after the completion of TBI and was given systemic chemotherapy. The remaining two patients required further localized superficial irradiation to residual skin lesions; one remains in complete remission at 16.5 months.

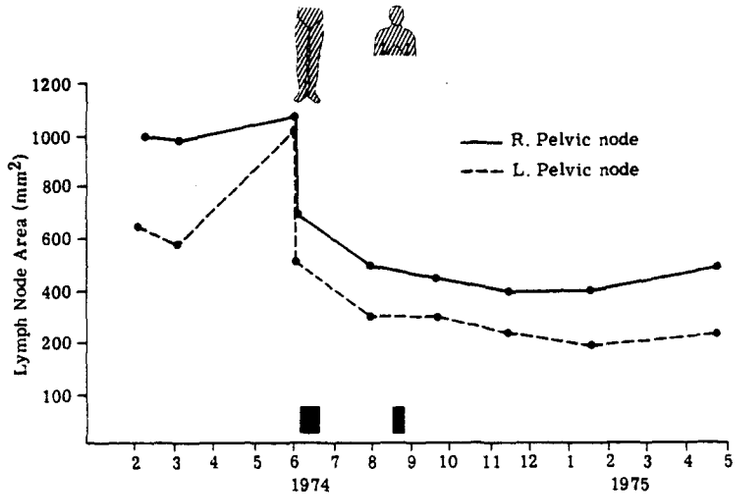
The third patient was in partial skin remission for 5.5 months following HBI. Subsequently, in relapse, one of the skin lesions was irradiated with a small local field to a total dose of 300 rad in 10 fractions over 12 days (HBI regime) with no effect. A second course of TBI was well tolerated and further regression occurred in the skin lesions. Post-mortem examination subsequently showed no evidence of bone marrow or nodal lymphoma but there was persistence of skin infiltration.

Effect on the lymph nodes

The changes in the size of involved retroperitoneal nodes opacified at lymphography were followed on sequential abdominal films by tracing the outlines of the nodes on to transparent sectional graph paper in 10 of the 24 patients. Examples of changes in nodal surface area are shown in Figs. 3 and 4. A prompt volume reduction tended to be followed by a second phase of slow regression occurring over several months (Fig. 4). An apparent abscopal effect was observed in two patients, one had complete regression of a left supraclavicular mass after the lower half of body was irradiated and in the second patient there was a reduction in size of pelvic and para-aortic nodes following upper half irradiation (Fig. 3a). Evidence of tumour progression occurring before TBI was initiated is shown in two patients with nodular lymphoma in Fig. 3 (a and b).



(a)



(b)

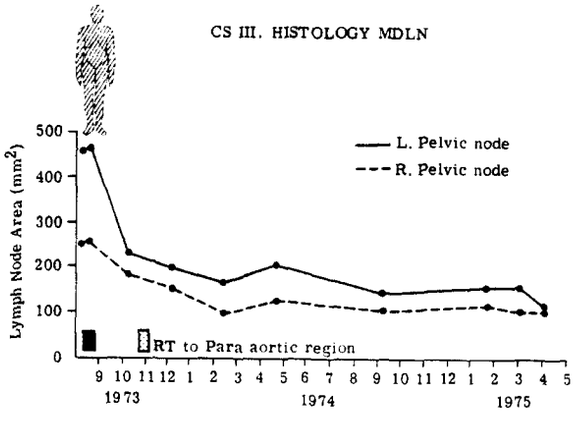

Fig. 4

Remissions

Of the 24 patients, two failed to respond to TBI. In nine of the remaining 22 patients the responses were of short duration (less than three months). In thirteen patients (54.2%) there was complete clinical and radiological regression of disease. The duration of complete remission ranged from 3.5 to 26 months with seven patients remaining in complete remission at the time of reporting (Figs. 5–7).

DISCUSSION

TBI is a simple method of treating patients with advanced non-Hodgkin's lymphoma and it is virtually unassociated with troublesome side

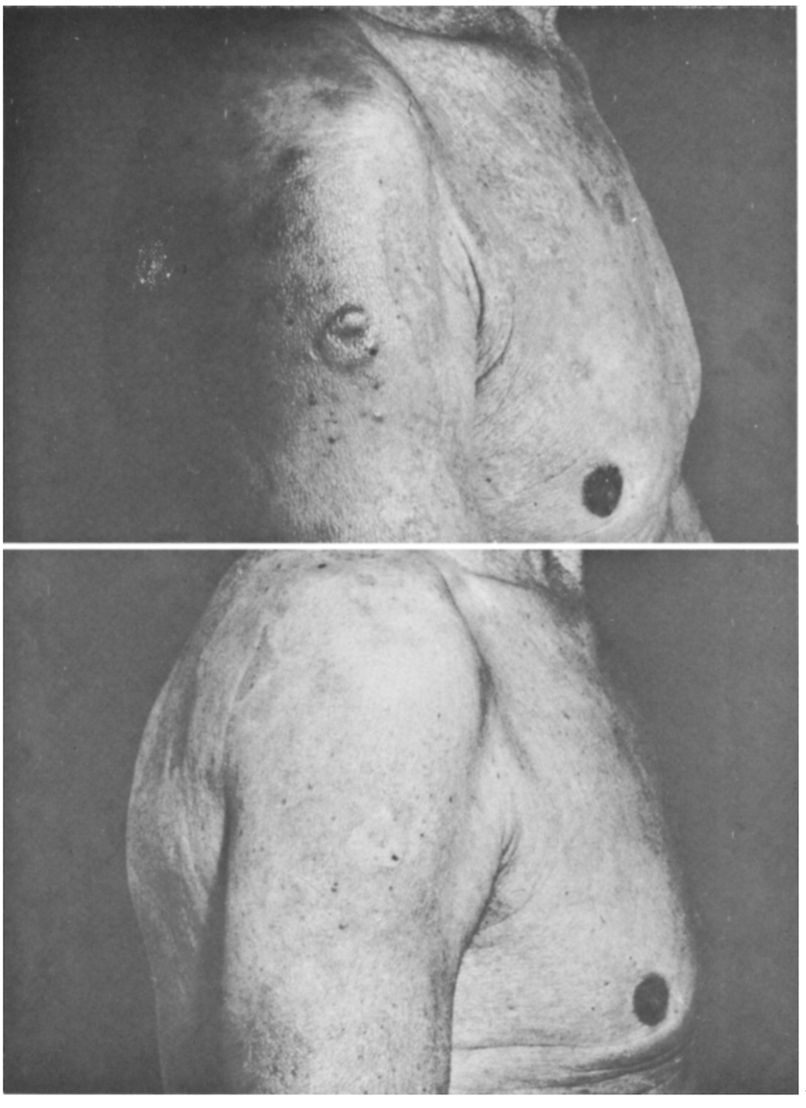

Fig. 2

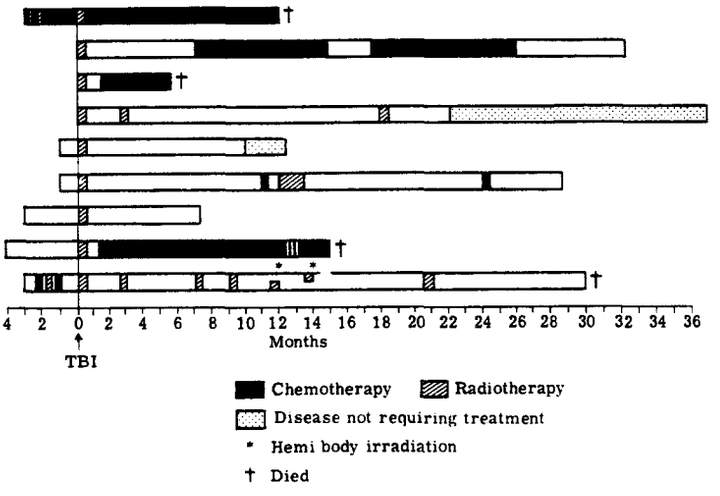

Fig. 5. *Total body irradiation.*

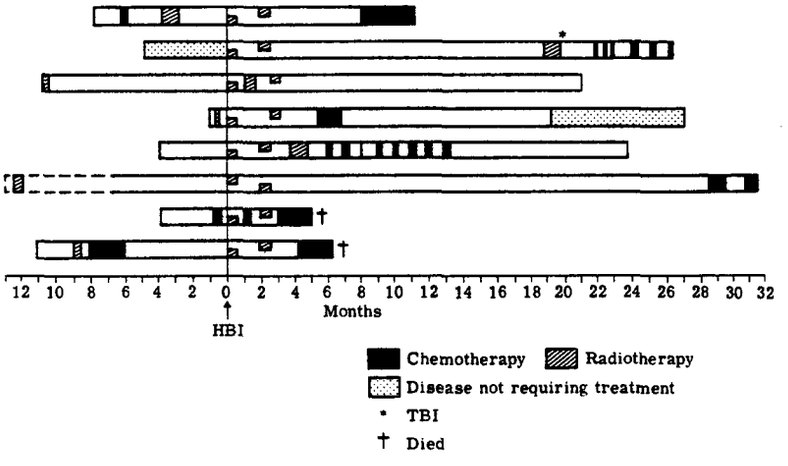

Fig. 6. *Hemi body irradiation.*

effects. The effect on the bone marrow is most pronounced in patients irradiated over a period of two weeks and is less marked when irradiation is protracted over a longer period of time or when the two halves of the body are treated sequentially, presumably because in the case of protraction bone marrow repopulation occurs between fractions and in the case of HBI the irradiated bone marrow is repopulated during the interval between the two treatments. We consider it important in patients with nodular lymphoma to observe the evolution of the tumour initially before irradiation is initiated. Adopting this approach patients with benign or slowly progressive lymphoma can be excluded. When attempting to assess the possible value of this form of low dose systemic radiotherapy it is important to bear in mind that some patients in the latter category may survive for prolonged periods with intermittent single agent chemotherapy. On the other hand the benign nature of nodular lymphoma has certainly been overstressed since 50% of patients in most series are dead by five years. Two studies have compared TBI with combination chemotherapy in lymphocytic lymphoma.

Canellos *et al.* [12] have reported the results of a randomized clinical trial comparing intensive cyclical chemotherapy (cyclophosphamide, vincristine, prednisone) and TBI in the treat-

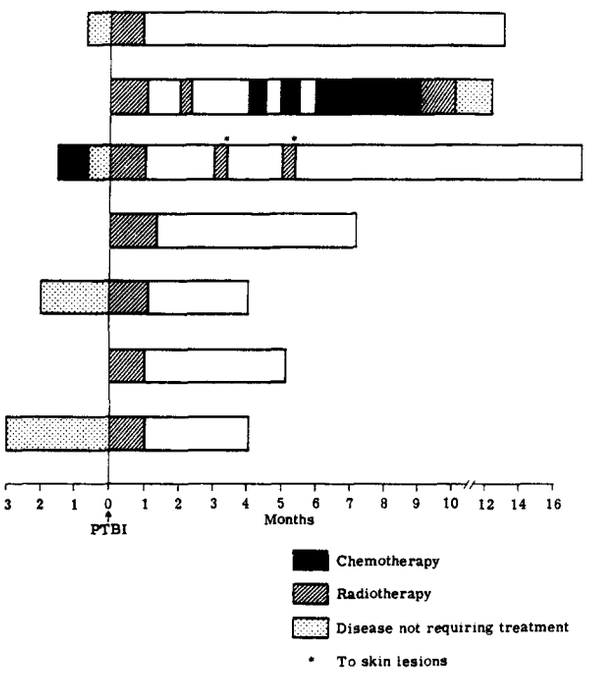

Fig. 7. Protracted total body irradiation.

ment of patients with Stage III and IV lymphocytic lymphoma. In the chemotherapy group 55% of patients achieved a complete remission compared with 56% for the irradiated group. In terms of survival there was no significant difference at three years between the two groups of patients. In a non-randomized study reported by Chaffey *et al.* [13], 80% of 25 advanced lymphocytic lymphoma patients achieved complete remission with TBI (similar to the protracted regime in the present series). In this group actual survival at two years was comparable with patients matched for age, sex and history and treated with combination chemotherapy.

The precise mechanism of action of fractionated TBI is unknown, however, there is no reason to suppose that it acts other than by a direct killing effect upon lymphoma cells since there is clearly in some patients an appreciable concomitant suppressive effect on bone marrow function. Both lymphoid cells and bone marrow stem cells show little evidence of an ability to repair damage to DNA sustained after small radiation doses. In addition to the observed marrow effects, progressive reduction in immunoglobulin levels provides evidence of an important effect of therapy on normal lymphoid function [14]. A recent experimental study demonstrates the effect of small fractions of TBI on the immune system (Davies, unpublished data).

In this experiment the clinical situation was simulated by irradiating two groups of 10 normal and 10 thymectomized CBA/Ca mice using 15 rad × 10 over 12 days to the whole body. On the third or sixtieth day following TBI, half the mice were bled and the spleen, thymus and axillary nodes were dissected and weighed. The results showed that there was up to 20% decrease in weight of the thymus and spleen at three days with slight increase of axillary lymph node weight at 60 days. Three days following TBI, leukopenia was evident in both groups, but by the sixtieth day recovery had taken place. This was more complete in the normal animals. At three days there was *ca.* 70% reduction of *T* lymphocytes which appear to be thymus independent and recovery was incomplete by the sixtieth day.

From data so far available it is clear that although a single course of TBI can produce an appreciable degree of tumour regression, relapse occurs in the majority of patients. In order to lengthen the growth delay produced by this form of treatment ways in which TBI can be integrated with chemotherapy or employed in repeated planned courses need to be explored.

It is not known whether TBI can be repeated at relatively close intervals in man. The treatment was repeated in two of our patients and produced further remissions of 2.5 and 7 months. No unexpected enhanced bone marrow toxicity was encountered. We are currently examining the feasibility of employing three courses of TBI each lasting two weeks, each course being separated by an interval of two months to allow bone marrow recovery to occur.

Abstract—*Injection of hydroxyurea (HU) resulted in degeneration after* 4 hr: *of* 94–100% *cells synthesizing DNA in small intestine crypts, of* 77% *such cells in colon epithelium and of only about* 10–15% *S-phase cells in stomach epithelium of the mouse. HU inhibited DNA synthesis in small intestine and stomach to the same extent. Thus, the ability of S-phase cells to withstand inhibition of DNA synthesis without degeneration accounts for the resistance of stomach epithelium to the cytotoxic effect of HU.*

Actinomycin D (Act D) decreased the resistance of stomach epithelium to HU. The cytotoxic effect of HU was significantly enhanced when ACT D was injected 4–16 hr *before HU. Degeneration of* 78–80% *S-phase cells in stomach epithelium was observed in these experiments. Act D injected simultaneously with HU did not increase the cytotoxic effect. Rubomycin (daunomycin) enhanced the sensitivity of stomach epithelium to HU, although to a lesser extent than did Act D.*

In animals treated with arabinosylcytosine, methotrexate, 5-fluorouracil, or phenylalanine mustard (sarcolysine) alone, the damage to colon and stomach epithelium was negligible. When Act D was injected 8 hr *before these drugs, a significant number of degenerating cells appeared in colon, but not in stomach epithelium.*

Resistance of stomach epithelium to cytotoxic effect of drugs and low sensitivity of stomach tumors to chemotherapy may have a common mechanism. The increase of cytotoxic effect of drugs by Act D or rubomycin (daunomycin) may have practical implications.

INTRODUCTION

THE TISSUE-SPECIFIC pattern of cell reaction to antitumor drugs has a significant influence on the sensitivity of tumors to chemotherapy [1, 2]. Obviously, the different sensitivity results, at least partly, from retention of some specific metabolic features of parent normal cells after malignant transformation. Therefore, some information about the mechanism of varying tumor sensitivity to chemotherapy may be obtained by studying reactions of normal tissues to chemotherapy. Also, such investigations could indicate some possibilities for increasing the tumor sensitivity.

The response of cells to inhibition of DNA synthesis is very much a function of the cell type [3]. In continuously proliferating tissues (small intestine, lymphoid tissue, tongue epithelium, erythropoietic tissue) inhibition of DNA synthesis by hydroxyurea (HU) or arabinosylcytosine (Ara-C) rapidly kill cells in the S-phase [4–7]. Cells synthesizing DNA in quiescent tissues stimulated to proliferate are resistant to the cytotoxic effect of these inhibitors.

This paper shows that cells synthesizing DNA in stomach epithelium are resistant to the damaging effect of HU, although DNA synthesis is inhibited in this tissue to the same extent as in highly sensitive epithelium of small intestine. It is estimated also that the resistance of stomach epithelium to HU can be abolished by preliminary injection of actinomycin D (Act D). This agent also enhances the sensitivity of colon epithelium to several antitumor drugs, which alone did not induce acute cell death.

MATERIAL AND METHODS

Male and female SHK albino mice were used when 7–8 weeks old. In all experiments mice received 1 μCi/g body weight of ^{3}H-thymidine (^{3}H-TDR, sp. act 20.5 Ci/mM, Moscow) injected i.p.

Accepted 26 April 1977.

HU (Calbiochem, U.S.A.), Act D (Reanal, Hungary), rubomycin (RM, antibiotic identical with daunomycin, Moscow), Ara-C (Upjohn Company, U.S.A.), methotrexate (MTX, Lederle Laboratories, U.S.A.), 5-fluorouracil (5-FU, Hoffman-LaRoche, Switzerland) and phenylalanine mustard (PAM, sarcolysine, Moscow) were dissolved in saline and administered i.p. in a volume of 10 ml/kg. The doses and schedules are indicated in the text. In all experiments the first injection was done at 10 a.m.

Mice were killed by cervical dislocation. Small intestine (a 1 cm segment beginning 1.5 cm from the pyloroduodenal junction), colon (a 1 cm segment beginning 3 cm from the anus) and stomach (dissected from the forestomach and opened along the small curvature) were removed. Tissues were fixed in Carnoy's solution and embedded in paraffin. Five μm sections were cut perpendicular to the longitudinal axis of intestine and stomach. Sections were dipped in autoradiographic emulsion (type M, Moscow), were exposed for 2 weeks and after development were stained with hemalaun–eosin.

A labeled cell was defined by the presence of at least 3 gr. The background in the autoradiographs was extremely low. Each degenerating cell counted was a round body containing condensed fragmented basophilic material, surrounded by a halo of eosinophilic cytoplasm or empty space.

The percentage of labeled degenerating cells of the whole amount of labeled cells was determined by scoring 100 degenerating and intact labeled nuclei. Degenerating non-labeled nuclei amounted to 10% or less of all degenerating nuclei and were not counted. The number of grains per cell was determined by scoring 50 labeled cells. Four mice were used in each experimental group and all data were presented as mean $\pm$ S.E.

RESULTS

Differential effect of HU on stomach and small intestine epithelium

Mice received different doses of HU 30 min after ^{3}H-TDR and the extent of cellular damage was determined in stomach and small intestine 4 hr later (Table 1). There was a significant difference in reaction of the two tissues.

Almost all cells synthesizing DNA in small intestine crypts degenerated subsequent to administration of HU in doses of 250 mg/kg or higher. This damage was a true necrogenic effect for epithelial cells and not an apparent damage resulting from destruction of intraepithelial lymphocytes. This is due to the fact that only single labeled cell or none at all, remained intact after HU. The same was observed by Farber and Baserga [6] after injection of 1500 mg/kg HU. In contrast to this, epithelial cells remained intact after administration of Ara-C [8].

Cells synthesizing DNA in stomach epithelium were resistant to the necrogenic effect of HU. Only approximately 10–15% of labeled cells degenerated after injection of 250–5000 mg/kg HU. Two doses of HU injected with a 3-hr interval also induced a weak cytotoxic effect. Thus, a 20-fold increase in the HU dose as compared to that which induced maximal damage to small intestine did not decrease the resistance of the stomach epithelium. Prolongation of HU action by administration of two doses was also ineffective.

To determine whether the observed variation

*Two injections with a 3 hr interval.
†^{3}H-TDR was injected 30 min before HU and mice were killed 4 hr after HU.
‡^{3}H-TDR was injected 1 hr after HU and 50 min later mice were killed.
0 is the number of grains corresponding to the background level.

in necrogenic effect of HU on stomach and small intestine resulted from different extent of DNA synthesis inhibition, mice received ^{3}H-TDR 1 hr after HU in different dose levels. As shown in Table 1, 10 mg/kg did not inhibit DNA synthesis, 50 mg/kg induced partial inhibition and 250 mg/kg induced complete (as seen in autoradiographs) inhibition in both tissues. Thus the extent of DNA synthesis inhibition by HU in small intestine and stomach was comparable, although the sensitivity of these tissues to necrogenic effect of HU was markedly different.

Increase in sensitivity of stomach epithelium to HU by Act D

To determine the effect of Act D on sensitivity of stomach epithelium to damage induced by HU, animals were given Act D (0.5 mg/kg) and, simultaneously or at intervals of 4, 8, 12 or 16 hr, they received HU (500 mg/kg). Table 2 shows that the percentage of degenerating labeled cells 4 hr after HU significantly increased when Act D was injected 4–16 hr before HU. Almost all degenerating nuclei were labeled. Administration of Act D simultaneously with HU did not enhance the cytotoxic effect. Degenerating cells were not observed in stomach epithelium 4–12 hr after injection of Act D alone.

Labeling index (LI) was determined as the number of labeled intact or degenerating nuclei per 100 μm length of epithelium. In these experiments ^{3}H-TDR was injected 30 min before HU, i.e., 3.5–15.5 hr after Act D. Since HU blocked the division of labeled cells, LI showed the number of cells synthesizing DNA at the time of HU injection. LI did not change in 4 hr after the administration of Act D and, thereafter, began to decrease (Table 2). Obviously, this resulted from blocking by Act D the G_1–S transition at the point 4–8 hr before start of DNA synthesis. Such an effect of Act D on forestomach squamous epithelium was described previously [9]. Obviously, a part of the G_1 period resistant to Act D (the so-called R-phase) exists both for stomach and for forestomach epithelium. These data indicate that, for both tissues, RNA synthesis (probably, ribosomal RNA), essential for DNA synthesis, terminates several hours before the beginning of the S-phase.

The decrease of resistance to the damaging effect of HU appeared 4 hr after the injection of Act D, at which time LI and, evidently, the composition of S-phase subpopulation were still unchanged. Thereafter the G_1–S transition was blocked which possibly lead to exhaustion of early S-phase cells.

To investigate the role of continuous DNA synthesis in the decrease of resistance to HU, mice were injected twice with HU, the first time simultaneously with Act D (Exp. No. 8, Table 2). ^{3}H-TDR was given 4 hr after the first injection, when partial restoration of DNA synthesis occurred. Comparison of experiments No. 4 and No. 8 shows that additional injection of HU did not change the number of degenerating cells. This indicates that continuous DNA synthesis after Act D was not necessary for enhancement of the sensitivity to HU.

Table 2. Increase in sensitivity of stomach epithelium to HU by Act D and RM (daunomycin)

Exp. No.	Drugs and schedule*	Degenerating labeled cells, %†	LI‡

*Animals were treated with 500 mg/kg HU, 0.5 mg/kg Act D and 4 mg/kg RM.

†^{3}H-TDR was injected: 30 min before HU in Exp. No. 1, 3–7, 12, 13; 30 min before second injection of HU in Exp. No. 8, and 30 min before Act D or RM in Exp. 2, 9–11. Mice were killed 4 hr after last injection of HU (Exp. 1, 3–10, 12, 13) or 4–12 hr after Act D and RM (exp. 2, 11).

‡Number of labeled nuclei per 100 μm length of epithelium.

In experiments Nos. 9 and 10, as distinct from others, ^{3}H-TDR was injected 30 min before Act D. When HU was injected twice to inhibit the exit of labeled cells from the S-phase, the number of degenerating labeled cells was high. When HU was injected 8 hr after Act D the number of degenerating cells decreased. This evidently was a consequence of exit of labeled cells from the S-phase by the time of HU injection.

To estimate the possibility that not only Act D, but also other drugs inhibiting RNA synthesis could enhance the sensitivity of stomach epithelium to HU, rubomycin (antibiotic identical with daunomycin) was used. Injection of rubomycin 8 hr before HU significantly increased the number of degenerating labeled cells, although to a lesser extent than did Act D (Table 2).

Effect of antitumor drugs on stomach and colon epithelium

On the basis of the data derived from the preceding experiments it seemed reasonable to investigate the effect of Act D on the sensitivity of epithelium to antitumor drugs other than HU.

The colon instead of the small intestine was investigated, because after injection of Act D alone cellular damage was observed in the small intestine but not in the colon. Also, PAM, 5-FU and Ara-C which alone induced negligible damage in colon led to appearance of significant number of karyorrhectic cells in small intestine. Obviously, the damage observed in small intestine resulted, at least in part, from necrosis of intraepithelial lymphocytes [8]. It may be suggested that the content of such lymphocytes in colon epithelium is much lower.

As shown in Table 3 colon epithelium was significantly more sensitive to HU than was the stomach epithelium. Thus the type of reaction to HU in colon was similar to that in small intestine as in both tissues the majority of S-phase cells degenerated.

In animals treated with Ara-C, 5-FU, PAM or MTX alone there were no or only single karyorrhectic cells in stomach and colon. When Act D was injected 8 hr before these drugs, a significant number of degenerating labeled cells appeared in colon epithelium but not in stomach epithelium (Table 3).

Thus colon epithelium appeared to be significantly more sensitive than stomach epithelium to the cytotoxic effect of drugs. Whereas sequential administration of Act D and HU was the only schedule at which a significant damage to stomach epithelium was induced, in the colon epithelium an abundance of degenerating cells appeared upon injection of HU alone or several drugs that were injected after Act D.

DISCUSSION

The mechanism of acute cell death induced in proliferating tissues by HU and other drugs does not seem to be quite clear. Prevention of acute cell death by inhibitors of protein synthesis indicates involvement of protein synthesis in this form of damage [7, 10, 11]. On the basis of these data acute cell death is considered as active reaction dependent upon new protein formation, possibly, enzyme induction [10].

The results of the present study are in agreement with this suggestion. Inhibition of RNA synthesis by Act D frequently induces an increase in the concentration (activity) of a specific protein (phenomenon of "superinduction") [12, 13]. Possibly, administration of Act D and RM lead to superinduction of a protein which is necessary for appearance of acute cell death in stomach epithelium. This effect was not specific for HU, as Act D increased the sensitivity of colon epithelium to 5-FU, MTX, PAM and Ara-C. The protective effect of

Table 3. Effect of antitumor drugs on stomach and colon epithelium

Drug	Dose mg/kg	Degenerating labeled cells, %*			
		Drug alone		Act D (0.5 mg/kg) – 8 hr – Drug	
		Stomach	Colon	Stomach	Colon
HU	500	16.2 ± 2.5	76.3 ± 4.8	77.5 ± 0.9	90.0 ± 3.8
Ara-C	50	4.2 ± 2.3	3.8 ± 1.0	18.5 ± 2.8	34.0 ± 4.3
MTX	50	0	4.3 ± 2.4	0	23.0 ± 3.9
5-FU	200	0	2.0 ± 0.9	9.2 ± 4.0	42.7 ± 1.7
PAM	4	0	0	6.3 ± 2.5	55.2 ± 10.5

*^{3}H-TDR was injected 30 min before HU, ara-C, MTX, 5-FU and PAM.

cyclohexemide also was not specific for inhibitors of DNA synthesis, as the cytotoxic effects of nitrogen mustard and X-rays also were diminished by this inhibitor [10]. Thus, Act D has an effect on some general mechanisms determining cell death.

Absence of an enhancing effect of Act D injected simultaneously with HU corresponds to superinduction as a mechanism of increase in sensitivity. Also in favour of this hypothesis is the nature of acute cell death, i.e. complete destruction of nuclei within 2–4 hr. This effect probably needs the contribution of enzyme activity.

The relation between acute cell death and loss of clonogenic activity (reproductive death), which is the most important effect of antitumor drugs, remains to be established. Obviously, not all the cells which lost clonogenic activity appeared within hours as karyorrhectic bodies. There are many examples of reproductive cell death without signs of acute cell damage. But there exist some common features between two types of cell death. Both types of cell death are prevented by cyclohexemide [10, 14]. Some parallelism exists between the sensitivity of cells to two types of damage. Human tumors of lymphatic origin are known to be highly responsive to chemotherapy [15], and normal lymphatic tissue is most sensitive to acute damage by metabolic inhibitors [3]. On the other hand, stomach tumors are resistant to almost all drugs, and normal stomach epithelium shows low sensitivity to the cytotoxic effect of drugs. Therefore, it seems possible that drug schedules which increase the sensitivity of cells to the acute damaging effect of drugs may also decrease the resistance of tumors to chemotherapeutic agents.

Glycine-N-Methyltransferase Levels in Human Breast Cancer Tissue

FRANÇOISE GUERINOT* and CLAUDE BOHUON

Laboratoire de Biologie Clinique et Expérimentale, Institut Gustave-Roussy—94800 Villejuif, France

Abstract—*The activity of glycine N methyltransferase was studied in 156 human mammary carcinomas, 24 metastatic ganglions and 46 benign breast tumors. This activity is higher than that of normal mammary tissue. The role of this enzyme in the regulation of the transfer RNA methylation in human mammary carcinoma is discussed*

INTRODUCTION

THE TRANSFER RNA methyltransferases are enzymes which modify the structure of preformed transfer RNA (t. RNA), by the insertion of methyl group into specific positions in the four main bases of t. RNA. These enzymes are species specific, organ specific and base specific. Alterations in the t. RNA methylating enzymes implicate not simply the specific activity of the enzymes, but also qualitative changes.

It was suggested that carcinogenesis was linked to a modification of the methylation of nucleic acids. In mammary carcinoma cells of a mouse strain, Turkington *et al.* [1] found 4 differences in the t. RNA methyl transferases activities when compared with normal mammary epithelial cells: the activity of the t. RNA methyltransferases in mammary carcinoma cells is higher than that of normal mammary cells, the intracellular content of t. RNA is not modified, the alterations are observed only for some enzymes such as uridine 5 methylase and often the appearance of new enzymes is associated. Borek *et al.* [2] reported hypermethylated t. RNA in tumor tissues whereas Randerath [3] described the undermethylation of t. RNA in some hepatomas: 7777 and 5123 D.

Some natural inhibitors of t. RNA methylating enzymes were found in crude extracts of adult animal tissues and they were implicated in *in vivo* regulation of these enzymes. One of them was obtained from rabbit or rat livers [4], it was resolved into 2 fractions, a high mol. wt protein and a low mol. wt compound. These two components were identified as an enzyme system which N-methylates glycine to yield sarcosine and S-adenosylhomocysteine [5]. Glycine-N-methyltransferase (GNMT) competes with the t. RNA methyltransferases, for the methyl donor, S-adenosylmethionine. The product of the reaction, S adenosylhomocysteine (the low mol. wt compound) is a potent inhibitor of the t. RNA methyltransferases.

It was suggested that this enzyme system regulates the t. RNA methyltransferases levels since an inverse relationship was shown between t. RNA methyltransferases and glycine-N-methyltransferase [6]. The levels of GNMT activity were high in adult tissues and very low in fetal and tumor tissues whose t. RNA methyltransferases exhibited elevated levels.

These studies were performed in fetal rabbit liver and hepatoma. No results about human mammary carcinoma glycine-N-methyltransferase were reported and the objective of our investigations was to determine whether this enzyme is a regulating system of the t. RNA methyltransferases which exhibited high levels in mammary tumors [7].

MATERIAL AND METHODS

Neoplastic and non neoplastic human mammary tissues were obtained during mastectomy or biopsy, and normal parenchymal mammary tissue was derived from cancer-free portions of the resected breast. Samples were trimmed of fat tissue, weighed and immediately treated for determination of glycine-N-methyltransferase.

Histopathological examination of samples pointed out their properties related to differentiation, mitoses, nuclear morphology, which reflect the degree of cancer aggressiveness (classes I, II and III).

Accepted 24 April 1977.

*Chargé de Recherches INSERM.

Tissues were homogenized in a buffer containing Tris–HCl buffer 10 mM, pH 7.4, NaCl 10 mM and $MgCl_2$ 1.5 mM. The homogenate was centrifuged successively for 10 min at 30,000 ***g*** and 60 min at 105,000 ***g***.

Glycine-N-methyltransferase was tested on the high speed supernatant (0.1 ml) according to Heady *et al.* [8]. The assay mixture contains 50 mM Tris–HCl buffer, 1 mM dithiothreitol, 12.5 μM S. adenosyl [Me–^{14}C] methionine (45 mCi/mM), 10 mM glycine, in a total volume of 0.2 ml. After incubation at 37°C for 30 min, the reaction is stopped by addition of 0.050 ml of 20% phosphotungstic acid. Non radioactive S. adenosyl methionine was added to precipitate S-adenosyl [Me–^{14}C] methionine. The reaction mixture is then made up to 1 ml with cold distilled water and is centrifuged at 30,000 ***g*** for 10 min. A 0.1 ml aliquot of the supernatant is added to 10 ml Instagel (Packard) and counted in a liquid scintillation system (Intertechnique).

A unit is the amount of enzyme which gives 1 nmole of sarcosine in 30 min. The determination of protein is performed by the method of Lowry [9].

Sarcosine was characterized by liquid chromatography with isopropanol–water-formic acid, 80–20–4, where it gave a ninhydrin positive spot.

RESULTS

Intracellular glycine-N-methyltransferase levels in tissue samples are summarized in Table 1. The average level of GNMT specific activity obtained from 156 malignant breast tissues is 455 pmole/mg protein. As it can be seen, this value is significantly higher than in normal breast tissues (the average level is 214 pmole/mg protein). Similar results were observed with metastatic ganglions. In benign tumors (proliferative dysplasias and fibroadenomas) specific activity of GNMT is in the normal range.

These last results (benign tumors GNMT differs significantly with that of malignant tissues: $P<0.001$) eliminate criticisms about the different cell populations present in different proportions in the tissues analyzed. It is known that malignant and benign tissues contain more epithelial cells than normal mammary tissues. Therefore differences observed here are bound to malignity and not to the proportion of epithelial cells.

In Table 2, results are expressed according to increasing enzymatic activity and it can be seen that distribution is statistically different between malignant and normal breast tissues, and between metastatic ganglions and benign breast tumors.

No significant relationship was found between GNMT levels and histological type of tissues.

DISCUSSION

Our results obtained in human neoplastic breast tissues appear contradictory to the idea that glycine N-methyltransferase can regulate the activity of the t. RNA methyl transferases both by competition for S-adenosylmethionine and by the generation of the inhibitory product S-adenosylhomocysteine.

This hypothesis was confirmed by Heady [6] who reported an inverse relation between t. RNA methyltransferase activity and glycine-N-methyltransferase activity which is very low in hepatomas.

In mammary carcinoma cells of the C3H mouse total t. RNA methyltransferases level was described higher than that of normal mammary cells [7], and it would be logical to have low levels of glycine-N-methyltransferase in human mammary carcinoma if this enzyme regulates the t. RNA methyltransferases in this tumor.

However, all these data were obtained *in vitro* in an artificial environment outside the regulatory controls imposed by tissue organization.

Yet, Turkington [10] described an increase of

Table 1. *Glycine-N-methyltransferase in nonneoplastic and neoplastic human mammary tissues*

Tissues	Samples	GNMT pmole mg protein/30 min	P*
Normal breast tissues	69	214 ± 37	
Benign breast tumors	46	282 ± 72	N.S.
Malignant breast tissues	156	455 ± 78	$<1.10^{-6}$
Metastatic ganglions	24	534 ± 235	$<1.10^{-4}$

The values are expressed as the mean ± S.E.M.
*Compared with normal breast tissue.

GNMT activity pmole/mg protein/30 min	Normal breast tissues	Benign breast tumors	Malignant* breast tumors	Metastatic* ganglions
0–100	20	7	11	1
101–200	20	14	17	5
201–300	8	12	38	4
301–400	14	5	36	4
401–500	3	4	14	0
501–1000	4	2	31	8
>1000	0	2	9	2

The results are expressed as the number of samples in each category.
*Significantly different from normal breast tissue (Xr test) $\alpha = 1\%$.

t. RNA synthesis and t. RNA methyltransferases activity in mouse mammary gland under the influence of hormones such as insulin, prolactin, and hydrocortisone, during pregnancy. t. RNA methyltransferase activity in rat uterus is under the dependance of oestrogens [11].

According to our results, it seems unlikely that glycine-N-methyltransferase is a regulating system for the t. RNA methyltransferases activity in human mammary carcinoma, and it is quite possible that the t. RNA methyltransferases are under the influence of hormones such as oestradiol which is known to regulate the growth of a great many breast tumors.

Enzyme Studies in Human Breast Tumours

N. DESHPANDE,* IRENE MITCHELL* and ROSEMARY MILLIS†

**Imperial Cancer Research Fund Laboratories, Lincoln's Inn Fields, London WC2A 3PX and †Hedley Atkins Unit, New Cross Hospital, London SE14 5ER, United Kingdom*

Abstract—*The activities of 7 enzymes associated with glycolysis were measured in both carcinomas and non-malignant breast tissues. The results were analysed in three different ways, i.e. according to tissue weight and enzyme/LDH and enzyme/6PGDH ratios. The following differences were observed.*

1. *The carcinomas showed higher enzyme activities than the non-malignant mammary tissues.*
2. *There were no differences between enzyme activities in primary carcinomas from patients with stage* I, II, III + IV *disease and metastatic tissue, indicating that enzyme activities in primary tumours are unrelated to the spread of the disease.*
3. *The analysis of results according to the malignancy grade of the carcinomas showed that there were no significant differences in enzyme activities between grades* I *and* II. *The grade* III *tumours showed higher activities for 6PGDH, PGM, LDH and PHI.*
4. *The enzyme patterns showed that the ratio of LDH to PFK, 6PGDH and α-GPDH were lower in carcinomas than in non-malignant tissues. Similarly, the ratio of 6PGDH to PGM and α-GPDH were also significantly lower in carcinomas.*
5. *Analyses of tumour enzyme ratios according to the stage of the disease showed no significant differences between stages* I *to* IV, *but when the same tumours were classified by malignancy grade, there was a gradual decrease in G6PDH/6PGDH and α-GPDH/6PGDH from grades* I *to* III.
6. *The significance of these findings is discussed in terms of alterations in the balance between metabolic pathways.*

INTRODUCTION

A MAJOR portion of research in human breast cancer is directed towards a search for biochemical parameters which will assist in predicting the clinical course of the disease. The studies on Morris and Novikoff hepatomas have shown that the growth rates of these animal tumours are related to the enzymes associated with carbohydrate metabolism [1]. Attempts have been made to form a similar concept for human breast tumours on the basis of similarities in enzyme patterns between these neoplasms and animal tumours whose growth rates and hormonal dependence are well established [2, 3]. It was therefore decided to test whether there is any correlation between enzyme patterns and the clinical course of the disease. This paper reports on these patterns in primary carcinomas of the breast on the basis of pathological staging and grading.

MATERIAL AND METHODS

All the chemicals used in the study were purchased from British Drug Houses Ltd. and were of analytical grade. α-GPDH, TPI, G6PDH, aldolase, NADH, $NADP^+$, ATP, F-6-P, G-6-P, 6PG and pyruvate were purchased from Boehringer Mannheim. G-1-P was purchased from Koch-Light Ltd. DHAP was prepared from the dicyclohexylammonium salt of the dimethylketal according to the manufacturer's (Boehringer Mannheim) instructions.‡

Accepted 25 April 1977.

‡The following abbreviations are used in this paper.

Enzymes

α-GPDH, α-glycerolphosphate dehydrogenase; TPI, triosephosphate isomerase; G6PDH, glucose-6-phosphate dehydrogenase; PFK, phosphofructokinase; 6PGDH, 6-phosphogluconate dehydrogenase; PGM, phosphoglucomutase; LDH, lactate dehydrogenase; PHI, phosphohexose isomerase.

Co-enzymes

NADH, reduced nicotinamide adenine dinucleotide; $NADP^+$, nicotinamide adenine dinucleotide phosphate; ATP, adenosine triphosphate.

Substrates

F-6-P, fructose-6-phosphate; G-6-P, glucose-6-phosphate; 6PG, 6-phosphogluconate; G-1-P, glucose-1-phosphate; DHAP, dihydroxyacetone phosphate.

Both malignant and non-malignant tissues were obtained from patients undergoing breast surgery. Non-malignant tissues were obtained from 17 patients with benign mammary dysplasia (BMD) and 4 undergoing reduction mammoplasty (RM) and from patients with fibroadenomas. As there were no statistically significant differences between BMD and RM in the enzyme activities the results were combined. Tissues from patients with benign mammary dysplasia included fibrocystic disease and fibroadenosis. Only involved tissues were assayed. No tissue with a marked epithelial hyperplasia was included as they were all processed for histological examination. Malignant tissue came from primary carcinomas and metastatic tumours in lymph nodes and skin. The tissues were classified by histological examination and a small piece (400 mg) adjacent to the one taken for histology was wrapped in aluminium foil, frozen on solid carbon dioxide and transferred to the laboratory where it remained frozen ($-20°C$) until further processing. Tumours were staged on pathological data according to the TNM classification [4]. The carcinomas were graded by the criteria of Bloom & Richardson [5]. This is based on the degree of tumour differentiation, the pleomorphism of nuclei, the number of hyperchromatic nuclei and mitotic figures. Grade I tumours are of lower malignancy and better differentiated than grade II tumours and grade III tumours are the most malignant.

The tissues were cleared of any surrounding fat, weighed and cut into small pieces. The semi-frozen tissues were then homogenized in a Silverson homogenizer according to the procedure of Shonk & Boxer [6]. The homogenates were centrifuged (800 ***g*** for 15 min) at 4°C, the cytosol faction was decanted off and used as a source of enzymes.

A 5% solution for malignant and 10% for non-cancerous tissues were used in these estimations. The activities of PFK, G6PDH, 6PGDH, PGM, LDH, α-GPDH and PHI were measured in all tissues. Enzyme assays were performed in a Beckman recording spectrophotometer according to the procedure of Shonk and Boxer [6] with the exception that 1 min readings were recorded automatically for 5 min and a mean of the last 4 was taken as an average change in optical density.

The results were calculated on the basis of units (U) of enzyme activity per gram wet weight of tissue. A unit is defined as that amount of enzyme which will catalyze the transformation of 1 μmole of substrate per minute. The results were analyzed in 3 different ways: as units of enzyme activity/g and as enzyme/LDH and enzyme/6PGDH ratios. They are presented as mean ± S.D. The means were tested for significance by a Student's *t*-test.

RESULTS

In this study the enzyme activities were estimated in 21 patients with BMD + RM, 24 with fibroadenomas, 125 with primary tumours and 25 from whom metastatic tumour was obtained.

The values (U/g) obtained in BMD + RM, fibroadenomas, stage I–IV cancers and metastases are shown in Table 1.

There is a significant increase in 6PGDH, LDH, PHI and a decrease in α-GPDH between BMD + RM and fibroadenomas. When values obtained for fibroadenomas were compared with stage I cancers, significantly higher values were obtained for all the enzymes in cancerous tissues. Similarly, comparison between BMD + RM and stage I carcinomas shows that, with the exception of α-GPDH, all the enzyme activities were higher in the carcinomas.

The differences between the malignant tissues were then evaluated. There were 53 patients with stage I, 49 with stage II, 23 with stages III and IV disease. No significant differences were found between stages I and II or between primary tumours from stages III + IV and metastatic tissue. When values from stage II carcinomas were compared with stages III + IV, significantly higher values were observed in the latter for PFK and PHI. Similarly when results from stage I primaries were compared with those from metastatic tissues significantly higher values were found in the metastatic tissues for G6PDH, 6PGDH and PHI.

The tumours were then separated on the basis of malignancy grade [5]. Table 2 shows the results expressed as enzyme activity per gram of tissue. There were no significant differences between grades I and II. 6PGDH and LDH activities were significantly higher in grade III compared to grade II. Similarly, higher activities for 6PGDH, PGM, LDH and PHI were observed when grade III tumours were compared with grade I.

The results shown in Table 1 for non-malignant tissues and stage I carcinomas were then re-analyzed as enzyme/LDH and enzyme/6PGDH ratios. The results which showed statistically significant differences are shown in Table 3.

Significant differences were observed between BMD + RM and fibroadenomas for both

The tumours were graded according to the classification of Bloom and Richardson (1957).
Numbers in parentheses indicate number of estimations. *P* values of less than 0.02 were taken as significant.
§Significant differences between grades II and III.
‖Significant differences between grades I and III.

α-GPDH ratios. When the results for BMD + RM and stage I cancers were compared, both ratios yielded significant differences for α-GPDH and for PGM. Only LDH ratios gave significantly different results for PFK and 6PGDH when stage I cancers were compared with either BMD + RM or fibroadenomas.

The ratios for malignant tissues were then analyzed to test for significance between stages I–IV. There was no significant difference between the stages for either the LDH or the 6PGDH ratios.

When tumours were separated according to grade, there were no significant differences for the LDH ratios. However, the 6PGDH ratios showed some differences between the grades. G6PDH ratios were significantly higher in grade II than in grade III. Similarly, the α-GPDH ratio was higher in grade I than in grade III (Table 4).

DISCUSSION

The technical problems associated with the storage, homogenization of tumours and the presentation of results have been discussed in detail in a review article by Shonk and Boxer [7]. In this study we have followed their suggestions as far as is possible. Of the parameters available, i.e. DNA, RNA, proteins, tissue wet weight and ratios of enzymes, the reviewers suggested that on balance, measurement of gram wet weight of tissue is easy and facilitates the comparison of results obtained in various laboratories. Alternatively, the use of enzyme ratios minimizes within tumour differences due to methodological variations, thus making the comparison between tumours more reliable. In this study, therefore, we have used both these parameters to analyze the results.

Comparisons between the data in this paper and that published by other workers show certain similarities. Four of the enzymes assayed by Smith, King, Meggitt and Allen [8] are also reported here but their results are expressed in terms of DNA measurements. If they are converted to enzyme/LDH ratios, they are within the range of values reported here. LDH activities in our study are significantly lower than those reported by Goldman, Kaplan and Hall [9] and PHI levels similar to those observed by others [8, 10, 11].

Hilf *et al.* [11] have reported on the activities of various enzymes in normal breast tissue, fibrocystic disease and infiltrating ductal carcinoma and found significant differences between cancerous and normal tissues. The results in Table 1 are in general agreement in that the activities in tumours are higher than those found in BMD + RM or fibroadenomas. However, our results show lower activities per gram weight for G6PDH and α-GPDH and higher values for PGM in these tissues. Furthermore, their values fluctuate within a narrow range whereas we have found considerable variations within these categories. The differences may be partially due to the methodological compromises required to enable such a number of enzyme activities to be assayed in a single tissue sample.

Lower enzyme activities on a weight basis may simply reflect differences in the cellularities of various tissues and do not necessarily show changes in enzyme patterns. However, the rise in LDH activity appears to be disproportionately high, a property which human breast carcinomas seem to share with other malignant tissues [12]. The reason for this high lactate production is not known but could be explained either on the basis of mitochondrial inability to oxidize pyruvate efficiently by way of the citric acid cycle enzymes or there is a change in the mechanism(s) regulating glycolysis. Lower α-GPDH activity coupled with high lactate production found in our study and reported by others for animal tumours [13] has resulted in the lowering of α-GPDH/LDH, which is one of the most significant metabolic differences between normal and malignant cells. This phenomenon indicates that lipids in neoplastic cells are channelled into the pathways of carbohydrate metabolism rather than fat deposition. The activity of PFK has been found to be a limiting factor in glycolysis in both HeLa cells and Ascites tumour cells [14, 15]. If the rate of glycolysis is correlated with the growth rate in human breast carcinomas, as has been demonstrated in hepatomas [1], one might expect this to be closely reflected in PFK activities. This was not borne out by the results presented here. Therefore, it would seem that, if any change does occur, it is likely to happen prior to the stage at which a benign condition requires surgical investigation. The activities of G6PDH either on a weight basis or as enzyme ratios showed no major differences between various categories of tumours suggesting that the hexose monophosphate pathway is unaffected by progression of the disease. PGM levels showed a gradual rise between BMD + RM and stage I carcinomas and when the tumours were separated according to grade, suggesting that the degree of potential malignancy may correlate with the rate of glycogen metabolism.

If the concept outlined by Hilf *et al.* [3] is valid and it is possible to employ enzyme patterns to predict the clinical course of the disease a new

and useful parameter will be available to the clinician. Therefore we have analyzed our results on the basis of currently known parameters such as stage of the disease or grade of the tumour. Our data clearly indicates that the presence or otherwise of metastases is unrelated to the enzyme patterns in primary tumours as there are no significant differences between stages I–IV. This is in agreement with the work of Silvestrini *et al.* [16] who have reported that the presence of metastases at the time of mastectomy has no effect on the proliferation rate of the primary tumour. Furthermore, the same authors [16] reported that there are no significant differences between primary tumours and involved lymph nodes with regard to proliferation rates; this was also true for the enzyme levels reported here. Thus, the spread of the disease, as measured by clinical staging, does not influence the enzyme activities in the primary tumours.

Significant differences were observed in the activities of 6PGDH, PGM, LDH and PHI when the tumours were separated on the basis of pathological grades which are representative of the potential malignancy of the neoplasm. Muir and Fawcett [10] measured PHI activities in breast tumours and reported a gradual rise from grades I to III. Our results are in agreement with their findings. However, they have reported even higher values for fibroadenomas which we are unable to confirm. When the ratios, enzymes/LDH and enzyme/6PGDH, were compared the LDH ratios showed no differences between the grades but 6PGDH ratios for both G6PDH and α-GPDH were significantly different. In particular the α-GPDH ratio showed a gradual decline as the potential malignancy of the tumour increased. Whether this represents a genuine difference in energy requirements remains to be seen.

In conclusion, analysis of data on the basis of these parameters showed some differences in enzyme activities in primary breast tumours. However, this approach in which the patients are grouped together on the basis of one parameter can only show differences when a profound change has occurred. It remains to be seen whether they correlate with either the recurrence rates or responsiveness to endocrine treatment on an individual basis.

Acknowledgements—The authors are indebted to Mr. J. L. Hayward and his staff for the supply of breast tissues and to Mrs. Diane Allen for statistical analyses of the data.

Further Studies on the Differences in Serum Dependence in EBV Negative Lymphoma Lines and Their *In Vitro* EBV Converted, Virus-Genome Carrying Sublines*

MICHAEL STEINITZ and GEORGE KLEIN

Karolinska Institute, Department of Tumor Biology, S-104 01 Stockholm 60, Sweden

Abstract—*Independently EBV-converted, viral genome carrying sublines of the originally EBV negative Ramos and BJAB lymphoma lines showed decreased serum dependence, in comparison with the progenitor lines. The virus negative lines could not grow in* 10% *dialysed FCS, unless reconstituted with the dialysate. The converted lines grew well on dialysed serum. Seeding of the EBV negative lines with larger inocula enabled them to "take off" on dialysed serum as well. The EBV converted lines were able to form colonies in soft agar, whereas the original negative lines failed to do so.*

INTRODUCTION

LYMPHOBLASTOID cell lines can be readily established by infecting cord blood lymphocytes with Epstein–Barr virus (EBV) or by explanting lymphocytes from EBV seropositive donors. EBV-carrying African Burkitt's lymphoma biopsies are also readily established as lines, known to represent the neoplastic cell itself in most cases. Lines of all these types contain EBNA and EBV–DNA. It is relatively easy to maintain EBV positive cell lines *in vitro*. In contrast, there are very few EBV negative lines with B cell characteristics. Their maintenance is far more difficult [1].

Two EBNA negative human lymphoma lines (Ramos and BJAB) have been converted to several EBV-carrying sublines by infecting them with two EBV strains (B958 and RP3HR1) [2, 3]. Briefly, P3HR1 and B958 supernatants were added to Ramos and BJAB cells, and then cultured. The cells were allowed to grow with regular feeding, and the EBNA was followed. In some of the cultures all nuclei became positive for EBNA and this characteristic was retained. Only these cultures at that stage were considered as EBV converted sublines. These lines carry EBV–DNA and EBNA [4]. They have the same HL–A antigens, membrane immunoglobulin, Fc, C3 and EBV receptors as their original EBV-negative progenitor line, although with some quantitative differences [5]. They differ markedly in their "capping" patterns [6], Con A agglutinability [7] and a variety of growth characteristics *in vitro* [1, 8]. The EBV-negative lines are very sensitive to saturation conditions. The EBV converted lines grow to a comparable cell density but instead of dying abruptly at this point, they can maintain a high concentration of living cells for a considerably longer period of time. The sensitivity of the negative lines to saturation conditions is not merely due to the exhaustion of serum factors, because addition of fresh serum had no compensatory effect.

As reported in another publication [8] the EBV negative Ramos and BJAB lines also differ from their EBV-converted derivatives in their serum dependence. The EBV carrying sublines could grow on much lower serum concentrations than their EBV-negative progenitors.

In the present work, we have made a first attempt towards the analysis of the serum factors involved.

Accepted 27 April 1977.

MATERIAL AND METHODS

Cell lines

Two EBV-negative lymphoma lines were tested, Ramos (also called Ra 1) [9] and BJAB [10], together with their EBV carrying sublines,

converted by the B958 or the P3HR1 virus strains *in vitro*, as indicated in Table 1. Cells were routinely maintained in stationary suspension cultures at 37°C, in an atmosphere of 5% CO_2 in air and 80–90% relative humidity. RPMI-1640 (Gibco) medium was used containing 10% fetal calf serum (FCS) unless otherwise mentioned, supplemented with penicillin, streptomycin and fungizone. Cells were incubated in Falcon 3012 flasks in 10 ml medium. In experiments with low serum concentration, the medium was supplemented with 10 mM N-2-hydroxyethyl piperazine-N-2-ethanesulfonic acid (Hepes). For the experiments with dialysed serum FCS was dialysed at least 3 times against a twenty fold excess of RPMI-1640. In some experiments, dialysed FCS was "reconstituted" with RPMI-1640 that has previously served as the dialysing environment in a proportion of 900:100 ml FCS. The final concentration of the added dialysate corresponded to the dialysable part of 10% FCS. Reconstitution of dialysed FCS was also performed adding an H_2O dialysate of FCS, concentrated by low pressure evaporation to the original volume of the dialysed FCS.

Cell counting

Cell number and percent viability were assessed with a Coulter Counter (Model B Coulter Electronics Inc.) and with trypan blue.

Colony formation

The cells were tested for colony forming ability in agarose, with a feeder layer. Human embryo lung fibroblasts (10^5) were seeded into microplate wells (Falcon 3040). When the fibroblasts covered the bottom of the well they were exposed to 6000 r (Siemens roentgen unit 220 kV, 15 mA, filtration 1 mm aluminium) and covered with 0.05 ml 0.45% agarose (Induboise A37, L'industrie Biologique Française S.A.) in RPMI-1640 with 20% FCS. Twenty-four hours later 0.1–0.2 ml of 0.35% agarose in RPMI-1640 with 20% FCS containing different cell numbers was layered on the top of the feeder layer. The cultures were allowed to solidify and incubated at 37°C, 5% CO_2 in air, in a high humidity box.

RESULTS

Figure 1 shows the growth of Ramos and 3 of its EBV converted sublines at different FCS concentrations. In order to keep the level of serum constituents relatively close to the initial concentration, two thirds of the medium were replaced with new medium every second day. The initial cell concentration was 0.7–1.1 $\times 10^5$/ml. Cells were sampled on day 2, 4 and 6 when the experiment was terminated. By that time the cells reached a relatively high density and it became difficult to maintain the serum component level, even by frequent change. As shown in Fig. 1, all 3 EBV converted lines grew on 0.6% serum or less whereas the EBV negative cells failed to grow on 0.6% FCS or less. Smaller but significant differences were seen in the growth of the individual converted lines at low serum concentrations. EHRB-Ramos did not grow in 0.3% RCS, compared to EHRA-Ramos and II-WA-Ramos which grew well. In another series of experiments we measured the growth of

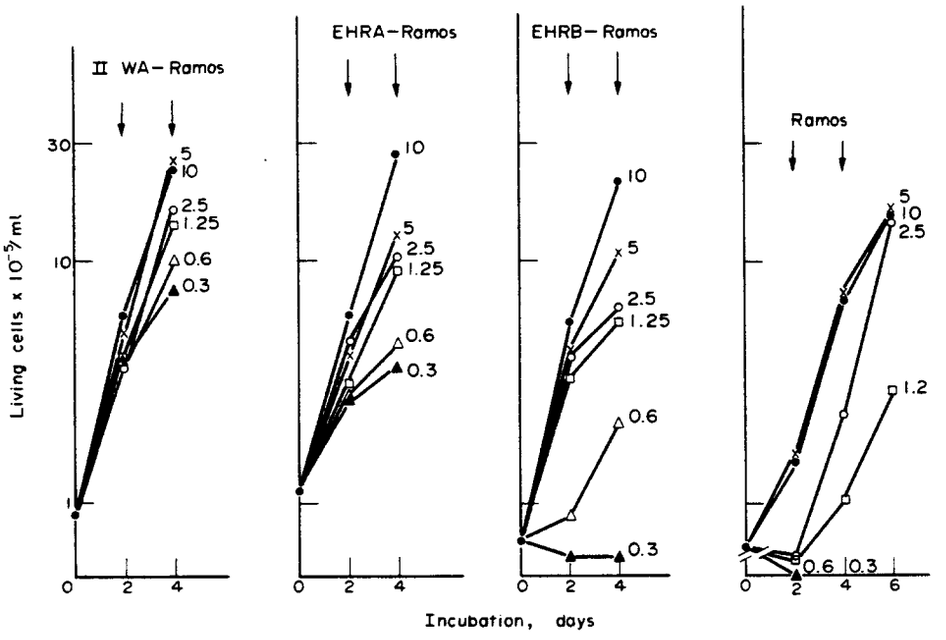

Fig. 1. Growth of Ramos and three EBV-converted Ramos sublines, II-WA-Ramos, EHRA- Ramos and EHRB-Ramos, in RPMI-1640 with 10 mM Hepes containing different concentrations of FCS. Cells were washed × 2 with PBS and then incubated in 10 ml medium at an initial concentration of 0.7–1.1 × 10^5 cells/ml. Two thirds of the medium were replaced with the corresponding fresh medium on day 2 and 4. Ramos did not grow on 0.6% FCS. The numbers to the right indicate percent FCS.

the EBV converted lines, in comparison with the original negative lines, after transfer to medium that contained serum concentrations ranging from 10 to 0.15%, but where the medium was not renewed during the experiment, in contrast to the previous series (Table 2). Growth was measured by daily cell counts and was approximately linear. All converted lines showed a decreased dependence on some serum factor(s) compared to the original Ramos and BJAB, like in the first experiment. A comparison between the two experimental designs shows that Ramos was capable of growing in 1.2% serum when the serum was regularly renewed (Fig. 1) but not in the absence of serum renewal (Table 2). Table 2 also shows that the cell numbers increased significantly in nearly all converted lines kept in 0.6 and 0.3% FCS. Ramos/B958 and Ramos/HR1K grew very well even at 0.15%. There was no systematic difference between the converted lines depending on the source of the converting virus.

*The initial cell concentration was 15–25 × 10^4 cells/ml.
†Not done.

Dulbecco and Elkington [12] described a system in which the inhibition of growth *in vitro* caused by low serum concentration could be overcome by addition of Ca-ions. In our system the growth of the negative lines in low serum concentrations did not improve by adding Ca-ions to the medium (results not shown).

The differences between the EBV-negative and positive lines could be either due to a quantitative decrease in the requirement of the converted lines for some serum factor(s) needed by the original negative line and/or to the development of complete independence from some limiting serum factor(s).

As a first approach to this problem, cell growth was compared in 10% complete with 10% dialysed FCS. Figure 2 is one out of a series of experiments in which the two negative lines failed to grow on the dialysed serum altogether but grew on dialysed serum, reconstituted with the dialysate (see Material and Methods). All EBV converted sublines grew equally well on 10% normal and dialysed FCS.

The requirement of Ramos and BJAB for dialysable serum factor(s) was not absolute. It could be obviated by raising the cell density in the initial explant (Fig. 3). With initial cell concentrations of 1.6×10^4/ml or higher, both lines could "take off" on dialysed FCS.

Figure 4 shows an experiment where 10% dialysed FCS was reconstituted with different amounts of the concentrated dialysate. Both

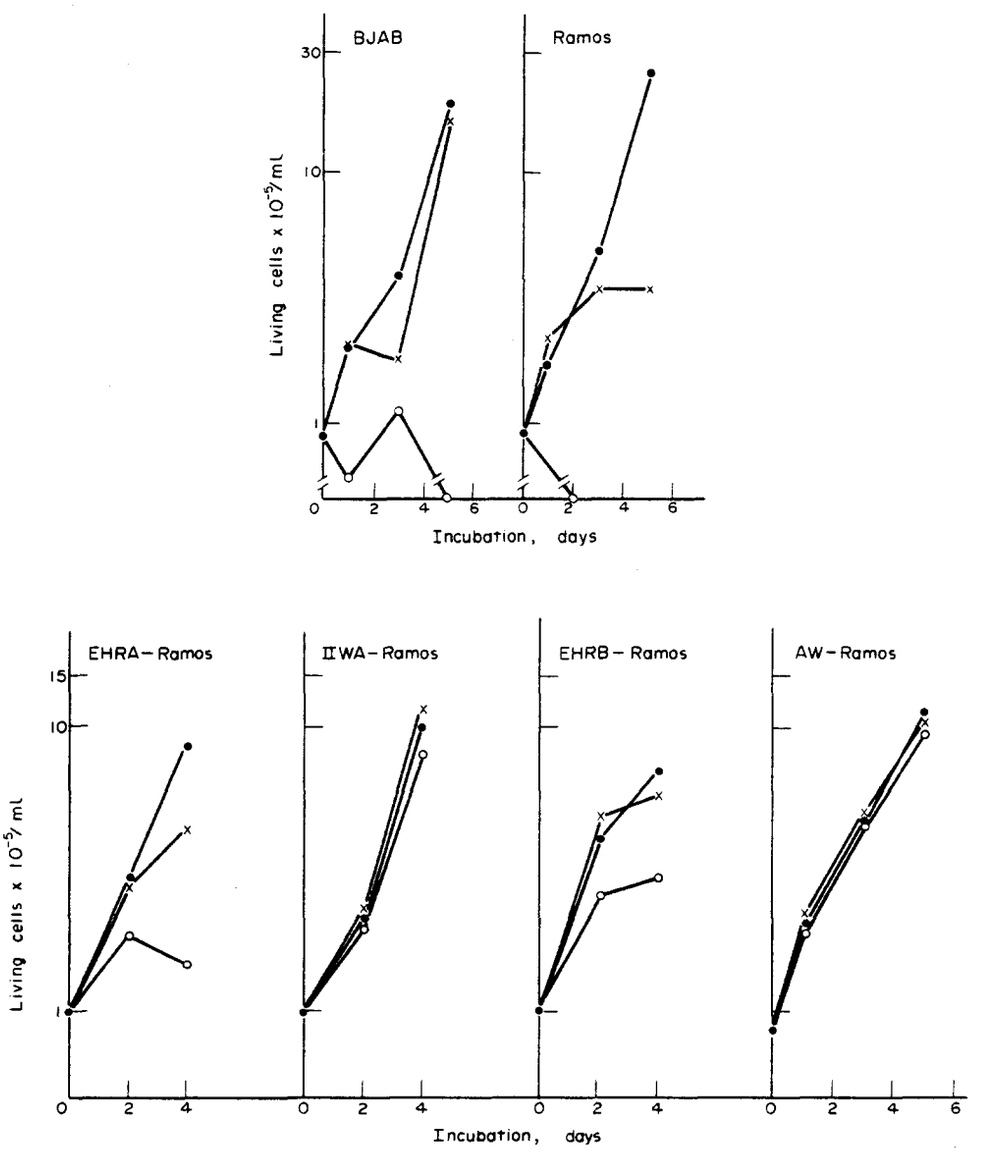

Fig. 2(A, B). Growth of Ramos, BJAB and four Ramos EBV-converted sublines in medium with 10% FCS (●——●), 10% dialysed FCS (○——○) and 10% dialysed FCS reconstituted with RPMI containing the FCS dialysate corresponding to 10% FCS (×——×).

negative lines could grow on reconstituted medium down to dialysate concentrations corresponding to 2% FCS. This is in good agreement with the serum dilution experiments presented above (compare Table 2 and Fig. 1). It is tempting to speculate that the limiting serum factors are at least partially identical in both experiments: if so, they would have to be dialysable.

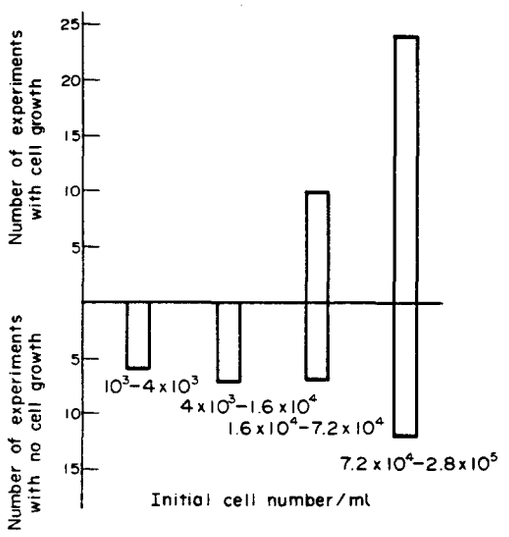

Fig. 3. The growth of Ramos and BJAB in 10% dialysed FCS in cultures inoculated with different numbers of cells. The control for each experiment shown was Ramos and BJAB cultures with 10% FCS with the corresponding cell number. All control cultures grew well. In parallel to many of the experiments exhibited, also some EBV positive cells were cultured in 10% dialysed FCS. In all these cases the cells grew well.

The cell lines were also compared for their ability to form colonies in soft agar. The negative lines did not form colonies in agarose on a human embryo lung fibroblast feeder layer. The EBV converted lines produced colonies but with different efficiencies (Table 3).

DISCUSSION

The present study confirms our previous finding [1, 8]. Conversion of two EBV negative human lymphoma lines, Ramos and BJAB leads to a decreased serum requirement. We have also shown that the negative lines are capable of growing at or slightly below the limiting serum concentration provided the serum is continuously renewed. The positive lines could grow at lower serum concentrations and even in the absence of medium renewal.

In the present paper, we also found that the two EBV negative lines differed from their converted sublines with regard to their ability to grow on dialysed 10% fetal calf serum. While the negative lines failed to grow altogether, the converted lines grew readily. The negative lines

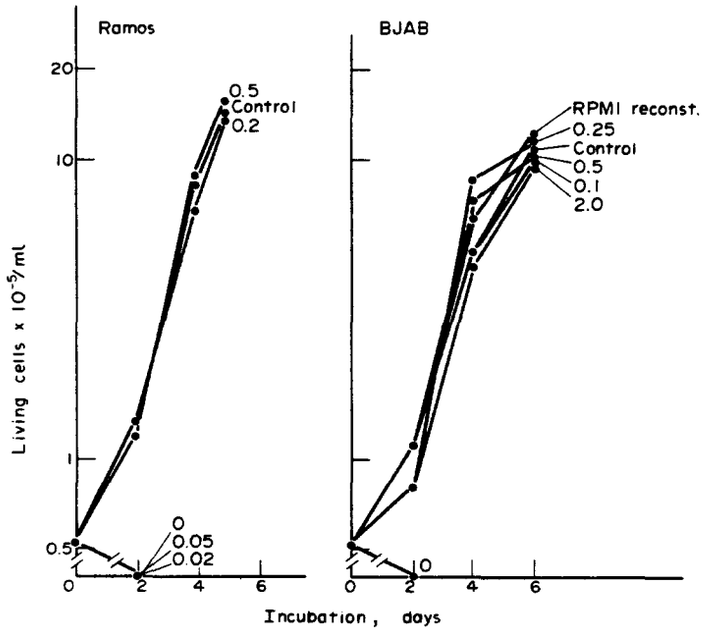

Fig. 4. Growth of Ramos and BJAB in medium with dialysed FCS and in reconstituted medium when 10% dialysed FCS was supplemented with different amounts of concentrated FCS dialysate. One ml concentrated dialysate was the dialysable equivalent of one ml serum. The numbers to the right indicate the volume of the concentrated dialysate (in ml) added per flask. "RPMI reconst." indicate the fully reconstituted medium.

Table 3. Colony formation in agarose. Cells were seeded into microplate wells containing human embryo lung fibroblasts as feeder layer. The number of colonies containing > 50 cells was scored after 8–10 days. Most of the colonies consisted of more than 100 cells

Cell line	No. of colonies			
	Initial no. of cells seeded per well			
	10^3	10^4	2×10^4	10^5
BJAB	0	0	0	0
BJAB/B958	N.D.*	120	250	N.D.
BJAB/HRIK	10	80	500	50
Ramos	0	0	0	0
EHRA-Ramos	0	60	140	N.D.

*N.D. = not done.

were able to grow on "reconstituted" medium, consisting of dialysed serum and the reintroduced, concentrated dialysate.

To some extent, the inability of the negative lines to grow on dialysed serum could be overcome by increasing the size of the inoculum.

In all likelihood, these changes were brought about by the EBV-conversion. The EBV positive sublines were selected on different occasions, by teams of investigators at two laboratories [3, 9]. Moreover, the same changes were found after EBV-conversion of two unrelated EBV negative lines. All this decreases the likelihood that the differences could have been due to some accidental event in connection with the selection procedure, rather than conversion to a viral genome positive status as such. The EBV associated changes are reminiscent of the decreased serum requirements characteristic for virus transformed monolayer cultures, derived from e.g. 3T3 or BHK-cells. The phenomenon was demonstrated after transformation with both DNA viruses (e.g. polyoma or SV40) and RNA viruses (e.g. RSV) [13, 14]. Like in the present case, the original line was already "immortalized" and aneuploid, and was changed further by the viral transformation. Conceivably, viral transformation may decrease the dependence of the cells on some serum factor(s). Holley [15] suggested that transformation leads to a membrane change that alters the interaction of necessary growth factors with membrane constituents. He visualized a change in the affinity or quality of relevant membrane receptors. Using partly the same EBV negative and converted lines as in the present study, Yefenof and Klein [6] previously showed that EBV conversion has led to certain changes in membrane behavior. This was expressed in a reduced ability of surface IgM and other membrane receptors to move in their lateral plane, as reflected in a reduced rapidity to redistribute and "cap" after contact with the appropriate ligand.

The differences between the EBV negative and positive lines with regard to their ability to grow in dialysed FCS suggested that the negative lines are dependent on some low molecular serum constituents. The recent demonstration [16] that small quantities of certain hormones may obviate the serum dependence of several lines warrants a search in that direction.

A further possibly EBV related difference between EBV negative and converted positive lines was restricted by the inability of the former to form colonies in soft agar, in contrast to the latter. This suggests a decreased dependence of the positive lines on some cell derived factors, capable to "condition" the medium.

Radioimmunoassay for Epstein–Barr Virus (EBV)-associated Nuclear Antigen (EBNA). Binding of Iodinated Antibodies to Antigen Immobilized in Polyacrylamide Gel*

GOTTFRIED DÖLKEN† and GEORGE KLEIN

Department of Tumor Biology, Karolinska Institutet, S-104 01 Stockholm, Sweden

Abstract—*A solid-phase radioimmunoassay was developed for the EBV-associated nuclear antigen (EBNA). Total homogenates of EBV-DNA and EBNA positive or negative cells were polymerized in polyacrylamide gel and compared for their ability to bind ^{125}I–IgG prepared from anti-EBNA positive and anti-EBNA negative sera. EBNA specific binding was demonstrated and confirmed by serological and cellular specificity controls. The assay allows the quantitation of antigen or antibody even in the presence of detergents and is suitable for biochemical characterization of the antigen. Reciprocal blocking studies with extracts from different cell lines showed quantitative and qualitative differences. One part of the EBNA specificiti(es) present in the human Burkitt lymphoma derived lines RAJI, DAUDI and AW-RAMOS was lacking in B95-8, a marmoset line carrying EBV derived from a human infectious mononucleosis line. This result may reflect differences in the viral genomes derived from Burkitt lymphoma and infectious mononucleosis lines or differences in the host cells.*

INTRODUCTION

B LYMPHOCYTES of human or simian origin can be transformed ("immortalized") by Epstein–Barr virus (EBV). The EBV genome present in these transformed cells convey on them the ability to grow and proliferate indefinitely *in vitro* [1, 2]. Under certain conditions EBV genome negative B lymphoma lines can be established as well [3, 4]. All EBV carrying cells, irrespective of their virus producer or nonproducer status, are characterized by the presence of EBV-associated nuclear antigen (EBNA, [5]). This antigen is of special interest since it may play a role in the maintenance of the immortalized state and/or the nonproducer status of the virus-DNA carrying, proliferating cell.

Several assays have been developed for the detection of a complement-fixing antigen in EBV transformed lymphoblastoid cells. An EBV-determined soluble complement-fixing antigen (CF-S) has been demonstrated in cell free extracts prepared from EBV genome carrying nonproducer cell lines [6–9]. Subsequently, a nuclear antigen (EBNA) was detected by anti-complementary immunofluorescence in fixed cells of EBV carrying lymphoblastoid lines and Burkitt lymphoma and nasopharyngeal carcinoma biopsy cells [5, 10–12]. There is suggestive evidence that CF-S and EBNA are closely related if not identical [13–15].

Previously a radioimmunometric assay was developed for EBNA, based on the direct and indirect binding of ^{125}I–IgG from polyvalent anti-EBV positive human sera, to nuclei prepared from nonproducer, EBNA positive cells or frozen–thawed cells [16, 17]. A certain quantitation of antigen and antibody became possible. Isolated nuclei or frozen–thawed cells as antigenic targets preclude the use of detergents or high salt concentrations in blocking assays aiming at antigen quantification. This is a serious limitation in experiments that require efficient antigen extraction and solubilization.

†Present address: Medizinische Universitätsklinik, Hugstetter Str. 55, D-78 Freiburg, Germany.

This paper describes a radioimmunoassay for EBNA based on the immobilization of EBNA positive cells in a polyacrylamide gel matrix, EBNA is then quantitated by reaction with ^{125}I–IgG prepared from a polyvalent anti-EBV positive human serum.

MATERIAL AND METHODS

Chemicals

Carrier free Na^{125}I was obtained from the Radiochemical Centre Amersham, Bucks., England. Acrylamide, N,N'-methylene-bis-acrylamide (BIS) and N,N,N',N'-tetramethylethylenediamine (TEMED) were obtained from Kodak Co., Rochester, U.S.A.

Cell lines

The cell lines (Table 1; [3, 4, 18–23]) were grown in RPMI 1640 medium supplemented with 100 μg/ml streptomycin, 100 i.u./ml penicillin, 5 μg/ml fungizone and 10% heat inactivated foetal bovine serum.

Table 1. Properties of the cell lines used in this study

*Low levels of EA positive cells (<0.1%) are found in RAJI cultures by autoradiography with iodine-labelled IgG from anti-EA positive sera [23].

Preparation of ^{125}I-labelled IgG

IgG was prepared from human sera by ammonium sulphate fractionation and chromatography on DEAE–sephadex A 50. Labelling of 50 μg of IgG with 1 mCi carrier free ^{125}Iodine was carried out using the chloramine T method described by Hunter and Greenwood [24]. The concentration of the labelled IgG was 10 μg/ml, the specific radioactivity was about 1×10^4 counts/min per ng protein. The labelled IgG was stored at 4°C in 0.02 M phosphate pH 7.2, 0.2% bovine serum albumin and 0.01% sodium azide.

Extraction procedure

Cells were harvested by centrifugation at 4°C, washed, resuspended in 0.02 M Tris/HCl pH 7.6, 0.15 M NaCl, 1.5 mM $MgCl_2$ at approximately 10^8 cells per ml and stored frozen at −79°C. The standard extraction procedure included three cycles of freezing and thawing (−79°/+37°C), homogenization with a Dounce homogenizer (9 strokes with a tight fitting pestle) and sonication in a MSE ultrasonic power unit at maximum power setting (1.5 A) for four 10-sec intervals. This homogenate was used for the preparation of immobilized antigen by polymerization in polyacrylamide gel. Alternatively, the homogenate was treated for 30 min at 4°C with 1% NP 40 (Nonidet P 40) prior to polymerization. In blocking assays with antigen containing extracts, the 100,000 × *g* (1 hr) supernatant fractions were used.

Preparation of immobilized antigen

Insoluble antigen was prepared by photopolymerization of cell homogenates within polyacrylamide gel using a modification of the method described by Carrel and Barandun [25]. Homogenate (0.8 ml) was mixed with 100 μl calf serum, 100 μl riboflavin (3 mg/ml), 5 ml 7.5% acrylamide containing 2.5% BIS and 2μl TEMED. After 1 hr at room temperature, the gel was homogenized with a loose fitting Dounce homogenizer and washed with 0.05 M Tris/HCl pH 7.5, 0.15 M NaCl until the supernatant became clear and the OD 280 was less than 0.05. In the case of NP 40 treated homogenates, the homogenized gel was washed with the same buffer containing 0.5% NP 40. More than 90% of the protein was incorporated in the gel matrix as determined by the Lowry method [26]. The gel suspension was stored at 4°C in the presence of 0.1% sodium azide.

Radioimmunoassay for EBNA

The homogenized gel was used as antigen

containing target material in a radioimmunoassay. In direct binding tests, 0.2 ml of packed gel suspended in 1 ml 0.05 M Tris/HCl pH 7.4, 0.15 M NaCl supplemented with 50% heat inactivated calf serum were incubated with ^{125}I–IgG (10–50 ng) prepared from a polyvalent anti-EBV positive serum "Adala" and an anti-EBV negative serum "BA". The mixtures were rotated overnight in the cold. Radioactivity bound to the gel was determined by crystal scintillation gamma counting after 4 washings with 0.05 M Tris/HCl pH 7.4, 0.15 M NaCl containing 20% calf serum. Blocking tests were performed either by preincubating the gel with various sera of known anti-EBV titers (Table 2; [27–31]) for 8 hr before adding ^{125}I–IgG "Adala" or by preincubating the iodinated IgG with 100,000 × ***g*** supernatant fractions from the cell homogenates of EBNA positive or negative cells for 8 hr prior to the addition of 1 ml gel suspension. Specific binding was defined as the difference between the binding of ^{125}I–IgG "Adala" and ^{125}I–IgG "BA". Blocking indices were calculated as follows:

$$BI = \frac{\text{specific binding from IgG "Adala"} - \text{specific binding from IgG "Adala" after preincubation with serum or extract}}{\text{specific binding from IgG "Adala"}}$$

KCC No. = Kenya Cancer Centre number of serum donor.
BL = Burkitt lymphoma.
NPC = Nasopharyngeal carcinoma.
HP = Healthy person, anti-EBV positive.
NC = Anti-EBV negative control.
VCA = Viral capsid antigen.
EA = Early antigen, D and R = subcomponents [27].
EBNA = EBV-associated nuclear antigen.
MA = Membrane antigen, BI = blocking index against FITC-Mutua [28, 29].
N.T. = Not tested.

The anti-VCA, anti-EA and anti-EBNA titers of the sera were determined by Henle and Henle, Philadelphia, in the course of previous collaborative studies (30, 31, Svedmyr, Jondal, Henle and Klein. To be published).

RESULTS

^{125}I–IgG binding to EBNA containing polyacrylamide gel (PAG)

Total homogenates of EBV-DNA and EBNA positive nonproducer cells (NAMALWA, AW-Ramos) and EBV negative cells (MOLT 4, Ramos) were photopolymerized in PAG. The homogenized gel was used in a direct binding assay with ^{125}I–IgG prepared from an anti-EBNA positive serum "Adala" and from a negative control serum "BA". Figure 1 illustrates a typical experiment. The gels containing EBNA positive cell homogenates showed specific

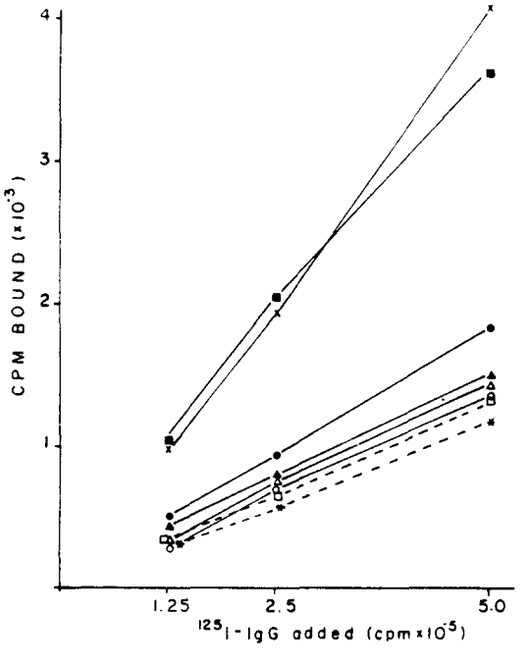

*Fig. 1. Binding of ^{125}I–IgG from anti-EBNA positive "Adala" and anti-EBNA negative "BA" serum to homogenized PAG containing homogenates of EBNA positive (AW-Ramos, Namalwa) and EBNA negative cells (Molt 4, Ramos), resp. Ramos (●—● Adala, ○—○ BA), Molt 4 (▲—▲ Adala, △—△ BA); Namalwa (■—■ Adala, □—□ BA), AW-Ramos (× —× Adala, *—* BA).*

binding of ^{125}I–IgG "Adala", in contrast to EBNA negative controls. The binding of ^{125}I–IgG "Adala" is apparently due to EBNA. detected even after cell homogenization and PAG-immobilization. The sensitivity of this assay permits EBNA to be determined with homogenates prepared from as few as $1-2\times10^6$ cells. The binding of iodinated IgG to EBNA is linear with increasing amounts of IgG added. This indicates that the antigen content of the homogenized gel is not limiting under the experimental conditions. This is of special importance for the interpretation of the results shown in Fig. 2. These data demonstrate the

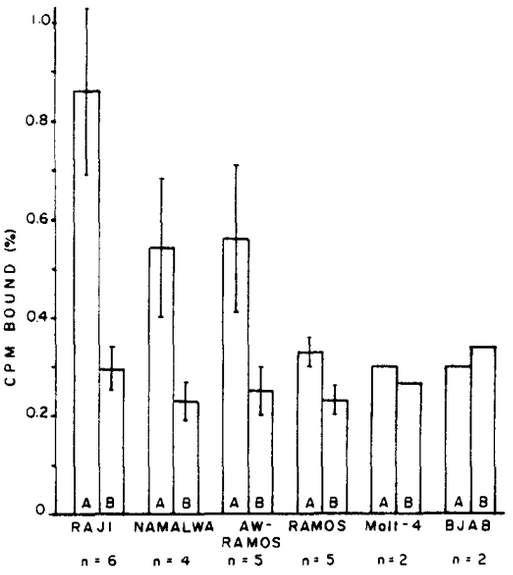

Fig. 2. Comparison of anti-EBNA positive ^{125}I–IgG "Adala" (A) and anti-EBNA negative ^{125}I–IgG "BA" (B) binding to EBV genome negative and positive cell homogenates polymerized in PAG. The standard deviations are indicated. Counts/min bound (%) were calculated from experiments as shown in Fig. 1.

EBNA specificity of the assay. The binding of iodinated IgG to PAG-homogenates prepared from NAMALWA or AW-Ramos was nearly identical, whereas the binding to RAJI-PAG was higher. The mean specificity ratios, i.e. counts/min bound from "Adala" divided by the counts/min bound from "BA", were 2.92 ± 0.44 (RAJI), 2.27 ± 0.44 (AW-Ramos) and 2.36 ±0.33 (NAMALWA). By using an autoradiographic method and ^{125}I–IgG of anti-EA positive sera, Moar *et al.* [23] recently showed that RAJI cells express EA in a low proportion ($<0.1\%$), whereas NAMALWA and AW-Ramos were completely negative for EA. It is conceivable that the assay described here detects both EBNA and low levels of EA in RAJI cells. It is also evident from Fig. 1 that the specific antibody concentration in the ^{125}I–IgG preparation is limiting under the conditions of the test. Therefore, an increased binding of ^{125}I–IgG "Adala" to RAJI-PAG compared to NAMALWA or AW-Ramos-PAG does not indicate a quantitative difference in a single antigenic specificity, but rather a qualitative difference, i.e. the existence of more antigenic specificities.

The 3 EBV-genome negative cells bound the EBV positive and negative reagents to nearly the same extent. The binding of ^{125}I–IgG "Adala" to the EBV genome negative PAG-homogenates was significantly lower than the binding to the corresponding EBNA positive target.

Blocking of ^{125}I–IgG binding by anti-EBV positive and negative sera

To check the EBNA specificity of the assay, blocking tests were carried out with a battery of sera with known anti-EBV antibody levels (Table 2). Figure 3 shows the blocking indices in the radioimmunoassay, plotted against the anti-EBNA, anti-EA and anti-VCA titers, respectively. There was a good correlation between the anti-EBNA titer and the blocking

Fig. 3. Correlation between the anti-EBNA, anti-EA and anti-VCA titers of sera (10 µl undiluted serum) with known anti-EBV reactivity (Table 2) and their ability to block the radioimmunoassay. PAG-homogenates of AW-Ramos (A, B, C) and Raji cells (D, E, F) were used as targets. (●) anti-EBV positive sera of healthy donors; (×) Burkitt lymphoma or nasopharyngeal carcinoma patients; (○) early infectious mononucleosis patients; (■) anti-EBV negative sera.

activity with AW-Ramos and RAJI-PAG homogenates, whereas there was no significant correlation between blocking and the anti-EA or anti-VCA titers. Anti-EBNA positive sera of healthy donors and tumor patients blocked the binding of ^{125}I–IgG "Adala" to the AW-Ramos antigen preparation in direct relation to their anti-EBNA titers, whereas the anti-EBNA negative but anti-EA and -VCA positive sera of IM patients did not block or showed only a slight inhibition. Similar results were obtained with the RAJI preparation, with the exception that IM sera gave a partial blocking. This may be related to the elevated anti-EA antibodies in these sera, together with the presence of small amounts of EA in RAJI, but not in AW-Ramos cells. However, there was no overall correlation between the blocking and anti-EA or anti-VCA titers in the total material, also suggesting that EBNA is the dominating antigen detected in RAJI. In a control experiment (Fig. 4), the binding of ^{125}I–IgG "Adala" to Ramos homogenate immobilized in PAG was not significantly lowered by preincubation with the same sera.

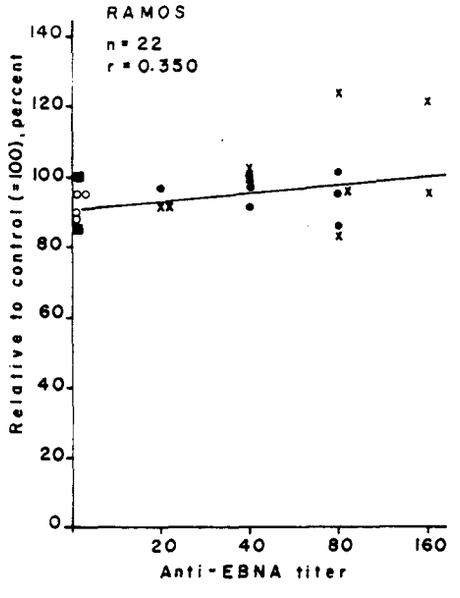

Fig. 4. Influence of preincubation of Ramos-PAG-homogenate with sera (10 µl undiluted serum) with different anti-EBNA titers on the binding of ^{125}I–IgG "Adala". The radioactivity bound to the gel is expressed as the percentage of a control incubation with ^{125}I–IgG "Adala" alone (= 100%). For symbols see Fig. 3.

Inhibition of ^{125}I–IgG binding by cell extracts

The specificity of the assay was also checked by inhibition tests with extracts from a variety of EBV genome carrying and negative lines. The test system offers the possibility to measure the amount of the relevant antigen even in the presence of detergents. Cross-inhibition tests may allow the dissection of qualitative differences. Figure 5 shows the data obtained in an experiment with 100,000 × *g* supernatants of NP 40 treated cell homogenates. RAJI and AW-Ramos extracts inhibited the binding of ^{125}I–IgG "Adala" to AW-Ramos PAG-homogenate nearly completely, whereas the EBNA negative BJAB extract had no effect. This suggests that AW-Ramos and RAJI contain identical or largely cross-reactive EBNA.

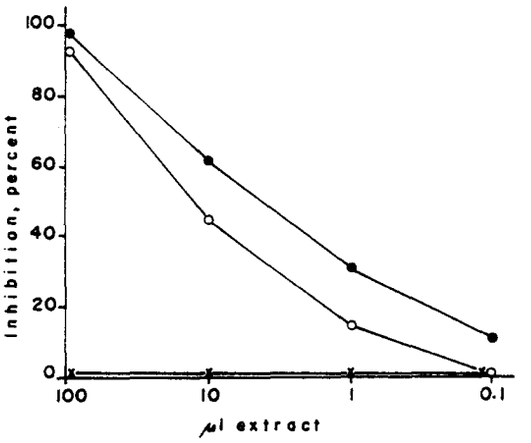

Fig. 5. Inhibition of ^{125}I–IgG "Adala" binding to AW-Ramos PAG-homogenate by preincubation of iodinated antibody with 100,000 × g supernatants of NP 40 treated total homogenates of BJAB (× — ×), AW-Ramos (●—●) and Raji cells (○—○).

Table 3 shows the results of an experiment with NP 40 treated (1% final concentration) total homogenates of 6 different cell lines. The iodinated antibody was preincubated for 8 hr with a cell homogenate prepared from 10^7 cells per test. After centrifugation for 15 min at 40,000 × *g* the supernatant was tested on the different PAG-homogenates indicated. The EBV-DNA, EBNA negative extracts showed no or only a slight inhibition of ^{125}I–IgG "Adala" binding in contrast to the EBNA positive cell extracts which gave a good inhibition. These data provide evidence that the EBNA specificity(ies) in these lines are largely cross-reactive.

Figure 6 shows a comparative titration of cell extracts tested in an inhibition assay with RAJI PAG-homogenate. The binding of ^{125}I–IgG "Adala" was inhibited to the same extent by RAJI and DAUDI extracts prepared without detergent, whereas B95-8 extracts gave only partial blocking. Since B95-8 cells contain EBNA, EA and VCA, as detected by immunofluorescence, whereas RAJI cells contain only EBNA and some EA, this finding suggests a qualitative difference in antigenic specificities, probably relating to the EBNA specificity that

Table 3. Inhibition of ^{125}I–IgG "Adala" binding to PAG-homogenates prepared from EBV-genome, EBNA positive cells by preincubation with NP40 treated homogenates of EBV genome positive and negative cells

Homogenates	PAG-homogenate prepared with AW-Ramos	Namalwa	Raji
Ramos	5	13	0
BJAB	17	18	7
Molt 4	6	3	0
AW-Ramos	94	70	70
Namalwa	89	85	63
Raji	75	86	93

Homogenates corresponding to 10×10^6 cells was used per test incubation. The data show the percent inhibition related to a control incubation with ^{125}I–IgG "Adala" alone.

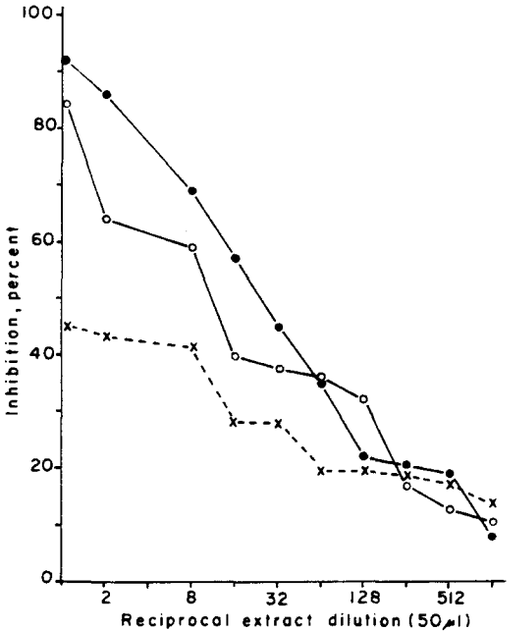

Fig. 6. Inhibition of ^{125}I–IgG "Adala" binding to Raji PAG-homogenate by preincubation of iodinated antibody with 100,000 × g supernatants of homogenates from Raji (○—○), Daudi (●—●) and B95-8 cells (×—×).

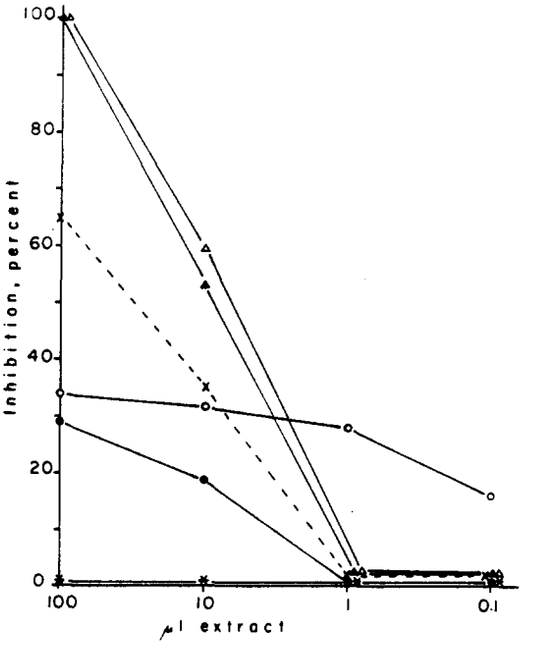

Fig. 7. Inhibition of ^{125}I–IgG "Adala" binding to Raji PAG-homogenate by preincubation of iodinated antibody with 100,000 × g supernatants prepared from NP-40 treated B95-8 (○—○), Raji (▲—▲), IUDR treated Raji (△—△), AW-Ramos (×—×), BJAB (—*) homogenates and a B95-8 extract (●—●), that was not exposed to NP40.*

dominates the test. Figure 7 shows a repeat test with additional cell extracts. Again, the detergent free B95-8 extract did not block the binding of ^{125}I–IgG "Adala" to the RAJI PAG completely. A corresponding extract prepared with NP 40 gave a slightly better, but still only partial blocking with a clear plateau. This suggests a qualitative difference. In contrast, the extracts of RAJI or IUDR treated RAJI (60 µl/ml medium for 2 days) blocked the binding of ^{125}I–IgG "Adala" completely at high concentrations, AW-Ramos extract showed less inhibition. This may have been a quantitative rather than a qualitative difference, since the curve had a similar shape and there was no plateau. Alternatively, the lack of EA in this cell line may have been responsible.

DISCUSSION

The method of protein immobilization in polyacrylamide gel introduced by Carrel and Barandun [25] was initially established for immunosorbent procedures. Subsequently, proteins fixed in polyacrylamide gel turned out to be useful as antigen sources in solid-phase radioimmunoassays for cell membrane antigens [32, 33]. In the present study, a radioimmunoassay for EBNA was developed based on this technique.

Total homogenates prepared from EBNA positive or negative cells polymerized in PAG served as the antigen. EBNA specificity could be confirmed by serum blocking and antigen inhibition tests. A collection of anti-EBV positive and negative sera was selected for the blocking tests, including positive sera that were discordant with regard to their anti-EBNA vs anti-EA or anti-EA and anti-VCA titers. Blocking of the radioimmunoassay showed a good correlation with the anti-EBNA titers, but not with the anti-EA or anti-VCA titers, provided that an EBNA positive nonproducer line was used for antigen preparation. However, if EA+, VCA+ producer cells were used as antigen sources, EA and VCA could be detected by this assay (Dölken and Klein, manuscript in preparation). EBNA positive nonproducer cells are therefore a prerequisite for monospecific EBNA detection.

Comparative binding studies with different EBV-genome positive and negative cells showed that the reference reagent "Adala" detects an EBV-associated specificity. Taking into account the immunofluorescence data and results obtained with autoradiography in case of AW-Ramos and NAMALWA (Table 1), EBNA was the only conceivable EBV-associated antigenic specificity. In RAJI cells, the specificity preferentially detected is EBNA, but possibly small amounts of EA are also detected.

Blocking assays with extracts from various EBNA positive producer and nonproducer lines were carried out to compare their EBNA content quantitatively and qualitatively. With RAJI PAG-homogenates as the antigen, the binding of ^{125}I–IgG "Adala" was completely blocked by RAJI, IUDR treated RAJI and DAUDI extracts. B95-8 cell extracts prepared with or without the detergents NP 40 did not inhibit completely (30–45% inhibition) and a plateau of inhibition was observed. The extract prepared from EA−, VCA−, MA−, EBNA+ AW-Ramos cells blocked more extensively and with no plateau effect compared to the EA+, VCA+, MA+, EBNA+B95-8 extract. In a separate experiment, the extracts of AW-Ramos and NAMALWA inhibited the binding of ^{125}I–IgG "Adala" to about the same extent, but still to a larger extent than the B95-8 extract. Taken together, these findings suggest that the EBNA of the B95-8 cells is partially different from the EBNA in AW-Ramos, NAMALWA, RAJI and DAUDI.

This finding appears particularly interesting in view of the origin of the different cell lines. RAJI, DAUDI, and NAMALWA are EBV carrying Burkitt lymphoma lines. AW-Ramos was derived by converting the EBV genome negative Ramos line with P3HR-1 virus, produced by the Burkitt lymphoma line P3HR-1 and is now an EBV-DNA, EBNA positive nonproducer line. The B95-8 line was established by infecting marmoset cells with EBV derived from the 833 L line of infectious mononucleosis (IM) origin. There is now accumulating evidence that the molecular weight of the circular DNA isolated from IM derived lines is about 12% smaller than the DNA obtained from Burkitt lymphoma lines (Adams *et al.*, manuscript in preparation). Also the findings of Pritchett *et al.* [34] showed that B95-8-EBV-DNA lacked approximately 15% of the DNA sequences of the P3HR-1-EBV-DNA. The possible difference in EBNA specificities between the B95-8 extract and the various Burkitt lymphoma lines tested may reflect the difference in the viral genomes. Alternatively, however, it is also possible that the difference described in this paper is related to the difference in the host cell species, human vs marmoset. Since both, the P3HR-1 and the B95-8 viruses have been now successfully introduced into the same EBV genome negative lines [35], this question can be subjected to critical examination.

In this paper data were presented showing that a test for EBNA can be established by using PAG immobilized homogenates of antigen positive cells. By using EBV genome positive producer cells that are positive for all known EBV-associated antigens, a radioimmunoassay detecting EBNA, EA and VCA has been established (Dölken and Klein, manuscript in preparation).

Urinary Steroid Profiles in Normal Women and in Patients with Breast Cancer in Britain and Japan: Relation to Thyroid Function

B. S. THOMAS,* R. D. BULBROOK,* J. L. HAYWARD,† S. KUMAOKA,‡ O. TAKATANI,‡ O. ABE§ and J. UTSUNOMIYA¶

**Dept of Clinical Endocrinology, Imperial Cancer Research Fund Laboratories, Lincoln's Inn Fields, London, WC2A 3PX, United Kingdom, †ICRF Breast Unit, Guy's Hospital, London, SE1 9RT, United Kingdom, ‡National Cancer Center Hospital, Tokyo, 104, Japan, §Keio University, Tokyo, Japan and ¶Tokyo Medical and Dental University, Tokyo, Japan*

Abstract—*Steroid profiles of urinary 17-oxosteroids, pregnanediol and pregnanetriol were studied by gas–liquid chromatography in normal Japanese and British women, and in women with breast cancer from both races. The results showed that both pre- and post-menopausal Japanese women excreted significantly less aetiocholanolone, 11-oxo aetiocholanolone, and 11-hydroxy aetiocholanolone than their British counterparts. Androsterone was significantly less in Japanese pre-menopausal women and pregnanetriol in post-menopausal women respectively..*

However, a significantly lower androsterone (5α): aetiocholanolone (5β) ratio was found in the Japanese cancer patients than in the normal Japanese women (pre-menopausal, $P = < 0.02$, post-menopausal, $P = < 0.05$).

In the British pre-menopausal breast cancer patients this 5α:5β ratio was higher than in the normal British control ($P = < 0.02$).

A comparison of blood plasma TSH levels with the urinary androsterone: aetiocholanolone ratios gave a significantly negative correlation in both the Japanese normal and cancer cases ($P = < 0.05$). No agreement was found in a similar comparison in the British women.

These results could signify that a diminished thyroid function may be a predisposing factor to breast cancer in Japanese women.

INTRODUCTION

THE ROLE of the thyroid in the aetiology of breast cancer is still not clear. Some early reports indicated that hypothyroidism was more common in women with breast cancer than among the normal population [1–3]. More recently, Mittra and Hayward [4] have shown that plasma TSH (thyroid stimulating hormone) was significantly higher in patients with early or advanced breast cancer, than among women in hospital with illnesses unrelated to breast disease. Furthermore, Mittra, Hayward and McNeilly [5] have postulated that suboptimal levels of circulating thyroid hormones may abnormally sensitize mammary epithelial cells to prolactin stimulation, which may lead to eventual neoplasia. Certainly, once breast cancer has been diagnosed, patients with a history of hypothyroid disorders have a much more rapid recurrence rate after mastectomy, together with a poorer survival experience than euthyroid or hyperthyroid women [6]. The ratio of the urinary androgen metabolite androsterone 3α-OH-5α-androstan-17-one to its isomer aetiocholanolone 3α-OH-5β-androstan-17-one has been shown to be a particularly sensitive index of thyroid function. This index which has been termed the 5α:5β ratio is high (i.e. > 2.0) in hyperthyroidism and low in myxoedema (i.e. > 0.25) [7, 8]. It has been found that normal Japanese women have a significantly higher 5α:5β ratio than comparable British women [9, 10] and it has been suggested that the lower incidence of breast cancer in Japanese women, compared with British or American women [11], might be due to high thyroid activity in the Japanese [10].

Methods are now available for an extensive survey of urinary androgen metabolites and other steroids. Similarly, TSH assays are now possible. This paper describes a study of the

Accepted 29 April 1977.

relationship of these factors in normal Japanese and British women and patients with breast cancer.

MATERIAL AND METHODS

The normal Japanese women comprised 20 pre-menopausal and 15 post-menopausal healthy women living in Tokyo. The normal British group were 19 pre-menopausal and 15 post-menopausal healthy white women living either in Guernsey or the London area. The Japanese breast cancer cases (26 pre-menopausal and 17 post-menopausal women) were from the National Cancer Center Hospital, Tokyo. The British breast cancer cases of 11 pre-menopausal and 21 post-menopausal women were from Guy's Hospital, London. Both groups consisted of early and advanced cases. Three 24 hr collections of urine were made at home by the normal volunteers, whilst the 3 urine specimens from the patients were collected in hospital before operation. All the specimens were stored in plastic (PVC) containers at −20°C; those from the Japanese were flown to London in insulated crates.

The urine was processed and analysed by gas–liquid chromatography using the method of Bailey, Fenoughty and Chapman [12], except that the enzyme used for the hydrolytic cleavage of the steroid glucosiduronate conjugates was β-Glucuronidase Pasteur d'origine bacterienne [13]. The gas chromatograph was a Becker (model 420) and the glass capillary column (25m) coated with methyl silicone (OV101) stationary phase was obtained from LKB Ltd. The plasma TSH assays used for comparison with the urinary 5α : 5β ratios have already been published [14].

The urinary steroids measured were as follows:

Androsterone
(3α-hydroxy-5α-androstan-17-one;
Aetiocholanolone
(3α-hydroxy-5β-androstan-17-one);
11-Oxo-aetiocholanolone
(3α-hydroxy-5β-androstan-11, 17-dione);
11-Hydroxy-androsterone
(3α, 11β-dihydroxy-5α-androstan-17-one);
11-Hydroxy-aetiocholanolone
(3α, 11β-dihydroxy-5β-androstan-17-one);
Pregnanediol
(3α, 20α-dihydroxy-5β-pregnane);
Pregnanetriol
(3α, 17β, 20α-trihydroxy-5β-pregnane).

Assessment of method

The assessment of the method is presented in Table 1.

RESULTS

(a) Normal Japanese and British women

The urinary steroid excretion of normal pre- and post-menopausal Japanese and British women is shown in Table 2. The Japanese pre-menopausal women excreted significantly less androsterone, aetiocholanolone, 11-oxo aetiocholanolone and 11-hydroxy aetiocholanolone than the British women. The 5α:5β ratios of both androsterone : aetiocholanolone and 11-hydr-

oxy androsterone : 11-hydroxy aetiocholanolone in the Japanese pre-menopausal women were significantly greater than in the corresponding British group. A similar difference was found between the Japanese and British post-menopausal group with the exception that the mean androsterone excretion in the Japanese was not significantly different from that of the British women.

(*b*) *Patients with breast cancer*

The urinary steroid excretion of pre- and post-menopausal Japanese and British women with breast cancer is shown in Table 3.

As in the normal controls, the Japanese patients with breast cancer excrete less androsterone and aetiocholanolone than comparable British patients. The difference is significant in the pre-menopausal women but not in the post-menopausal. Similarly, 11-OHE excretion is significantly lower in Japanese patients than in British patients and 11-KE excretion was also lower both in Japanese controls and patients. Japanese pre-menopausal patients have a significantly lower 5α:5β ratio than British patients.

(c) Comparison of steroid excretion of normal women and patients with breast cancer within populations

When the results given in Tables 2 and 3 were compared, no significant differences emerged between normal Japanese women and Japanese women with breast cancer, except that the androsterone : aetiocholanolone ratios were lower in the cancer cases than in the controls (pre-menopausal, $P \leqq = 0.02$; post-menopausal, $P = < 0.05$). In a similar comparison in British pre-menopausal women the androsterone : aetiocholanolone ratio was significantly higher in the patients with breast cancer ($P < 0.02$). No significant differences were found in the post-menopausal women with the exception that the amounts of aetiocholanolone were lower than in the normal controls ($P = < 0.01$).

(d) Relationship between blood plasma TSH and urinary androsterone : aetiocholanolone ratio

The comparison between blood plasma TSH and the urinary androsterone : aetiocholanolone ratio in the Japanese women is shown in Fig. 1. There is an inverse correlation between the two sets of data that is significant ($r = -0.29$, $P = < 0.05$). A similar comparison of plasma TSH and the urinary androsterone : aetiocholanolone ratios in the British women in Fig. 2, shows no correlation whatsoever.

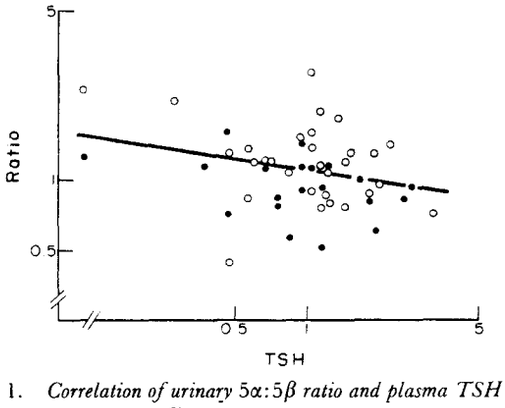

Fig. 1. Correlation of urinary 5α:5β ratio and plasma TSH in Japanese women.
○ = *Normal Japanese women.*
● = *Japanese women with breast cancer.*
$y = -0.21x + 1.25$ ($r = -0.32$, $P < 0.05$).

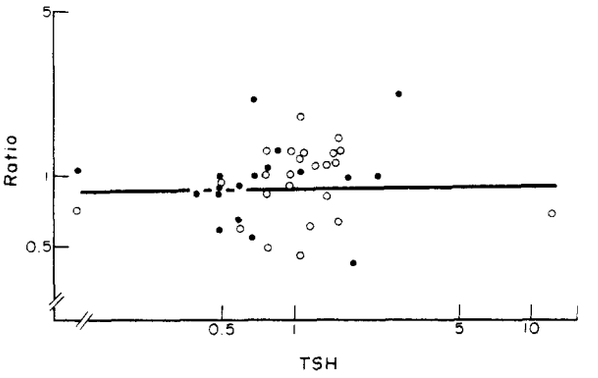

Fig. 2. Correlation of urinary 5α:5β ratio and plasma TSH in British women.
○ = *Normal British women.*
● = *British women with breast cancer.*
$y = 0.06x + 0.93$ ($r = 0.11$. *P—not significant*).

DISCUSSION

The results confirm earlier findings [9, 10] that the amounts of androsterone and aetiocholanolone excreted by normal Japanese women are lower than in British women, but the 5α:5β ratio of these two androgen metabolites is higher in Japanese women. Two urinary corticosteroid metabolites, 11-oxo aetiocholanolone and 11-hydroxy aetiocholanolone are excreted in smaller amounts by Japanese women, whilst the amounts of 11-hydroxy androsterone, a metabolite of 11-hydroxy-androst-4-en-3, 17-dione, are the same in both races. Thus, there should be a considerable difference in the activities of the 5β-reductase enzymes in the Japanese women to account for the relatively low aetiocholanolone, 11-oxo aetiocholanolone and 11-hydroxy aetiocholanolone. The latter two compounds are mainly derived from cortisol.

The steroid assays indicate a greater degree of thyroid activity in normal Japanese women in that the 5α:5β ratios of androsterone and aetiocholanolone, and of their 11-hydroxylated equivalents are higher than in the British women. Although the plasma TSH levels show no significant difference between the two races this may be due to these assays or the level of this hormone being less sensitive than the urinary steroids as an indicator of small changes in thyroid function. It is also possible that there may be differences in triiodothyronine (T_3) and thyroxine (T_4) levels in the two races. That the 5α:5β ratios are reliable indicators of major thyroid disturbances is beyond doubt [7, 8]. It is therefore reasonable to assume that smaller changes in thyroid metabolism are reflected by concomitant urinary steroid changes. The incidence of breast cancer may well be related to circulating levels of thyroid hormones and

enhanced thyroid activity could "protect" the Japanese population.

Another interesting feature of these results is that the urinary excretion of pregnanediol and pregnanetriol in pre-menopausal women is similar in both races. Only in the British post-menopausal group is pregnanetriol marginally higher. From this it may be deduced that the production rates and metabolic fate of progesterone and 17-hydroxy-progesterone are almost identical in both races. There are several differences between normal women and patients with breast cancer in each population. Aetiocholanolone levels are appreciably lower in the British cancer cases than in their normal controls thus confirming earlier findings [15, 16]. There was no difference between the similar group in the Japanese population. However, the comparison between normal Japanese women and those with breast cancer shows a difference in the androsterone : aetiocholanolone relationship in that the $5\alpha:5\beta$ ratio is significantly lower in the cancer cases resembling that of the normal British women. These differences do not occur among the normal British women and those with breast cancer, and in fact the $5\alpha:5\beta$ is actually significantly higher in the pre-menopausal cases. It is therefore possible that low thyroid activity could be correlated with increased risk of the disease in Japan. This possibility is further reinforced by the significant inverse correlation found between the androsterone : aetiocholanolone ratio and the blood plasma TSH values in the Japanese women. This feature is conspicuously absent among the British women.

Another piece of evidence suggestive of relatively high thyroid activity in normal Japanese women is that the plasma androstenedione level is lower than in British women [17]. It has previously been demonstrated that a diminished testosterone clearance rate together with a decrease in its conversion to androstenedione is present in hyperthyroidism [18].

Studies based on the rise of plasma TSH following intravenous injection of thyrotropin-releasing hormone (TRH) suggest a lower level of thyroid activity in British women with breast cancer than in women without the disease [4]. Therefore, on the basis of the results presented in this paper the TRH test should show a greater difference in TSH stimulation in Japanese women with breast cancer than among their control group and, in fact, this has been reported [19]. A relative degree of "hypothyroidism" appears to be present in Japanese women with breast cancer and this could be a factor in the aetiology of the disease in Japan. It must be emphasized that this conclusion is based on small and possibly unrepresentative samples from the British and Japanese populations and that changes now taking place in incidence rates, dietary and social habits may mean that subsequent studies would afford different results. But the results of this pilot study encourage us to pursue the present lead in larger cross sections of the two races.

Abstract—*The human clinical pharmacology, toxicity and antitumor activity of ICRF-159 are reviewed. Phase* II *trials, multi-drug combinations and adjuvant trials are discussed in reference to the future study of this agent.*

INTRODUCTION

MANY enzyme systems contain trace metals or depend upon them for activity. Furthermore, various chelating agents have been shown to affect the growth of cells and tumors [1]. Ethylenediamine tetraacetic acid (EDTA), one of the most potent chelating agents for divalent cations, has no significant antitumor activity [2]. This lack of activity has been ascribed to the high polarity of the molecule which would prevent entry into cells [3]. Less polar derivatives of EDTA have thus been synthesized with this approach culminating in the development of ICRF-159 [4].

A review of this new drug, with special emphasis on preclinical data, has been published recently [5]. The following analysis attempts to summarize the current clinical status of ICRF-159 and will hopefully define possible leads for further investigations.

EXPERIMENTAL DATA

ICRF-159 [(±), 1,2 bis(3, 5-dioxopiperazin-1-yl) propane, Razoxane or NSC-129943] is a bisdiketopiperazine derivative (Fig. 1) which was originally synthesized by the Imperial Cancer Research Fund Facilities in London, England. Its mechanism of action has not yet been fully elucidated. Using phytohemagglutinin stimulated human lymphocytes in synchronized cell culture, the late prophase and early metaphase (G_2-M) were found to be most sensitive to ICRF-159 [6]. In mouse fibroblast cell cultures, the drug inhibited DNA synthesis with little effect on RNA and protein synthesis, following a pattern reminiscent of the activity X-irradiation and radiomimetic agents [7]. In animal experiments, ICRF-159 was shown to inhibit the formation of platelet thrombi in blood vessels. This effect could not be related to a decrease in platelet counts or to a decrease in ionized serum calcium concentrations [8].

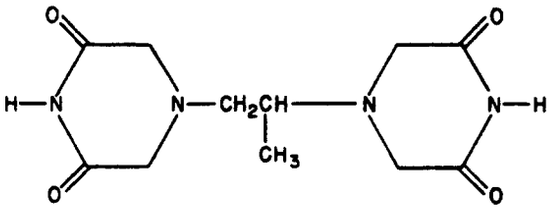

Fig. 1. *Structural formula of ICRF-159.*

Experimental antitumor effect was found in a wide range of animal tumors [4]. In the ascitic L1210 system, the drug exhibited schedule-dependency in accordance with its cell-cycle-phase-specificity, the optimal schedule being administration I.P. or P.O., every three hours on days 1, 5, 9.§ Like 5-fluorouracil and epipodophyllotoxin derivatives, ICRF-159 was shown to inhibit pulmonary metastases in the Lewis lung carcinoma at doses having little effect on the rate of growth of the primary implant [9, 10]. This inhibition was tentatively related to profound changes in the vascularization of the primary tumor [11, 12]. Antitumor synergism of ICRF-159 plus X-irradiation has been found in

Accepted 29 April 1977.

§Information from Drug Research and Development, Division of Cancer Treatment, National Cancer Institute.

the sarcoma S-180 system [13]. Synergism was also reported with other cytotoxic agents including daunomycin, adriamycin, 5-fluorouracil and *cis*-diamminedichloroplatinum in the L1210 model and cyclophosphamide in the Lewis lung carcinoma [14–16]. Finally, it must be noted that ICRF-159 was found to reduce the cardiotoxic effects induced by daunomycin and adriamycin in the isolated dog heart [17].

CLINICAL PHARMACOLOGY

Following oral ingestion of ^{14}C-ICRF-159, fecal and urinary recovery of radioactivity appeared to depend upon the schedule of drug administration [18]. After a single dose of 3 g/m^2, the urinary recovery within 96 hr averaged only 23% (range, 13–34%). When the drug was given at 3 g/m^2 in 3 divided doses in one day, the urinary recovery increased to 52% (range, 42–65%) of the administered radioactivity. At each schedule, radioactivity unrecovered in the urine was largely accounted for in the feces. The bulk of the fecal radioactivity was chromatographically identical to ICRF-159 whereas all of the urinary radioactivity appeared to be metabolite.

TOXIC EFFECTS

Toxic effects encountered following ICRF-159 administration mainly include myelosuppression, gastrointestinal intolerance and alopecia (Table 1) [19–21].

Table 1. *Toxic effects of ICRF-159 in 80 patients**

Toxic effects	Number of patients with toxic effects
Hematologic	
WBC < 2000/mm^3	34
Platelets < 100.000/mm^3	17
Gastrointestinal	
Nausea	27
Vomiting	17
Diarrhea	3
Alopecia	36
Miscellaneous	
Flu-like syndrome	2
Dermatitis	1
Stomatitis	1

*Cumulative results of 3 trials with oral ICRF-159 1 g/m^2/day in 3 divided doses each day for 3 consecutive days [19–21].

Myelosuppression

Leukopenia is the dose-limiting toxicity induced by ICRF-159, as observed with the drug given 3 times daily for 1 or 3 days at a total dose of 3 g/m^2 per course [22, 23]. When the drug is administered as single doses up to 10.5 g/m^2, only mild and inconsistent myelosuppression is noted, probably reflecting the peculiar intestinal absorption of the drug [23]. At the daily times 3 schedule, leukopenia persists for 1 week with the nadir occurring at day 12 (mean) and complete recovery by day 21. On subsequent courses, leukopenia is reproducible and dose-related. One drug-related death at the maximum tolerated dose was reported in a patient previously treated with radiotherapy.

Mild and transient thrombocytopenia may be observed simultaneously with leukopenia. Anemia necessitating red blood cell transfusion is noted after multiple courses of therapy.

Gastrointestinal intolerance

Approximately 60% of patients experience nausea during drug administration and half of them have minimal vomiting easily controlled by antiemetics. Diarrhea is relatively rare.

Alopecia

Alopecia is commonly encountered, becoming moderate to severe with multiple courses of therapy.

Miscellaneous

Various additional toxicities may occur with insignificant frequency. They include flu-like syndrome, stomatitis and dermatitis. Cutaneous erythema and scaling have been described in previously irradiated areas.

There was no evidence of hepatic, pulmonary, renal or cardiac toxicity in any patient treated with ICRF-159. No significant decrease in serum calcium level has been reported.

CLINICAL STUDIES

Initial therapeutic results with ICRF-159 were reported in 1969 [24]. Surprisingly, since then, only a limited number of disease-oriented studies have been undertaken and thus, little data has accumulated regarding the spectrum of activity of this compound.

Lymphoma

The efficacy of ICRF-159 in lymphoma was detected in early clinical trials [24]. In a phase II study carried out by the Western Cancer Study Group [25], the drug was given in a split dose on

a weekly schedule to 27 patients with far-advanced previously treated non-Hodgkin's lymphomas. Complete responses were achieved in 2 patients for 11+ and 15 months, and partial responses in 6 patients with a remission duration ranging from 0.5+ to 12+ months. In the same study, no response to ICRF-159 was seen in 9 additional patients with Hodgkin's disease; an inadequate dose-schedule of the drug was used and thus its value against this malignancy cannot yet be ascertained.

Colorectal carcinoma

ICRF-159 has been evaluated in advanced colorectal carcinoma with the same daily times 3 schedule by Marciniak *et al.* [20] and Bellet *et al.* [21]. In the first study, no response was seen in 12 patients previously treated with chemotherapy (5-fluorouracil alone or in various combinations). However, in 13 patients not previously exposed to cytotoxic agents, responses were seen in 3 cases. In the second study, all patients had received 5-fluorouracil and some received MeCCNU as single agents. Of the 35 patients evaluable for response to ICRF-159, partial remission was achieved in 5. The median duration of response was 4 months, ranging from 1 to 5 months. None of the responders had previously experienced antitumor effect following systemic chemotherapy with either 5-fluorouracil or MeCCNU.

Lung cancer

Promising results were obtained in early clinical trials with ICRF-159 in squamous cell carcinoma of the lung [26]. These results were not confirmed by a subsequent trial undertaken at the Mayo Clinic [27]. In the latter extensive Phase II study, most of the patients did not receive prior chemotherapy. After stratification for performance status, prior chemotherapy and cell type, patients were randomized to ICRF-159 alone or a combination of vincristine, bleomycin and adriamycin with cross-over after failure to either regimen. Responses to ICRF-159 in squamous cell, large cell and adenocarcinoma of lung were obtained in 1/17, 1/10 and 2/25 cases respectively.

Melanoma

ICRF-159 was evaluated in 20 patients with metastatic melanoma resistant to prior sequential single agent systemic therapy with DTIC and a nitrosourea [19]. No objective response was achieved. In that study, immunosuppressive effects as determined by a lymphocyte microcytotoxicity assay were minimal.

Sarcoma

ICRF-159 has been used for the treatment of 18 patients with Kaposi's sarcoma resistant to prior therapy [28]. One patient exhibited complete tumor regression for 5+ months and 10 had a partial response.

In a pilot study, 22 patients with soft tissue sarcomas and osteosarcomas were treated with a combination of radiation therapy plus ICRF-159 [29]. These tumors are generally radioresistant, but with the combination, 6 patients had complete remissions and 12 had partial remissions. Unexpectedly severe skin reactions in the irradiated fields were reported, reflecting a potentiation of the usual cutaneous toxicity encountered with irradiation alone.

Miscellaneous

Limited studies with ICRF-159 were devoted to trials involving acute leukemia. The preliminary available data warrants further investigation in this disease [24, 30].

Phase I studies have been conducted using ICRF-159 in combination with adriamycin [15] or *cis*-diamminedichloroplatinum [31]. Additional data should clarify whether the usefulness of these combinations, originally detected in animal experiments, might be reflected in clinical practice.

ONGOING CLINICAL TRIALS

Few studies of ICRF-159 as a single agent are presently ongoing. At the Southwest Oncology Group, the drug is being tested in pediatric solid tumors and in acute lymphocytic leukemia. Phase II trials in breast cancer are currently being carried out at the Mayo Clinic; phase II evaluation of ICRF-159 in breast cancer and in squamous cell carcinoma of head and neck are in progress at The Fox Chase Cancer Center. The single agent activity of ICRF-159 is presently also being investigated in pancreatic cancer, lung cancer and sarcoma by several cooperative groups in the United States.

DISCUSSION

ICRF-159 is a cytotoxic antitumor agent with a novel structure; its actual therapeutic potential remains generally uncertain at the present time. This agent has been clinically evaluated only in its oral form with intestinal absorption following a peculiar and incompletely understood pattern [18], underscoring the need for precise pharmacologic data prior to extensive clinical studies of

the efficacy of an oral agent. On the other hand, the oral form of ICRF-159 is subjectively well tolerated and intestinal absorption is apparently reproducible in the same patient. Thus far, the lack of solubility of ICRF-159 as a racemic mixture has precluded its parenteral administration. Recently, the separate use of enantiomers of the compound was shown to overcome this difficulty [32], and an intravenous formulation suitable for clinical testing will be soon available.

It is puzzling that relatively few studies involving ICRF-159 are ongoing. Perhaps its early introduction into many combination studies and the delay in establishing an optimal dose-schedule have hampered full evaluation of the drug. Too many investigational anticancer drugs have been discarded in the past without sufficient rationale [33, 34]. In the particular case of ICRF-159, a number of important signal tumors have not been treated. The necessity of testing drugs in a broad spectrum of tumor types has been repeatedly emphasized [35], and hints of clinical activity detected with ICRF-159 have been sufficiently meaningful to deserve further investigation.

Activity of ICRF-159 has been manifest in colorectal carcinoma [20, 21], probably with no cross-resistance to 5-fluorouracil or MeCCNU [21] (2 other agents of moderate activity in this disease). Its combination with 5-fluorouracil would be worth investigating in view of the reported synergism of this combination in the L1210 system [15, 16]. The prevention of metastases in several experimental tumor systems [9, 10] makes ICRF-159 attractive for adjuvant trials. Although 5-fluorouracil was also found to inhibit metastases in the Lewis lung carcinoma, its value as an adjuvant treatment in colorectal malignancies remains questionable. Adjuvant studies in this disease might be considered with ICRF-159 plus 5-fluorouracil in combination after careful phase I and phase II evaluation.

Other combinations warrant further investigation. Experimental potentiation by ICRF-159 of the antitumor activity of the anthracyclines [14–16], as well as the possible inhibition of drug induced cardiotoxicity [17], makes a combination attractive for clinical study. Initial results obtained with ICRF-159 plus radiotherapy in human sarcoma [29] have pointed to the possible radiosensitizing ability of ICRF-159. These findings need confirmation insofar as the many attempts to improve the effectiveness of radiation therapy by concomitant chemotherapy have to date been disappointing [36].

In conclusion, ICRF-159 is an antitumor agent endowed with many attractive properties. Additional studies are needed to accurately assess the role of this new drug in the treatment of cancer.

§*Department of Dermatology, University of Lund S*-221-85 *Lund, Sweden*

Abstract—*5-S-cysteinyldopa (5-S-CD) was determined in the tumors and urine of* 31 *primary and/or metastatic melanoma patients and* 8 *control subjects. 5-S-CD was present in all but one melanoma. Urinary excretion of 5-S-CD was in the normal range in patients with primary melanoma but often increased in disseminated melanoma. Determination of 5-S-CD in the tumors seems to be of value for the diagnosis of unpigmented tumors primary or metastasis and in the follow-up of treatment of patients with disseminated melanoma.*

There was no evident correlation between secretion of 5-S-CD and the ultrastructure of the tumors.

INTRODUCTION

DOPA and dopamine have been described as frequently occurring catechols in tumors and urine of Syrian hamsters with melanotic tumors [1] and in the urine of patients with malignant melanoma [2–3].

Since then it has been shown that 5-S-cysteinyldopa (5-S-CD), a catechol which plays a role in phaeomelanin production, can be detected in the urine of melanoma patients with tumors and during the evolution of the disease [4–8]. A recent study showed a wide variation in the amount of 5-S-CD in cultured cells and culture medium obtained from established cell lines of human malignant melanocytes [9–12]. Our aim was to determine 5-S-CD levels in primary and/or metastatic tumors and urine of patients with malignant melanoma. We compared these 5-S-CD levels with the ultrastructure of tumors, particularly in respect to the different structural characteristics of pathologic melanosomes [13]. We also tried to ascertain whether there was a relationship between therapeutic treatment and its usefulness for the follow-up of the patients.

Accepted 28 April 1977.

*This investigation was supported by a grant (CRL I.N.S.E.R.M. n° 76.5.124.2.) from the Institut National de la Santé et de la Recherche Médicale (Paris, France), the Swedish Cancer Society and the Swedish Medical Research Council.

MATERIAL AND METHODS

Thirty-one melanoma patients were investigated. Sex, age, hair colour, presence of freckles and pathologic data following Clark's classification [13] (levels of invasion) are given in Tables 1, 2 and 4.

Biochemical determinations

The presence of 5-S-CD in both the tumors and urine of 29 patients was tested by the method previously described [14].

5-S-CD in the tumors

The excised tumors tested consisted of: 13 primary melanomas, 5 primary tumors and regional lymph nodes, 11 solitary and/or multiple recurrent metastases (cutaneous metastasis and/or lymph nodes). For two patients (cases 28 and 30), 5-S-CD was determined in two different lymph nodes: one pigmented, and one unpigmented (Tables 1 and 2).

Two normal skins, one benign naevus, one

pigmented basal cell carcinoma, and one squamous cell carcinoma, were used as controls (Table 3).

5-S-CD in the urine

The urine of 31 patients were tested for 5-S-CD. For the 22 patients with primary or/and metastatic the level of 5-S-CD was determined immediately before surgical treatment. For 5 patients the urinary excretion of 5-S-CD was followed up monthly. For 3 patients (cases 2, 5 and 6) with loco regional disease we followed up the evolution levels in the urine during surgical and immunochemotherapic treatment (BCG + DTIC) (Fig. 1). For two patients with widespread lesions (cases 26 and 57) the monthly determinations were carried out up till death (Fig. 2). 5-S-CD determinations were also carried out on the urine of 8 control subjects (Table 3).

In addition dopa + dopamine levels were studied in 5 tumors and in the urine of 11 primary or metastatic melanoma patients (Table 4) according to Anton and Sayre [15].

Electron microscopy

All the tumor fragments were processed for electron microscopy by the classical method glutaraldehyde-osmium fixation, dehydration in alcohols and embedding in epon [16]. The sections obtained with an ultramicrotome Reichert (MT2) were counterstained with uranyl acetate and lead citrate [17] and observed with a Jeol electron microscope JEM 100C.

RESULTS

Biochemical results

In melanoma tumors. As seen from the Tables 1 and 2, a great variability in 5-S-CD levels was found in the tumors (primary and metastatic). It is of interest to note that the average level was higher in nodular melanoma than in superficial spreading melanoma.

It is important to note the presence of 5-S-CD in unpigmented tumors (cases 8, 25, 28, 30 and 36).

There was no correlation between 5-S-CD levels in the tumors and hair colour and freckles for the same patient.

In the control tumors. In normal skin and other cutaneous tumors, 5-S-CD was not detected (Table 3).

Varying amounts of dopa + dopamine were found in the tumors of 5 patients. Dopa was present in the absence of 5-S-CD in only one case (case 38) which was a highly pigmented tumor.

In urine. Healthy controls: The amount of 5-S-CD in the urine of eight healthy control subjects varied between 4 and 197 μg/24 hr. Dopa + dopamine varied between 22 and 558 μg/24 hr (Table 3).

Patients with primary melanoma: In patients with primary melanoma who had no signs of metastasis, the level of 5-S-CD ranged from 31 to 236 μg/24 hr were within the normal range, even when the amount of 5-S-CD in the tumor was high (Table 1).

Reg. l.n. = Regional lymph nodes; * = faintly pigmented; † = heavily pigmented.

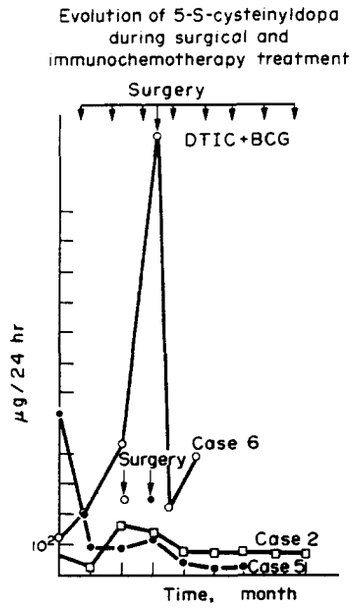

Fig. 1. Regional recurrence. Immunochemotherapy + surgical treatments.

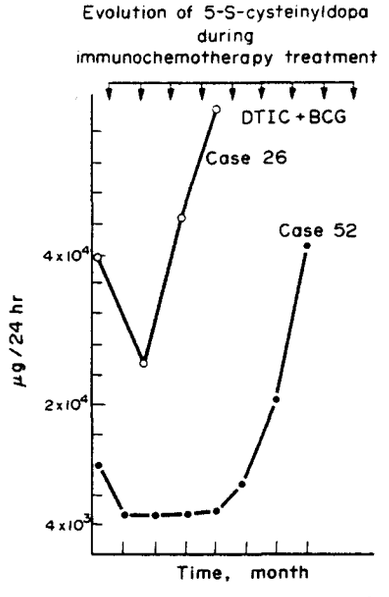

Fig. 2. General recurrence. Immunochemotherapy.

Patients with metastasis: in patients with primary melanoma and loco-regional metastasis (Table 1 (M)), 2 of the 8 had pathologically increased values of 5-S-CD (cases 5 and 6) while 6 patients had values from 29 to 228 µg/24 hr which were within the normal range.

In 6 patients with only recurrent disease (4 pigmented and 2 unpigmented tumors) we considered that the 5-S-CD urine values were definitely pathological (Table 2).

There was no correlation between 5-S-CD levels in the tumors and in the urine particularly when very high levels in the tumors were accompanied by low levels in the urine (cases 15 and 16) and inversely (case 6) even when the total tumor mass is taken into account (Table 1).

After treatment

Surgical treatment results in a decrease of the amount of 5-S-CD (Fig. 1). In case 6 the 5-S-CD level after surgery shows that all the tumor had not been excised as compared with cases 2–5 where there was complete excision.

During immunochemotherapy treatment, we observed (Figs. 1 and 2): First, a persistent increase in the urine 5-S-CD levels which indicated the inefficiency of the therapy (case 6). Secondly, after a decrease for a short time, the rapid increase in 5-S-CD showed a failure of the treatment (cases 2–26). Thirdly, a decrease with stabilization in the amount of 5-S-CD which showed that treatment was effective (cases 2–52). Lastly, when the treatment was not effective and or new metastases occurred, there was a subsequent increase in the urine level (cases 6, 26 and 52).

Dopa + dopamine levels in the urine were variable.

Electron microscopy

The premelanosome structures and presence of mature melanosomes appear in Tables 1 and 2. The specific cell structures and the morphology of the melanosomes are shown in Figs. 3–10.

In the tumors (primary and metastasis) we observed 4 typical structures of pathologic melanosomes [18, 19]: fibrillar (Fig. 3); granular (Fig. 4); lamellar organelles (Fig. 5); and "network structures" (Fig. 6).

From Table 1 it can be seen: in the primary tumors, we observed for lentigo maligna melanomas, for superficial spreading melanomas and non-cutaneous melanomas that the premelanosomes were often fibrillar. The premelanosomes of nodular melanomas were often granular. For the metastasis, different types of premelanosomes were observed but the fibrillar structure was more frequent. The different morphology of the mature melanosomes (oval-shaped (Figs. 7 and 8) and round (Figs. 9 and 10) were compared with 5-S-CD tumor levels, and no correlation appeared. There was also no correlation between hair colour and the melanosome morphology in the tumors.

DISCUSSION

5-S-CD determination in tumors is related to the presence of malignant melanocytes but is not

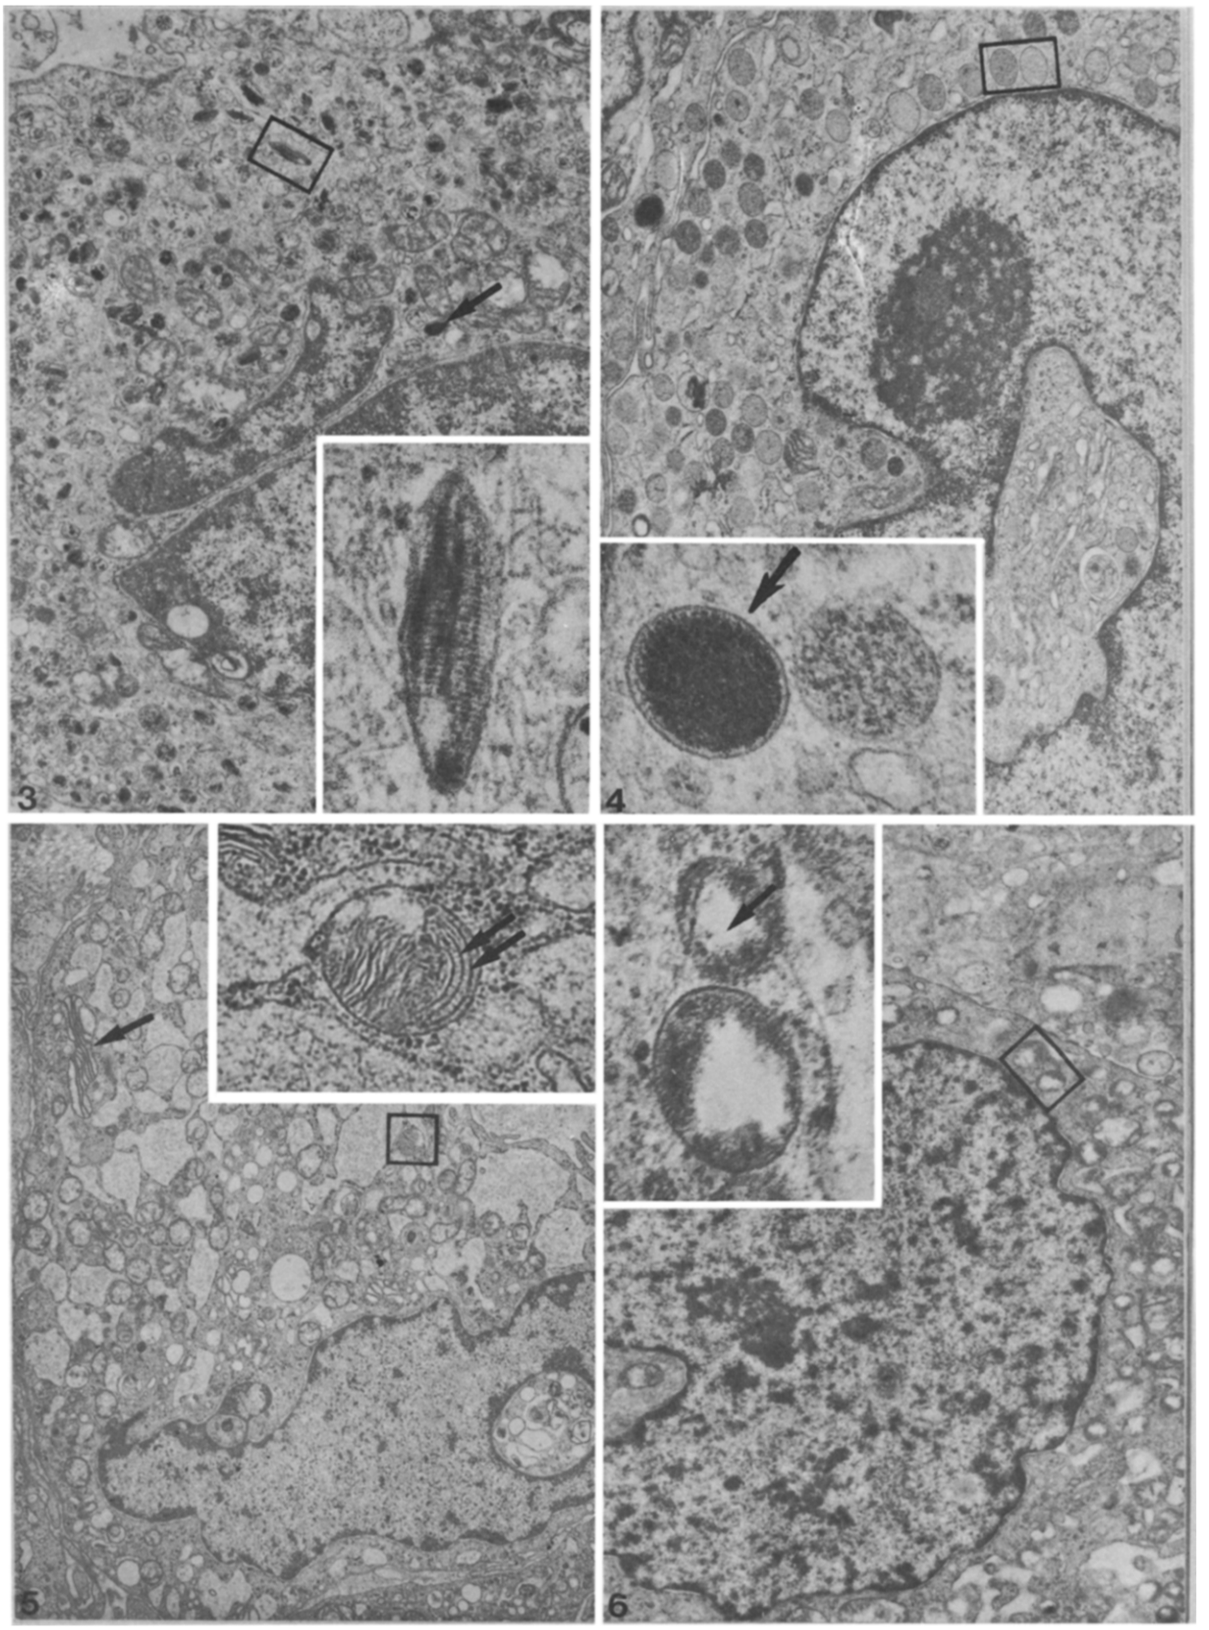

Fig. 3. Case No. 15. Mucosa melanoma: Very differentiated melanocytes showing complete mature (→) and typical fibrillar melanosomes, the structure of which is detailed in the inset. (Mag. × 15,000; inset mag. × 100,000).

Fig. 4. Case No. 21. Cutaneous metastasis. Melanocytes with typical granular melanosomes bound by the trilaminar membrane. (Mag. × 10,000; inset mag. × 50,000).

Fig. 5. Case No. 25: lymph node metastasis: poorly differentiated cell showing a pluri-infolded nucleus. Numerous mitochondria are present, some with a very characteristic appearance (→). Lamellar organelles are present, the detail of which, shown in the inset, revealed a striated structure (⇉). (Mag. × 8000, inset mag. × 50,000).

Fig. 6. Case No. 14. Primary tumor: nodular melanoma completely dedifferentiated cell showing network structures. They are single membrane-bound organelles with the same size as the granular melanosomes. They present a dense zone at the periphery and a clear central zone more or less criss-crossed by a fine network (→). (Mag. × 8750; inset mag. × 50,000).

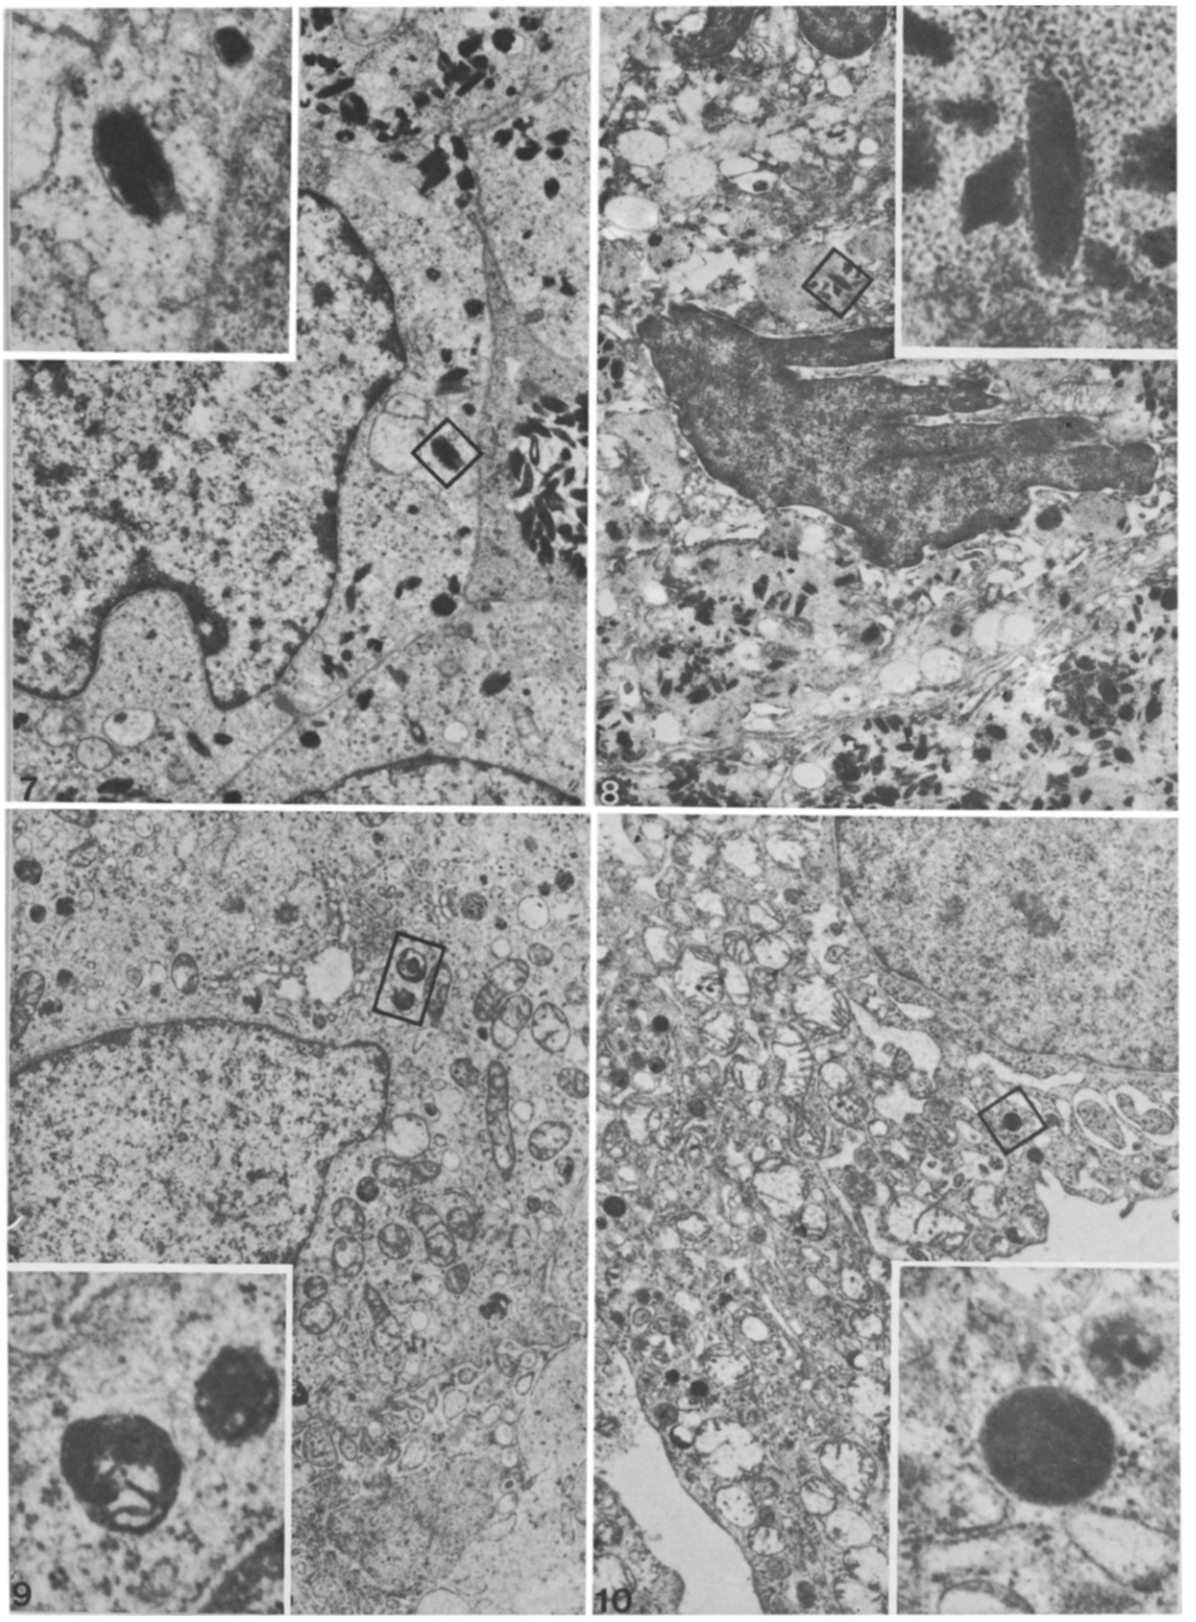

Fig. 7. Case No. 32. Lymph node metastasis. Malignant melanocyte with oval-shaped fully melanized melanosomes. The tumor was from a fair haired patient and produced no 5-S-CD. (Mag. × 1000; inset mag. × 68,000).

Fig. 8. Case No. 3 Primary tumor: superficial spreading melanoma. Fully melanized oval-shaped melanosomes. The tumor was from a fair haired patient and produced no 5-S-CD. (Mag. × 1000; inset mag. × 68,000).

Fig. 9. Case No. 25. Lymph node metastasis. Malignant with round, sometimes incompletely melanized melanosomes. The tumor was from a black haired patient and produced a high level of 5-S-CD. (Mag. × 12,000; inset mag. × 50,000).

Fig. 10. Case No. 24. Cutaneous metastasis. Typical round melanosomes in tumor cells from a fair haired patient. This tumor had a high level of 5-S-CD. (Mag. × 10,000; inset mag. × 56,000).

specific since this phaeomelanin metabolite is also found in some pigmented naevi but in much lower amounts [20].

On the contrary, we did not find 5-S-CD present in normal skin or in other types of cutaneous tumors, even when they were pigmented. Therefore, a substantial level of 5-S-CD in a tumor favors the diagnosis of malignant melanoma.

Moreover, positive 5-S-CD determinations allow the diagnosis of melanoma to be made for unpigmented tumors which are most difficult to diagnose [cases 8 (Table 1), 25, 31 and 36 (Table 2)].

No correlation between 5-S-CD levels and the tumor pigmentation was found. Some very heavily pigmented tumors had very small amounts of 5-S-CD. This is due to the fact that phaeomelanin gives a fainter pigmentation than eumelanin [21].

It should be noted that 5-S-CD is found in greater amounts in nodular melanoma, which has a poor prognosis, than in superficial spreading melanoma or lentigo maligna melanoma which have a relatively better prognosis. We suggest a possible importance of an admixture of connective tissue in superficial spreading melanomas and in lentigo maligna melanomas to be responsible for the lower 5-S-CD values.

Nevertheless, we cannot affirm that the amount of 5-S-CD in the tumor has any prognostical value.

The wide variability in the amounts found in the tumors suggests that the proportion of pathologic melanocytes able to synthesize 5-S-CD varies from one tumor to another one.

The absence of a correlation between 5-S-CD levels in the tumors and in the urine suggests that 5-S-CD production and excretion are not always related.

There was no evident relationship between the structure of the premelanosomes and the level of 5-S-CD. We noted that the morphology of the melanosomes in the tumors did not correspond to those that Parakkal [22] described in normal skin of blond and black-haired people. These results suggest either that melanosome shape does not always determine hair color, or that these patients do not present the same melanosome shapes in their normal skin or tumors.

So, the determination of 5-S-CD in the urine of the patients with primary tumors and with small metastases is of little interest.

A great variability in the amounts of 5-S-CD excreted in urine by patients was expected as a wide variation had been observed in healthy subjects [23] particularly after exposure to the sun [24].

In the tumor of one patient where 5-S-CD was absent, dopa + dopamine were present whereas the 5-S-CD level in the urine was pathologic which suggests an abnormality in the secretion of this metabolite.

However, 5-S-CD determinations are of great value in the case of widespread disease. In these cases, the 5-S-CD determinations allow the evaluation of the therapeutic treatment for immunochemotherapy. Thus, not only can post-surgical strategy be better decided, but the follow-up therapy and time of treatment can be adapted as required. Evidently, a sudden increase in the 5-S-CD level is an indication for instigating another treatment.

Acknowledgements—We wish to thank Pr. Henri Bonneau, Dr. Maurice Pierre and the surgeons of J. Paoli-I. Calmettes Institute (Marseille) especially Professors Henri Bureau and J. M. Spitalier, and Dr. Roger Amar for providing the tumors. The expert technical assistance of M. Rémy Galindo is gratefully acknowledged.

Urinary Excretory Patterns of tRNA Degradation Products: A Marker of Hodgkin's Cell Metabolism?

I. A. COOPER,*‡ G. R. WRAY† and T. L. MURPHY†

Department of Haematology Research, Cancer Institute, Melbourne, Australia

Abstract—*Aberrant tRNA methylase activity has been described in a significant variety of animal tumours of both viral and chemically-induced aetiology. The possibility has been entertained that this may result in, or be the result of, altered metabolism of tRNA, with increased turnover of this molecule being mirrored by the appearance of degradation products in the plasma and urine. It is also possible that the tRNA may become hypermethylated. Hodgkin's disease, while possessing a variety of histologic types, has distinctive cells which may be present in either small or large numbers. The clinical prognosis would appear to relate to this histologic variation. This paper presents observations in 96 patients on the urinary excretion pattern of tRNA degradation products, pseudouridine and methylated guanines and demonstrates the strongly significant relationship of increased levels of these compounds to the number of Hodgkin's cells (atypical histiocytes). In addition, it relates these observations to the significance of the constitutional symptoms of the disease.*

INTRODUCTION

A NOTABLE feature of tumour metabolism is the presence of aberrant tRNA methylase activity. Increased activity of these enzymes has been reported in several tumours and there is evidence of hypermethylation of tRNAs extracted from solid tumours [1]. We have found increased amounts of methyl guanosine in tRNA from some tumours [2], but it has been difficult to correlate methylation of tRNA with hyperactivity of the methylating enzymes themselves.

There is evidence of increased excretion of tRNA components, methylated purines, and pseudouridine, in patients with various neoplastic diseases [3–8]. We have made similar observations on elevated pseudouridine levels in the urine of untreated newly diagnosed patients with Hodgkin's disease [9]. A relationship between this and the presence of constitutional symptoms was also observed and it was suggested that this may relate to increased metabolic activity of the Hodgkin's cell (atypical histiocyte). Although some elevation of methyl purines was also observed, this was not as consistent as the results on excretion of pseudouridine. Since then, we have studied a further 96 patients with newly diagnosed Hodgkin's disease and have used more sensitive methods for quantitation. This report relates the levels of methylated guanines to other features of the disease.

MATERIAL AND METHODS

Twenty-four-hour urine specimens were obtained from 96 patients with newly diagnosed Hodgkin's disease. The patients were placed on a low purine diet for 4 days and urine was collected on the 4th day. An aliquot (2.5% of total volume) was prepared and analysed according to a previously described method [9]. However, on this occasion more sophisticated instrumentation using a Gilford scanning spectrophotometer facilitated identification and quantitation of the various major and minor bases. The 1-methyl and 7-methyl guanine were grouped together and 8-OH-7-methyl guanine was estimated separately. Histiocytes were scored by assessing the percentage of such cells in biopsy specimens. tRNA methylase activity of tumour tissue was assayed as previously de-

scribed [2]. The methylase assays were carried out in only 12 of the 96 patients as tumour material was available in only this number of the patients included in this study.

RESULTS

Among the 96 patients studied, 50 demonstrated a high pseudouridine excretion (Table 1). Of these patients, 22 also had elevated levels of methylguanine (Table 2). It was of interest to note that in the group of 46 patients with normal pseudouridine levels, 42 had normal or undetectable amounts of methyl guanines, whereas only 4 had above normal levels of excretion. A similar observation was also made in the case of 8-OH-7-methyl guanine (Table 3), both observations being highly significant.

The relationship between elevated levels of pseudouridine and the presence of constitutional symptoms was statistically highly significant (Table 1). Constitutional symptoms were present in 76% of patients with elevated pseudouridine levels but only in 39% of those with normal or reduced levels. The correlation between elevated pseudouridine levels and the number of atypical histiocytes (Hodgkin's cells) present in biopsy specimens was also significant (Table 4). Sixty-eight percent of patients with elevated levels had scores above 20% of

Hodgkin's cells, whereas 41% had a negative correlation.

DISCUSSION

This report confirms our earlier observations on increased excretion of pseudouridine and methylated bases in patients with Hodgkin's disease [9]. However, we are now better able to measure the levels of excretion of previously undetectable amounts of bases, due to the increased sensitivity of the present methods of quantitation. A highly significant number of patients have been shown to excrete abnormal amounts of 1 and 7-methyl guanines and 8-OH-7-methyl guanine, the latter being a degradation product of 7-methyl guanine.

Observations on increased excretion of pseudouridine and methylated purines have also been made in patients with leukaemia [3, 4], polycythaemia vera, gout and psoriasis [5, 6] and mental retardation [10]. More recently Waalkes showed increased excretion of pseudouridine, 1-methyl inosine and N^2N^2-dimethylguanine in patients with various neoplastic diseases [8, 11–13], and Ho and Lin [14] observed increased excretion in hepatomas of 1 and 7-methyl guanine, dimethyl guanine, 1-methylhypoxanthine and adenine.

Methylated nucleic acid bases and pseudouridine are found predominantly in tRNA [15], hence their presence in serum and urine is presumed to be due to degradation of tRNA. Methylation occurs after formation of the macromolecule [16–17], but after degradation, these compounds are not reincorporated into the tRNA structure [17]. Similarly, free pseudouridine is not synthesized into the tRNA molecule [18]. Elevated levels of excretion of methylated nucleosides could therefore suggest increased tRNA methylase activity and possibly tRNA turnover, if pseudouridine were also elevated.

The origin of methylated bases from degradation of tumour tRNA in particular has not been entirely proven. We have observed increased activity of tRNA methylases in Hodgkin's tumours of 11 out of 12 patients (Table 5) who also had increased urinary excretion of pseudouridine. This suggests that there is at least increased methylation occurring in the Hodgkin's tissue.

It would appear that altered metabolism is taking place in the Hodgkin's cell rather than in the tumours in general as such alteration is most common in those who have the highest percentage of Hodgkin's cells in tumour tissue. Studies are in progress to isolate tRNA from Hodgkin's tissue and to analyse its base composition in an attempt to obtain further evidence of aberrant methylation in the tumour cell.

Transplantability of Neuraminidase-Treated Ascites Tumour Cells

HONOR SMYTH,* D. J. FARRELL, R. O'KENNEDY and ANTONIA CORRIGAN

Department of Biochemistry, University College, Dublin, Ireland

Abstract—*Landschütz ascites tumour cells exposed* in vitro *to neuraminidase (VCN) were tested for viability, sialic acid depletion and subsequent tumour development in three mouse strains. Treatment with* 25 *U VCN*/10^7 cells/ml *released* 50% *of the total cellular sialic acid content and no further release was found using a* 20 *fold higher enzyme concentration at* pH 5.5. *The treated cells were normally viable as assessed by vital dye exclusion. VCN reduced tumour transplantability at certain inoculum levels but above a particular tumour dose for each mouse strain no such effect was observed.*

Sera from the three mouse strains used showed no cytotoxic activity in vitro *against untreated or VCN-treated cells.*

INTRODUCTION

EXPOSURE of tumour cells to VCN (neuraminidase from *Vibrio cholerae*) can have three distinct effects on subsequent growth of the tumour *in vivo* [1]. These are (i) decreased transplantability into normally susceptible host animals, (ii) stimulation of the host to reject later challenge with untreated tumour and (iii) immunospecific rejection of established tumours by injection of VCN-treated cells. Altered immune reactivity, resulting from removal of negatively changed sialic acid from the cell surface, is considered to be responsible for these effects but the exact mechanisms involved are still unknown.

While the immunostimulatory effects of VCN-treated cells and their role in rejection of established tumours appear to be well authenticated, considerable controversy exists as to whether VCN effects transplantability [1–3]. Decreased tumour development *in vivo* following *in vitro* exposure of the cells to VCN has been reported by various authors [4–10] while others [11–14] have failed to find such an effect. A possible source of error in assessment of transplantability changes has been pointed out [1, 12]. Sub-optimal conditions of pH or cell density during enzyme treatment can lead to diminished viability of the VCN-treated cell suspension, so that the relevant hosts receive less than the tumour LD_{100}. Furthermore, the accuracy of dye exclusion methods as tests for reproductive integrity has recently been called in question [15].

Apart from viability considerations, other factors which could contribute to the divergent findings in the literature are:
(a) variations in enzyme treatment conditions: for instance, VCN concentrations ranging from 10 to 500 U/ml and pH levels ranging from 5.5 to 7.4 have been used; (b) the fact that not all authors measured release of sialic acid; (c) the presence or absence in the host sera of factors preferentially cytotoxic towards VCN-treated cells; (d) the size of the tumour inoculum used for transplantation, a factor which is not usually taken into consideration and often comprises a single arbitrarily chosen dose.

The aim of the present study was to examine sialic acid removal from Landschütz ascites cells exposed to low or high concentrations of VCN, the viability of these cells and their subsequent growth in Schofield, BDF/1 and A2G mice in response to a wide range of inoculum levels. It will be shown that exposure to VCN concentrations of either 25 U/10^7 cells/ml at pH 7.4 or 500 U/2×10^7 cells/ml at pH 5.5 (accompanied by multiple washing) released 50% of the total cellular sialic acid, while leaving viability unaltered. When certain medium-sized tumour inocula were administered the incidence of takes in Schofield and BDF/1 mice was found to be reduced by VCN. No such reduction in tumour takes was observed using A2G hosts. In all three strains tumour developed normally from VCN-

treated cells when higher inoculum levels were administered. We also report the absence from the sera of these mice of cytotoxic activity against untreated or VCN-treated cells.

MATERIAL AND METHODS

Mice

Schofield albino (bred as a closed strain since 1967) and BDF/1 (C57 × DBA) mice were obtained from the Medical Research Council of Ireland Laboratories, Dublin. A2G strain were bred in this Department from a nucleus kindly presented by the M.R.C. Animal Laboratory Centre, Carshalton, Surrey.

Tumour

Landschütz ascites tumour, generously donated by Glaxo Research Ltd., Greenford, Middlesex, was passaged in Schofield mice by weekly intraperitoneal transfer. Seven to nine day tumour cells were washed twice in Tris-buffered saline (TBS) and suspended in this medium for use. The medium contained 25 mM Tris, 160 mM Na and 6 mM K and had a pH of 7.4.

Enzyme

VCN was obtained from Calbiochem and from Behringwerke AG as vials containing 500 U in 1.0 ml and used as specified. In each case a unit (U) is defined as the amount required to release 1 μg of *N*-acetylneuraminic acid from a glycoprotein substrate in 15 min at 37°C.

Incubation of cells

Two different conditions of treatment were used.

Procedure (*A*). VCN (Calbiochem) was diluted in TBS and added to twice-washed cells to give a final concentration of 25 U VCN/10^7 cells/ml at pH 7.4. TBS replaced VCN in controls. Incubation was at 37°C for 60 min in a shaking water bath, after which the suspensions were centrifuged at 500 ***g*** for 3 min. The cells were resuspended in TBS, assessed for viability and diluted in TBS when necessary for *in vivo* transplantability studies. The supernatants were retained for sialic acid estimation.

Procedure (*B*). The conditions of Currie and Bagshawe [6] were followed. The cells were washed 6 times in TBS and suspended in the undiluted enzyme preparation which consisted of 500 U VCN (Behringwerke) dissolved in 1 ml 0.05 M sodium acetate, pH 5.5, containing 9 mg NaCl and 1 mg $CaCl_2$. Final concentrations were 500 U VCN/2×10^7 cells/ml. Control samples were suspended in this medium without VCN and otherwise received identical treatment. After incubation at 37°C for 30 min the cells were washed 6 times in TBS, viability assessed and the suspensions appropriately diluted for injection into A2G mice. Supernatants from the incubations and combined supernatants from the subsequent washes were retained for sialic acid estimation.

Cell counts and viability

Counting was carried out in a Burker cytometer under phase contrast microscopy. Viability was determined by vital dye exclusion, using lissamine green and/or trypan blue in final concentration of 0.2 g/l TBS. Testing was carried out immediately after treatment, before dilution of the suspension for inoculation, using a minimum of 5×10^6 cells/ml. Thus the errors inherent in the use of overdilute suspensions [12] were avoided.

Sialic acid

Total cell sialic acid was determined on 2 $\times 10^7$–1×10^8 thrice washed cells. They were digested with 2 ml of 0.1 N HCl at 80°C for 1 hr, centrifuged to remove debris and deproteinised overnight at 4°C with 5% TCA. The dried supernatants were redissolved in 0.5 ml distilled water and free sialic acid estimated. The free sialic acid in supernatants from treated cells was determined after deproteinizing and drying as above. Two methods were used for free sialic acid. (i) Warren's [16] colorimetric assay which has a range of 2–10 μg; in this case the correction for colour produced by deoxyribose was applied (ii) the fluorimetric assay of Murayama *et al.*, [17] which is more sensitive, with a range of 0.1–10 μg. Results were identical using either method. A range of standards (*N*-acetylneuraminic acid, Sigma) was incorporated in all experiments.

Tumour transplantability

Each mouse received a 1.0 m intraperitoneal injection of the specified number of cells. When high cell numbers were used, tumour was allowed to develop for 7 days at which stage the animals showed obvious abdominal distension. With lower inoculum levels 7-day yields were too small for accurate weight determinations, so the growth periods were prolonged to 14–18 days. At the end of the specified time the mice were killed and the peritoneal tumour suspensions collected in TBS. Microscopic examination showed that contamination with white or red blood cells was never more than 8%. Transplantability was assessed as the number of tumour "takes" in proportion to the number of animals injected,

mice yielding ascites cells from the peritoneal cavity being designated as "takes". Neither in "takes" nor "non-takes" was there any evidence of solid tumour formation in the abdominal organs or at the injection site. Survival experiments were also performed, the mice being left until their abdominal cavities were grossly distended and then killed for humanitarian reasons. Post-mortem examination showed the distension to be due to accumulation of ascites tumour: there was no evidence of solid tumour formation.

Tumour yield

Cells obtained from mice which developed tumour were centrifuged at 500 ***g***, dried overnight at 104°C and dry weights recorded. The mean dry weight of cells from those mice in which the tumour grew was taken as an indication of tumour growth.

Serum cytotoxicity

Fresh serum samples, pooled from 3 mice of each strain, were tested for direct cytotoxicity against tumour cells which had been exposed to TBS or VCN according to procedures (A) or (B). Following the method of Sethi and Brandis [9] 10^7 cells/ml TBS were mixed with an equal volume of test serum, either undiluted or diluted 1:1 in TBS, and incubated at 37°C for 45 min without shaking. Cell viability was then tested using lissamine green and trypan blue.

RESULTS

Viability (dye exclusion)

Numerous tests using both lissamine green and trypan blue showed the viability of cells exposed to procedure (A) to be always greater than 90%. Readings for VCN-treated cells never differed from those of controls by more than 5% and these minor differences showed no consistent trend. Procedure (B), which involved extra manipulations and a low pH, resulted in mean viabilities of 80% for controls and 83% when VCN was used. This difference is not significant.

Sialic acid release

The total sialic acid content of untreated Landschütz tumour cells was 471 ± 14 nmole/10^9 cells (mean ± S.E.M. of 19 determinations). The free sialic acid released from treated cells was almost identical under both procedures, being 50% and 49% of the total cellular content in the cases of (A) and (B) respectively (Table 1). In the case of control cells, however, a marked difference was found in the degree of free sialic acid depletion between the two procedures; procedure (B), presumably due to the numerous washes involved, resulted in a loss of 28% of total cell sialic acid, while the corresponding value for cells subjected to procedure (A) was only 6%.

Transplantability

Cells treated according to procedure (A). Table 2 shows the incidence of tumour takes and the mean weights of tumour/mouse (for those animals in which tumour developed) resulting from administration of various inoculum levels to 3 strains of mice. Prior exposure to VCN reduced transplantability when certain cell doses were used. For example, Schofield mice receiving 10^5, 10^4 or 10^3 cells showed a decrease in incidence of tumour takes from VCN-treated inocula compared with the corresponding controls. The combined figures for tumour incidence at these three dose levels show a total of 13/37 (35 ± 2.8%) for VCN treated cells, which

Table 1. Sialic acid release (nmole/10^9 cells) *during treatment with low and high concentrations of VCN by procedures (A) and (B) (Mean values ± S.E.M.)*

	Procedure (A)		Procedure (B)

As % of total sialic acid in cells	6%	50%	28%	49%

is significantly lower ($P=0.02$) than the control value of 22/35 ($61 \pm 6.6\%$) for the controls. An additional phenomenon observed in Schofield mice was a significant ($P<0.01$) reduction in 15-day tumour yield in mice inoculated with 10^5 VCN-treated cells (Table 2). It can be seen that more concentrated inocula, from 10^6 up to and including 2.5×10^7, resulted in no difference between VCN-treated and control groups in incidence of takes or weights of tumour yield. (1.5×10^7–3.0×10^5 cells/mouse) but a significant reduction in tumour weight was observed in the group receiving 4×10^6 VCN-treated cells.

The data in Table 2 show that prior exposure of the cells to 25 U VCN/10^7 cells/ml at pH 7.4 affected tumour transplantability to a distinct degree in 2 of the 3 mouse strains tested provided that the number of cells administered was below the tumour ED_{100} for that strain, i.e. the

Significant reductions in mean tumour yield denoted by ‡ ($P<0.01$) and § ($0.02<P<0.05$).

Similarly, in BDF/1 mice, VCN-treated cells developed tumour to the same extent as control-treated cells when the upper inoculum levels (6×10^6–2.4×10^7 in this case) were used, but showed almost complete inhibition of development when administered in a dose of 1×10^6/mouse. In addition, the one BDF/1 mouse that developed tumour from 1×10^6 VCN-treated cells showed a reduced tumour yield. In A2G hosts VCN treatment had no effect on the incidence of takes over the range of inocula used inoculum level required to produce 100% tumour takes in the control group under our conditions.

In addition to short-term assessments, long-term survival was also tested in mice which had been given similarly treated cells. Two groups of Schofield mice were injected with 4×10^6 cells each, control or VCN-treated. The same dose was also given to 17 BDF/1 mice (8 control, 9 VCN) and all animals were observed daily. All mice in untreated and treated groups of each

strain were moribund from tumour by 30 days and were therefore killed. In a further experiment 2 groups of 10 Schofield mice received 10^2 cells, treated or untreated. Due to the low cell dose, neither group showed any obvious signs of tumour at the end of 2 weeks (cf. Table 2); nevertheless all eventually became equally distended with tumour and were therefore killed at 7 weeks. These survival experiments confirmed the results of short-term tests in showing that VCN-treated cells develop normally *in vivo* when administered in doses outside the critical ranges demonstrated by the results in Table 2.

Cells treated according to procedure (B). Currie and Bagshawe [6] reported that only 1/40 A2G mice injected with 4×10^6 VCN-treated Landschütz cells died from tumour, compared with a death rate of 100% in the control group. Since we had found no marked inhibition of transplantability in this mouse strain at any of the inoculum levels tested, we carried out additional experiments in which the treatment conditions used by these authors were closely followed. The cells were then used to test the transplantability in A2G mice of inocula of 4×10^6 and 2.5×10^5 cells.

It has already been shown (Table 1) that no extra free sialic acid was removed from the cells by using this greatly increased VCN concentration. The results of *in vivo* tests were as follows: 14 days after an inoculum of 4×10^6 cells the control group showed 6/6 tumour takes and a mean tumour yield of 234 ± 57 mg, the corresponding values for the VCN-treated group being 5/6 takes and 402 ± 32 mg/mouse. Thus the reduction in tumour yield found in A2G mice injected with 4×10^6 cells treated with VCN according to procedure (A) was not observed when procedure (B) was used to treat the cells. A further 7 mice in the treated group were observed for 25 days after injection, at which stage 2 were tumour-free. The remaining 5 (71%) were obviously near death and when killed yielded a mean wt of 388 ± 30 mg/mouse. On reducing the inoculum to 2.5×10^5, tumour takes after 21 days were 2/5 in both the control and the VCN-treated group and the mean tumour yields were 260 mg (2) and 158 mg (2), respectively.

Thus, VCN treatment under the conditions outlined in procedure (B) permitted normal tumour development in 66% (12/18) of A2G mice, compared with 72% (8/11) in the relevant controls.

Cytotoxicity of host sera

When cells subjected to procedures (A) or (B) were incubated with sera from host mice as described in Methods, viability was found to be unaltered in both control and VCN-treated samples. Thus, non-tumour-bearing Schofield, BDF/1 and A2G mice do not appear to carry serum factors directly cytotoxic to either VCN-treated or control-treated Landschütz cells.

DISCUSSION

In testing for an effect of VCN on tumour transplantability valid conclusions can only be drawn if the viability of the enzyme-treated inoculum can be shown to be normal. The report of Yuhas *et al.* [15] described a VCN-induced cytotoxic effect on line-1 cells which was not detectable by dye exclusion methods. In the present study, however, we found tumour development from VCN-treated cells to be normal in all 3 host strains when the upper ranges of inoculum levels were used. This indicates that VCN-treated and control cells were of equal viability and thus provides confirmation of our results using vital dyes.

It was interesting to find (Table 1) that free sialic acid was removed from the cells by VCN to the same extent using treatment procedures (A) and (B). This suggests that the amount concerned, 50% of the total content in these cells, is the maximum removable by VCN exposure and that this can be achieved using 25 U/ml at pH 7.4. Similarly, Bekesi *et al.* [8] found 20–50 U/ml to be optimal for the ascites tumour L 1210. Currie [5], although not measuring sialic acid release, found a progressive decrease in electrophoretic mobility with doubly increasing doses of VCN up to and including 500 U/ml. Our finding that no extra free sialic acid is removed by the use of high enzyme concentrations provides additional evidence for the proposal [1, 18] that the use of excessive VCN can decrease electrophoretic mobility by means other than removal of sialic acid, e.g. through absorbance of excess enzyme on the cell surfaces.

Our use of 500 U/ml was motivated by the work of previous authors [5, 6] who, under these conditions, found almost total inhibition of transplantability in A2G mice and showed [5] this concentration to be essential for the effect. Our present results, however, do not show any marked decrease in transplantability in these mice. The reason for this divergence is not clear.

As already mentioned, the results in Table 1 show a marked difference between the two controls in procedures (A) and (B) in that considerable loss of free sialic acid occurred in control cells subjected to procedure (B), amounting to 28% of total cell content. Theoretically therefore, it might be expected that these cells would be less oncogenic than

control cells prepared by procedure (A), but our results indicate that this is not the case: A2G mice showed 100% takes from 4×10^6 cells prepared by either procedure and the mean 14-day tumour yields/mouse of 380 ± 48 (5) and 284 ± 57 (6) (procedures (A) and (B) respectively) do not differ significantly. This suggests that a greater proportion than 28% of the total sialic acid has to be removed from Landschütz cells before tumourigenicity is reduced. It has been shown for L 1210 ascites tumour [8] that maximum enzymatic removal of free sialic acid must be achieved before an effect on transplantability is manifested.

The main point arising from the present study is that the choice of inoculum level can be of major importance for detection of an effect of VCN on transplantability, since at or above the ED_{100}, as defined above, no effect on tumour incidence was observed. That VCN can strongly reduce the transplantability of Landschütz ascites tumour in 2 of the 3 mouse strains tested is evident from the results using certain inoculum levels below the ED_{100} (Table 2). This finding may be compared with earlier observations [19] that large inocula of chemically transformed cells were able to override the immune system of host mice and grow progressively but medium sized inocula were rejected. The tumour doses at which an effect of VCN was observed were 1×10^6 cells for BDF/1 and between 1×10^5 and 1×10^3 cells for Schofield mice. In A2G hosts VCN treatment by either procedure had no effect on the incidence of tumour takes.

An additional phenomenon, found in Schofield mice, was a significant reduction in the 15-day yield of tumour weight in mice which had received 1×10^5 VCN-treated cells. This effect appeared to be specific for an inoculum of 10^5 cells. The results were repeatable in two experiments separated by a period of 1 yr and were not due to variations in experimental technique, since mice receiving higher and lower cell numbers were inoculated using the same concentrated incubation mixtures. A similar trend is seen in BDF/1 mice given 1×10^6 cells and in A2G mice receiving 4×10^6 cells.

It has been suggested [20, 21] that the transplantability of VCN-treated cells may depend on the absence or presence of antibody-like cytotoxic factors pre-existing in the sera of some host animals which can lyse VCN-treated but not untreated tumour cells. The *in vitro* cytotoxicity described by these authors was, however, dependent on the addition of guinea-pig complement (despite the fact that the mouse sera had not been heat-deactivated) and therefore would not seem to have any bearing on the *in vivo* fate of VCN-treated cells in mice. Furthermore, while VCN increases the sensitivity towards added complement of lymphoid cells [22] and Landschütz tumour [23], the latter author also found a similar effect after exposure of Landschütz cells *in vitro* to the proteolytic enzyme brinase, which has a growth enhancing effect on this tumour in Schofield mice [24]. We therefore considered direct single-stage cytotoxicity tests to be more relevant to the present problem. These were performed according to the method of Sethi and Brandis [9], who have described preferential lysis of VCN-treated Ehrlich and L 1210 ascites tumour cells *in vitro* by fresh serum from C3H, DBA, C57 and NMRI mice but not from BALB/c strain. We found no evidence of cytotoxicity in the serum of Schofield, BDF/1 or A2G mice towards control or VCN-treated cells which had been subjected to procedures (A) or (B). It appears, therefore, that in the mouse strains used in this study, VCN-induced inhibition of tumour was not mediated by pre-existing serum cytotoxic factors.

Sanford and Codington found that VCN reduced the transplantability of TA3 ascites tumour cells in C3H mice but permitted them to grow normally in DBA and A mice [21]. They attributed this to the existence, in C3H serum but not in that from the other two strains, of a cytotoxic activity in the presence of added complement, which was preferentially active aginst VCN-treated TA3 cells. We suggest, however, that their findings can be readily interpreted in terms of our present results, which emphasise the importance of using the optimum inoculum level for transplantability effects in each host strain. For example, their results (Table 1) show that in DBA and A mice the inoculum used (3×10^3 cells) caused the death of 100% of the control group and therefore was equal to, or possibly greater than the LD_{100} (or ED_{100} as defined earlier for our conditions) of the tumour in these hosts; hence, administration of the same number of VCN-treated cells had no effect on the incidence of tumour takes. In C3H mice, in contrast, the inoculum of 3×10^3 cells was only 75% effective in the control group and here prior treatment with VCN resulted in a reduction of approximately 50% in tumour incidence. Hauschka *et al.* [12] also used TA3 tumour in C3H and A strain mice and found (their Table 6) that 3×10^3 cells injected into A mice resulted in 100% tumour takes in the control group and the same effect when VCN was used. An inoculum of 3×10^3 cells from a less than normally viable suspension was evidently below the LD_{100} for strain A mice, since only 87% of the control group developed tumour and

in this case a slight reduction due to VCN (70%) was seen. Again, in C3H mice administration of fully viable cells only resulted in 78% takes in the controls and some effect of VCN on transplantability was evident, the incidence of tumour development falling to 63%. The use of a less than normally viable inoculum in C3H mice resulted in only 10% tumour takes from 3×10^3 untreated cells and no reduction in transplantability in the VCN-treated group: the low incidence of takes in this instance indicated that the tumour dose is outside the optimal range for detection of an effect of VCN as evidenced by the results in Table 2 of the present study.

It is suggested that other instances may exist where failure to observe reduced transplantability of VCN-treated tumour cells could be attributable to the use of unsuitably high tumour inoculum levels. Further work using a range of tumour-host systems may help to explain some of the divergencies in the literature on this subject.

Lysosomal Enzyme Inhibitors and Antimetastatic Activity in the Mouse*

T. GIRALDI,† C. NISI‡ and G. SAVA†

†*Istituto di Farmacologia and* ‡*Istituto di Chimica Farmaceutica, Università di Trieste, I-34100 Trieste, Italy*

Abstract—*Saccharo-1,4-lactone, a β-glucuronidase inhibitor, and three protease inhibitors did not affect primary tumour growth when tested against Lewis lung carcinoma in mice. The number of lung metastases was significantly reduced by aprotinin only. The inactivity of leupeptin and pepstatin seems to indicate that cathepsin B and D are not involved in metastasis formation. These results also indicate that aprotinin, a broad spectrum protease inhibitor, reduces tumour dissemination, in addition to the tumour invasion already reported by others.*

INTRODUCTION

THE ROLE of lysosomal enzymes in such malignant properties of solid tumours as invasiveness and formation of metastases has received the attention of several investigators. Although some controversy concerning the methodology of the assays arose in one instance [1], it is generally accepted that certain enzymes such as cathepsins, collagenase, hyaluronidase and β-glucuronidase, present in higher concentrations in tumour cells, tumour cell surface and/or the interstitial fluid of solid tumours than in normal tissues, might be responsible for tumour invasion and dissemination [2–4].

This evidence is further supported by the reported effects of enzyme inhibitors on *in vivo* tumour growth. The treatment of mice bearing Ehrlich carcinoma with saccharo-1,4-lactone, a β-glucuronidase inhibitor, markedly reduced tumour growth [5]. Aprotinin, a broad spectrum protease inhibitor, reduced tumour growth and invasion as well as increasing tumour necrosis, when administered to hamsters bearing a highly invasive fibrosarcoma or to mice bearing a similarly malignant mammary carcinoma [6]. The survival time of mice inoculated with a malignant thymoma was increased by the peritumoural administration of cysteine, an inhibitor of collagenase [7].

N-diazoacetyl glycine amide (DGA), a substance which belongs to a class of active site directed, irreversible inhibitors of proteolytic enzymes [8], has recently been shown to possess antimetastatic properties in mice bearing Lewis lung carcinoma [9], in addition to its previously reported antitumour effects on rodent transplantable neoplasms [10].

These reports and considerations led us to use the same experimental system to test the possible antimetastatic effects of a series of lysosomal enzyme inhibitors.

MATERIAL AND METHODS

The animals used for this investigation were C57Bl/6 Cr male mice, weighing 21–22 g. Tumour transplantation was performed by trocar s.c. implantation in the axillary region of a tumour homogenate, prepared using donor mice similarly inoculated 2 weeks before [11]. Primary tumour weight was evaluated by caliper measurement of tumour diameters [12]. Lung colonies were detected using the technique described by Wexler [13].

Aprotinin and saccharo-1,4-lactone were obtained from commercial sources (Bayer and Sigma respectively). Pepstatin and leupeptin were generously provided by Professor H. Umezawa, Institute of Microbial Chemistry, Tokyo, Japan.

The substances were administered i.p. as an aqueous solution using 0.1 ml (0.2 ml for aprotinin) per 10 g of animal weight.

RESULTS AND DISCUSSION

The experimental results obtained are reported in Table 1. For all the tested compounds, the effects on primary tumour growth were negligible and not statistically significant.

Accepted 5 May 1977.

Pepstatin	50 mg	3.26±0.48	0.90	+0.8	20.8±3.2	1.39
Leupeptin	50 mg	2.91±0.46	0.80	−7.7	16.9±1.7	1.13
Saccharo-1, 4-lactone	150 mg	2.82±0.46	0.78	−0.6	17.0±2.0	1.13

*T/C is the ratio of the average values of each treated group to that in controls. The treatment was performed daily, from day 1 to 14 after tumour inoculation: groups of 8 mice were used. The primary tumour mass was measured on day 15, and the lungs examined for metastases at sacrifice on day 24. The statistical analysis performed is a one way analysis of variance [21].

†Mean significantly different, $P < 0.05$.

At a dosage which has been reported to markedly inhibit *in vivo* tumour growth [5], saccharo-1,4-lactone was devoid of any effect on the number of metastases found at sacrifice. Among the protease inhibitors tested, pepstatin and leupeptin were similarly inactive, whereas aprotinin significantly reduced the number of lung colonies to about 50% of controls.

The possibility that the inactivity observed for leupeptin and pepstatin in our experimental system may be due to insufficient dosage can be ruled out on the basis of the following considerations. The leupeptin dose used has been shown to inhibit the *in vivo* carcinogenic effects of polycyclic hydrocarbons and also reduced the TAME esterase activity in the skin of the treated mice [14]. Pepstatin was administered at the same dosage used for leupeptin, and its effectiveness in inhibiting cathepsin D *in vitro* is 40 times greater than that of leupeptin for cathepsin B [15].

In addition to the reported reduction of the malignant growth of rodent tumours [6], these findings indicate that treatment with the protease inhibitor, aprotinin, also causes a depression in the number of haematogenous metastases in the experimental model employed. They are in agreement with the reported reduction of macroscopic metastases caused by aprotinin in hamsters bearing a fibrosarcoma, which was attributed to the enhancement of the immunological system of the host against the tumour cells [16]. In contrast to previous reports concerning the role of cathepsins, in particular cathepsin B, in the process of metastasis formation [17], the observed lack of activity of leupeptin and pepstatin seems to rule out the participation of cathepsin B and D in this process. These data also support the hypothesis that the antimetastatic effects reported for DGA might be attributed, at least in part, to an inhibition of proteolytic enzymes. Diazoacetyl derivatives of amino acids have been shown to inhibit acidic proteases via a k_{CAT} mechanism [18]; the inhibition being more pronounced in the presence of divalent metallic cations [19, 20]. Although the mechanism has still to be elucidated, these compounds have also been found to inhibit neutral proteases in the absence of cupric ions [22].

Further work is in progress aimed at testing additional inhibitors, of natural and synthetic origin and to see whether their mechanism of antimetastatic action *in vivo* involves actual inhibition of tumour proteases. The purpose of this investigation is to increase the knowledge of the process of metastasis formation and to increase the number of agents different from conventional cytotoxic drugs available for cancer treatment.

Histochemical, Light and Electron Microscopic Study of Polonium-210 Induced Peripheral Tumors in Hamster Lungs: Evidence Implicating the Clara Cell as the Cell of Origin*

ANN R. KENNEDY,† ROBERT B. McGANDY and JOHN B. LITTLE

Department of Physiology, Harvard School of Public Health, Boston, 02115, U.S.A.

Abstract—*Peripheral lung tumors induced in Syrian golden hamsters by intratracheally administered polonium-210 (^{210}Po) are similar to the peripheral lung tumors induced in many species by a variety of carcinogens. In addition, they show many of the histopathological features observed in human bronchiolar–alveolar carcinomas. Serial sacrifice studies of hamsters exposed to multiple instillations of ^{210}Po have been carried out to identify the cell of origin of these tumors. By means of thin, plastic (glycol methacrylate) sections, electron microscopy, and histochemistry, we conclude that the bronchiolar Clara cell is the probable cell of origin, and that this view is generally compatible with many of the reported cytological characteristics of the human tumor.*

INTRODUCTION

INTRATRACHEALLY administered polonium-210 (^{210}Po) is a potent lung carcinogen in Syrian golden hamsters, with tumor induction time and incidence related to dose over a broad range [1]. The tumors arise in the bronchiolar–alveolar region, and because they may show light microscopic features of both epidermoid and adenocarcinomas, have been classified by us as "combined tumors" [1]. The tumors themselves, as well as the precursor lesions, are often associated with a variable degree of periodic acid–Schiff (PAS)–positive secretory product.

^{210}Po is an alpha emitting radioisotope and is present in cigarette smoke [2] and cigarette smokers' lungs [3]. ^{210}Po has been shown to be carcinogenic to hamsters at whole lung doses as low as 15 rad [4]. In man, bronchiolo-alveolar carcinoma is a peripheral lung tumor similar in appearance to the ^{210}Po induced tumors; it is estimated to represent as much as 8% of all lung tumors [5] and there is some evidence that smoking plays a significant role in its pathogenesis [6].

Human bronchiolo-alveolar carcinoma, also known as alveolar cell cancer, malignant pulmonary adenomatosis, bronchiolar carcinoma etc. [7], is thought to arise from bronchiolar or alveolar epithelium. The tumor was first described by Malassez [8], who characterized the multiple nodular, and therefore possibly multicentric, form of the disease. However, Storey [9] in 1953 showed it to be of unicentric origin and thus a likely possibility for a surgical cure. Bronchiolar–alveolar carcinoma exhibits two basic cellular forms [9–12]. The first is a well differentiated carcinoma with a uniform, tall columnar cellular pattern and abundant mucin production. Mucin is present within the cytoplasm of tumor cells as well as in extracellular spaces. Since the tumor cells tend to grow along, rather than invade, the alveolar walls, the basic bronchiolar–alveolar architecture is maintained. Ciliated cells are rarely found, and there are rather few mitotic figures. The second form is less well differentiated and characterized by more solid areas of tumor with concomitant loss of alveolar architecture. The tumor cells are larger, pleomorphic and hyperchromatic [9];

Accepted 3 May 1977.

mucin production is infrequent or absent. In either form of the tumor, one may find areas of epidermoid differentiation [10]. According to McNamara *et al.* [11], the extent of cellular maturation is not related to the aggressiveness of these tumors and, as a group, the 5 yr survival is much higher than for epidermoid or adenocarcinomas of bronchogenic origin.

Experimentally induced ^{210}Po tumors also show considerable morphologic variations: among animals, among lobes in the same animal, and within microscopic fields of a large lesion; in the degree of glandular differentiation; in the degree of epidermoid differentiation or metaplasia; and in the presence of mucin. Even when the tumor cells appear cytologically innocent, some of these induced tumors show clear evidence of invasive and metastatic spread.

The cell of origin of the human tumor is controversial. There is some evidence that the tumor cells have ultrastructural characteristics of bronchiolar epithelium [13, 14]; however, several recent studies have attributed the origin to neoplastic type II alveolar epithelial cells [12, 15]. Type II alveolar epithelial cells have also been implicated as the cell of origin of many animal tumors of the peripheral lung [16–18], particularly mouse adenomas [16, 17]; however, the histogenesis of mouse adenomas may be very different from peripheral lung tumors of other species.

The cell of origin of the ^{210}Po induced tumors was not clear from our earlier work with animals bearing end-stage tumors [1]. The present series of experiments were designed to study the natural history of those lesions in the lungs and to determine the cell of origin. Three approaches have been used for this study: (1) a serial sacrifice experiment utilizing one-micron sections of glycol methacrylate (plastic) embedded lungs to study the early lesions in the lungs; (2) electron microscope sections of induced tumors to determine the ultrastructural characteristics of the cells involved; and (3) histochemical studies of tumors to determine the nature of the tumor secretions.

Identification of the cell type originating peripheral lung tumors will enable the calculation of radiation doses necessary to induce malignant transformation in that sensitive cell type. The relative hazards of various lung carcinogens can then be determined in terms of doses to critical cells. An estimation of risk from the inhaled plutonium isotopes, having alpha particle emissions similar to the ^{210}Po alpha particle, is particularly important due to the increasing likelihood of human exposure to these alpha emitting isotopes produced by the nuclear power industry. Plutonium isotopes have been shown to produce primarily bronchiolar–alveolar carcinomas in many species under a variety of exposure conditions [19]; these peripheral lung tumors are histologically like those seen in man [7–12] and our ^{210}Po exposed animals [1].

MATERIAL AND METHODS

Random-bred, male Syrian golden hamsters (Dennen Animal Industries in Gloucester, Mass.) weighing 100–125 g., were given 7 intratracheal instillations of 0.1 μCi ^{210}Po in 0.9% NaCl as has been previously described [1]. Animals were sacrificed weekly during and after the instillations for 60 weeks. All animals were sacrificed by Sodium Brevital (Lilly) overdose and exsanguination from a renal artery. Preparation of lungs for 1 μ glycol methacrylate (plastic) sections and staining procedures have been described in detail [20]. Tissue samples were cut from each lobe in planes parallel to the axis of the major bronchus, and from areas of suspected pathology.

For electron microscopy, three animals were sacrificed at 60 weeks after the instillation period and lungs were prepared for examination as follows. Lungs were inflated in the chest by cannulation (19-gauge needle, PE 190 Intramedic tubing) and injection of Karnovsky's glutaraldehyde-paraformaldehyde fixative [21] at 4°C (30 cm water pressure). After 5 min fixation in the chest, lungs were removed and placed in a beaker of Karnovsky's fixative for 3 hr. Lungs were cut into small pieces (less than 1 mm square), washed 4 times in cacodylate buffer (0.1 M, pH 7.4) and stored overnight in cold buffer. The blocks were then post-fixed in s-collidine-buffered osmium tetroxide (1.3% osmium tetroxide in 0.1 M s-collidine, pH 7.4) for 1 hr, washed 4 times in s-collidine buffer, dehydrated and embedded in epon. Tissue sections were cut on a Reichert ultramicrotome. One micron sections were stained with toluidine blue or PAS-hematoxylin. Appropriate blocks were trimmed for electron microscopy, and silver sections cut with a diamond knife (DuPont). Sections were mounted on 300 mesh copper grids, and stained with uranyl acetate and lead citrate. Sections were examined with a Philips 300 electron microscope.

To determine the nature of the secretion produced by the tumor cells, by the cells in non-neoplastic areas, and in control lungs, various histochemical staining procedures were used on sections from animals sacrificed 60 weeks after the instillation period and from normal controls.

For those stains in which chemical processing techniques would interfere with the histochemical nature of the tissue, frozen sections were used. For these studies, the collapsed lungs and trachea were removed *en bloc*, the trachea cannulated with PE 190 polyethylene tubing, lungs filled with O.C.T. embedding medium (Fisher Scientific Co.) and frozen rapidly by placing them for 1 min in isopentane cooled to the viscous stage by liquid nitrogen. The frozen lungs and trachea were then cut into pieces, mounted on chucks, and cut at 4 μ in a microtome cryostat (Harris Mfg. Co.) maintained at $-35°C$. For some of the stains used in this study, paraffin embedded tissue was commonly utilized. For paraffin sections, the inflated lungs and trachea were fixed in 10% neutral buffered formalin and embedded in paraffin blocks using conventional procedures.

The following staining procedures were done on frozen sections:

Sudan black B—formalin fixed frozen sections with acetone extraction [22];

PAS—with and without diastase digestion [23];

Best's carmine method for glycogen [23];

Hale's colloidal iron method [23]; and

Baker's acid hematein method—with and without pyridine extraction [23].

The following stains were done on paraffin sections:

PAS—with and without prolonged acetylation [23];

Mayer's mucicarmine method for mucin [24];

Muller's modification of Mowry's colloidal iron stain for acid mucopolysaccharides with Van Gieson's collagen fiber stain—with and without sialidase digestion [24];

Alcian blue pH 0.4 [24];

Alcian blue pH 2.5—PAS sequence [24];

Alcian blue pH 1.0—PAS sequence [24]; and the high iron method [25].

RESULTS

I. Serial sacrifice study, 1 μ sections—glycol methacrylate embedded lungs. Since a number of histopathologic findings in this study have been described elsewhere [26], only those results pertinent to the cell of origin of these tumors will be reported here.

As early as 7 days after the second instillation of ^{210}Po, type II alveolar epithelial cells responded to the treatment by undergoing hyperplasia and hypertrophy with an increased number of cytoplasmic inclusions or cytosomes. Subsequently, these enlarged cells were also often seen within tumors and in groups surrounding tumor areas. At 7 days after the 5th instillation of ^{210}Po, the first example of "alveolar epithelialization or bronchiolization" was seen (example, Fig. 1). By 4 weeks following the last instillation of ^{210}Po, such foci were seen in almost all animals sacrificed. Briefly, bronchiolar epithelial cells are found lining the surface of preexisting alveoli, where normally only alveolar-type cells occur. Both ciliated and typical bronchiolar columnar and cuboidal cells appear in these hyperplastic nodules [26], although ciliated cells were less frequently seen as the pathologic regions containing acinar structures became larger in size. These hyperplastic nodules were often seen with alveolar macrophages trapped inside. As early as 10 weeks after the last instillation of ^{210}Po, they consisted of many cells resembling Clara cells but containing PAS positive secreted materials (Fig. 2). Both single- and double-layered hyperplastic nodules were found. It is of interest that many Clara cells of the normal bronchiolar epithelium, not normally PAS positive cells, also began to display PAS positive granules (Fig. 3) similar to those seen in cells of the hyperplastic and tumor regions (Figs. 4 and 5). Squamous metaplasia was seen in many of the acinar structures (Fig. 6).

True lung tumors (combined epidermoid and adenocarcinomas), which we believe arise in these hyperplastic nodules, are aggressive, epithelial lesions which are usually multicentric, show varying cellular atypia, destroy the supporting lung stroma, and which occasionally invade airways, blood vessels or pleura. Mucus production is nearly always present. These tumors are transplantable [27], and their histopathologic characteristics have been described in detail elsewhere [1].

II. Electron microscopic study. One-micron epon sections from the three animals studied by light microscopy showed the presence of ^{210}Po induced tumors of the type previously described [1]. In addition, lung fields adjacent to the neoplasms and in other lobes showed many areas of alveolar epithelialization and hyperplastic nodules. Some of these foci were not associated with a secretory product (Fig. 1). Electron microscopic examination of these hyperplastic nodules showed cells resembling Clara cells but containing many more light secretion granules than usually found in normal hamster Clara cells [28].

The following cell types were found within the tumors:

A. The most frequent cell type encountered within the acinar structures was a cell covered by

prominent microvilli supported by tonofilaments, and having nuclei of irregular contour, often bilobed (Figs. 7 and 8) and containing clumped chromatin around the periphery (Fig. 7). These cells have a well-developed Golgi zone (Fig. 7), extensive granular endoplasmic reticulum (Figs. 7 and 8), often much apical agranular endoplasmic reticulum (Fig. 8), and many free ribosomes (Figs. 7 and 8). Membrane limited, electron dense mucous granules could be seen in the apical cytoplasm. Mitochondria were numerous, often swollen, and contained irregular cristae which only partially traversed the mitochrondria (Figs. 7 and 8). Lysosomes were often seen, and there were frequent myelin figures (Fig. 8). There were "dark" and "light" cells—the electron density depending on the amount of free ribosomes and agranular endoplasmic reticulum. Cell to cell connections included terminal bars and desmosomes.

B. Cells with clear evidence of epidermoid differentiation having irregular nuclei, tonofibrils (Fig. 9), bundles of tonofibrils, numerous desmosomes (Fig. 9), complex interdigitations between cells (Fig. 9), microvilli, vesiculation of the endoplasmic reticulum, many free ribosomes and some agranular endoplasmic reticulum. There are "dark" and "light" cells in this category, depending mainly on the amount of agranular endoplasmic reticulum present. Small round intracytoplasmic inclusion bodies, with a dense core of variable composition, were often seen in these cells (Figs. 9a and b). These particles were all smaller than 0.25 μm.

C. Another prominent cell type seen in the acinar structures, as well as in areas where no such structures were visible, was a cell resembling the Clara cell with prominent microvilli, extensive supranuclear agranular endoplasmic reticulum, nuclei having condensed chromatin around the edges, and many membrane bound granules of electron lucent material (Fig. 10). There were numerous small round or oblong mitochondria and occasional lysosomes. Myelin figures were often present.

D. Undifferentiated cells consisting primarily of ground substance with microvilli, tonofilaments, very deeply infolded nuclear membranes, some granular endoplasmic reticulum and particulate glycogen (Fig. 10).

E. Ciliated cells (Fig. 10)—having numerous apical mitochondria, a large Golgi zone, many ribosomes and lysosomes, many cilia, occasional centrioles and some microvilli. Most of these cells appeared to be regular ciliated cells, as have been described at the electron microscopic level in detail elsewhere [29].

F. Enlarged type II alveolar epithelial cells (Fig. 11)—very similar to normal type II alveolar epithelial cells, described elsewhere [29]. They were considerably larger than normal, with many more cytosomes or lamellar bodies than are usually found. With our system of processing, the cytosomes are extracted to a large degree. In the cytoplasm were numerous mitochondria, ribosomes, some granular endoplasmic reticulum, and a few lysosomes. There were occasional microvilli and large round nuclei.

There were also occasional cell types with extensive development of the endoplasmic reticulum or Golgi apparatus, or with very long microvilli. Other cell types found in the tumor, but probably having little to do with the malignant state, include macrophages (Fig. 10), polymorphonuclear leukocytes, connective tissue cells and blood and blood vessel cells, all of which have been described at the electron microscopic level elsewhere [29].

III. Results of histochemical studies for characterization of the secretory products, both in apical cytoplasm of tumor cells and extracellularly, in hyperplastic nodules and in adjacent Clara cells in bronchioles. Glycogen stains were negative. All of the mucin stains were positive in areas; the results have been interpreted as follows. The PAS positive granules and secretions within the acinar structures of tumors have the staining characteristics of both acidic and neutral mucosubstances. Although occasional sulfomucins (acidic mucosubstances) were observed, the primary acidic product is a sialomucin, neuraminidase resistant, a product also seen in some atypical Clara cells in bronchioles near tumor areas, as well as in some goblet cells and tracheobronchial glands. Most of the atypical Clara cells in bronchioles secrete a neutral mucopolysaccharide, a product also associated with hyperplastic nodules, secretory focal lesions with squamous metaplastic features, and many of the cells in acinar structures within the tumors themselves. Sudan black staining of frozen sections showed some sudanophilic areas not removed by acetone extraction, and as shown with the Baker acid hematein stain, most likely a phospholipid. A few of the atypical cells within bronchioles near tumor regions were also Sudan black B positive (with acetone extraction); however, most Clara cells were not sudanophilic.

DISCUSSION

What we regard as the first stage in the spectrum of responses leading to tumors is what is known as "epithelialization or bronchioliz-

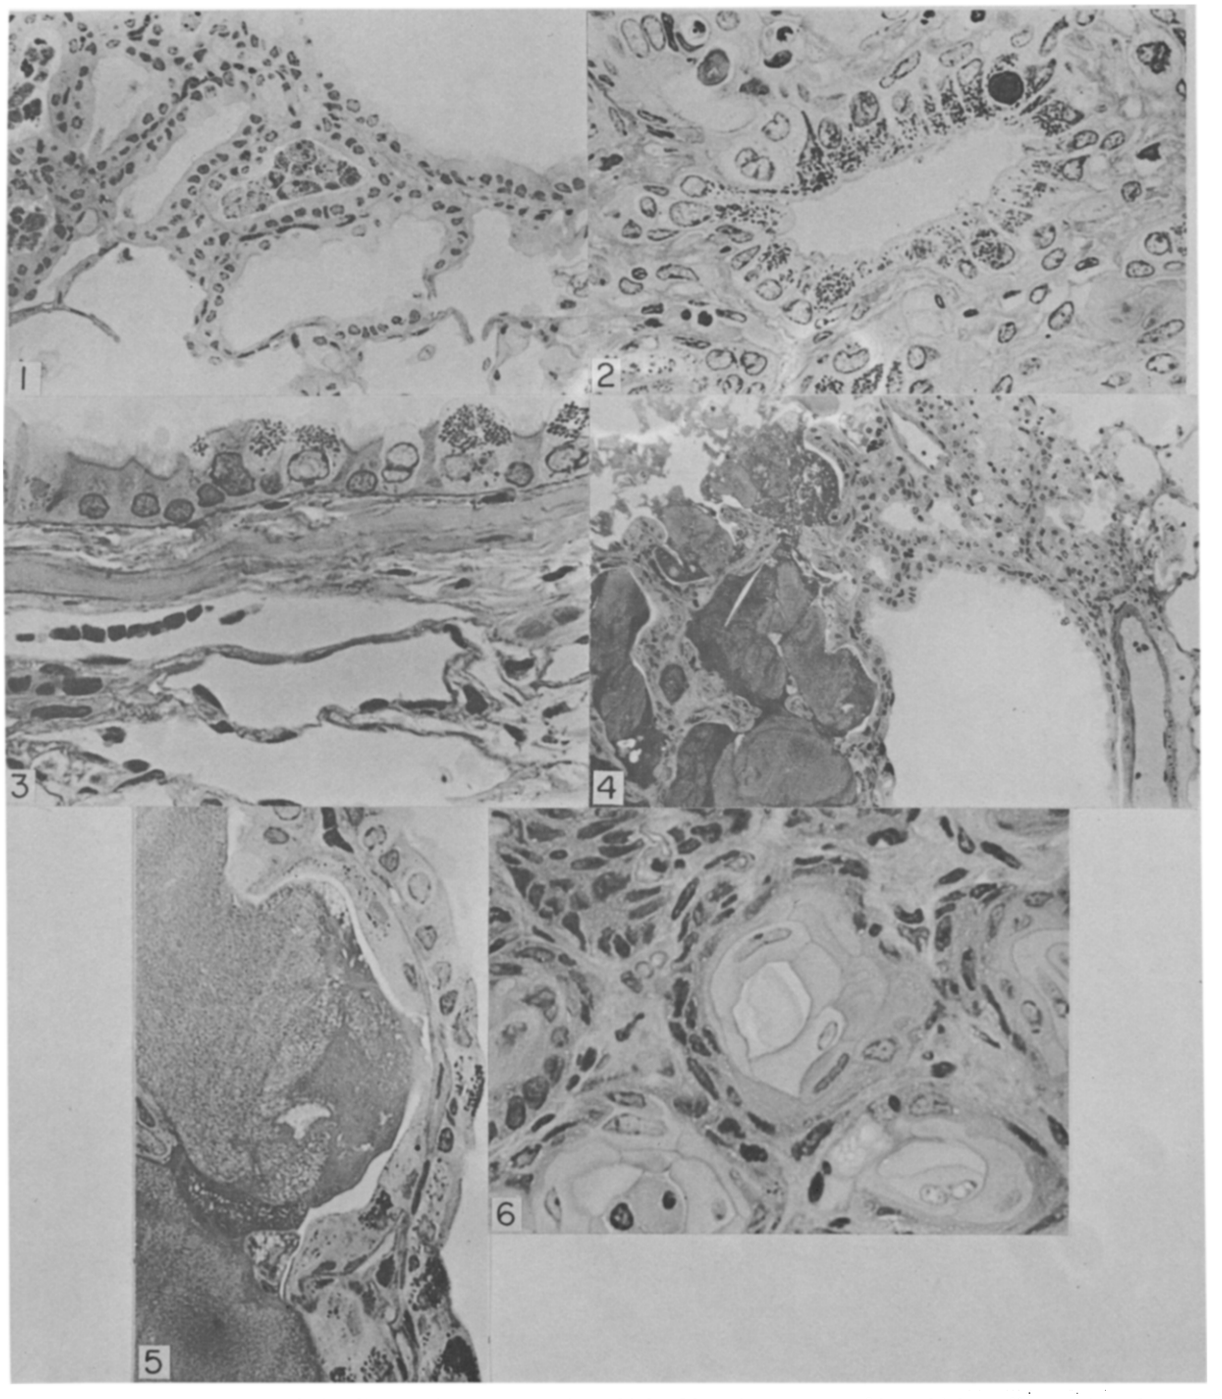

Fig. 1. Epithelialization of alveoli occurring next to a bronchiole. Note the presence of bronchiolar cells growing along the alveolar walls in a glandular pattern. Most of the epithelial cells are typical Clara cells, but ciliated cells are also found. Macrophages (center) are often seen trapped within the acinar structures. Four weeks after the ^{210}Po instillation period. PAS-hematoxylin. × 250.

Fig. 2. A single cell layered hyperplastic nodule within a ^{210}Po induced tumor at an early stage of development. Mucus can be seen as PAS positive granules in the apical region of cells within the acinar structure (center). Note that the nuclei of these cells are characteristic of Clara cells, often bilobed and containing condensed chromatin around the edges. Twenty-seven weeks after the ^{210}Po instillation period. PAS-hematoxylin. × 500.

Fig. 3. Bronchiole (top) near a tumor region of this lung. Normal bronchiolar Clara cells do not have a PAS positive secretion, but Clara cells exposed to ^{210}Po begin to secrete PAS positive mucous granules (top center, right). 18 weeks after the ^{210}Po instillation period. PAS-hematoxylin. × 500.

Fig. 4. Relatively normal bronchiole (right) and tumor region (left). There are normal Clara cells on the right side of the bronchiole and atypical Clara cells (mucus-secreting) on the left side. An artery appears at the right of the bronchiole. Twenty-nine weeks after the ^{210}Po instillation period, PAS-hematoxylin. × 125.

Fig. 5. Higher power view of left side of bronchiole shown in Fig. 4. Bronchiolar epithelium (far right) contains typical Clara cells (top) and atypical Clara cells (bottom) with PAS positive secretion granules. Note similarity of atypical bronchiolar cells to the epithelial tumor cells growing along the alveolar wall adjacent to the bronchiole. Twenty-nine weeks after the ^{210}Po instillation period. PAS-hematoxylin. × 500.

Fig. 6. Area of squamous metaplasia occurring within a ^{210}Po induced tumor. Hematoxylin-phloxine. Nineteen weeks after the ^{210}Po instillation period. × 500.

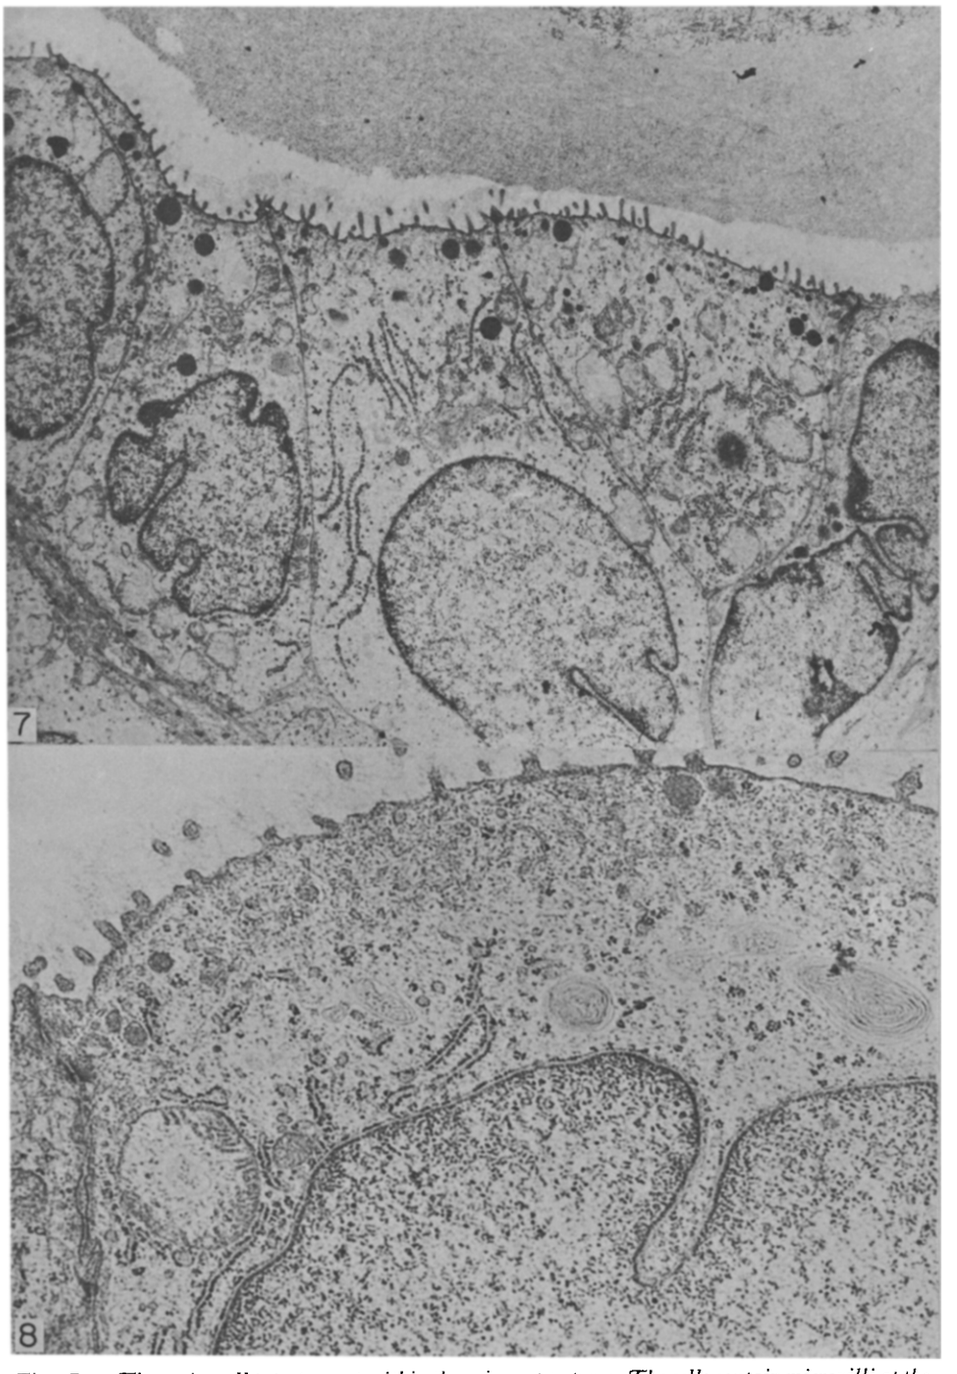

Fig. 7. The major cell type present within the acinar structures. The cells contain microvilli at the luminal margin, and have irregular nuclei which are often bilobed and usually contain clumped chromatin around the edges. Note the well developed Golgi zones, the myelin figures and the swollen mitochondria with irregular cristae only partially traversing the mitochondrial surface. The dense membrane limited granules present in the apical cytoplasm are mucous granules. Note the desmosomes and terminal bars connecting the cells. × 9300.

Fig. 8. Higher power view of the major cell type seen within the acinar structures. Note the prominent myelin figures (center, far right), swollen mitochondria, mucous granules (top), apical agranular endoplasmic reticulum (ER), free ribosomes and microvilli. × 15900.

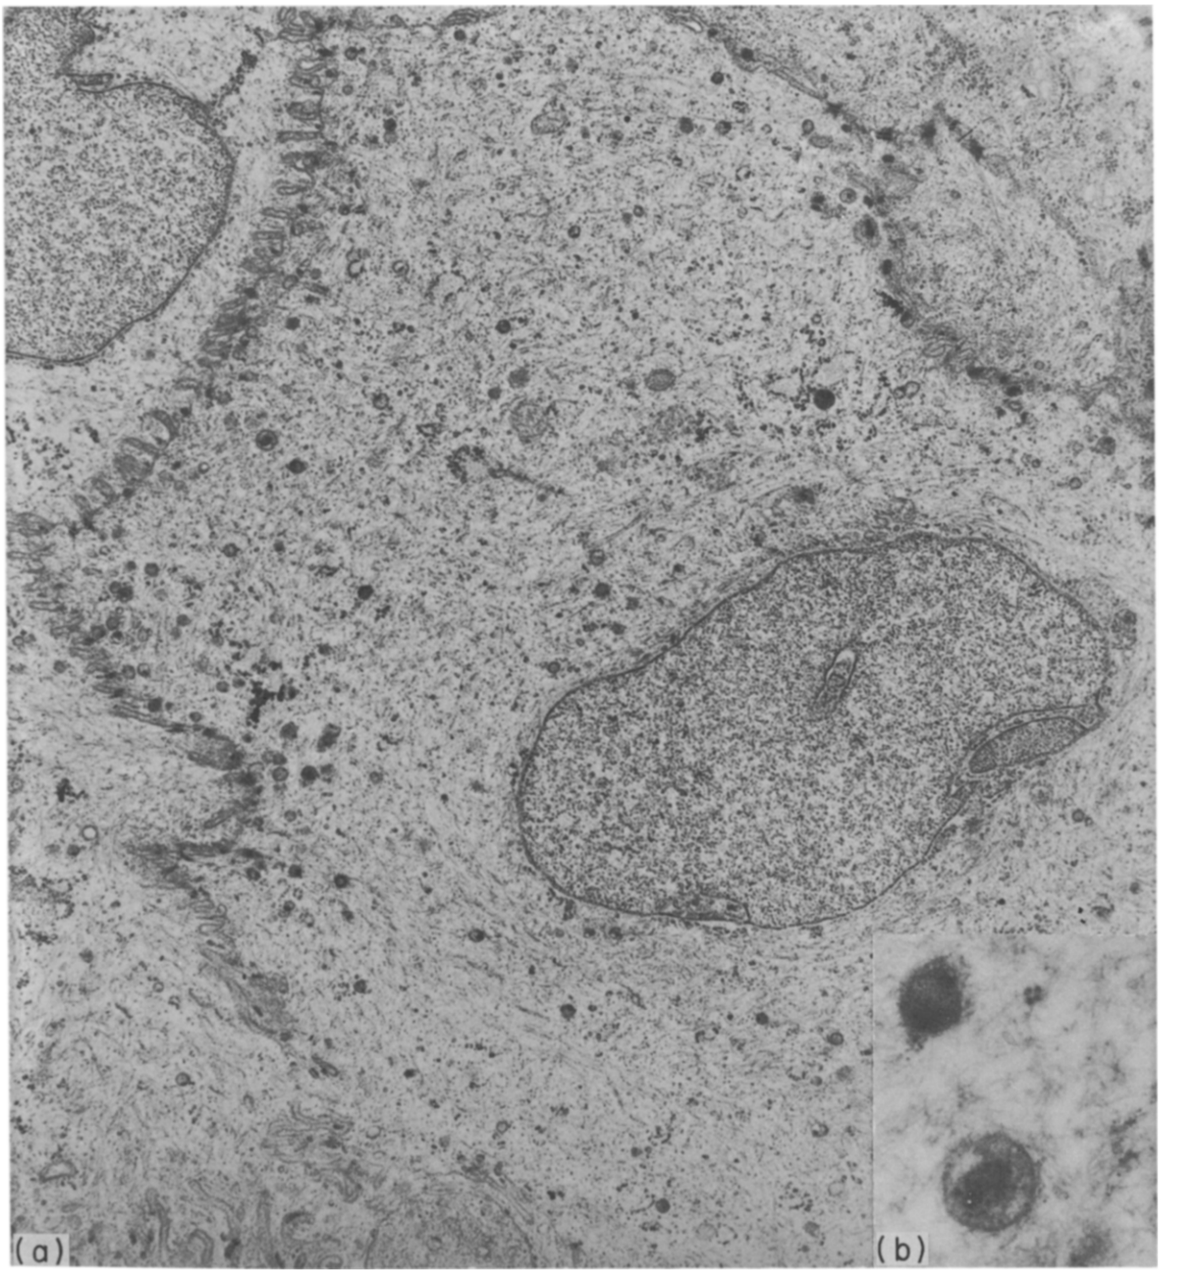

Fig. 9. (*a*) *Epidermoid type cells, showing complex interdigitations between cells, desmosomes, tonofibrils, many free ribosomes, and vesiculation of ER. These cells have very irregular nuclei with deep cytoplasmic invaginations. In many of the epidermoid cells, small round intracytoplasmic inclusion bodies are found* (*on the left side of the cell in center*). *The particles were all smaller than* 0.25 μm, *and are thought to be membrane coating granules* (*see text*). × 16,000. (*b*) (*Insert lower right*). *Higher power view of two membrane coating granules, as seen in Fig.* 9a. *Note that these particles have variable compositions, but often are seen with dense cores* (*lower left*). *The membrane coating granule appearing at the bottom of photomicrograph is the largest one found, slightly less than* 0.25 μm. × 40,415.

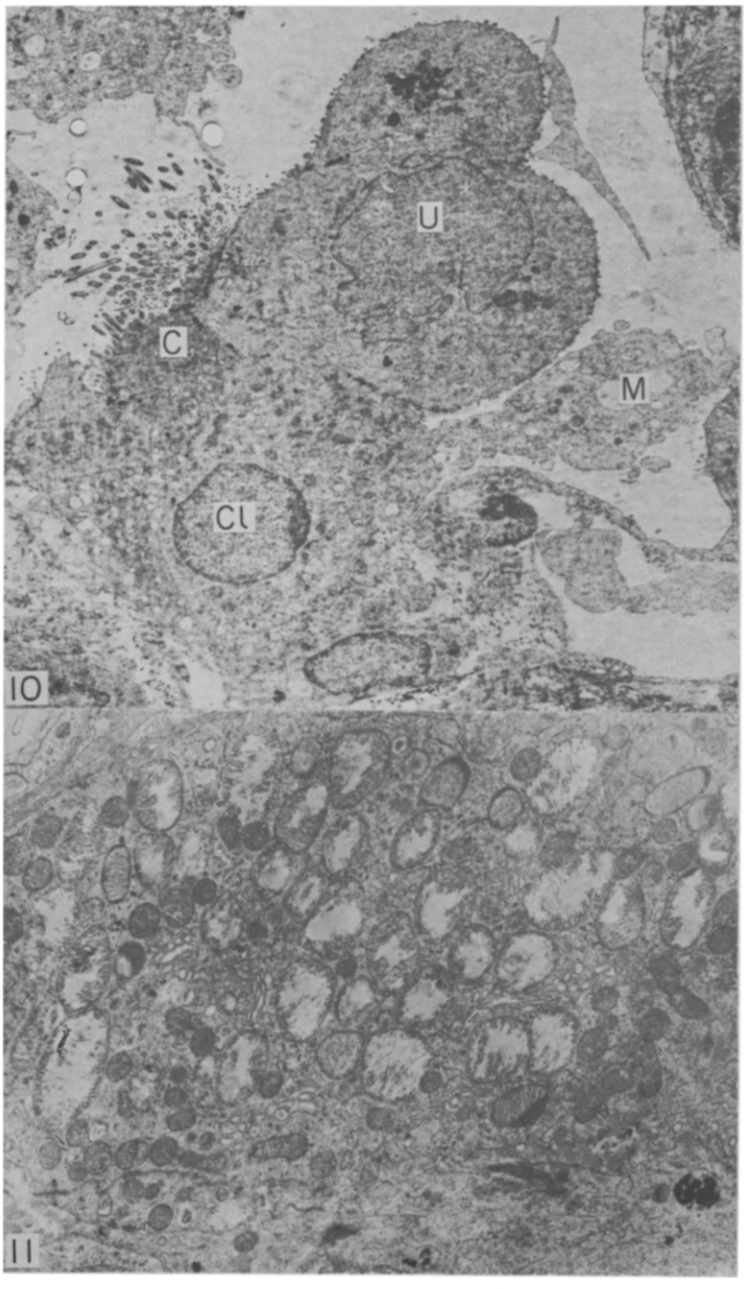

Fig. 10. *Four common cell types seen with the* ^{210}Po *induced tumors. At the top is an undifferentiated cell type (U) containing primarily ground substance, with microvilli, some granular ER and particulate glycogen, and always having an irregular nucleus with deep cytoplasmic invaginations. Below this cell and to the left is a ciliated cell (C), with typical cilia extending into the lumen. At the bottom-left is a cell resembling the Clara cell (Cl), with many granules containing electron lucent material, prominent microvilli, extensive supranuclear agranular ER, and a nucleus with condensed chromatin around the edges. A typical lung macrophage (M) can be seen at the right.* × 4133.

Fig. 11. *An enlarged type II alveolar epithelial cell containing many typical cytosomes, many small round mitochondria, several Golgi regions, and some free ribosomes. Such type II alveolar cells are seen scattered throughout the tumor region, and particularly around the edges of tumors.* × 6200.

ation of alveoli", a condition in which bronchiolar type cells line the preexisting alveolar walls. Ciliated and Clara cells, morphologically identical at the ultrastructural level to bronchiolar cells, suddenly appear in the alveolar region where they do not exist normally. This phenomenon has been observed after many unrelated injuries to the lung [30], including exposure to viruses [31, 32] and carcinogens [33]. It is not known whether these cells represent an abnormal extension of the bronchiolar epithelium or metaplasia of autochthonous alveolar epithelium, but the mechanism is thought to involve the colonization of alveoli with bronchiolar cells via bronchiolar–alveolar pores [30].

At a later stage in the epithelialization of alveoli, ciliated cells are not as prominent as cells resembling Clara cells. These Clara-like cells form acinar structures in the lung, or what we have called "hyperplastic nodules" [26], often with typical lung macrophages trapped inside. We consider these hyperplastic nodules a definite precursor lesion in tumor formation. It is interesting that Clara cell changes have been noted in other studies. A nodular hyperplasia of Clara-like cells at the bronchiolar–alveolar junction occurs after exposure to ozone in mice, and this is considered an irreversible lesion [34]. Hyperplasia of bronchiolar cells, presumably Clara cells, has also been observed after exposure to artificial smog [35] and virus infections [31, 35]. In separate autoradiographic studies accompanying our plastic section serial sacrifice experiment, Clara cells were shown to take up a significant fraction of the administered ^{210}Po [36].

In our studies, many of the Clara cells in the bronchioles, as well as the Clara-like cells in the acinar structures in the alveoli, begin to produce a PAS positive mucous secretion. Clara cells in the normal lung do not secrete granules that are PAS positive. There are a few reports that Clara cells do secrete a PAS positive secretion [13, 37, 38], but as we have pointed out [28] the confusion exists due to occasional PAS positive lysosomes and residual bodies present in the apical region of normal Clara cells. The real secretion product of Clara cells, seen as light secretion granules at the electron microscopic level [28, 39] is not PAS positive [28, 40, 41].

No cells, including Clara cells, produce mucus in human bronchioles; however a condition known as "goblet cell metaplasia", in which mucus secreting cells suddenly appear in the bronchiolar epithelium, occurs during chronic bronchitis [42] and is associated with respiratory failure [43]. It can be induced by experimental insults such as exposure to sulfur dioxide [42] and influenza virus infection [31, 35]. It is of interest that goblet cell metaplasia in bronchioles has also been observed in human lungs containing bronchiolar–alveolar carcinoma [13]. The term goblet cell metaplasia comes from paraffin section, light microscopic analysis of the phenomenon; an electron microscopic study of the cell type producing the PAS positive secretion apparently has not been done. In our study, the mucous cells in the tumors resemble goblet cells only by the nature of the secretion produced—they are not ultrastructurally normal hamster goblet cells (for a comparison, see reference [28]). How they arise is not clear. In man, it has been proposed that neurosecretory cells give rise to the goblet cell metaplasia [44]; however, neurosecretory cells do not exist in the hamster lung [28]. In our system, it is thought that these cells arise from preexisting Clara cells. Cycles of secretory products have also been observed in rat [42] and human [45] lung cells.

As is evident from the histochemical results, several mucous products are formed by the ^{210}Po induced tumors. Occasional cells produce sulfomucins or glycoproteins, while most of the secretory cells produce sialomucins or neutral mucopolysaccharides. All of these products are mucous secretions. Mucus is a general term used for a mixture of proteins and sugars, the chemical composition depending on the type of cell producing the mucus.

The acid product of the ^{210}Po induced tumor cells was shown to be a sialomucin which is resistant to neuraminidase (sialidase). Such a neuraminidase resistant sialomucin exists in the normal lung cells of the rat [46] and of man [45], and is also probably the main product of mucinous tumors of the trachea and bronchi in human lungs [47]. In our study, the neuraminidase resistant sialomucin was also found in a few atypical Clara cells in bronchioles near tumor regions, but most of the atypical Clara cells produced neutral mucopolysaccharides.

The cells in these ^{210}Po induced tumors apparently go through a cycle of secretion products. Using the AB pH 2.5–PAS staining sequence, the small lesions of the lung containing secretory acinar structures and squamous metaplastic lesions not connected with fully developed tumors contained only red material. Atypical Clara cells near tumor regions contained primarily red granules, although a few atypical Clara cells contained blue staining granules. Both red and blue granules appear in the tumor regions and only blue staining granules are found in the malignant cheek pouch tumors resulting from transplantation of the

^{210}Po induced tumors [48]. The red staining material is thought to be the simplest mucous secretion (neutral mucopolysaccharide), whereas blue granules are more complex products [45].

The changes in secretion products seen here are most likely occurring within a single cell type, as has been seen in other systems [42, 45]. After exposure to sulfur dioxide, rat lungs develop goblet cell metaplasia in the bronchioles and produce mucus which is at first sensitive to neuraminidase, but later becomes resistant to the enzyme [42]. It is thought that, in this case, a sialomucin appears first and later develops into a sulfomucin within the same cell. This change in the nature of the mucus also occurs after exposure to tobacco smoke and other irritants [42].

At later stages in tumor formation, some of the acinar structures containing the mucus-secreting cells became multi-layered and underwent squamous metaplasia. Squamous metaplasia in the lung is thought to be a reversible lesion which can be observed after chronic irritation [49, 50]. It has also been observed in experimentally produced lung cancers from ^{106}Ru [49] and polycyclic hydrocarbons [51]. In another study on peripheral lung tumors induced by pathogenic viruses, squamous metaplasia and the appearance of mucus-secreting cells in the alveoli were also considered early changes in the pathogenesis of squamous cell cancer [31].

At the electron microscopic level, the cells in the ^{210}Po induced tumors have many of the characteristics of glandular cells. In a well differentiated adenocarcinoma, the polarity of the individual cells is preserved, and desmosomes and terminal bars connect the cells as in normal bronchiolar epithelium [52]. This was commonly seen in the areas containing mucus-secreting cells. Other characteristics of adenocarcinoma cells include a well developed Golgi region [53], much rough endoplasmic reticulum [10, 54], microvilli [55], dark and light cells [54, 55], many mitochondria [52] which are often swollen [56, 57], mucus production [9], and "concentric membranes" [56]—here referred to as myelin figures. These are all common characteristics of the most prominent cell type present in ^{210}P0 induced tumors. In adenocarcinoma cells, the nuclear to cytoplasmic ratio is often small compared to other lung cancer cells [54]. This appeared to be the case for our ^{210}Po induced tumor cells, although the ratio was certainly large compared to normal bronchiolar or alveolar cells.

The ^{210}Po induced tumor cells have common characteristics of malignant cells in general, such as loss of the organized lamellar ergastoplasm, which is considered part of the dedifferentiation process occurring in cancer cells [57]. The ergastoplasmic membrane system is frequently altered in malignant cells so that the endoplasmic reticulum forms tubules or lamellae, and free ribosomes occur in the cytoplasm [57]. Both these phenomenon were seen in the mucus-secreting cells. These malignant cells are also transplantable, producing adenocarcinomas upon reinjection into hamsters [27, 48].

Mucus-secreting cells are not the only cell type present in ^{210}Po induced tumors. As seen by electron microscopy, there is a prominent epidermoid component as well. These cells have many desmosomes and tonofibrils, and a lack of cytoplasmic organelles such as mitochondria, endoplasmic reticulum and a Golgi complex. These are common characteristics of epidermoid differentiation seen in squamous cell carcinoma [52, 53, 56] and peripheral lung adenocarcinomas [10]. These epidermoid cells commonly had vesiculation of the endoplasmic reticulum, many free ribosomes in the cytoplasm, and cytoplasmic inclusion bodies with diameters less than 0.25 μm. These particles are probably "membrane-coating granules," which are known to develop within differentiating epithelial cells, move toward the cell periphery, fuse with the plasma membrane and empty their contents into the intercellular spaces [58]. These granules are considered specific differentiation products of epithelial cells.

Another cell type present in the tumors resembles Clara cells normally present in the bronchioles. There was extensive supranuclear agranular endoplasmic reticulum, many light secretion vesicles, and often bilobed nuclei with condensed chromatin around the edges; all of which are characteristics of Clara cells. Still another cell type, primarily composed of ground substance, appeared to contain glycogen particles, often a characteristic of normal Clara cells [29]. These undifferentiated cells had pleomorphic nuclei with deep cytoplasmic invaginations, a common characteristic of malignant cells [57]. These rather empty, anaplastic cells are typical examples of the dedifferentiation commonly occurring in neoplastic development [57].

Some of the cell types in the tumors were unique, with extraordinarily developed endoplasmic reticulum or Golgi apparatus, or with very long microvilli. These findings have been seen in lung cancer cells before and are thought to represent an incomplete maturation or differentiation of the cancer cells [54].

Normal ciliated cells and enlarged type II alveolar epithelial cells were also seen in these

tumors, but are thought to have little to do with the changes leading to malignancy. Ciliated cells have also been seen in other adenocarcinomas of the peripheral lung [7], but they are a rare occurrence in malignant tissue [57]. Nevertheless, some metastasizing tumor cells of hamster kidney origin have been known to form basal corpuscles of a fragmentary ciliated border [59]. When cilia are seen in bronchiolo–alveolar lung tumors, it is considered strong evidence for the cells of origin to be from bronchiolar epithelium [13].

The cells seen in the ^{210}Po induced tumors are very similar to the cell types seen at the electron microscopic level in the human peripheral lung carcinomas. For example, Mollo *et al.* [10] show a mucus-secreting cell (their Fig. 10) which looks ultrastructurally like our most prominent cell type (Figs. 7 and 8); their Fig. 9, a cell with light secretion granules resembling Clara cell granules, is very much like a cell type seen in our tumors (Fig. 10). Their tumors contained epidermoid cells with numerous desmosomes and tonofilaments (their Fig. 11) as seen in our Fig. 9. Kuhn [13] and Greenberg *et al.* [14] noted cells with glycogen granules similar to one of our cell types [Fig. 10] and Bedrossian *et al.* [60] and Geller and Toker [55] also described dark and light cells. These cells, commonly found in human bronchiolar–alveolar carcinomas, are considered indistinguishable at the electron microscopic level from the cells in well differentiated adenocarcinomas arising more centrally in the bronchial tree [60].

A wide variety of cell types might be expected in these tumors. When cheek pouch tumors are grown from cloned malignant cell lines derived from these ^{210}Po induced peripheral lung tumors [27, 48] the resultant tumors are made up of several different cell types. Thus, many of the cell types seen in the tumors discussed here could have come from a single transformed cell. The multipotential nature of the stem cells of squamous cell carcinoma, in which a single cell type can give rise to many types of tissue, has been shown previously by Pierce and Wallace [61].

The variety of cell types present in these tumors may help explain the different results obtained in the histochemical studies done here. The tumor areas present in the lungs studied showed a variety of secretion products, with the most frequent product being of a mucoid nature, as has been discussed. The frozen section studies showed some areas of the tumors, and some regions around the edges of tumors, to have sudanophilic areas shown to be phospholipid by Baker's acid hematein method. In the alveolar region of the normal lung, type II alveolar epithelial cells produce a substance of phospholipid nature [22, 62]; however, there is also evidence that Clara cells of the bronchioles may produce such a secretion [38, 40, 41, 63]. In our studies, Clara cells in the bronchioles were not normally Sudan black positive; however, in bronchioles near tumor regions, some Clara cells did produce sudanophilic granules. Some Sudan black positive results have been reported for normal Clara cells [38, 40]. Our lack of a sudanophilic reaction could be due to species' variations in Clara cells (for discussion, see reference [28]). Thus, normal type II alveolar epithelial cells, the hyperplastic and hypertrophic type II alveolar epithelial cells, or the cells resembling Clara cells with many secretion granules could be producing the phospholipid secretion found in our tumors.

The production of surfactant has been used by other workers to determine the cell of origin of bronchiolar–alveolar carcinomas. It has not been found in two studies of bronchiolar–alveolar carcinoma [13, 64], or in secretions obtained from a bronchiolar–alveolar carcinoma by bronchial lavage [65]. These studies related the histogenesis of the tumors to bronchiolar epithelium.

We have observed that the Clara cells in bronchioles of tumor-containing lungs undergo a variety of changes after ^{210}Po exposure, such as becoming sudanophilic or PAS positive in discrete areas. Some of the ultimate tumor cells are sudanophilic, some are PAS positive. In a separate study of enzyme reactions of normal and tumor-containing lungs, it was noted that the enzyme reactions occurring in the ultimate tumor cells most resembled those of normal Clara cells [66]. A significant finding was that Clara cells in bronchioles of tumor-containing lungs began producing large amounts of alkaline phosphatase, and alkaline phosphatase activity was high in the cells of the tumor region [66]. Clara cells originally present in the bronchioles and appearing in the alveolar region after ^{210}Po exposure may go through changes which ultimately lead to a malignant tumor. The normal secretion product of Clara cells is produced in great quantities in some of the bronchiolar Clara cells after ^{210}Po exposure, in Clara-like cells in hyperplastic nodules appearing in the alveoli, and in some of the ultimate tumor cells, as observed here ultrastructurally and histochemically. These cells are probably not malignant cells. However, bronchiolar Clara cells exposed to ^{210}Po, the cells in the hyperplastic nodules and the tumor cells also produce the same PAS positive secretions, neutral mucopolysaccharides

and neuraminidase-resistant sialomucins. Ultrastructurally, the mucus-secreting tumor cells still have a few basic characteristics of Clara cells [63]; e.g. apical agranular endoplasmic reticulum and often bilobed nuclei with condensed chromatin around the edges. Bronchiolar cells have been implicated previously as the cells of origin of bronchiolar–alveolar carcinoma [55]. Recent ultrastructural and strong histochemical evidence not discussed here have also singled out the Clara cells of the bronchioles as the cells of origin of human bronchiolar–alveolar carcinoma [13, 14]. That a tumor should arise in the alveolar region with bronchiolar characteristics is not surprising since the alveoli and bronchioles have a common embryologic origin [39, 67, 68]. It has been proposed that typical bronchiolar cells can colonize the alveoli through bronchiolo–alveolar pores [30], so the appearance of a carcinoma with bronchiolar cells in the alveolar region is conceivable. The most likely explanation is that the Clara cells of the respiratory bronchioles originate the tumors. The hamster respiratory bronchiole consists of very short stretches (only a few cells) of bronchiolar epithelium, primarily Clara cells, with extensive alveolar outpocketings [28], and thus appears histologically more like the alveolar region than the bronchiolar region.

Our conclusions about the histogenesis of these peripheral lung tumors are different from those reached by several other investigators studying such tumors. Adamson *et al.* [15], Nagaishi *et al.*[53] and Coalson *et al.*[12] have concluded that type II alveolar epithelial cells are the cells of origin of human bronchiolar–alveolar carcinoma, and several other studies such as those of Brooks [16], Klarner and Gieseking [17] and Okada *et al.*[69] have attributed the origin of peripheral lung tumors in animals to type II alveolar epithelial cells.

In our ^{210}Po serial sacrifice study, major early changes in type II alveolar epithelial cells were noted. These cells responded to the treatment by undergoing hyperplasia and hypertrophy with an increased number of cytoplasmic inclusions or cytosomes, resulting in foci that were composed entirely of type II alveolar epithelial cells. This response of the type II alveolar epithelial cells has been noted after a variety of injuries to the lung, including chronic irritation [70], nitrogen dioxide exposure [71], and drugs [72]. Enlarged type II alveolar epithelial cells continued to be conspicuous during and after the formation of the tumor, being seen in large numbers around the edges of the ^{210}Po induced tumors and scattered throughout the tumors. However, we do not feel that type II alveolar epithelial cells are involved in the ultimate formation of the tumor for three reasons: (1) The type II alveolar epithelial cells do not appear to be involved in the lesions of the lung we consider pre-neoplastic; (2) the tumor cells do not contain typical or atypical type II alveolar epithelial cell cytosomes; and (3) no cells resembling type II alveolar epithelial cells (i.e. containing cytosomes) grow out after the tumors have been transplanted [27, 48]. The prominent cell type in the ^{210}Po induced tumors contains myelin figures (Fig. 8) which might be mistaken for cytosomes (Fig. 11). Myelin figures, being composed of phospholipid [73] as are cytosomes [22, 62], are easily induced in Clara cells by exposure to ozone [34], chlorphentermine [74], and Iprindole [75]. We have seen small numbers of myelin figures in normal hamster Clara cells [28]. Sommers *et al.* [64] describe myelin figures in adenocarcinoma cells presumably derived from bronchiolar epithelium.

Three other recent studies [13, 14, 60], which attribute the origin of bronchiolar–alveolar carcinomas to bronchiolar epithelial cells, have also questioned previous conclusions that type II alveolar epithelial cells are the cells of origin. To explain the difficulty in determining the cell of origin, Greenberg *et al.* [14] point out that atypical areas of type II alveolar epithelial cells adjacent to tumors can often be confused with the tumor itself. In the studies of Coalson *et al.* [12], Nagaishi *et al.* [53] and Adamson *et al.* [15], which attribute the origin of bronchiolar–alveolar carcinomas to type II alveolar epithelial cells, it is impossible to tell the relationship of the atypical type II alveolar epithelial cells to the tumor since 1 μm sections are not shown. In some studies which attribute the origin of the tumors to type II alveolar epithelial cells, atypical cells resembling Clara cells and mucus-secreting cells can be seen in the tumor photomicrographs shown along with the atypical type II alveolar epithelial cells (see, for example, Okada *et al.* [69], Figs. 8 and 9; Nagaishi *et al.* [53], Figs. 2 and 11). Mollo *et al.* [10] attributed the development of some bronchiolar–alveolar carcinomas to type II alveolar epithelial cells; in other tumors, in which mucus production or an epidermoid component was prominent, the histogenesis was unclear. In systems other than the ^{210}Po induced tumors, type II alveolar epithelial cells may be the precursors for the malignant cells. They are considered the target cells for urethane-induced tumors in mice [16, 76], and the cells of origin of spontaneous lung tumors such as those in mice [16, 17] and sheep [18]. However, in a recent comprehensive review of all electron microscopic information

published about the origin of bronchiolar–alveolar carcinomas. Bedrossian *et al.* [60] concluded that if a neoplasm of great alveolar cells exists, definite documentation of its occurrence is still lacking.

Our studies strongly suggest that the Clara cell is the cell of origin of ^{210}Po induced peripheral lung tumors. These tumors have histopathological features observed in human bronchiolar–alveolar carcinomas [9–14] and in many species of animals after exposure to chemical carcinogens [77], alpha-emitting radioisotopes [19] and beta–gamma emitters [78], and oncogenic viruses [31]. ^{210}Po radiation doses to Clara cells can be calculated to obtain an estimate of risk for the induction of malignant transformation in this sensitive cell type. Similar calculations for the radiation doses from the plutonium isotopes might explain the differences in tumor incidence with varying methods of administration. Plutonium isotopes, which emit alpha particles similar in energy and path length to ^{210}Po, produce primarily bronchiolar–alveolar carcinomas in a wide variety of animal species and after many types of exposure conditions [19]. When injected intravascularly on zirconium oxide microspheres, however, plutonium produces minimal pathologic changes and few lung tumors [79]. The microspheres lodge in the peripheral lung capillaries of the alveolar septa and remain there as fixed radiation sources. Since the alpha particle track length in tissue is very short (approximately 40 μm), most of the radiation dose following this method of exposure may not reach the sensitive Clara cells of the terminal and respiratory bronchioles. Similarly, hamsters exposed to plutonium isotope aerosols [80] failed to develop lung cancer (although some of the hamsters in this study did have lesions we consider premalignant), perhaps because only a small fraction of the alpha radiation dose from inhaled plutonium isotopes actually reaches the terminal bronchiolar cells [81]. Indeed, the lack of tumors in both of these studies, as compared with the known lung tumor-inducing potential of plutonium [19], may be explained by differences in the distribution of radiation dose to the critical cell population. Thus, knowledge of the target cell for transformation may be particularly important for estimating the carcinogenic hazard from inhaled plutonium isotopes produced by nuclear power plants as well as from many chemical agents.

Acknowledgements—We would like to thank Mr. Frank Bettinelli for his expert assistance in the preparation of histologic materials, and Dr. Curtis C. Harris and Dr. David G. Kaufman for help in the preparation of this manuscript.

Morphologic and Histochemical Characteristics of Cell Lines Derived from Hamster Peripheral Lung Tumors*

ANN R. KENNEDY,† ROBERT B. McGANDY and JOHN B. LITTLE

Department of Physiology, Harvard School of Public Health, Boston, Massachusetts 02115, *United States of America*

Abstract—*Intratracheal instillation of the alpha emitter polonium-*210 (*^{210}Po*) *or benzo[a]pyrene induces peripheral lung tumors in Syrian hamsters which have a combined epidermoid and adenomatous morphology similar in appearance to human bronchiolar–alveolar carcinoma. Two permanent cell lines derived from such tumors have been studied in an attempt to determine the cell of origin of the original peripheral tumors. The ultrastructural and histochemical characteristics of both the cells and of cheek pouch tumors grown from HLAC-*4 *and HLAC-*14 *cells at various stages of passage in tissue culture in general support, but do not prove, our hypothesis that Clara cells found in the terminal and respiratory bronchioles are the cells of origin of the peripheral lung tumors induced in hamsters by these carcinogens.*

INTRODUCTION

As PART of a series of experiments designed to determine the cell of origin of ^{210}Po induced tumors in the peripheral hamster lung [1], we have studied the morphology of the cell lines originally derived from these tumors. The isolation and passaging of the malignant cell lines, both *in vivo* and *in vitro*, have been discussed by Terzaghi and Little [2]. Terzaghi and Little [2] also presented a brief description of the light microscopic morphology of the cell lines HLAC-4 and HLAC-14, the cell lines used for this more extensive morphologic study. The HLAC-4 and HLAC-14 cell lines were originally derived from combined epidermoid and adenocarcinomas of the peripheral lung induced by ^{210}Po or ^{210}Po and benzo[a]pyrene (BP). An examination of paraffin sections of tumors resulting from the inoculation of cells from either of these lines into hamster cheek pouches revealed that the epidermoid differentiation present in the primary tumor [3] did not occur in the cheek pouch tumors. Thus, there was an exclusive emergence of adenomatous and undifferentiated cell types in the cheek pouch tumors [2]. In the present investigation, we have examined the ultrastructural and histochemical characteristics of the cells in these cell lines in order to identify the cell which initiates the hamster lung peripheral tumors.

MATERIAL AND METHODS

The isolation and passaging of neoplastic cell lines, originally derived from peripheral hamster lung tumors induced by ^{210}Po or ^{210}Po and BP, have been described in detail by Terzaghi and Little [2]. Two of these tumor cell lines. designated HLAC-4 and HLAC-14, were studied here by both light and electron microscopy. Cellular morphology was studied using plastic sections for light and electron microscopy as described below and with standard paraffin embedded sections of alcoholic-zinc formalin fixed, cheek pouch tumors produced by cells at different stages of *in vivo* and *in vitro* passage. Determination of the nature of the mucin in the acinar structures of cheek pouch tumors at early

Accepted 3 May 1977.

passages of the cell lines was done on paraffin sections using the Alcian blue (AB) pH 2.5–periodic acid–Schiff (PAS) sequence [4], the AB pH 1.0–PAS sequence [4], and the high iron method [5].

For electron microscope examination, malignant cheek pouch tumors were grown from cells treated in each of the following ways: (1) HLAC-4 cells, which had been sequentially cloned [2] were grown *in vitro* for a total of 7 months. The cells originally isolated from a primary lung tumor were initially passed through a hamster cheek pouch, then passed in tissue culture for 5 months, passed through a hamster cheek pouch, and returned to tissue culture for an additional 2 months when used for electron microscopy. (2) HLAC-14 cells, like the HLAC-4 cells, were originally passed from the primary lung tumor into a hamster cheek pouch. A section of this original cheek pouch tumor was used for electron microscopic examination. Cells which had been sequentially cloned *in vitro* were then inoculated into a cheek pouch after 1 month in tissue culture, and after the HLAC-14 cells had been in tissue culture for 6 months.

HLAC-4 cells growing *in vitro* were also examined electron microscopically. After the initial passage through a hamster cheek pouch, exponentially growing cells were kept in tissue culture for 2 months before being taken for electron microscope examination.

Preparation of cheek pouch tumors for electron microscopy was as follows. Sections of tumors less than 1 mm^2 were placed in Karnovsky's glutaraldehyde–paraformaldehyde fixative [6] for 3 hr, then washed 4 times in cacodylate buffer (0.1 M, pH 7.4), and stored overnight in cold buffer. The blocks were then post-fixed in s-collidine-buffered osmium tetroxide (1.3% osmium tetroxide, 0.1 M s-collidine, pH 7.4) for 1 hr, washed 4 times in s-collidine buffer, and dehydrated and embedded in epon. For electron microscopic examination of the HLAC-4 cells *in vitro*, the preparation techniques of Gimbrone, Cotran and Folkman [7] were used. Briefly, cells growing exponentially in 60 × 15 mm Falcon tissue culture dishes were fixed in 25% glutaraldehyde in 0.1 M sodiumcacodylate buffer with $CaCl_2$, post-fixed in 2% osmium tetroxide and embedded in epon. Tissue sections were cut on a Reichert ultramicrotome. One micron sections were stained with toluidine blue. Appropriate blocks were trimmed for electron microscopy, silver sections cut with a diamond knife (DuPont), mounted on 300 mesh copper grids, and stained with uranyl acetate and lead citrate. Sections were examined with a Philips 300 electron microscope.

RESULTS

Light microscopy

When injected into hamster cheek pouches, both cell lines produced cheek pouch tumors having obvious adenomatous and undifferentiated components at the light microscope level (Figs. 1–3).* This included acinar structures resembling bronchiolar epithelium (Fig. 2) which appeared in varying amounts in cheek pouch tumors resulting from the injection of cells of either cell line at both early and late passages. When both original tumors were transplanted directly into cheek pouches and grown out, the cells retained the ability to produce a PAS positive secretion. This ability was lost, however, with continued passage through hamster cheek pouches. When either of the cell lines which had been continuously carried in tissue culture were injected into hamster cheek pouches, the cells in the acinar structures for the most part did not produce a PAS positive secretion.

To determine the nature of the PAS positive secretion in the early cheek pouch tumors, mucin stains were done with the following results:

AB pH 2.5–PAS sequence. This staining sequence distinguishes neutral (red) from acidic (blue) mucopolysaccharides. The acinar structures contained blue material within and blue granules in the epithelial cells. Blue nuclear staining is due to nucleic acids. Undifferentiated cells were red.

AB pH 1.0–PAS sequence. Neutral mucosubstances are still red, but alcinophilic substances at this pH include only sulfated mucopolysaccharides. Material within the acinar structures was red, and red granules were present in the cells within the structures. Some of the acinar structures showed cells with a very thin red and blue rim.

High iron method—to distinguish sulfomucins. Mostly negative results, with only a few positive cells in the acinar structures.

Electron microscopic examination

The cheek pouch tumors which grew out after the injection of cells from either of the cell lines were quite similar; and with the HLAC-14 cell line, the ultrastructural morphology did not markedly change from the original cheek pouch tumor to the tumors produced by cells that had been in tissue culture for 1–6 months.

*Figures 1–3 are light microscopic views of a cheek pouch tumor grown from a piece of a primary tumor in a hamster lung. The established cell line from the original tumor was designated HLAC-14.

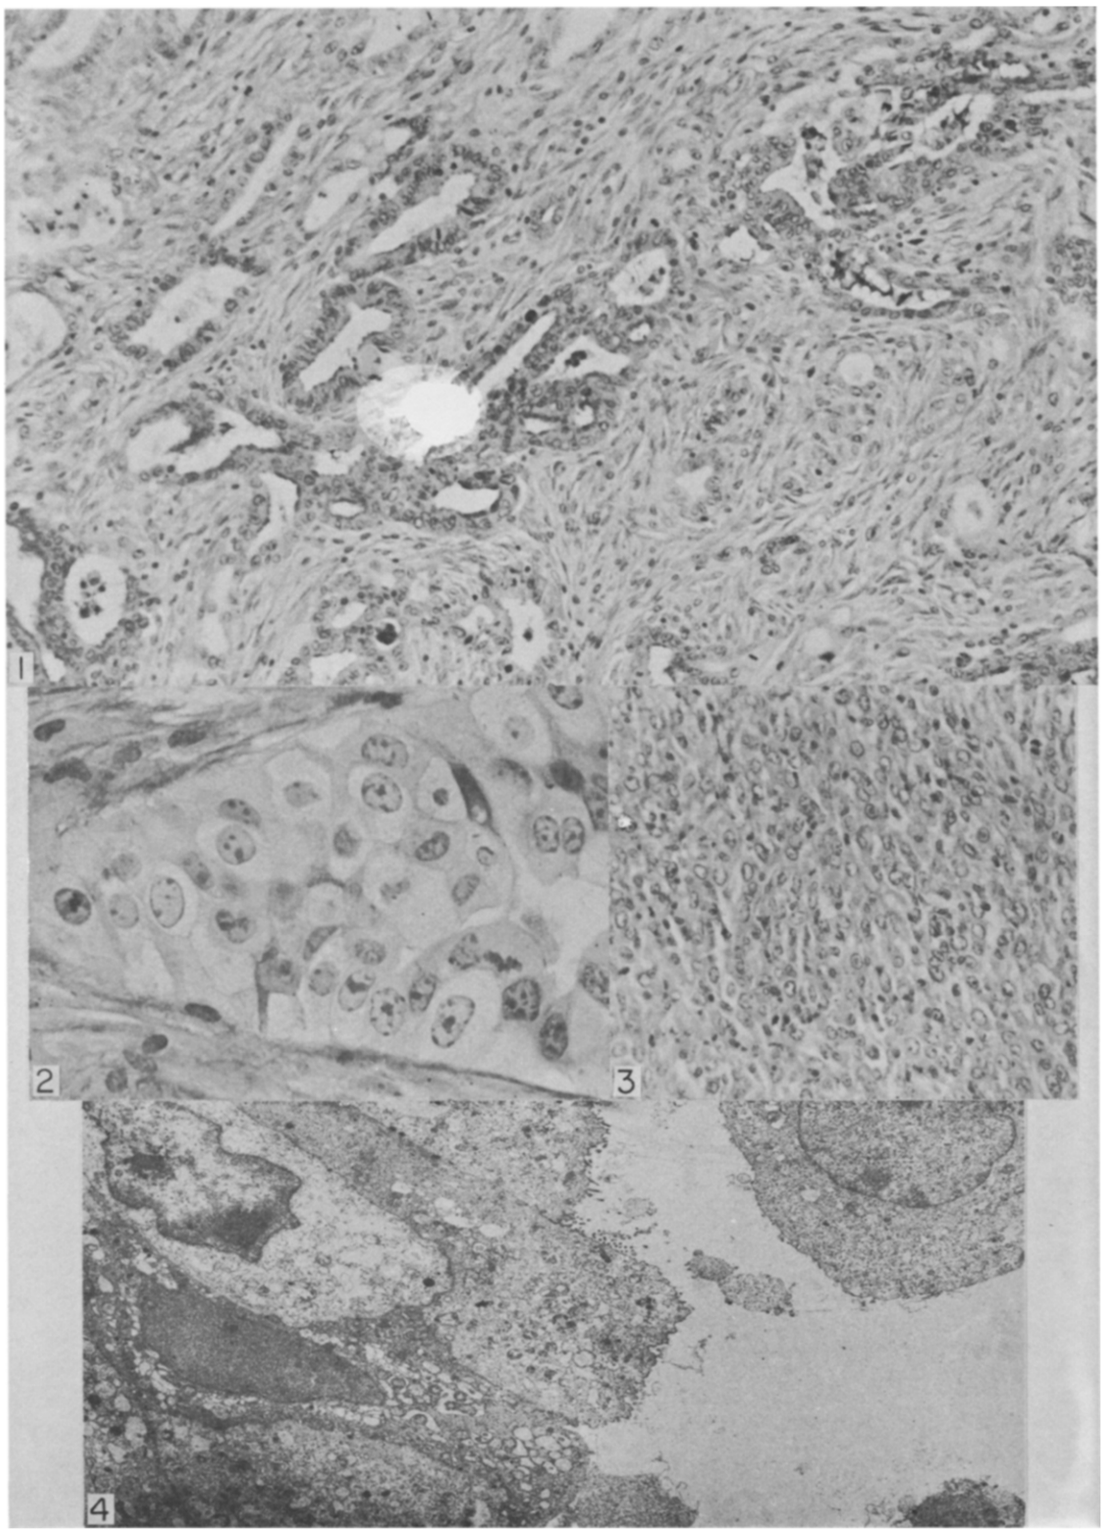

Fig. 1. *Low power view of paraffin embedded tissue: adenomatous (center) and undifferentiated (bottom right) cell types occur in these cheek pouch tumors. A PAS positive mucous secretion is produced by some of the cells in the adenomatous areas (center). PAS-hematoxylin.* × 200.

Fig. 2. *High power view of cell within adenomatous area. Note that both dark and light cells occur frequently in the glandular structures. Nuclei contain prominent nucleoli. One micron epon section, stained with toluidine blue.* × 500.

Fig. 3. *Paraffin embedded section of cheek pouch tumor showing undifferentiated sheets of cells. PAS-hematoxylin.* × 250.

Fig. 4. *HLAC-14 cell line. Cells within an acinar structure in a cheek pouch tumor produced by cloned HLAC-14 cells in tissue culture for one month. Note that both dark and light cells exist in these structures. The dark cells are large, with irregular microvilli. They usually contain large, homogeneous and electron dense nuclei (center left). There is extensive development of smooth and rough endoplasmic reticulum as well as many free ribosomes. The light cell type (top left) has very few cytoplasmic organelles compared to the dark cell type. There is some rough endoplasmic reticulum often arranged into vesicles (apical region of cell). Free ribosomes are also present, and occasional lysosomes (apical region of cell) can be seen. There are two nucleoli, and the nucleus contains both electron dense and electron lucent areas with a thin peripheral clumping of chromatin.* × 3616.

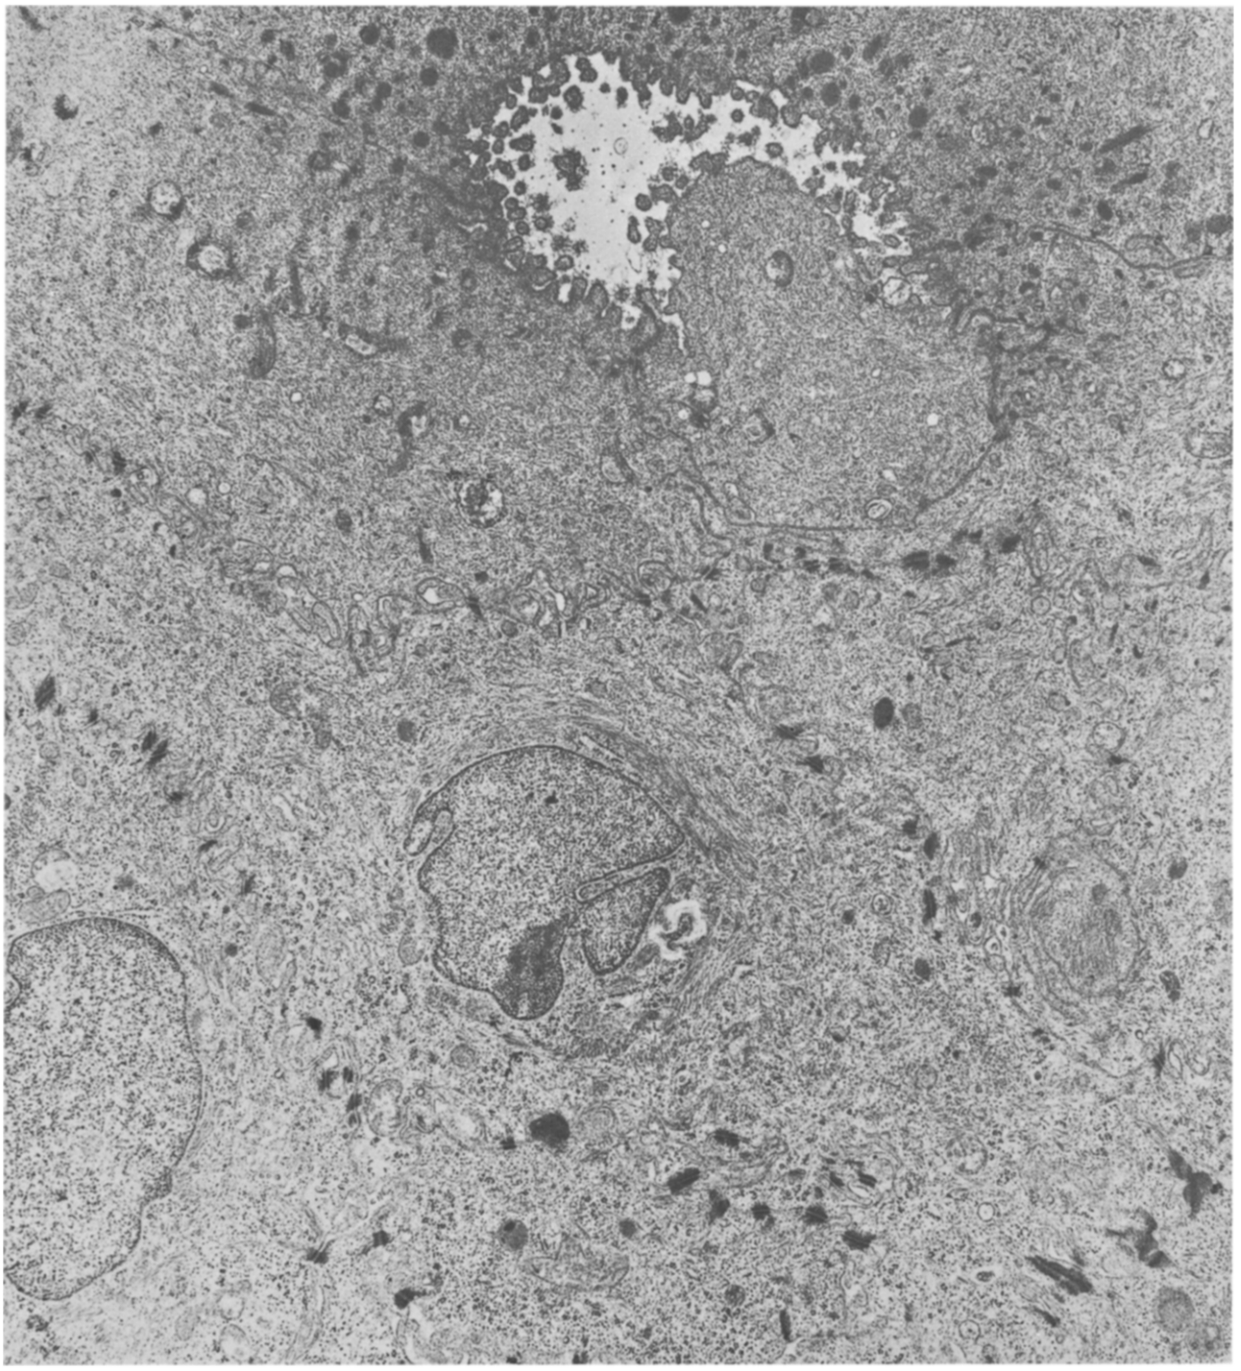

Fig. 5. Epidermoid cells growing within a cheek pouch tumor grown from the HLAC-14 cell line after 6 months in tissue culture. The epidermoid cells contain numerous tonofilaments (center) and free ribosomes, and irregular, uniformly dense nuclei with deep cytoplasmic invaginations and prominent nucleoli. Cell to cell connections include numerous desmosomes and complex interdigitations between cells. × 12400.

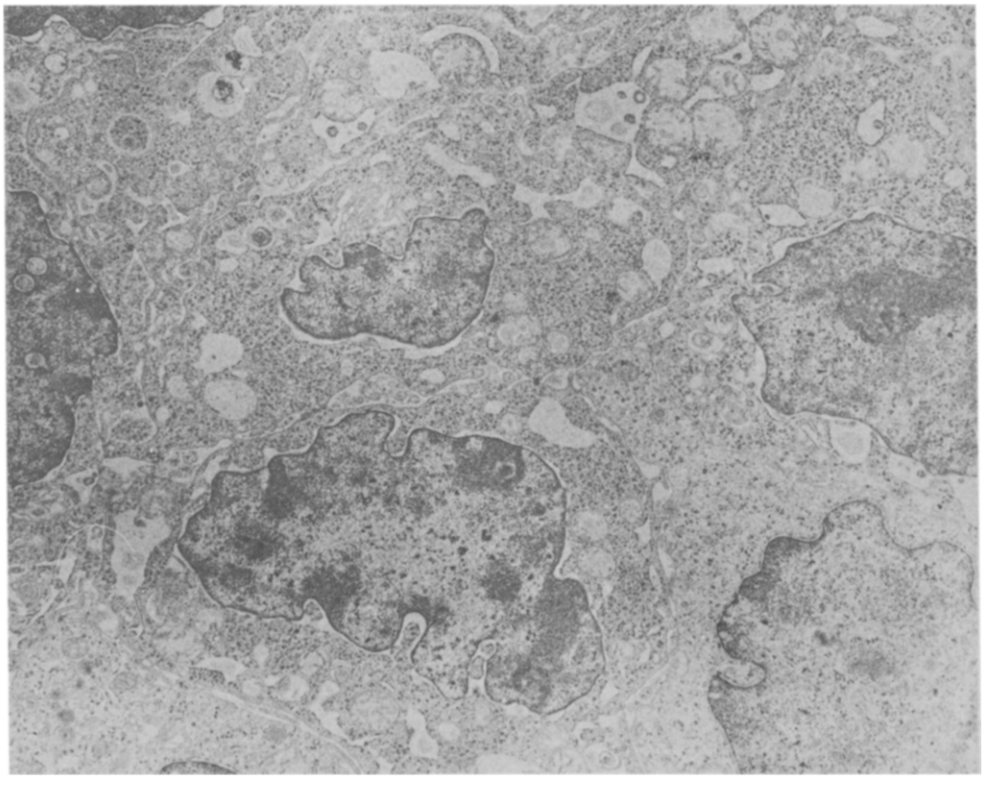

Fig. 6. *HLAC-4 cell line. Undifferentiated cells seen in a cheek pouch tumor produced by cells which had been in tissue culture for 7 months. Note the extensive dilation and vesiculation of rough endoplasmic reticulum, many free ribosomes, and many swollen mitochondria with cristae only partially traversing the mitochondria. Note the well developed Golgi region (near top, center). There is a large nuclear to cytoplasmic ratio, and the nuclei have large cytoplasmic invaginations and prominent nucleoli. An occasional microvillus can be seen, and there are occasional desmosomes (center) between cells.* × 9300.

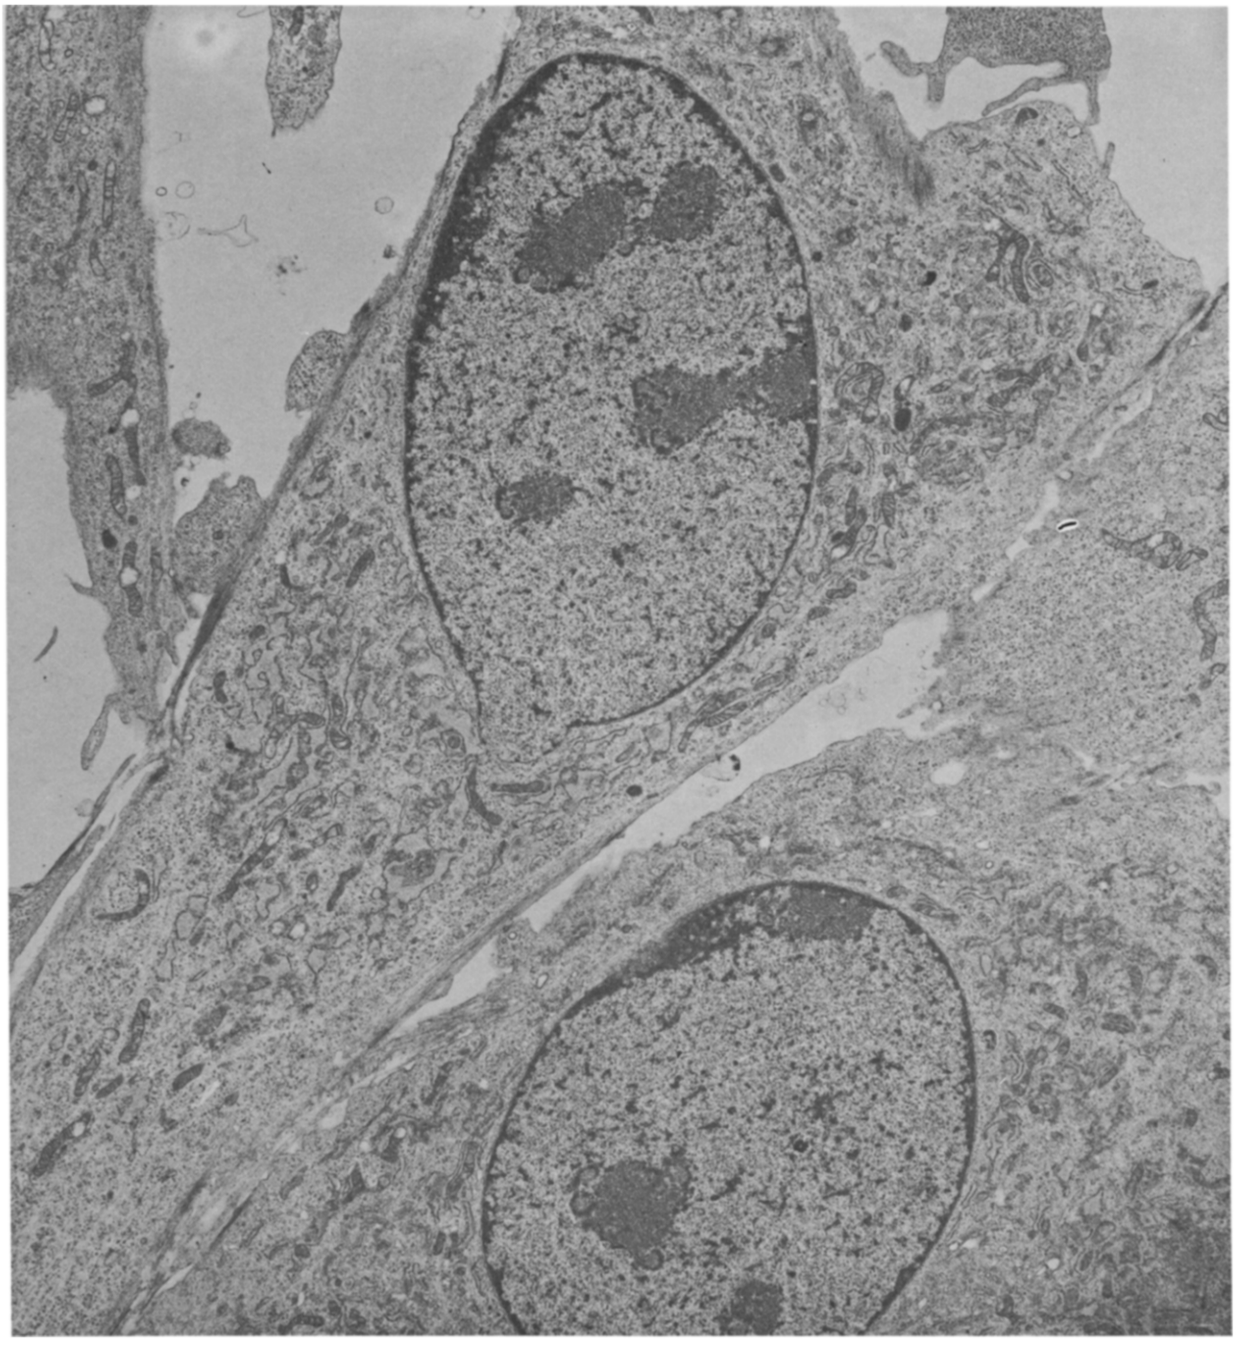

Fig. 7. HLAC-4 cells growing in vitro. *Note the regular, oval nuclei containing multiple, prominent nucleoli. There is extensive development of endoplasmic reticulum, both granular and agranular. Vesicles of granular endoplasmic reticulum are common, and there are many free ribosomes. Oblong mitochondria are numerous.* × 6000.

1. *HLAC-14 cell line* (*Figs.* 4–5). Results from the original cheek pouch tumor, and tumors produced by cells that had been in tissue culture for 1–6 months.

The cells in the acinar structures all had microvilli, and were large with pleomorphic nuclei having deep cytoplasmic invaginations and prominent nucleoli. Cell to cell connections included desmosomes and terminal bars. There were two basic cell types in the acinar structures—one was "dark" and had extensive development of smooth and rough endoplasmic reticulum, and many free ribosomes (Fig. 4). There were numerous round and oblong mitochondria, rich in matrix and often swollen with irregular cristae which only partially traversed the mitochondria. There were also many degenerating mitochondria. There were lysosomes in the basal to mid-portion of the cells, and occasional myelin figures in the apical region. There was a complete loss of organized lamellar ergastoplasm. In many cells, there was dilation and extensive vesiculation of the rough endoplasmic reticulum into round or irregular structures containing a material of moderate electron density, but in most cases the center of these structures was clear. In some cases, these structures contained electron dense cores or myelin figures. There was also much smooth endoplasmic reticulum and many free ribosomes contributing to the dark cytoplasmic matrix. In the original cheek pouch tumor, there were small round mucous secretion granules of moderate electron density—they were not seen in the other cheek pouch tumors studied at the electron microscopic level.

The other cell type in the acinar structures was "light" (Fig. 4) and had very few cytoplasmic organelles compared to the darker cells. These cells had very little rough endoplasmic reticulum, but when present was often arranged into irregular structures. There were occasional swollen mitochondria with irregular cristae which only partially traversed the mitochondria. There were occasional free ribosomes and some lysosomes. There were often multiple nucleoli in which the nucleolonema was prominent, and the nuclei always had electron lucent and electron dense areas with a thin peripheral clumping of chromatin. These same basic cell types were seen in the acinar structures at all three times studied, and their morphology remained relatively constant aside from the loss of secretion granules after prolonged passage of the original cheek pouch tumor.

Cell types found in the cheek pouch tumours other than in the acinar structures included epidermoid cells with many tonofibrils and desmosomes and cell borders containing complex interdigitations between cells (Fig. 5). These cells were very electron dense with many free ribosomes and some mitochondria, primarily round and rich in matrix. The nuclei were uniformly dense with multiple nucleoli and deep cytoplasmic invaginations. Interspersed among these epidermoid cells were "light" cells, which are very much like the light cells seen in the acinar structures described above. Desmosomes were not seen in the cell to cell borders of light cells.

Undifferentiated cell types contained much rough endoplasmic reticulum, many free ribosomes, and numerous swollen mitochondria with irregular cristae. Vesicles of endoplasmic reticulum often contained myelin figures. There was often a well-developed Golgi region. There were occasional microvilli and desmosomes between cells. Nuclear membranes were deeply infolded, and nuclei contained multiple nucleoli with prominent nucleolonemae. Cells similar to these but having a "lighter" cytoplasm, due primarily to the lack of many free ribosomes and agranular endoplasmic reticulum in the cytoplasmic matrix, were also seen.

2. *HLAC-4 cell line.* Within the acinar structures of cheek pouch tumors formed by the HLAC-4 line cells, the cells were quite uniform, and were quite similar at the electron microscopic level to the "dark" cell described above for the HLAC-14 cell line acinar structures.

Undifferentiated cells are shown in Fig. 6. There was extensive dilation and vesiculation of rough endoplasmic reticulum, often with myelin figures appearing within the vesicles, many free ribosomes, often a well developed Golgi region, and many swollen mitochondria with irregular cristae partially traversing the mitochondria. There was a very large nuclear to cytoplasmic ratio, and the nuclei had deep cytoplasmic invaginations. Occasional microvilli were seen. There were occasional desmosomes between these cells, and intercellular spaces were often small.

These two major cell types seen in the HLAC-4 cell line were basically similar to two of the cell types seen in the HLAC-14 cell line. However, the HLAC-4 cell line lacked both an epidermoid component and those cells referred to as light cells in the HLAC-14 cell line.

HLAC-4 cells growing *in vitro* are shown in Fig. 7. The cells were quite homogeneous in culture, containing electron dense, oval nuclei with multiple prominent nucleoli. There were many free ribosomes and much endoplasmic reticulum, both granular and agranular. Vesicles of endoplasmic reticulum could also be

found. Oblong mitochondria were numerous, often with cristae only partially traversing the mitochondria. There were occasional myelin figures. There were some desmosomes between cells and a few microvilli could be found.

DISCUSSION

The cells seen in these cheek pouch tumors have many of the characteristics often associated with malignant cells, including large pleomorphic nuclei with a deeply infolded nuclear membrane [8], prominent nucleoli as large as 3 μm with a distinct nucleolonema [9], and loss of the organized lamellar ergastoplasm with an increased number of free ribosomes throughout the cytoplasm [8]. In malignant cells, the ergastoplasmic membrane system is frequently altered so that tubules or lamellae form vesicles which often contain a homogeneous substance of medium electron density [8], as was commonly seen in the cheek pouch tumor cells. Bernhard [8] considers the vesiculation of endoplasmic reticulum an example of the dedifferentiation process occurring in malignant cells. In addition, most of the cells in the HLAC-4 and HLAC-14 cheek pouch tumors have malignant characteristics associated with adenocarcinomas. In a well differentiated adenocarcinoma, the polarity of individual cells is well preserved, as in normal bronchiolar epithelium, with desmosomes and terminal bars connecting the cells [10]. This is seen in the gland-like, acinar structures of both the HLAC-4 and HLAC-14 cell lines. Many cheek pouch tumor cells in areas without acinar structure were arranged irregularly and without distinct polarity, a characteristic of poorly differentiated adenocarcinoma. The cells in these areas have been termed undifferentiated at the light microscope level [2], but at the electron microscope level they actually have many of the ultrastructural characteristics common to adenocarcinoma cells. These include a well-developed Golgi region [9]; much rough endoplasmic reticulum which often forms enlarged cisternae and is frequently filled with granular material [11, 12]; microvilli [13]; dark and light cells [13, 14]; many mitochondria [10] which are often swollen [15]; and "concentric membranes" [15], here referred to as myelin figures. Mucus production, characteristic of adenocarcinomas *in vivo* [16], is also present in the gland-like structures of cheek pouch tumors at early cell passages. Although most of the cells in both cell lines have such adenomatous characteristics, some of the cells in the HLAC-14 cell line have characteristics associated with epidermoid carcinomas, including numerous desmosomes and tonofibrils and a lack of cytoplasmic organelles such as mitochondria, endoplasmic reticulum, or a Golgi complex [10, 15].

Although the cells in these tumor lines have many of the characteristics of malignant cells at the electron microscope level, proof of their malignancy can not be determined from electron micrographs. Unfortunately, specimens of tumors from which these cell lines were isolated were not obtained [2]; however, in subsequent studies, sections of transplanted tissue showed clear evidence of combined epidermoid and adenocarcinomas (unpublished data). The question always arises as to whether transplantation in the cheek pouch is evidence of malignancy. Three characteristics of these cell lines growing in cheek pouches are indicative of malignancy: (1) The cheek pouch tumors do not regress [2] as they would if they were derived from normal cells [17]; (2) the cheek pouch tumors resulting from growth of these cell lines can be passed to other hamsters [2, 17]; and (3) a cell inoculum of only 500 cells of these cell lines leads to cheek pouch tumors [2]; "normal" cells require a critical inoculum of $>10^4$ cells [17]. Furthermore, upon reinjection into hamsters via intraperitoneal or intratracheal routes, the HLAC cells lead to widespread metastatic and invasive tumors, and their *in vitro* growth characteristics are those of transformed cells [2].

The HLAC-4 cells growing *in vitro* also showed many of the malignant and adenomatous characteristics described above. However, these cells did not have the swollen mitochondria characteristic of the cheek pouch tumor cells grown from the injection of HLAC-4 cells. The cheek pouch tumors from which the electron microscopic sections were taken were quite large (about 0.5 cm), and many of the cells studied showed some evidence of degeneration. Swollen mitochondria are often seen in degenerating cells [18], so it seems likely that this characteristic, commonly attributed to adenocarcinoma cells [15] is really evidence of degeneration in our cheek pouch tumor cells. Dilation and vesiculation of endoplasmic reticulum are also considered evidence of degeneration [18]. This phenomenon was seen in both the HLAC-4 cells growing *in vitro* and in the cheek pouch tumor cells grown from the HLAC-4 cells. Thus, dilation and vesiculation of endoplasmic reticulum appear to be characteristics, as has been previously reported, of adenocarcinoma [11, 12] and malignant [8] cells.

These cell lines arise from adenocarcinomas by their morphologic characteristics, but the cell of origin of peripheral lung adenocarcinomas is a much debated issue, both in animal and human

tumors [1]. Typical type II alveolar epithelial cytosomes, composed largely of phospholipid, are not present in the HLAC-4 or HLAC-14 cell lines. Myelin figures, also phospholipid in nature [19], are quite common in these HLAC-4 and HLAC-14 cells, as well as in the tumor cells from which these cell lines were derived [1]. The difference between these myelin figures and cytosomes of type II alveolar epithelial cells in our tumors has been discussed [1]. Sommers *et al.* [20] saw laminar bodies (which we call myelin figures) in a line of transplantable human pulmonary adenocarcinoma cells. They concluded that these laminar bodies were different from cytosomes and that their tumor was of terminal bronchiolar origin.

Clara cells are considered the most likely cell of origin of our ^{210}Po-induced peripheral lung tumors [1], and have recently been implicated as the cell of origin of human peripheral lung tumors [21, 22]. However, neither Clara cells nor any other cell type in the normal hamster or human peripheral lung secretes mucus, and both adenocarcinomas of the peripheral lung and the original cheek pouch tumors grown from the HLAC-4 and HLAC-14 cell lines produce mucus. Our study of ^{210}Po-induced peripheral lung tumors suggests that Clara cells can be transformed into a mucus-secreting cell which is implicated in the progression of changes leading to malignancy [1]. Mucus production in the HLAC-4, HLAC-14, and SaBa [23] cell lines, all derived from the peripheral lung, ceases after continued passage. This is also the case for most other adenocarcinoma-derived cell lines [24], as well as for organ culture of normal lung [25]. However, mucus production continued in cell lines derived from adenocarcinomas of bronchial origin [23, 26]. This may be due to the different nature of mucus in the normal upper airway compared to the lower airway cells [27–29]. Whether mucus is actually produced by the cells in the HLAC-4 and HLAC-14 cell lines is not important for classification since they retain their adenomatous characteristics. The major cell types in cheek pouch tumors probably arise from the most prominent cell type of the primary lung tumor, a mucus-secreting adenomatous cell [1].

Various cell types are seen in cheek pouch tumors grown from cloned cell lines, each derived from a single parent cell. Such morphologic variation is common in epithelial tumors [30, 31]. HLAC-4 and HLAC-14 cells differ in their morphology, radiosensitivity and growth characteristics [2]. The epidermoid component of the original tumor remains in the transplanted HLAC-14 but not HLAC-4 cells. This may be related to differences in the original tumors, HLAC-14 cells having been derived from a tumor induced by combined ^{210}Po and benzo[a]pyrene treatment, and HLAC-4 from a peripheral lung tumor induced by ^{210}Po alone.

Acknowledgements—We thank Mr. Frank Bettinelli for his expert assistance in the preparation of histologic materials, Dr. Margaret Terzaghi Howe for providing the HLAC cell lines, and Dr. Curtis C. Harris and Dr. David G. Kaufman for help in the preparation of this manuscript.

Abstract—*Increase in time of presence of an ovarian transplant on castrated male (C3H × RIII) F_1 mice resulted in a decrease in latency time and an increase in the frequencies of mammary tumours. A month long presence of an ovarian transplant was required to stimulate mammary carcinogenesis. The presence of an ovarian graft for either 2 months or throughout the life of the animal induced mammary tumours with a similar frequency. A 3-month graft, however, was necessary to obtain latency times similar to those observed in animals bearing life long grafts.*

INTRODUCTION

THE ROLE of the ovaries in mammary carcinogenesis was first pointed out by Lathrop and Loeb [1] as early as 1916. Murray [2] obtained mammary cancers in castrated male mice implanted with ovaries. Later, Lacassagne [3] showed that administration of oestrogens induced mammary tumours in male RIII mice. Fekete, Wooley and Little [4] observed that the appearance of mammary tumours in ovariectomized DBA mice was often accompanied by adrenal hyperplasia. They suggested that oestrogens of adrenal origin probably played a role in mammary carcinogenesis in these animals. The Berkeley team [5, 6] showed that in female C3H/Crgl mice, oestrogens were essential for mammary duct development, but neither for induction nor for maintenance of hyperplastic alveolar nodules and their transformation into mammary tumours.

Richardson [7] pointed out the advantage of (C3H × RIII) F_1 hybrids as an experimental model and showed that, in these animals, mammary tumour formation was stimulated by synthetic oestrogens [8].

We have used this experimental model [9] in our laboratory to test the effect of several gestagens, oestrogens and contraceptives on mammary carcinogenesis [10, 11]. Results obtained with hybrid females ovariectomized at different ages, provided evidence for the role of adrenal secretion of oestrogens in mammary carcinogenesis [12].

The aim of the experiments described here was to determine how time of presence of an ovarian graft in castrated males could modify mammary carcinogenesis in these animals.

MATERIAL AND METHODS

(C3H × RIII) F_1 hybrids were obtained by breeding C3H/Bi females and RIII males. Animals were maintained in a temperature (22°C ± 1°C) and light controlled (12 hr/day), room and provided a commercial diet (UAR 113b) and water *ad libitum*.

One-month-old hybrid males were castrated by the scrotal route. At the same time, an ovary just excised from a 4–5-week-old (C3H × RIII) F_1 female, was implanted under the skin of the dorsal face of the ear using a trocar.

Ovaries were removed by ablation of the part of the ear bearing the graft, fixed in Holland Bouin, stained with hemalun, eosin, saffron (H.E.S.) and examined systematically.

From the age of 2 months, the mice were examined once a week for palpable mammary tumours. The age of the mouse when the first

Accepted 12 May 1977.
†To whom requests for reprints should be addressed.

tumour was detected was taken as the latency time.

Two control groups were used: one group (Te I) without ovarian graft and the second (Te II) with graft lasting the whole life-time. In the 6 experimental groups (E1 to E6), grafts were left in the ear for 10, 21, 30, 45, 60 and 90 days respectively.

Average latency times were compared using Student's *t*-test and frequencies using Pearson's χ^2 test.

RESULTS

Ovarian grafts

Out of 250 grafts performed, 4 were considered negative from the histology. These animals were discarded from statistical analysis.

Diameters of the excised grafts varied between 1 and 4 mm. The larger-sized grafts were observed especially during the 6-week-period after the grafts; they were congested. From 2 months on, the grafts became whitish; their size did not exceed 2 mm in diameter.

Histological appearance of the grafts varied as a function of time elapsed after the graft.

10-*day-post graft*

The ovaries were characterized by a dramatic hyperaemia and a vascular dilatation which disturbed the whole structure. Graafian follicles at all stages of maturation were observed.

21-*day-post graft*

The congestion was less important but a marked vascular dilatation persisted at the edge of the grafts and between the large follicles. They showed signs of atretic degeneration such as cystic dilatation, intrafollicular haemorrhage and compression of the granulosa cells. The follicles were surrounded by a dense fibrous *theca externa* (stroma) and interstitial cells. No corpora lutea were observed.

30-*day-post graft*

Vascular dilatation was still manifest around the grafts and near the ovarian hilus (Fig. 1A). Besides atretic follicles with blood-filled cavities, primary and secondary follicles were constantly observed. Corpora lutea-like structures appeared between the follicles at this time. They were often clearly delimited and consisted of several lobules of about 20 lutein cells (Fig. 1B).

90-*day-post graft*

The hyperaemia was greatly decreased. Many follicles at all stages of maturation and degeneration were present in the grafts (Fig. 1C). Blood was very rarely present in the follicular cavities but cystic degeneration was frequent. The degenerative follicles reached much bigger sizes than mature follicles *in situ* and were often delimited by fibrous stroma. Well-defined corpora lutea were constantly found (Fig. 1D).

The following stages of evolution of the grafted ovaries could be observed in animals bearing a graft for their whole life time. In several animals sacrificed 5–6 months after the graft, the ovaries showed the first signs of sclerosis and even of fatty degeneration. Nevertheless, in the majority of cases, the 6-month-old grafts were hardly different from those removed 2 or 3 months after the graft. One-year-old grafts showed a proliferation of the fibrous stroma, the presence of anovular follicles, and a decrease in the graft volume. All ovaries removed more than $1\frac{1}{2}$ yr after the graft were sclerotic.

Mammary carcinogenesis

Frequencies and average latency times of the mammary tumours for the various experimental groups are listed in Table 1. The distribution of latencies are represented by the cumulative curves of frequency of Fig. 2.

In animals bearing a 1-month-graft, there was a significant ($P < 0.02$) increase in the frequency of mammary tumours as compared to the control group Te I. The frequency of tumours in animals bearing a 2-month-graft was about the same as that in animals bearing a graft for their life-time.

The average latency was inversely proportional to the duration of the ovarian graft. An increase in time of presence (1–3 months) resulted in a progressive decrease of the average latency. However, latencies observed were the same whether animals had a 3-month- or a life-long graft.

DISCUSSION

We have studied the effect of the time of presence of an ovarian graft on mammary carcinogenesis in castrated male (C3H × RIII) F_1 mice. We have shown that a short-time graft (10–21 days) had no significant effect as regards either the frequency or the latency time of the tumours. On the contrary, 2–3 month-long grafts resulted in a stimulation of carcinogenesis, ranging about that obtained in animals with a life-long graft.

Richardson [13] reported that the frequency of mammary tumours in virgin (C3H × RIII) F_1 female mice was significantly reduced when ovariectomy was performed at 4 months (i.e., functional ovaries were present for 3 months), the frequency of mammary tumours was not

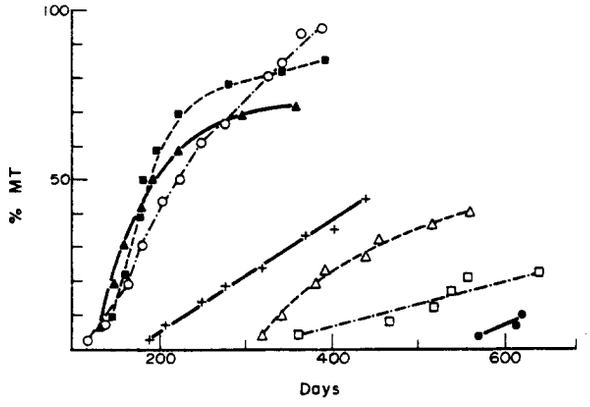

Fig. 2. Effect of the time of presence of ovarian graft on the frequency of palpable mammary tumor (MT) in castrated (C3H × RIII) F_1 male mice.
The time of presence of ovarian graft was respectively: ■----■ *life time,* ▲——▲ *90 days,* ○·—·—·○ *60 days,* +——+ *45 days,* △----△ *30 days,* □·—·—·□ *21 days,* ●——● *animals without ovarian graft.*

different from the one observed for intact females. Our results on the frequency of mammary tumours in castrated males bearing a 2 month graft (tumours in nearly all the animals) agree with this report [13]. The frequency of mammary tumours obtained in males bearing a 4–6-week-graft also agrees with the frequencies observed for ovariectomies performed at 2–3 months of age [13].

Our results for the latencies seem to indicate that the presence of the ovarian graft had no effect on the tumour growth during the stages just before the appearance of a palpable tumour. Castrated males bearing ovarian grafts for 2–3 months could be used as an experimental system for investigating the role and/or mechanisms of action of ovarian secretions on mammary carcinogenesis.

Acknowledgements—We are highly indebted for the excellent technical assistance of Mrs. F. Sangrado; we thank Mrs. C. Lipcey for reviewing and Ms L. Voullemier for typing the manuscript.

Letter to the Editor

Influence of Intravenously Injected ^{131}I-Labelled Albumin on the Growth Rate of a Sarcoma Transplanted into the Rat Stomach

H.-I. PETERSON,* L. APPELGREN, L. JAVELIN and B. ROSENGREN

Departments of Surgery I, *University of Göteborg, Göteborg and Radiotherapy, University of Linköping, Linköping, Sweden*

A HIGH permeability of the tumour capillary wall for large protein molecules and a temporary retention of labelled albumin and fibrinogen was found in transplantable rat tumours [1–3]. A high radioactivity was also recorded in normal rat stomach after intravenous (i.v.) injection of labelled albumin and was explained by albumin being eliminated in the stomach and upper small intestine [4]. These observations stimulated a study on the influence of intravenously injected, heavily ^{131}I-labelled albumin by local isotope irradiation on the growth rate of a 20-methylcholanthrene induced sarcoma transplanted into the rat stomach.

Tumours were transplanted under ether anaesthesia into the stomach of inbred Lister rats with a mean body weight of 200 g, according to a method described by Brøyn [5]. Through a small upper transverse abdominal incision, the rat stomach was lifted up into the wound. A polyethylene catheter was passed through the mouth into the stomach. A concentrated mechanically produced tumour cell suspension (1 ml) was injected into the stomach and the stomach wall was traumatized by an arterial clamp over an area of 10 mm^2. The stomach tube was withdrawn under aspiration and the abdominal wall was closed with two layers of sutures.

Two weeks after tumour transplantation, small tumours with a diameter of 3–5 mm were palpable in the traumatized stomach wall in 100% of the animals during a new laparotomy. These tumours grew and killed the animals within 3–4 weeks. The general condition of the animals was not influenced by repeated laparotomies. However, animals were sacrificed when their general condition was influenced by large tumours. Metastases to liver and lungs were found in 10% of the animals.

The tumour growth rate was recorded at repeated laparotomies by measuring 3 dia (a, b and c mm dia) on day 0 (2 weeks after transplantation), 5, 12 and 21 of the experiment. The tumour volumes were calculated from these diameters according to the formula for a spherical body:

$$\left(\frac{a}{2}\times\frac{b}{2}\times\frac{c}{2}\right)\times\frac{4\pi}{3}=\text{tumour volume in mm}^3.$$

Forty-five rats were transplanted with tumour 2 weeks before the start of the experiment. Fifteen animals were untreated controls, 15 animals were injected i.v. with a single dose of 1 mCi of a heavily ^{131}I-labelled human albumin (Kabi Diagnostica, Sweden) with a specific activity of 2.3 mCi/mg albumin, and 15 animals were injected with 0.35 mCi of labelled albumin 4 times with 2 days interval, starting on day 0. The tumour growth was followed in all groups and mean values are presented in Fig. 1. Control animals and animals given a single dose of labelled albumin were sacrificed on day 12 of the experiment due to large tumours, while animals given repeated injections could be followed until day 21.

A single injection of 1 mCi of labelled albumin did not significantly influence the tumour growth rate, which was, however, significantly

Accepted 5 May 1977.

*Address for correspondence: Hans-Inge Peterson, M.D., Ph.D., Department of Surgery I, Sahlgrenska University Hospital, S-413 45 Göteborg, Sweden.

retarded by repeated injections of labelled albumin, as could be seen on day 12 of the experiment. This retardation was temporary and large tumours were found in this group of animals at sacrifice on day 21.

A high tumour capillary permeability for large protein molecules suggests that radioactive substances bound to large protein molecules might be concentrated in tumours and used in diagnosis and therapy. However, this mechanism is limited by a passive plasma–tissue equilibration of proteins in tumours [3] and a sufficient therapeutic concentration of the active substance in tumour tissue is hard to reach in spite of administered high doses of isotope. This was observed in the present study, in which tumours were also transplanted into the stomach to reach a high radioactivity in normal tissue surrounding the infiltrating tumour, by labelled albumin being eliminated in this organ.

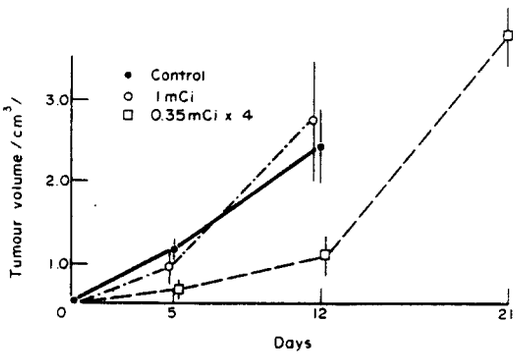

Fig. 1. Mean volumes (with S.E.M.) of gastric tumours in 15 control rats, 15 rats given a single i.v. dose of 1 mCi ^{131}I-labelled human albumin on day 0 and 15 rats given 0.35 mCi ^{131}I-labelled albumin 4 times with 2 days interval, starting on day 0. A significant ($P < 0.05$) but temporary reduction of the tumour growth rate was found in animals given repeated doses of labelled albumin on day 12.

Perspectives in Cancer Research

An Overlooked Aspect of the Mechanism of Action of Most Antineoplastic Drugs: The Inhibition of Macromolecular RNA Metabolism

UMBERTO TORELLI

Chair of Hematology, Institute of Medical Pathology, University of Modena, Modena 41100, *Italy*

IN THE majority of modern textbooks of hematology or clinical oncology, and sometimes in specialised papers also, the problem of the mechanism of action of almost all the cytostatic drugs is rapidly dismissed by referring to their ability to inhibit DNA synthesis. This appears, in view of the rapidly growing knowledge of RNA metabolism in animal cells, a gross oversimplification. As a matter of fact, some observations suggest that the very possibility that some drugs affect differentially normal and malignant cells rests on their ability to affect RNA macromolecular metabolism rather than DNA synthesis.

About 20 yr ago, radioautographic studies [1] had already shown a fact of basic relevance to the problem which will be discussed in this paper.

Whereas the activity of the DNA-directed DNA polymerases in a leukemic blast cell population occurs in a fraction of the whole cell population which is smaller than the comparable fraction of normal bone marrow precursor cells, a completely different behavior has been observed for the DNA-directed RNA polymerases. These enzymes display their activity in all blast cells, no matter they are in or out of cycle, and throughout the entire interphase.

This observation, in view of the evidence which will be reviewed beyond, clearly indicates that all leukemic cells, and not only DNA synthesizing cells, are the target for most cytostatic drugs.

MAIN FEATURES OF RNA MACROMOLECULAR METABOLISM

The really critical progress in this area is represented by the elucidation of the structural and metabolic characteristics of the primary product of the activity of the RNA polymerases. In fact, it has been shown that neither the 2 RNA components of the ribosomal subunits, 18S and 28S RNA, nor the messenger RNAs, are synthesized in their final forms. On the contrary, they are synthesized as much larger "precursors" which must undergo extensive "processing" to reach a condition of functional "maturity". As shown by Sherrer and Darnell several years ago [2, 3], the ribosomal RNA precursor is a very large molecule having a well definite molecular size, corresponding to an S value of 45. In terms of mol. wt, it is about 4.5×10^6 daltons. An electron microscopy picture of this giant molecule has been reported by Wellauer and Dawid [4]; it shows clearly, interspersed along the molecule, "loops", segments with secondary structure, which might have a critical role in the cleavage process [5].

The conversion of this giant molecule to its lower mol. wt final products follows a well definite pattern. 45S is cleaved into 41S and another large fragment, which is degraded. 41S gives rise to 32S and 20S, and these in turn are cleaved to 28S and 18S.

The precursors of messenger RNAs are represented by the so-called heterogeneous nuclear RNA [6, 7] an heterogeneous population of molecules ranging in size from 20S up to 100S. However, according to some authors [8], the "nascent" messenger precursor molecules are only those molecules larger than the 45S, which represent about 55% of the entire heterogeneous nuclear RNA. The smaller molecules should represent only intermediate products of the

cleavage process, which leads to messenger molecules of size not larger than 12–18S, leaving about 90% of the initial molecule to degradation by nucleases. No definite pattern of processing has been so far demonstrated for messenger precursors. The rates of processing of the ribosomal and messagerial precursors, and of consequence the life-span of these molecules, are largely different according to the functional state of the cell. In rapidly synthesizing cells, such as PHA-stimulated lymphocytes, the average life of the 45S ribosomal precursor, or of the giant messenger precursor RNA is only a few minutes. A quick indication of this fact is obtained by studying the distribution of radioactivity in fractions of whole cell RNA of different size after incubation of PHA-stimulated lymphocytes for 30–60 min with a radioactive RNA precursor. The large majority of the label is associated with RNA molecules smaller than 30S, and mainly with the 28S and 18S ribosomal RNA [9]. A markedly different pattern is obtained when we incubate with [5^3-H] uridine resting, out of cycle cells, such as small circulating lymphocytes. In this case, even after 8–12 hr of incubation, the majority of radioactivity is still associated with molecules larger than 30S [9].

Mechanisms controlling the rate of RNA processing in eukariotes are at present very poorly understood. Only in the last few yr the possibility has been explored that a group of specific RNases carry out highly complex reactions.

However, as pointed out recently by Robertson and Dickson [10], we must accept the idea that control by RNA processing should be considered coequal with control of transcription or translation as an important way in which cells regulate their expression.

ACTION OF CYTOSTATIC DRUGS ON MACROMOLECULAR RNA METABOLISM

It is commonly considered that RNA synthesis can be inhibited by drugs acting at 4 different levels: (1) by blocking *de novo* synthesis of purines and pyrimidines, or inhibiting the synthesis of nucleotides, thus acting at the level of the substrate; (2) by inactivating DNA, thus acting at the level of the template; (3) by directly affecting the catalytic activity of the enzyme, thus acting at the level of the enzyme; (4) by inhibiting the processing of the immediate products of transcription, causing accumulation of unprocessed molecules, thus acting at the level of the precursors.

Two clinically important drugs, whose antitumor effect is usually referred to their inhibitory activity on DNA synthesis, affect RNA metabolism through one of the first three mechanisms above mentioned. The first one is cytosine arabinoside (ara-C), which is currently one of the most successful drugs used to induce remission in acute myeloid leukemia. Its cytotoxic activity is universally ascribed to its ability to inhibit DNA polymerase after being phosphorilated intracellularly to its triphosphate derivative (araCTP) [11]. Studies with various cell lines have however shown that acute cell death induced by ara-C does not correlate well with the inhibition of DNA synthesis [12]. As a matter of fact, recent studies have shown that araCTP is a competitive inhibitor for the binding of CTP to RNA polymerase II, and that the affinities of ara-C for the RNA polymerase and the DNA polymerase are comparable [13]. These studies suggest the possibility that RNA polymerase is a target for ara-C action, so that inhibition of RNA synthesis must be considered to adequately understand the action of this drug.

Another well known drug whose action is universally referred to inhibition of DNA synthesis is the antifolate methotrexate. By inhibiting dihydrofolate reductase MTX causes a depletion of intracellular pools of reduced folates, which blocks many reactions, most critical of which may be the conversion of deoxyuridilate to thymidilate. However, it has been observed that addition of hypoxanthine to the culture medium as an exogenous source of purines considerably prevents the cytocidal effect of MTX. This suggests that MTX induces a "purineless" death as well as a "thymineless" death [14], and the mechanism of purineless death may be related to the suppression of RNA synthesis. MTX suppresses [5^3-H] uridine incorporation into RNA to a many fold greater degree in faster proliferating cells than in resting cells. In the two instances just mentioned, the effect on RNA metabolism may not be as important quantitatively as the effect on DNA synthesis. However, there is enough evidence to make difficult to assign the antitumor activity of the two drugs only to their ability to inhibit DNA synthesis. But far more interesting appear the results of the study of the action on RNA metabolism of almost all the other commonly used cytostatic drugs. These results indicate in fact that RNA synthesis is mainly inhibited by acting at the fourth level, i.e., at the level of processing of the precursors. Let us briefly examine the mechanism of action of some clinically important alkylating agents. Two well known and extensively used drugs of this class

have been studied in our and other laboratories, mechloretamine (HN_2) and 1,3-bis(2-chloroethyl) 1 nitrosourea (BCNU) [15, 16, 17]. We have shown some years ago [15] that exposure of PHA-stimulated lymphocytes to nitrogen mustard leads to inhibition of 45S RNA synthesis, possibly because of a block in the processing of the precursors, evidenced by accumulation of radioactivity in 45S and 32S, and by inhibition of methylation. A similar effect has been observed [16, 17] by studying the action of BCNU, which also strongly inhibits nucleolar processing of the 45S and 32S RNA, thus leading to decreased RNA synthesis. Both substances affect in some way the synthesis and processing of messenger precursors, since the appearance of cytoplasmic poly(A)-containing messenger RNA is completely inhibited [16]. CCNU also inhibits synthesis and processing of 45S RNA [17].

It must be pointed out that the effects of these three alkylating agents on macromolecular RNA metabolism appear to be relatively specific, and are not the result of a general deterioration in cellular metabolism following administration of the drugs. In particular, the action of these drugs, for several reasons, does not appear to result from any possible effect on DNA.

Let us examine the effects on RNA metabolism of another large family of antineoplastic drugs, the base analogs.

All purine and pyrimidine analogs studied so far have been found to inhibit processing and maturation of ribosomal precursor RNA [18–22]. Incorporation of the analogs into RNA is the most likely explanation of their ability to inhibit the maturation process. Such incorporation should alter the structure of the precursor RNA and should not allow normal processing.

It has to be emphasized that analogs of each natural base, i.e. cytidine analogs [18–20], uridine analogs [21], guanine analogs [19] and adenosine analogs [22] have been found to cause inhibition of ribosomal RNA maturation.

The peculiar activity on RNA metabolism of two further drugs whose action has been studied in the author's laboratory deserves attention. The first one is Daunorubicin, the glycosidic anthracycline which has shown high efficacy in the treatment of human leukemia and is widely used in several different antileukemic chemotherapy schedules. Daunorubicin is notoriously a strong inhibitor of both DNA and RNA synthesis. Exposure of normal proliferating lymphocytes to this antibiotic brings about an extremely rapid and complete inhibition of the appearance of 18S and 28S mature ribosomal subunits, and accumulation of 32S and 45S RNA is observed [15]. Although no definite explanation may be offered, it is worth to mention that it has been shown that, not unlike what happens with DNA, daunorubicin is able to form a complex with double-helical RNA [23]. As already mentioned, double-helical segments seem to have a critical role in processing of large ribosomal and messagerial precursor RNA molecules.

Even more interesting is the action shown on the processing of RNA precursor molecules by the vinca alkaloids. Vincristine sulfate is a well known mitotic poison, but it is less known that it also markedly affects macromolecular RNA metabolism. In the presence of vincristine the formation of 18S and 28S ribosomal RNA components is almost completely inhibited and 45S and 32S ribosomal precursors accumulate [15]. As observed by Wagner and Roizman [24] the same effect is shown by vinblastine sulfate, the other vinca alkaloid commonly used. So far, no explanation may be presented for this peculiar activity of these alkaloids.

Also in these cases, however, the effect of the drugs appears to be highly specific and is not the result of protein synthesis inhibition or of a general deterioration in cellular metabolism following the administration of the drugs.

RELEVANCE OF THE ACTION ON MACROMOLECULAR RNA METABOLISM TO THE CELLULAR PHARMACOLOGY OF ANTITUMOR DRUGS

The very fact that many drugs of several different classes far from each other, such as alkylating agents, base analogs, antibiotics and alkaloids, all of which are considerably clinically effective in treating malignancies, appear able to inhibit RNA synthesis by inhibiting processing of the precursor RNA molecules, seems to indicate that this effect is at least in part responsible for the antitumor activity of these molecules. Some basic consideration of cell physiology will lend support to this hypothesis. In rapidly dividing cells, ribosomal RNA synthesis goes on at a very high rate. It has been calculated that each ribosomal RNA cistron (and they have been estimated at more than one hundred), would have to be transcribed 20 times per min continuously during the 24 hr generation time to produce the average cell complement of ribosomal RNA [25, 26]. This means that the conversion of the high molecular weight

precursor of ribosomal RNA to its lower final products must go on very fast. This makes the rapidly proliferating cells very sensitive to the action of substances able to impair processing of large RNA molecules.

In resting cells, the demand for new ribosomal RNA synthesis is much less. This suggests that inhibition of ribosomal RNA maturation may be useful in selectively destroying a population of rapidly dividing cells. The effect of many antitumor drugs on RNA metabolism might thus help as well as the effect on DNA synthesis, to explain the observation that, generally speaking, proliferating cells are much more sensitive to anticancer agents than are non proliferating cells [27].

On the other hand, the ability to impair preribosomal RNA processing may also help to explain the effectiveness of several drugs in reducing rapidly the leukemic cell populations, which consist predominantly of cells in a more or less quiescent state.

Some light on this effect has been shed by the results of the study of the metabolism of nuclear RNA precursor molecules in leukemic blast cells. In these cells, the overall rate of synthesis of cellular RNA, 80% of which is represented by ribosomal RNA, is low, although this observation does not fit with the existence of highly developed nucleoli in these cells. These structures are in fact the site of synthesis and processing of preribosomal RNA. An explanation may be seen in the observation we made some years ago, that the life of 45S and 32S ribosomal precursor RNA of acute leukemia cells is much longer than that of rapidly synthesizing cells, such as PHA-stimulated lymphocytes [28, 29].

Further studies have shown that giant heterogeneous RNA molecules larger than 45S are processed at an even lower rate, so that they accumulate in leukemic blast cells [30].

Under these conditions, whatever may be the cause of the slow processing of the ribosomal and messagerial precursors, a further marked decrease in the rate of final RNA molecules "maturation", originated by exposure to a sufficiently high level of drug, must be severely detrimental to the cell, bringing to premature cell death. It has been recently pointed out [27] that, at this time, many experimental and clinical oncologists consider that the physiology and drug sensitivity of all out of cycle cells are the same, no matter they are normal or neoplastic, and base much of their conceptualization on the resting hemopoietic stem cell. Were the partial failure of the leukemic cells to convert the high mol. wt precursors to their final products to keep them "out of cycle", this might represent a major difference from the hemopoietic G_0 stem cells, whose quiescent state is presumably maintained through different mechanisms.

Use of Glycoprotein Antigen in the Immunodiffusion Test for Bovine Leukemia Virus Antibodies

J. M. MILLER and M. J. VAN DER MAATEN

National Animal Disease Center, North Central Region, U.S. Department of Agriculture, Agricultural Research Service, P.O. Box 70, Ames, IA 50010 U.S.A.

Abstract—*The agar gel immunodiffusion (AGID) test for detection of bovine leukemia virus (BLV) antibody was modified by substitution of glycoprotein antigen for p24, the ether-stable, internal viral antigen used in earlier investigations. This modified AGID test was compared with a complement fixation (CF) test that had shown superior sensitivity to the first AGID procedure.*

Sera from 263 cattle in commercial dairy herds were tested. The glycoprotein AGID test detected BLV antibodies in 171 sera, but the CF test detected only 134. In monthly examinations of sera from animals in a BLV experimental herd, the AGID test consistently detected more infected cattle. After experimental or natural infection, 14 of 19 cattle seroconverted to both the AGID and CF tests the same month. When antibodies were detected by only one test, it was usually the AGID test. Colostral antibodies in 2 calves from BLV-infected dams were detected longer by the AGID test than by the CF.

These results show that the glycoprotein AGID test is more sensitive than the CF test for detection of BLV antibodies in cattle sera. The AGID test also offers distinct advantages in its simplicity and specificity and promises to be a useful tool for the development of BLV control and eradication programs.

INTRODUCTION

In 1972, Miller and Olson [1] described an agar gel immunodiffusion (AGID) test that could be used to detect antibodies to bovine leukemia virus (BLV). The test was designed to identify antibodies to an antigen (p24) obtained by disruption of purified virus particles with ether. Several investigators used this AGID test in serologic studies that confirmed the association of BLV and bovine enzootic leukosis [2–6]. However, subsequent comparative studies with other serologic tests (complement fixation and indirect immunofluorescence) clearly showed that some BLV-infected cattle were not detected by the AGID test [7–9].

Recently, the finding of a second precipitating antigen associated with BLV was reported [10, 11]. The antigen was shown to be a glycoprotein and treatment with ether resulted in loss of antigenic activity. A procedure was devised for concentration and isolation of the BLV glycoprotein from fluids of persistently infected monolayer cell cultures, and the antigen recovered by this procedure was used to develop an improved AGID test for BLV antibody [11]. This paper presents a comparison of the new AGID test with the CF test described previously by us [12].

Accepted 23 February 1977.

MATERIAL AND METHODS

Cell cultures

Fetal lamb kidney cells persistently infected with BLV were the source of antigens used in this study. The development and maintenance of similar ovine cell lines have been described elsewhere [13, 14]. Fluids were collected weekly at the time cells were subcultured.

Antigens

Culture fluid was centrifuged at 1000 ***g*** for 30 min to remove cell debris and used without further treatment as antigen for the CF test. Glycoprotein antigen for the AGID test was precipitated from culture fluid by the addition of crystalline ammonium sulfate at the rate of 30 g per 100 ml. The salt was dissolved with the aid of a magnetic stirring device and then the mixture was allowed to stand at 4°C for 72 hr. At that time, the supernatant fluid was removed by aspiration and the precipitate was further concentrated by centrifugation at 7000 ***g*** for

15 min. The precipitate was resuspended in phosphate-buffered saline (PBS) to approximately one-tenth the original volume. The suspension was held overnight at 4°C and precipitate which formed during this holding period was removed by centrifugation at 1000 *g* for 30 min. The supernatant fluid was collected and passed through a column containing Con A-Sepharose (Pharmacia Fine Chemicals. Uppsala, Sweden). The column was then washed with PBS and the BLV glycoprotein was eluted with 0.1 M alpha-methyl-D-mannoside. Eluate fractions were tested for antigen content by AGID with BLV antiserum from an experimentally infected cow. Positive fractions were pooled and then concentrated or diluted as necessary to give a sharp line in AGID with an appropriate dilution of antiserum. The desired combination gave a precipitation line that was sharp, bright and long enough so that the line continued into adjacent wells that contained negative serum (Fig. 1). No preservative was added to the antigen and it was frozen when not in use. Specificity of the antigen for BLV antibody was tested with antisera to the following bovine viruses: infectious bovine rhinotracheitis, bovine virus diarrhea, bovine syncytial virus, bovine maedi-like virus, parainfluenza 3 and bovine respiratory syncytial virus.

AGID test

Test plates for AGID were prepared with 0.8% agarose (SeaKem, Marine Colloids, Inc., Rockland, ME) in 0.05 M Tris-HCl buffer, pH 7.2, which contained 8.5% sodium chloride. The agarose was distributed into 60-mm plastic Petri dishes; a vol of 6 ml per dish was used. The standard test pattern consisted of 1 central and 6 peripheral wells, each 8 mm dia, with a 2.5 mm distance between reactant wells (Fig. 1). The appropriate dilution of positive control serum was placed in 3 peripheral wells alternately with 3 undiluted test serums and the center well was filled with antigen. Test plates were held at room temperature in a humidified chamber and examined after 48 hr. Serums were recorded as positive when they formed lines of identity with the control serum or when they caused the ends of the control lines to "bend" inward toward the antigen well (Fig. 1).

CF test

A microtiter system (Cooke Engineering Co., Alexandria, VA) was used to make twofold dilutions of the test sera in veronal buffer. The serum dilutions were prepared in 25 μl vol and 25 μl of antigen was added to each well. Anticomplementary activity of each serum was also tested at dilutions of 1:2 and 1:4 by substitution of veronal buffer for antigen. Guinea pig serum was the source of complement. As described previously [12], it was supplemented with unheated normal bovine serum to a final concentration of 5%. The complement was diluted to give two, 100% hemolytic units in 25 μl of the final preparation. The test plates were incubated at 4°C for 16–20 hr, at which time sensitized sheep red blood cells were added. The sensitized cells were prepared by mixing equal vol of rabbit hemolysin and a red cell suspension that had been adjusted photometrically to give an optical density of 0.25 at 550 μm after lysis of the red cells in distilled water. The hemolysin-red cell mixture was left at room temperature for 20 min: then 25 μl was placed in all test and control wells. The plates were incubated at 37°C for 1 hr and examined visually to determine the titration endpoint of 50% hemolysis. Only serums with titers of 1:4 or greater in the absence of anticomplementary activity were considered positive.

Test sera

For an earlier report that compared the 1972 AGID test with the CF test [7], we used sera from cattle in commercial dairy herds known to have BLV-infected animals. These same sera were used in the present study to assess the relative sensitivity of the new AGID test. A second group of sera was available from cattle used in various BLV transmission experiments. These sera have been collected on a monthly basis and include samples from cattle with natural, as well as experimentally induced, infections.

RESULTS

Results of the CF and the new AGID test on sera from cattle in commercial dairy herds are given in Table 1. There was agreement between the 2 tests in 84% (222 of 263) of the sera examined, and more than half of these were in the positive category. The major discrepancy resulted from sera that were positive in AGID but negative in the CF test (39 sera). Only 2 sera gave positive CF reactions and negative AGID results. The CF titers of these samples were relatively low, 1:4 and 1:8, and neither serum had reacted in the old AGID test [1] with ether-treated antigen.

Comparison of the CF and AGID tests on sera taken from cattle in the BLV experimental herd are given in Table 2. At each sampling time, more sera were positive by the AGID test than by CF. When there was lack of agreement between the 2 tests, it was always due to a serum that gave a positive AGID reaction but was negative in the CF test.

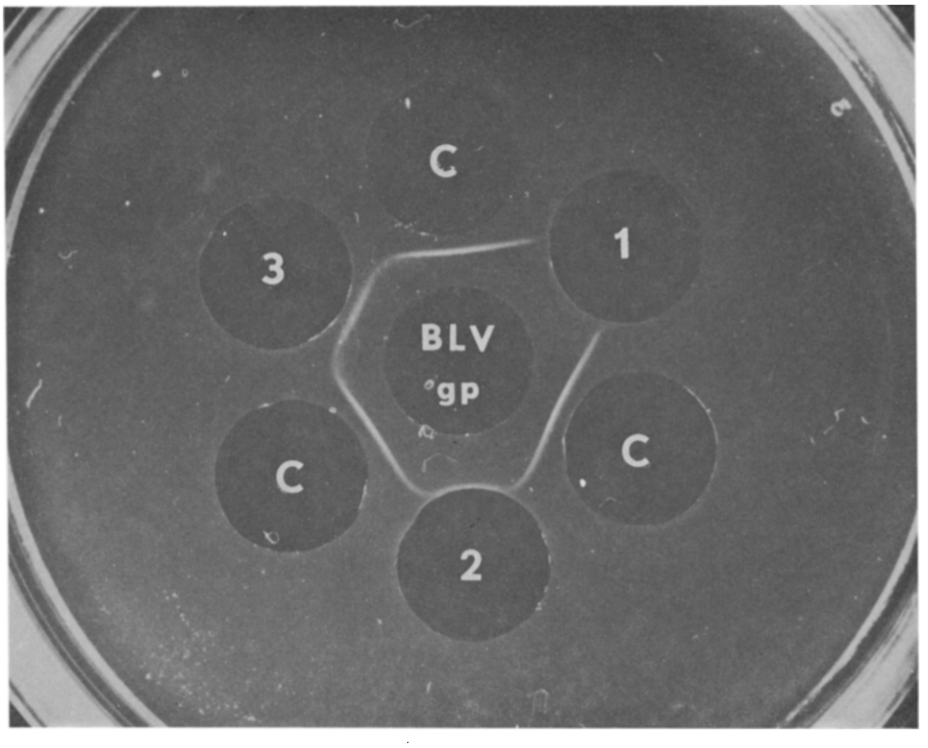

Fig. 1. Agar gel immunodiffusion test for detection of antibodies to BLV. Center well: BLV glycoprotein antigen. Peripheral wells: C—control positive serum from an experimentally infected cow; 1—serum from a cow in a BLV-free herd; 2 and 3—sera from 2 cows with naturally acquired BLV infections. Serum in well 2 is considered a weak positive because it only "bends" the ends of lines formed by the control serum.

Table 1. Comparison of glycoprotein AGID and CF tests for serologic detection of BLV infection in 263 cattle from commercial dairy herds

Result		No. of sera	Total examined (%)
AGID	CF		
+	+	132	50
−	−	90	34
			84% agreement
+	−	39	15
−	+	2	<1
			15% non-agreement

Table 2. Comparison of glycoprotein AGID and CF tests for detection of BLV-infected cattle in experimental herd

Month	No. tested	No. AGID+	No. CF+
Nov., 1975	50	40	37
Dec., 1975	50	40	39
Jan., 1976	52	39	35
Feb., 1976	52	40	38

Monthly serum samples from 19 cattle with experimentally induced or naturally acquired BLV infections were examined to determine the relative sensitivity of the AGID and CF tests in detection of early antibody responses. These results are summarized in Table 3. In most of the cattle, seroconversions were detected the same month by both tests. Only 1 animal had a detectable CF response before precipitating antibody appeared and in this serum the CF titer was only 1:4. In 4 animals, AGID reactions were positive before CF antibody was detected. With one exception, when the first positive reaction was detected by only 1 of the serologic tests, the other test was also positive the next month. The exception was a calf which developed BLV infection as a result of contact exposure. The AGID reaction of this animal was positive for 2 consecutive months before seroconversion was detected by CF.

Another comparison of the AGID and CF tests involved the monthly examination of sera from 2 calves of BLV positive dams. Precolostral sera were negative for antibody, and after colostrum feeding, both calves were seropositive by AGID and CF. In one calf, passive CF antibody persisted for only 1 month. The calf then remained seronegative until CF antibody was again detected at 6 months of age. During this 5-month interim, the serum samples continued to give positive reactions by the AGID test, although they gradually became weaker. At the time CF activity reappeared, the AGID response was again very strong. This animal then remained seropositive by both tests during the next 18 months of observation. The second calf

*No. of animals.

had a continuous but decreasing CF titer to BLV for 7 months and a positive AGID reaction for 10 months. After becoming seronegative at 11 months of age, the animal has remained negative through the next 13 months of observation.

DISCUSSION

The AGID test with glycoprotein antigen was shown by these studies to be substantially more sensitive than the CF test for detection of BLV antibodies in cattle sera. In the study of commercial dairy herds, 171 sera were determined positive by AGID but only 134 sera gave positive reactions in the CF test. A similar finding was reported in a more limited study involving sera submitted to a federal diagnostic laboratory. Of 16 sera that gave positive AGID reactions, only 13 had CF antibodies [15]. Note that although these results suggest that it is relatively common for cattle infected with BLV to have precipitating but not complement fixing antibodies, we cannot be certain that the AGID and CF tests measure antibodies to the same antigens. The antigen used in the AGID test described here has been isolated and characterized [16], but the antigen or antigens in culture fluid that react in the CF test have not been identified.

The AGID test was more consistent than the CF test in detecting BLV reactor cattle in our experimental herd although the difference in sensitivity was not as great as that observed in the commercial herds. This result might have been anticipated because experimentally infected animals were probably exposed to a larger dose of virus than those infected under natural conditions and could therefore be expected to develop higher antibody titers. Some of the test discrepancies involved sera from recently infected animals, and as the monthly serum tests indicated, seroconversions to BLV were often detected by AGID while the CF test was still negative. Furthermore, we have observed in our monthly serologic tests that a few cattle consistently have AGID-positive but CF-negative reactions. These animals have usually been infected for a long time and their CF titers during the early stages of infection were comparatively low.

The 2 sera that gave positive CF but negative AGID results in the commercial herd study may have resulted from non-specific reactions. We check the specificity of each lot of CF antigen by testing 24 sera from cattle in a BLV-negative herd, but these tests may not be adequate to accommodate the individual variability encountered when large numbers of sera are tested. In this respect, the AGID test has a distinct advantage over CF because a test serum that produces a line of identity with the positive control serum (or one that "bends" the control serum line) has satisfied the requirement of specificity.

The examination of sera from 2 calves of BLV-infected cows showed that the AGID test was also a more sensitive indicator system for detection of passive antibody than was the CF test. However, the CF test did offer the advantage of providing antibody titers. Using this information, we were able to follow the decrease of passive antibody levels and then observe in 1 calf a subsequent increase of titer, presumably due to an active BLV infection.

We have concluded from our investigations that the glycoprotein AGID test for BLV antibody is superior to the CF test in respect to sensitivity, simplicity and specificity. Straub has reported that AGID tests corresponded very well with hematological data in a study on experimentally-infected cattle [17]. Further comparisons with the hematologic test and with other serologic tests will be necessary to completely evaluate the glycoprotein AGID test for BLV.

Fine Structural, G-6-PD Isoenzyme, and HaLV *gs* Antigen Studies of Poly I/C and Antiestrogen Treated DES-Induced Hamster Renal Tumors*

ALICE H. DODGE

Departments of Anatomy, Stanford school of Medicine, Stanford University, Stanford, CA 94305 *and California College of Podiatric Medicine, San Francisco, CA* 94115, *U.S.A.*

Abstract—*Poly I/C an interferon inducer with secondary antiviral action and antiestrogens ICI* 46,474 *and U*-11,100*A were given to hamsters carrying DES-induced and dependent renal tumors. Both promoted a reversal in the G*-6-*PD isoenzyme pattern to that pattern observed in non-tumours adjacent kidney tissue and normal non DES-treated kidney. Poly I/C reduced the expression of HaLV* gs *antigen. Cytological changes in the DES-dependent tumors resulted from treatment by Poly I/C and antiestrogens. Growth of DES-independent tumors was not inhibited following Poly I/C treatment.*

INTRODUCTION

FINE structural characteristics, glucose-6-phosphate dehydrogenase (G-6-PD) isoenzyme pattern, and HaLV *gs* antigen activity have been studied and reported for stilbestrol (DES)-induced and DES-dependent and DES-independent (autonomous) renal tumors of the Syrian hamster [1, 2]. The two autonomous tumors studied 1098 (3482) and 1098 (7528),† were obtained from the tumor bank of Dr. H. Kirkman and have been described in a review of autonomous renal tumors of the Syrian hamster by Kirkman [3].

Both dependent and autonomous tumors appear to be made up of epithelial cells, although some of the cells have a spindle-shaped appearance. The cells contain rough endoplasmic reticulum, ribosomes, mitochondria, lysosomes, lipid droplets, and are connected by desmosomes; a basal lamina is observed with some cells. The DES-dependent tumors have been reported by Li to exhibit annular nexuses not observed in normal proximal tubules [4]. The DES-dependent tumor cells demonstrate a high expression for both the slow (B) and fast (A) migrating G-6-PD isoenzyme bands. Kidney samples from areas near the primary tumors demonstrate a lower expression of the faster migrating isoenzyme (A); the autonomous tumors studied demonstrate a high expression of the slow migrating band (B) and a low or non expression of the fast migrating band (A), [1]. Non DES-treated kidney also demonstrates a low expression of isoenzyme (A) (see Results). DES-dependent tumors have a lower expression of the HaLV *gs* antigen than the DES-independent tumors.

Dodge has suggested [1, 2] that the G-6-PD isoenzyme pattern of the DES-dependent tumor might be used to indicate a unique step in tumorigenesis of the renal tumor in the hamster. The tumor while still dependent on DES, has been shown to have a low expression of HaLV *gs* activity and at this particular point in tumor progression might be vulnerable to inhibitor treatment, i.e. antiviral agents or antiestrogens.

The following paper reports the results obtained when polyriboinosinic/polyribocytidylic acid (Poly I/C) a synthetic double stranded RNA was administered i.p. and antiestrogens, ICI 46,474-*trans*-isomer of 1-(*p*-beta-dimethylaminoethoxphenyl)-1,2-diphenylbut-1-ene and U-11,100A-nafoxidine hydrochloride, were administered orally and subcutaneously, respectively. The mode of administering Poly I/C varies from species to species (i.v., i.p., s.c.) [5–7]. It has been studied by a number of laboratories [5–10], and it has been suggested that it binds to the cell membrane and promotes interferon production [9] or that it acts on cell

bound immunity [11]. The antiestrogen activity of ICI 46,474 and U-11,100A may be attributed to interference with estrogen receptor sites or possibly blockage of estrogen dependent enzymes [12, 13]. U-11,100A has been reported to compete with estradiol for the specific 4S cytosol receptor in normal and estrogenized kidney [14]. All tissues sampled were studied with the electron microscope for fine structure and by electrophoresis to determine the G-6-PD isoenzyme patterns. HaLV *gs* antigen activity was determined on a representative number of tumors.

MATERIAL AND METHODS

Material

Stilbestrol (DES)-dependent tumors were induced in golden Syrian hamsters by subpannicular implantation of 30 mg of DES for an interval of 250 or more days. Stilbestrol-induced but autonomous renal tumors (3482 and 7528) were grown in adult male hamsters for 2–3 months before becoming palpable. Poly I/C (1 mg/ml pyrogen-free saline) was obtained from Microbiological Associates, Bethesda, MD; ICI 46,474 (powder) was obtained from ICI America Inc., Wilmington, Delaware, and U-11,100A (powder) was obtained from the Upjohn Company, Kalamazoo, MI.

Methods

All tissue samples obtained were used fresh or frozen quickly and stored at −20 C for future study. Tissues were homogenized in 3 vol of glass distilled water for 1 vol of tissue in glass tissue grinders. The homogenates were spun down at 10,000 ***g*** for 10 min. Protein determination was performed on all samples. Twenty to hundred microliter aliquots were applied to acrylamide gels. Electrophoretic procedures were conducted in flat bed acrylamide systems (Ortec Inc., Oak Ridge, TN). Gels were incubated in a medium consisting of 35 mg nicotinamide adenine dinucleotide phosphate (NAPD); 25 mg nitroblue tetrazolium (NBT); 50 ml Tris/HCL buffer, pH 6.8; 600 mg glucose 6-PO_4 (dipotassium); and the reaction was activated with 12 drops of phenazine methyl sulfate. All gels were photographed for permanent records.

Electron microscopic procedures were conducted routinely as reported earlier [2].

HaLV *gs* antigen tests were conducted in the laboratory of Dr. Robert J. Huebner, Bethesda, MD, according to the procedure reported earlier [2].

Poly I/C was administered in the following way: 1 ml (1 mg/ml) was injected s.c. near the periphery of the autonomous tumors and 1 ml (1 mg/ml) was injected i.p. into hamsters carrying primary DES-induced and dependent renal tumors. Injections were given every other day. ICI 46,474 was suspended in Tween 80, 0.6 mg/ml and 0.1 ml of this suspension was mixed with apple juice and fed by medicine dropper to the hamsters daily. U-11,100A was suspended in safflower oil, 100 mg/ml, and 1 ml was injected s.c. daily, for at least 5 days. All primary, DES-dependent renal tumors were viewed prior to treatment by means of an incision in the dorsal body wall and classified as small, medium or large. After Poly I/C or antiestrogen treatment the tumor size was inspected again to note any decrease in size. Tumors were classified as small (1–5 mm), medium (1 cm), large (greater than 1 cm) and huge (greater than the size of a normal kidney). All DES-independent tumors carried subcutaneously were measured along 2 axes prior to treatment and after it.

In one experiment the primary tumors were photographed prior to Poly I/C treatment and then photographed again after Poly I/C treatment.

RESULTS

Poly I/C was used to treat a group of 12 host animals with DES-dependent renal tumors. The duration of treatment and G-6-PD isoenzyme pattern have been summarized in Table 1. The G-6-PD banding pattern of all tumors treated reverted to that observed in surrounding adjacent kidney, demonstrating a low expression of isoenzyme (A) and to that observed in kidneys from normal non DES-treated hosts which also demonstrated a very low expression or absence of the faster migrating isoenzyme (A), (Fig. 1). Tumors C-162 and C-58, deprived of DES but not given Poly I/C, maintained the isoenzyme pattern observed in DES-dependent and treated tumors. When the tumors were between 1–5 mm in size prior to Poly I/C treatment there was evidence of actual regression in size after Poly I/C treatment. An example of this regression is illustrated in Fig. 2, which shows a primary renal tumor photographed prior to Poly I/C treatment and after Poly I/C treatment. The data from 5 autonomous tumors treated with Poly I/C have been summarized in Table 2. There were no changes in isoenzyme pattern from that observed in non-Poly I/C-treated hosts since in the autonomous tumors isoenzyme (A) was observed to be absent or faintly expressed. There were also no significant decreases in macroscopic size observed.

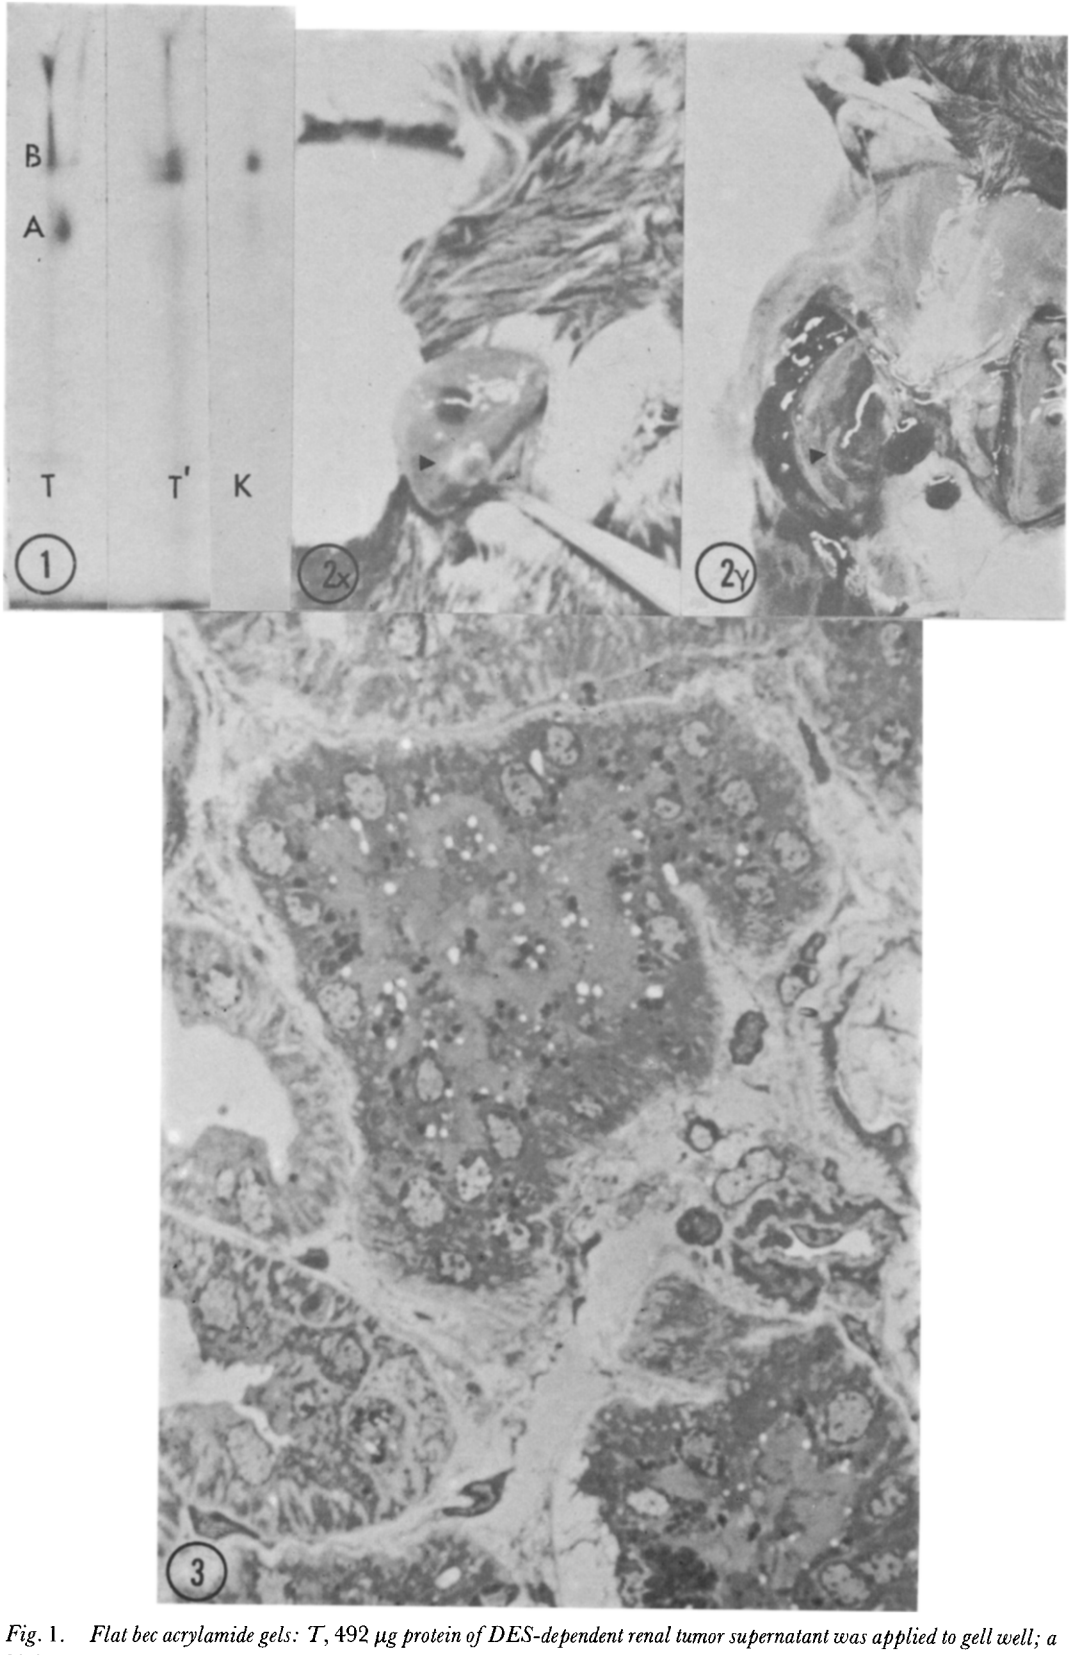

Fig. 1. *Flat bec acrylamide gels: T*, 492 μg *protein of DES-dependent renal tumor supernatant was applied to gell well; a high expression of both G-6-PD isoenzyme bands A and B is demonstrated. T'*, 1085 μg *protein of Poly I/C-treated DES-dependent renal tumor supernatant was applied to gel well; only isoenzyme B is demonstrated. K*, 722 μg *protein of non DES-treated adult male kidney supernatant was applied to gel well; isoenzyme B demonstrates a high expression and isoenzyme. A demonstrates a faint expression. The origin is at the top of photograph.*

The antiestrogen agents were used to treat 9 host animals with DES-dependent renal tumors (Table 3). All but one of the tumors showed a return of the G-6-PD isoenzyme pattern to that observed in adjacent kidney. One animal showed a regression in the size of the tumor.

Both Poly I/C and antiestrogen-treated renal tumors were tested for HaLV *gs* antigen activity by Dr. Robert J. Huebner, Bethesda, MD (Table 4). Four Poly I/C-treated DES-dependent tumors had complement fixation titers (CFT) of 2 or less than 2, compared to a CFT of 4–8 reported for DES-dependent renal tumors in an earlier paper [2]; therefore Poly I/C treatment appeared to cause some decrease in the CFT of DES-dependent tumors. The CFT of a tumor no longer supported by DES treatment and not treated with Poly I/C did not show a decrease in the titer. Three Poly I/C treated DES-independent autonomous tumors had CFTs from 8–16, which were within the range reported for non-Poly I/C-treated tumors; therefore Poly I/C did not affect the CFT of these tumors.

Cytological changes were observed with light and electron microscope studies of DES-dependent tumors treated with Poly I/C. In a light micrograph of the tumor, vacuoles and densities were observed in some of the tumor cells (Fig. 3). At the fine structural level cells were observed to contain membranous whorls often filling up most of the cytoplasm (Fig. 4). Non-Poly I/C treated DES-dependent tumors processed for microscopy in the same manner have never been observed to contain these whorls. Amorphous material was observed in some areas of the tumor where basal lamina was still apparent (Fig. 5); it occurred either between the basal lamina and cell membrane or outside the basal lamina. But where the basal lamina was no longer apparent the amorphous material seemed to have replaced it (Fig. 6). Poly I/C treatment did not appear to alter the cytological nature of the adjacent kidney tissue.

DES-independent renal tumors treated with Poly I/C had regions of unchanged tumor tissue (Fig. 7) and regions where there was a great deal of necrosis (Fig. 8). Focal irritation due to injections of Poly I/C every other day may have accounted for the necrosis; or the focal changes

may have resulted from vascular changes brought about by the Poly I/C treatment as suggested in ref. [4].

DES-dependent tumors treated with antiestrogens demonstrated cytoplasmic vacuoles which often contained lipid (Fig. 9). When the vacuoles filled most of the cytoplasm, membranous whorls were sometimes present.

DISCUSSION

In the progression of initially hormone-dependent tumors to hormone-independent tumors it would be clinically useful to be able to arrest tumorigenesis during periods of hormone vulnerability. It has been suggested earlier [1] that the isoenzyme pattern of G-6-PD of DES-induced and dependent renal tumors could be used as a marker of vulnerability. The data reported in this paper support this hypothesis in that both Poly I/C and antiestrogen treatment caused a reversal in G-6-PD isoenzyme pattern in DES-induced and dependent renal tumors to that of surrounding non-tumorous adjacent kidney tissue and non DES-treated kidney. Li *et al.* [15] reported 4 G-6-PD isoenzyme bands for the DES-induced and dependent renal tumors. The slower migrating bands described in his work correspond to the slower migrating diffuse staining zones observed in both DES-dependent tumors and Poly I/C treated DES-dependent tumors (Fig. 1). However it is the fastest migrating band (A) which is reduced in expression after Poly I/C treatment. Schmulker [16] reported that, when ammonium persulfate was used in the polyacrylamide gel system, the expression of the slower migrating positive region was enhanced in rat tissue. However, since ammonium persulfate was used routinely in both the work reported by Dodge (1973) and Li (1975) this could not explain the difference found by Dodge and Li.

The decrease of the HaLV *gs* CFT of Poly I/C-treated DES-induced and dependent renal tumors though small occurred concomitantly with the isoenzyme change. Therefore, during the period of vulnerability delimited by the G-6-PD isoenzyme pattern reversal there existed also an interval when HaLV antigen production could be influenced by the secondary action of Poly I/C. The period of vulnerability did not appear to extend to the DES-independent state since in the autonomous renal tumors the G-6-PD isoenzyme pattern and HaLV activity were not affected by Poly I/C treatment.

Cytological changes in the DES-dependent renal tumors, and in some cases actual tumor regression, were also observed in addition to the isoenzyme change and HaLV CFT reduction. Since Poly I/C-treated primary DES-dependent tumors demonstrated abundant extracellular

amorphous material and the primary DES-dependent tumors did not, it would be of interest to determine in future studies if the type of collagen produced by the DES-dependent tumor changed after Poly I/C treatment. Indeed increased production or accumulation of extracellular material in the Poly I/C-treated tumors might be responsible for the reported tumor regression. Therefore, in this preliminary study of the effects of Poly I/C and antiestrogens on DES-induced renal tumors the G-6-PD isoenzyme banding pattern appeared to be useful as a marker isoenzyme to characterize a stage in tumorigenesis vulnerable to inhibitor treatment.

Abstract—*The purpose of this randomized trial was to verify some experimental and clinical data suggesting a possible potentiating effect of bleomycin when used concomitantly with radiotherapy. Out of* 220 *patients with a biopsy proven epidermoid carcinoma of the oropharynx*, 186 *evaluable cases are reported here. One group of* 87 *patients was treated with radiotherapy alone (Cobalt* 60 ~ 6400 rad ~ 7–8.5 *weeks), the other group of* 99 *patients received radiotherapy combined with bleomycin, the latter administered at the dose of* 15 mg *i.m. twice a week for* 5 *weeks (total dose:* 150 mg).

Analysis of the treatment groups showed their comparability with regard to the most important prognostic factors (TNM, sites of primary, sex, age...). Complication rates of mucositis and epidermitis were significantly increased (71%) *in the radiotherapy + bleomycin group and were considered responsible of frequent denutrition and weight loss in this group. Such side effects necessitated a delay of radiotherapy in* 22% *of patients and definitive interruption in* 5% *in the combined treatment group whereas in the radiotherapy alone group no interruption of treatment was recorded and only* 5 *treatments* (6%) *were postponed.*

Considering tumor regressions measured 6 *weeks after completion of radiation therapy, total regression rates were not significantly different in both groups as far as primary tumor* (67.9–67%) *or neck nodes* (49–62%) *are concerned. Survival curves obtained by the actuarial method showed the same* 50% *survival in both groups at* 15 *months of follow-up.*

INTRODUCTION

RADIOTHERAPY is the usual treatment of epidermoid carcinomas of the oropharynx. Although the introduction of high energy irradiation through the use of cobalt 60 and electron therapy has allowed a better control of these tumors, their long term prognosis remains poor with a survival rate not exceeding 30% at 5 yr. The prognosis is even worse for infiltrative carcinomas of the base of the tongue and in cases with neck node involvement [1].

During the past 10 yr interest has grown in the use of bleomycin which accumulates in the epithelial layers and has been shown to be effective on carcinomas of the head and neck [2].

The sensitivity of tumor cells to the combined action of bleomycin and irradiation has been investigated in experimental studies [3]. In several models the cumulative effect of bleomycin and irradiation has been observed [4]. Other studies investigating a possible synergic action of bleomycin provided results which depended on the type of cellular strain used [5]

Accepted 23 May 1977.

and on the mode of combination of bleomycin with irradiation, either simultaneously or sequentially [6].

Pilot clinical studies recently carried out on patients with carcinomas of the head and neck suggest a cumulative antitumor effect when bleomycin is given in conjunction with radiotherapy [7].

The aim of the present randomized clinical trial is to compare bleomycin administered during irradiation to radiotherapy alone with regard to the rate of remission and duration of survival in carcinomas of the oropharynx.

MATERIAL AND METHODS

The following criteria were established for the entry of patients on study:

1. All patients must have had a biopsy proving advanced squamous cell carcinoma of the oropharynx.
2. The following localizations were included: the base of the tongue, the tonsillar fossa, the posterior wall and the soft palate.
3. The largest diameter of the primary tumor must have measured at least 2 cm (T2 of the UICC classification) or the tumor must have had an infiltrative character irrespective of its size.
4. Patients with neck node involvement ($N1$, $N2$, $N3$) were included in the trial, however those with distant metastases ($M1$) or a second primary lesion (other than skin carcinomas) were excluded.

Patients were randomized to receive one of two treatments:

1. Telecobalt alone: the schedule for the primary tumor and metastatic lymph nodes was a maximum total dose of 7000 rad in 7–8.5 weeks while regional uninvolved nodes were to receive 5000–5500 rad in 5–6 weeks.
2. Radiotherapy as above plus concomitant bleomycin (BLM): 15 mg of BLM to be administered by i.m. or i.v. shots twice a week from the start of radiotherapy for a period of 5 weeks (total dose 150 mg in 5 weeks). Each injection of BLM was to be given 2 hr prior to the start of each session of radiotherapy and prophylactic polaramine injections were to be given to prevent allergic reactions. The degree of tumor response (100%, $\geq 50\%$, $< 50\%$, none or growth) was to be evaluated 6 weeks after completion of radiotherapy by comparing the residual volume of the primary tumor and the invaded nodes to the initial volume. The second endpoint of the study is the comparison of the survival rates in the two treatment groups.

The Statistical Unit of the Institut Gustave-Roussy in Villejuif was responsible for the handling of the data. Statistical analysis was carried out mainly in Villejuif and partly at the E.O.R.T.C. Data Center in Brussels. Tables of random numbers were used to prepare randomization envelopes for each institution. The randomization was stratified according to institution and balanced after every 4 patients within each institution. To date all patients have reached at least 1 yr of follow-up and actuarial survival curves have been calculated for each treatment group.

RESULTS

1. *Distribution of patients entered into this study*

Two hundred and twenty-four patients entered into this study from 1 April, 1973 to 31 December, 1974. Thirty-eight patients were excluded from this analysis, 31 (14%) due to protocol violations and 7 (3%) due to incomplete data. Thus 186 patients (83%) were evaluable, 87 in the group receiving radiotherapy alone and 99 in the group receiving bleomycin and radiotherapy. Table 1 gives the distribution of evaluable patients by institution and treatment.

The 2 treatment groups were comparable with regard to the principal prognostic factors. With regard to age and sex, the average age is 57 yr in both groups while females comprise 6% of the radiotherapy group and 13% of the group receiving radiotherapy and bleomycin. With regard to the distribution of patients according to the initial tumor site, Table 2 shows the groups to be comparable with carcinomas of the tonsillar fossa (44%) and the base of the tongue (36%) being the most frequent. The distribution of patients according to the tumor extent, 1 site or more than 1 site, is given in Table 3 and it is seen that tumors are limited to 1 site in 32% of the patients. Tumors with deep invasion (infiltrative character) represent 78% of the patients in the bleomycin group and 86% of the patients in the radiotherapy alone group. The distribution of patients according to the UICC clinical classification of neck nodes is given in Table 4 and it is likewise seen that the treatment groups are comparable with respect to the N classification.

2. *Treatment received*

(a) *Radiotherapy.* The primary tumor was to receive a maximum total dose of 7000 rad in a

Differences are not significant.

period of 7–8.5 weeks. The actual distribution of the total dose received in each treatment group is given in Fig. 1. The average total nominal dose received was 6403 ± 204 rad in the group receiving radiotherapy alone and 6288 ± 168 rad in the group receiving bleomycin (difference not significant). In 30% of the patients receiving radiotherapy alone and in 25% of the patients receiving bleomycin, the total duration of radiotherapy (Fig. 2) was shorter than the scheduled 7 week period. In fact, the average duration of radiotherapy was 47 ± 2 days in the radiotherapy group and 52 ± 2 days in the bleomycin group [difference significant at $P = 0.01$ (2 sided test)]. This difference can be attributed to the more frequent delays in radiotherapy due to side effects experienced by the bleomycin group (Table 5). Treatment was not prematurely stopped in any of the patients in the radiotherapy alone group while treatment was stopped early in 5 patients in the bleomycin group due to severe mucositis and epidermitis within the field of irradiation. Such side effects were also responsible for postponement of radiotherapy courses in 5 patients receiving radiotherapy alone and in 25 patients receiving radiotherapy and bleomycin ($P < 0.001$). The nominal single dose (NSD) was calculated for patients selected from three different Institutions (Lille, Lyon and Villejuif). The average NSD varied considerably from one institution to another and was in most cases lower than the predetermined NSD for patients in the bleomycin group (Fig. 3). This figure also shows that Lyon systematically restricted the total amount of radiotherapy in the bleomycin group in order to obtain a uniform duration of treatment in both groups. In Lille, where the total dose of radiotherapy was considered as the main criteria of treatment, radiotherapy courses were delayed and extended over longer periods of time in the bleomycin group. In Villejuif, the NSD received was very close to the predetermined NSD in both treatment groups.

(b) *Bleomycin.* Bleomycin treatment began with the first course of radiotherapy in 97% of the patients, while, in 3%, the first dose of bleomycin was not given until after the first week of radiotherapy. Sixty-eight per cent of the patients received the prescribed dose of 150 mg while in 12% a maximum of 90 mg was administered due to local reactions (Fig. 4).

3. *Complications due to treatment* (*Table* 6)

The overall rate of secondary reactions was 23% in the group radiotherapy alone and 78% in the group radiotherapy and bleomycin ($P < 0.01$). This difference is due, in part, to the

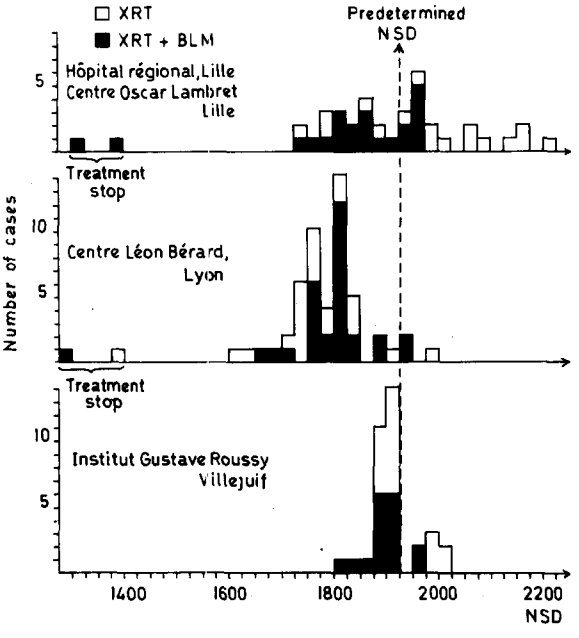

Fig. 3. *Distribution of NSD in three institutions.*

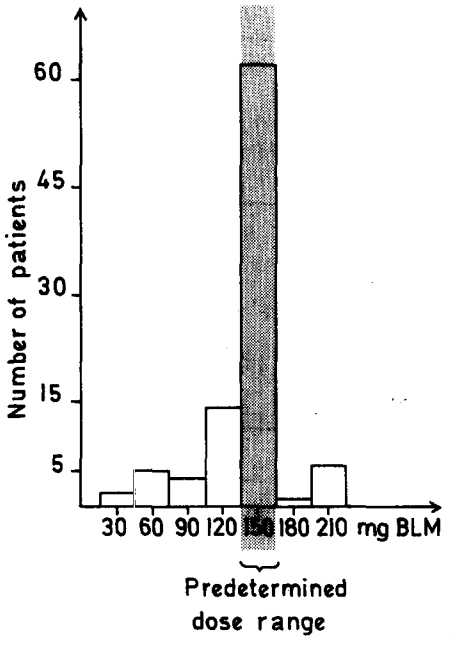

Fig. 4. *Distribution of total BLM dose.*

difference in the local toxic effects such as mucositis and mucositis with epidermitis experienced in the 2 groups. Twenty-one per cent of the patients in the radiotherapy alone group and 72% of the patients treated with bleomycin experienced mucositis and/or epidermitis ($P < 0.01$). The low incidence of local reactions in the radiotherapy alone group may be explained by the fact that these restrictions may have been minimized by the clinician and biased by the design of the forms.

Although slightly more common in the bleomycin group, there was no significant difference between the groups with respect to skin rash, pneumopathy, hemorrhage, severe dysphagia or fever. Weight loss (18% vs 6%) and profound weakness (19% vs 1%) are significantly more common in the group receiving bleomycin, where normal nutrition was impaired due to mucositis and in several patients necessitated feeding by a nasogastric tube.

4. *Tumor response*

The time of evaluation of the tumor response varied from less than 30 days to more than 3 months after completion of radiotherapy (Table 7). The average time of tumor evaluation was approximately 60 days: however, 13% were evaluated after 90 days. There is, however, no significant difference between the groups with respect to the time of evaluation. The response rate of the primary tumor is given in Table 8. A 100% response rate was observed in approximately 67% of the patients in both groups and there is no significant difference between the treatments with respect to the degree of response. There are also no significant differences between the response rates to the treatments when the tumor site, the tumor extent and the dose of bleomycin received were taken into consideration. There was likewise no significant difference between the treatments with respect to the response rate of clinically involved lymph nodes (Table 9).

Actuarial survival curves are given in Fig. 5 and indicate that there are currently no significant differences between treatment groups with respect to the duration of survival. The median duration of survival is approximately 15 months in each group.

DISCUSSION

This study, the first trial undertaken by the E.O.R.T.C. Head and Neck Cooperative Group shows the interest of people working together in a trial conducted on an international scale. Thirteen Institutions from 5 different countries entered 224 patients in less than 2 yr. Thirty-one patients (14%) have been definitively excluded from the trial due to protocol violations while 7 (3%) have been excluded from these results due to incomplete data.

The protocol was followed without deviation in 43% of the patients in the radiotherapy alone group and in 22% of the patients receiving bleomycin. The total dose and duration of radiotherapy as specified in the protocol was not generally attained in patients in either of the 2 treatment groups. Several Centers were reluctant to modify their own schedule of fraction-

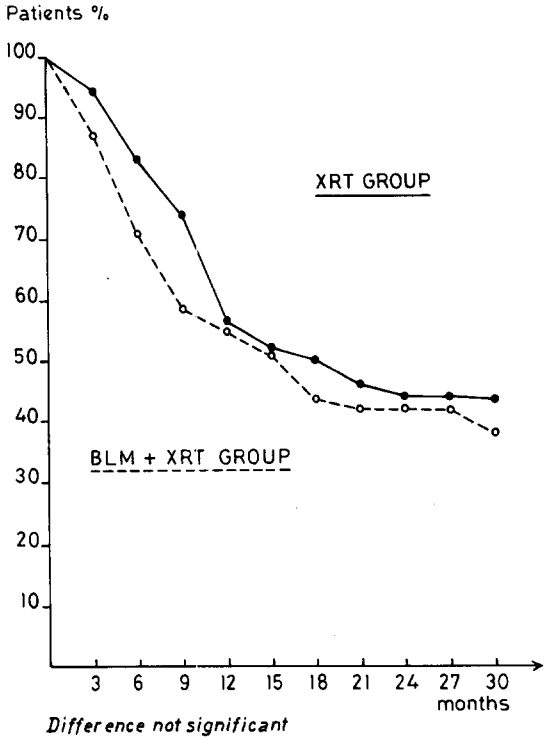

Fig. 5. Survival curves by the actuarial method.

ation while other centers delayed the continuation of radiotherapy in the presence of side effects in order to minimize local reactions. The variations from the protocol are, however, of the same frequency in the 2 treatment groups.

The concomitant use of bleomycin with radiotherapy as specified in the protocol was in fact not well tolerated and does not appear to be realizable. The incidence of both local and general complications was significantly higher in the bleomycin group, even for doses of less than 90 mg. In this group, radiotherapy was often delayed during the third week and had to be stopped prematurely in 5 patients. Modifications of radiotherapy received, occurred on a much lower scale in the radiotherapy alone group.

Analyzing the therapeutic results from a pragmatic point of view, that is considering the trial as it was actually carried out, bleomycin does not appear to enhance the efficacy of radiotherapy on advanced carcinomas of the oropharynx with respect to either the primary tumor or the invaded lymph nodes. With respect to the duration of survival there is no significant difference between the groups. However, initially it seems that patients with a poor prognosis die quicker in the group receiving bleomycin. This might be explained by the side effects of radiotherapy (dysphagia by mucositis) which are further aggravated through the concomitant administration of bleomycin. There is thus a higher initial risk of death in the bleomycin group brought about by the increase of major complications. It remains to be seen whether or not the long term survival of patients in the 2 groups will be the same now that 1 yr of follow-up has been completed on all patients.

Serological Characterization of a Putative Human C-Type Oncornavirus by Means of the Sepharose Bead Immunofluorescence Assay*

G. KOCH,† K. NOOTER,† P. BENTVELZEN† and J. J. HAAIJMAN‡

†*Radiobiological Institute TNO, 151 Lange Kleiweg, Rijswijk, The Netherlands and*
‡*Institute for Experimental Gerontology TNO, 151 Lange Kleiweg, Rijswijk, The Netherlands*

Abstract—*A putative human C-type oncornavirus isolate was found to be closely related to the simian sarcoma virus by means of the Sepharose bead immunofluorescence assay.*

Sepharose-beads coupled with antisera directed against purified major internal proteins of C-type oncornaviruses were incubated first with tissue culture supernatants and thereafter with antisera conjugated with fluorescein isothiocyanate. The fluorescence of individual beads was then measured microfluorometrically. This technique is a highly sensitive and reproducible assay for the detection of viral proteins.

The SKA21-3 culture of rabbit cornea cells, transformed by a murine sarcoma virus pseudotype with a presumably human derived C-type oncornavirus as helper proved to produce abundant amounts of proteins related to the p28 of simian sarcoma virus but not to the p30 of murine leukemia virus. When cells from a tumorous lymph node induced in a rat by the SKA21-3 virus were cocultivated with a canine thymus cell line, A7573, high concentrations of viral proteins were detected in the supernatant after a few passages. The same result was obtained when a leukemic lymph node from a rat inoculated with the presumed human virus, free of the murine sarcoma virus, was cocultivated with the human A204 line.

INTRODUCTION

C-TYPE oncornaviruses have been isolated from human leukemic bone marrow cells by cocultivation with animal cells in our laboratory [1, 2]. These isolates can serve as helper viruses for replication-defective murine sarcoma virus (MSV). They may therefore rescue the MSV genome from nonproducing transformed cells. The resulting MSV pseudotype is able to transform cells which are permissive to the human-derived helper virus. The focus forming activity of this new MSV pseudotype can be neutralized by a goat antiserum against the simian sarcoma virus, indicating that the human helper virus has envelope antigenic determinants in common with the simian sarcoma virus (SiSV) [2].

A clone of rabbit cornea (SIRC) cells transformed by such a derived MSV pseudotype, designated as SKA21-3, became a high producer of C-type oncornavirus (see Fig. 1 for the origin of this line). This made the further biological and serological characterization of the virus possible. The MSV-pseudotype produces angiomatous, fibrohistiocytic sarcomas in rats 2 months after inoculation. These lesions are typical for the Kirsten strain of MSV used in this investigation.

The defective MSV genome can be eliminated from the SKA21-3 virus by endpoint dilution. Human A204 cells infected with a high dilution of this virus produced C-type particles, which had no focus-forming activity in those cell lines which were readily transformed by SKA21-3 virus. Virus isolated from the A204 cell line (A204SKA) induces lymphosarcomas with leukemic involvement of the peripheral blood in rats in the absence of typical MSV lesions [3].

The present paper concerns further serological characterization and detection of this human-derived virus using a new immunological technique: the Sepharose bead immunofluorescence assay (SBIA) [4, 5].

Accepted 23 May 1977.

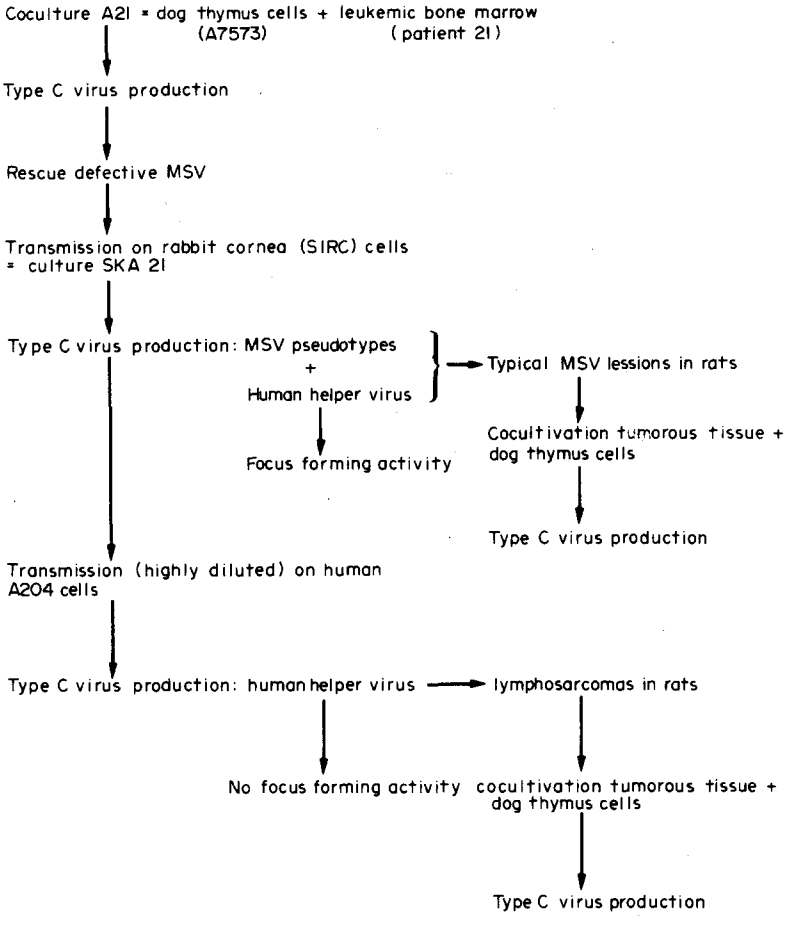

Fig. 1. Scheme of isolation procedure and subsequent passages of a human tissue-derived C-type oncornavirus.

MATERIAL AND METHODS

Cell cultures

The cell lines SKA21-3 and A204(SKA) were grown in plastic 75 cm^2 flasks (Costar 3075, Cambridge, Mass.) in Dulbecco's modified minimal essential medium supplemented with 10% fetal calf serum (Flow, Irvine, Scotland). Rat embryonic fibroblasts infected with SiSV were grown under the same conditions in a separate laboratory building of the Primate Center TNO, Rijswijk, The Netherlands. SiSV-infected NC37 cells were grown in suspension in Dulbecco's medium supplemented with 15% fetal calf serum. Manipulation of all of these cultures was done under strict biohazard conditions. Murine BALB/3T3 cells infected with Rauscher murine leukemia virus (RLV) were grown in the main tumor virological laboratory building. Uninfected SIRC, BALB/3T3, canine A7573, human A204 cells and WAG/Rij rat embryonic fibroblasts were cultured in a special tissue culture unit.

Cocultures of tumor cells with uninfected cell lines were prepared in a separate laminar flow cabinet. The cells were seeded in equal ratio (2×10^5/ml).

Viruses and antisera

Simian sarcoma virus and Rauscher murine leukemia virus, purified by density gradient ultracentrifugation and goat antisera directed against the major internal protein (p30) of each virus were kindly provided by Dr. J. Gruber of the Office of Program Resources and Logistics, Viral Oncology, National Cancer Institute, Bethesda, Maryland, U.S.A.

Focus formation in vitro

Supernatants of cultures were clarified by centrifugation for 15 min at 10,000 ***g*** and then filtered through a millipore filter (0.45 μm pore size). Cultures for focus formation, inoculated at 2×10^5 cells per 60 mm Petri dish 24 hr prior to infection, were treated with DEAE-dextran (25 μg/ml) for 30 min. The cultures were then incubated with two-fold dilutions of tissue culture fluids. Dilutions were made in fresh medium containing polybrene (2 μg/ml). Eight days after infection, foci of transformed cells

were counted unstained with the aid of an inverted microscope (75 ×).

Coupling of antisera to Sepharose beads

Before coupling, the antisera were subjected to chromatography on QAE-Sephadex A50 (Pharmacia, Uppsala, Sweden) in ethylenediamine–acetate (pH: 8.0; *I*: 0.1) [6]. The isolated IgG fractions were dialyzed against phosphate buffered saline (PBS). The IgG was then coupled covalently to Sepharose 4B beads (Pharmacia) by the cyanogen bromide method of March *et al.* [7], using 2–3 mg protein per 1 ml of activated beads. Residual active groups were deactivated by treatment of the beads for 6 hr with 0.5 M ethanolamine in 2% sodium hydrogen carbonate, pH 9.5. After coupling and deactivation, the beads were washed and stored in PBS with 0.01% merthiolate at 4°C.

Sepharose bead immunofluorescence assay of viral antigens

The method as developed for the quantitative assay of immunoglobulins [4, 5] has been adapted to the detection of viral antigens. Fifty microlitres of a 1% suspension of beads (1 ml bead pack to 100 ml of PBS) coupled with IgG were incubated for 1 hr with 50 μl of a cell-free sample, diluted in PBS containing 2% bovine hemoglobin in flat bottom microtitration plates under continuous agitation. After repeated washing, the beads were incubated with one or the other of the antisera conjugated with fluorescein isothiocyanate (FITC).

After repeated washing, the individual bead fluorescence was measured with a microfluorometer. At least 5 beads were measured per dilution. A calibration curve was prepared by incubation of the beads with different concentrations of purified SiSV or RLV, which were disrupted by incubation with 0.3% Nonidet for 1 hr. The amount of viral protein was determined by the method of Lowry [8]. Linear regression analysis was applied to fluorescence values falling in the concentration-dependent range.

Sepharose bead immunofluorescence assay of antiviral antibodies

Sepharose beads were covalently coupled with disrupted virus. They were then incubated with inactivated (45 min, 56°C) rat sera. After repeated washing, they were incubated with a goat antiserum to rat IgG conjugated with FITC (Nordic Immunological Laboratories. Tilburg, The Netherlands).

RESULTS

Figure 2 shows the fluorescence found with different dilutions of SKA21-3 tissue culture supernatant using an antiserum, directed against the p28 protein of SiSV, bound to Sepharose beads. Supernatants of uninfected SIRC and RLV-producing BALB/3T3 cells were used as controls. The protein concentration was adjusted to 10 mg/ml for each culture fluid. The antiserum directed against SiSV-p28 cross reacts with purified RLV only when the concentration of RLV protein is higher than 1700 μg per ml. The initial concentration of the SiSV preparation was 0.6 mg/ml. From Fig. 2, it can be roughly estimated that the SKA21-3 supernatant contained approximately 1 μg SiSV related proteins per ml, since a 25-fold dilution of the culture fluid corresponds with roughly a 15,000 dilution of the purified virus.

A more detailed calibration curve was prepared to measure the amount of SiSV related viral proteins quantitatively. This calibration curve, depicted in Fig. 3, has a sigmoid shape with a background plateau at 30 and a saturation plateau at 1200 ng per ml of SiSV.

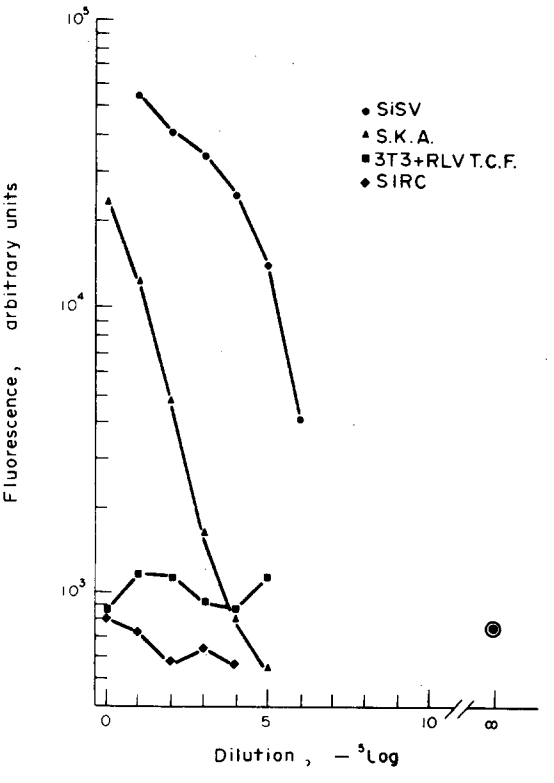

Fig. 2. Characterization of viral proteins in the culture fluid of SKA21-3. Sepharose beads coated with an immunoglobulin-G fraction of a goat serum directed against the p28 of simian sarcoma virus (Seph-GA SiSV/p28) were incubated with fivefold dilutions of samples of culture fluids of SKA21-3, SIRC and BALB/3T3 RLV and subsequently with GA SiSV p28 FITC. Each value represents the average fluorescence of at least five individual beads. The protein concentration of all undiluted samples was 10 mg/ml. *For comparison, a preparation of purified SiSV was used.*

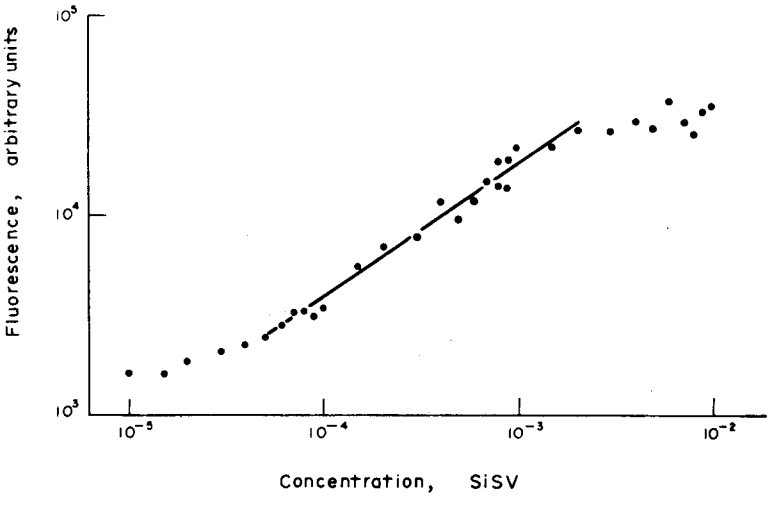

Fig. 3. Calibration curve for simian sarcoma viral antigens with Sepharose beads coupled with an immunoglobulin-G fraction of a goat serum directed against the p28 protein of simian sarcoma virus (Seph-GA SiSV/p28). The undiluted preparation contained 0.6 mg/ml *proteins. Seph-GA SiSV/p28 was incubated with different dilutions of the SiSV preparations and subsequently with GA SiSV/p28-FITC. Each value represents the average fluorescence of at least five individual beads. The equation for the solid line was calculated by the least squares method. The concentration of the undiluted sample was taken as* 1 *on the abscissa.*

The fluorescence is linearly dependent on the virus concentration between these two values. No reactivity of this antiserum was found with fetal calf serum, even at concentrations of 5 mg protein per ml.

The concentration of SiSV-related proteins in different experiments (Table 1) has been determined on the basis of the calibration curve. The A21 coculture of A7573 dog thymus cells and human leukemic bone marrow cells, which preceded the SKA21-3 line, was negative in the test. The amount of viral antigens in the supernatants of 2 different passages of the SKA21-3 culture was respectively 635 and 3320 ng per ml, while the concentration was considerably lower in supernatants of cultures infected with SiSV (73 and 151 ng/ml). The supernatant of the A204 line infected with SKA21-3, which did not produce focus-forming MSV, was also a high producer of a SiSV-related virus (767 ng/ml).

When lymph node cells of a rat with a SKA21-3 induced sarcoma was cocultivated with A7573 cells the culture became, after 3 weeks, a high producer of a C-type oncornavirus, as estimated by the reverse transcriptase assay. The Sepharose bead immunofluorescence assay indicated a concentration of 524 ng of SiSV-related proteins per ml culture fluid of this co-culture. The supernatant contained 80 focus forming units/ml when titrated on rat embryonic fibroblasts. The original SKA21-3 cultures produced 10^3 to 10^4 units/ml.

The coculture of A204 cells with lymph node cells of a rat in which leukemia had been induced by A204(SKA) virus also became a good virus

Table 1. Quantification of SiSV related antigens in tissue culture fluids

Tissue culture fluid	SiSV equivalents (ng/ml)
WAG/Rij rat embryonic fibroblasts infected with SiSV	151 ± 8*
NC37 suspension culture infected with SiSV	73 ± 6
SKA21-3 (a)	635 ± 84
SKA21-3 (b)	3332 ± 373
A204 (SKA)	767 ± 134
Sarcomatous lymph node + A7573	524 ± 94
Leukemic lymph node + A204	425 ± 86
RLV (1.7 mg/ml)	< 30
Fetal calf serum (24 mg/ml)	< 30

*av ± S.D. of quadriplo's.

producer after 4 passages. No focus-forming activity was detected in repeated assays on rat embryonic fibroblasts. The concentration of viral antigens determined with the antiserum to SiSV-p28 was 425 ng/ml. No reaction was observed with beads coupled with the antiserum directed against RLV (Fig. 4). SiSV related antigens were found also in the sera of three rats with leukemia induced by the MSV-free A204(SKA) virus. These sera contained no antibodies to either SiSV or RLV, whereas normal rats have a low titer of antibodies to SiSV and a considerably higher level of antibodies to RLV (Fig. 5).

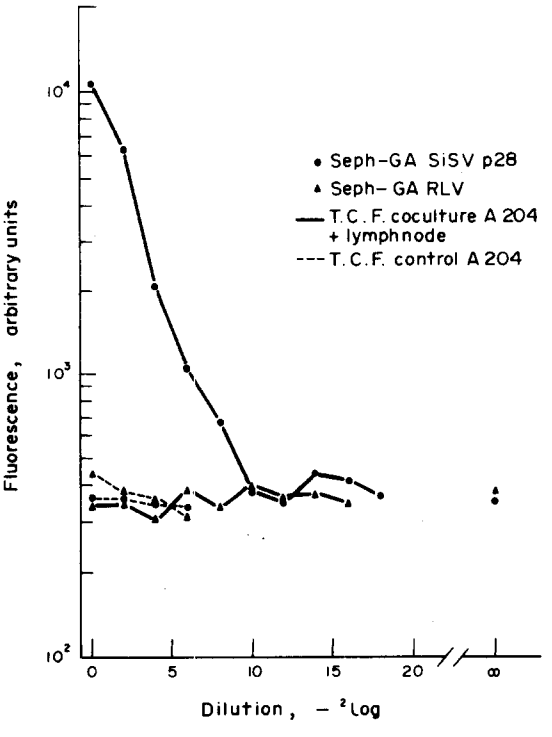

Fig. 4. Reactivity of culture fluid from cocultures of a leukemic lymph node and the human A204 line with beads coupled with an antiserum to Rauscher leukemia virus (Seph-GA RLV) or an antiserum directed against the p28 protein of simian sarcoma virus (Seph-GA SiSV/p28).

DISCUSSION

The Sepharose bead immunofluorescence assay (SBIA), developed for the measurement of immunoglobulins, can be successfully applied to the detection of oncornaviral proteins. As is the case with immunoglobulins [4, 5], the method proves to be reliable and accurate. The lowest concentration of viral antigens which can be detected with this method is 1.5 ng per sample of 50 μl. Such a sensitivity is comparable to that of the radioimmunoassay (RIA) which is widely used in tumor virology. The advantage of this new technique in comparison with RIA is the avoidance of false positives due to destruction of labeled antigens by proteolytic enzymes. Another advantage of the SBIA is that reagents can be stored indefinitely, while, in the RIA, the antigen must be iodinated, roughly, bimonthly.

The test, using antisera to purified viral polypeptides, proved to be specific, in that no

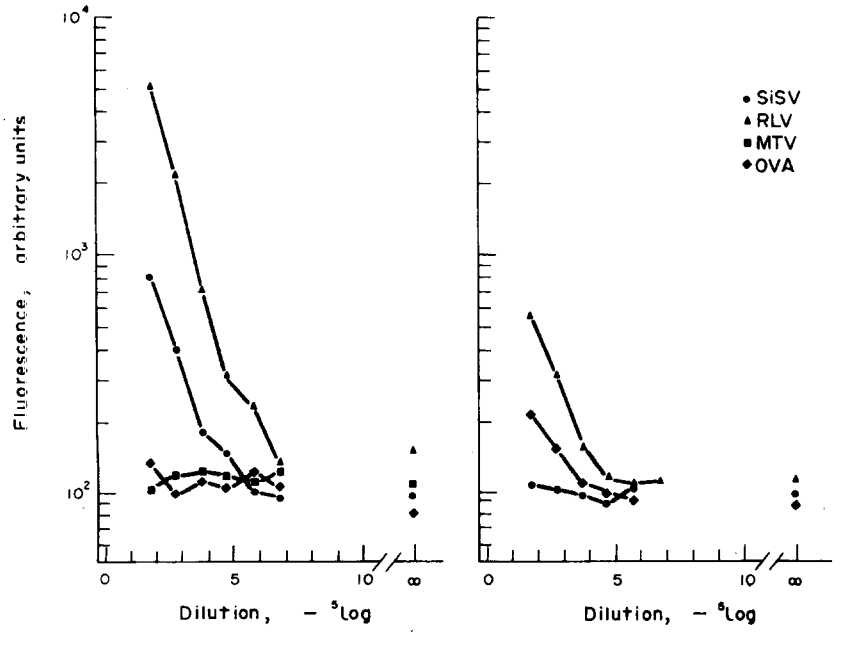

Fig. 5. Detection of antibody reactivity against SiSV and RLV in the serum of leukemic or normal rats using Sepharose beads coated with either virus.

reactions were found with culture fluids from uninfected cell lines or with (large amounts of) fetal calf serum. Only a very weak reaction of the antiserum to SiSV-p28 was found with high concentrations of Rauscher murine leukemia virus.

The high concentration of proteins antigenically related to SiSV-p28 in the SKA21-3 culture fluid indicates that the virus retrieved from human leukemic bone marrow cells is related to the simian sarcoma virus not only with regard to envelope antigens but also to the major internal polypeptide. Indirect immunofluorescence studies on acetone-fixed cells using a polyvalent antiserum to SiSV had already given an indication that more than the envelope proteins of the SKA21-3 virus would be antigenically related to SiSV [2].

The A21 coculture, which preceeded the SKA21-3 line, was negative with the SB1A. The reverse transcriptase values were low, while cytoplasmic immunofluorescence was clearly positive for SiSV. Probably there was considerable synthesis of internal viral proteins, but little release of complete virions. The recovery of an SiSV-related virus from a tumorous lymph node of a rat injected with SKA21-3 indicates that the human helper virus can establish itself in rats.

The A204(SKA) virus, which according to the focus-forming test would not contain MSV, induces lymphosarcomas in rats. The virus, retrieved from leukemic rats of a tumorous lymph node by cocultivation with A204 cells, is also related to SiSV and, in addition, does not contain MSV, as no focus-forming activity was found *in vitro*. The lymphosarcoma does not seem to be induced by MSV. Since no virus related to RLV has been detected in the tumor, it is unlikely that the disease was induced by mere activation of an endogenous rat virus. So far, we have failed to detect close antigenic relationship between SiSV and endogenous rat viruses released either spontaneously or after induction with halogenated pyrimidines. These rat viruses show considerable antigenic cross-reactivity with RLV. It seems therefore that the human-derived helper virus is itself leukemogenic in rats. It is an attractive hypothesis that a SiSV-related virus is also leukemogenic in man [9, 10].

A remarkable finding was the absence of antibodies in the leukemic rats, while normal WAG/rats have a low but significant titer of antibodies reacting with SiSV. Normal rat sera have a much higher specific reactivity with RLV than with SiSV and it is assumed that the natural antibodies are directed against an endogenous rat virus which is more closely related to RLV than SiSV (G. Koch, manuscript in preparation). It is to be expected, however, that infection with SiSV would enhance the reaction against determinants which the endogenous rat virus would have in common with SiSV. The absence of a reactivity with both RLV and SiSV could be due to either immune complexes or to immunosuppression. The latter can be explained by replacement of normal lymphoid elements by leukemic cells. However, several leukemia viruses have an immunosuppressive effect long before the onset of the neoplastic disease (for review, see [11, 12]).

In man, antibodies to SiSV seem to be widespread [13, 14]. However, the titer of such antibodies is low or they are virtually absent in leukemic patients [13]. The lymphosarcoma induced in rats by a human-derived SiSV-related virus might therefore be a relevant model for the human disease.

Abstract—*Plasma levels of IgA, IgG and IgM have been measured in 35 British and 37 Japanese normal adult women, in 22 British and 22 Japanese adolescent girls and in 30 Japanese women with breast cancer.*

Japanese women had significantly higher blood concentrations of IgG and IgM than British women. The amounts of plasma immunoglobulins in adolescent British and Japanese girls were similar to those in adults of the same race, except for IgG, where Japanese adolescent girls had significantly lower levels than in adult Japanese women.

In contrast to previous results showing no difference between the IgA, IgG and IgM levels of normal British women and patients with breast cancer, the IgM concentration was significantly lower in the Japanese patients compared with that in Japanese controls.

INTRODUCTION

WE HAVE been investigating various factors that might be related to geographical variation in the incidence of breast cancer. So far we have been unable to find any convincing difference in the endocrine function of normal British and Japanese women that could account for the marked difference in incidence [1–3], but 57% of Japanese patients with breast cancer have been shown to have a moderate or marked degree of sinus histiocytosis in their lymph nodes compared to only 4% in British patients [4]. Also the degree of lymphocyte infiltration is greater in tumours from Japanese patients than in those from Caucasian women [5].

These findings indicate a racial difference in cell-mediated response to breast cancer and prompted the investigation of humoral immune status by determining the concentration of plasma IgA, IgG and IgM in normal British and Japanese women and in Japanese patients with breast cancer.

Accepted 26 May 1977.

MATERIAL AND METHODS

Subjects

The general organization of the study and details of height, weight and menstrual history of the normal women have been reported [1].

The number, mean age and age range of the various groups studied are given in Table 1. The 30 Japanese and 22 British women with breast cancer had either Stage 1 or 2 disease. Blood was taken from these women 3–6 months after mastectomy.

Methods

The immunoglobulins IgA, IgG and IgM were measured by rocket immunoelectrophoresis [6].

Standards for IgA, IgG and IgM were commercially obtained from Millipore (UK) Ltd. In a previous publication [7] it has been demonstrated that the strength of these standards using WHO figures (1 i.u. is equivalent to 14.2 μg IgA, 80.4 μg IgG and 8.47 μg IgM) was remarkably similar to the potency obtained when they were compared to the MRC reference

Table 1. Number and age of women studied

Category	No.	Mean age	Age range
British adolescents	22	17.3	16–
Japanese adolescents	22	18.7	16–19
British adults	35	52.7	35–68
Japanese adults	37	49.6	35–66
British patients with breast cancer	22	56.6	44–68
Japanese patients with breast cancer	30	50.9	37–64

preparation (67/99) of IgA, IgG and IgM [7]. Thus all results have been expressed as i.u./ml as advocated by WHO.

Included in each batch of 8 samples analysed was a quality control plasma. If the results for the quality control were greater than 15% from the mean value of IgA, IgG or IgM, the batch of samples was assayed again.

Precision of the assay as calculated by comparing duplicate estimations showed that the coefficient of variations, in the range studied, was 12.6, 6.4 and 5.3% for IgA, IgG and IgM respectively [7].

RESULTS

1. *Normal British and Japanese women*

IgA. There was no statistical difference between the geometric mean level of plasma IgA in normal British and Japanese women nor did the level found in the adolescent girls differ from those found in the adults (see Table 2; Fig. 1).

IgG. The geometric mean plasma level of IgG was significantly higher in Japanese women than in British women ($t=3.4$; $P<0.01$; d.f. $=70$). The IgG levels in adolescent British girls were similar to those found in adults but in Japanese adolescents the levels were significantly lower than those in older women ($t=2.20$; $P<0.05$; d.f. $=57$). Even so, the average concentration in Japanese adolescents was significantly higher than in comparable British girls ($t=4.05$; $P<0.001$; d.f. $=42$).

IgM. The geometric mean level of IgM was significantly higher in Japanese adult women compared with that found in the British group ($t=5.2$; $P<0.001$; d.f. $=68$). The IgM levels in adolescent girls of each race resembled those found in the adults; that is to say, the IgM levels were higher in the Japanese adolescents than in the British.

2. *Patients with breast cancer*

The geometric mean levels of IgA and IgG in Japanese patients with breast cancer are comparable to those in normal Japanese women but the IgM levels in the patients were significantly sub-normal ($t=2.9$; $P<0.01$; d.f. $=61$). The IgM level in the Japanese women with breast cancer (131 i.u./ml) is similar to that found both in British patients (151 i.u./ml) and in normal British women (124 i.u./ml) [7]. The results are shown in Fig. 2.

In British women, the mean levels of IgA, IgG

Table 2. Immunoglobulin levels in British and Japanese women

	IgA	IgG	IgM
British adolescent	2.06 ± 0.19 (22)	2.09 ± 0.10 (22)	2.17 ± 0.18 (16)
Japanese adolescent	2.12 ± 0.17 (21)	2.20 ± 0.08 (22)	2.23 ± 0.22 (19)
British adult	2.10 ± 0.21 (33)	2.13 ± 0.11 (35)	2.09 ± 0.23 (35)
Japanese adult	2.16 ± 0.15 (36)	2.26 ± 0.11 (37)	2.26 ± 0.17 (35)
British breast cancer	2.04 ± 0.22 (21)	2.07 ± 0.25 (21)	2.18 ± 0.22 (19)
Japanese breast cancer	2.15 ± 0.16 (30)	2.23 ± 0.10 (30)	2.12 ± 0.22 (28)

All results expressed as mean $\log_{10}$ i.u./ml $\pm$ S.D.
The numbers in parentheses refer to the number of subjects studied.

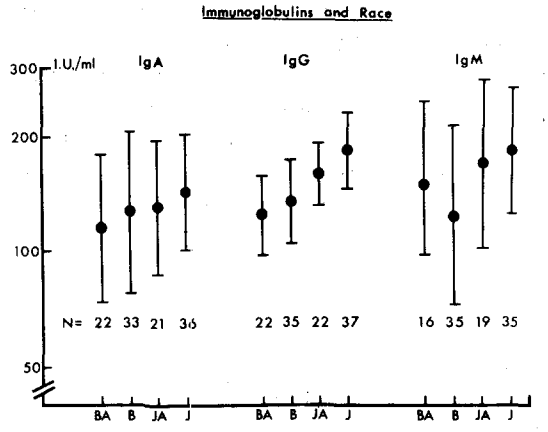

Fig. 1. Plasma immunoglobulin levels and race. BA and JA represent British and Japanese adolescents, respectively. B and J represent British and Japanese adults. N is the number of subjects in each group and the results are expressed as mean ± standard deviation.

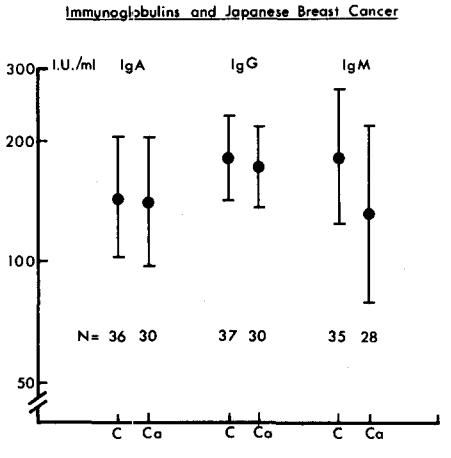

Fig. 2. Plasma immunoglobulin levels in normal Japanese women and patients with breast cancer. C and Ca represent Japanese normal control and breast cancer patients, respectively. N is the number of subjects in each group and the results are expressed as mean ± standard deviation.

and IgM do not differ significantly when normal women and patients with breast cancer are compared [7].

DISCUSSION

The amounts of IgA in the plasma were similar in both Japanese and British women, with and without breast cancer. In contrast IgM and IgG are significantly higher in normal Japanese women than in British women, in all age ranges studied. Although studies in twins indicate that levels of IgM and IgG are partially genetically determined [8, 9] the main factors affecting the concentration of these compounds in blood are environmental [10].

We have already reported that IgG levels are normal in British women with breast cancer [7] and this is similar to the finding of a normal IgG concentration in Japanese patients with breast cancer. Conversely, the similarity in IgM levels found by many workers [7, 11–15] in Caucasian women with and without breast cancer is not seen when normal Japanese women are compared to their compatriots with breast cancer; the latter have significantly subnormal levels of IgM.

It would be an attractive hypothesis that this abnormality is IgM levels in Japanese patients with breast cancer is associated with the aetiology of the disease. The fact that Caucasian women with breast cancer have been found to have normal levels of IgM one day before, 10–14 days or 3–6 months after mastectomy makes it unlikely that the abnormal levels in Japanese patients are a consequence of either the disease or its treatment [7].

There is evidence that abnormalities of humoral immunity are associated with increased incidence of neoplasms but these tend to occur mainly in lymphoid tissue [16]. However, common variable primary immunodeficiency (also referred to as acquired agammaglobulinaemia) is a disorder in which most individuals have abnormalities of both B and T cells. Of these patients who develop cancers, 39% are of epithelial tissue including breast [16]. Although there is no evidence linking IgM with the aetiology of any human cancer there is a body of evidence which connects IgM with tumorigenesis in the nude mouse.

Jensen and Wellings [17] have remarked on the lack of carcinomatous transformation of transplanted atypical lobules (type A) in nude mice and Schmidt and Good [18] have commented that human tumours with a high propensity to metastasize generally fail to do so in these animals. These authors have suggested that the residual immune system in this animal is responsible and it is significant that this appears to be mainly humorally mediated by normal levels of IgM since levels of IgA and IgG are only some 15% of those found in normal mice [19, 20]. T cell function appears to be minimal in nude mice since thymus rudiments transplanted into normal mice fail to support thymocyte proliferation [21].

It is also of interest that IgM synthesis is less dependent on thymus tissue than IgG and IgA production and this may account for the single abnormality found in Japanese patients with breast cancer [22, 23]. Thus the results could be interpreted to mean that Japanese women with breast cancer have a normally functioning

thymus producing a normal T cell population, IgA and IgG levels, but that the independent production of IgM is impaired.

In a comparative study concerned with the endocrine status of Japanese and British women the main finding was a lower plasma cortisol (unpublished observations), dehydroepiandrosterone sulphate and androstenedione [3]. However, the inter-racial differences in immunoglobulins do not seem to be related in any obvious way with these endocrine differences since the concentration of none of these hormones is significantly correlated, in either race, with the levels of any of the immunoglobulins.

Abstract—*Dimethyl myleran (DMM), an antitumor drug effective against several rodent and human tumors, has severe hematopoietic toxicity, but only moderate immunosuppressive activity in dogs. In the present study,* 18 *dogs with spontaneous lymphoma were treated with* 7.5–10 mg/kg *DMM followed by infusion of previously aspirated autologous marrow to protect against otherwise lethal hematopoietic toxicity. Eleven dogs died in less than* 14 days, *several of unexpectedly severe gastrointestinal toxicity. Seven dogs survived* 15–95 (*median* 38) days. *Only* 1 *dog achieved a transient complete clinical remission;* 12 *additional dogs showed a greater than* 50% *decrease in palpable adenopathy. All but* 1 *dog had histologic evidence of lymphoma at autopsy.*

Immune responses were studied in 6 *dogs surviving greater than* 30 days. *Antibody formation to sheep red blood cells was delayed, but ultimately titers were similar to those of normal dogs. Production of lymphocytotoxic antibody was slightly enhanced while production of antibody to bacteriophage was slightly impaired. Although high dose DMM alone does not appear to be effective in achieving complete remission in dogs with lymphoma, the relative lack of immunosuppression following DMM preserves the potential usefulness of this drug in the design of chemo-immunotherapy protocols.*

INTRODUCTION

MUCH attention has been devoted in both animal and human studies to the efficacy of active immunotherapy in the treatment of neoplastic disease [1, 2]. In general, an attempt is made to stimulate the immune reactivity of the tumor bearing individual by administration of either specific or non-specific agents. Frequently, however, such attempts may be impaired by concurrent administration of cytotoxic chemo- or radiotherapy. Such therapy is utilized in order to decrease the tumor burden, but unfortunately is usually also immunosuppressive. Design of active chemo- or radioimmunotherapy protocols would be facilitated by the availability of effective antitumor agents which were not immunosuppressive.

Dimethyl myleran (DMM), a more soluble and potent homologue of busulfan (Myleran®), is an agent with little immunosuppressive activity in rodents [3, 4] or dogs [5] but significant antitumor activity against Moloney lymphoma in mice [6] and granulocytic leukemia [7] and anaplastic carcinoma of the postnasal space in man [8]. However, the marked myelosuppressive activity of DMM has limited its clinical usefulness. In the current study, we treated dogs with naturally occurring lymphoma with a high single dose of DMM. Since spontaneous bone marrow recovery was not seen in healthy normal dogs after similar doses of DMM [5], we attempted to prevent death from marrow aplasia by infusion of previously aspirated autologous marrow. Tumor response and immune reactivity were assessed following DMM and marrow infusion.

MATERIAL AND METHODS

Procedures for procurement of dogs, initial evaluation, aspiration of marrow for autologous grafts, administration of DMM, post-grafting care and immune evaluation have all been previously published in detail [5, 9, 10] and will be only briefly summarized. Dogs of various breeds with generalized adenopathy were referred by veterinarians with consent of their owners. Eleven dogs were male, 7 were female; average age was 6.7 yr. Diagnosis of lymphoma was confirmed by histological examination of a peripheral lymph node biopsy. Marrow involvement with tumor was assessed from a single marrow aspirate by examination of smears and sections of Zenker's fixed, centrifuged particle preparations. Tumor measurements—perpendicular diameters of submandibular, prescapular, popliteal and inguinal nodes—were recorded before and after therapy. Eleven dogs had received no known prior chemotherapy; 2 had been treated with 9 and 16 day courses of L-asparaginase, 250–300 units/kg and 6-mercaptopurine, 1 mg/kg; and 5 had received combination chemotherapy consisting of cyclophosphamide, 5 mg/kg and vincristine, 0.025 mg/kg, on days 1 and 8 and L-asparaginase, 250 mg/kg and prednisolone, 2 mg/kg, on days 1–14.

Before DMM administration, marrow was aspirated under general anesthesia from both humeri and femora as previously described [11]. A mean of 1.2 ± 0.9 (S.D.) $\times 10^8$ nucleated marrow cells/kg (after correction for peripheral blood "contamination") was obtained, kept at 4°C until 6 hr after DMM administration and then infused intravenously. In one dog, cryopreserved autologous marrow was utilized [11]. DMM, 7.5 mg/kg in 16 dogs and 10 mg/kg in 2 dogs, was dissolved in warm absolute ethanol and given slowly intravenously as a bolus immediately after marrow aspiration [5].

Parenteral fluids, antibiotics and transfusion support were administered as clinically indicated following DMM and marrow infusion. Humoral immune responses to sheep red blood cells (SRBC) given on day 0 (i.e., the day of DMM and marrow infusion), to bacteriophage ØX174 (phage) given on day 14 and to allogeneic leukocytes in blood transfusions given on days 5–49 as clinically indicated for platelet support were measured as previously described [5, 10]. Dogs were immunized with Bacille Calmette–Guerin (BCG) on day 21 and tested for cutaneous reactivity to second strength purified protein derivative (PPD) on day 42.

Statistical comparisons were made using a two-sided Mann–Whitney U test.

RESULTS

Survival

The median survival of lymphoma dogs following 7.5–10 mg DMM and autologous marrow infusion was 10 (range 2–95) days. Eleven dogs died in less than 14 days, generally of gram negative septicemia or pneumonia while severely leukopenic. Unexpectedly severe gastrointestinal toxicity contributed to the death of 5 dogs during the first 14 days. Seven dogs survived 15, 32, 33, 38, 40, 50 and 95 days. The nadirs of peripheral granulocyte counts occurred on days 4–9 (median 8) with counts ranging from 0 to 275 (median 23) granulocytes/mm^3. The nadirs of platelet counts occurred on days 8 and 12 in 2 dogs with subsequent increases in platelet counts; in 4 dogs platelet counts never increased to sustained values of greater than 10,000/mm^3 (1 dog dying on day 15 is not evaluable with regard to platelet recovery). Among the dogs living greater than 30 days, 1 died of late gastrointestinal toxicity (onset day 8) and 3 died with septicemia (2 beta-hemolytic streptococci, 1 clostridia sp.) in spite of adequate peripheral granulocyte counts.

Dogs living more than 14 days were compared to those living less than 14 days with regard to prior exposure to chemotherapy, overall clinical status, number of marrow cells/kg infused and presence or absence of malignant cells in pregrafting marrow aspirates or peripheral blood smears. No difference between the groups with regard to any of these characteristics could be detected.

Tumor response

The maximal therapeutic effect upon clinically palpable tumor following DMM is indicated in Table 1. In order to quantify tumor response, the average maximal decrease in the product of perpendicular node diameters was estimated. Complete remission indicated inability to palpate any peripheral nodes. Dogs with greater than 75% decrease in tumor had minimal residual palpable adenopathy; dogs with 50–75% decrease had large reductions in tumor mass but significant persistent adenopathy; and dogs with less than 50% decrease had only minimal antitumor effect. As is evident in Table 1, most dogs had substantial, but not complete decrease in palpable tumor after receiving DMM. There is a tendency towards improved survival in dogs with greater decrease in palpable tumor, but the small number of dogs does not permit a firm conclusion. Dogs surviving more than 30 days achieved maximal decrease in adenopathy 14 days following

Table 1. Clinical response among dogs with lymphoma following dimethyl myleran and autologous marrow grafts

†Died on day 2.

DMM; increasing adenopathy was evident in all by day 28.

At autopsy all dogs grossly appeared to have residual (or recurrent) tumor. It was often difficult to distinguish histologically between lymphoma and regeneration of normal lymphoid cells following chemotherapy. Monomorphous clusters of cells similar to those present in pretransplant biopsies were considered malignant. Seventeen dogs had histological evidence of lymphoma: tumor was present in 61 of 84 lymph nodes examined and in the liver in 10 dogs, in the spleen in 14 dogs, in the marrow in 6 dogs and in miscellaneous sites in 9 dogs. No definite histological evidence of tumor was found in a single dog that died 5 days following DMM with greater than 75% clinical decrease in tumor.

Immune reactivity

Results of studies in 6 dogs to assess humoral immune reactivity following DMM and autologous marrow grafting are presented in Table 2. Comparable data obtained in previous studies in lymphoma dogs and in normal dogs under various conditions are also presented in Table 2. Hemagglutinin titers to SRBC injected on day 0 are delayed in development, but by day 20 reach the level seen in normal dogs by day 8. The primary antibody response to phage was normal in 2 of 6 evaluable dogs and the geometric mean of the maximal antibody level was slightly higher than in lymphoma dogs before therapy or after total body irradiation (TBI) and autologous grafting. Nevertheless, the mean phage antibody titer was less than that observed in normal dogs. Two dogs each received 3 allo-

geneic blood transfusions on days 7–13; 4 other dogs received 12–18 transfusions on days 5–49. One of the dogs receiving only 3 transfusions failed to make lymphocytotoxic antibodies while the other 5 dogs had detectable antibodies that appeared during the period of transfusion support.

Only 2 dogs lived long enough to be challenged with PPD following immunization with BCG. Both dogs had progressive adenopathy when tested on day 42 and failed to respond to PPD. No other tests of cellular immune reactivity were performed.

DISCUSSION

DMM appears to be more poorly tolerated by dogs with lymphoma than by normal dogs. Normal dogs receiving DMM, 3.0 or 5.0 mg/kg, experienced relatively prolonged granulocytopenia and thrombocytopenia, but ultimately recovered [5]. Higher doses (7.5 mg/kg) resulted in marrow aplasia and death but this could be averted by infusion of autologous marrow in 15 of 18 normal dogs given 7.5–10 mg DMM/kg. Following 15 mg/kg, however, 3 of 4 normal dogs succumbed secondary to severe enteritis in spite of autologous marrow infusion. In contrast, following 7.5–10 mg DMM and infusion of autologous marrow, only 7 of 18 dogs with lymphoma survived more than 14 days. Severe gastrointestinal toxicity was observed in 5 lymphoma dogs after 7.5 mg DMM/kg, i.e. at one-half of the dose required to produce comparable toxicity in normal dogs. Potential explanations for the increased toxicity observed include the age of the lymphoma dogs (mean 6.7 yr); their larger size (mean weight = 24.7 kg) and diverse breeds compared to the normal dogs studied (generally 6–14 month old, approximately 10 kg beagles); the effects of their underlying disease, previous chemotherapy and/or surgery and the lower number of marrow cells infused ($1.2 \pm 0.9 \times 10^8$/kg vs 4.5 $\pm 3.7 \times 10^8$/kg in normal dogs) [5]. Similar observations, i.e. increased toxicity in lymphoma dogs compared to normal dogs, have been previously reported following TBI and autologous [9] or allogeneic [12, 13] marrow grafting. Loss of a sizeable proportion of dogs in the first 2 weeks after drug administration and marrow infusion, however, still permits observations about the antitumor effect of DMM and studies of immune reactivity in dogs surviving more than 2 weeks.

In rodent studies, single high doses of DMM followed by normal syngeneic hematopoietic cells resulted in long-term, tumor-free survival in 51% of CBA mice bearing widespread Moloney lymphoma [6]. However, half the lethal dose was ineffective and neither lethal nor sublethal doses of DMM had significant antitumor effect against either Friend or Rauscher virus induced leukemias in C57Bl/6 mice [4]. DMM does have antitumor activity against canine lymphoma when utilized in maximally tolerated single doses followed by autologous marrow infusion (Table 1). Thirteen of 17 evaluable dogs had greater than 50% decrease in clinically palpable adenopathy. Complete remission, however, was achieved in only 1 dog and responses were transient. For comparison, TBI, in maximally tolerated single exposures, appears to be a more effective antitumor agent in this system. TBI resulted in greater than 75% decrease in palpable adenopathy in 12 of 17 evaluable dogs and complete remissions in 5 of these 12 [9]. Even though responses to TBI were also transient, median survival of dogs living more than 14 days was somewhat longer than following DMM (70 days vs 38 days, $P \sim 0.10$).

The results of the current study again emphasize the difficulty of correlating clinical and pathologic evaluation of tumor response to therapy [9]. One dog died with clinically palpable peripheral lymph nodes consistent with residual tumor, but histologically had lymphoid depletion, dilated sinusoids filled with granular debris and no definite evidence of tumor. Thus the tumor responses to DMM reported in Table 1 may underestimate the antitumor activity of the drug.

Our previous studies in normal dogs indicated that at doses of 3–10 mg/kg, DMM is only weakly immunosuppressive [5]. Antibody responses to SRBC and allogeneic histocompatibility antigens were normal while antibody responses to phage were mildly suppressed by 7.5–10 mg/kg. Cellular immune reactivity was not sufficiently suppressed by DMM to permit engraftment of incompatible allogeneic marrow in either mice [4] or dogs [5]. As indicated in Table 2, lymphoma dogs had little suppression of humoral immune reactivity by DMM. Responses were equal or greater than those in lymphoma dogs without therapy and appear to be superior to responses of lymphoma dogs following 1200 R TBI and autologous marrow grafting [9]. Unfortunately, too few tests are available to assess cellular immune reactivity.

The current study indicates that DMM has some, but limited, antitumor activity against spontaneous canine lymphoma. Although DMM should therefore not be the primary modality to minimize tumor burden prior to initiating active immunotherapy regimens, its

impressive lack of immunosuppressive activity may make DMM a useful agent in the design of such regimens. More frequent administration of lower doses might also result in less toxicity and obviate the need for autologous marrow aspiration and infusion.

†Lehrstuhl für Allgemeine Pathologie und Neuropathologie am Institut für Tierpathologie der Ludwig-Maxmilians-Universität, München, Federal Republic of Germany

Abstract—*Hybrid cells derived from mouse neuroblastoma line N18TG2 and rat glioma line C6-BU-1 are capable of generating tumors in athymic nude mice at 100% incidence. This fact provides a simple method for producing large quantities of cells needed for the biochemical characterization of some neuronal markers of the hybrid cells. Choline acetyltransferase specific activity, cloning efficiency, morphological differentiation and electrophysiological characteristics were similar for inoculated and tumor cells.*

INTRODUCTION

HYBRID cells obtained by fusion of mouse neuroblastoma line N18TG2 with rat glioma line C6-BU-1 display several neuronal functions including receptors for neurohormones and opiates [1–3]. These cells offer the possibility for further biochemical studies provided sufficient amounts of cells are available. One appropriate method of mass production of tumorigenic cells is the formation of tumors from cells injected into congenic animals. However, hybrid cells usually express the surface antigens of both parental cell lines [4]. Accordingly, the interspecific neuroblastoma × glioma hybrid cells were not expected to grow at high incidence in either rats or mice. Here we like to report the production and partial characterization of a tumor arising from interspecific neuroblastoma × glioma hybrid cells injected into athymic nude mice.

MATERIAL AND METHODS

Animals

The breeding and maintenance of athymic nude mice with the BALB/c genetic background has been described [5]. All animals were obtained from the animals house of the Max-Planck-Institut.

Cells

C6-BU-1 is a bromodeoxyuridine resistant rat glioma cell line [6]. N18TG2 is a 6-thioguanine resistant neuroblastoma cell line [7] derived from mouse neuroblastoma C1300. The formation of the hybrid cells 108CC5 and their culture in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% foetal calf serum (FCS), hypoxanthine (H) (0.1 mM), aminopterin (A) (10 μM) and thymidine (T) (16 μM) have been described [1–3]. Three days prior to the injection of the hybrid cells they were incubated in DMEM containing 10% FCS, (H) and (T) but not (A).

Production of tumors

After trypsinization, 1 million viable hybrid cells 108CC5 (P21) suspended in 0.2 ml DMEM were injected subcutaneously or intracerebrally into 3–4 weeks old nude mice. The passage number P designates the number of subcultivations.

Reintroduction of hybrid cells into culture and cloning

After mincing, a tumor grown intracerebrally, was dissociated into single cells by incubation with trypsin (0.05%) at 37°C for 5–20 min. After plating, the cells were cultured for 13 days in DMEM + 10% FCS and then seeded at low density. Three weeks later 10 colony clones from 10 different plates (designated 108CC5-T-1 PO

Accepted 7 June 1977.

*Five days after plating of 1×10^6 cells on plastic dishes (85 mm dia), cell homogenates were prepared and specific CAT activity was determined.

†Tumor homogenates were prepared by trituration of 15 days old tumors with a Pasteur pipette followed by sonication as done with the cell culture samples.

‡§Values are averages from duplicate‡ and triplicate§ samples (plates or tumors).

to 108CC5-T-10 PO) were picked with the aid of stainless steel cylinders.

Characterization of cellular markers

Chromosomes were analysed as described [6]. Harvesting of cells, cell homogenisation and assays for choline acetyltransferase (CAT) (E.C.2.3.1.6.) activity were carried out as described [8]. Intracellular recording of action potentials from single cells in a superfusion chamber was done with standard techniques [9].

RESULTS

A 100% tumor incidence was found for the hybrid cells injected into nude mice (Table 1), whereas no tumor was produced in Wistar rats and strain A mice. The tumors in nude mice showed high specific activity of CAT (Table 2). Results obtained from an electronmicroscopic investigation of the tumors will be published elsewhere [10]. Also the parental neuroblastoma and glioma cells caused tumors in all nude mice inoculated.

After formation of intracerebral tumors, hybrid cells were reintroduced into culture (cells 108CC5-T) and their properties were compared with those of the original cells (108CC5). CAT specific activity (Table 2), cloning efficiency (10%, if 2 cells per cm^2 are seeded) and growth rate (data not shown) were seen to be in the range found with the original hybrid cells. Both rat and mouse marker chromosomes were present in the 108CC5-T cells, but the exact number of chromosomes was not determined.

One prominent neuronal quality of the hybrid cells, the ability to fire action potentials, was investigated in the tumor clones. For this purpose the cells were differentiated morphologically by treatment with N^6, $O^{2'}$-dibutyryl adenosine 3′ : 5′-cyclic monophosphate, as described earlier [11]. Upon electrical stimulation these cells generated action potentials (16 out of 20 cells measured). Upon elevation of the Ca^{2+} con-

centration in the medium, repetitive firing was observed and the action potentials could no longer be blocked by tetrodotoxin. Thus, the characteristics of the electrical activity were similar to those found in the original hybrid cells [9].

DISCUSSION

The results show that interspecific hybrid cells produce tumors in nude mice at a 100% take incidence. The cellular markers studied in culture before and after animal passages served as indicators for the retention of neuronal functions in the hybrid cell tumor. Growth characteristics, electrophysiological behavior, morphological differentiation and CAT specific activity of the hybrid cells isolated from the tumors were similar to those of the cells used for the injection into the mice. Except for subclone 108CC5-T6, the specific activity of CAT in the hybrid subclones (isolated from a tumor) was in the range of the original hybrid cells whose activity was measured at low (P13) and high (P70) passage numbers (Table 2). The observed variability of the specific activity of CAT in the hybrid subclones might be explained by the appearance of probably many subpopulations of hybrid cells due to the loss of chromosomes from the hybrid cells at low passage numbers [12].

In congruence with the results on hybrid tumor cells reintroduced into culture, high specific activity of CAT was also found in the tumor itself. Moreover, the tumor has a high capacity for specific binding of opiates [13].

It is not self-evident that cellular markers are preserved in cells derived from tumors. After heterotransplantation into nude mice ultrastructural and biochemical changes were found in cultured human melanoma cells [14]. In the present case, however, another [15] example is given for the constancy of cellular properties after passage through nude mice.

The tumorigenicity of intraspecific hybrid cells has been studied by others previously [16]. By fusion of different malignant mouse cell lines it was demonstrated that malignancy is suppressed in hybrid cells if one of the parental cell lines is nonmalignant. However, intraspecific hybrid cells arising from two malignant cell lines were as tumorigenic as the parental cells. Thus malignancy behaved as a recessive lesion at a single gene locus in mouse hybrid cells [17]. Our results of tumorigenicity of the interspecific neuroblastoma × glioma hybrid cells are in line with the above characterization of malignancy, since both parental cell lines N18TG2 and C6-BU-1 are subclones from transplantable tumors [18, 19]. Non-transformed cells such as primary tissue explants do not produce tumors in athymic nude mice [5, 20]. Moreover, it has been shown recently, that tumorigenicity in nude mice seems to be the most reliable assay for transformation [21].

For two reasons tumors from neuroblastoma × glioma hybrid cells appear to be useful tools in neuro-biochemistry. Firstly, characteristic differentiated functions are obviously preserved in the tumor cells. Secondly, the tumor weight in nude mice can nearly reach the body weight of the animal [15]. Therefore the large masses of hybrid cell protein can be produced easily, that are required, e.g. for the isolation of hybrid cell constituents such as CAT or receptors for neurohormones.

The Specificity of the Oestrogen Receptor of DMBA-induced Mammary Tumours of the Rat

P. DAVIES, W. POWELL-JONES,* R. I. NICHOLSON and K. GRIFFITHS
Tenovus Institute for Cancer Research, Welsh National School of Medicine, Heath Park, Cardiff, CF4 4XX, Wales, U.K.

Abstract—*The comparative abilities of several naturally-occurring steroids to compete for [^3H]oestradiol-17β-binding sites in rat mammary tumour cytosol have been investigated. Apart from compounds containing a phenolic A-ring, the most effective compounds were 5-androstene-3β, 17β-diol, 5-androstene-3α, 17β-diol and 5α-androstane-3β, 17β-diol. 5-Androstene-3β, 17β-diol appears to compete by binding to the same site as oestradiol-17β. Those compounds most effective at diminishing cytoplasmic [^3H]oestradiol-17β binding also depressed nuclear binding of [^3H]oestradiol-17β. The presence of a nominal oestrogen receptor with a range of affinity for a number of steroids, including potential androgens, may indicate the presence of a regulatory mechanism superimposed on the basic oestrogen controlled system.*

INTRODUCTION

EVIDENCE which ascribes a role for androgens in the hitherto-designated oestrogen-target organs continues to accumulate. Certain of these tissues contain a discrete protein entity with definite selective affinity for androgenic steroids [1–3], while other reports [4, 5] suggest that the oestrogen receptor itself may sequester potential androgens to some extent. Previously [6], we have suggested that a macromolecule with varying ranges of affinity for steroids with different physiological roles may provide a regulatory system in the normal cell. Obviously, such a system achieves greater importance in the cancerous cell in view of its exploitation in therapy and, possibly, prognosis. This paper describes the study of the specificity of the cytoplasmic oestrogen receptors of mammary tumours induced in rats by 7,12-dimethylbenz[α]anthracene.

MATERIAL AND METHODS

Animals

Mammary tumours were induced in virgin female Sprague–Dawley rats (50 ± 2 days old) by intubations with a single dose of DMBA (20 mg in 1 ml sesame oil). Animals were housed in groups of 4 and allowed food and water *ad libitum*. Beginning 5 weeks after intubation with DMBA, rats were palpated for tumours at weekly intervals and tumour size was recorded as the mean of two perpendicular diameters, one measured across the greatest width. Tumours which did not attain an approximate size of 20 mm mean diameter in the 23-week period following carcinogen administration were not used in this study.

Preparation of subcellular fractions

Mammary tumours were homogenized [7] and cytoplasmic [8] and nuclear fractions [9] were prepared as previously described. The basic buffer system employed throughout comprised 50 mM-Tris–HCl buffer, pH 7.4, containing 5 mM-EDTA and 1 mM-dithiothreitol.

Detection of specific oestrogen-binding components in mammary tumour subcellular fractions

The labelling of subcellular fractions with [2, 4, 6, 7(*n*)-$^3H_4$] oestradiol-17β (specific radioactivity 85–110 Ci/mmole; Radiochemical Centre, Amersham, Bucks., U.K.), and subsequent sedimentation analysis has been adequately described [8, 10]. The quantitative assessment of receptor proteins selectively retaining [^{3}H]oestradiol-17β was performed by a charcoal adsorption technique [11] and analysis according to Scatchard [12]. The ability of certain other steroids to prevent the binding of

*Present address: National Institute of Environmental Health Sciences, P.O. Box 12233, Research Triangle Park, NC, U.S.A.

[^{3}H]-oestradiol-17β to specific cytoplasmic receptors was examined by the following two methods:

(a) Constant amounts of cytosol (100 μl) were incubated with a saturating concentration of [^{3}H]oestradiol-17β (5 nmole/l) in the presence of varying concentrations of non-radioactive competitor (see 'Results'). After incubation (2 or 16 hr at 4°C) 200 μl of charcoal suspension [0.5% (w/v) Norit A, 0.05% (w/v) Dextran T-70, 0.1% (w/v) gelatin] was added. After removal of charcoal (800 *g* for 15 min), aliquots (100 μl) of the supernatant were assessed for bound radioactivity in 5 ml of scintillation fluid (5 g 2, 5-diphenyloxazole, 500 ml Triton X-100, 1 l. toluene) in a Nuclear Chicago (Mark II) liquid scintillation spectrometer at a counting efficiency for tritium of 30–40% as determined by external standardisation.

(b) Constant quantities of cytosol (100 μl) were incubated with three constant concentrations (0.18, 0.46 and 0.92 nmole/l) of [^{3}H]oestradiol-17β in the presence of varying concentrations of nonradioactive competitor (as detailed in the 'Results' section). After incubation (2 hr at 4°C), charcoal suspension (200 μl) was added and removed (as described above) and aliquots (100 μl) of supernatant were assessed for bound radioactivity. Data were expressed graphically in the form of single and double reciprocal plots.

Chemical analyses

The protein concentration of cytosol fractions was estimated using the method of Lowry *et al.* [13].

RESULTS

Characteristics of [^{3}H]oestradiol-17β-binding components in rat mammary tumour subcellular fractions

Sedimentation profiles of specific oestrogen receptor proteins from rat mammary tumour cytosol [9] and nuclei [10] have received adequate exposure. It is sufficient to reiterate that two species of [^{3}H]oestradiol-17β-binding proteins are found in cytosol, one of sedimentation coefficient 8S which shows specificity by accepted criteria and one of sedimentation coefficient 4S which comprises predominantly nonspecific components. Saturation analysis indicated the presence of a single class of high-affinity binding sites with dissociation constants in the range 50–1000 pmole/l and with concentrations in the range 10–200 fmole/mg protein. Those cytosols used in the competition studies had receptor concentrations >80 fmole/mg protein. Salt-extraction [10] of nuclei labelled with [^{3}H]oestradiol-17β yielded a single peak of protein-bound radioactivity on sucrose gradients corresponding to a sedimentation coefficient 4–5 S.

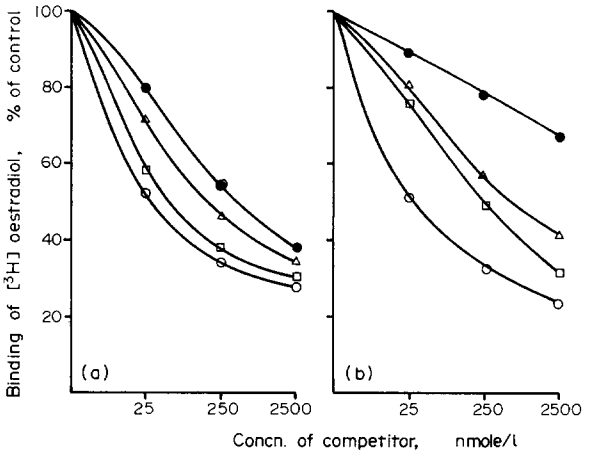

Fig. 1. Competition for [^{3}H]oestradiol-17β binding sites. Samples of cytosol were incubated with [^{3}H]oestradiol-17β (5 nmole/l) alone or in the presence of increasing concentrations of other steroids. Free and nonspecifically bound steroid was removed by charcoal adsorption and retained radioactivity was assessed by liquid scintillation spectrometry. Competing steroids were (a) oestradiol-17β (○), oestradiol-17α (□), oestriol (△) and oestrone (●); (b) oestradiol-17β (○), 5-androstene-3β, 17β-diol (□), 5-androstene-3α, 17β-diol (△) and 4-androstene-3β, 17β-diol (●). Binding is expressed as a percentage of charcoal-resistant binding in the presence of [^{3}H]oestradiol-17β alone (104 fmole/mg protein).

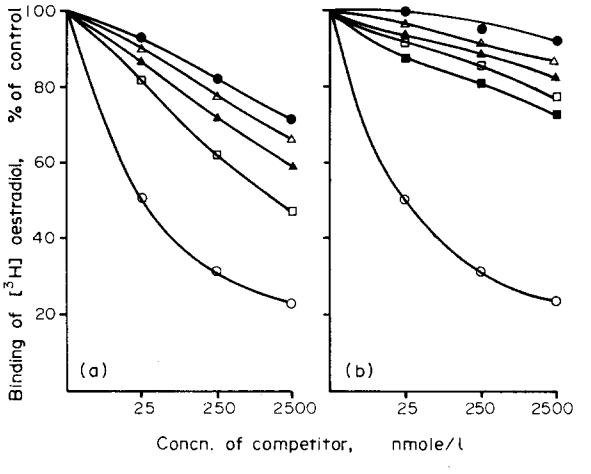

Fig. 2. Competition for oestradiol-17β binding sites. Details are essentially the same as for Fig. 1., but competing steroids were (a) oestradiol-17β (○), 5α-androstane-3β, 17β-diol (□), 5α-androstane-3α, 17α-diol (▲), 5α-androstane-3β, 17α-diol (△), 5α-androstane-3α, 17β-diol (●), and (b) oestradiol-17β (○), 5α-dihydrotestosterone (■), testosterone (□), androstanedione or epitestosterone (▲), dehydroepiandrosterone (△) and progesterone or corticosterone (●).

Competition for [^{3}H]oestradiol-17β-binding sites in mammary tumour cytosol

The comparative abilities of a number of steroids to compete with [^{3}H]oestradiol-17β for receptor sites is shown in Figs. 1 and 2.

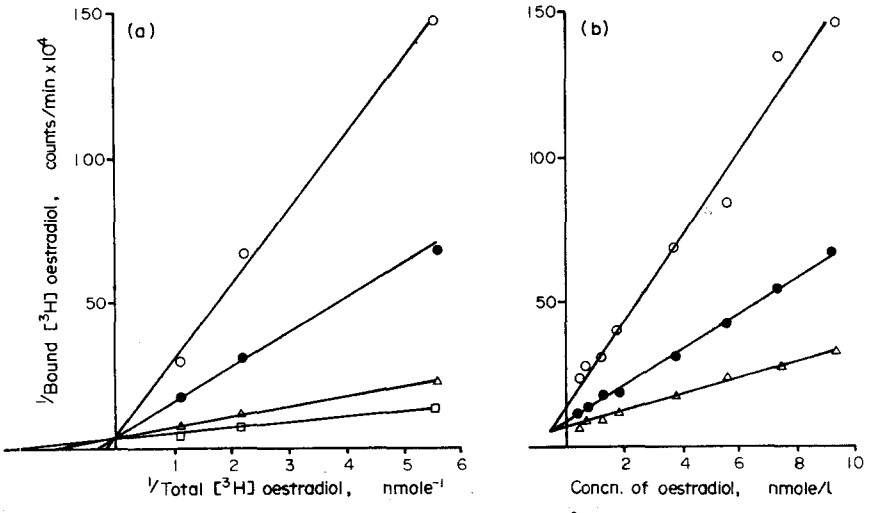

Fig. 3. Competition by unlabelled oestradiol-17β for specific [^3H]oestradiol-17β binding sites in mammary tumour cytosol. Aliquots (100 μl) of cytosol were incubated (2 hr at 4°C) with three constant concentrations of [^3H]oestradiol-17β (0.18, 0.46 and 0.92 nmole/l), alone or together with varying concentrations of oestradiol-17β in a total vol of 200 μl. After incubation, charcoal suspension (200 μl) was added and after 1 hr at 4°C was sedimented (800 g for 15 min) and aliquots (200 μl) of bound supernatant assessed for bound radioactivity. The concentrations of unlabelled oestradiol-17β used were 0.367 nmole/l (△), 3.67 nmole/l (●) and 9.19 nmole/l (○), (a) when the reciprocal values of bound [^3H]oestradiol-17β was plotted against the reciprocal value of total [^3H]oestradiol-17β. Control systems containing [^3H]steroid alone (□). (b) the reciprocal value obtained for bound [^3H]oestradiol-17β were plotted against total unlabelled oestradiol-17β concentrations, at concentrations of [^3H]oestradiol-17β of 0.18 nmole/l (○), 0.46 nmole/l (●) and 0.92 nmole/l (△).

Predictably, the most effective competitor was oestradiol-17β, together with oestradiol-17α (Fig. 1a). Oestriol and oestrone also competed very well (Fig. 1a). Of the three androstenediols studied, 5-androstene-3β, 17β-diol was the most effective compound, with 5-androstene-3α, 17β-diol able to reduce binding of [^{3}H]oestradiol-17β by 50–60% at the highest concentration used (Fig. 1b). 4-Androstene-3β, 17β-diol was less effective, causing a maximum decrease in specific binding of 30–40% (Fig. 1b). The 5α-androstanediols also showed variable potency, 5α-androstane-3β, 17β-diol being most effective (~55% decrease), followed by 5α-androstane-3α, 17α-diol (40%), 5α-androstane-3β, 17α-diol (35%) and 5α-androstane-3α, 17β-diol (~30%) (Fig. 2a). It must be emphasised that these degrees of competition are those achieved by the highest concentrations used i.e. 2500 nmole/l, or a 500-fold higher concentration than that of [^{3}H]oestradiol-17β. The compounds mentioned in Fig. 2b, therefore, can be regarded as relatively ineffective in decreasing the specific binding of [^{3}H]oestradiol-17β.

In view of the substantial reduction in [^{3}H]oestradiol-17β binding brought about by compounds such as 5-androstene-3β, 17β-diol it was thought worthwhile to test the hypothesis that these steroids are able to bind to the same site as oestradiol-17β, since competition could also be induced if the second steroid bound to an alternative site to alter protein conformation. This was done by monitoring competition under conditions of varying [^{3}H]oestradiol-17β concentration and varying concentrations of competing steroid (Figs. 3–6). Data obtained from competition studies using unlabelled oestradiol-

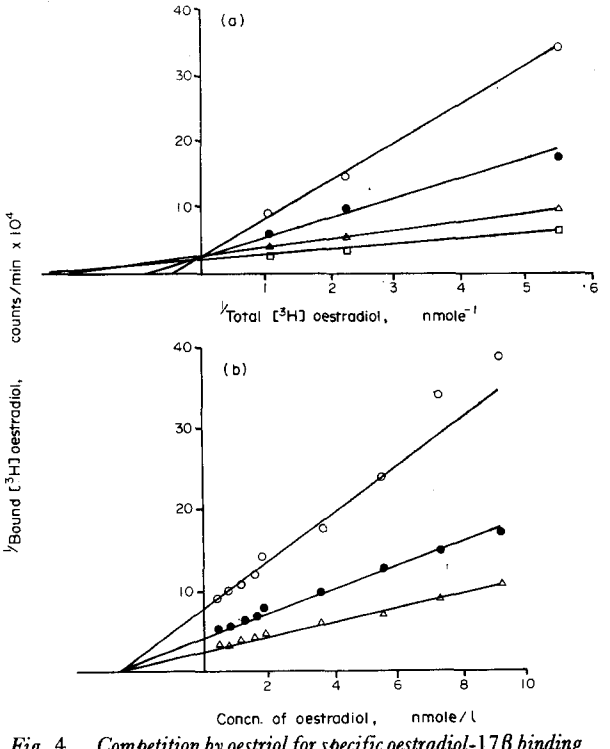

Fig. 4. Competition by oestriol for specific oestradiol-17β binding sites in mammary tumour cytosol. Details are essentially those in Fig. 3, except that oestriol was used as competitor. (a) [^3H]oestradiol-17β alone (□) and with oestriol at concentrations of 0.367 nmole/l (△), 3.67 nmole (●) and 7.35 nmole/l (○). (b) [^3H]oestradiol-17β at concentrations of 0.18 nmole (○), 0.46 nmole/l (●) and 0.92 nmole/l (△).

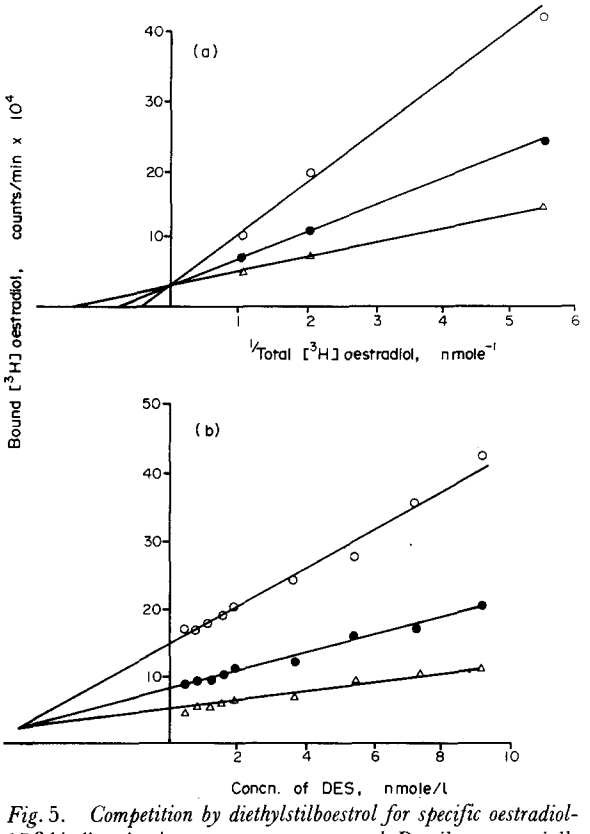

Fig. 5. Competition by diethylstilboestrol for specific oestradiol-17β binding sites in mammary tumour cytosol. Details are essentially those in Fig. 3, except that diethylstilboestrol was used as competitor. (a) [^{3}H]oestradiol-17β alone (△), or with diethylstilboestrol at 3.67 nmole/l (●) and 9.19 nmole/l (○) (b) [^{3}H]oestradiol-17β at 0.18 nmole/l (○), 0.46 nmole/l (●) and 0.92 nmole/l (△).

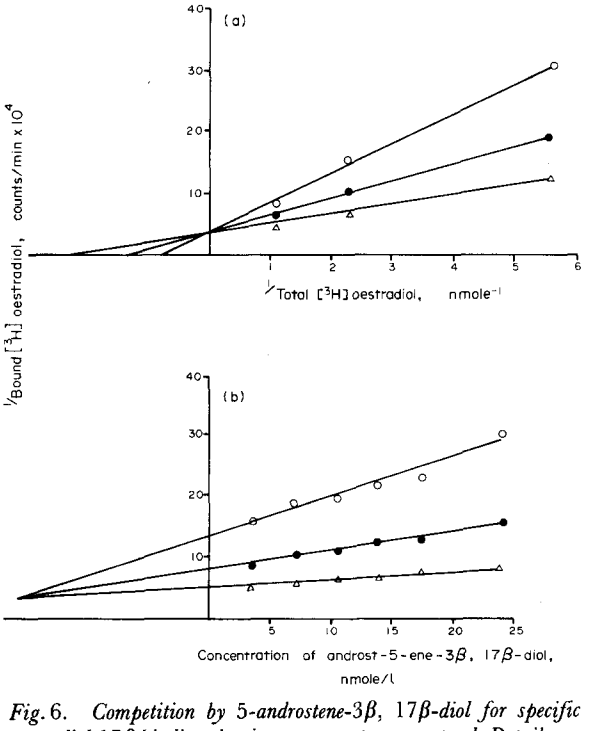

Fig. 6. Competition by 5-androstene-3β, 17β-diol for specific oestradiol-17β binding sites in mammary tumour cytosol. Details are essentially those in Fig. 3, except that 5-androstene-3β, 17β-diol was used as competitor. (a) [^{3}H]oestradiol-17β alone (△), or with 5-androstene-3β, 17β-diol at 10.30 nmole/l (●) or 25.86 nmole/l (○). (b) [^{3}H]oestradiol-17β at concentrations of 0.18 nmole/l (○), 0.46 nmole/l (●) or 0.92 nmole/l (△).

17β, oestriol (a steroidal oestrogen), diethylstilboestrol (a nonsteroidal oestrogen) and 5-androstene-3β, 17β-diol [the most effective of potential androgens in the competition studies (Fig. 1b)] as the competing substances were expressed graphically in the form of double reciprocal plots (Figs. 3(a)–6(a), respectively). The reciprocal value of bound [^{3}H]oestradiol-17β was plotted against the reciprocal value of total [^{3}H]oestradiol-17β. The patterns obtained were characteristic of competitive inhibition in that the presence of competitor altered the slope but not the intercept on the ordinate. To eliminate the possibility of allosteric inhibition, a plot of the reciprocal of bound radioactivity against the concentration of competitor was also used [Figs. 3(b)–6(b)]. Whereas allosteric inhibition would have resulted in hyperbolic curves, the substances under investigation produced a linear relationship indicative of direct competition. These data suggest that these compounds were competing with [^{3}H]oestradiol-17β for the same binding site.

Competition for oestrogen-binding sites in rat mammary tumour nuclei

Using methods described previously [10], the ability of various compounds to prevent the nuclear uptake of [^{3}H]oestradiol-17β was studied (see Fig. 7). A 1000-fold higher concentration of either oestradiol-17β or diethylstilboestrol completely depressed the 4-5S peak of radioactivity present in nuclear extracts after incubation with [^{3}H]oestradiol-17β alone, while similar concentrations of testosterone or 5α-dihydrotestosterone only slightly decreased the binding peak (Fig. 7). The inclusion of a 1000-fold higher concentration of 5-androstene-3β, 17β-diol or 5α-androstane-3β, 17β-diol resulted in a significant decrease in the binding of [^{3}H]oestradiol-17β (Fig. 7).

DISCUSSION

The ability of certain compounds to compete with [^{3}H]oestradiol-17β for specific binding sites has proved of great value in the development of anti-oestrogens [8, 14, 15], which may retard growth processes by impeding the obligatory retention step in mechanism of action of steroids. However, the possibility that naturally-occurring steroids may also compete for oestrogen-binding sites provides an attractive scenario for regulation of oestrogen action at the physiological level.

The data presented in Figs. 1 and 2 show that, apart from those compounds with a phenolic A-ring, i.e. naturally-occurring steroids with vary-

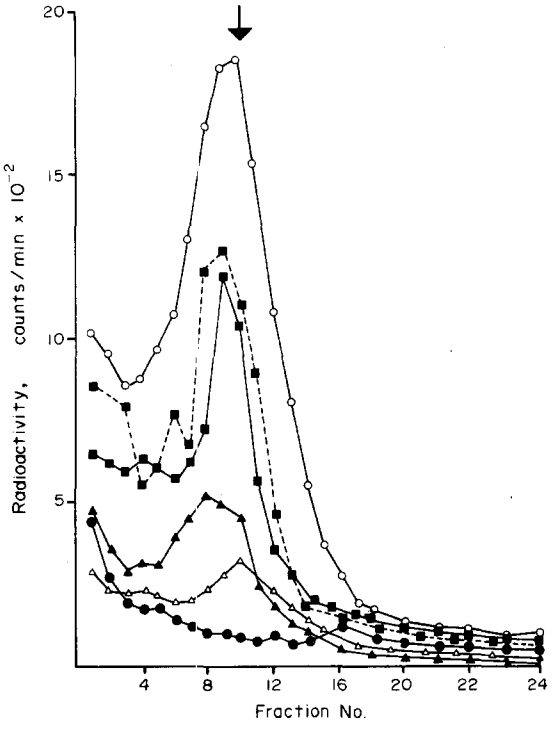

Fig. 7. Sedimentation analysis of the effect of various compounds on the binding of [^{3}H]oestradiol-17β by mammary tumour nuclei. Samples (1 g) of tumour tissue were minced and incubated (15 min at 30°C) in Eagle's basal medium (10 ml) supplemented with [^{3}H]oestradiol-17β (5 nmole/l) alone (○) or together with oestradiol-17β or diethylstilboestrol (●), 5-androstene-3β, 17β-diol (△), 5α-androstane-3β, 17β-diol (▲), testosterone (---■---) or 5α-dihydrotestosterone (■), (all at 5 μmole/l). After incubation, nuclei were purified, extracted with KCl (0.4 mole/l) and samples of extract analysed on sucrose gradients [10]. *Sedimentation marker (arrow) was bovine serum albumin ($S_{20,w}$ 4.6S). Direction of centrifugation was from left to right.*

ing oestrogenic potency, the compounds most effective in reducing specific binding of [^{3}H]oestradiol-17β were 5-androstene-3β, 17β-diol, 5-androstene-3α,17β-diol and 5α-androstane-3β, 17β-diol. This observation supports the suggested importance of the 3- and 17β-hydroxyl groups [4,5], although the alcoholic hydroxyl confers less affinity than the phenolic hydroxyl [16]. The 3-hydroxyl in the β-position results in higher affinity than when in the α-position, and the change in orientation caused by the change from a 5-ene to a 4-ene also decreased affinity. The presence of the keto groups rather than the hydroxyl group, e.g. testosterone, 5α-dihydrotestosterone, androstendione, dehydroepiandrosterone and epitestosterone, renders compounds relatively inactive in such competitive binding studies.

The comparative efficiency of the 5-androstenediols and 4-androstenediol is worthy of further note. 4-Androstene-3β, 17β-diol was shown to be relatively inactive in competition for the oestrogen receptor of human uterus [17] and human breast cancer [16], while 5-androstene-3β, 17β-diol was very effective in human myometrial and human breast cancer tissue [14], competing within the physiological range of concentration [18]. This may assume greater importance in rat mammary tissue, wherein 5-androstene-3β, 17β-diol is a metabolite of dehydroepiandrosterone [19]. Overall, these studies suggest a similar specificity of the oestrogen receptor of a number of tissues [4, 16–18].

In view of postulated regulatory roles of 5-androstene-3β, 17β-diol [4, 18], it is interesting to note that it behaves similarly to oestrogenic compounds by apparently binding to the same site as oestradiol-17β (Fig. 6). It is not unusual for 5α-dihydrotestosterone to be inactive as regards the oestradiol receptor (Fig. 2b) [20] since a spectrum of androgenic compounds have been shown to exert physiological effects [see ref. 21], among them 5α-androstane-3β, 17-β-diol [22] and 5-androstene-3β, 17β-diol [23]. Together with the data presented in Figs. 1 and 2, these observations suggest that the variety of 'active' androgens might be reflected in diverse binding characteristics, ranging from nominal androgen receptors to nominal oestrogen receptors.

Those substances which diminish cytosol retention of [^{3}H]oestradiol-17β also prevent nuclear accumulation of [^{3}H]steroid (Fig. 7). This is not unexpected and does not preclude androgen-induced translocation of receptor. We have previously shown [24] that pharmacological doses of androgen can translocate receptor to nuclei and that 5-androstene-3β, 17β-diol was most efficient in this respect. This data [24] agrees with concepts that not only those androgens which bind well to the oestrogen receptor promote its translocation, but also those which bind poorly may effect translocation if the intracellular concentration is sufficiently high [5, 25].

The role of androgens in oestrogen-target tissues remains obscure. Androgen-induced transfer of receptor to nuclei of immature rat uteri has been suggested to provide a pool of receptor inaccessible to oestrogen resulting in depletion of intracellular oestrogen-receptor complex and denigration of synthetic processes [25]. However, high doses of androgen can translocate oestrogen-receptor to nuclei of the same tissue and promote protein synthesis quantitatively and qualitatively similar to that produced by physiological quantities of oestrogen [26]. This would ascribe to androgens uterotrophic and antiuterotrophic responses induced by the same mechanism. However, the involvement of pharmacological doses of an-

drogens may result in aberrations. At physiological concentrations, androgens may deplete binding of oestradiol-17β but may not effect the necessary transformations for nuclear transfer. In this respect, a regulatory mechanism may operate which may be relevant to the study of human breast cancer, especially in view of observations on the competitive properties of 5-androstene-3β, 17β-diol [4, 5 and above].

‡Département de Calcul Scientifique, Faculté de Médecine, Université Libre de Bruxelles

Abstract – *In order to determine the possible effect of postoperative empyema on survival in lung cancer, we studied the registered data for* 148 *male patients operated on between January* 1961 *and June* 1972 *for pulmonary squamous cell and large cell carcinoma.*

In curative cases, the 3- *and* 5- yr *survival rates for the* 14 *patients that had empyema were* 57% *and* 42%, *and for the* 51 *patients without empyema,* 73% *and* 51% *respectively; the survival curves are not statistically different. In reductive cases, the* 3- *and* 5-yr *survival rates for the* 20 *patients with empyema were* 5%, *and for the* 63 *without empyema,* 18% *and* 11%; *the difference in the survival curves is statistically significant* ($P < 0.025$).

It is our conclusion that a postoperative empyema is not a favorable event.

INTRODUCTION

PUBLICATIONS on the effect of empyema on lung cancer survival report different and often misquoted results, but sustain the reputation of a favorable influence [1, 2]. Sensenig, Rossi and Ehrenhaft [3], Leroux [4], Virkkula and Kostiainen [5] are often quoted for offering evidence of the beneficial effect of intracavitary infection following lung resection for tumor. Nevertheless, their reports were not designed to study the empyema effect and no clear conclusion can be drawn.

Among the controlled studies, Cady and Cliffton [6] reported a 5 yr survival rate of 13% for 40 empyema and 35% for the others; Lawton and Keehn [7] reported 21.4% as opposed to 29.8%; Uzzan, Israel-Asselain and Personne [8] reported 25% for both groups.

On the other hand, Takita [9] noted 7 patients suffering from empyema, who survived for 5 yr, i.e. 54% compared to 27% in the control group; Ruckdeschel, Codish, McKneally *et al.* [10] found the 5 yr survival rate for the 18 empyemic patients to be 50% as compared to 18% for the 34 matched control patients.

The interpretation of these results is complicated due to a lack of coherent information on histology, tumor staging, type of operation, presence of postoperative residual neoplastic tissue and statistical methods.

We planned this study to analyze the effect of postoperative empyema on survival among defined patient groups operated for lung cancer, while using the records of the Thoracic Surgery Department of the Hôpital Saint-Pierre, in Brussels.

MATERIAL AND METHODS

The study was carried out on the basis of the recorded cases [11] of patients who underwent lung resection for primary lung neoplasia between January 1961 and June 1972 in the Hôpital Saint Pierre. The criteria of operability and resectability have been defined earlier [12–16].

Using the International T.N.M. Staging System [17], the surgical resections of tumors confined to $T_0 \rightarrow T_2, N_0 \rightarrow N_1, M_0$ (preoperative estimation and postsurgical status) without any postoperative known residual tumor were grouped as curative resections [18]. Palliative or reductive resection was used for the other cases (T_3, N_2). No patient with known metastases was operated upon. Time zero was the day of surgery. Patients who died within 30 days of operation were excluded from both control and empyema groups. All the patients were male smokers. All the empyemas occurred within 6 months of lung resection. In order to obtain homogeneous histological groups, we only studied well differentiated and poorly differentiated squamous cell along with large cell undifferentiated (neither giant cell nor mucinous) carcinomas [19, 20]. Of the 45 recorded cases of empyema (following 349 operations, i.e. an incidence of 12.9%), 36 belonged to this histologic specification.

Another clinical study was conducted at the same time in our service [18, 21] concerning the patients who underwent a curative operation for

Accepted 17 June 1977.

lung cancer: patients received at random postoperative prophylactic complementary radiotherapy. Because of this randomized study and the contraindication of radiotherapy when intracavitary infection occurs, no patient in the curative empyemic group was irradiated. So we only compared the cases without any adjunctive postoperative therapy when the surgery was curative. Fourteen cases of empyema were compared to 51 cases without empyema.

After reductive surgery, the patients were proposed for complementary therapy (radio- or chemotherapy). Since no standard postoperative therapy was planned, the groups with or without empyema had not been selected for postoperative treatment. Twenty cases of empyema were compared to 63 control cases.

Thus the patients studied here were selected according to the 4 following criteria: (1) male smokers, (2) squamous cell carcinoma, (3) survival longer than 1 month, (4) no radiotherapy after curative resections. This left us with a series of 148 patients out of the original 349.

The survival curves were calculated by the Kaplan–Meier method and compared by the adapted Wilcoxon test [22]. We have computed the expected life time (E.L.T.) under exponential hypothesis for each group of patients, defined as the ratio of total observed survival days over number of deaths.

RESULTS

Tables 1 and 2 give the contingency characteristics of the studied groups of patients. Empyema is not related to curative or reductive resection (Table 1, $P>0.5$ on chi-square test). Empyema is not a cause of increased postoperative mortality, as there were only two deaths within a month after the 36 operations complicated by empyema. The occurrence of an empyema is strongly related to pneumonectomy (Table 1, $P<0.001$ on chi-square test). It would be an important statistical parameter, but according to our data, the type of operation does not seem to influence the survival. In this study, the expected life times under exponential hypothesis (E.L.T.) for curative pneumonectomies vs curative lobectomies are 3105 days (9 deaths) vs 3192 days (14 deaths); for reductive pneumonectomies vs reductive lobectomies, the E.L.T.'s are 577 days (16 deaths) vs 813 days (29 deaths). The differences are not significant.

The data shown in Table 1 indicate a poorer prognosis for the patients suffering from empyema (survival status, $P<0.001$ on chi-square test). Empyema does not reduce the recurrence of cancer after lung surgery in either operative group ($P>0.3$ on chi-square test).

The patients with postoperative empyema tend to be older, 59.4 ± 7.3 yr vs 57.5 ± 6.4 yr but the difference is not significant ($P>0.1$ on chi-square test and $P=0.17$ on t-test).

Table 2 analyzes the patients who had reductive operations. Age, assumed postoperative residual tumor and chemotherapy rate are not significantly different. Only the postoperative radiotherapy rates are statistically different (30% vs 52%, $P<0.02$ on chi-square test).

Survival rates (Tables 3 and 4)

Survival rates compared by the appropriate Wilcoxon test are given in Table 3. Each empyema group has a shortened course, which is not due to higher postoperative mortality or to more frequent recurrence (Table 1). Only the survival curve of the patients suffering from empyema after palliative surgery is statistically lower than that of the control group ($P<0.025$). Half-life time and expected life time under exponential hypothesis (E.L.T.) are presented in Table 4. The values of E.L.T. are roughly reduced by half in each empyemic group.

In Table 2, we have noted a significant difference ($P<0.02$) in the postoperative radiotherapy rate between the palliative groups with and without empyema. This potential bias has been further analyzed. In the control group, eleven patients (28%) were surviving at the last follow-up period after postoperative radiotherapy. Their E.L.T. was 604 days. Without radiotherapy, seven patients survived (29%) and the E.L.T. was 753 days. The differences are not significant. Postoperative irradiation and simultaneous occurrence of an empyema tend to decrease the E.L.T.: 217 days vs 426 days (not significant on two-sided F-test).

Due to small populations, we were unable to test the influence of the number and types of causative organisms or the therapeutic methods of managing the empyema. The Karnofsky's index was introduced too late into the study to be assessed.

DISCUSSION

Table 5 recapitulates the reported cases and Table 6 the original controlled studies. For classification and comparison, we tried to use the same terminology. The characteristics are not at all uniform and the data are contradictory. No precise analysis was possible from the reported cases. Even more, the late-occurring empyemas are often included in the series to analyze the

survival rates. In the controlled studies, there is insufficient information to compare the observed differences. The study of Ruckdeschel *et al.* [10] with the selection of matched control patients has been criticized by some authors [1, 8] because of the low survival rate in the control group, the small samples and some discrepancies in the survival patterns. These studies and ours showed that the occurrence of empyema is related to pneumonectomy.

The misquotations of some reports are surprising. From Leroux [4], Cady and Cliffton [6] and Takita [9] report the 5-yr-survival rate to be 33% for 15 pneumonectomies, Uzzan *et al.* [8] report a 10/21 survival rate, while Ruckdeschel *et al.* [10] report the 10-yr survival to be 4 out of 6 patients. From Sensenig *et al.* [3], Cady and Cliffton [6] and Takita [9] report 4 five-yr survivors out of 7 pneumonectomies, Ruckdeschel *et al.* [10], 3 five-yr survivors and Uzzan *et al.* [8], 5 five-yr survivors. From Virkkula and Kostiainen [5] who report the treatment of 10 patients with empyema without analyzing the "cancer" survival rate, Ruckdeschel *et al.* [10] and Uzzan *et al.* [8] report a 4/7 rate after 5 yr. From Cady and Cliffton [6], Takita [9] and Uzzan *et al.* [8] report 5 five-yr survivors, the first out of 24 patients and the latter out of 35 patients.

Sensenig *et al.* [3] were the first to suspect a beneficial effect of empyema on lung cancer survival, possibly indicating stimulation of host defence against residual tumor cells. Many mechanisms may be advocated: physical blockage of lymphatics by the inflammatory process [3], tumoricidal effect of bacterial toxins [1, 3, 10] or of fever due to infection [24] (but Cady and Cliffton did not find a favorable effect of fever), or increased antigenicity of tumor cells by bacterial hydrolytic enzymes such as neuraminidase [25]. Cady and Cliffton [6] reported a trend (statistically not significant) for 5 yr survivors to have more infections due to staphylococcus and streptococcus pyogenes, to have a greater number of bacterial species per infection and to have fewer infections with only one species of organism. Ruckdeschel *et al.* [10] postulated an immunological hypothesis of a non-specific tumoricidal effect by lymphokines released by lymphocytes activated by bacterial antigens.

This study was primarily planned to examine the attractive hypothesis that empyema could enhance host defences.

It is a retrospective study and therefore cannot eliminate chronologic and detection biases. There are three further possible biases, age distribution, operative procedures (Table 1) and radiotherapy in palliative cases (Table 2). Age is in itself a cause of increased lethality [25]. The influence of age on the observed survival rates was minimized by the results of statistical tests concerning age distribution between the empyema and the control groups, which never reached statistical significance. The operation parameter (more frequent pneumonectomies in empyema groups could be disregarded according to E.L.T. values comparable in operative subgroups. The influence of radiotherapy in palliative cases with postoperative empyema was further analyzed. Irradiation and empyema together tend to lessen the E.L.T.: 7 months vs 14 months but the difference is not significant. Radiotherapy had no influence on survival in the control group.

In palliative cases, survival curves are significantly lower for patients suffering from empyema ($P < 0.025$). In curative cases, empyemic patients have a shorter survival. E.L.T.'s are of 51 months vs 104 months, but the survival curves cannot be differentiated on a statistical basis.

Therefore, as far as this study is concerned, by following up patients with spinocellular and large cell undifferentiated bronchogenic carcinoma, without postoperative prophylactic irradiation in curative cases, we were unable to demonstrate a favorable effect of empyema. We found no beneficial effect of empyema on lung cancer survival (Tables 3 and 4) or recurrence rates (Table 1). Furthermore, postoperative empyema contraindicates prophylactic radiotherapy which has been previously proved to increase survival rate in curative cases [27]. However, because the observed decrease of survival rates in cases with empyema may be due to the three possible biases discussed above, we cannot be certain that the unfavorable effects observed are due to empyema.

The literature is contradictory (Tables 5 and 6) and we think it will remain so. Empyema is a rare event (5–15%) and, therefore, authors' report only small numbers of patients. Unfortunately, the survival rate in lung cancer depends on many variables. Some are easily controllable i.e. age, sex, race, smoking habits and occupational hazards. For a comparative study, we need full information about histology and staging of the tumor. However, in retrospective studies, there are uncontrolled variables: methods of detection of metastases have changed and improved e.g.: percutaneous lung biopsy and mediastinoscopy vs Daniel's biopsy, osseous scintigraphy vs radiologic findings, hepatic scintigraphy and laparoscopy vs biologic data and laparotomy, cerebral scintigraphy and the new computerized transverse axial tomography vs neurological examination

and E.E.G. and so on. Occurrence of empyema following a bronchial fistula probably has a worse prognosis, as mentioned by Sensenig *et al.* [6]. The date of occurrence and duration of empyema seems likely to be crucial for its presumed action on host defences, as cell-mediated immunity to tumor-associated antigens has been shown to be depressed for 6–22 days after surgical operation [28]. Also, adjuvant chemotherapy and radiotherapy are known to decrease host defences against infectious diseases.

For all these reasons, we believe that a strictly conclusive clinical study is practically impossible and incidental empyema will remain a subject of controversy. A partial answer would be possible by studying the immunological status of each patient, while applying the new immunological methods: lymphocytic inhibition of macrophage migration by tuberculin, encephalitogenic protein and tumor extract, lymphocyte transformation by PHA, skin test with cell-mediated immunogens [29], rosette formation and their inhibition by the antilymphocyte globulin [30], and skin tests with tumor extract [31]. The immunological status of patients suffering from empyema has never been assessed. The ultimate answer is in clinical studies of experimental empyema with B.C.G. [32, 33] or with *Corynebacterium parvum* in randomized patients.

Despite our retrospective study and our review of the literature, we were unable to demonstrate a favorable effect of empyema on lung cancer survival.

The Effect of Subcutaneous Administration of Oestrogens on Plasma Oestrogen Levels and Tumour Incidence in Female Rats*

M. A. BLANKENSTEIN,†‡ J. J. BROERSE,§ J. B. de VRIES,§ K. J. VAN DEN BERG,§ S. KNAAN§ and H. J. VAN DER MOLEN†

§*Radiobiological Institute TNO, 151 Lange Kleiweg, Rijswijk, The Netherlands*

Abstract—*A study on a possible synergistic effect of oestrogens and ionizing radiation on mammary carcinogenesis required the use of female rats with elevated plasma levels of oestrogens in a longitudinal experiment. Following subcutaneous implantation of oestrogen pellets, plasma oestrogen levels were monitored as a function of time after administration, procedure of pellet preparation, chemical nature of the oestrogen and concentration of the oestrogen in the pellets. 17β-oestradiol (E_2), 17β-oestradiol 3-benzoate (E_2B) and 17α-ethynyloestradiol (EE_2) were studied in this respect. In initial studies, 5–20 mg E_2B were implanted; this resulted in extremely high peripheral plasma levels and caused deterioration in the physical condition of the animals. After a latent period of 10–12 months, pituitary and mammary tumours were observed in a considerable number of animals.*

Experiments with pellets containing tritium labelled 17β-oestradiol were performed in order to compare the kinetics of hormone release from pellets produced by various techniques. Based on the results of these experiments, implantation of oestrogen in a paraffin-cholesterol pellet was adopted for all further experiments. Peripheral plasma levels of oestrogen are reported for 17β-oestradiol and 17α-ethynyloestradiol at various time intervals after administration of pellets containing 1.0 and 2.5 mg of oestrogen to intact and ovariectomized rats.

INTRODUCTION

IN VIEW of the relatively high incidence of mammary cancer in the human, it is of great importance to unravel the mechanism of mammary gland carcinogenesis in experimental models. Previous studies have suggested a relationship between the occurrence of mammary tumours in the human and several factors, including radiation [1], nutritional status [2] and oestrogen use [3, 4]. Furthermore, it has been shown [5, 6] that, in the rat, oestrogen (diethylstilboestrol, DES) and ionizing radiation (X-rays and neutrons) act synergistically to produce mammary tumours. In these studies, DES was administered to female A × C rats via subcutaneous implantation of hand pressed DES-cholesterol pellets containing 5 mg DES and 15 mg cholesterol. However, the authors provided no data on the actual levels of DES in peripheral plasma after implantation. For a proper evaluation of the possible carcinogenic effect of the administered oestrogen, it is important to know the relationship of the oestrogen plasma level after oestrogen administration to the physiological oestrogen level.

The present study was designed to define the hormonal status of experimental animals during combined oestrogen and radiation treatment in terms of oestrogen levels in peripheral plasma, rather than in terms of the amount of oestrogen implanted in the animal. In this respect we have studied 17β-oestradiol (E_2), 17β-oestradiol-3-benzoate (E_2B) and 17α-ethynyloestradiol

Accepted 27 June 1977.

(EE_2), since these are either naturally occurring, therapeutic or contraceptive oestrogens.

MATERIAL AND METHODS

Animals

Female Wistar WAG/Rij rats either intact or after hystero-ovariectomy (Ovex) were used throughout this study. The animals were kept in rooms with controlled temperature, light and humidity conditions and received tap water and standard dry pellets *ad libitum*. Oestrogen pellets were implanted subcutaneously in the dorsal region of the neck under light ether anaesthesia. Blood was taken from the tail under light ether anaesthesia at regular intervals after pellet implantation. The blood was collected in heparinized tubes and centrifuged within 2 hr to obtain plasma, this was stored at −20°C until assay.

Preparation of oestrogen pellets

Oestrogen pellets were prepared by one of the following methods:

Method A

The oestrogen was mixed with an appropriate amount of cholesterol. The mixture was pressed with a small hand-operated press to give pellets weighing 21.8 ± 2.3 mg (mean ± S.D., $n = 109$) with a cross section of approximately 4 mm.

Method B

The oestrogen was mixed with cholesterol. The mixture was melted in an oil bath at 190°C and was aspirated into silicon tubing of 3 mm cross section in 0.5 ml portions. After cooling the tube at ambient temperature, segments of 2–3 mm were cut.

Method C

A mixture of oestrogen, cholesterol and paraffin was made and pellets were prepared as described for method B. Cholesterol and paraffin were used in a 1 : 10 (w/w) ratio [7]. The average pellet weight was 20.3 ± 1.3 mg (S.D., $n = 100$).

Pellets selected for implantation weighed 19–21 mg. Tritiated oestrogens were included in the pellets in some experiments and steroid release was monitored by liquid scintillation counting of small blood samples taken at regular intervals after pellet implantation. In a counting vial, 0.2 ml of heparinized blood, 0.2 ml of isopropyl alcohol and 0.2 ml of a 30% solution of hydrogen peroxide were mixed and incubated at 60°C for 1 hr to decolorize the blood. The residue was dissolved after incubation with 2 ml of Soluene (Packard) for another 2 hr at 60°C. Finally, 15 ml of Permablend scintillation cocktail (Packard) were added and the radioactivity was determined in a Nuclear Chicago Mark II liquid scintillation counter with a counting efficiency of approximately 10%.

Steroids

17β-Oestradiol and 17α-ethynyloestradiol for implantation were gifts from Organon, Oss, The Netherlands. 17β-Oestradiol 3-benzoate was purchased from Sigma, St. Louis, U.S.A. 17β-Oestradiol and 17α-ethynyloestradiol for use as standards in radioimmunoassay were obtained from Steraloids, Pawling, New York, U.S.A. (2,4,6,7,-^{3}H)-17β-Oestradiol was obtained from the Radiochemical Centre, Amersham, United Kingdom and had a specific activity of 85 Ci/mmole. (6,7-^{3}H)-17α-Ethynyloestradiol with a specific activity of 40 Ci/mmole was purchased from New England Nuclear, Frankfurt am Main, Germany. Radioactive steroids were purified by paper chromatography using a system light petroleum:benzene:ethanol:water, in the ratio of 5:5:7:3 by volume. Purity of radioactive steroids was checked every two months.

Steroid estimations

Plasma 17β-oestradiol was assayed as previously described by De Jong, Hey and van der Molen [8]. Cross reaction of 17β-oestradiol 3-benzoate in the 17β-oestradiol radioimmunoassay was 5%. Plasma 17α-ethynyloestradiol was measured essentially as described by Warren and Fotherby [9], but the method was adapted to the protocol for oestradiol radioimmunoassay.

E_2 and EE_2 were not separated by the chromatographic procedure used. We do not expect, however, that endogenous 17β-oestradiol interfered with the assay of EE_2 in the EE_2 treated rats, because the cross-reaction of E_2 with the EE_2 antiserum was 3.5% and because it appears reasonable to assume that only very little E_2 was present after administration of EE_2 which will suppress pituitary lutropin secretion and ovarian E_2 secretion.

Scoring of tumours

Animals which developed mammary tumours were killed either when tumour size was 5–6 cm, or as soon as indicated by the physical condition of the animals. Autopsy was performed on all animals and the occurrence of tumours was registered. Pituitary tumours were classified as such after histological examination.

RESULTS

In an initial experiment E_2B-cholesterol pellets were prepared according to method A.

These pellets contained 5 mg E_2B and 15 mg cholesterol. From 1 to 4 pellets were implanted in intact and ovariectomized rats. Blood samples were taken at day 0, 3, 7, 14 and 30 days after implantation and E_2 was assayed in the plasma. The results for the intact animals are given in Table 1. The results obtained for the ovariectomized animals were essentially the same. The condition of all animals was affected by the oestrogen administration and loss of hair and a decrease in body weight were generally observed. Furthermore within a latent period of 10–12 months, almost all rats (92%) developed pituitary tumours; some of the intact animals also developed mammary tumours. The tumour incidence in this group of animals is shown in Table 2; control animals were still tumour free. In view of the high peripheral plasma E_2 levels measured after administration of E_2B, which reflect a pharmacological rather than a physiological condition, it was decided to decrease the amount of oestrogen to be administered to the animals. Consequently, the second experiment was designed to compare three different methods of pellet preparation. Two doses of E_2 which were lower than the amounts of E_2B used in the first experiment were used. The results obtained are presented in Fig. 1 and show that implantation of the pressed E_2-cholesterol pellets (method A) tends to give higher plasma levels than the other two methods, especially during the first 40 days after implantation of the pellets. This observation was confirmed by the results of the measurements of radioactivity in the blood after implantation of pellets containing tritiated E_2; these are summarized in Table 3. The half-life of radioactivity in the blood was calculated from disappearance curves of plasma radioactivity. The part of the curve after the onset of the decrease in plasma E_2, which normally occurred about 4 days after implantation, was used for this calculation.

In a third experiment, a comparison was made of the oestrogen release from pellets prepared by method C for implantation of E_2 and EE_2 in intact and ovariectomized rats. The results of this experiment are shown in Fig. 2. There appears to be no difference between the rate of release of E_2 and EE_2 in intact and ovariectomized rats.

DISCUSSION

The present results show that, in the rat, an elevated level of plasma oestrogen can be effectuated and maintained by the subcutaneous

Pellet preparation method	$t_{1/2}$ (days)
A	7,8
B	9,5
C	10,9

Half-lives ($t_{1/2}$) were calculated as the time in which radioactivity in the blood decreased by a factor 2, starting at the top of the disappearance curves.

(s.c.) implantation of an oestrogen-containing pellet in the dorsal region of the neck. The initial plasma oestrogen levels after implantation depend on the method by which the pellets were prepared. From the differences in plasma oestradiol levels immediately after implantation (Fig. 1) and the shorter half-lives of radioactivity in the blood (Table 3) it appears that the release of oestrogen from pellets prepared by pressing an E_2-cholesterol mixture is more rapid than from pellets prepared by melting an E_2-cholesterol–paraffin mixture. There was no apparent difference between the rates of release of E_2 and EE_2 from cholesterol–paraffin fused pellets, nor did ovariectomy affect the plasma level of these oestrogens (Fig. 2). Other applications of sustained release hormonal preparations have been described by Kincl *et al.* [10]; Sundaram and Kincl [11]; Reddy and Prasad [12] and Coutinho *et al.* [13], who used a dimethylpolysiloxane pouch (silastic implant) through which the steroids have to diffuse before they can enter the circulation. To our knowledge, no results have

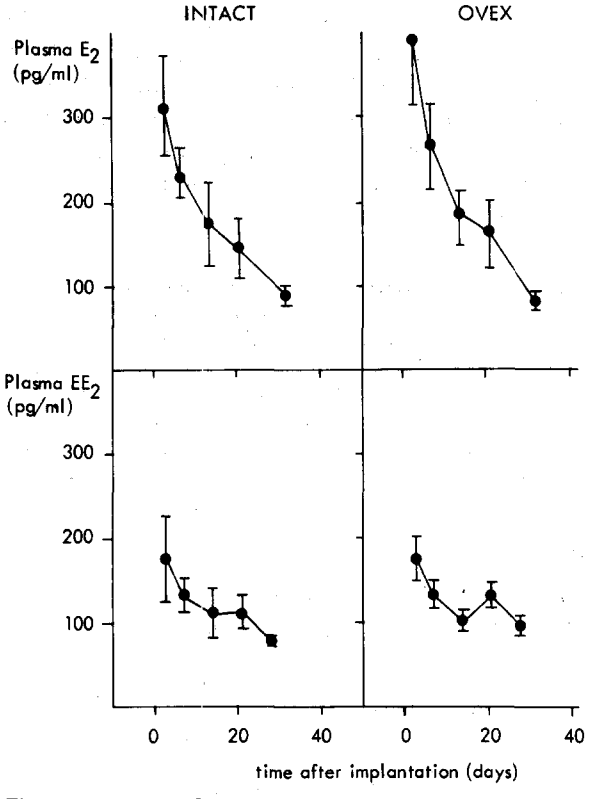

Fig. 2. Plasma 17β-oestradiol (E_2) and 17α-ethynyloestradiol (EE_2) in intact and ovariectomized (OVEX) rats at different times after implantation of an oestrogen–cholesterol–paraffin-pellet containing 1 mg of oestrogen (method C). Results are given as means ±S.E.M. ($n \geqq 3$).

been published on the plasma levels of oestrogens achieved after implantation of such silastic pouches.

From the results in Figs. 1 and 2, it is clear that the plasma oestrogen level reached after implantation is not very constant. In most of the experiments, plasma oestrogen levels were highest during the first month after implantation and gradually decreased thereafter. This might be due to an increase in the oestrogen metabolizing capacity of the liver due to continuous exposure to high levels of oestrogen. On the other hand, it was observed that pellets which were removed from the animal were encapsulated in fibrous tissue, which could have interfered with the transfer of oestrogen from the pellet into the circulation. Pellets prepared by method C which had been implanted for more than 150 days were found to contain still more than half the amount of E_2 originally present (results not shown). The results of our studies with different amounts of E_2 administered in a single pellet (Fig. 1) might reflect that the release of oestrogens was dependent on the surface of the pellet. A dose–response relationship was not observed in this experiment; however, it did occur in the first experiment with E_2B (Table 1), where different amounts of oestrogen were administered by varying the number of the pellets, i.e. a larger amount of oestrogen was administered via a larger surface.

In studying a possible (co)carcinogenic effect of oestrogens by using a synthetic steroid, like EE_2, it is important to consider the possibility that the metabolism of the synthetic steroid may differ from that of natural oestrogens. In order to obtain the results presented in Fig. 2, both E_2 and EE_2 were administered as oestrogen–cholesterol–paraffin pellets containing 1 mg of oestrogen. Yet the E_2 plasma levels rose higher than the EE_2 plasma levels, suggesting a higher metabolism of EE_2. In the human, there appears to be a close similarity between the metabolism of EE_2 and natural oestrogens, at least qualitatively [14]. EE_2 appears to be metabolized slower than E_2. In addition it has been shown [15] that after administration of tritiated EE_2 to women, 8–10% of the radioactivity in the urine could be identified as "de-ethynylated". This de-ethynylation was not observed in incubation studies with rat liver slices [16]. These possible differences between the metabolism of E_2 and EE_2 and the scarcity of data on the metabolism of EE_2 in the rat should be considered when the effects of EE_2 and E_2 are compared.

The occurrence of pituitary tumours in rats following administration of high amounts of oestrogens (Table 2) confirms similar observations of Shellabarger *et al.* [6]. The development of these tumours might have been due to a superstimulation of the prolactin secreting cells in the pituitary. In turn, the prolactin secreted by the hyperplastic pituitary could have caused the initiation of mammary carcinogenesis, since it has been emphasized [17, 18] that prolactin is the main agent in hormonally induced mammary carcinogenesis, whereas oestrogens would act mainly by promoting prolactin secretion. On the other hand, high amounts of oestrogens decrease prolactin binding activity and tumour growth in experimentally (7, 12 dimethylbenz(A)anthracene) induced mammary tumours in the rat [19]. These literature data seem to contradict each other, probably because the exact mechanism of mammary carcinogenesis is as yet ill understood. It has been shown by van der Gugten, Boot, Röpcke and Kwa [20] that a higher dose of oestrogens is required to initiate an elevated prolactin secretion in rats than in mice. Once established, however, a relatively low dose of oestrogen maintains prolactin secretion at a higher level. From the results in Table 1, it can be concluded that the latter situation might prevail in the rats treated with E_2B pellets. In view of these

considerations, it is quite possible that the carcinogenic effect of oestrogens on the mammary gland reported by Segaloff and Maxfield [5]; Shellaberger *et al.* [6] and found in the present study, is an oestrogen mediated prolactin effect rather than a direct effect.

The occurrence of mammary tumours in intact rats and the absence of such tumours in ovariectomized rats in spite of oestrogen administration could suggest the existence of another ovarian factor which is involved in the induction of mammary tumours. In mice and rats a synergistic action of progesterone and oestrone on prolactin-induced mammary tumours has been described [20, 21]. In contrast, others reported that progesterone may protect the mammary gland from becoming neoplastic [22]. Experiments with larger groups of animals are in progress to confirm our observations on the effect of ovariectomy on mammary tumour development and to study the role of prolactin and progesterone in this respect.

Acknowledgements—The anti-ethynyl oestradiol serum for radioimmunoassay was generously provided to us by Dr. K. Fotherby, Hammersmith Hospital and Royal Postgraduate Medical School, London, England. We wish to express our gratitude to Professor Dr. D. W. van Bekkum for stimulating discussions and Professor Dr. C. F. Hollander and Dr. J. D. Burek for histological identification of the tumours.

Tissue Culture and Transplantation Studies on Canine Mammary Carcinoma*

L. N. OWEN, D. R. MORGAN, D. E. BOSTOCK and R. J. FLEMANS

Department of Clinical Veterinary Medicine, University of Cambridge, Great Britain and Department of Haematological Medicine, University of Cambridge, Great Britain

Abstract—*Twenty-three of 27 canine mammary tumours grew in culture following overnight trypsination at room temperature. A solid carcinoma and a tubular adenocarcinoma are probable cell lines. The adenocarcinoma appeared fibroblastic in tissue culture but when transplanted into an immunosuppressed dog produced an adenocarcinoma similar to that in the original dog.*

INTRODUCTION

IN THE bitch malignant mammary tumours account for 25% of all neoplasms. The majority of these are carcinomas and can be subdivided into papillary, tubular, solid and anaplastic types. Other forms such as spindle cell, squamous and mucinous carcinomas may be seen but are rare [1]. Bostock [2] found that invasive carcinomas in the dog have a very poor prognosis, metastasise widely and may provide a good model for breast cancer in women.

The present experiments were designed to provide mammary carcinoma cell cultures for further virological and immunological studies and used tumours similar in morphology to those which have previously been fully described [2].

MATERIAL AND METHODS

Twenty-six primary tumours and one metastatic mammary tumour in the lungs were obtained within a few minutes of mastectomy or euthanasia of the dog. Following dissection of the mass and elimination of necrotic material apparently viable tumour was diced into 1–2 mm pieces and placed in 50 ml of 0.25% trypsin in Hanks BSS at room temperature with stirring. In some cases sufficient cells were obtained in 2 hr and overnight treatment usually resulted in at least 10^8 cells, with a viability between 63 and 90% using the trypan blue exclusion test.

Accepted 13 July 1977.

*This work was supported by a grant from the Cancer Research Campaign, the Medical Research Council and the Leukaemia Research Fund.

†M.R.C. Laboratory Animals Centre, Woodmansterne Road, Carshalton, Surrey.

Medium

The complex medium described by Cailleau *et al.* [3], containing supplements of insulin, cortisol, dexamethasone and glutathione, was used for the majority of primary cultures. Penicillin (200 i.u./ml) and streptomycin (100 μg/ml) were also added since the sterility of surgically excised tumours could not be guaranteed. Some tumours were also grown in TC 199 or RPMI 1640 with the addition of 20% foetal calf serum.

Transplantation into Nude *mice*

Outbred *Nu* mice† were barrier-maintained and bred by crossing male homozygotes *Nu Nu* with female heterozygotes *Nu*+. The offspring were injected with 10^7 or 5×10^7 tumour cells subcutaneously at 6–8 weeks of age [4].

Transplantation into dogs

Neonatal dogs were immunosuppressed with antilymphocyte serum (A.L.S.) as previously described [5] and injected with 8×10^7 epithelial type cells from a solid carcinoma metastatic to lungs. Injections were made at the 18th and 65th passage.

A further neonatal dog was given 25 R whole body X-irradiation on the day of birth and then received A.L.S. three times weekly. In this dog 5×10^8 cells from the fifth passage of a primary tubular adenocarcinoma were injected subcutaneously.

RESULTS

Maintenance in tissue culture

Three out of 27 tumours did not grow and a fourth tumour was heavily overgrown with mould.

Fifteen tumours died out between 2–17 passages and 8 tumours are still alive between 3 and 105 passages.

A solid carcinoma which originated from metastatic tumour in the lung has been in culture for over 2 yr and has been passaged 105 times. The tumour was originally grown in TC 199 medium with 20% foetal calf serum in several flasks. At 6 days one culture flask showed predominantly fibroblastic type cells and another flask predominantly epithelial-type cells. Other flasks were of mixed type. Following the 5th passage at 4 months, rapid growth of the epithelial type cells occurred and was subsequently maintained. After the 25th passage (1 yr) the cells were transferred to the complex medium where the growth rate increased further, the cells at this stage having a doubling time of 4 days and a karyotype of 86 chromosomes (the normal dog cell has 78 chromosomes, 76 of which are acrocentric).

The fibroblastic-type cells were also maintained in culture and were transferred to the complex medium at one year. However, by 14 months the growth-rate slowed and the cultures died out at the 39th passage.

A primary tubular adenocarcinoma was trypsinised overnight and the cells were cultured in the complex medium with 15% foetal calf serum. Growth was very rapid and by the 12th day the culture had reached its 5th passage and consisted of fibroblastic-type cells growing in dense plaques (Fig. 1). The tumour has now been passaged 50 times and has maintained its original morphology *in vitro*. On the 36th passage there was a karyotype of 96 chromosomes (Fig. 2).

Transplantation into Nude *mice*

Following the inoculation of 10^8 epithelial type cells of the solid carcinoma into 2 sites in a *Nude* mouse, tumour nodules became palpable after 22 days at which time the animal was killed. One tumour was used for histochemical studies and the other for growth in tissue culture. Histologically the appearance of the transplanted tumour was similar to the original metastatic solid carcinoma. The cells obtained from the transplanted tumour have been maintained in tissue culture and have a similar appearance and doubling size to those of the original tumour cells maintained *in vitro* throughout. The fibroblastic-type cells from the original solid carcinoma after 10 months in tissue culture were injected into a *Nude* mouse but there was no evidence of nodule formation over a 9-month period.

Tissue culture cells from the tubular adenocarcinoma injected at the 6th passage into a *Nude* mouse produced a 1 cm diameter tumour 55 days after injection. The histological appearance was of a tubular adenocarcinoma with a similar morphology to that of the original canine tumour.

Transplantation into dogs

Solid carcinoma. No detectable growth occurred with cells of the 18th passage in one puppy. In two further puppies injected subcutaneously with cells from the 65th passage tumour-like nodules appeared at 3 months but later regressed.

Tumour 2. By 22 days a tumorous mass (approximately 2 × 2 cm) had developed at the site of injection of the tissue culture cells. The histological appearance of this tumour (Fig. 3) was similar to the original tubular adenocarcinoma (Fig. 4) and cells placed in tissue culture had a similar appearance and doubling time to the cells used in the transplantation.

DISCUSSION

There has been a general lack of success in attempts to establish tumour cell lines from solid specimens of human breast carcinoma but better results have been obtained using pleural effusions [3, 6].

Our experience in dogs indicates that rapidly growing or metastatic tumours are the best starting material. Overnight incubation with trypsin at room temperature has consistently yielded better results than trypsinisation for 1 hr at 37°C or at +4°C overnight. Growth of fibroblasts and epithelial cells appears to vary from flask to flask and if a sufficient number of cells is available, seeding into multiple flasks is recommended.

The cells from the tubular adenocarcinoma which has been described appeared more fibroblastic than epithelial in tissue culture yet produced a typical adenocarcinoma when transplanted into an immuno-suppressed dog. It may be that in some human tumours cells of fibroblastic appearance grow in tissue culture and are wrongly discarded as being stromal cells while in fact they are malignant. Transplantation into *Nude* mice may resolve some of these difficulties.

Acknowledgements—We thank our colleagues who are in practice in many different areas for supplying us with the tumour material.

Letter to the Editor

Effect of the Combination of *Corynebacterium Parvum* and Levamisole on Murine Tumors*

A. ANACLERIO, G. CONTI, M. L. MORAS, C. BARALE and F. SPREAFICO

Laboratory of Immunology and Cancer Chemotherapy, Istituto di Ricerche Farmacologiche "Mario Negri", Via Eritrea, 62–20157 Milan, Italy

MUCH interest is currently centered in the use of non-specific immunostimulants in cancer treatment in view of the effectiveness of this approach when employed simply or in association with chemotherapy, in various experimental tumor models and in at least a number of human malignancies [1–3]. Although many studies are now available on the antitumoral activity of compounds such as BCG, *Corynebacterium parvum* (*C. parvum*) or levamisole (Leva), little attention appears so far to have been devoted to explore the therapeutic potential of combinations of immunostimulants. In view of the fact that quantitative as well as qualitative differences appear to exist in the mode of action of this type of compounds [2, 4], it could in principle be expected that appropriate combinations of immunomodulators may result in additive or synergistic effects. However, since paradoxical effects are often observed with supraoptimal doses of these compounds, the possibility of an immunodepression rather than of a stimulation could also be discussed. In order to obtain at least preliminary information on this problem the therapeutical activity of the *C. parvum*–Leva association was investigated in 2 murine experimental tumors.

The Lewis lung (3LL) carcinoma was maintained and transplanted in compatible C 57Bl/6 male mice; animals were sacrificed 25 days after the i.m. transplant of 2×10^5 line tumor cells and pulmonary metastases were evaluated by the technique of Wexler [5]. The P 815 mastocytoma was maintained in syngeneic DBA/2 mice and 10^6 cells transplanted s.c. in the footpad of compatible B6D2F1 male mice. Animals were obtained from Charles River Italy, Calco, Italy and weighed 20–22 g at the start of the tests.

The dose of *C. parvum* (Wellcome Res. Labs., Beckenham, England) and that of Leva (Janssen Pharma, Beerse, Belgium) employed were 0.7 mg/mouse i.v. and 3 mg/kg i.p., respectively. Both doses have repeatedly been shown to exert optimal antitumoral effects in a large number of mouse cancer systems [2, 6, 7]. Each experimental group consisted of at least 10 animals and the statistical analysis was performed by the Duncan's New Multiple Range Test and Mann-Whitney U. Test. As shown in Table 1 by one representative experiment of the 6 performed, a single injection of *C. parvum* on day 13, i.e. when the primary tumor weight was in the 1.8–2 g range, produced a significant decrease in both the number and weight of pulmonary metastases of 3LL-bearing mice. Conversely, single doses of Leva administered on day 7, 14 or 19 were not significantly effective in these conditions (results are reported only from animals treated with Leva on day 7). When Leva (day 7) preceded *C. parvum* injection on day 13, the activity obtained was equivalent to that seen with the latter agent alone, whereas a significantly greater antitumoral effect was observed when treatment with Leva followed *C. parvum* either by 1 or 6 days. Table 2 presents representative data obtained in the s.c. P 815 mastocytoma model; it may be observed that the treatments of Leva or *C. parvum* alone employed did not significantly prolong survival in these conditions, whereas the combination induced clear increases in lifespan over controls with both time intervals between *C. parvum* and Leva tested. However it is note-

worthy that when 10^4–10^6 P815 mastocytoma cells were transplanted i.p. in the same strain of mice no increase in the survival time was determined by the administration of *C. parvum* and Leva alone or in combination using different schedules.

These data thus show that the combination of *C. parvum* and Leva, both known immunomodulators, can result in increased antitumoral and antimetastatic activity although the experimental conditions seem to play a critical role for the evaluation of these effects.

The mechanism(s) at the basis of this synergistic activity are still unknown. More specifically, it is still undetermined whether the better antitumoral effect seen in these conditions was merely the result of a higher level of immune stimulation than attainable by either drug alone although used in optimal doses as in these experiments, or was the consequence of the stimulation of at least partially independent immune effector mechanisms acting synergistically. It is suggestive in this regard that main target of Leva is believed to be the T lymphocyte [7, 8], a cell lineage whose function is generally depressed by *C. parvum* [9]; the former agent is also generally regarded as acting more as a restorer of a depressed immune capacity rather than as a true immunostimulant [10]. These data however are still too limited to allow conclusions on these points and also at the light of recent findings showing that transient agranu-

locytosis can be associated to Leva administration in man [11], a larger number of experimental studies should be performed before evaluating the therapeutic potential of this agent in combination with other immunostimulants or chemotherapy.

Finally it should be mentioned that this favorable combination could be also related to an interference of *C. parvum* on the metabolism and/or distribution of Leva since it is known that the former agent inhibits liver microsomal enzymes [12].

NEWS FROM E.O.R.T.C.

The E.O.R.T.C. Data Center

M. STAQUET, R. SYLVESTER, D. MACHIN, M. VAN GLABBEKE, G. DE GRAUWE, A. WENNERHOLM, J. TYRRELL, J. RENARD, M. DE PAUW, D. EECKHOUDT, J. TYRRELL and H. J. TAGNON

E.O.R.T.C. Data Center, Institut Jules Bordet, rue Héger-Bordet 1, 1000 Bruxelles, Belgium

1. INTRODUCTION

IN RECENT years there has been an important increase in the number of clinical trials undertaken by the E.O.R.T.C.* clinical groups. The volume of data has become so large that it was felt necessary to have a central body in order to maintain a maximum amount of uniformity in design, follow-up, reporting and analyses. There are currently 23 groups actively engaged in clinical cooperative work. There are, as of 1 May, 1977, 64 clinical studies in progress under the supervision of the E.O.R.T.C. Council [1]. Most of these studies are monitored by the E.O.R.T.C. Data Center whose activities is the design and review of new clinical trials, the design of data forms, data collection, management and storage and final statistical analyses are described in this paper. About 1000 new cases are randomized every year in E.O.R.T.C. studies. A total of approximately 4200 patients from 130 different institutions in 13 countries have so far been entered into cooperative group studies handled by the Data Center.

2. STRUCTURE OF THE DATA CENTER

The E.O.R.T.C. Data Center is under the supervision of the E.O.R.T.C. Council to whom it reports its activities once a year. It is to-day composed of a Director,† 2 senior statisticians, ‡ 1 computer analyst,§ 1 programmer, || 4 data managers¶ and 2 medical secretaries.**

3. THE DESIGN OF A COOPERATIVE TRIAL

A clinical trial is to be considered as a human experimentation limited by ethical considerations. There must be experimental facts and logical arguments indicating that the new modality of treatment might be better than any known therapy for all patients included in the trial. When such a proposition can be made, it is imperative to design the study in such a way that generalization of the conclusions to other patients with the same disease will be possible.

The statistical staff of the E.O.R.T.C. Data Center work with the cooperative groups in the review of new and standard therapies, in selection of prognostic variables for stratification and covariate measurements and in the determination of sample sizes and the duration of the trial.

The design of a trial begins with a review of the principal endpoints and a listing of known prognostic variables for patient response. Depending on what is known about the statistical distribution of the endpoint responses and how they are related to the prognostic variables, one can determine which variables must be used for patient stratification, what will be the most efficient method known for analyzing the data, and either how sensitive a trial of fixed size will be to therapy differences of given orders of magnitude or, for specified minimal differences, how large a trial will have to be to achieve the sensitivity needed to detect these differences.

4. THE PROTOCOL

Once a protocol has been written by an E.O.R.T.C. group, it is submitted to the Data Center who, in conjunction with the Protocol Review Committee, checks it for accuracy, adds paragraphs concerning the registration and

*European Organization for Research on Treatment of Cancer.

†Maurice J. Staquet, ‡Richard Sylvester, David Machin, §Martine van Glabbeke, ||Georgette De Grauwe, ¶Ann Wennerholm, Jane Tyrrell, Josette Renard, Marleen De Pauw, **Dominique Eeckhoudt and Julie Tyrrell.

randomization of patients, the number of patients required, the expected duration of the study and the schedule for submission of forms. The final protocol must contain the following items before distribution to the Protocol Review Committee for final approval:

1. Background and introduction.
2. Purpose of the study.
3. Selection of patients.
4. Design of the study, including a schema.
5. Pretreatment studies.
6. Therapeutic regimens.
7. Toxicity.
8. Follow-up and duration of the study.
9. Criteria of evaluation.
10. Registration and randomization of patients.
11. Submission of forms.
12. Statistical considerations.
13. Administrative responsibilities.
14. References.

Appendices: Performance status scales, TNM classifications.

5. DESIGN OF FORMS

Once the protocol has been finalized, appropriate forms for the study are designed by the data manager together with the study coordinator, statistician and computer analyst. In general, each group requires its own individual set of forms and procedures, but the data forms, the structure of the data files and routine procedures for handling the data for all groups, are standardized as much as possible.

With some modifications the following basic forms are used by all groups:

(i) The registration form (Form I)
(ii) The on-study form (Form II)
(iii) The flow sheet (Form VII)
(iv) The summary form (Form IX)
(v) The progress report form (Form III)

Some groups may require additional forms such as:

(i) Radiotherapy and/or chemotherapy form (Form IV)
(ii) Surgical report form (Form V)
(iii) Measurement form (Form VIII)

Once the forms for a study are designed and typed by the Data Center, they are put into use for a trial period of several months in order to remove any final ambiguities and deficiencies before the final printing.

6. RANDOMIZATION

The basic feature of a randomized clinical trial is the random assignment of patients to different treatment groups. One of the treatment groups is usually a control group. Controls may consist of patients receiving no treatment at all, a standard treatment, or patients receiving the same treatment but a different dose or according to a different schedule. Using a control group chosen by any method other than by randomization requires the assumption that either the control and treatment groups are identical with respect to all important variables except the treatment under study, or that one can correct for any such differences (this assumes that all factors affecting the prognosis are known). Because our knowledge of those factors which may affect response to treatment is always incomplete, randomization is used as a method of assigning treatments to patients which permits valid statistical inferences to be drawn without any special assumptions.

There are three major advantages to randomization:

1. Bias is eliminated from the assignment of treatments.
2. Randomization tends to balance treatment groups with respect to factors related to the patients' prognosis whether or not these factors are known. Different treatment groups must be as similar as possible with regards to all possible factors so that after treatment, if differences in survival or length of remission do exist, these differences can be attributed to the treatment itself.
3. Randomization guarantees the validity of the statistical tests of significance which are used to compare treatments.

For randomized trials a random log must be created before patients can be entered on-study. The log is usually designed in such a way that treatments are balanced between patients from a participating institution and also balanced among important prognostic variables or strata as specified in the protocol. Such a log is created by a standard computer program which allows for the particular features of an individual study.

Randomizations are usually made by institutions telephoning the data managers' office at the Data Center, but can also be made by telex, telegram or letter. The first step in registering a patient for a particular study is for the data manager to check with the caller that the patient satisfies the eligibility criteria specified in the protocol. Once this preliminary check is made, the name of the patient is entered on the next space in the random log under the appropriate institution and stratum. The treatment assigned is then read from the random log and given to the caller. At this stage a "registration form" is completed by the data manager.

The physician in charge of the patient then completes an "on-study form" which contains basic patient information such as previous history, description of the disease and the treatment group assigned by randomization, and sends it to the Data Center, normally within one week of registration. The on-study form serves as a second check as to whether the patient is eligible to enter the study and whether the correct treatment is being given.

7. DATA RECEIPT AND MANAGEMENT

Once a randomization has been completed, a patient file is created by the data manager, in which copies of all forms, correspondence and information concerning a particular patient is kept. Naturally all records are treated strictly confidential. First steps are also taken to create a computer file: each patient is identified by a 15-digit code assigned at the time of registration. This code identifies the particular study, the participating institution, the date of patient registration and the sequence number.

Once a registration has been completed and the patient is "on-study", information is collected periodically on treatment forms and/or flow sheets as long as the patient remains "on-study". These forms are returned to the Data Center at specified intervals and indicate if the treatment has been given in accordance with the protocol, if side effects have been encountered, if consequent dose modifications have taken place and if laboratory and physical examinations have been performed. When a patient goes "off-study", usually either because the treatment period as specified in the protocol has ended, progression, death, or loss to follow-up, a summary form is returned to the Data Center specifying the reasons.

The most important function of the data manager is to review all patient forms that are received for drug toxicity, ambiguities, completeness and protocol violations. In addition, she must also send requests to institutions for overdue forms. This work involves close contact with the participating physicians and detailed knowledge of the individual protocols.

After the completed forms have been received and checked by the data managers, the data are then sent to be punched on cards, either directly from the forms themselves or from coding sheets prepared by the data managers. The punched cards, each of which contains in its first 15 columns the patient code already referred to, are ready to be read by and stored on the computer for eventual recall and processing. Each time a new form is received, it is added to the computer file after verification by the data manager and is further verified for accuracy by the computer itself.

8. PREPARATION OF ADMINISTRATIVE REPORTS

Each E.O.R.T.C. cooperative group meets twice a year. At these meetings, the Data Center presents interim administrative reports and statistical analyses when appropriate. The administrative reports usually include the following information listed separately for each participating institution: total number of patients registered on a particular trial, the numbers in each of the treatment arms, summaries of any toxicities observed, reasons for patients going "off-study" and the number of "overdue" forms.

9. THE COMPUTER

The Data Center uses two large and powerful C.D.C. computers, located at the Université Libre de Bruxelles, for storing, verifying and processing the patient data received. The Data Center requires the use of such computers for two main reasons:

1. The large quantity of data that must be stored and processed.
2. The complexity of the statistical techniques required to analyze the data.

The computer also allows speedy access to the print-out of information for any individual patient, while the graph plotter can produce survival curves in a clear and readily reproducable format.

All patient information received by the Data Center is stored on computer files. For every E.O.R.T.C. study, there is a computer data file, stored on a magnetic disc. Magnetic tape copies of these discs are made as a precaution against loss of data caused by computer breakdowns . . . or human failures. The structure of the data files is completely and clearly described in a special library file called "variable description file".

10. VARIABLE DESCRIPTION FILE

Before the start of any study, the data managers write a "variable description file". This file is a detailed description of the exact piece of information that is to be found on each card of a patient's computer file; for example, the 17th column of every card gives the number of the data form. The variable description file works in the following way: all "on-study forms"

usually contain information on the weight of a patient. If the study involves only mature male patients, then the probable range of weights might be from 50 to 100 kg. This range of weights is included in the "variable description file". The weight of any new patient entered on study is checked against the above range and an error message is printed out by the computer if it is outside this range. The attention of the data manager is then drawn to this item of information and she may find on checking, either a transposition error from the form to the punched card or a physician error in recording the weight. It is only when the correct information is available that the patient record is accepted or put on the computer file. More importantly the "variable description file" is written to examine and verify the most important criteria for a patient's eligibility to enter a particular study.

11. ACCESS TO THE COMPUTER FILES

Access to the computer files can be made in several ways:

(i) By a punch card reader: the cards themselves contain the basic data and/or directions for the computer to execute a particular procedure. The computer "replies" by printing out on a fast printer, usually after some delay. A deck of cards usually contains:
   1. Instructions for the computer (for example: a request that will allow the introduction of some patient information into a computer file).
   2. Data cards (for example: the new information to be introduced).

(ii) By a screeen terminal: instructions or data can be typed on the screen and sent directly to the computer. The results appear either on the screen itself or are directed to a printer, or both. The screen allows one to work in "conversational mode" with the computer giving rapid replies to keyboard instructions. Such a mode allows immediate corrections and amendments to files, retrieval of data and results of statistical analyses (at the speed of 900 characters/sec).

(iii) By a portable teletype, linked to the computer by means of any telephone receiver. This works in the same way as the screen terminal except that results are printed on paper (at the speed of 30 characters/sec).

12. PROCESSING OF THE DATA

Once information has been stored on the computer, it is essential that the computer is able to sort, count, analyze and print summary tables of the data as rapidly as possible. The E.O.R.T.C. Data Center has a system of programs similar to those used in Buffalo, NY, but which have been adapted and extended to the E.O.R.T.C. data processing problems.
The main features of this system are:

1. The data management programs.
   These include:
   (i) The "RANDOM" program that organizes the printing of the random logs, and balances treatments within strata and within participating institutions.
   (ii) The "UPDATE SYSTEM", a system of programs that checks new data and rejects the wrong ones, updates the data files on discs and prints out information helping the data managers to control the status of their computer files. Most of the programs of the "UPDATE SYSTEM" can be used in conversational mode.
   (iii) The "VARIABLE DESCRIPTION FILE UPDATE SYSTEM"..
2. The administrative programs.
   These include:
   (i) The "ADMIN" programs accessible by conversational procedure allows the print out of selected tables, either by study or by institution. For example:
      (a) allocation of treatment by institution;
      (b) patients "on-study", "off-study";
      (c) request of missing forms;
      (d) response to the treatment;
      (e) toxicity by treatment;
      (f) stratification (type of surgery ...);
      (g) sex (response to treatment);
      (h) age (response to treatment);
      (i) type of surgery, etc. ...
      The "ADMIN" program also allows print out of the complete patient record (treatment, randomization date, stratification, etc. ...).
   (ii) The "QUEST" program that allows one to retrieve any set of data for all the patients of a study. This program is accessible by a conversational procedure.
   (iii) The "REQUEST" program that prints forms requested from the computer file.
   Other administrative programs are printing out tables and information specific to particular studies.

3. The statistical programs.
   These include programs to estimate and plot survival (and remission) curves for individual treatments and to test for differences in survival or free interval between different groups of patients.
   Regression programs allow one to assess the influence of prognostic variables by use of different statistical models.
4. The mathematics and numerical analysis programs.
5. The system management programs.
   These are helping to manage discs, tapes and program libraries.

13. THE STUDY COORDINATOR FILE

Copies of each patient's data forms are collected during a trial and placed in a separate file for the study coordinator. Each form in this file is screened by the study coordinator (sometimes a committee is formed for this purpose) and a final decision is made concerning whether a patient is eligible and can be included in the final analysis. Reasons for patient exclusion at this stage vary but might be for example, a protocol violation which is beyond the investigator's control. It is important to stress that this final screening of the data is in the hands of the clinicians directing the trial and is of paramount importance if the published results of the trial are to have validity. It should be noted that no such rigorous screening is performed before interim reports so that care has to be taken not to be unduly influenced by trends suggested by data not so verified.

14. THE FINAL STATISTICAL ANALYSIS

The final analysis contains a detailed review of all aspects of the trial including:

(i) admintrative problems in running the trial;
(ii) verification of initial prognostic variables and examination of potentially new prognostic variables;
(iii) analysis of the principal endpoints of the trial as set out in the protocol.

13. CONCLUSION

In the 3 years that the E.O.R.T.C. Data Center has been in operation, the groundwork has been laid for the provision by an organization devoted full time to E.O.R.T.C., of a wide range of statistical and data processing capabilities oriented towards the special problems arising from cooperative clinical trials.

Perhaps, the primary achievement of the Data Center has been the development of close working relationships with 23 cooperative groups. The total cost and effort involved in developing such capabilities for each group in 13 different countries (Table 1) would have far exceeded the actual cost through the Data Center.

The goal of improving the quality of studies has been achieved (we believe) through the help provided in the planning of studies, the standardization of data handling procedures, the provision of efficient data processing techniques and sophisticated statistical analyses. Further improvements are anticipated through an increased awareness on the part of clinical investigators of the value of a reliable and experienced Data Center devoted to the special problems of clinical research.

Announcements

EUROPEAN PHARMACOKINETICS

E.O.R.T.C. is planning a meeting on pharmacokinetics and metabolism of anticancer agents at the beginning of next year. Investigators interested in this problem are asked to get in touch with Dr. M. Staquet, E.O.R.T.C. Coordinator, Institut Jules Bordet, rue Héger-Bordet 1, 1000 Bruxelles, Belgium (phone: 538.57.90).

FUNDAMENTAL AND PRACTICAL ASPECTS OF THE APPLICATION OF FAST NEUTRONS IN CLINICAL RADIOTHERAPY

A 3rd International Meeting on: "Fundamental and practical aspects of the application of fast neutrons in clinical radiotherapy" will be held on 13–15 September, 1978 in The Hague, sponsored by the Organization for Health Research TNO, The Netherlands.

The purpose of this meeting is firstly to evaluate the clinical experience obtained in recent years about responses of tumours and normal tissues irradiated with high LET radiation, in comparison with responses to conventional types of radiation. Secondly a discussion will be held about the significance of various radiobiological and physical factors which influence the magnitude of possible advantages of high LET radiation. Finally a discussion of protocols for clinical trials is foreseen. This is of special importance because at present protocols of cooperative trials are developed, in the U.S.A. supported by the National Cancer Institute and in Europe by the Neutron Therapy Project Group of the European Organization on Research and Treatment of Cancer.

The meeting can be attended by all who are actively engaged in the clinical application on high LET radiation and in research connected with the subjects described. Presentation of papers will be by invitation only, except that a limited part of the time will be allotted to short communications or to poster sessions about new special developments and results. These communications may have to be limited by the organizing committee.

Registration forms and further information can be obtained from Miss M. C. von Stein, Radiobiological Institute TNO, 151 Lange Kleiweg, Rijswijk, The Netherlands.

G. W. Barendsen, J. J. Broerse and K. Breur
