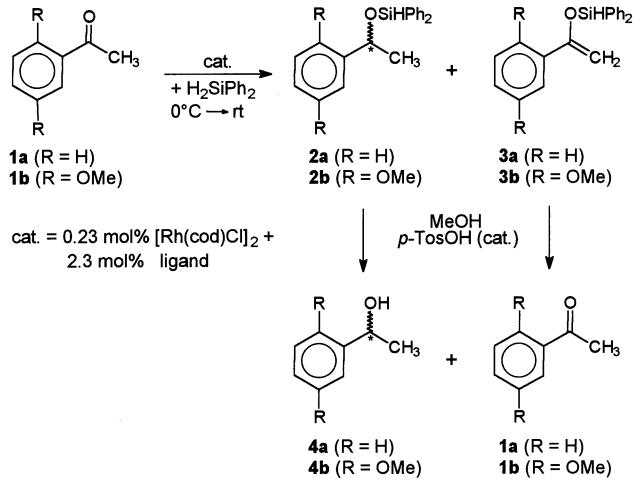
Keywords: Enantioselective hydrosilylation / Oxazoline ligands / Charge-transfer / 4,4-Bipyridine derivatives / 2,5-Dimethoxyacetophenone

Novel *N*′-methylated 2-(oxazolin-2-yl)-4,4′-bipyridinium salts, bearing a chiral oxazoline moiety, were tested in the Rh(I)-catalysed enantioselective hydrosilylation. After coordination to rhodium these electron-attracting ligands are supposed to exhibit charge-transfer effects with electron-donating substrates. Therefore, a new catalytic hydrosilylation reaction with 2,5-dimethoxyacetophenone as an electron-rich substrate was developed. The results were compared with those of the non-methylated 2-(oxazolin-2-yl)-4,4′-bipyridine and related ligands. In addition, the new ligands and Rh(I)-complexes were tested in the hydrosilylation of acetophenone.

Introduction

In the Rh(I)-catalysed enantioselective hydrosilylation of prochiral ketones, the substrate (e.g. acetophenone **1a**) reacts with diphenylsilane to yield the chiral silylalkyl ether **2a** (Scheme 1)[1][2][3]. After hydrolysis the chiral 1-phenylethanol **4a** is obtained. Asymmetric induction is brought about by in situ Rh(I)-catalysts consisting of $[Rh(cod)Cl]_2$ and preferably nitrogen ligands, e.g. chiral oxazolines[4][5][6][7].

Scheme 1



In the preceding paper, we proposed charge-transfer interactions for a possible pre-orientation of the substrate to be hydrosilylated with respect to the catalytic centre. We tried to find evidence for charge-transfer effects in the Rh(I)-catalysed hydrosilylation using the electron-rich 2,5-dimethoxyacetophenone as the substrate. As acceptor with electron-accepting properties we resorted to the Rh(I)-coordinated 2-(oxazolin-2-yl)-4,4′-bipyridinium salts **5**, described in the preceding publication. The adduct catalyst/substrate should resemble the charge-transfer complex paraquat/hydroquinone (both formulas are shown in the preceding paper, see Introduction). In the ligands of type **5** chirality is easily introduced into the oxazoline ring. Ligands **5** contain the same 2-(pyridin-2-yl)oxazoline chelating unit as the ligands of type **6** (Scheme 2), which were

among the first successful chiral nitrogen ligands in enantioselective catalysis[4][8].

To establish charge-transfer effects in the Rh(I)-catalysed enantioselective hydrosilylation, the catalytic results of the ligands of type **5** were compared with those of similar but less electron-accepting ligands. Obvious differences in the optical yield might originate from a charge-transfer mediated pre-orientation.

Hydrosilylation of 2,5-Dimethoxyacetophenone

2,5-Dimethoxyacetophenone (**1b**) has already been tested in the asymmetric hydrosilylation[9] and in two recent papers it has been reduced with chiral auxiliaries[10][11]. A standard procedure for the hydrosilylation of 2,5-dimethoxyacetophenone with diphenylsilane was set up[12], similar to the acetophenone/diphenylsilane system. Since the racemic alcohol **4b** was not well characterised in the literature[13], it was synthesised by reduction of **1b** with KBH_4 in methanol and spectroscopically characterised. The catalytic intermediates **2b** and **3b** were analysed in situ by ^1H NMR spectroscopy. The silylenol ether **3b** originates from the enol tautomer of **1b** and on hydrolysis reverts to the ketone **1b** (Scheme 1). Hence, it reduces the chemical yield of the chiral alcohol **4b**.

For quantification of the catalytic results three parameters were calculated from the ^1H NMR spectra (80 MHz, $CDCl_3$), which were recorded for each catalysis (reproducibility about ±5%): (i) the amount of silylenol ether **3** in the hydrosilylation product: **3**/(**2**+**3**); (ii) the total degree of hydrosilylation (conversion): (**2**+**3**)/(**1**+**2**+**3**) and (iii) the chemical yield of the silylalkyl ether **2**, which on hydrolysis is converted to the chiral product **4**: (**2**)/(**1**+**2**+**3**). The enantiomeric excess of the alcohol **4** was determined by GC with a Chirasil-DEX CB column (reproducibility ±0.5%). The values in the tables were averaged over usually two independent runs, differing in most cases less than 5% (conversion and chemical yield) and 1% (ee), respectively.

To compare the *N*′-methylated ligands **5a−e** with the non-methylated ligands **7a−e** (Scheme 2) each pair was doubly tested in parallel runs. No CCl_4 (see later) was added due to the limited solubility of the ionic compounds **5a−e** in chlorinated solvents. For reaction conditions and results see Table 1.

All the *N*′-methylated ligands **5a-e** induced much higher optical inductions than their non-methylated counterparts **7a−e** (Figure 1). The pair **5c/7c** exhibited the largest difference with an average Δee of about 40%. The degree of hydrosilylation was generally high (>79%), in some cases even quantitative. The amount of silylenol ether scattered around 14−58%.

The non-methylated bipyridines **7a** and **7e** performed much better if CCl_4 was added. No silylenol ether was formed and the optical yield increased remarkably (Table 1). This significant increase in asymmetric induction on conducting the hydrosilylation in CCl_4 is known as the CCl_4 effect[4][14][15] and will be referred to later.

Table 1. Hydrosilylation of 2,5-dimethoxyacetophenone with **5a−e**, **7a−e**, **8e**, **9c** and **9e**; reaction time: 90 h (no solvent) or 18 h (in CCl_4); catalyst: 0.23 mol% $[Rh(cod)Cl]_2$ (0.46 mol% Rh) and 2.3 mol% ligand; substrate/Rh: 214:1

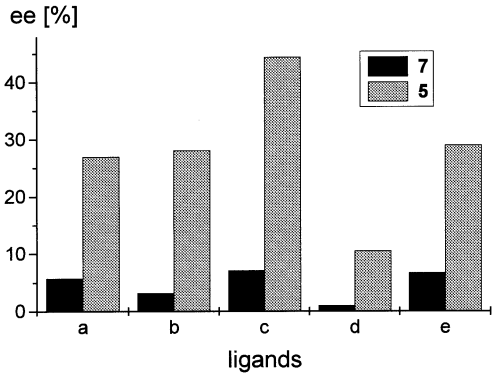
[a] No more diphenylsilane detectable by ^1H NMR spectroscopy (80 MHz, $CDCl_3$).

Figure 1. Comparison of the enantioselectivities of the hydrosilylation of 2,5-dimethoxyacetophenone with the ligands **7a−e** and **5a−e**



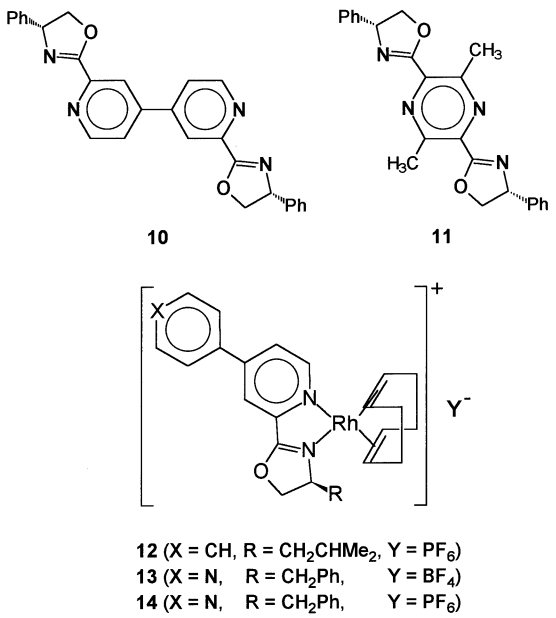
Unexpectedly, the anion exchanged **8e** (hexafluorophosphate instead of iodine in **5e**, Scheme 2) led to a much lower enantioselectivity than **5e** (Table 1), a result which does not fit into the picture of charge-transfer interactions between coordinated ligand and substrate.

The 2-(4-phenylpyridin-2-yl)oxazoline ligands **9c** and **9e** (Scheme 2) are sterically almost identical to **7c** and **7e**, respectively. As they are definitely less electron-attracting than **5c** and **5e**, no charge-transfer effects were expected in the hydrosilylation of 2,5-dimethoxyacetophenone. Surprisingly, both ligands yielded relatively high enantioselectivities (**9c**: 46.3% ee, **9e**: 44.8% ee, Table 1), which are slightly better than the *N*′-methylated ligands **5c** and **5e** and differ markedly from their sterically equivalent 4,4′-bipyridine counterparts **7c** and **7e**. An explanation of these findings might be the free *N*′-position in the ligands **7**. It is known that for the Rh(I)-catalysed hydrosilylation with nitrogen ligands, a ligand excess is beneficial. This points to equilibria involving catalytically active species containing at least two ligand molecules, one of which could be even monodentate[15]. Only the non-methylated ligands **7** can bind via

their free pyridine′ nitrogen and this might result in the low optical yields. Due to the methylation of this nitrogen in **5** and due to the phenyl substituent in **9** the formation of such species is impossible for these ligands.

Also, the bisoxazolines **10** and **11** (Scheme 3) were tested due to their potential charge-transfer properties if coordinated to two Rh-centres. A Rh/ligand ratio of 2:1 was used and CCl_4 was added (no precipitation as with ligands **5a−e** was observed). However, no asymmetric induction was observed with **10** and **11**[12].

Scheme 3



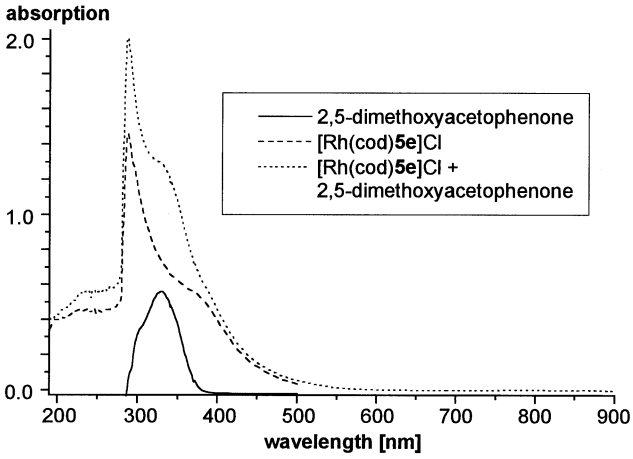
12 (X = CH, R = CH_2CHMe_2, Y = PF_6)
13 (X = N, R = CH_2Ph, Y = BF_4)
14 (X = N, R = CH_2Ph, Y = PF_6)

So far the hydrosilylation results did not provide definitive proof for charge-transfer interactions between coordinated ligand and substrate. Hence, we investigated the absorption behaviour of some presumed catalytic intermediates looking for charge-transfer transitions[16]. The UV spectra of equally concentrated methanol solutions of 2,5-dimethoxyacetophenone, [Rh(cod)**5e**]Cl (prepared in situ), and [Rh(cod)**5e**]Cl + 2,5-dimethoxyacetophenone (1:1) were recorded. 2,5-Dimethoxyacetophenone showed an absorption maximum at 330 nm in accord with the literature[17]. [Rh(cod)**5e**]Cl exhibited a maximum at 287 nm and a shoulder at ca. 380 nm. The spectrum of the 1:1 catalyst/substrate mixture was only a superposition of the compounds′ single spectra. No charge-transfer transitions were found up to 900 nm (Figure 2).

By substituting the electron-rich 2,5-dimethoxyacetophenone for the much less electron-donating acetophenone (to be described next), charge-transfer interactions should be strongly reduced. However, **5e** used as a cocatalyst in the hydrosilylation of acetophenone gave a higher optical induction than the non-methylated **7e** (17.8% compared to 9.6% ee, similar amounts of silylenol ether and chemical yields under identical conditions)[12].

All these experiments showed that the desired charge-transfer interactions, if existent at all, had only little influence on the catalytic results compared to other effects resulting from the nature of the ligands.

Figure 2. UV-Spectra in methanol (ca. 10^{-5} M)



Hydrosilylation of Acetophenone

The new ligands were tested in the hydrosilylation of acetophenone with diphenylsilane in CCl_4. The results of the oxazolines **7a-f** and the bisoxazoline **10** are shown in Table 2. In general good chemical (up to 95%) and optical yields (up to 74% ee) were obtained. In most cases no silylenol ether was formed.

Table 2. Hydrosilylation of acetophenone with **7a-f** and **10**; reaction time: 18 h; catalyst: 0.24 mol% $[Rh(cod)Cl]_2$ (0.48 mol% Rh) and 2.35 mol% ligand; substrate/Rh: 210:1

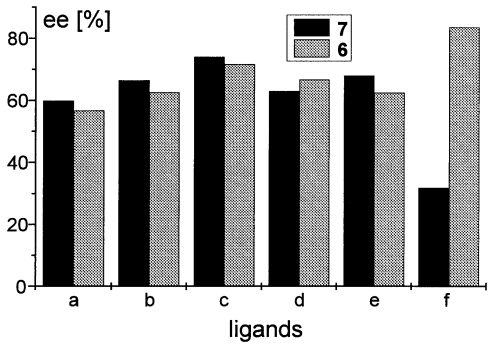
Figure 3 compares the enantioselectivities obtained with the ligands **7a−f** and the reported values (comparable conditions) of the 2-(pyridin-2-yl)oxazolines **6a−f** (Scheme 1)[4].

The 2-(4,4′-bipyridin-2-yl)oxazolines **7a−c** and **7e** induced a slightly higher optical induction compared to the corresponding 2-(pyridin-2-yl)oxazolines **6**. Only **7d** and **7f** performed worse than their counterparts **6d** and **6f**. The results with the *tert*-butyl substituted **7f** were surprising, because the enantiomeric excess dropped appreciably with re-

Figure 3. Comparison of the enantioselectivities of the hydrosilylation of acetophenone with the ligands **7a−f** and **6a−f** (values of **6a−f** taken from the literature[4])



gard to **6f**, which still is the best 2-(pyridin-2-yl)oxazoline for asymmetric hydrosilylation[4].

With the bisoxazoline **10** less than half the optical yield of its mono-oxazoline equivalent **7d** was obtained (Table 2), while the amount of silylenol ether was more than sevenfold. The pyrazine ligand **11** did not yield any optically active product at all (three double experiments with different concentrations of **11**)[12].

It is well known, that Rh(I)-catalysed hydrosilylations with nitrogen ligands tend to give higher chemical and, in particular, optical yields in the presence of CCl_4 ("CCl_4 effect")[4][14][15]. So far the highest increase in the asymmetric induction by conducting the catalysis in CCl_4 has been 18.3% ee compared to toluene solution or the solvent-free procedure[15]. As already mentioned, the bipyridine ligands **7a** and **7e** improved the optical yields in the hydrosilylation of 2,5-dimethoxyacetophenone in CCl_4 by striking 32.7 and 45.4% ee, respectively (Table 1).

Using acetophenone as the prochiral substrate and **7e** as the cocatalyst the optical induction in CCl_4 increased by 58.3% compared to the solvent-free reaction (Table 2). Therefore, we studied the hydrosilylation of acetophenone using the ligand **7e** in other polyhalide solvents (Table 2). None of these solvents increased the enantioselectivity compared to CCl_4. Replacing hexafluorobenzene by pentafluorobenzene the content of silylenol ether decreased from 46 to 11%, while the optical yield increased from 4.3 to 37.1%. In perchloroethylene only racemic alcohol was produced, whereas CCl_3Br totally inhibited the hydrosilylation. This inhibition had been reported for similar reactions[14] and explained by an oxidative addition of CCl_3Br to Rh(I) yielding a catalytically inactive Rh(III)-species.

The activity of in situ catalysts consisting of $[Rh(cod)Cl]_2$ and the 2-(4-phenylpyridin-2-yl)oxazolines **9c** and **9e** depended on the stage, when the additive CCl_4 came into play (Table 3). If the in situ catalyst (always easily recognised by its red colour) was prepared in the presence of CCl_4, no hydrosilylation activity was observed. If the in situ catalyst was prepared in acetophenone and CCl_4 was added later together with the diphenylsilane, smooth reaction took place as usual.

Since the Rh-complex **12** (Scheme 3), containing **9c** as the ligand, had been synthesised (preceding paper), it was tested in three different catalytic runs (Table 3). **12** proved to be a poor catalyst with respect to the chemical and optical yield. However, by adding a fourfold amount of ligand establishing the Rh/ligand ratio of 1:5, a catalytic system resulted, which formed almost no silylenol ether and which gave 74.8% ee, exceeding the asymmetric induction of the in situ system (70.5% ee) to some extent.

Table 3. Hydrosilylation of acetophenone with the ligands **9c**, **9e** and the complexes **12−14**; reaction time: 18 h (if not otherwise stated); 0.48 mol% Rh; substrate/Rh: 210:1

[a] No more diphenylsilane detectable by ^1H NMR spectroscopy (80 MHz, $CDCl_3$). − [b] After 90 h. − [c] Reaction time: 66 h. − [d] Reaction time: 42 h.

All these results show that the inhibition of the catalyst by CCl_4 is only possible during its formation. Once the catalyst is formed, CCl_4 cannot inhibit its activity. Instead, it leads to a lower amount of silylenol ether and a higher enantioselectivity compared to the hydrosilylation without CCl_4 (Table 3). The ″inertness″ of the prepared Rh(I)-complex **12** towards CCl_4 was also proven by recording ^1H NMR spectra of **12** in $CDCl_3$ before and after adding 25 vol% of CCl_4. Even 24 h after the addition no changes of the original spectrum were evident.

Two other Rh(I)-complexes **13** and **14** (Scheme 3) were tested in the hydrosilylation of acetophenone (Table 3). Although they only differ in the nature of their anion, the BF_4-complex **13** gave a much higher optical yield than the PF_6-complex **14**. The enantioselectivities of these complexes (Rh/ligand ratio: 1:1) are quite low compared to the in situ catalysts (Rh/ligand ratio: 1:5). In line with this, addition of a fourfold excess of **7e** to **14** resulted in similar chemical and optical yields as the in situ catalyst of $[Rh(cod)Cl]_2$ and **7e** (Tables 3 and 2).

We thank the *Fonds der Chemischen Industrie* for providing a *Kekulé* scholarship for R.S. and for financial support.

Experimental Section

Chromatography: Merck silica gel 60 (63−200 mesh). − Elemental analysis: Microanalytical Laboratory, University of Regensburg. − ^1H / ^{13}C NMR: Bruker AW-80 (80 MHz, T = 31°C) and AC-250 (250 / 62.9 MHz, T = 24°C), TMS as internal standard. − MS: Finnigan MAT 311 A (EI, 70 eV). − IR: Beckman IR 4240 (film between NaCl plates), only characteristic bands are listed. − UV/Vis: Kontron Instruments Spectrophotometer UVIKON 922. − All liquids were distilled and stored under argon. − η^4-1,5-Cyclooctadiene = cod.

Asymmetric Hydrosilylation of 2,5-Dimethoxyacetophenone: 8 mg (0.016 mmol) of $[Rh(cod)Cl]_2$ (0.032 mmol Rh) and ligand (0.16 mmol, if not otherwise stated) were dissolved in 2,5-dimethoxyacetophenone (1.1 ml, 7.0 mmol) under argon. Eventually, 1.7 ml of CCl_4 were added and the solution was stirred at r. t. for 30 min. After cooling to 0°C for at least 30 min diphenylsilane (1.3 ml, 7.0 mmol) was added and stirring in the ice bath, which was warming-up, continued for the period quoted.

To determine the amount of silylenol ether, the degree of hydrosilylation and the chemical yield, a sample was taken and a ^1H NMR spectrum ($CDCl_3$, 80 MHz) recorded. The following integrals were used: δ = 5.43 (s, Si*H*) and 5.36 (q, C*H*) together (silylalkyl ether I_A), δ = 5.10 and 4.77 (2 d, CH_2) together (silylenol ether I_E), and δ = 2.60 (s, CH_3, 2,5-dimethoxyacetophenone I_{DMAP}). Calculations: silylenol ether [%] = $[I_E/(I_A + I_E)]\cdot 100$, conversion [%] = $[(3\ I_E + 3\ I_A)/(3\ I_A + 3\ I_E + 2\ I_{DMAP})]\cdot 100$, and chemical yield [%] = $[3I_A/(3I_A + 3I_E + 2I_{DMAP})]\cdot 100$.

Hydrolysis was performed by adding methanol (8 ml) and a few crystals of *p*-TosOH. After stirring at r. t. for 30 min the solvents were evaporated. Ca. 0.1 ml of the residue were purified by chromatography (4−5 cm SiO_2 in a Pasteur pipette) with CH_2Cl_2 as eluent (R_f = 0.12). The first fraction (ca. 3 ml) was discarded, the following 10 ml were collected and evaporated. The enantiomeric excess was determined by injecting 0.4 µl of a solution of the resulting oil (1−2 drops) in 1 ml of CH_2Cl_2 (Merck Uvasol®) into a Fisons 8130 gas chromatograph. Column: Chrompack Chirasil-DEX CB (l = 25 m, ⊘ = 0.25 mm), integrator: Varian 4290, retention times (160°C): 8.6−8.8 min [*(R)*-1-(2,5-dimethoxyphenyl)ethanol] and 9.2−9.4 min [(*S*)-1-(2,5-dimethoxyphenyl)ethanol].

1-(2,5-Dimethoxyphenyl)ethenyl Diphenylsilyl Ether (**3b**)[18]. − ^1H NMR (250 MHz, $CDCl_3$): δ = 3.69 (s, 3 H, OCH_3), 3.72 (s, 3 H, OCH_3'), 4.77 (d, ^2J = 1.2 Hz, 1 H, C=C*H*H′), 5.10 (d, ^2J = 1.2 Hz, 1 H, C=CH*H*′), 5.64 (s, 1 H, Si*H*), 6.79−6.81 (m, 2 H, Ar-*H*), 7.15 (m, 1 H, Ar-H), 7.27−7.49 and 7.52−7.71 (m, 10 H, Ph-*H*).

rac-1-(2,5-Dimethoxyphenyl)ethanol (**4b**): 2,5-Dimethoxyacetophenone (1.5 ml, 9.5 mmol) and KBH_4 (800 mg, 14.8 mmol) in dry methanol (10 ml) were stirred for 15 h. After acidifying with 2 N HCl (10 ml) the solution was extracted with ether (3× 10 ml). The combined organic layers were washed with water (10 ml) and brine (10 ml), and dried over $MgSO_4$. Evaporation of the solvent yielded 1.73 g (100%) of the oily alcohol **4b**. − ^1H NMR (250 MHz, $CDCl_3$): δ = 1.48 (d, ^3J = 6.4 Hz, 3 H, CH_3), 2.76 (d, ^3J = 4.8 Hz, 1 H, O*H*), 3.76 (s, 3 H, OCH_3), 3.81 (s, 3 H, OCH_3'), 5.05 (dq, ^3J = 6.4 Hz, ^3J = 4.8 Hz, 1 H, CH_3CHOH), 6.74 (dd, ^3J = 8.7 Hz, ^4J = 2.8 Hz, 1 H, H-4), 6.79 (dd, ^3J = 8.7 Hz, ^5J = 0.8 Hz, 1 H, H-3), 6.94 (dd, ^4J = 2.8 Hz, ^5J = 0.8 Hz, 1 H, H-6). − ^{13}C NMR (62.9 MHz, $CDCl_3$): δ = 23.1 (CH_3), 55.8 and 55.9 (OCH_3), 66.4 (*C*HOH), 111.6 / 112.4 / 112.5 (C-3, C-4, C-6), 134.9 (C-1), 150.7 (C-2), 154.0 (C-5). − MS (EI): *m/z* (%) = 182 (100) [M^+], 167 (95) [$M^+ - CH_3$], 152 (24), 139 (88), 137 (32), 124 (33), 43 (29). − IR (film): $\tilde{\nu}$ (cm^{-1}) = 3400 s (O−H), 2960/2945 s (C−H), 2830 s (OC−H), 1275/1210/1070/1045/1020 s (C−O). − $C_{10}H_{14}O_3$ (182.22): calcd. C 65.91, H 7.74; found C 65.64, H 7.81.

Asymmetric Hydrosilylation of Acetophenone: 10 mg (0.02 mmol) of $[Rh(cod)Cl]_2$ (0.04 mmol Rh) and ligand (0.2 mmol, if not otherwise stated) were dissolved in acetophenone (1.0 ml, 8.5 mmol) under argon. Usually, 2.0 ml of CCl_4 were added and the solution was stirred at r. t. for 30 min. After cooling to 0°C for at least 30 min diphenylsilane (1.6 ml, 8.6 mmol) was added and stirring in the ice bath, which was warming-up, continued for the period quoted.

To determine the amount of silylenol ether, the degree of hydrosilylation and the chemical yield, a sample was taken and a ^1H NMR ($CDCl_3$, 80 MHz) recorded. The following integrals were used: δ = 5.70 ppm (s, Si*H*, silylenol ether I_E), δ = 5.40 (s, Si*H*, silylalkyl ether I_A), and δ = 2.50 (s, CH_3, acetophenone I_{AP}). Calculations: silylenol ether [%] = $[I_E/(I_A + I_E)]\cdot 100$, conversion [%] = $[(3\ I_E + 3\ I_A)/(3\ I_A + 3\ I_E + I_{AP})]\cdot 100$, and chemical yield [%] = $[3\ I_A/(3\ I_A + 3\ I_E + I_{AP})]\cdot 100$.

Hydrolysis was performed by adding methanol (10 ml) and a few crystals of *p*-TosOH. After stirring at r. t. for 30 min the solvents were evaporated and the residue was distilled in a kugelrohr apparatus at 100−120°C / ca. 1 Torr. The enantiomeric excess was determined by injecting 0.4 µl of a solution of the distillate (3−4 drops) in 1 ml of CH_2Cl_2 (Merck Uvasol®) into a Fisons 8130 gas chromatograph. Column: Chrompack Chirasil-DEX CB (l = 25 m, & osol; = 0.25 mm), integrator: Varian 4290, retention times (118°C): 7.3−7.7 min [(*R*)-1-phenylethanol] and 8.0−8.3 min [(*S*)-1-phenylethanol].

Keywords: Steroids / Rhenium / 7α-Substituted testosterone / Androgen receptor / Chelates

In an effort to assist in the preparation of metal-containing ligands for the androgen receptor, we have synthesized the first oxorhenium(V) complexes containing a pendant testosterone moiety. The key step in the synthesis involves the copper-catalysed, α-selective 1,6-Michael addition of a 4-pentenylmagnesium bromide to 6-dehydrotestosterone 17β-acetate. The α-stereoselectivity is governed by the presence of the C-19 methyl group. The absolute configurations of the epimers were investigated by ^{1}H-NMR studies. Further chemical transformations of the 7α-pentenyl spacer introduced the terminal thiol group, needed for complex formation. The complex formation was accomplished by the "3+1" mixed-ligand concept using two different rhenium precursors. The obtained complexes differ with respect to the central donor atom of the tridentate ligand part, namely, S and O.

Introduction

The development of radiolabeled ligands for the androgen receptor may make possible the imaging and detection of androgen-dependent tumors, such as prostate cancer, as well as greatly facilitate the study of androgen action in heterogeneous tissues[1]. Because of its wide availability, convenient half-life and appropriate γ energy, technetium-99m is frequently the radionuclide of choice for diagnostic imaging agents in nuclear medicine[2]. Therefore, the synthesis of technetium- and rhenium-containing steroids that are capable of binding to steroid-hormone receptors with high affinity has been a goal of many investigators[3]. A number of radiolabeled steroid ligands have been prepared as molecular probes for the estrogen and progesterone receptors[4]. A detailed study of the androgen receptor has lagged behind the other sex steroid receptors due in part to the low levels of androgen receptor present in most target tissues, and also to the relatively low stability of this receptor[5][6]. The recent developments of radiolabeled ligands for the androgen receptor involved only syntheses of radiohalogenated, C-11- and 3-H-labeled derivatives of testosterones, 19-nortestosterone and 5α-dihydrotestosterone[6][7][8]. To date, there are no reports using technetium or rhenium as androgen labels.

Recently, it has been shown that the androgen receptor can tolerate a bulky iodide at the 7α position[6]. Moreover, the access to 7α-alkyl and -(phenylalkyl) substituents is well known[9][10]. Therefore, we focused our attention on the introduction of a 7α-alkyl side-chain into the testosterone skeleton bearing a terminal oxorhenium(V) chelate according to the mixed-ligand concept[11][12]. In our preliminary investigations we used rhenium as a surrogate for the radioactive technetium.

Results and Discussion

In this paper we report the synthesis of 17β-hydroxy-7α-(5-mercaptopent-1-yl)-androst-4-en-3-one (**8**) and its conversion into the corresponding oxorhenium(V) "3+1" mixed-ligand complexes. The ω-mercaptoalkyl-functionalized testosterone derivative **8** binds as a monodentate ligand to the oxorhenium(V) core, with the remaining positions at the metal center occupied by a tridentate dithiolate ligand "SXS" . The latter ligand differs with respect to the central donor atom, which can be O or S. The key step of the synthesis of **8** (Scheme 1) involves the diastereoselective introduction of a 4-pentenyl group into the 7α position of the testosterone skeleton. This reaction succeeded by the copper-catalysed, 1,6-conjugate Michael addition of a 4-pentenyl chain to 6-dehydrotestosterone **1**[13]. We used a modification of the procedure by French et al.[10a], replacing pure THF as the solvent and 7 mol-% CuCN (related to 5-bromopentene) instead of a mixture of THF/Et_2O and 0.5 equiv. of CuI. The reaction proceeded with an α/β diastereoselectivity of 4.3:1 which is similar to that of French. The 19β-methyl group in **1** increases the steric bulk of the β face and therefore increases the α selectivity. The separation of both diastereomers of **2** was easily accomplished by flash chromatography to yield the desired diastereomers in 43% (**2a**) and 10% (**2b**). The 4-pentenyl group was used as nucleophilic component containing a masked primary alcohol. This strategy eliminates the need for protecting-group manipulations, contrary to other investigators who have used protected alcohols as nucleophilic compo-

nents[10b][10c]. The following transformation of **2a** into the required alcohol **5** was achieved by subsequent cleavage of the acetyl group of **2a** and introduction of a TBDMS protecting group followed by a hydroboration/oxidation step using 9-BBN, H_2O_2 and NaOH. The regeneration of the enone system in the A ring of **5** was accomplished by oxidation using *N*-bromoacetamide.

The introduction of a thiol group into the steroid molecule succeeded via a thiobenzoate by the Mitsunobu reaction[14] starting from alcohol **5**. This reaction is the method of choice for the introduction of a sulfur moiety under mild conditions in high yield. By treatment of alcohol **5** with the system PPh_3, DIAD and BzSH the thiobenzoate **6** was obtained in a satisfactory yield of 88%. The cleavage of the TBDMS ether in **6** by treatment with TBAF in THF as the otherwise usual TBDMS deprotecting agent failed. The removal of the silyl ether protecting group succeeded in the system 40% HF/acetonitrile in moderate yield of 68%. The last step of the synthesis involves the saponification of **7** by sodium methoxide in MeOH to give the desired thiol **8**. The overall yield for the end product **8** is 12% based on 6-dehydrotestosterone **1**.

The absolute configurations of the chromatographically separated compounds **2a** (7α isomer) and **2b** (7β isomer) were determined by ^{1}H-NMR measurements[10]. These measurements established the chemical shifts and the coupling pattern of the AB part of the 6α-H, 6β-H and 7-H ABX system of both diastereomers **2a** and **2b**. The assignment of 6α-H (**2a**: δ = 2.32, dd, $^2J_{6\alpha6\beta}$ = 14.3 Hz and $^3J_{6\alpha7\beta}$ = 2.5 Hz; **2b**: δ = 2.30, dd, $^2J_{6\alpha6\beta}$ = 14.5 Hz and $^3J_{6\alpha7\alpha}$ = 5.0 Hz) and 6β-H (**2a**: δ = 2.38, dd, $^2J_{6\alpha6\beta}$ = 14.3 Hz and $^3J_{6\beta7\beta}$ = 5.1 Hz; **2b**: δ = 2.18, dd, $^2J_{6\alpha6\beta}$ = 14.5 Hz and $^3J_{6\beta7\alpha}$ = 12.6 Hz) was confirmed by using the 2D-NOESY and COSY technique.

The large $^3J_{\text{axial-axial}}$ coupling constant of 12.6 Hz according to the Karplus curve between 6β-H and 7α-H indicates that the pentyl spacer at the 7-C of **2b** is β-substituted. This led us to the conclusion that compound **2a** therefore must be α-substituted.

The complex formation according to the "3+1" concept by the use of two different rhenium precursors **9**[12] and **10**[15] offers the access to oxorhenium(V) complexes which differ in the central donor atom of the tridentate ligand part, being S for **12** and O for **13**. The corresponding mixed-ligand complexes **12** and **13** could be obtained as reddish-brown and wine-red amorphous glasses in 71% (for **12**) and 14% (for **13**) yield, respectively (Scheme 2).

The common reaction of both the tridentate ligand "SOS" **11** and the thiol **8** with the oxorhenium(V) precursor **10** leads to the complex **13**. This reaction occurs immediately at 0°C due to the high reactivity of rhenium precursor **10**. For the preparation of rhenium complex **12** an alternative route is used, based on the chlorine-containing complex **9** as a precursor. The complex formation by exchange of the chlorine atom in **9** by the mercaptide sulfur of **8** requires heating for 2 hours. In the infrared spectra a strong absorption band at 961 cm^{-1} (for **12**) and 969 cm^{-1} (for **13**) is observed, which is indicative of the $Re{=}O^{3+}$ core. The ^{1}H-NMR spectrum of **12** shows at δ = 3.12, 3.91 and 4.30 complex coupling patterns of the tridendate "SSS" ligand protons. By using the "SOS" ligand resulting in complex **13** only broad signals could be observed.

The complexes **12** and **13** represent the first examples of rhenium-containing androgen receptor ligands. Further investigations concerning the biological evaluation of **12** and **13** and their technetium analogues under in vitro and in vivo conditions will be done in order to evaluate the useful-

Experimental Section

General: Solvents and reagents were purchased from the following commercial sources: Sigma, Fluka and Aldrich. THF was distilled from sodium/benzophenone ketyl prior to use. CuCN and magnesium turnings were dried prior to use. Other reagents were used as received. The synthesis involving air-sensitive compounds were carried out under argon using standard Schlenk technique. The standard workup procedure for product isolation involved quenching of the reaction mixture in an aqueous solution, followed by a thorough extraction with $CHCl_3$, washing of the extract, drying with $MgSO_4$, filtration and evaporation of the solvent under reduced pressure. Flash chromatography was performed according to Still[16], using Merck silica gel (0.040−0.063 mm). − IR: Specord M 80 Carl-Zeiss Jena. − NMR: Bruker DRX-500; Varian Inova-400. For ^1H NMR $CDCl_3$ as solvent $\delta_H = 7.26$; for ^{13}C NMR, $CDCl_3$ $\delta_C = 77.0$. − MS: Finnigan MAT 90.

17β-Acetoxy-7α-(4-penten-1-yl)androst-4-en-3-one (**2a**): 4.51 ml (38.16 mmol) of 5-bromopentene in 15 ml of dry THF was slowly added to 1.29 g (53 mmol) of magnesium turnings under argon. The resulting slurry was diluted with 5 ml of THF and heated for 1 h at 60°C while stirring. Afterwards, additional 60 ml of THF was added to adjust the Grignard solution to 0.75 M. The solution was cooled to −45°C and stirred for 30 min and 245 mg (2.73 mmol) of CuCN was added in one portion and stirring was continued for 30 min. Then 5 g (15.22 mmol) of dienone **1** in 60 ml of THF was added at −40°C over a period of 90 min. The solution was kept at −40 to −45°C for 30 min and then quenched with 5 ml of HOAc followed by filtration of the copper salts and standard workup. The resulting yellow oil contained the two diastereomers **2a** and **2b**. Separation of the diastereomers was accomplished by flash chromatography (EtOAc/*n*-hexane, 5:95). Yield: 2.6 g (43%) of the 7α product **2a** (pale yellow oil) and 0.6 g (10%) of the 7β-product **2b**. − IR ($CHCl_3$): $\tilde{\nu}$ = 1734 cm^{-1} (s, 17β-OAc), 1674 (s, 3-C=O), 1615 (m, C=C). − ^1H NMR ($CDCl_3$): δ = 0.82 (s, 3 H; 18-CH_3), 1.18 (s, 3 H; 19-CH_3), 2.02 (s, 3 H; 17β-$OCOCH_3$), 4.58 (t, ^3J = 8.4 Hz, 1 H; 17-H), 4.91−5.00 (m, 2 H; −CH=CH_2), 5.70 (s, 1 H; 4-H), 5.71−5.76 (m, 1 H; −CH=CH_2). − ^{13}C NMR ($CDCl_3$): δ = 199.0, 171.1, 169.7, 138.5, 125.8, 114.6, 82.4, 47.0, 45.8, 42.4, 38.7, 38.6, 36.6, 36.3, 36.3, 35.9, 33.9, 33.7, 27.3, 26.6, 24.5, 22.8, 21.1, 20.7, 18.0, 11.8. − HRMS (EI, 70 eV): calcd. for $C_{26}H_{28}O_3$ 398.2820, found 398.2812.

17β-Hydroxy-7α-(4-penten-1-yl)androst-4-en-3-one (**3**): 2.6 g (6.5 mmol) of the 17β-acetoxy steroid **2a** was dissolved in 60 ml of MeOH and 30 ml of THF and cooled to 0°C. 30 ml of 1 N NaOH was added drop by drop. The resulting mixture was stirred for 2 h at room temperature and 15 ml of 2 N HCl was added followed by standard workup and flash chromatography (EtOAc/*n*-hexane, 1:2). Yield 1.72 g (75%), m.p. 149−153°C. − IR (KBr): $\tilde{\nu}$ = 3455 cm^{-1} (s, OH), 3077 (w, =C−H), 1658 (s, 3-C=O), 1617 (m, C=C). − ^1H NMR ($CDCl_3$): δ = 0.79 (s, 3 H; 18-CH_3), 1.20 (s, 3 H; 19-CH_3), 3.66 (t, ^3J = 8.4 Hz, 1 H; 17-H), 4.92−5.01 (m, 2 H; CH=CH_2), 5.72 (s, 1 H; 4-H), 5.73−5.80 (m, 1 H; CH=CH_2). − ^{13}C NMR ($CDCl_3$): δ = 199.2, 170.0, 138.6, 125.8, 114.5, 81.6, 47.2, 46.0, 42.8, 39.0, 38.6, 36.6, 36.3, 36.2, 36.0, 34.0, 33.8, 30.3, 26.7, 24.6, 22.8, 20.9, 18.1, 10.9. − $C_{24}H_{36}O_2$ (356.54): calcd. C 80.85, H 10.18; found C 80.50, H 10.14.

17β-(tert-Butyldimethylsilyloxy)-7α-(4-penten-1-yl)androst-4-en-3-one (**4**): 1.24 g (18.2 mmol) of imidazole was dissolved in 12 ml of dry DMF. 1.37 g (9.1 mmol) of TBDMSCl in 6 ml of DMF was slowly added at 0°C. After 30 min, 1.3 g (3.64 mmol) of hydroxysteroid **3** in 5 ml of DMF was added in one portion and the mixture was stirred for 3 h at room temperature. After hydrolysis with a 0.1% K_2CO_3 solution, the mixture was extracted several times with $CHCl_3$, dried with $MgSO_4$ and the solvent was removed under reduced pressure. The residue was purified by flash chromatography (EtOAc/*n*-hexane, 1:3). Yield 1.7 g (98%), m.p. 117−119°C. − IR (KBr): $\tilde{\nu}$ = 3076 cm^{-1} (w, =C−H), 1676 (s, 3-C=O), 1616 (m, C=C). − ^1H NMR ($CDCl_3$): δ = 0.01 [s, 6 H; $Si(CH_3)_2$], 0.75 (s, 3 H; 18-CH_3), 0.88 [s, 9 H; $SiC(CH_3)_3$], 1.20 (s, 3 H; 19-CH_3), 3.57 (t, ^3J = 8.4 Hz, 1 H; 17-H), 4.93−5.01 (m, 2 H; CH=CH_2), 5.72 (s, 1 H; 4-H), 5.75−5.83 (m, 1 H; CH=CH_2). − ^{13}C NMR ($CDCl_3$): δ = 199.3, 170.3, 138.7, 125.8, 114.5, 81.6, 47.3, 45.6, 43.2, 39.1, 38.7, 36.7, 36.6, 36.4, 36.0, 34.1, 33.9, 30.7, 26.8, 25.8, 24.6, 22.9, 20.9, 18.1, 18.1; 11.2, −4.5, −4.8. − $C_{30}H_{50}O_2Si$ (470.81): calcd. C 76.53, H 10.70; found C: 76.35, H 10.46.

17β-(tert-Butyldimethylsilyloxy)-7α-(5-hydroxypent-1-yl)androst-4-en-3-one (**5**): 1.7 g (3.6 mmol) of the steroid **4** was dissolved in 15 ml of dry THF and cooled to 0°C. 44 ml of 9-BBN (0.5 M in THF; 22 mmol) was added dropwise to the stirred solution under argon. After the addition of 9-BBN was complete, the whole mixture was stirred at 60°C for 40 min. At 0°C 15 ml of water was added, followed by 15 ml of 3 N NaOH 5 min later. After another 5 min, 15 ml of 30% H_2O_2 was added very carefully and the mixture was stirred for 30 min. After standard workup using saturated $NaHCO_3$ solution a colorless oil containing the 3-hydroxy-7α-hydroxypentyl steroid was obtained. The residue was dissolved in a mixture of 13 ml of benzene and 26 ml of pyridine, and 0.75 g (5.43 mmol) of *N*-bromoacetamide was added. This was stirred overnight at room temperature. Standard workup involved treatment with 1 N HCl and flash chromatography (EtOAc/*n*-hexane, 1:1). Yield 1.2 g (68%), pale yellow oil. − IR ($CHCl_3$): $\tilde{\nu}$ = 3412 cm^{-1} (s, OH), 1673 (s, 3-C=O), 1614 (m, C=C). − ^1H NMR ($CDCl_3$): δ = −0.02 [s, 6 H; $Si(CH_3)_2$], 0.71 (s, 3 H; 18-CH_3), 0.84

[s, 9 H; $SiC(CH_3)_3$], 1.17 (s, 3 H; 19-CH_3), 3.53 (t, ^3J = 8.4 Hz, 1 H; 17-H), 3.59 (t, ^3J = 6.6 Hz, 2 H; CH_2OH), 5.68 (s, 1 H; 4-H). − ^{13}C NMR ($CDCl_3$): δ = 199.4, 170.5, 125.6, 81.5, 62.7, 47.3, 45.5, 43.1, 39.0, 38.6, 36.7, 36.6, 36.3, 35.9, 33.9, 32.6, 30.6, 27.1, 25.9, 25.8, 24.9, 22.8, 20.9, 20.5, 18.0, 18.0, 11.1, −4.6, −4.9. − LRMS (DCI positive, isobutane) for $C_{30}H_{52}O_3Si$: 489 [M+1].

7α-[(S)-5-Benzoylthiopent-1-yl]-17β-(tert-butyldimethylsilyloxy)androst-4-en-3-one (**6**): 880 µl (4.1 mmol) of 90% diisopropyl azodicarboxylate (DIAD) was added to an efficiently stirred solution of 1.08 g (4.1 mmol) of PPh_3 in 11 ml of dry THF at 0°C. The mixture was stirred at 0°C for 30 min and a white precipitate resulted. 1 g (2.05 mmol) of the hydroxy steroid **5** and 532 µl (4.1 mmol) of 95% thiobenzoic acid in 6 ml of dry THF were added dropwise over a period of 10 min and stirring of the mixture was continued for 1 h at 0°C and for 1 h at room temperature. To the resulting yellow solution 100 ml of $CHCl_3$ was added and the mixture was washed with saturated $NaHCO_3$ solution. After drying with $MgSO_4$ and evaporation of the solvent, a pale yellow residue was obtained which was purified by flash chromatography (EtOAc/*n*-hexane, 1:3). Yield 1.1 g (88%), pale yellow oil. − IR ($CHCl_3$): $\tilde{\nu}$ = 1666 cm^{-1} (s, 3-C=O), 1615 (m, C=C). − ^1H NMR ($CDCl_3$): δ = −0.02 [s, 6 H; $Si(CH_3)_2$], 0.73 (s, 3 H; 18-CH_3), 0.87 [s, 9 H; $SiC(CH_3)_3$], 1.18 (s, 3 H; 19-CH_3), 3.05 (t, ^3J = 7.3 Hz, 2 H; CH_2SBz), 3.56 (t, ^3J = 8.4 Hz, 1 H; 17-H), 5.71 (s, 1 H; 4-H), 7.41−7.97 (m, 5 H; $H_{aromat.}$). − ^{13}C NMR ($CDCl_3$): δ = 199.1, 191.9, 170.2, 137.1, 133.2, 128.5, 127.1, 125.7, 81.5, 47.3, 45.6, 43.1, 39.0, 38.6, 36.7, 36.6, 36.3, 35.9, 34.0, 30.6, 29.6, 29.3, 28.9, 26.9, 25.8, 24.9, 22.9, 20.9, 18.0, 18.0, 11.1, −4.6, −4.9. − LRMS (DCI positive, isobutane) for $C_{37}H_{56}O_3SSi$: 609 [M+1].

7α-[(S)-5-Benzoylthiopent-1-yl]-17β-hydroxyandrost-4-en-3-one (**7**): 3.5 ml of 40% aqueous HF was added to a solution of 0.9 g (1.48 mmol) of the steroid **6** in 20 ml of acetonitrile at room temperature. After stirring 1 h at room temperature, 20 ml of saturated $NaHCO_3$ solution was added and the product was extracted with $CHCl_3$. After drying with $MgSO_4$ and evaporation of the solvent, flash chromatography (EtOAc/*n*-hexane, 1:1) was used to isolate pure **7**. Yield 0.5 g (68%), m.p. 129−133°C. − IR (KBr): $\tilde{\nu}$ = 3060 cm^{-1} (w, =C−$H_{aromat.}$), 1662 (s, 3-C=O), 1615 (m, C=C). − ^1H NMR ($CDCl_3$): δ = 0.78 (s, 3 H; 18-CH_3), 1.19 (s, 3 H; 19-CH_3), 3.05 (t, ^3J = 7.3 Hz, 2 H; CH_2SBz), 3.64 (t, ^3J = 8.4 Hz, 1 H; 17-H), 5.71 (s, 1 H; 4-H), 7.41−7.97 (m, 5 H; $H_{aromat.}$). − ^{13}C NMR ($CDCl_3$): δ = 199.2, 192.0, 170.0, 137.1, 133.2, 128.5, 127.1, 125.8, 81.6, 47.1, 46.0, 42.8, 39.0, 38.6, 36.6, 36.3, 36.2, 35.9, 34.0, 30.3, 29.6, 29.0, 28.9, 26.9, 24.9, 22.8, 20.9, 18.0, 10.9. − $C_{31}H_{42}O_3S$ (494.74): calcd. C 75.26, H 8.56, S 6.48; found C 74.85, H 8.28, S 6.31.

17β-Hydroxy-7α-[5-mercaptopent-1-yl]androst-4-en-3-one (**8**): 70 mg (0.14 mmol) of the thiobenzoate **7** was dissolved in 4.5 ml of MeOH while stirring at room temperature under argon. To this solution 280 µl (0.28 mmol) of 1 N NaOMe was added. After 1.5 h, the pH was adjusted to 4−5 by 1 N HCl. Then, 5 ml of water was added and the solution was extracted with chloroform. Drying with $MgSO_4$ and evaporation of the solvent yielded a yellow residue which was purified by flash chromatography (EtOAc/*n*-hexane, 1:1). Yield 52 mg (95%), m.p. 150−153°C. − IR (KBr):$\tilde{\nu}$ = 3449 cm^{-1} (s, OH), 2551 (w, S−H), 1656 (s, 3-C=O), 1616 (m, C=C). − ^1H NMR ($CDCl_3$): δ = 0.79 (s, 3 H; 18-CH_3), 1.21 (s, 3 H; 19-CH_3), 1.59 (s-like, 1 H; SH), 3.76 (m, 1 H; 17-H), 5.72 (s, 1 H; 4-H). − ^{13}C NMR ($CDCl_3$): δ = 199.2, 170.0, 125.8, 81.7, 47.2, 46.0, 42.8, 39.0, 38.7, 36.7, 36.3, 36.2, 36.0, 34.0, 33.9, 30.3, 28.0, 26.9, 25.0, 24.6, 22.8, 20.9, 18.1, 10.9. − $C_{24}H_{38}O_2S$ (390.63): calcd. C 73.79, H 9.81, S 8.21; found C 73.54, H 10.06, S 7.86.

[5-(17β-Hydroxy-3-oxoandrost-4-en-7α-yl)pentan-1-thiolato]-oxo(3-thiapentane-1,5-dithiolato)rhenium(V)rhenium(V) (**12**): 78 mg (200 µmol) of chloro(3-thiapentane-1,5-dithiolato)oxorhenium(V) (**9**) was dissolved in 5 ml of hot acetonitrile while stirring. To this mixture a solution of the steroid **8** (117 mg, 300µmol) in 5 ml of acetonitrile was added . The mixture was refluxed for 2 h and then concentrated to dryness. The residue was purified by flash chromatography [*n*-hexane/ethylacetate, 1:1 and chloroform/methanol, 10:1]. After slow evaporation of the solvent, a brown glass was obtained. Yield 106 mg (71%). − IR (KBr): $\tilde{\nu}$ = 3437 cm^{-1} (s, OH), 1658 (s, C=O), 1613 (m, C=C), 961 (s, Re=O). − ^1H NMR ($CDCl_3$): δ = 0.79 (s, 3 H; 18-CH_3), 1.19 (s, 3 H; 19-CH_3), 3.12 (tt, 2 H, *J* = 14.3 Hz), 3.65−3.67 (m, 1 H; 17-H), 3.84 (t, 2 H, ^3J = 7.3 Hz; CH_2SReO"SSS"), 3.91 (br. d, 2 H, *J* = 10.2 Hz), 4.30 (br. d, 2 H, *J* = 13.2 Hz), 5.72 (s, 1 H; 4-H). − MS (FAB negative, tetraglyme); *m/z* (%): 741 (47.6), 742 (19.0), 743 (100) [M − 1], 744 (28.6), 745 (19.0), 746 (3.8). − $C_{28}H_{45}O_3S_4Re$ (744.13): calcd. C 45.20, H 6.10, S 17.24; found C 44.97, H 6.04, S 16.94.

[5-(17β-Hydroxy-3-oxoandrost-4-en-7α-yl)pentan-1-thiolato](3-oxapentane-1,5-dithiolato)oxorhenium(V) (**13**): 75 mg (128 µmol) of tetra-*n*-butylammonium tetrachlorooxorhenate(V) (**10**) was dissolved in 2 ml of EtOH and cooled to 0°C. At this temperature 50 mg (128 µmol) of the steroid **8** and 15 µl (128 µmol) of 3-oxapentane-1,5-dithiol (**11**) in 2 ml of chloroform was added while stirring. The color of the mixture immediately changed to red. The reaction mixture was stirred at 0°C for 2 h. The solution was then concentrated and the residue dissolved in chloroform yielding a red solution which was purified by flash chromatography [*n*-hexane/ethylacetate, 1:1 and chloroform/methanol, 10:1]. After slow evaporation of the solvent, a wine-red glass was obtained. Yield 13 mg (14%). − IR (KBr): $\tilde{\nu}$ = 3436 cm^{-1} (s, OH), 1659 (s, 3-C=O), 1613 (m, C=C), 969 (s, Re=O). − ^1H NMR ($CDCl_3$): δ = 0.79 (s, 3 H; 18-CH_3), 1.20 (s, 3 H; 19-CH_3), 2.87 (br. s, 1 H), 3.35 (br. s, 2 H), 3.52 (br. s, 2 H), 3.65−3.71 (m, 4 H), 3.94 (br. s, 1 H), 4.61 (br. s, 1 H), 4.70 (br. s, 1 H), 5.73 (s, 1 H, 4-H). − MS (FAB negative, tetraglyme); *m/z* (%): 725 (45.7), 726 (47.6), 727 (100) [M − 1], 728 (81.9), 729 (35.2), 730 (11.4). − $C_{28}H_{45}O_4S_3Re$ (728.05): calcd. C 46.19, H 6.23, S 13.21; found C 45.96, H 6.52, S 12.97.

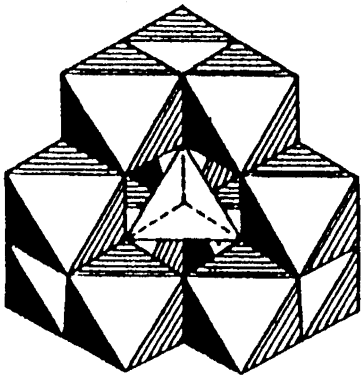
Keywords: Aluminium hydroxide chloride / Crystal structure / Tridecameric cation / Structure of cation / Formation

A basic aluminium chloride with high chlorine content (basicity 1.85) has been crystallized from a concentrated aqueous solution. Its crystal structure has been determined by X-ray structure analysis. The structure contains tridecameric cations of a novel type consisting only of interconnected AlO_6 octahedra. The formation of these polycations is discussed.

The structures of complex cations of basic aluminium chlorides, formed by hydrolysis and condensation, as well as the conditions of their formation, are of special interest because of their occurrence in natural water and their applications as antiperspirants and in water purification. Detailed information concerning the structures of similar complex cations has been provided by the crystal-structure analyses of basic aluminium sulfates and selenates carried out by Johansson and co-workers. They demonstrated the existence of a dimeric species[1] $[Al_2(OH)_2(H_2O)_8]^{4+}$, consisting of two octahedrally coordinated Al centres connected by a common edge (di-μ-OH^- bridge), and of a polycation $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$ (Figure 1) with a Keggin-type structure.[2] The latter structure is characterized by a particular resonance shift in its ^{27}Al-NMR spectrum, even in solutions of basic aluminium chlorides,[3] caused by the tetrahedrally coordinated, central aluminium, which is surrounded by 12 other octahedrally coordinated Al atoms. Various crystalline basic aluminium chlorides have been prepared from solutions by Walter-Levy and Breuil.[4] The crystalline phases were characterized by means of X-ray powder analysis and their thermal decomposition was investigated. The powder diagrams of some of these crystalline phases were unambiguously indexed and the lattice constants were determined. This is also the case for a cubic phase prepared at Dow Chemical Co.[5] However, as far as we are aware, results of crystal structure analyses have hitherto not been reported.

In this paper, we report on a structure analysis of the most chlorine-rich of the basic aluminium chlorides described by Walter-Levy and Breuil.[4][6] These authors obtained the salt as a crystalline precipitate that formed after several days following dilution and storage of concentrated basic aluminium chloride solutions. Suitable monocrystals for our structure analysis were obtained serendipitously, in the course of studies on the colloid structures of basic aluminium chlorides. Colloid solutions with an Al:Cl ratio in the range 1−2 tend to form gels after evaporation of the solvent, and these were the subject of rheological and light-scattering investigations[7]. In basic aluminium chloride solutions, besides the aforementioned monomeric, dimeric and tridecameric species, further oligomeric and polymeric cations exist. To date, only vague statements have been made regarding their size and shape.[3] For comparison, we also studied solutions rich in chloride. It was known that crystalline phases could be precipitated from such media. After very slow evaporation of water from a concentrated solution of a basic aluminium chloride with an Al:Cl ratio of 0.7, besides very large crystals of $AlCl_3 \cdot 6H_2O$, crystals of another phase grew, which were the subject of our investigations.

Figure 1. Tridecameric cation after Johansson[2]



Results and Discussion

The lattice constants of the formed monocrystal were determined by means of single-crystal X-ray diffractometry. On the basis of the monoclinic unit cell obtained, the unindexed powder data reported by Breuil for the hydroxide chloride 5 $AlCl_3 \cdot 8\ Al(OH)_3 \cdot 37.5\ H_2O$[8] become indexable. Therefore, we conclude that a crystal of this phase was pre-

sent. The results of its X-ray structure analysis confirmed this assertion, although not all the positions of the hydrogen atoms could be determined. The water content in the formal unit was found to be slightly lower than reported, being consistent with the composition 5 $AlCl_3 \cdot 8\ Al(OH)_3 \cdot 37\ H_2O$. The cell contains 4 formal units. The atomic positions determined in the structure analysis show two analogous types of large units, built up from connected AlO_6 octahedra (Figure 2). Two of each kind are present in the unit cell. The chlorine atoms are situated outside of these complex units, along with the oxygen and hydrogen atoms obviously belonging to water molecules. Considering the charges (Al^{3+}, Cl^-), the large units must be viewed as polycations. Each polycation consists of 13 octahedra (Figure 3): a central one, 6 further octahedra surrounding the central unit and connected to it by common edges, and finally 6 peripherally arranged octahedra, with each one joined to the inner ring by two common corners. The Al^{3+} ion in the central octahedron lies at an inversion centre of the space group, and thus the polycations are centrosymmetric. The central Al^{3+} and the 6 Al^{3+} of the ring are coplanar and together form a centred, almost regular, hexagon. The oxygen positions correspond to octahedra with varying degrees of distortion. The Al−O distances in the central octahedron are virtually equal (188−189 pm), and the O−Al−O angles are approximately equal (97°), but differ from the octahedral ideal of 90°. The ring octahedra are distorted to a greater extent. The peripheral octahedra occupy alternate positions above and below the plane of the hexagon. Accordingly, they show a certain degree of deformation; the Al−O distances to the free corners are obviously longer than those to the corners that are shared with the adjacent octahedra. Since not all of the hydrogen atom positions could be determined, the question remains as to which oxygen atoms the hydrogen atoms should be assigned so as to form hydroxide ions or water molecules. Consideration of the charges may elucidate this matter. In the polycation, we find 13 Al^{3+} ions with 39 positive charges. On the other hand, there are 15 Cl^- ions, giving 15 negative charges per polycation. This leaves 39 − 15 = 24 negative charges in the polycation to account for. This number corresponds to the number of linkage oxygen atoms. We can thus assume that these oxygen atoms belong to hydroxide ions. Water molecules must then be present at the 24 free corners of the peripheral octahedra. An additional 13 water molecules are situated outside of the polycation. The basic aluminium chloride investigated can therefore be assigned the formula $[Al_{13}(OH)_{24}(H_2O)_{24}]Cl_{15} \cdot 13\ H_2O$.

Hence, a further tridecameric cation species has been detected in addition to Johansson′s tridecamer. The new species is characterized by a single resonance of octahedrally coordinated Al in its ^{27}Al-NMR spectrum and needs to be formally distinguished from the previously identified species. The notation Al_{13} is no longer unambiguous. It seems reasonable to distinguish the two tridecameric species by using an auxiliary index that denotes the different coordination of the central aluminium: $Al_{13}{}^t$ (t: tetrahedral) for the Johansson species and $Al_{13}{}^o$ (o: octahedral) for the new structure. The two tridecamers have OH^- ($Al_{13}{}^o$) or O^{2-} groups ($Al_{13}{}^t$) that form a common vertex of three octahedra. Therefore, Brown et al.[9] and Baes and Mesmer[10] discuss the formation of $Al_{13}{}^t$ in terms of the assembly of trimers $[Al_3(\text{tri-}\mu\text{-}OH)(OH)_3(H_2O)_9]^{5+}$ (Figure 4), which are in turn formed by the condensation of a dimer $[Al_2(OH)_2(H_2O)_8]^{4+}$ with a monomer $[Al(OH)(H_2O)_5]^{2+}$. It has been assumed that the Keggin tridecamer is formed by the reaction of the hydroxide ions of an $[Al(OH)_4]^-$ anion with the nucleophilic tri-μ-OH^- of trimeric units, building up a tetrahedral arrangement of linking oxygen ions with the liberation of water. In our tridecamer $Al_{13}{}^o$, there are OH^- groups that connect three octahedra. The central Al^{3+} is surrounded by six tri-μ-OH^-. The formation of this polycation structure can also be envisaged as starting from trimers, formed by condensation of dimeric and monomeric

Figure 2. Crystal structure of $[Al_{13}(OH)_{24}(H_2O)_{24}]Cl_{15} \cdot 13\ H_2O$; section of the unit cell: polycations with centres in $z = 1/2$

units. However, in this case, the process continues with the addition of other dimers, which condense together after further protolysis and form the ring surrounding the central atom. The peripheral octahedra could clearly be attached subsequently by the condensation of monomer units with the compact planar core.

Experimental Section

General: The Al_{13}° hydroxide chloride was crystallized from a basic aluminium chloride solution with an Al/Cl ratio of 0.7. The solution was prepared by dissolution of partially thermally decomposed $AlCl_3 \cdot 6\ H_2O$ in hot water (80°C) at a mass ratio of solid material/water of 1:1. The thermal decomposition of the starting material was carried out at about 180°C in a whirling air stream. The solution was placed in an open dish at ambient temperature. After 4 months, well-grown crystals of suitable dimensions for X-ray structure analysis were obtained. The quality of separated crystals was tested by polarization microscopy. Solid-state ^{27}Al-NMR analysis was performed with a Bruker MSL300 instrument at a frequency of 15 KHz.

X-ray Crystallographic Study: T = 295°C; crystal size 0.20 × 0.20 × 0.15 mm, formula weight 1957.27, monoclinic, space group $P2_1/c$, a = 13.901(1), b = 23.483(3), c = 22.345(2) Å, β = 90.36(1)°, V = 7294.1(12) Å^3, Z = 4, $D_{calcd.}$ = 1.782 g cm^{-3}. Enraf-Nonius CAD4 diffractometer, graphite-monochromated Cu-K_α radiation (λ = 1.5418 Å), F(000) = 4040, μ = 7.736 cm^{-1}, ω-2θ scan, scan range (θ) 2.73−74.73°, *hkl* range +17, +29, ±27, no. of unique reflections 14942, no. of observed reflections 11292 with $I > 2\sigma(I)$, refined parameters 903, $R1$ for observed reflections 0.00527, $R1$ for all reflections 0.0776, $wR2$ for observed reflections 0.1341, $wR2$ for all reflections 0.1497, GooF = 1.077 for the observed and GooF = 1.025 for all reflections, residual electron density 0.80/−0.62 e Å^{-3}. The structure was solved by direct methods (SHELXS-86) and refined by full-matrix least-squares methods with SHELXL-93. DIFABS was used for empirical absorption correction. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-408095.

Keywords: Aminoalcohol ligands / Hydrogen bonds / Magnetic properties / Oxo complexes / Vanadium

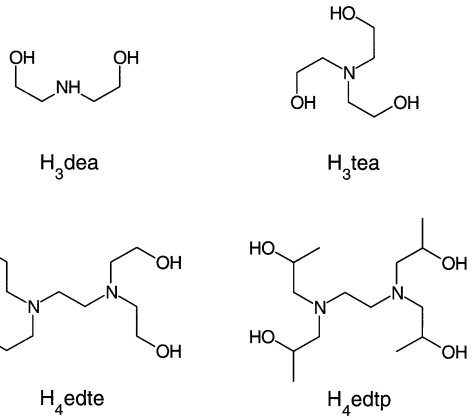
The aminoalcohol ligands diethanolamine (H_2dea) and triethanolamine (H_3tea) react with $[VO(acac)_2]$ to yield the tetranuclear oxovanadium(IV) complexes $[\{VO(dea)\}_2\{VO(acac)\}_2(\mu_2\text{-}OMe)_2]$ (**1**) and $[\{VO(Htea)\}_2\{VO(acac)\}_2(\mu_2\text{-}OMe)_2]$ (**2**). In the case of the potentially bridging aminoalcohol ligands *N,N,N′,N′*-tetrakis(2-hydroxyethyl)ethylenediamine (H_4edte) and *N,N,N′,N′*-tetrakis(2-hydroxypropyl)ethylenediamine (H_4edtp) the corresponding oxovanadium(IV) complexes could not be isolated. Instead after air oxidation the ligand supported binuclear oxovanadium(V) complexes $[\{VO(acac)\}]_2(edte)]$ (**3**) and $[\{VO(acac)\}_2(edtp)]$ (**4**) are obtained. The reaction of the ligand H_4edtp with ammonium *meta*-vanadate in methanol solution leads to the methoxy bridged binuclear oxovanadium(V) complex $[(VO)_2(edtp)(\mu_2\text{-}OMe)_2]$ (**5**). The tetranuclear oxovanadium(IV) complexes can be isolated as crystalline compounds **1**·2 MeOH and **2**·2 MeOH and have been characterized by IR, UV/Vis, and ESR spectroscopy as well as cyclic voltammetry and magnetic susceptibility measurements. Single-crystal diffraction studies reveal that the complexes **1** and **2** contain a tetranuclear $\{(VO)_4(\mu_3\text{-}OR)_2(\mu_2\text{-}OR)_4\}^{2+}$ core composed of three different types of edge-shared binuclear units, whereas the oxovanadium(V) complexes **3**, **4**, and **5** posses binuclear structures, that are either ligand supported as in the case of **3** and **4** or contain a μ_2-methoxy bridged $\{(VO)_2(\mu_2\text{-}OR)_2\}^{4+}$ core as in the case of **5**. ESR and magnetic data indicate a singlet ground state for **1**·2 MeOH and **2**·2 MeOH, although competing ferromagnetic exchange interactions are operative within the tetranuclear core structure. In the solid state compounds **1**·2 MeOH and **2**·2 MeOH hydrogen bridged supramolecular structures are found. The hydrogen bonding scheme of both compounds leads to the formation of a similar chain arrangement of the tetranuclear complexes **1** and **2**.

Introduction

The increasing interest in vanadium coordination chemistry is based on its well established biological function in the oxidations states +4 and +5, e.g. as essential element for enzymatic systems like vanadium-requiring haloperoxidases and nitrogenases and the insulin-mimetic action of vanadium compounds[1]. Related with this biological aspects the coordination chemistry of oxovanadium(IV) and -(V) complexes with aminoalcohols has found special attention[2][3][4][5]. In addition the coordination chemistry of oxovanadium(IV) complexes with aminoalcohols offers easy access to model systems for the magnetic behavior of corresponding polynuclear complexes and has already led to a magnetostructural relationship for such systems[6][7]. Similarly to the well established tris(hydroxymethyl)alkane family of ligands[8] aminoalcohols can be utilized as bridging units in the formation of higher nuclear oxovanadium(IV) complexes[9].

The present study describes a synthetic approach to oxovanadium(IV) and -(V) complexes with potentially bridging and/or chelating aminoalcohol ligands depicted in Scheme 1. Besides the structural and spectroscopic characterization of these complexes special emphasis is placed on their electrochemical and magnetic properties.

Scheme 1. Aminoalcohol ligands used in this study[a]



H_3dea H_3tea H_4edte H_4edtp

[a] Abbreviations: H_2dea = diethanolamine; H_3tea = triethanolamine; H_4edte = *N,N,N′,N′*-tetrakis(2-hydroxyethyl)ethylenediamine, H_4edtp = *N,N,N′,N′*-tetrakis(2-hydroxypropyl)ethylenediamine.

Results and Discussion

Syntheses

In methanol solution the aminoalcohol ligands diethanolamine (H_2dea) and triethanolamine (H_3tea) react with $[VO(acac)_2]$ (Hacac = 2,4-pentanedione) to form the neu-

tral tetranuclear oxovanadium(IV) complexes [{VO(dea)}$_2$-{VO(acac)}$_2$(μ_2-OMe)$_2$] (**1**) and [{VO(Htea)}$_2${VO(acac)}$_2$-(μ_2-OMe)$_2$] (**2**). The complexes **1** and **2** are obtained as green crystalline solid materials, which are insoluble in alcohols and water but readily soluble in DMF and DMSO. Under oxygen free reaction conditions the formation of the complexes **1** and **2** is virtually independent of the ligand to [VO(acac)$_2$] ratio. However, the vanadyl ion can easily be oxidized to the +5 oxidation state in the presence of either aminoalcohol ligand. With H_3tea the air oxidation leads to the well-known oxovanadium(V) triethanolaminate[4][10]. Similar reactions with the potentially bridging aminoalcohol ligands *N,N,N′,N′*-tetrakis(2-hydroxyethyl)ethylenediamine (H_4edte) and *N,N,N′,N′*-tetrakis(2-hydroxypropyl)-ethylenediamine (H_4edtp) did not yield any isolable vanadium(IV) complexes. Nevertheless after air oxidation the ligand supported binuclear oxovanadium(V) complexes [{VO(acac)}$_2$(edte)] **3**) and [{VO(acac)}$_2$(edtp)] (**4**) can be isolated, which are isoluble in common organic solvents. For both complexes **3** and **4** only one of the acetylacetonate ligands at the vanadyl ion is replaced by the aminoalcohol ligand. Utilizing ammonium *meta*-vanadate as starting material the reaction with the ligand H_4edtp in methanol solution afforded the methoxy bridged binuclear oxovanadium(V) complex [(VO)$_2$(edtp)(μ_2-OMe)$_2$] (**5**). **5** is readily soluble in DMF and DMSO but only sparingly soluble in alcohols.

Crystal Structure Descriptions

The molecular structures of the tetranuclear complexes **1** and **2** are shown in Figures 1 and 2. In both complexes the aminoalcohols, H_2dea and H_3tea, coordinate as tridentate ligands in their dianionic form and occupy three facial positions at the vanadium center V1 leading structurally similar {VO(dea)(OMe)}$^-$ and {VO(Htea)(OMe)}$^-$ fragments. Dimers of these fragments arranged in an *anti*-coplanar configuration constitute the central units of complexes **1** and **2** with the oxygen donors O3 and O3′ in the bridging positions. The formal condensation of two {VO(acac)}$^+$ fragments onto the trigonal faces of the central fragments established by the coordinated alkoxy ligands (O3, O4′, O5 and O3′, O4, O5′) leads to the tetranuclear complexes **1** and **2**. The resulting {(VO)$_4$(μ_3-OR)$_2$(μ_2-OR)$_4$}$^{2+}$ core structure of **1** and **2** generally resembles that of an earlier reported Schiff base substituted tetranuclear oxovanadium(IV) complex[9] and corresponds to the well-known {M_4O_{16}} condensation motif found for high valent transition-metal systems[8][11]. The actual orientation pattern of the oxo groups is directed by the *trans* effect generally observed for such strong terminal ligands, i.e. all are arranged *trans* to the μ_3-bridging oxygen donors O3 and O3′. Consequently, the {(VO)$_4$(μ_3-OR)$_2$(μ_2-OR)$_4$}$^{2+}$ core of **1** and **2** consists of five edge shared binuclear arrangements: one with *anti*-coplanar (V1···V1′: 329.0(2) pm for **1**, 326.6(2) pm for **2**), two with *syn*-coplanar (V1···V2 and V1′···V2′: 342.2(2) pm for **1**, 341.9(2) pm for **2**), and two with twist configuration (V1···V2′ and V1′···V2: 329.5(2) pm for **1**, 330.8(2) pm for **2**).

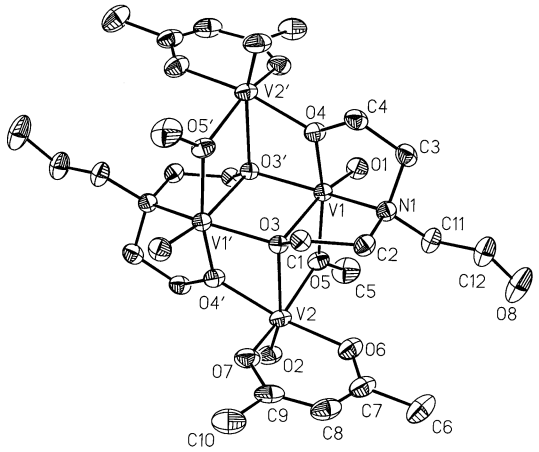
Figure 2. Molecular structure of **2** in crystals of **2**·2 MeOH[a]

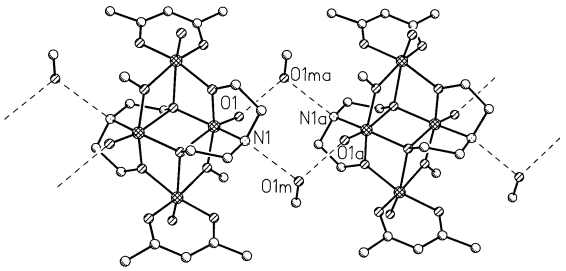


[a] The thermal ellipsoids are drawn at the 50% probability level; hydrogen atoms are omitted; atoms related by the crystallographic inversion center are denoted with a′ in the labelling scheme; selected bond lengths and metal−metal distances [pm]: V1−O1 160.8(2), V1−O3 219.8(2), V1−O3′ 201.4(2), V1−O4 193.9(2), V1−O5 203.5(2), V1−N1 217.7(3), V2−O2 159.6(2), V2−O3 237.3(2), V1−O4′ 200.4(2), V2−O5 197.5(2), V2−O6 200.8(3), V2−O7 200.1(3), V1···V2 341.9(2), V1···V2′ 330.8(2), V1···V1′ 326.6(2), V2···V2′ 588.2(2); selected bond angles [°]: O1−V1−O3 167.22(11), O2−V2−O3 163.32(11), V1−O3−V2 96.72(8), V1−O3−V1′ 101.57(9), V1′−O3−V2 97.54(9), V1−O4−V2′ 114.08(11), V1−O5−V2 116.97(11).

The crystal structures of the compounds **1**·2 MeOH and **2**·2 MeOH are characterized by the fact that both complexes contain hydrogen bond donors (**1**: NH, **2**: OH) as well as different possible acceptors. Moreover, also the additional molecules of methanol present in the crystal structures are involved in the hydrogen bonding networks. In the

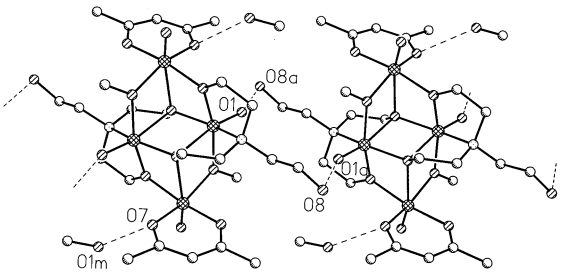
hydrogen bonding scheme of **1** · 2 MeOH depicted in Figure 3 each tetranuclear oxovanadium(IV) complex takes part in the four equivalent hydrogen bonds with a N−H···O−H···O=V arrangement (N1, O1m, O1a). This leads to the formation of a hydrogen bridged chain along the [010] direction with a shortest V···V separation of 673 pm between neighboring complexes. Although the nitrogen atom of the H_3tea ligand present in **2** has lost its hydrogen donor ability due to the third substituted ethoxy group, the hydrogen bonding scheme observed for **2** · 2 MeOH depicted in Figure 4 is rather similar to that found for **1** · 2 MeOH. Nevertheless, in contrast to **1** · 2 MeOH the crystal structure of **2** · 2 MeOH exhibits two topologically different types of hydrogen bonds that can be characterized as bridging and terminal. The bridging of the oxovanadium(IV) complexes is facilitated by O−H···O=V hydrogen bonds between the dangling ethoxy groups and the oxo groups of the central binuclear unit (O8···O1a). As a result a hydrogen bridged chain along the [100] direction with a shortest V···V separation of 650 pm between neighboring complexes is formed. Whereas the methanol molecules present in **2** · 2 MeOH participate in terminal hydrogen bonds to one of the oxygen donors of the acetylacetonate ligands (O1m···O7).

Figure 3. Representation of the hydrogen bonding scheme of **1** · 2 MeOH[a]



[a] Selected distances [pm]: O1−O1ma 274, N1−O1m 293.

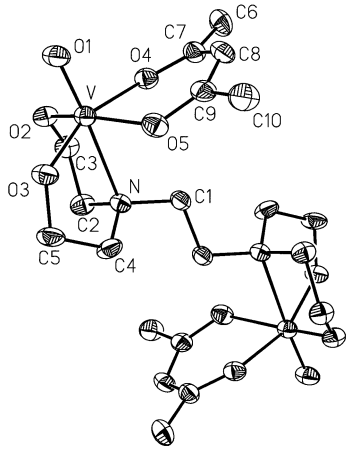
Figure 4. Representation of the hydrogen bonding scheme of **2** · 2 MeOH[a]



[a] The scheme is only shown for one of the enantiomeric chains; selected distances [pm]: O1−O8a 281, O1m−O7 289.

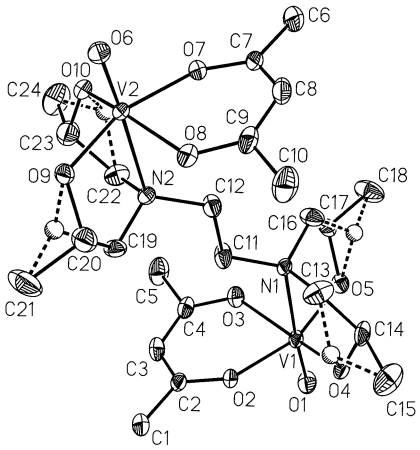
The centrosymmetric molecular structure of the ligand supported binuclear complex **3** is depicted in Figure 5. The oxovanadium(V) centers are coordinated by an acetylacetonate ligand and one of the diethanolamine fragments of the $edte^{4-}$ ligand affording an octahedral coordination environment. Basically the same molecular structure can be expected for the analogous binuclear oxovanadium(V) complex **4**, except that different stereochemical configurations are possible at the chiral carbon centers. Figure 6 shows the molecular structure derived for **4**. The observed disorder of the carbon atoms C14, C17, C20, and C23 is consistent with the occurrence of all possible stereochemical isomers in the solid state. As expected the observed bond lengths and angles for the oxovanadium(V) centers are the same for both complexes **3** and **4** within the estimated standard deviations.

Figure 5. Molecular structure of **3**[a]



[a] The thermal ellipsoids are drawn at the 50% probability level; hydrogen atoms are omitted; selected bond lengths [pm]: V−O1 159.3(4), V−O2 181.6(4), V−O3 181.8(4), V−O4 200.5(4), V−O5 201.3(4), V−N 242.7(4); selected bond angles [°]: O1−V−O2 99.2(2), O1−V−O3 100.3(2), O1−V−O4 99.0(2), O1−V−O5 96.3(2), O1−V−N 176.6(2).

Figure 6. Molecular structure of **4**[a]

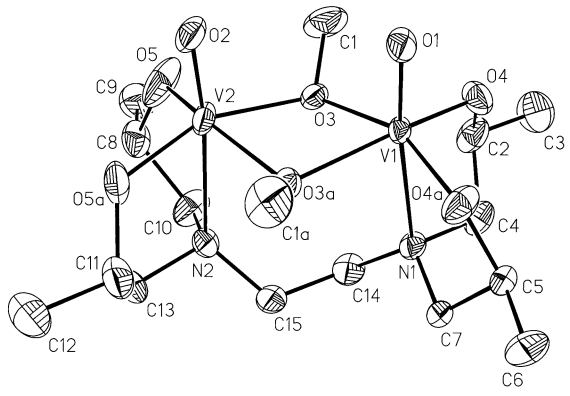


[a] The thermal ellipsoids are drawn at the 30% probability level; hydrogen atoms are omitted; C14, C17, C20, and C23 are disordered, the positions corresponding to the (*S*) configuration are represented by shaded circles and the corresponding bonds by broken lines; selected bond lengths [pm]: V1−O1 160.4(3), V1−O2 200.6(2), V1−O3 202.0(3), V1−O4 183.2(2), V1−O5 181.4(2), V1−N1 244.6(3), V2−O6 159.5(2), V2−O7 202.0(2), V2−O8 201.3(3), V2−O9 181.8(2), V2−O10 182.6(2), V2−N2 244.8(3); selected bond angles [°]: O1−V1−O2 98.76(12), O1−V1−O3 98.64(13), O1−V1−O4 99.78(13), O1−V1−O5 100.30(13), O1−V1−N1 176.43(12), O6−V2−O7 97.69(12), O6−V2−O8 98.93(13), O6−V2−O9 99.70(12), O6−V2−O10 101.31(13), O6−V2−N2 177.18(12).

The crystal structure analysis of **5** reveals the formation of a binuclear μ_2-methoxy bridged $\{(VO)_2(\mu_2\text{-}OR)_2\}^{4+}$ core

(see Figure 7). The coordination of the hexadentate aminoalcohol ligand edtp^{4-} leads to an octahedral coordination environment for both oxovanadium(V) centers. In contrast to **4** the crystal structure of **5** is consistent with the presence of just one diastereomer derived from the enantiomeric ligand pair (*R,R,R,R*)-H_4edtp and (*S,S,S,S*)-H_4edtp. In Figure 7 only the molecular structure of [$(VO)_2$\{(*S,S,S,S*)-edtp\}(μ_2-OMe)$_2$] is depicted, which is related to the enantiomeric structure of [$(VO)_2$\{(*R,R,R,R*)-edtp\}(μ_2-OMe)$_2$] by an crystallographic mirror plane (with V1, V2, O1, O2, and N1 lying on the mirror plane). Although not enforced by a crystallographic symmetry element the molecular structure of **5** is consistent with an approximate C_2 symmetry with the twofold axis perpendicular to the mean plane given by V1, O3, V2, and O3a ($\Sigma \measuredangle$ = 355°).

Figure 7. Molecular structure of **5**[a]



[a] The thermal ellipsoids are drawn at the 30% probability level; hydrogen atoms are omitted; atoms related by the crystallographic mirror plane are denoted with the suffix a in the labelling scheme; for the carbon and nitrogen atoms only the positions corresponding to the all (*S*) form of the edtp^{4-} ligand are shown; selected bond lengths [pm]: V1−O1 159.5(2), V1−O3 200.14(14), V1−O4 181.1(2), V1−N1 240.3(2), V2−O2 160.0(2), V2−O3 199.8(2), V2−O5 181.1(2), V2−N2 241.7(4); selected bond angles [°]: O1−V1−O3 99.60(8), O1−V1−O4 98.15(7), O1−V1−N1 173.75(1), O3−V1−O4 90.00(8), O3−V1−O3a 72.33(8), O3−V1−O4a 156.75(8), O2−V2−O3 99.70(8), O2−V2−O5 98.86(2), O2−V2−N2 170.93(12), O3−V2−O5 90.14(9), O3−V2−O3a 72.46(8), O3−V2−O5 90.14(9), V1−O3−V2 105.22(7).

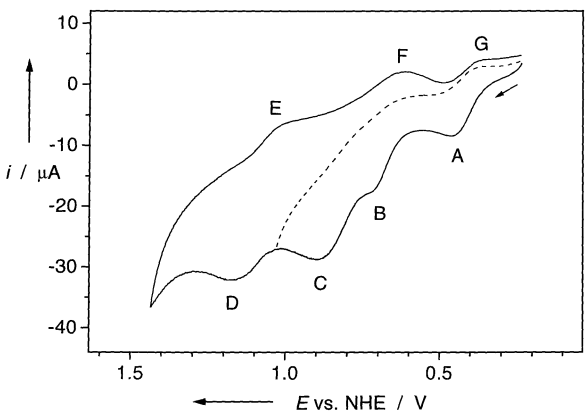
Spectroscopic and Electrochemical Characterization

The IR spectra of the tetranuclear complexes **1** and **2** are consistent with their centrosymmetric core structure and the presence of vanadyl acetylacetonate fragments. The bands related with the V=O stretching vibrations are observed at 950 and 975 cm^{-1}, with the latter being characteristic for an octahedral coordinated vanadyl acetylacetonate fragment[6][9]. Although the complexes **3** and **4** contain an oxidized oxovanadium(V) group, their band related with the V=O stretching vibration is observed at a similar value of about 970 cm^{-1}. For **1** · 2 MeOH and **2** · 2 MeOH the observed IR bands due to their O−H and N−H stretching vibrations are in accord with their hydrogen bridged supramolecular structure found in the solid state (cf. Figures 3 and 4).

The NMR spectra recorded for **5** are consistent with the presence of only one diastereomer with C_2 symmetry in solution. According to the results of the crystallographic analysis this corresponds to the enantiomeric pair [$(VO)_2$\{(*S,S,S,S*)-edtp\}(μ_2-OMe)$_2$] and [$(VO)_2$\{(*R,R,R,R*)-edtp\}(μ_2-OMe)$_2$]. Consequently the protons of the methylene groups are diastereotopic. The observed coordination induced shifts of the ^{1}H and ^{13}C resonances (see Experimental Section) toward lower fields are consistent with the structure of the chelate rings and generally an intact molecular structure of **5** in solution[2][4][5][12].

To probe the electrochemical properties of the tetranuclear oxovanadium(IV) complexes **1** and **2** cyclic voltammetry measurements have been performed. Figure 8 shows representative cyclic voltammograms of a solution of **2** · MeOH in DMF measured at a gold working electrode. As expected the neutral oxovanadium(IV) complexes **1** and **2** can be oxidized. Figure 8 shows that four oxidation half waves can be observed in the cyclic voltammogram (A, B, C, and D). The first oxidative peak at E_a = 0.47 V (A) possesses a reductive counterpart at E_c = 0.37 V (G). Based on the scan rate dependence of the peak separation and the peak current ratio ($i_a/i_c \approx 1$) the wave given by A/G is found to be quasi-reversible. On the contrary, for the oxidative peaks B (E_a = 0.73 V) and C (E_a = 0.90 V) no related reduction half waves are observed as can be seen from the cyclic voltammogram measured with an anodic potential limit of about 1.0 V (see broken line in Figure 8). Upon scanning through the fourth oxidation half wave D (E_a = 1.17 V) two new reduction half waves E (E_c = 1.01 V) and F (E_c = 0.61 V) are observed. The reduction half waves E and F can be assigned to a new species derived by a chemical reaction of the positively charged complex after the last oxidation step D. This is further evidenced by the observed scan rate dependence of the two reduction half waves E and F.

Figure 8. Cyclic voltammograms of **2**[a]



[a] Solvent DMF; tetra-*n*-buthylammonium perchlorate is used as supporting electrolyte at 0.1 M concentration and the concentration of the compound **2**·2 MeOH is about 1 mM; scan rate 50 mV/s; the broken line represents a scan with an anodic reversion potential of about 1.0 V; A, B, C, and D represent anodic peak potentials and E, F, and G stand for cathodic peak potentials (see text).

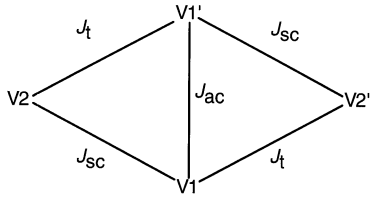
ESR Spectra and Magnetic Properties of 1 and 2

The X-band ESR powder spectra of **1** · 2 MeOH and **2** · 2 MeOH recorded at room temperature show a broad unstructured band at $g = 1.97$ and a second weak resonance at half-field, indicating the spectra are the result of exchange coupled spin systems[13]. The temperature dependence of the spectra indicates singlet ground states for **1** and **2**. At very low temperatures only the resonance signal of a residual monomeric oxovanadium(IV) impurity can be detected.

The magnetic susceptibility data of polycrystalline samples of **1** · 2 MeOH and **2** · 2 MeOH were measured in a temperature range from 4 to 280 K. The temperature dependence of the molar magnetic susceptibility χ_M in both cases goes through a maximum which is indicative for antiferromagnetic exchange interactions to be operative. At low temperatures χ_M is increasing again due to the presence of paramagnetic impurities. The $\chi_M T$ values at low temperatures are in accord with an $S = 0$ ground state of **1** and **2**, as suggested by the ESR spectra.

The observed ESR spectra and magnetic properties of **1** · 2 MeOH and **2** · 2 MeOH resemble those observed for an earlier reported oxovanadium(IV) complex with the same tetranuclear core structure[9]. On the basis of a general magneto-structural relationship for edge-shared binuclear oxovanadium(IV) units[6], both antiferro- and ferromagnetic interactions can be expected to be operative within the $\{(VO)_4(\mu_3\text{-}OR)_2(\mu_2\text{-}OR)_4\}^{2+}$ core of **1** and **2**. The spin topology and the notation of the magnetic exchange interaction parameters are depicted in Scheme 2. As a consequence of the given spin topology the expected antiferro- (J_{sc}) and ferromagnetic exchange interactions (J_{ac} and J_t) cannot be simultaneously satisfied.

Scheme 2. Spin topology of the $\{(VO)_4(\mu_3\text{-}OR)_2(\mu_2\text{-}OR)_4\}^{2+}$ core[a]



[a] The magnetic exchange coupling constants are denoted as follows: J_{ac} for *anti*-coplanar, J_{sc} for *syn*-coplanar, and J_t for twist configurations.

Based on data observed for other complexes with similar configurations of the binuclear oxovanadium(IV) units[6][9], the relative ratio of the exchange interaction parameters can be estimated as $-J_{sc} \gg J_{ac} \approx J_t$. Although competing magnetic interactions are operative within the tetranuclear core, a simplified binuclear model proved to be sufficient to describe the magnetic data of such a tetranuclear core structure with the given estimated parameter ratio[9]. This model refers to the picture that both pairs with *syn*-coplanar configuration (V1···V2 and V1′···V2′) should be predominantly coupled to form two virtually independent $S=0$ ground states. A quantitative analysis of the magnetic data has been performed using the Heisenberg−Dirac-van Vleck Hamiltonian given in Eq. 1.

$$\hat{\mathbf{H}} = -J(\hat{\mathbf{S}}_1 \cdot \hat{\mathbf{S}}_2 + \hat{\mathbf{S}}_{1'} \cdot \hat{\mathbf{S}}_{2'}) \quad (1)$$

Although only one exchange interaction constant is used in the analytical expression, reasonably good fits to the experimental data of **1** · 2 MeOH and **1** · 2 MeOH can be achieved. The magnetic parameters derived for the simplified isotropic spin Hamiltonian according to Eq. 1 are $g = 1.89$ and $J = -165$ cm^{-1} for **1** · 2 MeOH and $g = 1.94$ and $J = -171$ cm^{-1} for **2** · 2 MeOH. The rather strong antiferromagnetic coupling constants observed for both complexes are in good agreement with the data reported for other complexes containing binuclear units with *syn*-coplanar configuration (V···V 333 pm, $J = -334$ cm^{-1}[14] and V···V 341 pm, $J = -152$ cm^{-1}[9]) and can be explained on the basis of the possible superexchange mechanism through the bridging methoxy oxygen donors (O5 and O5′).

Experimental Section

NMR: ^{1}H, ^{13}C, ^{51}V, ^{1}H-^{1}H COSY, ^{1}H-^{13}C COSY, and ^{1}H-^{1}H NOESY NMR spectra were recorded on a Bruker DRX500 (^{1}H 500 MHz, ^{13}C 125.8 MHz, ^{51}V 131.5 MHz) spectrometer. Chemical shifts δ are reported with reference to external tetramethylsilan (^{1}H and ^{13}C) and $VOCl_3$ (^{51}V). − IR: Solid samples were measured either as KBr pellets or Nujol mulls between CsI plates using a Bruker IFS66 FT-IR spectrometer. − Raman: Solid samples were measured as powder on aluminium support using a Bruker IFS66/FRA106 (λ_e = 1064 nm) spectrometer. − UV/Vis: Spectra were recorded on Beckman Acta MIV (solid state reflection, cellulose as calibration standard) and Schimadzu UV-160A spectrometers (solution transmission). − Cyclic voltammetry: Princeton Applied Research VersaStat (Model 253). Cyclic voltammograms have been measured at room temperature with a three-electrode system composed of a gold working electrode, a platinum auxiliary electrode, and a platinum wire as reference electrode. The surface of the the gold working electrode was polished before each measurement. The reported potentials were referenced compared to the potential of the ferrocenium/ferrocene couple [$E^0(Fc^+/Fc) = 400$ mV vs. NHE] as internal standard[15]. The solvent DMF was dried and saturated with argon. Tetra-*n*-buthylammonium perchlorate was used as the supporting electrolyte at 0.1 M concentration and the solutions of the complexes were about 1 mM in concentration. − Powder diffraction: Powder diffraction diagrams were measured of solid samples on Al support with a Philips PW3710 powder diffractometer using Cu-$K\alpha$ radiation. − ESR: X-Band ESR spectra were recorded using a Bruker ECS106 spectrometer at a microwave frequencies of 9.48 GHz with 2,2-diphenyl-1-picrylhydrazyl as standard. − Magnetic susceptibility: Magnetic susceptibility measurements from 4 to 280 K were performed by using a Quantum Design MPMS2 SQUID magnetometer. All data were collected at an applied field of 10 kOe. The diamagnetic corrections were estimated from Pascal's constants. The susceptibility data were further corrected for temperature-independent paramagnetism (TIP) and the presence of paramagnetic impurity. For details see ref.[9]. − Melting points (uncorrected): Electrothermal melting point apparatus. − Elemental analyses: LECO CHNS-932 Analyzer.

Preparation of [{VO(dea)}$_2${VO(acac)}$_2$(μ_2-OMe)$_2$] · 2 MeOH (**1** · 2 MeOH) *and [{VO(Htea)}$_2${VO(acac)}$_2$(μ_2-OMe)$_2$] · 2 MeOH* (**2** · 2 MeOH): All manipulations were carried out under an argon atmosphere using Schlenk line techniques. The solvent methanol was purified and dried using standard methods. The ligand (9.5 mmol, i.e. 1.00 g of H_2dea or 1.42 g of H_3tea) dissolved in 5 ml methanol was added to a solution of 2.54 g (9.5 mmol) [VO(acac)$_2$] in 20 ml methanol. The resulting green solution was heated at reflux for 2 h and subsequently allowed to stand at room temperature. Within 3−4 days green crystals began to grow. After an additional week the crystalline compounds were isolated by filtration and washed with methanol. A second crop of material was obtained from the filtrate after removing solvent to about 1/3 of the original volume. The isolated solid materials can be handled in air. Within about 8 weeks the crystals start to decompose due to the loss of cocrystallized methanol.

1 · 2 MeOH: Yield 0.98 g (52%), dec. 165°C. − $C_{22}H_{46}N_2O_{16}V_4$ (798.4): calcd. C 33.10, H 5.81, N 3.51, found: C 33.31, H 5.69, N 3.68. − Selected IR data (Nujol mull between CsI plates, cm^{-1}): ν(OH) 3370 br. w, ν(NH) 3240 m, ν(C⩵C) + ν(C⩵O) 1583 vs and 1518 vs, ν(V=O) 978 vs (V2 cf. Figure 1), ν(V=O) 950 vs (V1 cf. Figure 1). − UV/Vis [DMF, $\tilde{\nu}_{max}$ in 10^3 cm^{-1} (ε in lmol^{-1} cm^{-1})]: 22.4 (23, sh), 16.0 (55), 11.5 (110). − UV/Vis (solid state, reflectance, $\tilde{\nu}_{max}$ in 10^3 cm^{-1}): 31.8, 26.7 (sh), 22.5 (sh), 16.2, 11.2.

2 · 2 MeOH: Yield 1.59 g (76%), dec. 159°C. − $C_{26}H_{54}N_2O_{18}V_4$ (886.5): calcd. C 35.23, H 6.14, N 3.16, found: C 35.01, H 5.82, N 3.11. − Selected IR data (Nujol mull between CsI plates, cm^{-1}): ν(OH) 3515 w, ν(OH) 3410 m, ν(C⩵C) + ν(C⩵O) 1582 vs and 1521 vs, ν(V=O) 973 vs (V2 cf. Figure 2), ν(V=O) 954 vs (V1 cf. Figure 2). − UV/Vis [DMF, $\tilde{\nu}_{max}$ in 10^3 cm^{-1} (ε in lmol^{-1} cm^{-1})]: 22.3 (20, sh), 16.1 (54), 11.7 (103). − UV/Vis (solid state, reflectance, $\tilde{\nu}_{max}$ in 10^3 cm^{-1}): 31.6, 26.3 (sh), 22.2 (sh), 16.4, 11.4.

Preparation of [{VO(acac)}$_2$(edte)] (**3**) *and [{VO(acac)}$_2$(edtp)]* (**4**): The ligand (7.5 mmol, i.e. 1.78 g of H_4edte or 2.19 g of H_4edtp, the latter being a mixture of all possible diastereomers) dissolved in 5 ml methanol was added to a solution of 4.00 g (15 mmol) [VO(acac)$_2$] in 40 ml methanol. At room temperature a slow stream of air was bubbled through the stirred green solution (for about 2 h). The resulting brown solution was kept at room temperature for crystallization. Orange needles began to grow after about 1 day and after additional 2 days the crystalline compound was isolated by filtration and washed with methanol. A second crop of material was obtained from the filtrate after reducing the solution volume to about 20 ml.

3: Yield 2.51 g (59%), dec. 148°C. − $C_{20}H_{34}N_2O_{10}V_2$ (564.4): calcd. C 42.56, H 6.07, N 4.96; found: C 42.37, H 6.28, N 4.68. − Selected IR data (Nujol mull between CsI plates, cm^{-1}): ν(C⩵C) + ν(C⩵O) 1574 s and 1527 s, ν(V=O) 970 vs. − Selected Raman data (powder on Al support, λ_e = 1064 nm, 35 mW, cm^{-1}): ν(V=O) 964 s.

4: Yield 2.32 g (50%), dec. 136°C. − $C_{24}H_{42}N_2O_{10}V_2$ (620.5): calcd. C 46.46, H 6.82, N 4.51; found: C 46.27, H 6.68, N 4.66. − Selected IR data (Nujol mull between CsI plates, cm^{-1}): ν(C⩵C) + ν(C⩵O) 1576 vs and 1531 vs, ν(V=O) 972 vs. − Selected Raman data (powder on Al support, λ_e = 1064 nm, 90 mW, cm^{-1}): ν(V=O) 969 s.

Preparation of [(VO)$_2$(edtp)(μ_2-OMe)$_2$] (**5**): NH_4VO_3 (2.8 g, 24 mmol) was added to a solution of H_4edtp (3.50 g, 12 mmol) in 50 ml methanol containing all possible diastereomers of the ligand. The resulting mixture was heated at reflux for 8 h. The hot reaction mixture was filtered to remove unreacted NH_4VO_3. Upon cooling the filtrate to room temperature orange crystals of **5** · *x* MeOH formed. The number of methanol molecules present in the crystalline material is estimated to x = 0.3 based on the elemental analysis and NMR data and is consistent with the crystal structure data.

5: Yield 0.38 g (6%), dec. 169°C. − $C_{16}H_{34}N_2O_8V_2$ · 0.3 MeOH (493.9): calcd. C 39.64, H 7.18, N 5.67; found: C 39.66, H 7.36, N 5.74. − Selected IR data (Nujol mull between CsI plates, cm^{-1}): ν(V=O) 963 vs. − Selected Raman data (powder on Al support, λ_e = 1064 nm, 150 mW, cm^{-1}): ν(V=O) 961 m. − ^{1}H NMR (500 MHz, [D$_6$]DMSO): δ = 1.00 (d, ^3J = 6.0 Hz, 6H, CH_3), 1.18 (d, ^3J = 6.0 Hz, 6H, CH_3), 2.23−2.31 [m; 6H, CH_2NCH_2CH(CH$_3$)OV], 2.62−2.67 (m, 2H, NCH_2CH(CH$_3$)OV), 2.80−2.85 [m, 2H, NCH_2CH(CH$_3$)OV], 3.23−3.31 (m, 2H, CH_2N), 4.21 (s, 6H, OCH_3), 4.70 (m, 2H, NCH$_2$CH(CH$_3$)OV], 4.81 (m, 2H, NCH$_2$CH(CH$_3$)OV). − ^{13}C NMR (125.8 MHz, [D$_6$]DMSO): δ = 19.7 (CH_3), 21.4 (CH_3), 51.6 (CH_2N), 59.7 [NCH_2CH(CH$_3$)OV], 63.7 [NCH_2CH(CH$_3$)OV], 67.5 (OCH_3), 76.3 [CH_2CH(CH$_3$)OV], 78.2 [CH_2CH(CH$_3$)OV]. − ^{51}V NMR (131.5 MHz, [D$_6$]DMSO): δ = −444.

Crystal Structure Determinations of **1** · 2 MeOH, **2** · 2 MeOH *and* **3**: The crystallographic data of **1** · 2 MeOH, **2** · 2 MeOH, and **3** were collected with ω-scan technique on a Siemens R3m/V diffractometer using graphite monochromated Mo-$K\alpha$ (λ = 71.073 pm) radiation. The unit cell parameters were obtained by least-squares refinement of the angular settings from well centered reflections in the 2Θ range of 18−30°. Lorentz and polarization corrections as well as an absorption correction based on azimuthal ψ scans were applied to the diffraction data. The structures were solved by direct methods (SHELXTL)[16] and subsequent full-matrix least-squares refinement of the function $\Sigma w(F_o^2 - F_c^2)^2$ $\{w = 1/[\sigma^2(F_o^2) + (A \cdot P)^2 + B \cdot P]$ with $P = (F_o^2 + 2F_c^2)/3\}$[17]. All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were treated using the riding model with their isotropic displacement parameters fixed at 1.2 times the value of the non-hydrogen atom attached. For the hydrogen atoms of the methyl as well as hydroxyl groups their conformation was additionally fitted to the difference Fourier map.

1 · 2 MeOH: $C_{22}H_{46}N_2O_{16}V_4$; formula weight 798.4; crystal size 0.5 × 0.5 × 0.4 mm; triclinic space group $P\bar{1}$ (No. 2); T = 188 K;; a = 773.5(3), b = 998.7(3), c = 1241.6(4) pm, α = 103.10(2), β = 107.69(2), γ = 106.13(2)°; V = 0.8255(5) nm^3; Z = 1; $\rho_{calcd.}$ = 1.606 g/cm^3; μ(Mo-K_α) = 1.168 mm^{-1}; 2Θ range 4−54°; 3553 independent reflections ($R_{int.}$ = 0.022); 204 parameters; A = 0.08, B = 0.5; $wR2$ = 0.137; $R1$ = 0.047 for 3064 reflections with $F > 4\sigma(F)$; max./min. residual electron density in the final difference Fourier map 0.9/−0.6 · 10^{-6} e/pm^3.

2 · 2 MeOH: $C_{26}H_{54}N_2O_{18}V_4$; formula weight 886.5; crystal size 0.3 × 0.2 × 0.2 mm; monoclinic space group $P2_1/c$ (No. 14); T = 188 K; a = 965.4(2), b = 1677.0(4), c = 1677.0(4) pm, β = 104.65(2)°; V = 1.8622(8) nm^3; Z = 2; $\rho_{calcd.}$ = 1.581 g/cm^3; μ(Mo-K_α) = 1.048 mm^{-1}; 2Θ range 4−54°; 4095 independent reflections ($R_{int.}$ = 0.020); 232 parameters; A = 0.05, B = 2.7; $wR2$ = 0.122; $R1$ = 0.046 for 3028 reflections with $F > 4\sigma(F)$; max./min. residual electron density in the final difference Fourier map 0.5/−0.5 · 10^{-6} e/pm^3.

3: $C_{20}H_{34}N_2O_{10}V_2$; formula weight 564.4; crystal size 0.25 × 0.15 × 0.05 mm; monoclinic space group $P2_1/n$ (No. 14); T = 188 K; a = 812.2(3), b = 1165.2(5), c = 1298.3(6) pm, β = 102.65(3)°; V = 1.1989(9) nm^3; Z = 2; $\rho_{calcd.}$ = 1.563 g/cm^3; μ(Mo-K_α) = 0.837 mm^{-1}; 2Θ range 4−54°; 2632 independent reflections ($R_{int.}$ = 0.030); 156 parameters; A = 0.07, B = 2.5; $wR2$ = 0.176; $R1$ = 0.067 for 1675 reflections with $F > 4\sigma(F)$; max./min. residual electron density in the final difference Fourier map 0.6/−0.4 · 10^{-6} e/pm^3.

Crystal Structure Determinations of **4** *and* **5**: The crystallographic data of **4** and **5** were collected on a Siemens SMART-CCD diffractometer (ω-scans with 0.3° per frame) using graphite monochromated Mo-$K\alpha$ (λ = 71.073 pm) radiation. The intensities of the reflections of a hemisphere have been measured (SMART). Lorentz and polarization corrections as well as an empirical absorption correction based on the intensities of equivalent reflections measured at different angular settings have been performed (SAINT and SADABS). The structure was solved by direct methods (SHELXTL)[16] and subsequent full-matrix least-squares refinement of the function $\Sigma w(F_o^2 - F_c^2)^2$ $\{w = 1/[\sigma^2(F_o^2) + (A \cdot P)^2 + B \cdot P]$ with $P = (F_o^2 + 2F_c^2)/3\}$[17]. All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were treated using the riding model with their isotropic displacement parameters fixed at 1.2 times the value of the non-hydrogen atom attached. For the hydrogen atoms of the methyl as well as hydroxyl groups their conformation was additionally fitted to the difference Fourier map.

For **4** the observed systematic absences suggest either of the orthorhombic space groups $Pca2_1$ and *Pbcm*. Attempts to solve the structure in the centrosymmetric space group *Pbcm* were unsuccessful. This led in agreement with intensity statistics to the noncentrosymmetric orthorhombic space group $Pca2_1$ as final choice. The refinement afforded a Flack parameter[18] of about 0.4, which could not be reduced upon inversion of the parameter set. Therefore the final structure refinement was performed assuming racemic twinning, which led to a refined Flack parameter of 0.42(2). Also the refinement in the chiral subgroup $P2_1$ was attempted but did not give any evidence for the presence of any particular chiral molecular structure. The presence of all possible diastereomers is consistent with the observed disorder of the chiral carbon atoms of the edtp^{4-} ligand (C14, C17, C20, and C23) on two positions corresponding to their respective (*R*) and (*S*) configurations (in Figure 6 only the positions for the (*R*) configurations are represented as ellipsoids).

The additional methanol molecule present in **5** is highly disordered and only the respective oxygen atom could be located from the difference Fourier map and refined with an isotropic displacement parameter.

4: $C_{24}H_{42}N_2O_{10}V_2$; formula weight 620.5; crystal size 0.4 × 0.4 × 0.4 mm; orthorhombic space group $Pca2_1$ (No. 29); T = 183 K; a = 2553.18(4), b = 823.11(1), c = 1396.16(1) pm; V = 2.93410(6) nm^3; Z = 4; $\rho_{calcd.}$ = 1.405 g/cm^3; μ(Mo-K_α) = 0.691 mm^{-1}; 2Θ range 4−54°; 5897 independent reflections ($R_{int.}$ = 0.027); 3298 reflections for Friedel opposites merged; 379 parameters; A = 0.06, B = 2.1; $wR2$ = 0.109; $R1$ = 0.039 for 5331 reflections with $F > 4\sigma(F)$; Flack parameter x = 0.42(2); max./min. residual electron density in the final difference Fourier map 0.5/−0.6 · 10^{-6} e/pm^3.

5: $C_{16}H_{34}N_2O_8V_2 \cdot 0.3$ MeOH; formula weight 493.9; crystal size 0.4 × 0.4 × 0.06 mm; orthorhombic space group *Pbcm* (No. 57); T = 183 K; a = 903.85(1), b = 1453.37(2), c = 1757.92(3) pm; V = 2.30925(6) nm^3; Z = 4; $\rho_{calcd.}$ = 1.421 g/cm^3; μ(Mo-M_α) = 0.852 mm^{-1}; 2Θ range 4−54°; 2593 independent reflections ($R_{int.}$ = 0.028); 208 parameters; A = 0.04, B = 1.8; $wR2$ = 0.097; $R1$ = 0.038 for 2204 reflections with $F > 4\sigma(F)$; max./min. residual electron density in the final difference Fourier map 0.5/−0.4 · 10^{-6} e/pm^3.

Keywords: Gold colloids / Self-assembly / Nanoporous alumina / Three-dimensional organization

Examples of a new class of three-dimensionally arranged gold colloids have been prepared in the nanoscale pores of alumina membranes. Immobilization of the colloid particles was achieved by a modification of the inner walls with alkoxysilanes $Y–(CH_2)_x–Si(OR)_3$ and $Y–(CH_2)_x–SiR(OR)_2$ bearing suitable functional groups (Y = NH_2, SH), followed by anchoring of the colloids by self-assembly onto the modified surface. This procedure gives tight and stable ensembles of colloids on the walls. TEM analyses revealed uniform and random colloidal dispersions on the walls in the form of sub-monolayers without any aggregation. UV/Vis spectra of the filled membranes showed an absorption maximum at ca. 525 nm arising from an excitation of the plasmon resonance of the gold colloids. The dimensions of the pores can be "tuned" and given the diverse range of different colloids available, routes to novel catalysts and sensors can be envisaged.

Introduction

Over the past decade, a wide variety of approaches have been proposed for the construction of nanostructured materials from nanoparticles. Organization of nanoscale particles is considered as a promising route for the development of new materials that can be classified as nanostructures. Since metal colloids represent one of the most extensively studied classes of nanoscale materials, and because they have the advantage of well-defined size and character, such systems are promising candidates for use as building blocks in the construction of nanostructured materials.[1] Nanostructures constructed from colloids are of interest for a wide range of applications[2] as a result of their chemical, catalytic, electrochemical, magnetic, and optical properties. For example, in catalysis they can be regarded as offering intermediate situations between homogeneous and heterogeneous catalysts[3], and unique catalytic features in reactions such as hydrogenation[4], hydrosilylation[5], and photocatalytic reactions[6] have been reported. Meanwhile, the adsorption of metal colloids onto organic and inorganic supports has been investigated as a means of preparing well-defined heterogeneous catalysts.[7]

Immobilization of metal colloid particles on a suitable structured matrix using a self-assembly technique is one of the most promising strategies for the construction of colloidal nanostructures.[8] Based on such a strategy, the preparation of two-dimensional metal colloid arrays on a flat surface has been reported by Natan et al.[9] and by Sato et al.[10] The use of colloids offers several advantages: (i) essentially monodispersed metal particles are easily obtained, (ii) the preparation and characterization of many kinds of colloidal metals has been well-researched, (iii) ordering of colloids is expected by self-assembly, (iv) anchoring on supports increases stability against agglomeration, and (v) new characteristics originate from an interaction between the colloidal particles and supports.

Since the construction of three-dimensional ensembles is necessary for the practical use of colloids, the development of three-dimensional structures from two-dimensional arrays is necessary.[11] Three-dimensional colloid arrangements have been reported to be produced from multi-layer films by sequential self-assembling[12] and by using sol-gel techniques[13], as well as from the use of reversed micelles[14], and by an external electric field induced layering of colloid crystals.[15] Assembling a homogeneous dispersion in a well-defined three-dimensional nanostructure offers an alternative route to these "stepwise"[12][13][14][15] constructions. Such a strategy requires careful selection of the appropriate matrix. Since a porous alumina membrane, which can be prepared by anodic oxidation of aluminum in diprotic acid solution, has a huge number of parallel pores of uniform diameter, we chose it as a promising matrix for supporting assemblies of colloids. The dimensions of the pores can be controlled by adjusting the anodization con-

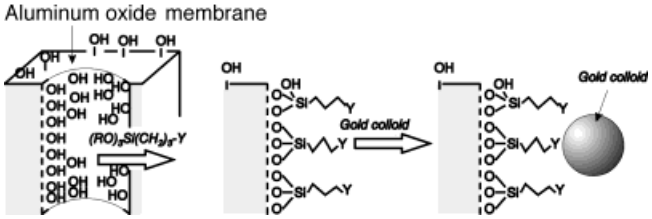
ditions; by varying the applied voltage their diameter can be varied from 5 to 150 nm and their depth, i.e. the thickness of the membrane, from 1 to >100 μm.[16] Such a porous alumina membrane has also been used as a unique template in the assembly of nanostructures.[17] The anodization procedure is readily applicable for the preparation of a membrane of large area and of appropriate shape. Here, we describe the assembly of gold colloids in the well-ordered pores of alumina membranes using a self-assembly technique. These materials belong to a new class of three-dimensional nanostructures, the structures of which can be "tuned" by modification of the matrix. Therefore, this strategy should be a potentially useful technique in the development of diverse applications in optics, as sensors, and as catalysts.

Results and Discussion

Immobilized Colloids in Membranes: Scheme 1 illustrates our strategy for the preparation of the target material and the colloid coordination. The procedure consists of the anodization of aluminum, the derivatization of pores in the alumina membrane with a functionalized alkoxysilane such as $Y-(CH_2)_x-Si(OR)_3$ or $Y-(CH_2)_x-SiR(OR)_2$ (Y = SH, NH_2), and the immobilization of colloidal particles.

Scheme 1. Modification of alumina membranes with functionalized alkoxysilane molecules and chemisorption of gold colloids

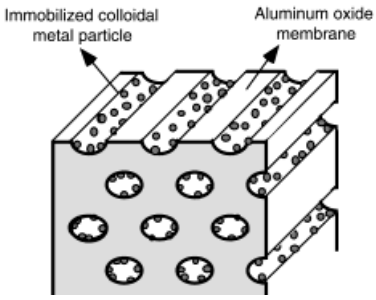


Aluminum plates form porous membranes on the surface upon anodization in 2% phosphoric acid solution. Pore size and pore density is largely governed by the applied voltage.[16] Membranes containing pores of 150 ± 10 nm in diameter are obtained by constant voltage anodization at 150 V. Detachment of the membrane by treatment with sulfuric acid gives a self-standing alumina membrane with a thickness of between 20 and 90 μm depending on the anodization period.

The hydroxyl groups present on the alumina surface are highly reactive and react readily with alkoxysilane molecules generating covalent Al−O−Si moieties. Functional groups Y are selected such that they show good affinity to the metal colloid. Reactions of the alkoxysilanes with the pore walls proceed smoothly in toluene solution under reflux conditions. The IR spectrum of a membrane reacted with 3-aminopropylmethyldiethoxosilane (APDMS) shows two signals at 2960 and 2930 cm^{-1}, which can be attributed to C−H stretching vibrations of the alkyl chains.[18] By monitoring the peak intensity during the course of the reaction, saturation is observed after ca. 14 h. The reactivity of the reagents is modified by the nature of the functional group Y and by the number of alkoxy groups. Compared to dialkoxysilanes, trialkoxysilanes show lower reactivity. On the other hand, aminoalkoxysilanes are highly reactive compared to mercapto derivatives.

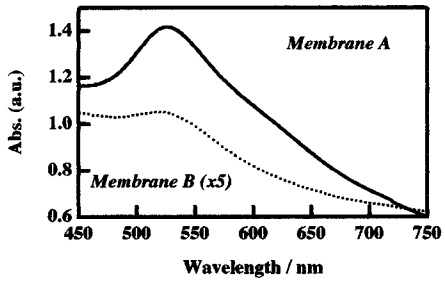
The immobilization of gold colloids in the pores can be performed by one of two types of vacuum incorporation. In the first, the modified membrane is placed on a short plastic tube connected to a water pump, and the gold colloid solution is sucked through the membrane. Alternatively, the membrane is placed in a flask and the colloid solution is added. Evacuation of the flask causes the solution to penetrate into the pores. In both cases it is necessary to exhaustively wash out remaining silane before the filling process. Even small amounts of unreacted reagents cause immediate aggregation of the gold colloids. Well-washed membranes take on a dark-red color upon incorporation of gold colloids. Figure 1 shows a schematic depiction of a membrane containing immobilized gold.

Figure 1. Model structure of a colloid-charged porous alumina membrane



Optical Properties: UV/Vis spectra of gold colloid solutions, prepared as described[21], show an absorption maximum at ca. 520 nm originating from an excitation of plasmon resonance.

Figure 2. UV/Vis spectra of immobilized gold colloids in nanoporous membranes derivatized with different alkoxysilanes − A: derivatized with APDMS; B: derivatized with MPDMS



The spectra of colloids in membranes show resonances at approximately the same position. Figure 2 shows the spectra of two colloid-containing membranes. Membrane A was modified with APDMS, membrane B with 3-mercaptopropylmethyldimethoxysilane (MPDMS). Both spectra show a peak at λ_{max} = ca. 525 nm, but the relative ab-

sorbances differ markedly. The peak position is close to that of the original solution, albeit slightly shifted to longer wavelengths. This shift can be explained in terms of interparticle coupling between the colloids[19], i.e. a reduction of the distance between particles compared to that in solution.

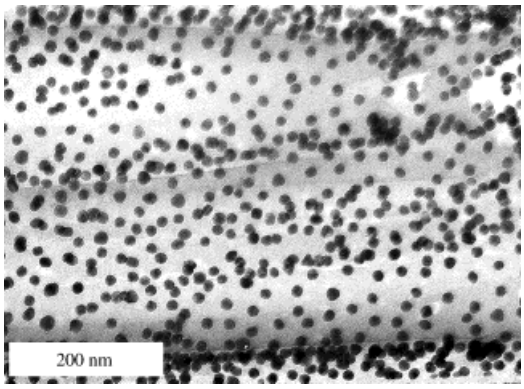
The difference in the absorbances of membranes A and B can be attributed to the different amounts of colloid that are immobilized. The different degree of immobilization can be explained by preferred interactions between the amino functions of APDMS and the colloids bearing citric acid molecules on the surface. The SH functions in MPDMS could be expected to form strong bonds to gold particles, but this effect is less in evidence compared to the acid-base interaction. Since neither spectrum shows aggregation peaks between 600 and 800 nm, aggregation of the colloids by migration can be excluded. The lack of aggregation indicates that the colloids are tightly bound to the surface through their interaction with the functional groups of anchored molecules. Assuming that the pores have a diameter of 160 nm and that there is a pore density of $1.1 \cdot 10^9$ cm^{-2}, in accordance with the data of Rigby and co-workers[16c], the internal surface area of the pores can be roughly calculated as $4 \cdot 10^2$ cm^2 for 1 cm^2 of membrane. The outer surface area is thus less than 1% of this value. Since the density of surface hydroxy groups on the alumina was reported to be 10 per nm^2 after treatment at 100°C[20], the total number of OH groups in the pores can be estimated as $4 \cdot 10^{16}$ for 1 cm^2 of membrane. If all OH groups are derivatized by silane molecules, about 23 nmol of functional groups are fixed in the pores. Considering the size of the colloid (13 nm), more than ca. 450 of the functional groups can be expected to be present within the area corresponding to the dimensions of one colloid particle. Of course, not all functional groups are able to interact with the colloids, but strong interactions by multi-anchoring between the surface and the particle are very reasonable as an interpretation of the absence of aggregation.[22]

Transmission Electron Microscopy: To confirm the dispersion of the colloids on the derivatized surface of the pores, transmission electron microscopy (TEM) investigations were carried out on sectioned samples. Figure 3 shows a TEM image of a porous membrane following derivatization with APDMS and treatment with a gold colloid by vacuum incorporation.

The gold colloid particles can clearly be recognized on the pore walls. Apart from the region near the surface of the membrane, the particles are randomly and uniformly distributed and cover the wall surface as a sub-monolayer extending over a large area. No aggregated or chained particles can be observed in either direction, i.e. in the plane of, or perpendicular to the wall. In contrast, a TEM image of an underivatized porous membrane following treatment with the colloid revealed only the presence of partly aggregated colloids of low density. Therefore, the random arrangement indicated by the UV/Vis spectrum is clearly confirmed by the TEM observation.

The average diameter of the immobilized colloids on the wall is found to be ca. 15 nm (for 131 measured particles).

Figure 3. TEM image of immobilized gold colloids (ca. 13 nm) in opened pores of alumina



This value is slightly larger but close to the size of the original colloids in aqueous solution, i.e. the colloidal particles do not grow or aggregate during immobilization. The sub-monolayer coverage of the wall with the gold colloids was found to represent ca. 25% of a full monolayer. Incomplete coverage of the wall can be attributed to an electrostatic repulsion between particles. This is consistent with previous observations on a two-dimensional array of gold colloids on a derivatized SiO_2 surface.[9]

Since the pores are cylindrical in shape, the walls are concave. Therefore, the particle density projected on the film appears to vary with position in the pore. Differently sectioned TEM photographs clearly show the effect of pore shape. Figures 4a to 6a show images of apparently different dispersions according to the sectioning, along with schematic depictions.

In order to make TEM imaging easy, Anopore™ with 250 nm pore widths was used for this special purpose. The sample was derivatized with APDMS and sectioned into sheets of thickness 100 nm. A part of the sample gave images showing the particles located only near the pore walls (Figure 4a). In this micrograph, closely packed, vertically overlapped particles are observed along the walls. This arrangement is interpreted as illustrated in Figure 4b. In this image, thin sectioning is considered to remove both walls, i.e. the upper and lower faces, of the pore. Since particles near the wall are viewed from the perpendicular direction, particles aligned vertically give a projected image of overlapped particles. As the result, the density of particles near the wall appears to increase. Figure 5a shows an image of an area similar to that depicted in Figure 4a (bottom), but additionally shows a pore with an intact rear side (upper part). Figure 5b illustrates a tubular pore cut in half, with immobilized particles on the surface. In accordance with the curvature of the bottom side, the apparent density of particles appears to be higher near the vertical walls and gradually decreases towards the center.

Figure 6a depicts two distinct areas in one pore (parts A and B). The two areas are distinguishable by the following criteria: (i) the observed density of particles in part A is much higher than that in part B, (ii) overlapped images of particles are apparent only in part A, (iii) the darkness

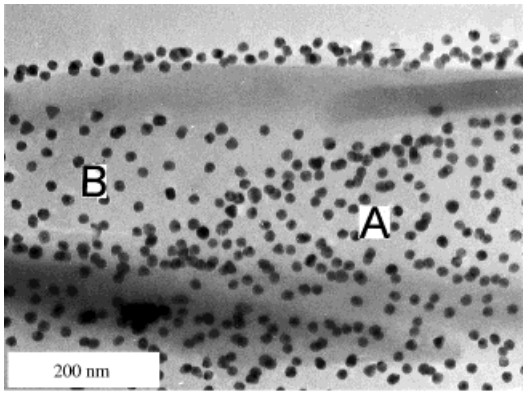
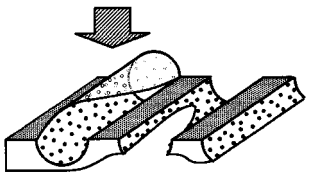
Figure 6. (a) Some distinct areas in a piece of membrane supporting gold colloids. Area B shows part of a pore opened on one side, while area A depicts a view through a thin, but colloid-bearing alumina wall; the density of colloids appears higher in A than in B due to the simultaneous imaging of particles on both the front and rear sides. The schematic representation in Figure 6b helps to clarify the relatively complicated situation in Figure 6a.



a



b

around the colloids in area A is more pronounced than that in area B. Part B is considered to be similar to the bottom part of a wall, as in Figure 4b. Figure 6b illustrates a cylindrical pore sliced slantwise. This scheme depicts two parts; one part is modelled in Figure 5b, while the other consists of a whole pore wall. The image of area A is assigned to a transmission view of the whole tube, i.e. the overlapped image of both upper and lower walls of one pore. This view can be considered to give an almost double particle density and an overlapped image of particles through projection of both walls within the same area. The model shown in Figure 6b interprets all characteristics of Figure 6a.

These three TEM photographs are consistent with the results of spectroscopic studies and clearly confirm the situation with gold colloids immobilized on the tubular walls of alumina membranes.

Conclusions

Gold colloids have been successfully immobilized in the parallel and uniform pores of alumina membranes. The ensemble of colloids forms a sub-monolayer on the pore walls (coverage = ca. 0.25), as shown by TEM and UV/Vis spectroscopy. The observations show that the colloids are tightly anchored on the surface, randomly and uniformly, without any aggregation. Thus, three-dimensionally arranged colloidal particles are distributed over a large area, as a result of their self-assembly on the derivatized surfaces of the structurally well-defined alumina. The thickness of the membranes in which the colloids are arranged ranges from 10 to 100 μm, and the pore size can be "tuned" by variation of the anodization conditions. Variation of the anchored colloids should be easily achieved by means of suitable combinations of derivatizing reagents and colloidal metals.

Experimental Section

General: Aluminum plates of 99.5% of purity were used. Of the alkoxysilanes used as derivatizing reagents, 3-mercaptopropylmethyldimethoxysilane (MPDMS) was purchased from ABCR GmbH & Co., Germany, while 3-aminopropylmethyldiethoxysilane (APDMS) was purchased from Fluka GmbH, Switzerland. Toluene was obtained as analytical grade and was dried by distillation from sodium benzophenone ketyl. Analytical grade methanol was used without further purification. Gold colloid solutions were prepared by an established method[21] through reduction of $HAuCl_4$ with sodium citrate. The average diameter of the colloids was measured as 13 ± 1 nm. Commercially available porous aluminum oxide membrane, Anopore™ (Merck, Germany; average pore diameter 250 nm), was also used as a porous alumina membrane.

Physical Measurements: IR spectra of derivatized membranes were recorded on a BIO-RAD FTS-175 infrared spectrometer. Electronic spectra of membranes containing gold colloids were measured on a Varian Cary-1 UV/Vis spectrometer equipped with a small aperture fitted to the sample. TEM images were obtained using a Philips CM 200 FEG microscope. Samples for TEM were embedded in a resin and sectioned. The thickness of the sample was varied from 100 to 50 nm. An Ultra Cut Microtom, Leica, Germany, was used for sectioning.

Preparation of Porous Alumina Membranes: Aluminum plates (99.5%, 70 × 55 × 2 mm) were electropolished before anodization in a mixture of sulfuric acid and phosphoric acid. Anodic oxidation was carried out in 2% (w/w) phosphoric acid under a constant voltage of 150 V at 6°C. The maximum current density was ca. 2.5 mA cm^{-2}. Anodization was allowed to proceed for 6 to 48 h depending on the required thickness of the membrane. Thereafter, the applied voltage was reduced in a stepwise manner from 150 V to 0.5 V and then stopped. The anodized plates were washed with water and dried in air, then immersed in 12.5% sulfuric acid at room temperature in order to detach the porous alumina membranes. The membranes were carefully washed with water and then immersed in 10% sulfuric acid for 10 min to remove the barrier layer on the rear side, so as make through pores. Subsequently, the membrane was rinsed with water and methanol, and dried.

Derivatization of Porous Alumina: A typical procedure for the derivatization with MPDMS and APDMA was as follows: the membrane was cut to a size of ca. 1 × 2 cm, then washed with methanol, and dried in air. Subsequent procedures were carried out under nitrogen. The specimen was placed in a 50 ml flask under anhydrous conditions. A dry toluene solution of the derivatization reagent (5%) was added to the flask, heated to reflux temperature, and maintained under these conditions for 18 h without stirring. After cooling, the solution was removed and the membrane was thoroughly rinsed with dry toluene. In order to ensure complete reaction of the surface hydroxy groups with the alkoxysilanes, each specimen was subsequently subjected to the reaction conditions for a further 1 h. Afterwards, the sample was repeatedly washed with hot toluene to ensure complete removal of the unreacted reagent.

Immobilization: The implantation of gold colloids into the modified pores was carried out by one of two vacuum filling methods. (a) The membrane was washed with water and then placed on a short plastic tube (⊘ = 5 mm) connected to a water pump via a 3-way control valve. A drop of gold colloid solution was applied to the other side of the membrane and drawn into the pores by applying a vacuum. (b) The washed membrane was placed in a 50-ml round-bottomed flask and 10 ml of the gold colloid solution was added. The flask was then carefully evacuated to water-pump pressure and maintained under these conditions overnight. In both methods, immobilization of the colloids was checked by observing the color of the membrane. After incorporation, the membrane was washed thoroughly with distilled water and dried in air at room temperature.

A new type of gold cluster has been synthesized using the silsesquioxane derivative (cyclopentyl)$_7$Si$_8$O$_{12}$(CH$_2$)$_3$SH (T_8-OSS−SH) to exchange the PPh_3 ligands in $(PPh_3)_{12}Au_{55}Cl_6$ by T_8-OSS−SH quantitatively. This exchange causes several important changes in the physical and chemical behavior of the compound. Owing to the presence of cyclopentyl substituents, the cluster becomes soluble in non-polar solvents such as pentane. The stability of this compound compared with that of the PPh_3-protected cluster is considerably higher meaning that decomposition in solution, and even under the high-energetic irradiation in the microscope, is not observed over longer periods of time. The increase in the total diameter from 2.1 to ca. 4.4 nm is probably responsible for these advantageous properties, supported by strong S−Au bonds. The increase in size is also expressed as an increase in the activation energy for electron-tunneling processes through the ligand shells of neighboring clusters in a densely packed pellet. This increase is from 0.16 eV for $(PPh_3)_{12}Au_{55}Cl_6$ to 0.26 eV for the T_8-OSS−SH-protected cluster.

Introduction

In nanoscale structures, the effect of size on the electronic properties (Quantum Size Effect) is an active area of research.[1][2] The main motivation for this work is to understand the change in the electronic properties on the way from the bulk to the nanosized species. By reducing the size of a three-dimensional metal particle, initially having bulk properties, to a zero-dimensional arrangement containing dozens or a few hundreds of atoms, a dramatic change in the electronic properties is observed. The electrons, which are free in all three dimensions, now behave like electrons in a box and the continuous density of states is replaced by a more discrete energy level structure. This band-gap structure can be considered as an intermediate between the typical band structure in the bulk and the bonding and antibonding system in a molecular state. In this way, if a metal cluster has a diameter in the order of the de Broglie wavelength of the valence electrons, the metal core could be regarded as a zero-dimensional quantum dot.

For the two-shell cluster $(PPh_3)_{12}Au_{55}Cl_6$, physical investigations have clearly indicated the existence of Quantum Size Effects.[2][3] Electronic inter-cluster tunneling processes through the ligand shell have been observed and are caused by an electron jump from one metal island to the other.

This class of small metal particle needs a protective ligand shell to prevent uncontrolled growth and the formation of macroscopic metal particles. It therefore seemed interesting to modify the nature and the size of this ligand shell in order to evaluate the influence of the latter on the chemical, physical, and electronic properties. Our investigations are based principally on functionalized organosilsesquioxane ligands (OSS) for several reasons. Firstly, it is likely that they should represent a satisfactory class of spacers to obtain well-separated ligand-stabilized quantum dots. On the other hand, the incomplete T_7-OSS (**1**; T = number of $RSiO_{3/2}$ units), which is used as a precursor in the synthesis of different functionalized OSS, has been subject to great attention since this molecule has a close similarity with the β-cristobalite form of silica.[4]

During the last few years, Feher et al. have focused a great deal of effort to describe a new approach for modeling the chemistry of silica-supported transition-metal complexes.[5][6] After corner-capping reactions with metal complexes, they obtained representative models for catalysts supported on hydroxylated silica. It appears fundamental to try to adapt this approach to cluster chemistry. Previous work with the functionalized T_8-OSS−ethyldiphenylphosphane ligand has already given good precursors to achieve gold clusters but has never led to the isolation of such materials.[7] We have therefore extended these studies with SH-functionalized OSS. We describe here the synthesis of a new thiol-substituted OSS that is obtained by treating 3-mercaptopropyltrimethoxysilane with the incompletely condensed $(cyclopentyl)_7Si_7O_9(OH)_3$. Subsequent use of this functionalized OSS as a protective ligand has allowed us to isolate a new Au_{55} cluster whose numerous advantages are reported.

Results and Discussion

Trichloro(cyclopentyl)silane, $(cyclopentyl)SiCl_3$, is obtained by hydrosilylation of cyclopentene and trichlorosilane in the presence of H_2PtCl_6 as catalyst.[8] The hydrolysis of $(cyclopentyl)SiCl_3$ in a mixture of water/acetone leads to the incompletely condensed $(cyclopentyl)_7Si_7O_9(OH)_3$ (**1**) after two weeks. The reaction between **1** and the (3-mercaptopropyl)trimethoxysilane allows the isolation of the thiol-substituted OSS **2**, whose elemental analysis, IR, ^{1}H-, $^{13}C\{^1H\}$-, and $^{29}Si\{^1H\}$-NMR data are given in the Experimental Section.

Marsmann et al. have already reported the synthesis of a similar thiol-functionalized OSS by co-hydrolysis of trichloro(*n*-propyl)silane with the (3-mercaptopropyl)trimethoxysilane in a 7:1 ratio.[9][10] In the case reported here, we have preferred to perform two successive hydrolyses in order to avoid the statistically possible formation of polythiol-functionalized OSS as products of a competitive reaction.

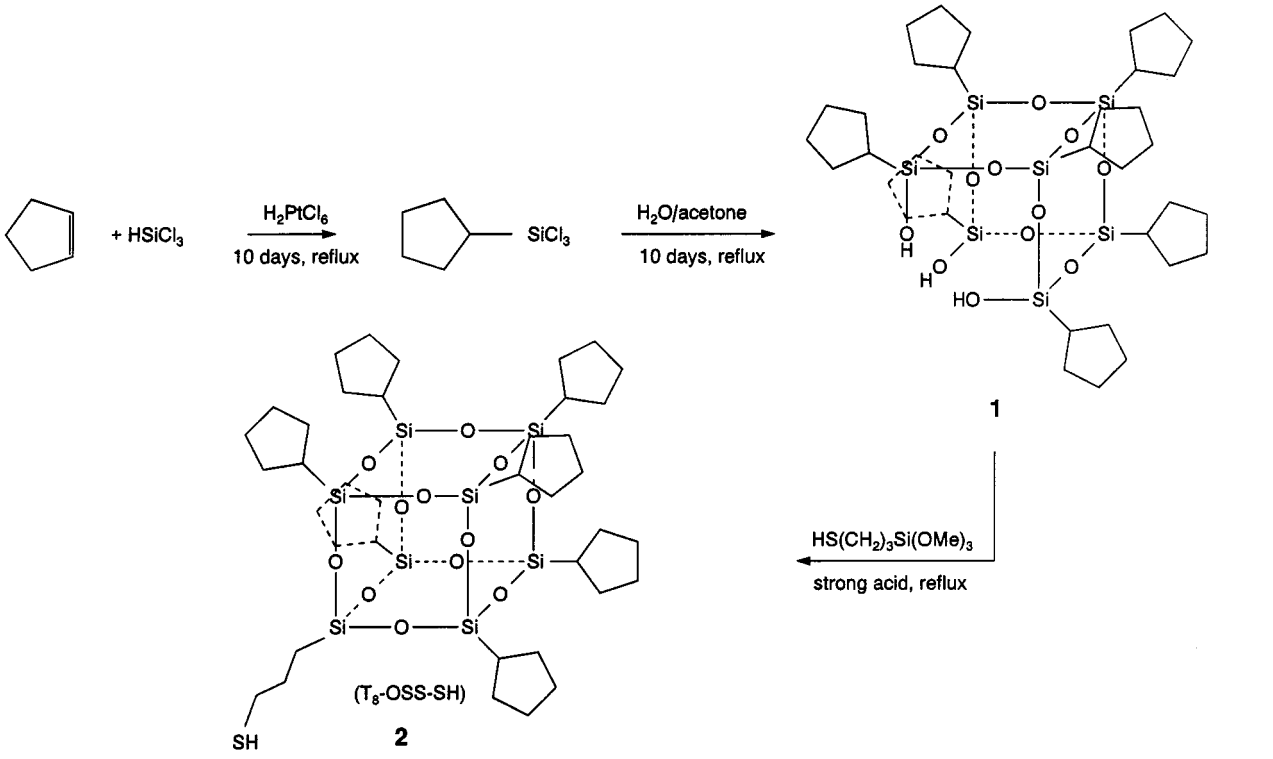
Although it is difficult to evaluate the exact size of **2** due to the flexibility of the propyl chain, the total diagonal length of this ligand should be in a range of 1.4−1.5 nm. As explained in the introduction, this size allows one to predict the possibility of obtaining well-separated quantum dots.

In previous works we described the exchange of the PPh_3 ligand shell in $(PPh_3)_{12}Au_{55}Cl_6$ by $Ph_2PC_6H_4SO_3Na$ in a phase-transfer reaction to give a water-soluble gold cluster.[11] Owing to the well-known affinity of thiol functions to gold atoms[12] and the labile nature of the phosphane ligands bound to the surface gold atoms,[13] we tried to use this method to synthesize thiol-functionalized OSS gold clusters (Equation 1).

$$(PPh_3)_{12}Au_{55}Cl_6 + 12\ T_8\text{-OSS}-SH \rightarrow (T_8\text{-OSS}-SH)_{12}Au_{55}Cl_6\ (\mathbf{3}) + 12\ PPh_3 \quad (1)$$

This approach has been successfully applied and allowed us to obtain the expected cluster in almost quantitative yield. However, to prevent coalescence special precautions should be taken (see Experimental Section). ^{1}H-, $^{31}P\{^1H\}$-NMR spectroscopy, and elemental analysis prove that all

Scheme 1. Synthesis of the silsequioxane ligand $(cyclopentyl)_7Si_8O_{12}[CH_2]_3SH$ (T_8-OSS−SH) (**2**)



twelve phosphane ligands are replaced by thiol-functionalized oligosilsesquioxanes.

The most remarkable changes in behavior are found in the solubility and in the stability of this new cluster. It is soluble in pentane as well as in dichloromethane and the solutions are stable over several months. This behavior is in contrast to the very labile $(PPh_3)_{12}Au_{55}Cl_6$ cluster which degrades, if dissolved, in the course of hours. Transmission electron microscopy (TEM) investigations show monodisperse particles (Figure 2).

Figure 2. Transmission electron microscopy image of a ca. 145 × 200 nm area of randomly oriented $(T_8\text{-OSS}-SH)_{12}Au_{55}Cl_6$ clusters

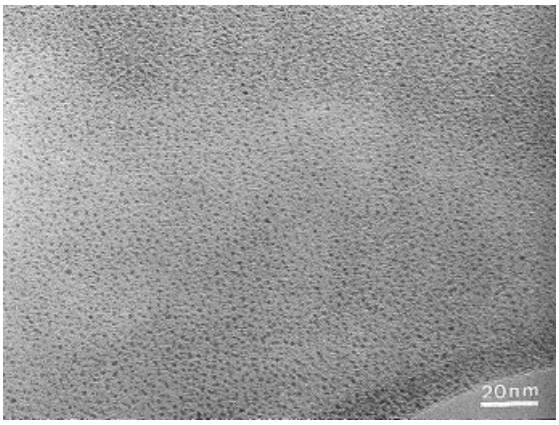


Figure 3 shows a high resolution electron microscopy (HRTEM) image of an area of a well-ordered two-dimensional arrangement of $(T_8\text{-OSS}-SH)_{12}Au_{55}Cl_6$ (**3**) clusters. The formation of ordered monolayers of nanosized metal particles has been observed previously.[14] Ordering seems to happen preferentially if clusters can arrange from solution on a support without chemical interactions between each other and the surface. In this way ideal arrangements may occur owing to the mobility of the clusters. If strong chemical interaction between cluster and surface is provoked organization is clearly hindered, as has been shown in numerous studies of cluster assemblies on chemically modified surfaces.[15] The quality of the ordered area in Figure 3 also becomes visible from a Fourier transform (insert in Figure 3). The angle between the visible peaks can be measured as ca. 75°. The size of the individual clusters can be determined as 1.4 ± 0.1 nm, a value that is in good agreement with the calculated value (1.4 nm). HRTEM results of this quality with other Au_{55} clusters, e.g. $(PPh_3)_{12}Au_{55}Cl_6$, have not been obtained in the past due to very fast coalescence and aggregation processes occurring under the influence of the electron beam[16] and so have led to misinterpretation of HRTEM work by other groups.[17]

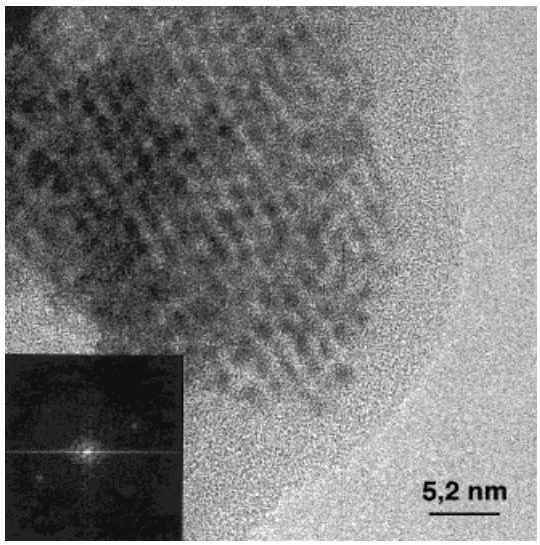
The increase in the thickness of the ligand shell on changing from PPh_3 to T_8-OSS−SH, i.e. from 2.1 to ca. 4.4 nm for the total size of the cluster, leads to considerable changes in the interelectronic relation between neighboring clusters. Recently, we determined the activation energy for electron-tunneling processes in densely packed Au_{55} cluster pellets containing different ligand shells or spacer molecules,[18] and this resulted in a linear relation between cluster spacing and activation energy. $(T_8\text{-OSS}-SH)_{12}Au_{55}Cl_6$ fits well into this series and shows a Coulomb gap of 0.26 eV, corresponding to a distance of the cluster nuclei of ca. 3 nm, a value that is in agreement with the theoretical value of 4.4 nm − 1.4 nm = 3.0 nm.[19]

Figure 3. High resolution transmission electron microscopy image of a 52 × 52 nm area of oriented $Au_{55}(T_8\text{-OSS}-SH)_{12}Cl_6$ clusters; the insert shows the Fourier transform of that area



These results impressively show that a change in the nature of the ligand molecules causes drastic effects in the physical properties. The solubility in pentane is explained by the presence of many non-polar cyclopentyl groups on the ligand. To understand the unusual stability we should consider the total cluster diameter including the metal gold core and the ligand shell. The diameter is close to 4.4 nm [2.1 nm for $(PPh_3)_{12}Au_{55}Cl_6$] and this is probably the main reason that agglomeration among clusters is efficiently prevented. However, this phenomenon is also due to the good affinity of thiols for gold atoms, even if at present we cannot assert anything about the nature of the sulfur−gold bond. Indeed two approaches can be considered. The first involves an elimination or migration of hydrogen and the formation of a covalent bond between gold and the ligand. The second is to consider an interaction of intact thiol with gold atoms and the formation of a dative bond.

Theoretically, there is also one other way that should allow us to synthesize this new cluster by a phase-transfer reaction, according to Equation 2.

$$(PPh_2C_6H_4SO_3Na)_{12}Au_{55}Cl_6 + 12\ T_8\text{-OSS}-SH \rightarrow (T_8\text{-OSS}-SH)_{12}Au_{55}Cl_6 + 12\ PPh_2C_6H_4SO_3Na \quad (2)$$

However, we did not observe any exchange of $PPh_2C_6H_4SO_3Na$ by T_8-OSS−SH. Despite this failure we do not believe that $PPh_2C_6H_4SO_3Na$ ligands have better affinity to gold atoms than T_8-OSS−SH. One hypothesis could be to consider that non-polar thiol-functionalized OSS encounters difficulties in crossing the water phase and the water layer surrounding the water-soluble gold cluster. The fact that no phase-transfer reaction is observed be-

tween $(T_8\text{-OSS}-SH)_{12}Au_{55}Cl_6$, dissolved in dichloromethane, and $PPh_2C_6H_4SO_3Na$, dissolved in water, supports this assumption and indicates clearly that we cannot have any doubts about the affinity of thiol groups for gold atoms.

Following this synthetic work, a number of investigations were undertaken to assess physical properties and applications.

In nanoporous membranes science, the size and the high stability of this newly synthesized gold cluster turned out to be very advantageous. Recent works have shown that in alumina membrane pores near 7 nm in diameter can be filled with this new Au_{55} cluster, leading to a monodisperse helical arrangement.[20] These results are very promising in terms of the elaboration of 1D quantum wires and are all the more interesting since it is still difficult, in practice, to make smaller pores near 3 nm in order to fill them with usual $(PR_3)_{12}Au_{55}Cl_6$ clusters, the size of which does not exceed 2.1−2.2 nm.

Conclusions

The 3-propylthiol-substituted T_8-OSS (T_8-OSS−SH) has allowed us to synthesize, for the first time and in very high yield, a new Au_{55} cluster stabilized with thiol-functionalized OSS ligands.

This work clearly demonstrates the dramatic influence of this new ligand on the cluster properties. Among these properties, the size and the high stability are the greatest advantages for future physical investigations and applications.

This newly synthesized Au_{55} cluster can also be considered as a valuable model for transition-metal complexes or clusters supported on silica surface since OSS show great similarities with the cristobalite form of silica.

Following these first results many future possibilities can be suggested. It should first be possible to modify the length of the functionalized OSS carbon chain to investigate inter-tunnel conductivity and quantum-size effects. Moreover, the functional group could also be changed to synthesize other ligands to stabilize different metal centers in clusters or colloids. In this way the trisilanol part of the incompletely condensed $(cyclopentyl)_7T_7(OH)_3$ allowed us to complex nickel clusters.[21]

Experimental Section

All reactions using air-sensitive reagents and products were performed under nitrogen using standard Schlenk techniques. In the work described here only the (3-mercaptopropyl)trimethoxysilane is highly sensitive in the presence of water and humidity. All solvents were dried and purified using standard procedures. − NMR spectra were recorded with a Bruker DPX working at 300 MHz for ^1H, 75.5 MHz for $^{13}C\{^1H\}$, 121.5 MHz for $^{31}P\{^1H\}$ and 59.6 MHz for $^{29}Si\{^1H\}$. − Infrared spectra were recorded with a Perkin-Elmer FT-IR 1600 spectrometer. − TEM images were recorded using Philips FEG-CM 200 and JEM-4000 EX machines working with 200 and 400 kV accelerating voltages, respectively. − Elemental analyses were carried out by the Analytical Laboratory of the Chemistry Department of the University of Essen.

(Cyclopentyl)SiCl$_3$ and (Cyclopentyl)$_7$T$_7$(OH)$_3$ (**1**): (Cyclopentyl)$SiCl_3$ and **1** were synthesized by well-known literature procedures. **1** was obtained with yields as high as 80% and the purity of this product was assessed by comparison of the NMR and IR data and elemental analysis. − IR: ν = 3200 cm^{-1} m ν(OH), 2949 s, 2865 s, ν(alkyl), 1452 m, 1250 s, δ(C−H), 1120 vs ν_{asym}(Si−O−Si), 498 m ν_{sym}(Si−O−Si). − ^1H NMR ($CDCl_3$): δ = 0.95−1.2 (m, 7 H, CH pentyl), 1.45−1.95 (m, 56 H, CH_2 pentyl), 6.10 (br., 3 H, OH). − $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 21.97, 22.10, 22.48 (s, CH, pentyl), 26.72, 26.75, 26.78 (s, CH_2), 26.99, 27.01, 27.02 (s, CH_2). $C_{35}H_{66}O_{12}Si_7$ (875.5): calcd. C 48.02, H 7.60; found C 47.98, H 7.68.

(Cyclopentyl)$_7$T$_8$(CH$_2$)$_3$SH (**2**): 272 mg (1.39 mmol) of $HS(CH_2)_3Si(OMe)_3$ was placed in a dry 100-ml three-necked round-bottomed flask filled with nitrogen. 30 ml of dried benzene and, with vigorous stirring, 1.2 g (1.39 mmol) of **1** and 10 mg of *p*-toluenesulfonic acid, diluted in few ml of dried acetone, were added. The solution was stirred for 20 h under reflux, then cooled with an ice bath, concentrated to 10 ml and carefully layered with 60 ml of acetonitrile whereupon **2** precipitated. In order to simplify the filtration, the resulting white solid was allowed to stand overnight in a cold place. After filtration and washing with acetonitrile, pure **2** was dried under vacuum. Yield 1.03 g (78%). − IR: ν = 2950 cm^{-1} s ν(alkyl), 2866 s, 2590 w ν(S−H), 1452 m δ(C−H), 1250 s, 1121 vs, ν_{asym}(Si−O−Si), 733 w ν(Si−CH_2), 693 w, 507 m ν_{sym}(Si−O−Si). − ^1H NMR (C_6D_6): δ = 0.75 (t, 2 H, CH_2−Si), 1.10 (t, 1 H, SH), 1.18−1.28 (m, 7 H, CH-pentyl), 1.45−1.90 (m, 56 H, CH_2-pentyl, m, 2 H, $CH_2-CH_2-CH_2SH$), 2.27 (m, 2 H, CH_2−SH). − $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 11.38 (d, CH_2−Si), 22.70, 22.71, 22.73 (s, CH-pentyl, 3:3:1), 27.35 (s, CH_2−SH), 27.43, 27.45, 27.46, 27.83, 27.85, 27.86 (s, CH_2-pentyl, 3:3:1:3:1:3), 28.24 (s, CH_2-CH_2SH). − $^{29}Si\{^1H\}$ NMR (C_6D_6): δ = −66.56 (Si−cyclopentyl, 3), −66.59 (Si−cyclopentyl, 1), −66.62 (Si−cyclopentyl, 3), −66.96 ($SiCH_2$, 1). − $C_{38}H_{70}O_{12}SSi_8$ (975.7): calcd. C 46.77, H 7.23; found C 46.35, H 7.32.

(T$_8$-OSS-SH)$_{12}$Au$_{55}$Cl$_6$ (**3**): 20 mg (1.41 μmol) of $(PPh_3)_{12}Au_{55}Cl_6$ and 16.5 mg (16.9 μmol) of **2** were placed in a dry 100-ml three-necked round-bottomed flask filled with nitrogen. 50 ml of dried benzene and, a few minutes later, 5 × 10 ml of dried dichloromethane were added with vigorous stirring. After evaporation of the solvents, the brown product was extracted with 50 ml of pentane and filtered through an ANOTOP® filter (20 nm). The pentane was removed under vacuum and the new gold cluster was precipitated with 30 ml of acetonitrile and filtered. The filtration pad was washed with copious amounts of acetonitrile in order to remove triphenylphosphane and dried overnight under vacuum. At this stage, the black powder obtained still contained an excess of T_8-OSS−SH due to a slight amount of decomposition during the ligand-exchange reaction. Usual purification methods such as extraction, recrystallisation or chromatography did not allow the isolation of the pure gold cluster and mainly led to progressive decomposition. The best way to purify **3** was found to be ultra-fast centrifuging. This method was successfully applied with a concentrated pentane solution with 28000 rpm (34000 *g*) over 24 h. Yield: 20−30 mg (60−90%). − The spectroscopic data (IR, ^1H, $^{13}C\{^1H\}$ NMR) are the same as for the free ligand (see above). ^{31}P-NMR signals could no longer be observed. − $C_{456}H_{840}Au_{55}Cl_6O_{144}S_{12}Si_{96}$ (22754.5): calcd. C 24.07, H 3.72, S 1.69; found C 25.36, H 3.81, S 1.53. − The slight excess of carbon and hydrogen, as well as the

low value for sulphur, can be explained by the presence of solvent molecules on the cluster surface. Indeed, if this cluster is sterically well covered and protected by functionalized OSS there would still be enough space in between to trap a few solvent molecules.

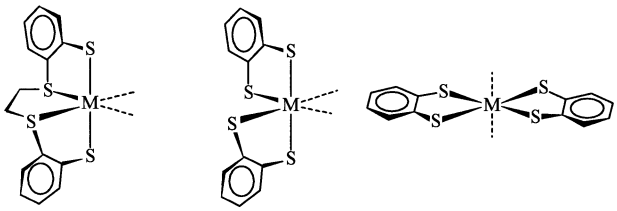
Keywords: S ligands / P ligands / Osmium / Solvent effects

In search for osmium complexes with sulfur-dominated coordination spheres that potentially bind and activate or stabilize nitrogenase relevant small molecules, several osmium−sulfur complexes containing 1,2-bis(2-mercaptophenylthio)ethane(2−) ('S_4'$^{2-}$) and benzenedithiolate ('S_2'$^{2-}$) ligands were synthesized. [Os^{II}(PR_3)$_2$('S_4')] [R = Ph (**1**), Et (**2**)], [Os^{IV}(PR_3)$_2$('S_2')$_2$] [R = Et (**3**), Pr(**4**), Me(**5**), Ph(**6**)], [Os^{IV}(PCy_3)('S_2')$_2$] (**7**), ($PHCy_3$)[Os^{III}('S_2')$_2$] (**8a**), (NMe_4)-[Os^{III}('S_2')$_2$] (**8b**), and (NBu_4)$_2$[Os^{IV}('S_2')$_3$] (**9b**) were obtained in reactions starting from commercially available osmium compounds and the sulfur and phosphane ligands. The presence or absence of reducing solvents strongly influenced these reactions. Octahedral (**3**), (**4**), and ($PHCy_3$)$_2$[Os^{IV}('S_2')$_3$] (**9a**) were characterized by X-ray structure analysis, leading to the conclusion that despite the high oxidation state of the osmium centers, innocent dithiolate ligands are present. The stabilization of the Os^{IV} centers is traced back to S→M π donation. Close inspection of **1** and **2** revealed a large influence of the phosphane ligands on the stability of Os^{II} thioether complexes. While **1** is reasonable stable, **2** readily gives **3** and ethylene via intramolecular 'S_4'$^{2-}$ ligand reduction and Os^{II} → Os^{IV} oxidation. UV-Vis spectra of **3**−**5** indicate phosphane dissociation in solution leading to pentacoordinate [Os(PR_3)('S_2')$_2$] complexes. This was confirmed by the synthesis of pentacoordinate [Os(PCy_3)('S_2')$_2$] (**7**).

Introduction

Transition metals in sulfur-dominated coordination spheres form the active centers of numerous oxidoreductases such as nitrogenases, hydrogenases and CO dehydrogenase[1]. In the search for low-molecular compounds that combine structural and reactivity features of these [MS] enzymes we have found that transition metal complexes containing [M('S_4')] (**A**) or [M('S_2')$_2$] fragments (**B** and **C**) ['S_4'$^{2-}$ = 1,2-bis(2-mercaptophenylthio)ethane(2−); 'S_2'$^{2-}$ = 1,2-benzenedithiolate(2−)] can bind and activate or stabilize a considerable number of small molecules that are key intermediates in enzymatic processes[2]. In a few cases, catalytic reaction cycles could be developed[3]. For example, [Rh(L)('S_4')]$^+$ complexes (L = CO, PCy_3) catalyze the heterolytic cleavage of dihydrogen and D_2/H^+ exchange that are features of hydrogenases[4].

Iron and ruthenium [M('S_4')] complexes bind key intermediates of N_2 fixation such as N_2H_2, N_2H_4 and NH_3[2]. However, attempts to coordinate also dinitrogen to such fragments have as yet remained unsuccessful. In this context it is to be noted that transition metal N_2 complexes with sulfur dominated coordination spheres are conspicuously rare. In fact, [Mo(N_2)$_2$(octamethyltetrathiacyclohexadecane)] is the only example for the coordination of N_2 to a metal center carrying exclusively sulfur coligands[5].



For this reason, we have started to explore the osmium chemistry of 'S_4'$^{2-}$ and 'S_2'$^{2-}$ ligands, anticipating that with [Os('S_4')] or [Os('S_2')$_n$] species complexes could become accessible that proved inaccessible with the iron and ruthenium homologues. [Os('S_4')] complexes have been unknown as yet, the chemistry of osmium benzene-1,2-dithiolate and related ligands is largely unexplored[6]. No benzenedithiolate complex was known, and only a very few complexes with toluenedithiolate, maleonitriledithiolate and similar ligands have been described[7].

Results

[Os($'S_4'$)] Complexes

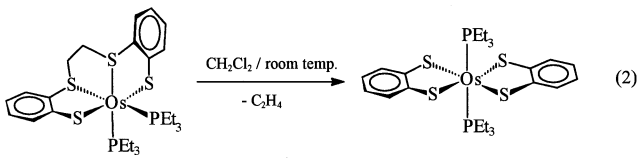
Two target complexes containing [Os($'S_4'$)] cores could be obtained from commercially available $OsCl_3 \cdot x\,H_2O$ by the reaction according to eq. (1).

$$OsCl_3{\cdot}xH_2O + {'S_4'}\text{-}H_2 + PR_3\ \text{exc.} \xrightarrow[\text{reflux}]{\text{THF / MeOH}} [Os(PR_3)_2({'S_4'})] \quad (1)$$

R = Ph (**1**), Et (**2**)

Heating to reflux, an excess of the respective phosphane, and the use of the solvent mixture MeOH/THF proved necessary. The excess of phosphane and the methanol probably serve as reducing reagents for $OsCl_3 \cdot x\,H_2O$. The methanol additionally causes precipitation of the resultant yellow to yellow-green [Os(PR_3)$_2$($'S_4'$)] complexes **1** (PPh_3) and **2** (PEt_3) from the reaction solutions. When pure THF was used as solvent, neither **1** nor **2** could be isolated.

In these experiments, it was noted that **2** is rather thermolabile. The reaction leading to its formation according to eq. (1) had to be quenched after ca. one hour of refluxing in order to avoid a drastic decrease in yield. Already at room temperature, [Os(PEt_3)$_2$($'S_4'$)] (**2**) slowly decomposes according to eq. (2).



(2)

2 **3**

An intramolecular redox reaction leads to release of C_2H_4 and formation of the Os^{IV} complex [Os(PEt_3)$_2$($'S_2'$)$_2$] (**3**). The evolving ethylene could be detected by its ^{1}H-NMR signal at $\delta = 5.24$[8].

Complexes **1** and **2** were characterized by the common spectroscopic methods. For example, the ^{1}H-NMR spectra of **1** and **2** exhibit signal patterns that are typical of C_2 symmetrical [ML_2($'S_4'$)][9] complexes. Cyclic voltammetry of **2** further revealed two reversible redox waves at $E_{1/2} = -20$ mV and $E_{1/2} = 950$ mV that can be assigned to the formation of the $[\mathbf{2}]^+$ and $[\mathbf{2}]^{2+}$ cations.

Attempts to substitute one PPh_3 ligand of **1** by N_2H_4 or CO remained unsuccessful. Complex **1** proved substitution inert even at elevated temperatures and pressures. In this respect, **1** contrasts the homologous [Ru(PPh_3)$_2$($'S_4'$)] which readily exchanges one PPh_3 ligand for numerous two electron donors at room temperature[10].

The facile formation of the Os^{IV} complex [Os(PEt_3)$_2$($'S_2'$)$_2$] (**3**) from the Os^{II} complex [Os(PEt_3)$_2$($'S_4'$)] (**2**) and the rareness of osmium benzene dithiolate complexes in higher oxidation states prompted us to investigate these species more closely, which are also potentially suited to yield complexes with [Os($'S_4'$)] cores via template alkylations[9].

Synthesis and Characterization of the Hexa- and Pentacoordinate Os^{IV} Complexes [Os(PR_3)$_2$($'S_2'$)$_2$] (R = Me, Et, Pr, Ph), and [Os(PCy_3)($'S_2'$)$_2$]

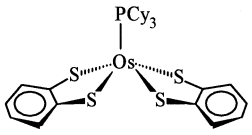
[Os(PR_3)$_2$($'S_2'$)$_2$] complexes were obtained with various PR_3 ligands according to eq. (3).

$$(NH_4)_2[OsBr_6] + 2\ {'S_2'}\text{-}Li_2 + 2\ PR_3 \xrightarrow[\text{reflux / 19 h}]{\text{THF / MeOH}} [Os(PR_3)_2({'S_2'})_2] \quad (3)$$

R = Et (**3**), Pr (**4**), Me (**5**), Ph(**6**)

The resultant complexes **3**–**6** are gray-black to black-violet and diamagnetic. While the PMe_3 and PPh_3 complexes **5** and **6** are only very sparingly soluble, the PEt_3 and PPr_3 complexes **3** and **4** readily dissolve in common organic solvents. The complexes were characterized by elemental analyses and spectroscopic methods, and **3** and **4** also by X-ray structure analyses. The Os^{IV} complexes **3** and **4** each exhibit a characteristic low field shifted ^{31}P-NMR signal in the region of $\delta = -200$ and contrast in this respect the Os^{II} complexes **1** and **2** whose ^{31}P-NMR signals appear at δ ca. -20. No ^{31}P-NMR spectrum could be recorded of the sparingly soluble PMe_3 complex **5**. The ^{31}P-NMR spectrum of the PPh_3 complex **6** revealed one broad signal at $\delta = -46.5$. The shift of this signal indicates dissociation of **6** to give pentacoordinate [Os(PPh_3)($'S_2'$)$_2$] (vide infra).

When the reaction according to eq. (3) was carried out with the sterically very demanding phosphane PCy_3, no hexacoordinate complex but the pentacoordinate [Os(PCy_3)($'S_2'$)$_2$] (**7**) formed. This even occurred when a fourfold excess of PCy_3 was applied. Complex **7** was obtained as violet microcrystals that proved diamagnetic and well soluble in organic solvents. The number and splitting of the ^{1}H- and ^{13}C-NMR signals of **7** indicate that **7** possesses lateral symmetry. The ^{31}P-NMR spectrum exhibits one signal at $\delta = -29.2$ whose chemical shift contrasts the ^{31}P-NMR shifts (-200 ppm) of the bisphosphane complexes **3** and **4**. The FD mass spectrum of **7** revealed the molecular ion at $m/z = 752$ and no ions of higher masses. These results and, in addition, the UV-Vis-NIR spectroscopic properties of **7** versus those of **3**–**5** (vide infra) indicate that **7** is mononuclear possessing the structure indicated by formula **D**.



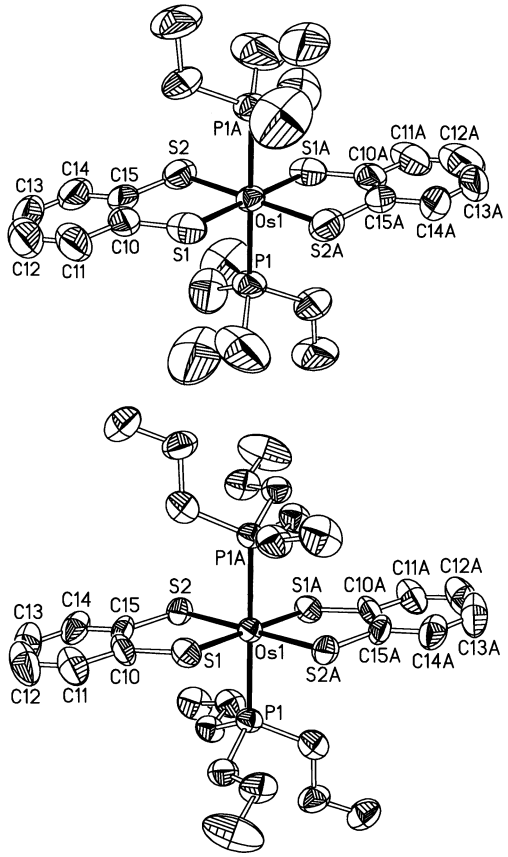
D

X-ray Structure Determination of [Os(PEt_3)$_2$($'S_2'$)$_2$] (3) and [Os(PPr_3)$_2$($'S_2'$)$_2$] (4)

The molecular structures of **3** and **4** are depicted in Figure 1.

Complexes **3** and **4** both possess crystallographically imposed inversion symmetry and exhibit pseudo-octrahedral coordination with the phosphane ligands in *trans* positions. The corresponding Os–P and Os–S distances in **3** and **4**

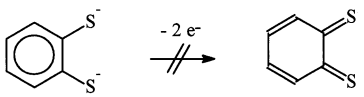
Figure 1. ORTEP plots of a) $[Os(PEt_3)_2(′S_2′)_2]$ (**3**) and b) $[Os(PPr_3)_2(′S_2′)_2]$ (**4**) drawn with 50% probability ellipsoids (H atoms omitted)[a]



[a] Selected distances [pm] and angles [°]: **3**: Os(1)−S(1) 231.1(2), Os(1)−S(2) 232.8(2), Os(1)−P(1) 244.8(2), S(1)−C(10) 174.8(8), S(2)−C(15) 173.1(8), C(10)−C(11) 142.4(10), C(11)−C(12) 138(2), C(12)−C(13) 130(3), C(14)−C(15) 141.2(9), C(10)−C(15) 139.0(11). S(1)−Os(1)−P(1) 90.58(7), S(2)−Os(1)−P(1) 90.46(7), S(1)−Os(1)−S(2) 86.33(7). − **4**: Os(1)−S(1) 231.2(2), Os(1)−S(2) 231.7(2), Os(1)−P(1) 244.2(2), S(1)−C(10) 172.8(11), S(2)−C(15) 172.6(9), C(10)−C(11) 137.9(13), C(11)−C(12) 137(2), C(12)−C(13) 136(2), C(14)−C(15) 138.1(12), C(10)−C(15) 145.3(14), S(1)−Os(1)−P(1) 89.85(8), S(2)−Os(1)−P(1) 90.65(8), S(1)−Os(1)−S(2) 86.29(8).

are identical within the 3σ criterion. The averaged Os−S distances of **3** and **4** [231.7(2) pm] are identical to the Ru−S distances of the analogous $[Ru(PMe_3)_2(′S_2′)_2]$ [231.7(1) pm][11] and are in the usual range of osmium(IV) thiolate complexes. Os−S distances of osmium(IV) thiolate complexes cover a range from 220 to 241 pm and depend on the coordination number and geometry[12].

Detailed inspection of the C−C and C−S bond distances in the $C_6H_4S_2^{2-}$ ligands revealed no evidence for a partial oxidation of the benzenedithiolate ligands to give dithiocyclohexadiene units according to eq. (4).



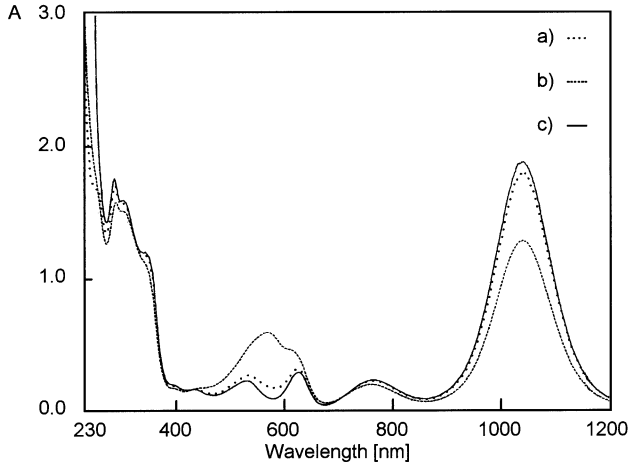
(4)

In this respect, the Os^{IV} complexes **3** and **4** behave identical to the homologous Fe^{IV} complex $[Fe(PMe_3)_2(′S_2′)_2]$ and related species, which have been extensively discussed previously[13]. They allow to conclude that benzenedithiolate behaves as "innocent" dithiolate ligand such that stabilization of higher metal oxidation states is rather due to increasing S→M π donation.

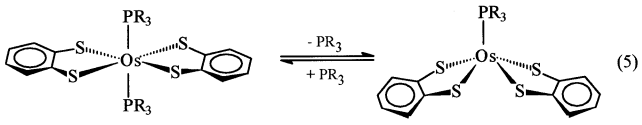
Reversible Dissociation of $[Os(PR_3)_2(′S_2′)_2]$ Complexes; UV-Vis-NIR Spectra

The UV-Vis-NIR spectra of the hexacoordinate complexes **3**−**5** exhibit very intense absorptions (ε > 40000 $l·mol^{-1}·cm^{-1}$) in the region of 950−1050 nm. These bands can be assigned to sulfur-metal LMCT transitions, and they slowly decrease in intensity when dilute solutions of **3**−**5** are kept at room temperature. Simultaneously, the solutions change color from deep red to violet blue. Addition of the respective phosphane reverses these effects (Figure 2).

Figure 2. UV-Vis-NIR spectra of a) **4** in CH_2Cl_2 (λ_{max} = 1043 nm, ε = 42740 $lmol^{-1}cm^{-1}$), b) after 12 h, c) after addition of excessive PPr_3



These observations indicate that the hexa-coordinate complexes reversibly dissociate in solution to yield pentacoordinate species according to eq. (5).



(5)

4

This assumption is supported by the electronic spectrum of the pentacoordinate complex $[Os(PCy_3)(′S_2′)_2]$ (**7**) which does not exhibit an absorption in the NIR region. It is further corroborated by the FD mass spectra of complexes **3**−**5**, which all show intensive signals of the fragment ions $[Os(PR_3)(′S_2′)_2]^+$ in addition to the molecular ions.

Synthesis and Properties of the Os^{III} Complex $(PHCy_3)[Os(′S_2′)_2]$ (8a)

The $[Os(PR_3)_2(′S_4′)]$ complexes **1** and **2** had shown that the solvent and reaction time could markedly influence the course of synthesis reactions. This was also observed when $(NH_4)_2[OsBr_6]$, $′S_2′$-Li_2 and an excess of PCy_3 were com-

bined not in THF as in the reaction according to eq. (3), but in a mixture of THF and MeOH, and refluxed for three days. In this case, not the Os^{IV} complex **7** but the Os^{III} complex $(PHCy_3)[Os('S_2')_2]$ (**8a**) formed as major product according to eq. (6).

$$(NH_4)_2[OsBr_6] + 2\ 'S_2'\text{-}Li_2 + \text{exc. } PCy_3 \xrightarrow[3\ d,\ reflux]{THF\ /\ MeOH} (PHCy_3)[Os('S_2')_2] \quad (6)$$

8a

Complex **8a** precipitated as orange micro-crystals from the boiling reaction mixture. The violet-blue $[Os(PCy_3)('S_2')_2]$ (**7**) formed only as minor by-product and could be isolated in negligible amounts when the mother liquors were cooled to −20 °C.

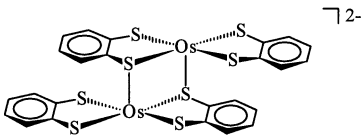
Apparently, in the reaction according to eq. (6) the solvent MeOH and possibly also the excess PCy_3 act as reducing reagents upon $(NH_4)_2[OsBr_6]$. Complex **8a**, whose elemental composition differs from that of the Os^{IV} complex $[Os(PCy_3)('S_2')]$ (**7**) only by one proton, was identified by its spectra, magnetism, and by the metathesis reaction with NMe_4OH yielding the NMe_4^+ salt $(NMe_4)[Os('S_2')_2]$ (**8b**) according to eq. (7).

$$(PHCy_3)[Os('S_2')_2] + \text{exc. } NMe_4OH \xrightarrow{THF} (NMe_4)[Os('S_2')_2] + (PHCy_3)OH \quad (7)$$

8a **8b**

The presence of the $PHCy_3^+$ cation in **8a** could further be concluded from the ^{1}H-NMR spectrum of **8a** which revealed the characteristic ^1J(PH) coupling constant (475 Hz) of the $PHCy_3^+$ cation.

8a is paramagnetic and exhibits a magnetic moment of μ_{eff} = 3.04 μ_B. The magnetic moment is compatible with three unpaired electrons at Os^{III} centers in square planar or tetragonal pyramidal coordination. In contrast octahedral Os^{III} thiolate phosphane complexes with one unpaired electron exhibit magnetic moments in the range μ_{eff} = 1.85−1.98 μ_B[14]. The structure of the anion in **8a** remains unknown, however, the dinuclear structure of the homologous iron complex that was revealed by X-ray structure analysis[15] suggests a similar structure for **8a** as indicated by formula **E.**



E

Complex **8a** is sparingly soluble in THF or MeOH, but readily dissolves in CH_2Cl_2. Also in the absence of air, the resultant orange CH_2Cl_2 solutions are unstable and turn to deep violet in the course of a few hours, because **8a** spontaneously forms **7** according to eq. (8).

$$(PHCy_3)[Os('S_2')_2] \xrightarrow[room\ temp.]{CH_2Cl_2} [Os(PCy_3)('S_2')_2] + H^+ + e^- \quad (8)$$

8a **7**

This reaction involves an $Os^{III} \rightarrow Os^{IV}$ oxidation, but the oxidizing reagent as well as the fate of the formally released proton and electron remain unknown. Evolution of H_2 could not be observed[16].

Synthesis and Properties of $(NBu_4)_2[Os('S_2')_3]$ and $(PHCy_3)_2[Os('S_2')_3]$

Single crystals that precipitated in minor amounts from the mother liquors of the $[Os(PCy_3)('S_2')_2]$ (**7**) synthesis could be characterized by X-ray structure analysis revealing that the crystals contained the salt $(PHCy_3)_2[Os('S_2')_3]$ (**9a**). The NBu_4^+ salt $(NBu_4)_2[Os('S_2')_3]$ (**9b**) was subsequently obtained in the straight forward synthesis according to eq. (9).

$$(NH_4)_2[OsBr_6] + 6\ NBu_4OH + 3\ 'S_2'\text{-}H_2 \xrightarrow[2\ h,\ reflux]{MeOH} (NBu_4)_2[Os('S_2')_3] \quad (9)$$

9b

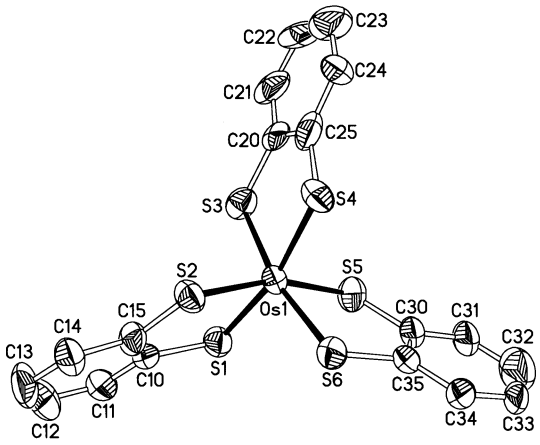
9b was isolated in form of dark red crystals, which were characterized by elemental analysis and spectroscopic methods. **9b** is diamagnetic. Its cyclic voltammogramm shows one irreversible (−580 mV) and two reversible anodic redox waves (−80 mV and 180 mV). They can be assigned to the redox steps indicated by eq. (10).

$$[Os('S_2')_3]^{3-} \underset{-e^-}{\overset{+e^-}{\leftarrow}} [Os('S_2')_3]^{2-} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [Os('S_2')_3]^{-} \underset{+e^-}{\overset{-e^-}{\rightleftharpoons}} [Os('S_2')_3]^{0} \quad (10)$$

- 580 mV - 80 mV 180 mV

Figure 3 depicts the molecular structure of the anion of $(PHCy_3)_2[Os('S_2')_3]$ (**9a**).

Figure 3. ORTEP plot of the anion of $(PHCy_3)_2[Os('S_2')_3]$ (**9a**) drawn with 50% probability ellipsoids (H atoms omitted)[a]



[a] Selected distances [pm]: Os(1)−S(1) 236.6(2), Os(1)−S(2) 235.7(2), Os(1)−S(3) 235.6(2), Os(1)−S(4) 234.5(3), Os(1)−S(5) 235.0(3), Os(1)−S(6) 236.0(3), S(1)−C(10) 175.8(9), S(2)−C(15) 173.6(9), S(3)−C(20) 177.4(10), S(4)−C(25) 172.7(11), S(5)−C(30) 176.7(11), S(6)−C(35) 177.2(10); average S−S(intra) 3.190, S−S(inter) 3.385. − Selected angles [°]: S(1)−Os(1)−S(4) 167.40(9), S(2)−Os(1)−S(5) 163.53(9), S(3)−Os(1)−S(6) 168.23(8), S(1)−Os(1)−S(2) 85.06(8), S(3)−Os(1)−S(4) 85.40(9), S(5)−Os(1)−S(6) 85.23(10).

The average Os−S distances in **9a** [235.6(3) pm] are longer than those in the neutral $[Os(PR_3)_2('S_2')_2]$ complexes **3** and **4** [231.7(2) pm]. This can be traced back to reduced

S→M π donation in **9a** which unlike **3** and **4** does not exhibit π acceptor phosphane ligands. As for **3** and **4**, scrutinizing the C−C and C−S distances yielded no evidence for cyclohexadienedithioketone-like structures of the $C_6H_4S_2$ ligands.

An important structural feature of numerous dithiolene type $[M(S_2C_2R_2)_3]$ complexes (R = H, Ph) is their trigonal prismatic coordination geometry. Potential factors, e.g., S···S interactions between vicinal S donors, metal-ligand π bonding and the overall charge of the complexes, stabilizing the trigonal pyramidal versus the octahedral coordination geometry have been elucidated[17]. The analysis of the S−Os−S angles in **9a** shows that **9a** is best described to possess pseudo-octahedral geometry. Due to the chelate bite of the $C_6H_4S_2$ units, the ideal S−M−S angle which can be reached for *'trans'* sulfur donors in octahedral complexes is 170° (instead of 180°)[18]. The corresponding angle in trigonal prismatic complexes is 136°. The respective S−Os−S angles in **9a** vary between 163.5(1)° and 168.2(1)° and are thus close to the ideal angle for octahedral coordination.

A literature search revealed that there are only two other dianionic $[M('S_2')_3]^{2-}$ complexes (M = Ti[19], Zr[18]) that exhibit octahedral geometry. The anion in $(AsPh_4)_2[W('S_2')_3]$ shows average S−W−S angles of 151.6°[20]. It thus represents an intermediate between octahedral and trigonal prismatic coordination comparable to the structure of the monoanion in $(AsPh_4)[Nb('S_2')_3]$[21].

Discussion and Summary

The Os^{II} complexes $[Os(PR_3)_2('S_4')]$ (**1**) (R = Ph) and **2** (R = Et) could be directly synthesized from $'S_4'^{2-}$, the respective phosphane and commercially available $OsCl_3 \cdot x\ H_2O$. Complexes **1** and **2** revealed a remarkable influence of the phosphane coligands upon the complex stability and reactivity. **1** proved temperature stable and substitution inert contrasting the homologous $[Ru(PPh_3)_2('S_4')]$, which readily exchanges one PPh_3 ligand. **2** is so labile that already at room temperature it readily releases C_2H_4 and forms the Os^{IV} complex $[Os(PEt_3)_2('S_2')_2]$ (**3**) via an intramolecular redox reaction. Evidently, the strongly electron donating PEt_3 and the a priori high electron density of the Os^{II} center destabilize the $'S_4'^{2-}$-ligand to such an extent that its C_2H_4 bridge is reductively eliminated. Such C_2H_4 eliminations from the $'S_4'^{2-}$-ligand have been observed previously with electron rich Fe and Mo species[22]. In this respect, **2** unexpectedly strongly differs from its iron and ruthenium alkylphosphane $[M(PR_3)_2('S_4')]$ counterparts which are perfectly stable at ambient conditions. Complex **3** and the PMe_3 **5**, PPr_3 **4**, and PPh_3 **6** analogues were directly obtained from $[OsBr_6]^{2-}$, $'S_2'^{2-}$ and the respective phosphanes. X-ray structure analyses of **3** and **4** revealed that these complexes possess planar $[Os('S_2')_2]$ cores and *trans* phosphanes. UV-Vis-NIR spectroscopy further showed that the hexacoordinate complexes **3** to **5** have very intense NIR bands and reversibly dissociate yielding pentacoordinate $[Os(PR_3)('S_2')_2]$ complexes. When PR_3 is the sterically very bulky PCy_3, only the pentacoordinate species $[Os(PCy_3)('S_2')_2]$ (**7**) could be isolated. The influence of solvents upon the course of reactions became particularly evident when the synthesis of (**7**) was tried in MeOH instead of THF. In this case, the Os^{III} complex $(PHCy_3)[Os('S_2')_2]$ (**8a**) formed. Complex **8a** probably possesses a dinuclear anion, is paramagnetic and spontaneously oxidizes in CH_2Cl_2 to give **7**. Cyclic voltammetry revealed redox activity also for **2**, **3**, and $(NBu_4)_2[Os('S_2')_3]$ (**9b**) which forms from stoichiometric amounts of $[OsBr_6]^{2-}$, NBu_4^+, and $'S_2'^{2-}$. X-ray structure analysis of the analogous $(PHCy_3)_2[Os('S_2')_3]$ (**9a**) revealed pseudo-octahedral coordination geometry of the $[Os('S_2')_3]^{2-}$ anion.

Scrutinizing the C−C and C−S distances in the $C_6H_4S_2$ units of **3**, **4**, and **9a** corroborates previous results. They indicate that benzenedithiolate behaves as "normal" dithiolate also when binding to metal centers in higher oxidation states. The stabilization of these oxidation states thus is better traced back to increasing S→M π donation than to a "non-innocence" of benzenedithiolate that involves a break-up of the aromatic benzene system.

In summary, first examples of complexes containing $[Os('S_4')]$ and $[Os('S_2')_2)]$ fragments have been synthesized and characterized. The complexes differ unexpectedly strongly from their iron and ruthenium homologues. While with $'S_4'^{2-}$ or $'S_2'^{2-}$ ligands the metal oxidation state +IV is found only in very few iron and only unsignificantly more ruthenium complexes, it is well accessible with Os complexes.

Financial Support of this work by the *Deutsche Forschungsgemeinschaft* and the *Fonds der Chemischen Industrie* is gratefully acknowledged.

Experimental Section

General Methods: Unless noted otherwise, all reactions were carried out under an atmosphere of dinitrogen at room temperature by using standard Schlenk techniques. Solvents were dried and distilled before use. − Physical measurements were carried out with the following instruments: IR spectra, Perkin Elmer 16PC FTIR spectrometer (IR spectra of solutions were recorded in CaF_2 cuvettes with compensation of the solvent bands, solids were measured as KBr pellets); mass spectra, Varian MAT 212; UV/Vis/NIR spectra, Shimadzu UV3101 PC spectrometer; NMR spectra, Jeol FT-JNM-GX 270, EX 270 and LA 400; Magnetic susceptibility: Johnson Matthey susceptibility balance; Cyclic voltammograms, EG&G potentiostat PAR model 264A with glassy carbon working electrode, Pt counter electrode and Ag/AgCl reference electrode. Conducting electrolyte: 0.1 M NBu_4PF_6. Potentials are referred to NHE via $Cp_2Fe^{0/+}$ as internal standard. $Cp_2Fe^{0/+}$ = 0.40 V vs. NHE[23]. − 1,2-benzenedithiol[24] and 1,2-bis(2-mercaptophenylthio)ethane $'S_4'$-H_2[25] were prepared as described in the literature.

[Os(PPh$_3$)$_2$('S$_4$')] (**1**): $OsCl_3 \cdot x\ H_2O$ (335 mg, 1.1 mmol), PPh_3 (1 g, 3.8 mmol), and $'S_4'$-H_2 (350 mg, 1.1 mmol) were suspended in MeOH (20 ml) and THF (40 ml) and refluxed for 24 h. The resultant suspension was cooled to room temperature, the precipitating yellow-green crystals were separated, recrystallized from CH_2Cl_2 (20 ml), and dried in vacuo. Yield: 500 mg of **1**·0.25 CH_2Cl_2 (44%). − $C_{50.25}H_{42.5}OsP_2S_4$ (1044.5): calcd. C 57.78, H 4.10, S 12.28; found C 57.55, H 4.15, S 12.22. − ^{1}H NMR (CD_2Cl_2): δ = 6.4−7.5 (m, 38 H, C_6H_4, C_6H_5), 2.15−2.4 (m, 2 H,

C_2H_4), 1.6−1.8 (m, 2 H, C_2H_4). − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 159.6, 136.2 (m), 135.4 (t), 133.1, 130.8, 129.8, 129.2, 128.1, 126.7 (t), 121.6 (C_6H_4, C_6H_5), 43.3 (C_2H_4). − $^{31}P\{^1H\}$ NMR (CD_2Cl_2) δ = −14.4 (s, *P*Ph_3).

[Os(PEt$_3$)$_2$('S$_4$')] (**2**): $OsCl_3 \cdot x\ H_2O$ (360 mg, 1.2 mmol), PEt_3 (4 ml, 26 mmol), and 'S$_4$'-H_2 (380 mg, 1.2 mmol) were suspended in MeOH (35 ml) and THF (20 ml) and refluxed for 1 h. The resultant solution was filtered and cooled to −20°C. Yellow crystals precipitated that were separated after one week, washed with MeOH (50 ml) and *n*-hexane (20 ml), and dried in vacuo. Yield: 550 mg of **2** (62%). − $C_{26}H_{42}OsP_2S_4$ (735.0): calcd. C 42.49, H 5.76, S 17.45; found C 42.85, H 5.75, S 17.54. − FD MS (CH_2Cl_2); *m/z*: 736 [M^+]. − ^1H NMR (CD_2Cl_2), δ = 7.3−7.6 (m, 4 H, C_6H_4), 6.65−7.0 (m, 4 H, C_6H_4), 2.45−2.7 (m, 2 H, C_2H_4), 1.7−2.2 (m, 12 H, CH_2), 1.4−1.7 (m, 2 H, C_2H_4), 0.8−1.2 (m, 18 H, CH_3). − ^{31}P NMR (CD_2Cl_2), δ = −26.3 (s, *P*Et_3). − CV (CH_2Cl_2, room temp., [mV]); *E* = −20 (rev.), −950 (rev.).

[Os(PR$_3$)$_2$('S$_2$')$_2$] with R = Me, Et, Pr, Ph

General Procedure: At −78°C, 2.5 M *n*BuLi in *n*-hexane (0.8 ml, 2 mmol) was added to a solution of 'S$_2$'-H_2 (0.12 ml, 1 mmol) in THF (10 ml). The solution was warmed to room temperature and added to a suspension of $(NH_4)_2[OsBr_6]$ (350 mg, 0.5 mmol) and PR_3 (0.15 ml, 1 mmol) in MeOH or THF (10 ml). The resultant suspension was heated under reflux for 19 h, filtered, and cooled to room temperature or −20°C. The resultant complexes precipitated as black crystals or gray-black powders that were collected after one week, washed with MeOH (20 ml) and dried in vacuo. Complex **6** required recrystallization from THF (20°C → −20°C) in order to obtain correct elemental analyses.

[Os(PEt$_3$)$_2$('S$_2$')$_2$] (**3**): Yield: 225 mg of **3** (50%). − $C_{24}H_{38}OsP_2S_4$ (707.0): calcd. C_6H_4). − CV (CH_2Cl_2, room temp., [mV]); E_1 = −80 (rev.), 180 (rev.), −580 (irrev.).

X-ray Structure Analysis of $[Os(PEt_3)_2('S_2')_2]$ (**3**), $[Os(PPr_3)_2('S_2')_2]$ (**4**), *and* $(PHCy_3)_2[Os('S_2')_3]$ (**9a**): Black single crystals of $[Os(PEt_3)_2('S_2')_2]$ (**3**) and $[Os(PPr_3)_2('S_2')_2]$ (**4**) were grown from MeOH (**3**) or MeOH/THF (**4**) solutions at −20°C. A few black single crystals of $(PHCy_3)_2[Os('S_2')_3]$ (**9a**) were obtained as minor by-product from the THF/MeOH mother liquor resulting from the synthesis of $[Os(PCy_3)('S_2')_2]$ (**7**). Suitable single crystals were sealed under N_2 in glass capillaries. The data were collected using a Siemens P4 diffractometer. The structures were solved with direct methods and refined using full-matrix least-squares procedures on F^2 values (SHELXTL 5.03)[26]. Non-hydrogen atoms were refined anisotropically, hydrogen positions were taken from the difference Fourier synthesis and fixed on their positions with a common isotropic thermal parameter in case of **4**, while for **3** and **9a** all H-atoms are geometrically positioned. One cyclohexyl group (C70−C75) of the cation in **9a** is disordered. Two different orientations were refined, with a site occupancy of 50%. Table 1 lists selected crystallographic data of **3**, **4**, and **9a**[27].

Zinc Complexes of Tripodal N_3O Ligands☆

Alexander Trösch and Heinrich Vahrenkamp*

Institut für Anorganische und Analytische Chemie der Universität Freiburg,
Albertstr. 21, D-79104 Freiburg, Germany

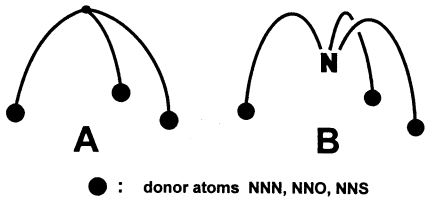
Received December 30, 1997

Keywords: Zinc complexes / Tripodal ligands / Ligand bridging / Halide, phenolate, thiophenolate, and phosphate coligands

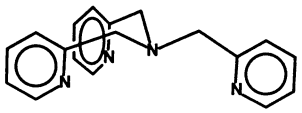
The tripodal N,O ligands bis(2-pyridylmethyl)(*o*-hydroxybenzyl)amine ($\mathbf{L}^1$) and bis(2-pyridylmethyl)(2-carboxyethyl)amine ($\mathbf{L}^2$) were tested for their ligating properties towards zinc. Zinc halides yielded $\mathbf{L}^1{\cdot}Zn{-}Hal$ (**1a**−**c**, Hal = Cl, Br, I) and $\mathbf{L}^2{\cdot}Zn{-}Hal$ (**2a**−**c**, Hal = Cl, Br, I). Subsequent treatment of $\mathbf{L}^1$ with $ZnEt_2$ or $Zn[N(SiMe_3)_2]_2$ and phenol, thiophenols or diphenylphosphate led to $\mathbf{L}^1{\cdot}Zn{-}OPh$ (**3**), $\mathbf{L}^1{\cdot}Zn{-}SAr$ (**4**) and $\mathbf{L}^1{\cdot}Zn{-}OPO(OPh)_2$ (**5**). Zinc salts of noncoordinating anions yielded oligonuclear ligand-bridged complexes $[\mathbf{L}^1{\cdot}Zn]ClO_4$ (**6**), $[\mathbf{L}^2{\cdot}Zn]ClO_4$ (**7**) and $[\mathbf{L}^2{\cdot}Zn]NO_3$ (**8**), of which **6** was identified as a phenolate bridged dimer and **8** as a η^1-η^2-carboxylate bridged polymer.

The challenge of modern coordination chemistry is the design of complexes in which an inert ligand matrix provides the metal ion with appropriate electronic properties and the right number of labile coordination sites to effect specific metal-mediated reactions. In practice this means the use of polydentate ligands, and specifically in the field of functionalized macrocycles a high level of sophistication has been reached for this purpose.

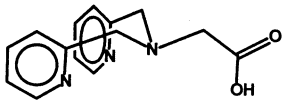
We are trying to contribute to this area of research in the field of zinc chemistry. Zinc ion catalysis, in organic synthesis as well as in biological systems, involves zinc complexes of low coordination numbers, e.g. 4 or 5[1]. Hence most macrocyclic ligands which favour coordination numbers 5 and 6 are not ideally suited for mechanistic or bioinorganic model studies here. The ligands of choice are the tripods of which very many have been synthesized in recent years. If constructed right, those of type **A** should favour tetrahedral zinc and those of type **B** should favour trigonal-bipyramidal zinc, each with one labile coordination site.



A typical representative of type **A** is the class of pyrazolylborate ligands[2] to which we have contributed synthetic, model complex, and complex reactivity studies[3]. One of the simplest representatives of type **B** is tris(picolyl)amine[4] which so far has been used sparsely in zinc chemistry[5]. In contrast to the pyrazolylborates, the type **B** tripods can easily be obtained with different donor "arms" in the same ligand. A recent example which has the additional advantage of bearing one negative charge is dipicolylglycinate[6] of which we have prepared the $[\mathbf{L}{\cdot}Zn{-}OH_2]^+$ complex and studied its reactivity[7].

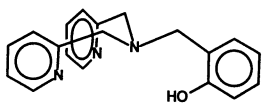


tris(picolyl)amine

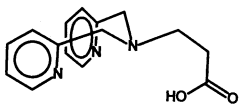


dipicolylglycine

Ligands like tris(picolyl)amine and dipicolylglycinate have an arrangement of donor atoms corresponding to that of ethylenediamine, i.e. they support valence angles near 90° and hence octahedral coordination at the metal ion, as we have experienced for zinc complexes of the latter[7]. In order to relax their bite, the length of their "arms" should be extended. Some reports on zinc complexes having type **B** ligands with "longer arms" seem to support this idea[8]. We therefore looked for such ligands to include them in our reactivity studies. Of the various possibilities we opted for the two dipicolylamine derivatives $H\mathbf{L}^1$ with a phenolate unit and $H\mathbf{L}^2$ with a carboxylate unit as the third "arm". Both could be expected to bind to zinc as the monoanions $\mathbf{L}^1$ and $\mathbf{L}^2$ and thereby ensure a reasonably good complex stability.



$H\mathbf{L}^1$



$H\mathbf{L}^2$

Both $H\mathbf{L}^1$[9] and $H\mathbf{L}^2$[10] have been described before and used for bioinorganic model studies[9][10][11][12][13]. The coordination chemistry of ligands like $\mathbf{L}^1$ with varying "arm lengths" was developed extensively by D. E. Fenton[13][14][15][16] including the modelling of the structure and reactivity of zinc enzymes[15][16] and the preparation of dinuclear copper and zinc complexes of $\mathbf{L}^1$[13][15]. One of the attractions in the zinc chemistry of $\mathbf{L}^1$ and $\mathbf{L}^2$ is that they

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0606−0827 $ 17.50+.50/0

allow to mimick the fivefold N_xO_y coordination of zinc in enzymes like the peptidase astacin [histidine (3×), tyrosine, H_2O][17] or Escherichia coli alkaline phosphatase [histidine (2×), aspartate (2×), H_2O][18]. With this in mind we intended to explore the basic zinc coordination chemistry of $\mathbf{L}^1$ and $\mathbf{L}^2$ (coordination numbers, ligand bridging) and to find complexes like $[\mathbf{L}\cdot Zn]^+$, $[\mathbf{L}\cdot Zn-OH_2]^+$ or $[\mathbf{L}\cdot Zn-OH]$ for reactivity studies involving a labile coordination site or a hydrolytically active function at the zinc ion.

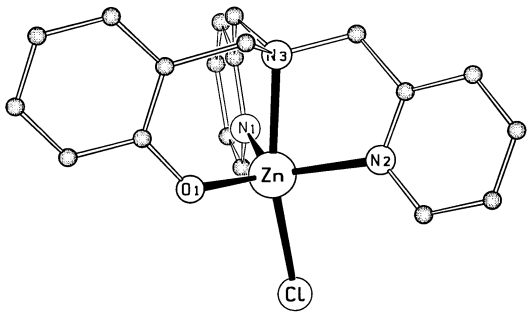
L·Zn−X Complexes

In order to test the ligating abilities of $\mathbf{L}^1$ and $\mathbf{L}^2$ their zinc halide complexes were prepared. This could be achieved with $ZnHal_2$ in methanol, using NaOH to deprotonate **L**H. All six complexes (**1** and **2**) were obtained. Complexes **1** are soluble in polar organic solvents like dichloromethane or ethanol, complexes **2** dissolve only in water or water/alcohol mixtures. The presence of the intact ligands **L** in the complexes is evident from their ^{1}H-NMR spectra (see experimental), their binding to zinc can be deduced from the low-field shifts of the signals for the pyridyl-H_α atoms.

$\mathbf{L}^1\cdot Zn-Hal$		$\mathbf{L}^2\cdot Zn-Hal$	
1a	Hal = Cl	**2a**	Hal = Cl
1b	Br	**2b**	Br
1c	I		

Proof for the molecular nature of complexes **L**·Zn−Hal was obtained by the structure determination of **1a**, see Figure 1. The geometry at zinc in **1a** is close to trigonal-bipyramidal, and it can be compared with that in related zinc complexes of tris(benzimidazolylmethyl)amine[19] or dipicolylglycinate[7]. This includes the bending along the trigonal axis (165°) and the lengthening of the axial Zn−N distance compared to the equatorial ones. The axial Zn−Cl distance (2.33 Å) seems long when compared to those in pyrazolylborate zinc complexes (2.14−2.18 Å)[20]. But it compares well with that in trigonal-bipyramidal (tren)Zn−Cl (2.31 Å)[21].

Figure 1. Molecular structure of $\mathbf{L}^1\cdot Zn-Cl$ (**1a**)[a]



[a] Bond lengths and angles around zinc: Zn−N1 2.109(5), Zn−N2 2.116(4), Zn−N3 2.240(4), Zn−O1 1.928(3), Zn−Cl 2.326(2) Å. − N1−Zn−N3 77.6(2), N2−Zn−N3 76.7(2), O1−Zn−N3 91.9(2), Cl−Zn−N3 165.1(1), Cl−Zn−N1 96.5(2), Cl−Zn−N2 95.3(1), Cl−Zn−O1 102.9(1), N1−Zn−N2 121.2(2), N1−Zn−O1 117.0(2), N2−Zn−O1 115.8(2)°.

In the subsequent derivatizations it turned out to be advantageous to use an acid-sensitive zinc compound {$ZnEt_2$ or $Zn[N(SiMe_3)_2]_2$} for the deprotonation of ligands **L**H. The resulting labile complexes {$\mathbf{L}\cdot Zn-Et$ or $\mathbf{L}\cdot Zn-N(SiMe_3)_2$} were then treated with the corresponding acid HX of the coligand X. This way the $\mathbf{L}^1\cdot Zn$ unit was converted to the phenolate **3** by treatment with $ZnEt_2$ and phenol. Likewise thiophenol could be incorporated as the thiophenolate **4a** via the $Zn-N(SiMe_3)_2$ intermediate. **4a** could, however, not be obtained in a pure form. Therefore alternatively *p*-chlorothiophenol was used, leading to **4b** which was fully characterized. Finally, using $ZnEt_2$ and diphenylphosphate the phosphate complex **5** was prepared. Complexes **3**−**5** are again soluble in moderately polar organic solvents, thereby indicating their molecular nature. Their ^{1}H-NMR spectra (see Experimental Section) are proof for their constitutions.

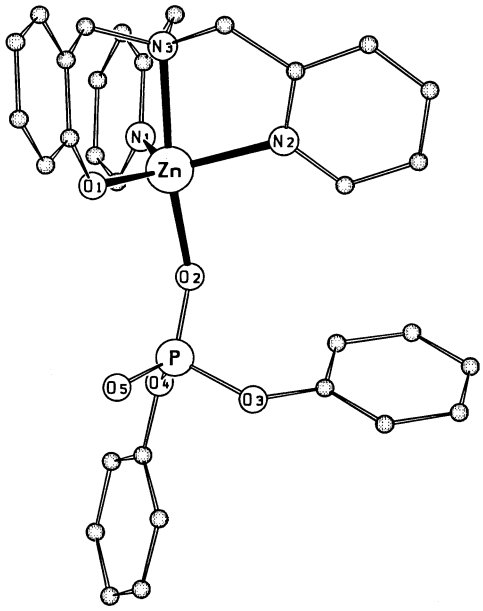
$\mathbf{L}^1\cdot Zn-OPh$ **3**	$\mathbf{L}^1\cdot Zn-SPh$ **4a**
$\mathbf{L}^1\cdot Zn-SC_6H_4-p\text{-}Cl$ **4b**	$\mathbf{L}^1\cdot Zn-O-PO(OPh)_2$ **5**

Crystals for a structure determination were obtained of **5**. Figure 2 shows that the coordination environment of zinc is very similar to that in **1a**, including the moderate deformation of the trigonal-bipyramidal geometry, the lengthening of the axial vs. equatorial Zn−X bonds and the bending of the N3−Zn−O2 axis. The orientation and the bonding situation of the phosphate ligand can be compared to that in a considerable number of pyrazolylborate−zinc−organophosphate complexes.[22] Specifically, the close similarity of the P−O2 and P−O5 bond lengths and the wide Zn−O−P angle are as observed before. This holds also for organophosphate complexes of dipicolylglycinate[7] and tris(picolyl)amine[5].

[L·Zn]$^+$ Complexes

The main purpose of this study was the preparation of zinc complexes in which the tripodal ligands **L** encapsulate the zinc ion such that they stabilize $[\mathbf{L}\cdot Zn]^+$ cations or cationic $[\mathbf{L}\cdot Zn-OH_2]^+$ complexes which can give access to reactive substrates **S** for zinc-mediated or zinc-catalyzed interconversions via intermediate complexes $[\mathbf{L}\cdot Zn-\mathbf{S}]$. To obtain such cationic complexes ligands **L** were treated with zinc salts of noncoordinating anions. In case of $\mathbf{L}^1$ and $\mathbf{L}^2$ this worked with $Zn(ClO_4)_2 \cdot 6\ H_2O$. When using methanol as a solvent and NaOH as a base the products **6** and **7** were isolated. Of these **6** was impure and insoluble while **7** could be recrystallized from water yet not obtained in the form of good single crystals. A form of **6** suitable for X-ray analysis was obtained by runing the reaction in CH_2Cl_2/methanol with KOH as a base, removing $KClO_4$ by filtration and allowing the product to crystallize from chloroform. This product **6** was not soluble in chloroform after isolation but could be subjected to NMR spectroscopy in DMSO. The ^{1}H-NMR and IR data of **6** and **7** (see Experimental Section) confirm the presence of **L** and ClO_4^- but give no indication of the complexes' structures. The insoluble form of **6** seems to be polymeric. **7** is likely to be a carboxylate-

Figure 2. Molecular structure of $\mathbf{L}^1$·Zn−OPO(OPh)$_2$ (**5**)[a]



[a] Pertinent bond lengths and angles: Zn−N1 2.073(4), Zn−N2 2.096(3), Zn−N3 2.221(3), Zn−O1 1.926(3), Zn−O2 2.030(3), P−O2 1.486(3), P−O3 1.598(3), P−O4 1.601(3), P−O5 1.461(3) Å. − N3−Zn−N1 79.5(1), N3−Zn−N2 77.5(1), N3−Zn−O1 91.7(1), N3−Zn−O2 168.5(1), N1−Zn−N2 111.9(1), N1−Zn−O1 121.0(2), N1−Zn−O2 93.3(2), N2−Zn−O1 122.6(2), N2−Zn−O2 97.4(1), O1−Zn−O2 99.8(1), Zn−O2−P 151.9(2)°.

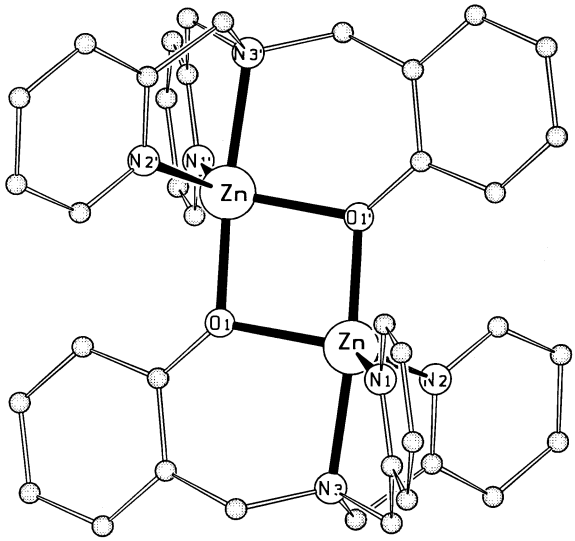
bridged oligomer, possibly a polymer like **8** (see below) or a trimer like the analogous dipicolylglycinate complex[7].

$[\mathbf{L}^1\cdot Zn]ClO_4$ **6** $\qquad$ $[\mathbf{L}^2\cdot Zn]ClO_4$ **7**

The structure determination of the soluble form of **6** showed it to be a chloroform-solvated dimer (see Figure 3). The unit cell contains two independent centrosymmetric dinuclear entities which differ slightly in their conformations but only marginally in the coordination environments of the zinc ions (bond lengths ±0.01 Å , angles ±2°). The coordination geometry of zinc is trigonal-bipyramidal, and all details associated therewith correspond to those for **1a** and **5**. The phenolate oxygen atoms provide the bridging function, as has been observed before, typically in zinc complexes of dinucleating ligands with central phenolate units[23]. The basic type of $[N_3Zn(\mu\text{-}O)_2]$ coordination is realized in $[\mathbf{L}\cdot Zn{-}OH]_2^{2+}$ with L = triazacyclononane[24] or tris(picolyl)amine[5] and zinc in a square-pyramidal environment. The Zn−N and Zn−O distances in **6** compare well with those in the reference compounds. The closest relation to **6** exists in the corresponding copper derivative of $\mathbf{L}^1$ which, however, contains square-pyramidal copper[13]. Fenton has also described two phenoxide-bridged dizinc complexes derived from $\mathbf{L}^1$-related tripod ligands with longer arms[15]:

When using zinc nitrate, a pure product, **8**, could only be obtained with $\mathbf{L}^2$. The structure determination showed this to be a polymeric methanol solvate with noncoordinating

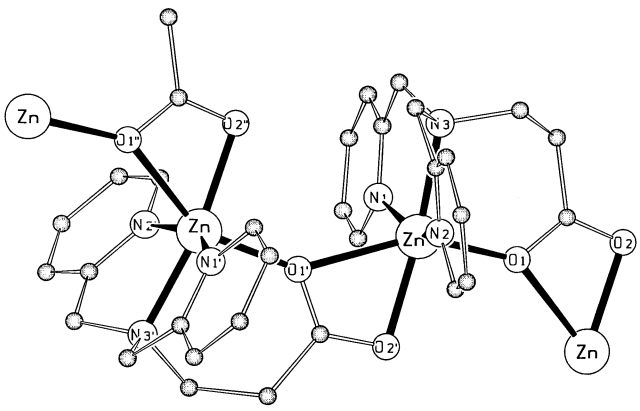
Figure 3. Molecular structure of the cations of **6**[a]



Average bond lengths and angles about zinc: Zn−O1 2.029(3), Zn−O1′ 2.002(4), Zn−N1 2.066(4), Zn−N2 2.066(4), Zn−N3 2.161(4), Zn···Zn 3.064(2) Å. N3−Zn−N1 80.4(2), N3−Zn−N2 79.9(2), N3−Zn−O1 93.0(2), N3−Zn−O1′ 172.5(2), N1−Zn−N2 126.6(2), N2−Zn−O1 122.8(2), N2−Zn−O1′ 99.6(2), O1−Zn−N1 112.6(2), O1′−Zn−N1 106.0(2), O1−Zn−O1′ 81.0(2), Zn−O1−Zn′ 99.0(2)°.

nitrate anions (see Figure 4). The linkage between the monomeric units is provided by the carboxylate groups in a manner which to our knowledge has not been observed for zinc before: one oxygen atom is bridging while the other is coordinated to the neighbouring zinc ion (η^1-η^2-carboxylate bridging)[25]. In contrast the trimeric complex $[\mathbf{L}\cdot Zn]ClO_4$ with L = dipicolylglycinate has one oxygen coordinating the ipso zinc ion and the other the neighbouring one[7]. The coordination geometry of the zinc ions in **8** is severley distorted octahedral with O1−Zn−O2 (58.7°) as the smallest and N3−Zn−O1′ (113.9°) as the largest *cis* angles and *trans* angles of 169.6 (N3−Zn−O2′), 150.0 (O1−Zn−O1′), and 154.8° (N1−Zn−N2). Carboxylate bridging between zinc ions is quite common[26], and all types of bridging[27] except for the η^1-η^2 type have been observed.

Figure 4. Solid-state arrangement of polymeric $[\mathbf{L}^2\cdot Zn]^+$ in **8**[a]



[a]Bond lengths: Zn−N1 2.084(3), Zn−N2 2.076(3), Zn−N3 2.179(3), Zn−O1 2.013(2), Zn−O1′ 2.302(2), Zn−O2′ 2.132(2) Å.

As can be seen from the Zn−N and Zn−O bond distances the coordination of $\mathbf{L}^2$ to zinc can be viewed as that in a trigonal-bipyramidal $\mathbf{L}^2$·Zn−X complex, i.e. the Zn−N3 bond is longer than the three other Zn−L bonds. Carboxylate atom O2′ then occupies the second axial ligand position, viz. Zn−O2′ is comparable in length to Zn−N3. The Zn−O1′ bond, i.e. the one that provides bridging to the neighbouring zinc ion, is the weakest, and O1 also occupies the most distorted octahedral ligand position. The distorted nature of the bridging assembly points to weak bridging, in accordance with the solubility of **8** in methanol.

Conclusions

The results of this paper indicate that ligands $\mathbf{L}^1$ and $\mathbf{L}^2$ are suitable for monofunctional zinc complexes L·Zn−X. Anionic coligands X providing Zn−Cl, −Br, −I, −OR, −SR, and −oxoanion linkages can be incorporated. The structures of the complexes are trigonal-bipyramidal with the pivotal N atom of the tripod and the coligand X on the axial positions. The complexes derived from $\mathbf{L}^1$ complement previous work on zinc complexes of similar tripodal ligands with one phenolate and two pyridyl donors[13][14][15][16].

In terms of functionality and possibly catalytic activity the complexes derived from $\mathbf{L}^2$ seem to be better suited. In case of $\mathbf{L}^1$ phenolate bridging and consequently oligomerization seem to be so preferred that we could not obtain a soluble $[\mathbf{L}^1{\cdot}Zn]^+$ complex or a species $[\mathbf{L}^1{\cdot}Zn{-}\mathbf{S}]^+$ with a labile solvent ligand **S** like H_2O. On the other hand the oligomeric $[\mathbf{L}^2{\cdot}Zn]^+$ complexes **7** and **8** are soluble in methanol and/or water indicating the presence of species $[\mathbf{L}^2{\cdot}Zn{-}\mathbf{S}]^+$. If such a species is [L·Zn−OH] it should be a catalyst for the cleavage of esters or peptides[15][28]. Our subsequent work in this field will therefore focus on the solution chemistry of the $\mathbf{L}^2$·Zn complexes, their acid-base behaviour and their reactivity towards hydrolysable substrates.

Experimental Section

General experimental methods and measuring techniques: see ref.[29]. The ligands $\mathbf{L}^1$[9] and $\mathbf{L}^2$[10] were prepared according to the published procedures.

1a: 400 mg (1.31 mmol) of $\mathbf{L}^1$ and 52 mg (1.31 mmol) of NaOH were dissolved in 40 ml of methanol. 177 mg (1.31 mmol) of $ZnCl_2$ in 10 ml of methanol were added, and the mixture was stirred for 2 h. Upon addition of 200 ml of ether the raw product **1a** was precipitated and filtered off. Recrystallization from methanol/water (1:1) yielded 218 mg (41%) **1a** as colourless crystals, m.p. 263°C (dec.). − $C_{19}H_{18}ClN_3OZn$ (405.2), calcd.: C 56.32, H 4.48, N 10.37, found: C 55.76, H 4.40, N 10.15. − ^{1}H NMR ($CDCl_3$): δ = 3.76 [s, 2 H, NCH_2Ph], 3.85 [d, J = 15.6 Hz, 2 H, NCH_2Py], 4.10 [d, J = 15.6 Hz, 2 H, NCH_2Py], 6.42−7.10 [m, 4 H, Ph], 7.29 [d, J = 7.8 Hz, 2 H, H_δ(Py)], 7.47 [dd, J = 5.4 Hz, 6.5 Hz, 2 H, H_β(Py)], 7.87 [dd, J = 7.8 Hz, 5.4 Hz, 2 H, H_γ(Py)], 9.45 [d, J = 6.5 Hz, 2 H, H_α(Py)]. − IR (KBr): $\tilde{\nu}$ = 1604s, 1479vs, 1438s, 1309vs.

1b: Like **1a** from 200 mg (0.66 mmol) of $\mathbf{L}^1$, 26 mg (0.66 mmol) of NaOH, and 149 mg (0.66 mmol) of $ZnBr_2$. Yield 229 mg (77%) of **1b**, colourless crystals, m.p. 259°C. − $C_{19}H_{18}BrN_3OZn$ (449.7), calcd.: C 50.75, H 4.03, N 9.34, found: C 48.80, H 3.88, N 9.06. − ^{1}H NMR ($CDCl_3$): δ = 3.73 [s, 2 H, NCH_2Ph], 3.85 [d, J = 15.8 Hz, 2 H, NCH_2Py], 4.08 [d, J = 15.8 Hz, 2 H, NCH_2Py], 6.39−7.08 [m, 4 H, Ph], 7.30 [d, J = 9.2 Hz, 2 H, H_δ(Py)], 7.43 [dd, J = 6.6 Hz, 5.2 Hz, 2 H, H_β(Py)], 7.86 [dd, J = 9.2 Hz, 6.6 Hz, 2 H, H_γ(Py)], 9.47 [d, J = 5.2 Hz, 2 H, H_α(Py)]. − IR (KBr): $\tilde{\nu}$ = 1605s, 1480vs, 1451m, 1433m, 1307s.

1c: Like **1a** from 200 mg (0.66 mmol) of $\mathbf{L}^1$, 26 mg (0.66 mmol) of NaOH, and 211 mg (0.66 mmol) of ZnI_2. Yield 268 mg (82%) of **1c**, colourless crystals, m.p. 168°C. − $C_{19}H_{18}IN_3OZn$ (496.7), calcd.: C 45.95, H 3.65, N 8.46, found: C 44.37, H 3.55, N 8.12. − ^{1}H NMR (DMSO): δ = 3.84 [s, 2 H, NCH_2Ph], 4.15 [s, 4 H, NCH_2Py], 6.39−7.06 [m, 4 H, Ph], 7.65−7.69 [m, 4 H, H_β(Py), H_δ(Py)], 8.17 [dd, J = 7.5 Hz, 6.6 Hz, 2 H, H_γ(Py)], 8.79 [d, J = 4.2 Hz, 2 H, H_α(Py)]. − IR (KBr): $\tilde{\nu}$ = 1609s, 1482vs, 1441m, 1293m, 1273s.

2a: 200 mg (0.74 mmol) of $\mathbf{L}^2$ and 30 mg (0.74 mmol) of NaOH were dissolved in 10 ml of methanol. 101 mg (0.74 mmol) of $ZnCl_2$ in 10 ml of methanol were added. A flask containing diethyl ether was then connected to the reaction flask by a glass tube. After 2 d, the product had precipitated and was filtered off. Recrystallization from methanol/water (1:1) yielded 96 mg (35%) **2a** as colourless microcrystals, m.p. 258°C (dec.). − $C_{15}H_{16}ClN_3O_2Zn$ (371.2), calcd.: C 48.54, H 4.34, N 11.32, found: C 48.07, H 4.16, N 10.95. − ^{1}H NMR (D_2O): δ = 2.15 [t, J = 7.1 Hz, 2 H, $CH_2(C_2)$], 3.89 [t, J = 7.1 Hz, 2 H, $CH_2(C_1)$], 4.23 [s, 4 H, NCH_2Py], 7.45−7.56 [m, 4 H, H_β(Py), H_δ(Py)], 8.00 [dd, J = 7.8 Hz, 7.7 Hz, 2 H, H_γ(Py)], 8.57 [d, J = 5.2 Hz, 2 H, H_α(Py)]. − IR (KBr): $\tilde{\nu}$ = 1605vs, 1441m, 1395m.

2b: Like **2a** from 150 mg (0.55 mmol) of $\mathbf{L}^2$, 22 mg (0.55 mmol) of NaOH, and 124 mg (0.55 mmol) of $ZnBr_2$. Yield 98 mg (43%) of **2b**, colourless microcrystals, m.p. 259°C (dec.). − $C_{15}H_{16}BrN_3O_2Zn$ (415.6), calcd.: C 43.35, H 3.88, N 10.11, found: C 42.43, H 3.81, N 9.79. − ^{1}H NMR (D_2O): δ = 1.99 [t, J = 6.9 Hz, 2 H, $CH_2(C_2)$], 2.75 [t, J = 6.9 Hz, 2 H, $CH_2(C_1)$], 4.12 [s, 4 H, NCH_2Py], 7.36−7.43 [m, 4 H, H_β(Py), H_δ(Py)], 7.87 [dd, J = 7.8 Hz, 7.7 Hz, 2 H, H_γ(Py)], 8.43 [d, J = 4.1 Hz, 2 H, H_α(Py)]. − IR (KBr): $\tilde{\nu}$ = 1600vs, 1440m, 1365m.

2c: Like **2a** from 200 mg (0.74 mmol) of $\mathbf{L}^2$, 30 mg (0.74 mmol) of NaOH, and 236 mg (0.74 mmol) of ZnI_2. Yield 282 mg (82%) of **2c**, colourless needles, m.p. 223°C (dec.). − $C_{15}H_{16}IN_3O_2Zn$ (462.6), calcd.: C 38.95, H 3.49, N 9.08, found: C 38.39, H 3.93, N 8.57. − ^{1}H NMR (D_2O): δ = 2.18 [t, J = 5.8 Hz, 2 H, $CH_2(C_2)$], 2.93 [t, J = 5.8 Hz, 2 H, $CH_2(C_1)$], 4.28 [s, 4 H, NCH_2Py], 7.50−7.60 [m, 4 H, H_β(Py), H_δ(Py)], 8.03 [dd, J = 7.8 Hz, 7.7 Hz, 2 H, H_γ(Py)], 8.60 [d, J = 4.8 Hz, 2 H, H_α(Py)]. − IR (KBr): $\tilde{\nu}$ = 1607s,1539vs, 1441m.

3: 200 mg (0.66 mmol) of $\mathbf{L}^1$ were dissolved in 10 ml of toluene. Diethylzinc (0.66 ml, 0.66 mmol) was added as a 1 M solution in hexane. Then, 62 mg (0.66 mmol) of phenol dissolved in 5 ml of toluene were added while stirring. Upon addition of the phenol the raw product **3** was precipitated and filtered off. Recrystallization from ethanol/water (1:1) yielded 162 mg (53%) of **3** as colourless crystals, m.p. 224°C. − $C_{25}H_{23}N_3O_2Zn$ (462.9), calcd.: C 64.87, H 5.01, N 9.08, found: C 63.74, H 4.98, N 8.97. − ^{1}H NMR ($CDCl_3$): δ = 3.68 [s, 2 H, NCH_2Ph], 3.70 [d, J = 15.8 Hz, 2 H, NCH_2Py], 4.00 [d, J = 15.8 Hz, 2 H, NCH_2Py], 6.42−7.23 [m, 13 H, Ph, H_β(Py), H_δ(Py), O-Ph], 7.72 [dd, J = 7.1 Hz, 6.3 Hz, 2 H, H_γ(Py)],

8.90 [d, J = 5.7 Hz, 2 H, H_α(Py)]. − IR (KBr): $\tilde{\nu}$ = 1607s, 1591s, 1478vs, 1454m, 1437m, 1308vs.

4a: 200 mg (0.66 mmol) of $\mathbf{L}^1$ were dissolved in 10 ml of toluene. $Zn[N(SiMe_3)_2]_2$ (255 mg, 0.66 mmol) were added. Then, 67 µl (73 mg, 0.66 mmol) of thiophenol dissolved in 5 ml of toluene were added while stirring. Upon addition of the thiophenol the raw product **4a** was precipitated and filtered off. Recrystallization from ethanol yielded 130 mg (41%) of **4a** as a colourless solid, m.p. 104°C. − $C_{25}H_{23}N_3OSZn$ (479.0), calcd.: C 62.70, H 4.84, N 8.77, found: C 57.38, H 4.17, N 7.91. − ^{1}H NMR ($CDCl_3$): δ = 3.67 [s, 2 H, NCH_2Ph], 3.78 [d, J = 15.7 Hz, 2 H, NCH_2Py], 3.98 [d, J = 15.7 Hz, 2 H, NCH_2Py], 6.30−7.73 [m, 15 H, Ph, H_β(Py), H_δ(Py), H_γ(Py), S-Ph], 9.02 [d, J = 5.4 Hz, 2 H, H_α(Py)]. − IR (KBr): $\tilde{\nu}$ = 1603s, 1478vs, 1437m, 1312s.

4b: Like **4a** from 200 mg (0.66 mmol) of $\mathbf{L}^1$, 255 mg (0.66 mmol) of $Zn[N(SiMe_3)_2]_2$, and 95 mg (0.66 mmol) of 4-chloro-thiophenol. Yield 149 mg (44%) of **4b** as colourless crystals, m.p. 142°C. − $C_{25}H_{22}ClN_3OSZn$ (513.4), calcd.: C 58.49, H 4.32, N 8.19, found: C 58.47, H 4.39, N 7.91. − ^{1}H NMR ($CDCl_3$): δ = 3.67 [s, 2 H, NCH_2Ph], 3.80 [d, J = 15.8 Hz, 2 H, NCH_2Py], 3.91 [d, J = 15.8 Hz, 2 H, NCH_2Py], 6.35−7.28 [m, 12 H, Ph, H_β(Py), H_δ(Py), S-Ph], 7.70 [dd, J = 9.5 Hz, 8.7 Hz, 2 H, H_γ(Py)], 9.00 [d, J = 5.5 Hz, 2 H, H_α(Py)]. − IR (KBr): $\tilde{\nu}$ = 1604s, 1477vs, 1438m, 1309s, 1093s.

5: Like **3** from 200 mg (0.66 mmol) of $\mathbf{L}^1$, 0.66 ml (0.66 mmol) of diethylzinc as a 1 M solution in hexane, and 164 mg (0.66 mmol) of diphenylphosphate. Yield 303 mg (74%) of **5** as colourless crystals, m.p. 91°C. − $C_{31}H_{28}N_3O_5PZn \cdot 2\ H_2O \cdot CH_3OH$ (618.9 + 36.0 + 32.0), calcd.: C 55.95, H 5.28, N 6.12, found: C 56.09, H 4.51, N 6.31. − ^{1}H NMR ($CDCl_3$): δ = 3.77 [s, 2 H, NCH_2Ph], 3.81 [d, J = 15.8 Hz, 2 H, NCH_2Py], 4.03 [d, J = 15.8 Hz, 2 H, NCH_2Py], 6.42−7.46 [m, 18 H, Ph, H_β(Py), H_δ(Py), P-O-Ph], 7.78 [dd, J = 7.6 Hz, 6.4 Hz, 2 H, H_γ(Py)], 9.04 [d, J = 4.4 Hz, 2 H, H_α(Py)]. − ^{31}P NMR ($CDCl_3$): δ = −11.63. − IR (KBr): $\tilde{\nu}$ = 1608s, 1595s, 1485vs, 1453m, 1437m, 1296s, 1267s, 1205s, 1104vs.

6: 200 mg (0.66 mmol) of $\mathbf{L}^1$ were dissolved in 10 ml of methylene chloride. 37 mg (0.66 mmol) of KOH in 5 ml of methanol were added, and the mixture was stirred for 10 min. Then, 244 mg (0.66 mmol) of $Zn(ClO_4)_2 \cdot 6\ H_2O$ in 5 ml of methanol were added while stirring. The solution became cloudy and was then refluxed for 30 min. After this, another 37 mg (0.66 mmol) of KOH in 5 ml methanol were added and the solution stirred overnight. The precipitate formed was removed by filtration. The filtrate was evaporated to dryness . Recrystallization from chloroform yielded 90 mg (23%) of **6** as colourless crystals, m.p. 274°C (dec.). − $C_{19}H_{18}ClN_3O_5Zn \cdot CHCl_3$ (469.2 + 119.4), calcd.: C 40.81, H 3.25, N 7.14, found: C 40.23, H 3.16, N 6.93. − ^{1}H NMR (DMSO): δ = 3.76 [s, 2 H, NCH_2Ph], 4.08 [s, 4 H, NCH_2Py], 6.36−6.99 [m, 4 H, Ph], 7.58−7.62 [m, 4 H, H_β(Py), H_δ(Py)], 7.91 [dd, J = 7.9 Hz, 7.7 Hz, 2 H, H_γ(Py)], 8.70 [d, J = 4.3 Hz, 2 H, H_α(Py)]. − IR (KBr): $\tilde{\nu}$ = 1611s, 1485s, 1445m, 1274m, 1090vs.

7: 200 mg (0.74 mmol) of $\mathbf{L}^2$ and 30 mg (0.74 mmol) of NaOH were dissolved in 10 ml of methanol. 244 mg (0.74 mmol) of $Zn(ClO_4)_2 \cdot 6\ H_2O$ in 10 ml of methanol were added, and the mixture was stirred for 10 min. The solution became cloudy and after 5 min, **7** precipitated as a white solid. Recrystallization from water yielded 171 mg (53%) of **7** as colourless microcrystals, m.p. 296°C (dec.). − $C_{15}H_{16}ClN_3O_6Zn$ (435.2), calcd.: C 41.40, H 3.71, N 9.66, found: C 41.14, H 3.49, N 9.56. − ^{1}H NMR (D_2O): δ = 2.10 [t, J = 7.0 Hz, 2 H, $CH_2(C_2)$], 2.85 [t, J = 7.0 Hz, 2 H, $CH_2(C_1)$], 4.19 [s, 4 H, NCH_2Py], 7.40−7.50 [m, 4 H, H_β(Py), H_δ(Py)], 7.96 [dd, J = 7.9 Hz, 7.7 Hz, 2 H, H_γ(Py)], 8.51 [d, J = 5.0 Hz, 2 H, H_α(Py)]. − IR (KBr): $\tilde{\nu}$ = 1607s, 1548s 1484m, 1441m, 1088vs.

8: 200 mg (0.74 mmol) of $\mathbf{L}^2$ and 30 mg (0.74 mmol) of NaOH were dissolved in 10 ml of methanol.193 mg (0.74 mmol) of

$Zn(NO_3)_2 \cdot 4\ H_2O$ in 10 ml of methanol were added. A flask containing diethyl ether was then connected to the reaction flask by a glass tube. After 2 d, crystallization yielded 191 mg (65%) of **8** as colourless crystals, m.p. 238°C (dec.). − $C_{15}H_{16}N_4O_5Zn \cdot CH_3OH$ (397.7 + 32.0), calcd.: C 44.72, H 4.69, N 13.04, found: C 43.24, H 4.13, N 13.36. − ^1H NMR (D_2O): δ = 2.17 [t, J = 5.6 Hz, 2 H, $CH_2(C_2)$], 3.91 [t, J = 5.6 Hz, 2 H, $CH_2(C_1)$], 4.27 [s, 4 H, NCH_2Py], 7.52−7.59 [m, 4 H, H_β(Py), H_δ(Py)], 8.03 [dd, J = 7.7 Hz, 7.6 Hz, 2 H, H_γ(Py)], 8.59 [d, J = 4.8 Hz, 2 H, H_α(Py)]. − IR (KBr): $\tilde{\nu}$ = 1609s, 1541m, 1384vs, 1363vs.

Structure Determinations[30]: Crystals were obtained from the reaction solutions. Diffraction data were recorded with the ω/2θ technique on a Nonius CAD4 diffractometer fitted with a molybdenum tube (K_α, λ = 0.7107 Å) and a graphite monochromator. No absorption corrections were applied. The structures were solved with direct methods and refined anisotropically with the SHELX program suite[31]. Hydrogen atoms were included with fixed distances and isotropic temperature factors 1.2 times those of their attached atoms. Parameters were refined against F^2. The R values are defined as $R_1 = \Sigma|F_o - F_c|/\Sigma F_o$ and $wR_2 = [\Sigma[w(F_o^2 - F_c^2)^2/\Sigma[w(F_o^2)^2]]^{1/2}$. Drawings were produced with SCHAKAL[32]. Table 1 lists the crystallographic data.

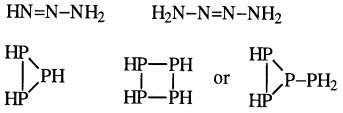
The violet THF adduct $(t\mathrm{Bu_3Si})_2\mathrm{P_3Na(THF)_4}$ (**1a**) of the triphosphide $(t\mathrm{Bu_3Si})_2\mathrm{P_3Na}$ (**1**) is prepared, (i) by protolysis of the tetraphosphide $(t\mathrm{Bu_3Si})_2\mathrm{P_4Na_2}$ (**2**) with an equimolar amount of $\mathrm{CF_3CO_2H}$ in THF (transformation of **2** into **1**), (ii) by the reaction of $t\mathrm{Bu_3SiNa}$ and the oligophosphane $(t\mathrm{Bu_3SiP_3})_n$ in THF (building-down of P_n), and (iii) by the action of $t\mathrm{Bu_3SiNa}$ on $\mathrm{PCl_3}$ in THF (building-up of P_n). According to X-ray structural analysis, the SiPPPSi skeleton of the anionic part $[t\mathrm{Bu_3SiPPPSi}t\mathrm{Bu_3}]^-$ of **1a** is W-shaped with two P–P $1^1/_2$ bonds; in addition, **1a** contains a planar deltoid $\mathrm{P_3Na}$ backbone with the 4 THF molecules coordinated to Na. The protolysis of **1a** leads to cyclotriphosphane $(t\mathrm{Bu_3Si})_2\mathrm{P_3H}$ (**11**), and the oxidation of **1a** leads to 1,1′-bicyclotriphosphane $(t\mathrm{Bu_3Si})_2\mathrm{P_3}$–$\mathrm{P_3}(\mathrm{Si}t\mathrm{Bu_3})_2$ (**12**) as the main product and bicyclo[3.1.0]hexaphosphane $(t\mathrm{Bu_3Si})_4\mathrm{P_6}$ (**13**) as an isomer of **12**. The structures of **11**, **12**, and **13** as well as the structure of **1a** have been unambiguously determined by ^{31}P-NMR studies. Ab initio structure and energy calculations show that the acyclic $\mathrm{P_3H_2^-}$ with allylic conjugation and P–P $1^1/_2$ bonds is thermodynamically more stable than the cyclic isomer whereas, in contrast, the neutral compound $\mathrm{P_3H_3}$ prefers the cyclic form. The exceptional downfield shift of the NMR signal of the central phosphorus in **1a** is in agreement with DFT NMR calculations for a model compound $[\mathrm{H_3SiPPPSiH_3}]\mathrm{Na}$ with P–P $1^1/_2$ bonds.

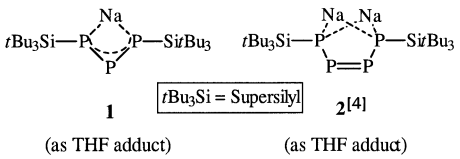
While nitrogen hydrides of the formula $\mathrm{N}_n\mathrm{H}_n$ and their derivatives have an acyclic structure with a double bond, phosphorus hydrides $\mathrm{P}_n\mathrm{H}_n$ and their derivatives show, in accordance with the double-bond rule, cyclic structures without a double bond[3]. This is demonstrated by a comparison of the structures of $\mathrm{N_3H_3}$ and $\mathrm{N_4H_4}$ with those of $\mathrm{P_3H_3}$ and $\mathrm{P_4H_4}$, (see Scheme 1).

Scheme 1



In contrast the tendency of phosphanes $\mathrm{P}_n\mathrm{H}_n$ to form unsaturated acyclic structures increases after deprotonation, because the negative charges of the phosphides obtained may be better stabilized by a π system containing a phosphorus chain. This is suggested by our studies in connection with the triphosphide $(t\mathrm{Bu_3Si})_2\mathrm{P_3Na}$ (see Scheme 2) and the tetraphosphide $(t\mathrm{Bu_3Si})_2\mathrm{P_4Na_2}$ (cf. refs.[4][5]) which have the structures **1** (disupersilyltriphosphenide) and **2** (disupersilyltetraphosphenediide), respectively.

Scheme 2



The unsaturated cluster anion $\mathrm{R_2P_3^-}$ with substituents R which are sterically constrained (such as supersilyl $t\mathrm{Bu_3Si}$[5]) is readily formed. Thus, **2** converts into **1** under suitable conditions (see below). The compounds $\mathrm{Mes^*{}_2P_2ELi}$ (Mes* = Supermesityl, E = P, As) and $(t\mathrm{Bu_3Si})_2\mathrm{E_3Na}$ (E = N, As) were both synthesized by Jutzi et al.[6] and this

group[7][8]. Finally the anions $[(Me_3Si)_2CPPPC(SiMe_3)_2]^-$[9a] and $[RPPPR]^-$ (RR = $-CH_2CH_2-$ and $-CHPhCHPh-$)[9b] containing a P_3 skeleton with a π system were prepared as alkali metal salts.

In this publication we deal with the syntheses and the structure of **1,** as well as with the protolysis and oxidation of the compound, which proceed by the formation of the triphosphane $(tBu_3Si)_2P_3H$ and two isomers of hexaphosphane $(tBu_3Si)_4P_6$, respectively. In addition, the question concerning the relative stabilities of cyclic and acyclic P_3H_3 and $P_3H_2^-$ is answered by ab initio calculations.

Formation of $(tBu_3Si)_2P_3Na$ (1)

As has already been mentioned, **1** is prepared by transformation of **2**. In addition, **1** may be formed from supersilylphosphanes $(tBu_3Si)_mP_n$ or supersilyldihalogenephosphanes tBu_3SiPX_2 by building-down or building-up the phosphorus framework. In the latter cases, supersilyl sodium tBu_3SiNa in tetrahydrofuran (THF) serves as the reaction partner. Details of the syntheses of **1** are discussed below. In this connection, not only **2**, but also the phosphides **3** and **4** as well as the phosphanes **5**−**8** play a role (see Scheme 3).

Transformation of 2

To convert the tetraphosphide **2**, which is easily prepared from P_4 and tBu_3SiNa in THF[4], into the triphosphide **1**, the former is protonated by equimolar amounts of a strong acid (CF_3CO_2H or CF_3SO_3H) in THF at −78°C. Then, by warming up the reaction mixture to room temp., **1** and tBu_3SiPH_2 are obtained according to Eq. 1.

$$3\ \mathbf{2} \xrightarrow[-4Na^+]{+4H^+} 2\ \mathbf{1} + 2\,tBu_3SiPH_2 \qquad (1)$$

In fact, **1** is produced simultaneously with the pentaphosphide **4** as well as oligophosphanes $(tBu_3SiP_3)_n$ (see below); in addition, the starting material **2** remains unreacted (**1**, **2**, and **4** exist in the molar ratio 2:1:1, increasing amounts of acid lead to a decrease in the amount of **2** and also of **1**[5][10]). As **1** cannot easily be separated from the other products, reaction (1) is less suitable for its preparation.

In the weak acid acetonitrile, **2** quickly transforms according to Eq. 1 ($NaCH_2CN$ may be another product), but the solutions obtained are unstable and after some weeks contain tBu_3SiPH_2 as the one and only soluble phosphorus compound.

Building-Down of Phosphorus Clusters

The reaction of oligophosphanes $(tBu_3SiP_3)_n$ (among others **8**[5]) with *n*-fold molar amounts of tBu_3SiNa is particularly suitable for the synthesis of **1**. In this way, the triphosphide **1** is obtained as the only product according to Eq. 2. The oligophosphanes, on the other hand, are prepared from **2** and a twofold molar amount of a strong acid (CF_3SO_3H) in pentane: $\mathbf{2} + 2H^+ \rightarrow 1/n\ (tBu_3SiP_3)_n + tBu_3SiPH_2$.

$$^1/_n\ (tBu_3SiP_3)_n \text{ (among others } \mathbf{8}) + tBu_3SiNa \rightarrow \mathbf{1} \qquad (2)$$

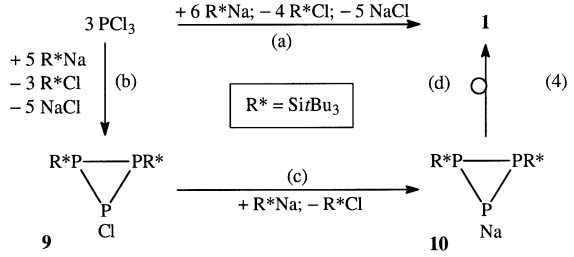
Reaction (2) demonstrates, as does reaction (1), the high tendency for the formation of **1**. The same holds for the reaction shown in (3): a twofold molar amount of tBu_3SiNa degrades the heptaphosphane **7** (which is easily prepared from P_4 and $tBu_3Si-SitBu_3$ in THF or toluene at 100°C together with the tetraphosphane **5**[11]) into the triphosphide **1** and the tetraphosphide **3**. The latter compound is also quantitatively obtained by reaction of the tetraphosphane **5** with equimolar amounts of tBu_3SiNa in THF[5].

$$\mathbf{7} + 2\ tBu_3SiNa \rightarrow \mathbf{1} + \mathbf{3} \qquad (3)$$

In addition, it is worth noting that the pentaphosphane **6** is transformed by tBu_3SiNa into the triphosphide **1** together with other phosphorus containing substances[10].

Building-Up of Phosphorus Clusters

To synthesize **1** by building-up the phosphorus chain, PCl_3 in pentane is slowly added dropwise to a solution of a threefold molar amount of tBu_3SiNa in THF, cooled to −78°C. While warming up the solution to room temp., the starting materials react according to (4a). In fact, **1** is produced simultaneously with the tetraphosphide **3**, the pentaphosphide **4** as well as some mono- and diphosphides (**1**, **3**, **4**, and the other phosphides are formed in the molar ratio 10:5:3:3).



An insight into the formation pathway of **1** is given by the reaction of PCl_3 with an equimolar amount of tBu$_3$SiNa, the products of which are some chlorine-free and some chlorine-containing supersilylphosphanes[5]; this will be thoroughly discussed elsewhere[12]. Obviously, the chlorine containing compound **9** plays an important role in the building-up of **1**, as it may react with tBu$_3$SiNa with exchange of Cl for Na (Eq. 4c). An isomerization of the phosphide **10** obtained in this way leads to **1** (Eq. 4d).

The formation of **9**, summarized by Eq. 4b, may be interpreted as follows: As a first reaction product, tBu$_3$SiPCl$_2$ is formed from PCl_3 and tBu$_3$SiNa by exchange of Cl^- for tBu$_3$Si$^-$. For steric reasons supersilyldichlorophosphane does not undergo any further supersilanidation[5]. Instead, with the cooperation of PCl_3 and tBu$_3$SiNa, it enters a building-up of phosphorus clusters which proceeds according to the reactions formulated in Eq. 5[5].

$$>\!P\text{–}Cl + Cl\text{–}P< \xrightarrow[-\,t\mathrm{Bu_3SiCl}]{+\,t\mathrm{Bu_3SiNa}} >\!PNa + Cl\text{–}P< \qquad (5)$$

$$>\!PNa + Cl\text{–}P< \xrightarrow{-\mathrm{NaCl}} >\!P\text{–}P<$$

Hereafter, tBu$_3$SiPCl$_2$, PCl_3, and tBu$_3$SiNa first of all may react according to tBu$_3$SiPCl$_2$ + tBu$_3$SiNa → tBu$_3$Si-PClNa + tBu$_3$SiCl and 2 tBu$_3$SiPClNa + PCl_3 → tBu$_3$Si-PCl−PCl−PClSitBu$_3$ + 2 NaCl under formation of trichlorodisupersilyltriphosphane, which then converts according to Eq. 5 into **9**.

Characterization and Structure of (tBu$_3$Si)$_2$P$_3$Na(THF)$_4$ (1a)

If a solution of 2.8 mmol of **1**, prepared by reaction of (tBu$_3$SiP$_3$)$_n$ with tBu$_3$SiNa in 6 ml of THF (cf. Eq. 2), is concentrated to 2 ml and mixed with 2 ml of pentane, then over several days, deep violet crystals of the THF adduct (tBu$_3$Si)$_2$P$_3$Na(THF)$_4$ (**1a**) of the triphosphide **1** may be obtained. These are extremely sensitive to air and moisture but comparatively stable thermally. However, the tendency of **1** to crystallize from THF is quite low and exchanging THF for another solvent is not advisable, since **1** decomposes when the THF is removed.

A suitable crystal of the phosphide **1a** selected from many unsuitable crystals was investigated by X-ray structure analysis. The view of the molecule in the crystal (orthorhombic), all atomic positions of which seem to be splitted, is shown in Figure 1. As can be clearly seen, the three P atoms and the Na atom in **1a** occupy the edges of a planar deltoid (P−P−P = 104.2, P−P−Na = 95.2, P−Na−P = 64.3°; sum of the angles of the mean values of the split positions is 358.9°). For each of the outer P atoms a planar surrounding may be outlined, consisting of one P, one Si, and one Na atom, the central P atom has two P atoms as neighbours forming an obtuse angle and the Na atom is coordinated by two P and four O atoms forming a distorted octahedron with a sharp P−Na−P angle. The O atoms are each coordinated to one Na and two C atoms. The P−P distances have a mean value of 2.10 Å, in between those found for P−P single bonds (around 2.20 Å) and those for P−P double bonds (around 2.00 Å)[3]. As can be seen from Table 1, the two P−P distances and the two P−P−Na angles are indeed slightly different [P1−P2 = 2.12, P1−P3 = 2.07 Å; P1−P2−Na = 96.6, P1−P3−Na = 93.7° (mean values); an analogous situation is also observed for the two N−N bonds and the N−N−Na angle of (tBu$_3$Si)$_2$-N$_3$Na(THF)$_2$ in the crystal[13]]. The distance of the sodium atom to the outer phosphorus atom showing the longer P−P bond is shorter than the distance to the outer phosphorus atom showing the shorter −P bond [P2−Na = 3.05, P3−Na = 3.18 Å (mean values)].

As shown by the X-ray structure analysis, the anionic W-shaped part of **1a** with two P−P $1^1/_2$ bonds represents a triphosphaallylic anion, the bonding situation of which can be described by a resonance formula with two limiting structures, as is shown in Eq. 6 (the triphosphenide Mes$_2$*-P$_3$Li was not investigated by means of X-ray diffraction; however according to ^{31}P-NMR it also has an acyclic structure[6]).

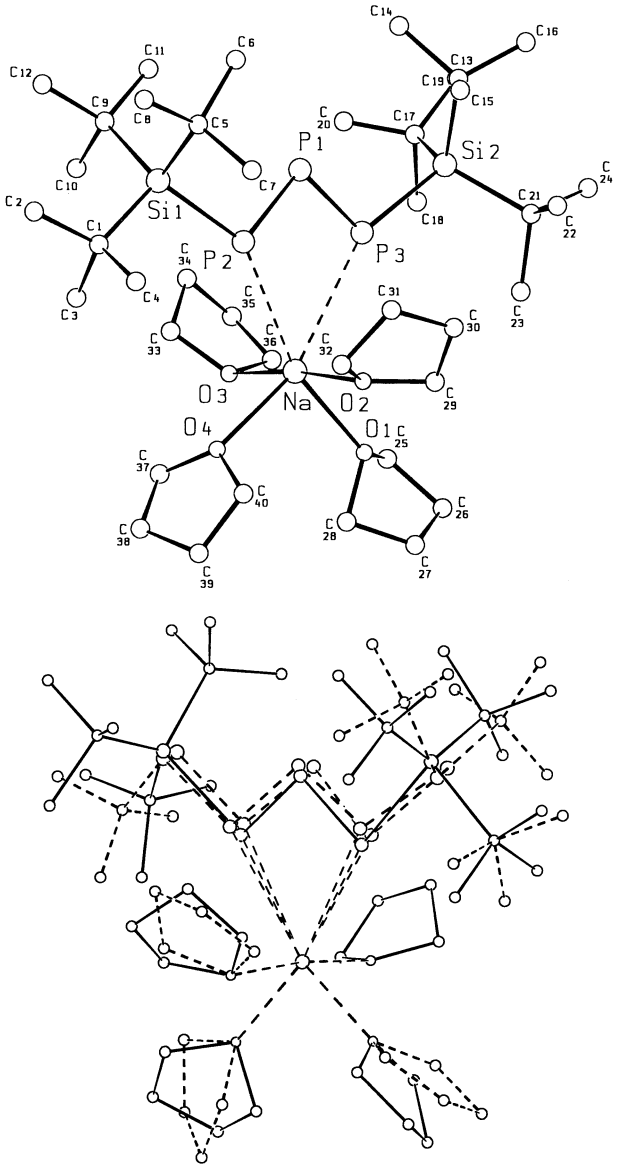
The ^{31}P{^{1}H}-NMR spectrum of the anion in **1a** shows two signals with the splitting pattern of an AX$_2$ spin system in the range typical for the unsaturated twocoordinate phosphorus atom in diphosphenes[14], and in a range which is possible for an unsaturated anionic phosphorus atom[9b] (Figure 2). This is in accord with the *trans-trans* configuration of the anion, as found in the crystal. An isomeric anion with *trans-cis* configuration is, according to the NMR spectra, not present in the C_6D_6 solution, obviously as a consequence of the steric crowding of the supersilyl groups; an isomer with *cis-cis* configuration is not possible for steric reasons and can be definitely ruled out from the signal pattern in the ^{29}Si{^{1}H}-NMR spectrum, which suggests a large $^2J_{PP}$ coupling constant. (In the case of Mes*$_2$P$_3$Li with the less bulky supermesityl substituents, the compound exists as a mixture of the *cis-trans* and the *trans-trans* isomer[6].)

Protolysis and Oxidation of (tBu$_3$Si)$_2$P$_3$Na (1)

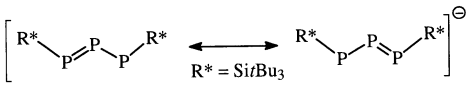
While the protolysis of the tetraphosphide **2** with trifluoroacetic acid in THF, as reported elsewhere[4][5], proceeds nonuniformly with the formation of a number of phosphanes and phosphides containing supersilyl groups, the triphosphide **1** is protolyzed with CF_3CO_2H in THF in a comparatively uniform reaction to form the ring compound **11**. The triphosphene tBu$_3$Si−P=P−PH−SitBu$_3$, which is expected to be the primary product of the protolysis of **1**, is presumably thermodynamically as well as kinetically unstable with respect to the cyclotriphosphane **11**. (In contrast, as product of the protolysis of Mes*$_2$P$_3$Li the unsaturated compound Mes*−P=P−PH−Mes* was obtained[6].)

The oxidation of **2** with tetracyanoethylene in THF proceeds, as reported[4][5], uniformly with the formation of the bicyclotetraphosphane **5**[4], i.e. with retention of the P$_4$ skeleton. On the other hand, the action of TCNE on the triphosphide **1** in THF leads to a doubling of the P$_3$ skeleton: the isomeric hexaphosphanes **12** and **13,** with connected and anellated rings of phosphorus atoms, respectively, are

Figure 1. Molecular structure of $(t\mathrm{Bu_3Si})_2\mathrm{P_3Na(THF)_4}$ (**1a**) in the crystal; top: atom numbering used; bottom: splitting of positions of atoms found (SCHAKAL plot; atoms drawn with arbitrarily chosen atom radii; without H atoms)[a]

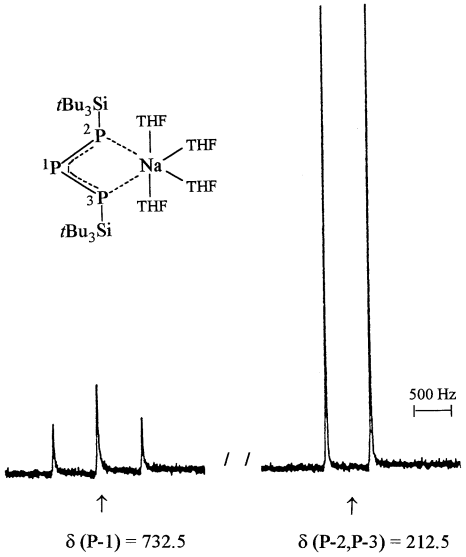


[a] Selected distances [Å] and angles [°] of the molecular structure of **1a** in the crystal with the standard deviations in units of the last significant position in parentheses (all positions of the P and Si atoms seem to be triply split): P(1A)−P(2A) 2.09(2), P(1B)−P(2B) 2.12(2), P(1C)−P(2C) 2.15(2), P(1A)−P(3A) 2.14(3), P(1B)−P(3B) 2.06(2), P(1C)−P(3C) 2.02(2), P(2A)−Si(1A) 2.47(2), P(2B)−Si(1B) 2.26(1), P(2C)−Si(1C) 2.23(2), P(3A)−Si(2A) 2.37(3), P(3B)−Si(2B) 2.26(1), P(3C)−Si(2C) 2.23(2), P(2A)−Na 2.92(2), P(2B)−Na 3.03(1), P(2C)−Na 3.19(2), P(3A)−Na 3.07(2), P(3B)−Na 3.20(1), P(3C)−Na 3.27(2), O(1)−Na 2.349(8), O(2)−Na 2.35(1), O(3)−Na 2.37(1), O(4)−Na 2.359(6); P(2A)−P(1A)−P(3A) 104.6(11), P(2B)−P(1B)−P(3B) 101.3(7), P(2C)−P(1C)−P(3C) 106.6(9), P(1A)−P(2A)−Na 96.2(8), P(1B)−P(2B)−Na 99.7(5), P(1C)−P(2C)−Na 93.9(6), P(1A)−P(3A)−Na 91.0(7), P(1B)−P(3B)−Na 96.1(5), P(1C)−P(3C)−Na 94.1(7), Si(1A)−P(2A)−Na 167.4(7), Si(1B)−P(2B)−Na 150.1(5), Si(1C)−P(2C)−Na 148.9(8), Si(2A)−P(3A)−Na 162.0(12), Si(2B)−P(3B)−Na 155.9(5), Si(2C)−P(3C)−Na 160.3(11), P(2A)−Na−P(3A) 68.0(4), P(2B)−Na−P(3B) 62.5(3), P(2C)−Na−P(3C) 62.4(5), Si(1A)−P(2A)−P(1A) 96.1(10), Si(1B)−P(2B)−P(1B) 104.3(6), Si(1C)−P(2C)−P(1C) 103.0(9), Si(2A)−P(3A)−P(1A) 97.3(11), Si(2B)−P(3B)−P(1B) 105.7(7), Si(2C)−P(3C)−P(1C) 105.5(12).



(6)

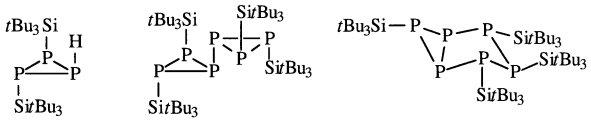
Figure 2. Observed $^{31}P\{^1H\}$-NMR spectrum of **1a** in C_6D_6 at 109.37 MHz (25°C; external 85% H_3PO_4); $^1J_{P1P2}$ = 552.6 Hz



formed. Presumably, in the first step TCNE oxidizes the triphosphide **1** to form the resonance stabilized triphosphanyl radical $[t\mathrm{Bu_3Si{-}P{=}P{-}P{-}Si}t\mathrm{Bu_3} \rightleftharpoons t\mathrm{Bu_3Si{-}P{-}P{=}P{-}Si}t\mathrm{Bu_3}]^{\bullet}$, which therefore exists for a longer period of time and changes into the 1,1′-bicyclotriphosphane **12** and the bicyclohexaphosphane **13**.

Unfortunately, the compounds **11**−**13** (see Scheme 4) have not so far been isolated in their pure state; however, their structures, as shown by the formula, can be proved unambiguously from their ^{31}P-NMR spectra (see below). The ^{31}P-NMR data of phosphorus compounds of type **11** ($t\mathrm{Bu_2P_3H}$[15]), **12** ($\mathrm{P_6}t\mathrm{Bu_4}$[16]), and **13** ($\mathrm{P_6}t\mathrm{Bu_4}$[17], $\mathrm{P_6Cp^*_4}$[18]), which were already known, were also quite helpful for this purpose. Other isomers of the cyclophosphanes **11**−**13** could not be spectroscopically detected using NMR. The molecular structures shown for the compounds are obviously the most sterically favorable, and therefore energetically lowest lying.

Scheme 4

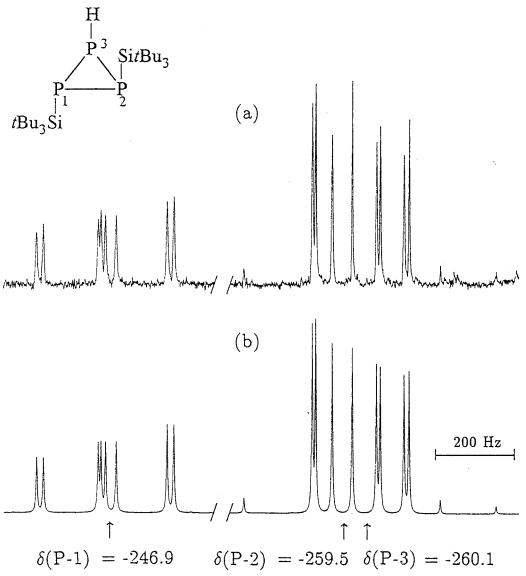


11 **12** **13**

The $^{31}P\{^1H\}$-NMR spectrum of the cyclotriphosphane **11** exhibits the signals of an ABC spin system [δ_A(P-1) = −246.9, δ_B(P-2) = −259.5, δ_C(P-3) = −260.1; $^1J_{P1P2}$ = −188.0 Hz, $^1J_{P1P3}$ = −141.3 Hz, $^1J_{P2P3}$ = −224.2 Hz]. In the proton coupled ^{31}P-NMR spectrum (Figure 3) it extends to an ABCX spin system ($^1J_{P3H}$ = 137.1 Hz, $^2J_{P1H}$ = 16.6 Hz, $^2J_{P2H}$ = 6.9 Hz; regarding the signs of $^1J_{PP}$ and

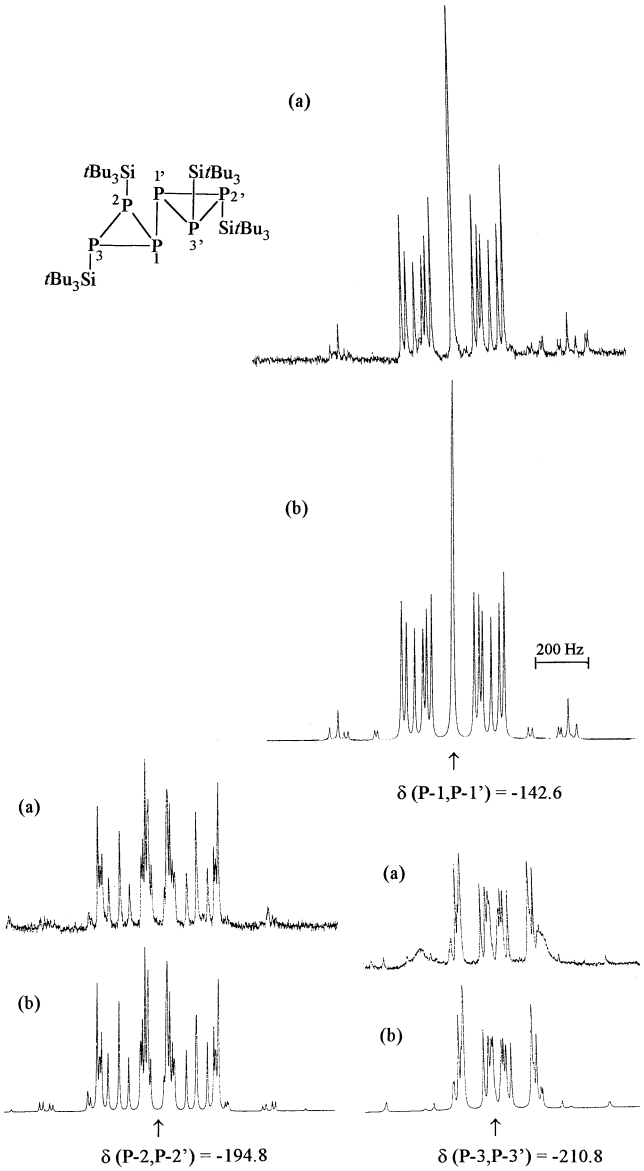
$^1J_{PH}$ see refs.[19][20][21]). Because of the small shift difference between the signals of P-2 and P-3 the spectra deviate strongly from first order. The difference in the PP couplings to P-3 allows an assignment of the signals to P-1 and P-2. The larger coupling constant between P-2 and P-3 indicates a *cis* orientation of the substituents H and Si*t*Bu$_3$ at these phosphorus atoms[22]. For **11** the ^{31}P-NMR chemical shifts, as well as the P−P coupling constants, fall in the range characteristic for cyclotriphosphanes[23][24].

Figure 3. Observed (a) and calculated[20] (b) ^{31}P-NMR spectrum of the cyclotriphosphane **11** at 161.84 MHz in C_6D_6 (0.01 M solution, 25°C, external 85% H_3PO_4); the shift difference between the NMR signals of P-2 and P-3 observed at this frequency is only 102.7 Hz; the relative signs of the coupling constants result from the iterative fitting of the spectrum assuming negative values for $^1J_{PP}$ and positive values for $^1J_{PH}$[19][20][21]: $^1J_{P1P2}$ = −188.0, $^1J_{P1P3}$ = −141.3, $^1J_{P2P3}$ = −224.2, $^1J_{P3H}$ = 137.1, $^2J_{P1H}$ = 16.6, $^2J_{P2H}$ = 6.9 Hz



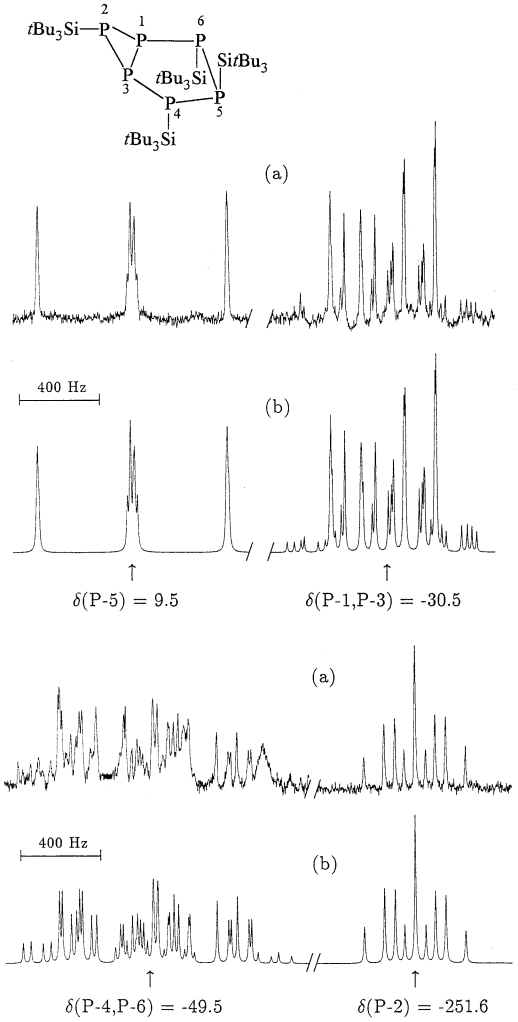
The ^{31}P{^{1}H}-NMR spectrum of the 1,1′-bicyclotriphosphane **12** shows three multiplets with the classical splitting pattern of an AA′BB′MM′ spectrum. Approximate values for δ_P and J_{PP} can be estimated by simple examination of the experimental spectrum[19]; starting from these values the spectrum can be solved by iterative fitting[20] (Figure 4). The ^{31}P-NMR data of **12** parallel, to a large degree, those of *t*Bu$_2$P$_3$−P$_3$*t*Bu$_2$[16]. The chemical shifts of the phosphorus nuclei appear at high field [δ(P-1) = −142.6, δ(P-2) = −194.8, δ(P-3) = −210.8], as is generally found for δ^{31}P in cyclotriphosphanes[23][24]. The direct connection of the two P_3 rings is indicated by the large and negative coupling constant between P-1 and P-1′. The spatial neighbourhood of the lone pairs at P-3 and P-1′ as well as P-1 and P-3′ causes a large and positive coupling constant (57.7 Hz) between these phosphorus atoms, while for $^2J_{P1'P2}$ and $^2J_{P1P2'}$ a much smaller value (1.7 Hz) is observed. This proves the *trans* orientation of the supersilyl substituents at the adjacent phosphorus atoms P-2 and P-3 as well as P-2′ and P-3′. In accord with this is also the sequence of magnitudes of $^1J_{P1P2}$ (−284.7 Hz) and $^1J_{P1P3}$ (−174.9 Hz)[22]. Obviously, like *t*Bu$_2$P$_3$−P$_3$*t*Bu$_2$[16], **12** also forms the sterically most favorable all *trans* isomer. In the case of **12**, however, coupling constants $^3J_{P2P2'}$ (7.6 Hz) and $^3J_{P3P3'}$ (0.4 Hz) are found to have the reverse order of magnitude. This difference, as well as the clearly more negative coupling constant $^3J_{P2P3'}$ (−14.1 Hz) observed for **12,** is presumably caused by a larger population of the rotamers with a wider torsion angle P-2,P-1,P-1′,P-2′.

Figure 4. Observed (a) and calculated[20] (b) ^{31}P{^{1}H}-NMR spectrum of **12** at 109.36 MHz in C_6D_6 (25°C; external 85% H_3PO_4): $^1J_{P1P1'}$ = −301.1, $^1J_{P1P2}$ = $^1J_{P1'P2'}$ = −284.7, $^1J_{P1P3}$ = $^1J_{P1'P3'}$ = −174.9, $^1J_{P2P3}$ = $^1J_{P2'P3'}$ = −171.8, $^2J_{P1P2'}$ = $^2J_{P1'P2}$ = 1.7, $^2J_{P1P3'}$ = $^2J_{P1'P3}$ = 57.7, $^3J_{P2P2'}$ = 7.6, $^3J_{P3P3'}$ = 0.4, $^3J_{P2P3'}$ = $^3J_{P2'P3}$ = −14.1 Hz; the relative signs of the coupling constants result from the iterative fitting of the spectra assuming negative values for $^1J_{PP}$[21]



The structure of the bicyclo[3.1.0]hexaphosphane **13** can be derived from the NMR data after a complete analysis of its ^{31}P{^{1}H}-NMR spectrum. It shows, as in the case for the analogous hexaphosphanes P$_6$*t*Bu$_4$[17] and P$_6$Cp*$_4$[18] the four multiplets of an AA′BB′MX spin system (Figure 5). The signal of P-2 (X part) appears at high field (δ =

Figure 5. Observed (a) and calculated[20] (b) $^{31}P\{^1H\}$-NMR spectrum of **13** at 109.37 MHz in C_6D_6 (25°C; external 85% H_3PO_4): $^1J_{P1P2} = {}^1J_{P2P3} = -159.5$, $^1J_{P1P3} = -245.9$, $^1J_{P1P6} = {}^1J_{P3P4} = -397.1$, $^1J_{P4P5} = {}^1J_{P5P6} = -487.7$, $^2J_{P1P4} = {}^2J_{P3P6} = 23.2$, $^2J_{P1P5} = {}^2J_{P3P5} = 11.7$, $^2J_{P2P4} = {}^2J_{P2P6} = 105.4$, $^2J_{P4P6} = 34.7$, $^3J_{P2P5} < 1.0$ Hz; the relative signs of the coupling constants result from the iterative fitting of the spectrum assuming negative values for $^1J_{PP}$[21]



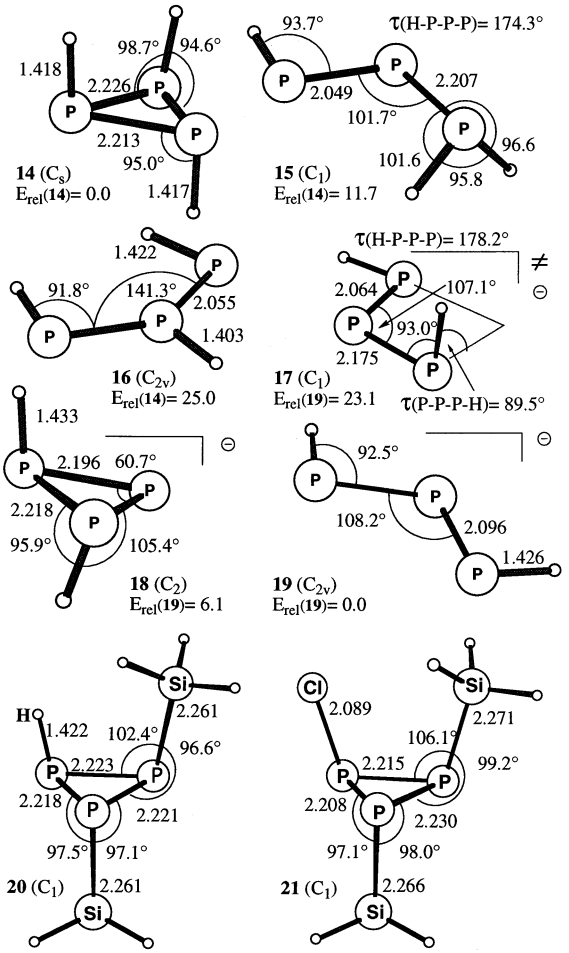
−251.6) as a triplet of triplets and can be understood, practically, according to a first order interpretation. On the other hand the signal of P-5 (M part, δ = 9.5) deviates considerably from the first order $(J_{P\text{-}4P\text{-}5})/\nu_0[\delta(P\text{-}4) - \delta(P\text{-}5)] = 0.08$ at 109.37 MHz). For the phosphorus atoms P-1 and P-3 at the bridgehead positions δ = −30.5, and for the adjacent phosphorus atoms P-4 and P-6 in the pentaphospholane ring δ = −49.5; the characteristic splitting pattern for the A and the B part of an AA′BB′M spin system[19] is observed, each doubled by coupling with P-2. The presence of a cyclotriphosphane ring in **13** is indicated by the chemical shift at high field for P-2 as well as by the large and negative coupling constant $^1J_{P1P3} = -245.9$ Hz (regarding the sign see ref.[21]). As in the case of P_6tBu_4[17] $^1J_{P1P6}$ and $^1J_{P5P6}$ are clearly larger than $^1J_{PP}$ in the cyclotriphosphane ring, and here have values of −397.1 Hz and −487.7 Hz, respectively, which are remarkably large values. The large and positive coupling constant between P-2, P-4 and P-6 (+105.4 Hz) indicates that the lone pairs at these phosphorus atoms are facing each other. The tBu_3Si substituents at P-2 as well as at P-4 and P-6 must therefore occupy in the first case the axial position and in the last two cases the equatorial positions, as shown by the X-ray structure analyses for P_6tBu_4[17] and $P_6Cp^*_4$[18] in the crystal.

Cyclic versus Acyclic $P_3H_2^-$, P_3H_3 and Derivatives: Ab initio Structure, Energy and NMR Calculations

Figure 6 comprises the results of ab initio calculations concerning structure and relative energies of cyclic P_3H_3 (**14**) and $P_3H_2^-$ (**18**) as well as of their acyclic isomers (**15**, **16**, **17**, **19**) and two derivatives of *cyclo*-P_3H_3 (**20**, **21**). Our RMP2/6-31+G* calculations of the parent $P_3H_2^-$ anion show that the acyclic planar *trans-trans* form **19** with allylic conjugation[25], $[HP\cdots P\cdots PH]^-$, and P−P $1^1/_2$ bonds[25] is thermodynamically 6.1 kcal/mol more stable than the cyclic isomer **18** (isomerization of **19** via **17** to a *trans-cis* isomer has a barrier of 23.1 kcal/mol, see Figure 6). With silyl substituents the allyl preference increases slightly [E_{rel} for cyclic $(H_3Si)_2P_3^-$ is 7.6 kcal/mol]. In contrast, neutral compounds with a P_3 framework like P_3H_3 (**14**)[26], $(H_3Si)_2P_3H$ (**20**), $(H_3Si)_2P_3Cl$ (**21**) prefer the cyclic form. Structural alternatives with a terminal PH_2 group are less stable than the global minimum for the neutral *cyclo*-P_3H_3 [E_{rel} (H_2PPPH, **15**) with respect to **14** is 11.7 kcal/mol, Figure 6] as well as for the anionic *acyclo*-$P_3H_2^-$ [E_{rel} (H_2PPP^-) with respect to **19** is 12.7 kcal/mol)]. Therefore, cyclization of the "protonated anion" **1** to **11** and ring opening of the "reduced halogenide" **9** to **1** is in agreement with our ab initio results for the simple models R_2P_3X and $R_2P_3^-$ with R = H or SiH_3 and X = H or Cl.

Both the acyclic anion $R_2P_3^-$ (in **1** with R = Si*t*Bu$_3$; calcd. for R = H, SiH_3) and the cyclic isomer could have two ^{31}P-NMR signals. The question is which R_2P_3Na model structure provides computed NMR data which are in agreement with the experiment? Unfortunately, ab initio NMR calculations which neglect electron correlation give $\delta^{31}P$ values for the model complexes, (RP⩬P⩬PR,Na) (R = H or SiH_3), with unusually large deviations of several hundred ppm. However, density functional NMR calculations (SOS-DFPT[27]), which include correlation are in good agreement with GIAO-MP2[28] (explicit consideration of correlation) and should only deviate by the order of 37 ppm from the experiment[29]. Our SOS-DFPT/Perdew-Wang functional '91/B3///RMP2/6-31G*, NMR values for an appropriate model of **1** (modeling the silyl substituent by SiH_3 and the solvated sodium by bare Na^+) are in reasonable agreement with the experiment for the W-shaped, C_S-symmetric acyclic form with a folded deltoid P_3Na moiety ($\delta DPB3^{31}P = 720$ and 176, corresponding to 733 and 213) and exclude any cyclic form[30]. The $\delta DPB3^{31}P$ values for the strictly planar Si_2P_3Na framework indicate that this transition structure of the molecule, in solution or in the crystalline framework, occurs only intermittently during the permanent internal motion of the molecule.

Figure 6. RMP2/6-31G* (and 6-31+G* for anions) geometries (bond length in [A], angles in [°] and relative energies (in [kcal/mol]) for P_3H_3, $P_3H_2^-$ and $(H_3Si)_2P_3X$ (X = H, Cl)



We would like to thank the *Deutsche Forschungsgemeinschaft* for supporting our research and the *Computer-Chemie-Centrum Erlangen* for computer time on an HP735 platform.

Experimental Section

All experiments were carried out under dry argon with strict exclusion of air and moisture. CF_3SO_3H, CF_3CO_2H, TCNE, CD_3CN, and PCl_3 were commercially available. $(t\mathrm{Bu_3Si})_2P_4Na_2$ (**2**) in THF[4], $t\mathrm{Bu_3SiNa}$ in THF[31], and $(t\mathrm{Bu_3Si})_3P_7$ (**7**)[11] were prepared according to literature procedures. The solvents (pentane, benzene, tetrahydrofuran) were distilled from sodium/benzophenone immediately before use.

The NMR spectra were recorded with a JEOL FX-90-Q (^{1}H/^{13}C/^{29}Si: 89.55/22.52/17.79 MHz), a JEOL GXS-270 (^{1}H/^{13}C/^{29}Si/^{31}P: 270.17/67.94/53.67/109.37 MHz), and a JEOL EX-400 (^{1}H/^{13}C/^{31}P: 399.78/100.53/161.84 MHz) spectrometer. The ^{29}Si-NMR spectra were recorded with the INEPT pulse sequence using empirically optimized parameters for polarization transfer from the *t*Bu substituents. The mass spectra (electron impact) were recorded with a Varian CH7 instrument.

Conversion of **2** *into* **1**: a) 5.22 mmol (0.4 ml) of CF_3CO_2H in 2 ml of pentane was added dropwise with stirring to a cooled (−78°C) solution of 5.22 mmol of **2** in 50 ml of THF and the resulting deep red reaction mixture was warmed up after 1 h to ambient temp. While warming, the solution changed colour to red-violet. According to the ^{31}P-NMR spectrum (C_6D_6) the reaction solution contained, in addition to $t\mathrm{Bu_3SiPH_2}$ and small amounts of $t\mathrm{Bu_3Si}$-PHNa (identified by comparison with authentical samples[32]), the phosphorus compounds **1** (see below), **2** (unreacted starting material) and **4** (identified by comparison with an authentic sample[10]) in a molar ratio of 2:1:1, as well as the oligophosphane $(t\mathrm{Bu_3SiP_3})_n$ (see below).

b) From a solution of 0.138 mmol of **2** in 2 ml of THF the solvent was removed in vacuo and 1 ml of CD_3CN added to the remaining deep red solid to yield a violet solution. According to the ^{31}P-NMR spectrum of this solution, **1** (identified by comparison with an authentic sample, see below) and $t\mathrm{Bu_3SiPD_2}$ (identified by comparison with an authentic sample[32]) were formed as the only phosphorus-containing products in a molar ratio of 1:1. After removing the CD_3CN in vacuo, $t\mathrm{Bu_3SiPD_2}$ was separated from the residue by sublimation (100°C/10^{-3} mbar) and isolated as colourless needles. − ^{1}H NMR (CD_3CN, internal TMS): δ = 1.14 (d; $^4J_{PH}$ = 0.46 Hz; 3 *t*Bu). − ^{13}C{^{1}H} NMR (CD_3CN, internal TMS): δ = 22.8:30.9 (d/d; $^2J_{CP}/^3J_{CP}$ = 6.1/3.0 Hz; 3 *t*Bu). − ^{29}Si NMR (CD_3CN, external TMS): δ = 24.0 (d; $^1J_{SiP}$ = 30.7 Hz; Si*t*Bu$_3$). − ^{31}P{^{1}H} NMR (CD_3CN, external 85% H_3PO_4): δ = −268.9 (quint; $^1J_{PD}$ = 29.4 Hz; PD_2).

Note: In the course of a few weeks the violet colour of the reaction solution vanished and it then contained, according to the ^{31}P-NMR spectrum, $t\mathrm{Bu_3SiPD_2}$ as the only phosphorus compound. According to the ^{29}Si-NMR spectrum $t\mathrm{Bu_3SiCN}$ also formed (identified by comparison with an authentic sample[33]).

c) **2**, dissolved in a pentamethyldiethyltriamine (PMDTA)/benzene mixture, converted in the course of several months at ambient temp. into **1** and $t\mathrm{Bu_3SiPHNa}$ (as PMDTA adducts); at the same time additional, and as yet unidentified, phosphorus-containing products were formed.

Formation of **1** *from Supersilylpolyphosphanes:* a) 3.45 mmol of **2** in 50 ml of THF was added dropwise to a solution of 6.94 mmol (0.61 ml) of CF_3SO_3H in 5 ml of pentane at ambient temp. The deep red colour of the solution of **2** changed to yellow on contact with the acid. According to the ^{31}P-NMR spectrum (C_6D_6) polyphosphanes together with $t\mathrm{Bu_3SiPH_2}$ were formed (molar ratio of the polyphosphane phosphorus to the monophosphane phosphorus in accord with Eq. 2 is 3:1). The solvent and all volatile materials were removed in vacuo, the residue dissolved in 10 ml of pentane and all insoluble material (CF_3SO_3Na) separated by filtration. After several days at −25°C, a yellow solid precipitated from the filtrate, which was separated, dissolved in heptane and precipitated again at −25°C. Repetition of this procedure several times afforded 0.820 g of a yellow and very air-sensitive solid polyphosphane product. According to the ^{31}P-NMR spectrum, this product was free of $t\mathrm{Bu_3SiPH_2}$, and according to elemental analysis had the composition $t\mathrm{Bu_3SiP_3}$[34]. After removal of the pentane and heptane in vacuo from the respective filtrates, solid $t\mathrm{Bu_3SiPH_2}$ was obtained from the remaining residue by sublimation at 100°C/10^{-3} mbar (identified by comparison with an authentic sample[32]).

A solution of 2.80 mmol of $t\mathrm{Bu_3SiNa}$ in 6 ml of THF was slowly added dropwise to a solution of 0.820 g (2.80 mmol with respect to the formula $t\mathrm{Bu_3SiP_3}$) of the solid yellow polyphosphane (see above) in 10 ml of THF. The colour of the reaction solution changed from yellow to deep violet. According to the ^{31}P-NMR spectrum, **1** was quantitatively formed, which proved the identity of the polyphosphane to be $(t\mathrm{Bu_3SiP_3})_n$. The reaction solution was concentrated to 5 ml and mixed with 2 ml of pentane. In the course of 10 d violet, and very air- and moisture-sensitive crystals of so-

dium 2,3-bis(tri-*tert*-butylsilyl)triphosphenide−tetrahydrofuran(1/4) (**1a**) separated. − ^{1}H NMR (C_6D_6/THF, internal TMS): δ = 1.38 (br.; 2 Si*t*Bu$_3$). − ^{13}C{^{1}H} NMR (C_6D_6/THF, internal TMS): δ = 25.3 (br.; 6 *C*Me$_3$), 32.3 (br.; 6 C*Me*$_3$). − ^{29}Si NMR (C_6D_6/THF, external TMS): δ = 18.3 (td; $^1J_{SiP}$ + $^3J_{SiP}$ = 47.1 Hz; $^2J_{SiP}$ = 7.1 Hz; 2 Si*t*Bu$_3$). − ^{31}P{^{1}H} NMR (C_6D_6/THF, external 85% H_3PO_4): cf. Figure 1. − X-ray structure investigation [cf. section on characterization and structure of (*t*Bu$_3$Si)$_2$P$_3$Na(THF)$_4$ (**1a**)].

b) A solution of 0.445 mmol *t*Bu$_3$SiNa in 1 ml of THF was added dropwise to 0.181 g (0.222 mmol) of **7** at ambient temp. The reaction mixture immediately adopted a red-violet colour. According to the ^{31}P-NMR spectrum **1** (identified by comparison with an authentic sample, see above) and **3** formed in a molar ratio of 1:1. After a longer period of time dark red crystals of highly air- and moisture-sensitive 1-[tri-*tert*-butylsilyl(sodio)phosphanidyl]-2,3-*trans*-bis(tri-*tert*-butylsilyl)cyclotriphosphane−tetrahydrofuran-(1/*n*) (**3**) were formed from the red-violet reaction solution (identified by comparison with an authentic sample[12]).

Note: The phosphide **3** was also formed quantitatively from the reaction of **5** with an equimolar amount of *t*Bu$_3$SiNa in THF.

Formation of **1** *from Phosphorus Trichloride:* A solution of 0.184 g (1.35 mmol) of PCl_3 in 0.5 ml of heptane was added dropwise to a cooled (−78°C) solution of 4.6 mmol *t*Bu$_3$SiNa in 10 ml of THF (procedure A); alternatively a solution of 11.5 mmol *t*Bu$_3$SiNa in 25 ml of THF was added dropwise to a cooled (−78°C) solution of 0.623 g (4.98 mmol) of PCl_3 in 20 ml of THF (procedure B). The resulting reaction mixtures were then warmed up to ambient temp. According to the ^{31}P-NMR spectrum the triphosphide **1** (see above), the tetraphosphide **3**[5], the pentaphosphide **4**[5][10], monophosphides (see below), and diphosphides (see below) were formed in a molar ratio of about 10:5:3:1:2 for procedure A, and of about 7:4:3:1:4 for procedure B [the compounds were identified by comparison of the ^{31}P-NMR data with those of authentical samples; cf. references given with the numbers of the compounds; the mono- and diphosphides were formed in only small amounts (giving one and two ^{31}P-NMR signals, respectively) and are not yet identified.

Note: After the insoluble materials from the reaction solution, obtained according to procedure B, were separated by filtration, and the solution was concentrated to 15 ml and cooled to −25°C, a microcrystalline precipitate of a mixture of the compounds mentioned above was obtained. The filtrate ("mother liquor"), which contains **1**, **3**, **4**, and other phosphides in a molar ratio of 8:5:3:3, was further treated with CF_3CO_2H and with TCNE (see below).

Reaction of **1** *with Trifluoracetic Acid:* A solution of 0.060 g (0.53 mmol) of CF_3CO_2H in 0.5 ml of heptane was added dropwise at ambient temp. to 2 ml of the "mother liquor" (described above and obtained from PCl_3 and *t*Bu$_3$SiNa in THF) which contained, as shown from titration, 0.56 mmol/ml of anionic phosphorus. The solvents and all volatile materials were removed in vacuo, the residue was dissolved in pentane, the insoluble material (CF_3CO_2Na) separated by filtration, and the pentane then removed in vacuo and the residue dissolved in 1 ml of C_6D_6. According to the ^{31}P-NMR spectrum, protonated **1** (≡ **11**), protonated **3**[5] and protonated **5**[5][10] were formed in a molar ratio of about 3:5:3, together with monophosphanes, diphosphanes, and other phosphanes. The structure of *trans*-bis(supersilyl)cyclotriphosphane (**11**), which could not be isolated from the reaction mixture, was unambiguously proved from the ^{31}P-NMR spectra [cf. section on the protolysis and oxidation of (*t*Bu$_3$Si)$_2$P$_3$Na (**1**)]. The ^{1}H-, ^{13}C-, and ^{29}Si-NMR spectra revealed no additional information for **11** because of superposition of its signals with the signals of other compounds present in the mixture.

Reaction of **1** *with Tetracyanethylene:* 2 ml of the "mother liquor" described above (obtained from PCl_3 and *t*Bu$_3$SiNa in THF, and which contained, as shown from a titration, 0.56 mmol/ml anionic phosphorus) was added dropwise to 0.059 g (0.46 mmol) of TCNE at ambient temp. The solvent and all volatile materials were removed in vacuo, the residue was dissolved in pentane, unsoluble materials were removed by filtration, and finally the pentane was evaporated in vacuo and the residue dissolved in 0.8 ml of C_6D_6. According to the ^{31}P-NMR spectrum, **5**[4][11], **6**[10], **12**, and **13** are formed in a molar ratio of 2:7:8:1 together with other phosphanes. Assuming, that **4** was oxidized uniformly to **6** and **1** was oxidized only to **12** and **13**, the compounds **1** and **4**, present in the "mother liquor" in a molar ratio of 8:3, must be found in the reaction solution, after the oxidation, in a molar ratio of 4:3 (experimentally observed 9:7 ≡ 4:3.1). The structures of 2,2′,3,3′-tetrasupersilyl-1,1′-bicyclotriphosphane (**12**) and 2,4,5,6-tetrasupersilylbicyclo[3.1.0]hexaphosphane (**13**), which could not be isolated from the reaction mixture, were unambiguously derived from the ^{31}P-NMR spectra [cf. section on the protolysis and oxidation of (*t*Bu$_3$Si)$_2$P$_3$Na (**1**)]. The ^{1}H-, ^{13}C-, and ^{29}Si-NMR spectra revealed no additional information for **12** and **13**, due to the superposition of their NMR signals with the signals of other compounds present in the mixture.

X-ray Structure Determination of (tBu$_3$Si)$_2$P$_3$Na(THF)$_4$ (**1a**): Diffractometer STOE IPDS, Mo-K_α radiation, λ = 0.71069 Å. A small violet crystal was fixed in perfluoroether and analyzed in a Mark-tube at T = 200(2) K. Crystallographic data: $C_{40}H_{86}NaO_4P_3Si_2$, M_f = 803.17, orthorhombic, space group $Pna2_1$ (No. 33), a = 24.433(6), b = 17.439(7), c = 12.005(6) Å, V = 5115(4) Å^3, Z = 4, $d_{calcd.}$ = 1.043 g cm^{-3}, μ = 0.204 mm^{-1}, F(000) = 1768. − Data collection: ω scans, 2Θ = 2.38−21.00° in $-32 \le h \le 32$, $-22 \le k \le 8$, $-15 \le l \le 15$. 10985 measured reflections, of which 4866 symmetry independent. − Solution of the structure: Restraints, 390 parameters optimized, $R1[I > 2\sigma(I)]$ = 0.0787, $wR2$ = 0.1802, GOF = 2.128; residual electron density = 0.389 and −0.388 e Å^{-3}. For further details of the crystal structure investigation (for example splitting of the positions of the atoms) see ref.[35].

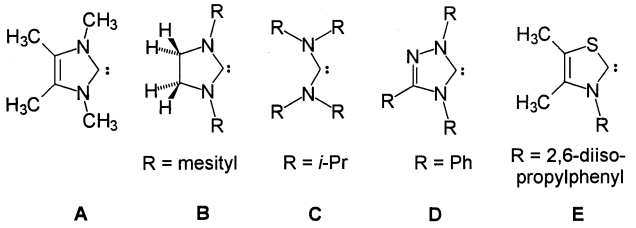
Keywords: Boranes / Carbenes / Carbene complexes / Heterocycles / Imidazoles

Reactions of the Lewis acids BH_3 and BEt_3 with trimethylimidazole (**1**) lead to the borane adducts **2a** and **2b**. Deprotonation of **2a** with *n*-butyllithium results in the formation of the novel *N*-borane-substituted imidazol-2-ylidene anion **3a**$^-$ whereas deprotonated **2b** rearranges unexpectedly to the anionic compound **3b**$^-$. This can be transformed into the carbene–borane adduct **4** by methylation. The reaction of **3a**$^-$ with $[Mn(CO)_5Br]$ yields the carbene complex **5**. Surprisingly, **3a**$^-$ attacks $Fe(CO)_5$ at a carbon atom which leads to the iron acyl complex anion **6**$^-$. The compositions of the products follow from spectroscopic and analytical data and from X-ray structure analyses for $Li(thp)^+$**3a**$^-$, $Li(thf)_2^+$**3b**$^-$ and $Li(thp)_3^+$**6**$^-$.

Introduction

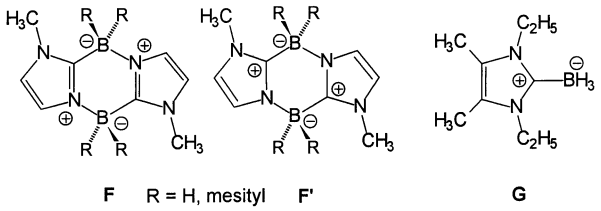
The chemistry of nucleophilic carbenes has become an area of particular interest since the discovery of the first stable carbenes, synthesized by Arduengo et al. in 1991[1]. Several derivatives of the imidazol-2-ylidene **A** as well as the imidazolin-2-ylidene **B**[2] and the chain-like carbene compound **C** have been reported[3]. Based on the heterocycles triazole and thiazole, the carbenes **D**[4] and **E**[5] have also been synthesized. Recently, a review of the chemistry of N-heterocyclic carbenes was published by Herrmann et al.[6].



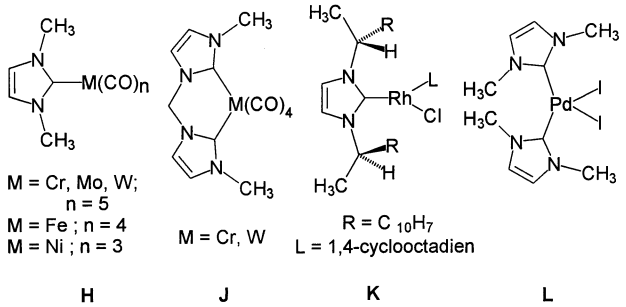
Compounds **A**–**E** have in common the presence of only organic substituents attached to the nitrogen atoms, whereas other main-group element substituted carbenes are not known. Fehlhammer et al.[7] synthesized a tris(carbene)iron complex in which the carbene units are connected via a BH group.

In 1994 Contreras, Wrackmeyer, et al.[8] published the synthesis of the imidazabole **F** (R = H) which may also be regarded as an intramolecular carbene–borane adduct **F′**. Its BH_2 groups function as Lewis acid centers for the carbene carbon atoms (see below).

Imidazol-2-ylidenes (e.g. **A**) have also proved to be excellent ligands in transition-metal complexes[9]. In particular, ligand exchange reactions with carbonylmetal compounds work easily yielding the expected carbene complexes. The



reactions occur at room temperature and, depending on the stoichiometry of the reactants, mono-substituted products of type **H** are formed as well as bis- and tris(carbene) complexes in the case of Mo, W, and Ni[10][11]. Beside complexes with the monodentate ligand **A**, compounds **J** with a bidentate ligand are known as well[10][11].



In complexes of imidazol-2-ylidenes the metal–carbene bond has weak π-backbonding character[6][10]. Therefore, these carbenes appear comparable to phosphanes, and could therefore also prove important in homogeneous catalytic processes[6][9e][10]. In fact, **K** and **L** are examples of useful carbene catalysts for asymmetric hydrosilylations (**K**)[12] and for the Heck reaction (**L**)[13].

In the following we report the deprotonation of the trimethylimidazol–borane adducts **2a** and **2b** with *n*-butyl-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434–1948/98/0606–0843 $ 17.50+.50/0

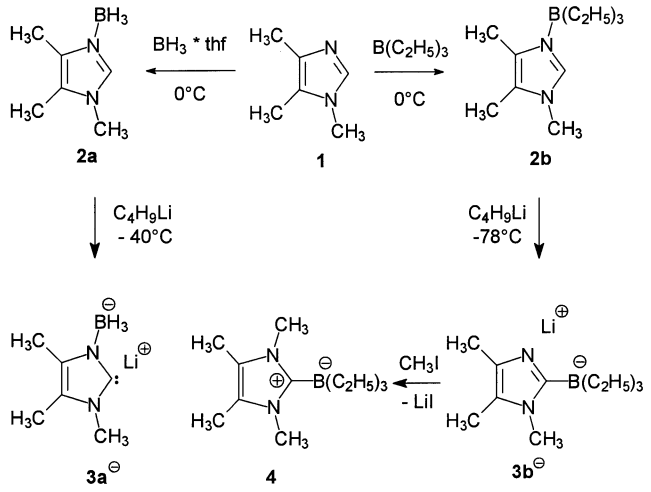
lithium which results in the formation of the novel anions **3a**$^-$ and **3b**$^-$. **3a**$^-$ forms the metal complexes **5** and **6**$^-$.

Results and Discussion

Synthesis

Analogous to the reaction of imidazoles with boranes[14], 1,4,5-trimethylimidazole (**1**) reacts with $BH_3 \cdot$ thf at 0 °C to yield 3-borane-1,4,5-trimethylimidazole (**2a**), a colorless, crystalline, and air-stable solid. Its composition follows from NMR and MS data. Deprotonation of **2a** leads to the formation of the 3-borane−1,4,5-trimethylimidazol-2-ylidene anion **3a**$^-$. The salt Li(thp)$^+$**3a**$^-$, thp being tetrahydropyran, is obtained as a colorless crystalline solid, which is sensitive to air and moisture. This first example of a borane-substituted nucleophilic carbene is dimeric in the solid state (see below). It is derived from **A** by formal substitution of a methyl group by the isoelectronic BH_3^- unit.

Scheme 1



A characteristic feature of nucleophilic carbenes is the low-field ^{13}C-NMR shift of the carbene carbon atom signal (δ = 211−256 for **A**−**E**)[1][2][3][4][5]. **3a**$^-$ shows a resonance at δ = 191.3 which is shifted 22.4 ppm to high field compared to that of the corresponding carbene **A**[1]. Obviously, there is a transfer of electron density from the negatively charged boron atom to the carbene carbon atom. The remaining ^{13}C-NMR data are very similar to those of **A**. The signals for C4 and C5 appear at δ = 121.8 and 128.7 while those for the three methyl groups appear at δ = 8.3, 10.4, and 33.8. The ^{11}B-NMR spectrum shows one signal at δ = −21.1 which is broadened so that coupling with the hydrogen atoms is not observed, in contrast to **2a** ($^1J_{B\text{-}H}$ = 94 Hz).

Treatment of **1** with BEt_3 at 0 °C leads to 3-(triethylborane)−1,4,5-trimethylimidazole (**2b**) in quantitative yield. **2b** is a crystalline, colorless solid which is, in contrast to **2a**, sensitive to air. By analogy to the formation of **3a**$^-$, treatment of **2b** with *n*-butyllithium was expected to yield a carbene; however, surprisingly the rearranged anion **3b**$^-$ was obtained. After deprotonation, migration of the triethylborane from the nitrogen to the carbene carbon atom took place. This follows from the NMR data and from an X-ray structural analysis of Li(thf)$_2^+$**3b**$^-$. Obviously, the different Lewis acidities of BH_3/BEt_3 are responsible for this result.

The ^{13}C-NMR spectrum of **3b**$^-$ exhibits two signals at δ = 119.9 and 123.8 for the C4 and C5 atoms, the one for C2 not being observed. The resonances for the methyl groups are found at δ = 8.3, 9.4, and 32.0 while the ethyl substituents show two signals at δ = 10.7 and 14, the latter for the CH_2 carbon atom being broadened.

The different electronic behavior of BH_3 and BEt_3 as Lewis acids is reflected in the ^{11}B-NMR spectra. **2a** exhibits a resonance at δ = −20.9 whereas for **2b** a low-field shift to δ = −1.5 is observed. Comparing the shifts of **2a** and **2b** with those of **3a**$^-$ and **3b**$^-$ it is striking that for **3a**$^-$ (δ = −21.1) there is only a slight difference relative to **2a** whereas in the case of **3b**$^-$ (δ = −14.6) compared with **2b** a significant shift to higher field is observed. These data indicate that the migration of the triethylborane from the nitrogen to the carbon atom results in a larger electronic saturation of the boron atom. This is supported by comparing the ^{11}B-NMR shifts for tetraalkyl- and trialkyl(amino)-borates. $[BEt_4]^-$ shows a resonance at δ = −17.5[15] whereas for $[Et_3BNH_2]^-$ a low-field shift to δ = −9.8 is observed[16].

The reaction of **3b**$^-$ with iodomethane results in the formation of the 2-(triethylborane)−1,3,4,5-tetramethylimidazoline (**4**). Carbene adducts of this kind are known for a large variety of electrophiles and are usually obtained by addition of the Lewis acid to the free imidazol-2-ylidene[17]. Thus, carbene adducts with BH_3 and BF_3 have been described[18]. The method presented herein is a new route to generate triethylborane−carbene adducts. In the first step the trialkylborane is introduced, which on deprotonation and rearrangement gives **3b**$^-$. In the last step methylation of the anion **3b**$^-$ with CH_3I leads to the carbene adduct **4**.

4 is characterized by ^{1}H-, ^{13}C-, ^{11}B-NMR spectroscopy, and mass spectrometry. The ^{1}H-NMR spectrum shows the expected two signals at δ = 1.29 and 3.26 for the two sets of equivalent methyl substituents. In the ^{13}C-NMR spectrum only one signal for the imidazole carbon atoms C4 and C5 (δ = 123.6) is found, while that of C2 is, as for **3b**$^-$, not observed. The methyl substituents give rise to two signals at δ = 12.1 and 32.9. The ^{11}B-NMR shift of δ = −12.6 is comparable with that of **3b**$^-$.

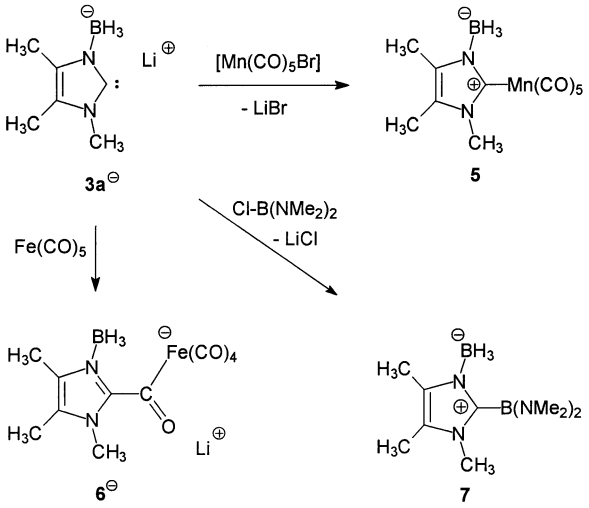
Complex Formation

The reactivity of **3a**$^-$ in ligand-exchange reactions was studied. When $[Mn(CO)_5Br]$ is added to a solution of **3a**$^-$, the expected complex **5** is obtained. In contrast to this, the reaction of **3a**$^-$ with $Fe(CO)_5$ results in the formation of the acyl complex **6**$^-$. Treatment of **3a**$^-$ with chlorobis(dimethylamino)borane leads to the borane compound **7** (Scheme 2).

The orange-yellow complex **5** is extremely sensitive to air and moisture, and is obtained by reaction of the in situ generated carbene **3a**$^-$ with $[Mn(CO)_5Br]$ at −40 °C. The IR spectrum of the reaction mixture indicates the presence of several products, for which pure **5** can be isolated by column chromatography in 33% yield. **5** is characterized by

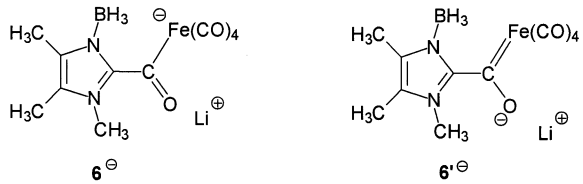
^{1}H-, ^{13}C-, ^{11}B-NMR, IR spectroscopy, and mass spectrometry. The ^{1}H-NMR spectrum shows two signals at δ = 2.22 and 2.24 for the C-CH_3 groups and one for the N-CH_3 group at δ = 3.81. In the ^{13}C-NMR spectrum the signals of the imidazole carbon atoms are found at δ = 129.0, 130.9 (C4, C5) and 146.9 (C2). This high-field shift of 44.4 ppm relative to that of **3a**$^-$ is in the same range as those for other carbenes and their complexes[10]. For the carbonyl ligands two signals at δ = 214.6 and 256.1 are observed. The assumption that **5** possesses a structure analogous to **6**$^-$ can be ruled out on the basis of the NMR data. The ^{11}B-NMR shift of δ = −22.3 is comparable with the data mentioned above. Again the signal is broadened so that no coupling to the hydrogen atoms can be observed. The IR spectrum of **5** shows four absorptions at $\tilde{\nu}$ = 2081, 2004, 1992 and 1974 cm^{-1}. In the mass spectrum (EI) of **5** the molecular ion of *m*/*z* = 318 with the expected isotopic distribution is observed as well as the fragmentation pattern for the sequential loss of up to five CO molecules, with the resulting base peak at *m*/*z* = 178 [M$^+$ − 5 CO].

Scheme 2



At room temperature **3a**$^-$ attacks one carbonyl ligand in $Fe(CO)_5$, analogously to the reaction of alkyllithium with carbonyl complexes[19], with formation of the complex anion **6**$^-$. The reaction occurs rapidly and quantitatively as monitored by IR spectroscopy. This behavior represents an important difference relative to the reactivity of the imidazol-2-ylidenes known today. Obviously, **3a**$^-$ is much more nucleophilic than the classic nucleophilic carbenes. In the presence of tetrahydropyran, $Li(thp)_3^+$**6**$^-$ is obtained as a crystalline yellow solid which is extremely sensitive to air and moisture. It decomposes slowly even at temperatures < −10°C.

For the anion **6**$^-$ two structures may be expected, the acyl complex **6**$^-$ with an Fe−C single bond or the carbene complex **6′**$^-$. The X-ray diffraction study of $Li(thp)_3^+$**6**$^-$ reveals that in the solid state the complex has the acyl structure **6**$^-$ (see below). In case of an equilibrium between the two structures in solution, it should be possible to transform the complex into a Fischer carbene complex by methylation as preliminary experiments indicate.



The NMR data for **6**$^-$ reveal the expected pattern: In the ^{13}C-NMR spectrum a low-field shift to δ = 154.3 for the C2 atom is observed, compared with δ = 135.7 in **2a**. This can be explained by the electron-withdrawing effect of the acyl group. Its carbon atom shows a resonance at δ = 280.8 while for the four other carbonyl groups only one signal is observed at δ = 219.4. The ^{11}B-NMR shift of δ = −22.9 differs little from those for **2a** and **3a**$^-$. Again, the signal is broadened so that no coupling with the hydrogen atoms can be observed. Its IR spectrum shows four CO absorptions at $\tilde{\nu}$ = 2031, 1949, 1928, and 1911 cm^{-1}.

The reaction of **3a**$^-$ with chlorobis(dimethylamino)borane at −30°C leads to **7** in 72% yield. It was characterized by ^{1}H-, ^{13}C-, ^{11}B-NMR spectroscopy, and mass spectrometry. The ^{1}H-NMR spectrum shows two signals for the aminoboryl and the N-CH_3 groups at δ = 2.56 and 3.39, in an intensity ratio of 4:1. This indicates a free rotation of the dimethylamino substituents. The two C-CH_3 groups show resonances at δ = 2.10 and 2.11. In the ^{13}C-NMR spectrum two signals can be found in the aromatic region at δ = 123.4 and 131.0 for the atoms C4 and C5, while that of C2 is not observed. The four CH_3 substituents resonate at δ = 8.5, 10.0, 31.4, and 40.0. The ^{11}B-NMR shift of the BH_3 group is nearly unchanged with δ = −21.8, and the second boron signal is observed at δ = 27.8, a typical shift for a diamino(organo)borane.

Crystal Structures

To elucidate the structure of **3a**$^-$, an X-ray diffraction study was carried out (crystal data and structure refinement for **3a**$^-$, **3b**$^-$, and **6**$^-$ are shown in Table 1). A single crystal of $Li(thp)^+$**3a**$^-$ was grown from a tetrahydropyran solution at 4°C. Its structure (Figure 1) is built up by dimeric units of two carbene anions which are connected by the two lithium cations.

It was found that for imidazoles and imidazol-2-ylidenes the distances and angles at C2 show characteristic differences[1]. In imidazol-2-ylidenes the angle N1−C2−N3 (101.4−102.2°) is significantly smaller than that in imidazoles and imidazolium ions (107−109°)[20]. The C2−N distances are a little elongated and approximately equal (1.363−1.373 Å)[1], while in imidazoles an alternation of bond lengths is observed (e.g. 1.32 and 1.37 Å[21]). The C2−N1 and C2−N3 bond lengths (1.373 and 1.368 Å) in **3a**$^-$ are in good agreement with those of **A**[1], while the N1−C2−N3 angle of 104.0° is enlarged by 2.5°. This slight increase can be explained by the interaction of the carbene center with the lithium cation. The imidazole ring is almost planar with deviations from the best plane through the ring

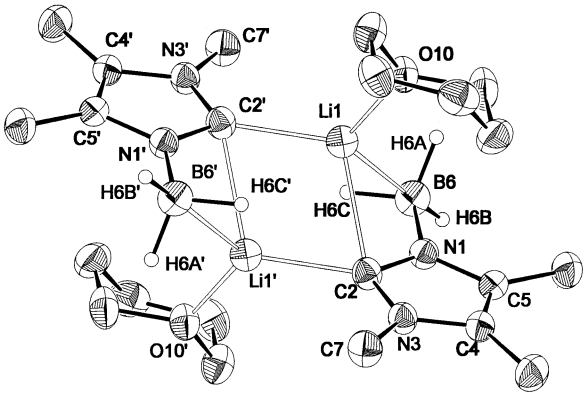
atoms being less than 0.006 Å. The B6−N1 distance of 1.572 Å is characteristic for a B−N single bond. For each of the lithium cations a short (Li−C2′ 2.169 Å) and a longer contact (Li1−C2 2.339 Å) with the carbene carbon atoms are observed. The coordination around the Li cation is completed by the thp molecule and a weak interaction with the BH_3 group.

Figure 1. Structure of Li(thp)$^+$**3a**$^-$ in the crystal[a]



[a] Selected bond lengths [Å] and angles [°]: N1−C2 1.373(3), C2−N3 1.368(3), N3−C4 1.393(3), C4−C5 1.355(3), C5−N1 1.398(3), B6−N1 1.572(3), Li1−B6 2.417(5), Li1−N1 2.489(5), Li1−C2 2.339(5), Li1−C2′ 2.169(5), Li1−H1 2.315(5), Li1−H3 2.214(5), B6−H1 1.156(32), B6−H3 1.185(30), B6−H2 1.102(30), N1−C2−N3 104.0(2), C2−N3−C4 112.2(2), N3−C4−C5 105.7(2), C4−C5−N1 107.9(2), C5−N1−C2 110.3(2).

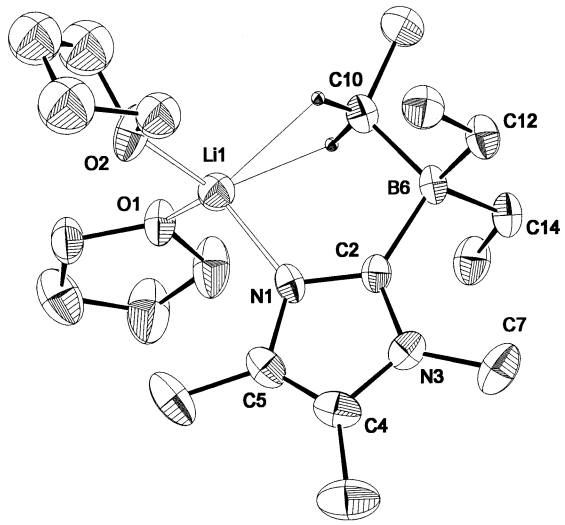
3a$^-$ is the first example of an isolable borane-substituted imidazol-2-ylidene, although carbene−borane adducts such as 2-borane−1,3-diethyl-4,5-dimethylimidazoline (**G**) are already known[18]. **F** has not attracted any attention as a carbene although the structural data[8] support the assumption that it may be regarded as a carbene−borane adduct (**F′**) as well.

In **F′** (R = mesityl)[8b] the C2−N bonds (1.356 and 1.357 Å) are nearly identical and match the distances found in **G**. The N−C−N angle of 106.4° has increased by 1.7° compared with that in **G**, but is still significantly smaller than in an imidazole or imidazolium ion. The C2−B distance in **F′** is 1.635 Å (**G**: 1.603 Å) which may be explained by the effect of the sterically demanding mesityl substituents. In contrast, **F** represents a description as an adduct in which the BH_2 group of a 2-boryl-substituted imidazole acts as Lewis acid and the imidazole nitrogen atom as Lewis base. This should lead to a characteristic imidazole structure with alternation of the C2−N bond lengths and a larger N−C−N angle. Another indication for the carbene character of **F′** (R = H) is its ^{13}C-NMR shift of δ = 161.0[8a] which is observed in the typical low-field area of carbene adducts and is comparable with the shift of δ = 166.6 for **G**[18].

A different structure is found for Li(thf)$_2^+$**3b**$^-$. A single crystal was grown from a hexane solution at 4°C and the structure is shown in Figure 2. The crystal-structure determination reveals the occurrence of a migration of the BEt_3 group from the nitrogen to the carbon atom, leading to a 1-methyl-2-borane-substituted imidazole anion.

The C2−N1 and C2−N3 bond lengths of 1.337 Å and 1.373 Å show the typical alternation of a 1-substituted imi-

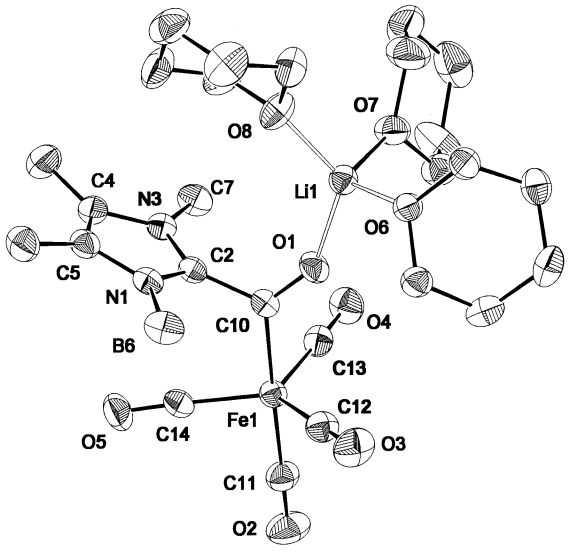
Figure 2. Structure of $Li(thf)_2^+\mathbf{3b}^-$ in the crystal[a]



[a] Selected bond lenghts [Å] and angles [°]: N1−C2 1.337(4), C2−N3 1.373(4), N3−C4 1.389(5), C4−C5 1.346(5), C5−N1 1.388(5), N2−C7 1.464(5), B6−C2 1.645(5), B6−C10 1.655(5), B6−C12 1.646(5), B6−C14 1.639(5), Li1−N1 1.932(7), Li1−C10 2.511(7), N1−C2−N3 107.4(3), N1−C5−C4 109.4(3), C2−N1−N3 108.2(3), N3−C4−C5 105.7(3), C2−N3−C4 109.3(3).

dazole[21] and the N1−C2−N3 angle of 107.4° has increased considerably when compared to that of **A**[1] and $Li(thp)^+\mathbf{3a}^-$. The N1 atom interacts strongly with the lithium cation (Li1−N1 1.932 Å), whose coordination is completed by the two thf molecules and weak agostic interactions with the hydrogen atoms of the methylene group at C10.

Figure 3. Structure of $Li(thp)_3^+\mathbf{6}^-$ in the crystal[a]



[a] Selected bond lengths [Å] and angles [°]: N1−C2 1.326(3), C2−N3 1.347(3), N3−C4 1.395(3), C4−C5 1.351(4), C5−N1 1.397(4), N1−B6 1.596(4), N3−C7 1.465(4), C2−C10 1.512(4), Fe1−C10 1.966(3), C10−O1 1.237(3), Li1−O1 1.905(5), Fe1−C11 1.800(3), Fe1−C12 1.792(3), Fe1−C13 1.781(3), Fe1−C14 1.787(3), N1−C2−N3 109.4(2), C2−N1−C5 107.7(2), C2−N3−C4 108.3(2), N3−C4−C5 106.4(2), N1−C5−C4 108.2(2), C2−C10−O1 114.6(2), C2−C10−Fe1 118.7(2), Fe1−C10−O1 126.6(2), C10−Fe1−C11 178.3(1).

The bonding in $Li(thp)_3^+\mathbf{6}^-$ is of significant interest in order to distinguish whether it is an acyl or a carbene compound. The answer was found by carrying out an X-ray diffraction study. Single crystals were grown from a thp solution at 4°C. The X-ray structure of $\mathbf{6}^-$ shows the complex anion with $Li(thp)_3^+$ as counter ion that is attached to the acyl oxygen atom (Figure 3). There is no doubt that $\mathbf{6}^-$ must be regarded as an acyl complex. It exhibits a trigonal-bipyramidal coordination of the iron atom by four CO ligands and the acyl group, derived from the addition of $\mathbf{3a}^-$ to one of the axial carbon monoxide in $Fe(CO)_5$. The C10−Fe1−C11 axis is nearly linear with an angle of 178.7°. The $Li(thp)_3^+$ ion is coordinated by the oxygen atom of the acyl group. The length of the Fe1−C10 bond (1.966 Å) is in agreement with the formulation as an acyl complex, for which Fe−C distances between 1.92 and 1.99 Å[22] are typically observed, compared with 1.84−1.87 Å for carbene complexes[23]. The C2−C10 (1.512 Å) and C10−O1 (1.237 Å) distances also fit with the data found for acyl complexes[22]. Obviously the acyl ligand has nearly no influence on the *trans*-CO group, with the Fe1−C11 bond length of 1.800 Å being comparable to those for the equatorial carbonyl groups (1.781−1.792 Å). The distances and angles of the imidazole ring indicate the loss of carbene character. The alternating bond lengths N1−C2 (1.326 Å) and C2−N3 (1.347 Å) as well as the large N1−C2−N3 angle of 109.4° are typical for an imidazole.

Experimental Section

General: Reactions were carried out under dry argon, using standard Schlenk techniques. Solvents were dried, distilled, and saturated with nitrogen. Glassware was dried with a heat-gun in high vacuum. − ^{1}H-, ^{13}C-, ^{11}B-NMR: Bruker AC 200 spectrometer, NMR references are $(CH_3)_4Si$ and $BF_3 \cdot Et_2O$. − IR spectra were recorded with a Bruker IFS 28 Fourier transformation spectrometer with CaF_2 cells. − Mass spectra were obtained with a Finnigan MAT 8200 plus spectrometer using the EI technique. − Melting points (uncorrected) were obtained with a Büchi apparatus, using a capillary which was filled under argon and sealed. − 1,4,5-trimethylimidazole (**1**)[24a] and $[Mn(CO)_5Br]$[24b] were prepared according to literature procedures.

3-Borane−1,4,5-trimethylimidazole (**2a**): To a solution of 790 mg (7.2 mmol) of **1** in 20 ml of thf, 7.2 ml of $BH_3 \cdot$ thf (1.0 M in thf) was added dropwise at 0°C, after which the mixture was allowed to warm to room temp. and stirred for 24 h. By that time a white solid had precipitated. The product was dissolved by heating and then allowed to crystallize at −30°C. Yield: 760 mg (85%) colorless, air-stable needles, m.p.: 160°C. − ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 2.10 (s, 3 H, C-CH_3), 2.14 (s, 3 H, C-CH_3), 3.53 (s, 3 H, N-CH_3), 7.62 (s, 1 H, N=CH-N). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 9.2 (C-*C*H_3), 10.6 (C-*C*H_3), 33.2 (N-CH_3), 125.3 (C=*C*-N), 132.2 (C=*C*-N), 135.7 (N=CH-N). − ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = −20.9 (q, $^1J_{B\text{-}H}$ = 94 Hz). − $C_6H_{13}BN_2$ (124.0): calcd. C 58.12, H 10.56, N 22.59; found C 57.72, H 10.40, N 22.43.

3-(Triethylborane)−1,4,5-trimethylimidazole (**2b**): To a solution of 1.52 g (13.8 mmol) of **1** in 20 ml of toluene, 2.2 ml of BEt_3 was added dropwise at 0°C. The mixture was allowed to warm to room temp. and stirred for 24 h. The solvent was evaporated in vacuo and the colorless oil was allowed to crystallize at −30°C, and then washed with pentane and dried. Yield: 2.84 g (99%); colorless crys-

tals, m.p.: 65°C. – ^{1}HNMR (200.1 MHz, $CDCl_3$): δ = 0.37 (t, 9 H, CH_2-CH_3), 0.57 (q, 6 H, CH_2-CH_3), 2.11 (s, 3 H, C-CH_3), 2.20 (s, 3 H, C-CH_3), 3.54 (s, 3 H, N-CH_3), 7.45 (s, 1 H, N=CH-N). – ^{13}C-NMR (50.3 MHz, $CDCl_3$): δ = 8.0 (C-*C*H_3), 9.3 (CH_2-*C*H_3), 11.0 (C-*C*H_3), 14 (br., *C*H_2-CH_3), 32.2 (N-CH_3), 124.5 (C=C-N), 130.8 (C=C-N), 134.2 (N=CH-N). – ^{11}B-NMR (64.2 MHz, $CDCl_3$): δ = −1.5 ($\Delta\nu_{1/2}$ = 290 Hz).

Lithium 3-Borane−1,4,5-trimethylimidazol-2-ylidene [Li(thp)$^+$-**3a**$^-$]: To a suspension of 860 mg (6.9 mmol) of **2a** in 25 ml of thf 3.2 ml of *n*-butyllithium (2.5 N in hexane) was added dropwise at −40°C. The mixture was allowed to warm to room temp. and stirred for 24 h. The solvent was evaporated in vacuo and the resulting solid was recrystallized from thf/hexane at −30°C. Yield: 1.14 g (82%) colorless crystals, m.p.: 210−220°C (decomp.). – ^{1}H NMR (200.1 MHz, C_6D_6): δ = 1.38 (m, 12 H, thf), 1.74 (s, 3 H, C-CH_3), 2.34 (s, 3 H, C-CH_3), 3.43 (s, 3 H, N-CH_3), 3.57 (m, 12 H, thf). – ^{13}C NMR (50.3 MHz, C_6D_6): δ = 8.3 (C-*C*H_3), 10.4 (C-*C*H_3), 25.1 (thf), 33.8 (N-CH_3), 67.6 (thf), 121.8 (C=C-N), 128.7 (C=C-N), 191.3 (N=C-N). – ^{11}B NMR (64.2 MHz, C_6D_6): δ = −21.1 ($\Delta\nu_{1/2}$ = 290 Hz).

Lithium Triethyl(1,4,5-trimethylimidazolyl)borate [Li(thf)$_2^+$**3b**$^-$]: To a suspension of 950 mg (4.6 mmol) of **2b** in 20 ml of thf 2.0 ml of *n*-butyllithium (2.5 N in hexane) were added dropwise at −78°C. The mixture was allowed to warm to room temp. and stirred for 24 h. The solvent was evaporated in vacuo and the resulting white solid was recrystallized from thf/hexane. Yield: 1.07 g (77%) colorless crystals, m.p.: 150−160°C (decomp.). – ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 0.29 (q, 6 H, CH_2-CH_3), 0.59 (t, 9 H, CH_2-CH_3), 1.83 (m, 8 H, thf), 2.06 (s, 3 H, C-CH_3), 2.10 (s, 3 H, C-CH_3), 3.58 (s, 3 H, N-CH_3), 3.72 (m, 8 H, thf). – ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 8.3 (C-*C*H_3), 9.4 (C-*C*H_3), 10.7 (CH_2-*C*H_3), 14.0 (br., *C*H_2-CH_3), 25.6 (thf), 32.0 (N-CH_3), 67.9 (thf), 119.9 (C=C-N), 123.8 (C=C-N), C2 not observed. – ^{11}B NMR (64.2 MHz, C_6D_6): δ = −14.6.

2-(Triethylborane)−1,3,4,5-tetramethylimidazoline (**4**): 810 mg (3.9 mmol) of **2b** was dissolved in 15 ml of thf and 1.7 ml of *n*-butyllithium (2.5 N in hexane) was added dropwise at −78°C. The mixture was allowed to warm to room temp. and stirred for 1 h. Then 0.5 ml of iodomethane was added at −30°C, the solution was warmed to room temp. and stirred for another hour. The solvent was evaporated in vacuo, the resulting white solid was dissolved in hexane and filtered. After cooling to −30°C, a white precipitate had formed which was filtered and dried. Yield: 600 mg (69%) white powder. – ^{1}H NMR (200.1 MHz, C_6D_6): δ = 1.01 (q, 6 H, CH_2-CH_3), 1.18 (t, 9 H, CH_2-CH_3), 1.29 (s, 6 H, C-CH_3), 3.26 (s, 6 H, N-CH_3). – ^{13}C NMR (50.3 MHz, C_6D_6): δ = 8.3 (C-*C*H_3), 12.1 (CH_2-*C*H_3), 15.0 (br., CH_2-CH_3), 32.9 (N-CH_3), 123.6 (C=C-N), C2 signal not observed. – ^{11}B NMR (64.2 MHz, C_6D_6): δ = −12.6. – EI-MS; *m/z* (%): 193 (45) [$M^+ - C_2H_5$], 137 (100), 124 (44) [$M^+ - BEt_3$].

(3-Borane−1,4,5-trimethylimidazol-2-ylidene)pentacarbonylmanganese (**5**): To a suspension of 240 mg (1.9 mmol) of **2a** in 20 ml of thp was added 0.85 ml of *n*-butyllithium (2.5 N in hexane) dropwise at −40°C. The reaction mixture was allowed to warm to room temp. and stirred for 1 h. Then 535 mg (1.9 mmol) of [$Mn(CO)_5Br$] were added at −40°C and the solution was again warmed to room temp. and stirred for another hour. While warming, the solid dissolved, the solution became orange-colored and at room temp. deep red. The solvent was evaporated in vacuo, the residue dissolved in toluene and separated by column chromatography (SiO_2/toluene). Yield: 200 mg (33%) yellow powder. – ^{1}H NMR (200.1 MHz, [D_8]thf): δ = 2.22 (s, 3 H, C-CH_3), 2.24 (s, 3 H, C-CH_3), 3.81 (s, 3 H, N-CH_3). – ^{13}C NMR (50.3 MHz, [D_8]thf): δ = 8.3 (C-*C*H_3), 9.6 (C-*C*H_3), 32.3 (N-CH_3), 129.0 (C=C-N), 130.9 (C=C-N), 146.9 (N-C-N), 214.6 (CO), 256.1 (CO). – ^{11}B NMR (64.2 MHz, C_6D_6): δ = −22.3. – IR (hexane): $\tilde{\nu}$(CO) [cm^{-1}] = 2081 (w), 2004 (s), 1992 (vs), 1974 (s). – EI-MS; *m/z* (%): 318 (22) $[M]^+$, 290 (17) $[M - CO]^+$, 262 (20) $[M - 2\ CO]^+$, 234 (48) $[M - 3\ CO]^+$, 206 (29) $[M - 4\ CO]^+$, 178 (100) $[M - 5\ CO]^+$.

Lithium (3-Borane−1,4,5-trimethylimidazol-2-ylcarbonyl)tetracarbonyliron [Li(thp)$_3^+$**6**$^-$]: To a suspension of 500 mg (4.0 mmol) of **2a** in 20 ml of thp was added 1.8 ml of *n*-butyllithium (2.5 N in hexane) dropwise at −40°C. The mixture was allowed to warm to room temp. and stirred for 1 h. Then 0.55 ml of $Fe(CO)_5$ was added at −40°C. At −30°C a yellow solid was formed which dissolved at 5°C. The orange-colored solution was stirred for 1 h at room temp. and afterwards half of the solvent was removed in vacuo. Crystallization at −30°C yielded 1.29 g (78%) yellow needles, m.p.: 120−127°C (decomp.). – ^{1}H NMR (200.1 MHz, C_6D_6): δ = 1.29 (m, 24 H, thp), 1.44 (s, 3 H, C-CH_3), 2.01 (s, 3 H, C-CH_3), 3.42 (s, 3 H, N-CH_3), 3.52 (m, 16 H, thp). – ^{13}C NMR (50.3 MHz, [D_8]thf): δ = 8.2 (C-*C*H_3), 10.0 (C-*C*H_3), 24.7 (thp), 27.8 (thp), 31.1 (N-CH_3), 69.3 (thp), 121.1 (C=C-N), 128.1 (C=C-N), 154.3 (N-C-N), 219.4 (CO), 280.8 (CO). – ^{11}B NMR (64.2 MHz, C_6D_6): δ = −22.9 (br.). – IR (thp): $\tilde{\nu}$(CO) [cm^{-1}] = 2031 (s), 1949 (s), 1928 (vs), 1911 (vs).

3-Borane−2-[bis(dimethylamino)boryl]-1,4,5-trimethylimidazoline (**7**): To a suspension of 500 mg (4.0 mmol) of **2a** in 20 ml of thf was added 1.6 ml of *n*-butyllithium (2.5 N in hexane) dropwise at −40°C with dissolving of the solid. The mixture was allowed to warm to room temp. and stirred for 1 h. Then 540 mg (4.0 mmol) of chlorobis(dimethylamino)borane was added at −30°C, the solution warmed to room temp. and stirred for another hour. The solvent was removed in vacuo and the white precipitate dissolved in toluene. LiCl was separated by filtration and the product was allowed to crystallize from a toluene/hexane solution. Yield: 640 mg (72%) colorless needles, m.p.: 74°C. – ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 2.10 (s, 3 H, C-CH_3), 2.17 (s, 3 H, C-CH_3), 2.56 (s, 12 H, N-CH_3), 3.39 (s, 3 H, N-CH_3). – ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 8.5 (C-*C*H_3), 10.0 (C-*C*H_3), 31.4 (N-CH_3), 40.0 (N-CH_3), 123.4 (C=C-N), 131.0 (C=C-N), C2 signal not observed. – ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = −21.9 (br., BH_3), 27.8 [br., $B(NMe_2)_2$]. – EI-MS; *m/z* (%): 221 (13) [$M^+ - H$], 207 (7) [$M^+ - CH_3$], 123 (100) [$M^+ - B(NMe_2)_2$].

Crystal-Structure Determinations of Li(thp)$^+$**3a**$^-$, Li(thf)$_2^+$**3b**$^-$, *and* Li(thp)$_3^+$**6**$^-$: Crystal data and details of the structure determinations are listed in Table 1. Unique sets of intensity data were collected at −70°C with a four-circle diffractometer (Mo-K_α radiation λ = 0.7107 Å, graphite monochromator, ω-scan). Empirical absorption corrections (ψ-scans) were applied. The structures were solved by direct methods [SHELXS86][25] and refined by least-squares methods based on F^2 with all measured reflections [SHELXL97][26]. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms in **3b**$^-$ were included in calculated positions or as part of rigid groups (CH_3), in **3a**$^-$ and **6**$^-$ hydrogen atoms were located in difference Fourier maps and refined. The thf molecules in **3b**$^-$ and one of the thp molecules in **6**$^-$ are disordered.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallograhpic Data Center as supplementary publication no. CCDC-101057. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; fax: int. code + 44(0)1223/336-001; e-mail: deposit@ccdc.cam.ac.uk

Keywords: Neutron diffraction / Donor-acceptor complex / Bridging hydride ligand / Rhenium / Chromium

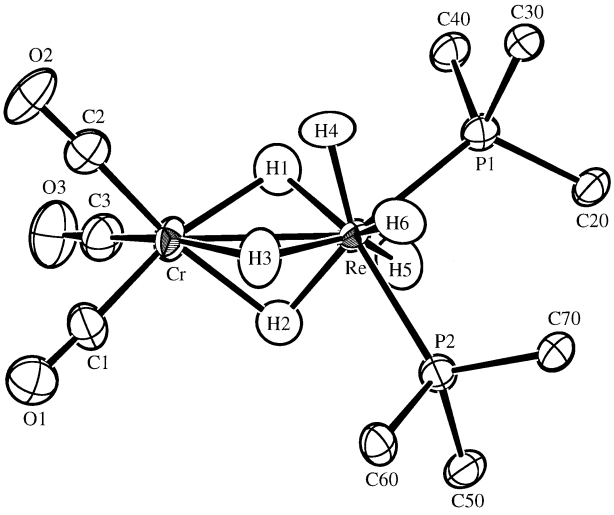
A neutron diffraction analysis was carried out at 120 K on a single crystal of $[K(18\text{-crown-6})][(PPh_3)_2ReH_6Cr(CO)_3]\cdot THF$ in order to locate the hydride ligands. Three of the hydrides are bound terminally to the Re atom while the other three bridge the Re–Cr bond; the bridging hydrides are closer to the Re atom. This compound can be thought of as a donor–acceptor complex, with $[(PPh_3)_2ReH_6]^-$ acting as the donor to the $Cr(CO)_3$ fragment. Average distances and angles: Re–Cr = 2.58(1), Re–H(br) = 1.75(1), Cr–H(br) = 1.92(2), Re–H(t) = 1.69(1) Å; Re–H–Cr = 89.1(7)°. Final agreement factors: $R(F)$ = 6.4% for 3443 reflections with $I > 2\sigma(I)$, and $R(F)$ = 8.3% for all data (4195 reflections).

The concept of a transition metal hydride complex functioning as a ligand has been attracting an increasing amount of attention.[1][2][3][4][5][6][7] In recent years, several cases have been documented in which a metal hydride acts as a donor to a second (otherwise electron-deficient) metal atom. The donor-acceptor interaction in the resulting compound takes place through the bridging hydride ligands, much as in a borohydride complex.[8] In this communication we report the neutron structure determination of one such compound, the $[(PPh_3)_2ReH_6Cr(CO)_3]^-$ anion, and provide the first accurate characterization of a Re−H−Cr bridging system.

$[K(18\text{-crown-6})][(PPh_3)_2ReH_6Cr(CO)_3]$ is made by reaction of $[K(18\text{-crown-6})]$ $[(PPh_3)_2ReH_6]$ with $(CH_3CN)_3Cr(CO)_3$ in THF.[1] Crystals were obtained by the addition of diethyl ether to a THF solution of the title compound. Neutron diffraction data were collected at the Institut Laue-Langevin at 120 K on a sample with volume 4 mm^3, and the structure was refined to a final agreement factor of $R(F)$ = 6.4% (Experimental Section).

The structure of the $[(PPh_3)_2ReH_6Cr(CO)_3]^-$ unit is shown in Figure 1, and selected distances and angles listed in Table 1. Three of the H ligands bridge the Re−Cr bond and three are terminal on Re, as predicted.[1] The bridging H atoms are closer to the Re atom [average Re−H = 1.75(1) Å, average Cr−H = 1.92(2) Å], despite the smaller size[9] of chromium. This suggests that the complex as a whole is best viewed as a donor-acceptor complex in which an 18-electron $[(PPh_3)_2ReH_6]^-$ moiety serves as a 6−electron donor, through the three bridging H atoms, to a 12-electron $Cr(CO)_3$ fragment. The average Re−H−Cr angle is 89.1(7)°, comparable to other compounds having M−(μ−H)$_3$−M bridges.[10] The Re−Cr bond length, 2.58(1) Å, is much shorter than the single-bonded Re−Cr distance of 3.05 Å,[11] suggesting some level of multiple bonding. Indeed, $[(PPh_3)_2ReH_6Cr(CO)_3]^-$ as a whole is isoelectronic with $[Re_2H_9(triphos)]^-$, a compound considered to have a formal triple bond.[3]

Figure 1. A plot of the core of the $[(PPh_3)_2ReH_6Cr(CO)_3]^-$ anion, with all but the *ipso* carbons of the phenyl groups removed for clarity



As anticipated earlier,[1] the eight ligands around the Re atom (not counting the Re−Cr bond) define the familiar dodecahedral arrangement[12] of two interpenetrating trapezoids. Figure 2 shows this clearly: atoms H1, H4, H6, and P2 are virtually co-planar (within ±0.01 Å), and define one trapezoid, which is essentially perpendicular to the other

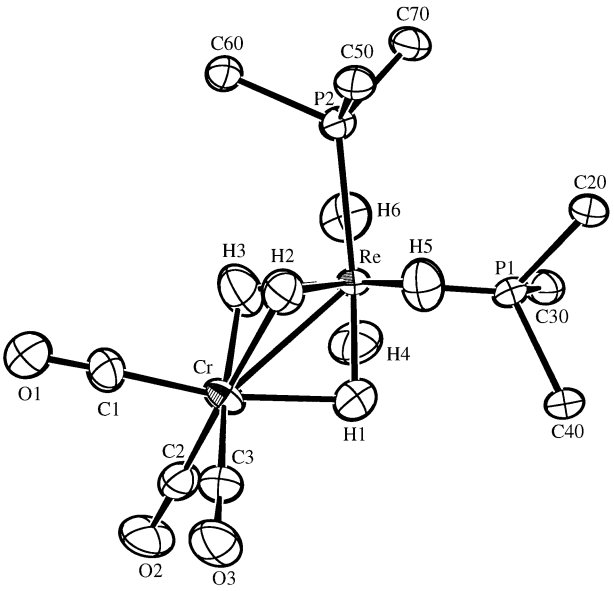
trapezoid, defined by atoms H3, H2, H5, and P1 (co-planar within ±0.05 Å). The Re atom is slightly out of plane of both trapezoids. Because of the unsymmetrical positioning of the Re−Cr bond relative to these two interpenetrating trapezoids (one trapezoid contains two bridging H ligands while the other one has only one bridging hydride), the Cr−Re−P angles are unequal [Cr−Re−P1 = 136.1(4), Cr−Re−P2 = 121.1(4)°]. The closest H···H non-bonding contacts are those along the "sides" of the trapezoids (Figure 2): H4···H6 = 1.85, H1···H4 = 1.96, H2···H3 = 2.02, H2···H5 = 2.07 Å.

The average terminal Re−H distance in the title compound [1.69(1) Å] is, as expected,[3][13] shorter than the average bridging Re−H distance [1.75(1) Å]. The former is comparable to terminal Re−H distances found from other neutron structure determinations (range 1.66 to 1.69 Å),[10] but the latter is unusually short (standard Re−H bridging bond lengths range from 1.81 to 1.88 Å[10]). This suggests that the Re−H bridge in $[(PPh_3)_2ReH_6Cr(CO)_3]^-$ is stronger than a normal bridge (i.e., is somewhat more "terminal" in character).

The Cr atom has the expected distorted octahedral geometry, with C−Cr−H (*trans*) angles that have a mean value of 168.1(8)°. The average Cr−H bond length [1.92(2) Å] is much longer than normal bridging Cr−H distances

Figure 2. An alternative view of the $[(PPh_3)_2ReH_6Cr(CO)_3]^-$ core, plotted in such a way as to show the coordination around the Re atom, which consists of two intepenetrating trapezoids. The coplanar atoms H3, H2, H5, and P1 define one trapezoid, which is approximately perpendicular (87°) to the other trapezoid, defined by the coplanar atoms H1, H4, H6, and P2. Because of this arrangement, the three H−Re−H angles are decidedly unequal to each other, as are the three H−Cr−H angles



[range: 1.72−1.73 Å],[14] suggesting a weaker-than-usual chromium-hydrogen interaction.

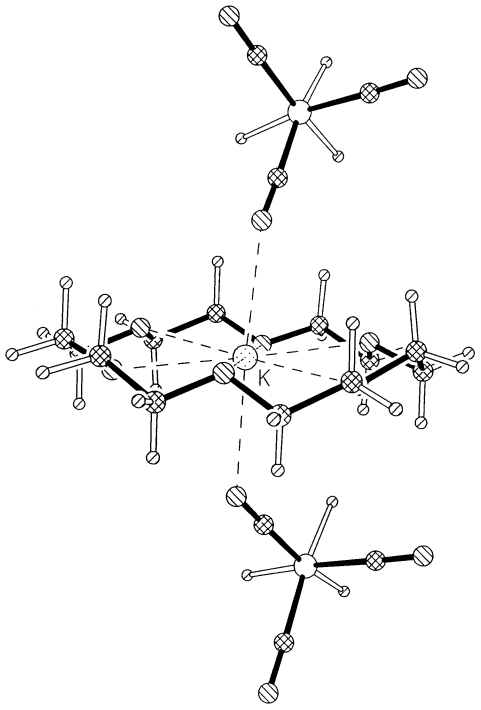
Curiously, the H−Cr−H angles show an unequal distribution [63.6(6), 68.2(6), 80.9(7)°] as do the H−Re−H angles [70.5(6), 76.9(6), 90.3(7)°], presumably because of the steric requirement for maintaining a dodecahedral arrangement of ligands around rhenium.

The K^+ coordination sphere is quite interesting, being made up of the 18-crown-6 ligand and two CO oxygens from separate $Cr(CO)_3$ fragments. This approximately D_{6h}, 8-fold coordination is shown in Figure 3. The THF solvate molecule, which does not bind to the potassium ion and has no other strong interactions, is disordered and was refined as a rigid body in two orientations.

The present structure determination represents the first time that a Re−H−Cr bridging system has been analyzed by neutron diffraction. An earlier X-ray analysis[15] on the single-hydride-bridged complex $(OC)_5Re(H)Cr(CO)_5$ revealed a Re−Cr distance of 3.435(1) Å, but did not locate the bridging H atom. It was originally proposed that the Re−H−Cr bridge in that compound was linear,[15] but that suggestion was made before it became generally accepted that 3-center/2-electron M−H−M bridge bonds are inherently bent.[7][14][16]

Only a few metal hydride complexes of the donor-acceptor type have been accurately analyzed by neutron diffraction. Earlier examples include $[Re_2H_9(triphos)]^-$ {in which $[ReH_9]^{2-}$ is formally a ligand to a $[Re(triphos)]^+$ moiety},[3] $[Pt_2H_3(dppe)_2]^+$ {a complex between $PtH_2(dppe)$ and $[PtH(dppe)]^+$},[4] $[PtIrH_4(PEt_3)_4]^+$ {a complex between $PtH_2(PEt_3)_2$ and $[IrH_2(PEt_3)_2]^+$},[5] and

Figure 3. The coordination around the K^+ ion, which is surrounded by six oxygen atoms from the 18-crown-6 ligand and two carbonyl oxygen atoms in an approximately D_{6h} arrangement. The two axial ligands are the O2 and O3 atoms of the $H_3Cr(CO)_3$ portions of two neighboring anions



$[(PEt_3)_2(C_6Cl_5)PtHAg(H_2O)]^+$, in which a Pt−H bond is a donor to a Ag^+ ion.[6] Also worthy of mention are two complexes in which $[Na(18\text{-crown-}6)]^+$ and $[K(18\text{-crown-}6)]^+$ act as acceptors from a $[WH_5(PMe_3)_3]^-$ fragment.[17] In most cases {except $[Re_2H_9(triphos)]^-$},[3] the hydride ligands are unsymmetrically bridging in such a way as to indicate that they are held much more tightly to the donor atom than the acceptor atom. The structure of the title compound is consistent with this general trend: the short/long pattern of distances in the Re−H−Cr linkage is certainly suggestive of a higher bond order for the Re−H portion than the H−Cr portion of the bridge.

This research was supported by the *National Science Foundation* and the *American Chemical Society* (Petroleum Research Fund).

Experimental Section

The neutron diffraction data set was collected at the Institut Laue-Langevin, Grenoble, France, on the thermal-beam instrument D19, which is equipped with a 4° × 64° position-sensitive detector.[18] A platelike single crystal of dimensions 1.2 × 1.6 × 2.0 mm, volume 4 mm^3, was sealed in epoxy on an Al pin and placed in a Displex cryorefrigerator.[19] It was then indexed and cooled at 2 degrees per minute while the strong (0, 0, 4) reflection was being monitored. Below 117 K the mosaic spread increased and at 95 K the peak was much broader and weaker, so the temperature was raised to 120 K where the mosaic spread was acceptable and the peak intensity restored. Data were initially collected at a neutron wavelength of 1.3139 Å, but this was changed to 1.5394 Å to increase the intensity of the reflections. Bragg intensities were integrated in three dimensions using the ILL program RETREAT.[20] The two sets of intensities were then scaled and merged, and corrected for attenuation by the cylindrical heat shields, and for absorption effects (μ = 2.31 cm^{-1} at 1.3139 Å; 2.55 cm^{-1} at 1.5394 Å) using the program D19ABS, based on the ILL version of the CCSL system.[21] Refinement was begun using the positions of the non-hydrogen atoms obtained from the x-ray structure determination;[1] the positions of the organic hydrogen atoms were calculated and subjected to several cycles of least-squares refinement. The hydride ligands were readily found in a difference Fourier map. All atoms except those of the disordered THF molecule were refined anisotropically[22a] to yield final agreement factors of $R(F) = 6.4\%$ for 3443 reflections with $I > 2\sigma(I)$, and $R(F) = 8.3\%$ for all data (4195 reflections). The neutron scattering lengths used in the refinement were those tabulated by Sears.[22b]

Supplementary Material: A summary of the results of the neutron diffraction study, with final atomic positions and a complete listing of distances and angles in the title compound, have been deposited with the Cambridge Crystallographic Data Centre as Supplementary Publication No. CCDC−100889. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (e-mail: deposit@ccdc.cam.ac.uk; fax: +44(0)1223/336-033).

[9] The Re and Cr covalent radii can be estimated as 1.371 and 1.249 A, respectively, using half of the Re−Re distance in rhenium metal and half of the Cr−Cr distance in chromium metal: see *Interatomic Distances Supplement*, Chemical Society, London, **1965**. From these values one can estimate that Cr is about 0.12 A smaller than Re. Essentially the same difference (0.11 A) can be obtained by comparing average Re−H (1.837 A) and Cr−H (1.728 A) bridging distances (see ref.[10]).

Keywords: Borazines / Silyl borazines / Oligomers / Pyrolysis / Ceramics

The reactions of $LiSi(SiMe_3)_3$ with $Cl(Me)_2B_3N_3(Me)_3$, $Cl_2(Me)B_3N_3(Me)_3$, $(ClBNMe)_3$, and $(ClBNH)_3$ result in the formation of molecular species $(Me_3Si)_3Si(Me)_2B_3N_3(Me)_3$, $[(Me_3Si)_3Si]_2(Me)B_3N_3(Me)_3$, $[(Me_3Si)_3SiBNMe]_3$, and $[(Me_3Si)_3SiBNH]_3$. The new compounds have been characterized by spectroscopic techniques, and a single-crystal X-ray diffraction analysis for $[(Me_3Si)_3SiBNMe]_3$ has been completed. The monomer $(Me_3Si)_3Si(Cl)_2B_3N_3H_3$ was also prepared and combined with $(Me_3Si)_2NH$ in hexane to form an organic solvent soluble oligomer. Pyrolysis of this oligomer provides composites containing BN and an $Si_XN_YC_Z$ phase that suppresses the crystallization of BN.

After about a decade of intense study, it has been demonstrated that inorganic and organometallic polymers may be used to produce a number of ceramic powders including SiC, Si_3N_4, BN, B_4C, and AlN[1][2][3], albeit at greater expense than traditional metallurgical routes. Despite the economic drawback, many polymer precursors offer the advantage that they can be processed into useful physical forms (e.g., fibers, coatings, binders, and porous bodies) that cannot be achieved by classical powder-processing approaches. One additional area where polymer precursors are showing potentially useful benefits and applications is in the fabrication of composite materials[2][3][4][5]. Polymer-derived syntheses of ceramic-ceramic composites have most often been accomplished by three chemical approaches: blending and pyrolysis of a liquid or soluble polymeric precursor with an elemental filler, blending and pyrolysis of two or more processible polymeric precursors, and pyrolysis of a "single-source" preceramic polymer[4][5]. Successes have been demonstrated with each approach. However, until very recently the least attention and fewest successes have been realized with the "single-source" approach, primarily due to the lack of appropriate monomers and polymers. This situation has begun to change. In particular, several groups have noted that addition of boron to silicon-based ceramics can produce enhanced stability in the resulting composite, as well as improve property performances[6]. These observations, in turn, have resulted in new efforts to obtain processible single-source preceramic polymers that convert readily to so-called SiNCB ceramic composites[7][8][9][10][11][12][139][14][15][16][17][18][19][20][21]. In this report, the syntheses of model molecular silyl-substituted borazines and a silylborazine oligomer are described along with our initial efforts to define the pyrolysis chemistry of the polymer that results in formation of SiNCB composites.

Results and Discussion

Relatively few compounds with boron−silicon bonds have been prepared, and the interesting development of this chemistry has been briefly summarized by Berry and coworkers[22]. Pertinent to our work, two reports of the formation of *B*-silylborazines, $(Ph_3SiBNMe)_3$ and $(Ph_3SiBNPh)_3$, formed from salt-elimination reactions, have appeared[23][24]. Similarly, salt-elimination reactions involving the *B*-chloroborazines, $Cl(Me)_2B_3N_3(Me)_3$, $Cl_2(Me)B_3N_3(Me)_3$, $(ClBNMe)_3$, and $(ClBNH)_3$ with $LiSi(SiMe_3)_3$ produce *B*-silylborazines $[(Me_3Si)_3Si](Me)_2B_3N_3(Me)_3$ (**2**), $[(Me_3Si)_3Si](Me)B_3N_3(Me)_3$ (**3**), $[(Me_3Si)_3SiBNMe]_3$ (**4**), and $[(Me_3Si)_3SiBNH]_3$ (**5**) in high yields as summarized in Eq. 1. Compound **2** is obtained as a white solid, which when recrystallized from benzene gives blocky, colorless crystals. The remaining compounds are isolated as waxy or gummy solids. Each compound is soluble in Et_2O, THF, benzene, and pentane and is moisture-sensitive in both the solid state and in solutions.

Compounds **2**−**4** give satisfactory CHN analyses; however, **5** retains small amounts of reactants and adequate analyses are not obtained. All of the compounds display a moderately intense parent ion peak in the EI-mass spectrum that provides confirmation of the molecular composition. The $^{11}B\{^1H\}$-NMR spectra for **2** and **3** show two reso-

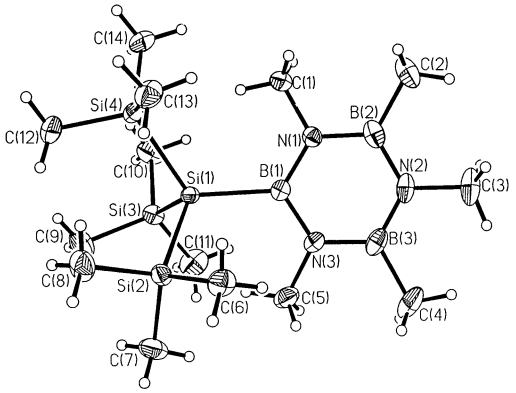
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0606−0855 $ 17.50+.50/0

nances; one resonance, in the range $\delta = 36.3-37.1$, is assigned to the BMe group[25] and the second resonance, in the range $\delta = 42.2-42.8$, is assigned to the $BSi(SiMe_3)_3$ group. Compounds **4** and **5** produce a single resonance at $\delta = 42.2$ and 38, respectively which are assigned to the $BSi(SiMe_3)_3$ group. The ^1H- and $^{13}C\{^1H\}$-NMR spectra are also consistent with the proposed structures showing resonances assigned to BMe, $BSi(SiMe_3)$, and NMe groups.

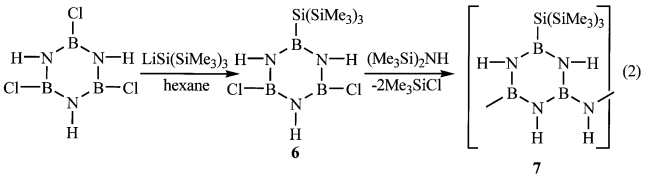
The molecular structure of compound **2** was determined by single-crystal X-ray diffraction analysis. A view of the molecule is shown in Figure 1 and selected bond lengths and angles are given in Table 1. As expected, the B_3N_3 ring is planar and the $(Me_3Si)_3Si$ group occupies an *exo* position bonded to B(1). The average B−N distance, 1.434 Å [range 1.453(6)−1.407(8) Å] is identical to the average values in several borazine compounds: $(HNBH)_3$[26], 1.436 Å; $(Me_2NBNH)_3$[27], 1.433 Å; and $(Me_3N_3Me_2B_3)_2NH$[28], 1.438 Å. Four of the B−N distances are within one standard deviation of the average value, while the two distances associated with B(3) vary from the average by slightly more than 3σ. Such a variation is not typical for borazine rings although a similar behavior was found in $[Me_3N_3Me_2B_3]_2NMe$[28] [B−N distance range 1.463(6) Å−1.414(7) Å]. The average $B-CH_3$ and $N-CH_3$ distances, 1.593 and 1.475 Å, are comparable with the values in $(Me_3N_3Me_2B_3)_2NH$, 1.580 and 1.476 Å, and in $(Me_3N_3Me_2B_3)_2NMe$, 1.586 and 1.479 Å[28]. The terminal B−Si bond length, 2.097(4) Å, is somewhat unique. We are unaware of structural data for closely comparable compounds containing an *exo*, two-center, two-electron B−Si bond with the boron atom having formal sp^2 hybridization. The observed distance is longer than the sum of covalent radii: 0.88 Å (B) + 1.17 Å (Si) = 2.05 Å[29], and not surprisingly it is significantly longer than the distance in tBuN≡B−Si$(SiMe_3)_3$, 1.976(4) Å[30], which contains a formally sp-hybridized B atom (N≡B−Si, 176.6°). On the other hand, the B−Si distances in $Cy_3P \cdot B(H)_2SiMe_3$, 2.007(4) Å[31] and in $Cp_2Ta[\eta^2\text{-}BH_3\{Si(t\text{Bu})_2H\}]$, 2.02(1) Å[22], which contain sp^3-hybridized boron atoms, are also significantly shorter than the distance in **2**. The long distance in **2** may result from steric interactions between the bulky Me_3Si groups on the Si atom and the Me groups on the *ortho* N atoms in the borazine ring. The molecular structure of the *B,B′,B′′*-trisilyl derivative **4** was also determined[32], but disorder in several silylmethyl carbon atoms led to a large *R* value. Nonetheless, the composition and anticipated structure of **4** is confirmed. It is also noteworthy that the B−Si bond lengths are long: 2.11(2) Å (average).

In previous reports[28][33] we have described the syntheses of polyborazinylamine oligomers by reaction of chloroborazine with hexamethyldisilazane and heptamethyldisilazane. Extending this approach, the borazine monomer $H_3N_3B_3(Cl)_2Si(SiMe_3)_3$ was prepared from the 1:1 reaction of $(HNBCl)_3$ and $LiSi(SiMe_3)_3$ in hexane. The reaction mixture was filtered to remove LiCl and the monomer solution containing **6** was combined with $(Me_3Si)_2NH$ at 23°C. This produces a glassy, colorless solid (**7**), following solvent evaporation, that is soluble in pentane, hexane, benzene,

Figure 1. Molecular structure and atom-labeling scheme for $[(Me_3Si)_3Si](Me)_2B_3N_3(Me)_3$ (**2**)



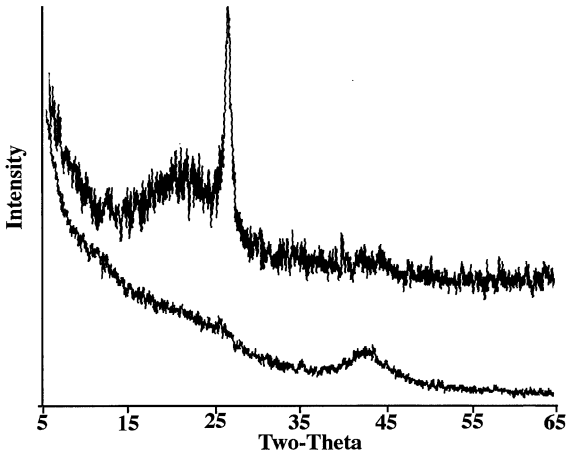
and Et_2O. The oligomer formation is summarized in Eq. 2. Elemental analysis (CHN) of the oligomer is in close agreement with the calculated values for **7** although a small amount of residue is typically found according to the combustion analysis. The ^1H-NMR spectrum displays a sharp resonance at $\delta = 0.25$ that is assigned to the $Si(SiMe_3)_3$ groups in the oligomer and a broad peak at $\delta = 0.35$ is assigned to N−H groups. The ^{11}B-NMR spectrum displays two broad resonances centered at $\delta = 18$ and 38. No further attempts were made to characterize the structure of the oligomer.



The pyrolysis behavior of **7** was initially surveyed by TGA from 50−1400°C under argon. There are two primary weight loss ranges. From 100−300°C about 35% of the mass is lost and from 350−500°C another 18% of the mass is lost. No significant further change occurs above 600°C. The overall ceramic yield is ca. 47%. Bulk samples of the polymer were initially pyrolyzed at 1200°C for 12 h under a slow stream of pure nitrogen. The product is a shiny black hard solid. The infrared spectrum of the material shows a strong, broad peak centered at ca. 1400 cm^{-1} and a medium-intensity band at ca. 800 cm^{-1}. These bands closely resemble those of a standard sample of turbostratic BN[33]. In addition, weaker bands appear at 1030, 840, and 470 that may be tentatively assigned to Si_3N_4. The XRD pattern (Figure 2) for this sample shows only a weak, broad peak centered at $2\theta = 42°$ ($d = 2.1$ Å). This is interesting since pyrolyzed samples of polyborazinylamine polymers typically show a strong reflection at $2\theta = 26°$ ($d = 3.3$ Å) and weaker, broad reflections centered at $2\theta = 34°$ and 42° following pyrolysis at temperatures as low as 900°C. This leads to the tentative conclusion that the crystallization of the boron nitride formed in this study is depressed by the pres-

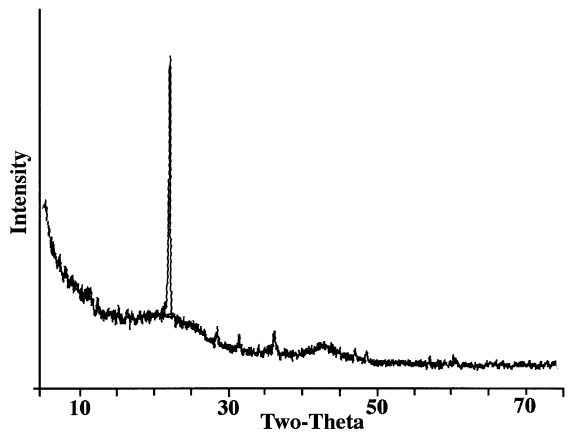
ence of the silicon present as amorphous Si_3N_4, SiC, and/or a ternary SiNC material.

Figure 2. Powder XRD patterns from pyrolysis of polymer precursor **7**; lower trace: 1200°C, 12 h under N_2; upper trace: 1400°C, 12 h under N_2



Further heating of the black, glassy solid to 1400°C under nitrogen gave a gray solid. The sample analyzed as $B_{1.0}N_{1.28}Si_{0.29}C_{0.12}$. An infrared spectrum shows a strong, broad band at ca. 1400 cm^{-1} and a sharper band at ca. 800 cm^{-1} that are assigned to BN and additional bands at 1080, 930, 470, and 420 cm^{-1}. The XRD pattern (Figure 2) shows a broad reflection at 2θ = 26° (*d* = 3.37 Å) and very weak peaks at 2θ = 21° (*d* = 4.0 Å, broad), 39° (*d* = 2.28 Å), 44° (*d* = 2.06 Å), 50° (*d* = 1.83 Å) and 57° (*d* = 1.60 Å). Further heating of this material at 1600°C under Ar leads to gray solid that analysed as $B_{1.0}N_{1.26}Si_{0.25}C_{0.10}$. The XRD pattern (Figure 3) for this material now shows a sharp reflection at 2θ = 22° (*d* = 4.06 Å) and very weak reflections at 2θ = 28° (*d* = 3.13 Å), 32° (*d* = 2.84 Å), 36° (*d* = 2.48 Å), 47° (*d* = 1.93 Å), 48° (*d* = 1.87 Å), 60° (*d* = 1.53 Å). The reflection at 2θ = 22° and weak reflections at 2θ = 32° and 48° may be tentatively ascribed to α-Si_3N_4 that has begun to form in this sample. Other weak reflections may correspond to Si and β-SiC.

Figure 3. Powder XRD pattern from pyrolysis of polymer **7** at 1600°C, 12 h under N_2



A sample of the glassy polymer **7** was also heated at 350°C for 12 h under a flowing stream of NH_3 and then for 6 h under N_2. The resulting residue was heated at 1200°C for 12 h under N_2. The remaining solid was cream-colored, displayed no crystallinity, and analyzed as $B_{1.0}N_{1.42}Si_{0.27}$.

The silyl-substituted monomer molecules **2**−**5** have been prepared and characterized by spectroscopic techniques, and the molecular structure determination for **2** confirms substitution of the very bulky $(Me_3Si)_3Si$ group on the borazine ring at a boron atom. The monomer **6** has also been produced but not isolated. It has been combined with hexamethyldisilazane to provide an organic solvent soluble $(Me_3Si)_3Si$-derivatized polyborazinylamine oligomer **7**. Pyrolysis of this oligomer in nitrogen produces a ceramic product rich in boron and nitrogen containing small amounts of silicon and carbon. The Si appears to suppress the crystallization of BN at 1200°C. At approximately 1400°C the Si present begins to form crystalline phases that at 1600°C show some evidence for formation of α-Si_3N_4. These results are similar to findings reported by Sneddon and coworkers on the pyrolysis of borazine/silazane backbone copolymers. The results suggest that related silyl-substituted borazine monomers should be explored as potential SiNCB precursors.

This work was supported by the *UNM/NSF Center for Microengineered Materials* and its industrial partners.

Experimental Section

Standard vacuum-line and inert-atmosphere techniques were used for the manipulation of reactants and products. − Infrared spectra were obtained with a Nicolet 6000 FT-IR spectrometer and NMR spectra were recorded with Bruker AC-250 and JEOL GSX-400 spectrometers. − NMR spectra were recorded from C_6D_6 solutions and referenced with Me_4Si (^1H, ^{13}C) and $BF_3 \cdot OEt_2$ (^{11}B). − Mass spectra were obtained with a Finnegan mass spectrometer through a solids probe. − Reagents $(Me_3Si)_3SiLi \cdot 3THF$[34], $(ClBNMe)_3$ (**1c**)[35], $(ClBNH)_3$ (**1d**)[36], $Cl_2(Me)B_3N_3(Me)_3$ (**1b**)[37], and $Cl(Me)_2B_3N_3(Me)_3$ (**1a**)[38] were prepared as described in the literature. Solvents were dried by standard procedures and vacuum-transferred from storage vessels into reaction flasks immediately before use.

Synthesis of Molecular Model Compounds [(Me$_3$Si)$_3$Si]-(Me)$_2$B$_3$N$_3$(Me)$_3$ (**2**): A sample of $LiSi(SiMe_3)_3 \cdot 3$ THF (1.0 g, 2.1 mmol) was added over 10 min to a stirred solution (−78°C) of 2-chloro-1,3,4,5,6-pentamethylborazine, $(Cl(Me)_2B_3N_3(Me)_3$; 0.4 g, 2.1 mmol) in 40 ml of hexane. The reaction mixture was warmed to 25°C and stirred overnight. Volatile materials were removed in vacuo. The white residue was combined with hexane (50 ml) and filtered. Solvent removal from the filtrate afforded a solid **2** that was recrystallized from a minimum of hexane. Yield: 0.75 g (90%); mp 85°C; soluble in Et_2O, pentane, THF, benzene. − IR (KBr): $\tilde{\nu}$ = 2953 cm^{-1} (m), 2899 (m), 1477 (s,sh), 1447 (s), 1400 (s), 1388 (s), 1244 (m), 1105 (m), 1075 (m), 997 (m), 863 (s,sh), 836 (s), 682 (m), 625 (m), 515 (w), 430 (w). − MS (50 eV); *m/z* (%): 397 (28) $[M^+]$, 382 (24) $[M - CH_3^+]$, 324 (32) $[M - SiMe_3^+]$, 250 (17) $[M - 2\ SiMe_3^+]$, 150 (11) $[M - (Me_3Si)_3Si^+]$, 73 (100) $[Me_3Si^+]$. − ^1H NMR: δ = 0.36 (CH_3−Si, 27 H), 0.43 (CH_3−B, 6 H), 2.68 (CH_3−N, 3 H), 3.09 (CH_3−N, 6 H). − $^{13}C\{^1H\}$ NMR: δ = 1.92 (CH_3−B), 4.22 (CH_3−Si), 34.2 (CH_3−N), 41.8 (CH_3−N). −

$^{11}B\{^1H\}$ NMR: δ = 36.3 (B−CH_3, 2 B), 42.2 [B−Si($SiMe_3$)$_3$, 1 B]. − $C_{14}H_{42}B_3N_3Si_4$ (397.28): calcd. C 42.32, H 10.60, N 10.60; found C 42.28, H 10.77, N 10.67.

[(Me$_3$Si)$_3$Si]$_2$(Me)B$_3$N$_3$(Me)$_3$ (**3**): A sample of LiSi($SiMe_3$)$_3$ · 3 THF (1.4 g, 3.0 mmol) was added over 15 min to a stirred solution (−78°C) of 2,4-dichloro-1,3,5,6-tetramethylborazine ($Me_3N_3B_3(Me)Cl_2$; 0.32 g, 1.5 mmol) in hexane (40 ml). The mixture was subsequently warmed to 25°C and stirred for 12 h. The volatile components were evaporated leaving a white residue that was extracted with hexane (50 ml). The solution was filtered, the filtrate concentrated and a white waxy solid **3** was recovered. Yield: 0.80 g (85%); mp 103−106°C; soluble in Et_2O, pentane, benzene, and THF. − IR (KBr): $\tilde{\nu}$ = 2520 cm^{-1} (m), 2509 (m), 1484 (m), 1433 (m), 1381 (s,sh), 1357 (s), 1239 (s), 1107 (w), 1064 (m), 984 (m), 947 (w), 832 (s), 696 (w), 684 (m), 608 (m). − MS (50 eV); *m/z* (%): 629 (35) [M^+], 614 (20) [M − CH_3^+], 556 (40) [M − $SiMe_3^+$], 382 (18) [M − Si($SiMe_3$)$_3^+$], 73 (100) [Me_3Si^+]. − ^1H NMR: δ = 0.36 (CH_3−Si, 54 H), 0.44 (CH_3−B, 3 H), 3.07 (CH_3−N, 6 H), 3.56 (CH_3−N, 3 H). − $^{13}C\{^1H\}$ NMR: δ = 4.27 (CH_3−Si), (CH_3−N), 47.8 (CH_3−N). − $^{11}B\{^1H\}$ NMR: δ = 37.1 (B−CH_3, 1 B), 42.8 [B−Si($SiMe_3$)$_3$, 2 B]. − $C_{22}H_{66}N_3B_3Si_8$ (629.90): calcd. C 41.97, H 10.50, N 6.67; found C 40.92, H 10.99, N 6.91.

[(Me$_3$Si)$_3$Si]B$_3$N$_3$(Me)$_3$ (**4**): A sample of LiSi($SiMe_3$)$_3$ · 3 THF (1.95 g, 4.2 mmol) was added over 15 min to a stirred solution (−78°C) of 1,3,5-trimethyl-2,4,6-trichloroborazine ($Me_3N_3B_3Cl_3$; 0.32 g, 1.4 mmol) in hexane (40 ml). The reaction mixture was warmed to 25°C and stirred overnight. Removal of the volatiles from the reaction mixture afforded a white residue that was extracted with hexane (50 ml) and filtered. The solvent was removed from the filtrate under vacuum leaving a white waxy solid. Yield: 1.06 g (88%); soluble in Et_2O, pentane, benzene, and THF. − IR (KBr): $\tilde{\nu}$ = 2952 cm^{-1}(s), 2893 (s), 1924 (w), 1864 (w), 1472 (m), 1434 (w), 1348 (br., s) 1261 (m, sh), 1244 (s), 1074 (s), 967 (m), 838 (s, br.), 748 (m), 681 (m), 622 (m), 438 (w). − MS (50 eV); *m/z* (%): 862 (15) [M^+], 847 (15) [M − $SiMe_3^+$], 789 (35) [M − $SiMe_3^+$], 614 (52) [M − Si($SiMe_3$)$_3^+$]. − ^1H NMR: δ = 0.38 (CH_3−Si), 3.58 (CH_3−N). − 13{^1H} NMR: δ = 4.37 (CH_3−Si), 47.7 (CH_3−N). − $^{11}B\{^1H\}$ NMR: δ = 42.2. − $C_{30}H_{90}B_3N_3Si_{12}$ (862.52): calcd. C 41.80, H 10.50, N 4.88; found C 42.10, H 10.54, N 5.29.

[(Me$_3$Si)$_3$Si]$_3$B$_3$N$_3$H$_3$ (**5**): A sample of (Me_3Si)$_3$SiLi · 3 THF (1.55 g, 3.38 mmol) was added to a cooled (−78°C), stirred solution of $Cl_3B_3N_3H_3$ (0.208 g, 1.13 mmol) in hexane (40 ml). The solution was warmed slowly to 23°C and stirred overnight. The solvent was removed by vacuum evaporation leaving a white residue that was redissolved in fresh hexane (50 ml) and filtered to remove entrained LiCl. The filtrate was concentrated leaving a gummy solid **5** that was vacuum-dried. Yield: 0.81 g (88%); mp 78−83°C. Further attempts to purify this compound by sublimation and recrystallization were unsuccessful. − MS (50 eV); *m/z* (%): 819 (4) [M^+], 804 (1) [M − Me^+], 746 (1) [M − Me_3Si^+], 731 (1) [M − (Me_3Si)(Me)$^+$], 658 (4) [M − (Me_3Si)$_2$(Me)$^+$, 247 (4) [Si($SiMe_3$)$_3^+$]. − ^1H NMR: δ = 0.36 (CH_3Si). − $^{13}C\{^1H\}$ NMR: δ = 1.94 (CH_3Si). − $^{11}B\{^1H\}$ NMR: δ = 38.

Synthesis of Polymer **7**: In a typical reaction, LiSi($SiMe_3$)$_3$ · 3 THF (1.3 g, 2.9 mmol) was added with stirring over 15 min to (ClBNH)$_3$ (0.53 g, 2.9 mmol) in hexane (60 ml) cooled to −78°C. The mixture was warmed to 23°C and stirred overnight. The resulting mixture was filtered to remove LiCl, and the filtrate containing **6** was combined with (Me_3Si)$_2$NH (0.6 ml, 2.9 mmol). This mixture was stirred (23°C) for 24 h and the volatiles removed by vacuum evaporation. This left a glassy, colorless solid **7**. Yield: 0.9 g (90%); soluble in hexane, pentane, benzene, and Et_2O. − IR (KBr): 3446 cm^{-1} (s), 2956 (s), 2922 (s, sh), 2900 (s), 1456 (s), 1413 (s), 1251 (m), 1186 (w), 1111 (w), 1064 (m), 836 (s), 754 (m), 712 (w), 687 (m), 623 (w), 609 (w). − ^1H NMR: δ = 0.35−0.25 (br., m). − $^{13}C\{^1H\}$ NMR: δ = 3.9−1.9 (br.). − $C_9H_{31}B_3N_4Si_4$ (340.14): calcd. C 31.76, H 9.11, N 16.47; found C 32.29, H 8.52, N 14.43.

Polymer Pyrolysis: The TGA of the polymer was recorded under Ar (50−1400°C, 10°C/min). There is a significant weight loss (ca. 35%) between 100 and 350°C and a more gradual weight loss (ca. 18%) up to 500°C. Beyond this temperature, there is minimal weight loss. − Bulk pyrolyses were performed under a variety of conditions, and some representative results are summarized. Typically, a sample (0.35 g) of glassy polymer was placed in a Pt boat in a quartz pyrolysis tube, and the tube was evacuated and backfilled with dry N_2. The sample was then heated at 1200°C under a slow stream of N_2 purge gas. After 12 h, a black solid was collected and characterized. − IR (KBr): $\tilde{\nu}$ = 1410 cm^{-1} (vs), 1030 (vs), 830 (m), 800 (m), 470 (m). − XRD: *d* = 2.1 Å (br.). − The sample was further heated to 1400°C under N_2 for 12 h, and the resulting gray solid was characterized. − IR (KBr): $\tilde{\nu}$ = 1400 cm^{-1} (vs), 1130 (m), 1080 (s), 930 (m), 800 (s), 470 (m), 420 (w). − XRD: *d* = 4.0 Å, 3.38, 2.28, 2.06, 1.83, 1.60. − Found C 3.76, B 28.21, N 46.78, Si 21.25. − Continued heating of this sample at 1600°C for 12 h under N_2 results in a dark gray solid. − IR (KBr): $\tilde{\nu}$ = 1382 cm^{-1}, 1088, 894, 784, 476. − XRD: *d* = 4.06 Å, 3.13, 2.84, 2.48, 1.93, 1.87, 1.53. − Found C 3.27, B 29.47, N 48.11, Si, 19.14. − A sample (0.35 g) of glassy polymer was also heated at 350°C under

NH_3 for 12 h, then under N_2 at 350°C for 6 h, and 1200°C for an additional 12 h. The resulting solid was cream-colored. − IR (KBr): 1388 cm^{-1} (s), 1033 (s), 788 (m), 696 (w), 448 (w). − Found B 28.24, N 51.95, Si 19.81.

Crystallographic Measurements and Structure Solution: A suitable crystal of **2** was mounted in a glass capillary and centered on a Syntex P3/F automated diffractometer. Determinations of the crystal class, orientation matrix, and unit-cell dimensions were performed in a standard fashion. Data were collected with use of Mo-K_α radiation (λ = 0.71069 Å), a highly oriented graphite crystal monochromator, a scintillation counter, and pulse-height analyzer. Selected data-collection parameters are summarized in Table 2. The space-group assignment was made by inspection of a small data set[39], and no absorption correction was required. Redundant and equivalent data were averaged and converted to unscaled $|F_o|$ values following corrections for Lorentz and polarization effects. Standard intensities decayed by about 10% during data collection and intensities were scaled accordingly. All calculations were performed with the SHELXTL PLUS structure solution package[40]. The structure was solved by direct methods and refined with full-matrix least-squares techniques[41]. The heavy atoms were refined anisotropically, and the H atoms were initially refined (riding model) in idealized positions with fixed U_{iso} = 1.2 U_{equiv} of the parent atom. The hydrogen positions were then allowed to vary to achieve the final *R* value. Further information on the X-ray crystallographic structure determination for $(Me_3Si)_3SiBB_2Me_2N_3Me_3$ may be obtained from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB21EZ, England, and may be ordered by quoting the depository number CCDC-101122.

Keywords: Trinuclear *triangulo* palladium complex / 2-Hydroxyacetophenone N^4-ethylthiosemicarbazone / Dimethylformamide aggregation

The X-ray crystal structure of a palladium(II) complex of 2-hydroxyacetophenone N^4-ethylthiosemicarbazone (H_2Ap4E) shows it to be a *triangular,* trinuclear complex with bridging thiosemicarbazonato sulfur atoms. This species can be formed from a monomer on dissolution in DMF or directly from Li_2PdCl_4 and the thiosemicarbazone in methanol-ammonia solution.

Thiosemicarbazones of aromatic *ortho*-hydroxy aldehydes and ketones have recently attracted considerable attention because of their potential biological properties[1] and catalytic activity[2]. These aromatic thiosemicarbazones most often coordinate as the dianion on loss of the phenoxy hydrogen and thiosemicarbazone moiety′s to form mononuclear [M(ONS)X] (ONS represents the dianionic thioseicarbazone ligand coordinated via the phenoxy oxygen, azomethine nitrogen and thiolato sulfur and X represents a neutral molecule such as ammonia or pyridine)[3], or dinuclear $[M(ONS)]_2$ {M=Ni(II) or Cu(II) and M−O,O−M bridging pattern}[4][5][6][7] have been isolated on deprotonation of the ring hydroxy group and loss of the N(2) hydrogen of the thiosemicarbazone (tsc) moiety. Most recently, a trinuclear nickel(II) complex with both Ni−O,O−Ni and Ni−S,O−Ni bridging patterns has been reported[8]. Two monomers combine to form a butterfly-shaped dimer by Ni−O,O−Ni bonding and a third monomer binds to the dimer via Ni−S,O−Ni bridging. Palladium(II) complexes of tscs of 2-acetylpyridine have been studied with regard to their structural and biological properties, and some of them show remarkable antitumour activity[9][10][11]. Therefore, we expanded our studies of palladium(II) complexes to include other potentially tridentate tsc ligands and report here the structure of $[Pd(Ap4E)]_3 \cdot$DMF (Ap4E is the dianion of 2-hydroxyacetophenone N^4-ethylthiosemicarbazone) with Pd−S−Pd bridging.

Although numerous dinuclear palladium complexes are known, only a few trinuclear palladium complexes have been reported[12][13]. Triangular complexes[12][13], as well as linear complexes[14], have been structurally characterized. Linear tripalladium structures have been found for the complexes $Pd_3[\eta^3$-1,3-di(pyvaloyl)allyl$]_2(\mu,\eta^2$-acetate$)_4$[14b], $Pd_3[1\text{-}3\eta^3$-6-(α-chloroethyl)cyclooctenyl$]_2Cl_4$[14c] and $[Pd_3(\mu\text{-}SCy)_4Cl_2(PMe_3)2]$[14h] with four bridging ligands and palladium atoms at non-bonding distances. Bent trimetallic structures have been proposed for $[Pd_3(\mu\text{-}PPh_2)_2(\mu\text{-}Cl)_2(PPh_3)_2]$[14f], $[NEt_4]_2[Pd_3(\mu\text{-}Cl)_4Cl_2(C_6F_5)_4]$[14g], $[Pd_3(\eta^3$-1,2,3-tri(*p*-methoxyphenyl)allyl$)_2(acac)_2]$[14d] and $[Pd_3(\eta^3$-2-methylallyl$)_2(Cl)_4]$[14e]. In the case of allyl complexes, it is believed that the bent structures may result from crystal packing forces rather than steric interactions.

Palladium acetate has been found to be trinuclear with a triangular arrangement of non-bonded palladium[12f] and $[Pd_3(\mu\text{-}O_2CMe)_3(\mu\text{-}MeSCHR)_3]$[13a] is a mixed-sphere palladium complex in which the solid state nuclearity and structure of palladium acetate is retained. Complexes that are cationic and triangular trinuclear with two triply bridging ligands include $[Pd_3(\mu_3\text{-}SPPh_2)_2(PhN{=}NC_6H_4)(PPh_3)_2]ClO_4$[13c] and $[Pd_3(C_6H_4CH_2NMe_2)_3(pyS)_2]BF_4$[13d] and with three bridging ligands, capped by a lone sulfur atom as $[Pd_3(\mu_3\text{-}S)(SC)(\mu\text{-}Ph_2PCH_2PPH_2)_3][SCN]\cdot 3C_2H_4Cl_2$[13b] have been studied. Neutral tripalladium triangular complexes with two bridging ligands $[Pd_3(\mu\text{-}SO_2)_2(BuNC)_5]\cdot 2(C_6H_6)$[12b] and with three bridging ligands

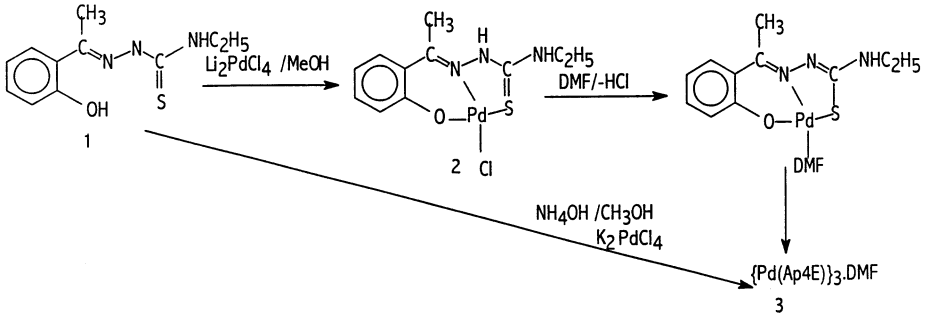
Figure 1. The reaction path for the synthesis of $[Pd(Ap4E)]_3 \cdot DMF$



$[Pd_3(\mu\text{-}Pcy)_2(m\text{-}SPh)(PCyH)_2(SPh)]$[13e] have been studied. However, to our knowledge this is the first report of an approximately symmetric, *triangular* palladium(II) complex, $[Pd(Ap4E)]_3 \cdot DMF$, with three bridging ligands having the same formal charge and bonding pattern.

Results and Discussion

The reaction of Li_2PdCl_4 with HAp4E afforded the complex **2**. The microanalytical data are consistent with the empirical formula $C_{36}H_{46}N_{10}O_4Pd_3S_3$, which indicates the structure $[Pd(HAp4E)Cl]_n$, and suggests a mononuclear or binuclear structure. A mononuclear is suggested by the IR spectrum, which revealed the appearance of a strong band at 346 cm^{-1} consistent with a terminal $\nu(Pd-Cl)$ bond. Figure 1 shows the reactions used to form the trinuclear complex $[Pd(Ap4E)]_3 \cdot DMF$ with three doubly deprotonated phenolato-thiosemicarbazonato ligands and its molecular structure is shown in Figure 2. Each Ap4E ligand coordinates via its phenoxy oxygen and azomethine nitrogen atoms and bridges to another palladium(II) with its thiolato sulfur atom. The metal-ligand bond distances are as follows: Pd1−O1, 1.967(5) Å; Pd2−O1a, 1.993(5) Å and Pd3−O1b, 1.994(6) Å; Pd1−N1, 2.005(6) Å; Pd2−N1a, 2.002(6) Å and Pd3−N1b, 2.020(5) Å; Pd1−S1, 2.226(2) Å; Pd2−S1a, 2.250(2) Å and Pd−S1b, 2.231(2) Å. The bridging sulfur atoms are closer (ca. 0.1 Å) to one Pd atom, having distances of 2.332(2) Å, 2.315(2) Å and 2.337(2) Å to the second Pd atom. The distances between the palladium centres [Pd1−Pd2, 3.945(1); Pd2−Pd3, 4.146(1); Pd1−Pd3, 3.500(1)] indicate that there are no metal-metal bonds. The three bond angles involving bridging sulfur atoms are as follows: Pd1−S1−Pd2, 120.6(1)°; Pd2−S1a−Pd3, 129.3(1)° and Pd3−S1b−Pd1, 100.2(1)°.

Figure 2. Molecular structure of $[Pd(Ap4E)]_3 \cdot DMF$ and numbering scheme

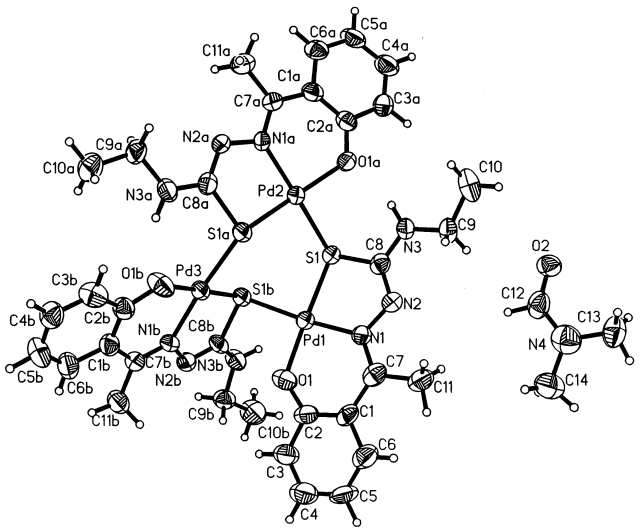


Figure 3. a) UV spectra of 5×10^{-5} M H_2Ap4E (——) [Pd(HAp4E)Cl] and (----) $[Pd(Ap4E)]_3 \cdot DMF$ (− −) in DMF and b) in $CHCl_3$

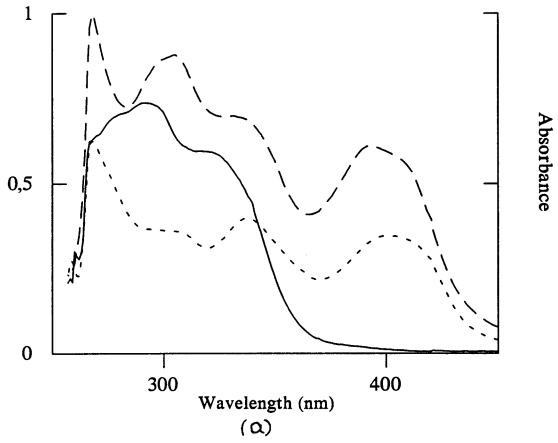

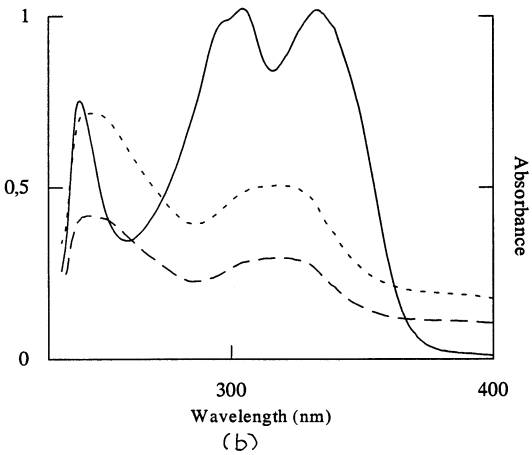

The coordination planes Pd1−O1−N1−S1−S1b, Pd2−O1a−N1a−S1a-S1 and Pd3−O1b−N1b−S1b−S1a have mean plane deviations of 0.066, 0.157 and 0.048 Å, respectively, and form dihedral angles of 42.24(6)°, 20.23(5)° and 43.98(6)° respectively, with Pd1−S1−Pd2−S1a−Pd3−S1b, which has a mean plane deviation of 0.436 Å.

A kinetically labile ligand and polar solvent like dimethylformamide affords the elimination of hydrogen chloride from **2** and the deprotonation of H_2Ap4E to form [Pd(Ap4E)]$_3$·DMF (Figure 1). The electronic spectra of the complexes **2** and **3** exhibit the same spectral pattern in $CHCl_3$, suggesting conversion of the trinuclear to the mononuclear complex (Figure 3). A different spectral pattern is shown in DMF solution, consistent with the slow transformation of the monomer to the trinuclear complex. Although transformation of **2** to **3** occurs in DMF solution (and the trinuclear complex can be prepared by this method), a non-coordinating, non-polar solvent such as $CHCl_3$ causes **3** to be reverted to **2** (Figure 3b). In contrast dinuclear complexes of copper(II)[5] and nickel(II)[6][7][8] when dissolved in solvents like DMSO and DMF are able to partly monomerize and crystals of a monomer were isolated from DMF solution[7].

Experimental Section

H_2Ap4E = 2-hydroxyacetophenone N^4-ethylthiosemicarbazone, **1**, was prepared by reacting equimolar amounts of 2-hydroxyacetophenone (2 mmol) and N^4-ethyl-3-thiosemicarbazide (2 mmol) in 30 ml ethanol. Two drops of concentrated sulfuric acid were added and the reaction mixture was refluxed for three hours. On partial evaporation of the solvent a white solid formed, which was filtered, washed with cold 2-propanol and dried. [Pd(HAp4E)Cl], **2**, was prepared by reacting lithium tetrachloropalladate (1.2 mmol) prepared in situ from palladium chloride and lithium chloride in methanol and H_2Ap4E (1 mmol) in methanol. The reaction mixture was stirred for 24 hours at room temperature and the resulting yellow powder was filtered, washed with methanol followed by ether and dried in vacuo over silica gel. Calcd for [Pd(HAp4E)Cl]·H_2O: C, 33.35; H, 4.04; N, 10.65; Cl, 8.95. Found: C, 33.05; H, 4.02; N,10.52; Cl, 9.10. Yield 43%. Slow evaporation of **2** from dimethylformamide gives dark red crystals of the complex **3** suitable for X-ray structural analysis. Also, the complex [Pd(Ap4E)]$_3$ was prepared directly from the reaction of K_2PdCl_4 (1.2 mmol) and H_2Ap4E (1 mmol) in 25 ml of H_2O, by adjusting the pH of the reaction to *ca.* 9 with drops of a 1.5 M NH_3 solution. Figure 1 shows the two routes to the trinuclear [Pd(Ap4E)]$_3$. Calcd for [Pd(Ap4E)]$_3$: C 38.66; H 3.80; N 12.30; found: C 39.13, H 4.10; N 12.40. Yield 50%.

Crystal Data: $C_{36}H_{46}N_{10}O_4Pd_3S_3$, molecular mass 1098.2, triclinic, space group *P*1bar, α = 8.874(2) Å, b = 15.680(2) Å, c = 16.273(2) Å, α = 97.80(2)°, β = 105.76(2)°, γ = 103.31(2)°, U = 2072.5(5) Å^3, Z = 2 , d = 1.760 Mg/m^3, F(000) = 1100, Mo$K\alpha$ (λ = 0.71073 Å). A red-wine prism with dimensions 0.36 × 0.10 × 0.08 mm was mounted in random orientation on a glass fiber and data were acquired with a Siemens P4 Four-Circle Diffractometer. The structure was solved with direct methods and missing atoms were found by difference-Fourier synthesis. All non-hydrogen atoms were refined with anisotropic temperature factors. The H atoms were allowed to ride on the C atoms and assigned fixed isotropic temperature factor, U = 0.06 Å^2. Hydrogen atoms on a heteroatom, H3D, H3E and H3 C, were refined in found positions. Refinement of the structure was made by full-matrix least-squares. The minimized function was $S_w(F_o - F_c)^2$ with, $w^{-1} = [\sigma^2(F) + 0.0009(F)^2]$, with final g = 0.0005 for [Pd(Ap4E)]$_3$·DMF. Scattering factors were taken from International Tables for X-ray Crystallography (**1974**, Vol. IV). All calculations were done with the SHELXTL PC™ program package.

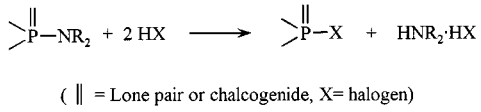
Keywords: *N′,N′,N′′,N′′*-Tetramethylguanidine / Triphenylmethyl / Phosphorus-substituted ammonium salts / Steric hindrance / Cleavage reactions

The dependence of the protolytic decomposition rate of phosphorus amides on the substituents at phosphorus is decribed. On treatment with HCl, the *N′,N′,N″,N″*-tetramethylguanidine(= TMG)-substituted σ^4(P) compounds **5** and **9** formed salts that were protonated at the imino nitrogen atoms and were completely stable in the solid state, and surprisingly stable in solution. Even with a large excess of HCl, only the imino nitrogen atom underwent protonation, with formation of HCl_2^- as a counter anion, without cleavage of the P–N bond. The basicity of the imino nitrogen atom also protected σ^3(P) species from electrophilic attack, and the ionic compounds **12**, **14**, and **20c** were formed, providing examples of the first stable σ^3(P) amides with one or two protonated P-N bonds. Such unusual stability is associated with steric protection by the Ph_3C (= trityl) group and charge delocalization over the TMG-moiety. In contrast, $MeP(TMG)_2$ was unstable towards HCl, whereas treatment with $HSbF_6$ led to the phosphonium salt **24**, where protonation had occurred at phosphorus. The same result was obtained when triphenylmethylphosphonous dichloride **1** was allowed to react with 3 equivalents of HTMG, forming the stable phosphonium salt **19**, soluble in water, which was converted to the bicationic species **20c** upon treatment with HCl. – The basicity of the tritylated phosphorus compounds was found to increase in the order **5** < **2** < **19** < **13** < HTMG < **21**; the basic centre is the phosphorus atom in **21** and the imino nitrogen atom in all other compounds. The fluorinating agent $Et_3N \cdot 3$ HF caused rapid conversion of compound **6** to **25**, the nucleophilic attack of fluoride ion at phosphorus could not be prevented by the stabilizing effects mentioned. – All compounds were investigated by ^{1}H- and ^{31}P-NMR spectroscopy. The crystal structures of compounds **5**, $Ph_3CP(=O)$-(H)TMG,and **6**, [**5** · 2 HCl], were determined; **6** is protonated at the imino nitrogen, leading to a longer P–N bond [**5**: 161.6(2), **6**: 168.7(2) pm], and the counterion is HCl_2^-. In the structure of **20c**, $[Ph_3CP(TMG)_2] \cdot 3$ HCl, the cation is protonated at both imino N atoms and the counterions are Cl^- and HCl_2^- (one of each).

Introduction

The bond between phosphorus and nitrogen is particularly susceptible to attack by acids; this is exploited in a general method of forming phosphorus halides from the corresponding phosphorus amides (Eq. 1). The hydrolytic cleavage of the P−N bond is complex and takes place under mild conditions to give an ammonium salt and the corresponding phosphorus halide[1][2].



(1)

(‖ = Lone pair or chalcogenide, X= halogen)

Because alkyl groups are the most widely used substituents at nitrogen, and in connection with our own studies on *N′,N′,N′′,N′′*-tetramethylguanidine (TMG)-derivatives[3], we wished to apply the method to TMG-substituted phosphorus compounds. In particular, we wanted to prepare the monochloride of (triphenylmethyl)phosphonous acid **8**, which could, in principle, be formed by the process described in Eq. 1, via compound **5**.

In contrast to expectation, the reaction of **5** with HCl furnished the ionic compound **6**, an intermediate that was reasonably stable in solution and completely stable in the solid state.

Such cases of protonation of the nitrogen atom with preservation of the P−N bond are scarce in the literature. However, a few examples of compounds are known in which the P−N bond was not affected by protonic acids; e.g., Riess et al. were able to isolate stable ammonium salts with tetra- and penta-coordinated phosphorus[4]. Furthermore, Schmidpeter et al. have investigated 5-membered ring systems containing −P=N− moieties, from which stable ammonium salts could also be obtained[6]. However, σ^3(P) compounds with protonated phosphorus-nitrogen single bonds have only been postulated as reaction intermediates[7][8][9][10]. Most reactions of phosphorus amides with protonic acids proceed via protonation at phosphorus, which is due mainly to the nucleophilic character of the phosphorus atom; a few examples of such phosphonium salts with various counterions have been reported[11][12].

Thus, the intermediates formed by HCl attack on TMG-substituted phosphanes need to be identified and investi-

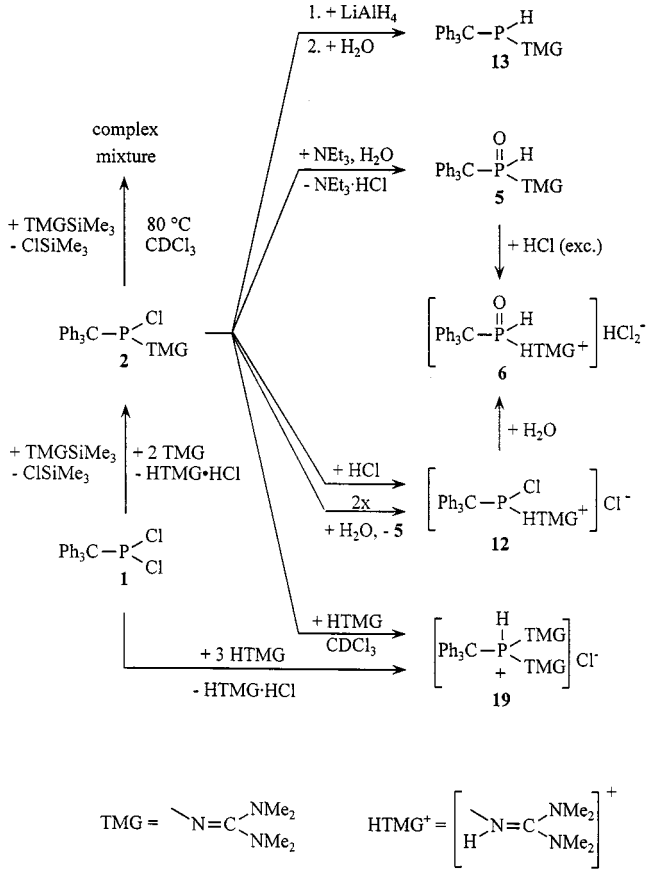
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0606−0865 $ 17.50+.50/0

gated with regard to their stability (e.g., by varying the environment of the phosphorus atom). The protolytic stability of the P−N bond must be determined by electronic (a conjugative delocalization of the cationic charge on phosphorus or at TMG) and steric factors (shielding of the phosphorus atom by a bulky substituent). In our investigations we used trityl-TMG substituted phosphorus compounds, which proved suitable in forming intermediates of interest, especially in the acid-catalysed nucleophilic substitution at σ^3(P) amides[8][12][13].

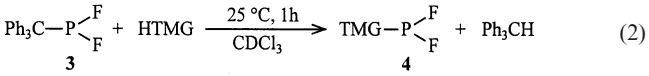
Results and Discussion

The phosphonous dichloride **1**, which has been known since 1933[14], was used as starting material for the preparation of compounds containing the trityl-moiety bonded to phosphorus. It reacted vigorously with 2 equivalents of HTMG, forming compound **2** (Scheme 1).

Scheme 1

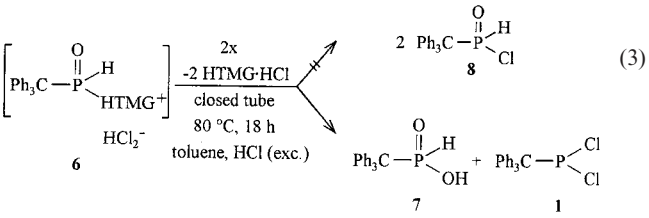


Using the less reactive agent Me_3SiTMG (Scheme 1) partial aminolysis of **1** was also effected. The reaction of triphenylmethylphosphonous difluoride **3** and HTMG, however, involved an unusual preferential cleavage of the phosphorus−carbon rather than the phosphorus−fluorine bond, with formation of the known phosphonous difluoride **4**[15] (Eq. 2); this interesting phenomenon had previously been observed by Nixon in connection with aminolysis reactions of Cl_3CPF_2[16].



(2)

Treatment of **2** with H_2O and NEt_3 led spontaneously to triphenylmethylphosphonous *N′,N′,N′′,N′′*-tetramethylguanidinide **5** (Scheme 1). The attempted preparation of the monochloride of triphenylmethylphosphonous acid **8** using excess HCl led to the hydrogendichloride **6** (formally **5**·2 HCl), which was stable at room temperature and was converted to Ph_3CPCl_2 **1** and $Ph_3CPH(O)OH$ **7** upon heating in excess HCl at 80°C (Eq. 3).



(3)

This result is at variance with the observation that organo(chloro)phosphonous acids are usually stable when they contain sterically demanding substituents[17].

[a] Selected bond lengths [pm] and angles [°]: P−O 147.2(2), P−N(1) 168.7(2), P−C(10) 186.0(2), P−H(1) 132(2), N(1)−C(1) 137.8(3), N(1)−H(2) 90(3), N(2)−C(1) 133.0(3), N(2)−C(3) 145.8(3), N(2)−C(2) 146.7(3), N(3)−C(1) 132.2(3), N(3)−C(4) 145.8(3), N(3)−C(5) 146.6(3), Cl(1)−H(3) 187(3), Cl(2)−H(3) 135(3), O−P−N(1) 112.38(10), O−P−C(10) 113.61(10), N(1)−P−C(10) 108.25(11), O−P−H(1) 114.9(8), N(1)−P−H(1) 103.3(8), C(1)−N(1)−P 126.3(2), C(1)−N(1)−H(2) 114.5(1.7), P−N(1)−H(2) 118.6(1.7), C(1)−N(2)−C(3) 123.5(2), C(1)−N(2)−C(2) 121.2(2), C(3)−N(2)−C(2) 115.2(2), C(1)−N(3)−C(4) 121.6(2), C(1)−N(3)−C(5) 123.1(2), C(4)−N(3)−C(5) 114.9(2), N(3)−C(1)−N(2) 121.6(2), N(3)−C(1)−N(1) 118.8(2), N(2)−C(1)−N(1) 119.6(2), Cl(1)−H(3)−Cl(2) 173(2).

was located at the imino nitrogen N1; this hydrogen and all other non-C-bonded hydrogen atoms of **5** and **6** were refined freely.

The P−O, P−C, and P−H bonds are marginally shorter in **6** than in **5** [**5**: P−O 148.1(2), P−C10 187.5(2), P−H1 136(2) pm; **6**: P−O 147.2(2), P−C10 186.0(2), P−H1 132(2) pm]. The increase in coordination number at the imino nitrogen leads, as expected, to a marked increase in the P−N bond length [**5**: P−N 161.6(2), **6**: P−N 168.7(2) pm]. In compound **5** the imino N−C bond [N1−C1 131.5(3) pm] is naturally shorter than the amino N−C bonds [N2−C1 137.3(3), N3−C1 134.5(3) pm]. In compound **6** the N1−C1 bond [137.8(3) pm] is about 5 pm longer than N2−C1 [133.0(3) pm] and N3−C1 [132.2(3) pm]; this indicates that the positive charge is delocalized over the two dimethylamino groups. The average $N-C_{methyl}$ bond lengths differ insignificantly [**5**: 145.6, **6** 146.22 pm].

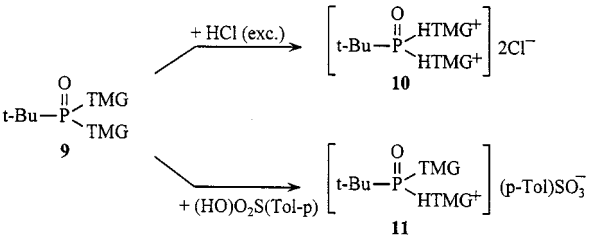
The phosphorus atom, as expected, displays somewhat distorted tetrahedral coordination geometry, with the largest angles involving the doubly bonded O atom. In the case of **5** O−P−N1 [117.35(11)°] is the largest, C10−P−H1 [101.7(9)°] the smallest angle; in **6** O−P−H1 [114.9(8)°] and C10−P−H1 [103.5(8)°].

The counteranion in compound **6** is the hydrogendichloride anion. The angle at H3 is 173(2)°. One Cl−H bond is significantly longer than the other [Cl1−H3 187(3), Cl2−H3 135(3) pm], so the negative charge is mainly located at Cl1. The Cl−Cl distance is 320.8(1) pm, which is normal for hydrogendichloride anions (cf. [(4-$CH_3OC_6H_4$)$(CH_3)PCl_2$] [ClHCl]: Cl···Cl 321.0(3) pm; [(4-$C_2H_5OC_6H_4$)PCl_3] [ClHCl]: Cl···Cl 318.9(1) pm)[18].

The H2 atom forms a hydrogen bond to Cl1 at [1.5 − x, 0.5 + y, −0.5 − z], with the following dimensions: H2···Cl1 237(3) pm, N1···Cl1 321.9(2) pm and N1−H2···Cl1 157(2)°. The H1 atom is linked to O [at 1.5 − x, 0.5 + y, 0.5 − z] via short contacts that may be interpreted as hydrogen bonds [H1···O 255(2), P···O 386.6(2) pm, P−H1···O 170.4(1.2)°].

The formation of compounds **1** and **7** from **6** would appear to be the result of the conversion of $Ph_3CPH(=O)Cl$ **8**, formed as an intermediate by nucleophilic attack of chloride anion on **6**. This process is complex and will be discussed in a subsequent publication.

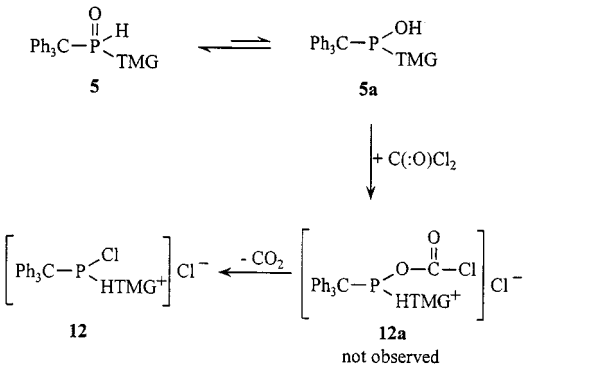
The unusual stability of **6** is caused by the kinetically stabilizing effect of the trityl group[19], and the possibility of charge delocalisation in TMG-substituted phosphorus compounds[3]. The latter might be the reason for the possibility of the isolation of compound **10**, a doubly protonated species whose formation was concluded from analytical data (Eq. 4).



(4)

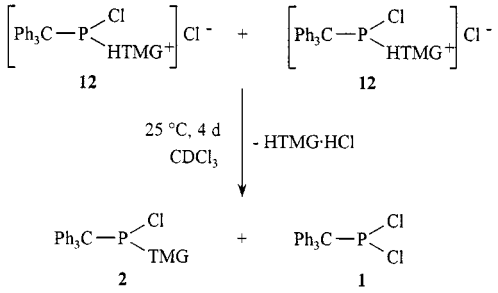
The possibility of rearrangement of the dichloride **10** to the hydrogendichloride in the solid state was considered, in the mass spectrum, from the observation of only the monoprotonated parent ion. The cation **11** was formed in good yield by treatment of **9** with *p*-tolylsulfonic acid. This counterion, of low nucleophilicity, gave rise to additional stabilization, compared to the chloride ion.

The displacement of halogen by water was of particular importance and led, as mentioned above, to compound **5** in the presence of NEt_3, or to a mixture of **5** and **12**, in which a second molecule of **2** acted as a scavenging agent for the HCl liberated (Scheme 1). In the presence of excess water the same treatment afforded compound **6**. Compound **12** was also formed by reaction of **2** with HCl (Scheme 1) and **5** with phosgene (Eq. 5), respectively.



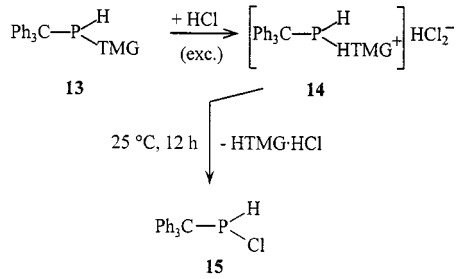
(5)

The latter reaction was preceded by the formation of the tautomeric parent acid **5a**, where the proton was more strongly acidic than in **5**, and the reaction with $C(=O)Cl_2$ took place rapidly. The assumed intermediate **12a** was unstable and was transformed to **12**. This salt was stable as a solid, but in solution slowly decomposed to **1**, **2**, and HTMG·HCl (Eq. 6).



(6)

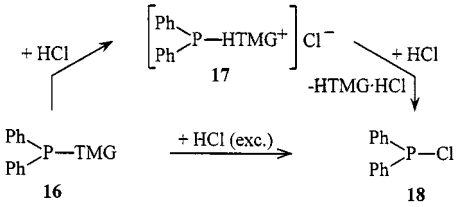
To define the effects causing the unusual stability of **12**, further investigations were conducted that involved variation of the nucleophilicity and steric congestion at the phosphorus atom. Thus, the nucleophilicity of the tritylated phosphorus compounds should increase if the chlorine atom in **2** were substituted by hydrogen. This was realized when **2** was allowed to react with $LiAlH_4$ (Scheme 1). The isolation of **13** was not possible because Ph_3CH was also formed and could not be separated from the reaction mixture. A toluene solution of the resulting crude product was, therefore, treated with excess HCl, and the colourless solid precipitated was identified as the hydrogendichloride **14**, where protonation had occurred at the imino nitrogen atom (Eq. 7).



(7)

The identity of **14** was established by analytical and NMR spectral data, and by its decomposition to triphenylmethylphosphonous chloride **15**. Compounds like **15** are sufficiently stable only in the presence of bulky groups, and only a few examples, mainly referred to as intermediates, are mentioned in the literature[20][21][22]. Compound **15**, which is completely stable, will be described elsewhere in connection with alternative synthetic routes and further investigations.

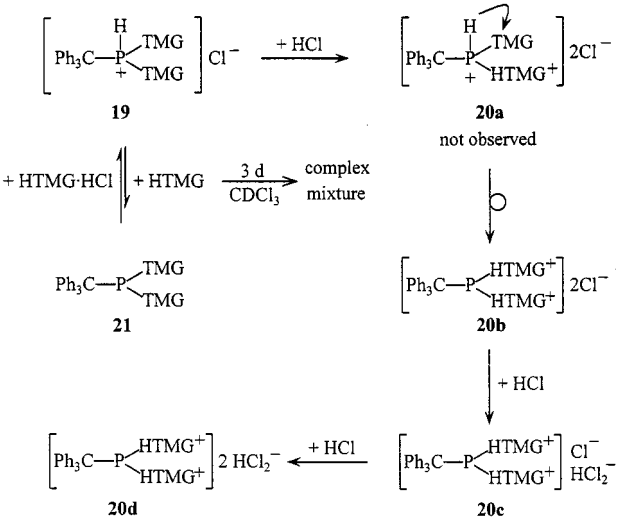
To exclude the steric hindrance effect of the trityl group, the protonation reaction was repeated with compound **16** where, moreover, the nucleophilicity of phosphorus should be higher than in both **2** and **13** (Eq. 8).



(8)

The reaction pathway is not clear. The solid that precipitated from toluene consisted of HTMG·HCl and a phosphorus compound separated that could not be isolated (in a 1:1 ratio). The product soluble in toluene was characterized by ^{31}P NMR as diphenylphosphinous chloride **18**, which was formed as shown (Eq. 8). The precise location of the proton in **17** could not be established, because the ^{1}H NMR resonance of the proton bonded to phosphorus or nitrogen was not observed.

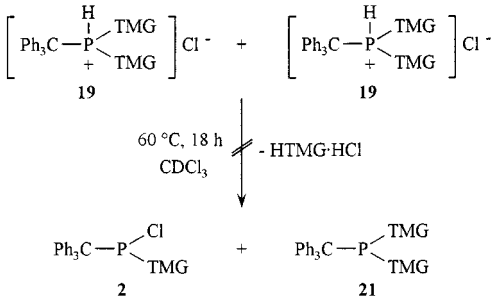
Scheme 2



When the reaction of HTMG with **1** was carried out in a molar ratio 3:1, the final product was the phosphonium salt **19**, which was also obtained when **2** was allowed to react with HTMG (Scheme 1). In both cases, the strongly basic properties of the phosphorus atom of $Ph_3C-P(TMG)_2$ **21** were evident (based on ^{31}P NMR studies). The equilibrium between **19** and **21** was established spontaneously (molar ratio **19/21** = 6:4). After removing the volatile products, the phosphonium salt **19** was isolated.

The isolation of **21** from this equilibrium mixture was, however, not possible. After the components were left in solution in $CDCl_3$ for 3 d, a complex mixture was obtained (Scheme 2). The attempted preparation of **21** via reaction of **2** with Me_3SiTMG was also unsuccessful because under the reaction conditions (temperature ca. 80°C), decomposition with formation of an oily product took place (Scheme 1). The above-mentioned acid-base equilibrium could not be observed when **19** was treated with excess NEt_3. This provides additional evidence of the high basicity of **21**. The basic properties of the phosphorus atom in amino-substi-

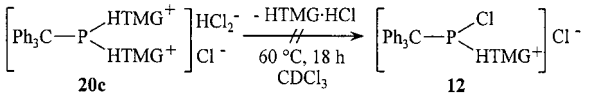
tuted phosphorus compounds are well known[23][24]. However, it should be noted that in the preparation of $RP(TMG)_2$ (R = Me, *t*Bu, and Ph) by treatment of $RPCl_2$ with HTMG (molar ratio: 1:4) these compounds could be obtained readily and in good yield by distillation of the corresponding crude products[3]. The formation of **19** took place quantitatively, but the separation from HTMG·HCl by washing with H_2O resulted in low yields, because **19** also showed hydrophilic properties. The phosphorus atom in $Ph_3C-P(TMG)_2$ seemed to be more basic than the imino nitrogen atom in HTMG and, therefore, **19** showed (in contrast to the conversion of compounds **12** and **14**) no decomposition to the chlorinated compound **2** and the unprotonated species **21**, respectively (Eq. 9).



(9)

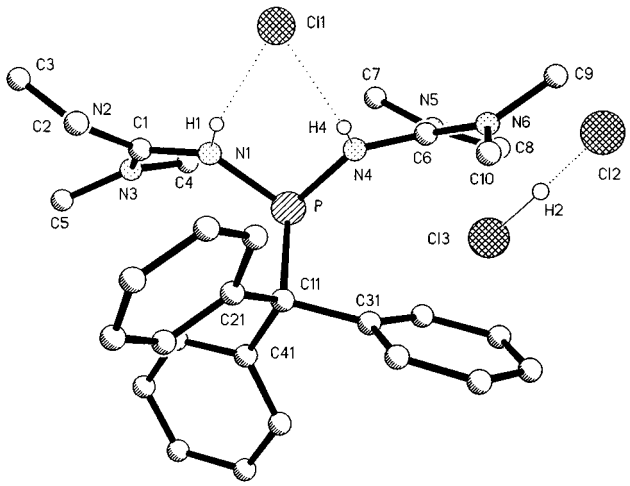
The TMG moieties in $[Ph_3C-PH(TMG)_2]^+$ also were found to display basic properties at the imino nitrogen atoms and additional HCl should lead to a doubly protonated species. Surprisingly, the product resulting from the reaction of **19** with HCl was, instead of the expected compound **20a**, the σ^3(P) compound **20b**, where both imino nitrogen atoms were protonated (Scheme 2).

The migration of the proton in **20a** is caused by the electron-withdrawing effect of the $HTMG^+$ moiety, which is comparable to that of a chlorine atom. The electron density at the phosphorus atom in **20b** is comparable to that in **12**, and a decreasing tendency of electrophilic attack was established by treatment of **20b** with excess hydrogen chloride, leading to HCl_2^- as counter anion. There was no protonation at the phosphorus atom. Treatment of **19** with HCl (ratio 1:1) led to the ionic species **20b** with chloride as counterion. Compound **20b** was insoluble in $CDCl_3$, whereas the corresponding hydrogendichloride **20d** was well soluble in chlorinated solvents and, as expected from its structure, insoluble in nonpolar solvents. The crystals, obtained from the reaction mixture (in CH_2Cl_2/Et_2O, ratio: 7:1) at room temperature by treatment of **19** with HCl (ratio: 1:3), contained both chloride and hydrogendichloride anions (see below). The solubility of this compound (**20c**) lies between that of **20b** and **20d**. Surprisingly, the attempted conversion of **20c** did not afford the expected compounds **12** and HTMG·HCl, and reflected the increasing influence of steric congestion by the second $HTMG^+$ moiety (Eq. 10). Thus, in contrast to **12** and **14**, nucleophilic attack at the phosphorus atom was not possible, even on raising the temperature (60 °C).



(10)

Figure 3. Structure of **20c** in the crystal. Methyl and phenyl hydrogen atoms and solvent have been omitted for clarity[a]



[a] Selected bond lengths [pm] and angles [°]: P−N(4) 171.7(3), P−N(1) 173.4(2), P−C(11) 195.8(3), N(1)−C(1) 135.4(4), N(1)−H(1) 81.9(40), N(2)−C(1) 133.9(4), N(2)−C(2) 146.1(4), N(2)−C(3) 146.8(4), N(3)−C(1) 133.4(4), N(3)−C(4) 146.1(4), N(3)−C(5) 146.5(4), N(4)−C(6) 135.9(4), N(4)−H(4) 74.4(36), N(5)−C(6) 133.7(4), N(5)−C(7) 146.1(4), N(5)−C(8) 146.8(4), N(6)−C(6) 133.0(4), N(6)−C(10) 145.8(4), N(6)−C(9) 146.3(4), Cl(2)−H(2) 170.1(54), Cl(3)−H(2) 145.5(54), N(4)−P−N(1) 93.07(12), N(4)−P−C(11) 104.53(12), N(1)−P−C(11) 105.30(12), C(1)−N(1)−P 130.2(2), P−N(1)−H(1) 114(3), C(1)−N(1)−H(1) 115(3), C(1)−N(2)−C(2) 121.7(3), C(1)−N(2)−C(3) 120.7(3), C(2)−N(2)−C(3) 115.4(3), C(1)−N(3)−C(4) 123.4(2), C(1)−N(3)−C(5) 121.8(3), C(4)−N(3)−C(5) 114.7(3), C(6)−N(4)−P 124.8(2), P−N(4)−H(4) 119(3), C(6)−N(4)−H(4) 115(3), C(6)−N(5)−C(7) 122.1(2), C(6)−N(5)−C(8) 122.8(3), C(7)−N(5)−C(8) 114.9(2), C(6)−N(6)−C(10) 121.5(2), C(6)−N(6)−C(9) 123.2(3), C(10)−N(6)−C(9) 114.9(2), N(3)−C(1)−N(2) 120.0(3), N(3)−C(1)−N(1) 122.2(3), N(2)−C(1)−N(1) 117.7(3), N(6)−C(6)−N(5) 121.8(3), N(6)−C(6)−N(4) 118.1(3), N(5)−C(6)−N(4) 120.1(3), Cl(2)−H(2)−Cl(3) 177(4).

Discussion of the X-ray Structure of 20c

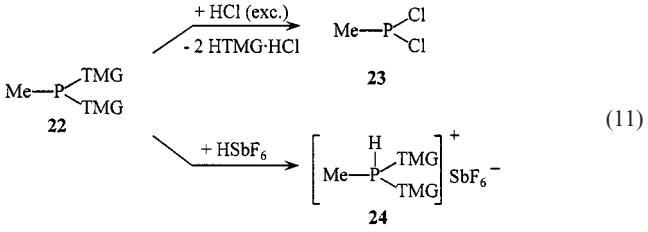
Compound **20c** crystallises as a dichloromethane solvate. All three non-C-bonded hydrogen atoms were refined freely.

The P−N bonds in **20c** [P−N1 173.4(2), P−N4 171.7(3) pm] are longer than those of $Ph_2P(TMG)$ **A**[25] [P−N1 169.6(3) pm]. The N1−C1 [135.4(4) pm] and N4−C6 [135.9(4) pm] bonds are about 5 pm longer [**A**: P−N1 129.3(4) pm], but the amino N−C bonds [133.0(4) (N6−C6) to 133.9(4) (N2−C1) pm] are much shorter than those of **A** [N2−C1 138.2(4), N3−C1 136.4(4) pm]. In compound **20c** the formal imino N−C double bond is longer than the amino N−C bonds, which means that the positive charge is effectively delocalized via π bonding to N2, N3, N5, and N6. The N−methyl bond lengths vary from 145.8(4) pm (N6−C10) to 146.8(4) pm (N2−C2 and N5−C8).

The phosphorus atom displays a pyramidal configuration, lying 82 pm out of the plane of its α-substituents. The smallest angle at phosphorus is between the two TMG substituents [N1−P−N4 93.07(12)°], the angles involving C11 of the triphenylmethyl group are 105.30(12)° (N1−P−C11) and 104.53(12)° (N4−P−C11), respectively. The P−C11 bond [195.8(3) pm] is extremely long.

The hydrogendichloride anion displays dimensions of 145(5) pm (Cl3−H2), 170(5) pm (Cl2−H2), 177(4)° (Cl2−H2−Cl3). The distance between Cl2 and Cl3 is 315.5(1) pm. The other counterion is a chloride ion, which forms hydrogen bonds to both N−H groups; the Cl···H distances are 247(4) pm (Cl1···H1) and 237(4) pm (Cl1···H4).

In compound **22** the steric hindrance effect of the organic group was essentially absent, and treatment with excess HCl afforded the chlorinated product **23**, with no P- or N-protonated intermediates being observed (Eq. 11).



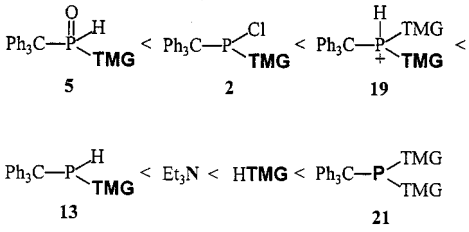
(11)

The ^{31}P-NMR spectrum of the adduct between **22** and $HSbF_6$ also suggested that electrophilic attack on the polar P−N bond led to the phosphonium cation, an intermediate that was stable in combination with weakly nucleophilic anions but not in the presence of chloride ions.

A measure of the relative basicity of compounds **2**, **5**, **13**, and **19** was obtained through the acid-base reactions outlined in Scheme 3.

The basicity of the tritylated compounds increased in the order shown in Figure. 4 (in comparison to HTMG and NEt_3) and, in agreement with this, the acidity of the corresponding acids (**6**, **12**, **20**, **14**, and **19**) increased in the reverse order, as was evident from ^{1}H NMR studies.

Figure 4. The relative basicities of tritylated *N′,N′,N″,N″*-tetramethylguanidino-substituted phosphorus compounds in comparison to NEt_3 and HTMG (**bold print**: main basic centres)



Increasing acidity effects an increasing tendency to proton exchange and influences the observed ^{1}H NMR spectra. Figure. 5 shows the ^{1}H-NMR spectra of **5** observed after interaction with HCl in various ratios (employing the corresponding mixtures of **5** and **6**).

The ^1J(PH) values may be considered as diagnostic of the extent of the protonation of compound **5**, and of the deprotonation of **6**. These values lay between 494 Hz (sharp doublet, compound **5**) and 550 Hz (broad doublet, compound **6**). If the ratio of HCl to **5** was increased to 1:1, HCl_2^- was formed and because of proton exchange processes δ(^{1}H)(P*H*) and ^1J(PH) could not observed. A dynamic phenomenon that can be explained by a fast bond exchange, relative to the NMR time scale, also led to the averaging of the NMR signals in the ^{31}P-NMR spectra and caused the absence of the N*H* proton resonance in the ^{1}H NMR. In contrast, in the ^{31}P-NMR spectra ^1J(PH)-coupling of the phosphorus nuclei of **5** was observed, even in the presence of HCl. The δ(^{31}P) values observed for mixtures of **5** and HCl showed a linear relationship, and ranged between δ = 24.8 (compound **5**) and δ = 27.4 (compound **6**) (Figure. 6).

Scheme 3

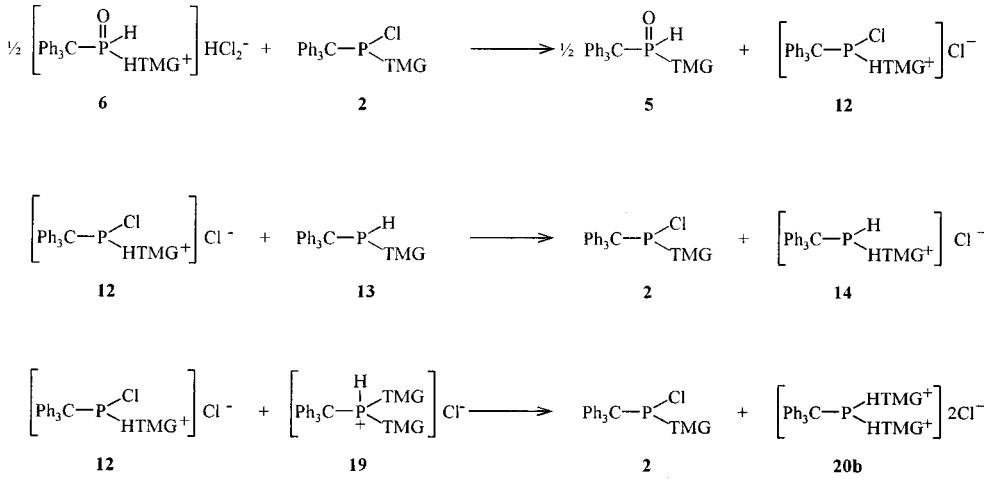


Figure 5. ^{1}H NMR spectra of mixtures of **5** with various ratios of HCl

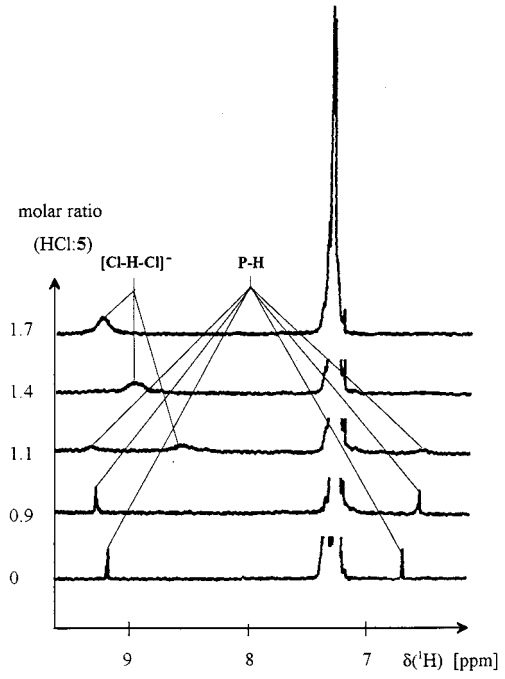

Figure 6. Dependence of $\delta(^{31}P)$ (upper curve) and $^1J(PH)$ (lower curve) of **5** on the degree of protonation at the imino nitrogen atom

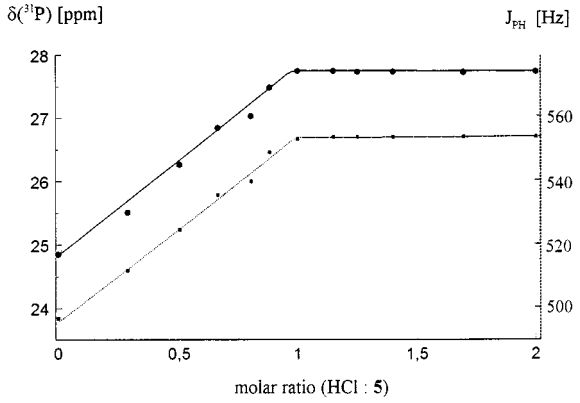


The ^{1}H NMR signal of the HCl_2^- proton moved significantly downfield when the proportion of HCl was increased (broad hump at room temperature).

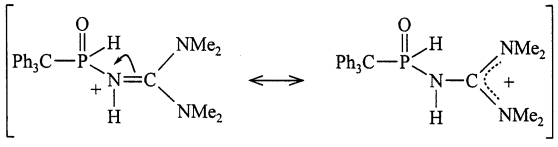
The ^{1}H-NMR spectra of compounds **10**, **11**, and **17** were also influenced by such dynamic phenomena, whereas the NMR spectra of **12** and **14** were more informative, and clear evidence for the presence of hydrogen atoms in both compounds came from ^{1}H-NMR spectra. The increasing basicity in the series led to restricted proton interactions, and the NMR spectra of **12**, **14**, and **20c** exhibited broadened singlets, caused by the protons bonded to the imino nitrogen atoms. Furthermore, in **14** the resonance of the P*H* proton was observed as a broad doublet of doublets, making the accurate determination of $^1J(PH)$ and $^3J(HH)$ impossible. However, the observed value of $J(PH)$ (ca. 235 Hz) is typical of $\sigma^3(P)$ compounds[26], and suggested the structure proposed for **14**.

The restricted proton exchange (as concluded from the ^{1}H-NMR spectra) was also proved by ^{31}P-NMR spectroscopy. Mixtures of compounds **2** and **13** with the corresponding protonated species (**12** and **14**) did not give rise to single averaged peaks. Furthermore, both systems (**2/12**; **13/14**) showed, in contrast to the system **5/6**, separate resonances for the protonated and unprotonated species.

For TMG·HCl, the signals of the $N(CH_3)_2$ protons of all protonated compounds (**6**, **10**, **11**, **12**, **14**, **17**, and **20c**) were shifted downfield, compared to those of the related unprotonated species. All the spectra exhibited sharp singlets, and demonstrated the chemical equivalence of the $N(CH_3)_2$ groups, caused by a three step isomerisation via, a: deprotonation, b: inversion of configuration at the imino nitrogen atom, and c: reprotonation; a mechanism that was reported previously for other TMG-substituted compounds[27][28][29].

In addition to structural parameters (see X-ray studies), the ^{31}P-NMR data also could be used as a sensitive probe to evaluate the electronic structure of the C=N double bond. Surprisingly, the ^{31}P-NMR signals of the protonated $\sigma^3(P)$ species (**12**, **14**, **20c**) were markedly shifted to high field, relative to the corresponding unprotonated compounds (**2**, **13**, **21**). This phenomenon can be rationalized as a consequence of the delocalisation of the positive charge along the $P-N=C(NMe_2)_2$ grouping (Figure. 7).

Figure. 7. Possible charge delocalisation over the TMG moiety (illustrated for molecule **6**)



6

Thus, the ^{31}P-NMR data of the protonated species should generally be comparable to those of the corresponding amino-substituted phosphorus compounds. A compilation of such data is shown in Table 1, supporting this assumption through similar $\delta(^1H)$ values of corresponding N(H)−*t*Bu-substituted phosphorus compounds.

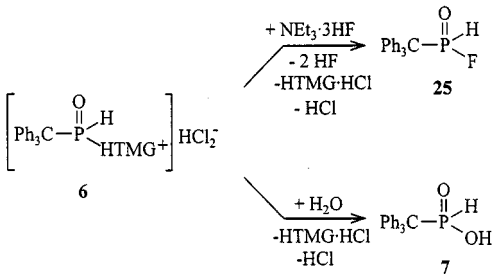
Table 1. $\delta(^{31}P)$ values of unprotonated and protonated tritylated *N′,N′,N″,N‴*-tetramethylguanidino-substituted phosphorus compounds, compared to those of the corresponding *tert*-butyl derivatives

R =	TMG	HTMG⁺	-N(H)t-Bu [30]
$Ph_3C-P(Cl)R$	154.7 ppm **2**	122.1 ppm **12**	129.1 ppm
$Ph_3C-P(=O)(H)R$	24.7 ppm **5**	27.7 ppm **6**	26.3 ppm
$Ph_3C-P(H)R$	33.1 ppm **13**	15.4 ppm **14**	18.7 ppm
Ph_3C-PR_2	114.3 ppm **21**	83.5 ppm **20**	-

The observation that the resonance of the phosphorus atom in **17** was shifted downfield, in the direction of the unprotonated precursor **16**, cannot be explained. Compounds **19** and **24** were characterized from their ^1J(PH) values, which were typical of σ^4(P) compounds[26].

Reactivity of Protonated Compounds

Because of the protonation at the imino nitrogen atom of aminosubstituted trityl-phosphane compounds, the phosphorus becomes more electrophilic and thus more susceptible to nucleophilic attack (e.g. by H_2O). In agreement with this it has been found that the chemical behaviour of protonated species is similar to that of the corresponding halogenated compounds. Thus **6** reacted slowly with H_2O, forming triphenylmethylphosphonous acid **7** (Eq. 12), whereas hydrolysis of the unprotonated compound **5** was not observed.



(12)

However, the sensitivity to nucleophilic attack at the protonated P−N bond of these species appeared to be lower than at the P−Cl bond, because hydrolysis of **12** initially led to the displacement of the chlorine atom (Scheme 1).

The bis(TMG)-substituted phosphorus compound **19** was attacked by H_2O to a lesser extent, forming **6** and additional phosphorus compounds that could not be characterized (decomposition of **19** after 7d at room temperature in dichloromethane and excess H_2O: ca. 10%). Unexpectedly, **20c** was soluble in water, and showed no conversion to the expected compounds (**6** or **7**, and HTMG · HCl). This must be due to steric congestion.

On changing the counterion to F^-, the displacement of $HTMG^+$ took place rapidly. For instance, the reaction of **6** with $NEt_3 \cdot 3$ HF in a 1:1 molar ratio spontaneously led to triphenylmethylphosphonous fluoride **25** (Eq. 12), providing an alternative convenient synthesis to that reported previously[19].

We are grateful to *BASF AG, Bayer AG* and *Hoechst AG* for generous supplies of chemicals used in this research, and to *Fonds der Chemischen Industrie* for financial assistance.

Experimental Section

All experiments were carried out with exclusion of air and moisture; solvents were purified and dried according to the usual methods[31][32]. – NMR spectra were recorded in $CDCl_3$ (unless otherwise noted) at 298 K, using a Bruker AC-200 instrument at 200.1 MHz (^{1}H), 81.3 MHz (^{31}P) and 50.3 MHz (^{13}C) and referenced internally to residual solvent resonances. – Electron impact mass spectra were recorded on solid samples, using a Finnigan MAT 8430 (70 eV) instrument. – Melting points were taken in sealed capillaries and are uncorrected (Instrument: Büchi 510). – IR spectra were recorded on a BIO-RAD IR-165 instrument. – The abbreviation "in vacuo" indicates a pressure of 0.1 mm Hg.

The following compounds were synthesized according to the literature: Ph_3CPCl_2[14], Ph_3CPF_2[19], (*t*Bu)P(=O)(TMG)$_2$[33], Ph_2P(TMG) and MeP(TMG)$_2$[3], Me_3SiTMG[34]. All other compounds were obtained commercially.

Reactions which were investigated solely by ^{31}P-NMR spectroscopy in $CDCl_3$ are not described in the Experimental Section, because the products were synthesized by alternative methods reported in the present work, and also in previous publications.

Chloro Triphenylmethylphosphonous N′,N′,N″,N″-Tetramethylguanidinide (**2**). – *Method A: Reaction of Triphenylmethylphosphonous Dichloride* **1** *with HTMG:* HTMG (1.80 g, 15.64 mmol) was added dropwise with stirring over 10 min at room temperature to a solution of **1** (2.70 g; 7.82 mmol) in 30 ml of dichloromethane. The solvent was evaporated and toluene (50 ml) was added to the residue. The precipitate was filtered off and the solvent from the filtrate was removed in vacuo. The residue was dissolved in 15 ml of dichloromethane and the product was obtained as an amorphous, colourless solid. Yield 2.1 g (63.3%); m.p. 145°C (dec.). – ^{1}H NMR: δ = 2.59 (s, 12 H, N(CH$_3$)$_2$), 7.16−7.37 (m, 15 H, Ph_3C). $C_{24}H_{27}ClN_3P$ (423.92): calcd. C 68.00, H 6.42, N 9.91; found C 67.70, H 6.64, N 9.91.

Method B: From **1** *and* Me_3SiTMG: To a solution of 1.0 g (2.9 mmol) **1** in 7 ml of toluene, 543 mg (2.9 mmol) of Me_3SiTMG was added at room temperature. After 3 h the precipitate was filtered off, washed with 5 ml of diethyl ether and dried in vacuo. Yield 1.03 g (83.9%); m.p. 143°C (dec.).

Triphenylmethylphosphonous N′,N′,N″,N″-Tetramethylguanidinide (**5**): *N′,N′,N″,N″*-Tetramethylguanidine (1.6 g; 13.9 mmol) was added dropwise with stirring over 10 min at room temperature to a solution of **1** (2.40 g, 6.95 mmol) in 40 ml of toluene. To this solution a solution of H_2O (0.5 g; 27.76 mmol) in HTMG (0.8 g; 6.95 mmol) was added with stirring at 0°C during 30 min. The reaction mixture was allowed to reach room temperature and the precipitate was filtered off. The solvent was removed from the filtrate in vacuo, and the product was left as a colourless solid. Yield 2.4 g (85.1%); m.p. 175°C (dec.). – ^{1}H NMR: δ = 2.61 [s, 12 H, N(CH$_3$)$_2$], 7.18−7.35 (m, 15 H, Ph_3C), 7.92 [d, ^1J(PH) = 493.7 Hz, 1 H, PH]. – ^{13}C NMR: δ = 39.73 (s, CH$_3$), 62.96 [d, ^1J(PC) = 90.7 Hz, Ph_3C], 143.25 [d, ^2J(PC) = 3.1 Hz, C_6H_5], 130.73 [d, ^3J(PC) = 6.5 Hz, C_6H_5], 127.88 (s, C_6H_5), 126.45 [d, ^5J(PC) = 2.0 Hz, C_6H_5], 162.58 (s, C=N). – ^{31}P NMR: δ = 24.8 (s). – IR (KBr): ν = 1339 (P=O), 2307 (P−H). – $C_{24}H_{28}N_3OP$ (405.48): calcd. C 71.09, H 6.96, N 10.36; found C 70.53, H 6.91, N 10.04.

[Triphenylmethylphosphonous N′,N′,N″,N″-Tetramethylguanidinide] · 2 HCl (**6**): To a solution of $Ph_3CPH(O)$TMG **5** (1.01 g; 2.5 mmol) in 10 ml of toluene were added at room temperature 3 equivalents of HCl (7.5 ml of a 1 M solution in diethyl ether; 7.5 mmol HCl). The precipitate was filtered off and the product was obtained as a colourless solid. Yield 1.12 g (95.6%); m.p. 220°C (dec.). – ^{1}H NMR: δ = 2.88 [s, 12 H, N(CH$_3$)$_2$], 7.13−7.32 (m, 15 H, Ph_3C), 9.58 (s, 1 H, HCl_2^-), no resonances for P*H* and N*H* were observed. – ^{13}C NMR: δ = 41.65 (s, CH$_3$), 63.32 [d, ^1J(PC) = 77.7 Hz, Ph_3C], 139.12 [d, ^2J(PC) = 2.4 Hz, C_6H_5], 130.38 [d, ^3J(PC) = 7.3 Hz, C_6H_5], 129.02 (s, C_6H_5), 128.04 [d, ^5J(PC) = 2.6 Hz, C_6H_5], 159.65 (s, C=N). – ^{31}P NMR: δ = 27.7 (s). – IR (KBr): ν = 1291 (P=O), 2340 (P−H). – $C_{24}H_{30}Cl_2N_3OP$ (478.40): calcd. C 60.25, H 6.32, N 8.78; found C 60.33, H 6.21, N 8.82.

6 (*Preparation of Crystals*): A solution of $Ph_3CPH(=O)$TMG **5** (1.01 g; 2.5 mmol) in 10 ml of toluene was combined with a solu-

tion of 2 equivalents of HCl (5.0 ml; 5 mmol HCl of a 1 M solution in diethyl ether) in toluene (20 ml). After 4 d the resulting colourless crystals were filtered off. Yield 1.15 g (98.1%).

Decomposition of **6**; *Formation of* **1** *and* **7**: A solution of **5** (1.0 g; 2.5 mmol) in toluene (20 ml) was treated with gaseous hydrogen chloride for (ca.) 2 min but the precipitate (**6**) formed instantaneously was found to be dissolved again after prolonged action of HCl. This solution was heated in a sealed tube for 18 h at 80°C. The solvent was removed in vacuo and the products were characterized by ^{31}P NMR spectroscopy. The data were identical to those of **1** and **7**[19].

[tert-Butylphosphonic Bis(N′,N′,N′′,N′′-tetramethylguanidinide)] · 2 HCl (**10**): Addition of 2 equivalents of HCl (4.52 ml of a 1 M solution in diethyl ether; 4.52 mmol) to a stirred solution of **9** (0.75 g; 2.26 mmol) in toluene (20 ml) at room temperature resulted in a yellow oil. After decanting the solvent the oil was washed with n-hexane (2× 10 ml), was dried in vacuo and **10** was obtained as a colourless solid. Yield 0.89 g (97.3%); m.p. 79°C (dec.). − ^{1}H NMR: δ = 1.42 [d, ^3J(PH) = 18.72, 9 H, PC(CH$_3$)$_3$], 3.21 [s, 24 H, N(CH$_3$)$_2$], no resonance for N(*H*)=C< was observed. − ^{31}P NMR: δ = 31.70 (s). − FAB-MS chemical ionization with nitrobenzyl alcohol (= NBA)]: positive *m/z* (%): 666 (2) [(*t*BuP(=O)(TMG)$_2$·H)$_2$]$^+$, 333 (78) [*t*BuP(=O)(TMG)$_2$·H]$^+$, 218 (100) [*t*BuP(=O)TMG]$^+$, 71 (12) [HNCNMe$_2$]$^+$; negative (*m/z*) (%): 188 (100) [Cl$^-$·NBA]$^-$. − IR (KBr): ν = 1253 (P=O). − $C_{14}H_{35}Cl_2N_6OP$ (405.35): calcd. C 41.48, H 8.70, N 20.73; found: C 41.60, H 8.73, N 20.46.

tert-Butylphosphonic Bis(N′,N′,N′′,N′′-tetramethylguanidinide)] · (p-Tol)SO$_3$H (**11**): A solution of a mixture of **9** (0.45 g; 1.35 mmol) and *p*-toluenesulphonic acid (0.25g; 1.31 mmol) in 10 ml of toluene was stirred at room temperature for 16 h. The oily precipitate formed was separated from the solvent and after washing with n-hexane (two 5 ml portions) **11** was obtained as a colourless solid. Yield 0.62 g (94.5%); m.p. 135°C (dec.). − ^{1}H NMR: δ = 1.23 [d, ^3J(PH) = 16.85, 9 H, PC(CH$_3$)$_3$], 2.31 (s, 12 H, *Me*C$_6$H$_4$SO$_3^-$), 2.98 [s, 12 H, N(CH$_3$)$_2$], 7.10/7.74 [m (AA′XX′), 4 H, MeC$_6$*H*$_4$SO$_3^-$]. − ^{31}P NMR: δ = 20.28 (s). − FAB-MS (NBA): positive *m/z* (%): 333 (86) [*t*BuP(=O)(TMG)$_2$·H]$^+$, 218 (100) *t*BuP(=O)TMG]$^+$, 71 (14) [HNCNMe$_2$]$^+$; negative (*m/z*) (%): 324 (16) [MeC$_6$H$_4$SO$_3$·NBA]$^-$, 171 (100) [MeC$_6$H$_4$SO$_3$]$^-$. − $C_{21}H_{37}N_6O_4PS$ (500.60): calcd. C 50.39, H 7.45, N 16.79, S 6.40; found: C 50.02, H 8.07, N 16.53, S 6.21.

[Chloro Triphenylmethylphosphonous N′,N′,N′′,N′′-Tetramethylguanidinide] · HCl (**12**): − *Method A : Treatment of* **5** *with Phosgene:* A solution of C(=O)Cl$_2$ (0.27 g; 2.7 mmol) in toluene (1.4 ml) was added to a solution of **5** (1.1 g; 2.7 mmol) in toluene (20 ml) at room temperature. After 10 min the evolution of CO_2 had ceased, and the solid product was separated and washed with diethyl ether (10 ml). The product was dried in vacuo and the product was obtained as an amorphous solid. Yield 1.0 g (80.0%); m.p. 168°C (dec.). − ^{1}H NMR: δ = 2.95 [s, 12 H, N(CH$_3$)$_2$], 7.13−7.41 (m, 15 H, Ph$_3$C), 7.85 (s, 1 H, NH$^-$). − $C_{24}H_{28}Cl_2N_3P$ (460.4): calcd. C 62.61, H 6.13, N 9.13; found: C 62.80, H 6.29, N 8.94.

Method B: Treatment of **2** *with HCl:* To a solution of **2** (1.0 g, 2.36 mmol) in 10 ml of toluene was added at room temperature 1 equivalent of HCl (2.36 ml of a 1 M solution in diethyl ether; 2.36 mmol HCl). After 5 min the colourless precipitate of **12** was collected by filtration, washed with diethyl ether (5 ml), and dried in vacuo. Yield 1.0 g (91.7%), m.p. 167°C (dec.).

Method C: Via Hydrolysis of **2**: To a solution of **2** (1.0 g; 2.36 mmol) in 10 ml of toluene were added at room temperature 0.5 equivalents of H_2O (21 mg; 1.18 mmol). After 15 min the colourless precipitate of **12** was collected by filtration, washed with diethyl ether (5 ml), and dried in vacuo. Yield 0.48 g (88.4%), m.p. 166°C (dec.).

Triphenylmethylphosphonous N′,N′,N′′,N′′-Tetramethylguanidinide (**13**): To a solution of 1.3 g (3.1 mmol) of **2** in 20 ml of diethyl ether 0.2 g (5.3 mmol) of LiAlH$_4$ were added at 0°C with stirring. The mixture was allowed to warm up to room temperature and stirring was continued for another hour. The reaction was quenched by addition of water (20 ml), using a water bath for cooling. The precipitate was filtered off and the solvent was removed from the filtrate in vacuo. To the residue 10 ml of diethyl ether was added and the product was obtained as a colourless amorphous substance, containing small amounts of Ph$_3$CH (4%), on cooling this solution to −20°C. Yield 0.81 g (67.8%); m.p. 118°C (dec.). − ^{1}H NMR: δ = 2.55 [s, 12 H, N(CH$_3$)$_2$], 7.25 (s, 15 H, Ph$_3$C), 5.67 (d, ^1J(PH) = 188.4 Hz, 1 H, PH).

[Triphenylmethylphosphonous N′,N′,N′′,N′′-Tetramethylguanidinide]·2 HCl (**14**): To a solution of Ph$_3$CPH(TMG) **13** (0.6 g; 1.5 mmol) in 10 ml of toluene were added at room temperature 3 equivalents of HCl (4.5 ml of a 1 M solution in diethyl ether; 4.5 mmol HCl). The precipitate was filtered off and the product was obtained as a colourless solid. Yield 0.51 g (71.6%); m.p. 145°C (dec.). − ^{1}H NMR: δ = 2.84 [s, 12 H, N(CH$_3$)$_2$], 7.09−7.43 (m, 15 H, Ph$_3$C), 5.81 [dd, 1 H, J(PH) = 235.6 Hz, J(HH) = 4.6 Hz, P-H], 7.99 (m, 1 H, NH), 10.60 (s, 1 H, HCl$_2^-$). − $C_{24}H_{30}Cl_2N_3P$ (462.4): calcd. C 62.34, H 6.54, N 9.08; found C 62.49, H 6.52, N 8.96.

Decomposition of **14**: A 60 mg (0.13 mmol) sample of **14** was dissolved in CDCl$_3$ (0.5 ml) and placed into a 5-mm NMR tube, capped with a rubber septum. The decomposition was monitored by ^{31}P NMR; it was complete after 18 h. Product **15** was characterized by comparison of its ^{1}H and ^{31}P NMR data to those of an authentic sample[30].

[Diphenylphosphinous N′,N′,N′′,N′′-Tetramethylguanidinide] · HCl (**17**): A solution of **16** (0.61 g; 2.01 mmol) in toluene (30 ml) was treated with gaseous hydrogen chloride until precipitation of a colourless solid commenced. The solid product was separated by filtration and investigated by ^{31}P- and ^{1}H-NMR spectroscopy. The spectra indicated a mixture of **17** and HTMG·HCl. In the ^{31}P-NMR spectrum of the filtrate a signal was observed which was due to Ph$_2$PCl [δ(^{31}P) in C$_6$D$_6$ = 82.2[35]]. − ^{1}H NMR: δ = 2.98 [s, 12 H, N(CH$_3$)$_2$], 7.12−7.79 (m, 5 H, C$_6$H$_5$); no resonance for N(*H*)=C< was observed. − ^{31}P NMR: δ = 41.2 (s).

Bis(N′,N′,N′′,N′′-tetramethylguanidino) Triphenylmethyl Phosphonium Chloride (**19**): *N′,N′,N′′,N′′*-Tetramethylguanidine (2.0 g; 17.4 mmol) was added dropwise with stirring over 10 min at room temperature to a solution of **1** (2.0 g, 5.80 mmol) in 20 ml of dichloromethane. After stirring for 0.5h at room temperature the reaction mixture was washed with water (10 ml) and was cooled to 0°C. The dichloromethane layer was separated from the mixture and dried over Na$_2$SO$_4$ (5.0 g). The solvent was removed in vacuo, and the residue was washed with 10 ml of diethyl ether, resulting in a colourless, amorphous substance. Yield 1.59 g (50.9%); m.p. 146°C (dec.). − ^{1}H NMR: δ = 2.70 [s, 24 H, N(CH$_3$)$_2$], 7.05−7.25 (m, 15 H, Ph$_3$C), 8.23 [d, ^1J(PH) = 471.5 Hz, 1 H, PH]. − ^{31}P NMR: δ = 5.1. − $C_{29}H_{40}ClN_6P$ (539.1): calcd. C 64.61, H 7.48, N 15.59; found C 62.19, H 7.63, N 14.24.

[Triphenylmethylphosphonous Bis(N′,N′,N′′,N′′-tetramethylguanidinide)] · 3 HCl (**20c**): To a solution of [Ph$_3$CPH-(TMG)$_2$]$^+$Cl$^-$ (**19**) (0.5 g; 0.93 mmol) in 10 ml of dichloromethane were added at room temperature 3 equivalents of HCl (2.8 ml of a

1 M solution in diethyl ether; 2.79 mmol HCl). After leaving the resulting solution at room temperature for 18 h the product was obtained as colourless crystals. Yield 0.55 g (84.8%); m.p. 146°C (dec.). – ^{1}H NMR: δ = 2.92 [s, 24 H, $N(CH_3)_2$], 7.06–7.41 (m, 15 H, Ph_3C), 8.55 (s, 2 H, NH), 12.2 (s, 1 H, HCl_2^-). – ^{31}P NMR [a striking solvent effect on δ(^{31}P) was noted]: δ ($CDCl_3$) = 83.5, δ (D_2O) = 61.4, δ (CD_3OD) = 72.5. – $C_{29}H_{42}Cl_3N_6P \cdot CH_2Cl_2$ (696.96): calcd. C 51.70, H 6.36, N 12.06; found C 52.96, H 6.55, N 12.65.

Attempted Preparation of [Methylphosphonous Bis(N′,N′,N″,N″-tetramethylguanidinide)] · 4 HCl; Formation of Methylphosphonous Dichloride (**23**): The reaction was carried out in a manner similar to that for **17**, using $MeP(TMG)_2$ (0.5 g; 1.82 mmol) in toluene (30 ml). The ^{31}P-NMR spectrum of the filtrate exhibited one signal only, which was due to **23** [δ(^{31}P) in C_6D_6 = 191.2][36].

Methyl Bis(N′,N′,N″,N″-tetramethylguanidino)phosphonium Hexafluoroantimonate (**24**): Addition of $HSbF_6$ (0.50 g, 2.11 mmol) to a stirred solution of **22** (0.54 g; 1.97 mmol) in n-hexane (10 ml) at room temperature resulted in a colourless oil. After removal of the solvent, the oil was redissolved in dichloromethane (5 ml) and reprecipitated by addition of *n*-hexane (10 ml). This process was repeated twice, giving only a mixture of **24** and $HSbF_6$. – ^{1}H NMR: δ = 0.81 (s, br, 3 H, PCH_3), 2.61 [s, br, 24 H, $N(CH_3)_2$], 6.82 [d, 1 H, J(PH) = 483 Hz, PH]. – ^{31}P NMR: δ = 17.43 (s).

Attempted Preparation of [Triphenylmethylphosphonous N′,N′,N″,N″-Tetramethylguanidinide] · 2 HF; Formation of Triphenylmethylphosphonous Fluoride (**25**): $Et_3N \cdot 3$ HF (337 mg; 2.1 mmol) was added dropwise with stirring over 2 min at room temperature to a solution of **6** (1.0 g, 2.1 mmol) in 10 ml of dichloromethane. The solvent was evaporated in vacuo, and toluene (20 ml) was added to the residue. The precipitate was filtered off and the solvent from the filtrate was removed in vacuo. The product was obtained as an amorphous, colourless solid. Yield 0.6 g (92.5%); m.p. 159°C (dec.)[19].

Determination of Crystal Structures – Data Collection and Reduction: Crystals were mounted on glass fibres in inert oil and transferred to the cold gas stream of the diffractometer (Stoe STADI-4 for **5** and **20c**, Siemens P4 for **6**, both with LT-2 low temperature attachment). The cell constants for **5** and **20c** were refined from ±ω angles of 52 reflections in the 2θ range 20–23°. The orientation matrix for **6** was refined from setting angles of 62 reflections in the 2θ range 5–25° (monochromated Mo-K_α radiation).

Structure Solution and Refinement: The structures were solved by direct methods and refined anisotropically on F^2 (program system: SHELXL-93, G.M.Sheldrick, University of Göttingen). H atoms were included using a riding model or rigid methyl groups, except for P–H, N–H and Cl–H hydrogens, which were refined freely. Weighting schemes of the form $w^{-1} = [\sigma^2(F_o^2) + (aP)^2 + bP]$ were employed, with $P = (F_o^2+2F_c^2)/3$. Full details of the crystal structure determinations (except structure factors) have been deposited under the number 100815 at the Cambridge Crystallographic Data Centre. Copies may be obtained free of charge from: The Director, CCDC, 12 Union Road, GB-Cambridge CB2 1EZ [Telefax: Int. +44 (0)1223/336–033; E-mail: fileserv@chemcrys.cam.ac.uk.]

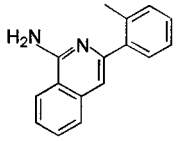
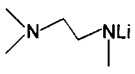
Keywords: Isoquinoline / Lithium / Self-condensation / Solid-state structure / Solution structure

The product of reaction between *ortho*-methylbenzonitrile (*o*-MeC_6H_4CN) and lithium *N,N,N′*-trimethylethylenediamide [$LiN(Me)(CH_2)_2NMe_2$], the 1:1 complex 1-lithioamido-3-(2-methylphenyl)isoquinoline–*N,N,N′*-trimethylethylenediamine (**1**-Li·HTriMEDA), has a solid-state structure which shows a new type of $(NCNLi)_2$ core and a solution structure in which the coordination mode of the diamine by-product varies with temperature.

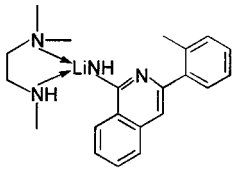
The reactions of organolithium reagents with benzonitrile have long been known to induce cyclotrimerisation[1] to yield, amongst other products, fully unsaturated 2,4,6-triphenyl-1,3,5-triazine[2] by 1,4-elimination of organolithium from a lithio-1,4-dihydrotriazine precursor. More recently, we reported a nitrile addition product, an imidolithium species of the type which probably acts as an initial intermediate in the cyclisation reaction[3]. Given this latter result, we sought to investigate the reactions of organolithium reagents with *ortho*-methylbenzonitrile, for which addition across the nitrile triple bond is known to be in competition with *ortho* lithiation[4]. It has also been reported[5] for this system that a nitrile self-condensation product, a substituted 1-aminoisoquinoline (**1**-H), can result in various yields (2−80%) depending on the organolithium reagent employed and on the reaction conditions.



1-H



LiTriMEDA



1-Li·HTriMEDA

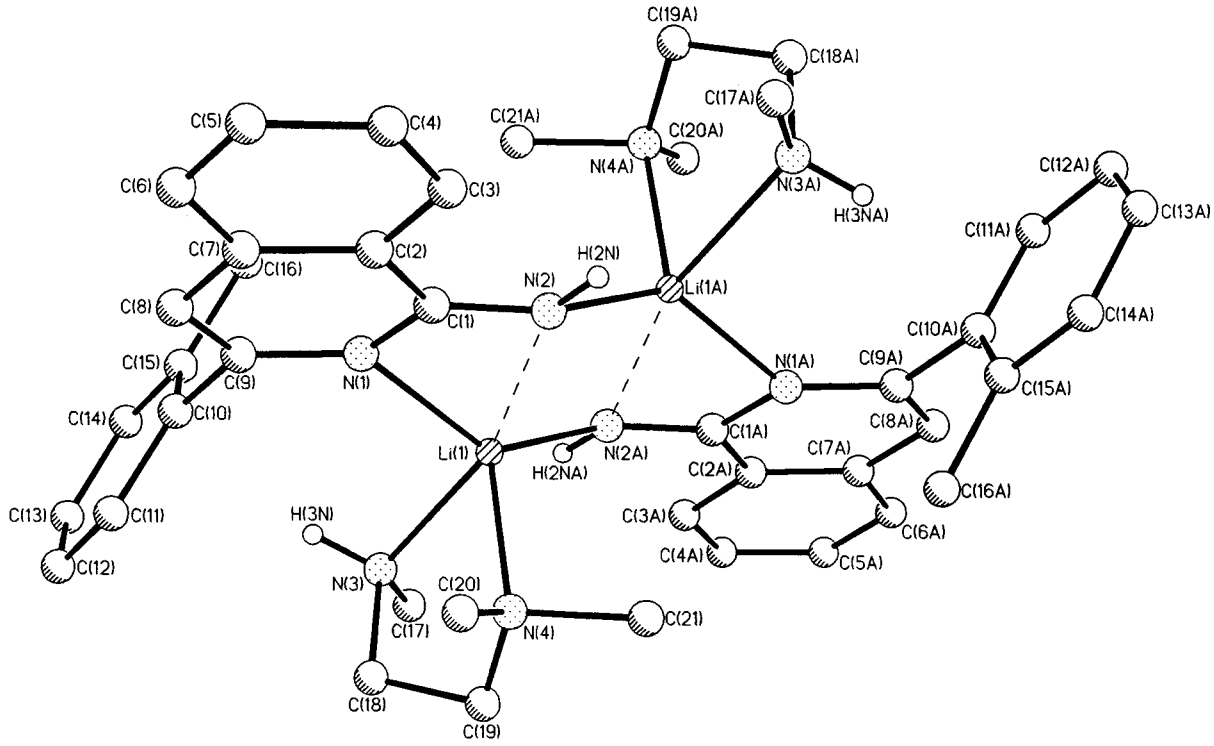
The reaction of lithium *N,N,N′*-trimethylethylenediamide (LiTriMEDA) with *o*-methylbenzonitrile in toluene at −78°C affords a red solution which becomes yellow at room temperature. Addition of hexane and storage at ambient temperature overnight yields orange crystals identified as the 1:1 complex, 1-lithioamido-3-(2-methylphenyl)isoquinoline−*N,N,N′*-trimethylethylenediamine (**1**-Li·HTriMEDA). X-ray crystallography shows that in the solid state **1**-Li·HTriMEDA is a transoid dimer (Figure 1), in which the primary amidolithium centre[6] in the self-assembled 1-lithioamidoisoquinolino moiety is chelated by the concomitantly formed secondary amine. This dimer demonstrates several unusual structural features. At first sight it appears to incorporate a straightforward four-membered Li(1)−N(2)−Li(1A)−N(2A) ring at its core, with further stabilisation of the metal being afforded by isoquinoline N centre donation to lithium. However, closer inspection reveals that, within the supposed four-membered ring, two of the N−Li distances are short [Li(1A)−N(2) 2.055(6) A] while the other two are unusually long [Li(1)−N(2) 2.394(7) A]. It seems, therefore, to be the relatively short (isoquinoline)N−Li interactions [N(1)−Li(1) 2.081(6) A] which are mainly responsible for dimerisation. Consequently, the central unit of the structure is best viewed as being an eight-membered [(isoquinoline)N−C−(amido)N−Li]$_2$ ring resulting from inter-monomer (isoquinoline)N−Li interactions, with very weak (amido)N−Li cross-ring interactions. A search of the Cambridge Crystallographic Database locates only two examples of eight-membered $(NCNLi)_2$ rings[7], neither of which shows any cross-ring interactions whatsoever. Thus the structure of **1**-Li·HTriMEDA, containing as it does partial cross-ring contacts, is unique. The coordination sphere of each metal centre is completed by chelation of the HTriMEDA ligands which, unusually, have also been formed during the reaction. While at 2.130(7) A the Li(1)−N(4) bond is of a length normal for such an interaction, the Li(1)−N(3) bond is, at 2.358(7) A, surprisingly long. Alkali metal complexes containing protic amine bases are not common, and those which are known have generally been synthesised by allowing an organolithium compound to react with an excess of amine[8], by having the amine ligand present in a 1:1 reaction between a lithiating agent and a (more acidic) organic substrate, or by adding the amine after the lithiation reaction

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0707−0879 $ 17.50+.50/0

is complete. Indeed, the last method has been used to give enolatolithium and amidolithium complexes containing HTriMEDA itself[9]. In both of these cases diamine chelation of the metal centre was accompanied by a hydrogen bonding interaction involving the acidic proton of HTriMEDA. While in $[H_2C{=}C(NMe_2)OLi{\cdot}HTriMEDA]_2$ the interaction was directed towards the enamine N-centre, in $[H_2C{=}C(t\text{Bu})OLi{\cdot}HTriMEDA]_2$ it was directed towards the enolato π system [N−H···C distances 2.62 and 2.73 A]. This last structural feature pinpoints a final interesting facet of the structure of **1**-Li·HTriMEDA in that here a somewhat analogous, but rather stronger, interaction is observed. The N(3)−H(3N) bond points approximately at the *centre* of the 3-(2-methylphenyl) ring [H(3N)···ring centroid 2.440 A, N(3)−H(3N)−ring centroid 172.3°]. This interaction appears to account for the massive N(1)C(9)C(10)C(11) torsional angle of 114.3°. However, it is also noticeable that in $[H_2C{=}C(t\text{Bu})OLi{\cdot}HTriMEDA]_2$, where the hydrogen bonding interaction is somewhat weaker than in **1**-Li·HTriMEDA, bonds between the lithium centre and the chelating diamine are essentially equivalent and, at 2.11(1) and 2.09(1) A[9], of lengths typical for such interactions. It seems, therefore, that the relative strength of the hydrogen bond in **1**-Li·HTriMEDA is the most likely reason for the surprising length of the Li(1)−N(3) interaction.

o-methylbenzonitrile in THF/HMPA [HMPA = $O{=}P(NMe_2)_3$] at −78°C afforded predominantly *o*-lithiomethylbenzonitrile, **1**-H was best synthesised by the 1:1 reaction of Me_2NLi with the nitrile in THF/HMPA at −78°C, subsequent addition of a second equivalent of nitrile and heating at 60°C for 1 hour resulting, after workup, in the high yield formation (80%) of **1**-H. In this current work, a 2:2 reaction of LiTriMEDA with *o*-methylbenzonitrile affords **1**-Li·HTriMEDA, the immediate precursor to **1**-H, essentially quantitatively (first batch yield of crystals 90%, with respect to nitrile) in non-donor media (toluene) at ambient or sub-ambient temperature. The yield of the complex, with respect to nitrile, is unaffected if the correct stoichiometry (2:1 nitrile/LiTriMEDA) is used. It is logical, therefore, that the initial 1:1 reaction, which yields either an imidolithium (**2a**, which rapidly isomerises to *o*-lithiated imine **2b**) or, more probably, a complexed *o*-lithiated nitrile (**2c**) (Scheme 1) is *slow* relative to subsequent insertion of the second equivalent of *o*-methylbenzonitrile (yielding **3b/c**). Presumably ring closure by **3b/c** yields **4b/c** which, in turn, gives the title complex via a simple rearrangement (accompanied by elimination of HTriMEDA in the case of **4b**). It is presently impossible to say whether the first stage of the reaction is addition/isomerisation or *o*-lithiation, although it has been observed that in the presence of benzonitrile, LiTriMEDA readily gives an extremely stable addition product[3].

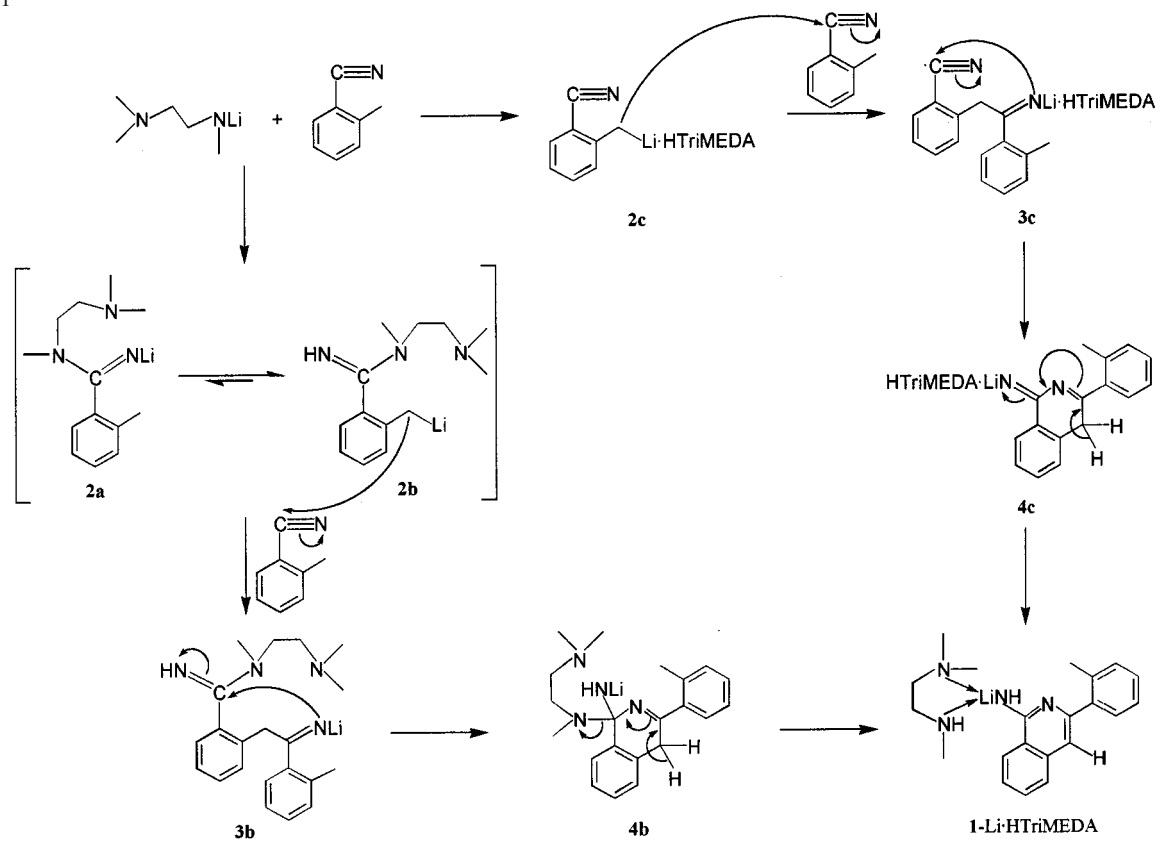
Figure 1. Structure of dimeric **1**-Li·HTriMEDA; hydrogen atoms (except the primary amidolithium and secondary amine hydrogen atoms) have been omitted for clarity; the symmetry operation which relates original atoms to their "A" equivalents is $-x+1, -y+1, -z+1$



Although the self-condensation reaction of two equivalents of *o*-methylbenzonitrile in the presence of one equivalent of certain lithium reagents has been reported earlier[5], no lithiated intermediates have been isolated previously. Given the finding[4] that the reaction of Me_2NLi with

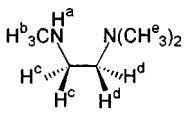
A solution of **1**-Li·HTriMEDA (12.0 mg ml^{-1} in $[D_6]$benzene) yields a ^{1}H-NMR spectrum in which, unusually, extensive coupling is observed through the secondary amine

Scheme 1



N centre. Consequently, therefore, the $H_3C(H)NCH_2$ triplet at δ = 2.46 ($^3J_{H\text{-}(C)H}$ = 5.46 Hz) is split into two ($^3J_{H\text{-}(N)H}$ = 6.64 Hz) and the $H_3C(H)N$ resonance at δ = 2.26 is a doublet ($^3J_{H\text{-}(N)H}$ = 6.43 Hz); irradiation of the $H_3C(H)N$ multiplet at δ = 0.93 causes these signals to appear as a triplet and singlet respectively. At the same concentration, ^{1}H-NMR spectroscopy in [D_8]toluene indicates that as a function of temperature there is a significant change in the behaviour of the HTriMEDA with respect to the metal centre. It appears either to change from (i) free base to mono- or bidentate coordinated ligand or (ii) monodentate ligand to bidentate chelate of the lithium centre. This is suggested by the observation that while at 60°C the HTriMEDA methylene protons bonded to either N centre (Table 1, H^c and H^d) demonstrate chemical shifts downfield of the (same species) *N*-methyl protons (H^b and H^e) bonded to *the same N-centre* [i. e. δ(H^c) > δ(H^b) and δ(H^d) > δ(H^e)], as the temperature is lowered so the former protons drift to positions *upfield* relative to their methyl counterparts [i. e. δ(H^b) > δ(H^c) and δ(H^e) > δ(H^d)]. This observation is consistent with the known behaviour of free and complexed TMEDA [$(H_3C)_2N(CH_2)_2N(CH_3)_2$][10], and indeed a comparison of the spectra of **1**-Li·HTriMEDA with those of pure HTriMEDA in toluene suggests that it is only in the range 25−60°C that the base is essentially free. Moreover, extensive coordination of the metal centres by HTriMEDA at low temperature is suggested by variable-temperature ^{7}Li-NMR spectroscopy. In toluene the dominant lithium

Table 1. ^{1}H-NMR data for the secondary amine ligand in **1**-Li·HTriMEDA in [D_8]toluene over the range 60°C to −80°C; (−) indicates that the signal was not observable at that temperature; the H^a signal was obscured by that of H^e at low temperature while those of H^b and H^c were obscured by the [D_8]toluene resonance



Temp. [°C]	δ [ppm]				
	H^a	H^b	H^c	H^d	H^e
60	0.84	2.26	2.46	2.20	2.03
40	0.91	2.25	2.42	2.18	2.01
25	1.10	2.17	2.29	2.03	1.93
0	1.41	−	−	1.87	1.84
−25	−	−	2.05	1.72	1.76
−50	−	−	1.95	1.61	1.71
−80	−	−	1.90	1.48	1.65

Table 2. Cryoscopic data for **1**-Li·HTriMEDA in benzene over the concentration range 2.0−15.4 mg ml^{-1}

Conc. [mg ml^{-1}]	Av. mol. mass (±5)	*n* (±0.1)
2.0	274	0.8
3.9	305	0.9
7.0	349	1.0
10.3	386	1.1
15.4	413	1.2

environment moves from δ = 1.79 (at 60°C) to δ = 1.43 (at 25°C) to δ = 0.90 (at 0°C) and finally to δ = 0.53 (at −80°C). Clarification comes from cryoscopy in benzene. Results suggest (Table 2) that whereas at low concentration (2.0 mg ml^{-1}) HTriMEDA is ostensibly free in solution, at higher concentrations (ca. 10−15 mg ml^{-1}) the secondary amine and metal centre interact. This clearly suggests, given the evidence from NMR spectroscopy, that at these higher concentrations **1**-Li·HTriMEDA dissolves in non-donor solvents to give a species in which, at or about cryoscopy temperature (5°C), the secondary amine acts as a *monodentate* ligand, probably [judging from the relative Li(1)−N(3) and Li(1)−N(4) distances observed in the solid-state structure] through its $(H_3C)_2N$ centre, and as a *bidentate* one only at much lower temperatures.

The reaction of LiTriMEDA with *o*-methylbenzonitrile clearly demonstrates the significant effect of ring substituents on the chemistry of benzonitriles. The observed condensation reaction is enabled by the contrasting behaviour of LiTriMEDA as either a nucleophile (with benzonitrile)[3] or a base (with *o*-methylbenzontrile)[4], the isolated complex, **1**-Li·HTriMEDA, demonstrating a variety of interesting features in both the solid state and in non-polar solution.

We thank the *U.K. EPSRC* (A.E.H.W) for financial support and Dr. *Basil J. Wakefield* and Dr. *Gregory P. Shields* for useful discussions.

Experimental Section

General: All operations were carried out using standard inert-atmosphere Schlenk techniques with a dual nitrogen/vacuum line. Schlenk tubes were pre-dried at 180°C prior to evacuation to less than 0.1 Torr three times, being filled with dry nitrogen from the house supply between each evacuation. *N,N,N′*-Trimethylethylenediamine and *o*-methylbenzonitrile were used as received from Aldrich Chemical Company and stored over 4 A molecular seive. Toluene (freshly distilled and maintained at reflux over sodium), hexane (freshly distilled and maintained at reflux over sodium-potassium amalgam) and *n*-butyllithium were added directly to the nitrogen-filled Schlenk tube using standard syringe techniques. − NMR spectroscopy: Bruker AM 400 and DRX 400 (400.137 MHz and 155.508 MHz, for ^1H and ^7Li, respectively). For ^1H-NMR spectroscopy, [D_6]benzene and [D_8]toluene as solvents, TMS at 25°C as external standard; for ^7Li-NMR spectroscopy, [D_6]benzene and [D_8]toluene as solvents, PhLi in [D_6]benzene and [D_8]toluene respectively at 25°C as external standards.

N,N,N′-Trimethylethylenediamine (HTriMEDA): ^1H NMR (60°C, 3.6 mg ml^{-1} in [D_8]toluene): δ = 2.52 [t, 2 H, $H_3C(H)NCH_2$, $^3J_{H\text{-}(C)H}$ = 6.01 Hz], 2.32 [s, 3 H, $H_3C(H)N$], 2.27 [t, 2 H, $CH_2N(CH_3)_2$, $^3J_{H\text{-}(C)H}$ = 6.01 Hz], 2.07 [s, 6 H, $N(CH_3)_2$], 0.88 [s, br., 1 H, $H_3C(H)N$]. Spectra at 60, 40, 25, 0, −25, −50, and −80°C showed no significant variation.

1-Lithioamido-3-(2-methylphenyl)isoquinoline−N,N,N′-trimethylethylenediamine (**1**-Li·HTriMEDA): *n*-Butyllithium (1.88 ml, 1.6 M in hexanes, 3.0 mmol) was added to *N,N,N′*-trimethylethylenediamine (0.38 ml, 3.0 mmol) in toluene (2 ml) at −78°C under nitrogen. After stirring for 15 min, *o*-methylbenzonitrile (0.36 ml, 3.0 mmol) was added and the resultant red solution was stirred for a further 15 min at −78°C. Warming to room temp. gave a yellow solution, to which hexane (1 ml) was added. Storage overnight at room temp. afforded orange crystals of **1**-Li·HTriMEDA, yield 90% (with respect to nitrile), m.p. > 300°C. − $C_{21}H_{27}LiN_4$ (342.41): calcd. C 73.68, H 7.89, Li 2.05, N 16.37; found C 73.06, H 7.97, Li 2.00, N 16.07. − ^1H NMR (60°C, 12.0 mg ml^{-1} in [D_6]benzene): δ = 7.50 (d, 1 H, Ar, $^3J_{HH}$ = 8.16 Hz), 7.38 (d, 1 H, Ar, $^3J_{HH}$ = 7.69 Hz), 7.32 (dd, 1 H, Ar, $^3J_{HH}$ = 6.92, 5.94 Hz), 7.14 (dd, 1 H, Ar), 7.07 (br., 1 H, Ar), 6.93 (br., dd, 1 H, Ar), 6.85 (d, 1 H, Ar, $^3J_{HH}$ = 6.66 Hz), 6.69 (br., 1 H, Ar), 6.43 (s, 1 H, Ar), 4.71 (s, br., 1 H, NHLi), 2.46 (dt, 2 H, $H_3C(H)NCH_2$, $^3J_{H\text{-}(C)H}$ = 5.46 Hz, $^3J_{H\text{-}(N)H}$ = 6.64 Hz), 2.26 [d, 3 H, $H_3C(H)N$, $^3J_{H\text{-}(N)H}$ = 6.43 Hz], 2.21 [t, 2 H, $CH_2N(CH_3)_2$, $^3J_{H\text{-}(C)H}$ = 5.97 Hz], 2.03 [s, 6 H, $N(CH_3)_2$], 1.99 (s, br., 3 H, $ArCH_3$), 0.93 [m, br., 1 H, $H_3C(H)N$]. − ^7Li NMR (25°C, 12 mg ml^{-1} in [D_6]benzene): δ = 1.69 (s, 1 Li), 1.38 (s, ca. 13 Li). − ^7Li NMR (25°C, 12 mg ml^{-1} in [D_8]toluene): δ = 1.86 (s, 1 Li), 1.43 (s, ca. 14 Li); (0°C): δ = 1.81 (s, 1 Li), 0.90 (s, ca. 18 Li); (−25°C): δ = 0.78 (s); (−50°C): δ = 0.55 (s); (−80°C): δ = 0.69 (s, 1 Li), 0.53 (s, ca. 11 Li).

X-ray Crystallographic Study of **1**-Li·HTriMEDA: $C_{21}H_{27}LiN_4$, triclinic, space group *P*1, *a* = 10.093(2), *b* = 11.523(4), *c* = 8.700(2) A, α = 93.28(2), β = 100.050(10), γ = 96.97(2)°, *V* = 985.7(5) A^3, M_r = 342.41, *Z* = 2, D_c = 1.154 Mg m^{-3}, μ(Mo-K_α) = 0.069 mm^{-1}, *F*(000) = 368. Data were collected by the ω/2θ scan method on a Rigaku AKC5R four-circle diffractometer at 150(2) K using graphite-monochromated Mo-K_α radiation (λ = 0.71069 A) in the range 5.10 < 2θ < 50.00°, +*h*, ±*k*, ±*l*; 3691 reflections of which 3474 were independent (R_{int} = 0.0391) and used in all calculations. The structure was solved using direct methods[11] and subsequent Fourier difference syntheses and refined[12] by full-matrix least-squares on F^2 with anisotropic thermal parameters for all non-hydrogen atoms. H(2N), H(2NA), H(3N) and H(3NA) were located from the Fourier difference map and their coordinates and isotropic temperature factors were allowed to refine. All other hydrogen atoms were placed in geometrically idealised positions and refined using a riding model or as rigid methyl groups. Methylene groups in the HTriMEDA chelates were disordered over two positions. In the final cycles of refinement a weighting scheme of the form $w^{-1} = [\sigma^2(F_o^2) + (0.0840P)^2 + 0.63P]$, where $P = (F_o^2 + 2F_c^2)/3$, was employed which produced a flat analysis of variance. Final $R(F)$ = 0.0623 for 3462 reflections with $[I > 2\sigma(I)]$, $wR(F^2)$ = 0.1865 for all data; 277 parameters; goodness of fit = 1.165. Maximum peak and hole in final Fourier difference map 0.297 and −0.210 eA^{-3} respectively. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101025. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: (int. code) + 44-1223/336-033, E-mail: deposit@ccdc.cam.ac.uk, www: http://www.ccdc.cam.ac.uk].

Treatment of (1*S*,2*S*)-$C_5H_8(PH_2)_2$ (**1**) with $OC(OCCl_3)_2$ gave (1*S*,2*S*)$C_5H_8(PCl_2)_2$ (**2**) as the first example of an optically active bis(phosphonous dichloride). **2** was converted to (1*S*,2*S*)-$C_5H_8(PX_2)_2$ [PX_2 = $P(OMe)_2$ (**3**), $P(OPh)_2$ (**4**), P[OCH(Me)Et-(*S*)]$_2$ (**5**), P[2-$OC_{10}H_6C_{10}H_6O$-2′-(*R*)] (**6**), $P(NC_4H_8O$-*cyclo*$)_2$ (**7**), $P(C_6H_{11}$-*cyclo*$)_2$ (**8**)] by reactions with oxygen, nitrogen, and carbon nucleophiles.

The design of new chiral phosphanes for use in transition metal-based asymmetric catalysis continues to play an important role in synthetic organic and organometallic chemistry[2]. Our current research in this field has been focused on the development of variable methods of synthesis for chiral bidentate phosphorus ligands with electron-rich and/or electron-poor donor atoms, starting from the resolved enantiomers of chiral bis(primary phosphanes)[3][4]. We herein report the details of a synthetic procedure that allows the facile transformation of (1*S*,2*S*)-cyclopentane-1,2-diyl-bisphosphane, (1*S*,2*S*)-$C_5H_8(PH_2)_2$[3] (**1**), into its PCl_2 homologue (1*S*,2*S*)-$C_5H_8(PCl_2)_2$ (**2**) and present selected examples of how the optically pure multi-purpose P−Cl reagent **2** is easily converted to the 1*S*,2*S* enantiomers of various $C_5H_8(PX_2)_2$ ligands containing sterically and electronically different P−C-, P−N-, or P−O-bonded substituents X on phosphorus.

Results

Formerly, primary phosphanes RPH_2 were reported to produce bis(phosphonous dichlorides) $RPCl_2$ on treatment with chlorine in inert halogenated solvents[5]. These results could not be reproduced, however, in later work where it was shown that both phosphonous and phosphinous chlorides are more readily prepared from a primary or secondary phosphane by oxidizing the P−H bond with $COCl_2$ ("phosgene") rather than with Cl_2[6][7]. Bis(trichloromethyl) carbonate, $OC(OCCl_3)_2$ ("triphosgene"), has served as a convenient crystalline alternative to the highly toxic phosgene in miscellaneous laboratory reactions and its use as an electrophile, dehydrating agent, or specific oxidant in the preparation of many classes of organic compounds has been studied thoroughly during the past decade[8]. We reasoned that triphosgene would also turn out useful as a synthetic auxiliary in the conversion of the easily accessible (1*S*,2*S*)-$C_5H_8(PH_2)_2$[3] (**1**) to the more reactive and, hence, more versatile (1*S*,2*S*)-$C_5H_8(PCl_2)_2$ (**2**). Actually, bis(phosphonous dichloride) **2** formed smoothly when bis(primary phosphane) **1** and $OC(OCCl_3)_2$ where combined in THF at 50°C in 3:4 stoichiometry, as required for the quantitative transformation of the two $-PH_2$ groups into $-PCl_2$ functions. This procedure provided solutions of **2** exhibiting no extraneous signals in their ^{31}P-NMR spectra, from which the pure product was isolated in 66% yield by vacuum distillation.

Compound **2** represents the hitherto only example of an optically active P_2 ligand possessing reactive P−Cl bonds, opening up variable synthetic routes to a wide range of enantiomerically pure electron-rich and electron-poor P−C-, P−N-, and P−O-bonded derivatives (1*S*,2*S*)-$C_5H_8(PX_2)_2$, potentially useful as supporting ligands in asymmetric catalysis. So far, we have prepared bidentates of the former type with PX_2 = $P(OMe)_2$ (**3**), $P(OPh)_2$ (**4**), P[OCH(Me)Et-(*S*)]$_2$ (**5**), P[2-$OC_{10}H_6C_{10}H_6O$-2′-(*R*)] (**6**), $P(NC_4H_8O$-*cyclo*$)_2$ (**7**), and $P(C_6H_{11}$-*cyclo*$)_2$ (**8**) by conventional reactions of **2** with mono- and difunctional alcohols, secondary amines, and Grignard reagents (Scheme 1). The ease of synthesis of ligands **3**−**8**, starting from enantiopure **2**, may be contrasted with, e. g., the previously described tedious preparation of **8**, which involved oxidation of *rac*-$C_5H_8[P(C_6H_{11}$-*cyclo*$)_2]_2$ to *rac*-$C_5H_8[P(O)(C_6H_{11}$-*cyclo*$)_2]_2$, followed by optical resolution of the *P*,*P*′-dioxide with (+)-di-*O*-benzoyl tartaric acid and reduction of the resolved P=O enantiomers in neat diphenylsilane at 150°C[9].

Discussion

The usefulness of the above procedures for the synthesis of optically active P_2 ligands rests on the following features[10]: First, the formation of bis(phosphonous dichlorides) or bis(phosphinous chlorides) by chlorination with triphosgene of bis(primary phosphanes) or bis(secondary phosphanes) can conceivably be performed with any other suitable chiral $H_2P{\cap}PH_2$ or H(R)P∩P(R)H precursor, as will be examplified elsewhere for the correspondent transformations of systems as different as $C_5H_8[P(H)R]_2$[11] and $Fe(C_5H_4PH_2)_2$[12]. Second, substitution reactions undergone by P−Cl functional phosphorus(III) compounds upon treatment with carbon, nitrogen or oxygen nucleophiles are among the most general and most easily accomplished coupling methods in organic chemistry. Finally, the fact that it is possible to incorporate virtually any other P−O-, P−N-, or P−C-bonded residue R into chiral $Cl_2P{\cap}PCl_2$ or Cl(R)P∩P(R)Cl frameworks makes it possible to utilize the method for the preparation of a wide range of optically active P_2 ligands having fine-tunable and, perhaps, rationally designed steric and electronic requirements.

Financial support from the *Deutsche Forschungsgemeinschaft* (Bonn) and the *Fonds der Chemischen Industrie* (Frankfurt/Main) is gratefully acknowledged. We are also indebted to *Hoechst AG* (plant Vlissingen/NL) for a generous gift of P_4.

Experimental Section

All manipulations were performed under nitrogen using standard Schlenk techniques. Solvents were distilled from the appropriate drying agents prior to use. − NMR: Bruker DPX 300 (300.1 MHz for ^1H, 75.5 MHz for ^{13}C, 121.5 MHz for ^{31}P) at ambient temperature with TMS as internal or H_3PO_4 as external standard (downfield positive). − Mass spectra: Jeol MS 700. − Optical rotation: Schmidt & Haensch POLARTRONIC E.

CAUTION: Although at the time of writing this article no conclusive data on the toxicity of triphosgene were available to the authors, the reagent should be handled using similar precautions as for the more dangerous phosgene, even if $OC(OCCl_3)_2$ is safer because of its lower vapor pressure and higher stability[8][13].

(1S,2S)-$C_5H_8(PCl_2)_2$ (**2**): A solution of 23.7 g (80 mmol) of $OC(OCCl_3)_2$ (Aldrich) in 250 ml of THF was added dropwise within 2 h to a stirred solution of 8.1 g (60 mmol) of (1*S*,2*S*)-$C_5H_8(PH_2)_2$[3] in 400 ml of THF, heated to 50°C. The mixture was stirred overnight at 50°C, solvent was then evaporated, and the residue was distilled in the vacuum of an oil pump at 80 to 110°C (pot temperature) to give 10.8 g (66%) of **2** as a colorless liquid. − ^1H NMR (C_6D_6): δ = 1.25 [qui, ^3J(H,H) = 7.1 Hz; 2 H, CH_2-4], 1.60 (m; 4 H, CH_2-3,5), 2.36 (m; 2 H, CH-1,2). − $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 26.9 [t, ^3J(P,C) = 3.1 Hz; C-4], 29.6 [*A*XX′-d, ^2J(P,C) + ^3J(P′,C) = 14.5 Hz; C-3,5], 50.5 [dd, ^1J(P,C) = 51.8, ^2J(P,C) = 13.6 Hz; C-1,2]. − $^{31}P\{^{13}C\}$ NMR (C_6D_6): δ = 188.6 (s). − $[\alpha]_D^{25}$ = −19.8 (neat).

(1S,2S)-$C_5H_8\{P[OCH(Me)Et\text{-}(S)]_2\}_2$ (**5**): At dry-ice temperature, a quantity of 1.95 g (7.1 mmol) of **2**, dissolved in 20 ml of diethyl ether, was added dropwise, within 30 min, to a stirred solution containing 2.65 ml (28.7 mmol) of (*S*)-(+)-butan-2-ol (Aldrich) and 4.0 ml (28.7 mmol) of triethylamine in 200 ml of diethyl ether. Precipitation of $[Et_3NH]Cl$ occurred immediately to give a pasty suspension which was diluted by adding additional quantities of solvent in order to maintain stirring. After warming to room temperature overnight, the mixture was filtered and evaporated to leave bis(phosphinite) **5** as an opaque oil. Occasionally, this material contained impurities which in view of their $^{31}P\{^1H\}$ NMR signals (δ ca. 40−45) were strongly suspected to be onium salts, e. g., $[(1S,2S)\text{-}C_5H_8\{P[OCHC(Me)Et\text{-}(S)]_2\}_2H_n]Cl_n$ (*n* = 1, 2). These could be removed quantitatively by stirring the crudes with excess sodium amide in toluene. Subsequent filtration and evaporation of solvent afforded diastereomerically pure **5** as a colorless liquid (1.37 g; 45%), spectroscopically free from contaminating admixtures. − $^{13}C\{^1H\}$ NMR (C_6D_6): δ = 9.9, 10.1 (both s; both $CH_2\mathit{C}H_3$, pairwise diastereotopic), 22.0, 22.1 (both s; both $CH\mathit{C}H_3$, pairwise diastereotopic), 27.5 [m; $(CH_2)_3$], 31.6, 31.7 (both s; both $\mathit{C}H_2CH_3$, pairwise diastereotopic), 43.5 [dd, *J*(P,C) = 10.8 and 18.0 Hz; PCH], 75.5, 76.6 [both *A*XX′-t, Σ*J*(P,C) = 16.5 Hz; both POCH, pairwise diastereotopic]. − $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 179.6 (s). − MS (FD; toluene, 35 mA, 10 kV): *m*/*z* = 423 [M^+].

(1S,2S)-$C_5H_8\{P[2\text{-}OC_{10}H_6C_{10}H_6O\text{-}2'\text{-}(R)]\}_2$ (**6**) was obtained analogously from 1.78 g (6.5 mmol) of **2** and 3.75 g (13.1 mmol) of (*R*)-(+)-1,1′-bi(2-naphthol) (Aldrich) in 200 ml of diethyl ether containing 3.68 ml (26.4 mmol) of added triethylamine; yield: 3.69 g (81%) of a yellow waxy solid. − $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 21.5 (s; $CH_2\mathit{C}H_2CH_2$), 27.0 [*A*XX′-t, ^2J(P,C) + ^3J(P′,C) = 20.3 Hz; $\mathit{C}H_2CH_2\mathit{C}H_2$], 41.9 [dd, ^1J(P,C) = 38.6, ^2J(P,C) = 17.9 Hz; PCH], 121.4, 122.2, 123.6, 124.7, 125.2, 125.6, 126.5, 126.9, 127.1, 128.5, 128.7, 129.3, 130.1, 130.8, 131.4, 131.7, 133.0, 133.2 (all s; 18 anisochronous aromatic C), 149.5, 150.7 th d, ^2J(P,C) = 6.9 Hz; both POC]. − $^{31}P\{^1H\}$ NMR (C_6D_6): δ = 203.5 (s). − MS (FD; toluene, 35 mA, 10 kV): *m*/*z* = 698 [M^+].

Compounds **3**, **4**, **7**, and **8** were prepared as described previously for the associated racemats[1][9]. As expected, the products exhibited NMR and MS data corresponding in all respects to those reported for the racemic mixtures.

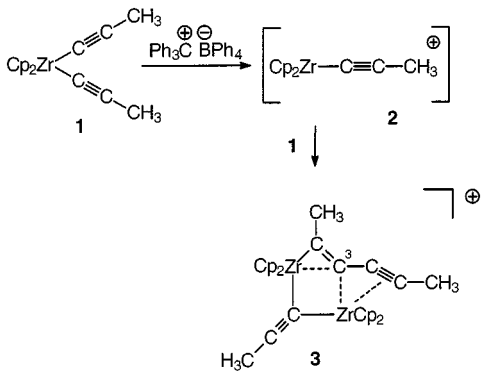
Keywords: Zirconocene / Metallocene cation / Isonitrile insertion / Isonitrile complex

Hydrozirconation of propyne followed by treatment with propynyllithium yields the (σ-propenyl)(σ-propynyl)zirconocene complex **11**. Its treatment with the organometallic Lewis acid $B(C_6F_5)_3$ results in transfer of the σ-propynyl group from zirconium to boron followed by insertion of the alkynylborate triple bond into the zirconium carbon bond of the remaining metallaallyl cation to furnish the zirconocene–(μ-hydrocarbyl)borate betaine complex **14**. This reacts with three molar equivalents of *tert*-butyl isocyanide to give **16**. Complex **16** contains a five-membered carbocyclic ring, formed by carbon-carbon coupling of the former propenyl and propynyl groups with the C≡N–R reagent, to which a (η^2-iminoacyl)(κ-*tert*-butyl isocyanide)zirconocene moiety is attached. Complex **16** was characterized by an X-ray crystal structure analysis.

Introduction

Allyl- and propargyl-conjugation effects are of great importance in organic chemistry. They greatly influence the chemistry of allylic and propargylic substrates due to the thermodynamic stabilization of the respective cations, radicals or anions.[1] Organometallic group 4 metallocene cations [$^{R}Cp_2Zr-R^+$] play a very important role as the active species of the homogeneous metallocene Ziegler catalysts.[2] It is therefore of interest to know about the electronic effects that influence and alter the properties of such cationic organometallic systems, i.e. whether allylic[3] or propargylic conjugation effects may lead to chemical consequences in such cations. We have recently investigated two potential synthetic entries into "metallapropargyl"-cation systems of the type [$^{R}Cp_2Zr-C\equiv C-R^+$].[4][5] Such species can be generated in situ, but they are extremely reactive. Their interesting chemical behavior has led to the development of a variety of rather simple synthetic pathways to a number of novel organometallic frameworks. Here are two representative examples: treatment of bis(propynyl)zirconocene (**1**) with trityltetraphenylborate[6] generated the reactive intermediate [$Cp_2Zr-C\equiv C-CH_3^+$] that instantaneously attacked an equivalent of the starting material **1** to form the CC-coupled product **3** which contains a planar-tetracoordinate carbon atom (C^3) at a bridgehead-position of the dimetallabicyclic framework.[3]

When **1** is treated with the strong organometallic Lewis acid tris(pentafluorophenyl)borane (**4**)[7] a propynyl anion equivalent is transferred[8] from zirconium to boron with generation of a 1,1-bis(cyclopentadienyl)zircona-propargyl cation intermediate (**5**). This then inserts the alkynyl moiety of the resulting anion to give the observed product **6**. The



metallocene (μ-hydrocarbyl)borate betaine **6** exhibits a unique reactivity. It seems to be in an (endothermic) equilibrium with its isomer **7**, formally obtained by an intramolecular alkyne insertion reaction into the Zr−C(sp^2) σ-bond, from which the stable corresponding methylenecyclopropene derivatives are obtained in high yield by treatment with suitable insertion reagents, e.g. isonitriles (see Scheme 1). Subsequent hydrolysis of **8** led to interesting novel organic three-membered ring systems.[5][9]

It would be interesting to know whether this chemistry of conjugated metallocene cations could be extended from metallapropargyl to metallaallyl systems.[3] Which of the two cations is preferrentially formed in a competitive situation? Do ring closure reactions of the **6** ⟹ **7** type require the presence of two acetylide-derived building blocks (i.e. to make cyclopropenylium product stabilization possible as in **8**) or would building blocks of lower unsaturation being tolerable in the chemistry depicted in Scheme 1? To address these and related questions experimentally we have pre-

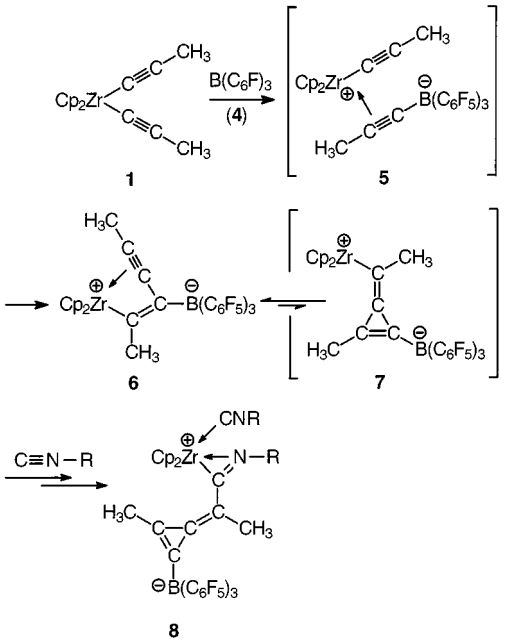
Scheme 1

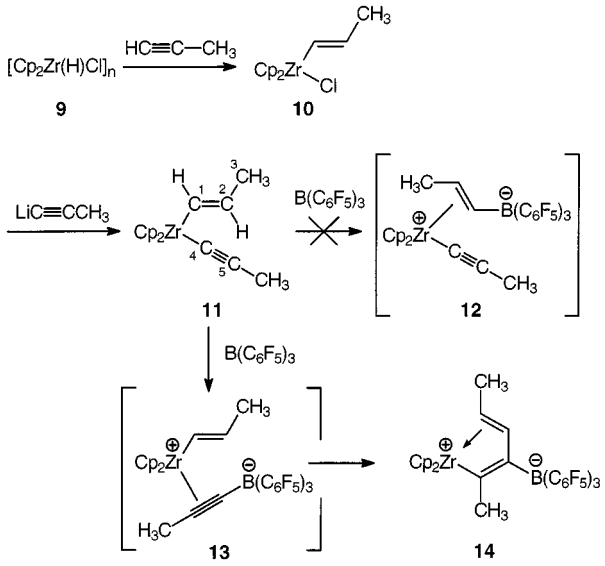


pared a "mixed" (σ-alkenyl)(σ-alkynyl)metallocene and investigated its metallocene cation chemistry initiated by treatment with $B(C_6F_5)_3$.

Results and Discussion

(σ-Propenyl)(σ-propynyl)zirconocene **11** was synthesized in the following way. Propyne was hydrozirconated by treatment with the oligomeric $[Cp_2Zr(H)Cl]_n$ reagent **9** in toluene at ambient temperature[10] to give the (*trans*-1-propenyl)zirconocene chloride complex **10** (74%). Subsequent treatment with propynyllithium in toluene furnished **11** in good yield (>90%). It shows the characteristic spectroscopic features of the *trans*-1-metallated alkene (^{1}H NMR: δ 6.98, 5.88, ^3J = 17.4 Hz; ^{13}C NMR: δ 182.2 (C1); IR: ν = 1635 cm^{-1}) and of the σ-alkynyl unit [IR: ν = 2086 cm^{-1}; ^{13}C NMR: δ 129.1, 118.1 ($C^4{\equiv}C^5$)].

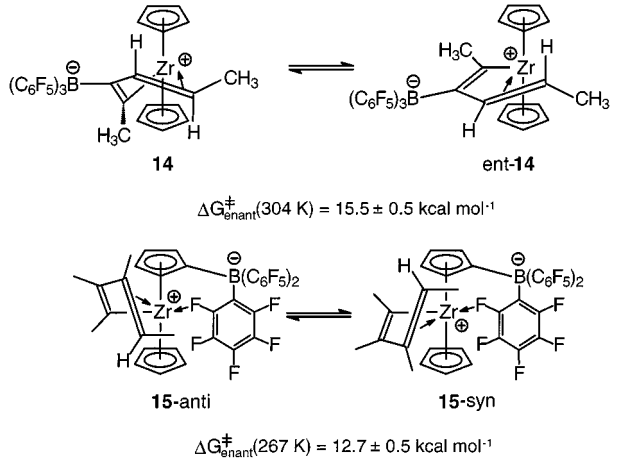
Scheme 2



Complex **11** reacts instantaneously with $B(C_6F_5)_3$ at room temperature. A mixture of products is formed containing a major component (**14**) that amounts to ca. 80%, but this product has turned out not to be very stable. In the course of several hours it decomposes unspecifically. Therefore, the product **14** was not isolated but only characterized spectroscopically from freshly prepared solutions (in [D_6]benzene, [D_8]toluene, or [D_5]bromobenzene). The NMR spectra clearly showed that carbon-carbon coupling of the two unsaturated σ-ligands at zirconium had occurred under the influence of the borane Lewis acid. The product exhibits the signals of a terminal *trans*-$H_3C^6-C^5H=C^4H$ moiety [233 K, [D_8]toluene: ^{1}H NMR: δ 7.40, 5.78, ^3J = 16 Hz; ^{13}C NMR: δ 158.8 (C4), 115.5 (C5)].

The C4=C5 double bond is probably coordinated to the electrophilic zirconium center, according to the corresponding ^{13}C-NMR chemical shifts and a comparison with typical reference data from the literature.[12a] Compound **14** at 233K in [D_8]toluene at 564 MHz exhibits a set of 15 ^{19}F NMR signals, which indicates hindered rotation about the C(sp^2)−B bonds. In addition, complex **14** exhibits a pair of diastereotopic cyclopentadienyl ligands (^{1}H-/^{13}C-NMR signals in [D_8]toluene at 233 K: δ 5.16, 5.02/112.8, 111.0). Raising the temperature results in a coalescence of the Cp-signals [T_{coal} (^{1}H NMR, 600 MHz) = 304 K], and a Gibbs activation energy of $\Delta G^{\ddagger}_{isom}$ (304 K) = 15.5 ± 0.5 kcal mol^{-1} for the dynamic exchange process.[11] This NMR behavior has precedence for substituted (1-butadienyl) ligand systems bonded to a cationic Cp_2M^+ unit: we assume a weak π-interaction of the $C^4=C^5$ double bond with the very electrophilic group 4 metallocene unit in **14**.[12] Conformational equilibration of the helically arranged C_4 unit in **14** may then occur by reversible cleavage of this weak π-complexation similarly as it was previously observed in the structurally and chemically related betaine system **15** (see Scheme 3).[13][14]

Scheme 3

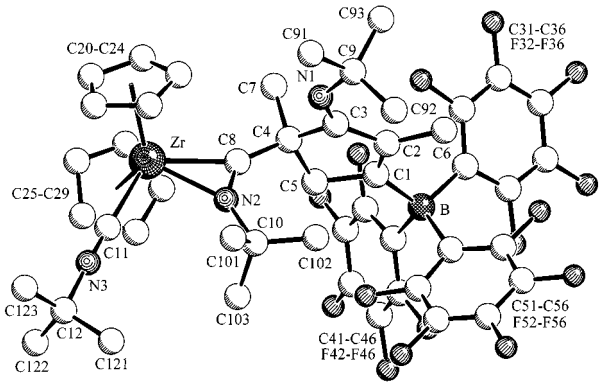


Complex **14** reacts readily with *tert*-butyl isocyanide (it consumes three equivalents of this reagent) to give an insertion/addition product **16**, that was isolated in >80% yield as a very pale yellow amorphous solid. Recrystallization from chloroform by slow evaporation of the solvent eventually

gave single crystals that were suited for an X-ray crystal structure analysis (see Figures 1 and 2). An overall view of the structure is given in Figure 1.

Figure 2 shows a projection of the central core of atoms of the newly formed product. This reveals that two equivalents of the isonitrile reagent were inserted. The first was used to couple the alkenyl- and alkynyl-derived moieties of the starting material together to form a five-membered carbocycle (C1−C5). The carbon framework $H_3C^6-C^2=C^1[B]-C^5H_2-C^4-C^7H_3$ of the product **16** corresponds exactly to the connectivity of the framework of its precursor **14**, only that the number of hydrogen atoms at carbon centers C5 and C4 does not correspond with the starting material.

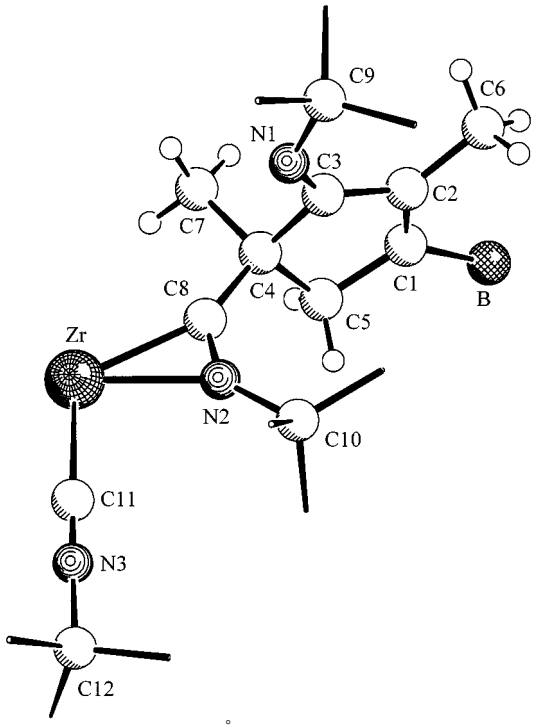
Figure 1. A view of the molecular structure of **16**



Unfortunately, we could not find any intermediate along the reaction pathway. Therefore, a detailed mechanistic picture of the **14**→**16** transformation must remain speculative at this time. A possible pathway is formulated in Scheme 4, starting with isonitrile insertion followed by electrophilic addition of the activated iminoacyl group at the C=C double bond to form the five-membered ring. We must assume a subsequent 1,2-hydride migration, potentially assisted by zirconium−carbon σ-bond formation to form the likely intermediate **19**. This is then trapped by insertion of an additional *tert*-butyl isocyanide insertion into the Zr−C σ-bond, followed by coordination of the third C≡NR molecule to give the observed stable reaction product.[15]

The X-ray crystal structure analysis of **16** shows the presence of the newly formed carbocyclic five-membered ring system (C1−C5) that contains the C1−C2 double bond [1.346(7) A] in conjugation to the ketimine functionality [C3−N1 1.266(7) A]. The bulky $-B(C_6F_5)_3$ substituent is attached to the sp^2-carbon atom C1 [C1−B 1.662(8) A]. Noteworthy is the presence of a η^2-iminoacyl group at the group 4 bent metallocene unit. The corresponding Zr−C8 bond length is 2.209(5) A, the Zr−N2 distance is 2.234(4) A. The angles inside the organometallic three-membered ring system are small [C8−Zr−N2 32.9(2)°, Zr−C8−N2 74.7(3)°, Zr−N2−C8 72.4(3)°]. The C8−N2 bond length is 1.258(6) A which is marginally shorter than the uncomplexed N1=C3 imino double bond at the adjacent five-membered ring (see above).

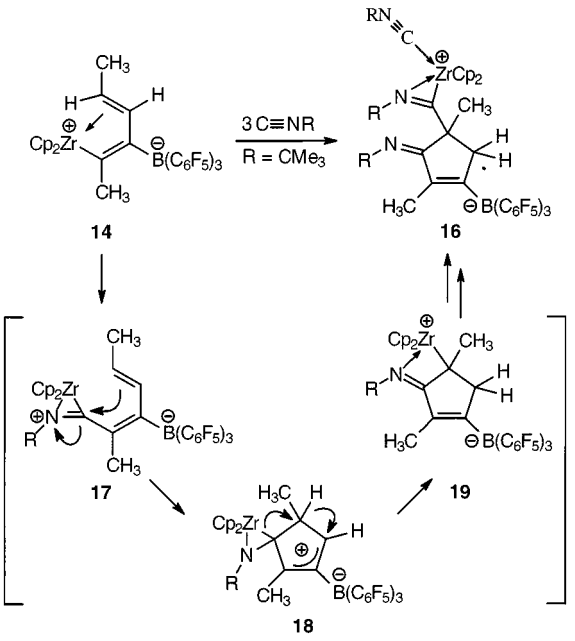
Figure 2. A view of the central atom framework of **16** with atom numbering scheme[a]



[a] Selected bond lengths [A] and angles [°]: Zr−C8 2.209(5), Zr−N2 2.234(4), Zr−C11 2.338(7), C11−N3 1.153(7), N3−C12 1.477(8), N2−C8 1.258(6), N2−C10 1.498(6), C8−C4 1.525(7), B−C1 1.662(8), C1−C2 1.346(7), C1−C5 1.517(7), C2−C3 1.500(7), C2−C6 1.503(7), C3−C4 1.545(7), C3−N1 1.266(7), N1−C9 1.471(7), C4−C5 1.548(7), C4−C7 1.537(7); Zr−C8−C4 148.8(4), Zr−C8−N2 74.7(3), Zr−N2−C8 72.4(3), Zr−N2−C10 148.5(3), Zr−C11−N3 175.5(5), C11−N3−C12 175.8(7), C11−Zr−N2 84.1(2), C11−Zr−C8 117.0(2), N2−Zr−C8 32.9(2), C8−N2−C10 139.0(5), N2−C8−C4 136.4(5), C8−C4−C5 111.8(4), C8−C4−C3 115.0(4), C8−C4−C7 108.4(4), B−C1−C2 126.3(5), B−C1−C5 122.4(5), C1−C2−C3 111.9(5), C1−C2−C6 123.1(5), C2−C3−C4 114.8(5), C2−C3−N1 140.1(5), C3−C4−C5 104.7(4), C3−C4−C7 106.6(4), C3−N1−C9 130.8(5), C5−C4−C7 110.2(4), C4−C5−C1 104.4(4); α(Zr,C8,N2)/(C1,C2,C3,C4,C5) 85.4.

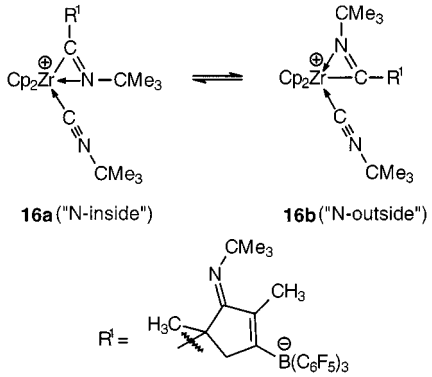
The complex framework of **16** corresponds to a zirconium−borate-betaine structure, which means that the zirconium center bears a partial positive charge. Its high electrophilicity and coordinative unsaturation has led to the complexation of the *tert*-butyl isocyanide ligand. In view of the special stereoelectronic features of the group 4 bent metallocene framework[16] it is likely that the metal−isonitrile coordination is dominated by ligand to metal σ-donation of electrons, without a significant π-backbonding contribution. This is confirmed by the bonding parameters of the Zr←C≡NR unit of **16** and its spectroscopic properties.[17] The C≡N bond length in the free isonitrile is 1.145 A. The C11−N3 distance of the coordinated *tert*-butyl isonitrile ligand in **16** is only marginally elongated at 1.153(7) A. The RN≡C→Zr unit is close to linear [angle N3−C11−Zr 175.5(3)°], and the Zr−C11 distance is 2.338(7) A. Thus the $Cp_2Zr^+\leftarrow C\equiv N-CMe_3$ unit in **16** shows very similar bonding features as found in the pure donor/acceptor adduct $[Cp_3Zr\leftarrow C\equiv N-CMe_3^+]$ (**20**)

Scheme 4



[Zr−C: 2.313(3) Å, C−N 1.145(4) (identical with the uncomplexed ligand); angle Zr−C−N 178.4(2)°].[18] The IR (C≡NR) band of **16** is at ν = 2197 cm^{-1} (**20**: 2209 cm^{-1}) which is above the free ligand value of ν = 2140 cm^{-1} as expected.[17]

The η^2-iminoacyl ligand and the isonitrile donor ligand are both oriented in the σ-ligand plane of the bent metallocene group, as expected. Therefore, two isomeric arrangements of these ligands are possible, which are characterized by central or lateral positioning of the iminoacyl nitrogen atom, respectively.[19] In the crystal we have only found the N-inside isomer (**16a**). But an investigation of the system in solution has revealed the presence of the other, the N-outside isomer (**16b**) and shown that the two stereoisomers **16a** and **16b** are interconverted on the NMR time scale.



In [D$_8$]THF solution complex **16** exhibits two complete sets of ^{1}H- and ^{13}C-NMR signals at 213 K in a ratio of 70:30 which correspond to the two isomers **16a** and **16b**. The chemical shifts of the sets of signals are mostly very similar, some of them are overlapping. The presence of the two isomers can clearly be monitored e.g. by observing six ^{13}C NMR signals of the $-C(CH_3)_3$ substituents at the nitrogen atoms (major isomer **16a**: δ 30.57, 26.61, 26.30; minor isomer **16b**: 30.66, 26.56, 25.58) or the narrowly separated Cp signals at δ 105.23/103.87 (**16a**) and δ 105.28/103.91 (**16b**). Two of the ^{1}H-NMR Cp resonances of the isomers are isochronous (δ 6.00), but the others are split into a 70:30 intensity pair of signals at 5.80 (**16a**) and 5.82 (**16b**). Upon increasing the temperature, coalescence of the two sets of spectra takes place to give an averaged single set of signals corresponding to the equilibrated chiral isomers (leading e.g. to a single pair of ^{1}H-NMR signals of the diastereotopic Cp-ligands at δ 5.94 and 5.75). From the temperature dependent ^{1}H NMR spectra the activation barrier of the **16a** ⟹ **16b** isomerization reaction was determined at $\Delta G^{\neq}_{isom}$ (273 K) = 14 ± 1 kcal mol^{-1} using the DNMR5 dynamic NMR simulation program.[20]

It is very clear that the dynamic process monitored by the temperature dependent ^{1}H- and ^{13}C-NMR spectra as described above corresponds to the iminoacyl N-inside ⟹ N-outside isomerization reaction and not from an equilibration process that solely involves the advent or disappearance of a persistent propeller conformation at the $-B(C_6F_5)_3$ borate group attached at the sp^2-C carbon atom C1 of the five-membered ring system. We are quite sure about this interpretation since we were able to observe this "freezing" of the chiral propeller-geometry at the boron center[5] independently by temperature dependent ^{19}F-NMR spectroscopy (at 564 MHz). As expected for this overall scenario we have observed a total of 30 ^{19}F-NMR resonances of the $B(C_6F_5)_3$ residues at 233 K in [D$_8$]THF, 15 arising from the major isomer **16a** (70% intensity) [δ −128.4, −130.2, −130.7, −133.3, −134.8, −135.6 (*ortho*), −164.6, −165.3, −165.6 (*para*), and −167.4, −168.3, −168.5, −168.6, −169.2, −169.3 (*meta*)] and 15 of lower intensity (30%) due to the minor isomer **16b** [δ −128.9, −130.5, −131.2, −133.2, −133.9, −135.3 (*ortho*), −164.9, −165.2, −165.9 (*para*), and −167.6, −167.8, −168.7, −169.2, −169.7, −169.9 (*meta*)]. Increasing the temperature results in massive line broadening which is first due to giving the (sp^2-C)−B rotation free and thus leading to individual equilibration of the six −*o*-F, three −*p*-F, and six −*m*-F signals for each of the isomers − which gives rise to the observation of a set of two *ortho*-F, two *meta*-F and two *para*-F resonances, each in a ca. 70:30 ratio. Raising the temperature further eventually leads to rapid **16a** ⟹ **16b** equilibration also on the ^{19}F-NMR time scale and thus gives rise to a very simple limiting high temperature spectrum showing only three remaining lines corresponding to the *o*-, *m*-, and *p*-F substituents at the $B(C_6F_5)_3$ unit under rapidly equilibrating conditions.

Conclusions

In principle, the reaction of the (σ-propenyl)(σ-propynyl)zirconocene complex **11** with the strong organometallic Lewis acid $B(C_6F_5)_3$ proceeds very similar to the reaction of bis(σ-propynyl)ZrCp_2 with tris(pentafluorophenyl)borane.[5][9] The propynyl ligand is transferred, followed by an insertion reaction with carbon-carbon coupling to give the group 4 metallocene−(μ-hydrocarbyl)borate betaine com-

plex **14**. The reaction of **11** with $B(C_6F_5)_3$ proceeds rather selectively. Within the limits of detection it is the σ-propynyl group that is transferred. The σ-propenyl ligand remains bonded to zirconium in the first step, it is only used subsequently as a reactive reagent in the insertion reaction. This pronounced selectivity might indicate an increased thermochemical stabilization of the 1,1-bis(cyclopentadienyl) "zircona-allyl" cation over the corresponding "zircona-propargyl" cation system, but this experimental result could also merely reflect the higher mobility of the σ-propynyl group in the transfer step. In any case the resulting "zircona-allyl" cation complex is extremely unstable and rapidly reacts with the in situ generated alkynyl-functionalized borate anion by insertion to yield the metallocene−betaine complex **14**. We conclude that metalla-allyl type reagents can readily be generated by the synthetic route applied in this study, but we must note that such systems seem to be very reactive. If there should be any thermodynamic stabilization at all it is certainly overruled by a very high kinetic reactivity of this organometallic cationic system.

The reaction of **14** with *tert*-butyl isocyanide yields the product **16** which is very interesting in view of its specific bonding features that are derived from the dipolar (i.e. betaine) structure of this metal complex. The connection of the borate anion part $[R-B(C_6F_5)_3^-]$ with the $Cp_2Zr(\eta^2$-iminoacyl) group by means of the bridging carbocyclic framework in fact creates a situation where the zirconocene unit effectively behaves like a metallocene cation that is completely separated from its anion.[21] This shows up in its property to serve as an organometallic Lewis acid strongly coordinating an isonitrile donor ligand. The structural and spectroscopic features of the resulting local $[Cp_2Zr(R')\leftarrow C\equiv NR^+]$ moiety are as expected for an (isonitrile)-zirconocene cation donor-acceptor adduct. This provides additional evidence that a variety of group 4 metallocene−(μ-organyl)borate betaines are very suited organometallic molecules to detect, study, and eventually use a typical metallocene cation reactivity in an overall *neutral* molecule.

Experimental Section

All reactions were carried out in an inert atmosphere (argon) using Schlenk-type glassware or in a glovebox. Solvents, including deuterated solvents, were dried and distilled under argon prior to use. For additional general information, including a list of spectrometers used, see ref.[5] and ref.[9]. The reagents (hydrido)zirconocene chloride[10] and tris(pentafluorophenyl)borane[7] were prepared according to literature procedures.

Preparation of (1-Propenyl)zirconocene Chloride (**10**): (Hydrido)-zirconocene chloride (1.10 g, 4.32 mmol) was suspended in 10 ml of toluene. The Schlenk flask was evacuated and filled with propyne. The mixture was stirred and additional propyne was entered into the gasphase in ca. 20 min intervals. A clear solution was obtained after ca. 4 h. Solvent was removed in vacuo and the residue stirred with pentane (3 ×) to give 950 mg (74%) of **10** as a pale yellow solid, m. p. 78°C (decomp.). − ^{1}H NMR ([D$_6$]benzene): δ 6.88 (dq, ^3J = 17.2 Hz, ^4J = 1.5 Hz, 1 H, Zr-C^1*H*=), 5.89 (dq, ^3J = 17.2 Hz, 6.0 Hz, 1 H, =C^2*H*-), 5.81 (s, 10 H, Cp), 1.79 (dd, ^3J = 6.0 Hz, ^4J = 1.5 Hz, 3 H, CH_3). − ^{13}C NMR ($CDCl_3$): δ 177.2 (C1), 138.6 (C2), 112.8 (Cp), 23.8 (CH_3).

Preparation of (1-Propenyl)(1-propynyl)zirconocene (**11**): (Propenyl)zirconocene chloride **10** (1.00 g, 3.47 mmol) and propynyllithium (165 mg, 3.59 mmol) were mixed as solids. At −78°C 10 ml of cold toluene was added with stirring. The cooling bath was removed after 1 h and the mixture allowed to warm to room temperature. After stirring overnight a lithium chloride precipitate was removed by filtration and the solvent evaporated in vacuo from the filtrate. The oily residue was solidified by treatment with pentane (12 h stirring) and the product dried in vacuo to yield 956 mg (91%) of **11**, m.p. 129°C (decomp.). − ^{1}H NMR ([D$_6$]benzene): δ 6.98 (dq, ^3J = 17.4 Hz, ^4J = 1.2 Hz, 1 H, Zr-CH=), 5.95 (s, 10 H, Cp), 5.88 (dq, ^3J = 17.4 Hz, 5.8 Hz, 1 H, =CH-), 1.78 (s, 3 H, C=C-CH_3), 1.77 (dd, ^3J = 5.8 Hz, ^4J = 1.2 Hz, 3 H, =CH-C*H*$_3$). − ^{13}C NMR ([D$_6$]benzene): δ 182.2 (Zr-*C*H=), 135.6 (=CH-), 110.6 (Cp), 129.1, 118.1 (-C=C-), 23.9 (=CH-*C*H$_3$), 5.90 (=C-*C*H$_3$). − IR (KBr): ν = 2086 (C=C), 1635 (C=C). − $C_{16}H_{18}Zr$ (301.5): C 63.67, H 5.97; found: C 62.68, H 5.49%.

Reaction of **11** *with B(C$_6$F$_5$)$_3$: Generation of* **14**: 5 mg (16.6 μmol) of **11** and 8.5 mg (16.6 μmol) of $B(C_6F_5)_3$ were mixed as solids. 0.5 ml of the respective deuterated solvent (see below) was added and the clear orange colored solution characterized spectroscopically. The solutions were not stable for prolonged periods of time. They turned brownish and a dark colored oil precipitated. Spectroscopic characterization of **14**: ^{1}H NMR ([D$_8$]toluene, 600 MHz, 233 K): δ 7.40 (d, ^3J = 16.2 Hz, 1 H, 4-H), 5.78 (br. s, 1 H, 5-H), 5.16 (s, 5 H, Cp), 5.02 (s, 5 H, Cp), 1.86 (s, 3-H, 2-CH_3), 0.80 (d, ^3J = 6.0 Hz, 3 H, 5-CH_3). − ^{13}C NMR ([D$_8$]toluene, 150 MHz, 233 K): δ 158.8 (C4), 149.3 [$^1J_{CF}$ = 253 Hz, o-$B(C_6F_5)_3$], 115.5 (C5), 112.8 (Cp), 111.0 (Cp), 26.9 (2-CH_3), 19.1 (5-CH_3) [C2, C3, *m*-, *p*-, and *ipso*-C of $B(C_6F_5)_3$ not observed]; the spectral assignment was secured by GCOSY, GHSQC, and GHMBC-NMR experiments[22]. − ^{11}B NMR ([D$_6$]benzene): δ −13.2. − ^{19}F NMR ([D$_8$]toluene, 233K, 564 MHz): δ −128.7, −129.2, −129.8, −133.3, −133.8, −138.2 (*o*-), −160 to −164 (*p*-), −164.5, −164.7, −165.7, −167.0, −167.3, −168.3 [*m*-$B(C_6F_5)_3$]. From the temperature-dependent dynamic NMR spectra (^{1}H-NMR coalescence of the Cp-signals) a Gibbs activation energy of the enantiomerization process of **14** was derived at $\Delta G^{\neq}_{enant}$ (T_c = 304 K) = 15.5 ± 0.5 kcal mol^{-1} (Δν = 20.6 Hz, in [D$_8$]toluene) using the Gutowsky-Holm approximation.[11]

Reaction of **14** *with tert-Butyl Isocyanide: Preparation of* **16**: The betaine **14** was generated in situ by treatment of 200 mg (0.66 mmol) of **11** with 340 mg (0.66 mmol) of $B(C_6F_5)_3$ in 8 ml of toluene at −78°C. The mixture was stirred for 30 min at −78°C and then allowed to warm to 0°C during 1 h. 1 ml of *tert*-butyl isocyanide was added to the orange colored turbid solution. The reaction mixture was stirred overnight at ambient temperature. Volatiles were removed in vacuo and the residue washed twice with 5 ml of pentane. The resulting solid was dissolved in 5 ml of dichloromethane and the product precipitated by the addition of 10 ml of pentane, collected by filtration and dried in vacuo; yield of **16** 527 mg (81%). Single crystals of **16** suited for the X-ray crystal structure analysis were obtained from $CDCl_3$ by a slow evaporation of the solvent. Characterization of **16**: m.p. 141°C (decomp.). In solution two isomers **16a** and **16b** were detected in a 70:30 ratio. − ^{1}H NMR ([D$_8$]THF, 600 MHz, 213 K) major isomer (**16a**): δ 6.00 (s, 5 H, Cp), 5.80 (s, 5 H, Cp), 2.75, 2.68 (AB, ^2J = 16 Hz, each 1 H, 5-H,

5-H′), 1.86 (s, 3 H, 4-CH_3), 1.65 (s, 3 H, 2-CH_3), 1.75, 1.35, 1.30 [s, each 9 H, C(CH_3)$_3$]; minor isomer (**16b**): δ 6.00 (s, 5 H, Cp), 5.82 (s, 5 H, Cp), 2.78, 2.36 (AB, ^2J = 16 Hz, each 1 H, 5-H, 5-H′), 1.92 (s, 3 H, 4-CH_3), 1.88 (s, 3 H, 2-CH_3), 1.72, 1.30, 1.02 [s, each 9 H, C(CH_3)$_3$]. – ^{13}C NMR ([D$_8$]THF, 150 MHz, 213 K) major isomer (**16a**): δ 230.0 (Zr-C=N), 179.4 (C3), 147.8 (Zr←C≡NR), 146.2 ($^1J_{CF}$ = 246 Hz), 136.6 ($^1J_{CF}$ = 240 Hz), and 135.0 [$^1J_{CF}$ = 254 Hz, *o*-, *p*-, *m*-B(C_6F_5)$_3$], 133.2 (C2), 122 [*ipso*-C of B(C_6F_5)$_3$], 105.23 and 103.87 (Cp), 58.8, 58.1, and 51.9 (*ipso*-C of *tert*-butyl), 55.1 (C4), 48.9 (C5), 28.1 (4-CH_3), 30.57, 26.61, and 26.30 [C(CH_3)$_3$], 16.6 (2-CH_3), C1 not observed; minor isomer (**16b**): δ 230.0 (Zr-C=N), 179.4 (C3), 147.3 (Zr←C≡NR), 146.2 ($^1J_{CF}$ = 246 Hz), 136.6 ($^1J_{CF}$ = 254 Hz), and 135.0 [$^1J_{CF}$ = 240 Hz, *o*-, *p*-, *m*-B(C_6F_5)$_3$], 132.6 (C2), 122 [*ipso*-C of B(C_6F_5)$_3$], 105.28 and 103.91 (Cp), 58.3, 52.00 (*ipso*-C of *tert*-butyl, 1 signal not observed), 54.2 (C4), 48.3 (C5), 30.66, 26.56, and 25.58 [C(CH_3)$_3$], 29.4 (4-CH_3), 16.2 (2-CH_3), C1 not observed. – These assignments were supported by the results of GCOSY, GHSQC and GHMBC NOE-difference, and ROESY NMR experiments[22]. – ^{11}B NMR ($CDCl_3$): δ −15.1. – ^{19}F NMR ([D$_8$]THF, 564 MHz, 233 K) major isomer (**16a**): δ −128.4, −130.2, −130.7, −133.3, −134.8, −135.6 (*ortho*-), −164.6, −165.3, −165.6 (*para*-), −167.4, 168.3, −168.5, −168.6, −169.2, −169.3 [*meta*-B(C_6F_5)$_3$]; minor isomer (**16b**): δ −128.9, −130.5, −131.2, −133.2, −133.9, −135.3 (*ortho*-), −164.9, −165.2, −165.9 (*para*-), −167.6, −167.8, −169.2, −169.7, −169.9 [*meta*-B(C_6F_5)$_3$]. IR (KBr): ν = 2197 (N≡CR), 1611 (C=C). – UV/Vis (dichloromethane): λ_{max} = 306 nm (ε = 34500), 254 (ε = 36000), 233 (ε = 21700). – $C_{49}H_{45}BF_{15}N_3Zr$ (1062.9): C 55.37, H 4.27, N 3.97; found: C 55.41, H 4.50, N 4.26%.

X-ray Crystal Structure Analysis of **16**: Formula $C_{49}H_{45}BF_{15}N_3Zr \cdot 1.5\ CHCl_3$, M = 1241.96, 0.30 × 0.20 × 0.10 mm, a = 12.105(1), b = 13.146(1), c = 17.167(1) A, α = 88.97(1), β = 82.62(1), γ = 82.29(1)°, V = 2684.7(4) A^3, ρ_{calc} = 1.536 g cm^{-3}, μ = 5.19 cm^{-1}, empirical absorption correction via φ scan data (0.891 ≤ C ≤ 0.999), Z = 2, triclinic, space group P1bar (No. 2), λ = 0.71073 A, T = 223 K, ω/2θ scans, 9916 reflections collected (±h, +k, ±l), [(sinθ)/λ] = 0.59 A^{-1}, 9463 independent and 4891 observed reflections [$I \geq 2\ \sigma(I)$], 705 refined parameters, R = 0.061, wR^2 = 0.141, max. residual electron density 1.06 (−0.75) e A^{-3}, hydrogens calculated and refined as riding atoms.

Data set was collected with an Enraf Nonius MACH3 diffractometer. Programs used: data reduction MolEN, structure solution SHELXS-86, structure refinement SHELXL-93, graphics SCHAKAL-92.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100939. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [fax: int. code +44(1223)336-033, e-mail: deposit@ccdc.cam.ac.uk].

[14] From the observed experimental data two slightly different stereochemical situations can be envisaged for the characterization of **14**. If the C(sp^2)-B(C_6F_5)$_3$ unit (under ″frozen″ static NMR conditions) contains a *chiral* borate propeller geometry, than two diastereomeric isomers of **14** would result. However, it could also be possible that the C(sp^2)-B(C_6F_5)$_3$ unit favours a *prochiral* conformation that only leads to 15 diastereotopic ^{19}F NMR signals due to the presence of the adjacent chiral metal complex framework (for a discussion of such an example see e.g. S. Döring, G. Erker, R. Fröhlich, O. Meyer, K. Bergander, *Organometallics*, in press.) In the case of **14** we cannot decide between these two alternative stereochemical interpretations at present because it was not possible to identify the minor components of the obtained product mixture.

Keywords: Platinum / Nickel / Stannyl complexes / Oxidative addition / Tin

Reaction of $Ni(COD)_2$ (COD = 1,5-cyclooctadiene) with two equivalents of $Ph_2PCH_2CH_2SnPh_3$ or of $(Ph_3P)_2Pt(C_2H_4)$ with two equivalents of $Ph_2PCH_2CH_2SnR_3$ (R = Ph, Me, Bu) results in the immediate formation of the complexes $(R_3SnCH_2CH_2Ph_2P)M[PPh_2CH_2CH_2SnPh_2(M–Sn)](R)$ (M = Ni, Pt) with a *cis* arrangement of the two phosphorus atoms. The structure of $(Me_3SnCH_2CH_2Ph_2P)Pt[PPh_2CH_2CH_2SnMe_2(Pt–Sn)](Me)$ was confirmed by an X-ray structure analysis. In the presence of PPh_3, this complex shows dynamic behavior in solution due to $Ph_2PCH_2CH_2SnMe_3$/PPh_3 exchange. When the phosphanylalkylstannanes $Ph_2PCH_2CH_2SnPh_{3-x}Me_x$ (x = 1, 2) are employed in the reaction with $Ni(COD)_2$ or $(Ph_3P)_2Pt(C_2H_4)$, the Sn–Ph groups are more prone to oxidative addition than the Sn–Me groups. When $Ni(COD)_2$ is treated with one equivalent of $Ph_2PCH_2CH_2SnPh_3$ and PR'_3 (PCy_3 or PMe_2Ph) each, the complexes $(R'_3P)M(PPh_2CH_2CH_2SnPh_2)(Ph)(M–Sn)$ are formed. Heating of $(Ph_3SnCH_2CH_2Ph_2P)Ni[PPh_2CH_2CH_2SnPh_2(Ni–Sn)](Ph)$ to 70 °C induces the oxidative addition of a Sn–Ph group of the dangling ligand, and *cis*-$Ni[PPh_2CH_2CH_2SnPh_2(Ni–Sn)]_2$ is obtained. The same complex is formed upon reaction of $Ni(COD)_2$ with $Ph_2PCH_2CH_2SnPh_2H$. Reaction of $Ni(COD)_2$ with $Ph_2PCH_2CH_2SnMe_3$ results in the immediate formation of *trans*-$Ni[(PPh_2CH_2CH_2SnMe_2(Ni–Sn)]_2$.

Contrary to Sn−H bonds that readily add to a variety of transition-metal complex fragments,[2] there are only few examples for the oxidative addition of non-activated Sn−C bonds. For example, $SnPh_4$ only adds to electron-rich fragments such as $(Ph_3P)_2Pt$ to give $(Ph_3P)_2Pt(SnR_3)(Ph)$.[3][4][5] Sn−Me bonds are even less reactive than Sn−Ph bonds.[6] The weaker Sn−C bonds in alkynylstannanes also add to less electron-rich metal centers.[7][8]

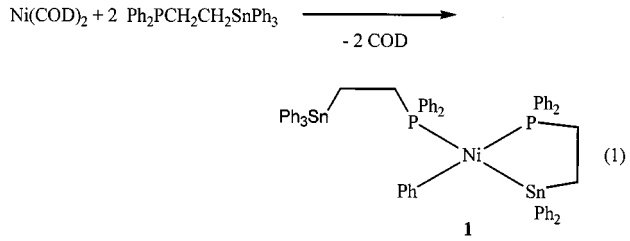
One of the possibilities to promote oxidative addition reactions is "chelate assistance", introduced by Stobart et al. for phosphanylalkylsilyl ligands with Si−H bonds.[9] We previously used this option to add Sn−C bonds to electron-rich Pd and Pt fragments[10] as well as to the less reactive $Fe(CO)_4$ fragment,[11] using ligands of the type $Ph_2P(CH_2)_nSnR_3$. Richmond et. al. observed reversible Sn−Ph addition in the reaction of a $SnPh_3$-substituted ethylenediamine derivative with $W(CO)_3(CH_3CN)_3$.[12] The concept was also extended to Si−Si and Si−Sn bonds.[13][14]

In the present paper, we first describe the reaction of $Ni(COD)_2$ with $Ph_2PCH_2CH_2SnR_3$. The results led us to re-examine some of our experiments with Pt compounds and to correct some of our previous results.[10]

[◇] Part 11: Ref.[1].

Results and Discussion

When $Ni(COD)_2$ (COD = 1,5-cyclooctadiene) was treated with two equivalents of $Ph_2PCH_2CH_2SnPh_3$ in THF, the color of the yellow solution changed to deep orange, and a broad signal in the ^{31}P-NMR spectrum at $\delta \approx 28$ indicated the immediate formation of phosphanenickel complexes. Additional stirring for 2.5 h resulted in the almost quantitative formation of the oxidative addition product **1** (Eq. 1) according to the ^{31}P-NMR spectrum.



(1)

1

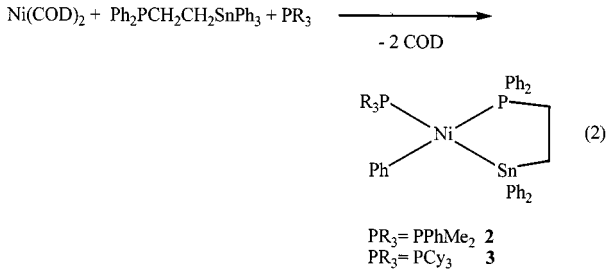
We were not able to separate traces of $Ph_2P(O)CH_2CH_2SnPh_3$ and unreacted $Ph_2PCH_2CH_2SnPh_3$. However, the structure of the complex was unequivocally confirmed by multinuclear NMR spectroscopy. The spectra are discussed in detail in the following paragraph because they are representative for most of the complexes reported in this paper.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0707−0897 $ 17.50+.50/0

The $^{31}P\{^1H\}$-NMR spectrum of **1** showed the expected two doublet signals of an AB system. The resonance at δ = 58.3 is attributed to the phosphorus atom in a five-membered ring because of the significant downfield shift of ca. 32 ppm relative to the resonance of the other phosphorus nucleus at δ = 26.1. This downfield shift is a well-known phenomenon upon chelation,[15] and was also observed in the related Pt complexes $Pt[Ph_2PCH_2CH_2SiR_2(Pt-Si)]_2$[9] and $(Ph_3P)Pt(Ph_2PCH_2CH_2SiR_2)(SiR_3)(Pt-Si)$.[13] The $^2J_{PNiP}$ coupling constant of 6.1 Hz proved the *cis* disposition of the phosphorus nuclei. The $J_{117/119SnP}$ coupling constant of 219.8 Hz between the Sn and P nucleus at δ = 58.3 of the chelate ring is typical for the *cis* position of both nuclei. On the other hand, the signal at δ = 26.1 showed the typical *trans*-$^2J_{SnNiP}$ (^{117}Sn: 1065.9 Hz; ^{119}Sn: 1109.3 Hz) and an additional set of Sn satellites attributed to the $^3J_{117/119SnCCP}$ coupling within the dangling ligand. The NMR data confirm the *trans* position of the non-chelated ligand and the metal-bonded tin atom. The ^{119}Sn-NMR spectrum corroborates the assignment of the phosphorus resonances by showing a doublet of doublets at δ = 23.6 for the tin atom bound to nickel, with *trans* $^2J_{119SnNiP}$ of 1116.9 Hz and J_{SnP} of 223 Hz. This resonance is distinctly shifted downfield by ca. 120 ppm relative to the resonance at δ = −97.6 for the non-coordinated $SnPh_3$ group. This resonance appears as a doublet with the appropriate $^3J_{119SnCCP}$ of 183.8 Hz.

The ^{1}H-NMR spectrum lacked essential structural information because the methylene proton signals appear as complex multiplets superimposing each other (see Experimental Section). The only interesting feature is the resonance of the protons of the *Ni*-bonded phenyl group. Their multiplet was significantly shifted to higher field (δ = 6.75−7.05), compared to the other phenyl resonances. This highfield shift seems to be a typical phenomenon for complexes of this kind because it is also reported for $(CO)_3Fe(Ph_2PCH_2CH_2SnPh_2)(Ph)(Fe-Sn)$[11] and $(Ph_3P)Pt(Ph_2PCH_2CH_2SnPh_2)(Ph)(Pt-Sn)$.[10] The ^{13}C-NMR spectrum confirms that there are two different phosphanylalkylstannane units in the molecule because of two separate resonances for the $SnCH_2$ and the PCH_2 group. While the resonances for the methylene carbon atoms of the dangling ligand appear as doublets due to the coupling with the phosphorus atom within the ligand, the resonances of the CH_2 groups of the chelating ligand appear as doublet of doublets because of the additional coupling with the other phosphorus nucleus. This observation seems reasonable if one takes into account that in this case the second phosphorus atom is in a kind of *transoid* position with respect to the carbon nuclei while in the first case the second phosphorus nucleus is *cisoid*. In the very complex range of the phenyl carbon signals no assignment for the *ipso*-carbon atom of the metal-bonded phenyl group was possible.

Since the second $Ph_2PCH_2CH_2SnPh_3$ in **1** just acts as a monodentate ligand, we also treated $Ni(COD)_2$ with a 1:1 mixture of $Ph_2PCH_2CH_2SnPh_3$ and $PPhMe_2$ or PCy_3 (Eq. 2). $(PhMe_2P)Ni(Ph_2PCH_2CH_2SnPh_2)(Ph)(Ni-Sn)$ (**2**) was



formed in 90% yield (^{31}P NMR) together with **1** and a small amount of $PhP(O)Me_2$ as by-products.

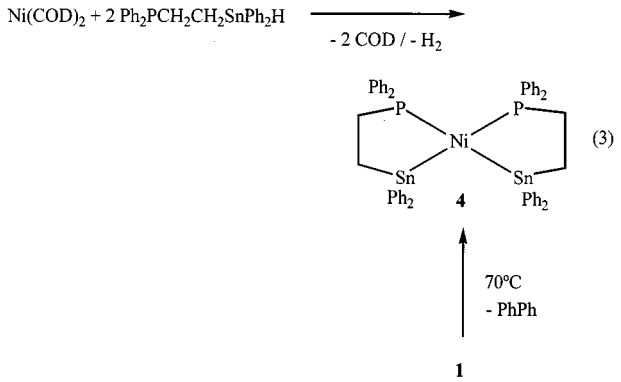
Unfortunately, **2** was even more difficult to purify than **1**. The reaction of PCy_3 resulted in almost quantitative formation of $(Cy_3P)Ni(Ph_2PCH_2CH_2SnPh_2)(Ph)(Ni-Sn)$ (**3**) (^{31}P-NMR). It was possible to isolate the complex analytically pure as a yellow-brown powder by column chromatography. Contrary to **1**, it was even possible to assign the resonance for the *ipso*-carbon atom of the metal-bonded phenyl group. It appears at δ = 155.6 (dd) with two $^2J_{PNiC}$ couplings of 59.2 and 7.9 Hz due to the *trans*- and *cis*-phosphorus nuclei. These values are in good agreement with those found for the *ipso*-carbon atom in $(Me_3P)_2Ni[CH_2C(CH_3)_2C_6H_4(Ni-C)]$ (δ = 171.1, *trans*-$^2J_{PNiC}$ = 79 Hz).[16]

In the reaction with $Ph_2PCH_2CH_2SnPh_3$, nickel resembles platinum and does not parallel the reactivity pattern of palladium that formed the product of a double oxidative SnPh addition and consecutive reductive biphenyl elimination, *trans*-$Pd[Ph_2PCH_2CH_2SnPh_2(Pd-Sn)]_2$.[10] Therefore, the possibility to induce a second SnPh oxidative addition was probed. Crude **1** was dissolved in toluene and heated to about 70°C for 9 h. Monitoring the reaction by ^{31}P-NMR spectroscopy showed a new singlet resonance at δ = 63.3 with a double set of tin satellites. The coupling constants of 930.1 Hz (^{119}Sn), 891.0 Hz (^{117}Sn), and 161.1 Hz ($^{119/117}$Sn) are in the typical range for a *trans*- and a *cis*-tin nucleus relative to the phosphorus atoms, thus excluding *trans*-$Ni[Ph_2PCH_2CH_2SnPh_2(Ni-Sn)]_2$.

The singlet resonance in the ^{31}P-NMR spectrum is due to two equivalent phosphorus nuclei in molecules where both tin atoms are ^{118}Sn isotopes. A doublet-of-doublet resonance at δ = 56.8 was observed (*trans*-J_{119SnP} = 933.3 and *cis*-J_{119SnP} = 164.0 Hz) in the ^{119}Sn-NMR spectrum. Even if one takes into account that the values given for the couplings are based on a first-order interpretation of the spectra because the resolution was too poor to observe all couplings needed for a interpretation as an ABXY spin system, the data clearly indicate the formation of the *cis* product **4** resulting from the oxidative addition of a second Sn−Ph bond (Eq. 3). Unfortunately, the course of the reaction was not completely straightforward because some decomposition occurred, and the resulting product still contained small amounts of **1** besides the impurities present in the starting complex.

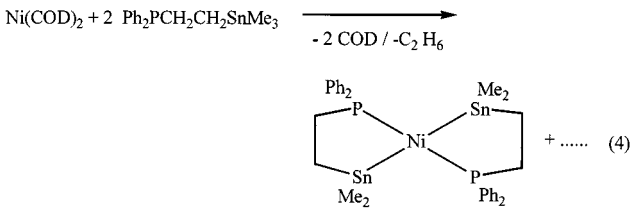
We therefore prepared **4** independently from $Ni(COD)_2$ with two equivalents of $Ph_2PCH_2CH_2SnPh_2H$, utilizing the fact that Sn−H bonds are more prone to oxidative addition

than Sn−C bonds. On addition of the phosphanylalkylstannane at room temperature, the color of the solution changed immediately, and gas evolution was observed after a short period. The yellow oil resulting after work-up showed the same resonances in the ^{31}P- and ^{119}Sn-NMR spectra as were observed in the thermal reaction of **1**. This proves that for SnH the second oxidative addition is facilitated, as expected (Eq. 3).



(3)

In the reaction of $Pd(PPh_3)_4$ with either $Ph_2PCH_2CH_2SnPh_3$ or $Ph_2PCH_2CH_2SnMe_3$, the *trans* complexes $Pd[PPh_2CH_2CH_2SnR(Pd-Sn)]_2$ were formed.[10] Because of the somewhat surprising formation of the *cis* product **4** from **1** at elevated temperatures the question arises which isomer is obtained when $Ph_2PCH_2CH_2SnMe_3$ is treated with $Ni(COD)_2$ (Eq. 4).



(4)

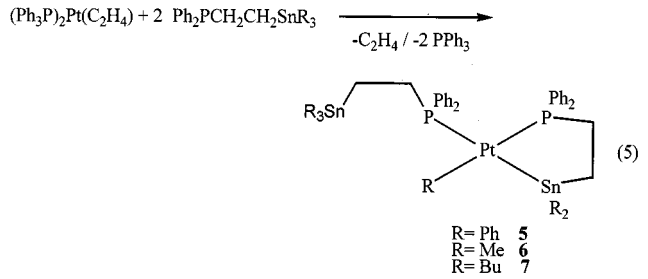
The ^{31}P-NMR spectrum of the residue obtained after removal of all volatiles showed two resonances. The one at $\delta = 30.6$ with an Sn coupling of 149 Hz was assigned to $Ph_2P(O)CH_2CH_2SnMe_3$ as shown by the ^{31}P-NMR spectrum of a sample of $Ph_2P(O)CH_2CH_2SnMe_3$, independently prepared by oxidation of the phosphane with H_2O_2. Despite of the fact that all solvents were thoroughly dried and degassed, and air was excluded as far as possible by standard Schlenk techniques, it was impossible to suppress the formation of phosphane oxides completely. The fact that Ni^0 complexes, that are intermediates in the reactions, are very good catalysts in the phosphane oxidation by oxygen may be the reason that even very small traces of air led to significant phosphane oxidation. The singlet resonance at $\delta = 41.5$ was assigned to *trans*-$Ni[Ph_2PCH_2CH_2SnMe_2(Ni-Sn)]_2$ because of the typical *cis* coupling to $^{117/119}$Sn of 137.9 Hz and the equivalence of the two phosphorus nuclei (if both are ^{118}Sn). The *trans* conformation was confirmed by the virtual triplet observed in the ^{119}Sn spectrum at $\delta = 5.9$ due to the inequivalence of the two phosphorus atoms in molecules with a ^{118}Sn and a ^{119}Sn nucleus. The triplet pattern is caused by the fact that $^2J_{SnNiP}$ and the "mixed" $^2J_{SnNiP}/^3J_{SnCCP}$ coupling constant have approximately the same value. Thus, in the case of $Ph_2PCH_2CH_2SnMe_3$, the outcome of the reaction of $Ni(COD)_2$ parallels that of Pd.

Comparing the higher reactivity of Sn−Ph bonds with that of Sn−Me it is somewhat surprising that elevated temperatures are needed to induce oxidative addition of a second Sn−Ph bond while the addition of a second Sn−Me bond takes place at room temperature. This may have steric reasons. Steric effects may also be responsible for the formation of different isomers in both reactions. In the reaction of the $SnPh_3$ derivative, the stereochemical outcome of the reaction is probably controlled by electronic reasons because all atoms bonded to the Ni center are equally substituted by phenyl groups. Contrary to that, steric factors may dominate in the reaction of the trimethylstannyl derivative, leading to the *trans* arrangement that minimizes the steric repulsion between the bulkier phosphane substituents.

The ligand $Ph_2PCH_2CH_2SnPh_2Me$ offers the possibility of either Sn−Ph or Sn−Me addition. Unfortunately, the reaction carried out as before was not straightforward. Nevertheless, the evolution of small amounts of gas was observed during the reaction. The ^{31}P-NMR spectrum of the residue after work-up showed two characteristic doublet resonances at $\delta = 57.9$ and 25.3 ($^2J_{PNiP} = 6.1$ Hz) for the main product. The reasonably close agreement of the NMR data with those of **1** ($\delta = 58.3$, 26.1; $^2J_{PNiP} = 6.1$ Hz) suggested that $(MePh_2SnCH_2CH_2Ph_2P)Ni[(PPh_2CH_2CH_2SnPhMe)(Ni-Sn)](Ph)$ with a dangling phosphanylalkylstannane ligand is the main product. The tin satellites at the downfield signal with $J_{SnP} = 213$ Hz supported this interpretation. However, due to the poor resolution of the spectrum no tin satellites at the highfield signal were observed. A compound with a singlet resonance at $\delta = 42.5$ was formed as a minor product. No tin satellites were resolved at this signal, but it can be supposed that due to the chemical shift and the gas evolution observed during reaction, *trans*-$Ni[Ph_2PCH_2CH_2SnPh_2(Ni-Sn)]_2$ may be the by-product.

The somewhat different results for the oxidative addition of Sn−C bonds to Ni^0 compared to Pd^0 and the fact that we had found complexes of the type $(R_3Si-SiR_2CH_2CH_2Ph_2P)Pt[PPh_2CH_2CH_2SiR_2(Pt-Si)](SiR_3)$ in our previous investigations on chelate-assisted Si−Si oxidative addition to $(Ph_3P)_2Pt(C_2H_4)$, we re-checked the experiments on the Sn−C addition of phosphanylalkylstannanes to Pt^0 published by us some years ago.[10] First, we treated $(Ph_3P)_2Pt(C_2H_4)$ with two molar equivalents of $Ph_2PCH_2CH_2SnPh_3$ according to the published procedure and observed almost quantitative formation of a complex with the ^{31}P-NMR data in good agreement with those previously assigned to $(Ph_3P)Pt[Ph_2PCH_2CH_2SnPh_2-(Pt-Sn)](Ph)$ as product of this reaction. However, on scrutinizing the better data obtained now, we have to correct the assignment. Instead of the PPh_3 derivative, the complex

$(Ph_3SnCH_2CH_2Ph_2P)Pt[PPh_2CH_2CH_2SnPh_2(Pt-Sn)](Ph)$ (**5**) was formed (Eq. 5).



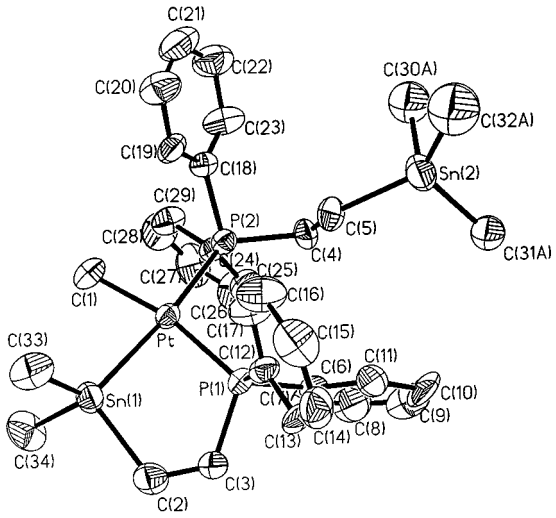
This is confirmed by the fact that a coupling to Sn (179.9 Hz) in the typical range for a $^3J_{SnCCP}$ was now observed at the resonance for the phosphorus of the non-chelated ligand. The ^{119}Sn-NMR spectrum also corroborates that there is a dangling phosphanylalkylstannane ligand because there is an additional doublet at $\delta = -97.5$ with the correct phosphorus coupling besides the doublet of doublets resonance for the chelated tin nucleus at $\delta = 97.2$. Complex **5** corresponds to the analogous Ni complex **1**. It therefore seemed reasonable to study whether a second oxidative Sn−Ph addition is also possible for Pt. However, a toluene solution of **5** heated to 70°C for 10 h and then analyzed by ^{31}P-NMR spectroscopy did not indicate any formation of the product of a second oxidative addition.

This led us to re-examine also the reaction of two equivalents $Ph_2PCH_2CH_2SnMe_3$ with $(Ph_3P)_2Pt(C_2H_4)$, for which we had previously postulated the formation of the Pt^{IV} complex $Pt[PPh_2CH_2CH_2SnMe_2(Pt-Sn)]_2(Me)_2$.[10] On inspection of the better spectroscopic data obtained now we realized that the formerly observed doublet resonance in the ^{119}Sn-NMR spectrum is contradicting the proposed structure. The product was instead the Pt^{II} complex $(Me_3SnCH_2CH_2Ph_2P)Pt[PPh_2CH_2CH_2SnMe_2(Pt-Sn)](Me)$ (**6**) (Eq. 5). The spectrum of the yellow oil left after removal of all volatiles from the reaction mixture mainly showed two broad resonances at $\delta \approx 55$ and 27, and a broad signal at $\delta = -3$ in the ^{31}P-NMR spectrum. The signals sharpened on lowering the temperature, and at 240 K the dynamic process was completely frozen. At this temperature, the expected spectrum for **6,** the typical AB pattern with the corresponding Sn satellites, was observed in addition to a sharp resonance for free PPh_3. The fact that the resonances of the dangling phosphorus ligand and the PPh_3 continually broaden on rising the temperature from 240 K to 360 K while the resonance of the ring-integrated phosphorus first broadens to a much smaller extend, and then re-sharpens (starting at about 310 K) indicates that the dynamic process is a $Ph_2PCH_2CH_2SnMe_3/PPh_3$ exchange at the Pt^{II} center. This suggestion is in agreement with results obtained for the complexes *cis*-$(Ph_3P)_2Pt(SiR_3)(H)$ where similar interchange processes with excess PPh_3 were observed[17]. The authors also observed the phenomenon that the resonance of the PPh_3 ligand *cis* to the silyl ligand that does not take part in the dynamic process is only slightly broadened.

To elucidate the role of the PPh_3 in the dynamic process, **6** was independently prepared from $Pt(COD)_2$. As expected, the product **6** formed in almost quantitative yield showed no dynamic features at room temperature because of the absence of PPh_3. On addition of PPh_3, a dynamic process was initiated similar to that observed for the product resulting from the reaction of $(Ph_3P)_2Pt(C_2H_4)$ at room temperature.

Colorless crystals of **6** suitable for an X-ray crystal structure analysis were obtained by diffusion of heptane into a concentrated benzene solution of the complex. The structure analysis proved the *cis* arrangement of the two phosphorus ligands with one dangling phosphanylalkylstannane (Figure 1). The Pt−C(1) distance [214 (1) pm] is in the normal range for $Pt-CH_3$ compounds (202−220 pm).[18]The Pt−Sn(1) bond length of 259.36(8) pm is significantly shorter than that in *trans*-$(Ph_3P)_2Pt(SnPh_3)(H)$ (265.4 pm).[19] This difference is reasonable if one takes into account the different influence of a hydride and a phosphane ligand. The P(1)−Pt−P(2) angle is widened [104.30(9)°] due to the steric repulsions between the bulky phenyl groups at the phosphorus atoms. This distortion from the regular square-planar arrangement is compensated by the angles C(1)−Pt−P(2), C(1)−Pt−Sn(1) and P(1)−Pt−Sn(1) being smaller than 90° [87.8(3), 85.3(3), and 82.55(7)°]. The latter is partially due to chelation. The methyl groups at the tin atom of the dangling ligand are disordered in the crystal.

Figure 1. ORTEP diagram of **6**; the hydrogen atoms are omitted for clarity[a]



[a] Selected bond lengths [pm] and angles [°]: Pt−C(1) 213.7(11), Pt−P(1) 227.4(3), Pt−P(2) 232.7(3), Pt−Sn(1) 259.36(8), Sn(1)−C(2) 213.7(11), P(1)−C(3) 184.5(10), P(2)−C(4) 187.2(9), Sn(2)−C(5) 213.1(10), Sn(1)−C(33) 213.0(11), Sn(1)−C(34) 215.0(12); C(1)−Pt−P(1) 167.4(3), C(1)−Pt−P(2) 87.8(3), P(1)−Pt−P(2) 104.30(9), C(1)−Pt−Sn(1) 85.3(3), P(1)−Pt−Sn(1) 82.55(7), P(2)−Pt−Sn(1) 173.13(7), C(33)−Sn(1)−C(34) 104.4(5), C(33)−Sn(1)−C(2) 109.2(5), C(34)−Sn(1)−C(2) 106.4(5), C(33)−Sn(1)−Pt 118.2(3), C(34)−Sn(1)−Pt 115.6(4), C(2)−Sn(1)−Pt 102.5(3), C(24)−P(2)−Pt 110.8(3), C(18)−P(2)−Pt 115.3(4), C(4)−P(2)−Pt 121.3(4), C(12)−P(1)−C(3) 103.7(5), C(6)−P(1)−C(3) 100.2(4), C(12)−P(1)−Pt 114.6(3), C(6)−P(1)−Pt 120.0(4), C(5)−C(4)−P(2) 114.8(7), C(3)−C(2)−Sn(1) 107.9(8), C(2)−C(3)−P(1) 113.2(7), C(4)−C(5)−Sn(2) 113.9(7).

Attempts to induce the oxidative addition of one of the SnMe bonds of the dangling ligand by heating a toluene solution of **6** to about 90°C for 10 h failed. The ^{31}P-NMR spectrum did not indicate any reaction.

Contrary to the results obtained for Ni^0, an increase of the steric bulk at the Sn atom by changing the methyl groups in the phosphanylethylstannane against butyl groups did not influence the general outcome of the reaction. Besides the main product $(Bu_3SnCH_2CH_2Ph_2P)Pt[PPh_2CH_2CH_2SnBu_2(Pt-Sn)](Bu)$ (**7**) (formed in 90% yield according to the ^{31}P-NMR spectrum), a minor amount of $(Ph_3P)Pt[PPh_2CH_2CH_2SnBu_2(Pt-Sn)](Bu)$ was observed as a by-product [^{31}P NMR(C_6D_6): δ = 53.9 (d, $^2J_{PPtP}$ = 9.7 Hz, $J_{117/119SnP}$ = 105.0 Hz, $^1J_{PtP}$ = 1914.1 Hz), 32.1 (d, $^2J_{PPtP}$ = 9.7 Hz, $^2J_{119SnNiP}$ = 1666.3 Hz, $^2J_{117SnPtP}$ = 1597.9, $^1J_{PtP}$ = 2119.2].

The use of the previously unknown derivative $Ph_2PCH_2CH_2SnMe_2Ph$, synthesized similar to its congeners by radical addition of $PhMe_2SnH$ to $CH_2{=}CHPPh_2$, led to the formation of $(PhMe_2SnCH_2CH_2Ph_2P)Pt[PPh_2CH_2CH_2SnMe_2(Pt-Sn)](Ph)$ (**8**) and thus corroborates the fact that SnPh addition is favored over SnMe addition. The exclusive formation of the product of Sn−Ph activation was proven in the ^{1}H-NMR spectrum by a slightly broadened singlet resonance for the methyl groups at the metal-bonded Sn with a coupling to platinum of 7.3 Hz. This coupling constant was too small a value for $^2J_{PtCH}$, but in good agreement with a $^3J_{PtSnCH}$ coupling. The proton signals of the Pt−Ph moiety once again show the significant high-field shift and appear at δ = 6.87−6.98. The ^{13}C-NMR spectrum in the range for the sp^2-carbon atoms and their Pt satellites is very complex. Therefore, no assignments are possible. The complexes **7** and **8** are not dynamic at room temperature in the presence of PPh_3.

Conclusions

The present and our previous results on corresponding palladium complexes,[10] allow to draw a complete picture on the reactivity pattern of $Ph_2PCH_2CH_2SnR_3$ (R = Me, Ph) with complexes of the zero-valent metals of the nickel triad. For R = phenyl, the reactivity of $Ni(COD)_2$ parallels that of $(Ph_3P)_2Pt(C_2H_4)$. Complexes of the type $(Ph_3SnCH_2CH_2Ph_2P)M[PPh_2CH_2CH_2SnPh_2(M-Sn)](Ph)$ [M = Ni (**1**), Pt (**5**)], with a dangling $Ph_2PCH_2CH_2SnR_3$ ligand and a *cis* disposition of the two phosphorus atoms, were formed in both cases. For the nickel complex **1**, the oxidative addition of an Sn−Ph bond of the dangling $Ph_2PCH_2CH_2SnR_3$ ligand was observed at elevated temperatures during which the *cis* arrangement of the phosphorus atoms was retained. The resulting complex is *cis*-$Ni[PPh_2CH_2CH_2SnPh_2(Ni-Sn)]_2$ (**4**). The same reaction was not observed for the corresponding Pt complex **5**. The higher reactivity of Ni for the formation of the second chelate ring by oxidative addition of an Sn−Ph bond of the dangling phosphanylalkylstannyl ligand is somewhat surprising, because the heavier metals in a group are more prone to oxidative addition reactions. The driving force for the formation of **4** from **1** therefore may be the easier reductive elimination of biphenyl from the intermediate Ni^{IV} complex.

In the corresponding reactions of the tri*methyl*stannyl derivative $Ph_2PCH_2CH_2SnMe_3$ the reactivity pattern of $Ni(COD)_2$ parallels that of $Pd(PPh_3)_4$. In both cases the bischelated complexes *trans*-$M[PPh_2CH_2CH_2SnMe_2(M-Sn)]_2$ were formed, while the reaction with $(Ph_3P)_2Pt(C_2H_4)$ stopped at the stage of the mono-chelated complex *cis*-$(Me_3SnCH_2CH_2Ph_2P)Pt[(PPh_2CH_2CH_2SnMe_2)(Pt-Sn)](Me)$ (**6**). The change in geometry of $Ni[PPh_2CH_2CH_2SnMe_2-(Ni-Sn)]_2$ compared to the $SnPh_2$ derivative (**4**) is probably caused by steric effects overriding the electronic preference of the *cis* isomer.

When the phosphanylalkylstannanes $Ph_2PCH_2CH_2-SnPh_{3-x}Me_x$ (x = 1, 2) are employed, there is the possibility of either Sn−Ph or Sn−Me oxidative addition. For both Ni^0 and Pt^0, the Sn−Ph groups are more prone to oxidative addition than the Sn−Me groups, as was previously observed by us for Fe complexes.[11]

Complex **6**, whose structure was unambiguously confirmed by an X-ray structure analysis, showed dynamic behavior in the presence of PPh_3 that may be attributed to a $PPh_3/Ph_2PCH_2CH_2SnMe_3$ exchange process.

Experimental Section

All operations were carried under dry and oxygen-free argon by standard Schlenk-tube techniques. All solvents were dried by standard procedures, saturated with argon and stored over molecular sieves. The THF used was freshly distilled from potassium. The phosphanylalkylstannanes were synthesized according to literature procedures[11][20] from $Ph_2P(C_2H_3)$ and $HSnR_3$. − The NMR spectra were recorded with a Bruker AC 250 spectrometer. ^{1}H- and ^{13}C-NMR data were referenced against the solvent resonances, while ^{31}P- and ^{119}Sn-NMR data were referenced against the external standards 85% H_3PO_4 and $SnMe_4$. Integrations of the ^{1}H-NMR signals are omitted if there are overlaps with residual proton resonances of the deuterated solvents (especially C_6D_6). − DSC analyses were performed with a Shimadzu Thermal Analyzer DSC 50. The expression J_{XY} is used for those cases where coupling is possible through different nuclei.

Preparation of (Ph$_3$SnCH$_2$CH$_2$PPh$_2$)Ni(Ph)[Ph$_2$PCH$_2$CH$_2$-SnPh$_2$(Ni−Sn)] (**1**): An amount of 922 mg (1.63 mmol) of $Ph_2PCH_2CH_2SnPh_3$ was added to a solution of 213 mg (0.77 mmol) of $Ni(COD)_2$ in 25 ml of THF. The color of the yellow solution immediately turned to deep orange. After additional 2.5 h of stirring at room temperature, the reaction mixture was yellowish brown. Then the solvent and most of the COD was removed in vacuo at 40°C, leaving a slightly oily golden brown residue that contained **1** as the main product, according to the ^{31}P-NMR spectrum. Neither recrystallisation nor column chromatography on silica with common organic solvents resulted in analytically pure samples of **1**. − ^{31}P NMR (101.25 MHz, C_6D_6): δ = 58.3 (d, $^2J_{PNiP}$ = 6.1 Hz, $J_{117/119SnP}$ = 219.8 Hz), 26.1 (d, $^2J_{PNiP}$ = 6.1 Hz, $^2J_{119SnNiP}$ = 1109.3 Hz, $^2J_{117SnNiP}$ = 1065.9 Hz, $^3J_{SnCCP}$ = 183.0 Hz). − ^{119}Sn NMR (93.276 MHz, C_6D_6) δ 23.6 (dd, $^2J_{SnNiP}$ = 1116.7 Hz, J_{SnP} = 223 Hz), −97.6 (d, $^3J_{SnCCP}$ = 183.8 Hz). − ^{13}C NMR (62.90 MHz, C_6D_6): δ = 3.9 (d, $SnCH_2$, $^2J_{PCC}$ = 5.1 Hz),

6.3 (dd, $SnCH_2$, $^2J_{PCC}$ = 31.7 Hz, J_{PC} = 13.4 Hz), 23.7 (d, PCH_2, $^1J_{PC}$ = 11.5 Hz), 32.6 (dd, PCH_2, $^1J_{PC}$ = 24.5 Hz, J_{PC} = 7.9 Hz), 127.8−146.5 (C_6H_5). − ^{1}H NMR (250.130 MHz, C_6D_6): δ = 1.01−1.38 (m, overlapping $SnCH_2$), 1.59−1.84 (m, PCH_2), 2.40−2.61 (m, PCH_2), 6.75−7.05 (m, NiC_6H_5), 7.00−7.62 (m, C_6H_5).

Preparation of (PhMe$_2$P)Ni(Ph)[Ph$_2$PCH$_2$CH$_2$SnPh$_2$(Ni−Sn)] (**2**): A solution of 51 mg (0.37 mmol) of $PhPMe_2$ and 207 mg (0.37 mmol) of $Ph_2PCH_2CH_2SnPh_3$ in 6 ml of THF was added to a solution of 101 mg (0.37 mmol) of $Ni(COD)_2$ in 10 ml of THF. The mixture turned orange and, during further stirring for 4 h, yellow-brown. After removal of all volatiles, a sticky yellowish brown residue was obtained. It contained 90% of **2** and some **1** and $PhP(O)Me_2$ according to the NMR spectra. − ^{31}P NMR (101.25 MHz, C_6D_6): δ = 60.0 (d, $^2J_{PNiP}$ = 4.2 Hz, $J_{117/119SnP}$ = 239.0 Hz), −6.8 (d, $^2J_{PNiP}$ = 4.2 Hz, $^2J_{119SnNiP}$ = 1199.5 Hz, $^2J_{117SnNiP}$ = 1150.3 Hz). − ^{119}Sn NMR (93.276 MHz, C_6D_6): δ = 35.0 (dd, $^2J_{SnNiP}$ = 1199.1 Hz, J_{SnP} = 239.1 Hz). − ^{13}C NMR (62.90 MHz, C_6D_6): δ = 6.2 (dd, $SnCH_2$, $^2J_{PCC}$ = 31.1 Hz, $^3J_{PNiSnC}$ = 11.0 Hz), 12.9 (d, PCH_3, $^1J_{PC}$ = 22.6 Hz), 32.9 (dd, PCH_2, $^1J_{PC}$ = 33.0 Hz, $^3J_{PNiPC}$ = 9.2 Hz, 126.7−146.8 (C_6H_5). − ^{1}H NMR (250.130 MHz, C_6D_6): δ = 0.73 (d, PCH_3, $^2J_{PCH}$ = 6.1 Hz), 1.17−1.33 (m, $SnCH_2$), 2.59−2.78 (m, PCH_2), 6.90−7.73 (m, C_6H_5).

Preparation of (Cy$_3$P)Ni(Ph)[Ph$_2$PCH$_2$CH$_2$SnPh$_2$(Ni−Sn)] (**3**): A solution of 258 mg (0.92 mmol) of PCy_3 and 518 mg (0.92 mmol) of $Ph_2PCH_2CH_2SnPh_3$ in 5 ml benzene was added to a suspension of 252 mg (0.92 mmol) of $Ni(COD)_2$ in 15 ml of heptane. A red-brown solution formed almost immediately. After additional stirring for 4 h, during which the color slightly lightened, the solution was filtered through glass wool. From the resulting deep red solution all volatiles were removed in vacuo. The remaining golden-red oil was chromatographed on silica gel with Et_2O/petroleum ether (1:50). The complex **3** was eluted as a deep yellow zone. After removal of the solvent, 620 mg (75%) of **3** was obtained as a brown-yellow powder. M.p. 69°C (dec.). − $C_{50}H_{62}P_2NiSn$ (902.3): calcd. C 66.6, H 6.93; found C 65.9, H 6.81. − ^{31}P NMR (101.250 MHz, C_6D_6): δ = 51.9 (d, $^2J_{PNiP}$ = 8.6 Hz, J_{119SnP} = 222.2 Hz, J_{117SnP} = 206 Hz), 22.5 (d, $^2J_{PNiP}$ = 8.6 Hz, $^2J_{119SnNiP}$ = 1036.3 Hz, $^2J_{117SnNiP}$ = 991.2 Hz). − ^{119}Sn NMR (93.276 Hz, C_6D_6): δ = 16.7 (dd, $^2J_{119SnNiP}$ = 1036.3 Hz, $^2J_{119SnNiP}$ = 218.7 Hz). − ^{13}C NMR (62.90 MHz, C_6D_6): δ = 5.2 (dd, $SnCH_2$, $^2J_{PCC}$ = 29.6 Hz, $^3J_{PNiSnC}$ = 12.2 Hz), 32.7 (dd, PCH_2 $^1J_{PC}$ = 31.4 Hz, $^2J_{PNiPC}$ = 6.9 Hz), 34.7 (d, $^1J_{PC}$ = 11.6 Hz), 30.7 (s), 27.8 (d, J_{PC} = 9.4 Hz), 26.8 (s), signals of PCy_3, 121.1−156.2 (C_6H_5), 155.6 (dd, NiC, $^2J_{PNiC}$ = 59.2 Hz, $^2J_{PNiC}$ = 7.9 Hz). − ^{1}H NMR (250.130 MHz, C_6D_6): δ = 0.93−0.98 (m, $SnCH_2$, 2 H), 1.15 (s, br.) 1.51−1.80 (m) (cyclohexyl, 33 H), 2.65−2.87 (m, PCH_2, 2 H), 6.95−7.10 (m, NiC_6H_5), 7.07−7.79 (m, C_6H_5).

Thermal Reaction of **1**: An amount of 350 mg of the crude complex **1** was dissolved in 20 ml of toluene and heated in a sealed Schlenk tube for 9 h to 70°C. Then the solvent was removed in vacuo. The oily yellowish brown residue was analyzed by ^{31}P- and ^{119}Sn-NMR spectroscopy, which showed partial formation of $Ni[Ph_2PCH_2CH_2SnPh_2(Ni-Sn)]_2$ (**4**) and some decomposition. The reaction products could not be separated. The NMR data are given in the next paragraph.

Preparation of Ni[(Ph$_2$PCH$_2$CH$_2$SnPh$_2$(Ni−Sn)]$_2$ (**4**) *from Ph$_2$PCH$_2$CH$_2$SnPh$_2$H*: A solution of 400 mg (0.82 mmol) of $Ph_2PCH_2CH_2SnPh_2H$ in 6 ml of THF was added to a yellow solution of 108 mg (0.41 mmol) of $Ni(COD)_2$ in 10 ml of THF. The reaction mixture immediately turned red, and a gas was evolved. During additional 3 h of stirring, the color of the solution lightened to yellowish brown with further weak gas evolution. Then all volatiles were removed in vacuo leaving a yellowish brown oily residue containing **4** in about 85% yield, as confirmed by ^{31}P- and ^{119}Sn-NMR spectroscopy. Washing the residue twice with 3 ml of pentane each left a slightly oily yellowish brown powder that still contained some impurities that could not be removed. − ^{31}P NMR (101.250 MHz, C_6D_6): δ = 63.3 (s, $^2J_{119SnNiP}$ = 930.5 Hz, $^2J_{117SnNiP}$ = 891.1 Hz, $J_{117/119SnP}$ = 161.1 Hz. − ^{119}Sn NMR (93.276 MHz, C_6D_6): δ = 56.8 (dd, $^2J_{PNiSn}$ = 933.3 Hz, J_{SnP} = 164.0 Hz).

Reaction of Ni(COD)$_2$ with Ph$_2$PCH$_2$CH$_2$SnMe$_3$: A solution of 1.47 g (3.86 mmol) of $Ph_2PCH_2CH_2SnMe_3$ in 8 ml of THF was added to a solution of 532 mg (1.93 mmol) of $Ni(COD)_2$ in 40 ml of THF. The resulting red solution was stirred for 3 h during which a gas evolved and the color of the solution deepened. The red-brown solution was concentrated in vacuo, and the resulting yellow-brown slightly sticky residue was analyzed by ^{31}P- and ^{119}Sn-NMR spectroscopy. − ^{31}P NMR (101.250 MHz, C_6D_6): δ = 41.5 (s, J_{SnP} = 137.9 Hz). − ^{119}Sn NMR (93.276 MHz, C_6D_6): δ = 5.9 (t).

Reaction of Ni(COD)$_2$ with Ph$_2$PCH$_2$CH$_2$SnPh$_2$Me: A solution of 1.08g (2.16 mmol) of $Ph_2PCH_2CH_2SnPh_2Me$ in 5 ml of THF was added to 297 mg (1.08 mmol) $Ni(COD)_2$, dissolved in 20 ml of THF. The deep red solution was stirred for 4 h while a small amount of gas was evolved. Removal of all volatiles in vacuo left a brown oil. − ^{31}P NMR (101.250 MHz, C_6D_6): δ = 57.9 (d, $^2J_{PNiP}$ = 6.1 Hz, $J_{117/119SnP}$ = 213 Hz), 25.3 (d, $^2J_{PNiP}$ = 6.1 Hz).

Preparation of (Ph$_3$SnCH$_2$CH$_2$Ph$_2$P)Pt[PPh$_2$CH$_2$CH$_2$SnPh$_2$-(Pt−Sn)](Ph) (**5**): A solution of 193 mg (0.35 mmol) of $Ph_2PCH_2CH_2SnPh_3$ in 3 ml of benzene was added to a solution of 117 mg (0.17 mmol) of $(Ph_3P)_2Pt(C_2H_4)$ in 12 ml of benzene. An immediate color change to bright yellow and gas evolution occurred. The solution was stirred for additional 10 h at room temperature, resulting in a pale yellow solution. A yellow oil remained after removal of all volatiles in vacuo. Complex **5** was obtained as a pale yellow powder on washing the oil three times with 5 ml of petroleum ether each at 0°C and drying in vacuo. Yield 128 mg (57%). M.p. 95°C (dec.). − $C_{64}H_{58}P_2PtSn_2$ (1321.6): calcd. C 58.2, H 4.42; found C 57.9, H 4.30. − ^{31}P NMR (101.250 MHz, C_6D_6): δ = 51.8 (d, $^2J_{PPtP}$ = 11.0 Hz, $^1J_{PtP}$ = 2020.2 Hz, J_{SnP} = 115.0 Hz), 24.1 (d, $^2J_{PPtP}$ = 11.0 Hz, $^1J_{PtP}$ = 2184.9 Hz, $^2J_{119SnPtP}$ = 1712.6 Hz, $^2J_{117SnPtP}$ = 1635.7 Hz, $^3J_{SnCCP}$ = 179.4 Hz). − ^{119}Sn NMR (93.276 MHz, C_6D_6): δ = 97.2 (dd, $^2J_{119SnPtP}$ = 1711.5 Hz, J_{119SnP} = 117.0 Hz), −97.5 (d, $^3J_{119SnCCP}$ = 180.6 Hz). − ^{13}C NMR (62.90 MHz, C_6D_6): δ = 4.1 (d, $^2J_{PCC}$ = 7.5 Hz, $SnCH_2$), 5.2 (dd, $^2J_{PCC}$ = 23.6 Hz, $^3J_{PPtSnC}$ = 12.0 Hz, $SnCH_2$), 24.4 (d, $^1J_{PC}$ = 20.8 Hz, PCH_2) 36.6 (dd, $^1J_{PC}$ = 37.5 Hz, J_{PC} = 8.8 Hz, PCH_2), 124.3−156.3 (C_6H_5, no assignment was possible due to different phenyl groups and Pt satellites). − ^{1}H NMR (250.130 MHz, C_6D_6): δ = 0.80−1.28 (m, overlapping, 4 H, $SnCH_2$), 2.15−2.32 (m, 2 H, PCH_2), 2.45−2.68 (m, 2 H, PCH_2), 6.78−7.73 (m, C_6H_5).

Preparation of (Me$_3$SnCH$_2$CH$_2$Ph$_2$P)Pt[PPh$_2$CH$_2$CH$_2$SnMe$_2$-(Pt−Sn)](Me) (**6**). − *Method a:* A solution of 128 mg (0.17 mmol) of $(Ph_3P)_2Pt(C_2H_4)$ in 10 ml of benzene was treated with 130 mg (0.35 mmol) of $Ph_2PCH_2CH_2SnMe_3$ in 4 ml of benzene at room temperature for 12 h. After removal of the solvent in vacuo, an orange oil remained. The product was crystallized from a concentrated benzene solution by heptane diffusion as pale yellow crystals in 55% yield (89 mg). M.p. 132°C. − $C_{34}H_{46}P_2PtSn_2$ (949.2): calcd. C 43.0, H 4.88, found C 43.4, H 4.65.

Method b: To a beige solution of 131 mg (0.32 mmol) of $Pt(COD)_2$ in 3 ml of benzene, 242 mg (0.64 mmol) of

$Ph_2PCH_2CH_2SnMe_3$ was added, resulting in a color change to yellow-brown. On stirring for 16 h, the color of the reaction mixture became lighter. All volatiles were removed in vacuo after filtration through glass wool, and the remaining slightly oily solid was washed twice at 0°C with 3 ml of pentane each. After drying, **6** was obtained as a beige powder (210 mg, 69%).

^{31}P NMR (101.250 MHz, C_6D_6): δ = 55.9 (d, $^2J_{PPtP}$ = 7.3 Hz, $^1J_{PtP}$ = 2152.2 Hz, J_{SnP} = 108.6 Hz), 27.9 (d, $^2J_{PPtP}$ = 7.3 Hz, $^1J_{PtP}$ = 2065.5 Hz, $^2J_{119SnPtP}$ = 1726.2 Hz, $^2J_{117SnPtP}$ = 1696.8 Hz, $^3J_{SnCCP}$ = 213.6 Hz). – ^{119}Sn NMR (93.276 MHz, C_6D_6): δ = 147.2 (dd, $^2J_{119SnPtP}$ = 1732.1 Hz, J_{119SnP} = 111.9 Hz), −29.5 (d, $^3J_{119SnCCP}$ = 218.7 Hz). – ^{13}C NMR (62.90 MHz, [D$_8$]toluene): δ = −11.7 (dd, *trans*-$^2J_{PPtC}$ = 82.9 Hz, *cis*-$^2J_{PPtC}$ = 7.6 Hz, $PtCH_3$), −9.6 (s, $SnCH_3$), −6.5 (d, $^3J_{PPtSnC}$ = 8.2 Hz, $^2J_{PtSnC}$ = 78.5 Hz, $SnCH_3$), 5.8 (s, br., $SnCH_2$), 6.1 (d, J_{PC} = 13.1 Hz, $SnCH_2$), 25.4 (d, br., $^1J_{PC}$ = 12.0 Hz, PCH_2), 39.4 (dd, $^1J_{PC}$ = 39.2 Hz, J_{PC} = 8.7 Hz, PCH_2). – ^{1}H NMR (250.130 MHz, [D$_8$]toluene): δ = −0.11 (s, $^2J_{SnCH}$ = 51.3 Hz, 9 H, $SnCH_3$), 0.55 (s, $^2J_{SnCH}$ = 41.5 Hz, $SnCH_3$, 6H), 0.65 (d, $^3J_{PPtCH}$ = 6.1 Hz, $PtCH_3$), 0.71− 0.95 (m, $SnCH_2$), 1.44−1.52 (m, $^2J_{117/119SnCH} \approx$ 59 Hz, 2 H, $SnCH_2$), 2.03−2.12 (m, PCH_2), 2.48−2.61 (m, PCH_2, 2 H), 6.98−7.75 (m, C_6H_5).

Preparation of (Bu$_3$SnCH$_2$CH$_2$Ph$_2$P)Pt[PPh$_2$CH$_2$CH$_2$SnBu$_2$-(Pt−Sn)](Bu) (**7**): The reaction was carried out in benzene as described for **6**, using 160 mg (0.22 mmol) of $(Ph_3P)_2Pt(C_2H_4)$ and 227 mg (0.45 mmol) of $Ph_2PCH_2CH_2SnBu_3$. Removal of all volatiles in vacuo resulted in a yellow oil (consisting of **7** in about 90% yield according to the ^{31}P-NMR spectrum). By washing the oil twice with 8 ml of pentane each and drying in vacuo, a yellow powder was obtained that contained **7** and only traces of impurities according to the ^{31}P-NMR spectrum. – ^{31}P NMR (101.25 MHz, C_6D_6): δ = 53.2 (d, $^2J_{PPtP}$ = 9.3 Hz, $^1J_{PtP}$ = 1899.5 Hz, $J_{117/119SnP}$ = 110.2 Hz), 27.9 (d, $^2J_{PPtP}$ = 9.3 Hz, $^1J_{PtP}$ = 2097.2 Hz, $^2J_{119SnPtP}$ = 1671.2 Hz, $^2J_{117SnPtP}$ = 1596.7 Hz, $^3J_{119SnCCP}$ = 185.6 Hz, $^3J_{117SnCCP}$ = 178.2 Hz). – ^{119}Sn NMR (93.276 MHz, C_6D_6): δ = 175.8 (dd, $^2J_{119SnPtP}$ = 1673.4 Hz, J_{119SnP} = 111.9 Hz), −4.8 (d, $^3J_{PCC119Sn}$ = 185.7 Hz). – ^{1}H NMR (250.130 MHz, C_6D_6): δ = 0.75−1.96 (complex overlapping multiplets of butyl groups and $SnCH_2$), 2.20−2.51 (m, PCH_2), 2.65−2.80 (m, PCH_2) 6.99−7.90 (m, C_6H_5).

Preparation of (PhMe$_2$SnCH$_2$CH$_2$Ph$_2$P)Pt[PPh$_2$CH$_2$-CH$_2$SnMe$_2$(Pt−Sn)](Ph) (**8**): An amount of 123 mg (0.16 mmol) of $(Ph_3P)_2Pt(C_2H_4)$ and 144 mg (0.16 mmol) of $Ph_2PCH_2CH_2SnMe_2Ph$ was treated as described above. After removal of all volatiles, the yellow oil was analyzed by multinuclear NMR which indicated the almost quantitative formation of **8** according to ^{31}P NMR. – ^{31}P NMR (101.250 MHz, C_6D_6): δ = 52.8 (d, $^2J_{PPtP}$ = 11.0 Hz, $^1J_{PtP}$ = 2116.0 Hz, $J_{117/119SnP}$ = 104.1 Hz), 24.4 (d, $^2J_{PPtP}$ = 11.0 Hz, $^1J_{PtP}$ = 2046.2 Hz, $^2J_{119SnPtP}$ = 1572,3 Hz, $^2J_{117SnPtP}$ = 1503.7 Hz, $^3J_{119/117SnCCP}$ = 200.0 Hz). – ^{119}Sn NMR (93.276 MHz, C_6D_6): δ = 161.2 (dd $^2J_{119SnPtP}$ = 1572.9 Hz, J_{119SnP} = 104.4 Hz) −25.5 (d, $^3J_{119SnCCP}$ = 208.0 Hz). – ^{13}C NMR (62.90 MHz, C_6D_6): δ = −11.1 [s, $Sn(CH_3)_2Ph$], −7.4 [d, $^3J_{PPtSnC}$ = 6.9 Hz, $^2J_{PtSnC}$ = 74.9 Hz, $Sn(CH_3)_2$], 3.7 (d, $^2J_{PCC}$ = 7.4 Hz, $SnCH_2$), 6.6 (d, $^2J_{PCC}$ = 16.2, $SnCH_2$), 25.4 (d, br., $^1J_{PC}$ = 18.5 Hz, PCH_2) 37.6 (dd, $^1J_{PC}$ = 38.4 Hz, J_{PC} = 8.8 Hz, PCH_2), 121.9−156.6 (C_6H_5, no assignment possible due to different phenyl groups and Pt satellites). – ^{1}H NMR (250.13 MHz, C_6D_6): δ = 0.04 (s, $^2J_{SnCH}$ = 53.0 Hz, 6 H, $SnCH_3$), 0.36 (s, br, $^3J_{PtSnCH}$ = 8.1 Hz, 6 H, $SnCH_3$), 0.58−0.73 (m, $SnCH_2$), 1.05−1.19 (m, $SnCH_2$), 2.09−2.21 (m, 2 H, PCH_2), 2.53−2.67 (m, 2 H, PCH_2), 6.87−6.98 (m, 5 H, PtC_6H_5), 7.10−7.86 (m, C_6H_5).

X-ray Structure Analysis of **6**: Triclinic, space group *P*1, *a* = 1241.42(1), *b* = 1280.91(2), *c* = 1578.98(3) pm, α = 66.396(1), β = 69.796(1), γ = 66.749(1)°, *V* = 2060.91·10^6(3) pm^3, $d_{calcd.}$ = 1.655 g cm^{-3} for *Z* = 2. *F*(000) = 1000, μ(Mo-K_α) = 4.690 mm^{-1}, λ = 71.073 pm, *T* = 302 K, crystal size = 0.5 × 0.4 × 0.25 mm. A crystal was sealed in a glass capillary and mounted on a Siemens SMART diffractometer with a CCD area detector. A hemisphere of data was collected by a combination of three sets of exposures (17343 reflections). Each set had a different φ angle for the crystal, and each exposure took 15 s and covered 0.3° in ω (2.9° ≤ 2Θ ≤ 60.1°). The crystal-to-detector distance was 3.85 cm. The data were corrected for polarization and Lorentz effects, and an empirical absorption correction (SADABS) was applied (11897 unique reflections). The structure was solved by the Patterson method (SHELS86). Refinement was carried out with the full-matrix least-squares method based on F^2 (SHELXL93) with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were inserted in calculated positions and refined riding with the corresponding atom. Refinement converged at R_1 = 0.0595 [for 1847 reflections with $I > 2\sigma(I)$], wR_2 = 0.1344 {$w = [\sigma^2(F_o)^2 + (0.0 \cdot x P)^2 + x \cdot P]^{-1}$, where $P = (F_o^2 + 2F_c^2)/3$}; final GOF = 0.511. The final difference map showed no peak larger than +2.008 e^{-3} and no hole larger than −1.243 e^{-3}.[21]

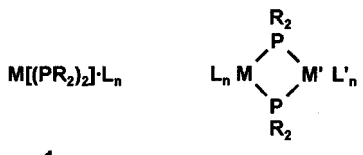
Keywords: Phosphane complexes / Alkaline earth metal compounds / Phosphanomethanides

The reaction of lithium[bis(dimethylphosphanyl)(trimethylsilyl)methanide] Li[$(PMe_2)_2C(SiMe_3)$] with $BeCl_2$ gave the homoleptic compound Be[$(PMe_2)_2C(SiMe_3)]_2$ (**5**) with four beryllium–phosphorus bonds constituting a distorted tetrahedron around the beryllium center. The reaction of $MgCl_2$ with Li[$(PMe_2)_2C(SiMe_3)$] resulted in the formation of the bis-chelate complex Mg[$(PMe_2)_2C(SiMe_3)]_2 \cdot 2$ THF (**7**), where the distorted *cis*-octahedral magnesium center is additionally coordinated by two THF ligands. In the reaction of **7** with an additional equivalent of Li[$C(PMe_2)_2(SiMe_3)$], THF is released and the magnesate anion {Mg[$(PMe_2)_2C(SiMe_3)]_3$}$^-$ (**8**) was obtained. This compound is not only the first reported hexacoordinated magnesate, but also the first magnesium compound with six magnesium–phosphorus bonds. With $CaCl_2$ and Li[$C(PMe_2)_2(SiMe_3)$], a heptacoordinated complex Ca[$(PMe_2)_2C(SiMe_3)]_2 \cdot 3$ THF (**10**) with three coordinating THF ligands was isolated. The complexes were characterized using ^{9}Be{^{1}H}-, ^{31}P{^{1}H}-, ^{1}H-, ^{13}C{^{1}H}-NMR spectroscopy, and elemental analysis and by X-ray diffraction. The neutral compounds are highly soluble in nonpolar solvents.

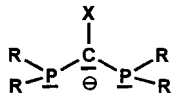
Introduction

The alkaline earth metals are very hard coordination centers. In general, they do not form stable complexes with soft donors such as phosphanes and it seems a challenging task to create stable alkaline earth metal−phosphane donor bonds. Only three complexes of diorganometal centers R_2M with "normal" (i.e. neutral) phosphane ligands R_3P, two examples for beryllium[1] and one for magnesium[2], have been reported in the literature, but none have been well characterized. Phosphane complexes of alkaline earth metals are promising precursors for chemical vapor deposition (CVD) processes and possible candidates for metal-mediated organic synthesis. Moreover, with phosphane donor ligands it might be possible to stabilize low-valency alkaline earth metal compounds and mixed alkaline earth/transition-metal bi- or multinuclear complexes. A promising strategy for creating alkaline earth metal to phosphorus bonds makes use of *anionic* phosphanide ligands containing phosphorus of formal valency number two, and in fact several alkaline earth metal compounds with phosphanide ligands **1** have been described[3]. Bridged heterobimetallic phosphanides **2** may also be formed in this way[4].



1 **2**

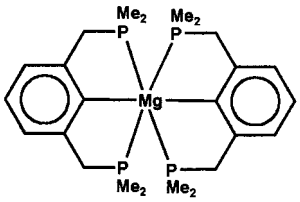
An alternative class of anionic phosphane donor ligands is established by diphosphanomethanides **3**[5].



3

In this class of ligands, in contrast to phosphanides, the negative charge is not localized at the phosphorus atom and the phosphorus valency number is three, as is typical for phosphanes. Anionic diphosphanomethanides have been ligated to hard metal centers (e.g. aluminium[6] and rare earth metals[7]) and they often enable high phosphane coordination numbers even at these metal centers.

Thus, it emerged that phosphane coordination to alkaline earth metals might be achieved by using anionic diphosphanomethanide ligands. Meanwhile, using a related strategy, a hexacoordinated magnesium compound **4** with four magnesium−phosphorus bonds has been successfully synthesized[8].



4

The use of diphosphanomethanides additionally might provide access to homoleptic species exhibiting exclusively metal−phosphorus bonds. Furthermore, the monoanionic nature of these ligands and their tendency to form four-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0707−0905 $ 17.50+.50/0

membered chelates allows comparisons to be made with other recently synthesized compounds of alkaline earth metals derived from amidinates and aminoiminophosphoranates[9]. Additionally, for the heavier alkaline earth metals the question of d-orbital participation may be considered.

This paper is concerned with the synthesis and full characterization of phosphane donor adducts to alkaline earth metal centers ranging from beryllium to calcium, including the first homoleptic examples of beryllium and magnesium with exclusive metal−phosphorus bonds.

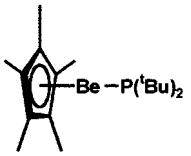
Results and Discussion

$Be[(PMe_2)_2C(SiMe_3)]_2$ (5)

This first molecular compound with beryllium exclusively joined to phosphorus was obtained by treating anhydrous $BeCl_2$ with two equivalents of $Li[(PMe_2)_2C(SiMe_3)]$ according to Eq. (1) and isolated from pentane as colorless crystals **5**. The substance is extremely air and moisture sensitive.

$$BeCl_2 + 2\ Li[C(PMe_2)_2(SiMe_3)] \xrightarrow{THF} \mathbf{5} \qquad \text{(eq.1)}$$

The first $^9Be\{^1H\}$-NMR spectrum of a beryllium−phosphorus compound was obtained from **5** in C_6D_6 at room temperature. It exhibits a quintet at $\delta = 6.4$ with a $^1J_{Be-P}$ coupling constant of 33.5 Hz. The same coupling constant can be extracted from the $^{31}P\{^1H\}$-NMR quartet signal ($\delta = -30.8$). This is an indication of a highly symmetrical structure with four equivalent phosphorus atoms in solution. As expected, the coupling constant is smaller than that observed in the $^{31}P\{^1H\}$-NMR spectrum of the phosphanide compound Cp*BeP(*t*Bu)$_2$ (**6**) ($^1J_{Be-P} = 50$ Hz), the only other hitherto known, sufficiently characterized molecular beryllium−phosphorus compound[10].



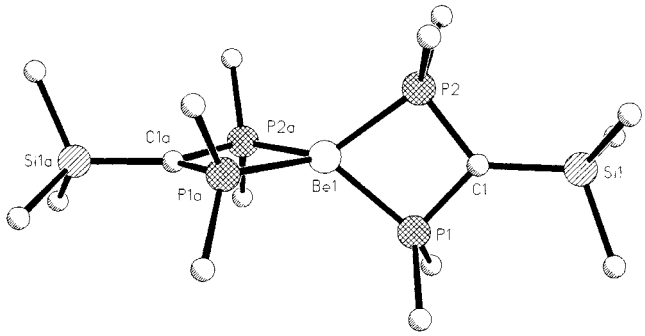
6

The spectra are essentially temperature independent (−80 to +40°C).

X-ray analysis reveals 1/2 (**A**) and 1/4 (**B**) molecule in the asymmetic unit. The whole molecules can be generated by symmetric transformations (#1: $x + 1 - 1, -y + 1/2, -z + 3/2$; #2: $-x, y, -z + 1/2$; #3: $-x + 1 - 1, -y + 1/2, z$; #4: $-x, y, -z + 3/2$). The bond lengths and angles are nearly identical for both molecules **A** and **B**, but the $SiMe_3$ group in **B** is disordered and could not be resolved computationally. Therefore, only molecule **A** will be discussed.

In the solid state, compound **5** is a monomer. The central beryllium dication is coordinated by two chelating $[(PMe_2)_2C(SiMe_3)]^-$ monoanions resulting in a distorted tetrahedral BeP_4 arrangement. The normals to the two BeP_2 planes intersect at an angle of 90°. Both BePCP four-membered rings are planar, as is the environment of the endocyclic C atoms C1 and C1a. The Be−P bond lengths are remarkably short; a comparison with the only two structurally characterized beryllium−phosphorus compounds shows that the bond lengths in **5** [2.134(2) and 2.137(3) Å] are just between the respective bond lengths in **6** (2.083 Å)[10] and in the binary solid-state phase Be_3P_2 (2.20 Å)[11], but in both cases anionic phosphanide- and phosphide-type ligating atoms, respectively, are involved. The endocyclic P−C bond lengths [1.740(4) and 1.744(4) Å] are quite short and of nearly equal length, as is the case in a variety of other diphosphanomethanide complexes[5]. This has been explained in terms of an ylidic bonding model with some charge delocalization within the PCP moiety. The nonbonding P1−P2 distance [2.685(1) Å] is significantly shorter than the van der Waals radii, as is the case with other chelating diphosphanomethanide derivatives and must be regarded as a consequence of the geometric restraints[12].

Figure 1. Crystal structure of **5** (only molecule A is shown)

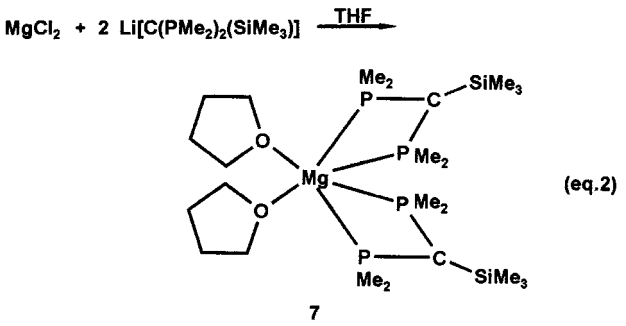


$Mg[(PMe_2)_2C(SiMe_3)]_2 \cdot 2$ THF (7)

Diphosphanomethanides can span tetrahedral coordination sites only with centers from the second period (lithium[13], beryllium: this paper, boron[14]). With increasing atomic radii, i.e. with the heavier elements, either higher coordination numbers at the coordination center M (which decreases the P−M−P angle; Si[15], P[12]) or a monodentate ligating mode is observed (Si[15], P[16]). Consequently, in the analogous reaction of anhydrous $MgCl_2$ with $Li[(PMe_2)_2C(SiMe_3)]$, the formation of the bis-chelate complex **7** is observed.

In contrast to the beryllium compound, where the central atom is tetrahedrally coordinated by four phosphorus atoms, the magnesium center in **7** is additionally coordinated by two THF molecules, completing a distorted octahedral environment at the metal center.

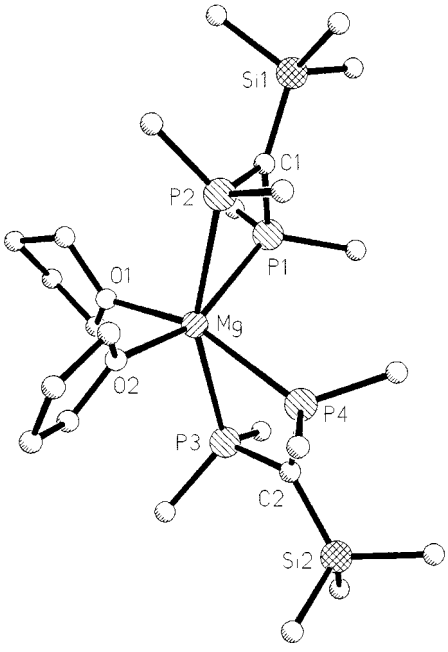
$^{31}P\{^1H\}$-NMR variable-temperature experiments at −80°C show a multi-line, symmetric pattern, tentatively assigned to a not completely resolved AA′BB′ spin system



7

(centered at $\delta = -16.7$). At room temperature only one singlet ($\delta = -16.2$) was detected, due to a fast exchange of axial and equatorial sites. These experiments indicate a *cis*-octahedral coordination, in contrast to the only hitherto known magnesium−phosphorus compound **4** with four Mg−P bonds[8]. The *cis*-octahedral coordination was confirmed by X-ray analysis.

Figure 2. Crystal structure of **7**



The Mg−P bond lengths [2.654(1)−2.684(1) Å] are equal within one standard deviation and are significantly shorter than in **4** [2.761(1) and 2.770(1)[8]], but more comparable with those in tetracoordinated magnesium−phosphanide compounds, e.g. in $[Mg(PHPh)_2(TMEDA)]$ [2.592(5) and 2.587(5) Å][17].

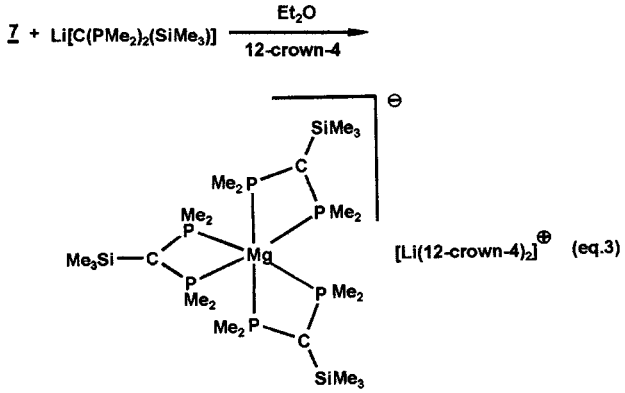
In contrast, the Mg−O bond lengths [2.137(2) and (2.122(2) Å] are significantly longer than in tetrahedral reference compounds [e.g. $Ph_2Mg(THF)_2$: 2.03 Å][18], and therefore it seems possible to remove the THF ligands. In fact, a substitution of the THF ligands by a third diphosphanomethanide ligand is possible (see below).

The average bond lengths of P1/2−C1 and P3/4−C2 (1.75 Å) range between the bond lengths of an ylidic P−C bond (typically around 1.68 Å) and a single P−C bond (ca. 1.83 Å), consistent with the carbanionic character of C1 and C2. The mean lengths of $P-C_{methyl}$ bonds (1.85 Å) are roughly within this latter range.

The sums of the angles in the four-membered rings MgPCP are 359.8° and 359.9° respectively, which indicates the planarity of chelate rings. The environment of the carbanionic carbon atoms is also planar, the silicon atom of the $SiMe_3$ groups adopting a position in the same plane as the four-membered chelate rings.

$[Li(12\text{-crown-}4)_2]^+\{Mg[(PMe_2)_2C(SiMe_3)]_3\}^-$ (8)

The homoleptic "magnesate" anion **8** is obtained as described in Eq. 3. Hitherto known "magnesate" anions exhibit coordination numbers of four[19] or five[20]. It is also the first molecular magnesium compound with six magnesium−phosphorus bonds.



8

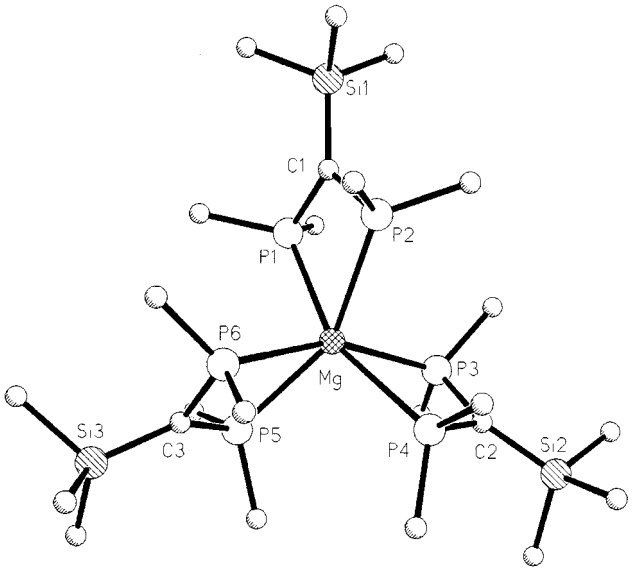
The $^{31}P\{^1H\}$-NMR spectrum (C_6D_6) shows a singlet ($\delta = -15.8$), which does not vary with temperature and thus indicates the equivalence of all six phosphorus atoms.

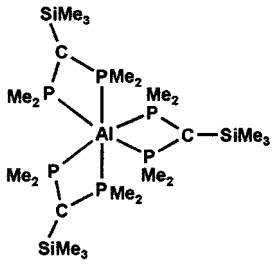
The ^1H-NMR spectrum (C_6D_6) reveals, besides the signals of the phosphanomethanide ligand, the presence of two 12-crown-4 molecules ($\delta = 2.9$) per anion. Colorless crystals of **8** have been grown from diethyl ether solution. The X-ray analysis shows the structure containing a $Li[12\text{-crown-}4]_2^+$ cation[21], two molecules of C_6H_6 and a hexacoordinated "magnesate" anion, which is isoelectronic with the neutral aluminium complex **9**[6]. The cation and anion units are well separated without any noticeable interionic contacts.

The $Li[12\text{-crown-}4]_2^+$ cation shows considerable disorder, which influences the *R* values, but has no influence on the structural findings concerning the anion. Again, as in **5** and **7**, the three four-membered chelate rings in **8** are planar, as are the environments of the carbanionic carbon atoms. The deviation from the ideal octahedral geometry at magnesium can be described by the torsion angle ϕ of the trigonal P_3 planes P1, P3, P5 and P2, P4, P6 ($\phi = 32.2°$). This angle indicates a slightly enhanced torsion towards a trigonal-prismatic coordination compared to **9** ($\phi = 35.9°$)[6].

A magnesium ion of coordination number six can also be assigned in the polymeric solid-state phase of MgP_4[22],

Figure 3. Crystal structure of **8** (only the anion is shown)





9

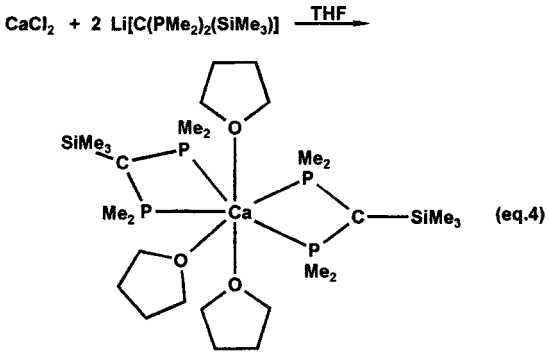
although a description in terms of 4 + 2 coordination may be more appropriate. There are two quite different Mg−P distances in MgP_4 (four short contacts: 2.608 A and two long contacts: 2.862 A), in marked contrast to the case of **8**. In **8**, the Mg−P bond lengths are more similar, ranging from 2.635(3) to 2.698(3) A, with a mean Mg−P bond length of 2.66 A. In **9**, the Al−P distance amounts to 2.490 A[6]. Altogether, as expected, a high ionic contribution to the metal to ligand bonding in both **8** and **9** may be extracted from these data.

$Ca[(PMe_2)_2C(SiMe_3)]_2 \cdot 3$ THF

The diphosphanomethanides are also suitable phosphane donor ligands for the heavier alkaline earth metals. An example is given by Eq. 4. Colorless crystals of **10** are obtained from the pentane extraction of the reaction mixture.

The $^{31}P\{^1H\}$-NMR spectrum displays a singlet (δ = −28.6) which essentially remains unchanged on cooling (−80°C).

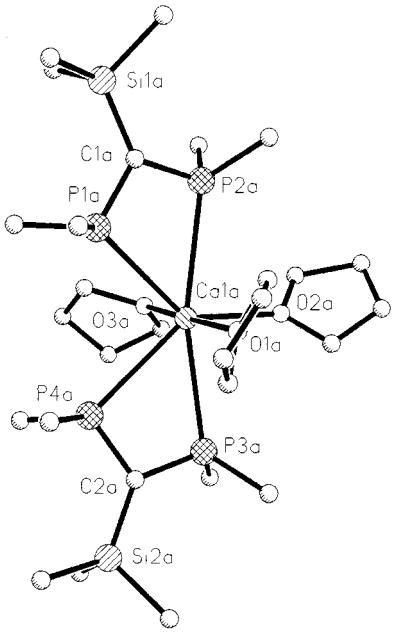
The X-ray analysis of the colorless crystals of **10** shows two identical molecules in the asymmetric unit and reveals phosphane coordination to a calcium atom for the first time. Three THF molecules and two chelating diphosphanomethanide ligands generate a distorted pentagonal-bipyramidal coordination polyhedron. Two of the THF ligands are in a *trans*-axial position with a bond angle



10

O1−Ca1−O3 of 177.0(1)°; the third THF ligand and the two planar four-membered chelate rings of the diphosphanomethanides complete the pentagon. The sum of internal angles is 361.3° indicating the near planarity of the pentagon. The higher coordination number of Ca^{2+} can easily be understood in terms of the increasing ion radius in going from Mg^{2+} to Ca^{2+}.

Figure 4. Crystal structure of **10** (only molecule A is shown)



The angles P2−Ca1−O2 and P3−Ca1−O2 are close to rectangular (81.96° and 81.95°, respectively) indicating that the two chelating diphosphanomethanide ligands are located essentially in one hemisphere of the central atom, as is the case in the magnesium compound **7** (which in the case of **10** is more or less trivial, however). The partial ylidic character of the $P-C_{carbanion}$ bond again is evident from the average bond lengths of 1.75 A (see above). The mean Ca−P (3.043 A) and Ca−O bond lengths (2.391 A) are within the range found in known phosphanide and THF complexes of calcium[3][23]. An indication of d-orbital participation is not obvious, at least as extracted from the planarity of the chelate rings and of the endocyclic C atoms,

as it also was found in most other diphosphanomethanide complexes, including **5**, **7**, **8**, and **9**. In marked contrast to **10**, the chelate rings in the scandium complex $Sc[(PMe_2)_2C(SiMe_3)]_3$[7] show a considerable deviation from planarity.

Comparison of 5, 7, and 10

All three compounds are monomeric and contain chelating diphosphanomethanides. As a consequence of the monomeric nature, these alkaline earth metal−phosphane complexes are soluble in nonpolar organic solvents such as pentane. With increasing metal radii, the coordination number increases from 4 (beryllium) to 6 (magnesium) to 7 (calcium), resulting in more or less distorted tetrahedral, octahedral, and pentagonal-bipyramidal coordination geometry, respectively. The additional coordination sites are occupied by two (magnesium) or three (calcium) THF donor molecules. In all cases the four-membered chelate rings including the metal atom are planar. For the magnesium and the calcium compounds a cisoid coordination of the diphosphanomethanide ligands is observed. The P−C bond lengths within the four-membered rings in all cases are close to 1.75 A which is well between the bond lengths of a single and an ylidic P−C double bond. This is in accordance with other diphosphanomethanide chelate rings and reflects the partial ylidic character of this bond. Since all P−C and M−P endocyclic bond lengths within a given compound are almost identical, an "unisobidentate" coordination mode, as present in some diphosphanomethanide[14] and related complexes with potentially bidenate ligands[24], is not observed. One may speculate whether the restriction of the diphosphanomethanide coordination to one hemisphere of the metal (magnesium, calcium) may be attributed to effects which are also responsible for the bending in simple MX_2 molecules[25]. It is interesting to note that similar behavior has been observed in amidinate and aminoiminophosphoranate complexes of the heavier alkaline earth metals[9]. This observation can now be extended: it is no longer restricted to N-donor-type ligands, but includes also P-donor-type ligands and is probably a quite general phenomenon. Moreover, magnesium coordination centers can also be added to the series, which is particularly noteworthy since d orbitals are not available for this element.

The proposed generality of this observation is augmented by the fact that the chelate rings in **5**, **7**, and **10** not only span quite different coordination polyhedra but also vary considerably in the M−P bond lengths in going from beryllium to magnesium to calcium. Likewise, as a consequence of this bond lengthening, the endocyclic angles at phosphorus increase and at the metal decrease (see Table 1). Hence, although the geometric constraints are quite different, the cisoid arrangement of the anionic ligands is retained.

Comparison of 7 and 8

The replacement of the two THF ligands in **7** by a third diphosphanomethanide ligand leads to the first reported hexacoordinated "magnesate" anion **8** with six magnesium−phosphorus bonds.

The Mg−P bond lengths in both compounds are nearly equal, as are the bond lengths and angles in all four-membered chelate rings. This shows that the anionic nature of **8** has no influence on the radius of the Mg^{2+} dication; the bonding thus seems to be mainly ionic.

In accord with the long Mg−O bonds in **7**, the THF ligands can be removed thermally by heating **7** in vacuo. However, a simple THF-free derivative of **7** was not ob-

tained, the nature of the resulting compound being currently under investigation.

Conclusion

For the first time it has been demonstrated that not only phosphanide donors (with two-coordinated phosphorus), but also "normal" phosphane donors (with three-coordinated phosphorus) are able to coordinate to alkaline earth metal centers. Even "classic" ligands for alkaline earth metals, such as halides, diethylether, or THF can be replaced successfully by diphosphanomethanides. These results emphasize the exceptional role of diphosphanomethanides in phosphane coordination chemistry. The preference for a cisoid arrangement of anionic ligands in alkaline earth metal compounds can be emphasized and further extended. This seems to be a quite general phenomenon that is not restricted to the heavier metal centers but has now also been established for magnesium compounds.

The neutral compounds described are soluble in nonpolar solvents and represent promising precursors for chemical vapor deposition (CVD) processes. In addition they are possible candidates for metal-mediated organic synthesis and for a wide range of reactions in nonpolar solvents.

Experimental Section

General: All reactions were performed in a two-armed glass vessel as described elsewhere[26]. Exclusion of air and moisture was essential and glassware was treated accordingly. All solvents were dried over Na/K alloy and distilled prior to use. − For ^1H- and $^{13}C\{^1H\}$-NMR spectra TMS (δ = 0) was used as an internal standard. The $^{31}P\{^1H\}$-NMR spectra were obtained in C_6D_6 ([D_8]toluene for low temperature experiments) with H_3PO_4 (85%) as the external reference on a JEOL GX 270 spectrometer. The ^9Be-NMR spectrum was obtained in C_6D_6 with $BeSO_4 \cdot 7\ H_2O$ as the external standard on a JEOL Lambda 400 spectrometer.

The alkaline earth metal chlorides were used in the anhydrous form and prepared as described[27]. 12-crown-4 was purchased from commercial sources and dried over molecular sieve (4 A). Li[(P-$Me_2)_2C(SiMe_3)$] was prepared as described previously[28].

Elemental analyses were performed by the Mikroanalytisches Labor des Anorganisch-chemischen Instituts der Technischen Universität München.

Hazard: Beryllium compounds are extremely toxic and may cause cancer[29]. Handle with care! Avoid inhalation and any skin contact!

Preparation of the Diphosphanomethanide Complexes with Be, Mg, and Ca: 7.0 mmol of $Li[(PMe_2)_2C(SiMe_3)]$[28] and 3.5 mmol of MCl_2 (M = Be, Mg, Ca) were dissolved in 40 ml of THF at −78°C. After being stirred overnight at room temperature, the solvent was removed and replaced by pentane. After filtration, colorless crystals were isolated from pentane in all cases by slowly cooling the solutions.

Preparation of $[Li(12\text{-crown-}4)_2]^+\{Mg[(PMe_2)_2C(SiMe_3)]_3\}^-$: 2.20 mmol of $Li[(PMe_2)_2C(SiMe_3)]$[28] were dissolved in ether (40 ml) at −78°C. After adding 2.20 mmol of 12-crown-4 and 2.06 mmol of $Mg[(PMe_2)_2C(SiMe_3)]_2 \cdot 2$ THF (**7**), the mixture was warmed up to room temperature and stirred overnight. The ether was removed and the remaining solid was washed with 30 ml of pentane. After replacing pentane by ether, colorless crystals were grown from the solution by cooling.

All compounds were extremely air and moisture sensitive. Therefore, elemental analysis were not completely satisfactory in all cases.

Be[(PMe$_2$)$_2$C(SiMe$_3$)]$_2$ (**5**): *M* = 423.571 g/mol, yield: 87.2%. – ^{1}H (C_6D_6): δ = 0.20 (s, 18 H), 1.21 (s, 24 H). – ^{31}P{^{1}H} (C_6D_6): δ = −30.8 (1:1:1:1 quart., $^1J_{Be-P}$ = 33.5 Hz). – ^{13}C{^{1}H} (C_6D_6): δ = 4.70 [s, Si(CH_3)$_3$] 20.17 ["quint.", P(CH_3)$_2$], 22.31 (s, P$_2$*C*Si). – ^{9}Be (C_6D_6): δ = 6.4 (quint., $^1J_{Be-P}$ = 33.5 Hz). – $C_{16}H_{21}BeP_4Si_2$: calcd. (found): C, 49.26 (49.11); H, 10.33 (10.07).

{Mg[(PMe$_2$)$_2$C(SiMe$_3$)]$_3$}$^-$Li(12-crown-4)$_2^+$ (**8**): *M* = 1005.494 g/mol, yield: 55.0%. – ^{1}H (C_6D_6): δ = 0.40 (s, 27 H), 1.49 (s, 36 H), 2.90 (s, 32 H). – ^{31}P{^{1}H} (C_6D_6): δ = −15.5 (s); ^{31}P{^{1}H} ([D$_8$]toluene, −80°C): δ = −14.8 (s, br). – ^{13}C{^{1}H} (C_6D_6): δ = 6.94 [s, Si(*C*H$_3$)$_3$], 22.05 ["quint.", P(*C*H$_3$)$_2$], 22.63 (s, P$_2$*C*Si), 65.46 (s, 12-crown-4).

Ca[(PMe$_2$)$_2$C(SiMe$_3$)]$_2$·3 THF (**10**): *M* = 670.951 g/mol, yield: 85.7%. – ^{1}H (C_6D_6): δ = 0.46 (s, 18 H), 1.27 (m, THF, 12 H), 1.31 (s, 24 H), 3.50 (m, THF, 12 H). – ^{31}P{^{1}H} (C_6D_6): δ = −28.6 (s). – ^{13}C{^{1}H} (C_6D_6): δ = 7.75 [s, Si(*C*H$_3$)$_3$], 21.89 ["quint.", P(*C*H$_3$)$_2$], 22.70 (s, P$_2$*C*Si), 25.58 (s, THF), 68.71 (s, THF). – $C_{28}H_{45}CaO_3P_4Si_2$: calc, (found): C, 50.12 (48.57); H, 9.91 (9.79).

X-ray Measurements: The single crystals were sealed in thin-walled capillaries and mounted on a four-circle diffractometer CAD4 (Fa. ENRAF-NONIUS) with graphite-monochromated Mo-Kα radiation (λ = 0.71073 A). All data were collected at low temperatures (−74°C). The structures were solved by direct methods with the software package SHELXTL PC[30] and refined with the program SHELXL-93[31]. All non-hydrogen atoms were refined anisotropically, and a riding model was employed in the refinement of the hydrogen atom positions. Further details can be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen under following CSD-numbers: Be[(PMe$_2$)$_2$C(SiMe$_3$)] 407270, Mg[(PMe$_2$)$_2$C(SiMe$_3$)]$_2$·2 THF 407238, {Mg[(PMe$_2$)$_2$C(SiMe$_3$)]$_3$}$^-${Li(12-crown-4)$_2$}$^+$ 407252, Ca[(PMe$_2$)$_2$C(SiMe$_3$)]$_2$·3 THF 407239.

Keywords: Chiral carbenes / Carbene complexes / Rhodium complexes / Axial chirality / Asymmetric hydrosilylation

Deprotonation of chiral triazolium salts **1** and reaction of the resulting nucleophilic carbenes with $[(COD)RhCl]_2$ or $[(NBD)RhCl]_2$ afforded square-planar complexes **2–6** in yields of 65–95%. The complexes contain an axis of chirality and a diastereomeric excess of up to 97% was achieved. The relative and absolute configurations of these complexes were determined by NMR spectroscopic investigations and X-ray structure analysis. The application of the rhodium(COD) complexes as catalysts in an asymmetric hydrosilylation reaction has been examined, resulting in enantiomeric excesses of up to 44%. Similar results were achieved for aromatic and aliphatic ketones and a nonlinear temperature effect (principle of isoinversion) was observed.

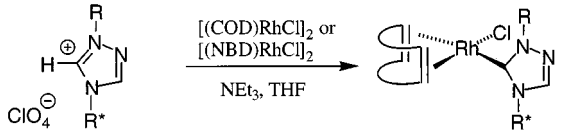
Introduction

Metal complexes of nucleophilic carbenes have already been investigated[1][2]. Recent investigations have included chiral modifications and the application of these complexes as catalysts in asymmetric synthesis. The first chiral carbene complexes bearing imidazolidinylidene ligands were introduced by Lappert et al. in 1983[3], followed by chiral imidazolinylidene complexes by Herrmann et al.[4] and by complexes containing chiral imidazolinylidenes and triazolinylidenes by our group[5][6]. Using the C_1-symmetrical triazolinylidenes as ligands, different rotamers were obtained as a result of hindered rotation about the carbene carbon−metal bond[5]. To prevent the formation of these various rotamers, one possibility is to employ chelating carbene ligands. These ligands have previously been used to prepare ruthenium and rhodium complexes bearing a stereogenic center at the metal atom[6]. Another possibility is to use nonchelating carbene ligands with hindered rotation about the carbene carbon−metal bond, causing an axis of chirality when in a perpendicular orientation to the square-plane of the metal complex. We now report the diastereoselective synthesis of rhodium(I) complexes containing this kind of chirality and the application of these complexes in a hydrosilylation reaction.

Results and Discussion

Following our work on palladium(II) complexes containing two carbene ligands and therefore two axes of chirality in the *cis* form (resulting in two diastereomers and one *meso* form according to our nomenclature[5]), we prepared square-planar rhodium complexes containing one carbene ligand perpendicular to the square-plane of the complex[3][7].

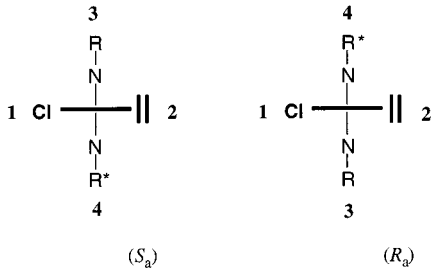
Scheme 1. Preparation of rhodium(COD) and -NBD complexes



1 **2-6**

The axis of chirality is represented by the carbene carbon−rhodium bond. The two substituents of the first plane are the chlorine atom and the olefin *trans* to the chlorine, whereas the substituents of the second plane are the nitrogen atoms neighboring the carbene carbon atom (see Figure 1).

Figure 1. Axis of chirality



Rhodium(COD) Complexes: The rhodium(COD) complexes **2−4** were prepared by reaction of a triazolium salt **1** with$[(COD)RhCl]_2$ in THF with NEt_3 in yields of 65−95%, the yield depending on the substituent R at *N*1. With a

[a] Determined by ^{1}H-NMR spectroscopy.

The benzyl group in complex **2** (two doublets of ^2J = 14 Hz for the two benzylic protons in the ^{1}H-NMR spectrum) indicates the existence of the axis of chirality within the complex, the two protons becoming diastereotopic because of the hindered rotation about the carbene carbon–rhodium bond. Calculation of the barrier for rotation of the carbene–carbon rhodium bond at the MP2/TZVP//RI-DFT/SV(P) level of theory yielded an energy of 93 kJ/mol, which is consistent with the experimentally found hindered rotation[8]. The diastereomeric excess of the complexes with chiral substituents R*, **3** and **4**, was determined by ^{1}H-NMR spectroscopy to be 36–41% for **3a–c** [R* = (*R*)-1-phenylethyl]. Using the 2,2-dimethyl-4-phenyl-1,3-dioxanyl residue as chiral substituent R* **4a–c**, diastereomeric excesses of up to 97% could be achieved, the best obtained being with the bulky *t*-butyl group (**4c**). Despite the mixture of diastereomers in solution, the major diastereomer of **4a** could be crystallized and its structure in the solid state was determined by X-ray structure analysis (Figure 2).[9][10]

The X-ray structure shows the rhodium atom with a square-planar arrangement of the ligands and a bond angle Cl–Rh–C(carbene) of 88.3(2)°. The interatomic distances within the triazolinylidene heterocycle are similar to those obtained for other (triazolinylidene)metal complexes[5][6]. The carbene carbon bond length amounts to 2.004(7) A, identical to the value obtained by Lappert et al. for an (imidazolidinylidene)rhodium(COD) complex [2.004(4) A][3]. The configuration of the axis of chirality was assigned as (S_a) for this complex **4a**.

Rhodium(NBD) Complexes: The rhodium(NBD) complexes **5–6** were prepared in the same way as the rhodium(COD) complexes.

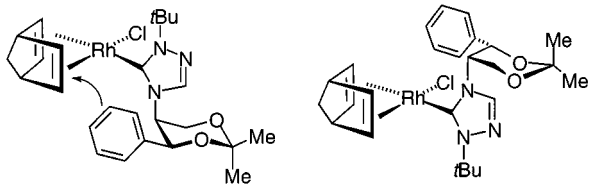
6b	95	[b]
6c	75	87

[a] Determined by ^{1}H-NMR spectroscopy. – [b] Due to broad signals (rotation of the ligand), a diastereomeric excess could not be determined.

They did not show the same hindrance of rotation about the carbene carbon–rhodium bond as the rhodium(COD) complexes. For the achiral benzyl group, at room temperature no splitting of the benzylic protons was observed in the ^{1}H-NMR spectrum. These findings were again supported by MP2/TZVP//RI-DFT/SV(P) calculations, which gave a rotational barrier of 58 kJ/mol for the rotation about the carbene carbon–rhodium bond in complex **5**, much lower than that of complex **2**[8]. This is probably due to the significantly smaller size of the NBD ligand compared to the COD ligand, which leads to a considerably decreased steric interaction in the course of the rotation. By analogy, no evidence for the existence of two diastereomers was observed in the NMR spectra of complexes **6a** and **6b** with a chiral ligand, and only very broad signals were observed for the triazolinylidene ligand. Nevertheless, complex **6c** with a bulky *t*-butyl substituent showed a hindered rotation. A diastereomeric excess of 87% was determined, lower than that for the rhodium(COD) complex **4c** (97%). NMR spectroscopic investigations (NOE′s and ring-current effects) re-

vealed the relative and therefore the absolute configuration of complex **6c**.

Figure 3. NMR spectroscopic investigations of complex **6c**



6c major diastereomer **6c** minor diastereomer

In both diastereomers, the dioxane ring in the chair conformation points away from the rhodium atom. For the major diastereomer (S_a), the phenyl substituent of the dioxanyl group points at the olefinic protons of the double bond *trans* to the chlorine atom, causing a ring-current effect and a NOE. The former leads to a significant highfield shift of these protons. For the minor diastereomer (R_a) with the phenyl group pointing at the chlorine atom, neither this ring-current effect nor the NOE was observed. This conformation and configuration of **6c** in solution is identical to the structure obtained for **4a** in the solid state. The lower diastereomeric excess of the rhodium(NBD) complex **6c** compared to rhodium(COD) complex **4c** and the rotation of the ligand in case of complexes **5, 6a−b** may be caused by a lower steric hindrance of the NBD ligand compared to the COD ligand. Upon cooling to −40°C, the broad signal of the benzylic protons of complex **5** in the ^{1}H-NMR spectrum sharpened due to a more hindered rotation, now appearing as two doublets. NMR spectroscopic investigations of Rh, Cr, Mo, and W complexes with hindered carbene ligand rotation at lower temperatures have already been reported[11].

Substitution Reactions: The chlorine atom of the complexes **2−6** was exchanged with iodine using NaI in MeOH and the resulting complexes were purified by column chromatography. Some examples for this substitution reaction are summarized in Table 3.

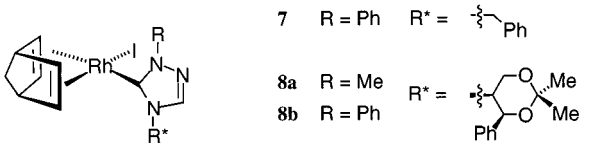


Table 3. Yields and diastereomeric excesses (*de*) of rhodium(NBD) complexes **7** and **8**

	Yield [%]	*de* [%][a]
7	90	–
8a	70	87
8b	83	87

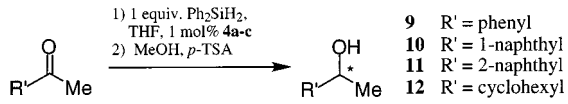
[a] Determined by ^{1}H-NMR spectroscopy.

The (iodo)rhodium(NBD) complexes **7** and **8** showed a hindered rotation at room temperature, in contrast to the chloro complexes **5, 6a−b**. The diastereomeric excess of the complexes **8a−b** was determined to be 87%, identical to the result obtained for the chloro complex **6c**. For complex **7**, the barrier for the rotation about the carbene carbon−rhodium bond was again calculated at the MP2/TZVP//RI-DFT/SV(P) level of theory, yielding a barrier height of 73 kJ/mol[8]. The energy obtained is somewhat higher than for the corresponding chloro complex **5**, suggesting that the steric interaction of the iodine ligand is more significant. This is in agreement with experiment, since we did not observe rotation about the carbene carbon−rhodium bond in the NMR spectra.

Asymmetric Hydrosilylation: The hydrosilylation reaction with achiral (imidazolidinylidene)rhodium(COD) complexes, by Lappert et al.[12] was further developed by Herrmann et al. using chiral imidazolinylidene ligands, which gave enantiomeric excesses of up to 32%[4].

The potential of the (triazolinylidene)rhodium(COD) and -(NBD) complexes as catalysts was examined in a hydrosilylation reaction. The best enantioselectivities were achieved with complexes **4a−c**. In typical hydrosilylations, the methyl ketones **9−12** were reduced to the corresponding alcohols with diphenylsilane and 1 mol% of the catalyst in THF[13].

Scheme 2. Asymmetric hydrosilylation of methyl ketones **9−12**



Enantiomeric excesses of up to 44% were achieved with similar results being observed for aromatic and aliphatic ketones. The configuration of the resulting alcohol depends upon the achiral group R at *N*1 of the triazolinylidene ligand. For example, the enantiomeric excess changes from 44% (*S*) (catalyst **4a**) to 43% (*R*) (catalyst **4c**) with acetylcyclohexane **12** as the starting material and no change of the chirality information within the catalyst.

Table 4. Reaction conditions, yields and enantiomeric excesses for the hydrosilylation reaction

Catalyst	Ketone	Temperature [°C]	Time	Yield [%]	*ee* [%]
4a	**9**	22	4h	90	20 (*S*)
4c	**9**	11	6d	60	40 (*R*)
4a	**10**	42	4h	80	37 (*R*)
4b	**10**	2	10d	40	32 (*R*)
4a	**11**	2	5d	90	19 (*S*)
4c	**11**	22	16h	40	24 (*R*)
4a	**12**	−10	6d	75	44 (*S*)
4b	**12**	2	4d	80	43 (*S*)
4c	**12**	22	3d	70	43 (*R*)

The optimum reaction temperature in order to achieve the highest enantioselectivities varies from +42°C to −10°C for the different systems. We found a decreasing enantioselectivity with increasing or decreasing temperature with respect to the optimum conditions (principle of isoinversion[14]). This nonlinear temperature effect has also been observed by Scharf et al.[15] for a hydrosilylation reaction with rhodium(NBD) complexes and chiral cyclic monophosphonite ligands.

Conclusion

Axially chiral (triazolinylidene)rhodium(COD) and -(NBD) complexes have been prepared with diastereomeric excesses of up to 97%. The NMR spectroscopic and theoretical investigations show the steric requirements needed for hindered rotation about the carbene carbon−rhodium bond. This new type of chiral complex was examined in asymmetric hydrosilylation reactions with enantiomeric excesses of up to 44% for aromatic and aliphatic ketones. This represents a good result for a nonchelating ligand, probably caused in part by the axis of chirality.

Experimental Section

General: All solvents were dried and distilled before use. The triazolium perchlorates[16], $[(COD)RhCl]_2$ and $[(NBD)RhCl]_2$[17] were prepared according to literature procedures. − Column chromatography: Merck silica gel 60, 0.040−0.063 mm (230−400 mesh) (flash). − Optical rotation values: Perkin-Elmer P 241, solvent UVASOL-quality. − Melting points (uncorrected): Büchi 510. − IR: Perkin-Elmer FT 1750. − NMR: Varian VXR 300 and Gemini 300 (300 and 75 MHz for ^1H and ^{13}C, respectively), Varian Unity 500 (500 and 125 MHz for ^1H and ^{13}C, respectively), $CDCl_3$ as solvent, TMS as internal standard, room temperature if not otherwise noticed. − MS: Finnigan MAT (70 eV) and Finnigan SSQ 7000 (70 eV).

1. General Procedure for the Preparation of (Chloro)rhodium-(COD) Complexes **2−4**: $(COD)RhCl]_2$ (50 mg, 0.10 mmol), NEt_3 (0.2 ml, 1.4 mmol) and 1.1 equiv. of the corresponding triazolium perchlorate **1** (0.22 mmol) were dissolved in 40 ml of THF and the solution was stirred at room temperature for 14 h. The solution was evaporated to dryness in vacuo and the products were purified by column chromatography (silica gel, Et_2O/pentane, 2:1).

Chloro(η⁴-1,5-cyclooctadiene)(1-phenyl-4-benzyl-4,5-dihydro-1H-1,2,4-triazol-5-ylidene)rhodium(I) (**2**): Yield 86 mg (90%), m.p. 184°C. − IR (KBr): ν = 3110 cm^{-1} (m), 3047 (m), 3005 (m), 2931 (s), 2880 (s), 2833 (m), 1595 (s), 1545 (m), 1497 (s), 1476 (m), 1457 (m), 1435 (m), 1396 (s), 1355 (s), 1333 (s), 1222 (s), 766 (s), 723 (s), 706 (s), 650 (s). − ^1H NMR (300 MHz): δ = 1.66 (m, 1 H, CH_2CH_2), 1,84 (m, 4 H, CH_2CH_2), 2.12 (m, 1 H, CH_2CH_2), 2.30 (m, 2 H, CH_2CH_2), 2.74 (m, 1 H, CHCH), 3.08 (m, 1 H, CHCH), 5.12 (m, 1 H, CHCH), 5.22 (m, 1 H, CHCH), 5.86 (d, *J* = 14.83 Hz, 1 H, $PhCH_2$), 6.06 (d, *J* = 14.83 Hz, 1 H, $PhCH_2$), 7.50 (m, 8 H, C_6H_5), 7.90 (s, 1 H, N_2CH), 8.56 (m, 2 H, C_6H_5). − ^{13}C NMR (75 MHz): δ = 28.64, 28.87, 32.23, 32.60 (CH_2CH_2), 53.37 ($PhCH_2$), 69.07 (d, *J* = 14.3 Hz, CHCH), 70.35 (d, *J* = 14.3 Hz, CHCH), 98.83 (d, *J* = 7.4 Hz, CHCH), 99.53 (d, *J* = 7.4 Hz, CHCH), 123.75, 128.48, 128.73, 128.82, 128.90, 129.31 (C_5H_5CR), 134.70, 139.74 (C_5H_5CR), 142.42 (CHN), 186.94 (d, *J* = 51.0 Hz, NCRh). − MS (70 eV); *m/z* (%): 481.1 (38.2) [M^+], 445.0 (12.1) [M^+ − HCl], 372.9 (43.6) [M^+ − COD], 336.9 (100) [M^+ − COD − Cl]. − HR-MS; *m/z*: $C_{23}H_{25}ClN_3Rh$ [M^+]: calcd. 481.0785; found 481.0785.

4. General Procedure for a Catalytic Hydrosilylation Reaction: Under a nitrogen atmosphere, the ketones **9−12** (1 mmol) and Ph_2SiH_2 (184 mg, 1 mmol) were added to a solution of the (triazolinylidene)rhodium(COD) complex **4a−c** (1 mol%) in 2 ml of THF stirred at reaction temperature. The reaction was quenched by addition of methanol (0.5 ml) containing 1% of *p*-toluenesulfonic acid (*p*-TSA). After evaporation of the solvent in vacuo and purification of the product by column chromatography (silica gel, pentane/Et_2O, 2:1), the enantiomeric excess of the product alcohol was determined by gas chromatography (LIPODEX E, CP-CHIRASIL-DEX CB, 7-CD PERME).

[10] Suitable crystals were obtained from CH_2Cl_2/pentane mixtures at room temp. The compound crystallizes in the orthorhombic space group $P2_12_12_1$; a = 10.601(5), $^\circ b$ = 11.441(3), c = 19.178(6) A. At a cell volume of 2326.1 A^3, Z = 4 and $M_{ber.}$ = 519.87, the calculated density and the absorption coefficient are ρ = 1.484 mg m^{-3} and μ = 7.180 mm^{-1}, respectively. The total number of electrons per unit cell amounts to F(000) = 1072. The data collection was performed at 203 K on a Siemens P4 diffractometer, Cu-K_α radiation (graphite monochromator, λ = 1.54178 A), 1735 reflections measured (+h, +k, +l), 1735 independent reflections, 4.50° < θ < 55.85°. Structure solved by direct methods [SHELXTL (G. M. Sheldrick, Univ. Göttingen, Germany), refinement on F^2]. The hydrogen atoms were located and refined isotropically. 1733 observed reflections [$I > 2\sigma$ (I)] were used in the final refinement of 295 parameters terminating at R = 0.0327 (R_W = 0.0738). Maximal residual electron density −0.314/+ 0.339 e A^{-3}. Keywords: Aluminium / Chelates / Lewis acids

Sodium nitrite ($NaNO_2$) dissolves readily in THF, when the methylene-bridged dialuminium compound $R_2Al–CH_2–AlR_2$ [R = $CH(SiMe_3)_2$] **1** with two coordinatively unsaturated aluminium atoms is added. Compound **1** reacts as a chelating Lewis acid, and, as shown by a crystal structure determination of the $[Na([18]crown-6)(Et_2O)]^+$ derivative **5c**, a compound (**5**) is formed, in which one oxygen atom and the nitrogen atom of the nitrite ion are each coordinated by one aluminium atom to form a five-membered Al_2CNO heterocycle. The second oxygen atom of the nitrite anion is not affected. Similarly, lithium nitrate ($LiNO_3$) reacts with **1** to yield a THF soluble product (**6a**). Single crystals were obtained of the $[Li(N,N',N''\text{-trimethyltriazinane})_2]^+$ derivative **6c**, whose structure shows each aluminium atom to be coordinated by one oxygen atom of the nitrate ion to give a six-membered Al_2CNO_2 heterocycle.

Chelating Lewis bases for the effective coordination of cations are extraordinarily important in all areas of chemistry as can be seen from thousands of known compounds. In contrast, chelating Lewis acids as anion receptors for the complexation and recognition of anions are investigated to a much lower extent, and by far the most of these ligands were obtained by the protonation of amino groups of macrocyclic or polycyclic compounds[1]. Organoelement derivatives of the elements of the third main-group have a coordinatively unsaturated central atom and are therefore suitable as Lewis acids, but only few examples exist, which have more than one atom of those elements and could possibly be useful as a chelating ligand. Well documented and characterized[2] compounds of this type are for instance 1,8-naphthlenediylbis(dimethylborane)[3], $Cl_2Al-CH_2-AlCl_2$[4], $Cl_2Al-CH_2CH_2-AlCl_2$[5], $R_2Al-CH_2-AlR_2$ **1** [R = $CH(SiMe_3)_2$][6], $R(Cl)Al-CH_2-Al(Cl)R$ [R = $CH(SiMe_3)_2$][7], $Me_2(THF)AlOC_6H_4OAl(THF)Me_2$[8], $Cl_2In-CH_2-InCl_2 \cdot 2\,TMEDA$[9], and $Hg(C_6H_4-InCl_2 \cdot THF)_2$[10]. However, most of these compounds have up to now not been investigated concerning their ability to act as a chelating Lewis acid. Exceptions are the diborane compound with a single example of a hydrido bridge[3] and the methylene bridged tetraalkyl dialuminium derivative **1**, which was recently synthesized by our group[6]. Few chelate complexes of **1** have been isolated and characterized, in which heterocycles are formed by the coordination of both aluminium atoms to one hydride (**2**)[11], hydroxide[12], or thiomethanolate anion[13]. A remarkable five-membered ring (**3**) was obtained by the reaction of **1** with $LiCH(PMe_2)_2$, in which one Al atom is coordinated to the central carbanion and the other one to a phosphorus atom[14]. A terminal coordination of a neopentyl group is observed by the reaction of **1** with neopentyllithium (**4**)[15]. Much more interest deserve, however, the up to now unknown complexes with multidentate inorganic anions like nitrate, nitrite, azide, sulfate etc. in order to find specific anion receptors or in order to use a Lewis-acid like **1** as a phase transfer reagent to dissolve ionic compounds in organic solvents and to study their changed, possibly enhanced reactivity. We started now with systematic investigations into those reactions and wish to report here on the complexes of **1** with sodium nitrite and lithium nitrate. Carbon bridged dialuminium compounds have recently been used in organic syntheses to form for instance C=C double bonds, but they usually were only used as reactive intermediates, and they were not isolated or well characterized[16].

Reactions of the Methylene-Bridged Dialuminium Compound 1 with $NaNO_2$ and $LiNO_3$

Both, sodium nitrite and lithium nitrate are insoluble even in a large excess of THF. But upon addition of one equivalent of the chelating Lewis-acid μ-methylene tetraalkyldialuminium $R_2Al-CH_2-AlR_2$ **1** the complete dissolution of the crystalline salts occurred within several hours by stirring

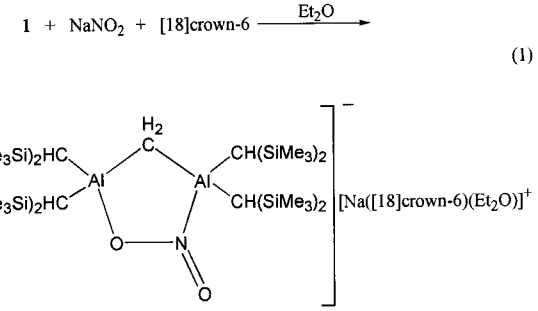
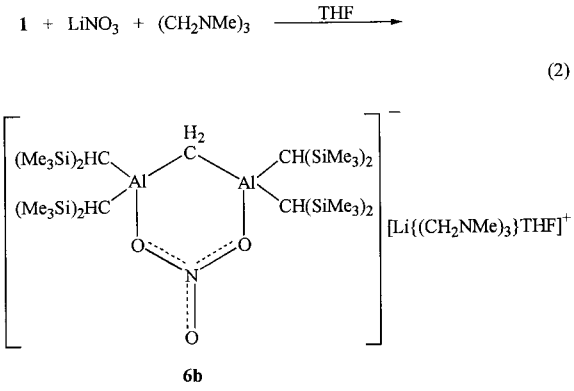
R = $CH(SiMe_3)_2$

at room temperature. Yellow solutions were formed, from which the yellow addition products **5a** and **6a** were isolated after concentration and cooling to −50°C in a high yield. The crystals rapidly became amorphous upon drying in vacuo and had low melting points of 92°C and 135°C (**5a** and **6a**, respectively). The ^{1}H- and ^{13}C-NMR spectroscopic characterization gave some important changes in comparison to the neutral starting compound **1**, and all signals of groups bound to aluminium showed a significant shift to high field. In **1** the protons of the Al−CH_2−Al group resonated at δ = −0.50, and we observed the methine protons at δ = −0.22 and the corresponding carbon atoms at δ = 13.2; in **5a** and **6a** these resonances were shifted to δ(Al-CH_2Al) = −1.24 and −1.27, δ(AlC*H*Si_2) = −1.06 and −1.05, δ(Al*C*HSi_2) = 4.1 and 4.3, respectively. Such shifts to a higher field are very indicative of the enhancement of the coordination number at the aluminium atoms from three to four[11][12][13][14][15][17].

Both compounds were stable in THF solutions, but slow decomposition by the precipitation of $NaNO_2$ or $LiNO_3$ and the formation of **1** was observed in more nonpolar solvents like diethyl and diisopropyl ether or in mixtures of ether with toluene or pentane. Single crystals of the nitrate derivative **6a** with the counterion $[Li(THF)_4]^+$ could not be obtained, while single crystals of **5a** showed a severe disorder of the $Na(THF)_3$ cation, and the structure could not be refined satisfactorily. Therefore, we synthesized several derivatives of **5** and **6** by using different chelating Lewis-bases like the crown ether [18]crown-6, tetramethylethylenediamine (TMEDA), tetramethylpropylenediamine (TMPDA), pentamethyldiethylenetriamine (PMDETA), and *N,N′,N′′*-trimethyltriazinane. Some of the isolated products are described in detail in the Experimental Section, the spectroscopic properties of their anions as well as their solubility in polar or nonpolar solvents differ only slightly from those of the THF adducts. But owing to the chelating coordination of the cations they show a significantly increased stability and can be stored in diethyl ether solution at room temperature without decomposition and precipitation of the corresponding salts. High quality single crystals were obtained of compounds **5c** {[Na([18]crown-6)(Et_2O)]$^+$} (Eq. 1) and **6c** {[Li(triazinane)$_2$]$^+$}; the last one crystallized from a dilute solution of the mixed triazinane/THF adduct **6b** (Eq. 2) in diethyl ether in the presence of triazinane.



5c



6b

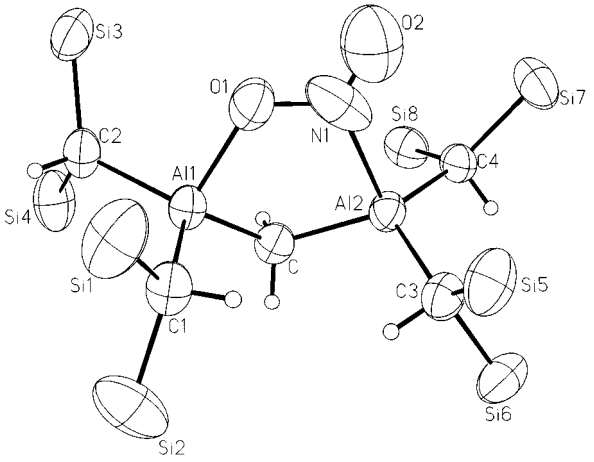
As shown in Eq. (1), the structure of the complex **5c** comprises the nitrite anion coordinated by one oxygen atom and the lone pair at the central nitrogen atom. This structure should result in two chemical different AlR_2 moieties, but at room temperature only one singlet was detected in the ^{1}H-NMR spectrum for both the methine and the $SiMe_3$ protons. However, a splitting into two resonances was observed upon cooling a sample of **5**c dissolved in [D_{10}]diethyl ether to −70°C indicating a fast exchange process at elevated temperatures.

Crystal Structures of 5c and 6c

The molecular structures of the nitrito complex **5c** and the nitrato complex **6c** are depicted in Figures 1 and 2. To the best of our knowledge, it is the first time, that chelating Lewis-acids like compound **1** with coordinatively unsaturated atoms of the elements of group 13 are successfully used for the coordination of at least bidentate anions and that the coordination mode could be determined by crystal structure determinations. Both anions are coordinated in a chelating manner by both aluminium atoms of **1**. As expected, the nitrate anion in **6c** is bound by two oxygen atoms to form a six-membered Al_2CO_2N heterocycle, while a five-membered Al_2CNO heterocycle is observed in **5c** with the nitrite anion coordinated via one oxygen and the central

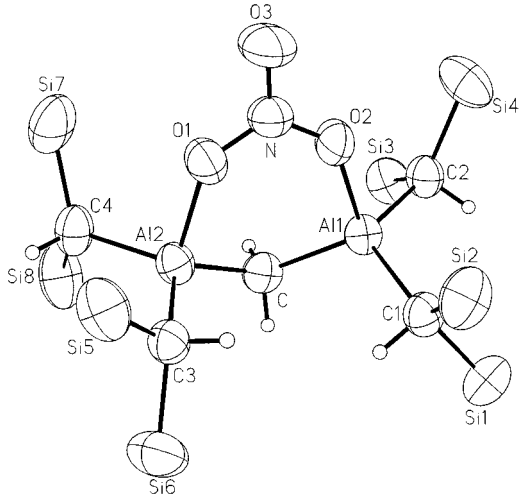
nitrogen atom. One oxygen atom of each anion is in a terminal position.

Figure 1. Molecular structure and numbering scheme of the anion of **5c**; the thermal ellipsoids are drawn at the 40% probability level; methyl groups are omitted for clarity[a]



[a] Selected bond lengths [pm] and angles [°]: Al1−O1 196.0(3), Al2−N1 212.3(5), N1−O1 137.6(5), Al1−C 196.1(3), Al2−C 195.0(3), Al1−C1 202.7(3), Al1−C2 202.6(3), Al2−C3 199.9(3), Al2−C4 201.3(3), C−Al1−O1 96.8(1), Al1−O1−N1 114.4(2), O1−N1−Al2 119.2(2), N1−Al2−C 89.5(2), Al1−C−Al2 111.3(2).

Figure 2. Molecular structure and numbering scheme of the anion of **6c**; the thermal ellipsoids are drawn at the 40% probability level; methyl groups are omitted for clarity[a]



[a] Selected bond lengths [pm] and angles [°]: Al1−O2 193.9(3), Al2−O1 195.7(3), N−O1 126.1(4), N−O2 125.2(4), N−O3 121.4(4), Al1−C 194.5(4), Al2−C 195.0(4), Al1−C1 201.4(3), Al1−C2 202.7(4), Al2−C3 203.8(4), Al2−C4 200.8(4), C−Al2−O1 99.8(2), Al2−O1−N 136.0(3), O1−N−O2 121.3(4), N−O2−Al1 135.9(3), O2−Al1−C 100.4(2), Al1−C−Al2 116.2(2).

The methylene bridged tetraalkyldialuminium moieties of both compounds are quite similar. The Al−C distances of the $CH(SiMe_3)_2$ substituents are 201.6 (**5c**) and 202.2 pm (**6c**) on average, and the smallest distances are observed to the aluminium atom bound to nitrogen. The bond lengths to the carbon atom of the methylene bridge are 195.6 (**5c**) and 194.8 pm (**6c**). As expected from the enhancement of the coordination number at the aluminium atoms[11][12][13][14][15][17], all distances are lengthened compared with the starting compound **1**[6], which had the corresponding values at 195.7 and 193.8 pm. The structure of **1** showed a strongly enlarged Al−C−Al angle (129.6°) caused by steric and electrostatic repulsion between the bulky substituents and the positively charged Al atoms[6]. Owing to the formation of five and six membered heterocycles this angle is reduced in **5c** and **6c** to 111.3° and 116.2°, respectively.

The Al−O distance in the nitrito compound **5c** is slightly lengthened to 196.0 pm compared with complexes of trimethylaluminium with sulfate or nitrate anions (ca. 191 pm)[18][19]. The Al−N1 distance is long (212.3 pm) with respect to some [bis(trimethylsilyl)methyl]aluminium compounds recently obtained in our group[20], which may indicate only a weak coordinative interaction to the Al atom Al2. Unfortunately, the N−O distances N1−O1 137.6 pm and N1−O2 103.1 pm, which is in the range of the triple bond in NO^+, are incorrect due to a disorder of the atoms N1 and O2. Both atoms could not be refined in split positions to give acceptable positions. The same disorder was observed for the THF adduct, which could not be completely refined due to the severe disorder of the cation. The distances should therefore not further be discussed in detail, but it seems clear, that strong differing distances are present with one value approaching a double bond and one approaching a single bond similar to the situation in nitrous acid HONO (N−O = 142 and 118 pm)[21]. A similar coordination mode with bridging μ-NO_2-N,O groups has been observed before in several coordination compounds of the transition metals. As expected, the N−O distances of the bridging NO groups of these complexes are elongated compared to those of terminal N=O groups by up to 17 pm[22]. The atoms of the nitrito group (N1, O1, O2) and the aluminium atom coordinated by nitrogen (Al2) lie almost ideally within a plane (sum of the angles 359.8 pm). The most acute angles in the five-membered central heterocycle are at the Al atoms with 96.8° at Al1 and 89.5° at Al2, the last one is coordinated by the nitrogen atom. The heterocycle adopts an envelope conformation with the four atoms Al1, Al2, O1, and N1 almost ideally within a plane and the bridging carbon atom 58 pm above the plane. The angle between the normals of the planes (Al1O1N1Al2 and Al1-CAl2) is 31.7°.

In contrast to the strongly differing N−O distances of **5c**, a more delocalized electronic system is observed in the nitrato compound **6c** with three quite similar N−O distances. The N−O bond length to the terminal oxygen atom is 121.4 pm, which is only 4.5 pm shorter than the distance between nitrogen and the bridging oxygen atoms (125.7 pm on average). The longer distances are similar to the N−O bond lengths of the nitrate ions in many salt-like compounds, which are in the range of about 126 pm[23]. Two metal atoms bridged by two different oxygen atoms of a nitrato group as in **6c** are for instance observed in some aquo Zn-, Cu-, or Ni nitrato complexes[24]. The Al−O distances of **6c** are similar to **5c** (194.8 pm on average). The most acute angles of the six-membered heterocycle are

found at the aluminium atoms (100.1° on average), while the angles Al−O−N are much enlarged to 136°. As expected, the nitrogen atom is planar surrounded by three oxygen atoms (sum of the angles = 360.0°). The heterocycle has an envelope conformation similar to **5c** with the bridging carbon atom 59.2 pm above the plane spanned by the five atoms Al1, Al2, O1, O2, and N, which have a maximum deviation from this plane of only 2.5 pm (angle between the normals of the planes 34.9°).

No short bonding distances are observed between atoms of the complex anions and the corresponding cations in both compounds. The sodium atom in **5c** is coordinated by six oxygen atoms of the crown ether (Na−O = 248.7 to 271.8 pm) and one oxygen atom of an ether molecule (Na−O 247.0 pm) with a distorted coordination geometry. In **6c**, the Li atoms of the counterions $[Li(triazinane)_2]^+$ are located on a crystallographic inversion center; the Li atoms are coordinated by six nitrogen atoms with Li−N distances between 215.7 and 234.0 pm.

We are grateful to the *Deutsche Forschungsgemeinschaft* and the *Fonds der Chemischen Industrie* for generous financial support.

Experimental Section

General: All procedures were carried out under purified argon in dried solvents (THF and diethyl ether over Na/benzophenone). Compound **1** was synthesized as described in ref.[6], *N,N′,N″*-trimethyltriazinane and pentamethyldiethylenetriamine (PMDETA) were distilled over Na (PMDETA under reduced pressure) and stored over molecular sieve, commercially available crown ether 18-crown-6 (Merck-Schuchardt), $NaNO_2$ (Aldrich), and $LiNO_3$ (Riedl-deHaen) were thoroughly evacuated at room temperature and used without further purification.

Synthesis of $[(\mu\text{-}NO_2\text{-}N,O)R_2AlCH_2AlR_2]^-[Na(THF)_3]^+$ (**5a**): A solution of 0.362 g (0.514 mmol) of **1** in 25 ml of THF is added to an excess (0.057 g, 0.826 mmol) of solid $NaNO_2$. The mixture is vigorously stirred for 22 h, and the solution adopts a pale yellow color. After filtration the solution is concentrated in vacuo at room temp. and cooled to −50°C. The product is isolated as yellow crystals, which rapidly become amorphous at room temperature and normal pressure. Yield: 0.404 g (79%). − M. p. (argon, sealed capillary): 92°C. − ^{1}H NMR ($[D_{10}]Et_2O$, 300 MHz): δ = 3.66 (m, 12 H, OCH_2 of THF), 1.82 (m, 12 H, CH_2CH_2 of THF), 0.09 (s, 72 H, $SiMe_3$), −1.06 (s, 4 H, $AlCHSi_2$), −1.24 (s, 2 H, $AlCH_2Al$). − ^{13}C NMR ($[D_{10}]Et_2O$, 75.5 MHz): δ = 68.4 (OCH_2 of THF), 26.2 (CH_2CH_2 of THF), 5.9 ($SiMe_3$), 5.0 (br., $AlCH_2Al$), 4.1 ($AlCSi_2$). − IR (CsBr, paraffin): ν = 1497 m cm^{-1} νNO; 1462 vs, 1377 s paraffin; 1339 w, 1316 w, 1244 vs δCH_3; 1192 m, 1159 m, 1049 vs, 1028 s νCC, νCO; 1003 vs δCH; 934 vs, 918 vs, 899 vs, 843 vs, 777 vs, 750 vs, 725 s ρCH_3(Si); 698 s, 669 vs ν_{as}SiC; 629 m, 613 w ν_sSiC; 588 w, 561 s, 521 m, 503 w, 496 m, 448 w νAlC, νAlO; 386 vw, 366 vw δSiC. − UV/vis (diethyl ether) (ε): 240 (1750), 290 (sh, 700), 370 nm (sh, 90). − $C_{41}H_{102}Al_2NNaO_5Si_8$ (990.90): calcd. Al 5.4, Na 2.3; found Al 5.4, Na 2.2.

Synthesis of $[(\mu\text{-}NO_2\text{-}N,O)R_2AlCH_2AlR_2]^-[Na(PMDETA)_2]^+$ (**5b**): An excess of solid $NaNO_2$ (0.070 g, 1.01 mmol) is treated with a solution of 0.513 g (0.727 mmol) of **1** in 50 ml of diethyl ether. 2 ml of PMDETA is added to the suspension, and the mixture is vigorously stirred for 18 h. The solution adopts a pale yellow color. After filtration the solution is concentrated in vacuo at room temp. to about 4 ml and cooled to −50°C. The product is isolated as yellow crystals, which become amorphous at room temperature. Yield: 0.588 g (72%). − M. p. (argon, sealed capillary): 140°C. − ^{1}H NMR ($[D_{10}]Et_2O$, 300 MHz): δ = 2.48 and 2.38 (each: pseudo-t, 8 H, NCH_2 of PMDETA), 2.26 (s, 6 H, N-Me of PMDETA), 2.22 (s, 24 H, NMe_2 of PMDETA), 0.10 (s, 72 H, $SiMe_3$), −1.05 (s, 4 H, $AlCHSi_2$), −1.23 (s, 2 H, $AlCH_2Al$). − ^{13}C NMR ($[D_{10}]Et_2O$, 75.5 MHz): δ = 58.6 and 56.7 (NCH_2 of PMDETA), 46.4 (NMe_2 of PMDETA), 43.7 (NMe of PMDETA), 6.0 ($SiMe_3$), 4.9 (br., $AlCH_2Al$), 4.3 ($AlCSi_2$). − IR (CsBr, paraffin): ν = 1497 m cm^{-1} νNO; 1464 vs, 1377 s, 1366 s, 1355 m paraffin; 1341 vw, 1308 s, 1291 s, 1252 vs, 1242 vs, 1225 vs δCH_3; 1161 s, 1150 s, 1127 m, 1111 s, 1096 m, 1065 m, 1026 vs νCC, νCN; 1007 vs δCH; 930 vs, 901 vs, 843 vs, 777 vs, 750 vs, 727 s ρCH_3(Si); 667 vs ν_{as}SiC; 629 m, 615 w ν_sSiC; 590 w, 559 s, 517 m, 503 m, 496 m, 465 w, 449 w, 424 vw νAlC, νAlO; 380 w, 353 vw δSiC. − UV/vis (diethyl ether) (ε): 240 (2050), 270 nm (sh, br., 1230). $C_{47}H_{124}Al_2NaN_7O_2Si_8$ (1210.84): calcd. Al 4.8, Na 2.0; found Al 4.8, Na 2.0.

Synthesis of $[(\mu\text{-}NO_2\text{-}N,O)R_2AlCH_2AlR_2]^-[Na([18]crown\text{-}6)(Et_2O)]^+$ (**5c**): An excess of solid $NaNO_2$ (0.061 g, 0.884 mmol) is treated with a solution of 0.507 g (0.719 mmol) of **1** and 0.252 g (0.953 mmol) [18]crown-6 in 50 ml of diethyl ether. The mixture is vigorously stirred for 18 h, and the solution adopts a pale yellow color. After filtration the solution is concentrated in vacuo at room temp. and cooled to −50°C. The product is isolated as yellow crystals, which become amorphous upon thorough drying in vacuo and include about 0.4 molecules of diethyl ether in each formula unit. Yield: 0.455 g (59%). − M. p. (argon, sealed capillary): 163°C. − ^{1}H NMR ($[D_{10}]Et_2O$, 300 MHz, 300 K): δ = 3.69 (s, 24 H, [18]crown-6), 3.39 (q, 1.6 H, OCH_2 of Et_2O), 1.12 (t, 2.4 H, CH_3 of Et_2O), 0.11 (s, 72 H, $SiMe_3$), −1.04 (s, 4 H, $AlCHSi_2$), −1.23 (s, 2 H, $AlCH_2Al$). − ^{1}H NMR ($[D_{10}]Et_2O$, 500 MHz, 203 K): δ = 3.65 (s, 24 H, [18]crown-6), 3.38 (q, 1.6 H, OCH_2 of Et_2O), 1.15 (t, 2.4 H, CH_3 of Et_2O), 0.15 and 0.06 (each: s, 36 H, $SiMe_3$), −1.0 and −1.1 (each: br., 2 H, $AlCHSi_2$), $AlCH_2Al$ not detected. − ^{13}C NMR ($[D_{10}]Et_2O$, 75.5 MHz): δ = 69.8 ([18]crown-6), 6.0 ($SiMe_3$), 5.0 (br., $AlCH_2Al$), 4.2 ($AlCSi_2$). − IR (CsBr, paraffin): ν = 1501 m cm^{-1} νNO; 1462 vs, 1377 s, 1354 m paraffin; 1321 vw, 1296 m, 1244 vs δCH_3; 1157 m, 1111 s, 1100 s, 1026 m νCC, νCO; 1005 s δCH; 953 sh, 932 s, 899 s, 845 vs, 777 s, 750 s, 725 m ρCH_3(Si); 669 s ν_{as}SiC; 629 w, 610 w ν_sSiC; 588 w, 561 m, 517 w, 505 w, 498 w, 463 vw, 449 vw νAlC, νAlO; 388 vw, 359 vw δSiC. − UV/vis (diethyl ether) (ε): 230 (2530), 280 (sh, 870), 360 nm (90). $C_{41}H_{102}Al_2NaNO_8Si_8 \cdot 0.4\ C_4H_{10}O$ (1068.55): calcd. Al 5.1, Na 2.2; found Al 5.1, Na 2.0.

Synthesis of $[(\mu\text{-}NO_3\text{-}O,O')R_2AlCH_2AlR_2]^-[Li(THF)_4]^+$ (**6a**): Solid $LiNO_3$ (0.038 g, 0.554 mmol) is treated with a solution of an equimolar amount of 0.391 g (0.554 mmol) of **1** in 50 ml of THF. The mixture is vigorously stirred for 12 h. The yellow solution is concentrated to about 1 ml, and the product crystallizes as yellowish crystals upon cooling to −50°C. Yield: 0.490 g (83%). − M. p. (argon, sealed capillary): 135°C. − ^{1}H NMR ([D$_{10}$]diethyl ether, 300 MHz): δ = 3.64 (m, 16 H, OCH_2 of THF), 1.79 (m, 16 H, CH_2CH_2 of THF), 0.10 (s, 72 H, $SiMe_3$), −1.05 (s, 4 H, $AlCHSi_2$), −1.27 (s, 2 H, $AlCH_2Al$). − ^{13}C NMR ([D$_{10}$]diethyl ether, 75.5 MHz): δ = 68.2 (OCH_2 of THF), 26.3 (CH_2CH_2 of THF), 5.7 ($SiMe_3$), 5.0 (br., $AlCH_2Al$), 4.3 ($AlCSi_2$). − IR (CsBr, paraffin): ν = 1501 s cm^{-1} νNO; 1462 vs, 1377 vs paraffin; 1344 m, 1281 vs, 1248 vs δCH_3; 1179 w, 1067 s, 1044 vs νCC, νCO; 1007 s δCH; 930 vs, 912 s, 845 vs, 777 vs, 750 s, 725 s ρCH_3(Si); 667 s ν_{as}SiC; 629 m, 611 w ν_sSiC; 583 w, 556 s, 521 m, 505 m, 465 vw, 452 w, 421 w νAlC, νAlO, νLiO; 372 vw, 334 vw, 316 vw δSiC. − UV/vis (THF) (ε): 225 (2470), 260 nm (sh, br., 990). $C_{45}H_{110}Al_2LiNO_7Si_8$ (1062.96): calcd. [a] Programmes SHELXL-93; SHELXTL[26]; solutions by direct methods, full matrix refinement with all independent structure factors.

Synthesis of [(μ-NO$_3$-O,O′)R$_2$AlCH$_2$AlR$_2$]$^-$[Li{(CH$_2$NMe)$_3$}-THF]$^+$ (**6b**): Solid $LiNO_3$ (0.048 g, 0.696 mmol) is treated with a solution of an equimolar amount of 0.490 g (0.694 mmol) of **1** and 2 ml of trimethyltriazinane in 45 ml THF. The mixture is vigorously stirred for 24 h. The yellow solution is evaporated, the residue is treated with 5 ml of diethyl ether, and THF is added dropwise until a clear solution is obtained. Product **6b** crystallizes as yellow crystals upon cooling to −50°C, which contain one molecule of THF and one molecule of trimethyltriazinane in each formula unit. The product (**6c**) with two trimethyltriazinane molecules coordinated to lithium, which was used for the crystal structure determination, was obtained on slow cooling of a dilute solution of **6b** in diethylether by the addition of a small amount of trimethyltriazinane. Yield of **6b**: 0.465 g (69%). − M. p. (argon, sealed capillary): 99°C. − ^{1}H NMR ([D$_8$]THF, 300 MHz): δ = 3.62 (m, 4 H, OCH$_2$ of THF), 3.10 (br., 6 H, NCH$_2$ of triazinane), 2.20 (s, 9 H, Me of triazinane), 1.78 (m, 4 H, CH$_2$CH$_2$ of THF), 0.10 (s, 72 H, SiMe$_3$), −1.06 (s, 4 H, AlCHSi$_2$), −1.28 (s, 2 H, AlCH$_2$Al). − ^{13}C NMR ([D$_8$]THF, 75.5 MHz): δ = 78.3 (NCN of triazinane), 40.5 (Me of triazinane), 5.8 (SiMe$_3$), 5.1 (br., AlCH$_2$Al), 4.4 (AlCSi$_2$). − IR (CsBr, paraffin): ν = 1503 m cm^{-1} νNO; 1466 vs, 1377 s paraffin; 1346 w, 1289 m, 1274 m, 1244 s δCH$_3$; 1159 m, 1119 s, 1051 vs νCC, νCO, νCN; 1015 s δCH; 916 s, 843 vs, 777 s, 737 m, 725 m ρCH$_3$(Si); 671 s ν$_{as}$SiC; 631 m, 611 w ν$_s$SiC; 579 m, 554 m, 519 s, 506 m, 465 m, 452 w, 419 w νAlC, νAlO; 395 w, 372 w, 339 w, 316 w δSiC. − UV/vis (THF) (ε): 240 (1710), 260 nm (sh, br., 1320). − $C_{39}H_{101}Al_2LiN_4O_4Si_8$ (975.84): calcd. Al 5.5, Li 0.7; found Al 5.6, Li 0.7.

Crystal Structure Determinations: Single crystals of compound **5c** were obtained by recrystallization from diethyl ether, the crystals of compound **6c** were grown by recrystallization of **6b** from a dilute solution in ether in the peresence of a small quantity of triazinane. Crystal data and structure refinement parameters are given in Table 1[27]. One of the [Li(triazinane)$_2$]$^+$ cations shows a disorder with a partial overlap of the atoms of the triazinane molecules. Crystal data of **5a** and of **5**[Na(TMPDA)$_2$] (**5d**) (TMPDA = tetramethylpropylenediamine) are also given in Table 1; both structures could not be satisfactorily refined due to the severe disorder of the cations. **5d** was obtained on the same route as compound **5b**, but was not isolated in a high yield.

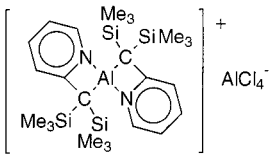
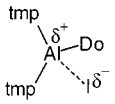
Keywords: Bis(tetramethylpiperidino)aluminum halide complexes / Tricoordinated aluminum cations / ^{27}Al-NMR spectroscopy / X-ray crystal structure analysis / Ab initio calculations

Upon treatment with Lewis bases Do (Do = pyridine bases or THF), the Lewis acids tmp_2AlX (X = Cl, Br, I) are converted exclusively to the monoadducts $tmp_2AlX \cdot Do$ (**2–4**). The Al–X bonds of these addition compounds are considerably elongated, indicating a tendency towards the formation of ionic species $[tmp_2Al(Do)]X$. Due to the steric requirements of the bulky tmp ligands, addition of an excess of the Lewis base does not force these compounds to form tetracoordinated aluminum cations $[tmp_2Al(Do)_2]^+$ or pentacoordinated adducts $tmp_2AlX \cdot Do_2$. Attempts to prepare ionic representatives by reaction of $tmp_2AlX \cdot Do$ with "ate" complexes of comparatively low nucleophilicity [MY = $NaBPh_4$, $AgBPh_4$, $LiB(C_6F_5)_4$, $AgBF_4$, AgOtos] result in phenylation products [e.g. tmp_2AlPh (**5a**) and $BPh_3 \cdot py$ (**5b**)] or tetracoordinated addition compounds $tmp_2AlY \cdot Do$ (Y = anion). However, addition of one equivalent of AlX_3 (X = Br, I) initiates halide abstraction with formation of the ionic $[tmp_2Al(Do)]AlX_4$ species **6a–f**, as indicated by ^{27}Al-NMR data and conductivity measurements. Solid $[tmp_2Al(py)]AlI_4$ (**6b**) decomposes readily into $tmpAlI_2$ and $tmpAlI_2 \cdot py$ (**7c**). Addition of non-polar aliphatic solvents to solutions of $[tmp_2Al(Do)]AlX_4$ (**6**) leads to slow decomposition into tmp_2AlX and $AlX_3 \cdot Do$ (**7a–b**, **d**). This also occurs in polar donor solvents, where compounds $AlX_3 \cdot Do$ are favoured due to the formation of penta- or hexacoordinated species $AlX_3 \cdot Do \cdot Solv_n$ (n = 1, 2). Semiempirical AM1 calculations reveal the gas-phase stability of the tricoordinated bis(tmp)aluminum cation in the salt $[tmp_2AlPy]AlCl_4$ as the only representative in a series of calculated aluminum cations $[(R_2N)_2AlPy]AlCl_4$ (R_2N = Me_2N, Et_2N, iPr_2N, tmp). According to these calculations, the stability of a given cation increases when tetrachloroaluminate is replaced by tetraiodoaluminate. Ab initio calculations have been performed on two cations $[(H_2N)_2Al(Do)]^+$ (Do = NH_3, py) and indicate very short Al–N bond lengths owing to ionic bonding contributions.

As aluminum compounds exhibit the highest Lewis acidity amongst main group III species[3][4], tetra-, penta- and hexacoordinated Lewis acid−base complexes with many different neutral donor molecules have been described in the literature[5]. Due to their importance in industrial processes[6], complexes involving $AlCl_3$ and trimethylaluminum as Lewis acids [e.g. $AlCl_3 \cdot NMe_3$, $AlCl_3 \cdot (NMe_3)_2$, $AlBr_3 \cdot$diglyme (diglyme = diethylene glycol dimethyl ether), $AlMe_3 \cdot OMe_3$, etc.][4][7][8] have been particularly well studied. These addition compounds can exist as covalent molecules or as ion pairs, as shown by X-ray crystal structure determinations {e.g. $[AlCl_2(py)_4]AlCl_4$}[3], ^{27}Al-NMR and conductivity measurements, e.g. of solutions of $AlCl_3$ or $AlBr_3$ in THF, diglyme, DME etc.[8][9]. A fine example of this feature has recently been published by Atwood et al.[10]. They investigated reactions of Me_2AlX (X = Cl, Br, I) with tBuNH$_2$ as a donor molecule. Whereas the chloride gave the molecular adduct $Me_2AlCl \cdot NH_2t$Bu, the bromide and iodide were forced to dissociate upon addition of excess tBuNH$_2$, forming the salts $[Me_2Al(NH_2t$Bu$)_2]X$ (X = Br, I). The chemistry of tetracoordinated aluminum cations has so far been explored only fleetingly, and apart from the latter compounds, as far as we are aware, only two other species of this type have been reported, namely $[t$Bu$_2$Al(tmeda)$]^+$ by Uhl[11] and **A** by Raston[12].



A



B

To the best of our knowledge, tricoordinated aluminum cations $[R_2Al(Do)]^+$ (Do = monofunctional ligand) have yet to be observed and characterized.

In contrast to the aminoboron halides, aminoaluminum halides can be expected to be sufficiently acidic to form addition compounds [see $(Me_3Si)_2NAl(H)(Cl) \cdot NMe_3$][13]. Even aminoorganylalanes form Lewis acid−base adducts, as exemplified by $Ph_2NAlMe_2 \cdot NMe_3$ and $Ph_2NAlMe_2 \cdot OEt_2$[14]. Thus, the question arose as to whether the recently synthesized series of monomeric bis(amino)aluminum halides, tmp_2AlX (tmp = 2,2,6,6-tetramethylpiperidino, X = Cl **1a**, Br **1b**, I **1c**)[15] and some products of nucleophilic substitution derived from these[16][17] would still show

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0707−0927 $ 17.50+.50/0

Lewis acidity. This was indeed found to be the case for **1a–c**. Here, we report on the addition compounds $tmp_2AlX \cdot Do$ (X = Cl, Br, I) as well as the salts $[tmp_2Al(Do)]Y$ (Y = AlI_4).

Synthesis and Reactions

Addition of one equivalent of a donor molecule Do to *n*-hexane solutions of tmp_2AlX, **1a–c**, leads to immediate precipitation of the adducts $tmp_2AlX \cdot Do$ **2a**, **b**, **3a–c**, and **4a–c** in almost quantitative yield, according to Eq. 1.

$$tmp_2AlX + Do \xrightarrow{\text{hexane}} tmp_2AlX{*}Do \quad (1)$$

2-4

	2a	2b	3a	3b	3c	4a	4b	4c
X	Cl	Cl	Br	Br	Br	I	I	I
Do	iq	thf	thf	py	iq	py	iq	γ-pic

The adducts **2–4** are stable in vacuo and do not lose their donor molecules, even when subjected to high vacuum conditions at 50°C. On the other hand, Et_2O, tBuPH$_2$, NEt_3, and acridine do not give stable addition compounds (with respect to the application of vacuum). Moreover, tmp_2AlI (**1c**), the most Lewis acidic compound in the series of the halides **1a–c**, crystallizes from Et_2O as its tricoordinated monomer, as proven by NMR and by examination of its unit cell parameters[15]. Compounds **2–4** are readily soluble in aromatic hydrocarbons, CH_2Cl_2, CH_2Br_2, THF, and Et_2O. Addition of a large excess of donor (up to tenfold, or, in the case of THF, using the donor as solvent) does not force coordination of a further donor molecule (i.e. bring about pentacoordination at the aluminum atom), nor does it induce dissociation into ionic $[tmp_2Al(Do)_2]X$ species. The addition compounds **2–4** can be crystallized from THF and no replacement of Do by the solvent is observed.

Attempts to prepare low coordinated ionic species of the type $[tmp_2Al(py)]Y$ (Y = anion) by addition of $NaBPh_4$, $AgBPh_4$, or $LiB(C_6F_5)_4$ to solutions of $tmp_2AlI \cdot py$ in various solvents at ambient temperature, did not lead to substitution of the iodine atom by the weakly coordinating ions BR_4^-, even after a reaction time of several weeks. In the case of the reaction with $AgBPh_4$, the only species detectable after heating were tmp_2AlPh (**5a**) and $BPh_3 \cdot py$ (**5b**). This implies that $[tmp_2Al(py)]BPh_4$ is formed initially, which then decomposes to give **5a** and **5b**. The aluminum compound **5a** has been synthesized independently from PhLi and tmp_2AlCl[17].

Upon reaction with AgOtos (Otos = tosylate), **4a** gives only the tetracoordinated, covalent product of nucleophilic substitution, $tmp_2AlOtos \cdot py$ (**5c**). Likewise, a mixture of $AgBF_4$, 2,6-lutidine (= lut) and **1b** yields the adduct $tmp_2Al(BF_4) \cdot lut$ (**5d**). Replacing the sterically hindered, less powerful donor 2,6-lutidine by pyridine leads to $tmp_2Al(BF_4) \cdot py$ (**5e**). The latter compound, molecular in *n*-pentane solution, dissociates in CH_2Cl_2 to give an ion pair $[tmp_2Al(py)]BF_4$. This dissociation is accompanied by dramatic shifts of the ^{11}B- and ^{19}F-NMR resonances.

$$tmp_2AlI{*}py + \begin{matrix}+\ NaBPh_4\\ +\ AgBPh_4\\ +\ LiB(C_6F_5)_4\end{matrix} \xrightarrow[\text{weeks}]{\text{r.t., various solvents}} [tmp_2Al(py)^+]BPh_4^- \quad (2a)$$

4a

$$tmp_2AlI{*}py + \begin{matrix}NaBPh_4\\ +\ AgBPh_4\end{matrix} \xrightarrow[110\ °C,\ 3d]{\text{toluene}} \left[[tmp_2Al(py)^+]BPh_4^- \right] \quad (2b)$$

4a

$$tmp_2AlPh\ (\mathbf{5a}) + BPh_3{*}py\ (\mathbf{5b})$$

$$tmp_2AlI{*}py + AgOtos \xrightarrow[\text{r.t.; 12 h}]{\text{benzene}} tmp_2AlOtos{*}py \quad (2c)$$

4a **5c**

$$tmp_2AlBr + AgBF_4 + \text{N} \xrightarrow{\text{hexane}} tmp_2Al(FBF_3)(lut) \quad (2d)$$

lut = 2,6-lutidine **5d**

$$tmp_2AlX{*}py + AgBF_4 \xrightarrow{\text{hexane/ pentane}} \begin{matrix}tmp_2Al(py)BF_4\ \mathbf{5e}\\ [tmp_2Al(py)^+]BF_4^-\ (CH_2Cl_2/\ CDCl_3)\end{matrix} \quad (2e)$$

As all the tested tetraphenylborates and tetrafluoroborates turned out to be either unstable (due to dephenylation) or too basic (formation of adducts) to give ionic compounds of the type $[tmp_2Al(Do)]Y$, a different approach was evaluated, in which strong halide acceptors were employed in order to induce a reaction according to Eq. 3a.

$$tmp_2AlX{*}Do + AlX_3 \xrightarrow{\text{solv.}} tmp_2AlDo]^+[AlX_4]^- \quad \mathbf{6}$$

solv. = CH_2Cl_2, CH_2Br_2, Et_2O => -78°C
solv. = toluene, benzene => 0°C

	6a	6b	6c	6d	6e	6f
X	Br	I	I	I	I	I
Do	iq	py	γ-pic	4-tBu-Py	iq	acr

Addition of one equivalent of AlX_3 (X = Br, I) to solutions of $tmp_2AlX \cdot Do$ (X = Br, I) in CH_2Br_2 (for **6a**) or in aromatic solvents such as toluene leads smoothly to the ionic compounds $[tmp_2Al(iq)]AlBr_4$ (**6a**), $[tmp_2Al(py)]AlI_4$ (**6b**), $[tmp_2Al(4\text{-Me-py})]AlI_4$ (**6c**), $[tmp_2Al(4\text{-}t\text{Bu-py})]AlI_4$ (**6d**), $[tmp_2Al(iq)]AlI_4$ (**6e**), and $[tmp_2Al(acr)]AlI_4$ (**6f**), (iq = isoquinoline, acr = acridine). If a solution of $tmp_2AlCl \cdot thf$ (**2a**) in THF is treated with $AlCl_3$, only the adduct $AlCl_3 \cdot (thf)_2$ is formed, according to the ^{27}Al-NMR spectrum. In contrast to the iodide $[tmp_2Al(acr)]AlI_4$ (**6f**), ad-

dition of $AlBr_3$ to a 1:1 mixture of tmp_2AlBr (**1b**) and acridine leads to exclusive formation of $AlBr_3 \cdot acr$ (**7d**), leaving **1b** uncoordinated. The tetraiodoaluminates were found to be the most stable of all the tetrahaloaluminates. Nevertheless, NMR spectroscopic evidence was found even for the formation of ionic tetrachloroaluminates. Solutions of **6b−f** in aromatic hydrocarbons or CH_2Cl_2 are stable for weeks at ambient temperature, but addition of *n*-pentane (in an attempt to induce crystallization) results in slow decomposition to give tmp_2AlI (**1c**) and $AlI_3 \cdot Do$. This was proven by the isolation and full characterization of $AlI_3 \cdot iq$ (**7a**) and $AlI_3 \cdot$(4-*t*Bu-py) (**7b**), as well as by NMR spectroscopic characterization of tmp_2AlI (**1c**) (see Eq. 4a and 4b)[15]. The preparation of **6b** also proceeds smoothly in Et_2O, but storing the concentrated solution at −78°C in the hope of obtaining crystals leads to decomposition into soluble $AlI_3 \cdot py \cdot (OEt_2)_n$ and insoluble tmp_2AlI (**1c**), according to Eq. 4c[15]. Upon standing for one week at 35°C, solid **6b** disproportionates into $tmpAlI_2$ and $tmpAlI_2 \cdot py$ (**7c**).

$$[tmp_2AlDo]AlX_4 \xrightarrow[\text{weeks}]{Et_2O\ -78°C} tmp_2AlX\ (s) + AlX_3{*}Do{*}(OEt_2)_n\ (solv.) \quad (4a)$$

$$[tmp_2AlDo]AlX_4 \xrightarrow[\text{rapid}]{\text{n-pentane}} tmp_2AlX\ (solv.) + AlX_3{*}Do\ (s) \quad (4b)$$

$$\underset{\textbf{6b}}{[tmp_2Al(py)]AlI_4} \xrightarrow[T = 35°C]{\text{as a solid at}} \underset{\textbf{7c}}{tmpAlI_2{*}Py} + tmpAlI_2 \quad (4c)$$

Characterization

Compared to the shifts and half-widths of the ^{27}Al-NMR signals of the tricoordinated alanes tmp_2AlX **1a−c** ($\delta^{27}Al$ = 130−131, $\Delta_{1/2}$ = 9100−13700 Hz)[15], the signals of the adducts **2−4** are shifted by 30−60 ppm to higher field due to the higher electron-density at the aluminum center and are narrower. As compounds **2−4** have tetracoordinated aluminum atoms, and thus the local symmetry at the aluminum nuclei is increased (as compared to **1a−c**), the average half-widths of the ^{27}Al-NMR signals are reduced to approximately 6800 Hz (see Table 1)[18][19]. Single sets of lines are observed in the ^{1}H- and ^{13}C-NMR spectra of the tmp ligands, indicating free rotation about the Al−N bond as well as rapid inversion of the piperidinyl ring. Compared to the halides **1a−c**, the signals are shifted downfield [by about 0.3 ppm (^{1}H NMR) and 2.7 ppm (^{13}C NMR)]. Moreover, the chemical shifts show a strong solvent dependence. In $CDCl_3$, the signals are found at higher field than in C_6D_6. The decrease in Lewis acidity in the series Al−I > Al−Br > Al−Cl[3][4] and the bond enthalpy order Al−X (Al−I < Al−Br < Al−Cl)[6] are mirrored by the chemical shifts of the tmp methyl groups. For $tmp_2AlCl \cdot iq$ (**2b**), the methyl protons give rise to a signal at δ = 1.29; for $tmp_2AlBr \cdot iq$ (**3c**) at δ = 1.37, and for $tmp_2AlI \cdot iq$ (**4b**) at δ = 1.41. Similarily, the methyl protons resonate at δ = 1.58 in $tmp_2AlBr \cdot py$ (**3b**) and at δ = 1.62 in $tmp_2AlI \cdot py$ (**4a**). These changes point to a predissociation of the weakest Al−X bond (Al−I). The aluminum centre thus becomes more positively charged (see **B**), and the resonances appear at lower field.

The chemical shifts of hydrogen and carbon atoms adjacent to the heteroatoms of the donor molecules proved to be valuable indicators in ascertaining whether or not a compound $tmp_2Al(Do)Y$ (Y = anion or ligand) is dissociated into an ion pair (see Table 2). In comparison with the free pyridine bases, the resonances for these bases in the adducts **2−4** are shifted downfield by 0.6 to 1 ppm (^{1}H-NMR) and by 0.6 to 3.5 ppm (^{13}C-NMR), respectively.

The decomposition products of the tetraphenylborate, as described by Eq. 2b, were identified by their ^{1}H-, ^{13}C-, and ^{27}Al-NMR shifts, as reported in the literature (tmp_2AlPh, **5a**)[17], or by the known ^{11}B-NMR shift of δ = 5.0[20]. Further evidence was provided by the ^{1}H-NMR spectrum, elemental analysis, and X-ray crystal structure determination of $BPh_3 \cdot py$ (**5b**)[21].

Since $tmp_2AlOtos \cdot py$ (**5c**) exhibits a ^{27}Al-NMR signal in the same range as the adducts **2−4** ($\delta^{27}Al$ = 97, $\Delta_{1/2}$ = 5500 Hz), as well as a similar shift of the *ortho*-protons on the pyridine ring (δ^1H = 9.29, cf. the data in Table 1), it appears that this species is not ionic. A very similar situation is found for $tmp_2Al(lut)BF_4$ (**5d**). In its ^{27}Al-NMR spectrum, a line at δ = 1 ($\Delta_{1/2}$ = 3400 Hz) is found, too narrow to be attributable to a tricoordinated aluminum centre. Moreover, the ^{11}B-NMR spectrum consists of a single, broadened line at $\delta^{11}B$ = 17.9. Due to the coordination at the aluminum centre, the resonance is deshielded by 18 ppm compared to the free, ionic tetrafluoroborate[20]. Similarly, a solution of $tmp_2Al(py)BF_4$ (**5e**) in pentane exhibits a signal at $\delta^{11}B$ = 19.3. If the spectrum is recorded in $CDCl_3$ or CH_2Cl_2, a line at $\delta^{11}B$ = 0.9 is observed, indicating the presence of uncoordinated, free BF_4^-[20]. This is accompanied by correspondingly dramatic differences in the ^{19}F-NMR signals. Whereas in pentane a broadened resonance at $\delta^{19}F$ = −111 (analogous to **5d**: $\delta^{19}F$ = −104.5 and −111.0) is found, in $CDCl_3$ a 1:1:1:1 quartet at $\delta^{19}F$ = −151 with ^1J(B,F) = 12 Hz supports the salt formation [*cf.* F_3BOH, ^1J(B,F) = 16.4 Hz; $F_3B \cdot N(H)_xMe_{3-x}$, x = 0−3,

^1J(B,F) = 15.1 to 16.4 Hz][20]. The ^{27}Al-NMR signal of **5e** in CH_2Cl_2 is additional evidence for the ionic behavior in polar solvents: a very broad signal is observed, covering the full spread of the spectrum. The ^{1}H-NMR signals of the *ortho*-protons on the pyridine ring also reflect this change: the shift for **5e** (δ = 8.71) is consistent with an ionic structure {cf. [tmp_2Al(py)]AlI_4, (**6b**), δ^1H = 8.59}, but not with the adduct $tmp_2AlI\cdot$py (**4a**), where the corresponding signal appears at δ = 9.06.

Compared to the adducts **2**–**4**, the formation of the ionic species **6a**–**f** is accompanied by dramatic changes in the line-widths of the ^{27}Al-NMR signals. Whereas **2**–**4** exhibit average line widths of 6800 Hz, a single sharp line attributable to the AlX_4^- fragment ($\Delta_{1/2}$ = 17 to 134 Hz) is found for compounds **6a**–**f**. The second aluminum nucleus, assumed to be tricoordinated, should contribute to the spectra with a very broad line. Due to the presence of highly symmetrical, NMR-sensitive and unsymmetrical, tricoordinated aluminum centres, this line is not usually detected {e.g. in the ambient temperature ^{27}Al-NMR spectrum of [Al(O*i*Pr)$_3$]$_4$ one sharp line, assigned to the central, hexacoordinated aluminum atom is readily detected (δ^{27}Al = −2.62, $\Delta_{1/2}$ = 102 Hz), while signals due to the tetracoordinated aluminum atoms are not seen[19]}. As the chemical shifts of the tetrahaloaluminates (**6a**: δ^{27}Al = 104; **6b**–**e**: δ^{27}Al = 50−55; **6f**: δ^{27}Al = −22) are, with the exception of **6f**, found at lower field than those reported in the literature [$AlBr_4^-$: δ^{27}Al = 80−83, AlI_4^-: δ^{27}Al = −27 (CH_2Cl_2)][19], a weak coordination of the anions to the cationic aluminum center is indicated. Considering the narrow line-width for **6a**–**f** ($\Delta_{1/2}$ = 17−134 Hz), this interaction cannot be very strong, since the aluminum nucleus is very sensitive to a disturbance of symmetry. Due to the positive charge of **6a**–**f**, the ^{1}H- and ^{13}C-NMR signals of the protons and the carbon atoms adjacent to the heteroatoms of the donor molecules are shifted by about 0.4 ppm (^{1}H NMR) and 1−3 ppm (^{13}C NMR), respectively, to higher field, compared to the corresponding signals in compounds **2**–**4**. This is a characteristic feature for these ionic compounds (see Table 2 and compare with the data in Table 1).

Table 2. Selected NMR data of compounds **6**

[a] Broad. − [b] ^3J(H,H) = 6.4 Hz. − [c] At C7, *trans* to N1. − [d] ^3J(H,H) = 8.1 Hz.

Single sets of lines are observed for the tmp ligand in **6**, indicating free rotation about the Al−N bond and rapid inversion of the piperidinyl ring. Compared to the adducts **2**–**4**, the signals appear at higher field and resemble those found for the halides **1b**–**c**. This is in line with calculated AM1 data[29] for **1b**, **c** and [tmp_2Al(py)]AlX_4 (X = Br, I). As the calculated Al−N bond lengths and N−Al−N bond angles are very similar (to within ±0.01 A and ±1°), similar NMR spectroscopic data can be expected.

Addition of *n*-pentane to a solution of **6b** or **6d** in aromatic hydrocarbons leads to disproportionation according to Eq. 4c. In solution, the characteristic chemical shifts of tmp_2AlI (**1c**) could be detected (^{1}H-, ^{13}C-, ^{27}Al-NMR)[15]. Crystals of $AlI_3\cdot$4-*t*Bu-py (**7b**), which separated on cooling to 5°C, were characterized spectroscopically and analytically, as was a sample of $AlBr_3\cdot$acr (**7d**), obtained according to Eq. 3b. Due to the highly symmetrical coordination at the aluminum nuclei, these compounds give sharp lines at δ^{27}Al = 51 ($\Delta_{1/2}$ = 46 Hz) (**7b**) and δ = 83 ($\Delta_{1/2}$ = 34 Hz) (**7d**). Since only one distinct line was observed in each ^{27}Al-NMR spectrum, dissociation into ionic species as found for $AlCl_3\cdot py_2$ can be ruled out[5]. Moreover, $AlI_3\cdot$iq (**7a**) precipitated under these conditions as a molecular adduct. It was only characterized by its X-ray crystal structure.

In the solid state, **6b** decomposes into $tmpAlI_2$ and $tmpAlI_2\cdot$py (**7c**) (Eq. 4c). This is demonstrated by its ^{27}Al-NMR spectrum: one signal at δ^{27}Al = 69 ($\Delta_{1/2}$ = 2640 Hz) is observed for **7c**, the half-width of which resembles that of signals of other $tmpAlX_2\cdot$Do compounds[15][19]. The ^{1}H- and ^{13}C-NMR shifts of **7c** are very similar to those observed for $tmp_2AlI\cdot$py (**4a**), differing by only about 0.01 ppm (δ^1H) and 0.1 ppm (δ^{13}C). Thus, it is most likely that **7c** is present in solution as a tetracoordinated adduct.

Conductivity Measurements

To prove the formation of ions, conductivity measurements were carried out on well-defined CH_2Cl_2 solutions of **5d**, **6a**–**b**, **e** and the dissociation patterns were deduced from the calculated gradients of the resulting Fuoss-Kraus plots[22]. These salts are stable in CH_2Cl_2 solution and do not undergo halogen-exchange with the solvent, as is observed for AlX_3 solutions (X = Br, I). The gradient of these plots gives an indication of the ion pair formation from the undissociated parent species. An equilibrium as described by Eq. 5a corresponds to a gradient of −0.5, that according to Eq. 5b exhibits a gradient of 0, while a dissociation pattern described by Eq. 5c is represented by a value of 0.5.

$$AB \rightleftharpoons A^+ + B^- \quad (5a)$$

$$2\,AB \rightleftharpoons A^+ + A_2B \quad (5b)$$
$$2\,AB \rightleftharpoons A_2B^+ + B^-$$

$$3\,AB \rightleftharpoons A^+ + A_2B_3^- \quad (5c)$$
$$3\,AB \rightleftharpoons A_2B^+ + AB_2^-$$
$$3\,AB \rightleftharpoons A_3B_2^+ + B^-$$

A solution of **5d** in CH_2Cl_2 shows no electrical conductivity and thus this compound remains as a molecular adduct, as already shown by its NMR data. Solutions of **6a**, **b**, **e** exhibit electrical conductivity, indicating ion pair formation. The gradient of the plot for **6b** reaches a value of approximately −0.6, indicating a reaction according to Eq. 5a. However, the gradients for **6a**, **e** are −0.1 and −0.2,

respectively. This corresponds with ion formation according to Eq. 5a and Eq. 5b, with a greater percentage of the dissociation behavior conforming to Eq. 5b. **8a** and **8b** represent two possible structures of the ionic products formed according to Eq. 5b.

Crystal Structures

The adducts of tmp_2AlCl (**2a**, **b**) and tmp_2AlBr (**3a**) crystallize in the monoclinic space group $P2_1/n$ with four molecules in the unit cell, while $tmp_2AlBr \cdot py$ (**3b**) and $tmp_2AlI \cdot py$ (**4a**) are isotypical having the monoclinic space group $C2/c$ ($Z = 8$). Structural parameters of these compounds are given in Table 3, crystallographic details in Table 6.

Each of the aluminum centres in the five compounds is coordinated in a distorted tetrahedral fashion by one tmp ligand in the chair conformation, one tmp ligand in the twist conformation, the N or O atom of the donor molecule, and the halogen atom. The N and O atoms of the ligands are tricoordinated and exhibit bond angle sums close to 360° (358.8−360.0°). The most interesting feature of these adducts are the long Al−X bond lengths: 2.220(1) to 2.227(3) Å for X = Cl; 2.408(2) to 2.429(2) Å for X =

Br, and 2.704(1) A for X = I. The Al−N bond lengths fall in a narrow range, varying only from 1.836(5) to 1.854(4) A. There are no differences in the bond distances between the tmp ligand present in the chair conformation and that in the twist conformation. Al−Do distances range from 1.913(2) to 1.928(4) A (THF) and from 2.022(3) to 2.041(7) A (pyridine bases). As the tmp ligands are quite bulky, the N−Al−N bond angle [125.7(2) to 126.7(2)°] shows a considerable deviation from the tetrahedral bond angle of 109.5°.

Compared to the sums of their covalent radii (Al−Cl 2.10, Al−Br 2.28, Al−I 2.48 A, corrected for ionic contributions by the Schomaker-Stevenson method[23]), which normally correspond well with the experimental Al−X atom distances (X = Cl, Br, I), the bond lengths found for $tmp_2AlX\cdot Do$ (**2−4**) are unusually long. They exceed the sums of their covalent radii by 12 (Cl) to 23 pm (I). The bond lengths *d*(Al−Cl) in **2a**, **b** and the Al−Cl distance found in the molecular adduct $Me_2AlCl\cdot NH_2tBu$ [2.204(2) A][10] reveal that the adducts **2a**, **b** are in a state of predissociation {cf. the related salts $[Me_2Al(NH_2tBu)_2]X$, X = Br, I}[10]. Thus, Al−Cl bond lengths shorter than those in the adducts **2a**, **b** have been observed even for usually longer bridging Al−Cl−Al distances, e.g. in the centrosymmetric organoaluminum dichloride $Ar(Cl)Al(\mu\text{-}Cl)_2Al(Cl)Ar$ (Ar = 2,6-$Mes_2C_6H_3$), where the Al−Cl bond lengths amount to 2.195(2) A, terminal: 2.125(2) A][24]. This is also true for **3−4**, which exhibit long Al−X distances in the range typical of bridging Al−X−Al units, e.g. of the same order as those in $(tBu_2Al\mu\text{-}X)_2$ [X = Br 2.463(3) A, X = I 2.708 A][25] or in $(trip_2Al\mu\text{-}Br)_2$ [*d*(Al−Br) = 2.475(4) and 2.500(3) A; trip = 2,4,6-$iPr_3C_6H_2$][26]. This elongation can be viewed as the initial stage of dissociation. For the Al−I bond in particular, a strongly polar $Al^{\delta+}-I^{\delta-}$ bonding situation follows [cf. $Me_2AlI\cdot NMe_3$; *d*(Al−I) = 2.58 A][28], which also explains the poor solubility of these compounds in non-polar solvents.

Crystals of the adduct $AlI_3\cdot iq$ (**7a**) are monoclinic, space group *C*2/*c* (*Z* = 8, Figure 7). For compound $tmpAlI_2\cdot py$ (**7c**), the monoclinic space group $P2_1/n$ with four molecules in the unit cell has been determined (Figure 8). The aluminum atoms in these adducts are tetracoordinated by the pyridine base, the iodine atoms, and the tmp ligand. The latter substituent adopts the chair conformation and possesses a planarized nitrogen centre (sum of bond angles 356.2°). The Al−N distance to the donor molecule decreases from 1.978(5) A (**7c**) to 1.947(9) A (**7a**) (cf. the adducts **2−4** in Table 2) as the number of iodine atoms increases. This gives an indication that AlI_3 is a stronger Lewis acid than $tmpAlI_2$. For $AlCl_3\cdot NMe_3$, *d*(Al−N) amounts to 1.96 A[4], while for *cyclo*-$Me_2NCH_2CH_2(Et)\text{-}NAlCl_2$, this distance is 1.963(2) A[27]. However, in **7c**, the Al−N bond to the tmp ligand is short [1.809(5) A] and resembles that in $[tmp(Br)Al\mu\text{-}OEt]_2$, [*d*(Al−N) = 1.810(3) A][15]. Thus, the difference between the coordinative Al−N linkage and the covalent Al−N bond is about 0.17 A. Given these bonding parameters for **7a**, **c**, it is not surprising that the Al−I bond lengths in **7a** are − on average − 6.5 pm shorter than those in **7c** [**7a**: 2.500(4) to 2.510(4), **7c**: 2.572(2) and 2.573(2) A]. This is in accord with a decrease of the Lewis acidity of the aluminum centre in **7c** and compares well with the *d*(Al−I) of 2.58 A observed in $Me_2AlI\cdot NMe_3$[28].

Semiempirical and Ab Initio Calculations

Semiempirical AM1[29] calculations have been performed in order to investigate the extent of steric shielding and the bond strength factors that are necessary to favor ionization. Thus, the structures of the cations $[(R_2N)_2Al(py)]^+$ and the salts $[(R_2N)_2Al(py)^+]AlCl_4^-$, as well as of the halide-bridged adduct compounds $(R_2N)_2(py)Al-Cl-AlCl_3$ were computed (R = Me, Et, *i*Pr, and R_2N = tmp). The heats of formation of the respective minimum geometries and the shortest $Al-ClAlCl_3$ distances are presented in Table 4.

Figure 6. Molecular structure of **7b** in the solid state. Thermal ellipsoids are shown at a 25% probability level[a]

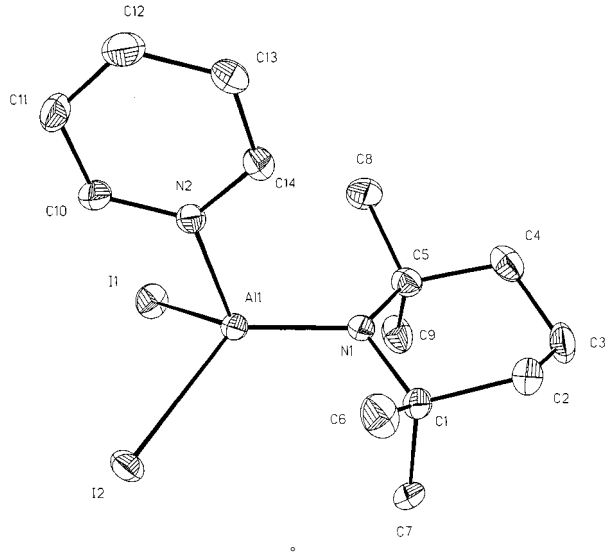
Figure 7. Molecular structure of **7c** in the solid state. Thermal ellipsoids are shown at a 25% probability level[a]



[a] Selected atom distances [A] and bond angles [°]: Al1−I1 2.573(2), Al1−I2 2.572(2), Al1−N1 1.809(5), Al1−N2 1.978(5); N1−Al1−I1 122.3(2), N1−Al1−I2 123.5(2), N1−Al1−N2 106.3(2), I1−Al−N2 103.4(2), I2−Al−N2 101.2(2), I1−Al1−I2 96.89(6), C1−N1−Al1 120.1(4), C5−N1−Al1 118.7(4), C1−N1−C5 117.4(5).

Table 4. AM1 calculated heats of formation of various model compounds

R_2N	Heat of formation $[(R_2N)_2Al(py)]^+$	Heat of formation $(R_2N)_2(py)Al\cdots Cl - AlCl_3$	$Al\cdots ClAlCl_3$ $d(Al-Cl)$ [A]
Me_2N	+113.1 kcal/mol	−231.1 kcal/mol	2.42
Et_2N	+93.3 kcal/mol	−251.7 kcal/mol	2.41
iPr_2N	+82.5 kcal/mol	−254.3 kcal/mol	2.42
tmp	+90.1 kcal/mol	−235.0 kcal/mol	4.45

The free cations exhibit positive heats of formation (in the range +82.5 to +113.1 kcal/mol), whereas the tetrachloroaluminum compounds are exergonic by −231.1 to −254.3 kcal/mol. Shielding of the aluminum center by the amido ligands R_2N (R = Me, Et, *i*Pr) is insufficient to prevent coordination of one chlorine atom [*d*(Al−Cl) of the tetrachloroaluminate to the aluminum center of the cation: 2.41−2.42 A]. It is only the sterically most demanding amido ligand, tmp, that allows the induction of ionization, as demonstrated by the shortest Al−Cl distance of 4.45 A. In another series of calculations, the enthalpies for the formation of $[tmp_2Al(py)]AlX_4$ (X = Cl, Br, I), as well as for the observed decomposition reactions of the salts into tmp_2AlX and $AlX_3 \cdot py$, were calculated from the computed heats of formation of every compound involved (see Scheme 1) using Hess′ rule.

Scheme 1. AM1 computed heats of formation and enthalpies of reaction for the formation and decomposition of $[tmp_2Al(py)]AlX_4$ (X = Cl, Br, I)

All enthalpies in kcal/mol

$$tmp_2AlCl + py + 0.5\ Al_2Cl_6 \xrightarrow[K = 3.56]{\Delta G_r = -0.7} [tmp_2Al(py)]AlCl_4$$

ΔG_f = -116.0 + 31.9 -150.2 -235.0

$$\xrightarrow[K = 4.4*10^5]{\Delta G_r = -7.7} tmp_2AlCl + AlCl_3{*}py \qquad (6a)$$

ΔG_f = -116.0 -126.7

$$tmp_2AlBr + py + 0.5\ Al_2Br_6 \xrightarrow[K = 133]{\Delta G_r = -2.9} [tmp_2Al(py)]AlBr_4$$

ΔG_f = -103.7 + 31.9 -124.5 -199.2

$$\xrightarrow[K = 113]{\Delta G_r = -2.8} tmp_2AlBr + AlBr_3{*}py \qquad (6b)$$

ΔG_f = -103.7 -98.3

$$tmp_2AlI + py + 0.5\ Al_2I_6 \xrightarrow[K = 5.28*10^{11}]{\Delta G_r = -16.0} [tmp_2Al(py)]AlI_4$$

ΔG_f = -76.8 + 31.9 -54.0 -116.9

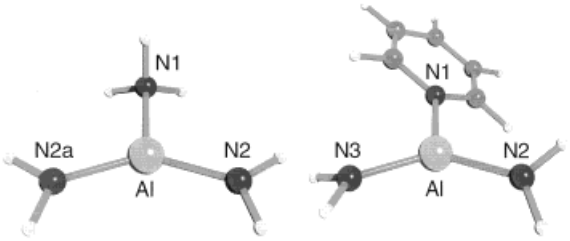
$$\xrightarrow[K = 4.48*10\text{-}6]{\Delta G_r = 7.3} tmp_2AlI + AlI_3{*}py \qquad (6c)$$

ΔG_f = -76.8 -32.8

Two opposing trends are observed: whereas the heat of formation for the salt $[tmp_2Al(py)]AlX_4$ decreases on going from the chloride to the iodide (but still remains exergonic), the enthalpies for the formation of the salts increase in this direction. In fact, in the case of the iodide, the salt is stable with respect to decomposition into tmp_2AlI and $AlI_3 \cdot py$. This is partly due to the thermodynamically less favored Al−I bond [E(Al−Cl) = 494 kJ/mol; E(Al−I) = 364 kJ/mol][6], but is mainly attributable to the contribution of electrostatic stabilization of the tetraiodoaluminate, since the decomposition products, which also contain Al−X bonds, are less favored on going from the chloride to the iodide.

As no X-ray crystal structures of the ionic species could be determined, an ab initio study (MP2/6-31+G*)[30] of two model compounds $[(H_2N)_2Al(Do)]^+$ (Do = NH_3 **8a**, py **8b**) was performed, in order to assess the structural parameters of these cations. The minimum structures of the cations **8a**, **b** are depicted in Figure 9, and their structural parameters are given in Table 5.

Figure 8. Computed structures of $[(H_2N)_2Al(NH_3)]^+$ (**8a**) and $[(H_2N)_2Al(py)]^+$ (**8b**)



8a 8b

Table 5. Selected ab initio calculated bonding parameters for the two model cations, **8a**,**b**

Compound[a]	Sym.	*d*(Al−N) [A]	*d*(Al−L) [A]	N−Al−N [°]	*q*(Al) [e]	*q*(N) [e]	*q*(L) [e]	B.O. Al−N	LP*[b] (Al)
$[(H_2N)_2Al(NH_3)]^+$ **8a**	*C*s	1.758	1.996	139.34	2.12	−1.54	−1.26	0.62	0.19
$[(H_2N)_2Al(py)]^+$ **8b**	*C*1	1.764	1.947	136.86	2.14	−1.54	−0.78	0.60	0.13

[a] All calculations MP2/6-31+G*. − [b] Number of electrons in $3p_z$ orbital of Al.

The tricoordinated aluminum cations **8a**, **b** represent highly charged species [*q*(Al) = +2.12e and +2.14e, *q*(N) = −1.54e and −1.54e, *q*(Do-N) = −1.26e and −0.78e], with short Al−N bond lengths of 1.758 A (**8a**) and 1.764 A (**8b**) as well as wide N−Al−N bond angles of 139.3° and 136.8°, respectively. The Al−N distances to the nitrogen atoms of the donor molecules reflect their degree of hybridization. As expected, for the sp^3-hybridized donor NH_3, a longer Al−N bond length (1.996 A) was calculated, compared to that for the aromatic pyridine donor [*d*(Al−N) = 1.947 A]. According to NBO analysis, the $3p_z$(Al) orbital is populated with 0.19 (**8a**) and 0.13 (**8b**) electrons, indicating the presence of only weak pp(π) Al−N bonding. This compares well with the calculated minimum structures of $(H_2N)_2AlY$ [Y = Cl, OH, SH, NH_2, PH_2, CH_3, SiH_3, $Al(NH_2)_2$][17]. For these compounds, it was shown that the Al−N bond is highly polar and that the shorter the Al−N distance, the wider the N−Al−N bond angle[17]. Since the Al−N bond lengths in **8a**, **b** are 2 pm shorter than in $(H_2N)_2AlCl$ (**9**) [the compound with the shortest Al−N bond in the $(H_2N)_2AlY$ series, *d*(Al−N) = 1.782 A], the N−Al−N bond angles in **8a**, **b** of 139.3° and 136.8° are widened by about 16° compared to that in the chloride **9** (123.2°). The short Al−N bonds are mirrored by an increased positive charge of 0.16e and 0.18e residing on the aluminum centres of **8a**, **b**, compared to that calculated for the chloride **9**. Since the charge on the nitrogen atoms in **8a**, **b**, and **9** remains almost constant (−1.53 to −1.55e), a strongly polar Al−N bond is responsible for the short Al−N distances in **8a**, **b**.

Discussion

The aim of this study was the synthesis and characterization of low coordinated, cationic aluminum compounds. In contrast to the $R_2AlX/tBuNH_2$ system described by Atwood et al.[10], the compounds tmp_2AlX (X = Cl, Br, I) could not be forced to ionize by the addition of an excess of a donor molecule. The steric demand of the tmp and donor ligands prevents the formation of cations of the type $tmp_2Al(Do)_2^+$ and of adducts of the type $tmp_2AlX \cdot Do_2$. However, comparison of the Al−X bond lengths determined for **2**−**4**, having conventional terminal and bridging Al−X bonds, reveals that $tmp_2AlX \cdot Do$ shows the early stages of dissociation into $[tmp_2Al(Do)^+]X^-$. Dissociation of compounds of the type $tmp_2AlX \cdot Do$ should be facilitated by weakly coordinating anions X^-. However, such a strategy did not succeed with X = BPh_4^-, $B(C_6F_5)_4^-$, BF_4^-, or tosylate. Instead, decomposition reactions or coordination of the various anions occurred. Nevertheless, the tetrabromo- and tetraiodoaluminates turned out to be sufficiently non-basic (and suitably large) to stabilize the salts $[tmp_2Al(Do)]AlX_4$ (**6a**−**f**) in solution. The formation of the AlX_4^- units (X = Br, I) is favoured due to the decreasing strength of the Al−X bonds in $tmp_2AlX \cdot Do$ on proceeding from chlorine to iodine, so that the additional stabilization energy provided by ion pair formation governs the overall enthalpy for the decomposition of $[tmp_2Al(py)]AlI_4$ (as predicted by AM1 calculation). Since decomposition products of even tetraiodoaluminates have been found [e.g. $AlI_3 \cdot iq$ (**7a**), $AlI_3 \cdot 4$-*t*Bu-py (**7b**)], this seems to be contradictory. However, the calculations can only simulate gaseous species in vacuo. As the variations in the reaction enthalpies are small, solvent effects must play a role in the behavior of the tetrahaloaluminate salts. Nevertheless, both the experimental and theoretical approaches indicate that the iodo compounds represent the most stable species. Non-polar solvents disfavour the formation of ionic species of type $[tmp_2Al(Do)]AlX_4$ (**6a**−**f**), whereas polar donor solvents stabilize the ions, but may also abstract AlX_3 as $AlX_3 \cdot Do \cdot (Solv.)_n$ (*n* = 1, 2), providing an alternative decomposition pathway for the system.

Conclusion

The aluminum atoms in the tricoodinated bis(tetramethylpiperidino)aluminum halides **1a**−**c** are Lewis acidic and form monoadducts of the type $tmp_2AlX \cdot Do$ (**2**−**4**) with THF and pyridine bases. Since the Al−X (X = Cl, Br, I)

bonds in **2−4** are considerably longer than those in **1a−c**, a tendency towards dissociation into $tmp_2(Do)Al^+$ and X^- is indicated. Attempts to prepare salts of the type $[tmp_2Al(Do)]Y^-$ [Y = BPh_4, $B(C_6F_5)_4$, Otos] led either to decomposition or to the formation of molecular adducts. The solution behavior of $tmp_2Al(py)BF_4$ (**5e**) shows a solvent dependence: in pentane, a tetracoordinated molecular product is observed, while in CH_2Cl_2 or $CDCl_3$ solution, it dissociates into an ion pair. However, halide abstraction from $tmp_2AlX\cdot Do$ can be achieved by the addition of AlX_3 to generate salts of the type $[tmp_2Al(Do)]AlX_4$, as demonstrated by electrical conductivity in CH_2Cl_2 solution. These experimental results are supported by semiempirical AM1 calculations on the $[(R_2N)_2Al(py)]AlX_4$ species. The results show that the steric demand of the tmp ligand is essential for ion pair formation. The formation of tetraiodoaluminate compounds is favored over that of the corresponding tetrabromo- or tetrachloroaluminates. Further ab initio studies of some model systems explain the presence of short Al−N distances in terms of ionic contributions to the Al−N bond. Whether the Lewis acidic aluminum centre in these cations can act as catalyst, e.g. in olefin polymerization, needs to be evaluated experimentally. Since these salts are highly Lewis acidic, are soluble in aromatic hydrocarbons, and are sterically encumbered so as to possibly induce regioselectivity, these aspects will be investigated and communicated in forthcoming reports.

Once again, the tmp ligand is found to produce a remarkable stabilizing effect and allows the generation of unusual bonding situations, such as the tricoordinated aluminum cations. As yet, the most weakly coordinating anions $CB_{11}H_{11}X^-$ (X = H, Cl) have not been tested[31], but they are certainly good candidates for achieving the formation of $tmp_2Al(Do)^+$ cations, or the even more demanding goal of generating the dicoordinated cation tmp_2Al^+.

We are grateful to the *Fonds der Chemischen Industrie* and *Chemetall mbH* for supporting our studies. We also thank Mrs. *G. Käser* and Mrs. *C. Ullmann* for performing the elemental analyses, Mr. *P. Mayr*, Dr. *R. Waldhör* and Dr. *C. Miller* for recording many NMR spectra, Mrs. *D. Ewald* for mass spectra and Mrs. *E. Kiesewetter* for IR spectra. Access to the calculation facilities of *Leibniz Rechenzentrum* is also acknowledged.

Experimental Section

All manipulations were performed using Schlenk techniques under a dinitrogen or argon atmosphere. All solvents were rigorously dried prior to use and stored under N_2 or argon. Discrepancies in the elemental analyses of a number of compounds can be attributed to insufficient protection against oxidation and hydrolysis of the air- and moisture-sensitive compounds during the weighing procedures. − NMR: Bruker ACP 200, Jeol GSX400 and Jeol GSX270. − IR: Nicolet FT-IR spectrometer model 6000, CsI plates, Nujol. − MS: Varian Atlas CH7 spectrometer.

General Procedure for the Synthesis of the Adducts $tmp_2AlX\cdot Do$ **2−4**: The concentrations of stock solutions of tmp_2AlX (X = Cl, Br, I), **1a−c**, in *n*-hexane were determined by titration of aluminum and halide. At ambient temperature, the stoichiometric amount of the appropriate donor was added as a hexane solution. Most of the adducts precipitated immediately. After filtration and concentration of the filtrate to one-third of its original volume, storage at −20°C overnight led to the deposition of well-shaped crystals of **2−4**. Precipitates were washed twice with pentane and dried in vacuo. Yields varied between 80 and 95%. Where suitable crystals for X-ray diffraction studies were required, aromatic solvents or *n*-hexane/THF mixtures proved to be appropriate media for recrystallization.

$tmp_2AlCl\cdot iq$ (**2a**): tmp_2AlCl (43.2 ml, 0.11 M, 4.8 mmol); isoquinoline (0.99 g, 4.8 mmol), yield of **2a**: 1.95 g (86%), m.p. 148−151°C. − ^1H NMR ($CDCl_3$) (400 MHz): δ = 1.37 (t, 8 H, tmp-β-CH_2), 1.29 [s, 24 H, tmp-C(CH_3)$_2$], 1.62 (m, 4 H, tmp-γ-CH_2), 7.80 (t, 1 H, iq-C*H*), 7.93 (m, 3 H, iq-C*H*), 8.15 (d, 1 H, iq-C*H*), 9.14 [d, 1 H, ^3J(H,H) = 6.5 Hz, iq-C*H*], 10.10 (s, 1 H, iq-C*H*). − ^{13}C NMR ($CDCl_3$) (100 MHz): δ = 18.1 (tmp-*C*4), 34.0 (tmp-*C*7-10), 41.5 (tmp-*C*3/5), 52.7 (tmp-*C*2/6), 122.0 (iq-*C*), 126.8 (iq-*C*), 127.7 (iq-*C*), 129.2 (iq-*C*), 129.5 (iq-*C*), 134.3 (iq-*C*), 137.3 (iq-*C*), 141.1 (iq-*C*), 155.1 (iq-*C*). − ^{27}Al NMR ($CDCl_3$) (70 MHz): δ = 102 ($\Delta_{1/2}$ = 8300 Hz). − $C_{27}H_{43}AlClN_3$ (473.10): calcd. Reaction of tmp$_2$AlI·py **4a** *with AgBPh$_4$ To Give BPh$_3$·py* (**5b**) *and tmp$_2$AlPh* (**5a**): $AgBPh_4$ (0.58 g, 1.36 mmol) was suspended in 10 ml of benzene. A solution of tmp$_2$AlI·py (18.1 ml, 0.075 M, 1.36 mmol) in benzene was added at ambient temperature. The mixture was heated to reflux for 3 days and the insoluble material was filtered off (0.46 g, calcd. AgI: 0.32 g). From the resulting filtrate, all volatiles were removed in vacuo. The residue was extracted with 20 ml of toluene and this solution was stored overnight at –78°C. A microcrystalline precipitate of BPh3·py (**5b**), (0.17 g, 39%) separated; tmp$_2$AlPh (**5a**) was characterized in solution by its NMR data[15].

5b: ^{1}H NMR (C_6D_6) (270 MHz): δ = 7.25 (t, 3 H, *p*-Ph-*H*), 7.32 (t, 6 H, *m*-Ph-*H*), 7.51 (d, 6 H, *o*-Ph-*H*), 6.15 (br s, 2 H, *m*-py-*H*), 6.57 (br. s, 1 H, *p*-py-*H*), 8.15 (br s, 2 H, *o*-py-*H*). – ^{11}B NMR (C_6D_6) (64 MHz): δ = 5.1 (br). – $C_{23}H_{20}BN$ (321.23): calcd. C 86.00, H 6.28, N 4.36; found C 84.20, H 6.61, N 4.28.

tmp$_2$AlOtos·py (**5c**): To a suspension of AgOtos (1.00 g, 3.6 mmol) and pyridine (0.29 ml, 3.6 mmol) in 30 ml of toluene, a solution of tmp$_2$AlBr (13.3 ml, 0.27 M, 3.6 mmol) in *n*-hexane was added at ambient temperature. Immediately, a yellow precipitate of tmp$_2$AlBr·py separated. The mixture was allowed to stir overnight, and then the insoluble material, which had become somewhat brown, was filtered off and weighed (2.41 g, calcd. AgBr 0.67 g). Extraction with 50 ml of benzene resulted in a yellow solution, which was concentrated in vacuo to a volume of 10 ml. Storage of this solution overnight at 8°C afforded tmp$_2$AlOtos·py as a colorless precipitate. Yield of **5c**: 0.54 g (28%), decomp. > 311°C. – ^{1}H NMR ($CDCl_3$) (270 MHz): δ = 1.27 (t, 8 H, tmp-β-C*H*$_2$), 1.09 [br s, 24 H, tmp-C(C*H*$_3$)$_2$], 1.54 (m, 4 H, tmp-γ-C*H*$_2$) 2.24 (s, 3 H, tos-C*H*$_3$), 7.55 (t, 2 H, *m*-py-*H*), 7.96 (t, 1 H, *p*-py-*H*), 9.29 (br s, 2 H, *o*-py-*H*). – ^{13}C NMR ($CDCl_3$) (100 MHz): δ = 18.1 (tmp-*C*4), 33.9 (tmp-*C*7-10), 40.9 (tmp-*C*3/5), 52.2 (tmp-*C*2/6), 21.4 (tos-*C*H$_3$), 125.0 (py-*C*), 141.8 (py-*C*), 149.8 (py-*C*), 127.0 (tos-*C*), 128.3 (tos-*C*), 128.8 (tos-*C*), 139.1 (tos-*C*). – ^{27}Al NMR (C_6D_6) (70 MHz): δ = 97 ($\Delta_{1/2}$ = 5500 Hz).

tmp$_2$Al(lut)(BF$_4$) (**5d**): $AgBF_4$ (1.65 g, 8.5 mmol) and 2,6-lutidine (0.86 g, 8.5 mmol) were suspended in 50 ml of *n*-hexane and the mixture was cooled to –78°C. A solution of tmp$_2$AlBr (22.9 ml, 0.35 M, 8.0 mmol) in *n*-hexane was then added slowly and the mixture was allowed to attain ambient temperature. After stirring overnight, the brownish insoluble material was filtered off (2.32 g, calcd. AgBr 1.61 g) and the resulting yellow filtrate was stored for several days at –78°C. Colorless crystals of tmp$_2$Al(lut)(BF_4) **5d** separated. Yield: 2.47 g (62%); m.p. > 328°C (decomp.). – ^{1}H NMR (C_6D_6) (400 MHz): δ = 1.23 (t, 8 H, tmp-β-C*H*$_2$), 1.06 [s, 24 H, tmp-C(C*H*$_3$)$_2$], 1.53 (m, 4 H, tmp-γ-C*H*$_2$), 2.41 (s, 6 H, lut-C*H*$_3$), 6.57 (d, 2 H, lut-*H*), 7.00 (t, 1 H, lut-*H*). – ^{13}C NMR (C_6D_6) (100 MHz): δ = 18.8 (tmp-*C*4), 32.0 (tmp-*C*7-10), 38.6 (tmp-*C*3/5), 49.6 (tmp-*C*2/6), 52.4 (lut-*C*H$_3$), 119.8 (lut-*C*), 136.9 (lut-*C*). – ^{27}Al NMR (C_6D_6) (70 MHz): δ = 1 ($\Delta_{1/2}$ = 3900 Hz). – ^{11}B NMR (C_6D_6) (64 MHz): δ = 17.9. – ^{19}F NMR (C_6D_6) (85 MHz): δ = –104.5 (s), –111.0 (s). – IR (Nujol): ν = 421 w, 452 m, 468 s, 507 vs, 527 vs, 551 vs, 568 s, 596 s, 745 w, 762 w, 851 w, 870 w, 900 m, 918 s, 936 vs, 957 vs, 982 vs, 997 vs, 1064 s, 1082 w, 1130 vs, 1180 s, 1202 m, 1236 vs, 1294 w, 1346 m, 1364 s, 1375 s, 1384 s, 1435 m, 1470 s, 1594 w, 1645 w, 1732 w, 2458 w, 2672 w, 2766 w, 2873–3007 vs. – $C_{25}H_{45}AlBF_4N_3$ (501.44): calcd. C 59.88, H 9.05, N 8.38, Al 5.4; found C 60.06, H 10.07, N 7.47, Al 6.0.

tmp$_2$Al(py)BF$_4$ (**5e**): To a solution of $AgBF_4$ (1.06 g, 4.96 mmol) in 35 ml of CH_2Cl_2, a solution of tmp$_2$AlI·py (37.0 ml, 0.134 M, 4.96 mmol) in toluene was added at ambient temperature. Immediately, a dark precipitate formed. After stirring the mixture overnight, the insoluble material was filtered off and the filtrate was concentrated in vacuo. The resulting yellow oil (1.89 g, 80%) was found to be soluble in aliphatic as well as in aromatic or chlorinated solvents. Crystallization could not be achieved. – ^{1}H NMR ($CDCl_3$) (270 MHz): δ = 0.83 (t, 8 H, tmp-β-C*H*$_2$), 1.23 [s, 24 H, tmp-C(C*H*$_3$)$_2$], 1.60 (m, 4 H, tmp-γ-C*H*$_2$), 7.75 (t, 2 H, py-*H*), 8.22 (t, 1 H, py-*H*), 8.71 (br s, 2 H, py-*H*). – ^{27}Al NMR ($CDCl_3$) (70 MHz): Only an extremely broad, poorly-defined signal was observed. – ^{11}B NMR ($CDCl_3$) (64 MHz): δ = 0.9; (pentane): δ = 19.3 (no BF coupling observed). – ^{19}F NMR ($CDCl_3$) (85 MHz): δ = –151.0 [q, ^1J(B,F) = 12 Hz]; (pentane): δ = –111.0 (br s).

[tmp$_2$Al(iq)]AlBr$_4$ (**6a**): To a solution of tmp$_2$AlBr·iq in CH_2Br_2 (33.1 ml, 0.178 M, 5.89 mmol), $AlBr_3$ (1.57 g, 5.89 mmol) in 10 ml of CH_2Br_2 was added dropwise at 0°C. After 30 min., the clear red solution was reduced to half of its original volume and stored overnight at –20°C. **6a** separated as an orange microcrystalline powder. Yield: 4.43 g (96%), m.p. > 302°C (decomp.). – ^{1}H NMR ($CDCl_3$) (270 MHz): δ = 1.34 (t, 8 H, tmp-β-C*H*$_2$), 1.47 [s, 24 H, tmp-C(C*H*$_3$)$_2$], 1.62 (m, 4 H, tmp-γ-C*H*$_2$), 7.94 (t, 1 H, iq-C*H*), 8.10 (m, 2 H, iq-C*H*), 8.28 (d, 1 H, iq-C*H*), 8.30 (d, 1 H, iq-C*H*), 8.94 [d, 1 H, ^3J(H,H) = 6.4 Hz, iq-C*H*], 9.89 (s, 1 H, iq-C*H*). – ^{13}C NMR ($CDCl_3$) (100 MHz): δ = 17.5 (tmp-*C*4), 34.2 (tmp-*C*7-10), 39.9 (tmp-*C*3/5), 52.5 (tmp-*C*2/6), 124.2 (iq-*C*), 127.0 (iq-*C*), 127.5 (iq-*C*), 130.1 (iq-*C*), 130.1 (iq-*C*), 136.4 (iq-*C*), 137.1 (iq-*C*), 137.7 (iq-*C*), 152.5 (iq-*C*). – ^{27}Al NMR ($CDCl_3$) (70 MHz): δ = 102 ($\Delta_{1/2}$ = 66 Hz); (CH_2Br_2): δ = 104 ($\Delta_{1/2}$ = 53 Hz). – IR (Nujol) [ν(Al–Br)]: ν = 429 cm^{-1} vs. – $C_{27}H_{43}Al_2Br_4N_3$ (783.24): calcd. C 41.40, H 5.53, N 5.36, Al 6.9, Br 40.8; found C 36.01, H 5.12, N 4.43, Al 7.2, Br 40.7 (C, H, N ratio: calcd. 9:14.33:1; found 9.48:16.06:1).

[tmp$_2$Al(py)]AlI$_4$ (**6b**): To AlI_3 (0.62 g, 1.5 mmol) dissolved in 5 ml of benzene, a solution of tmp$_2$AlI·py (20.0 ml, 0.075 M, 1.5 mmol) in benzene was added at ambient temperature. The mixture was stirred overnight. Subsequent addition of 5 ml of pentane led to the precipitation of yellowish **6b**. Yield: 1.10 g (79%), decomp. at *T* > 166 C (blackens). – ^{1}H NMR (C_6D_6) (270 MHz): δ = 1.31 (t, 8 H, tmp-β-C*H*$_2$), 1.48 [s, 24 H, tmp-C(C*H*$_3$)$_2$], 1.55 (m, 4 H,

tmp-γ-CH_2), 6.21 (t, 2 H, py-C*H*), 6.57 (t, 1 H, py-C*H*), 8.59 (br s, 2 H, py-C*H*). – ^{13}C NMR (C_6D_6) (100 MHz): δ = 18.1 (tmp-*C*4), 34.5 (tmp-*C*7-10), 40.2 (tmp-*C*3/5), 52.9 (tmp-*C*2/6), 125.5 (py-*C*), 142.2 (py-*C*), 147.0 (py-*C*). – ^{27}Al NMR (C_6D_6) (70 MHz): δ = 50 ($\Delta_{1/2}$ = 134 Hz). – IR (Nujol) [ν(Al–I)]: ν = 338 cm^{-1} vs. – $C_{23}H_{41}Al_2I_4N_3$ (921.18): calcd. C 29.99, H 4.49, N 4.56, Al 5.9, I 55.1; found C 29.55, H 4.62, N 3.67, Al 5.8, I 55.6.

[tmp$_2$Al(4-Me-py)]AlI$_4$ (**6c**): To a solution of tmp$_2$AlI (50 ml, 0.10 M, 5.0 mmol) in *n*-hexane, γ-picoline (0.50 ml, 5.0 mmol) was added at ambient temperature. From the resulting suspension, all volatiles were removed in vacuo. The residue was redissolved in 50 ml of diethyl ether and the solution was cooled to −78°C. After the addition of AlI_3 powder (2.04 g, 5.0 mmol), the mixture was allowed to warm to ambient temperature (1.5 h). The cloudy solution was filtered and the filtrate was concentrated to a volume of 25 ml. At this stage, the NMR spectra of **6c** were recorded by removal of all volatiles from a portion of the solution in vacuo and redissolving the residue in C_6D_6. Storage of the filtrate for several weeks at −78°C afforded colorless crystals of tmp$_2$AlI **1c** (2.07 g, 95%) (characterized by its NMR spectra and check of the unit cell parameters)[15].

6c: ^{1}H NMR (C_6D_6) (270 MHz): δ = 1.29 (t, 8 H, tmp-β-CH_2), 1.46 [s, 24 H, tmp-C(CH_3)$_2$], 1.56 (m, 4 H, tmp-γ-CH_2), 1.49 (s, 3 H, γ-pic-CH_3), 6.12 (d, 2 H, γ-pic-C*H*), 8.47 (br. s, 2 H, γ-pic-C*H*). – ^{13}C NMR (C_6D_6) (100 MHz): δ = 18.1 (tmp-*C*4), 34.5 (tmp-*C*7-10), 40.0 (tmp-*C*3/5), 52.8 (tmp-*C*2/6), 21.3 (γ-pic-*C*H$_3$) 126.5 (γ-pic-*C*), 145.9 (γ-pic-*C*), 156.9 (γ-pic-*C*). – ^{27}Al NMR (C_6D_6) (70 MHz): δ = 51 ($\Delta_{1/2}$ = 35 Hz).

[tmp$_2$Al(4-tBu-py)]AlI$_4$ (**6d**): To a solution of tmp$_2$AlI (25 ml, 0.10 M, 2.5 mmol) in *n*-hexane, 4-*t*Bu-py (0.36 ml, 2.5 mmol) was added at ambient temperature. From the resulting suspension of tmp$_2$AlI·4-*t*Bu-py, all volatiles were removed in vacuo and the yellow residue was redissolved in 35 ml of toluene. AlI_3 powder (1.01 g, 2.5 mmol) was then added in one portion. The mixture was stirred for 1 h, then the cloudy solution was filtered. After concentration of the filtrate to one-third of its original volume, the solution was cooled to −78°C. NMR spectra of **6d** were obtained from this solution. Even after weeks at various temperatures and at different concentrations, no crystals suitable for X-ray structure determination were formed. – ^{1}H NMR (C_6D_6) (270 MHz): δ = 1.28 (t, 8 H, tmp-β-CH_2), 1.45 [s, 24 H, tmp-C(CH_3)$_2$], 1.56 (m, 4 H, tmp-γ-CH_2), 0.69 (s, 9 H, *t*Bu-CH_3), 6.35 (d, 2 H, 4-*t*Bu-py-C*H*), 8.54 (br s, 2 H, 4-*t*Bu-py-C*H*). – ^{13}C NMR (C_6D_6) (100 MHz): δ = 18.1 (tmp-*C*4), 34.4 (tmp-*C*7-10), 40.0 (tmp-*C*3/5), 52.8 (tmp-*C*2/6), 29.5 (4-*t*Bu-*C*H$_3$) 127.8 (4-*t*Bu-py-*C*), 146.6 (4-*t*Bu-py-*C*), 156.9 (4-*t*Bu-py-*C*). – ^{27}Al NMR (C_6D_6) (70 MHz): δ = 51 ($\Delta_{1/2}$ = 74 Hz).

[tmp$_2$Al(iq)]AlI$_4$ (**6e**): To tmp$_2$AlI·iq (1.71 g, 3.03 mmol) dissolved in 15 ml of toluene, a solution of AlI_3 (1.24 g, 3.03 mmol) in 10 ml of toluene was added at a temperature of 5–10°C. After stirring for 1.5 h, the mixture was filtered and the clear filtrate was concentrated to dryness in vacuo. A reddish-brown residue of [tmp$_2$Al(iq)]AlI$_4$ was obtained. Yield: 2.91 g (99%); m.p. > 330°C (decomp.). – ^{1}H NMR ($CDCl_3$) (270 MHz): δ = 1.32 (t, 8 H, tmp-β-CH_2), 1.41 [s, 24 H, tmp-C(CH_3)$_2$], 1.61 (m, 4 H, tmp-γ-CH_2), 7.91 (t, 1 H, iq-C*H*), 8.08 (m, 2 H, iq-C*H*), 8.14 (d, 1 H, iq-C*H*), 8.26 (d, 1 H, iq-C*H*), 8.75 [d, 1 H, ^3J(H,H) = 8.4 Hz, iq-C*H*], 9.70 (s, 1 H, iq-C*H*). – ^{13}C NMR ($CDCl_3$) (100 MHz): δ = 17.6 (tmp-*C*4), 34.0 (tmp-*C*7-10), 39.5 (tmp-*C*3/5), 52.0 (tmp-*C*2/6), 124.4 (iq-*C*), 127.1 (iq-*C*), 127.7 (iq-*C*), 130.1 (iq-*C*), 130.8 (iq-*C*), 136.4 (iq-*C*), 137.0 (iq-*C*), 137.9 (iq-*C*), 152.4 (iq-*C*). – ^{27}Al NMR ($CDCl_3$) (70 MHz): δ = 55 ($\Delta_{1/2}$ = 17 Hz); (CH_2Cl_2): δ = 54 ($\Delta_{1/2}$ = 43 Hz). – IR (Nujol) [ν(Al–I)]: $\tilde{\nu}$ = 362 cm^{-1} vs. – $C_{27}H_{43}Al_2I_4N_3$ (783.24): calcd. C 33.39, H 4.46, N 4.33, Al 5.6, I 52.3; found C 35.54, H 4.97, N 3.98, Al 5.2, I 52.8 (C,H ratio: calcd. 1:1.59; found 1:1.65).

[tmp$_2$Al(acr)]AlI$_4$ (**6f**): To a solution of tmp$_2$AlI (0.81 g, 1.84 mmol) in 50 ml of CH_2Cl_2, a solution of acridine (8.80 ml, 0.209 M, 1.84 mmol) in CH_2Cl_2 was added at −78°C. The mixture was kept at this temperature for 1 h and then 0.75 g (1.84 mmol) of AlI_3 was added in one portion. The suspension was slowly allowed to warm to ambient temperature and then filtered. From the orange-red filtrate, all volatiles were removed in vacuo. The residue was characterized as **6f** (1.86 g, 99%). Attempts to crystallize the product from various solvents were not successful. – ^{1}H NMR ($CDCl_3$) (270 MHz): δ = 1.34 (t, 8 H, tmp-β-CH_2), 1.47 [s, 24 H, tmp-C(CH_3)$_2$], 1.65 (m, 4 H, tmp-γ-CH_2), 7.53 (t, 2 H, acr-C*H*), 7.78 (t, 2 H, acr-C*H*), 8.01 (d, 2 H, acr-C*H*), 8.21 (d, 2 H, acr-C*H*), 8.80 (s, 1 H, acr-C*H*). – ^{13}C NMR ($CDCl_3$) (100 MHz): δ = 17.7 (tmp-*C*4), 34.3 (tmp-*C*7-10), 39.8 (tmp-*C*3/5), 52.6 (tmp-*C*2/6), 125.8 (acr-*C*), 126.6 (acr-*C*), 128.3 (acr-*C*), 128.8 (acr-*C*), 136.6 (acr-*C*), 148.7 (acr-*C*). – ^{27}Al NMR ($CDCl_3$) (70 MHz): δ = −22 ($\Delta_{1/2}$ = 70 Hz); (CH_2Cl_2): δ = −27 ($\Delta_{1/2}$ = 65 Hz). – $C_{31}H_{45}Al_2I_4N_3$ (1021.28): calcd. Al 5.3, I 49.7; found Al 5.1, I 50.0.

AlBr$_3$·acr (**7a**): To a solution of tmp$_2$AlBr (50 ml, 0.12 M, 6.0 mmol) in *n*-hexane, a solution of acridine (4.88 ml, 1.23 M, 6.0 mmol) in toluene was added at ambient temperature. After the addition of $AlBr_3$ (1.60 g, 6.0 mmol), a greenish-yellow precipitate of $AlBr_3$·acr formed immediately. The insoluble material was filtered off and washed twice with pentane. Yield: 2.40 g (90%); decomp. at T > 186°C. – The ^{27}Al-NMR spectrum of the filtrate exhibited the chemical shift of tmp$_2$AlBr (**1b**) (d^{27}Al = 130; $\Delta_{1/2}$ = 10200 Hz)[15]. – ^{1}H NMR ($CDCl_3$) (270 MHz): δ = 7.68 (t, 2 H, acr-*H*), 7.96 (t, 2 H, acr-*H*), 8.16 (d, 2 H, acr-*H*), 8.45 (br d, 2 H, acr-*H*), 9.14 (s, 1 H, acr-*H*). – ^{27}Al NMR ($CDCl_3$) (70 MHz): δ = 83 ($\Delta_{1/2}$ = 38 Hz). – IR (Nujol) [ν(Al–Br)]: ν = 404 cm^{-1} vs, 460 vs. – $C_{13}H_9AlBr_3N$ (379.68): calcd. C 35.02, H 2.03, N 3.14; found C 35.59, H 3.18, N 3.28.

AlI$_3$·4-tBu-py (**7b**): A solution of tmp$_2$AlI (51.5 ml, 0.10 M, 5.15 mmol) in *n*-hexane was diluted with a further 150 ml of the solvent. Then, 4-*t*Bu-py (0.75 ml, 5.15 mmol) was added. To this clear solution, powdered AlI_3 (2.10 g, 5.15 mmol) was added at ambient temperature. On leaving the mixture to stand overnight, a copius amount of a colorless precipitate was deposited, which was removed by filtration. Washing the solid with pentane afforded (2.70 g, 96%) of **7b**, m.p. 154–158°C (becomes red). NMR analysis of the filtrate showed only the signals of **1c**. – ^{1}H NMR (C_6D_6) (400 MHz): δ = 0.65 [s, 9 H, *t*Bu-C(CH_3)$_3$], 6.42 (t, 2 H, py-C*H*), 8.63 (d, 2 H, py-C*H*). – ^{13}C NMR (C_6D_6) (100 MHz): δ = 29.3 [*t*Bu-C(*C*H$_3$)$_3$], 35.1 [*t*Bu-*C*(CH$_3$)$_3$], 122.9 (py-*C*), 146.6 (py-*C*). – ^{27}Al NMR (C_6D_6) (70 MHz): δ = 51 ($\Delta_{1/2}$ = 46 Hz). – IR (Nujol) [ν(Al–I)]: ν = 371 cm^{-1} vs, 385 vs. – $C_9H_{13}AlI_3N$ (542.89): calcd. C 19.91, H 2.41, N 2.58; found C 21.08, H 2.88, N 2.63.

tmpAlI$_2$·py (**7c**): To a solution of tmp$_2$AlI·py (28.7 ml, 0.134 M, 3.85 mmol) in toluene, AlI_3 (1.57 g, 3.85 mmol) was added at 0°C and the mixture was kept stirring overnight. The turbid solution was then filtered and the filtrate was concentrated to dryness in vacuo. The resulting brownish oil was stored for some days at temperatures up to 35°C. After one week, colorless crystals of **7c** formed. These were isolated from the oil (1.70 g, 88%) and washed twice with pentane; m.p. > 202°C (decomp.). – ^{1}H NMR (C_6D_6) (400 MHz): δ = 1.39 (t, 4 H, tmp-β-CH_2), 1.63 [s, 12 H, tmp-C(CH_3)$_2$], 1.60 (m, 2 H, tmp-γ-CH_2), 6.26 (t, 2 H, py-C*H*), 6.59 (t, 1 H, py-C*H*), 9.05 (br s, 2 H, py-C*H*). – ^{13}C NMR (C_6D_6) (100

X-ray Crystal Structure Determinations: Data collection for X-ray structure determinations was performed on a Syntex P4 or a Syntex R3 four-circle diffractometer using graphite-monochromated Mo-K_α (λ = 0.71073 A) radiation. Single crystals were mounted in Lindemann capillaries and sealed under argon atmosphere. Other data collection for X-ray structure determinations was performed on a Siemens P4 four-circle diffractometer equipped with a CCD area detector[32]. Single crystals were mounted in polyfluoroether oil and fixed on top of a glass fibre. Data was collected at −80 to −100°C. All calculations were performed on PC′s and workstations using the Siemens SHELXTL-Plus[33] or SHELX-93[34] software packages. The structures were solved by direct or heavy atom methods and successive interpretation of the difference Fourier maps, followed by least-squares refinement. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were included in the refinement in calculated positions by a riding model using fixed isotropic thermal parameters. Data relevant to the crystallography, data collection and refinement are compiled in Table 6. Further details of the crystal structure determinations are deposited at the Cambridge Crystallographic Data Centre and may be requested by quoting the depository number CSD-101038, the names of the authors, and the full journal citation.

[21] $BPh_3 \cdot py$ (**5b**) precipitates in triclinic crystals of space group $P\bar{1}$ ($Z = 2$) from benzene/pentane solutions. As the B−N and C−C bonds are isoelectronic, the pyridine and phenyl ligands are site disordered, so that every phenyl position is occupied to 1/4 by the pyridine molecule. Therefore, bond lengths cannot be discussed, but the structure is an additional proof for the reaction described by Eq. 2b.

Metal Tetrahydridoborates and Tetrahydridometallates, 22[◇]

Structural Chemistry of Lithium Tetrahydroborate Ether Solvates☆

Hans-Hermann Giese, Heinrich Nöth*, Holger Schwenk, and Steffen Thomas

Institute of Inorganic Chemistry, University of Munich,
Meiserstraße 1, D-80333 München, Germany

Received December 23, 1997

Keywords: Lithium tetrahydridoborate diethyl ether (1:1) / Lithium tetrahydridoborate diveron (1:1) / Lithium tetrahydridoborate dimethoxyethane (1:2) / Lithium tetrahydridoborate triglyme (1:1) / Lithium tetrahydridoborate tetrahydrofuran (1:3) / Lithiumtetrahydridoborate 1,3-dioxolane (1:1) / Hydride-bridge bonding

$LiBH_4 \cdot OEt_2$ (**1**) and $LiBH_4 \cdot O(Me)CMe_3$ (**2**) form double-stranded chains in the solid state. While 3 hydrides of the BH_4 group in **1** bind to three different Li atoms through Li···H–B interactions, the fourth H atom interacts with three adjacent Li centers. In contrast, in compound **2** there are two single Li···H–B bonds and two doubly bridging hydrogen atoms, the latter again interacting with three lithium centers. Moreover, the arrangements of the ether molecules in **1** and **2** are different. $LiBH_4 \cdot 2$ DME (**3**) (DME = dimethoxyethane) forms a molecular lattice, in which the BH_4^- anions are present in Li···H_2BH_2 bridges. The same structural feature is present in $LiBH_4 \cdot$ TG (**4**) (TG = triglyme = triethylene glycol dimethyl ether), but the TG molecule coordinates to two Li centers through two of its four oxygen atoms in such a manner that a chain structure results. The compound $LiBH_4 \cdot 3$ THF (**5**) exists as discrete molecules in the lattice. Its BH_4^- anion is triply bridging to the Li center. In contrast, $LiBH_4 \cdot C_3H_6O_2$ (**6**) (1,3-dioxolane) is polymeric. Due to the presence of two μ^2_2-BH_4 groups, a chain of the type ···Li(H_2BH_2)Li(H_2BH_2)··· is formed, and the 1,3-dioxolane molecules connect the chains through Li–O coordination to form a three-dimensional array. In spite of the variations in the bonding of the BH_4 group to Li centers, the Li atoms are hexacoordinated in **3** to **6** but are heptacoordinated in **1** and **2**.

Introduction

Lithium tetrahydridoborate is a commercially available reagent which surpasses $NaBH_4$ in terms of its reactivity[2]. It is widely used, and most reactions are performed in diethyl ether (OEt_2) or tetrahydrofuran (THF) as $LiBH_4$ is more rapidly hydrolyzed than $NaBH_4$[3]. Several ether solvates of $LiBH_4$ are known, but the only one to have been structurally characterized is 2 $LiBH_4 \cdot$18-crown-6[4] and more recently $LiBH_4 \cdot OEt_2$[17]. Most of the other ether solvates of $LiBH_4$ were first described in the period from 1950 to 1974[5], and only a few have subsequently been investigated in detail by vibrational and/or NMR spectroscopy[6]. To date, the following solvates have been characterized: $LiBH_4 \cdot n OEt_2$ (n = 0.5, 1, 2)[7][8], $LiBH_4 \cdot n$THF (n = 1, 2)[2c][8], $LiBH_4 \cdot O i Pr_2$[2c], and $LiBH_4 \cdot$1,4-dioxane[2c][9].

Meanwhile, several modes of bonding or interaction of the BH_4^- ion with metal centers have been established[5]. In mononuclear species $M(BH_4)_n$ or $L_mM(BH_4)_n$, μ_1-, μ_2-, or μ_3-BH_4 groups may be present, as shown in formulae **A**–**C**, which have local C_{3v}, C_{2v}, and C_{3v} point-group symmetry, respectively. BH_4 groups acting as bridges between two metal centers (type **D**) are found in solid $Be(BH_4)_2$[10], $Zr_3(BH_4)_6H_6 \cdot 4$ PMe_3[11], and $Cr_2(BH_4)_4 \cdot dipy_2 \cdot Cr(BH_4)_2 \cdot dipy \cdot$TMEDA[12]. Although the double μ_2-bridging mode **B** prevails, other bonding modes are possible as depicted in **E**–**I**. Type **G** has been observed in dimeric $LiBH_4 \cdot$TMEDA[13]. We use the notation shown in **A** to **I** to describe the hydride bridges. The subscripts indicate the number of hydrogen atoms of the BH_4 group that interact with *one* metal atom, while the superscripts denote the number of hydrogen atomss that interact with different metal centers. Thus, for example, μ_1^3 would indicate a hydrogen atom of the BH_4^- anion that forms bridges to three metal atoms. The examples given demonstrate that the BH_4^- anion is a very versatile ligand[14].

Synthesis

The synthesis of ether solvates of $LiBH_4$ can be achieved in various ways. One method is to dissolve $LiBH_4$ in the respective ether, and to crystallize the solvates either by cooling of the saturated solution or by removal of the solvent. A second method is to replace the solvate molecule with a more strongly coordinating ether. Thirdly, the ether can be added to a suspension of $LiBH_4$ in hexane or toluene. Using these methods, the following solvates have been obtained as single crystals (see Experimental Section for the method used): $LiBH_4 \cdot OEt_2$ (**1**), $LiBH_4 \cdot$DIV (**2**), $LiBH_4 \cdot 2$ DME (**3**), $LiBH_4 \cdot$TG (**4**), $LiBH_4 \cdot 3$ THF (**5**), $LiBH_4 \cdot$DIOXL (**6**) [DIV = $MeOCMe_3$, DME = $MeOCH_2CH_2OMe$, TG = $MeO(CH_2CH_2O)_3Me$, DIOXL = $C_3H_6O_2$, 1,3-dioxolane]. No single crystals could be obtained in the case of $LiBH_4 \cdot$1,4-dioxane[9] due to its very low solubility.

IR and NMR Spectra

In order to obtain some information on the interaction of the Li^+ center with the BH_4^- anion, IR spectra were recorded of the solid compounds as Nujol/Hostaflon mulls. The data attributable to BH stretching vibrations are summarized in Table 1. There are four strong bands in this region, irrespective of the type of ether solvate molecule present, and the pattern observed is not characteristic for a BH_4^- group of either T_d, C_{3v}, or C_{2v} symmetry. Bands due to $\nu^{10}BH_4$ are not resolved. The strong band at 2240 ± 65 cm^{-1} seems to be the overtone of the δBH_2 vibration at 1130 ± 10cm^{-1}. The IR spectra of solid $LiBH_4$ and $NaBH_4$ do not differ significantly[15]. It is only the triglyme solvate that shows a better resolution. Obviously, the bonding between the BH_4^- group and Li^+ is predominantly ionic, and the IR spectra do not allow any firm conclusions to be drawn regarding type of interaction of the BH_4 group with the Li center (μ_1, μ_2, or μ_3 bonding).

Table 1. IR bands in the stretching vibration region for the $LiBH_4$ ether solvates: crystalline material in Nujol/Hostaflon suspension

1[a]	**2**	**3**	**4**	**5**	**6**
2230 st	2180 m	2134	2198 m	2111 m	2180 st
2234 st	2277	2258	2264 st	2127 m	2256 st
2286 st	2306	2281	2295 st	2176 st	
2364 st	2320	2373	2560 st	2237 st	
	2410 sh		2330 m st	2272 st	2317 st
			2382 m st	2334 m st	
				2382 m st	

[a] In crystalline solid $LiBH_4$ the following bands were observed in the IR spectrum and assigned (in cm^{-1}): 2525 ($2\nu_2$), 2408 ($\nu_2 + \nu_4$), 2308 (ν_3), 2182 ($2\nu_4$)[15].

Likewise, the ^{11}B-NMR spectra of solutions of the $LiBH_4$ solvates in their respective ethereal solvents, or of the solid solvate in C_6D_6, did not yield any additional information (see Table 2). With the exception of $LiBH_4 \cdot TG$, each solvate gave rise to a 1:4:6:4:1 quintuplet with $^1J(^{11}B^1H)$ in the small range of 81−83 Hz, and $\delta^{11}B$ varying only within a range of ± 2.6 ppm. The shielding at the ^{11}B center decreases slightly when C_6D_6 is used as a solvent instead of the respective ether. This may be taken as evidence for a slightly stronger $Li(BH_4)$ interaction within an ion pair. No NMR data could be recorded for $LiBH_4 \cdot$1,4-dioxane, neither in dioxane nor in C_6D_6, due to its very low solubility in both solvents. This suggests that its structure in the solid state consists of an extended lattice. $LiBH_4 \cdot 3$ THF and $LiBH_4 \cdot$1,3-dioxolane are also practically insoluble in deuterated benzene. However, for a solution of $LiBH_4$ in triglyme, two additional signals are observed at $\delta = +3.7$ and $\delta = +7.5$. The signals in this case are broad, even that for the BH_4 anion at $\delta = -39.7$, and they show no resolved lines due to B-H coupling. The signal at $\delta = +3.7$ may be due to the presence of a BH_3 adduct to the ether (cf. $\delta^{11}B = 2.5$ for $H_3B \cdot OMe_2$)[16].

Table 2. ^{11}B- and ^{7}Li-NMR data of $LiBH_4$ solvates [δ is given in ppm, the coupling constant $^1J(^{11}B^1H)$ is given in Hz (in parentheses)

	2.54(1)	2.520(4)	–	–	–	2.431(3)

In benzene solution, the shielding of the ^{7}Li nucleus also varies considerably, but is more in line with the number of solvent molecules attached to the $LiBH_4$ molecule. This becomes evident by comparing the δ values for the DME and TG solvates with those of diethyl ether and diveron. The δ^7Li data for compounds **1**−**6** in their respective ether solutions are difficult to rationalize. The excellent shielding of the Li nucleus in **5** is most likely due to ion-pair formation $[Li(THF)_4]BH_4$, but then it is hard to understand why the Li center in **3** is less shielded than that in **2**, and why the Li resonance for **1** in diethyl ether solution is found at very low field. Since the degrees of association of $LiBH_4 \cdot OEt_2$ and $LiBH_4 \cdot$DIV in C_6D_6 solution are unknown, it is difficult to interpret the δ^7Li data, which suggest much stronger solvation in benzene (ratio Li/O only 1:1) than in ether. A

better shielding in benzene can only be expected when strong interactions between $LiBH_4$ molecules remain, while the indications seem contrary to this. Therefore, association through the BH_4 groups must remain in benzene solution. As both compounds have been found to be moderately soluble, it is evident that the chain structures present for these compounds in the solid state (vide infra) must be broken down into smaller $[LiBH_4 \cdot Do]_n$ units (Do = coordinated solvent).

Crystal and Molecular Structures

Coordination Compounds of $LiBH_4$ with Noncyclic Ethers: Neither the NMR data of solutions of $LiBH_4$ in the respective ethers nor the IR data of the solid ether solvates allowed an unambiguous assignment of the structure of the $LiBH_4$-ether solvates, particularly with respect to the type of Li···H−B interaction. Therefore, it was necessary to determine the molecular structures of the ether solvates of $LiBH_4$ by X-ray diffraction analysis.

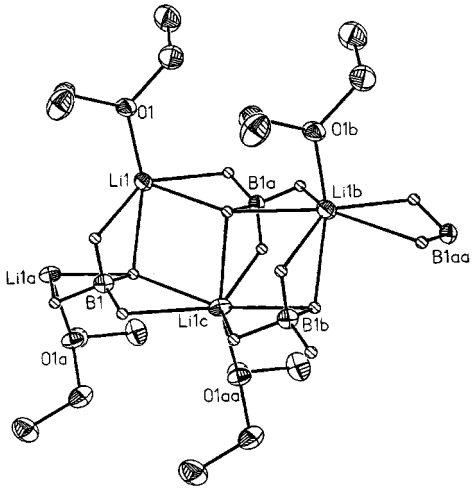
$LiBH_4 \cdot OEt_2$ (**1**), whose crystal structure has recently been reported[17], crystallizes from a diethyl ether solution in colorless needles of the orthorhombic system and, therefore, only a few features will be discussed.

Figure 1 shows that three of the four H atoms of the BH_4^- anion each interact with one Li center and that the fourth hydrogen atom coordinates to three Li^+ ions. This hydrogen atom is tetracoordinated. Moreover, each Li center is coordinated by six hydrogen atoms and one ether oxygen atom. The sum of bond angles subtended at the ether oxygen atoms is 359.8°. Li−H atom distances range from 1.94(5) to 2.25(5) A, while bond angles at Li span the wide range from 48.0 to 161.4°, with many falling in the interval 90 ± 15°. This shows that the coordination polyhedron can be described as a very strongly distorted octahedron. As expected, the coordination polyhedron around the boron atom is close to a tetrahedron.

The units shown in Figure 1 are the building blocks for the formation of doubly stranded chains in the lattice of **1** as depicted in Figure 2. In the lattice, each BH_4 group has to be described as $3\mu_1{}^1$, $\mu_1{}^3$, i.e. all four hydrogen atoms of the BH_4^- ion are involved in coordination to Li^+ ions, which are heptacoordinated. The ether molecules are arranged in such a manner that an organophilic "skin" partially shields the $(LiBH_4)_n$ core. This most probably explains why $LiBH_4 \cdot OEt_2$ not only dissolves in ether but also to a small extent in toluene. The structure in solution will, of course, differ significantly from that in the solid state.

$LiBH_4 \cdot$ DIV (**2**) crystallizes from toluene solution in thin monoclinic plates. Figure 3 depicts a single molecule, showing a doubly bridging BH_4 anion. These molecules are associated as shown in Figure 4a. Here, it can be seen that each Li center shares hydrogen atoms with three BH_4 groups, and this leads to heptacoordination at Li (6 H atoms and 1 O atom). Of the four hydrogen atoms of each BH_4^- anion, two are involved in bridging two Li centers, while the other two are involved in single B−H···Li interactions ($2\ \mu_1{}^1$-, $2\ \mu_1{}^2$-BH_4). Figure 4a depicts the arrangement in a double-stranded chain. It also shows that the *tert*-butyl

Figure 1. ORTEP plot of four $LiBH_4 \cdot OEt_2$ (**1**) molecules; estimated standard deviations in parentheses[a]



[a] Selected bond lengths and atom distances [A]: Li1−O1 1.927(6), Li1−H1 1.97(3), Li1−H2 2.11(3), Li1−H 42.08(3), B1−H1 1.12(3), B1−H2 1.14(3), B1−H3 1.01(5), B1−H4 1.19(4), Li1···B1 2.53(1), Li1···B1B 2.54(1). − Selected bond angles [°]: C1−O1−C3 115.0(3), C11−O1−Li1 122.3(4), C3−O1−Li 122.5(3), H1−B1−H3 109(3), H1−B1−H2 107(2), H1−B1−H4 110(3), H2−B1−H3 116(3), H2−B1−H4 107(3), H3−B1−H4 108(2), O1−Li1···B1 122.5(3), O1−Li1···B1A 106.2(4), Li1−H2−Li1A 161(2), Li1−H1−B1 105(2), Li1A−H3−B1 104(3), B1−H4−Li1B 105(3). − Atom Li1B is part of the adjacent chain (see Figure 2).

groups of the diveron molecules are ordered in such a manner that allows one methyl unit of each DIV molecule to be arranged in a zipper-like orientation. Thus, the organyl groups shield the $LiBH_4$ part of the $[(LiBH_4)_2]_\infty$ chain better than in **1** (Figure 4b). However, every second pair of *trans*-oriented ether molecules are turned by 69.7° to one another. Therefore, the arrangement of the molecules of **2** in the chain is different to that observed for **1**.

$LiBH_4 \cdot 2$ DME (**3**) forms colorless monoclinic crystals. There is half a molecule in the asymmetric unit. The Li and B atoms occupy special positions on a C_2 axis. Figure 5 depicts the molecular structure of compound **3**.

It is apparent that the hexacoordinated Li atoms are surrounded by four oxygen atoms of two DME molecules and two hydrogen atoms from a $\mu_2{}^1$-BH_4 group.

The B−H bonds to the bridging hydrogen atoms are slightly, although not significantly, longer than those to the terminal hydrogen atoms. In the case of the Li−O coordination, one Li−O distance is significantly shorter than the other [2.058(2) A for O2, 2.133(1) A for O1]. The rather acute O1−Li−O2 bond angle is due to the small bite angle of the DME molecule. Consequently, the deviation from octahedral symmetry around the Li ion is substantial; the smallest bond angle is 55.9(9)° (H2−Li1−H2a), the largest 150.8(5)° (H2−Li1−O2). Bond angles subtended at atoms O1 and O2 are rather different, the largest C−O−Li bond angles being those to the methyl groups of the DME molecule, which range from 122.0(1) to 126.30(9)°. More interesting in terms of the coordination geometry is the fact that the bond angle sums at atoms O1 and O2 are 321.1(3)° and 349.5(3)°, respectively. Considering the C−O−C bond

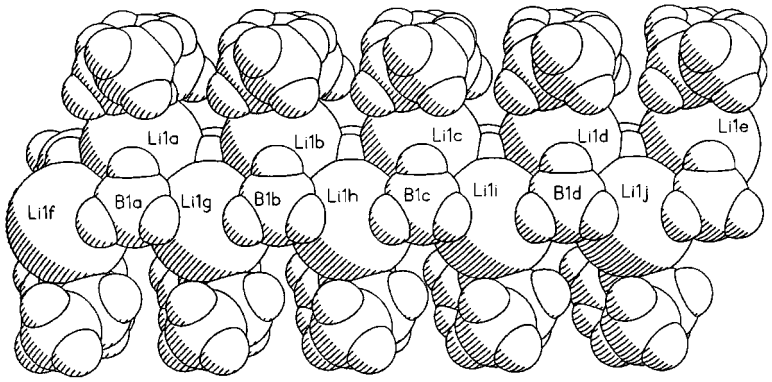

Figure 3. ORTEP plot of $LiBH_4 \cdot OMe(CMe_3)$ (**2**) in the asymmetric unit[a]

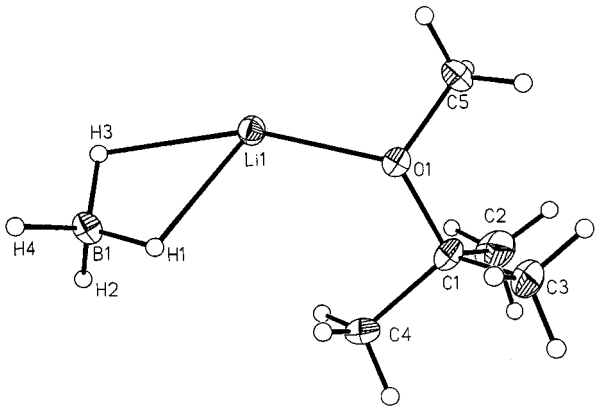

[a] Selected bond lengths and atom distances [A]: Li1−O1 2.000(4), Li1−H1 2.11(2), Li1−H3 2.16(2), Li1B−H1 2.16(2), H2−Li1A 2.00(2), H3−Li1A 2.08(2), Li1−H4B 2.08(2), Li1−HaB 2.16(2), B1−H1 1.11(2), B1−H2 1.12(3), B1−H3 1.14(2), B1−H4 1.11(3), Li1···B1 2.560(4), Li1−B1A 2.505(4), Li1−B1B 2.529(4). − Selected bond angles [°]: O1−Li1−H1 110.9(6), O1−Li1−H3 159.1(6), H1−B1−H2 110(2), H1−B1−H3 110(2), H1−B1−H4 108(2), H2−B2−H3 106(2), H2−B1−H4 114(2), H3−B1−H4 109(2), B1−H1−Li1 101(1), B1−H3−Li1 97(1), B1−H4−Li1B 100(1), B1−H2−Li1A 104(2) Σ∠ at O1: 356.0°.

angles of 112.6 and 111.3(3)°, respectively, it would appear that these oxygen atoms are best described as being sp^3-hybridized. The O1−Li−O2 bond angle of 79.49(6)° as well as the Li1−O1−C2 and Li1−O2−C3 bond angles [112.6(1)° and 111.87(8)°] indicate that the Li···O interaction is predominantly polar. However, it should be borne in mind that **3** is nevertheless a molecular compound.

The $LiBH_4 \cdot TG$ solvate **4** forms colorless, orthorhombic crystals. There are four molecules in the unit cell. However, the triglyme ligand does not coordinate to only one Li center. As shown in Figure 6, the triglyme ligand binds to *two* different Li centers through two of its four oxygen donor atoms. Therefore, a chain structure results, in which the Li centers are hexacoordinated. The Li ions are coordinated by four oxygen atoms of *two* different triglyme molecules, as well as by a $\mu_2{}^1$-bonding BH_4 group.

The C−O atom distances in **4** fall in the fairly narrow range from 1.425(2) (O1−C2) to 1.432(2) A (O2−C4). However, the sum of bond angles at atom O1 is only 335.4°, in contrast to atom O2, where the sum is 359.3°. This points to two different bonding situations for O1 and O2, as suggested also by the *shorter* Li1−O2 atom distance. On the other hand, the O2−Li1−O1 bond angle of 79.67(8)° does not deviate at all from the analogous bond angle in **3** [79.49(8) A], and we take this as evidence that the Li···O interactions in **4** are again primarily determined by polar factors, irrespective of the bond angle sums at the O atoms.

Coordination Compounds of $LiBH_4$ with Cyclic Ethers: Cyclic ethers such as THF, 1,4-dioxane, 1,3,5-trioxolane, and many others add to $LiBH_4$. However, to date we have been unsuccessful in obtaining good single crystals of these solvates, apart from the case of THF and 1,3-dioxolane solvates.

$LiBH_4 \cdot 3$ THF (**5**) crystallizes from a THF solution at −40°C in extensively intergrown platelets. Crystal selection at low temperature was difficult, as was the mounting using oxygen-free perfluoroether oil. Several crystals had to be examined and even the best one was comparatively weakly diffracting. Consequently, the quality of the structure determination is less than satisfactory. Nevertheless, a model structure was found that seems to be reliable, even though the hydrogen atoms at the boron center had to be fixed in their found positions in the final cycles of refinement. Figure 7 shows the result.

It is apparent that **5** is a molecular compound that may be regarded as a contact ion pair. The Li center is hexacoordinated by three oxygen atoms and three hydrogen atoms. Thus, the BH_4 group acts as a $\mu_3{}^1$-ligand. Li−O atom distances vary significantly, ranging from 1.952(6) to 2.017(6) A, while the O−Li−O bond angles span the small range from 100.6(3) to 102.5(3)°. On the other hand, the bite of the BH_4 group is very small, as exemplified by H−Li−H bond angles in the range 45.5−54.4°. The Li···B atom distance is 2.319(7) A, which is shorter than the Li···B distances found for $\mu_2{}^1$-BH_4 groups.

$LiBH_4 \cdot 1,3$-DIOXL (**6**) separates from saturated 1,3-dioxolane solutions. The crystals are monoclinic. The contents of the asymmetric unit is depicted in Figure 8. The structure features tricoordinated Li ions, which are, of course, coordinatively unsaturated. These units associate to

Figure 4. a) Four molecules of **2** in a chain; b) space-filling model

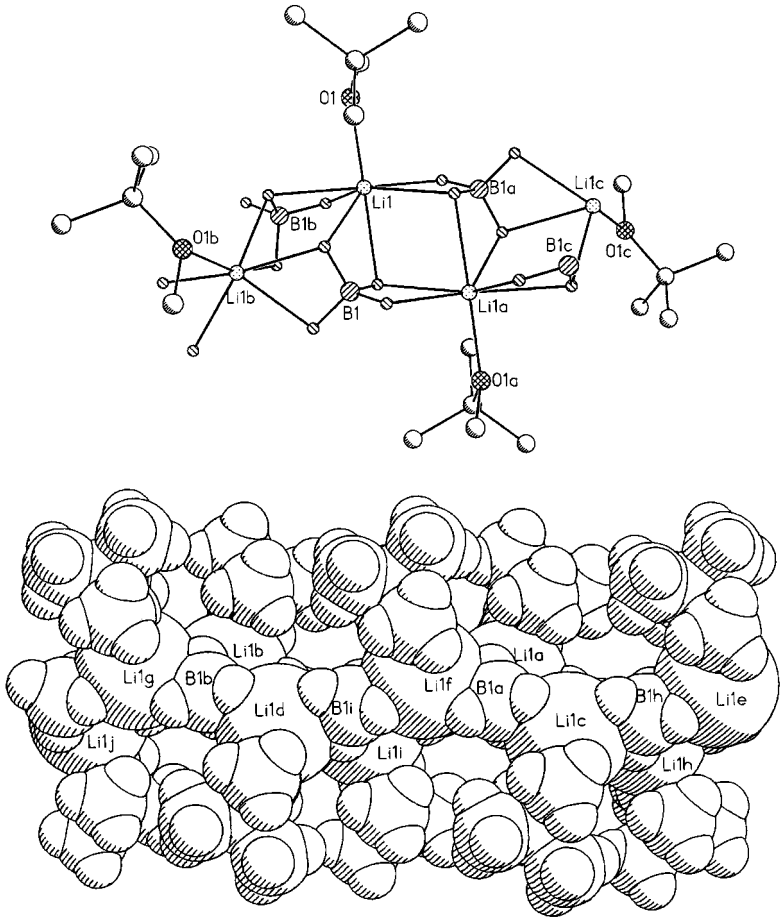

Figure 5. ORTEP plot of the molecular structure of $LiBH_4 \cdot 2$ DME (**3**)[a]

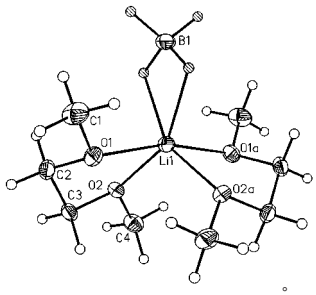

[a] Selected bond lengths and atom distances [A]: Li1−O1 2.133(1), Li1−O2 2.058(2), Li1−H2 1.17(2), B1−H1 1.15(2), B1−H2 1.17(2), Li1···B1 2.470(4). − Selected bond angles [°]: O1−Li1−O2 79.49(6), O1−Li1−O1a 165.9(2), O1−Li1−O2a 92.60(7), O2−Li1−O1a 92.60(7), O2−Li1−O2a 111.9(2), Li1−H2−B1 98.1(9), H1−B1−H1a 110(2), H1−B1−H2 111(1). Σ∠ O1 = 341.2°, O2 = 349.5°.

form an extended structure, as shown in Figure 9. The BH_4 groups join strands of Li(1,3-dioxolane) units.

The BH_4 groups are of the $4\mu_1{}^1$-type, i.e. there are four singly bridging hydrogen atoms to 4 Li centers. Moreover, both oxygen atoms of the 1,3-dioxolane are involved in coordination. This leads to hexacoordinated Li ions with an H_4O_2 environment. The two Li−O distances are 1.993(3) and 2.031(3) A, and the O−Li−O bond angles are 94.6(1)° for Li1 and 96.2(1)° for Li2. It is also interesting to note that the Li···B atom distances are 2.445(3) and 2.439(3) A, respectively. These are definitely longer than the Li···B distance in **4** as a result of the "unusual" Li−H−B interactions. The two OCO planes of the dioxolane molecules coordinated to a Li center are twisted by almost 90° with respect to one another. The symmetry at atom Li2 is higher than that at atom Li1. Moreover, the Li···B···Li angles differ considerably, amounting to 174.1(1)° at atom B1 and 162.8(1)° at atom B2.

Discussion

It is well known that $LiBH_4$ forms many well-defined solvates with various kinds of ethers[2]. Although the compositions of some of these solvates have been determined, their structures in the solid state and in solution have never been adequately described.

In the present study, it is demonstrated that an IR-spectroscopic investigation does not allow unambiguous conclusions to be drawn concerning the coordination mode of the anion BH_4^- to the Li centers. Such information can only be obtained from X-ray structure determinations, which are of course confined to the solid state. Thus, the structure of $(LiBH_4)_2 \cdot 18$-crown-6 has been determined, which reveals $\mu_1{}^1$-BH_4 interactions with the Li centers[4].

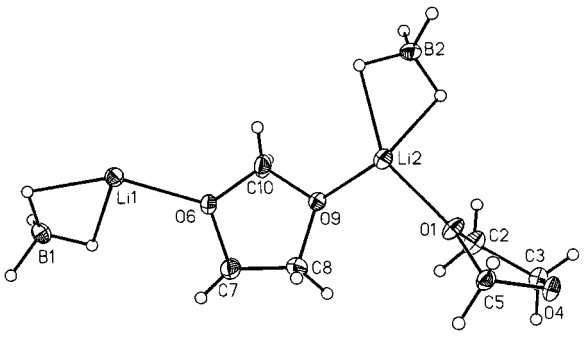
Figure 8. ORTEP plot of the molecular structure of $LiBH_4 \cdot 1,3$-dioxolane (**6**)[a]

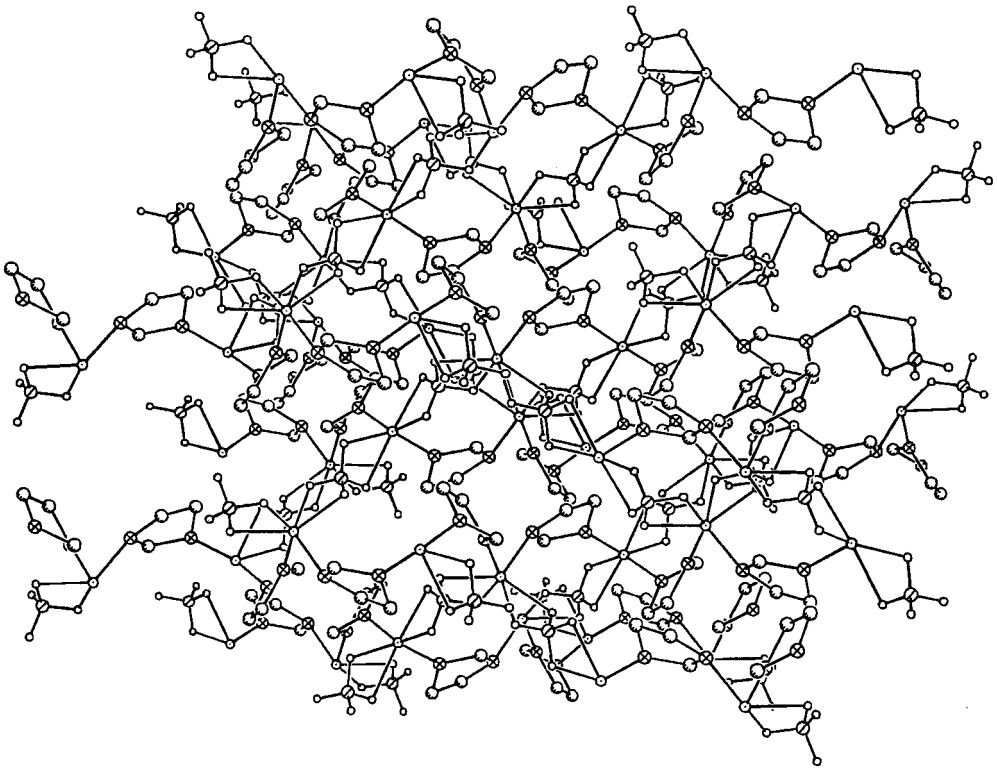


[a] Selected bond lengths and atom distances [A]: Li1−O6 2.004(3), Li1−O4A 1.993(3), Li1···B1 2.445(3), Li1−B2B 2.447(3) Li2···B2 2.431(3), Li2C−B1 2.428(3), Li2−O1 1.984(3), Li2−O9 2.031(3). Selected bond angles [°]: O6−Li1−B1 117.4(1), B1−Li1−O4A 100.6(1), O6−Li1−O4A 96.2(1), O4A−Li1···B2B 118.6(1), O6−Li1···B2B 98.7(1).

The compound can therefore be regarded as a "double" contact ion pair, in which each Li atom is coordinated by a hydrogen atom and four oxygen atoms. Although all the molecular solvates described herein, such as $LiBH_4 \cdot 2$ DME and $LiBH_4 \cdot 3$ THF, may also be regarded as contact ion pairs, this seems to be an inadequate description as the BH_4 group definitely favors μ_1, μ_2, or μ_3 interactions with the Li^+ center. The structure determinations presented in this study clearly show a preferential orientation of the BH_4 moiety. Using Edelstein's correlation of metal−boron distances as a measure of the denticity of the BH_4 group[18], it is shown that this holds not only for typical covalent metal tetrahydridoborates, but also for more polar metal tetrahydridoborates.

It is also evident that strongly coordinating ether ligands such as THF and DME lead to the formation of molecular $LiBH_4$ complexes, while more weakly bound ethers such as OEt_2 or diveron lead to polymers. This is apparent from ether/Li ratios of 1:1 with weak donors and ratios of up to 4:1 with strong donor molecules. As the O/Li ratio decreases, coordination unsaturation at the Li ion increases and this is counterbalanced by additional Li···H interactions. Therefore, we observe BH_4 groups of type **A** ($\mu_3{}^1$-BH_4) for $LiBH_4 \cdot 3$ THF, of type **B** ($\mu_2{}^1$-BH_4) for $LiBH_4 \cdot 2$ DME and $LiBH_4 \cdot TG$, and $4\mu_1{}^1$-BH_4 for $LiBH_4 \cdot 1,3$-DIOX. Type-**D** BH_4 groups ($2\mu_1{}^1$,$2\mu_1{}^1$-BH_4) are present in $LiBH_4 \cdot DIV$ and $3\mu_1{}^1$,$\mu_1{}^3$-bonding is found in $LiBH_4 \cdot OEt_2$. Thus, in these cases, each hydrogen atom of the BH_4 group is involved in interactions with the Li^+ ions. Amongst the $LiBH_4$−ether complexes described here, there are hydrogen atoms of the BH_4 group that coordinate to three Li centers, as for example, in **1**. Consequently, these are H^- ions in a tetracoordinated environment. However, in complexes of $LiBH_4$ with nitrogen ligands, the interaction of BH_4 hydride with three Li centers is more common than with ethers[19], and we have recently found an example where even four metal centers coordinate to one hydride, namely $LiAl_3H_5(OR)_5$[20].

Figure 9. View of the three-dimensional array of compound **6**



It is evident that the BH_4 group is a very versatile ligand, and it can be expected to show still further variations in coordination mode as a ligand in competition with ethers or other donor ligands. Studies in this area are currently in progress in our laboratory.

We thank *Chemetall GmbH* for support of this study. Moreover we are indebted to the *Fonds der Chemischen Industrie* for unbureaucratic help over many years, and we are also grateful to Mrs. *E. Kiesewetter* and Mrs. *G. Hanatschek* for recording the IR spectra.

Experimental Section

The hydrolytic sensitivity of $LiBH_4$ requires the exclusion of moisture in all experiments. Therefore, the Schlenk-tube technique was used with N_2 or Ar as the protecting gas. All solvents were carefully dried, and only flame-dried glassware was used. $LiBH_4$ (Chemetall GmbH) was crystallized from diethyl ether and dried in vacuum. NMR spectra were recorded with Jeol EX 270 and EX 400 instruments [standards: TMS (^1H, ^{13}C), 1 M LiCl (^7Li), $BF_3 \cdot OEt_2$ (^{11}B)]. – IR: Nicolet FT-IR.

Lithium Tetrahydridoborate–Diethyl Ether (**1**): Diethyl ether (35 ml) was added to $LiBH_4$ (0.94 g, 43 mmol) at 20°C with stirring. After heating to reflux for 4 h, a turbid solution formed, from which the insoluble material was removed by filtration (G3 glass frit). On cooling to 5°C, needles formed which were not suitable for X-ray crystallography. Yield: 3.36 g of **1** (81%), m.p. ca. 5°C. The ether adduct was dissolved in a minimum amount of an Et_2O/toluene (5:3) mixture. Single crystals of sufficient quality grew at −20°C. Isolation and the selection of suitable crystals was carried out at this temperature. **1** was found to be readily soluble in Et_2O and benzene, but insoluble in hexane. – $C_4H_{14}BLiO$ (95.91): calcd. B 11.27, Li 7.24; found B 11.09, Li 7.11 (by titration); B 10.33, Li 6.92 (by AAS).

Lithium Tetrahydridoborate–tert-Butyl Methyl Ether (**2**): Prepared analogously to **1** from $LiBH_4$ (0.76 g) and diveron (25 ml). **2** crystallized from the solution in very thin, interwoven needles. Yield: 3.07 g (79%), dec. 283°C. Single crystals were obtained from the saturated solution at 20°C by cooling to 5°C. The compound was found to be soluble in diveron and benzene, but insoluble in hexane. – $C_5H_{16}BLiO$ (128.08): calcd. B 9.83, Li 6.31; found B 9.69, Li 6.22 (by titration); B 8.93, Li 6.43 (by AAS).

Lithium Tetrahydridoborate–Bis(dimethoxyethane) (**3**): Prepared analogously to **1** from $LiBH_4$ (0.61 g, 28 mmol) and dimethoxyethane (60 ml). A clear solution resulted after heating. Since no crystals separated at 20°C, the solution was cooled to −20°C. Well-shaped needles separated. Yield: 2.4 g of **3** (42%). The compound was found to be soluble in DME, THF (reaction), and benzene, but insoluble in hexane. – $C_8H_{24}BLiO$ (154.03): calcd. B 5.35, Li 3.44; found B 5.41, Li 3.53 (by titration); B 5.45, Li 3.41 (by AAS).

Lithium Tetrahydridoborate–Triglyme (**4**): Obtained by dissolving $LiBH_4$ (250 mg, 11.5 mmol) in 10 ml of triglyme. After heating to reflux (20 min), the hot suspension was filtered and the clear solution was cooled to −20°C. Well-shaped needles formed, which were isolated by filtration. Yield: 600 mg of **4** (26%), m.p. 59°C. The compound was found to be soluble in triglyme and benzene, but insoluble in hexane. – $C_8H_{22}BLiO$ (152.01): calcd. B 5.41, Li 3.47; found B 5.40, Li 3.42 (by titration); B 5.28, Li 3.24 (by AAS).

Lithium Tetrahydridoborate–Tris(tetrahydrofuran) (**5**): To $LiBH_4$ (3.2 g, 146 mmol), tetrahydrofuran (50 ml, 615 mmol) was added with stirring. Most of the $LiBH_4$ dissolved exothermically. The turbid solution was heated to reflux for 10 min, and any insoluble material was then removed at ambient temperature by fil-

tration. A 25-ml aliquot of the solution was cooled to −75°C. Extensively intergrown crystals were deposited. Single crystals were selected at −75°C and investigated crystallographically. The crystals, which proved to be $LiBH_4\cdot 3$ THF, melted at ca. −60°C. The remaining solution was subjected to NMR (^7Li, ^{11}B) and IR analysis. The compound loses THF readily at ambient temperature, and finally gives $LiBH_4\cdot$THF[8]. As yet, we have not been able to obtain the latter in the form of single crystals.

Lithium Tetrahydridoborate−1,3-Dioxolane (**6**): $LiBH_4$ (780 mg, 35.8 mmol) was added to 1,3-dioxolane (40 ml). The suspension was heated to reflux for 20 min, and insoluble material was removed by filtration at −30°C. On storing the clear solution at −30°C, colorless crystals formed within 3 d. Yield: 2.67 g of **6** (78%). Recrystallization from 20 ml of toluene at −30°C gave well-shaped single crystals of **6**. − $C_3H_{10}BLiO_2$ (95.86): calcd. C 37.62, H 10.44, B 11.27; found C 36.93, H 10.43, B 11.15.

Crystal-Structure Determinations: Single crystals were grown by slow evaporation of the solvent from the ethereal solutions ($LiBH_4\cdot OEt_2$, $LiBH_4\cdot$DIV, $LiBH_4\cdot 3$ THF) or by cooling solutions in toluene (all others) to low temperatures. The crystals of **1**, **2**, and **5** were removed from the cold solution and transferred directly into precooled perfluoroether oil at −60°C. The selected specimen was mounted on a glass fiber, which was rapidly transferred to the goniometer head. The crystal was cooled in an N_2 cold stream to −100°C. Most crystals of $LiBH_4\cdot$DIV and $LiBH_4\cdot 3$ THF were found to be weakly diffracting. Only the best data obtained are reported here. A Siemens P4 four-circle diffractometer equipped with a SMART-CCD detector was used for data collection with graphite-monochromated Mo-K_α radiation. Preliminary determinations of the cell constants used reflections of 4 different sets of 15 frames. The dimensions of the unit cell reported in Table 4 are those calculated from all data. Data reduction was performed using the program SAINT[21]. The structures were solved by the direct methods implemented in the SHELXTL and SHELX-93 program packages[22]. Hydrogen atoms bonded to the boron atom were refined freely, except for those in **3**. Non-hydrogen atoms were described anisotropically. Hydrogen atoms bonded to carbon atoms were placed in calculated positions and refined with a riding model. The positions of hydrogen atoms bonded to boron atoms were taken from difference Fourier maps. Crystallographic data have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication CCDC-101311. Copies of the data can be obtained free of charge on application to CCCD, 12 Union Park, Cambridge CB2 1EZ, U.K. [Fax: (internat.) + 44(0)1223/336033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Ab initio calculations / Phosphorus / Strained molecules / Substituent effects / Pericyclic reactions

According to quantum chemical calculations at an ab initio level parent 1,2-diphosphete is slightly more stable than its corresponding 1,4-diphosphabutadiene structural isomer. The quantum chemical calculations indicate that substituents at phosphorus and to a much less extent at carbon exert strong influences on the equilibrium geometries of 1,2-diphosphete structures: π donors at phosphorus strongly elongate the P–P bond while electronegative substituents at phosphorus increase the interflap angle of the four-membered ring systems, bringing an envelope conformation to the fore. The lengthening of the P–P bond gives rise to a Möbius-type delocalization within the ring moiety.

Introduction

Since the first described route for the syntheses of 1,2-diphosphetes **1** by condensation of cyclopolyphosphanes with alkynes[1] a variety of procedures have been reported, involving the [2+2] cycloaddition reaction of diphosphene complexes with alkynes[2], insertion of a phosphenium cation into a three-membered phosphirene ring[3], the reaction of sterically stabilized iminophosphanes with phosphirenes[4], the Zr-to-P metathetical exchange on 1-phospha-2-zirconacyclobutenes[5], and the reaction of butadiynes with terminal phosphanylidene complexes[6]. In addition a variety of other procedures exist[7]. The versatility of 1,2-diphosphetes has been summarized in recent reports[7].

Here we present quantum chemical calculations which reveal that substituents with strong donor capabilities have sizable effects on the P−P bond equilibrium geometries, ranging from usual (P−P = 2.2 A) to strongly stretched (P−P = 2.5 A) bonds. Furthermore, the substituents strongly affect the interflap angle of the four-membered ring system. On this basis we propose 1,2-diphosphetes with noticeable irregular geometries, which are best described by a cyclic delocalized ring system with 4 electrons (Möbius-type aromaticity).

We note that the recent experimental effort in the synthesis of 1,2-diphosphophosphetes has opened a new convenient general access to symmetrically or unsymmetrically substituted species. On the basis of the phosphanylidene complex addition reaction[6], it might be possible to introduce suitable functional groups at the phosphorus atoms. Corresponding precursor phosphanylide complexes have hitherto been reported for the alkoxy[8], alkoxycarbonyl[9], dialkylamino[10], and vinyl[11] substituents. Thus, our quantum chemical predictions should be amenable to experimental verification.

Methodology

Previous investigations[12] demonstrate that the barriers for valence isomerization as well as the equilibrium geometries of the various stationary points on the electronic hypersurface are strongly sensitive to explicit treatment of electron correlation in the wavefunction. Within this line we have chosen for the present investigations the MP2 level of optimization, conducted by analytically determined gradients[13]. As a basis set we have used a double-ζ basis set

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0707−0951 $ 17.50+.50/0

augmented by polarization functions at the heavy atoms [6-31g(d)][14]. In addition for the anions one set of diffuse s,p functions was added. All details are provided in the discussion. The calculations were performed with the GAUSSIAN-94[15] set of programs.

Results and Discussion

a. Qualitative Considerations

We begin our discussion with an analysis of the electronic hypersurface for the ring-opening reaction of parent **1** (R^1 to R^4 = H) to its valence isomer, the *cis*-diphosphabutadiene **2**. It is valence-isoelectronic to cyclobutene, which undergoes a conrotatory ring opening ($\pi^2 + \sigma^2$) reaction to *cis*-butadiene according to the Woodward-Hoffmann rules[16]. Thus, one expects a similar reaction mode for the case at hand. However, there is an essential difference in bonding between cyclobutene and the 1,2-diphosphete. It becomes apparent by an inspection of bond energies (Table 1).

Table 1. Bond energies (in kcal/mol)

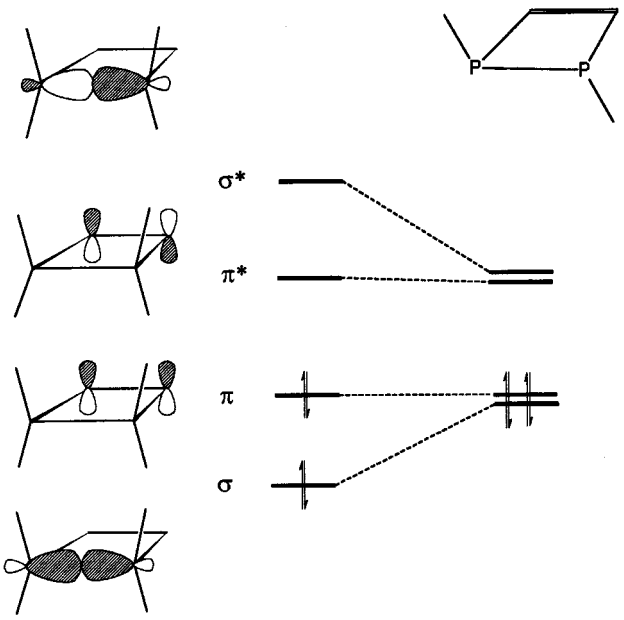
Type	*E* [kcal/mol]	Ref.
σ C−C	83	[a]
π C−C	65	[b]
σ P−P	50	[a]
π P−P	34	[b]
σ P−C	71	[c]
π P−C	43	[b]

[a] K. F. Purcell, J. C. Kotz, *Inorganic Chemistry*, Holt-Saunders International Editions, Honkong, **1977**. − [b] M. W. Schmidt, P. N. Truong, M. S. Gordon, *J. Am. Chem. Soc.* **1987**, *109*, 5217; W. W. Schoeller, C. Begemann, U. Tubbesing, J. Strutwolf, *J. Chem. Soc., Faraday Trans. 2* **1997**, *93*, 2957. − [c] Estimated by the Pauling relationship for heteropolar bonds, see: W. W. Schoeller, R. Schneider, *Chem. Ber.* **1997**, *130*, 1013; see Appendix.

A P−P σ bond is essentially weaker than a C−C σ bond. An estimate for the bond energy from (parent) **1** (R^1 to R^4 = H) to **2** results endothermic in $-E_\sigma^{PP} + 2\,E_\pi^{PC} - E_\pi^{CC} = -29$ kcal/mol, with the energy values given in Table 1. This estimate neglects (a) possible ring strain which would be released upon ring opening and (b) rehybridization effects. Since factor (a) is small in phosphorus ring systems[17] it does not contribute significantly to the energy balance. In comparison with, a corresponding energy balance for ring opening in cyclobutene, based on the consideration of bond transformations, results also endothermic ($E_\sigma^{CC} + 2\,E_\pi^{CC} - E_\pi^{CC} = -18$ kcal/mol). However, in cyclobutene the ring strain is large (65 kcal/mol[18]). It has to be added to the energy balance and makes the ring-opening reaction for this case exothermic, in accord with experiment[19] as well as theory[20]. A further consequence of these considerations may be noticed here, schematically shown in Scheme 2.

In cyclobutene the C−C π (π*) orbitals are higher (lower) in energy than the C−C σ (σ*) orbitals. In (parent) **1** the situation is different. The corresponding orbitals σ and π (σ* and π*) are similar in energy. It is in accord with the result of the quantum chemical calculations (not recorded here). As a consequence of the weaker P −P σ bond (in reference to the C−C σ bond) the energy barrier for an electrocyclic reaction from **1** to **2** should be smaller than in cyclobutene and the P−P σ bond sensitive to donating and/or σ-accepting substitutents attached to the phosphorus atoms. Regarding the ring-opening reaction, experimental investigations on parent **1** are not available, since the structures have to be synthesized with bulky substituents, in order to protect these compounds kinetically.

Scheme 2



b. Valence Isomerization of Parent 1 to 2

According to recent quantum chemical calculations[12] the ring opening of the 1,2-diphosphete occurs with an energy barrier of 16.9 kcal/mol, a value comparable with an estimate at an RHF level of quantum chemical sophistication[21]. The energy balance to the *trans*-1,4-diphosphabutadiene **3** is endothermic by 2.9 kcal/mol[12]. The primary product in the ring-opening reaction of **1** is the *cis*-1,4-diphosphabutadiene **2**. It is less stable by 5.1 kcal/mol than its *trans* isomer **3**. It must be noted that the rotational barrier from **2** (C_2 symmetry) to **3** (C_{2h} symmetry) is fairly small[21]. Experimentally only the *trans* isomers are known[22][23] which is the most favoured butadiene structure because of the low-energy barrier for rotation. Overall these investigations indicate that the 1,2-diphosphete is the most stable species, but separated by a relatively small barrier from the butadiene derivatives.

c. Substituent Effects on 1

The conclusion that the P−P σ bond is weaker than a C−C σ bond raises the question about the magnitude of substituent effects on the geometries of 1,2-diphosphetes. To evaluate this aspect in more detail we first performed calculations on a variety of mono-substituted 1,2-diphosphetes, the substituents attached to one phosphorus center.

All geometries were determined at the MP2(fc)/6-31g(d). No symmetry restrictions were imposed in the structural energy optimizations.

Table 2. Relevant structural parameters (bond lengths in Å, bond angles in degrees) in mono-P-substituted 1,2-diphosphetes, at MP2 (fc)/6-31g(d) level, anions calculated at MP2(fc)/6-31+g(d) level

[a] $R^2 = R^3 = R^4 = H$. − [b] P−C bond in vicinity to the the substituent R.

A typical spectrum of substituents at phosphorus were chosen. For the calculations of the anions one set of diffuse s,p functions was added to the heavy atoms.

A sizable lengthening of the P−P bond is already observed to R(P) = NH_2 (P−P = 2.291 Å), in reference to the parent compound (R = H; P−P = 2.252 Å). It is in conformity with the result of recent experimental findings[24]. An even stronger elongation of the P−P bond results for the substituents which carry a negative charge, $PH^{(-)}$ (2.399 Å), $PSiH_3^{(-)}$ (2.348 Å). The investigations indicate that π donors strongly elongate the P−P bond. Finally, for R = $NH^{(-)}$ the butadiene structure is already more stable than the diphosphete. Evidently the ring-opening reaction within the latter occurs without an energy barrier. Strong electronegative substituents, e.g., R = F do not exert considerable changes in the P−P bond lengths. Similarly operates a typical electron-accepting substituent, e.g., SiH_3. There is, however, a strong effect on the torsional angle ∠ R−P−C−C and the folding angle ∠ P−C−C−P of the ring moiety. In comparison to the parent compound, **1** (R^1 to R^4 = H), electronegative substituents (e.g., F) tend to increase and electropositive substituents (e.g., SiH_3) to decrease these torsional angles. A plot of both quantities (Figure 1) affirms an approximate relationship between both types of torsional angles (for a related discussion on torsional angles in cyclobutenes, see ref.[25]).

A rationale for the substituent effects can be given in an interaction diagram, as follows. For the case of simplicity we analyze these effects for the case of di-substitution at phosphorus, invoking simple symmetry arguments (Figure 2).

Two π donors at the phosphorus atoms (**B**) form a positive (p^+, *a* within C_2 symmetry) or negative (p^-, *b* within C_2 symmetry) combination of p orbitals, suitable for interaction with the bonding (σ, π) or antibonding (σ*, π*) orbitals of the ring moiety (**A**). Mutual interaction occurs in either of two ways. (i) Interaction among the *a* set of orbitals (<σ/p^+>) is overall four-electron destabilizing (type I). (ii) In comparison, the mingling of the *b* set of orbitals (<σ*/p^->) results in an overall stabilization (type II), since it involves donation of electron density of a doubly occupied orbital (p^- at **B**) into the empty (σ*) orbital (at **A**). With increasing donor capability (lower ionization potential) the stabilizing interaction (type II) comes to the fore. It will cause a weakening of the P−P bond with concomitant

Figure 1. Plot of torsional angles ∠ RPCC vs. ∠ PCCP, for mono-substituted 1,2-diphosphetes (angles in degrees)

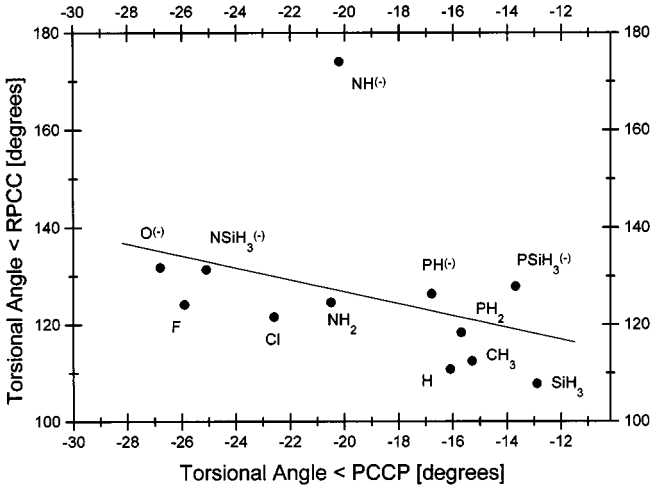

Figure 2. Interaction diagram of two donor p orbitals (**A**) with the σ (σ*) of the P−P bond (**B**)

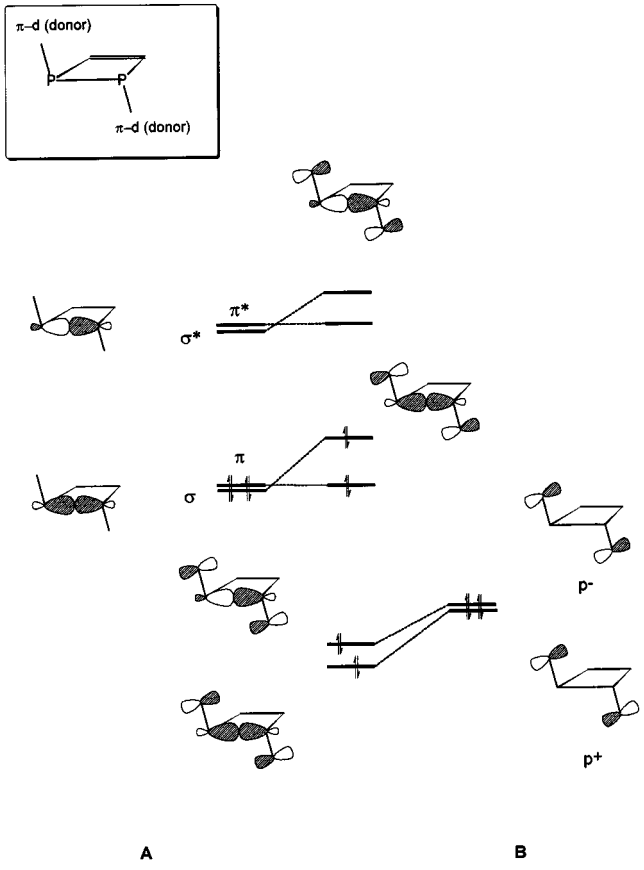
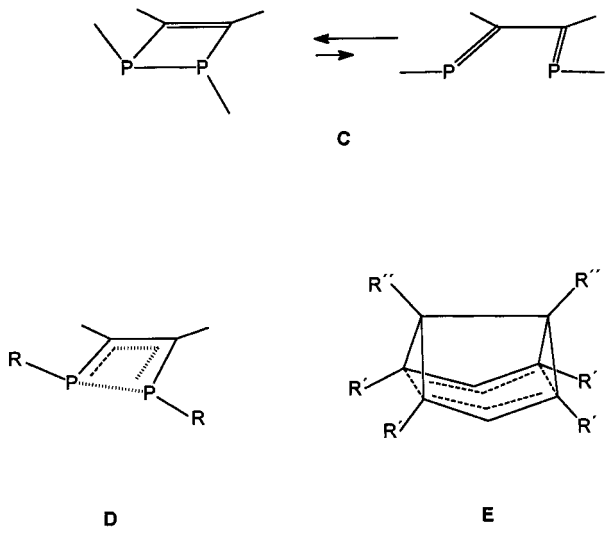


lengthening. Alternatively, if the donor p orbitals at R are low in energy, which refers to the case of electronegative substituents (with a high ionization potential, e.g., R = F) the type-II interaction will be weak and the P−P bond length almost unchanged. This tendency is reflected also for the case of the mono-substitution at phosphorus (see Table 2). We note that within this simplified picture the interactions of the donor orbitals (p^+, p^-, at P) with the π (π*) orbitals are not included in the discussion. To a first order the latter molecular orbitals are not effected, since they are in 1,3-position to the p-set of donor orbitals.

A variety of substituents were also calculated for the cases of di-substitution (a) at phosphorus and/or (b) at the carbon atoms. In contrast to phosphorus substitution, the various carbon-substituted 1,2-diphosphetes do not show considerable changes in the structures. Thus, the unusual bonding properties are only obtained for the case of phosphorus substitution. The di-substitution at phosphorus exerts additive trends on the P−P bond lengths. Corresponding investigations will not be reported here in detail. However, the most important results for the cases (a) and (b) are listed in the Appendix (Table 3).

One important point deserves further discussion. Following our analysis electron-donating substituents weaken the P−P bond. What is its effect on the energy barrier of the conrotatory ring opening reaction? We have examined this aspect in detail for the case of amino di-substitution at the diphosphete **1** ($R^1 = R^4 = NH_2$; $R^2 = R^3 = H$). The energy barrier disappears in fact [at a MP2(fc)/6-31g(d) level, plus additional MP4SDTQ(fc) and zero-point vibrational corrections]. In other words the description of **1** and **2** as two species in equilibrium, **C**, which implies separation by an energy barrier[7], is not valid for the case at hand, i.e., with a strong π-donor substitution at the phosphorus atom(s).

Scheme 3



Consequently, **1** can be considered as a structure with pericyclic electron delocalization. Such a species, **D**, with 4 delocalized electrons may be described as a Möbius aromatic system[26][27].

We note that the discussion presented here is reminescent to the analysis of substituents for the design of a "frozen-in" transition-state geometry in semibullvalene[28][29], **E**. There, a structure with $[\sigma^2 + \pi^2 + \pi^2]$ delocalization is promoted for the cases R′ = σ acceptor, R′′ = σ donor. It refers to a delocalized Hückel aromatic system. In comparison, our investigations indicate that such a delocalized system may also exist for a Möbius-type arrangement, which involves 4 electrons in pericyclic delocalization $[\sigma^2 + \pi^2]$. This view does, however, imply that the phosphorus lone pairs are not included in the delocalization. It results in unusual structures for the 1,2-diphosphetes. The experimental verification of the concept of 1,2-diphosphete structures with strongly elongated P−P bonds remains, however, a challenge to the experimentalist. In addition, the validity of the presented concept of delocalized Möbius-type structures has to be analyzed for the related cases, such as the mono- and triphosphetes. The bonding situation in the diphosphetes may also be compared with that in the dithietes[33][34]. There, the ring structure (dithiete) and the corresponding open structures (dithioglyoxal) are similar in energy and their mutual energy differences are a balance of delicate substituent effects.

This work has been supported by the *Deutsche Forschungsgemeinschaft* and the *Fonds der Chemischen Industrie.*

Appendix

While the case of mono-substitution at phosphorus in the 1,2-diphosphetes was studied at the MP2(fc)/6-31g(d) or for the anions at the MP2(fc)/6-31+g(d) level, for the heterosubstituted cases (at phosphorus and carbon) we employed the less costly 3-21g(d) basis set[30], accounting within the density functional formalism[31][32] [B3LYP/3-21g(d)] for the importance for electron correlation. The results of these investigations are summarized in Table 3.

Table 3. Relevant geometrical parameters (bond lengths in A, angles in degrees) for disubstituted 1,2-diphosphetes, obtained at B3LYP/3-21g(d) level of sophistication

$R^1 = R^4$	$R^2 = R^3$	P−P	P−C	C−C	∠ P−C−C−P	∠ R−P−C−C
H	H	2.279	1.851	1.346	−11.5	104.4
F	H	2.292	1.805	1.365	−30.3	129.0
Cl	H	2.307	1.822	1.357	−22.9	120.2
CH_3	H	2.276	1.846	1.350	−11.8	109.3
SiH_3	H	2.290	1.850	1.350	−8.0	102.0
PH_2	H	2.297	1.842	1.351	−11.6	113.8
NH_2	H	2.349	1.817	1.360	−20.5	124.8
NH_2	CN	2.338	1.824	1.379	−22.0	126.1
NH_2	NH_2	2.304	1.824	1.471	−17.0	120.3
NH_2	F	2.323	1.823	1.350	−15.1	117.8
Ph	H	2.307	1.838	1.353	−15.0	113.7
CN	H	2.295	1.846	1.347	−15.4	110.3
H	CN	2.269	1.855	1.364	−12.3	105.6
CN	CN	2.289	1.856	1.364	−15.7	110.6
CN	NH_2	2.268	1.839	1.369	−14.5	109.8
F	F	2.282	1.811	1.351	−23.2	120.0

The results, although obtained at a lower level of sophistication, yield similar trends. In addition they indicate that substituents at the carbon position(s) do not exert strong substituent effects at the P−P bond length. As shown for the case of the mono-substitution electronegative substituents at phosphorus tend to increase the

folding angle of the four-membered ring. Full details of the obtained equilibrium geometries are available on request.

Keywords: Amino acids / Bioinorganic chemistry / Copper / Luminescence / Ruthenium

A series of heterobimetallic complexes [{Ru(bipy)$_2$}m-AA{Cu(phen)(H$_2$O)}](PF$_6$)$_3$ (m-AA = N^{ω}-(4-carbonyl-4′-methyl-2,2′-bipyridyl)-L-α,ω-diamino acid; diamino acid (AA): **1b**, L-2,3-diaminopropionic acid; **2b**, L-2,4-diaminobutyric acid; **3b**, L-ornithine, **4b**, L-lysine) has been synthesized and characterized starting from the 2,2′-bipyridineruthenium(II)-substituted amino acids [{Ru(bipy)$_2$}m-AA-$^{\alpha}N$-^{t}Boc]$^{2+}$ ($^{\alpha}N$-^{t}Boc-**1a–4a**, $^{\alpha}N$-^{t}Boc = N^{α}-*tert*-butoxycarbonyl). The metal centers in **1b–4b** are bridged by insulating alkyl chains. Consequently, spectroscopic and electrochemical investigations confirmed the absence of any appreciable ground-state coupling between ruthenium(II) and copper(II). However, the luminescence of **1b–4b** is significantly quenched compared to that of the parent compounds **1a–4a**. Quenching was found to proceed only intramolecularly and to be most efficient in **1b** with the shortest alkyl spacer. Equilibrium constants for the formation of **1b–4b** were determined from luminescence titrations of the respective ruthenium-substituted amino acid with [Cu(phen)(NO$_3$)$_2$]. The complexes **2b–4b** (K = 1.61–2.08 × 10^7 M^{-1}) were found to be significantly more stable than **1b** (K = 5.7 × 10^6 M^{-1}). This is explained by a stronger electrostatic repulsion between the two metal centers in the latter compound.

Introduction

Owing to their fundamental importance in biological photosynthesis, photoinduced electron- and energy-transfer processes have attracted much attention in the context of supramolecular chemistry.[1][2][3][4] A particularly interesting challenge for synthetic chemists is the design of redox-active devices in which a photoinduced electron-transfer process triggers a chemical reaction. The light-dependent reduction of CO_2 by macrocyclic Ni^{II} complexes which have been covalently tethered to a polypyridineruthenium moiety may illustrate this goal.[5][6] In these compounds the electron-accepting nickel complex functions as a catalytically active site for substrate turnover, whereas the ruthenium chromophore serves the purpose of converting light into chemical energy.

Work in our laboratories has focussed on the design and synthesis of modified amino acids with well-defined binding sites for transition-metal complexes.[7] Our aim is to use these ligands as building blocks for the construction of polyfunctional supramolecular systems. Here we report the synthesis and characterization of novel dinuclear Ru^{II}-Cu^{II} complexes [{Ru(bipy)$_2$}m-AA{Cu(phen)(H$_2$O)}](PF$_6$)$_3$, **1b**−**4b** (Figure 1), with bridging bipyridyl-substituted α,ω-diamino acids (m-AA). The photoredox active [Ru(bipy)$_3$] subunit in **1b**−**4b** is thought to be suitable for the photochemical generation of phenanthrolinecopper(I).

It has been known for twenty years that phenanthrolinecopper(I) complexes can function as efficient chemical nucleases, catalysing the oxidative cleavage of ribose links of DNA in the presence of oxygen and a reducing agent.[8] This has stimulated considerable interest in using these systems as chemical probes for DNA structures.[9] DNA-strand scission occurs through a series of reactions starting with hydrogen-atom abstraction from a ribose unit.[9] The active agent is probably a metal-oxo or metal-hydroxyl intermediate formed upon reaction of hydrogen peroxide with a [Cu(phen)$_2$]$^+$ molecule bound to the surface of DNA within the minor groove.[9][10]

An interesting approach to the in situ generation of active Cu^{I} species has been reported by Strekas et al.[11] The authors have synthesized and characterized heterobimetallic complexes containing Cu^{I} and Cu^{II} fragments, and a bis(diimine)ruthenium(II) complex. It was shown that the compounds interact with DNA and that oxidative strand cleavage occurs in the presence of reducing agents. The combination of [Cu(phen)]$^{2+}$ fragments with photoredox-active polypyridineruthenium(II) complexes thus seems to be a promising route to bimetallic DNA-cleavage reagents. Photoinduced electron transfer should be possible between the ruthenium and the copper centers in dinuclear complexes, triggering oxidative strand-scission reactions upon irradiation with visible light.

Furthermore, both metal fragments are expected to interact with DNA with different affinities and selectivities. Polypyridineruthenium compounds typically intercalate into the base stacks of DNA,[12][13] whereas bis(phenanthroline-)copper(I) predominantly binds to the minor groove.[9][14] The combination of metal fragments with different DNA

binding patterns has been exploited by Brewer and co-workers for the synthesis of Ru^{II}-Pt^{II} and Os^{II}-Pt^{II} heterobimetallic complexes.[15] These compounds can interact with DNA by intercalation and/or covalent bonding.

It was first the aim of our studies on **1b**−**4b** to establish fundamental structure-function relationships in order to provide a basis for the applications described above. The compounds were investigated structurally by NMR and EPR spectroscopy. UV/Vis spectroscopy and cyclic voltammetry were used to confirm the absence of an efficient electronic coupling between the two metal centers. Finally, luminescence spectroscopy was applied as a tool to determine the effects of bridge structures on quenching efficiencies and complex stability constants.

Synthesis and Characterization of the Complexes

Synthesis

Our synthesis of the dinuclear Ru^{II}-Cu^{II} complexes **1b**−**4b** started from the $^{\alpha}N$-^{t}Boc-protected (amino acid)ruthenium(II) complexes $[\{Ru(bipy)_2\}m\text{-AA-}^{\alpha}N\text{-}^{t}Boc](PF_6)_2$ [$^{\alpha}N$-^{t}Boc-**1a**−**4a**; AA = L-2,3-diaminopropionic acid; L-2,4-diaminobutyric acid; L-ornithine; L-lysine (Figure 1)]. The latter compounds were prepared by coupling the succinimido ester $[Ru(bipy)_2(m\text{-OSu})](PF_6)_2$ with the appropriate $^{\alpha}N$-^{t}Boc-protected α,ω-amino acid according to a procedure reported earlier for the lysine derivative $^{\alpha}N$-^{t}Boc-**4a**.[16] Full experimental details will be published elsewhere.[17]

The ^{t}Boc protecting groups of $^{\alpha}N$-^{t}Boc-**1a**−**4a** were removed by acid deprotection in dioxane/HCl.[18] Deprotonation of the amine hydrochloride and subsequent reaction with one equivalent of commercially available $[Cu(phen)(NO_3)_2]$ in methanol yielded the desired complexes **1b**−**4b** (Figure 1). The compounds were isolated as PF_6^- salts from water in approximately 70% yield. Coprecipitated salts can be removed by stirring the complexes with water for one day. However, it is advantageous to use only a small excess (< 5 times) of NH_4PF_6 in order to prevent coprecipitation of ammonium hexafluorophosphate.

^{1}H NMR

Proton-NMR spectroscopy proved to be a valuable tool for structural investigations of the Ru^{II}-Cu^{II} mixed-metal complexes **1b**−**4b**. Binding of the paramagnetic $[Cu](phen)^{2+}$ fragment is easily confirmed by the disappearance of all signals related to the $^{\alpha}CH$ and $^{\beta-\omega}CH_2$ protons of the amino acid moieties.[19][20] In contrast, the resonances of the $[Ru(bipy)_2m]^{2+}$ fragments in **1b**−**4b** are broader than those of the parent compounds **1a**−**4a** but readily observable. This is a consequence of the $1/r^6$ dependence of longitudinal relaxation rates, $1/T_1$, on the distance between protons and paramagnetic centers such as Cu^{2+}.[19]

Most interesting are changes of the signals assigned to the m3 protons of **1b**−**4b** at $\delta \approx 8.96$ (notation see Figure 1). A clear dependence on the Ru−Cu distance is evident as the intensities decrease with the number of methylene spacers, *n*. Assuming fully extended hydrocarbon chains, the Ru−Cu distances can be calculated to range from ca. 13 Å in **4b** to ca. 9 Å in **1b**. We think this model is justified because of the electrostatic repulsion between the positively charged metal centers.

EPR

The EPR spectra of **1b**−**4b** in frozen methanol solutions at 77 K are anisotropic with $g_{||} > g_{\perp} > 2.04$ and large parallel hyperfine splittings ($A_{||} \approx 180 \times 10^{-4}$ cm^{-1}). These values are typical for copper(II) complexes with a $d_{x^2-y^2}$ (or d_{xy}) ground state.[21]

No significant differences are observed between the spectra of **1b**−**4b** (Table 1). This is expected since the copper centers possess identical local environments in these compounds. The spectrum of **3b** is shown in Figure 2 as an example.

Our data compare well with others reported in the literature for copper(II) complexes with square-pyramidal or elongated octahedral coordination geometries.[22] Particularly relevant examples are several ternary phenanthroline-copper(II) dipeptide complexes ($g_{||} \approx 2.24$, $A_{||} \approx 170 \times 10^{-4}$ cm^{-1}).[23] Slightly lower $g_{||}$ values (< 2.20) were found for square-planar complexes.[22] One or two solvent molecules may thus be coordinated to the copper centers of **1b**−**4b** in solution. Elemental analysis data confirm the

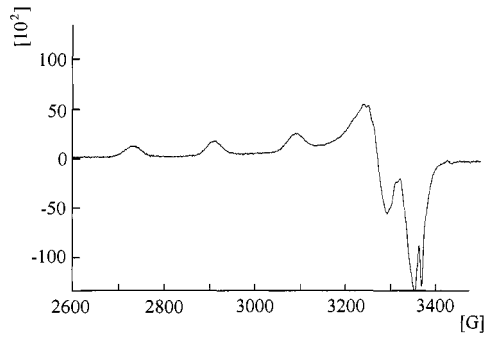
2b	2.268	2.046	179
3b	2.276	2.046	177
4b	2.274	2.049	179

Figure 2. EPR spectrum of complex **3b** in frozen methanol solution at 77 K (DPPH as internal reference)



presence of at least one water molecule in the solid state. The water contents vary from 1−3.5 equiv. after several days under vacuum at elevated temperatures. We propose the solid-state structures shown in Figure 1 with water occupying the apical positions of square pyramidal coordination environments around the copper centers in our complexes. However, the presence of two weakly bound solvent molecules in solution cannot be ruled out and seems likely.

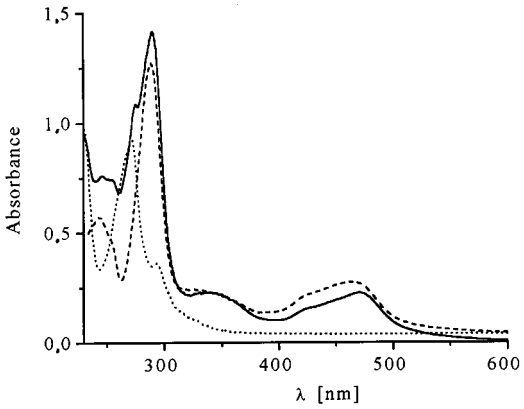
Absorption Spectra

The absorption spectra of **1b**−**4b** in methanol are dominated by the typical features of polypyridineruthenium(II) complexes.[24][25] Most significant is an MLCT band with a maximum at 455 nm and a shoulder at 427 nm. A weak absorption at around 340 nm may be assigned to either an MC[24][25] or an MLCT[26] transition. In the UV region a strong intraligand π-π* band is centered at 288 nm.

The presence of the $[Cu(phen)]^{2+}$ subunit is apparent from a shoulder at 274 nm due to a phenanthroline-based intraligand π-π* transition. A comparison of the absorption spectra in methanol obtained for **3a**, **3b**, and $[Cu(phen)(NO_3)_2]$ is shown in Figure 3. The spectrum of **3b** appears as the sum of the spectra of its constituents, consistent with the absence of any significant ground-state electronic coupling between the two metal centers. In addition, no intervalence charge-transfer absorption bands were observed for **1b**−**4b** in the near-infrared region (ε < 10 for the IT transition). According to the Hush theory[27][28][29] this is further evidence for weak electronic coupling in polynuclear complexes with noninteracting redox centers (class I according to the Robin−Day classification[30][31]).

Similar results were reported in the literature for dinuclear Ru^{II}-Ru^{II} and Ru^{II}-Pt^{II} compounds with bridging alkyl spacers.[32] The amino acid bridges in **1b**−**4b** evidently act as insulators between Ru^{II} and Cu^{II} and thus may be

Figure 3. Absorption spectra of 1.5×10^{-5} M solutions of **3a** [------, λ_{max} (lg ε) = 457 nm (4.24), 287 (4.89), 246 (4.53)], **3b** [——, λ_{max} (lg ε) = 455 nm (4.22), 287 (4.94), 256 (4.64)], and $[Cu(phen)(NO_3)_2]$ [·····, λ_{max} (lg ε) = 294 (4.38), 272 (4.79)] in methanol



considered to play only a structural role. Each complex fragment is therefore expected to keep its essential individual properties. This condition has been discussed to be important for the definition of supramolecular systems[33] and is crucial for the prediction of properties such as DNA binding and cleavage abilities.

Cyclic Voltammetry

The weak coupling between ruthenium(II) and copper(II) in **1b**−**4b** is also evident from electrochemical data (Table 2). Figure 4 shows the cyclic voltammogram (2nd cycle) of **2b** as an example. Two redox couples are observed. One reversible at a half-wave potential of 1.30 V ($\Delta E_P \approx 80$ mV) is typical for the $Ru^{II/III}$ transition in $[Ru(bipy)_3]^{2+}$ derivatives[24][25] and similar to those observed for the mononuclear precursor complexes **1a**−**4a**. The other couple is irreversible and occurs at $E_{1/2} = 0.1$ V ($\Delta E_P \approx 280$ mV). This value is in good agreement with data reported in the literature for other phenanthrolinecopper complexes.[34][36]

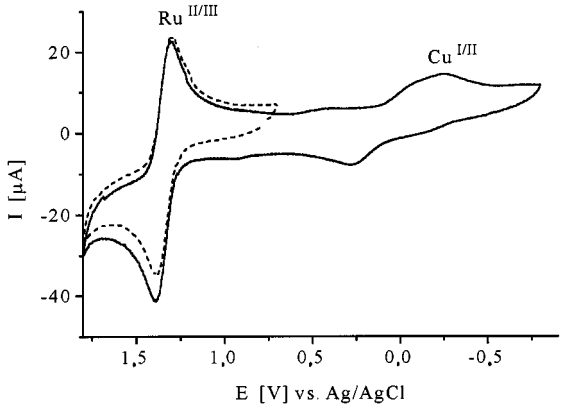
Table 2. Electrochemical data of complexes **1b**−**4b** as measured by cyclic voltammetry[a]

Complex	$E_{1/2}$ [V] (ΔE_P [mV])		
	metal oxidation		ligand reduction
	$Ru^{II/III}$	$Cu^{I/II}$	
1b	1.31 (80)	0.14 (290)	−1.23 (120), −1.45, −1.68 (70)
2b	1.31 (80)	0.10 (280)	−1.23 (100), −1.39, −1.69 (130)
3b	1.30 (90)	0.08 (285)	−1.25 (90), −1.44, −1.66 (130)
4b	1.29 (80)	0.10 (285)	−1.23 (110), −1.44, −1.66 (130)

[a] All measurements were recorded against an Ag/AgCl reference electrode: $E_{1/2,\ Ag/AgCl} = E_{1/2,\ NHE} - 0.222$ V.

The irreversibility of the $Cu^{I/II}$ couple is most likely due to a change in coordination number and stereochemistry upon reduction of Cu^{2+} to Cu^{+}.[22][37][38] This is important since it may impose a kinetic barrier on electron-transfer reactions. It is interesting to note that relatively slow self-exchange rates of 1.5×10^4 M^{-1} s^{-1} have been reported for phenanthrolinecopper complexes.[39] However, an excited-state electron transfer from Ru^{*II} to Cu^{II} in our complexes is possible based on thermodynamic consideration.

Figure 4. Cyclic voltammograms of **2a** (------) and **2b** (——) in CH_3CN



A negative driving force ΔG^0 of -80 kJ mol^{-1} is calculated from the reduction potential E^0_{Red} for $Cu^{I/II}$ (0.10 V), and the excited-state oxidation potential E^{*0}_{Ox} for $Ru^{*II/III}$ (-0.90 V). E^{*0}_{Ox} was obtained according to Equation (1).[40]

$$E^{*0}_{Ox}([M]/[M]^+) = E^0_{Ox}([M]/[M]^+) + E_{0\text{-}0} \quad (1)$$

$E^0_{Ox}([M]/[M]^+)$ is the oxidation potential of the ground-state molecule and E_{0-0} is the one-electron potential corresponding to the energy of the zero-zero transition (2.26 eV). They were determined from the cyclic voltammograms and the intersection between absorption and emission spectra, respectively.

Another characteristic feature of the $Cu^{I/II}$ redox couple is the broad reduction wave at -0.25 V which appears to consist of two unresolved contributions. This is typical for $[(phen)Cu]^{2+/+}$ complexes and has been ascribed to adsorption processes at the glassy carbon electrode.[36] Similar observations have also been reported for several polynuclear ruthenium complexes.[41]

Cyclic voltammetry and absorption spectroscopy both confirm that the individual properties of the two metal fragments are retained in our Ru^{II}-Cu^{II} complexes. No indication for efficient ground-state electronic coupling between the two metal ions was found. The amino acid bridge acts as an insulator and serves only the purpose of connecting the independent constituents. This observation is important for the following discussion of luminescence properties.

Luminescence Quenching Studies

The $[Ru(bipy)_3]^{2+}$-based emission of **1a−4a** is significantly quenched in the presence of $[Cu(phen)]^{2+}$. This is evident from the emission titration curves shown in Figure 5a. Stern−Volmer plots of the data are found to be non linear (Figure 5b). Saturation is observed at higher copper concentrations. It is therefore concluded that luminescence quenching occurs by intramolecular rather than intermolecular mechanisms.[42][43] This was further supported by titration of $[Ru(bipy)_3]^{2+}$ with $[Cu(phen)(NO_3)_2]$ under similar conditions, where no significant luminescence quenching was detectable. As has been discussed in the previous sections the alkyl bridges in **1b−4b** do not mediate efficient electronic interactions between the metal centers. We therefore propose that a bridged outer-sphere quenching mechanism without direct participation of the bridge in either electron- or energy-transfer processes seems most likely. The alkyl bridge is important for keeping the two metal centers together in a "precursor complex" and is therefore crucial for excited-state interactions even though it does not directly facilitate electronic exchange.

It is obvious from Figure 5a that the titration curves have not reached their minima at a Cu/Ru ratio of 1:1. An excess of copper is necessary to achieve maximum luminescence quenching. Since bimolecular processes have been shown to be negligible this must be a consequence of complex dissociation according to the equilibrium shown below.

$$\textbf{1a - 4a} + [Cu(phen)]^{2+} \overset{K}{\rightleftharpoons} \textbf{1b - 4b}$$

Luminescence-quenching studies have been employed earlier for the determination of equilibrium constants, K.[44][45][46] Two requirements have to be met for this approach to be valid. The first is that bimolecular processes do not contribute significantly to the observed quenching, as we have already demonstrated for our compounds. The second is a linear dependence of the observed emission intensities on complex concentrations as shown in Equation (2),

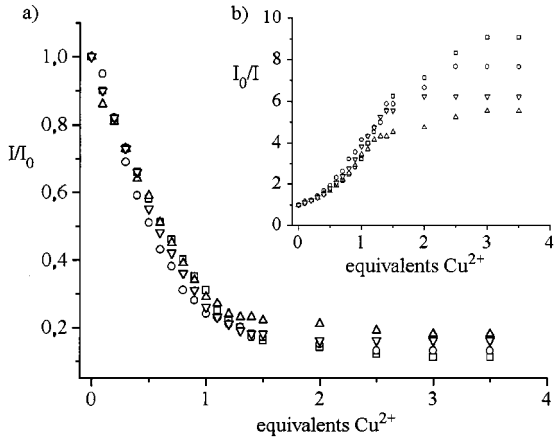
$$I_{obs} = I_{[Ru]} + I_{[Ru\text{-}Cu]} = i_{Ru}\,[Ru] + i_{Ru\text{-}Cu}\,[Ru\text{-}Cu] \quad (2)$$

where I_{obs} is the observed emission intensity, i_{Ru} and $i_{Ru\text{-}Cu}$ are the molar intensities of the mono- and bimetallic species, respectively, and [Ru] and [Ru-Cu] are the concentrations of the respective complexes in solution. The simple equation (2) generally applies if the absorbance of the solution is smaller than 0.05 at the excitation wavelength, λ_{exc}. This was the case in our studies at ruthenium concentrations of 2.5×10^{-6} M or lower. However, we repeated our experiments at several concentrations ranging from 2.5×10^{-6} M to 1.0×10^{-4} M and found no significant deviations for the obtained K values.

The validity of Equation (2) allows emission intensities to be treated similar to absorbances. Thus, Equation (3) can be derived which relates log K and the equilibrium concentration of free $[Cu(phen)]^{2+}$ to experimentally accessible luminescence data.

I_0 and I_∞ are the luminescence intensities at [Cu] = 0 and [Cu] = ∞, respectively. Computer programs have been developed for the treatment of absorbance data. We have employed the program PSEQUAD[47] for our evaluation of equilibrium constants. Emission intensities have been used instead of absorbances. The results are summarized in Table 3. Most significant is the observed lower stability of the diaminopropionic acid derivative **1b** compared to the three other compounds with increased spacer lengths. The obtained log K values follow the order **1b** < **2b** ≈ **3b** ≈ **4b** and are smaller than those reported in the literature for binary

Figure 5. a)Titrations of **1a** (□), **2a** (○), **3a** (△), and **4a** (▽) (2.5×10^{-6} M, 3 equiv. NaOMe, methanol) with $[Cu(phen)(NO_3)_2]$ (2.5×10^{-4} M); intensities are relative to the values obtained at [Cu] = 0. – b) Stern–Volmer plot of the titration curves



$$\log K + \log [Cu]_{eq} = \log \left(\frac{I_{obs} - I_0}{I_\infty - I_{obs}} \right) \qquad (3)$$

copper complexes of amino acids with uncharged side chains such as $[Cu(Ala)]^+$ (log K = 8.15) or $[Cu(Ile)]^+$ (log K = 8.45).[48]

The electrostatic repulsion between the two positively charged metal ions in our compounds apparently results in a destabilization of the complexes. This explains why **1b** is the least stable derivative in the series since it possesses the shortest alkyl spacer. The differences in stability between the other three compounds are insignificantly small within the experimental errors. This may in part be due to the increased flexibility of the bridges allowing the metal fragments to get closer in space. However, the following discussion of quenching efficiencies in **1b–4b** will support the view that the electrostatic repulsion results in a preference of structures with fully extended alkyl chains.

Table 3. Stability constants of complexes **1b–4b** obtained from luminescence spectra in methanol (c[Ru] = 2.5×10^{-6} M) using the program PSEQUAD[47]

Complex	log K
1b	6.76 ± 0.10
2b	7.30 ± 0.15
3b	7.21 ± 0.25
4b	7.32 ± 0.05

Two factors determine the experimentally observed steady-state luminescence intensities at different copper concentrations. The effect of complex stabilities has been discussed in the previous section. The other factor is how efficiently the ruthenium-based emission is quenched in the dinuclear complexes **1b–4b**. Table 4 shows the fraction of **1b–4b**, $x_{Ru\text{-}Cu}$, present in solution at a Ru/Cu ratio of 1:1, together with the corresponding relative luminescence intensities I/I_0 and $(I/I_0)_{100}$ (I = observed steady state emission intensities, I_0 = emission intensity at [Cu] = 0, $(I/I_0)_{100} = I/I_0$ for $x_{Ru\text{-}Cu} = 1$). The relative intensities $(I/I_0)_{100}$ have been calculated from $x_{Ru\text{-}Cu}$ and I/I_0 according to Equation (4).

$$\left(\frac{I}{I_0} \right)_{100} = \frac{\left(\frac{I}{I_0} \right) - (1 - x_{Ru-Cu})}{x_{Ru-Cu}} \qquad (4)$$

Table 4. Luminescence quenching data of complexes **1b–4b**

Complex	x_{Ru-Cu}[a]	I/I_0[b]	$(I/I_0)_{100}$[c]
1b	0.77	0.31	0.10
2b	0.87	0.24	0.13
3b	0.85	0.29	0.16
4b	0.87	0.26	0.15

[a] Fractions of **1b–4b** in solution at [Ru] = [Cu] = 2.5×10^{-6} M. – [b] I = observed emission intensity, I_0 = observed emission intensity at [Cu] = 0. – [c] Calculated value for I/I_0 at $x_{Ru\text{-}Cu} = 1$.

The data shown in Table 4 confirm a dependence of luminescence intensities on the bridge lengths in **1b–4b**. As would be expected intuitively, quenching is most efficient in compound **1b** with the shortest alkyl chain. $(I/I_0)_{100}$ follows the order **1b** < **2b** < **3b** ≈ **4b**. A slightly smaller number is found for **4b** than for **3b**, but the difference is not significant. Interesting in this context are observations made by Osman and Vogler.[49] These authors studied a series of alkyl-bridged naphthalene-Co^{III} complexes. In contrast to our results, photoinduced electron transfer from naphthalene to Co^{III} was reported to be most efficient in compounds with longer alkyl chains. This has been explained by an increased flexibility of the bridges resulting in reduced donor-acceptor distances. The opposite bridge-length dependence in our complexes therefore supports the statement made above that electrostatic repulsion between Ru^{II} and Cu^{II} forces the alkyl chains in **1b–4b** to adopt a fully extended conformation.

Conclusions

We have designed and synthesized the amino acid bridged heterobimetallic Ru^{II}-Cu^{II} complexes **1b–4b** as potential photoredox-active DNA-binding and -cleaving reagents. The studies described in this report served to clarify several important questions concerning fundamental structure-function relationships in the complexes.

We were able to demonstrate that **1b–4b** are typical supramolecular systems, i.e. the metal fragments retain their individual ground-state properties. This is important for the prediction of DNA-binding properties since the two functional sites are expected to follow different patterns. Luminescence quenching in our systems was shown to occur only intramolecularly indicating that the bridge efficiently mediates special interactions between the metal centers. A marked dependence of the stability constants and quenching efficiencies on the amino acid bridge structures of **1b–4b** was found. The data suggest that the electrostatic repulsion between Ru^{II} and Cu^{II} forces the bridges to adopt a fully extended configuration in solution. These results

provide valuable insight into the structural and functional roles of our amino acid ligands in solution.

Further mechanistic investigations will focus on photoinduced electron- or energy-transfer processes, as well as DNA binding and cleavage studies.

The authors gratefully acknowledge financial support from the *Deutsche Volkswagenstiftung* and the *Deutsche Forschungsgemeinschaft* (Habilitandenstipendium for R. A.). We thank Prof. *R. van Eldik* who generously let us share his equipment, laboratory space, and funding. We also thank Prof. *U. Zenneck* and Prof. *H. Kisch*, Universität Erlangen-Nürnberg, for offering EPR and luminescence-spectrometer capacities.

Experimental Section

General Methods: Spectra were recorded with the following instruments: UV/Vis: Shimadzu UV-2101PC. − NIR (acetonitrile solutions): Cary 5G. − IR (KBr pellets): Mattson Polaris FT IR. − Emission: Perkin Elmer LS 50B. − ^{1}H NMR: Bruker Avance DPX 300. All chemical shifts are referenced to residual solvent signals as internal standards previously referenced to TMS, with high-frequency shifts recorded as positive. − ESR: Bruker ESP 300 E. All spectra were recorded at 77 K in frozen methanol. DPPH radical (g = 2.0036) was used to standardize the klystron frequency. − Elemental analysis: Carlo Erba EA 1106. − Cyclic voltammetry was performed with a PAR potentiostat 263 using a three-electrodes cell with glassy carbon working, Ag/AgCl reference and Pt counter electrodes. Acetonitrile solutions of the complexes containing $TBAPF_6$ (10^{-1} M) as supporting electrolyte were used. $E_{1/2}$ values were calculated from half the difference between E_P values for the anodic and cathodic waves from cyclic voltammograms. The ferrocene-ferrocenium couple was observed at 0.45 V (ΔE_P = 88 mV) in acetonitrile under the measurement conditions. − $RuCl_3$ was a donation from Degussa. The synthesis of the $^{\alpha}N$-^{t}Boc-protected (amino acid)ruthenium(II) complexes [{Ru(bipy)$_2$}m-AA-$^{\alpha}N$-^{t}Boc](PF$_6$)$_2$ ($^{\alpha}N$-^{t}Boc-**1a**−**4a**, AA = DAPA, DABA, Orn, Lys) and [{Ru(bipy)$_2$}m-AA] (PF$_6$)$_3$ is described elsewhere.[17] Reagent-grade solvents were obtained from Roth NMR solvents, and all other chemicals, including [Cu(phen)(NO$_3$)$_2$], from Aldrich. Water for preparations was demineralized.

[{Ru(bipy)$_2$}m-AA{Cu(phen)(H$_2$O)}](PF$_6$)$_3$ (AA = DAPA **1b**, DABA **2b**, Orn **3b**, Lys **4b**). − *General Procedure:* A solution of the respective $^{\alpha}N$-protected (amino acid)ruthenium(II) complex [{Ru(bipy)$_2$}m-AA-$^{\alpha}N$-^{t}Boc](PF$_6$)$_2$ in 4 N HCl/dioxane (10 ml) was stirred at 0°C for 1 h. All solvent and excess HCl were removed by rotary evaporation and the residue dried in vacuo overnight. The resulting amine hydrochloride was dissolved in 15 ml of methanol and deprotonated with a solution of NaOMe (1.5 equiv.) in methanol (c = 10^{-1} M). Solid [Cu(phen)(NO$_3$)$_2$] (1.0 equiv.) was added and the suspension stirred at room temperature for 2 h. After the methanol was removed by rotary evaporation, the product was dissolved in 10 ml of water and precipitated with a 1.5-fold excess of NH_4PF_6 in 1 ml of water. The brown-orange suspension was stirred for 2 h and then the precipitate was isolated by filtration, washed three times with small amounts of water and dried in a desiccator over silica gel. The so obtained products contained varying amounts of water.

[{Ru(bipy)$_2$}m-DAPA{Cu(phen)(H$_2$O)}](PF$_6$)$_3$ (**1b**): Yield: 219 mg (78%). − $C_{47}H_{41}CuF_{18}N_{10}O_4P_3Ru \cdot H_2O$ (1409.4·H$_2$O): calcd. [{Ru(bipy)$_2$}m-Lys{Cu(phen)(H$_2$O)}](PF$_6$)$_3$ (**4b**): Yield: 296 mg (68%). − $C_{50}H_{47}CuF_{18}N_{10}O_4P_3Ru \cdot 2.5\ H_2O$ (1451.5·2.5 H$_2$O): calcd. C 40.13, H 3.50, N 9.36; found C 40.05, H 3.26, N 9.21. − ^{1}H NMR (300 MHz, CD_3OD, all signals broad): δ = 2.59 (s, 3 H, m4′-CH_3); 7.34 (s, 1 H, m5′); 7.47 (s, 4 H, b5); 7.60 (s, 1 H, m5); 7.79 (s, 5 H, 4 × b6, m6′); 7.91 (s, 1 H, m6); 8.10 (s, 4 H, b4); 8.66 (s, 5 H, 4 × b3, m3′); 8.95 (d, 1 H, m3). − IR (KBr): ν = 3080 cm^{-1} (m), 2930 (m), 2869 (m), 1650 (s, COO$^-$), 1542 (m), 1465 (m), 1445 (m), 1432 (m), 1312 (m), 1271 (m), 1239 (m), 1107 (m), 842 (vs, PF_6^-), 766 (s), 728 (m), 558 (s). − UV/Vis (CH_3OH): λ_{max} (lg ε) = 455 nm (4.25), 288 (4.96), 255 (4.64).

Titration Curves: Emission titration curves were followed by uncorrected luminescence spectra obtained with a Perkin Elmer LS 50B spectrophotometer (λ_{exc} = 400 nm, λ_{obs} = 500−690 nm). 25 ml of 2.5−10 × 10^{-6} M solutions of the complexes [{Ru(bipy)$_2$}m-AA](PF$_6$)$_3$ in methanol, containing 3.0 equiv. of NaOMe to yield the deprotonated complex form, were titrated with 2.5−10 × 10^{-4} M solutions of [Cu(phen)(NO$_3$)$_2$] in methanol. The solutions were deaerated by bubbling with dry nitrogen for at least 10 min prior to each measurement. The results were evaluated using the program PSEQUAD.[47]

[30] It should be noted out that one of the referees suggested that the intervalence bands for our compounds may appear at higher energies in the visible range of the spectrum where they could be obscured by other absorptions. This is possible since the reorganization energies should be large, as will be discussed in the following section. The compounds would then belong to the Robin−Day class II.

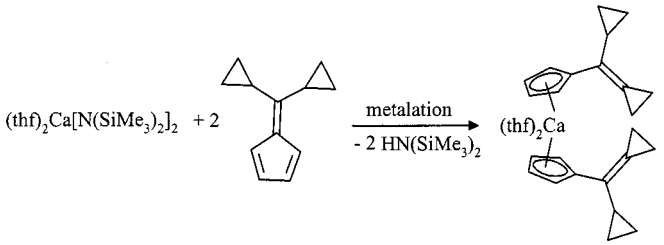
The reaction of *n*/*sec*-dibutyl magnesium with 6-methyl-6-phenyl- and 6,6-dicyclopropylfulvene gives the β-hydride transfer products 1,1′-bis(1-phenylethyl)- and 1,1′-bis-(dicyclopropylmethyl)magnesocene, respectively. The latter crystallizes in the eclipsed conformation, whereas the first one shows an *anti* conformation in the solid state. Dimethylmagnesium deprotonates 6-methyl-6-phenylfulvene with formation of 1,1′-bis(1-phenylethen-1-yl)magnesocene, which decomposes upon isolation. The deprotonation of 6,6-dicyclopropylfulvene with $MgMe_2$ in thf solution yields [bis(tetrahydrofuran-*O*)]iro{cyclopropane-1,2′(1′-η^5-cyclopentadienyl-1′,3′,3′-tricyclopropyl-1′,2′,3′,3a′-tetrahydropenalene)}-3a′-6′-η^2-enyl]magnesium. In the absence of β-hydrogen atoms at the organometallic reagent as well as at the fulvene the addition reaction is the only possible reaction pathway. Thus, one Mg−C bond of $MgMe_2$ adds to tetramethylfulvene to give quantitatively dimeric methylmagnesium ethyltetramethylcyclopentadienide. The bridging methyl groups are sterically shielded against further attack of the fulvene.

The metalation of 6-methyl-6-phenylfulvene with calcium bis[bis(trimethylsilyl)amide] in tetrahydrofuran yields the bis(thf) complex of 1,1′-bis(1-phenyl-1-ethenyl)calcocene.[1] The bis(trimethylsilyl)amides of strontium and barium react in the same manner.[2] Enhancement of the ring strain leads to extended reaction periods. Therefore, the reaction of $(thf)_2Ca[N(SiMe_3)_2]_2$ with two equivalents of 6,6-dicyclopropylfulvene according to Eq. (1) needs several days even at elevated temperatures,[3] however, the yield of 1,1′-bis-(cyclopropylcyclopropylidenemethyl)calcocene is only moderate. The cyclopentadienide fragments and the alkenyl groups show no electronic interaction, free rotation around the C−C bond between these moieties is observed. An addition of the Ca−N bond to the fulvene has never been observed. In contrast to these findings, the addition of methyl lithium to 6,6-dimethylfulvene gives tert.-butylcyclopentadienyllithium,[4] whereas sterically demanding nucleophiles favor the metalation reaction. For example, lithium diisopropylamide metalates (α-deprotonates) fulvenes in tetrahydrofuran to alkenylcyclopentadienyllithium.[5] Erker and coworkers[5g] investigated the dependency of this reaction on the solvent and observed in diethylether a β-hydride transfer from alkyl lithium to the fulvenes. Based on the investigations of Fischer and coworkers[6a] addition reactions of anionic nucleophiles such as methyllithium, potassium diphenylphosphanide or sodium cyclopentadienide to 6,6-dimethylfulvene as well as the corresponding chromium tri(carbonyl) complex were reported by Edelmann et al.[6b][6c]



We were interested in the synthesis of magnesocenes by the reaction of halogen-free magnesium compounds with fulvenes to compare the magnesocenes with the heavier homologues. In contrast to calcium bis[bis(trimethylsilyl)-amide], the homologous magnesium bis(amide)[7] does not react with fulvenes. Although a monomer-dimer equilibrium is observed for $Mg[N(SiMe_3)_2]_2$ in toluene solution,[8a] the X-ray structure reveals the steric shielding of the Mg−N bonds of the dimer in the solid state.[8b] Due to a large cone angle of the bis(trimethylsilyl)amide substituent,[9] even in the monomer the metal center is not accessible to fulvenes. Therefore, we investigated the reactivity of dimethylmagnesium as well as commercially available *n*/*sec*-dibutylmagnesium towards 6-methyl-6-phenyl- and 6,6-dicyclopropylfulvene. The reductive coupling of 6,6-dimethylfulvene with magnesium, calcium or strontium in the presence of a catalytic amount of $HgCl_2$ gives the corresponding *ansa*-alkaline earth metallocenes in a good yield,[10] however, our interest was centered on protonation and deprotonation reactions with fulvenes and we could show that not only the substituents at the fulvene and the

[+] X-ray structure determinations.

metal led to different reaction products but that the size of the alkaline earth metal influenced the reaction pathway.

Synthesis

The reaction of dimethylmagnesium[11] with 6-methyl-6-phenylfulvene yields nearly quantitatively the metalation product 1,1′-bis(1-phenyl-1-ethenyl)magnesocene **1** according to Eq. (2). The ^{1}H- and ^{13}C{^{1}H}-NMR spectra are very similar to those of the heavier homologous alkaline earth metallocenes of calcium,[1] strontium and barium.[2] In Table 1 characteristic resonances are listed in comparison to the corresponding calcocene[1] and lithium derivative.[6] An isolation of **1** failed due to decomposition upon isolation. The use of butyl ligands instead of methyl groups leads to a β-hydride transfer from *n*/*sec*-dibutyl magnesium to 6-methyl-6-phenylfulvene and to the elimination of butene in a good yield. Butene was collected during the reaction and identified by IR spectroscopy. 1,1′-Bis(1-phenyl-1-ethyl)magnesocene **2** is a colorless, moisture-sensitive solid. Freshly prepared magnesium dihydride does not react with fulvenes to give 1,1′-dialkylmagnesocenes, therefore, β-hydride transfer reactions of *n*/*sec*-dibutyl magnesium with cyclic transition states as already known[12] are proposed.

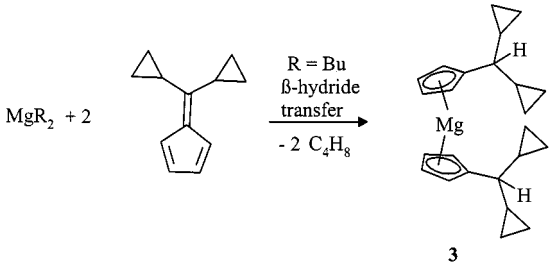
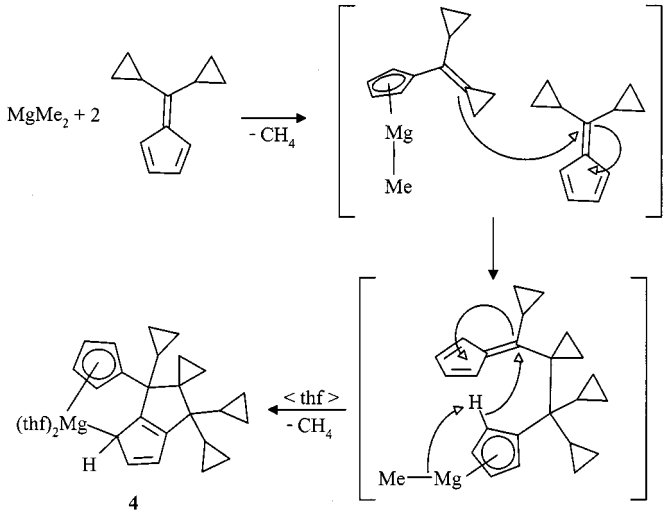
These different reaction behaviors of dimethyl- and dibutylmagnesium allows the synthesis of two different compounds **1** and **2** without impurities stemming from the other reaction type.

To compare the reactivity of dimethyl- and dibutylmagnesium with the reactivity of $(thf)_2Ca[N(SiMe_3)_2]_2$ both the dialkylmagnesium compounds were reacted with 6,6-dicyclopropylfulvene. The calcium derivative metalates the fulvene and 1,1′-bis(cyclopropylcyclopropylidenmethyl)calcocene was isolated.[3] The use of *n*/*sec*-dibutylmagnesium gives quantitatively the β-hydride transfer product 1,1′-bis(dicyclopropylmethyl)magnesocene **3** [Eq. (3)]. Dimethylmagnesium on the other hand reacts with dicyclopropylfulvene in a completely different and unexpected manner. During the reaction methane is eliminated, however, the NMR parameters showed no similarities to the product obtained from the metalation with the above mentioned calcium bis(amide).



Eq. (4) describes the formation of [bis(tetrahydrofuran-*O*)]spiro{cyclopropane-1,2′(1′-η^5-cyclopentadienyl-1′,3′,3′-tricyclopropyl-1′,2′,3′,3a′-tetrahydropentalene)}-3a′-6′-η^2-enyl]magnesium **4** and proposes a reaction mechanism. The first step is the metalation of 6,6-dicyclopropylfulvene as also observed for the reaction of calcium bis[bis(trimethylsilyl)amide] according to Eq. (1).[3] This step is supported by the solvent-dependent studies of Erker and coworkers[5g] who found in tetrahydrofuran a favoring of the α-deprotonation against a β-hydride transfer. The ring strain of the thus formed cyclopropylidene fragment is released by the reaction with another molecule of 6,6-dicyclopropylfulvene. The second methyl nucleophil at the magnesium atom metalates the cyclopentadienyl moiety, a ring closure follows and a bis(cyclopentadienyl)magnesium derivative forms. Due to the enforced orientation of the cyclopentadienyl groups to each other, the aromatic fragments are not coplanar and two thf molecules occupy the coordination gap at the alkaline earth metal center. A rather similar mechanism was suggested to explain the reaction of sodium cyclopentadienide with 6,6-dimethylfulvene.[13]

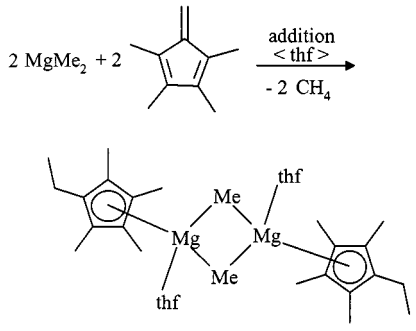
Further enhancement of ring strain during the formation of an alkenyl substituted magnesocene prevents a metalation (α-deprotonation) of the fulvene. Therefore, dimethylmagnesium shows no reaction with cyclopentadienylideneadamantane.[14] The absence of α-CH moieties in the fulvene molecule would enforce another reaction mechanism, because the formation of an alkenylcyclopentadienyl substituent as an intermediate is impossible. Consequently, also 6,6-diphenylfulvene[15] does not react with $MgMe_2$. An-



4

other conceivable reaction pathway would be the addition of a Mg-Me bond to the exocyclic C=C double bond of 6,6-diphenylfulvene, however, this reaction was not observed, probably due to steric reasons.

The reaction of dimethylmagnesium with tetramethylfulvene only allows the addition reaction, because the requirements for a β-hydride transfer reaction as well as for a α-deprotonation of the fulvene are not given. In the presence of Lewis bases such as thf and 1,4-dioxane the addition of one methyl substituent to tetramethylfulvene yields the tetrahydrofuran complex of bis(η^5-ethyltetramethylcyclopentadienyl)dimethyldimagnesium **5**. Due to the coordination of a thf molecule to the metal center and the formation of a four-membered Mg_2C_2 cycle the methylmagnesium moiety is sterically too shielded for an addition reaction to an additional molecule of tetramethylfulvene.



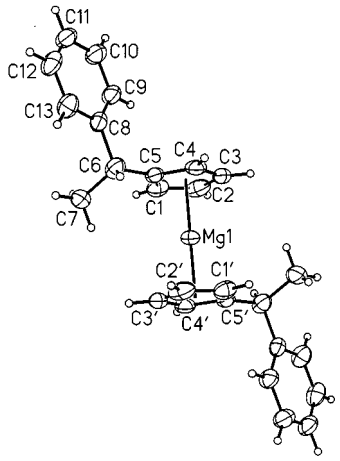
5

Heteroleptic cyclopentadienylmagnesium derivatives are well known since decades. The diethylether and tetrahydrofuran adducts of the halides RMgX are dimeric with a central Mg_2X_2 cycle[16][17] whereas the addition of tmeda yields monomeric complexes.[18] The Schlenk equilibrium interconverts Cp′MgX into magnesium dihalides and magnesocens.[19] Methylmagnesium cyclopentadienide is dimeric via methyl bridges as confirmed by IR spectroscopy,[20] however, diethyl ether leads to a partial cleavage of the dimer, whereas thf and tmeda cleave the methyl bridges completely.[20][21] In contrast to these findings neither the reaction of compound **5** with additional tetramethylfulvene occurs nor redistribution reactions to the homoleptic dimethylmagnesium and the substituted magnesocene are observable even in the presence of Lewis bases such as thf.

Molecular Structures

The alkaline earth metallocenes gained interest not only for their synthetic potential but moreover quite unusual solid state structures[22] led to theoretical investigations.[23] Although numerous magnesocenes are characterized by X-ray structure determinations we describe the molecular structures of **2** to **5**, however, only **2** and **3** show the characteristic sandwich structure. Figure 1 und 2 show the molecular structures and numbering schemes of **2** and **3**, respectively. The crystallographic inversion center in the structure of **2** lies on the magnesium atom and therefore, a *anti*-configuration of the alkyl substituents is enforced (Figure 3). The Mg−C bond lengths differ between 230.0 and 231.6 pm and the distance between Mg and the center Z of the cyclopentadienyl moiety lies at 198 pm. The molecular structure of **3** shows an eclipsed-conformation (Figure 3). This arrangement leads to steric repulsion between the dicyclopropylmethyl groups. As a consequence, the Z1−Mg−Z2 angle of 176.3° shows a small deviation from linearity and furthermore, the deviation from coplanarity of the cyclopentadienyl ligands amounts 4.4°.

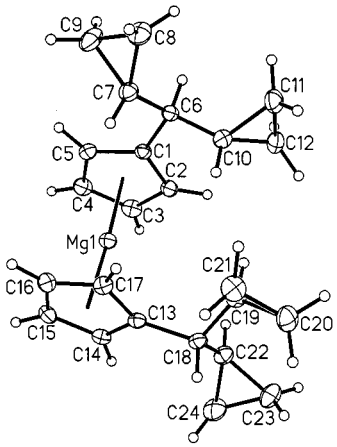
Figure 1. Molecular structure and numbering scheme of **2**; symmetry-related atoms are marked by an apostrophe. Thermal ellipsoids are drawn at a 40% probability level[a]



[a] Selected bond lengths [pm]: Mg1−C1 230.8(2), Mg1−C2 231.5(2), Mg1−C3 231.0(2), Mg1−C4 230.0(2), Mg1−C5 231.6(2), C1−C2 140.5(4), C1−C5 140.8(3), C2−C3 137.9(4), C3−C4 139.0(3), C4−C5 140.0(3), C5−C6 151.3(3), C6−C7 151.2(4), C6−C8 153.1(3).

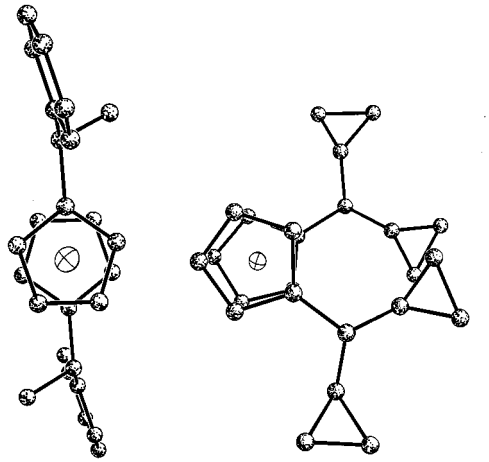
Magnesocene $Mg(C_5H_5)_2$ shows Mg−C distances of 230.4[24] and 233.9 pm[25] in the solid state and the gas phase, respectively. In contrast to the antiprismatic (staggered) conformation in the crystalline state an eclipsed (prismatic) structure is found in the gas phase. A linear arrangement is also observed for 1,1′-di-*tert*-butylmagnesocene[26] with an average Mg−C bond length of 233.6 pm. Intramolecular steric repulsion leads to a bending of hexakis(trimethylsilyl)magnesocene.[27] In contrast to these

Figure 2. Molecular structure and numbering scheme of **3**; thermal ellipsoids are drawn at a 40% probability level[a]



[a] Selected bond lengths [pm]: Mg1−C1 235.7(2), Mg1−C2 232.2(2), Mg1−C3 231.8(2), Mg1−C4 233.1(2), Mg1−C5 234.6(2), Mg1−C13 235.8(2), Mg1−C14 233.9(2), Mg1−C15 231.8(2), Mg1−C16 230.9(2), Mg1−C17 231.8(2), C1−C2 142.7(2), C1−C5 142.4(2), C1−C6 151.5(3), C2−C3 141.3(3), C3−C4 141.0(3), C4−C5 141.1(3), C13−C14 141.7(3), C13−C17 142.6(2), C13−C18 152.2(2), C14−C15 141.4(2), C15−C16 140.2(3), C16−C17 141.9(3).

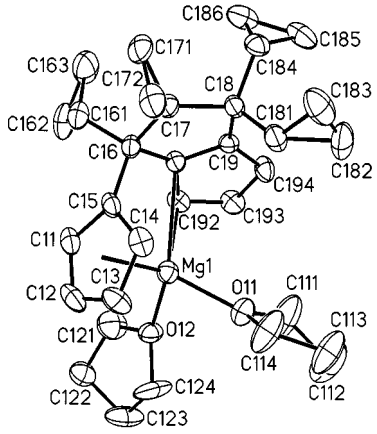
Figure 3. Comparison of the conformations of **2** (left) and **3** (right) with a view perpendicular to the cyclopentadienide ligands; the carbon atoms are drawn with arbitrary radii and the hydrogen atoms omitted for clarity. The magnesium atoms are drawn at a 40% probability level.



monomeric magnesocenes bis(indenyl)magnesium exhibits infinite chains with bridging and terminal indenyl substituents[28] bonded in η^1, η^2, or η^5 fashion.

The asymmetric unit of the crystal structure of **4** consists of two independent molecules. These two molecules are distinguished by the first number $n = 1$ or 2 following the element symbol. Due to the similar constitution the discussion of the molecular structure is limited to the molecule with $n = 1$ shown in Figure 4. The magnesium atom is η^5-bonded to the cyclopentadienyl fragment and the magnesium−carbon distances vary between 237.4 and 252.2 pm. Due to the rather unflexible backbone of the carbdianionic ligand the tetrahydropentalene unit acts as a η^2-bonded substituent with a short Mg1−C192 bond length of 227.2 pm, whereas the distance to the neighboring atom C191 is approximately 40 pm larger. Nevertheless, a delocalization of the double bonds within this five-membered cycle exists because the bonds C19−C191 (137.2 pm) and C193−C194 (139.1 pm) are only approximately 4 pm shorter than the other endocyclic C−C bonds with values of 141.0, 141.8, and 143.7 pm. In this molecule there are three neighboring quarternary carbon atoms C16, C17, and C18. Due to the steric repulsion, the C−C distances of these carbon atoms are unusual large (157.0 and 158.2 pm).

Figure 4. Molecular structure und numbering scheme of **4**; thermal ellipsoids are drawn at a 40% probability level. The hydrogen atoms are omitted for clarity[a]



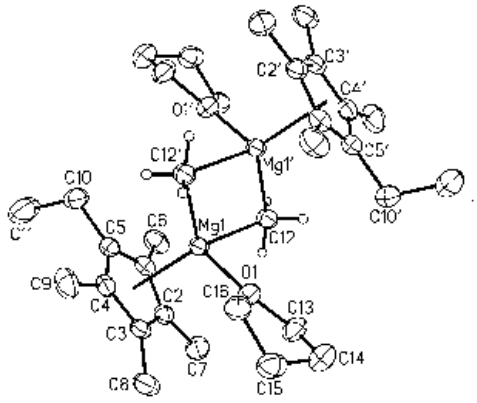
[a] Selected bond lengths [pm]: Mg1−O11 203.7(3), Mg1−O12 204.5(3), Mg1−C11 246.5(5), Mg1−C12 252.2(5), Mg1−C13 247.4(5), Mg1−C14 237.4(4), Mg1−C15 238.7(4), Mg1−C191 265.8(4), Mg1−C192 227.2(4).

The Mg−O bond lengths of 204 pm to the coordinated tetrahydrofuran molecules lie within the characteristic range and depend on the degree of steric strain. They are also influenced by the coordination number of the metal center; a comparison with published data[29] account for four to five-fold coordinated magnesium centers. Moreover, the Mg1−C192 bond length lies in the characteristic range for Mg−C σ bonds of a four or five-fold coordinated metal center[29] as for example in $(Et_2O)_2Mg(Br)CPh_3$ (225 pm[30]) and the anthracenyl derivatives $(thf)_3Mg(An)_2$ (229 pm[30]).

The molecular structure of **5** as well as the numbering scheme is represented in Figure 5. Symmetry related atoms are marked with an apostroph. The isotropic refinement of the methyl hydrogen atoms was successful and therefore, these H atoms are included in Figure 5. Bridging methyl substituents were also found in solvent-free dimethylmagnesium.[31]

Figure 5 shows the dimeric molecule of ethyltetramethylcyclopentadienylmagnesium methanide **5**. The methyl group bridges the magnesium atoms, the Mg−C bonds amount 227.0 and 228.5 pm. In polymeric dimethyl-[31] and diethylmagnesium[32] similar Mg−C distances of 224 and 226 pm were observed by Weiss. The magnesate anion

Figure 5. Molecular structure und numbering scheme of **5**; thermal ellipsoids are drawn at a 40% probability level. Only the hydrogen atoms of the bridging methyl substituents are represented[a]



[a] Selected bond lengths [pm] and angles [°]: Mg1−O1 209.2(2), Mg1−C1 242.7(2), Mg1−C2 246.9(2), Mg1−C3 251.2(2), Mg1−C4 248.4(2), Mg1−C5 243.8(2), Mg1−C12 228.5(2), Mg1···Mg1′ 280.96(12), O1−Mg1−C12 94.22(8), O1−Mg1−C12′ 96.02(8), C12−Mg1−C12′ 103.82(7), Mg1−C12−Mg1′ 76.18(7).

$[Mg_3Me_8]^{2-}$ is best described as a tetramethylmagnesate dianion, where two methyl groups are bridged by $MgMe_2$ units.[33] The central Mg−C bond lengths lie in the expected region of approximately 224 pm, whereas the bonds between the outer magnesium atoms and the bridging methyl groups are more than 10 pm longer. Terminally bonded methyl groups show approximately 10 pm shorter Mg−C bond lengths.[21]

NMR Spectroscopic Characterization

The comparison of the NMR data of **1** with those of 1-phenylethen-1-ylcyclopentadienyllithium[6] and bis(tetrahydrofuran-*O*)calcium bis(1-phenylethen-1-ylcyclopentadienide)[1] shows nearly no dependency on the nature of the metal atom. On the other hand the composition of **1** can be proven by these NMR data which are listed in Table 1. Similar findings also hold for **2** and the corresponding lithium derivative.[6]

A different situation is observed for **4**. Whereas the aromatic CH protons of the cyclopentadienyl moiety of the lithium derivative show an AA′XX′coupling pattern, the ^{1}H-NMR spectrum of **4** is more complicated due to the fixed geometry of this fragment in regard of the rotation around the C−C bond between the cyclopentadienyl and the tetrahydropentalene units. Furthermore, large differences in the chemical shifts of the CH groups of the pentalene fragment are observed. This can be explained by the mainly η^2-coordination of the pentalene unit to magnesium in **4** whereas lithium forms a η^5-complex. The chemical $^{13}C\{^1H\}$ and ^{1}H shifts of the magnesium-bonded fragment (C192 in Figure 4) are δ = 75.1 and 4.6, respectively. The other CH fragments show values of approximately δ = 110 for the carbon (C193 and C194 in Figure 4) and δ = 6 for the ^{1}H nuclei.

The characteristic feature in the NMR spectra of **5** is the high field shift of the bridging methyl groups at δ = −2.1 for the ^{1}H and δ = −18.1 for the ^{13}C nuclei. The dimeric, but thf-free molecule is even present in the gas phase as shown by mass spectroscopy. Regarding the dimeric nature of this compound in solution as well as in the gas phase it is not surprising that the bridging methyl groups cannot add to another equivalent of tetramethylfulvene.

Conclusion

Erker and coworkers[5g] demonstrated the solvent dependency on the reaction of organyl lithiums whether a protonation (β-hydride transfer from alkyl lithium) or a deprotonation (metalation) of the fulvene is favored. Due to the absence of β-hydrogen atoms the alkaline earth metal bis-[bis(trimethylsilyl)amides] of calcium, strontium and barium deprotonate the fulvenes to give alkenyl substituted alkaline earth metallocenes. The corresponding magnesium derivative is not reactive enough to interact with fulvenes. If β-hydrogen atoms are present in dialkylmagnesium as for example in *n*/*sec*-dibutylmagnesium only the β-hydride transfer to the fulvene is observed. Dimethylmagnesium always deprotonates the fulvene, however, the reaction with 6,6-dicyclopropylfulvene proceeds different than the reaction with 6-phenyl-6-methylfulvene, which yields 1,1′-bis(1-phenylethen-1-yl)magnesocene. One of the fulvene molecules is not metalated at the alkyl substituent but in *ortho*-position at the cyclopentadienyl fragment. Thus, the ring strain induced by the formation of a cyclopropylidene moiety is avoided. Now a ring closure reaction gives [bis(tetrahydrofuran-*O*)]spiro{cyclopropane-1,2′(1′-η^5-cyclopentadienyl-1′,3′,3′-tricyclopropyl-1′,2′,3′,3a′-tetrahydropentalene)}-3a′-6′-η^2-enyl]magnesium. Thus far, an addition of an alkyl magnesium moiety to a fulvene is only observed when both the β-hydride transfer to and the deprotonation (metalation) of a fulvene is impossible.

This research was supported by the *Deutsche Forschungsgemeinschaft*, Bonn, and the *Fonds der Chemischen Industrie*, Frankfurt/Main.

Experimental Section

All experiments and manipulations were carried out under argon purified by passage through BTS catalyst and P_4O_{10}. Reactions were performed by using standard Schlenk techniques and dried, thoroughly deoxygenated solvents. The starting materials 6-methyl-6-phenylfulvene,[34] 6,6-dicyclopropylfulvene,[35] and dimethylmagnesium[11] were prepared by literature procedures. − NMR spectra were recorded on the Bruker spectrometers AM200, AC250, and AM400 or Jeol spectrometers GSX270 and EX400. − A Perkin-Elmer Paragon 1000 PC spectrophotometer was used to record the IR spectra; solid substances were measured in nujol between CsBr windows (vs very strong, s strong, m medium strong, w weak, vw very weak, sh shoulder). The frequencies in the region of the nujol vibrations were not listed. − The sensitivity towards moisture and oxygen during the handling of the compounds and the formation of carbides during combustion lead to low carbon values in the elemental analysis. Due to the moisture and air sensitivity of **4** and **5** the elemental analysis gave no reasonable results, even though if crystalline material was used. During handling of these compounds they turned dark and became waxy.

1,1′-Bis(1-phenyl-1-ethenyl)magnesocene (**1**). At 0°C 4.5 ml of 6-methyl-6-phenylfulvene were added to 13.8 mmol of dimethylmag-

nesium dissolved in 20 ml of the solvent mixture of thf, diethyl ether, and 1,4-dioxane. Stirring at r.t. for a few days led to quantitative formation of **1** as could be shown by NMR spectroscopy. The addition of 30 ml of pentane and cooling to 5°C yielded a precipitation of **1**. The nearly colorless precipitate turns dark upon removal of the mother liquor and drying in vacuum. Therefore, we used this solution without further purification or isolation of **1**. The NMR data is summarized in Table 1.

1,1′-Bis(1-phenyl-1-ethyl)magnesocene (**2**). At −30°C 3.3 ml (20.0 mmol) of 6-methyl-6-phenylfulvene were dropped to 10.0 ml of a 1 M solution of dibutylmagnesium in heptane. After complete addition the reaction mixture was stirred for 2 days, till the color changed from orange to bright yellow. The solution was decanted from the precipitate and reduced in vacuum. 2.6 g of compound **2** crystallized as colorless cuboids (72%), m.p. 47−48°C. − ^{1}H NMR (C_6D_6): δ = 1.48 [d, ^3J(H,H) = 7 Hz, Me], 3.85 [q, ^3J(H,H) = 7 Hz, CpC*H*], 5.7−5.9 [m, Cp], 7.0−7.2 [m, Ph]. − ^{13}C{^{1}H} NMR (C_6D_6): δ = 22.92 [Me], 40.05 [Cp-*C*H], 104.95, 105.08, 105.70, 106.56 [*C*H of Cp], 126.20 [*para*-C of Ph], 127.30, 128.58 [*meta* and *ortho*-C of Ph], 129.50 [*ipso*-C of Ph], 147.40 [*ipso*-C of Cp]. − IR (nujol): ν = 1688 cm^{-1} w, 1601 m, 1296 w, 1271 w, 1236 w, 1201 w, 1182 w, 1156 w, 1066 m, 1051 m, 1026 s, 1003 w, 978 m, 917 m, 895 sh, 862 w, 825 s, 768 s, 703 s, 632 w, 617 w, 584 w, 529 m, 504 sh, 452 w. − MS (70 eV); *m/z* (%): 169 (100) [CpCHMePh$^+$], 154 (99) [CpCHPh$^+$], 105 (95) [PhCHMe$^+$], 77 (42) [Ph$^+$]. − $C_{26}H_{26}Mg$ (362.78): calcd. C 86.07, H 7.22; found C 83.88, H 7.20.

1,1′-Bis(dicyclopropylmethyl)magnesocene (**3**). 5.0 ml (30 mmol) of 6,6-dicyclopropylfulvene were added to a cooled solution of 15.0 ml of 1 M dibutylmagnesium in heptane. After stirring for 2 days at r.t. the solution was reduced in vacuum. At 5°C 4.8 g of slightly yellow crystals of **3** precipitated (93%), m.p. 53−54°C. − ^{1}H NMR (C_6D_6): δ = 0.14−0.28 and 0.39−0.54 [m, CH_2], 0.92−1.01 [m, CH of ^{c}Pr], 1.22 [t, ^3J(H,H) = 9 Hz, CpC*H*^{c}Pr$_2$], 6.06 [s, Cp]. − ^{13}C{^{1}H} NMR (C_6D_6): δ = 3.80, 4.15 [CH_2], 17.45 [CH of ^{c}Pr], 47.90 [Cp*C*H^{c}Pr$_2$], 105.53 and 106.04 [CH of Cp], 128.72 [*ipso*-C of Cp]. − IR (nujol): $\tilde{\nu}$ = 1271 cm^{-1} s, 1261 sh, 1216 w, 1201 w, 1163 w, 1110 w, 1057 w, 1043 s, 1030 s, 1019 s, 1011 s, 973 m, 933 s, 916 m, 899 m, 855 sh, 829 s, 778 sh, 769 s, 750 s, 676 w, 530 w, 496 m, 453 m, 426 w, 321 w. − MS (70 ev); *m/z* (%): 158 (31) [Cp-C(C$_3$H$_5$)$_2^+$], 131 (100), 117 (63) [Cp-CH(C$_3$H$_5$)$^+$], 95 (28) [CH(C$_3$H$_5$)$_2^+$]. − $C_{24}H_{30}Mg$ (342.81): calcd. 1.02 g of 1,2,3,4-tetramethylfulvene in *n*-pentane. Stirring at r.t. for 4 d resulted in a yellow solution. Recrystallization from pentane yielded 0.74 g of colorless **5** (75%), m.p. 124°C. – ^{1}H NMR ([D$_8$]THF): δ = −2.08 [s, Mg-Me], 0.90 [t, ^3J(H,H) = 7.6 Hz, CH$_3$ of Et], 1.76 [m, THF], 1.91 [Cp-Me], 1.94 [Cp-Me], 2.42 [q, ^3J(H,H) = 7.6 Hz], 3.60 [m, THF]. – ^{13}C{^{1}H} NMR ([D$_8$]THF): δ = −18.13 [Mg-Me], 10.41 [Cp*C*H$_3$], 10.56 [Cp*C*H$_3$], 15.75 [CH$_3$ of Et], 19.55 [CH$_2$ of Et], 25.44 [THF], 67.35 [THF], 106.70 [Cp], 107.45 [Cp], 114.23 [Cp]. – IR (nujol): ν = 1363 cm^{-1} m, 1339 m, 1310 w, 1293 w, 1242 m, 1182 vs, 1138 sh, 1126 w, 1105 w, 1070 w, 1053 w, 1025 vs, 985 w, 956 w, 944 sh, 927 m, 912 w, 870 vs, 844 m, 675 m, 637 sh, 564 s, 494 s, 429 s, 404 s, 390 sh, 353 sh, 330 s, 295 sh. – MS (70 eV); *m/z* (%): 377 (8) [M$^+$ − 2 THF], 299 (74) [M$^+$ − Cp′ − 2 THF], 285 (91), 269 (92), 149 (100) [Cp′$^+$], 134 (99) [Cp′$^+$-CH$_4$].

X-ray Crystallography.[37] The single crystals were covered with nujol, sealed in thin-walled capillaries and mounted on a diffractometer with graphite monochromated Mo-K_α radiation (λ = 71.073 pm). A Siemens SMART-CCD area detector was used to monitor the reflections. Crystallographic parameters and details of data collection performed at −80°C are summarized in Table 2.

All structures were solved by direct methods with the software package SHELXTL Plus[39] and refined with the program SHELXL-93.[40] Neutral atom scattering factors were taken from Cromer and Mann[41] and for the hydrogen atoms from Stewart et al.[42] The non-hydrogen atoms were refined anisotropically. The H-atoms were refined with a riding model under restriction of ideal symmetry at the corresponding carbon atom. The hydrogen atoms of the bridging methyl substituents of **5** were refined isotropically.

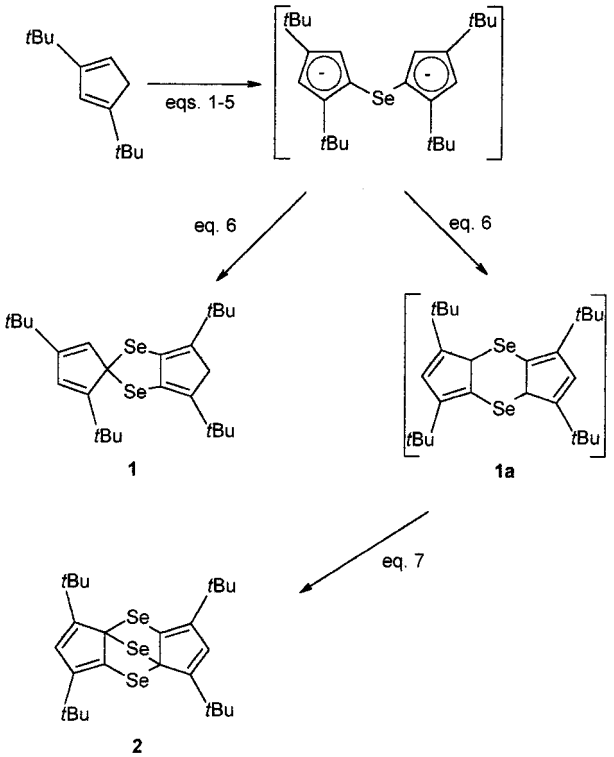
Keywords: Cyclopentadiene / Selenium / Ketal

Reaction of di-*tert*-butylcyclopentadiene with excess potassium *tert*-butoxide in the presence of elemental selenium leads to cyclopentadienes bridged by two or three selenium atoms through one or two diselenoketal functionalities. 2,5,4′,6′-Tetra-*tert*-butyl-5′*H*-spirocyclopentane-1,2′-cyclopenta[*b*][1,3]diselena-2,4-diene (**1**) and 1,3,5,7-tetra-*tert*-butyl-3a,7a-dihydro-3a,7a-*epi*-selenodicyclopenta[*b,e*][1,4]diselenine (**2**) have been characterized by single-crystal X-ray diffraction.

Introduction

We have recently reported that lithium cyclopentadienides substituted by *t*Bu or Me_3Si groups, obtained by deprotonation of the corresponding cyclopentadiene with *n*-butyllithium, insert several equivalents of elemental selenium with formation of lithium cyclopentadienylpolyselenolates[1]. Subsequent in situ disproportionation leads to substituted bis(cyclopentadienyl)selanes, cp'_2Se_n ($n = 1-5$). If *n*-butyllithium is replaced by potassium *tert*-butoxide, a base of low nucleophilicity which itself reacts with elemental selenium and is able to cleave C−Se and Se−Se bonds if present in excess, the reaction pathway changes drastically. The hitherto unknown doubly and triply selenium-bridged cyclopentadienes **1** and **2** are obtained in moderate to good yield in a one-pot reaction. Bridging occurs through a previously unknown cyclopentadiene-centered diselenoketal functionality. Other identified products are labile and could not be isolated, e.g. $(tBu_2C_5H_3)_2Se$[2], which is formed primarily in the initial stages of the reaction, while a small amount of tetra-*tert*-butylpentafulvalene[3] was obtained as deep-red crystals (Scheme 1).

Scheme 1. Synthesis of compounds **1** and **2**



Results and Discussion

The formation of **1** and **2**, although entirely unexpected, can be understood in terms of a sequence of established reactions (Scheme 2).

The main driving force is the successive deprotonation of cyclopentadiene and subsequent insertion of elemental selenium into the formed cyclopentadienide anions (Eqs. 1 and 2). These processes are accelerated in a cascade-like manner owing to the increased acidity of the cyclopentadiene protons that results from the increasing selenium substitution of the cyclopentadiene. Disproportionation of the intermediate cyclopentadienylpolyselenolates leads to selenium-bridged cyclopentadiene species (Eq. 3). Bridges containing more than one selenium atom are known to be increasingly unstable and are degraded by lithium cyclopentadienide (Eq. 4). Repetition of these steps finally affords **1** and **2** (Eqs. 5−7). **1** is generated if bridging occurs with formation of a 1,3-diselenolane heterocycle. If, on the other hand, the postulated heterocyclic intermediate 1,4-diselenane **1a** is formed, an additional deprotonation−insertion−disproportionation sequence leads to **2**. The two *t*Bu groups serve to control the above reactions and thus prevent extensive oxidation and/or polymerization of cyclopentadiene.

The molecular structure of **1** consists of a 1,3-diselenolane heterocycle, which spans between an allylic spiro car-

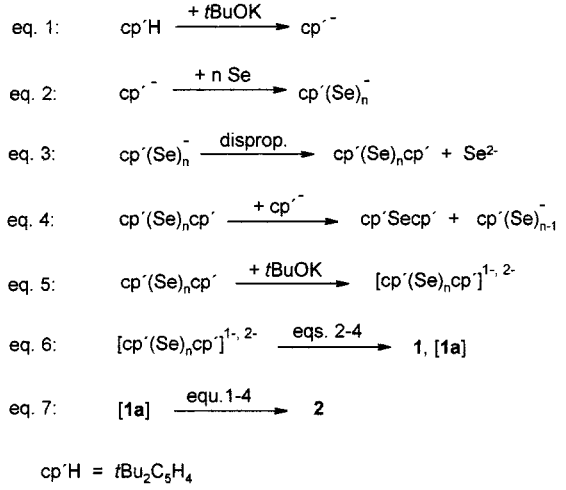
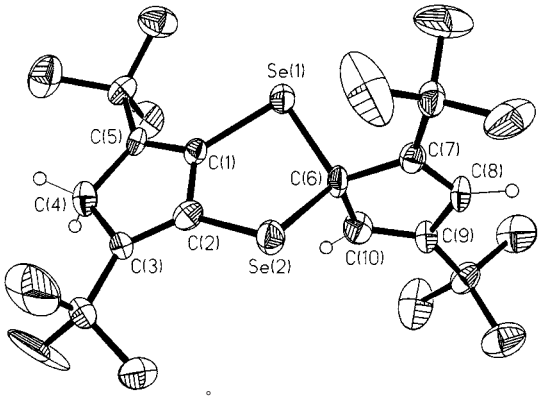
Scheme 2. Proposed reaction steps leading to **1** and **2**



bon atom of the cyclopentadiene bearing the diselenoketal functionality, and the other cyclopentadiene, which is annelated via vicinal vinylic carbon atoms (Figure 1). This results in an almost mutually perpendicular orientation of the two cyclopentadiene rings [interplane angle: 87.7(3)°] and consequently to an optimal staggering of all the *t*Bu groups. The angle at the selenium atoms of 92.5(3)° is comparable to that found in other diorganylselanes such as $[(Me_3Si)_2C_5H_3]_2Se$ (97.9°)[2] and Me_2Se (96.3°)[4] and indicates negligible ring strain. However, the difference between the C(sp²)−Se and C(sp³)−Se bond lengths [1.914 A compared to 1.986 A (mean values)] is striking. The extreme shortening of the former represents a further example of a strong electronic interaction between selenium bound in a vinylic position and the π system of cyclopentadiene[1][2][5][6] (Table 1).

Figure 1. Molecular structure of **1**; anisotropic displacement parameters depicting 50% probability; hydrogen atoms of methyl groups have been omitted for clarity[a]



[a]Selected bond lengths [A] and angles [°]: Se(1)−C(1) 1.915(7), Se(1)−C(6) 1.992(7), Se(2)−C(2) 1.913(7), Se(2)−C(6) 1.980(7); C(1)−Se(1)−C(6) 92.5(3), C(2)−Se(2)−C(6) 92.5(3); interplane angle 87.7(3).

The molecular structure of **2** can be described as a kind of hexagonal pyramid, based on a 1,4-diselenane heterocycle in boat conformation (Figure 2). The unique Se(1) atom is at the top of the pyramid and is common to two 1,3-diselenolane heterocycles, which each bridge the two cyclopentadiene moieties in a similar manner as in **1**. The molecule possesses a twofold symmetry axis which passes through Se(1) and bisects the Se(2)−Se(2a) vector. The key difference between **1** and **2** is that in **2** the allylic positions of both cyclopentadienes are substituted by a diselenoketal functionality. Also in contrast to **1**, there appears to be considerable strain within the heterocyclic framework, as indicated by the extremely acute C−Se(1)−C angle of 82.6(2)°. Nevertheless, the striking difference in the C(sp²)−Se and C(sp³)−Se bond lengths seen in **1** is also seen in **2** [1.888 A compared to 1.985 A (mean values)]. In fact, these are amongst the shortest and longest C−Se bonds ever reported [e.g. 1.879(5) A in TMTSF[7] and 2.018(5) A in 3,3,5,5-tetrakis(trimethylsilyl)-1,2,4-triselenolane[8]] (Table 1). Whereas other cyclopentadienylselenium compounds form $W(CO)_5$ complexes[2][5][9], the multisubstitution of cyclopentadiene with selenium reduces the donor capacity of each selenium and no interaction of **2** with $[(CO)_5W(THF)]$ occurs.

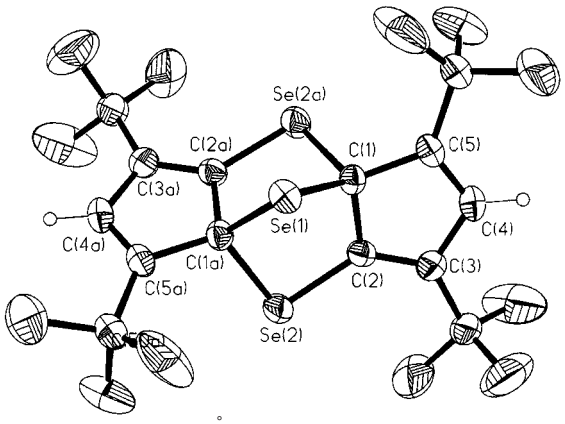
[a] $R1 = \Sigma\|F_o| - |F_c\|/\Sigma|F_o|$. − [b] $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$.

The packing of **2** shows a highly oriented stacking along the *y* axis (Figure 3). This is accomplished by Se−Se interactions between the unique Se(1) of one molecule and Se(2) and Se(2a) of the neighbouring molecule. The former fits into a cavity formed by the latter (Figure 4). The intrastack Se(1)−Se(2, 2a) distances of 3.978 A are almost identical to the Se−Se intrastack distances in selenium-based organic metal superconductors $(TMTSF)_2X$[10]. In contrast to these materials, however, there are no Se−Se interstack interactions in **2**. Attempts at chemical doping have to date been unsuccessful. TCNQ does not interact, while nitrosyl salts react too vigorously with extrusion of elemental selenium.

Figure 2. Molecular structure of **2**; anisotropic displacement parameters depicting 50% probability; hydrogen atoms of methyl groups have been omitted for clarity[a]



[a]Selected bond lengths [A] and angles [°]: Se(1)−C(1) 1.979(3), Se(2)−C(2) 1.888(3), Se(2)−Se(1a) 1.990(3); C(1)−Se(1)−C(1a) 82.6(2), C(2)−Se(2)−C(1a) 89.56(13); interplane angle 57.6(1).

We thank Dr. *L. Call,* Institut für Organische Chemie der Universität Innsbruck, for his assistance in naming **1** and **2** according to the latest IUPAC proposals for the nomenclature of fused and bridged fused ring systems and of spiro compounds.

Experimental Section

General: All reactions were performed under argon by using standard Schlenk techniques. THF was purified and dried according to standard methods. KO*t*Bu and elemental grey selenium were obtained from Aldrich and Fluka, respectively. $t\mathrm{Bu_2C_5H_4}$[11] was prepared as described previously. Flash chromatography was performed on Merck silica gel (Type 60, 230−400 mesh ASTM) with petroleum ether as eluent. − ^{1}H- and ^{13}C-NMR spectra were recorded with a Bruker AC 200 spectrometer. ^{1}H and ^{13}C chemical shifts are referred to solvent signals [$CDCl_3$: (residual $CHCl_3$): $\delta_H = 7.26$; $\delta_C = 77.7$]. − Mass spectra were recorded with a Varian CH-7 instrument.

Preparation of Compounds **1** *and* **2**: KO*t*Bu (3.72 g, 33.1 mmol) was added to a solution of $t\mathrm{Bu_2C_5H_4}$ (1.97 g, 11.1 mmol) in THF (50 ml) at −30°C. After stirring the resulting suspension for 1 h at ambient temp., 2.63 g of grey selenium (33.3 mmol) was added and stirring was continued for a further 12 h. The solvent was then removed in vacuo, 100 ml of petroleum ether was added, and the resulting suspension was filtered through silica gel. Chromatography afforded 0.13 g of tetra-*tert*-butylpentafulvalene (7%) as deep-red crystals, 0.13 g of **1** (5%) as yellow crystals, and 1.28 g of **2** (39%) as yellow crystals. Single crystals of the air-stable compounds **1** and **2** were obtained from Et_2O/MeOH.

C 61.17, H 7.90; found C 61.06, H 7.99.

2: M.p. 211−213°C. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.19 (s, $^1J_{CH}$ = 18 Hz, 9 H, *t*Bu), 1.40 (s, $^1J_{CH}$ = 18 Hz, 9 H, *t*Bu), 6.56 (s, $^1J_{CH}$ = 18 Hz, 1 H, 4-H). − ^{13}C NMR (50 MHz, $CDCl_3$): δ = 29.9 [C(CH_3)$_3$], 32.6 [C(CH_3)$_3$], 35.1 [*C*(CH_3)$_3$], 92.1 (1-C), 131 (4-C), 138 (5-C), 147 (2-C), 154 (3-C). − EI MS (70 eV): *m/z* (%): 588 (100) [M^+], 573 (26) [M^+ − Me], 512 (21) [M^+ − Se]. − $C_{26}H_{38}Se_3$ (587.44): calcd. C 53.16, H 6.52; found C 53.31, H 6.59.

Solution and Refinement of Structures **1** *and* **2**: Crystal data for structures **1** and **2** are given in Table 1. Data were collected with a Siemens P4 diffractometer with Mo-K_α (λ = 0.71073 A) radiation (graphite monochromator) using ω scans and were corrected for Lorentz and polarization effects. An empirical absorption correction based on a series of ψ scans was applied. The structures were solved by direct methods using SHELXS-86[12], and refined by a full-matrix least-squares procedure on F^2 using SHELXL-93[13]. The positions of the hydrogen atoms were calculated and were included in the refinement with isotropic temperature parameters 1.2 or 1.5 times higher than U_{eq} of the carbon atom to which they were attached. The methyl groups of *t*Bu at C(3) and C(7) of **1** are disordered by a rotation of 60° about the C−C(CH_3)$_3$ bond. The ratios of the two possible orientations are almost 5:3 at C(3) and 4:1 at C(7). Figure 2 shows the methyl groups in the major position. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101066. Copies of the data can be obtained free of

Synthesis and Properties of Silver(I) and Copper(I) Helicates with Imine-Bridged Oligobipyridine Ligands

Regine Stiller[+] and Jean-Marie Lehn*

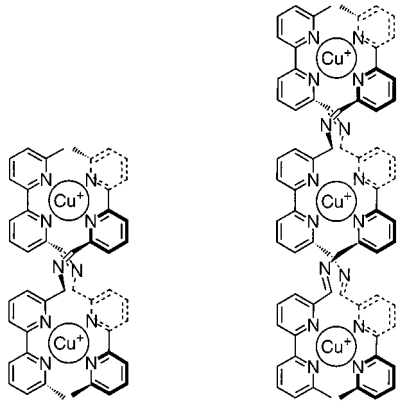
Institut Le Bel, Université Louis Pasteur,
4, rue Blaise Pascal, F-67000 Strasbourg, France

Received February 12, 1998

Keywords: Helicates / Oligobipyridine ligands / Self-recognition / NMR titration / Self-assembly

Oligobipyridine ligands containing one or two imine bridges were found to form double helicates by treatment with copper(I) or silver(I). The properties of the complexes are similar to those of oxapropylene-bridged oligobipyridines. Titration of a mixture of the bis(bipyridine) and the tris(bipyridine) ligands with silver(I) hexafluorophosphate showed that helicates formed with strict self-recognition.

In recent years, the design and study of properties of double and triple helical complexes organized by self-assembly of two or three ligand strands and metal ions to the so-called helicates have been subject to detailed investigations.[1][2][3][4][5][6][7][8] The architectural information is found in the matching between the ligand binding sites and the stereochemical preferences of the metal ion. Complexation of oligo-bidentate strands with tetrahedrally or octahedrally coordinating ions leads respectively to double or triple helices[1][2][3][4][5][][7][8][9]. On the other hand, oligotridentate strands give double or triple helices with octahedrally or nine coordinated ions[2][3][10][11]. The helicate formation with oligobipyridine ligands was found to occur with positive cooperativity[12], self-recognition and self/non-self-discrimination.[1][9] In the case of oligobipyridine ligands, spacers are introduced which separate the different metal-binding centers and dispose them in a suitable way for formation of multinuclear complexes. The features (length, flexibility, constitution) of the spacer separating the 2,2′-bipyridines (bpy) should be such as to allow the helical arrangement around metal ions but hinder the coordination of several binding units to the same metal ion by back-folding of the strand. Several spacers have been tested so far, of which the oxapropylene bridge (CH_2-O-CH_2) was the most studied.[1][2][5] The analogous bridge (CH_2-S-CH_2) did not allow helicate formation perhaps due to the competition of sulfur for Cu^I binding.[13] The ethylene bridge (CH_2-CH_2) permits helicate formation with Cu^I[14][15] whereas the unsaturated bridge (CH=CH) does not because of its rigidity.[16] In continuation of these studies, we report here on the syntheses of two novel oligobipyridine strands **1** and **2** with imine bridges. These ligands contain a rigid double bond and a nitrogen atom as potentially competing binding site, so that it has first to be shown whether helicate formation does occur. This −CH=N− bridge can easily be formed from monomer bpy units bearing amine and aldehyde functional groups in a reversible reaction, thus opening the way to the design of a system which might display self-generation and self-replicating properties.



1-H **2-H**

Synthesis of the Oligobipyridine Ligands 1 and 2

The synthetic precursors for the formation of ligands **1** and **2** were all obtained from 6,6′-dimethyl-2,2′-bipyridine **3** (Scheme 1). After radical NBS bromination to **4** followed by amination with hexamethylene tetramine[17][18] the symmetrical diamine **5** was obtained. For the monosubstituted precursors **10** and **11**, another strategy proved to be more practical. Compound **3** was unsymmetrically functionalized by *N*-oxidation with *meta*-chloroperbenzoic acid[19] followed by rearrangement to acetate **6** and hydrolysis to monoalcohol **7**, which, after activation as monomesylate **8**, was converted into monobromide **9**.[5] The monobromide **9** was then converted into the monoamine **10** with hexamethylene tetramine. Alcohol **7** was also oxidized to monoaldehyde **11** under Swern conditions. The ligand synthesis was completed by Schiff base formation between the

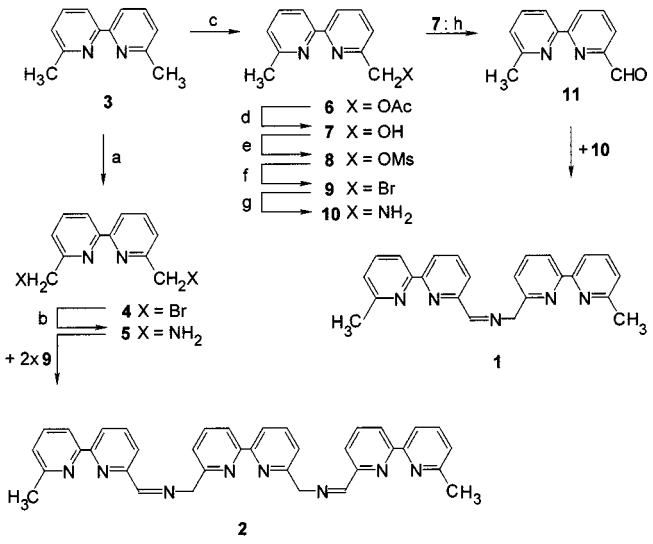
monoaldehyde **11** and either monoamine **10** or diamine **5** to form the dimer **1** or the trimer **2**, respectively.

Scheme 1. Synthesis of the oligobipyridine ligands **1** and **2**



Formation of the Helicates 1-H and 2-H with Ag^I

The helicate complexes of ligands **1** and **2** were formed in situ by stoichiometric addition of the Ag^I salt to the ligands dissolved in CD_2Cl_2 with a minimal amount of CD_3CN. Their helical structure was proved by 500-MHz NMR and 2-dimensional H,H-correlated ^{1}H-NMR spectroscopy (COSY). In line with earlier observations[1][5] helicate formation results in characteristic changes in the NMR spectrum compared to that of the free ligands **1** and **2**. Shifts to lower δ values are observed for the methylene, imine, and methyl protons in the range of $\delta = 0.6-0.8$. As a result of helicate formation, the singlet for the methylene protons of the free ligand is split into an AB system ($J \approx 18$ Hz) because these protons are no longer equivalent in the complex. Furthermore, the singlet for the imine proton is also shifted to smaller δ values and now overlaps with the signals of the aromatic ring protons (compare Figure 3).

The self-assembly of the silver(I) helicates **1-H** and **2-H** was investigated by NMR titration experiments, which were performed by progressively adding a solution of $AgPF_6$ in CD_2Cl_2/CD_3CN (1:1) to a solution of the ligand in CD_2Cl_2 (spectra not shown, compare Figure 3). For trimer **2**, the following changes in the NMR spectrum were observed. Immediately after addition of only 0.28 equiv. of Ag^I with respect to binding sites, the A_2 system of the methylene protons splits into an AB system typical for helicity. Also, the aromatic peaks are significantly shifted up-field. With further addition of Ag^I, the AB pattern is still present, and even with an excess of Ag^I the helix is not destroyed. The dimer helicate is not as stable as the trimer helicate. Titrations of dimer **1** with $AgPF_6$ solution show that in the range of 0.2−0.9 equiv. of Ag^I added, the spectrum only consists of broad signals resulting from fast exchanges. The AB system only appears after addition of exactly one equiv. of Ag^I. On further titration, this signal rapidly converges into an A_2 signal which is shifted upfield (ca 0.7 ppm) compared to the free ligand, indicating that a species different from the helicate or the free ligand is formed. These observations can be explained by dissociation of the helicate structure and fast ligand exchange with the complex(es) formed. This agrees with the following observations: (1) in the new species, the methylene protons give again only an A_2 signal; (2) the imine proton is no longer shielded by the pyridine rings of the second strand, indeed a singlet at $\delta = 8.35$ appears which can be assigned to the imine proton; (3) on further addition of Ag^I the spectrum does not change.

Spectral and Thermodynamic Properties of the Copper(I) Helicates

The UV spectra of the colorless ligands **1** and **2** in dichloromethane as well as their monomers **5**, **10**, and **11** display two intense absorptions around 240 nm and 300 nm attributed to $\pi_2 \rightarrow \pi^*$ and $\pi_1 \rightarrow \pi^*$ by comparison with 2,2′-bipyridine.[20] Upon complexation with Cu^I ions, the $\pi_2 \rightarrow \pi^*$ band is split into several bands and the $\pi_1 \rightarrow \pi^*$ band is slightly red-shifted. Most significant is the appearance of a new band near 450 nm, which is responsible for the red color of the complexes. It can be assigned to MLCT ($Cu^I \rightarrow \pi^*$) transitions typical for pseudotetrahedral $[Cu(a,a'\text{-diimine})_2]^+$ chromophores.[21]

Figure 1. UV spectra for the titration of the bis(bipyridine) ligand **1** with $[Cu(CH_3CN)_4](PF_6)$ in dichloromethane; the amount of salt added increases from 1 to 19

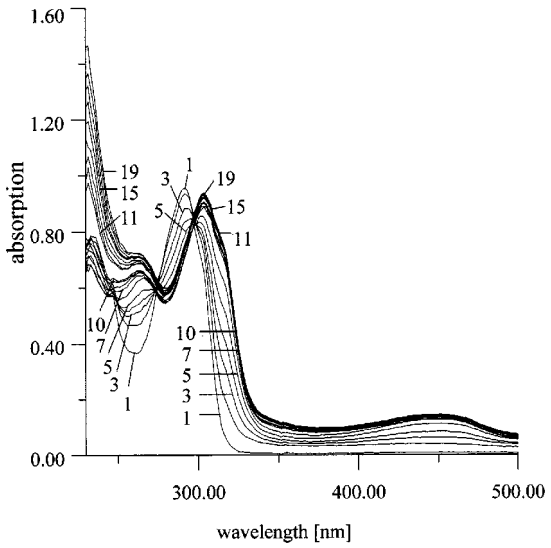


Figure 1 displays the UV spectra of the titration of dimer **1** with $[Cu(CH_3CN)_4](PF_6)$. Two isosbestic points can be distinguished at 299 nm and 273 nm. This indicates that either only two main products exist in solution or that eventual intermediates have the same molar extinction coefficient ε. With increasing Cu^I concentration, the bands for the $\pi \rightarrow \pi^*$ transitions are red-shifted because of complex formation. The absorbance diagram (not shown) for the MLCT band indicates that the final level is reached at a

ratio $c_M/c_L = 1$, which corresponds to equivalency for helicate formation.

The data obtained from the titration spectra were used for the determination of the binding constants with the LETAGROP-SPEFO program.[12a] This program allows the calculation of the binding constants β_{ml} for each species M_mL_l of a proposed model in a non-linear best fit of spectrophotometric data. For the dimer, the following equilibria should be considered:

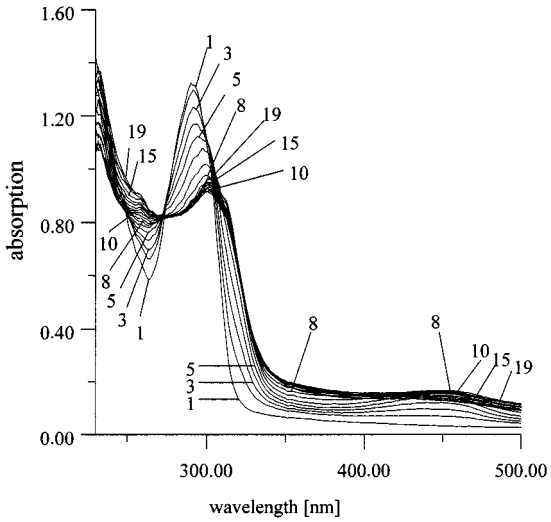
$$M + L \rightleftharpoons ML$$
$$ML + L \rightleftharpoons ML_2$$
$$ML_2 + M \rightleftharpoons M_2L_2$$

The first equilibrium was neglected as its inclusion did not yield satisfactory results. This is reasonable since the formation of a 1:1 complex is unlikely for steric reasons. The log β_{ml} values calculated are in good agreement with those determined for a 4,4′-substituted dimer:[22]

$$\log \beta_{12} = 9.1 \qquad M + 2\,L \rightleftharpoons ML_2$$
$$\log \beta_{22} = 13.05 \qquad 2\,M + 2\,L \rightleftharpoons M_2L_2$$

Titration spectra for the trimer **2** are given in Figure 2. An isosbestic point is found at 273 nm. It should be noted that the absorbance at 450 nm first increases with the concentration of Cu^I as the trimer helicate is formed, but with an excess of more than 1.35 equiv. of Cu^I, it sinks again indicating the destruction of the helicate. This differs from the results obtained for NMR titrations with Ag^I (see above) and may be related to the higher stability of Cu^I versus Ag^I helicates. The ε value of the $\pi_1 \rightarrow \pi^*$ transition decreases much more than in the case of the dimer, and a shoulder develops at 313 nm.

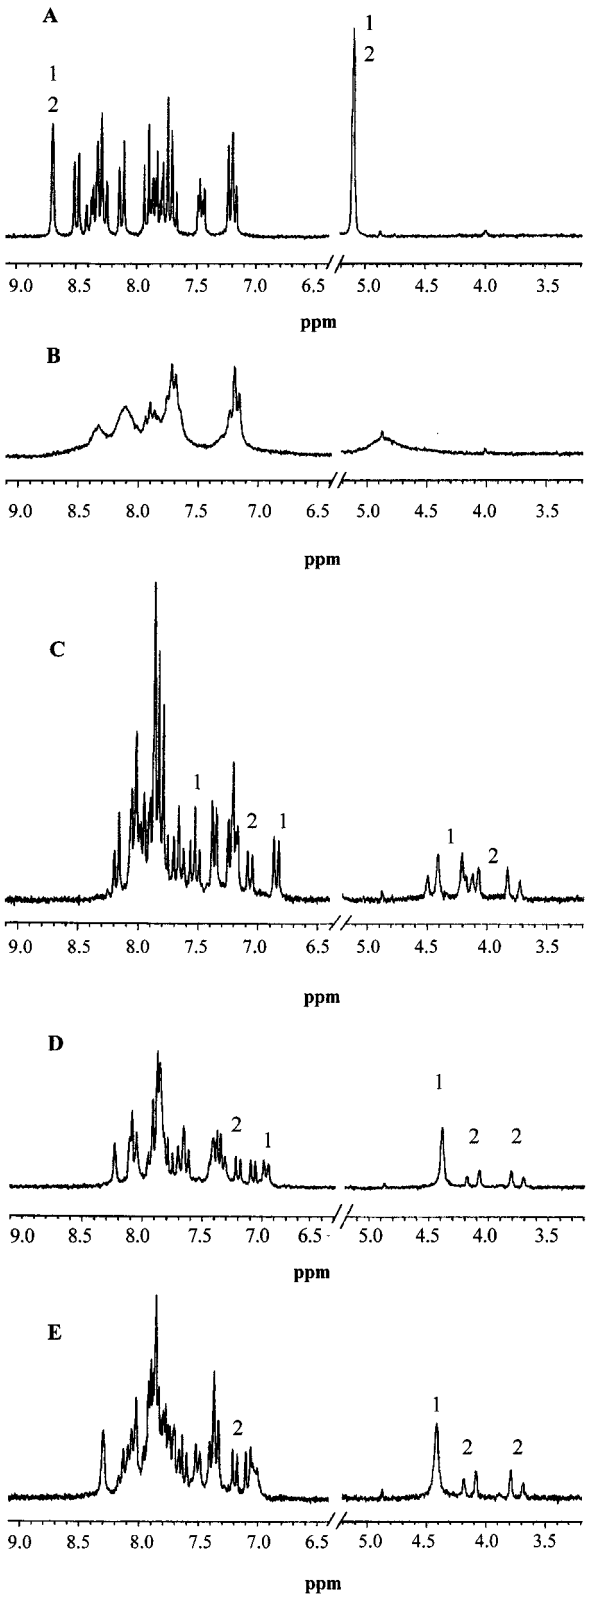
Figure 2. UV spectra for the titration of the tris(bipyridine) ligand **2** with $[Cu(CH_3CN)_4](PF_6)$ in dichloromethane; the amount of salt added increases from 1 to 19



Self-Recognition in the Self-Assembly of the Helicates 1-H and 2-H

It has been found earlier that helicate formation from mixtures of oligobipyridine ligands occurs with self-recog-

Figure 3. 200-MHz ^{1}H-NMR spectra for the titration of ligands **1** and **2** in CD_2Cl_2 with $AgPF_6$ in CD_2Cl_2/CD_3CN (1:1); signals ascribed to the dimer are identified by **1**, those of the trimer by **2**; the following equivalents of Ag^I were added: A−E: 0, 0.2, 0.61, 0.75, 1 equiv. with respect to bipyridine binding sites



nition, each strand assembling with an identical partner.[9] In order to investigate whether this was also the case with the present ligands **1** and **2**, we performed a competition experiment by titrating mixtures of the two compounds. In a vernier mechanism[9][23], two complementary components differing in length aggregate to give linear side-by-side adducts; growth may then continue until the tips of the adjacent aggregates are in register. According to this model, an aggregate of 2 trimers, 3 dimers, and 6 Ag^I ions would form, whereas self-recognition of identical ligands leads to two individual helicate species. A mixture of 1.5 equiv. of dimer **1** and 1 equiv. of trimer **2** in CD_2Cl_2 was titrated with a solution of $AgPF_6$ in CD_2Cl_2/CD_3CN (1:1) and the titration was followed by recording the 200-MHz ^{1}H-NMR spectra (Figure 3). In agreement with titrations of the individual ligands, the singlet for the methylene protons collapsed to a broad signal immediately after addition of Ag^I. At low salt concentration, all signals were broad and badly resolved due to fast exchange. After addition of ca. 0.5 equiv. Ag^I per binding site, helicate formation can be anticipated, and indeed with 0.6 equiv. Ag^I added, two individual AB systems corresponding to the dimer and trimer helicates were clearly resolved. These titration NMR spectra (Figure 3) combine the features of the individual titration spectra indicating strict self-recognition as no new species are found. A polymer resulting from the vernier mechanism would be destabilised by steric interaction in the center of the structure between the methyl groups. On the other hand, its formation is entropically disfavored as the number of particles formed is smaller than in the case of a mixture of helicates. This agrees with the previous results where self-recognition in helicate formation with (CH_2-O-CH_2)-bridged oligobipyridine ligands was observed.[9] The ability to form helicates as well as to perform self-recognition make imine-bridged oligobipyridine strands potential candidates for setting up systems displaying self-generation and self-replication processes.[29]

We thank the *Alexander von Humboldt Stiftung* for a *Feodor Lynen* stipend to R. S. as well as the *CNRS* (URA422) and the *College de France* for financial support. We are also grateful to Dr. *Annie Marquis* for her help in some experiments and measurements and for the binding constants computations.

Experimental Section

General: All solvents were freshly distilled: chloroform from $CaCl_2$; acetonitrile and DMSO from CaH_2; dichloromethane, CCl_4 and TEA from P_2O_5; toluene from Na; THF from Na/benzophenone. Ethyl acetate and solvents used for imine syntheses and UV experiments were filtered through basic alumina before use. Reagents were used without further purification unless otherwise noted. $AgPF_6$ was obtained from Merck. $[Cu(CH_3CN)_4]PF_6$, $[Cu(CH_3CN)_4]BF_4$ and $[Cu(CH_3CN)_4]ClO_4$ were prepared according to a literature procedure.[24] − M.p. (uncorrected): Digital melting-point apparatus (Electrothermal). − UV/Vis: Cary 13 spectrometer. − NMR: Bruker AC-200 and Bruker ARX 500; chemical shifts in ppm rel. to TMS ($\delta = 0$). − 6-Bromo-2-picoline[25], 6,6′-dimethyl-2,2′-bipyridine[26] (**3**), 6,6′-bis(bromomethyl)-2,2′-bipyridine (**4**)[27], 6,6′-bis(aminomethyl)-2,2′-bipyridine (**5**)[18], 6-(hydroxymethyl)-6′-methyl-2,2′-bipyridine (**7**)[19], 6-(bromomethyl)-6′-methyl-2,2′-bipyridine (**9**)[28] were prepared according to literature procedures. Crude monoalcohol **7** was further purified by chromatography [alumina; A: dichloromethane; B: dichloromethane/2% methanol; elution procedure: 700 ml of A, followed by 400 ml of A/B (3:1), followed by 300 ml of A/B (2:1)]. In some cases, crude **7** was partitioned between water (pH = 2−3) and chloroform/hexane (1:1). The water phase containing **7** was neutralized with $NaHCO_3$ and extracted with chloroform. The organic layer was then dried with Na_2SO_4 and concentrated.

Bis(bipyridine) Ligand **1**: 30 mg (0.15 mmol) of monoamine **10** was suspended in 1 ml of acetonitrile. A solution of 30 mg (0.15 mmol) of monoaldehyde **11** in 1 ml of acetonitrile was added slowly. Immediately, a white precipitate formed. The mixture was stirred at room temp. under argon for 2 h. The white precipitate was centrifuged off, washed with acetonitrile, again centrifuged, and dried under vacuum yielding 46 mg of **1** (0.12 mmol, 80%) as a white solid, m.p. 181−182°C. − $C_{24}H_{21}N_5$ (379.18): calcd. Tris(bipyridine) Ligand **2**: 50 mg (0.23 mmol) of diamine **5** was suspended in 2 ml of acetonitrile. A solution of 93 mg (0.47 mmol) of monoaldehyde **11**, dissolved in 3 ml of acetonitrile, was added. The mixture was stirred for 2 h under argon at room temp. The white precipitate was centrifuged off, washed with acetonitrile, again centrifuged and dried under vacuum yielding 96 mg of **2** (0.17 mmol, 72%) as a white solid, m.p. 186−188°C. − $C_{36}H_{30}N_8$ (574.69): calcd. C 75.24, H 5.26, N 19.50; found C 74.21, H 5.25, N 19.50. − FAB-MS: *m/z* calcd. for M^+: 574.3; found for MH^+: 575.1. − ^{1}H NMR (500 MHz, CD_2Cl_2): δ = 8.70 (s, 2 H, imine-*H*), 8.49 (dd, 2 H, aromatic-3^{II}), 8.39 (d, 2 H, aromatic-3^{III}), 8.31 (d, 2 H, aromatic-3^{I}), 8.12 (dd, 2 H, aromatic-5^{II}), 7.90 (t, 2 H, aromatic-4^{II}), 7.84 (t, 2 H, aromatic-4^{III}), 7.74 (t, 2 H, aromatic-4^{I}), 7.47 (d, 2 H, aromatic-5^{III}), 7.21 (d, 2 H, aromatic-5^{I}), 5.11 (d, 4 H, C*H*$_2$), 2.62 (s, 6 H, C*H*$_3$). − ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 164.67 (imine-*C*), 158.34 (C-C), 137.49, 137.18, 123.52, 122.41, 122.29, 121.00, 119.72, 118.25 (C-H), 66.74 (*C*H$_2$), 24.72 (*C*H$_3$). UV/Vis (dichloromethane): λ_{max} (lg ε) = 291 nm (4.68); shoulder (lg ε) = 303 nm (4.55), 247 (4.50).

6-Aminomethyl-6′-methyl-2,2′-bipyridine (**10**): 0.81 g (5.8 mmol) of hexamethylenetetramine was stirred at 40°C in 12 ml of chloroform until everything was dissolved. A solution of 1.32 g (5.6 mmol) of 6-(bromomethyl)-6′-methyl-2,2′-bipyridine (**9**) in 10 ml of chloroform was added slowly. A white precipitate formed immediately. The addition funnel was washed with 3 ml of chloroform and the mixture was refluxed for 2 h. After cooling to room temp., the precipitate was filtered and dried. The solid was refluxed for 2 h at 70°C with a mixture of 11 ml of ethanol, 1.5 ml of water, and 1.5 ml of conc. HCl. The solution was left in a refrigerator overnight. The precipitate was filtered off, the filtrate was concentrated

to give more precipitate. The solids were dried under vacuum, redissolved in a minimal amount of water and adjusted to pH = 13 with 6 N NaOH. The water phase was extracted with dichloromethane (3 × 50 ml), the organic phase was dried with Na_2SO_4, concentrated and dried under vacuum yielding 0.33 g **10** (1.7 mmol, 30%) as a yellow solid. − TLC (Al_2O_3; dichloromethane/2% methanol): R_f = 0.10. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 8.28 (d, 1 H, aromatic H), 8.24 (d, 1 H, aromatic H), 7.76 (t, 1 H, aromatic H), 7.69 (t, 1 H, aromatic H), 7.25 (d, 1 H, aromatic H) 7.16 (d, 1 H, aromatic H), 4.04 (s, 2 H, CH_2), 2.63 (s, 3 H, CH_3), 1.73 (*s*, NH_2). − UV/Vis (dichloromethane): λ_{max} (lg ε) = 239 nm (4.13), 292 (4.34); shoulder (lg ε) = 245 nm (4.11), 283 (4.27), 301 (4.20).

6-Methyl-2,2′-bipyridine-6′-carbaldehyde (**11**): A solution of 2.5 ml of freshly distilled oxalyl chloride in 30 ml of dichloromethane was cooled to −60°C. A mixture of 1.5 ml of DMSO in 6 ml of dichloromethane was added in 10 min and it was stirred for another 10 min at −60°C. A solution of 1.48 g of highly purified 6-hydroxymethyl-6′-methyl-2,2′-bipyridine (**7**) in 12 ml of dichloromethane was added slowly, keeping the temperature at −60°C. The mixture was stirred for 30 min at that temperature. Then, 7.5 ml of TEA was added slowly. After the addition was complete, the mixture was warmed up to room temp. and 30 min later 60 ml of water was added. The organic phase was separated and the water was extracted with dichloromethane (2 × 40 ml). The combined organic phases were washed with 50 ml of brine, dried with Na_2SO_4, and concentrated. The residue was chromatographed [silica gel (2 × 14 cm); A: dichloromethane; B: dichloromethane/2% TEA/2% methanol; elution procedure: 300 ml of A followed by 200 ml of A/B (9:1)]. Recrystallization from ethanol gave 0.31 g of **11** (1.56 mmol, 21%), cream colored solid, m.p. 135−136°C. − TLC (Al_2O_3; dichloromethane/1% methanol): R_f = 0.66. − ^{1}H NMR (200 MHz, $CDCl_3$): δ = 10.16 (s, 1 H, C*H*O), 8.68 (dd, 1 H, aromatic H), 8.34 (d, 1 H, aromatic H), 7.98 (m, 2 H, aromatic H), 7.75 (t, 1 H, aromatic H), 7.22 (d, 1 H, aromatic H), 2.66 (s, 3 H, CH_3). − UV/Vis (dichloromethane): λ_{max} (lg ε) = 287 nm (4.08), 229 (4.15); shoulder (lg ε) = 299 nm (3.92), 253 (3.86).

General Procedure for the Preparation of the Helicate Complexes: Solvents were freshly distilled and filtered through a column of basic alumina and molcular sieves (4 A) before use. Copper(I) salts and silver(I) salts were dissolved in dichloromethane/acetonitrile (1:1). They were stable in solution for several weeks. Complexes were prepared by mixing a solution of the ligand in dichloromethane and adding the proper amount of salt solution (usually 0.5 equivalents per binding site). The complexes were characterized by UV and NMR.

Complexes of the Bis(bipyridine) Ligand **1**

*[Cu_2(**1**)$_2$](ClO_4)$_2$*: UV/Vis (dichloromethane): λ_{max} (lg ε) = 450 nm (3.81), 302 (4.74), 263 (4.62); shoulder (lg ε) = 317 nm (4.62). − FAB-MS: calcd. for $C_{48}H_{42}ClCu_2N_{10}O_4$: 983.17; found for $\{[Cu_2(\mathbf{1})_2](ClO_4)\}^+$: 985.2. − ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 8.55 (d, 1 H, aromatic H), 8.47 (d, 1 H, aromatic H), 8.41 (d, 1 H, aromatic H), 8.24 (d, 1 H, aromatic H), 8.19 (t, 1 H, aromatic H), 8.08 (t, 1 H, aromatic H), 7.96 (t, 1 H, aromatic H), 7.62 (m, 2 H, aromatic H), 7.49 (t, 1 H, aromatic H), 7.36 (d, 1 H, aromatic H), 6.90 (d, 1 H, aromatic H), 4.57 (dd, 1 H, CH_2), 4.32 (dd, 1 H, CH'_2), 2.15 (s, 3 H, CH_3), 1.88 (s, 3 H, CH'_3).

*[Cu_2(**1**)$_2$](PF_6)$_2$*: UV/Vis (dichloromethane): λ_{max} (lg ε) = 451 nm (4.01), 301 (4.84), 267 (4.68), 231 (4.77); shoulder (lg ε) = 317 nm (4.66).

*[Ag_2(**1**)$_2$](PF_6)$_2$*: ^{1}H NMR (500 MHz, CD_2Cl_2): δ = 8.19 (d, 1 H, aromatic-3^{IV}), 8.01 (s, 1 H, imine-*H*), ca. 8.01 (t, 1 H, aromatic-4^{IV}), 7.99 (d, 1 H, aromatic-3^{I}), ca. 7.90 (d, 1 H, aromatic-3^{II}), ca. 7.87 (t, 1 H, aromatic-4^{II}), ca. 7.82 (d, 1 H, aromatic-3^{III}), ca. 7.81 (t, 1 H, aromatic-4^{I}), 7.52 (t, 1 H, aromatic-4^{III}), 7.36 (d, 1 H, aromatic-5^{II}), 7.21 (d, 1 H, aromatic-5^{I}), 7.16 (d, 1 H, aromatic-5^{IV}), 6.84 (d, 1 H, aromatic-5^{III}), 4.46 (d, 1 H, CH_2), 4.17 (d, 1 H, CH'_2), 2.33 (s, 6 H, CH_3). − FAB-MS: calcd. for $[Ag_2(\mathbf{1})_2](PF_6)^+$: 1117.1; found: 1118.7; calcd. for $[Ag_2(\mathbf{1})_2]^{2+}$: 972.1; found: 973.8.

*[Ag_2(**1**)$_2$](*Tf*)$_2$*: ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 8.20 (d, 1 H, aromatic-3^{IV}), ca. 8.01 (m, 3 H, aromatic H/imine-*H*), ca. 7.87 (m, 4 H, aromatic H), 7.52 (t, 1 H, aromatic-4^{III}), 7.42 (d, 1 H, aromatic-5^{II}), 7.20 (d, 1 H, aromatic-5^{I}), 7.15 (d, 1 H, aromatic-5^{IV}), 6.84 (d, 1 H, aromatic-5^{III}), 4.47 (d, 1 H, CH_2), 4.15 (d, 1 H, CH'_2), 2.34 (s, 6 H, CH_3).

Complexes of the Tris(bipyridine) Ligand **2**

*[Cu_3(**2**)$_2$](ClO_4)$_3$*: UV/Vis (dichloromethane): λ_{max} (lg ε) = 450 nm (3.78), 302 (4.71); shoulder (lg ε) = 313 nm (4.66), 260 (4.68). − FAB-MS: calcd. for M^+ ($C_{72}H_{60}Cl_3Cu_3N_{16}O_8$): 1634.15; found 1638.2. − ^{1}H NMR [200 MHz, CD_2Cl_2/CD_3CN (1:1)]: δ = ca. 8.49 (d, aromatic H), ca. 8.14 (m, aromatic H), ca. 8.00 (m, aromatic H), ca. 7.88 (m, aromatic H), 7.62 (t, aromatic H) 7.51 (m, aromatic H), 7.32 (t, aromatic H), 7.16 (d, aromatic H), 7.00 (d, aromatic H), 6.81 (d, aromatic H), 4.12 (d, CH_2), 3.98 (d, CH'_2), 1.95 (s, CH_3).

*[Cu_3(**2**)$_2$](PF_6)$_3$*: UV/Vis (dichloromethane): λ_{max} (lg ε) = 451 nm (4.03)ł 302 (4.80), 231 (4.87); shoulder (lg ε) = 313 nm (4.75), 260 (4.74).

*[Ag_3(**2**)$_2$](PF_6)$_3$*: ^{1}H NMR (500 MHz, CD_2Cl_2): 8.07 (d, 1 H, aromatic-3^{I}), 7.93 (s, 1 H, imine-*H*), ca. 7.88 (t, 1 H, aromatic-4^{I}), 7.86 (d, 1 H, aromatic-3^{II}), 7.65 (t, 1 H, aromatic-4^{II}), ca. 7.61 (d, 1 H, aromatic-3^{III}), 7.47 (t, 1 H, aromatic-4^{III}), 7.13 (d, 1 H, aromatic-5^{II}), 7.02 (d, 1 H, aromatic-5^{I}), 6.74 (d, 1 H, aromatic-5^{III}), 4.44 (d, 1 H, CH_2), 4.32 (dd, 1 H, CH'_2), ca. 1.96 (s, 6 H, CH_3,). − FAB-MS: calcd. for $[Ag_3(\mathbf{2})_2](PF_6)_2^+$: 1762.9, found: 1763.1; calcd. for $\{[Ag_3(\mathbf{2})_2](PF_6)\}^{2+}$: 1614.2, found: 1617.2; calcd. for $[Ag_3(\mathbf{2})_2]^{3+}$: 1469.2, found: 1471.2.

Titration of Ligand **1** *with Ag^I:* 2 mg of dimer **1** (5.3 μmol) was weighed into an NMR tube and dissolved in 0.5 ml of CD_2Cl_2. The solution was then titrated with a 0.125 M $AgPF_6$ solution. NMR spectra were recorded with 70 scans after addition of 7 μl (0.17 equiv.), 14 μl (0.33 equiv.), 19 μl (0.45 equiv.), 24 μl (0.57 equiv.), 31 μl (0.74 equiv.), 37 μl (0.88 equiv.), 42 μl (1 equiv.), 47 μl (1.12 equiv.), 52 μl (1.24 equiv.), 57 μl (1.36 equiv.) 63 μl (1.5 equiv.), 70 μl (1.67 equiv.), 80 μl (1.91 equiv.), 90 μl (2.15 equiv.), 100 μl (2.39 equiv.), 110 μl (2.63 equiv.) and 130 μl (3.11 equiv.) of the Ag^I solution. Equivalents refer to mols of binding site.

Titration of Ligand **2** *with Ag^I:* 4.8 mg of trimer **2** (8.4 μmol) was weighed into an NMR tube and dissolved in 0.5 ml CD_2Cl_2. A solution of AgTf in CD_3CN (78 mM) was prepared. NMR spectra (200 MHz) were recorded with 50 scans after addition of 30 μl (0.28 equiv.), 45 μl (0.42 equiv.), 60 μl (0.56 equiv.), 75 μl (0.7 equiv.), 100 μl (0.84 equiv.), 130 μl (1.12 equiv.), 150 μl (1.31 equiv.), 170 μl (1.50 equiv.), 185 μl (1.64 equiv.) and 205 μl (1.83 equiv.) of the Ag^I solution. Equivalents refer to mols of binding site.

Competition Experiment: 2 mg of dimer **1** (5.3 μmol) and 2 mg of trimer **2** (3.5 μmol) corresponding to 21.1 μmol binding sites were given into an NMR tube and dissolved in 0.75 ml of CD_2Cl_2. The solution was then titrated with a 0.125 M $AgPF_6$ solution. NMR spectra were recorded with 70 scans after addition of successive amounts of Ag^I solution from 7 μl (0.042 equiv.) to 207 μl (1.23 equiv.) in 7−10 μl aliquots. Equivalents refer to mols of binding site, so helicity should be complete after addition of 0.5 equiv.

UV Titration of Ligand **1** *with* Cu^{I}*:* A stock solution of 23.5 μM dimer **1** in dichloromethane was prepared. 1 ml of this solution containing 23.5 nmol of dimer was titrated with a 0.43 mM solution of $[Cu(CH_3CN)_4](PF_6)$ in dichloromethane/acetonitrile (1:1). UV spectra were recorded after addition of successive amounts of Cu^{I} solution from 10 μl (0.18 equiv.) to 260 μl (4.76 equiv.) in 10−15-μl aliquots. Equivalents refer to mols of binding site. Absorption values and spectra were automatically corrected for dilution by an internal ADL program of the Cary spectrophotometer.

UV Titration of Ligand **2** *with* Cu^{I}*:* A stock solution of 28.7 μM of trimer **2** in dichloromethane was prepared. 1 ml of this solution containing 28.7 nmol of the trimer was titrated with a 0.43 mM solution of $[Cu(CH_3CN)_4](PF_6)$ in dichloromethane/acetonitrile (1:1). UV spectra were recorded after addition successive amounts of Cu^{I} solution from 10 μl (0.15 equiv.) to 180 μl (2.69 equiv.) in 10-μl aliquots. Equivalents refer to mols of binding site. Absorption values and spectra were automatically corrected for dilution by an internal ADL program of the Cary spectrophotometer.

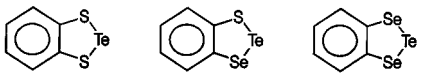
Keywords: Telluroles / Neutralization−reionization mass spectrometry / DFT calculations

2,2-Dichloro-1,3-dichalcogena-2-telluroles of sulfur and selenium, $C_6H_4[XTe(Cl)_2Y]$ with X, Y = S, Se, serve as precursors to generate the cation radicals of 1,3-dichalcogena-2-telluroles $C_6H_4[XTeY]^{+\bullet}$ as well as the corresponding neutral counterparts by means of neutralization-reionization mass spectrometry. These neutral 2-telluroles are intrinsically stable for at least 1 μs in the gas phase. The most abundant fragmentation channel at the neutral and cationic stages is due to loss of atomic tellurium to afford the corresponding benzo-1,2-dichalcogena-cyclobutenes. For the latter, partial isomerization to the related dichalcogena-*ortho*-quinones is indicated by the mass-spectrometric fragmentation pattern.

Fused aromatic ring systems comprise a huge body of heterocyclic chemistry including several natural products, e.g. indole derivatives. Heterocycles containing chalcogens are of particular relevance in redox processes, but knowledge about heteroindenes with several chalcogenes directly attached to each other is limited[1]. In particular, benzodichalcogena-2-telluroles, viz. 1,3-dichalcogena-2-telluraindenes, have not been isolated so far.

Scheme 1

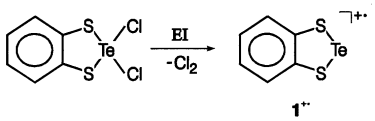


In this contribution, we describe the generation of the ionized and neutral 1,3-dichalcogena-2-telluroles **1**−**3** (Scheme 1) by means of neutralization-reionization mass spectrometry (NR)[2].

Results and Discussion

The cation radicals of the 1,3-dichalcogena-2-telluroles **1**−**3** are readily formed upon electron ionization (EI) of the corresponding 2,2-dichlorides, as shown in Scheme 2 for the dithia compound. The ease of one-electron oxidation of 1,2,3-trichalcogenoles has been demonstrated previously,[1] but the mass spectra do not reveal whether two chlorine atoms or molecular chlorine is lost from the precursors upon ionization. Thermal dechlorination appears unlikely, however, because $Cl_2^{+\bullet}$ is hardly observed in the EI mass spectra. None of the precursors yields a significant signal for the respective molecular ion of the corresponding dichloride, while weak isotope patterns for the monochloro derivatives were observed.

Scheme 2



The metastable ion (MI) and collisional activation (CA) mass spectra of the cation radicals $\mathbf{1}^{+\bullet}$−$\mathbf{3}^{+\bullet}$ (Table 1) are dominated by loss of atomic tellurium (Δm = 130) yielding the corresponding $C_6H_4XY^{+\bullet}$ cations (X, Y = S, Se), while loss of neutral C_6H_4XY concomitant with $Te^{+\bullet}$ is hardly observed. Location of the positive charge on the organic fragment can be accounted for by the fact that already the dithiete $C_6H_4S_2$ has an ionization energy (IE) of ca. 8.2 eV[3] which is significantly lower than that of atomic Te (IE = 9.0 eV)[4]; thiaselenete C_6H_4SSe and diselenete $C_6H_4Se_2$ are expected to have IEs even lower than 8.2 eV. Additional fragmentation channels of the cation radicals are due to bond cleavages involving the other chalcogene atoms, while degradation of the hydrocarbon backbone is negligible. Interestingly, also losses of the chalcogene dimers S_2, SeS, Se_2, TeS, and TeSe, respectively, are observed to some extent. The three former of these fragments indicate the possible occurrence of some rearrangements prior to fragmentation because the connectivities of these diatomic entities are not contained in the precursor molecules (see below).

In neutralization-reionization (NR) mass spectrometry, fast-moving ions are subjected to a double-collision event in which first the ion is neutralized, then any remaining ions are deflected, and subsequently the neutrals are reionized

Table 1. Mass differences (Δm in amu) in metastable ion (MI) and collisional activation (CA) mass spectra of $\mathbf{1}^{+\bullet}-\mathbf{3}^{+\bullet}$ (data are given as percentages of the base peak)[a]

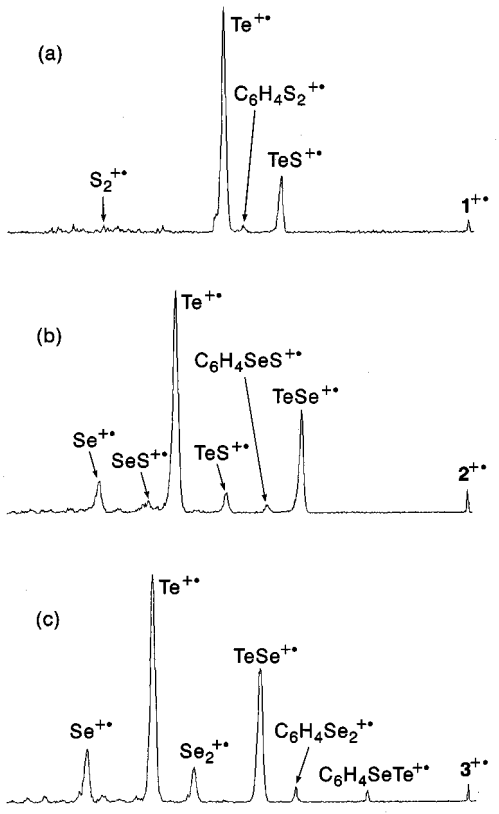
Δm (amu)[b] neutral lost[c]		−32 S	−64 S_2	−80 Se	−108 C_6H_4S	−112 SeS	−130 Te	−156 C_6H_4Se	−160 Se_2	−162 TeS	−194 TeS_2
$\mathbf{1}^{+\bullet}$	MI		3				100				
	CA	3	10		5		100		8	2	1
$\mathbf{2}^{+\bullet}$	MI			4			100			1	
	CA	2		12	15	8	100	3		4	
$\mathbf{3}^{+\bullet}$	MI			10			100		3		
	CA			15			100	8	3		

[a] For the sake of clarity in the MI spectra intensities of less than 1% are omitted, and for the CA spectra only the leading fragments are given. − [b] All data refer to the most abundant isotopes ^{32}S, ^{80}Se, and ^{130}Te, respectively. − [c] Some of the neutrals may also arise from multiple fragmentations, e.g. $\Delta m = 206$ may either correspond to loss of intact C_6H_4Te or to consecutive losses of Te and C_6H_4.

to allow for conventional mass-spectrometric detection[2]. Often, xenon is used as a collision gas for the neutralization of cations having kinetic energies in the keV range. For $\mathbf{1}^{+\bullet}-\mathbf{3}^{+\bullet}$, however, no recovery signals due to the reionized neutrals **1**−**3** are detectable when xenon is used for neutralization of the cation radicals, while recovery signals are observed when other collision gases are used. Target gas effects in NR mass spectrometry have been analyzed by Holmes[5] and have been associated with the thermochemistry of the neutralization step. In analogy to other heteroindenes, we can certainly estimate that the ionization energies of **1**−**3** are below 8 eV. Thus, due to the high ionization energy (IE) of xenon (12.1 eV), electron transfer from xenon to the cation radicals $\mathbf{1}^{+\bullet}-\mathbf{3}^{+\bullet}$ is highly endothermic and requires a large amount of energy transfer in the collision. As a consequence, the Franck−Condon factors for neutralization are unfavorable and fragments prevail the NR mass spectra instead. Therefore, we have examined some other collision gases for which electron transfer to the cation radicals $\mathbf{1}^{+\bullet}-\mathbf{3}^{+\bullet}$ is less endothermic, and the best results were obtained using cyclopropane (IE = 9.9 eV) and trimethylamine (IE = 7.8 eV), respectively.

The NR spectrum of $\mathbf{1}^{+\bullet}$ is dominated by signals due to $Te^{+\bullet}$ and $TeS^{+\bullet}$ (Figure 1a), but an unambiguous signal due to the reionized neutral parent is also detected. Similarly, recovery signals for the reionized neutral counterparts are present in the NR spectra of $\mathbf{2}^{+\bullet}$ and $\mathbf{3}^{+\bullet}$ along with $Te^{+\bullet}$, $TeS^{+\bullet}$, and $TeSe^{+\bullet}$ fragments (Figures 1b and 1c). The mere observation of the recovery signals implies that in the gas phase the neutral 1,3-dichalcogena-2-telluroles **1**−**3** correspond to stable species which can survive the flight time between the neutralization and the reionization events (about 1 μs). Although this time interval appears to be short, these telluroles can be considered as being long-lived as far as unimolecular processes are concerned, because the microsecond range is likely to allow for energy distribution over all internal modes. In addition to the recovery signals, several fragment ions are observed which are in accord with the structures **1**−**3** as deduced from the connectivities of the corresponding 2,2-dichlorides used as precursors. Note that the weak, but yet significant loss of atomic Se in Figure 1c points toward the formation of the hitherto unknown benzoselenatellurete, C_6H_4SeTe, from **3**.

Figure 1. NR mass-spectra (trimethylamine/O_2, both 80% *T*) of *B*(1)-mass-selected $C_6H_4\{XTeY\}^{+\bullet}$ cation radicals generated by electron ionization of (a) $C_6H_4\{STe(Cl)_2S\}$, (b) $C_6H_4\{STe(Cl)_2Se\}$, and (c) $C_6H_4\{SeTe(Cl)_2Se\}$



One particular series of fragments in the NR spectra should, however, be discussed in some more detail. Thus, the CA and NR spectra of $\mathbf{1}^{+\bullet}-\mathbf{3}^{+\bullet}$ show weak, but yet distinct signals due to the $S_2^{+\bullet}$, $SeS^{+\bullet}$, and $Se_2^{+\bullet}$, respectively, which are *not* in keeping with the proposed connectivities, because these do not contain S−S, Se−S, and Se−Se bonds, respectively. The most pronounced signal in this respect is the $Se_2^{+\bullet}$ fragment in the NR spectrum of $\mathbf{3}_3^{+\bullet}$ (Figure 1c).

Conceptually, there exist at least two possible scenarios − occurring either at the cationic or the neutral stage − which can account for this result. Route ⓐ involves re-

arrangement of the 2-telluroles (X, Y = S, Se) to the corresponding 1-telluroles **4** and subsequent formation of XY. In contrast, route ⓑ involves a stepwise fragmentation in which first atomic tellurium is lost to yield the dichalcogeno-*ortho*-quinones **5** which may rearrange via X−Y bond formation to bicyclic **6** from which XY can subsequently be formed. In order to get a handle for the distinction of these routes, we have examined the $C_6H_4XY^{+\bullet}$ cation radicals (X, Y = S, Se) which are also formed upon electron ionization of the dichloro telluroles used as precursors for $\mathbf{1}^{+\bullet}$−$\mathbf{3}^{+\bullet}$.

Scheme 3

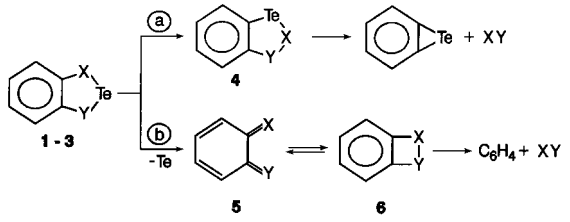


Figure 2. NR mass-spectra (cyclopropane/O_2, both 80% *T*) of *B*(1)-mass-selected $C_6H_4XY^{+\bullet}$ cation radicals generated by electron ionization of (a) $C_6H_4\{STe(Cl)_2S\}$, (b) $C_6H_4\{STe(Cl)_2Se\}$, and (c) $C_6H_4\{SeTe(Cl)_2Se\}$

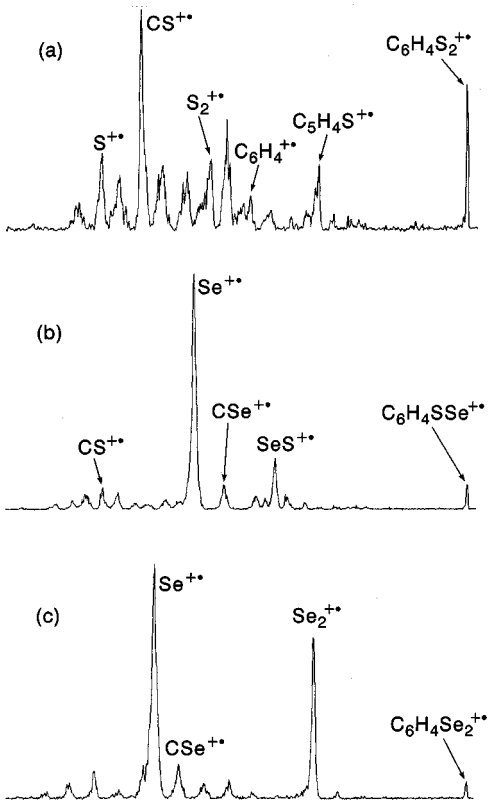


Besides sizable recovery signals, the NR spectra of these $C_6H_4XY^{+\bullet}$ ions show numerous fragments. In fact, the particularly rich fragmentation pattern in the NR spectrum of $C_6H_4S_2^{+\bullet}$ (Figure 2a) can account for the seemingly noisy low-mass region in the NR spectrum of $\mathbf{1}^{+\bullet}$ (Figure 1a) in that this is due to the many fragments formed upon reionization of neutral $C_6H_4S_2^{+\bullet}$. Notwithstanding, all three ions give rise to the corresponding signals due to formation of XY according to route ⓑ in Scheme 3.

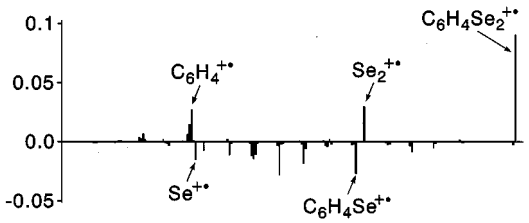
Neutral benzodithiete $C_6H_4S_2$ has previously been examined by matrix isolation methods as well as photoelectron spectroscopy[3][6]. These studies have provided strong evidence for the existence of benzodithiete (**6**; X, Y = S), whereas contribution of the dithioquinone structure **5** (X, Y = S) was excluded[7]. Similarly, several substituted 1,2-dichalcogenacyclobutenes of sulfur and/or selenium have been characterized by various means[8][9]. Nevertheless, trapping reactions of dithiete with appropriate dienophiles led to cycloaddition products consistent with the formation of transient **5** (X, Y = S)[3].

Qualitatively, the NR spectra lead to a similar conclusion in that formation of the dichalcogenes XY is consistent with **6**, while the signals due to CS and/or CSe losses point towards **5**. Thus, for $C_6H_4S_2^{+\bullet}$ (Figure 2a), the loss of neutral CS and the complementary signal due to reionized CS can be considered to be indicative for the quinone structure **5** (X, Y = S), while the $S_2^{+\bullet}$ fragment is in keeping with structure **6**. The ratios of the corresponding (CX + CY) versus XY fragments decrease from ca. 3:1 for X, Y = S (Figure 2a), to about 1:1 for X = S, Y = Se (Figure 2b) and ca. 1:8 for X, Y = Se (Figure 2c). This trend can be interpreted in the sense that the bicyclic structure **6** is favored over **5** the more Se is incorporated. Moreover, the increasing abundance of the XY fragments going from X, Y = S to X, Y = Se provides a rationale for the $XY^{+\bullet}$ signals in the NR spectra of $\mathbf{1}^{+\bullet}$−$\mathbf{3}^{+\bullet}$ by involving route in Scheme 3. In fact, the low-mass parts of the NR spectra shown in Figure 1 can by and large be represented by a superposition of the NR spectra of the C_6H_4XY fragments with that of atomic Te.

In order to distinguish at which stage of the experiment formation of XY from C_6H_4XY takes place, we subjected $C_6H_4Se_2$ to some additional experiments because the corresponding fragment $Se_2^{+\bullet}$ is most pronounced in Figure 1c. In the MI spectrum of $C_6H_4Se_2^{+\bullet}$, loss of atomic Se leading to $C_6H_4Se^{+\bullet}$ is observed almost exclusively (100%). Formation of $Se_2^{+\bullet}$, as the only other fragment, is very minor (3%) and may be due to collisional activation with residual gas in the high-vacuum device. In fact, the 100:3 ratio of $C_6H_4Se^{+\bullet}$ and $Se_2^{+\bullet}$ becomes 100:30 upon collisional activation; in addition, a series of other fragments is formed among which $C_6H_4^{+\bullet}$ is most intense (8%). Accordingly, the fragmentation of the cation via route ⓑ in Scheme 3 can in part account for the $Se_2^{+\bullet}$ signal in the NR spectrum of $\mathbf{3}^{+\bullet}$, but nevertheless, the cation route cannot be a major route because otherwise also $C_6H_4Se^{+\bullet}$ must be much more intense. Accordingly, isomerization via route ⓐ of Scheme 3 can only be neglected, if Se_2 can be formed at the neutral stage. Conventional mass spectrometry cannot provide distinct information about the neutral's reactivity, but some variants of the NR method can be applied[10d]. One of the most sensitive and also straightforward approaches in this respect represents the NIDD method[10] which is based on the comparison of two different ways to accomplish two-

electron transfer either from an anion to a cation or vice versa. To this end, charge reversal (CR)[11] and NR mass spectra are compared with each other. In brief, the resulting NIDD spectra reflect the reactivity of the neutral species, and the scheme is defined as such that reactions occurring at the neutral stage appear as positive peaks, while processes

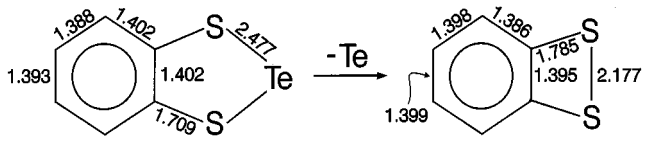
Figure 3. NIDD mass spectrum of *B*(1)-mass-selected $C_6H_4Se_2^{-\bullet}$ anion radicals generated by electron ionization of $C_6H_4\{SeTe(Cl)_2Se\}$ in the negative mode; note that reionization leads to cations; the NIDD spectrum was obtained by subtracting the normalized ion intensities in the CR mass spectrum (O_2, 80% *T*) of $C_6H_4Se_2^{-\bullet}$ from those in the corresponding NR mass spectrum (O_2/O_2, each 80% *T*); for further details of the NIDD method, see ref.[10]



taking place in the ionic stage give rise to negative signals.

The NIDD spectrum of the $C_6H_4Se_2^{-\bullet}$ anion radical (Figure 3) shows three prominent signals at the positive scale, i.e. an intense recovery signal due to neutral counterpart reionized to the cation radical and signals due to reionized Se_2 and C_6H_4. As the latter two fragments are complementary to each other and appear on the positive scale, this observation identifies the occurrence of the reaction $C_6H_4Se_2 \rightarrow C_6H_4 + Se_2$ at the neutral stage. Accordingly, route ⓑ in Scheme 3 can account for the observation of $Se_2^{+\bullet}$ in the NR spectrum of $\mathbf{3}^{+\bullet}$, and although we cannot definitively rule out the isomerization to **4**, there is no need to invoke it. Further, we may assume that the anion radical $C_6H_4Se_2^{-\bullet}$ has an open structure similar to **5** (X, Y = Se), such that the formation of the Se_2 fragment indicates rearrangement to the bicyclic benzodiselenete at the neutral stage.

Figure 4. Calculated structures of C_{2v}-symmetrical **1** and **6** (X, Y = S) using the B3LYP method (bond lengths in A); for the sake of clarity, the hydrogen atoms are left out (all C−H bond lengths are close to 1.085 A)



In order to assess the stability of the neutral 2-telluroles, we briefly examined the thermochemistry of the reaction **1** → Te + **6** (X, Y = S) by ab initio methods using the B3LYP method (Figure 4). The calculated structures are consistent with the description of **1** as 1,3-dithia-2-tellurole and formation of benzodithiete upon loss of tellurium. Both species exhibit singlet ground states and the similarity of the C−C bond lengths in the carbon skeleton suggest that these systems maintain aromaticity without any tendency for bond localization. At the B3LYP level of theory we could not locate **5** (X, Y = S) on the singlet surface, but a low-lying triplet state of **5** (X, Y = S) was found which is only about 15 kcal/mol less stable than singlet **6** (X, Y = S). Interestingly, the endothermicity associated with loss of tellurium from neutral **1** is predicted to be as small as 43 kcal/mol. This rather low value is consistent with loss of atomic Te as a low-lying fragmentation channel at the neutral stage and thus can account for the intense signals due to atomic Te present in the NR spectra. As we may expect that the reactions **1** → Te + **6** are even less endothermic when selenium is involved, the computational results add further confidence to the assignment of route ⓑ as the origin for the formation of $S_2^{+\bullet}$, $SeS^{+\bullet}$, and $Se_2^{+\bullet}$ under the experimental conditions.

Conclusions

Neutral 1,3-dithia-, 1-selena-3-thia-, and 1,3-diselena-2-telluroles can be generated by one-electron reduction of the corresponding cation radicals by means of neutralization-reionization mass spectrometry. In this respect, it is, however, of prime importance to choose appropriate neutralization agents, because otherwise long-lived neutrals cannot be assessed and dissociation by loss of atomic tellurium prevails. Thus, this study indicates that target-gas effects are particularly important in the neutralization of heavy, polyatomic ions. Finally, the present experimental results provide evidence for the formation of 3,4-benzo-1,2-dichalcogenacyclobutenes of sulfur, selenium, and tellurium.

Experimental Section

The experiments were performed with a modified VG ZAB/HF/AMD 604 four-sector mass spectrometer of *BEBE* configuration (*B* stands for magnetic and *E* for electric sectors), which has been described elsewhere[12]. The cation radicals of the 1,3-dichalcogena-2-telluroles were generated by electron ionization (EI, 70 eV) of the corresponding 2,2-dichlorides. After acceleration to a kinetic energy of 8 keV, the ions of interest were mass-selected using the magnetic and electric sectors as indicated further below. Metastable ion (MI) and collisional activation (CA) spectra of *B*(1)/*E*(1)-mass-selected ions were obtained by monitoring the fragments formed in the field-free region preceding *B*(2) by scanning *B*(2); for CA, helium (80% transmission, *T*) was used as a collision gas. NR experiments were performed by colliding *B*(1)-mass-selected cations with either xenon, cyclopropane, or trimethylamine (80% *T*), deflecting the remaining ions by applying a potential of 1 kV, reionizing the fast neutrals by collision with oxygen (80% *T*), and scanning *E*(1) to monitor the cations formed. The NR spectra recorded for *B*(1)/*E*(1)-mass-selected ions show similar fragmentation pattern, but somewhat poor signal-to-noise ratios. All spectra were accumulated and on-line processed with the AMD/Intectra data system; 5−40 scans were averaged to improve the signal-to-noise ratio. The natural abundances (I_{nat}) of the chalcogenides' isotopes pose quite some restrictions for the mass selection of isotopically pure ion[13]. Accordingly, from the clusters of isotope patterns those ions were

chosen which contain the most abundant isotopes, i.e. ^{32}S (I_{nat} = 95%), ^{80}Se (I_{nat} = 50%), and ^{130}Te (I_{nat} = 34%), respectively. Nevertheless, the correspondingly mass-selected ions are not isotopically pure, e.g. the combination $^{80}Se^{130}Te$ is always accompanied by about 20% of $^{82}Se^{128}Te$. The intensities tabulated further below were corrected according to the natural isotope distributions. Charge reversal (CR)[11] and NR experiments were also performed with $C_6H_4Se_2^{-\bullet}$ anion radicals using oxygen as collision gas in all cases. The CR and NR spectra can be used to assess the unimolecular reactivity of the neutral species by converting them to neutral and ion decomposition difference (NIDD) spectra; for details of the NIDD approach, see ref.[10].

The 2,2-dichloro-1,3-dichalcogena-2-telluroles were prepared in analogy to a previously described method for substituted derivatives[14], and the synthesis of the compounds as well as their spectroscopic characterization will be published elsewhere.

Some quantum-chemical calculations employing the B3LYP density functional were performed using Gaussian94[15]. For tellurium, a relativistic effective core potential with a valence basis set of DZP quality was used[16], while all other atoms were described by the standard 6-311G* basis sets included in Gaussian94.

Keywords: Gold(I) / Gold(II) / Diphenyl(trimethylsilylmethyl)phosphane / Ligand effects

The reaction of diphenyl(trimethylsilylmethyl)phosphane with [AuCl(tht)] affords the gold(I) complexes [AuCl($PPh_2CH_2SiMe_3$)] (**1**) or [Au($PPh_2CH_2SiMe_3$)$_2$]Cl (**2**). An X-ray study of **1** does not reveal any Au···Au interaction. Treatment of [Au(tht)$_2$](CF_3SO_3) or [Au(tht)(PPh_3)](CF_3SO_3) with diphenyl(trimethylsilylmethyl)phosphane results in the displacement of the thioether ligands to give the ionic complexes [Au($PPh_2CH_2SiMe_3$)$_2$](CF_3SO_3) (**3**) or [Au($PPh_2CH_2SiMe_3$)(PPh_3)](CF_3SO_3) (**4**), the latter mixed with the symmetrical derivatives [Au(PPh_2R)$_2$](CF_3SO_3) (R = Ph, CH_2SiMe_3). The molecular structure of complex **3** has been established by X-ray diffraction and shows an antiperiplanar arrangement of the two PR_2R' rotors in the solid state. The reaction of the phosphane ligand with [Au$_2${μ-$(CH_2)_2PPh_2$}$_2$(tht)$_2$](ClO_4)$_2$ affords the dinuclear gold(II) complex [Au$_2${μ-$(CH_2)_2PPh_2$}$_2$($PPh_2CH_2SiMe_3$)$_2$](ClO_4)$_2$ (**5**).

Introduction

The supramolecular aggregates of gold(I) complexes of type L−Au−X (X = halide or pseudohalide) include dimers, trimers, higher oligomers, and polymers. The degree of oligomerization is determined by several factors, the steric requirement of the ligands being the most clear.[1][2][3]

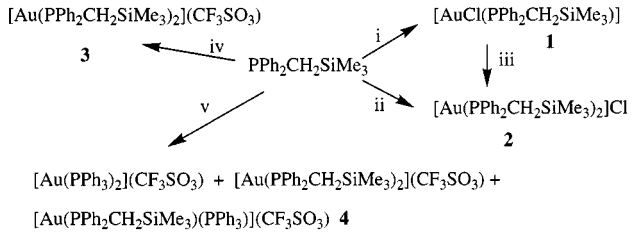
Gold(I) complexes with silanes attracted particular attention after it was found that auration reactions of silanes or silylated alkylgold complexes afford gold(I) clusters with hypercoordinated carbon or nitrogen centers.[4][5][6][7] Gold complexes containing a silicon unit via a bridging O, S, Se, Te, or As donor atom are also known.[8][9][10][11][12] In contrast, no gold complexes with (silylmethyl)phosphanes have been described so far.

In this paper we describe the synthesis of gold(I) and gold(II) complexes with diphenyl(trimethylsilylmethyl)-phosphane. The crystal structures of [AuCl($PPh_2CH_2SiMe_3$)] and [Au($PPh_2CH_2SiMe_3$)$_2$](CF_3SO_3) have been solved by X-ray diffraction studies.

Results

The reaction of diphenyl(trimethylsilylmethyl)phosphane with [AuCl(tht)] (tht = tetrahydrothiophene), in molar ratio 1:1, proceeds by displacing the tht ligand to give complex **1**, which by reaction with another $PPh_2CH_2SiMe_3$ affords complex **2** (see Scheme 1). The latter can be also synthesised by reaction of $PPh_2CH_2SiMe_3$ and [AuCl(tht)] (molar ratio 2:1). Treatment of [Au(tht)$_2$](CF_3SO_3) with $PPh_2CH_2SiMe_3$ in a 1:2 molar ratio gives complex **3**, containing two phosphane ligands. Treatment of this phosphane with [Au(tht)(PPh_3)](CF_3SO_3) or [Au(thf)(PPh_3)](CF_3SO_3) (thf = tetrahydrofuran) leads to a mixture of **4** and the corresponding symmetric complexes, **3** and [Au(PPh_3)$_2$](CF_3SO_3), as shown in the $^{31}P\{^1H\}$-NMR spectra (Scheme 1).

Scheme 1. (i) [AuCl(tht)]; (ii) 2 [AuCl(tht)]; (iii) [AuCl(tht)]; (iv) [Au(tht)$_2$](CF_3SO_3); (v) [Au(tht)(PPh_3)](CF_3SO_3) or [Au(thf)(PPh_3)](CF_3SO_3)



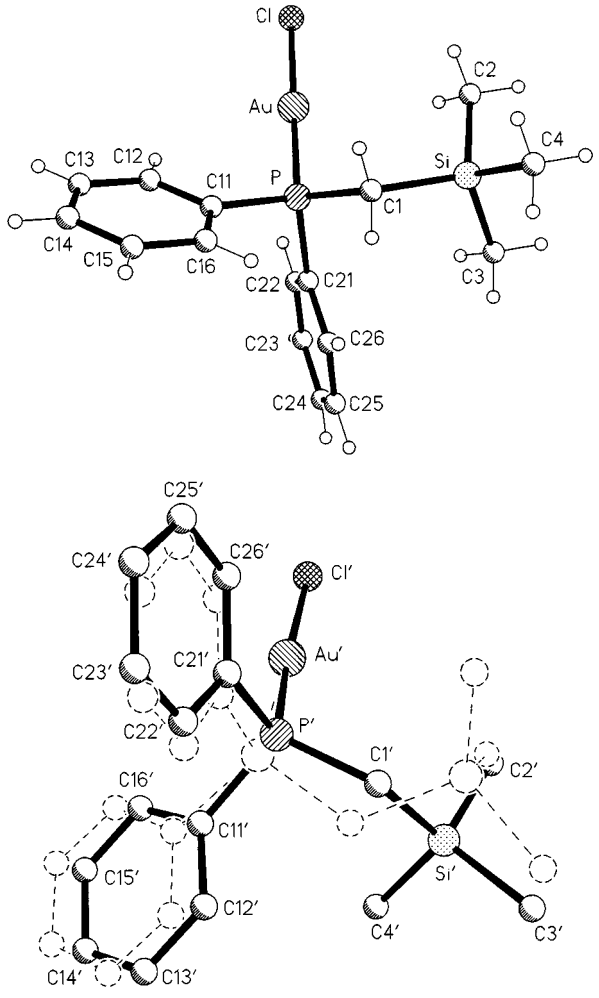
These complexes are air- and moisture-stable white solids at room temperature. They were readily characterised by ^1H and $^{31}P\{^1H\}$ NMR. Their $^{31}P\{^1H\}$-NMR spectra show a singlet at δ = 21.6 (**1**), 27.6 (**2**), and 36.4 (**3**); an AB spin system is observed for **4** (δ_A = 46.7, δ_B = 36.5, $^2J_{AB}$ = 331 Hz), besides two singlets corresponding to symmetric phosphane complexes. In the ^1H-NMR spectra the resonance of the CH_2 is observed at δ ≈ 2: a doublet for **1**−**2** [$^2J_{HP}$ = 15.3 (**1**) and 14.3 (**2**) Hz], a pseudotriplet for **3** (part A of an $A_2XX'A'_2$ system, N = 5.9 Hz) and a doublet of doublets for **4** ($^2J_{HP}$ = 13.7 Hz and $^4J_{HP}$ = 3.5 Hz). Their IR spectra show absorptions at 338 (**1**, medium) and 331 (**2**, very weak) cm^{-1} due to ν(Au−Cl)[13] and to 1264 (br., s) and 636 (m) from triflate[14] (**3**). The LSI-MS mass spectra show peaks at *m/z* (complex, abundance in%) 469 (**1**, 55), 741 (**2**, 100), 741 (**3**, 100), and 731 (**4**, 85) corresponding to $[M - X]^+$ (X = Cl or CF_3SO_3).

The crystal structures of **1** and **3** have been determined by means of X-ray diffraction studies. Complex **1** crystallises

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0707−0989 $ 17.50+.50/0

with two independent molecules (Figure 1), of which one is disordered over two positions for all atoms except Au and Cl; a suitably restrained refinement proved successful, but the molecular dimensions of the disordered molecule should be interpreted with caution. Here we discuss only the ordered molecule. The gold(I) center displays an almost linear coordination with Cl−Au−P 176.86(6)°. The Au−P distance is 2.236(2) A, similar to that found in other chlorophosphanegold(I) complexes, 2.235(3) A in [AuCl(PPh$_3$)],[15] 2.236(6) A in [AuCl(PPhMe$_2$)],[16] 2.232(9) A in [AuCl(PEt$_3$)],[17] but somewhat longer than in [AuCl(PPh$_2$CH$_2$CONHMe)] [2.221(1) A].[18] The Au−Cl distance is 2.292(2) A, similar to that found in [AuCl(PEt$_3$)] [2.305(8) A], longer than in [AuCl(PPh$_2$CH$_2$CONHMe)] [2.275(2) A] or in [AuCl(PPh$_3$)] [2.279(3) A], and marginally shorter than in [AuCl(PPhMe$_2$)] [2.316(6) A].

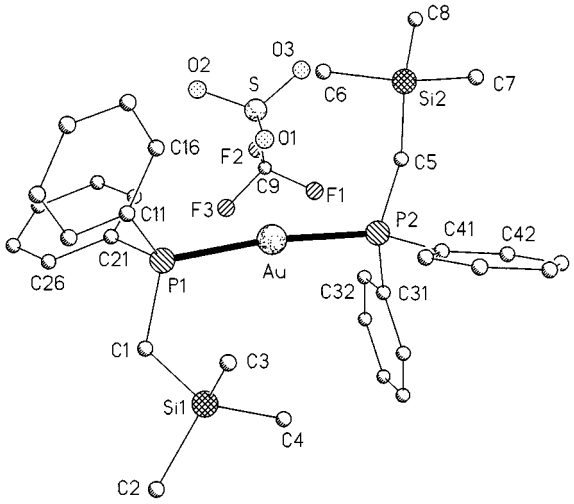
Figure 1. The two independent molecules of compound **1** in the crystal: (a) the ordered molecule; (b) the disordered molecule showing both alternative sites (see text); H atoms omitted for clarity



There are no short gold···gold contacts, the shortest Au−Au distance being 6.6 A. This long distance can be rationalised in terms of the steric bulk of the ligand, but it contrasts with other cases, as the 2.881 (1) A found in [Au(PPhMe$_2$)$_2$][Au(GeCl$_3$)$_2$][3], ca. 3.1 A in [AuX(PPhMe$_2$)] [X = Cl, 3.091(2) and 3.230(2) A; Br, 3.119(2) A; and I 3.104(2) A] or even the 5.916(1) A found in [AuCl(AsPh$_3$)][19]. There are no other contacts that could compete with gold−gold interactions, such as the Au···Cl found in [Au{P(*o*-Tol)$_3$}(GeCl$_3$)][3] or the hydrogen bonds in [AuCl(PPh$_2$CH$_2$CONHMe)].

The crystal structure of cation of **3** is shown in Figure 2. The geometry around the gold atom is distorted linear, P(1)−Au−P(2) = 172.12(4)°. The Au−P bond lengths are 2.3080(10) and 2.3149(10) A, similar to that found in other [Au(PR$_2$R′)$_2$]$^+$ complexes, 2.309(3) in [Au(PPh$_2$Me)$_2$][3,4-S$_2$C$_6$H$_3$CH$_3$)$_2$][20], and 2.316(4) A in [Au(PPh$_2$Me)$_2$]PF$_6$,[21] but longer than in [AuCl(PPh$_2$CH$_2$CONHMe)] [2.221(1) A][18] and in **1** [2.236(2) A] probably as a consequence of the lesser *trans* influence of Cl. The PR$_2$R′ ligands adopt an approximately antiperiplanar arrangement, with the torsion angle C1−P1···P2−C5 166°.

Figure 2. The cation of compound **3** in the crystal; H atoms omitted for clarity



As in the similar complexes [Au(PPh$_2$Me)$_2$]$^+$,[20][21][22] there are no short gold−gold contacts, the shortest Au−Au distance being 9.1 A.

The presence of a pseudotriplet (which can be attributed to two superposed doublets) in the ^{1}H-NMR spectrum instead of the expected doublet could indicate a case of propeller isomerism. Schmidbaur and coworkers[23] reported recently that *ortho*-substituted triarylphosphanes can induce this kind of isomerism in complexes with a coordination number of two, even at room temperature, by hindered rotation of the aryl groups about the P−C$_{ipso}$ axes. The variable-temperature ^{1}H-NMR spectrum of **3** shows a triplet for the CH$_2$ resonance and the ^{31}P{^{1}H} spectrum a singlet from −60 to +20°C in CDCl$_3$ solution; when a ^{1}H{^{31}P}-NMR experiment is carried out at −60°C only one singlet (rather than two) is found, which confirms that there is no propeller isomerism but only two magnetically inequivalent CH$_2$ units (as the parts A of an A$_2$XX′A′$_2$ spin system).

We have also prepared gold(II) complexes by displacement of tht from [Au$_2${μ-(CH$_2$)$_2$PPh$_2$}$_2$(tht)$_2$](ClO$_4$)$_2$ [see Eq. (1)]. Complex **5** is a green solid, air- and moisture-stable

at room temperature. We were unable to obtain single crystals of **5** but expect its structure to be similar to that of $[Au_2(CH_2PPh_2CH_2)(PPh_3)_2](ClO_4)_2$[24]. The IR spectrum shows absorptions at 1092 (br., s) and 623 (m) cm^{-1} from the perchlorate anion[25] and at 568 (m) from ν(Au−C_{ylide})[26]. The $^{31}P\{^1H\}$-NMR spectrum shows two triplets at δ = 46.7 and 23.6 ($^3J_{PP}$ = 38.8 Hz) as expected for an A_2X_2 spin system. In the ^1H-NMR spectra the resonance of the CH_2−Si unit appears as a pseudotriplet (*N* = 5.4 Hz) at δ = 1.98 whilst a doublet at δ = 1.61 ($^2J_{HP}$ = 11.5 Hz) is observed for CH_2−Au; again when a $^1H\{^{31}P\}$-NMR experiment is carried out only a singlet is found for the CH_2−Si unit. The LSI-MS mass spectrum show peaks at *m/z* (abundance in%) 1463 (25) from $[M - ClO_4]^+$ whilst the base peak appears at 741, corresponding to $[Au(PPh_2CH_2SiMe_3)_2]^+$.

$$[Au_2\{\mu\text{-}(CH_2)_2PPh_2\}_2(tht)_2](ClO_4)_2 + 2\ PPh_2CH_2SiMe_3 \rightarrow [Au_2\{\mu\text{-}(CH_2)_2PPh_2\}_2(PPh_2CH_2SiMe_3)_2](ClO_4)_2 + 2\ tht \quad (1)$$

Experimental Section

General: All the reactions were carried out under argon at room temperature. $[Au(tht)_2](CF_3SO_3)$, $[Au(tht)(PPh_3)](CF_3SO_3)$ and $[Au(thf)(PPh_3)](CF_3SO_3)$ were prepared in situ by reaction of [AuCl(tht)] or $[AuCl(PPh_3)]$ with $[Ag(CF_3SO_3)(tht)]$ or $[Ag(CF_3SO_3)]$ according to a standard procedure: [AuCl(tht)][27], $PPh_2CH_2SiMe_3$[28], and $[Au_2\{\mu\text{-}(CH_2)_2PPh_2\}_2(tht)_2](ClO_4)_2$[24] were prepared according to literature procedures. − IR spectra were recorded on a Perkin-Elmer 883 spectrophotometer, over the range 4000−200 cm^{-1}, by using Nujol mulls between polyethylene sheets. − ^1H- and ^{31}P-NMR spectra were recorded with a Bruker ARX·300 or GEMINI 2000 apparatus in $CDCl_3$ solutions; chemical shifts are quoted relative to $SiMe_4$ (external, ^1H) and H_3PO_4 (external, ^{31}P). − C, H, and N analyses were performed with a Perkin-Elmer 2400 microanalyser. − Melting points were measured with a Büchi apparatus and are uncorrected. − Mass spectra were recorded with a VG Autospec using LSI-MS^+ techniques (with Cs gun) and 3-nitrobenzyl alcohol as matrix.

Caution: Perchlorate salts or derivatives must be manipulated with caution, mainly by avoiding evaporation to dryness.

[AuCl(PPh$_2$CH$_2$SiMe$_3$)] (**1**): To a dichloromethane solution (15 ml) of [AuCl(tht)] (96 mg, 0.3 mmol) was added $PPh_2CH_2SiMe_3$ (82 mg, 0.3 mmol). After stirring for 3 h, the solution was concentrated to ca. 2 ml and hexane (15 ml) was added to obtain **1** as a white solid. **1** was washed with hexane (2 × 5 ml). Yield: 70%, m.p. 118°C. − ^1H NMR: δ = 7.7−7.4 (m, 10 H, Ph), 1.83 (d, 2 H, $^2J_{HP}$ = 15.3 Hz, CH_2−P), 0.08 (s, 9 H, Me). − $C_{16}H_{21}AuClPSi$ (504.82): calcd. C 38.05, H 4.2; found C 37.75, H 3.85.

[Au(PPh$_2$CH$_2$SiMe$_3$)$_2$]Cl (**2**): This product can be synthesised by two different routes: a) To a solution of [AuCl(tht)] (0.064 g, 0.2 mmol) in dichloromethane (10 ml) was added $PPh_2CH_2SiMe_3$ (109 mg, 0.4 mmol). After stirring for 1 h, the solution was concentrated to ca. 2 ml and hexane (15 ml) was added. **2** appeared as a white solid which was washed with hexane (2 × 5 ml). Yield: 70%. b) To a dichloromethane solution (15 ml) of **1** (50 mg, 0.1 mmol) was added $PPh_2CH_2SiMe_3$ (27 mg, 0.1 mmol). After stirring for 1 h, the solution was concentrated to ca. 2 ml and hexane (15 ml) was added. **2** appeared as a white solid which was washed with hexane (2 × 5 ml). Yield: 80%, m.p. 125°C. − ^1H NMR: δ = 7.8−7.3 (m, 10 H, Ph), 2.00 (d, 2 H, $^2J_{HP}$ = 14.3 Hz, CH_2−P), −0.03 (s, 9 H, Me). − $C_{32}H_{42}AuClP_2Si_2$ (777.22) : calcd. C 49.45, H 5.45; found C 49.25, H 5.55.

[Au(PPh$_2$CH$_2$SiMe$_3$)$_2$](CF$_3$SO$_3$) (**3**): To a dichloromethane solution (20 ml) of $[Au(tht)_2](CF_3SO_3)$ (0.15 mmol, prepared "in situ") was added $PPh_2CH_2SiMe_3$ (82 mg, 0.3 mmol). After stirring for 2 h, the solution was concentrated to ca. 2 ml and diethyl ether (15 ml) was added to obtain **3** as a white solid. **3** was washed with diethyl ether. Yield: 70%, m.p. 136°C. − ^1H NMR: δ = 7.7−7.5 (m, 10 H, Ph), 2.08 (t, 2 H, $^2J_{HP}$ = 5.9 Hz, CH_2−P), −0.02 (s, 9 H, Me). − ^1H NMR (−60°C): δ = 7.7−7.5 (m, 10 H, Ph), 2.01 (t, 2 H, $^2J_{HP}$ = 5.7 Hz, CH_2−P), −0.01 (s, 9 H, Me). − $^{31}P\{^1H\}$ NMR (−60°C): δ = 35.8 (s). − $^1H\{^{31}P\}$ NMR (−60°C): δ = 7.8−7.5 (m, 10 H, Ph), 2.01 (s, 2 H, CH_2−P), −0.02 (s, 9 H, Me).− $C_{33}H_{42}AuF_3O_3P_2SSi_2$ (890.84) : calcd. C 44.5, H 4.75, S 3.6; found C 44.4, H 4.65, S 3.8.

[Au(PPh$_2$CH$_2$SiMe$_3$)(PPh$_3$)](CF$_3$SO$_3$) (**4**): This complex, mixed with the corresponding symmetric $[Au(PPh_2R)_2](CF_3SO_3)$ (R = Ph, CH_2SiMe_3), was prepared by two different ways. a) To a dichloromethane solution (20 ml) of $[Au(tht)(PPh_3)](CF_3SO_3)$ (0.15 mmol, prepared "in situ") was added $PPh_2CH_2SiMe_3$ (41 mg, 0.15 mmol). After stirring for 2 h, the solution was concentrated to ca. 2 ml and diethyl ether (15 ml) was added. The white solid was washed with diethyl ether. b) As for a) but using $[Au(thf)(PPh_3)](CF_3SO_3)$, prepared in situ in thf.

[Au$_2${μ-(CH$_2$)$_2$PPh$_2$}$_2$(PPh$_2$CH$_2$SiMe$_3$)$_2$](ClO$_4$)$_2$ (**5**): To a dichloromethane solution (10 ml) of $[Au_2\{\mu\text{-}(CH_2)_2PPh_2\}_2(tht)_2](ClO_4)_2$ (60 mg, 0.05 mmol) was added $PPh_2CH_2SiMe_3$ (27 mg, 0.1 mmol). After stirring for 2 h, the solution was concentrated to ca. 1 ml and diethyl ether (15 ml) was added to obtain **5** as a green solid. **5** was washed with diethyl ether. Yield: 85%, m.p. 120°C (decomp.). − ^1H NMR: δ = 7.5−7.0 (m, 40 H, Ph), 1.98 (t, 4 H, $^2J_{HP}$ = 5.4 Hz, P−CH_2−Si), 1.61 (d, 8 H, $^2J_{HP}$ = 11.5 Hz, Au−CH_2−P), −0.20 (s, 18 H, Me). − $^1H\{^{31}P\}$ NMR: δ = 7.5−7.0 (m, 40 H, Ph), 1.95 (s, 4 H, P−CH_2−Si), 1.60 (s, 8 H, Au−CH_2−P), −0.20 (s, 18 H, Me). − $C_{60}H_{70}Au_2Cl_2O_8P_4Si_2$ (1564.11) : calcd. C 46.05, H 4.5; found C 45.75, H 4.15.

Crystal Structure Determinations: Crystal data and refinement details are given in Table 1. Crystals of **1** were obtained by slow evaporation of a dichloromethane/ethanol slution; crystals of **3** were obtained by slow diffusion at −18°C of diethyl ether into a dichloromethane solution. − *Data collection:* Crystals were mounted in inert oil and transferred to the cold gas stream of a Siemens P4 diffractometer. Intensity measurements were performed using Mo-K_α radiation. Absorption corrections were based on ψ scans. − *Structure solution and refinement:* Solution by the heavy-atom method, anisotropic refinement on F^2 (program SHELXL-93, G.M. Sheldrick, University of Göttingen). H atoms with riding model or as rigid methyl groups. − *Special features*: For **1**, the second independent molecule is disordered, all atoms except Au and Cl occupying two alternative orientations. Nevertheless, the use of appropriate similarity restraints enabled a satisfactorily stable refinement to be performed. Disordered C and Si atoms were refined isotropically. − Full details of the crystal structures (except structure factors) have been deposited at the Cambridge Crystallo-

Keywords: Azabutadienes / Tricarbonyliron complexes / Transfer reagents / Molecular structure / Fluxionality

The (η^4-1-azabuta-1,3-diene)tricarbonyliron complexes **10** are easily prepared in high yield by condensation of the corresponding arylamines **7** with the cinnamaldehydes **8** and subsequent ultrasound-promoted complexation of the resulting 1-azabuta-1,3-dienes **9** with nonacarbonyldiiron. The complexes **10** are shown to represent excellent reagents for the transfer of the tricarbonyliron fragment onto cyclohexa-1,3-diene (**1a**). The structural characterization for the complexes **10** is achieved by IR, ^{1}H-NMR, and ^{13}C-NMR spectroscopy, as well as X-ray crystallography of **10b**, **10c**, and **10l**. Using variable temperature ^{13}C-NMR spectroscopy the fluxionality of the complexes **10a**, **10b**, **10c**, **10e**, and **2** is investigated and the activation barrier for the turnstile rotation of the tricarbonyliron fragment is determined. The transfer reaction and the structural factors influencing the transfer of the tricarbonyliron fragment are extensively investigated.

Introduction

Tricarbonyl(η^4-cyclohexa-1,3-diene)iron complexes have found many useful applications in synthetic organic chemistry and have been shown to represent excellent starting materials for the stereoselective synthesis of natural products.[1] The parent complex, tricarbonyl(η^4-cyclohexa-1,3-diene)iron (**2**), was prepared first in 1958 by Pauson via complexation of cyclohexa-1,3-diene (**1a**) with pentacarbonyliron under thermal reaction conditions (yield: 21%).[2] The yield of this complexation was later improved by photolytic reaction of cyclohexa-1,4-diene (**1b**) with pentacarbonyliron in benzene (yield: 56%),[3] by reaction of cyclohexa-1,4-diene (**1b**) with pentacarbonyliron in di-*n*-butyl ether at reflux (yield: 46%),[4] by reaction of cyclohexa-1,3-diene (**1a**) with nonacarbonyldiiron in tetrahydrofuran at reflux (yield: 43%),[5] and by photolytic reaction of cyclohexa-1,3-diene (**1a**) with pentacarbonyliron in hexane (yield: 77%)[5] (Scheme 1).

The high synthetic potential of tricarbonyl(η^4-cyclohexa-1,3-diene)iron (**2**) became evident in 1960, when E. O. Fischer found the possibility of hydride abstraction using triphenylmethyl tetrafluoroborate.[6] The reactivity of the resulting tricarbonyl(η^5-cyclohexadienylium)iron tetrafluoroborate (**3**) can be utilized for regio- and stereoselective bond formation with a broad range of nucleophiles.[1] Projected synthetic applications of the complex salt **3** require an access to the iron complex **2** in large scale and high yield. However, the methods described above, involving either thermally or photochemically induced direct complexation of the cyclohexadienes **1a** or **1b** with pentacarbonyliron or nonacarbonyldiiron, afford complex **2** in only 21−77% yield. Moreover, these procedures lead to the formation of pyrophoric iron which is hazardous during

Scheme 1. Complexation of cyclohexa-1,3-diene (**1a**) and cyclohexa-1,4-diene (**1b**) with $Fe(CO)_5$ or $Fe_2(CO)_9$ and preparation of the complex salt **3**

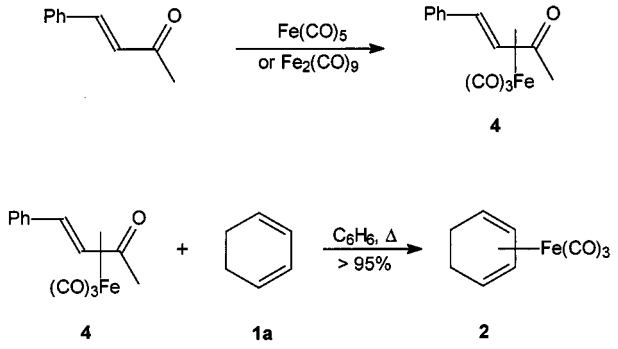
workup, especially on large scale complexations. This problem can be circumvented by using labile tricarbonyliron complexes in order to transfer the tricarbonyliron fragment from the weakly bound ligand to cyclohexa-1,3-dienes or buta-1,3-dienes under mild reaction conditions. The development of such tricarbonyliron transfer reagents for the efficient complexation of 1,3-dienes has been extensively investigated over the last 25 years.[7]

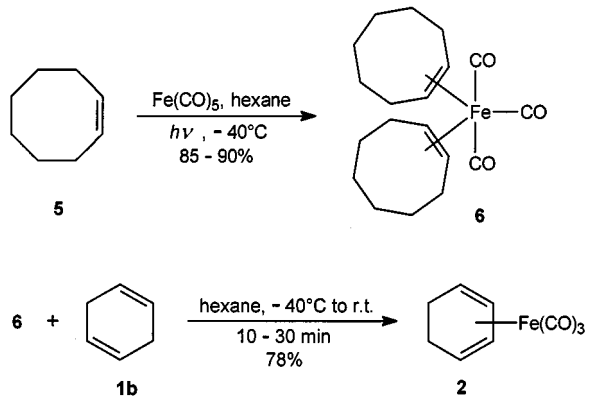
The ability of tricarbonyl(η^4-1-oxabuta-1,3-diene)iron complexes to serve as a mild source of the tricarbonyliron fragment was first described by Lewis in 1972.[8] The (η^4-benzylideneacetone)tricarbonyliron (**4**) was found to represent an especially efficient transfer reagent. Brookhart reported the transfer of the tricarbonyliron fragment of **4** to cyclohexa-1,3-diene (**1a**) in a thermal reaction that affords the iron complex **2** in over 95% yield (Scheme 2).[9]

Scheme 2. Complexation of benzylideneacetone to **4** and tricarbonyliron transfer to cyclohexa-1,3-diene (**1a**) using the complex **4**



However, the problematic step of this reaction sequence is the preparation of the transfer reagent **4**. The original procedure described by Lewis involved complexation of benzylideneacetone with 1 equivalent of nonacarbonyldiiron in toluene at 60°C and afforded complex **4** in only 32% yield.[8] Brookhart improved this yield to 60% by a photolytic and subsequent thermal reaction of benzylideneacetone with pentacarbonyliron.[9] Only by heating a solution of benzylideneacetone with an excess of nonacarbonyldiiron in diethyl ether at reflux, as reported by Thomas, the tricarbonyliron complex **4** was obtained in reasonable yields (74–81%).[10]

Scheme 3. Complexation of cyclohexa-1,4-diene (**1b**) to **2** using Grevels′ reagent **6**



A further tricarbonyliron transfer reagent was developed by Grevels in 1984. Photolytic reaction of pentacarbonyliron with an excess of *cis*-cyclooctene (**5**) in hexane at −40°C afforded tricarbonylbis(η^2-*cis*-cyclooctene)iron (*Grevels′ reagent*) (**6**), which can be isolated as yellow crystals in 85–90% yield (Scheme 3).[11] While the solid compound can be handled at room temperature, complex **6** is labile in solution at temperatures above −35°C. The advantage of Grevels′ reagent is that the transfer of the tricarbonyliron fragment to 1,3-dienes occurs under extremely mild reaction conditions at temperatures below 0°C. Moreover, using Grevels′ reagent **6** also non-conjugated 1,4-dienes can be complexed with concomitant migration of the double bond, e.g. the transfer of the tricarbonyliron fragment of Grevels′ reagent **6** to cyclohexa-1,4-diene (**1b**) provides tricarbonyl(η^4-cyclohexa-1,3-diene)iron (**2**) in 78% yield (Scheme 3).

The high lability of the tricarbonyl(η^4-1-oxabuta-1,3-diene)iron complex **4** and the Grevels′ reagent **6** in solution at room temperature and in the air induced our search for alternative tricarbonyliron transfer reagents, whose higher stability should make them useful for a wider range of applications in synthetic organometallic chemistry.

Results and Discussion

Our investigations led us to the (η^4-1-azabuta-1,3-diene)-tricarbonyliron complexes **10** as efficient and selective tricarbonyliron transfer reagents of high stability (Scheme 4).[12][13] (η^4-1-Azabuta-1,3-diene)tricarbonyliron complexes were first described by Otsuka[14] and Lewis[15] and have been applied to the synthesis of dicarbonyl(η^4-styrene)iron carbene complexes,[16] substituted pyrroles,[17] and to the preparation of labile Schiff bases in the form of their metal complexes.[18] The following methods were previously used for the preparation of the complexes **10**: 1. condensation of amines with tetracarbonyl(η^2-1-oxabuta-1,3-diene)-iron complexes;[14a][18] 2. thermal reaction of the 1-azabuta-1,3-dienes **9** with nonacarbonyldiiron;[14][17] and 3. aza-Wittig reaction of tetracarbonyl(η^2-1-oxabuta-1,3-diene)iron complexes.[19] We found that the yields of the (η^4-1-azabuta-1,3-diene)tricarbonyliron complexes **10** are considerably improved by an ultrasound-promoted complexation[20] of 1-azabuta-1,3-dienes **9** with nonacarbonyldiiron at room temperature.[12][13] In the present paper we describe an extensive investigation of the transfer reaction of the tricarbonyliron fragment from the complexes **10** to cyclohexa-1,3-diene (**1a**) as well as the structural factors influencing the transfer of the metal fragment.

The synthesis of the 1-azabuta-1,3-dienes **9** was achieved by adaptation of standard literature procedures for the imine condensation of the arylamines **7** with the cinnamaldehydes **8**. Reaction of 1 equivalent of the freshly distilled or sublimated arylamine **7** and 1 equivalent of the cinnamaldehyde **8** in an inert solvent, generally with addition of a drying agent, afforded the 1-azabuta-1,3-dienes **9** in high yields (Scheme 4, Table 1). Most of the arylamines **7** and the cinnamaldehydes **8** are commercially available. 2,4,6-Trimethoxyaniline (**7i**) was prepared in 88% yield by hydrogen-

[a] Chemical shift of the H-C2 signal in the ^{1}H-NMR spectrum. – [b] No assignment possible, due to coincidental overlap of signals.

ation of 2,4,6-trimethoxynitrobenzene.[21] The synthesis of 4-cyanocinnamaldehyde (**8p** = **8q**; R^6 = CN, R^7 = H) was achieved in 78% yield by Wittig reaction of 4-cyanobenzaldehyde and (formylmethylene)triphenylphosphorane in toluene at reflux.

As shown below, the electron density at the nitrogen of the 1-azabuta-1,3-dienes **9** is crucial for the efficiency of the tricarbonyliron transfer from the corresponding complexes **10** and for the catalytic complexation[12][13] of cyclohexa-1,3-diene (**1a**) using **9** and nonacarbonyldiiron or pentacarbonyliron. The chemical shift of the imine proton (H-C2) in the ^{1}H-NMR spectra of the 1-azabuta-1,3-dienes **9** is a measure of the electron density at the imine nitrogen atom. A larger downfield shift of H-C2 correlates with a higher electron density at the nitrogen. Thus, this value can be used to estimate the activity of the 1-azabuta-1,3-dienes **9** for catalytic complexations and the transfer ability of the corresponding complexes **10**. Donor substituents in the *ortho* and *para* positions of the 1-aryl ring (R^1, R^3, R^5) cause a downfield shift of the signal of the imine proton relative to the value obtained for the parent compound **9a** (δ = 8.27). The maximum is observed for the 2,4,6-trimethoxy derivative **9i** with a chemical shift of δ = 8.51, which can be at least partly ascribed to the influence of the anisotropy of the oxygen atoms. In contrast, a highfield shift is found with donor substituents in the *para* position of the 4-aryl ring (R^6). Exactly the opposite effects on the chemical shift of H-C2 are observed with acceptor substituents in these positions. In a few cases steric effects are overriding, since substituents in the *ortho* positions of the aryl ring cause larger torsion angles between the aryl ring and the 1-azabuta-1,3-diene plane, resulting in decreased π-overlap.

The complexation of the 1-azabuta-1,3-dienes **9** to the (η^4-1-azabuta-1,3-diene)tricarbonyliron complexes **10** was conveniently achieved by reaction with nonacarbonyldiiron under sonication in tetrahydrofuran at room temperature

(Scheme 4, Table 1). The ultrasound-promoted tricarbonyliron complexation, previously applied by Ley and coworkers to buta-1,3-dienes and cyclohexa-1,3-dienes,[20] was found to be superior to the thermal complexation of the 1-azabuta-1,3-dienes **9**. With respect to the diastereoselectivity of the complexation of chiral 1-azabuta-1,3-dienes,[22] the ultrasound procedure also provides better results than the thermal reaction, since it does not require elevated temperatures, which were shown to cause epimerization of the planar chirality.[23]

The red crystalline (η^4-1-azabuta-1,3-diene)tricarbonyliron complexes **10** are stable in the air for months and therefore appeared to represent appropriate potential transfer reagents for our purposes. The IR spectra of the iron complexes **10** in KBr exhibit intense broad bands in the region of 1960−2060 cm^{-1}, which are typical of carbonyl ligands of tricarbonyliron−diene complexes (Table 2). The wave number of the CO stretching vibration represents an indirect measure of the strength of the bonding between the metal and the organic ligand. A shift to lower wave numbers relative to the value for the parent compound **10a** is observed by donor substituents in the *para* position of the 1-aryl ring (e.g. **10b**: R^3 = OMe, **10d**: R^3 = NMe_2) indicating a reduced back bonding from the iron atom to the azadiene ligand in these complexes, which is explained by an increase in energy of the π* orbitals of the 1-azabutadiene.

The ^{1}H-NMR spectra of the η^4-tricarbonyliron-complexed 1-azabuta-1,3-dienes **10** exhibit the characteristic high field shifts for the protons at the carbon atoms which are coordinated to the metal (C2 to C4). A closer inspection of the chemical shifts which are found for the signals of the imine protons (H-C2) of the complexes **10** reveals that generally a highfield shift of about 1.3−1.4 ppm relative to the value for the corresponding free ligand **9** is observed (Table 1). For those derivatives of **10** having one methoxy substituent in the *ortho* position of the 1-aryl ring (R^1 = OMe; **10c**, **10g**, **10n**, and **10q**) this highfield shift relative to **9** is decreased to 1.13−1.18 ppm, which is ascribed partly to a steric effect of the *ortho* substituent (increase of the torsion angle) leading to reduced π-overlap and partly to the anisotropy of the oxygen atom. For complex **10i** with two *ortho* methoxy substituents in the 1-aryl ring (R^1 = R^5 = OMe) the highfield shift of the imine proton relative to the value observed for **9i** drops to 0.57 ppm.

Almost all of the (η^4-1-azabuta-1,3-diene)tricarbonyliron complexes **10** described in this paper show no or at best three very broad signals for the carbon atoms of the carbonyl ligands in their ^{13}C-NMR spectra when taken in deuterochloroform at room temperature, although the IR spectra in KBr exhibit the typical three bands for the carbonyl ligands at 1960−2060 cm^{-1}. The trifluoromethyl-substituted compounds **10e** and **10m** are exceptions and exhibit three only slightly broadened signals in their ^{13}C-NMR spectra under these conditions (**10e**: δ = 204.77, 208.30, 211.49; **10m**: δ = 205.07, 208.94, 211.97). The ^{13}C-NMR spectra of (η^4-carba-1,3-diene)tricarbonyliron complexes show in most cases only one singlet at δ = 210−213 for the three carbonyl ligands at room temperature. The fluxionality of these complexes leading to equivalency of the three carbonyl ligands is caused by the turnstile rotation of the tricarbonyliron fragment. This dynamic process is sufficiently slow on the NMR time scale at low temperatures to allow the observation of two peaks for the three carbonyl ligands with an intensity ratio of 2:1 in the case of symmetrical diene ligands or three peaks of equal height for unsymmetrical diene ligands.[24] Previous investigations of the fluxional behavior of tricarbonyliron-diene complexes have demonstrated that the activation barriers for this intramolecular basal-apical exchange of the carbonyl groups for complexes with carbadiene ligands are significantly lower than those of 1-heterodiene ligands.[25] Takats concluded that the variations in the activation barrier for the turnstile rotation of the tricarbonyliron fragment can be rationalized by the metal-carbonyl back bonding, however steric factors also contribute to this value.[25c]

We determined precisely the activation barrier for the intramolecular carbonyl ligand exchange of four (η^4-1-azabuta-1,3-diene)tricarbonyliron complexes (**10a−c** and **10e**) and for tricarbonyl(η^4-cyclohexa-1,3-diene)iron (**2**) by dynamic ^{13}C-NMR spectroscopy at 125 MHz in deuterated toluene (Figure 1a−e, Table 2). The stepwise increase of the temperature up to 373 K during the measurement of the ^{13}C-NMR spectra of the complexes **10** provided a single signal for the three carbonyl ligands, which still showed some line broadening. As expected the low temperature spectra of the 1-azadiene complexes **10** at 233 K exhibited three sharp singlets for the carbonyl ligands. The coalescence temperature T_C of the dynamic process was clearly above room temperature for all four cases investigated. This was already indicated by the fact that the signals for the carbonyl ligands were missing in the ^{13}C-NMR spectra in deuterochloroform at room temperature for most of the 1-azadiene complexes **10** prepared in the present work. For the cyclohexadiene complex **2** one sharp singlet for the three carbonyl ligands is observed at room temperature, while the ^{13}C-NMR spectrum at 185 K exhibits two singlets at δ = 211.32 and 216.05 in a ratio of 2:1. The coalescence temperatures could be determined with a tolerance of ±5 K. With the value for δν taken from the low temperature spectrum, the free enthalpy of activation for the intramolecular exchange of carbonyl ligands could be calculated in good approximation by using the formula $\Delta G^{\neq} = R \cdot T_C [22.96 + \ln(T_C/\delta\nu)]$.[26] The activation barrier for this turnstile rotation of the tricarbonyliron fragment in the 1-*p*-anisyl-substituted 1-azadiene complex **10b** is 13.5 ± 0.3 kcal/mol. For the other 1-azadiene complexes that were investigated by dynamic ^{13}C-NMR spectroscopy (**10a**, **10c**, and **10e**), the value was found to be increased by about 1 kcal/mol (Table 2). Thus the intramolecular ligand exchange of the carbonyl groups is facilitated by a donor substituent in the *para* position of the 1-aryl ring (complex **10b**) as compared to the parent compound **10a**. This finding is again in agreement with the assumption of reduced back bonding from the iron atom to the 1-azadiene ligand in complex **10b** relative to **10a**. The opposite effect is observed with an acceptor group in this position (complex **10e**) and also with

a donor group in the *ortho* position of the 1-aryl ring, because of the increased torsion angle (compound **10c**). For the cyclohexa-1,3-diene complex **2** the activation barrier for the rotation of the tricarbonyliron fragment has been determined as 8.7 ± 0.3 kcal/mol, which is in good agreement with the value of 8.8 ± 0.5 kcal/mol obtained earlier by Takats et al. in [D$_6$]DMSO/CS$_2$.[25c] For the related (η^4-buta-1,3-diene)tricarbonyliron complex activation barriers of 9.5 kcal/mol[24] and 10.5 ± 0.5 kcal/mol[25c] have been reported. These findings emphasize that the free enthalpy of activation for the turnstile rotation of the tricarbonyliron fragment for the complexes of 1-hetero-1,3-dienes is generally about 4−5 kcal/mol higher than for the corresponding complexes of carba-1,3-dienes, no matter whether they are cyclic or acyclic. The data are in agreement with decreased back donation of electrons from filled iron d-orbitals into the LUMO of the carbonyl group for the tricarbonyliron

complexes of 1-hetero-1,3-dienes, as compared to 1-carba-1,3-dienes. This is confirmed by the higher stretching frequencies for the carbonyl bands in the IR spectra of 1-hetero-1,3-diene complexes. In consequence the averaged chemical shifts in the ^{13}C-NMR spectra observed at high temperatures are shifted to higher field and the activation barrier for the rotation of the tricarbonyliron fragment is higher for the 1-heterodiene complexes.

The X-ray crystal structure determinations of the (η^4-1-azabuta-1,3-diene)tricarbonyliron complexes **10b**, **10c**, and **10l** confirm the tetragonal pyramidal coordination of the iron atom (Figure 2−4, Table 4). Two basal positions are occupied by the two π bonds, the two others by carbonyl ligands. The third carbonyl ligand adopts the apical position of these complexes. Similar arrangements were previously found for tricarbonyliron complexes of buta-1,3-dienes and cyclohexa-1,3-dienes and also for the parent complex **10a**.[14b] The bond lengths found in the tricarbonyliron complexes of 1-azabuta-1,3-dienes, compared to those of cyclohexa-1,3-dienes and buta-1,3-dienes, correlate very well with the concept of increased back bonding from the filled iron d-orbitals into the π* orbitals of the organic ligand for the heterodiene complexes. This is emphasized by the IR, ^{1}H-NMR, and ^{13}C-NMR data described above. Some anomalies in the spectral data of the 1-azabuta-1,3-diene complexes presented above were ascribed to steric factors, especially for those cases of 1-azabuta-1,3-dienes resulting from an *ortho*-substituted arylamine. The X-ray crystal structures reveal an increased torsion angle for the complexes with an *ortho*-methoxy substituent. It is noteworthy that the out-of-plane arrangement of the 1-aryl ring relative to the 1-azabuta-1,3-diene plane in these complexes proceeds in a way that the oxygen atom of the methoxy group is oriented towards the iron atom. For electronic reasons this arrangement becomes most evident for complex **10l** with an *ortho*-methoxy substituent in the 1-aryl ring and a *para*-methoxy substituent in the 4-aryl ring. The torsional angle between the 1-aryl ring and the 1-azabuta-1,3-diene plane of **10l** is 37.4° and the distance Fe−O4 is only 3.35 A, suggesting the possibility of chelation of the tricarbonyliron fragment by coordination of the oxygen to the iron atom on haptotropic $\eta^4 \rightarrow \eta^1$ migration during the transfer of the metal fragment (see below).

The transfer of the tricarbonyliron fragment from the (1-azabuta-1,3-diene)tricarbonyliron complexes **10** to cyclohexa-1,3-diene (**1a**) was extensively investigated. It was shown that a smooth transfer of the metal fragment from all 1-azabuta-1,3-diene complexes described in this study was achieved simply by heating the reaction mixture of complex **10** and **1a** in tetrahydrofuran at reflux (Scheme 4, Table 1). The variation of the reaction time for the transfer of the tricarbonyliron fragment to cyclohexa-1,3-diene (**1a**) was investigated for the complexes **10b**, **10c**, and **10g** (Table 3). At all three different reaction times the transfer reagent **10b** was superior. Complex **10b** transfers the metal fragment faster and provides the best yield after 2 h. With increasing turnover, the transfer of the tricarbonyliron fragment from complex **10** to already generated corresponding free 1-azabuta-1,3-diene ligand **9** can compete with the desired transfer to **1a** and finally becomes dominant if only a 1:1 ratio

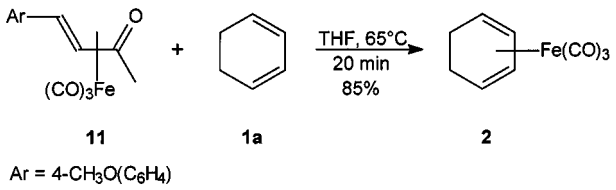
of complex **10** and **1a** is employed. Therefore, an excess of cyclohexa-1,3-diene (**1a**) is used in order to bring the reaction to completion.

Using a standard set of reaction conditions, the transfer of the metal fragment to cyclohexa-1,3-diene (**1a**) was compared for the various (1-azabuta-1,3-diene)tricarbonyliron complexes **10** (Table 1, Scheme 4). By far the best overall result was achieved using tricarbonyl[(1-4-η)-1-(4-methoxyphenyl)-4-phenyl-1-azabuta-1,3-diene]iron (**10b**) as transfer reagent. First, the free 1-azabuta-1,3-diene **9b** can be prepared quantitatively and crystallizes very easily. Secondly, the complexation of **9b** with nonacarbonyldiiron promoted by ultrasound provided the tricarbonyliron complex **10b** in a yield of 88%. Thirdly, the reaction of **10b** with cyclohexa-1,3-diene (**1a**) afforded tricarbonyl(η^4-cyclohexa-1,3-diene)iron (**2**) in 95% yield. Thus, the complexation of **1a** using this 3-step sequence could be realized in an overall yield of 84%. Moreover, the free 1-azadiene **9b** can be recovered from the reaction mixture by simple crystallization in more than 95% yield.

Scheme 5. Transfer of the tricarbonyliron fragment from the 4-methoxybenzylideneacetone complex **11** to cyclohexa-1,3-diene (**1a**)

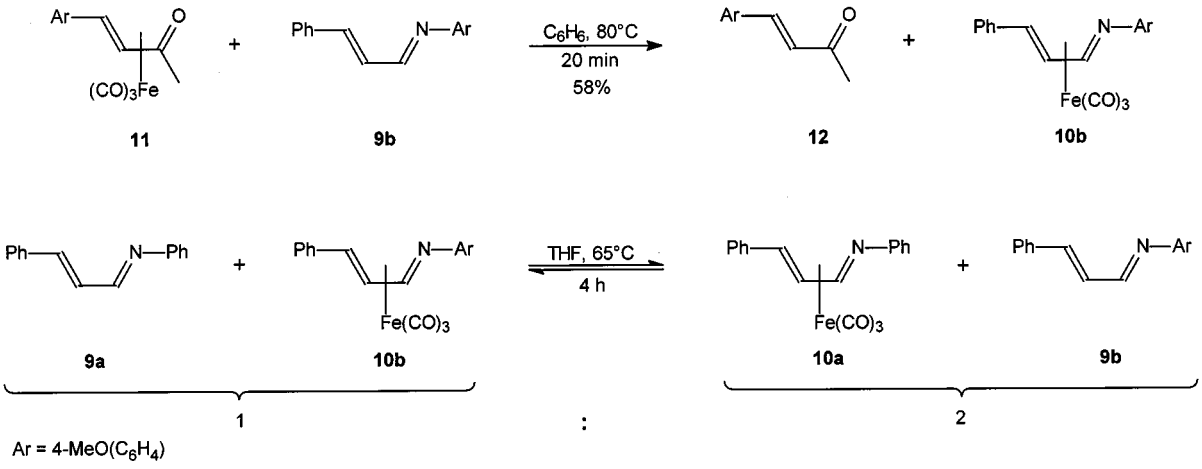


Some information on the relative reactivities of various tricarbonyliron transfer reagents was provided by competition experiments. For this purpose we prepared the tricarbonyliron complex **11** containing the more electron-rich 4-methoxybenzylideneacetone ligand. Complex **11** was reported to be more reactive in transfer reactions than the tricarbonyliron complex **4** with unsubstituted benzylideneacetone as ligand.[27] A smooth transfer of the metal fragment was observed on reaction of complex **11** with cyclohexa-1,3-diene (**1a**) in tetrahydrofuran at reflux and afforded the iron complex **2** after 20 min in 85% yield (Scheme 5). Thus, the required reaction time for comparable yields of **2** with the 1-oxabuta-1,3-diene complex **11** as transfer reagent is significantly shorter than with the 1-azabuta-1,3-diene complexes **10** (cf. Table 3). On direct comparison of the transfer reagents **11** and **10b** this difference in reactivity becomes even more evident (Scheme 6). The transfer of the tricarbonyliron fragment from the tricarbonyl(4-methoxybenzylideneacetone)iron complex **11** to the free 1-azadiene **9b** by heating in benzene at reflux for 20 min afforded exclusively the (1-azabuta-1,3-diene)tricarbonyliron complex **10b** along with the free 1-oxabuta-1,3-diene **12**. However, a transfer of the metal fragment from complex **10b** to the free ligand **12** could not be achieved. This result confirmed the higher reactivity of the 1-oxabuta-1,3-diene complexes for the transfer of the tricarbonyliron fragment.

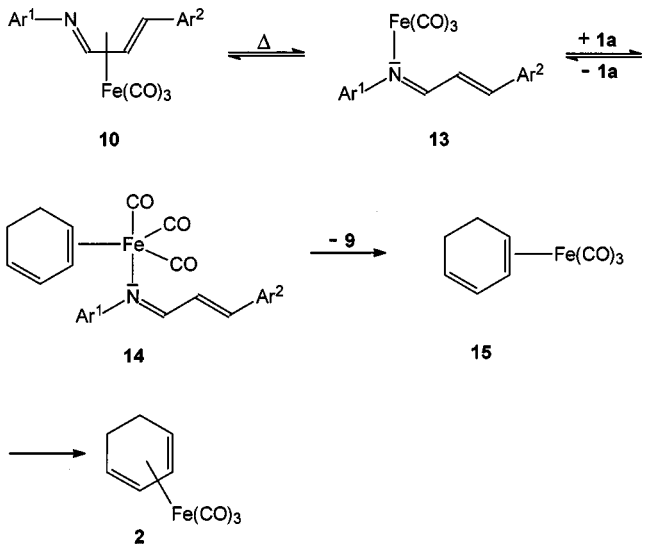
A direct comparison of the (η^4-1-azabuta-1,3-diene)-tricarbonyliron complexes **10a** and **10b** demonstrated the higher transfer reactivity of the latter reagent. Reaction of either equimolar amounts of the free 1-azabuta-1,3-diene **9a** with the iron complex **10b** of the free ligand **9b** with the iron complex **10a** in tetrahydrofuran at reflux led within 4 h to an equilibrium with a 2:1 ratio of the iron complexes **10a** and **10b**. This result confirms again that the transfer of the tricarbonyliron fragment is facilitated by the donor substituent in the *para* position of the 1-aryl ring.

Based on previous kinetic studies on ligand exchange reactions at complex **10a**[28] and our own mechanistic investigations,[23][29] the following mechanism is proposed for the transfer of the tricarbonyliron fragment using (η^4-1-azabuta-1,3-diene)tricarbonyliron complexes **10** (Scheme 7). Complex **10** generates, by a thermally induced haptotropic migration, the 16-electron tricarbonyl(η^1-imine)iron complex **13**. This type of 16-electron η^1-imine complex is also considered as the intermediate in the thermal epimerization of tricarbonyliron complexes of chiral 1-azabuta-1,3-dienes[23] and was obtained on matrix photolysis studies of (η^4-1-azabuta-1,3-diene)tricarbonyliron complexes.[30] The vacant coordination site of complex **13** is filled by η^2-coor-

Scheme 6. Competition experiments between various tricarbonyliron transfer reagents



Scheme 7. Proposed mechanism of the tricarbonyliron transfer from 1,4-diaryl-1-azabuta-1,3-diene complexes **10** to cyclohexa-1,3-diene (**1a**)



dination of cyclohexa-1,3-diene (**1a**) to provide complex **14**. This 18-electron complex, which could not be isolated, represents the crucial intermediate of the transfer reaction. Based on X-ray crystal structure determinations of (η^1-1-azabuta-1,3-diene)tetracarbonyliron complexes[29][31] and additional experimental evidence,[29][32] complex **14** is proposed to have a trigonal-bipyramidal structure with the η^2-coordinated 1,3-diene in equatorial and the η^1-coordinated α,β-unsaturated imine in an axial position. Disengagement of the 1-azabuta-1,3-diene **9** from complex **14** leads to the 16-electron complex **15**, which affords the tricarbonyliron complex **2** by haptotropic ($\eta^2 \rightarrow \eta^4$) migration of the metal fragment.

Conclusion

We have shown that the tricarbonyliron complexes of 1,4-diaryl-substituted 1-azabuta-1,3-dienes serve as highly efficient tricarbonyliron transfer reagents for the complexation of cyclohexa-1,3-diene. Complexation using these transfer reagents can also be applied to a broad range of other 1,3-dienes.[12] After the transfer of the metal fragment the 1-azabuta-1,3-dienes **9** are recovered almost quantitatively by simple crystallization. This fact has been exploited for the development of a complexation of 1,3-dienes using only catalytic amounts of the 1-azabuta-1,3-dienes **9**.[12][13] Most importantly, it has been demonstrated that high asymmetric inductions are achieved on the catalytic complexation of prochiral 1,3-dienes using chiral 1-azabuta-1,3-dienes.[32]

Experimental Section

General: All reactions were carried out using anhydrous and degassed solvents under an argon atmosphere. − Flash chromatography: Baker or Merck silica gel (0.03−0.06 mm). − Ultrasound: Bandelin Sonorex-TK52H cleaning bath; frequency: 35 kHz, used at 50% power. − Melting points: Leitz hot stage and Büchi 535. − IR spectra: Bruker IFS-88, Perkin-Elmer 882 and 1710. − ^{1}H-NMR and ^{13}C-NMR spectra: Bruker WP-200, AC-250, AM-400, and DRX-500; internal standard: tetramethylsilane or the signal of the deuterated solvent; coupling constants in Hz. − Mass spectra: Finnigan MAT-312 and MAT-90: ionization potential: 70 eV. − Elemental analysis: Heraeus CHN-Rapid. Bulb-to-bulb distillation: Büchi glass tube oven GKR-51. − X-ray analyses: The data were collected on a STOE STADI-4 diffractometer using Mo-K_α radiation. The structures were solved by direct methods (SHELXS-86) and refined anisotropically by full-matrix least squares based on all unique F^2 (SHELXL-93); the program SCHAKAL-92 was used for the graphical representation of the crystal structures (E. Keller, a computer program for the graphic representation of molecular and crystallographic models, Universität Freiburg, Germany, 1992).

2,4,6-Trimethoxyaniline (**7i**): A mixture of 2,4,6-trimethoxynitrobenzene[21] (500 mg, 2.35 mmol) and Pd/C (100 mg) in EtOH (30 ml) was stirred under a hydrogen atmosphere (1.1 bar) for 20 h. The reaction mixture was filtered through a short path of Celite/Alox B and the solvent was removed under reduced pressure. Bulb-to-bulb distillation (120°C, 0.1 mbar) of the residue afforded **7i** (380 mg, 88%). Pale yellow solid. M.p. 33−35°C. − IR (drift): ν = 3449, 3362, 2939, 2837, 1611, 1512, 1164 cm^{-1}. − ^{1}H NMR (400 MHz, $CDCl_3$): δ = 3.48 (br s, 2 H), 3.74 (s, 3 H), 3.81 (s, 6 H), 6.15 (s, 2 H). − ^{13}C NMR and DEPT (100 MHz, $CDCl_3$): δ = 55.91 (3 CH_3), 91.40 (2 CH), 118.97 (C), 148.13 (2 C), 152.62 (C). − MS (30°C): *m/z* (%) = 183 (100) [M$^+$], 168 (87), 140 (39), 125 (28); HRMS: 183.0910 ($C_9H_{13}NO_3$, calcd. 183.0895).

4-Cyanocinnamaldehyde (**8**; R^6 = CN, R^7 = H): A solution of 4-cyanobenzaldehyde (823 mg, 6.28 mmol) and (formylmethylene)triphenylphosphorane (2.10 g, 6.90 mmol) in toluene (40 ml) was stirred at 80°C for 24 h. The solvent was evaporated in vacuo and the residue was subjected to flash chromatography (gradient elution, first with Et_2O/pentane, 1:3 and then elution with Et_2O) on silica gel. Evaporation of the solvent afforded a crude product, which was dissolved in Et_2O (30 ml). Recrystallization at −30°C provided the aldehyde **8** (R^6 = CN, R^7 = H) as a mixture of diastereoisomers (771 mg, 78%, (*E*)/(*Z*) ≥ 10:1). Yellow solid. M.p. 132°C. − IR (drift): ν = 2228, 1685, 1627, 1420, 1293, 1129, 987, 817 cm^{-1}. − ^{1}H NMR (250 MHz, $CDCl_3$) [(*E*)-isomer]: δ = 6.78 (dd, *J* = 16.1, 7.5 Hz, 1 H), 7.49 (d, *J* = 16.1 Hz, 1 H), 7.67 (d, *J* = 8.5 Hz, 2 H), 7.74 (d, *J* = 8.5 Hz, 2 H), 9.78 (d, *J* = 7.5 Hz, 1 H). − MS (25°C): *m/z* (%) = 157 (100) [M$^+$], 156 (92), 129 (57), 128 (46), 103 (14), 102 (20), 101 (17); HRMS: 157.0516 ($C_{10}H_7NO$, calcd. 157.0528).

1,4-Diphenyl-1-azabuta-1,3-diene (**9a**): Na_2SO_4 (3 g) was added to a solution of cinnamaldehyde (**8**; R^6 = R^7 = H) (1.91 ml, 2.00 g, 15.1 mmol) and freshly distilled aniline (**7a**) (1.38 ml, 1.41 g, 15.1 mmol) in Et_2O (30 ml). The reaction mixture was stirred at room temp. for 1 h, then filtered, and the residue was washed with Et_2O (20 ml). Crystallization from the filtrate at −20°C afforded the product **9a** (2.56 g, 82%). Pale yellow needles. − IR (drift): ν = 2958, 2839, 1630, 1605, 1505, 1295, 1251, 1032, 986, 720 cm^{-1}. − ^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.17 (m, 5 H), 7.38 (m, 5 H), 7.54 (m, 2 H), 8.27 (dd, *J* = 7.2, 1.0 Hz, 1 H). − ^{13}C NMR and DEPT (63 MHz, $CDCl_3$): δ = 120.87 (2 CH), 126.07 (CH), 127.44 (2 CH), 128.52 (CH), 128.87 (2 CH), 129.13 (2 CH), 129.55 (CH), 135.50 (C), 143.98 (CH), 151.64 (C), 161.60 (CH). − MS (35°C): *m/z* (%) = 207 (40) [M$^+$], 206 (100), 130 (3), 115 (7), 77 (22); HRMS: 207.1062 ($C_{15}H_{13}N$, calcd. 207.1048).

1-(4-Methoxyphenyl)-4-phenyl-1-azabuta-1,3-diene (**9b**): Cinnamaldehyde (**8**; $R^6 = R^7 = H$) (10 ml, 10.5 g, 79.3 mmol) was added to a solution of freshly sublimated *p*-anisidine (**7b**) (9.77 g, 79.3 mmol) in EtOAc (150 ml). $MgSO_4$ (4 g) was added and the mixture was stirred for 1 h at room temp. The solution was separated and the residue was washed with EtOAc. The solutions were combined and the solvent was evaporated slowly at 40°C until crystallization could be observed. Then pentane (100 ml) was added to the warm solution. Recrystallization at −20°C afforded the azadiene **9b** (18.8 g, 100%). Yellow-green crystals. M.p. 122°C. − IR (drift): ν = 3060, 1625, 1600, 1576, 1150, 999, 994, 753 cm^{-1}. − ^{1}H NMR (400 MHz, $CDCl_3$): δ = 3.83 (s, 3 H), 6.92 (br d, *J* = 9.0 Hz, 2 H), 7.11 (m, 2 H), 7.21 (br d, *J* = 9.0 Hz, 2 H), 7.38 (m, 3 H), 7.53 (m, 2 H), 8.30 (dd, *J* = 4.5, 3.8 Hz, 1 H). − ^{13}C NMR and DEPT (63 MHz, $CDCl_3$): δ = 55.29 (CH_3), 114.27 (2 CH), 122.11 (2 CH), 127.24 (2 CH), 128.61 (CH), 128.75 (2 CH), 129.23 (CH), 135.60 (C), 142.85 (CH), 144.37 (C), 158.25 (C), 159.29 (CH). − MS (55°C): *m/z* (%) = 237 (63) [M$^+$], 236 (100), 115 (17); HRMS: 237.1137 ($C_{16}H_{15}NO$, calcd. 237.1154). − $C_{16}H_{15}NO$: C 80.98, H 6.37, N 5.90; found: C 81.14, H 6.35, N 6.35.

1-(2-Methoxyphenyl)-4-phenyl-1-azabuta-1,3-diene (**9c**): Na_2SO_4 (1.5 g) was added to a solution of cinnamaldehyde (**8**; $R^6 = R^7 =$ H) (1.91 ml, 2.00 g, 15.1 mmol) and freshly distilled *o*-anisidine (**7c**) (1.70 ml, 1.86 g, 15.1 mmol) in Et_2O (30 ml). The reaction mixture was stirred at room temp. for 3 h. The solution was separated and the residue was washed with Et_2O. The solution of the combined organic layers was evaporated in vacuo to a volume of 5 ml. Crystallization from the filtrate at −20°C provided the product **9c** (3.11 g, 87%). Yellow crystals. M.p. 67°C. − IR (drift): ν = 1627, 1602, 1581, 1493, 1447, 1296, 1247, 1115, 1027, 1001, 754, 747 cm^{-1}. − ^{1}H NMR (400 MHz, $CDCl_3$): δ = 3.90 (s, 3 H), 6.95 (m, 2 H), 7.00 (dd, *J* = 7.7, 2.0 Hz, 1 H), 7.12 (d, *J* = 16.0 Hz, 1 H), 7.19 (m, 1 H), 7.23 (dd, *J* = 16.0, 8.7 Hz, 1 H), 7.33−7.41 (m, 3 H), 7.53 (m, 2 H), 8.28 (d, *J* = 8.7 Hz, 1 H). − ^{13}C NMR and DEPT (100 MHz, $CDCl_3$): δ = 55.75 (CH_3), 111.22 (CH), 119.41 (CH), 120.93 (CH), 126.99 (CH), 127.47 (2 CH), 128.89 (2 CH), 129.06 (CH), 129.47 (CH), 135.66 (C), 141.21 (C), 143.66 (CH), 152.73 (C), 162.01 (CH). − MS (45°C): *m/z* (%) = 237 (100) [M$^+$], 236 (81), 220 (21), 130 (12), 115 (17); HRMS: 237.1140 ($C_{16}H_{15}NO$, calcd. 237.1154). −$C_{16}H_{15}NO$: C 80.98, H 6.37, N 5.90; found: C 80.46, H 6.37, N 6.30.

1-(4-N,N-Dimethylaminophenyl)-4-phenyl-1-azabuta-1,3-diene (**9d**): A solution of cinnamaldehyde (**8**; $R^6 = R^7 =$ H) (0.95 ml, 1.00 g, 7.57 mmol) and freshly sublimated 4-*N*,*N*-dimethylaminoaniline (**7d**) (1.03 g, 7.57 mmol) in Et_2O (30 ml) was stirred at room temp. for 1 h. Na_2SO_4 (2 g) was added and the reaction mixture was stirred at room temp. for additionally 2 h. The solution was separated and evaporated in vacuo to a volume of 15 ml. Crystallization at −20°C provided the product **9d** (760 mg, 40%). Yellow crystals. M.p. 146°C. − IR (drift): ν = 1625, 1605, 1512, 1448, 1349, 1220, 1169, 955, 821, 752, 693 cm^{-1}. − ^{1}H NMR (400 MHz, $CDCl_3$): δ = 2.99 (s, 6 H), 6.75 (br d, *J* = 9.0 Hz, 2 H), 7.07 (d, *J* = 15.9 Hz, 1 H), 7.14 (dd, *J* = 15.9, 8.2 Hz, 1 H), 7.25 (br d, *J* = 9.0 Hz, 2 H), 7.33 (m, 1 H), 7.39 (m, 2 H), 7.53 (m, 2 H), 8.35 (d, *J* = 8.2 Hz, 1 H). − ^{13}C NMR and DEPT (100 MHz, $CDCl_3$): δ = 40.68 (2 CH_3), 112.76 (2 CH), 122.33 (2 CH), 127.25 (2 CH), 128.86 (2 CH), 129.07 (CH), 129.15 (CH), 136.03 (C), 140.31 (C), 141.63 (CH), 149.58 (C), 156.94 (CH). − MS (65°C): *m/z* (%) = 250 (84) [M$^+$], 249 (100), 233 (12), 124 (4); HRMS: 250.1450 ($C_{17}H_{18}N_2$, calcd. 250.1470).

1-(4-Trifluoromethylphenyl)-4-phenyl-1-azabuta-1,3-diene (**9e**): A solution of cinnamaldehyde (**8**; $R^6 = R^7 =$ H) (1.26 ml, 1.32 g, 10.0 mmol) and freshly sublimated 4-trifluoromethylaniline (**7e**) (1.61 g,

10.0 mmol) in Et_2O (30 ml) was stirred at room temp. for 2 h. The mixture was subsequently dried over Na_2SO_4. The solution was separated and the residue was washed with Et_2O. The solution of the combined organic layers was evaporated to a volume of 20 ml. Crystallization at −20°C provided a crude product, which was washed with a mixture of cold Et_2O/pentane (1:7) to afford **9e** (1.97 g, 72%). Yellow crystals. − IR (drift): ν = 1628, 1611, 1586, 1333, 1313, 1156, 1109, 1073, 841, 753 cm^{-1}. − ^1H NMR (400 MHz, $CDCl_3$): δ = 7.11 (dd, *J* = 15.9, 8.7 Hz, 1 H), 7.22 (d, *J* = 15.9 Hz, 1 H), 7.22 (d, *J* = 8.2 Hz, 2 H), 7.40 (m, 3 H), 7.56 (m, 2 H), 7.64 (d, *J* = 8.2 Hz, 2 H), 8.24 (d, *J* = 8.7 Hz, 1 H). − ^{13}C NMR and DEPT (100 MHz, $CDCl_3$): δ = 121.03 (2 CH), 124.51 (CF_3, q, $^1J_{CF}$ = 276 Hz), 126.38 (2 CH, q, $^3J_{CF}$ = 3.4 Hz), 127.67 (2 CH), 128.08 (CH), 129.00 (2 CH), 129.99 (CH), 135.25 (C), 145.51 (CH), 154.87 (C), 163.30 (CH), the signal of one carbon atom is missing. − MS (35°C): *m/z* (%) = 275 (34) [M^+], 274 (100), 145 (7), 115 (4); HRMS: 275.0907 ($C_{16}H_{12}F_3N$, calcd. 275.0922).

1-(3-Nitrophenyl)-4-phenyl-1-azabuta-1,3-diene (**9f**): A solution of cinnamaldehyde (**8**; $R^6 = R^7$ = H) (0.95 ml, 1.00 g, 7.57 mmol) and freshly sublimated 3-nitroaniline (**7f**) (1.05 g, 7.57 mmol) in C_6H_6 (30 ml) was stirred with activated molecular sieves (4 A, 5 g) at room temp. for 17 h. The reaction mixture was filtered over a short path of Celite. The solvent was evaporated and the residue dissolved in EtOAc (15 ml). The crude product was crystallized by addition of pentane (80 ml). The solid was recrystallized twice from EtOAc/pentane (1:10) to afford the product **9f** (1.07 g, 56%). Yellow needles. − ^1H NMR (200 MHz, $CDCl_3$): δ = 7.11 (dd, *J* = 16.0, 8.4 Hz, 1 H), 7.27 (d, *J* = 16.0 Hz, 1 H), 7.38−7.59 (m, 7 H), 8.00 (m, 1 H), 8.07 (dt, *J* = 7.2, 2.1 Hz, 1 H), 8.30 (d, *J* = 8.4 Hz, 1 H).

1-(2,4-Dimethoxyphenyl)-4-phenyl-1-azabuta-1,3-diene (**9g**): Na_2SO_4 (5 g) was added to a solution of cinnamaldehyde (**8**; $R^6 = R^7$ = H) (2.86 ml, 3.00 g, 22.7 mmol) and freshly distilled 2,4-dimethoxyaniline (**7g**) (3.24 ml, 3.48 g, 22.7 mmol) in Et_2O (50 ml) and the reaction mixture was stirred at room temp. for 2 h. The mixture was filtered and the residue was washed with Et_2O. The solution of the combined ethereal layers was evaporated in vacuo to a volume of 25 ml. Crystallization at −20°C provided the product **9g** (4.91 g, 81%). Yellow crystals. M.p. 75°C. − IR (drift): ν = 1628, 1602, 1588, 1497, 1280, 1259, 1206, 1157, 966, 824, 754 cm^{-1}. − ^1H NMR (250 MHz, $CDCl_3$): δ = 3.82 (s, 3 H), 3.89 (s, 3 H), 6.48 (dd, *J* = 8.5, 2.6 Hz, 1 H), 6.53 (d, *J* = 2.6 Hz, 1 H), 7.01 (d, *J* = 8.5 Hz, 1 H), 7.07 (d, *J* = 16.0 Hz, 1 H), 7.22 (dd, *J* = 16.0, 8.6 Hz, 1 H), 7.35 (m, 3 H), 7.50 (m, 2 H), 8.31 (d, *J* = 8.6 Hz, 1 H). − ^{13}C NMR and DEPT (63 MHz, $CDCl_3$): δ = 55.50 (CH_3), 55.82 (CH_3), 99.24 (CH), 104.33 (CH), 119.53 (CH), 127.36 (2 CH), 128.87 (2 CH), 129.25 (CH), 129.39 (CH), 134.50 (C), 135.90 (C), 142.59 (CH), 154.21 (C), 159.37 (C), 159.90 (CH). − MS (50°C): *m/z* (%) = 267 (93) [M^+], 266 (100), 130 (6), 115 (13); HRMS: 267.1254 ($C_{17}H_{17}NO_2$, calcd. 267.1259).

1-(3,4,5-Trimethoxyphenyl)-4-phenyl-1-azabuta-1,3-diene (**9h**): Na_2SO_4 (5 g) was added to a solution of cinnamaldehyde (**8**; $R^6 = R^7$ = H) (2.86 ml, 3.00 g, 22.7 mmol) and freshly sublimated 3,4,5-trimethoxyaniline (**7h**) (4.16 g, 22.7 mmol) in Et_2O (50 ml) and the reaction mixture was stirred at room temp. for 2 h. The mixture was filtered and the residue was washed with Et_2O. The solution of the combined organic layers was evaporated in vacuo to a volume of 25 ml. Crystallization at −20°C provided the product **9h** (5.33 g, 79%). Yellow needles. M.p. 88−91°C. − IR (drift): ν = 1627, 1584, 1503, 1446, 1417, 1243, 1232, 1008, 991, 838, 753, 693 cm^{-1}. − ^1H NMR (250 MHz, $CDCl_3$): δ = 3.87 (s, 3 H), 3.90 (s, 6 H), 6.48 (s, 2 H), 7.09 (dd, *J* = 15.9, 7.9 Hz, 1 H), 7.19 (d, *J* = 15.9 Hz, 1 H), 7.39 (m, 3 H), 7.55 (m, 2 H), 8.30 (d, *J* = 7.9 Hz, 1 H). − ^{13}C NMR and DEPT (100 MHz, $CDCl_3$): δ = 56.09 (2 CH_3), 60.97 (CH_3), 98.29 (2 CH), 127.46 (2 CH), 128.41 (CH), 128.93 (2 CH), 129.60 (CH), 135.57 (C), 136.67 (C), 143.97 (CH), 147.42 (C), 153.58 (2 C), 160.70 (CH). − MS (70°C): *m/z* (%) = 297 (100) [M^+], 296 (84), 282 (52), 115 (19), 74 (68), 59 (91); HRMS: 297.1347 ($C_{18}H_{19}NO_3$, calcd. 297.1365).

1-(2,4,6-Trimethoxyphenyl)-4-phenyl-1-azabuta-1,3-diene (**9i**): A solution of cinnamaldehyde (**8**; $R^6 = R^7$ = H) (195 µl, 204 mg, 1.54 mmol) and freshly sublimated 2,4,6-trimethoxyaniline (**7i**) (282 mg, 1.54 mmol) in Et_2O (20 ml) was stirred at room temp. for 2 h. The solvent was evaporated and the residue was dissolved in Et_2O (5 ml). Crystallization at −20°C provided the product **9i** (336 mg, 73%). Yellow crystals. M.p. 114°C. − IR (drift): ν = 1628, 1607, 1579, 1468, 1449, 1334, 1228, 1201, 1149, 1121, 812 cm^{-1}. − ^1H NMR (400 MHz, $CDCl_3$): δ = 3.82 (s, 3 H), 3.83 (s, 6 H), 6.21 (s, 2 H), 7.02 (d, *J* = 16.0 Hz, 1 H), 7.20 (dd, *J* = 16.0, 8.9 Hz, 1 H), 7.35 (m, 3 H), 7.51 (m, 2 H), 8.51 (d, *J* = 8.9 Hz, 1 H). − ^{13}C NMR and DEPT (100 MHz, $CDCl_3$): δ = 55.45 (CH_3), 56.12 (2 CH_3), 91.43 (2 CH), 123.64 (C), 127.34 (2 CH), 128.81 (2 CH), 129.02 (CH), 130.19 (CH), 136.15 (C), 142.04 (CH), 153.22 (2 C), 158.09 (C), 165.18 (CH). − MS (75°C): *m/z* (%) = 297 (100) [M^+], 296 (99.7), 266 (9), 130 (12), 115 (17); HRMS: 297.1351 ($C_{18}H_{19}NO_3$, calcd. 297.1365).

4-(4-Methoxyphenyl)-1-phenyl-1-azabuta-1,3-diene (**9j**): Na_2SO_4 (3 g) was added to a solution of 4-methoxycinnamaldehyde (**8**; R^6 = OMe, R^7 = H) (2.00 g, 12.3 mmol) and freshly distilled aniline (**7j**) (1.12 ml, 1.15 g, 12.3 mmol) in Et_2O (30 ml). The mixture was stirred for 3 h at room temp. and then filtered. The residue was washed with Et_2O and the solvent of the combined organic layers was evaporated. The crude product was dissolved in a mixture of Et_2O (80 ml) and EtOAc (10 ml). Recrystallization afforded the azadiene **9j** (2.58 g, 88%). Light yellow crystals. − ^1H NMR (400 MHz, $CDCl_3$): δ = 3.80 (s, 3 H), 6.90 (d, *J* = 8.4 Hz, 2 H), 6.98 (dd, *J* = 15.9, 8.5 Hz, 1 H), 7.07 (d, *J* = 15.9 Hz, 1 H), 7.18 (m, 3 H), 7.36 (t, *J* = 7.5 Hz, 2 H), 7.46 (d, *J* = 8.4 Hz, 2 H), 8.21 (d, *J* = 8.5 Hz, 1 H). − ^{13}C NMR and DEPT (100 MHz, $CDCl_3$): δ = 55.37 (CH_3), 114.40 (2 CH), 120.95 (2 CH), 125.91 (CH), 126.46 (CH), 128.40 (C), 129.07 (2 CH), 129.18 (2 CH), 143.85 (CH), 151.90 (C), 160.86 (C), 161.92 (CH).

1,4-Di-(4-methoxyphenyl)-1-azabuta-1,3-diene (**9k**): 4-Methoxycinnamaldehyde (**8**; R^6 = OMe, R^7 = H) (1.62 g, 10.0 mmol) and freshly sublimated *p*-anisidine (**7k**) (1.23 g, 10.0 mmol) were dissolved in a mixture of Et_2O (30 ml) and THF (15 ml). On cooling the reaction mixture to 5°C for 15 h, the azadiene **9k** crystallized (1.03 g, 39%). The solvent of the mother liquor was evaporated and the residue was dissolved in EtOAc (200 ml) at 65°C. Recrystallization at −20°C afforded **9k** (1.50 g, 56%). Total yield of the azadiene **9k**: 2.53 g (95%). Light yellow crystals. M.p. 182°C. − IR (drift): ν = 1900, 1627, 1602, 1576, 1504, 1441, 1307, 1290, 1245, 1178, 1031, 864, 816 cm^{-1}. − ^1H NMR (400 MHz, $CDCl_3$): δ = 3.82 (s, 3 H), 3.84 (s, 3 H), 6.91 (br d, *J* = 8.8 Hz, 4 H), 6.98 (dd, *J* = 15.9, 8.4 Hz, 1 H), 7.07 (d, *J* = 15.9 Hz, 1 H), 7.19 (br d, *J* = 8.8 Hz, 2 H), 7.47 (br d, *J* = 8.8 Hz, 2 H), 8.26 (d, *J* = 8.4 Hz, 1 H). − ^{13}C NMR and DEPT (63 MHz, $CDCl_3$): δ = 55.74 (CH_3), 55.86 (CH_3), 114.75 (2 CH), 114.78 (2 CH), 122.53 (2 CH), 127.08 (CH), 128.99 (C), 129.28 (2 CH), 143.19 (CH), 145.17 (C), 158.59 (C), 160.24 (CH), 161.07 (C). − MS (80°C): *m/z* (%) = 267 (34) [M^+], 266 (100), 252 (12), 145 (6); HRMS: 267.1264 ($C_{17}H_{17}NO_2$, calcd. 267.1259).

1-(2-Methoxyphenyl)-4-(4-methoxyphenyl)-1-azabuta-1,3-diene (**9l**): A solution of 4-methoxycinnamaldehyde (**8**; R^6 = OMe, R^7 =

H) (1.62 g, 10.0 mmol) and freshly distilled *o*-anisidine (**7l**) (1.13 ml, 1.23 g, 10.0 mmol) in Et_2O (30 ml) was stirred at room temp. for 2 h. Subsequently, the reaction mixture was dried over Na_2SO_4. The solution was separated and the residue was washed with Et_2O. The solution of the combined organic layers was evaporated in vacuo to a volume of 20 ml. Crystallization at −30°C afforded **9l** (2.11 g, 79%). Light yellow needles. M.p. 105°C. − IR (drift): ν = 1626, 1580, 1492, 1307, 1246, 1025, 810, 754 cm^{-1}. − ^1H NMR (400 MHz, $CDCl_3$): δ = 3.82 (s, 3 H), 3.90 (s, 3 H), 6.90−7.00 (m, 5 H), 7.04−7.20 (m, 3 H), 7.47 (br d, *J* = 8.8 Hz, 2 H), 8.24 (dd, *J* = 7.5, 0.8 Hz, 1 H). − ^{13}C NMR and DEPT (100 MHz, $CDCl_3$): δ = 55.30 (CH_3), 55.70 (CH_3), 111.12 (CH), 114.30 (2 CH), 119.34 (CH), 120.88 (CH), 126.69 (CH), 126.95 (CH), 128.46 (C), 128.96 (2 CH), 141.38 (C), 143.40 (CH), 152.69 (C), 160.69 (C), 162.21 (CH). − MS (50°C): *m/z* (%) = 267 (40) [M^+], 266 (100), 252 (24), 250 (8), 236 (6); HRMS: 267.1249 ($C_{17}H_{17}NO_2$, calcd. 267.1259).

1-(4-Trifluoromethylphenyl)-4-(4-methoxyphenyl)-1-azabuta-1,3-diene (**9m**): 4-Methoxycinnamaldehyde (**8**; R^6 = OMe, R^7 = H) (1.62 g, 10.0 mmol) and freshly distilled 4-trifluoromethylaniline (**7m**) (1.25 ml, 1.61 g, 10.0 mmol) were dissolved in a mixture of Et_2O (50 ml) and THF (15 ml). The reaction mixture was cooled to 5°C for 15 h and was dried over Na_2SO_4. After filtration the solvent was evaporated and the residue was crystallized from Et_2O/EtOAc (3:1, 80 ml) to afford the azadiene **9m** (1.81 g, 59%). Yellow crystals. M.p. 121°C. − IR (drift): ν = 1628, 1588, 1513, 1330, 1270, 1130, 1011, 850 cm^{-1}. − ^1H NMR (400 MHz, $CDCl_3$): δ = 3.85 (s, 3 H), 6.94 (br d, *J* = 8.8 Hz, 2 H), 6.99 (dd, *J* = 15.9, 8.9 Hz, 1 H), 7.16 (d, *J* = 15.9 Hz, 1 H), 7.21 (d, *J* = 8.4 Hz, 2 H), 7.50 (br d, *J* = 8.8 Hz, 2 H), 7.62 (d, *J* = 8.4 Hz, 2 H), 8.20 (d, *J* = 8.9 Hz, 1 H). − ^{13}C NMR and DEPT (100 MHz, $CDCl_3$): δ = 55.39 (CH_3), 114.44 (2 CH), 121.02 (2 CH), 124.30 (CF_3, q, $^1J_{CF}$ = 272 Hz), 125.93 (CH), 126.35 (2 CH, q, $^3J_{CF}$ = 3.5 Hz), 127.53 (C, q, $^2J_{CF}$ = 32.5 Hz), 128.06 (C), 129.27 (2 CH), 145.33 (CH), 155.04 (C), 161.15 (C), 163.54 (CH). − MS (40°C): *m/z* (%) = 305 (25) [M^+], 304 (100), 290 (13), 261 (7), 145 (7); HRMS: 305.1006 ($C_{17}H_{14}F_3NO$, calcd. 305.1027).

1-(2,4-Dimethoxyphenyl)-4-(4-methoxyphenyl)-1-azabuta-1,3-diene (**9n**): A solution of 4-methoxycinnamaldehyde (**8**; R^6 = OMe, R^7 = H) (1.00 g, 6.17 mmol) and freshly distilled 2,4-dimethoxyaniline (**7n**) (0.88 ml, 945 mg, 6.17 mmol) in THF (30 ml) was stirred at 40°C for 1 h. The solvent was evaporated and the residue was crystallized from a mixture of Et_2O (200 ml) and EtOAc (30 ml) at −20°C to provide the product **9n** (1.46 g, 80%). Yellow solid. M.p. 123°C. − IR (drift): ν = 1625, 1603, 1587, 1509, 1497, 1259, 1246, 1206, 1176, 1157, 1128, 1025, 824 cm^{-1}. − ^1H NMR (400 MHz, $CDCl_3$): δ = 3.80 (s, 3 H), 3.81 (s, 3 H), 3.88 (s, 3 H), 6.46 (dd, *J* = 8.6, 2.5 Hz, 1 H), 6.52 (d, *J* = 2.5 Hz, 1 H), 6.89 (d, *J* = 8.7 Hz, 2 H), 6.98 (d, *J* = 8.6 Hz, 1 H), 7.02 (d, *J* = 15.9 Hz, 1 H), 7.09 (dd, *J* = 15.9, 8.3 Hz, 1 H), 7.45 (d, *J* = 8.7 Hz, 2 H), 8.26 (d, *J* = 8.3 Hz, 1 H). − ^{13}C NMR and DEPT (100 MHz, $CDCl_3$): δ = 55.33 (CH_3), 55.49 (CH_3), 55.80 (CH_3), 99.20 (CH), 104.26 (CH), 114.33 (2 CH), 119.41 (CH), 127.30 (CH), 128.72 (C), 128.85 (2 CH), 134.72 (C), 142.40 (CH), 154.13 (C), 159.14 (C), 160.22 (CH), 160.57 (C). − MS (85°C): *m/z* (%) = 297 (56) [M^+], 296 (100), 282 (22), 145 (5); HRMS: 297.1354 ($C_{18}H_{19}NO_3$, calcd. 297.1365).

1-(4-Methoxyphenyl)-4-(2-methoxyphenyl)-1-azabuta-1,3-diene (**9o**): Na_2SO_4 (5 g) was added to a solution of 2-methoxycinnamaldehyde (**8**; R^6 = H, R^7 = OMe) (2.00 g, 12.3 mmol) and freshly sublimated *p*-anisidine (**7o**) (1.52 g, 12.3 mmol) in Et_2O (100 ml). The reaction mixture was stirred at room temp. for 2 h. The solution was separated and the residue was washed with Et_2O. The solvent of the combined organic solutions was evaporated and the residue was dissolved in Et_2O/pentane (2:1, 100 ml). Precipitation of the product was completed by cooling this solution to −78°C and subsequent warming to 40°C. Repetition of this procedure several times afforded the product **9o** (2.82 g, 86%). Yellow solid. M.p. 62°C. − IR (drift): ν = 2839, 1620, 1596, 1504, 1484, 1467, 1244, 1028, 990, 956, 756 cm^{-1}. − ^1H NMR (250 MHz, $CDCl_3$): δ = 3.82 (s, 3 H), 3.89 (s, 3 H), 6.88−7.01 (m, 2 H), 6.91 (br d, *J* = 8.9 Hz, 2 H), 7.11−7.23 (m, 2 H), 7.17 (dd, *J* = 16.1, 9.0 Hz, 1 H), 7.32 (m, 1 H), 7.48 (d, *J* = 16.1 Hz, 1 H), 7.57 (dd, *J* = 7.7, 1.6 Hz, 1 H), 8.31 (d, *J* = 9.0 Hz, 1 H). − ^{13}C NMR and DEPT (63 MHz, $CDCl_3$): δ = 56.13 (2 CH_3), 111.72 (CH), 115.04 (2 CH), 121.51 (CH), 122.85 (2 CH), 125.38 (C), 128.30 (CH), 129.90 (CH), 131.24 (CH), 138.96 (CH), 145.43 (C), 158.12 (C), 158.90 (C), 161.24 (CH). − MS (70°C): *m/z* (%) = 267 (32) [M^+], 266 (24), 252 (16), 237 (16), 236 (100), 115 (6); HRMS: 267.1237 ($C_{17}H_{17}NO_2$, calcd. 267.1259).

4-(4-Cyanophenyl)-1-phenyl-1-azabuta-1,3-diene (**9p**): A solution of 4-cyanocinnamaldehyde (**8**; R^6 = CN, R^7 = H) (157 mg, 1.00 mmol) and freshly distilled aniline (**7p**) (182 µl, 186 mg, 2.00 mmol) in THF (10 ml) was stirred at room temp. for 1.5 h. After addition of pentane (30 ml) the product was crystallized at −30°C to afford the azadiene **9p** (181 mg, 78%). Yellow crystals. M.p. 104°C. − IR (drift): ν = 3049, 2221, 1627, 1608, 1583, 1488, 1413, 1156, 983, 954, 816, 764 cm^{-1}. − ^1H NMR (250 MHz, $CDCl_3$): δ = 7.32−7.47 (m, 5 H), 7.58 (m, 2 H), 7.77 (d, *J* = 7.9 Hz, 2 H), 7.83 (d, *J* = 7.9 Hz, 2 H), 8.47 (d, *J* = 7.0 Hz, 1 H). − ^{13}C NMR and DEPT (63 MHz, $CDCl_3$): δ = 112.93 (C), 119.11 (C≡N), 121.48 (2 CH), 127.22 (CH), 128.27 (2 CH), 129.79 (2 CH), 132.27 (CH), 133.14 (2 CH), 140.35 (C), 141.68 (CH), 151.70 (C), 161.00 (CH). − MS (60°C): *m/z* (%) = 232 (53) [M^+], 231 (100), 77 (21); HRMS: 232.1015 ($C_{16}H_{12}N_2$, calcd. 232.1000).

4-(4-Cyanophenyl)-1-(2,4-dimethoxyphenyl)-1-azabuta-1,3-diene (**9q**): A solution of freshly distilled 2,4-dimethoxyaniline (**7q**) (141 µl, 153 mg, 1.00 mmol) in Et_2O (14 ml) was added to a solution of 4-cyanocinnamaldehyde (**8**; R^6 = CN, R^7 = H) (157 mg, 1.00 mmol) in Et_2O (20 ml). The reaction mixture was stirred for 10 min at room temp. and then cooled to −20°C for 15 h without stirring. Evaporation of the solvent afforded the product **9q** (289 mg, 99%). Orange solid. M.p. 121°C. − IR (drift): ν = 2223, 1623, 1604, 1585, 1498, 1311, 1258, 1210, 1161, 1130, 1047, 843, 827 cm^{-1}. − ^1H NMR (400 MHz, $CDCl_3$): δ = 3.83 (s, 3 H), 3.90 (s, 3 H), 6.49 (dd, *J* = 8.6, 2.6 Hz, 1 H), 6.54 (d, *J* = 2.6 Hz, 1 H), 7.05 (d, *J* = 8.6 Hz, 1 H), 7.06 (d, *J* = 16.0 Hz, 1 H), 7.28 (dd, *J* = 16.0, 8.9 Hz, 1 H), 7.58 (br d, *J* = 8.4 Hz, 2 H), 7.65 (br d, *J* = 8.4 Hz, 2 H), 8.36 (d, *J* = 8.9 Hz, 1 H). − ^{13}C NMR and DEPT (100 MHz, $CDCl_3$): δ = 55.54 (CH_3), 55.86 (CH_3), 99.23 (CH), 104.49 (CH), 112.06 (C), 118.69 (C≡N), 119.73 (CH), 127.59 (2 CH), 132.63 (2 CH), 132.69 (CH), 133.80 (C), 139.62 (CH), 140.27 (C), 154.45 (C), 158.43 (CH), 159.92 (C). − MS (85°C): *m/z* (%) = 292 (43) [M^+], 291 (42), 157 (100), 156 (82), 153 (25), 138 (28), 129 (51), 128 (43); HRMS: 292.1203 ($C_{18}H_{16}N_2$, calcd. 292.1212).

1-(4-Methoxyphenyl)-4-(4-N,N-dimethylaminophenyl)-1-azabuta-1,3-diene (**9r**): A solution of 4-*N*,*N*-dimethylaminocinnamaldehyde (**8**; R^6 = NMe_2, R^7 = H) (1.00 g, 5.71 mmol) and freshly sublimated *p*-anisidine (**7r**) (703 mg, 5.71 mmol) in CH_2Cl_2 (30 ml) was stirred at room temp. for 1 h. Na_2SO_4 (2 g) was added and the reaction mixture was stirred at room temp. for an additional 2 h. The solution was separated and by addition of Et_2O/pentane (1:7, 50 ml) the product **9r** was precipitated (1.36 g, 85%). Green crystals. M.p. 146−150°C. − IR (drift): ν = 2540, 2057, 2006, 1887,

1609, 1575, 1503, 1248, 1156, 836, 810 cm^{-1}. − ^1H NMR (250 MHz, $CDCl_3$): δ = 3.01 (s, 6 H), 3.82 (s, 3 H), 6.63−6.76 (m, 2 H), 6.87−6.94 (m, 2 H), 6.92 (dd, *J* = 15.7, 8.5 Hz, 1 H), 7.05 (d, *J* = 15.7 Hz, 1 H), 7.18 (br d, *J* = 8.9 Hz, 2 H), 7.42 (br d, *J* = 8.9 Hz, 2 H), 8.24 (d, *J* = 8.5 Hz, 1 H). − ^{13}C NMR and DEPT (125 MHz, $CDCl_3$): δ = 40.11 (2 CH_3), 55.40 (CH_3), 111.96 (2 CH), 114.30 (2 CH), 122.02 (2 CH), 123.74 (C), 124.08 (CH), 128.87 (2 CH), 143.90 (CH), 145.05 (C), 151.11 (C), 157.86 (C), 160.35 (CH). − MS (110°C): *m/z* (%) = 280 (45) [M^+], 279 (100), 265 (3), 158 (7); HRMS: 280.1563 ($C_{18}H_{20}N_2O$, calcd. 280.1576).

1-(4-Methoxyphenyl)-4-(4-nitrophenyl)-1-azabuta-1,3-diene (**9s**): A solution of 4-nitrocinnamaldehyde (**8**; R^6 = NO_2, R^7 = H) (713 mg, 4.02 mmol) in THF (20 ml) was added to a solution of freshly sublimated *p*-anisidine (**7s**) (495 mg, 4.02 mmol) in THF (20 ml). The reaction mixture was stirred at room temp. for 1 h. The solvent was evaporated and the residue was recrystallized from EtOAc (60 ml) to afford the azadiene **9s** (848 mg, 75%). Yellow needles. M.p. 164°C. − IR (drift): ν = 1622, 1608, 1595, 1441, 1415, 1300, 953, 758 cm^{-1}. − ^1H NMR (250 MHz, $CDCl_3$): δ = 3.84 (s, 3 H), 6.94 (br d, *J* = 8.9 Hz, 2 H), 7.14 (d, *J* = 16.1 Hz, 1 H), 7.23 (dd, *J* = 16.1, 8.3 Hz, 1 H), 7.24 (br d, *J* = 8.9 Hz, 2 H), 7.66 (br d, *J* = 8.8 Hz, 2 H), 8.25 (br d, *J* = 8.8 Hz, 2 H), 8.34 (d, *J* = 8.3 Hz, 1 H). − ^{13}C NMR and DEPT (100 MHz, $CDCl_3$): δ = 55.51 (CH_3), 114.52 (2 CH), 122.46 (2 CH), 124.25 (2 CH), 127.78 (2 CH), 132.86 (CH), 139.45 (CH), 142.02 (C), 143.95 (C), 147.76 (C), 157.90 (CH), 158.98 (C). − MS (100°C): *m/z* (%) = 282 (100) [M^+], 281 (74), 235 (65), 192 (9); HRMS: 282.0998 ($C_{16}H_{14}N_2O_3$, calcd. 282.1004).

Preparation of the (η⁴-1-Azabuta-1,3-diene)tricarbonyliron Complexes **10** *by Sonochemical Reaction of the 1-Azabuta-1,3-dienes* **9** *with Nonacarbonyldiiron at Room Temperature − General Procedure:* A solution of the 1-azabuta-1,3-dienes **9** (1 eq.) and $Fe_2(CO)_9$ (1.5 eq.) in THF (15 ml) was sonicated at room temp. for 16 h. Removal of the solvent by evaporation and flash chromatography (Et_2O/pentane) of the residue on silica gel afforded the tricarbonyliron complexes **10** as red crystals (Table 5).

The following reactions were run on a different scale: [a] Cyclohexa-1,3-diene **1a** (0.20 ml, 168 mg, 2.10 mmol) and azadiene complex **10a** (250 mg, 0.720 mmol). − [b] Cyclohexa-1,3-diene **1a** (0.20 ml, 168 mg, 2.10 mmol) and azadiene complex **10b** (200 mg, 0.531 mmol). − [c] Cyclohexa-1,3-diene **1a** (0.25 ml, 210 mg, 2.62 mmol) and azadiene complex **10d** (200 mg, 0.513 mmol).

Preparation of Tricarbonyl(η^4-cyclohexa-1,3-diene)iron (**2**) *by Direct Complexation of Cyclohexa-1,3-diene* (**1a**) *with Nonacarbonyldiiron:* Cyclohexa-1,3-diene (**1a**) (13.9 ml, 146 mmol) was added to a suspension of nonacarbonyldiiron (44.2 g, 121.5 mmol) in THF (250 ml) and the heterogeneous mixture was stirred at reflux for 6 h. The mixture was cooled to room temp., filtered through a short path of Celite, and the solvent was removed. The residue was dissolved in light petroleum and filtered through a short path of Alox B. Evaporation of the solvent in vacuo afforded the iron complex **2** (11.5 g, 43%), which could be subjected directly to hydride abstraction. Yellow oil. − IR (film): ν = 3009, 2926, 2907, 2887, 2850, 2042, 1957, 1467, 1333, 1180, 1029, 1007, 938, 879, 865, 642, 623 cm^{-1}. − ^1H NMR (400 MHz, C_6D_6): δ = 1.18 (br d, *J* = 12 Hz, 2 H), 1.45 (br dt, *J* = 12, 2 Hz, 2 H), 2.74 (dd, *J* = 5, 2 Hz, 2 H), 4.63 (dd, *J* = 5, 3 Hz, 2 H). − ^{13}C NMR and DEPT (100 MHz, C_6D_6): δ (*T* = 298 K) = 23.82 (2 CH_2), 62.52 (2 CH), 85.37 (2 CH), 212.63 (3 CO); ^{13}C NMR (125 MHz, [D_8]toluene): δ (*T* = 185 K) = 23.45 (2 CH_2), 62.30 (2 CH), 85.09 (2 CH), 211.32 (2 CO), 216.05 (CO); δ (*T* = 298 K) = 23.89 (2 CH_2), 62.47 (2 CH), 85.41 (2 CH), 212.56 (3 CO). − MS (20°C): *m*/*z* (%) = 220 (9) [M^+], 192 (32), 164 (5), 162 (10), 134 (100), 56 (33); HRMS: 219.9834 ($C_9H_8FeO_3$, calcd. 219.9823).

Synthesis of the Tricarbonyl(η^5-cyclohexadienylium)iron Tetrafluoroborate (**3**) *by Hydride Abstraction of the Iron Complex* **2**: A solution of tricarbonyl(η^4-cyclohexa-1,3-diene)iron (**2**) (11.5 g, 52.4 mmol) in CH_2Cl_2 (70 ml) was added to a solution of triphenylmethyl tetrafluoroborate (20.8 g, 62.9 mmol) in CH_2Cl_2 (70 ml). The reaction mixture was stirred for 40 min at room temp. and then poured into wet Et_2O (700 ml). The resulting yellow precipitate was washed twice with Et_2O (150 ml) and dried in vacuo to provide pure tricarbonyl(η^5-cyclohexadienylium)iron tetrafluoroborate (**3**) (15.7 g, 98%). Yellow crystals. − IR (KBr): ν = 2118, 2060, 1455, 1410, 1311, 1062, 603, 589, 558 cm^{-1}. − ^1H NMR (200 MHz, CD_3CN): δ = 1.91 (d, *J* = 15.7 Hz, 1 H), 2.92 (dt, *J* = 15.7, 6.3 Hz, 1 H), 4.24 (t, *J* = 6.3 Hz, 2 H), 5.83 (t, *J* = 6.3 Hz, 2 H), 7.16 (t, *J* = 6.3 Hz, 1 H).

Keywords: Rare earth metals / Lanthanides / Chelating sulfonamides / Silylamide route / C_2 symmetry

The reaction of rare earth silylamides $Ln[N(SiHMe_2)_2]_3(thf)_n$ [n = 1 for Sc (**1a**); n = 2 for Y (**1b**), La (**1c**), Nd (**1d**)] with *trans*-1,2-bis(2,4,6-triisopropylbenzenesulfonamido)cyclohexane (H_2L, *rac*-**2**) in toluene at ambient temperature proceeds via an extended silylamide route, affording highly soluble complexes $Sc(L)[N(SiHMe_2)_2]$ (**3**) and $Ln(L)[N(SiHMe_2)_2](thf)$ (**4a–c**) in excellent yields. An X-ray crystallographic study performed on the solvent-free, dinuclear yttrium derivative **5** revealed an unusual $\mu_2,\eta^4:\eta^1$-coordination of the disulfonamide ligand, involving bridging S=O groups. In solution, equilibria between dimeric and monomeric forms, dependent on the presence of a donor molecule, were observed by NMR techniques.

In the last decade rare earth metals have gained considerable interest as highly efficient catalysts for a variety of organic transformations.[1] Dicyclopentadienyl complexes, e.g., *ansa*-lanthanidocenes as depicted in Figure 1, represent key compounds in precatalyst design. Although the cyclopentadienyl backbone imposes a unique electronic and steric situation including complex chirality, broader application of these systems is hampered by their pronounced sensibility towards moisture. Recently, alternative ligands were successfully introduced to cope with the peculiarities of organolanthanide chemistry, e.g., lanthanide binaphthol derivatives in Lewis acid catalysis.[2] Our current research interests put main emphasis on the replacement of the dicyclopentadienyl backbone by other divalent auxiliary ligands, which are prone to fine-tuning in the sense of solubility, chirality and steric and electronic factors. In the course of these studies we found synthetic access to the first monomeric salen complexes of the lanthanide elements via an extended silylamide route (Figure 1).[3] Encouraged by these results we anticipated application of this synthetic route to other catalytically relevant ligand systems. Disulfonamides constitute a class of ligands well established in the coordination chemistry of strongly Lewis acidic metal centers such as boron(III),[4] aluminum(III),[5] and titanium(IV).[6][7] These complexes are of significant importance in several catalytic transformations such as the Diels-Alder reaction or the alkylation of carbonyl groups.[8] Analogous lanthanide complexes, though postulated once,[9] have never been characterized. Here, we report the synthesis and characterization of the first soluble rare earth complexes derived from chelating disulfonamides.

[*] The use of $Ln[N(SiMe_3)_2]_3$ as a synthetic precursor is hampered by partial product oligomerization.

Results and Discussion

The synthesis of the novel disulfonamide complexes **3** and **4a–c** was achieved by an extended silylamide route,[3][10][11] utilizing $Ln[N(SiHMe_2)_2]_3(thf)_n$ as synthetic precursors as shown in Scheme 1. The ligand *trans*-1,2-bis(2,4,6-triisopropylbenzenesulfonamido)cyclohexane (*rac*-**2**) was chosen according to the following considerations: (i) *trans*-1,2-diaminocyclohexane provides a relatively rigid backbone. Additionally, it offers easy access to enantiomerically pure ligands, which should lead to enantioselective precatalysts.[12] (ii) The sterically demanding triisopropylphenyl groups should favor monomeric complexes, and (iii) induce increased solubility in non-polar solvents. The rare earth elements Sc, Y, and La were selected to cover the entire range of cation radii and in the case of Nd to visually follow the reaction by color effects. Our examinations on rare earth salen derivatives revealed that cation size and ligand bite angle are important factors to direct the formation of monomeric complexes.[3b]

The disulfonamide complexes **3** and **4a–c** are formed by the subsequent aminolysis of two rare earth bis(dimethylsilyl)amide bonds[*] by the more acidic sulfonamide (pK_a ca. 10–11, measured in water).[13] The remaining third bis(dimethylsilyl)amide ligand was characterized by a sharp Si–H vibration at ca. 2065 cm^{-1}. Interestingly, the reaction is accompanied by the loss of one molecule THF (GC-MS analysis). Compounds **3** and **4a–c** are obtained in yields > 90% after evaporation of the volatiles. Their excellent solubility even in non-polar solvents such as toluene or *n*-hexane indicates the formation of non-oligomerized products for the differently sized cations. Although the enhanced solubility hampered further purification by recrystallization, satisfying elemental analyses were obtained in most

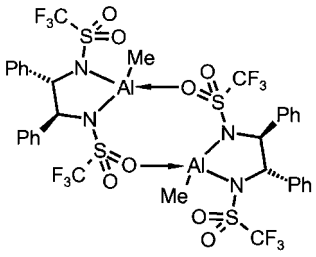
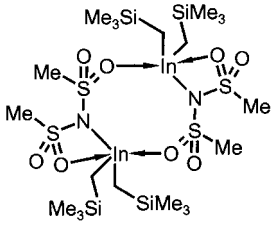
cases, indicating a very clean reaction under mild conditions. Elemental analysis revealed that one THF solvent molecule coordinates to the larger lanthanide cations while scandium can accomodate no THF molecule. This finding could also be confirmed by ^{1}H-NMR spectroscopy. The yttrium derivative **4a** could be further desolvated by prolonged exposure to high vacuum to yield the less soluble compound **5**, crystals of which could be grown from hot *n*-hexane.

First NMR spectroscopic examinations of compounds **3**–**5** in C_6D_6 revealed spectra rather difficult to understand with broad, poorly resolved, overlapping signals. We assume two major effects to be responsible for this behavior. Firstly, sulfonyl moieties are known to serve as electron donors capable of forming Lewis acid-base adducts with metal cations. Depending on geometric and electronic factors Lewis acid-base adduct formation can occur in both an intra- and intermolecular fashion. As shown previously for aluminum (**6**)[5a] and indium (**7**)[14] sulfonamides, organization to dimers leads to extended heterocyclic ring systems (Figure 2).

Figure 2. Intermolecular bridging of sulfonamide ligands via S=O donor interactions; for **7**, even intramolecular interactions are discussed



6

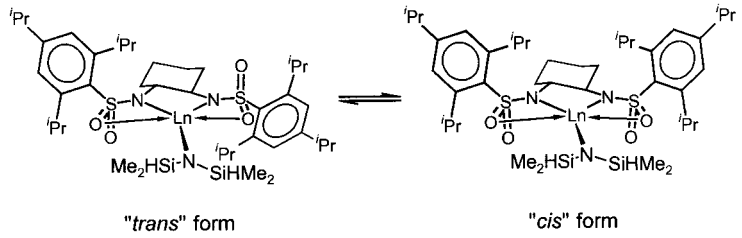


7

A monomer-dimer equilibrium in solution is supposed to partly contribute to the poor NMR spectra observed in C_6D_6. The second reason can be found in an unusually strong *intramolecular* coordination of the sulfonamido group. Very recently, Walsh and Gagne independently reported a η^2-coordination of the sulfonamido group in titanium complexes, resembling strongly our lanthanide derivatives.[6][7] Although these monomeric complexes do not show similar solution behavior, we postulate *cis*/*trans* isomers observable on NMR time scale, resulting from a hindered rotation around the S–N bond (Scheme 2). Evidence for both of these assumptions is given by an X-ray diffraction study performed on the yttrium complex **5** (vide infra).

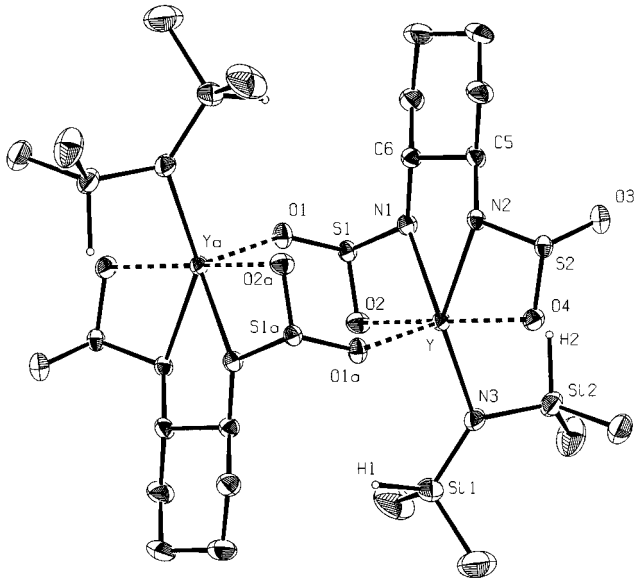
Consequently, the NMR spectra simplified remarkably when recorded in a donor solvent like [D_8]THF. THF coor-

Scheme 2. Dynamic equilibrium between *trans*- and *cis*-rotamers (coordinated THF has been omitted for clarity)



dination reduces the Lewis acidity of the metal center and thus lowers the rotation barrier around the S−N bond. Furthermore, THF coordination counteracts dimerization by replacing *intermolecular* sulfonyl bridging. The observed set of resonances is in agreement with a C_2-symmetric structure on the NMR time scale. As expected, ^{1}H-, ^{13}C-, and ^{29}Si-NMR spectra of **3**−**5** are very similar to each other. Moreover, addition of only one equivalent of a strong donor, e.g., triphenylphosphane oxide, is sufficient to achieve the same result, proven in case of the ^{1}H-NMR spectrum of THF-free **5** in C_6D_6. Trends within the series cannot be determined easily, except the rising high field shift of the ^{29}Si resonance from $\delta = -23.4$ to $\delta = -26.1$ which correlates to the decreasing Lewis acidity from Sc to La. No fluxional behavior could be observed by variable temperature NMR studies in the range of −80 to 110°C in [D_8]toluene.

Figure 3. Solid-state structure of dimeric complex **5** (PLATON[16] plot). Thermal ellipsoids are drawn at the 50% probability level. 2,4,6-Triisopropylphenyl groups at the sulfur atoms and all carbon bonded hydrogen atoms are omitted for clarity[a]



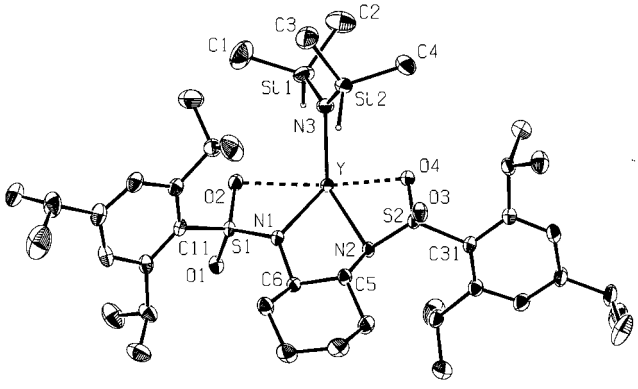
[a] Selected bond lengths [A] and angles [°]: Y−N(1) 2.365(2), Y−N(2) 2.403(2), Y−N(3) 2.239(2), Y−O(1)a 2.234(2), Y−O(2) 2.600(2), Y−O(4) 2.358(2), S(1)−O(1) 1.482(2), S(1)−O(2) 1.463(2), S(2)−O(3) 1.438(2), S(2)−O(4) 1.491(2), S(1)−N(1) 1.546(2), S(2)−N(2) 1.563(2), Y−Si(1) 3.5401(3), Y−Si(2) 3.1058(7), Y−H(1) 3.573(9), Y−H(2) 2.619(1); N(1)−Y−N(2) 66.41(6), Y−N(1)−S(1) 101.64(9), Y−N(2)−S(2) 96.45(8), O(2)−S(1)−N(1) 103.11(9), O(4)−S(2)−N(2) 100.87(9), Y−O(2)−S(1) 94.25(7), Y−O(4)−S(2) 100.45(7), O(2)−Y−N(1) 56.45(5), O(4)−Y−N(2) 59.29(5), Y−N(3)−Si(1) 127.6(1), Y−N(3)−Si(2) 103.57(9), Si(1)−N(3)−Si(2) 128.4(1).

The X-ray structure determination of **5** (triclinic, space group *P*1) both revealed its dimeric nature and an unusual coordination of the formally bidentate disulfonamide ligand. Complex **5** consists of the two enantiomers located on a crystallographic inversion center, forming a structure which could be described as a "racemic dimer" (Figure 3). The sulfonyl oxygen bridging results in the formation of an eight-membered chair-shaped ring system comparable to those in **6** and **7**.[5][14] A similar structural motif is also found in μ,η^2-SO_3CF_3 bridged lanthanidocene triflate complexes (cf. $[(C_5H_5)_2Yb(\mu\text{-}O_2SOCF_3)]_2$).[15] The resulting coordination polyhedron of the central yttrium is best considered as a bi-capped tetrahedron with the intramolecularly coordinating O(2) and O(4) in the capping positions.

In the solid state complex **5** adopts a *trans* configuration, which is fixed via intramolecular coordination of two sulfonyl oxygen atoms, as depicted in Figure 4. The detection of the *trans* form gives additional evidence of the solution behavior of compound **5** (Scheme 2).

Closer inspection of the yttrium disulfonamide bonding reveals an unprecedented $\mu_2,\eta^4{:}\eta^1$-coordination mode of this ligand system. The η^4-coordination results from two $Y-N^{(sulfonamide)}$ and two intramolecular $Y-O^{(sulfonyl)}$ bonds. The $Y-N^{(sulfonamide)}$ bond distances of 2.365(2) A and 2.403(2) A are longer than $Y-N^{(dialkylamide)}$ or $Y-N^{(silylamide)}$ bond lengths and are comparable to Y−N bonds containing delocalized charge density within the organic amide ligand. Representative examples include benzamidinate $[\{p\text{-}MeOC_6H_4C(NSiMe_3)_2\}_2YCH(SiMe_3)_2]$

Figure 4. Structure of the mononuclear unit of **5** (PLATON[16] plot). Thermal ellipsoids are drawn at the 50% probability level. All carbon bonded hydrogen atoms are omitted for clarity



[Y−N 2.325(4)−2.345(4) A],[17] aminotroponiminate (ATI) [(*i*Pr$_2$ATI)YCl$_2$(thf)$_2$]$_2$ [2.331(5), 2.430(5) A],[18] phthalocyanine (Pc) [Y(Pc^{2-})(Pc$^-$)]·CH$_2$Cl$_2$ [2.395(3)−2.406(4) A],[19] or alkoxydimethylsilylamide [{Me$_2$Si(N*t*Bu)(O*t*Bu)}$_2$YCH(SiMe$_3$)$_2$] [2.20(2), 2.32(1) A].[20] The Y−O distances range between 2.234(2)−2.600(2) A. The Y−O(4) distance of 2.358(2) A of the non-bridging sulfonyl moiety together with the adjacent Y−N(2) bond of similar length resemble the bonding in η^2-coordinating carboxylates, e.g., [Cp$_2$Y{η^2-O$_2$C(CH$_2$)$_3$NMe$_2$}] [2.390(3), 2.406(3) A].[21] The bridging sulfonyl moiety forms a long intramolecular contact of 2.600(2) A [Y(1)−O(2)] which lies in the long range order of Y−O$^{(donor)}$ bonds and a relatively short Y−O(1a) contact which approaches bridging Y−O$^{(alkoxide)}$ bond lengths.[22] The marked differences in the Y−O bond distances arise from two effects: While the attractive interaction in Y−O(4) is affected by ring tension of the four-membered Y−N−S−O cycle [cf. Y−N(1)−S(1) 101.64(9)°, Y−N(2)−S(2) 96.45(8)°], reduced partial charge of the doubly coordinating SO$_2$ moiety additionally weakens the Y−O(2) interaction. The Y−O(1a) displays the unperturbed case and hence shows the shortest contact.

The charge delocalization in the disulfonamide ligand is also clear from the S=O and S−N bonding. The S=O bonds of the Y-bonded oxygen atoms average 1.479(2) A, whereas the bond distance of S(2)=O(3) [1.434(2) A] lies in the typical non-interacting range (1.423−1.444 A).[23] The S−N distances amount to an average of 1.555(2) A, clearly indicating a partial double bond character (cf. RNH−SO$_2$R′ 1.600-1.623 A).[23] The special mode of coordination is best understood by a charge delocalized model, as shown in Scheme 3. While **I** represents the classic case of a deprotonated sulfonamide, **II** displays a sulfonate type coordination, resulting in elongated S=O distances and shortened S−N bonds.

Scheme 3. Charge delocalized description of a η^2-coordinating sulfonamido group

I **II**

In contrast, the metal sulfonyl interactions in similar titanium complexes are weak and ascribed to crystal packing forces.[6] In fact, all Ti−O contacts are by far longer (0.17−0.38 A) than the Ti−N bonds.[6][7] In compound **5** the Y−N and Y−O bonds approximately equal each other which is consistent with strong metal oxygen interaction. The different metal oxygen bonding in the titanium and lanthanide complexes is also reflected in the different solution behavior described above.

The Y−N(3) bond length [2.239(2) A] of the silylamide ligand is comparable to that of the precursor silylamide [2.229(4)−2.276(4) A].[11] Interestingly, the N(SiHMe$_2$)$_2$ moiety coordinates asymmetrically to the yttrium center, featuring structural details previously ascribed to β-SiH agostic interactions.[24] The Y−N−Si angles differ significantly [103.57(9), 127.6(1)°] and the H(2) of one SiHMe$_2$ group could be localized relatively close to the yttrium center [Y−Si(2) 3.1058(7) A]. However, the sharp Si−H stretch frequencies in complexes **3**−**5** clearly range in the area of non-interacting Si−H groups,[25] although shoulders often termed as agostic could be detected at ca. 1950 cm^{-1}. If electronically forced, e.g., agostic, the Y···(Si−H) interaction in **5** would indicate electron deficiency at the metal center, which is highly desirable for the anticipated catalytic applications.

In conclusion, we have synthesized highly soluble rare earth complexes with formally bidentate disulfonamide ligands according to an extended silylamide route. The obtained heteroleptic complexes of type "(L)Ln^{III}R" bearing the disulfonamide ligand as a divalent auxiliary ligand L and the silylamide ligand R as a reactive, readily exchangeable moiety are potential candidates for rare earth mediated catalysis. The complexes show unprecedented ligand coordination, as evidenced by a $\mu_2,\eta^4{:}\eta^1$-coordination of a desolvated dinuclear complex in the solid state. The presence of a strong metal sulfonyl coordination is further suggested by the solution behavior (NMR experiments). The asymmetric coordination of the bis(dimethylsilyl)amide ligand appears to be sterically forced, albeit the metal···(Si−H) coordination might qualify as a sensitive probe to evaluate the electronic situation at early transition metal centers. Current studies concentrate on ligand variations and examinations of the resulting complexes in Lewis acid catalysis.

Experimental Section

General: All rare earth complexes were synthesized and manipulated under an argon atmosphere using either standard high-vacuum techniques or a glovebox (MBraun MB150B; O_2 < 2 ppm, H_2O < 1 ppm). Toluene and *n*-hexane were distilled from Na/K/benzophenone and stored under argon. Deuterated THF was dried by stirring over Na/K alloy. All starting materials were purchased from Aldrich Chemical Co. and used without further purification. The synthesis of the disulfonamide *rac*-**2** is described in detail, because slight modifications of the established synthesis procedures were applied.[26] The bis(dimethylsilyl)amides of Sc, Y, La, and Nd (**1a**−**d**) were prepared according to the literature procedure.[27] − NMR: Jeol JNM-GX-400 (399.80, 100.51, and 79.43 MHz for ^{1}H, ^{13}C, and ^{29}Si, respectively). Spectra were referenced internally using the residual solvent resonances (^{1}H, ^{13}C) or referenced externally to TMS (^{29}Si; δ = 0). [D$_8$]THF as solvent δ_H = 3.58/1.73, δ_C = 67.7/25.5. − FTIR: Perkin-Elmer 1650. − Elemental analyses: Mikroanalytisches Laboratorium at the department of inorganic chemistry of the Technische Universität München.

trans-1,2-Bis(2,4,6-triisopropylbenzenesulfonamido)cyclohexane (*rac*-**2**): Racemic **2** was prepared by addition of a pre-cooled solution of 6.36 g (21.0 mmol) of 2,4,6-triisopropylbenzene sulfonyl chloride in 30 ml of CH_2Cl_2 to an ice-cold, stirred solution of 1.14 g (10.0 mmol) of *trans*-1,2-diaminocyclohexane and 2.13 g (21.0 mmol) of triethyl amine in 50 ml of CH_2Cl_2. The mixture was

stirred overnight while it was allowed to warm up to room temperature. The solution was washed successively with 50 ml of hydrochloric acid (1 N), saturated $NaHCO_3$ solution, and brine. Drying of the organic phase over Na_2SO_4 and evaporation of the solvent gave a crude product which was purified by column chromatography (silica, CH_2Cl_2/EtOAc, 40:1 v/v, R_f = 0.32) to yield 5.96 g of *rac*-**2** (92%) as a white solid, m.p. 206−207°C. NMR and IR spectroscopic data and elemental analysis are in agreement with the data reported for (1*R*,2*R*)-1,2-bis(2,4,6-triisopropylbenzenesulfonamido)cyclohexane.[26]

General Procedure for the Preparation of the Rare Earth Metal Disulfonamide Complexes (**3** *and* **4a−c**): To a stirred solution of 0.50 mmol of the rare earth bis(dimethylsilyl)amide Ln[N(SiHMe$_2$)$_2$]$_3$(thf)$_n$ (Y, La, Nd: n = 2; Sc: n = 1) in 15 ml of toluene an equimolar amount (0.50 mmol) of *rac*-**2** was added slowly. The ligand dissolved within a few minutes (Sc: 1 h). To ensure complete reaction the mixture was stirred for further 24 h. Then the solvent and volatile products were evaporated in vacuo to yield the complexes **3** and **4a−c**.

[trans-1,2-Bis(2,4,6-triisopropylbenzenesulfonamidato)cyclohexane-N,N′][bis(dimethylsilyl)amido]scandium(III) (**3**): 385 mg (94%), colorless, amorphous solid. X-ray Crystal Structure Analysis of **5**: C$_{80}$H$_{140}$N$_6$O$_8$S$_4$Si$_4$Y$_2$; M_r = 1732.44; a = 12.3022(5), b = 13.4696(8), c = 14.8607(9) Å, α = 74.823(6), β = 79.688(5), γ = 78.454(5)°; triclinic, *P*1 (Int. Table Nr.: 2); V = 2307.6(2) Å^3; Z = 1; D_{calc} = 1.247 g cm^{-3}; μ = 1.45 mm^{-1} (Mo-K_α); F(000) = 924; A colorless crystal was mounted on a STOE IPDS[28] diffractometer (graphite-monochromated Mo-K_α radiation). 32070 reflections (Θ range: 1.65°−26.05°; −13 < h < 13, −16 < k < 16, −18 < l < 18) were collected at 193 K and corrected for Lorentz, polarization and X-ray absorption

effects (program FACEIT[28]: T_{min} = 0.6779; T_{max} = 0.8307). Preliminary positions of heavy atoms were found by direct methods,[29] while positions of the other non-hydrogen atoms were determined from successive Fourier difference maps coupled with initial isotropic least square refinement.[30] All none-H atoms were refined anisotropically. The hydrogen atoms, except for Si−H, were placed in calculated positions. They were included in the structure factor calculation but not refined. The final refinement (on F_o^2) of 477 parameters with 8176 independent reflections (R_{merge} = 0.049) converged at R_1 = 0.0399, wR_2 = 0.0660 and GOF = 0.931. The final weighting scheme was calculated to $w^{-1} = \sigma^2(F_o^2)+(0.0392\cdot P)^2$ with $P = (F_o^2+2\cdot F_c^2)/3$. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 101422. Keywords: Ab initio calculations / π interactions / Agostic interactions / Electronic structure

Rotational barriers and π conjugation effects have been studied in H_2X–YR systems (X = Al, B; Y = O, S; R = H, CH_3) by means of ab initio calculations at the MP4/6–311G**//MP2/6–311G** level. In non-substituted systems H_2X–YH, it is shown that the rotational barrier depends on three factors: (i) π conjugation strength between the X vacant p orbital and the Y p-lone pair; (ii) the opening ability of the Y-valence angle and (iii) a possible direct interaction between X and the Y hydrogen substituent. The conjugation stabilization has been estimated through Valence Bond calculations and is found to decrease in the order BO (22.6 kcal/mol), BS (16.6 kcal/mol), AlO (10.2 kcal/mol), and AlS (8.1 kcal/mol). Study of the methylated systems confirm the results found in unsubstituted species. The most important feature is the location of a deconjugated secondary minimum for H_2B–SCH_3 species. An acute B–S–C angle (69.6°) is found, thus evidencing a direct H···B agostic interaction with a four-membered (BSCH) heterocycle. To further evidence our analysis, additional calculations have been performed on carbocationic species H_2C^+–YR (Y = O, S; R = H, CH_3) for which the H_2C^+ moiety is a strong π acceptor. As expected, the C^+–O and C^+–S conjugation are strong (about 60 kcal/mol). Only two minima have been located for the H_2C^+–OCH_3 species. In the sulfur case, the Potential Energy Surface (PES) is more complicated and six stationary points have been characterized. A strong agostic interaction is found for a secondary deconjugated minimum for which an hydrogen symmetrically bridges the two carbon atoms. A schematic energy profile connecting the various extrema is given for this cationic species.

Introduction

The question of π conjugation between Al and O in alkoxy derivative of aluminium has not received a definite answer until now although much theoretical and experimental work has been devoted to the problem. Following Brothers and Powell,[1] the conjugation in 3-coordinated species is expected to be weak: for instance, the rotational barrier around the Al−O bond has been shown to have an upper limit of 8 kcal/mol. In addition, the Al−O bond length in 3-coordinated species is found to decrease in the series R_2Al-OR', $RAl(OR')_2$, $Al(OR')_3$, a trend which seems to be in contradiction with a strong π Al−O bonding. Different conclusions concerning the π Al−O bonding have been reached by Barron:[2] a noticeable π Al−O conjugation should be responsible for short Al−O bond lengths in 3-coordinated aluminium alkoxides. The lack of rotational barrier in these compounds is expected to have the same origin as in transition metal alkoxides where no rotational barrier is found although π-bonding in these complexes is not doubtful. In addition, similar π Al−O conjugation is also proposed in 4-coordinated alkoxy aluminium compounds.

Theoretical calculations by Barron, Dobbs and Francl[3] indicate that π Al−O conjugation in 3- and 4- coordinated systems may explain the geometrical distortions observed in these compounds. On the opposite, recent calculations by Fink, Power and Allen[4] give a low rotational barrier in both model compounds, H_2Al-OH (3.5 kcal/mol) and $(CH_3)_2Al-OCH_3$ (1.7 kcal/mol). However, large geometric distortions in the deconjugated conformer do not allow a definite conclusion regarding the π bonding in these 3-coordinated aluminium alkoxides.

To shed some light on this problem, we have undertaken ab initio calculations on H_2Al-OR model molecules (R = H, CH_3) in order to get a more detailed description of Al−O π bonding; the results are compared to those obtained when oxygen is replaced by sulfur. In order to calibrate our results, additional calculations where performed on boron systems H_2B-YR (Y = O, S; R = H, CH_3) for which B−O B−S π conjugation is well etablished. These calculations are expected to check our previous conclusions for $H_2X-Y-XH_2$ species[5] (X = Al, B; Y = O, S) where it was found that X−Y π conjugation is a determining factor for understanding the geometrical structure of these compounds.

The results will be presented as follows: first, calculations on model species H_2X-YH at a conventional MO level of theory will be followed by Valence-Bond (VB) calculations. Secondly, the effect of Y substitution by a methyl group will be studied. Finally, the conclusions drawn from these

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0707−1015 $ 17.50+.50/0

two sets of results will be checked with systems in which X is replaced by a strong π acceptor: C^+. Both model systems H_2C-YH^+ and $H_2X-YCH_3^+$ (Y = O, S) will be analyzed.

Method of Calculation

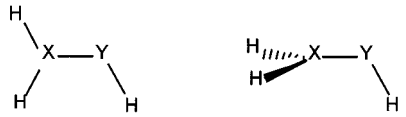
The 6−311G** basis set was used throughout the paper. All geometries were optimized at the MP2 level with the help of an analytical gradient method. Characterization of the extrema were made by analytical frequencies calculations at this level. The stationary points may be minima (Min, no imaginary frequency) or transition states (TS, only one imaginary frequency) or *n*-order saddle points (*n*-SP, *n* imaginary frequencies). In this last case ($n > 1$), the stationary point has no chemical significance. Subsequent calculation of the correlation energy was made at the MP4(SDTQ) level on the geometries optimized at the MP2 level. Our level of calculation is therefore MP4/6−311G**//MP2/6−311G**. In the simplest model systems (H_2X-YH) we have tested the influence of improving the correlation energy by optimizing the geometries at the MP4 level. The GAUSSIAN 92 set of programs[6] was used. Valence-Bond calculations were made with the help of the Turtle program.[7]

Results

A. Unsubstituted Systems

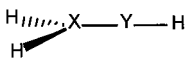
Energetical Analysis

For each system (referred as BS, BO, AlS and AlO in the following), three geometries [planar (**1**), perpendicular (**2**) and linear (**3**)] have been optimized and fully characterized by analytical frequencies calculations.



1

2



3

All twelve structures are found to be stationary points on the various potential energy surfaces. In each case, the planar geometry is a real minimum while the perpendicular geometry is a transition state (TS, one imaginary frequency). Following the transition vector associated with the imaginary frequency leads to the planar minimum. The linear structure is found to be a second-order saddle point (2-SP, two imaginary frequencies) and the two associated transition vectors lead to the planar minimum or to the perpendicular transition state. The geometrical parameters of the optimized structures (MP2/6−311G** level) are given in Figure 1 and the corresponding relative energies in Table 1.

Figure 1. Geometrical optimized parameters of the H_2X-YH species (bonds in A and angles in degrees)

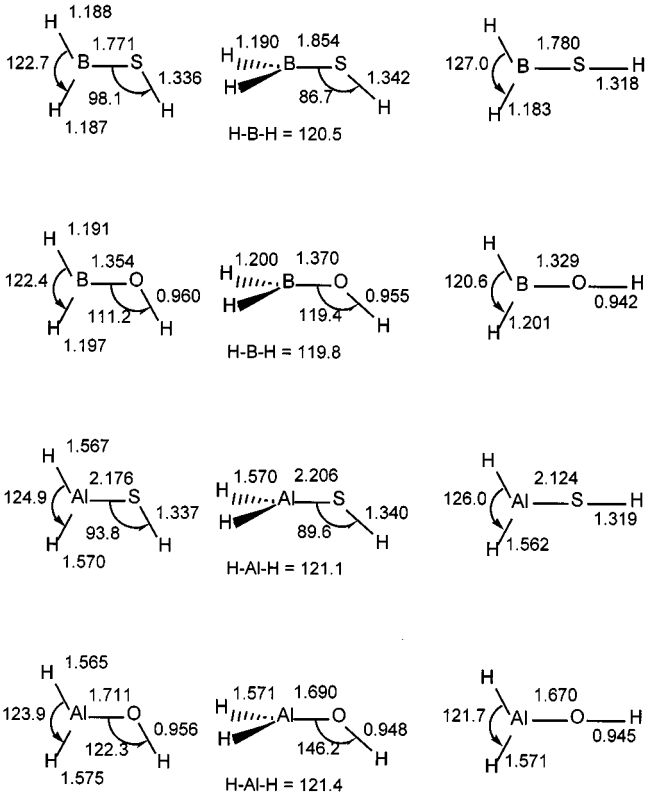


Table 1. Relative energies (in kcal/mol) of the three geometries for each species at the MP2/MP2 level of calculation.

	BS	BO	AlS	AlO
planar	0	0	0	0
perpendicular	20.5	16.9	7.6	3.6
linear	54.4	20.5	31.7	3.9

All the extrema have been recalculated at the MP4 level at the MP2 optimized geometries. The relative energies at the MP4/6−311G**//MP2/6−311G** level are given in Table 2.

Table 2. Relative energies (in kcal/mol) of the three geometries for each species at the MP4/MP2 level of calculation

	BS	BO	AlS	AlO
planar	0	0	0	0
perpendicular	20.6	17.1	7.8	3.9
linear	54.4	21.0	32.0	4.2

The results at MP2/MP2 and MP4/MP2 levels are very similar: improving the correlation energy calculation increases the energy differences by less than 0.5 kcal/mol. However, to be sure that improvement of the correlation energy calculation does not affect the optimized parameters, the planar and perpendicular geometries have been reoptimized at the MP4 level. The rotational barriers

[*E*(perp)−*E*(planar)] are exactly the same as that found at the MP4/MP2 level. In addition, the geometrical changes are less than 0.007 A for bond lengths and 1.5° for bond angles (except for the Al−O−H bond angle whose change is 3° in the perpendicular structure). Therefore, our calculation level can be considered as satisfactory. Note finally that our results agree well with those previously published: 18.0, 14.3, 7.3, and 3.5 kcal/mol for BS, BO,[8] AlS, and AlO[4] systems respectively. Similar values (19, 14, 8, and 4 kcal/mol) have been obtained by Zyubina and Charkin.[9]

The evolution of the rotational barrier should well illustrate the basic concept of conjugation in such compounds. In the planar structure, the vacant p orbital on aluminium or boron conjugates with the π-doubly occupied lone pair of sulfur or oxygen, leading to a 2-electron stabilization. A 90° rotation of the Y−H group destroy this conjugation and the rotational barrier could be a measure of the strength of the π X−Y bond. It is indeed found that the rotational barrier is very low when X and Y electronegativities are different (X = Al and Y = O) and becomes higher as the X and Y electronegativities become closer. As a result, the highest barrier is found when X = B and Y = S. In fact this interpretation of the barrier evolution is somewhat oversimplified as shown below.

Geometrical Analysis

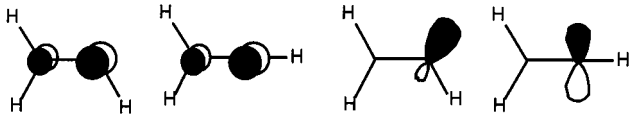
The X−Y bond lengths and X−Y−H angles for each system are reported in Table 3. To our knowledge only the unsubstituted H_2BOH species has been experimentally characterized (Microwave Spectrum).[10] Our optimized parameters (B−O = 1.354 A; O−H = 0.960 A; B−O−H = 111.2°; O−B−Hc = 120.9°; O−B−Ht = 116.7°; BHc = 1.197 A; BHt = 1.191 A) are in excellent agreement with the experimental ones (B−O = 1.352 A; O−H = 0.967 A; B−O−H = 112.0°; O−B−Hc = 121.8°; O−B−Ht = 117.2°, the B−H bond length being assumed to be 1.200 A).

Table 3. X−Y bond lengths (in A) and X−Y−H bond angles (in degrees) in the various optimized extrema

X−Y Bond lengths	BS	BO	AlS	AlO
planar	1.771	1.354	2.176	1.711
perpendicular	1.854	1.370	2.206	1.690
linear	1.780	1.329	2.124	1.670
X−Y−H Bond angles				
planar	98.1	111.2	93.8	122.3
perpendicular	86.7	119.4	89.6	146.2

Let us first compare the X−Y bond lengths in planar and linear structures: in both structures π conjugation is at work between the p orbitals of X and Y (Scheme 1).

Scheme 1

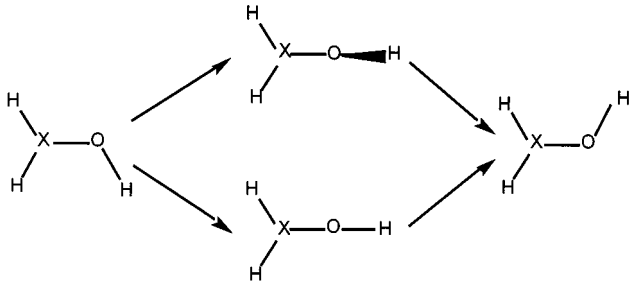


The main electronic difference between the two geometries comes from the interaction of the second Y lone pair with the H_2X moiety. The lone pair is expected to be strongly hybridized in the planar structure while it is a pure p orbital in the linear geometry (Scheme 1). In each case except H_2BSH, the X−Y bond length shortens from the planar to the linear geometry (Table 3). This shortening may come from a negative hyperconjugation interaction between this Y lone pair and the symmetry adapted H_2X antibonding orbitals (see below).

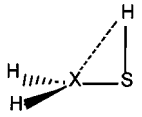
The geometrical evolutions from planar to perpendicular geometries are different for oxygen and sulfur systems and will be discussed separately. In *oxygen compounds*, the perpendicular structure is reminiscent of the linear geometry. The X−Y−H angle opens when going from the planar to the perpendicular geometries (by 8.2 and 23.9° in boron and aluminium cases respectively) which allows the dehybridization of the in-plane lone pair and therefore ensures a better conjugation with the p vacant orbital on the H_2X moiety. This effect is rather small in the boron compound and the BO bond length increases upon OH rotation (from 1.354 to 1.370 A). On the other hand, the Al−O−H angle dramatically increases by 23.9° upon rotation and that leads to a strong residual conjugation in the perpendicular geometry. This is illustrated by an Al−O bond length (1.690 A) which is intermediate between those of the planar (1.711 A) and linear (1.670 A) geometries. Consequently, the rotational barrier in H_2AlOH is not a measure of the π Al−O conjugation since a noticeable conjugation still remains in the perpendicular structure. A similar interaction (although attenuated) exists in H_2BOH, as previously pointed out by Ashby and Sheshtawy;[8] following these authors, the hydroxy group should be considered as a double-faced π-donor. Thus, the oxygen's ability to conjugate in both the planar and perpendicular geometries is further illustrated by the small energy differences between the perpendicular and linear geometries: it is 3.9 and only 0.3 kcal/mol for H_2BOH and H_2AlOH respectively (Table 2). These low values indicate that the energetical cost of dehybridization of the oxygen second lone pair is almost compensated by the additional conjugation interaction. This result gives an insight in the mechanism of aluminum alkoxides isomerization. Since the two (perpendicular and linear) structures are almost isoenergetic, this reaction may proceed by rotation or linearization of the alkoxide moiety (Scheme 2). As previously noted by Ashby,[8] the competition between the two mechanisms should be in favor the intermediacy of a perpendicular structure for H_2BOH because of the larger energy difference.

Fo the *sulfur derivatives*, linearization of the X−S−H arrangment costs much more energy (54.4 and 32.0 kcal/mol for H_2BSH and H_2AlSH respectively, Table 2). As a result, no dehybridization occurs in the perpendicular structure that is well illustrated by an X−S−H angle which is roughly equal to 90° in both planar and perpendicular geometries. The π residual conjugation is expected to be small in the rotated structure and, consequently, both Al−S and B−S bond lengths increase upon rotation (Table 3). A surprising

Scheme 2



point is the decrease of the X−S−H angle in the planar → perpendicular interconversion: this variation is small in H_2AlSH (4.2°) and becomes rather large (11.4°) in H_2BSH. It allows a shortening of the X···H distance (**4**) and we attribute this geometrical change (which is opposite to that found in oxygenated systems) to a direct interaction between the H_2X p vacant orbital and the hydrogen atom. Such interactions are well-known in organometallic chemistry and have been called "agostic" by Brookhart and Green.[11] Similar interactions will be analyzed in more details in the study of substituted species. Note that, following Ashby,[8] this angle decrease may be attributed to a relief of Pauli repulsion.



4

π-Conjugation in H_2X-YH Species?

Since the rotational barrier cannot be a good measure of X−Y conjugation in these species, additional VB calculations have been performed on planar and linear structures at the MP2 optimized geometries. In a first step, the total energy is recalculated in a "normal" manner i.e. all the interaction are taken into account. In a second step, the π interaction in both geometries is set to zero by forbiding any delocalization of the π lone pair of the Y atom on the XH_2 moiety in both planar and linear geometries. The energy differences between the two sets of results give a reasonable estimation of the π interaction in those systems. (Note that a more accurate calculation of the conjugation interaction should require a full geometry reoptimization in the deconjugated species that is not possible with our VB program.) Similar calculations have been performed in the linear geometry by cancelling the delocalization of the in-plane Y p-lone pair in order to get a measure of the hyperconjugation (HC) with the XH_2 moiety. Finally, in the linear geometry, both conjugation and hyperconjugation have been cancelled. The results of these calculations are given in Table 4 for each system under study.

For each species the conjugation stabilizations are not identical for the planar and linear geometries since the X−Y bond lengths are not the same in both geometries (Table 3). However the two sets of values are rather close to each others and the results obtained in the planar geometry are expected to correctly reflect the stabilization due to conjugation in H_2X-YH species. The lowest value (8.1 kcal/mol) is found in the Al−S case, confirming that the π bonds are weak between two second-row atoms.[12] The X−Y conjugation is still weak in H_2Al-OH (10.2 kcal/mol) and becomes stronger in the boron compounds (16.6 and 22.6 kcal/mol for H_2B-SH and H_2B-OH respectively, Table 4). As expected the highest stabilization is found for H_2B-OH in which conjugation develops between two first-row atoms.

Table 4. Stabilization (in kcal/mol) due to conjugation (planar and linear structures) and to hyperconjugation (linear structure only)

	BS	BO	AlS	AlO
planar conjugation	16.6	22.6	8.1	10.2
linear conjugation	19.0	21.1	9.6	9.6
linear HC	7.0	7.9	6.0	6.6
linear conjugation + HC	27.0	30.6	16.6	17.3

In the four linear structures, the hyperconjugation of the in-plane Y lone pair with the H_2X moiety is found to be stabilizing and almost constant (between 6 and 8 kcal/mol) whatever the nature of the X and Y atoms. Finally, it is worth noting that the two contributions (conjugation and hyperconjugation) are fairly additive in the linear structure: adding the stabilization due to conjugation (entrie 2) and to hyperconjugation (entrie 3) in Table 4, gives (within about 2 kcal/mol) the total stabilization (entrie 4) obtained when both lone pairs are allowed to delocalize.

In Table 5 are brought together the values of conjugation stabilization (Table 4) and rotational barrier (energy difference between planar and perpendicular geometries, Table 2).

Table 5. Conjugation stabilization and rotational barrier for the various systems; all quantities are in kcal/mol.

	BS	BO	AlS	AlO
planar conjugation	16.6	22.6	8.1	10.2
rotational barrier	20.6	17.1	7.8	3.9

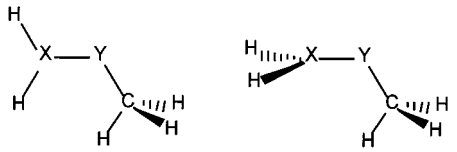
The values are reasonably close in the sulfur-substituted systems but differ notably in the oxygenated cases. In these cases, the rotational barrier is systematically lower than the conjugation interaction (by 5.5 and 6.3 kcal/mol in boron and aluminium cases respectively) which indicates the reminiscent conjugation in the rotated structure as shown above. The two values notably differ in the H_2Al-OH case where the Al−O−H angle dramatically increases in the perpendicular geometry (Table 3).

B. Methyl-Substituted Systems

Energetical Analysis

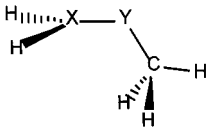
Calculations on substituted systems H_2X-YCH_3 have been made in order to get more detailed informations on the various interactions in these species. As shown previously,[13] the eclipsed conformer (**5**) is the most stable in the planar geometry. Two rotamers have been fully optim-

ized and characterized in the perpendicular geometry. In the first one (**6**), a CH methyl bond eclipses the X−Y bond while in the second one (**7**), the CH methyl bonds are staggered with respect to the X−Y bond. The energetical results are reported in Table 6 together with the characterization of the various structures. The rotational energy barriers in unsubstituted species have also been reported for sake of comparison.



5

6



7

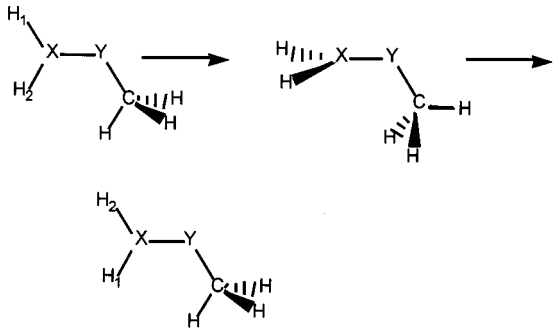
Table 6. Relative energies (in kcal/mol) at the MP4/MP2 level of the planar (**5**) and perpendicular (**6** and **7**) geometries in H_2X-YCH_3 species; the rotational barrier in unsubstituted species is also given for sake or comparison

	BS	BO	AlS	AlO
planar **5**	0 (Min)	0 (Min)	0 (Min)	0 (Min)
perpendicular **6**	22.2 (Min)	18.6 (2-SP)	9.2 (2-SP)	-[a]
perpendicular **7**	22.3 (TS)	17.2 (TS)	8.7 (TS)	3.0 (TS)
unsubst. R.B.	20.6	17.1	7.8	3.9

[a] No stationary point found, see text.

All the planar structures (**5**) are found to be real minima on the Potential Energy Surface (PES). Staggered perpendicular geometries (**7**) are found to be transition states (one imaginary frequency) and we have verified that they belong to the isomerization reaction path depicted in Scheme 3.

Scheme 3



The rotational barriers in the methylated species are therefore equal to the energies differences between structures **5** and **7**. They are found to be very close to that of the hydrogenated systems: for each molecule, the barrier in methylated and unsubstituted systems are the same within 1.7 kcal/mol (Table 6). It is worth to compare our calculated barriers on methyl-substituted species to those experimentally determined. In BS and BO cases, the theoretical values (22.3 and 17.2 kcal/mol) are larger than the experimental values (18.2−19.7 kcal/mol (BS)[14][15] and 11.2−13.9 kcal/mol (BO)[15][16]. The presence of bulky substituents may well be at the origin of this discrepancy since steric repulsion should be smaller in the perpendicular structure that lowers the rotational barrier. In aluminium compounds, there are few experimentally determined values: it is found to be less than 8 kcal/mol in Al−O case[17] and between 8 and 9 kcal/mol in AlS case.[18] (This last value is obtained in bisthiolate derivative of aluminium. To our knowledge, no data on monosubstituted compound are available). Both these values are in agreement with our theoretical values.

In the perpendicular geometries, the methyl group bonded to the Y atom does not seem to exhibit strong conformational preference: the energy differences between structures **6** (eclipsed) and **7** (staggered) are about 0.5 kcal/mol for BS, and AlS and increases up to 1.4 kcal/mol in H_2B-OCH_3 system. However these small energy differences originate from very different interaction as shown below. More puzzling, the characterization of this structure depends on the nature of X and Y atoms. In BO and AlS cases, the eclipsed geometries are 2-order saddle points as expected. The transition vector associated with one imaginary frequency essentially develops on the twist angle between H_2X and XYC planes and corresponds to the **6** → **5** motion. The second transition vector involves the in-block rotation of the methyl substituent and corresponds to the **6** → **7** motion. For Al−O, we did not find any stationary point corresponding to the eclipsed perpendicular conformer **6**. Optimization of this geometry leads to an opening of the Al−O−C angle beyond 180° and this structure collapses to the conformer **7** which is a transition state located 3.0 kcal/mol above the planar structure. More puzzling is the fact that in BS case, the eclipsed perpendicular structure is found to be a secondary minimum on the PES.

Geometrical Analysis

The main optimized geometrical parameters are given in Figure 2. For each structure, the X−Y bond length is slightly shorter than that found in the unsubstituted species: for instance, B−O = 1.345 A in H_2B-OCH_3 and 1.354 A in H_2B-OH for the planar structures. Our optimized parameters (X−Y and Y−C bond lengths and X−Y−C angles are in reasonable agreement (Table 7) with the experimental data available on monosubstituted compounds (except in Al−S case where only bis-thiolate derivative has been characterized). It should be noted that we find a large X−Y−C angle only in Al−O−C case, in accordance with the experimental data.

Partial deconjugation (**5** → **6** or **7**) leads in each case to a lengthening of the X−Y bond, except in $H_2Al-OCH_3$. In this case, the shortening of the Al−O bond length may be explained (as in the unsubstituted species) by the quasi-linear geometry of the rotated structure (Al−O−C = 170.9°, Figure 2).

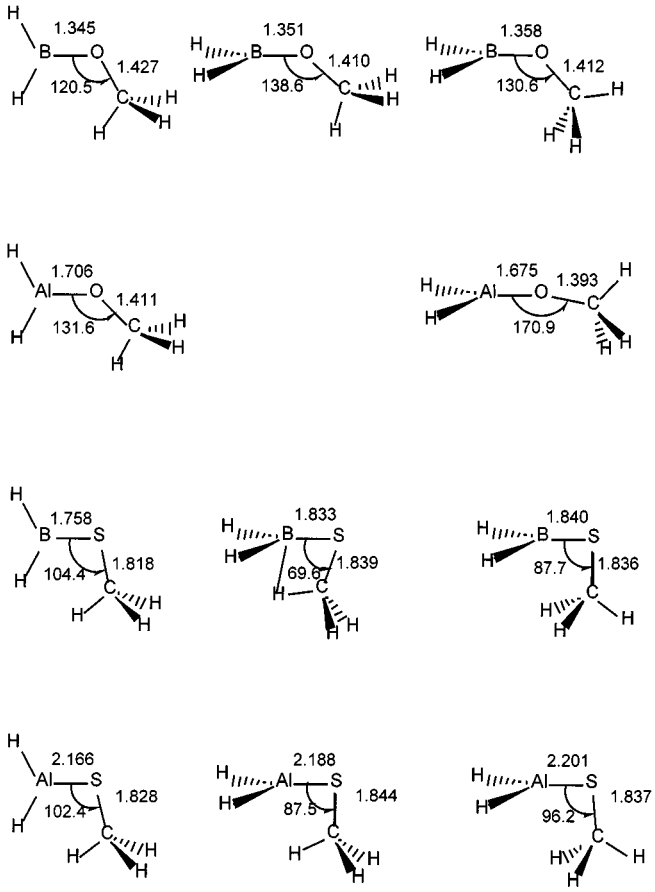
Figure 2. Geometrical optimized parameters of the H_2X-YCH_3 species (bonds in A and angles in degrees)



In oxygenated compounds, the 90° rotation of the X−O−C plane relative to the H_2X plane leads to an opening of the oxygen valence angle as already noted in the unsubstituted species. In sulfur compounds, we find a smaller X−S−C angle in perpendicular **7** geometry than in the planar **5** one. The angular variations are in the same range as in unsubstituted species (6.2 vs. 4.2° in Al compounds and 16.7 vs. 11.4° in B compounds).

A dramatic change occurs in H_2B-SCH_3 perpendicular geometry **6**: the B-S-C angle is found to be very acute (69.6°), about 35° smaller than in the planar geometry. This very small sulfur valence angle may be attributed to a direct interaction between the eclipsing methyl hydrogen and the boron atom. A short distance (B···H = 1.764 A) is indeed found and is accompanied with a noticeable lengthening of the C−H bond (C−H = 1.102 A which may be compared to the standard value (1.09 A) found in H_2B-OCH_3). As a result of this stabilizing agostic interaction, the eclipsed geometry **6** is found to be a secondary minimum on the PES. A similar interaction − although attenuated − is found in $H_2Al-SCH_3$: the Al−S−C angle is small (87.5°) and the eclipsing C−H bond lengthens to 1.10 A. However, the Al···H distance remains large (2.50 A) and leads to a rather weak interaction. As a consequence, the eclipsed perpendicular structure **6** is a 2-order saddle point which may be stabilized by a 90° rotation of the methyl group (**6** → **7**). The difference between these two molecules ($H_2Al-SCH_3$ and H_2B-SCH_3) may be attributed to the lower π-acceptor ability of the aluminium relative to the boron due to its lower electronegativity.

In summary of the study of these methylated and hydrogenated systems, the rotational energy barrier in H_2X-YR (R = H, CH_3) depends on three factors: (i) the strength of π-conjugation between X and Y; (ii) the plasticity of the Y valence angle and (iii) possible agostic iteraction with the unsaturated H_2X moiety. Note that a similar direct interaction between the deficient central atom and a non bonded hydrogen has already been shown in aluminium[17][22][23] and gallium[18][22][24][25] derivatives. In order to check these conclusions, we have performed additional calculations on similar systems obtained by taking a strong π-acceptor X atom: C^+.

C. Carbocationic Systems

Unsubstituted Compounds

The unsubstituted cationic species H_2C-OH^+ and H_2C-SH^+ have been fully optimized in planar (**1**), perpendicular (**2**) and linear (**3**) geometries. The energetic results and main optimized parameters are given in Tables 8 and 9. Our optimized parameters are very close to that found by Suarez and Sordo[26] in their recent study of the H_2 elimination from these cations.

Table 8. Relative energies (in kcal/mol, MP4/MP2 level) and characterization of the various extrema for the H_2C-OH^+ and H_2C-SH^+ systems

	1 (planar)	**2** (perpendicular)	**3** (linear)
Y = O	0 (Min)	-[a]	25.4 (TS)
Y = S	0 (Min)	50.3 (Min)	76.3 (2-SP)

[a] No stationary point found.

Since the H_2C^+ moiety is a strong π-acceptor, a strong π conjugation is expected between the C^+ and the Y atoms. VB calculations of the same type as presented before indeed give a C^+-O π-bond strength of 59.5 kcal/mol (planar geo-

Table 9. Main optimized parameters of the two cations H_2C-OH^+ and H_2C-SH^+; bond lengths are in A and angles in degrees

	CS	CO	COH	CSH
planar	1.617	1.354	114.1	98.0
perpendicular	1.680	—[a]	—[a]	50.3
linear	1.619	1.227		

[a] No stationary point found.

metry) and 57.3 kcal/mol (linear geometry). This π bond is therefore much stronger than that found between B and O (22.6 kcal/mol) or Al and O (10.2 kcal/mol). Similarly, the C^+-S π bond is calculated to be of 59.0 kcal/mol (planar) and 66.6 kcal/mol (linear);[27] as in the oxygen case, it is stronger than B−S (16.6 kcal/mol) or Al−S (8.1 kcal/mol) π bonds (Table 4).

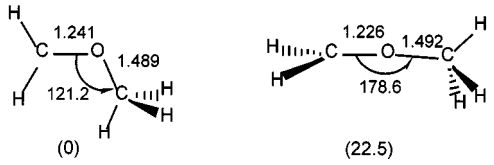
Rotation of the Y−H moiety about the C^+-Y bond destroys this strong conjugation that is energetically much unfavorable. Geometrical deformations therefore occur in order to diminish this energetical cost. In H_2C-OH^+, the C−O−H angle opens up to 180° and the dehybridization of the perpendicular lone pair allows a favorable π interaction. As a result, no stationary point corresponding to a perpendicular geometry is found. The linear structure is then the transition state allowing the isomerization of this species with a 25.4 kcal/mol activation energy (Table 8). In H_2C-SH^+, similar linearization of the C−S−H angle is too much expansive: the linear structure is located 76.3 kcal/mol above the planar geometry. It is a 2-order saddle point, the two transition vectors associated with the imaginary frequencies leading to the planar or perpendicular structures. However, a diminution of the C−S−H angle to 50.3° allows a noticeable interaction between the H atom and the cationic carbon. As a result, the S−H bond lengthens (from 1.346 A in the planar geometry to 1.519 A in the perpendicular structure) and the $C^+\cdots H$ distance is only 1.368 A. This bridged structure is located 50.3 kcal/mol above the planar geometry and is found to be a real minimum (Table 8). We did not try to locate the transition state connecting these two minima. This has been previously done by Suarez and Sordo[26] who found the transition state only 0.2 kcal/mol above the secondary minimum.

Methylated Compounds

The potential energy surfaces associated with the methylated species $H_2C-OCH_3^+$ and $H_2C-SCH_3^+$ have also been investigated. The $H_2C-OCH_3^+$ cation behaves as its unsubstituted analog: the planar structure is found to be a real minimum and no stationary point corresponding to a perpendicular geometry has been found. A quasi-linear (C−O−C = 178.6°) transition state has been located 22.5 kcal/mol (MP4/MP2 level) above the minimum. The main geometrical parameters are depicted in Figure 3.

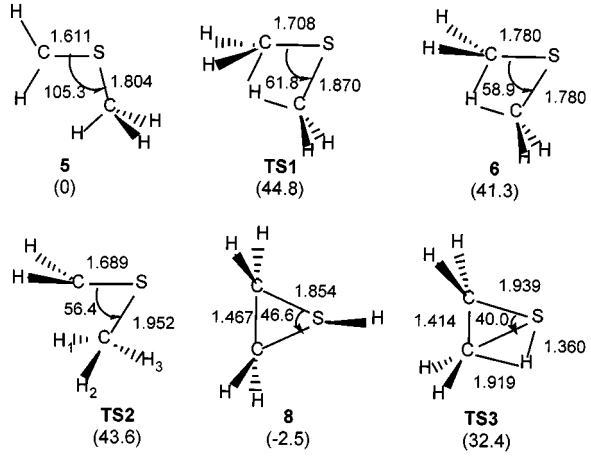
The PES associated with the $H_2C-SCH_3^+$ cation is more complicated. As in boron and aluminium systems, a planar (**5**) conformation and two perpendicular geometries (eclipsed **6** and staggered **7**) have been optimized.

Figure 3. Main geometrical parameters [A,°] and relative energies (kcal/mol, MP4/MP2 level) of the optimized structures of $H_2C-OCH_3^+$



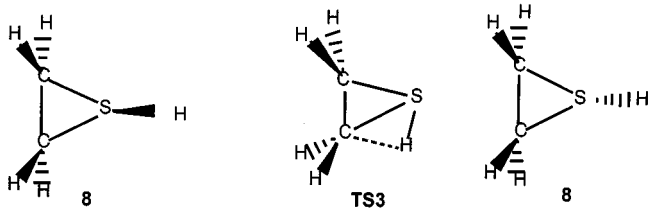
The planar structure **5** is a real minimum and we have verified that the conformation where a C−H bond eclipses the C−S bond is the most stable (by 0.6 kcal/mol with respect to the staggered conformation). The eclipsed perpendicular conformation **6** is also a real minimum located 41.3 kcal/mol above the planar geometry. In this structure, the $C^+\cdots H$ agostic interaction is strong and a C_{2v} geometry is found: the methyl hydrogen symmetrically bridges the two carbon atoms, both C−H distances being equal to 1.279 A (Figure 4). The sulfur valence angle is acute (58.9°) and the two S−C bond are lengthened to 1.780 A. The transition state connecting these two minima (**TS1**) has been located. Its geometry ressembles that of the secondary minimum **6** (Figure 4) and is located 3.5 kcal/mol above it.

Figure 4. Main geometrical parameters [A,°] and relative energies (kcal/mol, MP4/MP2 level) of the optimized isomers of $H_2C-SCH_3^+$

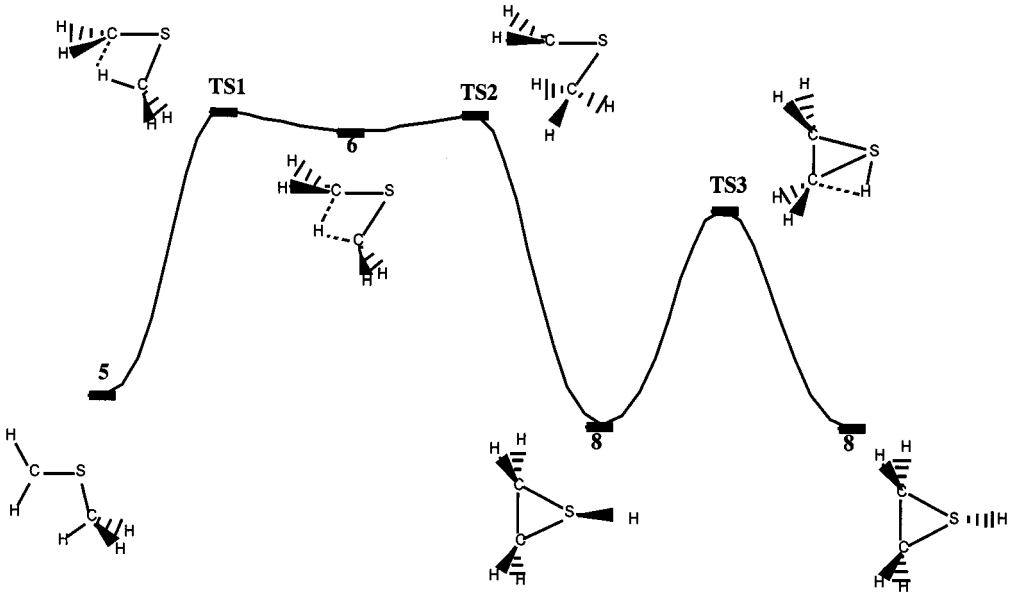


Optimization of the staggered conformation **7** leads to the location of two stationary points. Both of them are characterized to be transition states, **TS2** and **TS3**. The highest one, **TS2** is located 43.6 kcal/mol above the minimum **5**. It is of C_1 symmetry and its geometry is rather close to that of the secondary minimum **6** (C^+-S = 1.689

Scheme 4



Scheme 5



Å; C−S = 1.952 Å; C−S−C = 56.4°, Figure 4). Two C−H bonds of the methyl group are elongated (C−H_2 = 1.108 Å; C−H_3 = 1.104 Å). Following the transition vector associated with the imaginary frequency leads to a cyclic minimum which is the protonated thiooxirane **8**. This minimum is located 2.5 kcal/mol below the planar structure **5** (Figure 4). The structure **TS2** is therefore the transition state allowing the interconversion of the secondary minimum **6** into the protonated thiooxirane **8**. From a geometrical point of view, it should be noted that the migration of the hydrogen from carbon to sulfur is possible because the C_S symmetry plane has been removed in the **TS2** geometry. The second transition state (**TS3**) is of C_S symmetry and is located 32.4 kcal/mol above the minimum **5**. Formally, it is a conformer of the $H_2C-SCH_3^+$ cation, but severe distortions appear in this geometry: the C−C distance is very short (1.414 Å) indicating the presence of a C−C bond (Figure 4). In addition, the S−H (1.360 Å) and C−H (1.919 Å) distances indicate that a S−H bond is formed whereas a C−H bond is broken. With respect to the $H_2C-SCH_3^+$ cation, an hydrogen atom has moved from carbon to sulfur. The transition vector associated to the imaginary frequency almost only develops on the out-of-plane motion of the hydrogen atom bound to sulfur. This transition state is therefore thought to connect the two enantiomeric forms of the protonated thiooxirane (Scheme 4).

A schematic representation of the connection between these different extrema is given in Scheme 5.

Summary and Conclusion

Our theoretical study of H_2X-YR systems (X = Al, B, C^+; Y = O, S; R = H, CH_3) sheds some lights on π bonding in such compounds. π bonding is strong when X = C^+ (from 57 to 67 kcal/mol), intermediate for X = B (from 16 to 23 kcal/mol) and weak for X = Al (from 8 to 10 kcal/mol). The nature of the Y atom (Y = O or S) does not seem to strongly affect the strength of the X−Y π bond. The value of the rotational barrier is not a measure of the π conjugation because important geometrical deformations occur in the deconjugated perpendicular structure in order to compensate for -at least in part- the loss of the stabilization interaction. When Y = O, the X−O−R angle opens so that a X−O π conjugation still exists between the p(X) vacant orbital and the second oxygen lone pair which is partly dehybridized. The linearization of the X−O−R arrangment is more pronounced in methylated than in the unsubstituted systems. When Y = S, the opposite deformation is found, probably because of the reluctance of sulfur for obtuse valence angles. The X−S−R angle becomes more obtuse in the perpendicular geometry and a direct agostic interaction takes place between the X atom and the Y substituent R (R = H, CH_3). For R = H, as the π-acceptor capability of X increases, the X−S−H angle decreases [89.6° (Al); 86.7° (B); 50.3° (C^+)]. In methylated systems, the four-membered (X−S−C−H) ring seems to be particularly favorable and, provided that the agostic interaction is strong enough, the bridged structure is a secondary minimum on the PES (X = B, C^+). For X = C^+, this interaction is found to be rather strong and the bridging hydrogen is equally shared between the two carbon atoms.

[27] We did not find any satisfactory explanation of the 7.6 kcal/mol difference between the two values of this π conjugation. However, it should be noted that in sulfur compounds, conjugation is always found to be larger in the linear geometry than in the planar geometry. The reverse tendency is found in oxygenated species.

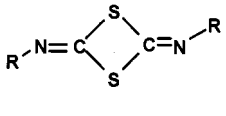
Keywords: Sulfur heterocycles / Hydrolyses / Isothiocyanate / Dithiocarbamic acids

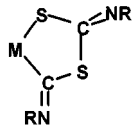
The reaction of ethoxyxcarbonyl isothiocyanate with water in the absence of a solvent has yielded the new compound $[EtO_2CN{=}CS_2C\{N(H)CO_2Et\}\{S_2CN(H)CO_2Et\}]$ (**1**) in 76% yield that has been isolated in a crystalline form that contains one equivalent of ethoxyxcarbonyl isothiocyanate. Compound **1** can be viewed as an adduct of a dimer of $EtO_2CN{=}C{=}S$ and the dithiocarbamic acid **2**. Compound **1** dissociates in solution to yield **2** and free ethoxyxcarbonyl isothiocyanate. Compound **2** can be isolated chromatographically, but it is slowly oxidized when allowed to stand in the open air to form the thiuram disulfide **3**. Compounds **1** and **3** were characterized crystallographically. Compound **1** contains an imino-substituted dithietane ring with a dithiocarbamate substitutent bonded to one of the ring carbon atoms. Compound **3** is a thiuram disulfide which has C_2 crystallographic symmetry.

Introduction

Organic isothiocyanates have been used for the synthesis of a variety of new heterocycles.[1] They are also effective ligands for transition metals.[2][3] There are claims that isothiocyanates with electron withdrawing substitutents couple to form dimers **A**,[4] and there is an example of a coupled form **B** of two isothiocyanates coordinated to a transition metal atom that has been verified crystallographically[5]



A



B

Organic isothiocyanates readily react with water to form amines with a release of CO_2 and H_2S (eq. 1).[6] H_2S is known to add to organic isothiocyanates to yield dithiocarbamic acids (eq. 2).[6]

$$RN{=}C{=}S + 2\ H_2O \rightarrow RNH_2 + H_2S + CO_2 \quad (1)$$

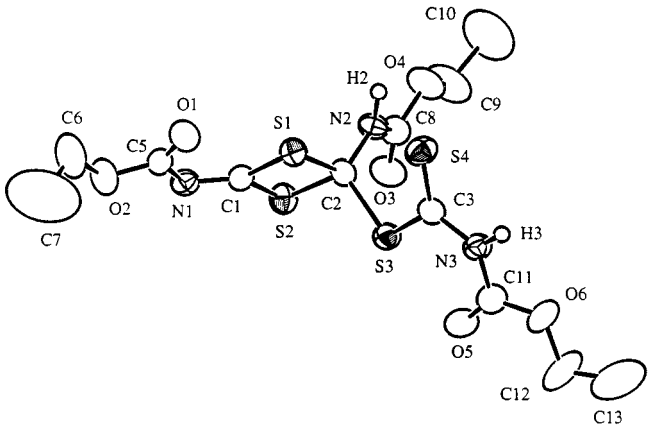
$$RN{=}C{=}S + H_2S \rightarrow RNHCS_2H \quad (2)$$

Dithiocarbamic acids are generally unstable, but the dithiocarbamate anions are a good ligands for transition metals and a large number of complexes have been made with them.[7] In this report we describe a reaction of the ethoxycarbonyl isothiocyanate with water. We have isolated and structurally characterized the new compound **1** which can be viewed as an adduct of the dimer **A**, and the ethoxycarbonyl dithiocarbamic acid (**2**).

Results and Discussion

When small amounts of water are allowed to mix with pure ethoxycarbonyl isothiocyanate, pale yellow crystals of compound **1** with one equiv. ethoxycarbonyl isothiocyanate are formed in up to 75% yield. The product actually forms crystals suitable for analysis by single crystal X-ray diffraction methods in the reaction mixture. Accordingly, a single crystal X-ray diffraction analysis of **1** was performed. An ORTEP diagram of the molecular structure of **1** is shown in Figure 1.

Figure 1. An ORTEP diagram of $\{EtO_2CN{=}CS_2C[N(H)CO_2Et]$-$[S_2CN(H)CO_2Et]\}$ (**1**) found in the crystal of **1**·$EtO_2CN{=}C{=}S$[a]

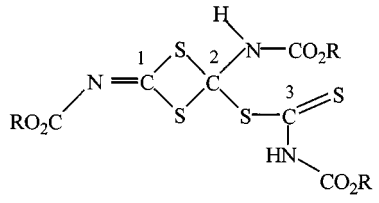


[a] Selected interatomic distances (A) and angles (°): S(1)−C(1) 1.755(8), S(2)−C(1) 1.715(9), S(1)−C(2) 1.831(8), S(2)−C(2) 1.870(7), S(3)−C(2) 1.824(8), S(3)−C(3) 1.762(8), S(4)−C(3) 1.630(8), S(5)−C(4) 1.51(2), C(1)−N(1) 1.28(1), C(2)−N(2) 1.41(1), C(3)−N(3) 1.39(1); S(1)−C(1)−S(2) 102.3(5), S(1)−C(2)−S(2) 93.8(4), S(2)−C(2)−S(3) 103.8(4), S(1)−C(2)−S(3) 115.5(5), N(2)−C(2)−S(1) 113.1(6), N(2)−C(2)−S(2) 112.5(6), N(2)−C(2)−S(3) 115.5(6).

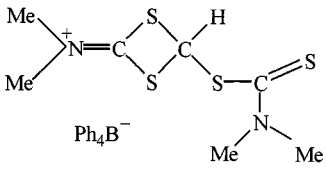
Compound **1** can be viewed as an adduct of the dimer **A** of ethoxycarbonyl isothiocyanate and ethoxycarbonyldithiocarbamic acid. The dimeric ethoxycarbonyl isothiocyanate portion of the molecule is distinguished by a dithiet-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0707−1025 $ 17.50+.50/0

ane ring. One of the sulfur atoms of the ethoxycarbonyldithiocarbamyl grouping S(3) is bonded to one of the imino carbon atoms of the EtO_2CNCS dimer at C(2) atom. Thus, C(2) has three sulfur atoms, S(1), S(2), and S(3) bonded to it with bond lengths typical of C−S single bonds, S(1)−C(2) 1.831(8), S(2)−C(2) 1.870(8), S(3)−C(2) 1.824(8) A. The C−S bonds to C(1) are shorter, S(1)−C(1) 1.755(8) A, S(2)−C(1) 1.715(9) A due to partial multiple bonding character to C(1). A line drawing of the structure is shown below.



1



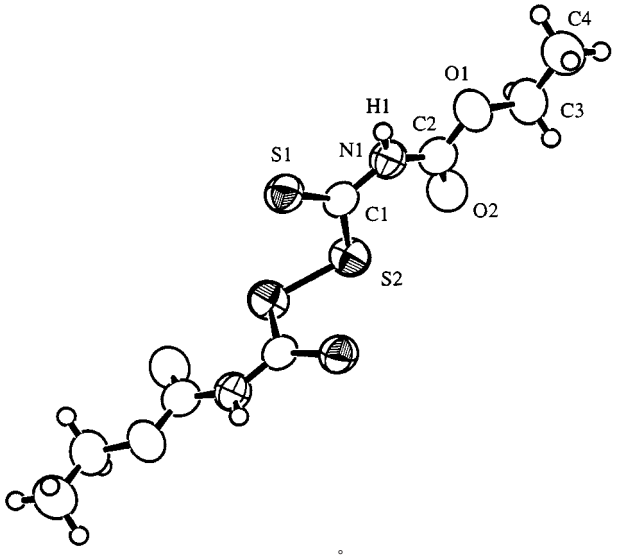
4

The molecule contains an imino-substituted four-membered dithietane ring which imposes a highly distorted tetrahedral structure around atom C(2). There are few molecules that are structurally similar to **1**. Perhaps, its closest relative is the cation of the compound $[Me_2N{=}CS_2C(H)S_2CNMe_2]BPh_4$ (**4**) which contains an amino-substituted dithietane ring.[8] The ^{1}H-NMR spectrum of **1** shows the presence of three ethyl groups, as expected, and two slightly broadened, deshielded resonances of intensity one at δ = 9.02 and 7.23. The latter are attributed to hydrogen atoms that have been assigned to sites on N(2) and N(3) since the C(1)−N(1) bond length is indicative a double bond, C(1)−N(1) 1.283(9) A while the lengths of other two, C(2)−N(2) and C(3)−N(3), 1.41(1) and 1.386(9), respectively, are more consistent with single bond lengths. One equivalent of ethoxycarbonyl isothiocyanate is crystallized with **1** in the same crystal lattice. There are no significant bonding interactions between **1** and the ethoxycarbonyl isothiocyanate solvate.

In solution compound **1** slowly dissociates to form the dithiocarbamic acid **2** and ethoxycarbonyl isothiocyanate as shown by ^{1}H-NMR analysis. Separation of the reaction mixture by column chromatography yielded pale yellow **2** in 85%. Compound **2** was characterized by IR and ^{1}H-NMR spectroscopy. The S−H vibration is observed at 2476 cm^{-1} in the region that is characteristic of this group.[9] Efforts to obtain crystals of **2** suitable for X-ray analysis have been unsuccessful.

Compound **2** decomposes when allowed to stand in the open air, and is converted to a dimer **3** of the dithiocarbamic acid **2**. Crystals of **3** suitable for single crystal X-ray diffraction analysis were obtained and the analysis has been completed. An ORTEP diagram of the molecular structure of **3** is shown in Figure 2.

Figure 2. ORTEP diagram of $[EtO_2CN(H)CS_2]_2$ (**3**)[a]



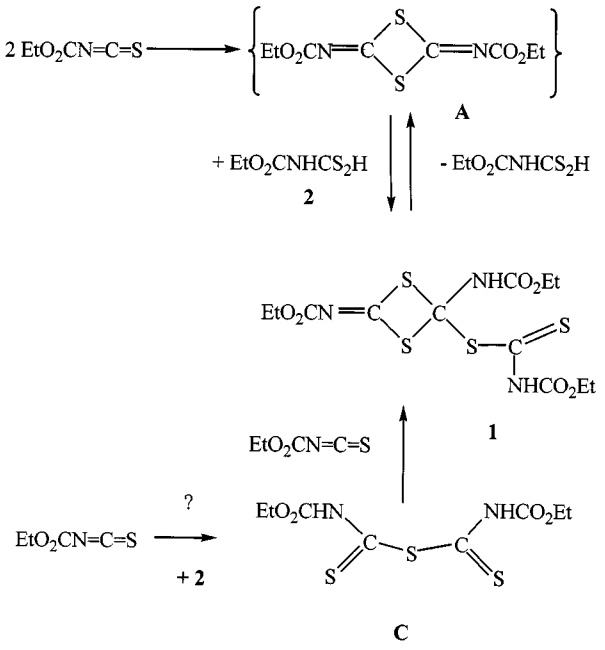
[a] Selected interatomic distances (A) and angles (°): S(2)−S(2′) 2.034(3), S(2)−C(1) 1.780(4), S(1)−C(1) 1.631(4), C(1)−N(1) 1.364(6), C(2)−O(1) 1.330(5), C(2)−O(2) 1.200(5); S(1)−C(1)−S(2) 125.3(3), N(1)−C(1)−S(1) 120.9(3), N(1)−C(1)−S(2) 113.8(3), C(1)−N(1)−C(2) 128.1(5).

Due to crystal symmetry only half of the molecule is present in the asymmetric unit. The two halves are related by a C_2 rotation. A similar situation was observed in both the structure of tetramethylthiuram disulfide and the structure of dipyrrolidylthiuram disulfide (space group *C*2/*c*).[10a][10b][10c] Compound **3** is a bis(ethoxycarbonyl)thiuram disulfide formed by the oxidation and coupling of two molecules of **2**. The geometry about C(1) of the S_2CN group is essentially planar. These two groups are connected by a S−S single bond with a C−S−S−C torsion angle of −86.2(3)°. The configuration about the S−S bond is similar to that found in the structures of other thiuram disulfides $(S_2CNR_2)_2$ [R_2 = Me_2, Et_2, $(CH_2)_4$, $(CH_2)_5$, Et, cyclo-C_6H_{11}].[10] The S−S bond distance 2.034(2) A, is slightly longer than that found for other thiuram disulfides 1.995−2.009.[11] However, an even longer S−S bond distance, 2.069(1) A, with a *trans*-C−S−S−C torsion angle has been found in a centric thiuram disulfide, tetraisopropylthiuram disulfide.[11] The ^{1}H-NMR spectrum of **3** shows only one set of resonances for the ethyl group and only one deshielded resonance for the hydrogen atoms bonded to nitrogen atoms at δ = 9.23 (s, br, 2 H, NH). This is consistent with the fact that the two halves of the molecule are symmetry equivalent.

The formation of **1** can be explained by the combination of one equivalent of **2** [formed by the series of reactions (1) and (2) of the isothiocyanate with water and H_2S] with two equiv. of the isothiocyanate. Mechanistically, this could occur by either of two mechanisms shown in Scheme 1: (1) The addition of the S−H bond to one of the two C−N double bonds of a dimer such as **A** formed by the combi-

nation of two equiv. of the ethoxycarbonyl isothiocyanate. The hydrogen atom is added to the nitrogen atom and the sulfur atom is added to the carbon atom. While there have been several well documented examples of adducts containing four membered rings formed by the addition of carbodiimides to isothiocyanates,[12] the isothiocyanate dimers are not yet well characterized[4]; (2) alternatively the dithiocarbamic acid could combine with the isothiocyanates in a sequential fashion. The combination of **2** with one equiv. of the ethoxycarbonyl isothiocyanate could yield a thiuram monosulfide **C**. A variety of stable thiuram monosulfide derivatives have been characterized.[13]

Scheme 1



The addition of an equivalent of the ethoxycarbonyl isothiocyanate across one of the C=S double bonds in the thiuram monosulfide **C** could give the product **1**. Complex **1** is stable in the solid state, but it is readily dissociated into compound **2** and free isothiocyanate when dissolved in chloroform. This fact would support the first mechanism (microscopic reverse of the dissociation) as the mechanism of the formation of **1**.

Compound **2** can be obtained in a pure form when **1** is passed over a silica gel chromatography column. However, like most dithiocarbamic acids,[9][11][14] it is slowly oxidized upon standing in air to yield the corresponding thiuram disulfide **3**.

These studies were supported by the *Division of Chemical Sciences of the Office of Basic Energy Sciences of the U. S. Department of Energy*. Support for an upgrade of the NMR facilities at the University of South Carolina was provided by an *NSF ARI grant*, Grant No. CHE-9601723.

Experimental Section

General: Unless specified otherwise, all reactions were performed under an atmosphere of nitrogen. All solvents were appropriately dried and degassed prior to use. Ethoxycarbonyl isothiocyanate were purchased from Aldrich and freshly distilled prior to use. – TLC separations were performed in air by using silica gel (60 A, F_{254}) on plates (whatman, 0.25 mm). – Elemental analyses were performed by Desert Analytics, Tucson, AZ. – Mass spectra were obtained with a VG Model 70SQ mass spectrometer (direct inlet, electron impact ionization).

Preparation of [EtO$_2$CN=CS$_2$C{N(H)CO$_2$Et}{S$_2$CN(H)CO$_2$Et}] (**1**): A 60.0-µl amount (3.34 mmol) of distilled H_2O was added to a 200-µl amount (1.70 mmol) of $EtO_2CN=C=S$ in a small capped vial, and the mixture was simply allowed to stand at room temp. for 2 d. Pale yellow crystals formed and were separated. The crystals were washed with 10 × 1 ml of hexane and dried in vacuo. This yielded 175.6 mg (75%) of **1** with one equiv. of ethoxycarbonyl isothiocyanate. – ^{1}H NMR ($CDCl_3$): δ = 9.02(s, 1 H, NH), 7.23 (s, 1 H, NH), 4.27(q, $^3J_{H-H}$ = 7.1 Hz, 2 H, O*CH*$_2$Me), 4.24 (q, $^3J_{H-H}$ = 7.1 Hz, 2 H, O*CH*$_2$Me), 4.15 (q, $^3J_{H-H}$ = 7.1 Hz, 2 H, O*CH*$_2$Me), 4.10(q, $^3J_{H-H}$ = 7.1 Hz, 2 H, O*CH*$_2$Me), 1.32(t, $^3J_{H-H}$ = 7.1 Hz, 3 H, *CH*$_3$), 1.31(t, $^3J_{H-H}$ = 7.1 Hz, 3 H, *CH*$_3$), 1.25(t, $^3J_{H-H}$ = 7.1 Hz, 3 H, *CH*$_3$), 1.24(t, $^3J_{H-H}$ = 7.1 Hz, 3 H, *CH*$_3$). – $C_{16}H_{22}N_4O_8S_5$ (558.67): calcd. (found): C 33.71 (33.16), H 4.01 (4.12), N 9.83 (9.89).

Transformation of **1** *to EtO$_2$CNHCS$_2$H* (**2**): (a) A 400.0 mg amount (0.72 mmol) of **1**·(EtO_2CNCS) was dissolved in a minimum amount of CH_2Cl_2. The solution was transferred to a silica gel column and was eluted with a CH_2Cl_2/ethylacetate (6:1) solvent mixture to yield an orange band of EtO_2CNHCS_2H (**2**) (140 mg, 85% yield). – IR (CH_2Cl_2): ν = 3365 cm^{-1} (N–H), 2476(S–H), 1755(C=O). – ^{1}H NMR ($CDCl_3$): δ = 8.98 (s, br, 1 H, NH), 6.56 (s, br, 1 H, SH), 4.29 (q, $^3J_{H-H}$ = 7.1 Hz, 2 H, O*CH*$_2$Me), 1.33 (t, $^3J_{H-H}$ = 7.1 Hz, 3 H, *CH*$_3$).

(b) A 5.0 mg amount of **1**·($EtO_2CN=C=S$) was dissolved in 0.6 ml of $CDCl_3$ and placed in a 5-mm NMR tube at 25°C. The transformation of **1** was followed by ^{1}H-NMR spectroscopy. After 24 h, compound **1** was converted to **2** and $EtO_2CN=C=S$ completely.

Transformation of **2** *to (EtO$_2$CNHCS$_2$)$_2$* (**3**): A 15.0 mg amount (0.091 mmol) of **2** was dissolved in 5 ml of CH_2Cl_2. The solution was stirred at room temp. in open air for 48 h. After the solvent was removed, the residue was redissolved in a CH_2Cl_2/C_6H_6 (3:1) solvent mixture at room temp. Colorless crystals formed were collected and washed with 5 × 0.5 ml of hexane. This yield 9.2 mg (62%) of $[EtO_2CN(H)CS_2]_2$ (**3**). – ^{1}H NMR ($CDCl_3$): δ = 9.23 (s, br, 2 H, NH), 4.31 (q, $^3J_{H-H}$ = 7.1 Hz, 4 H, O*CH*$_2$Me), 1.35 (t, $^3J_{H-H}$ = 7.1 Hz, 6 H, *CH*$_3$). – $C_8H_{12}N_2O_4S_4$ (328.43): calcd. (found): C 29.26 (29.40), H 3.68 (3.44), N 8.53 (8.25).

X-ray Structural Analyses of **1** *and* **3**: Crystals of **1** suitable for X-ray diffraction analysis were obtained by crystallization of an $EtO_2CN=C=S$ solution at −4°C. Crystals of **3** suitable for X-ray diffraction analysis were obtained by slow evaporation of solvent from a CH_2Cl_2/benzene (3:1) solution at 25°C. The crystals used in intensity measurements were mounted in thin-walled glass capillaries. Diffraction measurements for **1** and **3** were made on a Rigaku AFC6S fully automated four-circle diffractometer using graphite-monochromated Mo-K_α radiation. The unit cells were determined and refined from 15 randomly selected reflections obtained by using the AFC6S or AFC5R automatic search, center, index, and least-squares routines. All data processing was performed on a Silicon Graphics Indigo2 computer by using the TEXSAN structure solving program library obtained from the Molecular Structure Corp., The Woodlands, TX. Neutral atom scattering factors were calculated by the standard procedures.[15a] Anomalous dispersion corrections were applied to all non-hydro-

gen atoms.[15b] Lorentz-polarization (*Lp*) and absorption corrections were applied in each analysis. Both structures were solved by a combination of direct methods (MITHRIL) and difference Fourier syntheses, and all nonhydrogen atoms were refined with anisotropic thermal parameters. Full matrix least-squares refinements minimized the function: $\Sigma_{hkl}w(|F_o| - |F_c|)^2$, where $w = 1/\sigma(F)^2$, $\sigma(F) = \sigma(F_o^2)/2F_o$, and $\sigma(F_o^2) = [\sigma(I_{raw})^2 + (0.02 \cdot I_{net})^2]^{1/2}/Lp$.

Compound **1** crystallized in the triclinic crystal system. The space group *P*1bar was assumed and confirmed by the successful solution and refinement of the structure. One equiv. of $EtO_2CN{=}C{=}S$ (unreacted reagent) cocrystallized with the product in the lattice. This was included in the calculations employing anisotropic thermal parameters for the sulfur atom S(5), a fixed thermal parameter for the carbon atom C(14) and isotropic thermal parameters for the other nonhydrogen atoms. In all cases, the positions of all hydrogen atoms were calculated by assuming idealized geometries with all C−H distances at 0.95 A. The scattering contributions of calculated hydrogen atoms were added to the structure factor calculations, but their positions were not refined.

[a] $R = \Sigma_{hkl}(||F_{obs}| - |F_{calc}||)/\Sigma_{hkl}|F_{obs}|$; $R_w = [\Sigma_{hkl}w(|F_{obs}| - |F_{calc}|)^2/\Sigma_{hkl}wF_{obs}^2]^{1/2}$, $w = 1/\sigma^2(F_{obs})$; GOF = $[\Sigma_{hkl}(w(|F_{obs}| - |F_{calc}|)^2)/(n_{data} - n_{vari})]^{1/2}$.

Compound **3** crystallized in the monoclinic crystal system. The systematic absences were consistent with either of the space groups *C2/c* or *Cc*. This structure was solved and refined in the higher symmetry centrosymmetric space group *C2/c*. The hydrogen atom H(1) on the nitrogen atom N(1) was located and the positions of other hydrogen atoms were calculated by assuming idealized geometries. These hydrogen atoms were successfully refined with isotropic thermal parameters.[16]

Keywords: Pd-catalyzed P–C coupling / Nucleophilic phosphanylation / Mono- and bisphosphonated phosphanes / Monoesters / Water solubility

The triphenylphosphane derivatives **2a** and **5**, bearing one and two phosphonic ester groups, are accessible in high yields by consecutive Pd-catalyzed P–C coupling reactions of *p*-bromoiodobenzene with Ph_2PH and $PhPH_2$, respectively, and then with diethyl phosphite. Ester hydrolysis yields the highly water-soluble sodium salts of mono- and bisphosphonated triphenylphosphane, **3a** and **6**, respectively. On reaction of the *p*- and *m*-fluorophenylphosphonic diethyl esters **7a**, **7b** with Ph_2PK and subsequent ester hydrolysis the isomeric disodium (diphenylphosphano)phenylphosphonates **3a**, **3b** were obtained. The X-ray structure of $Ph_2P(C_6H_4–m\text{-}PO_3Na_2) \cdot 5.5\ H_2O \cdot$ *i*PrOH (space group $Cmc2_1$) has been determined. In the solid state, it forms a layer structure with hydrophilic (PO_3^{2-}, H_2O, *i*PrOH) and hydrophobic (Ph_2P) compartments, in which the PO_3^{2-} anionic groups are not engaged in coordination of the sodium cations.

The introduction of the aqueous two-phase technique may be considered as a cornerstone in the development of homogeneous catalysis over the last two decades. The environmental benefits of using water instead of organic solvents and the ease with which the water soluble catalyst may be separated from the products are the principal advantages of this technique. Water solubility of the complex catalysts is achieved by incorporation of phosphanes bearing cationic[2], anionic[3], or non-charged hydrophilic[4] groups, respectively. The phosphonate group has been employed only very recently as a polar functionality to enhance the solubility of aliphatic and aromatic phosphanes in aqueous media. Thus, DuBois et al.[5] have reported the syntheses of tridentate phosphane ligands bearing $(EtO)_2(O)PCH_2CH_2$ side chains. Köckritz et al.[6] and Schull, Fettinger, and Knight[7] have developed a multistep synthesis for the sodium salts of monophosphonated triphenylphosphane, moderate yields being achieved in both cases. Phosphanorbornadiene monophosphonates are formed by addition of (phenylethynyl)phosphonates to 1-phenyl-3,4-dimethylphosphole[8].

The great potential of phosphonated and phosphinated derivatives of triphenylphosphane as catalyst ligands in two-phase catalysis has been demonstrated by the Pd-catalyzed carbonylation of benzyl chloride[7] and by Suzuki-type C−C coupling reactions[9].

Syntheses of Mono- and Bisphosphonated Aromatic Phosphanes Using Consecutive Pd-Catalyzed P−C Coupling Reactions

Previously, we reported a novel synthetic route to multifunctional phosphanes by cross-coupling of aryl halides with primary or secondary phosphanes in the presence of a base and catalytic amounts of a palladium catalyst[10]. Using this method, *p*-bromophenyldiphenylphosphane[11] (**1a**) and bis(*p*-bromophenyl)phenylphosphane[12] (**4**) were obtained in high yields by reaction of *p*-bromoiodobenzene with diphenylphosphane and phenylphosphane, respectively in the presence of 0.1 mol-% $Pd(Ph_3P)_4$ (Eq. 1a, 2a). The *m* and *o* isomers **1b** and **1c** are also accessible by this synthetic procedure.

The final steps in the syntheses of the mixed-ligand phosphanophosphonates required the introduction of the phosphonic ester groups into **1a** and **4**. This was achieved by Pd-catalyzed P−C coupling reactions with diethyl phosphite, $HP(O)(OEt)_2$. The mono- (**2a**)[7] and bisphosphonated (**5**) *p* isomers were formed in high yields (Eq. 1b, 2b). The anionic derivatives **3a** and **6** were obtained by transesterification of **2a** and **5** using Me_3SiBr[14], followed by hydrolysis of the intermediate silyl esters and subsequent neutrali-

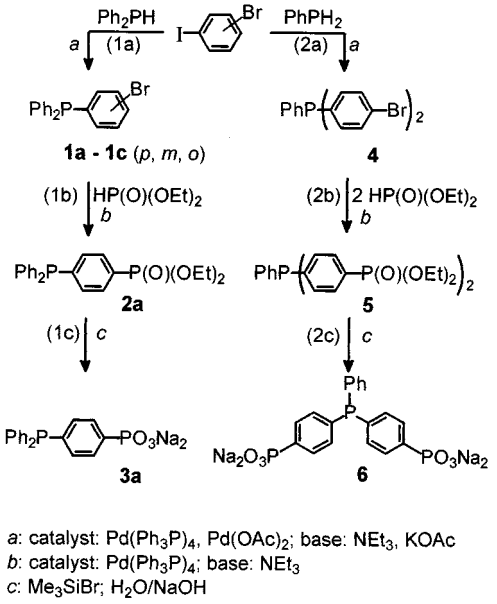
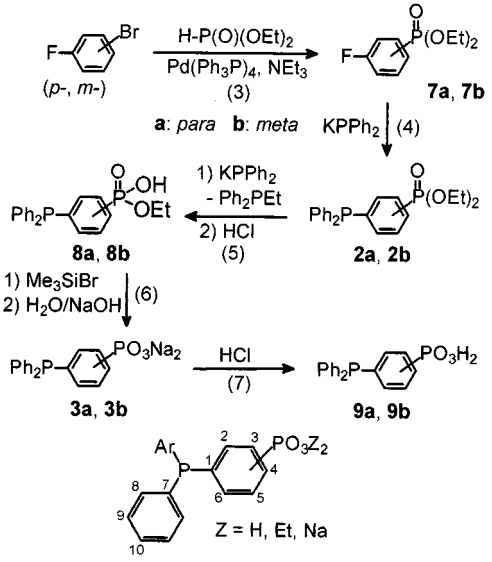


Scheme 2



zation of the phosphonic acids with aqueous NaOH (Eq. 1c, 2c). As expected, the solubility of **6**, bearing two polar groups, was much higher (1000−1100 g/kg water, 20°C) than that of **3a** (300−400 g/kg water, 20°C).

Syntheses of *m*- and *p*-Phosphonated Aromatic Phosphanes by a Combination of Pd-Catalyzed P−C Coupling and Nucleophilic Substitution

Nucleophilic phosphanylation of fluorobenzene derivatives bearing electron-withdrawing substituents[1][3b][15] may be employed for the synthesis of a great variety of water-soluble phosphanes. In combination with the Pd-catalyzed coupling[10], the reaction has many attractive features as a general P−C bond-formation method. This is illustrated by the syntheses of the *p* and *m* isomers **2a**, **2b** of monophosphonated triphenylphosphane (Eq. 4). The starting materials, **7a**[16a], **7b**[16b], were obtained by P−C coupling reactions of *p*- and *m*-bromofluorobenzene with diethyl phosphite using catalytic amounts of $Pd(Ph_3P)_4$ in the presence of NEt_3 as the base (Eq. 3). This method was found to be more efficient than the multistep syntheses reported in the literature for **7a**[16a] and **7b**[16b].

Upon treatment of **7a** with Ph_2PK, a mixture of the expected diester **2a** and the potassium salt of the monoester **8a** was formed (Eq. 4, 5). The diester **2a** is formed initially until about half an equivalent of Ph_2PK has been added. The addition of further Ph_2PK yields Ph_2PEt and the potassium salt of **8a** as a result of dealkylation of the ester group in **2a** or **7a**. This indicates that in the initial stages of the reaction nucleophilic phosphanylation is faster than dealkylation. In contrast to our results, from a similar reaction of the *p* isomer **7a**, using Ph_2PLi instead of Ph_2PK, Köckritz et al.[6] obtained only the diester **2a** and, surprisingly, no dealkylation products were detected. However, the diester **2a** was formed only in moderate yields and no experimental details were given. Phosphanylation of diethyl *m*-fluorophenylphosphonate (**7b**) with Ph_2PK in THF solution proceeded much more slowly than that of the corresponding *p* isomer **7a**, the anion of **8b** being formed exclusively.

After acidification of the reaction mixtures, the monoesters **8a**, **8b** were precipitated as colorless crystals (Eq. 4, 5). Transesterification of **8a**, **8b** with Me_3SiBr and subsequent reaction of the intermediate silyl esters with NaOH gave the disodium salts **3a** and **3b**, respectively (Eq. 6), in overall yields much higher than those reported previously in the literature[7]. The free phosphonic acids **9a**, **9b** were precipitated from aqueous solutions of **3a**, **3b** on acidification with HCl (Eq. 7).

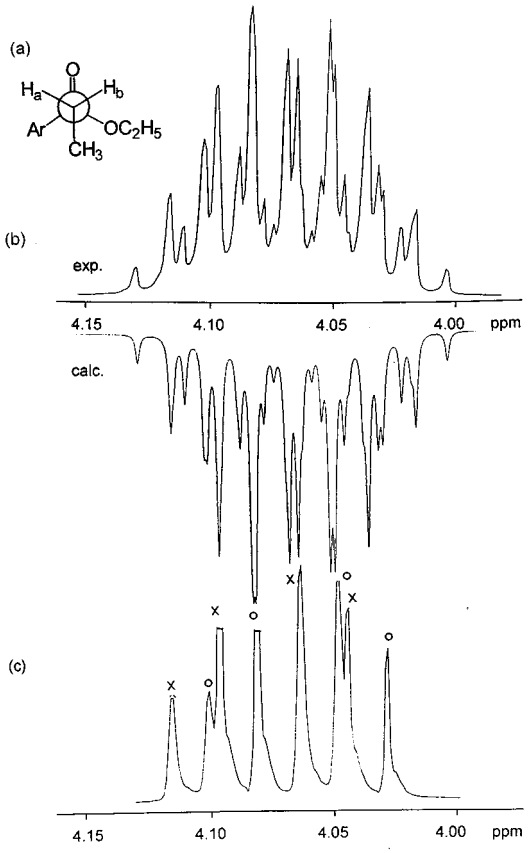
NMR-Spectroscopic Identification of 1a−11b

The $\delta P(P^{III})$ values of the phosphonated phosphanes differ only marginally from that of Ph_3P[11][17a] ($\delta P = -5.9$ to -8.0), with $\delta P(P^V)$ values (20.0−8.9) falling in the range typical for aromatic phosphonic acids and their esters[17b]. Assignment of all $^{13}C\{^1H\}$-NMR signals of **1a**−**1c**, **2a**, **3a**, **3b**, **4**, **5**, **6** and **7a**, **7b**, **9a**, **9b** was achieved with the aid of DEPT experiments[18a] and by comparison of the δC values and P−C coupling constants with the relevant data for Ph_3P[18b]. Further support was gained from the relative magnitude of the coupling constants $^nJ(PC)$, which decrease in the order $^2J(PC) > {}^3J(PC) > {}^4J(PC)$, with $^1J(PC)$ being smaller than $^2J(PC)$[18c]. Large coupling constants (160−190 Hz) are observed for the signals of the carbon atoms (C3 or C4, respectively) bound to P^V[18d] (for the numbering of the carbon atoms in the Experimental Section see Scheme 2).

The protons of the CH_2 groups of the $P(O)(OEt)_2$ substituents in **2a**, **7a**, and **7b** are diastereotopic[19] (Figure 1a, **7a**). In the ^{1}H-NMR spectra, complicated multiplet patterns are observed, representing the AB parts of ABM_3X spin systems [A, B = $H_{a,b}(CH_2)$, M = $H(CH_3)$, X = ^{31}P]. Analysis of these line patterns (Figure 1b) could be ac-

complished in the case of **7a** using $^1H\{^1H(CH_3)\}$ homo nuclei decoupling experiments (Figure 1c).

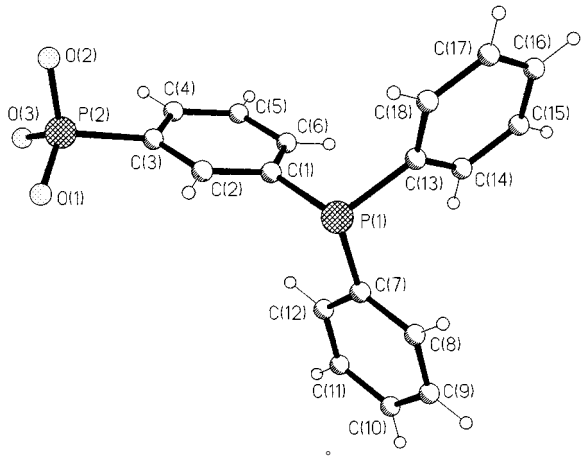
Figure 1. (a) Newman projection along the P···(O)···$C(H_2)$ axis. – (b) ^{1}H-NMR spectrum of **7a** (experimental/calculated); δH_a = 4.06, δH_b = −4.12, $^2J(H_aH_b)$ = 10.2, $^3J(H_aP)$ = 8.2, $^3J(H_bP)$ = 7.8, $^3J(HH)$ = 7.1 Hz. – (c) $^1H\{^1H(CH_3)\}$-NMR spectrum of **7a**, P(O)(O−CH_2−CH_3)$_2$ group



X-ray Structure of $Ph_2P(C_6H_4-m\text{-}PO_3Na_2)\cdot 5.5\ H_2O\cdot i$PrOH

Colorless crystals of the composition $Ph_2P(C_6H_4-m\text{-}PO_3Na_2)\cdot 5.5\ H_2O\cdot i$PrOH were formed at the interface between the two layers obtained on addition of 2-propanol to a concentrated aqueous solution of **3b**. The results of an X-ray structural analysis are shown in Figures 2 and 3, crystallographic data are collected in Table 1, and selected bond lengths and angles are given in the caption to Figure 2. A comparison of the structural parameters of triphenylphosphane[20] with those of the isolated diphenylphosphanophenyl-*m*-phosphonate dianion of **3b** and its *p* isomer **3a**[7], reveals that the PO_3^{2-} group in the *p* or *m* position of the aromatic ring system has only marginal influence on the geometry of the triarylphosphane subunit. The propeller-like arrangement of the phenyl rings (Figure 2), which are each rotated in the same sense, is found in all three structures. In contrast to $Na_2[Ph_2P(C_6H_4-p\text{-}PO_3)(H_2O)_3(CH_3OH)](CH_3OH)$[7], which is dimeric and contains two formula units in the unit cell, the phosphorus atom in the phosphonate group of $Na_2[Ph_2P(C_6H_4-m\text{-}PO_3)\cdot 5.5\ H_2O\cdot i$PrOH] displays only a slightly distorted tetrahedral geometry. The O−P−O bond angles and P−O bond lengths are identical within experimental standard deviation, and the P−O distances fall within the typical range[21][22].

Figure 2. Structure of the anion of **3b**[a]



[a] Selected interatomic distances [A] and angles [°]: P(1)−C(1) 1.843(5), P(1)−C(7) 1.836(8), P(1)−C(13) 1.842(8), P(2)−C(3) 1.823(5), P(2)−O(1) 1.522(6), P(2)−O(2) 1.520(7), P(2)−O(3) 1.521(7); C(1)−P(1)−C(7) 103.7(4), C(7)−P(1)−C(13) 101.9(4), C(1)−P(1)−C(13) 102.6(4), C(2)−C(1)−P(1) 116.6(4), C(6)−C(1)−P(1) 123.3(4), O(1)−P(2)−O(2) 111.9(4), O(1)−P(2)−O(3) 111.6(4), O(2)−P(2)−O(3) 110.9(4).

Within the unit cell, the sodium cations are solvated by water and 2-propanol, thus forming a three-dimensional network supported by O···H−O hydrogen bonding (Figure 3). The shortest distance between the oxygen atoms of the $Ph_2P(C_6H_4-m\text{-}PO_3^{2-})$ dianions and the sodium atoms is 2.987(6) A [O(1)−Na(1)]. This is around 0.45−0.60 A larger than that of other Na−O interactions in the structure, implying that the phosphonate groups are not engaged in the primary coordination sphere of the sodium. The Na···O(P) distances found in $Na_2[Ph_2P(C_6H_4-p\text{-}PO_3)(H_2O)_3(CH_3OH)](CH_3OH)$[7] [Na(1)−O(2) 2.448(3), Na(2)−O(1) 2.249(3) A] are shorter than the closest Na−O contact in $Na_2[Ph_2P(C_6H_4-m\text{-}PO_3)\cdot 5.5\ H_2O\cdot i$PrOH] [Na(1)−O(1) 2.987(6) A]. Interestingly, the structure contains sodium cations in three different environments. Na(1) is coordinated to five water molecules in a trigonal-bipyramidal arrangement (Na···O distances 2.30−2.58 A), two of the water molecules [O(13), O(14)] form bridges to the hexacoordinate Na(2) (Na···O distances 2.36−2.46 A), which in turn is connected to Na(3) and symmetry-equivalent Na(3a) via two water molecules [O(21a), O(21)] in axial positions. Na(3a) is pentacoordinated, with the two axial positions in a strongly distorted trigonal-bipyramid being occupied by bridging oxygen atoms [O(21a) and O(12c)]. 2-Propanol and two water oxygen atoms lie in the equatorial plane of Na(3), with one of the latter [O(22)] bridging the symmetry-related Na cations [Na(3) and Na(3a)]. The closest cation−cation contact is 3.314(6) A [Na(2)···Na(3)].

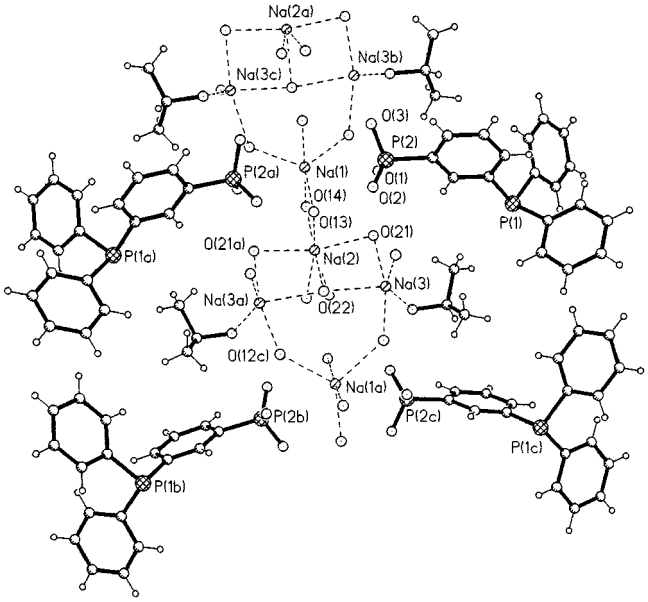
Figure 3. Solid-state structure of **3b**·5.5 H_2O·*i*PrOH



Experimental Section

For experimental details see Part 9 of this series[1]. Phenylphosphane, diphenylphosphane[23], and $Pd(Ph_3P)_4$[13] were prepared according to literature methods. Ph_2PK, 2-, 3-, and 4-bromoiodobenzene, 3- and 4-bromofluorobenzene, as well as bromotrimethylsilane were purchased from Aldrich Chemical Co. and used without further purification.

Preparation of **1a**−**1c** *by Palladium-Catalyzed Coupling of 2-, 3-, and 4-Bromoiodobenzene with Ph_2PH:* A mixture of 20.0 g (70.8 mmol) of the appropriate bromoiodobenzene, 7.64 g (78.0 mmol) of potassium acetate, and 28.4 ml of a $5.0 \cdot 10^{-3}$ M solution of palladium(II) acetate in dimethylacetamide was dissolved in 120 ml of dimethylacetamide. To this solution, 13.16 g (70.8 mmol) Ph_2PH was added and the mixture was heated for 5 d at 130°C. The reaction mixture was then poured into 200 ml of deoxygenated water and the resulting suspension was extracted with 200 ml of dichloromethane. The organic phase was separated, washed with 100 ml of saturated aqueous KCl solution, and dried with magnesium sulfate. After removal of the solvent under reduced pressure (20°C, 10 mbar), the residue was distilled in vacuo (0.1 mbar) at 200−300°C. Yields: 15.0 g (62%) **1a**, 18.4 g (76%) **1b**, 18.0 g (75%) **1c**. For further purification, **1a**−**1c** were recrystallized from water/ethanol.

Preparation of **4** *by Pd-Catalyzed Coupling of 4-Bromoiodobenzene with $PhPH_2$:* A Schlenk flask was charged with 250 ml of acetonitrile, 7.91 g (71.8 mmol) of phenylphosphane, 40.65 g (143.7 mmol) of 4-bromoiodobenzene, and 16.00 g (158.1 mmol) of triethylamine. The mixture was deoxygenated and 1.66 g (1.43 mmol, 1 mol-%) of $Pd(Ph_3P)_4$ was added. After heating the reaction mixture under reflux for 24 h, the solvent was removed in vacuo, and the residue was dissolved in 200 ml of dichloromethane. The resulting solution was washed with three 100-ml aliquots of water. The organic phase was separated and dried with magnesium sulfate. After removal of the solvent under reduced pressure (30°C, 10 mbar), the residue was distilled in vacuo (0.1 mbar) at 200−300°C. Yield: 19.03 g (63%). − **4**: $C_{18}H_{13}Br_2P$ (420.1): calcd. C 51.47, H 3.12; found C 51.12, H 3.25. − MS: $[M^+]$: *m/z* = 418 (^{79}Br), 420 (^{81}Br,^{79}Br), 422 (^{81}Br). − $^{31}P\{^1H\}$ NMR ($CDCl_3$): δP = −6.0; $^{13}C\{^1H\}$ NMR ($CDCl_3$): δC (C1−C10) = 135.9 (12.2), 135.1 (20.3), 131.7 (7.1), 123.6, 131.7 (7.1), 135.1 (20.3), 136.0 (10.2), 133.6 (19.3), 128.7 (7.1), 129.2.

Preparation of **2a**/**3a** *and* **5**/**6**: To a solution of 2.0 g (5.9 mmol) of **1a** or 4.26 g (10.1 mmol) of **4** in 40 or 80 ml of toluene, 0.89 g (6.45 mmol) or 3.08 g (22.3 mmol) of $HP(O)(OEt)_2$ and 0.65 g (6.45 mmol) or 2.26 g (22.3 mmol) of NEt_3 were added. After deoxygenation in vacuo, 68 mg (0.06 mmol, 1 mol-%) or 0.23 g (0.2 mmol, 1 mol-%) of $Pd(Ph_3P)_4$ was added. The reaction mixtures were then heated to 80°C for 50 h or 72 h. After cooling to ambient temperature and washing with three 25- or 50-ml aliquots of water, the toluene phases were collected and dried with $MgSO_4$. Evaporation of the solvent in vacuo left **2a** and **5** as yellow, viscous oils. Yields: 1.46 g (62%) **2a**, 3.78 g (70%) **5**. − **2a**: $^{31}P\{^1H\}$ NMR ($CDCl_3$): δP = −3.8 (P^{III}), 19.4 (P^V). − **5**: MS: $[M^+]$: *m/z* = 534. − $^{31}P\{^1H\}$NMR ($CDCl_3$): δP = −3.4 (P^{III}), 19.3 (P^V).

To a solution of 3.79 g (7.1 mmol) of **5** in 50 ml of dichloromethane at room temperature 6.5 g (42.4 mmol) of Me_3SiBr were added with stirring. After 12 h, all volatiles were removed in vacuo (60°C, 0.01 mbar) and the residual oily liquid was taken up in 50 ml of acetone. To the resulting solution 1.02 g (56.7 mmol) of water was added and the mixture was stirred at ambient temperature for 2 h. Thereafter, all volatiles were removed in vacuo (20°C, 0.01 mbar), and the pale-yellow solid (the free phosphonic acid) thus obtained was redissolved in 20 ml of conc. NaOH solution. On pouring this solution into 200 ml of ethanol, **6** was precipitated as pale-yellow crystals, which were separated by suction using a fritted Buchner funnel. The residue was washed with two 10-ml aliquots of ethanol and dried in vacuo (60°C, 0.01 mbar). Yield: 2.58 g (71.2%) **6**.

3a was obtained in high yield by the analogous procedure using **2a** as the starting material.

3a: $^{31}P\{^1H\}$ NMR (D_2O): δP = −5.5 (P^{III}), 12.0 (P^V). − **6**: $C_{18}H_{13}O_6Na_4P_3 \cdot 1.5\ H_2O$ (537.2): calcd. C 40.25, H 3.00; found C 40.19, H 3.24. − $^{31}P\{^1H\}$ NMR (D_2O): δP = −6.0 (P^{III}), 12.0 (P^V). − $^{13}C\{^1H\}$-NMR (D_2O): δC (C1−C10) = 138.5 (5.1, 3.1), 135.1 (18.8, 13.2), 132.8 (8.1, 8.1), 144.3 (165.8), 132.8 (8.1, 8.1), 135.1 (18.8, 13.2), 138.3 (5.1), 136.0 (19.3),131.2 (7.1), 131.7.

Preparation of **7a**, **7b**: A Schlenk flask was charged with 200 ml of toluene, 20.0 g (114.3 mmol) of 4-bromofluorobenzene or 25.0 g (142.8 mmol) of 3-bromofluorobenzene, 17.3 g (125.7 mmol) or 21.7 g (157.1 mmol) of $HP(O)(OEt)_2$, and 12.7 g (125.7 mmol) or 15.9 g (157.1 mmol) of NEt_3. Dissolved oxygen was removed by freeze-thaw cycles and after addition of 5.3 g (4.6 mmol, 4 mol-%) or 6.6 g (5.7 mmol, 4 mol-%) of $Pd(Ph_3P)_4$ the reaction mixture was heated to 70−80°C for 24 h. Thereafter, the mixture was washed with three 200-ml aliquots of water. The toluene phase was

dried with $MgSO_4$. The liquid obtained after removal of the solvent in vacuo was fractionated. Yields: 21.5 g (81%) **7a**, 28.0 g (84%) **7b**.

7a: $C_{10}H_{14}FO_3P$ (232.2): calcd. C 51.73, H 6.08, P 13.34; found C 51.94, H 6.18, P 13.13. – B.p. 96°C, 0.4 mbar. – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δP = 18.9 [^5J(PF) = 1.4]. – $^{13}C\{^1H\}$ NMR ($CDCl_3$): δC (C1–C6) = 165.4 [4.1, 253.8 ^1J(CF)], 115.8 (16.3, 21.4), 134.4 (11.2, 8.6), 124.7 (192.8, 3.6), 134.4 (11.2, 8.6), 115.8 (16.3, 21.4), 62.2 (5.6, CH_2), 16.3 (6.6, CH_3). – **7b**: $C_{10}H_{14}FO_3P$ (232.2): calcd. C 51.73, H 6.08; found C 51.64, H 6.13. – B.p. 96°C, 0.4 mbar. – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δP = 17.4 [^4J(PF) = 8.6]. – $^{13}C\{^1H\}$ NMR ($CDCl_3$): δC (C1–C6) = 162.3 (21.2, 249.2), 118.3 (10.2, 22.4), 131.2 (188.2, 6.1), 127.3 (9.2, 3.1), 130.4 (17.3, 8.1), 119.3 (3.1, 21.4), 62.2 (6.1, CH_2), 16.1 (6.1, CH_3).

Nucleophilic Phosphination of **7a** *with Ph_2PK in a 1:1 Molar Ratio:* To the solution of 1.63 g (7.0 mmol) **7a** in 20 ml of THF 17 ml of a 0.5 M solution of Ph_2PK in THF (8.5 mmol) was added at room temp. After completion of the addition, the solvent was evaporated under reduced pressure. From the oily residue Ph_2PEt formed during the reaction was removed at 100°C, 0.01 mbar using a short-path distillation apparatus. The remaining solid was extracted with a mixture of 20 ml of water and CH_2Cl_2. The organic phase was separated and dried with magnesium sulfate. After removal of the solvent in vacuo, **2a** was obtained as a colorless oil. Yield: 1.52 g (54.5%).

2a: $C_{22}H_{24}O_3P_2$ (398.4): calcd. C 66.33, H 6.07, P 15.55; found C 65.49, H 6.29 P 14.60. – MS: [M^+]: *m/z* = 398. – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δP = –3.8 (P^{III}), 19.4 (P^V). – $^{13}C\{^1H\}$ NMR ($CDCl_3$): δC (C1–C10) = 143.6 (15.3, 3.1), 133.2 (18.3, 14.2), 131.6 (6.1, 12.2), 128.7 (188.2), 131.6 (6.1, 12.2), 133.2 (18.3, 14.2), 136.2 (10.2), 134.0 (20.3), 128.8 (7.1), 129.3, 62.2 (5.1, CH_2), 16.5 (6.1, CH_3).

Synthesis of **8a** *and* **8b**: A 0.5 M solution of Ph_2PK (250 mmol) in 500 ml of THF was added to 27.86 g (120 mmol) of **7a** dissolved in 500 ml of THF over a period of 3 h at 20°C. After completion of the addition, the reaction mixture was stirred for a further 1 h. Thereafter, the solvent was distilled off under normal pressure and the remaining residue was partitioned between 500 ml of water and 500 ml of dichloromethane. The organic phase was separated and dried with magnesium sulfate. The residue obtained after evaporation of the solvent at normal pressure was fractionated in vacuo (0.1 mbar) to afford 11.10 g of Ph_2PEt (b.p. 102°C, 0.1 mbar, yield 43%). The aforementioned aqueous phase was treated with HCl until a pH value of 2 was reached, and then extracted with three 150-ml aliquots of dichloromethane. The combined extracts were dried with magnesium sulfate. Removal of the solvent in vacuo left a colorless solid. Yield: 36.50 g (82%) **8a**.

8b was obtained in an analogous manner starting from 6.82 g (29.4 mmol) of **7b**, dissolved in 100 ml of THF, and 130 ml of a 0.5 M solution of Ph_2PK (65.0 mmol) in THF. Due to the lower reactivity of **7b**, a longer reaction time was needed, even at reflux temperature (72 h). Yield: 8.80 g (81%).

8a: $C_{20}H_{20}O_3P_2$ (370.3): calcd. C 64.87, H 5.44, P 16.73; found C 64.72, H 5.38, P 16.56. – MS: [M^+]: *m/z* = 370. – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δP = –3.6 (P^{III}), 20.0 (P^V). – **8b**: $C_{20}H_{20}O_3P_2$ (370.3): calcd. C 64.87, H 5.44, P 16.73; found C 64.19, H 5.32, P 16.14. – MS: [M^+]: *m/z* = 370. – $^{31}P\{^1H\}$ NMR ($CDCl_3$): δP = –3.9 (P^{III}), 19.9 (P^V).

Preparation of **3a** *and* **3b**: To the solutions of 35.54 g (96.0 mmol) of **8a** or 8.11 g (21.9 mmol) of **8b** in 300 ml or 100 ml of dichloromethane 44.08 g (287.9 mmol) or 10.1 g (66.0 mmol) of Me_3SiBr was added. After stirring the reaction mixtures for 12 h at ambient temperature, all volatiles were removed in vacuo (60°C, 0.01 mbar). The intermediate silyl esters formed were obtained as very moisture-sensitive colorless oils. They were dissolved in acetone (300 ml or 100 ml, respectively), 4.13 g (229.4 mmol) or 1.44 g (80.0 mmol) of water was added and the reaction mixture was stirred at ambient temperature for 2 h. After removal of all volatiles in vacuo (20°C, 0.01 mbar), the respective diphenylphosphanophenylphosphonic acid was obtained as a colorless solid. The product was redissolved in 150 ml or 50 ml of conc. NaOH and the resulting solution was poured into 4.0 l or 400 ml of ethanol, whereupon the disodium salt of the diphenylphosphanophenylphosphonic acid was precipitated as colorless crystals. The product was filtered off using a Buchner funnel, washed with ethanol, and dried in vacuo (60°C, 0.01 mbar). Yields: 30.5 g (76%) **3a**, 5.81 g (63%) **3b**.

3a: $C_{18}H_{14}Na_2O_3P_2 \cdot 2\ H_2O$ (422.2): calcd. C 51.20, H 4.30; found C 51.43, H 4.34. – $^{31}P\{^1H\}$ NMR (D_2O): δP = –5.5 (P^{III}), 12.0 (P^V). – $^{13}C\{^1H\}$ NMR (D_2O): δC (C1–C10) = 136.8 (9.2, 2.0), 132.9 (19.3, 13.2), 130.7 (7.1, 8.1), 142.2 (166.8), 130.7 (7.1, 8.1), 132.9 (19.3, 13.2), 136.2 (6.1), 133.8 (19.3), 129.0 (7.1), 129.4. – **3b**: $C_{18}H_{14}Na_2O_3P_2 \cdot 2\ H_2O$ (422.2): calcd. C 51.20, H 4.30; found C 51.34, H 4.39. – $^{31}P\{^1H\}$ NMR (D_2O): δP = –5.1 (P^{III}), 11.8 (P^V). – $^{13}C\{^1H\}$ NMR (D_2O): δC (C1–C10) = 135.3 (12.2, 7.1), 136.1 (29.6, 9.5), 141.8 (9.2, 165.8), 133.2 (9.2), 128.4 (4.1, 12.2), 131.5 (9.2), 136.3 (6.1), 133.7 (18.3), 129.0 (8.1), 129.3.

The diphenylphosphanophenylphosphonic acids **9a** and **9b** were obtained as oily liquids in quantitative yields by acidification of aqueous solutions of the disodium salts **3a** and **3b** with HCl. The crude products were extracted with dichloromethane, and the combined extracts were dried with magnesium sulfate. After evaporation of the solvent, the diphenylphosphanophenylphosphonic acids **9a** and **9b** were obtained as colorless solids. The products were characterized by $^{31}P\{^1H\}$-NMR spectroscopy and APCI mass spectrometry. **9a**, **9b**: APCI-MS: [MH^+]: *m/z* = 343; [MH^+ – PO_2H]: *m/z* = 279; [MH^+ – PO_3H]: *m/z* = 263.

Crystal-Structure Analysis of $Na_2[Ph_2P(C_6H_4$–m-$PO_3) \cdot 5.5\ H_2O \cdot i$PrOH]: Experimental data for the X-ray structural analysis are collected in Table 1. Unit-cell constants were determined from a least-squares fit to the settings of 25 reflections centred on a Siemens P4 diffractometer. Intensity data were collected with the

Keywords: α,ω-Bis(trifluorosulfur)perfluoroalkanes / α,ω-Bis(fluorosulfinyl)alkanes / Fluorosulfur anions / Fluorosulfur cations / Ab initio calculations

The title compound $(–CF_2–SF_3)_2$ (**2**) is prepared from $(–CF_2–SCl)_2$ (**1**) and F_2 at –90 °C in 83 % yield. Reaction of **2** with CsF and TASF yields $Cs[(–CF_2–SF_3)_2F]$ (**8**), TAS $[(–CF_2SF_3)_2F]$ (**9**) and $(TAS)_2[(–CF_2–SF_4)_2]$ (**10**). Fluoride-ion abstraction yields $[(–CF_2SF_2)_2F]$ $[AsF_6]$ (**6**), BF_3-catalysed solvolysis in SO_2 gives $[–CF_2–S(O)F]_2$ (**4**), and CsF-catalysed oxidation with F_2 leads to the previously reported $(–CF_2–SF_5)_2$ (**11**). Ab initio calculations of the molecular structures of **2** and the related methane derivative $F_2C(SF_3)_2$ are reported.

Introduction

α,ω-Bis(trifluorosulfur)perfluoroalkanes, $SF_3–(CF_2)_n–SF_3$, should show a rich and interesting chemistry as a result of the bifunctionality and high reactivity of the SF_3 groups. The only compound of this class known to date is $F_2C(SF_3)_2$, which is prepared by the direct fluorination of CS_2[1][2][3]. As well as the chemistry of this compound and its reaction product $CF_2[S(O)F]_2$[4], the gas-phase structure of bis(trifluorosulfur)difluoromethane has been studied by electron diffraction[5]. There is an intramolecular interaction between the two SF_3 groups in the gas phase; one of the axial fluorine atoms of the pseudo-trigonal bipyramidal sulfur atom interacts equatorially with the other sulfur center and vice versa.

We thought it would be interesting to observe the effect that increasing the length of the perfluoroalkane chain would have on the interaction between the sulfur centers, the stability and the reactivity. We report here the synthesis of 1,2-bis(trifluorosulfur)tetrafluoroethane and illustrate the diverse reaction possibilities with some examples. The structures of $SF_3(CF_2)_nSF_3$ (n = 1, 2) calculated by ab initio methods are compared to that of $CF_2(SF_3)_2$[5] determined by electron diffraction.

Results and Discussion

Synthesis of 1,2-Bis(trifluorosulfur)-1,1,2,2-tetrafluoroethane ($F_3S–CF_2–CF_2–SF_3$)

The bis(trifluorosulfur)ethane derivative **2** was prepared in high yield by low-temperature fluorination of the corresponding chlorosulfenyl derivative **1**[6].

$$\underset{\mathbf{1}}{ClS–CF_2–CF_2–SCl} + 3\,F_2 \xrightarrow{-\,90°C} \underset{\mathbf{2}}{F_3S–CF_2–CF_2–SF_3} + Cl_2 \qquad (1)$$

Fluorine was expanded through a metal vacuum line under reduced pressure into a cooled nickel reactor containing compound **1** as a thin film on the inner surface. Decomposition products and the resulting chlorine were periodically removed on reaching a pressure of approximately 100 mbar. The reaction was taken as complete when no more fluorine uptake was observed, i.e. a subsequent oxidation of compound **2** to the respective sulfur(VI) derivative **11** does not occur under these conditions.

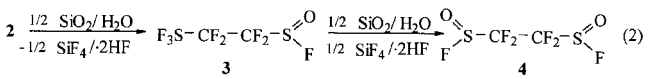
Compound **2** was prepared by this reaction on a preparative scale with a yield of 83%. **2** is a colourless, hydrolysis-sensitive liquid, as is the corresponding methane derivative $CF_2(SF_3)_2$.

In an analogous way to $CF_2(SF_3)_2$, which was described in the Introduction, α,ω-bis(trifluorosulfur)perfluoroalkanes display intramolecular donor-acceptor properties as a result of the acid-base amphoteric behaviour of the SF_3 groups, a phenomenon that leads to a chemical stabilization of the SF_3 groups. Evidence for such an interaction was also obtained by NMR spectroscopy. The ^{19}F-NMR spectra of SF_4 and CF_3SF_3 show only one signal for the sulfur-bonded fluorine atoms as a result of Berry pseudorotation at room temperature. However, the fluorine atoms do become non-equivalent at −20 °C. In the ^{19}F-NMR spectrum of **2** [and also of $CF_2(SF_3)_2$], no inequivalence of the sulfur-bonded fluorine atoms is observed even at −80 °C. We assume that, in addition to Berry pseudorotation, fast intra-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434–1948/98/0707–1035 $ 17.50+.50/0

molecular fluorine exchange between the two SF_3 groups is responsible for this behaviour.

NMR measurements of **2** and $CF_2(SF_3)_2$ at −30°C show that **2** is less stable to hydrolysis than $CF_2(SF_3)_2$ and forms the sulfinyl products $F_3S-CF_2-CF_2-S(O)F$ (**3**) and $[-CF_2-S(O)F]_2$ (**4**), while $F_2C(SF_3)_2$ is stable under these conditions.



(2)

3 **4**

While **4** can be synthesized simply by BF_3-catalysed solvolysis of **2** in SO_2, **3** has only been observed as an intermediate (see Eq. 2). The ^{19}F-NMR spectrum of **3** shows a complex AA′BB′MX_3 splitting pattern with $\delta(SF_3) = +8.0$ (s, br.), δ[S(O)F] = −13.1 (m), $\delta(CF_2SF_3) = -102.2$ and $\delta[CF_2S(O)F] = -118.1$ (m).

The intramolecular interaction between the two SF_3 groups in **2** appears to be weaker than in $CF_2(SF_3)_2$ and the reactivity higher as a result of the longer perfluoroalkane chain. Evidence for this hypothesis through structural analysis of **2** has not yet been obtained.

Reaction of $(-CF_2SF_3)_2$ with BF_3 and AsF_5 in SO_2: Synthesis of $[-CF_2S(O)F]_2$ and $[(-CF_2SF_2)_2F][AsF_6]$

Perfluoroalkanesulfinyl fluorides can be obtained by two synthetic routes: (i) from perfluoroalkenes and SOF_2[7] or SO_2[8] and (ii) by hydrolysis of perfluoroalkylsulfur trifluorides[7]. The second route is particularly unsatisfactory due to the difficulty in controlling the reaction. As a result of our attempt to synthesize sulfonium salts $R_FSF_2^+BF_4^-$ from the corresponding perfluoroalkylsulfur trifluorides by fluoride abstraction using BF_3 in SO_2, we observed the quantitative formation of $R_FS(O)F$[4]. On addition of BF_3 to a solution of **2** in SO_2 at −40°C, a colourless solid precipitated. This precipitate disappeared on slow warming to room temperature and was not observed again on cooling.

(3)

5 **4**

It is likely that the colourless precipitate is salt **5**. As discussed previously[4], the FSO_2^- ions resulting from the SO_2/BF_4^- equilibrium attack the cations of **5** leading to the formation of **4**. Compound **4** is isolated as a colourless liquid in > 90% yield.

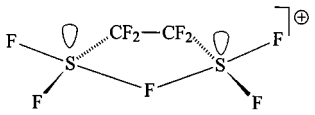
The ^{19}F-NMR spectrum of compound **4** shows two AA′BB′XX′ spin patterns (see Experimental Section), demonstrating the presence of two isomers in a 1:1 ratio, which can be assigned to the *meso* and D,L compounds as a result of the two chiral sulfinyl centers.

If reaction (3) is performed with AsF_5 as a Lewis acid, the salt **6** is isolated in almost quantitative yield.

(4)

6 **7**

The formation of the dicationic compound **7** is not observed, even with a large excess of AsF_5. We assume that the abstraction is prevented due to the mutual interaction of both sulfonium centers. In the ^{19}F-NMR spectrum of **6** only one signal is observed for the *C*- and *S*-bonded fluorine atoms, even at low temperature [δ(CF) = −98.3 (s), δ(SF) = −37.2 (s, br.)]. This equivalence suggests a fast intramolecular fluoride exchange between the two sulfonium centers via a cyclic transition state in which the sulfur centers have pseudo-trigonal bipyramidal coordination through bridging over axially bonded fluoride. Single crystals of **6** suitable for an X-ray-structural analysis have not been obtained to date. In comparison with other sulfonium salts $R_FSF_2^+AsF_6^-$ ($R_F = CF_3$, C_2F_5, C_3F_7)[9][10][11], **6** is not very stable; **6** can only be stored satisfactorily at room temperature in Kel-F or Teflon vessels.



Reactions of $F_3SCF_2CF_2SF_3$ with Fluoride Ions

$R_FSF_4^-$ anions can be prepared by fluoride-ion addition to R_FSF_3 derivatives [$R_F = CF_3$, $(CF_3)_2CF$][12]. Spectroscopic studies show that the sulfur atom has a pseudo-octahedral geometry in these complexes, with the four fluorine atoms in the basal and the perfluoroalkyl groups in the apical positions. These anions correspond to the transition state of a nucleophilic S_N2 substitution at pseudo-pentacoordinated sulfur.

As we showed recently, fluoride-ion addition to $F_2C(SF_3)_2$ leads to a stable four-membered cyclic anion with a symmetrical S−F−S′ bridge[13]. Similarly, fluoride-ion addition to **2** with CsF and TASF [$(Me_2N)_3S^+Me_3SiF_2^-$] leads to the stable salts **8** and **9**.

(5)

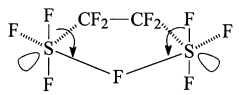
8

(6)

9

In contrast to the neutral starting material **2**, the salts **8** and **9** are much more stable. They can be stored in glass vessels at room temperature under an inert atmosphere for several weeks. The attack by nucleophiles (e.g. H_2O) is impeded through anion formation.

The ^{19}F-NMR spectra of the salts **8** and **9** each show two signals, and these have been assigned to the sulfur- and carbon-bonded fluorine atoms, respectively. Although only broad singlets are observed for the Cs salt **8** [δ(CF) = −96.0 (s), δ(SF) = +12.0 (s, br.)], the S*F* signal in the TAS salt **9** [δ(CF) = −95.6 (s, br.), δ(SF) = +12.5 (quint)] is split into a quintuplet (^3J = 15.6 Hz). The equivalence of all S*F* and C*F* atoms deduced from the ^{19}F-NMR spectra can be explained by a fast intramolecular exchange between the two sulfur centers and a rotation around the C−S bonds.



Although it was not possible to add a second fluoride ion to $CF_2(SF_3)_2$, the reaction of **2** with an excess of TASF led quantitatively to **10**, a salt containing a dianion with two pseudo-octahedrally coordinated sulfur centers.

$$\mathbf{2} + 2\ TASF \longrightarrow (TAS^+)_2[(-CF_2-SF_4)_2]^{2-} + 2\ Me_3SiF \quad (7)$$

10

These reactions show, on the one hand, that the interaction between the two sulfur centers in α,ω-bis(trifluorosulfur) derivatives of the type $F_3S-(CF_2-)_nSF_3$ seems to decrease with increasing chain length and, on the other hand, that the S−F−S′ bridge in **8** and **9** can only be broken by using "naked" or nearly naked, highly reactive fluoride ions such as those in TASF. The colourless stable salt **10** (mp 132°C, decomp.) was characterized by elemental analysis and IR spectroscopy (Experimental Section). Due to the high charge on the anion of **10** it is very insoluble in acetonitrile, the most convenient solvent for reactions with TASF, and, as a result, neither NMR-spectroscopic investigation nor recrystallization of the salt was possible.

CsF-Catalysed Oxidative Fluorination of $SF_3-CF_2-CF_2-SF_3$ to $SF_5-CF_2-CF_2-SF_5$ (11)

CsF-catalysed oxidative fluorinations have found wide use in fluorine chemistry. The oxidation is made easier through intermediate anion formation, as shown by numerous examples in the chemical behaviour of the elements of groups 15−18. Compound **2** can be oxidized to the corresponding sulfur(VI) oxidation state in a way similar to the conversion of $CF_2(SF_3)_2$ to $CF_2(SF_5)_2$[3].

$$\mathbf{2} + 2\ F_2 \xrightarrow[-196° \longrightarrow r.t.]{CsF} F_5S-CF_2-CF_2-SF_5\ (21.5\ \%) \quad (8)$$

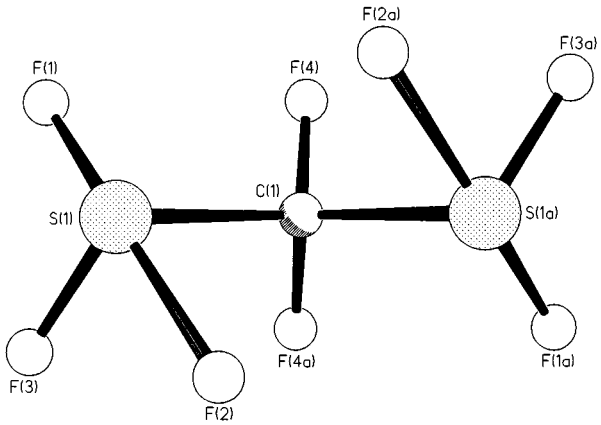
11

11 was first observed as a by-product in the electrofluorination of 3-oxapentane-1,5-dithiol[14]. The ^{19}F-chemical shifts of the fluorine atoms of our product differ only slightly from the literature values. For the *C*-bonded fluorine atoms we observe a nonuplet of triplets, since $^3J(CF-SF_4) = {}^4J(CF-SF_4) = 14.6$ Hz and $^3J(CF-SF_{apical}) = {}^4J(CF-SF_{apical}) = 3.0$ Hz. The fine splitting of the A and B_4 parts of the SF_5 groups ($^2J = 152.3$ Hz) indicates a spin system of type $AA'B_4B_4'X_2X_2'$. From the splitting of the ^{13}C signal (δ = 119.9, ttq) we determined the following coupling constants: $^1J(C-F) = 314.2$ Hz, $^2J(C-F) = 35.5$ Hz and $^2J(C-SF_4) = 28.4$ Hz.

Structure and Bonding in $F_3S(CF_2)_nSF_3$ (n = 1, 2)

The gas-phase structure of the methane derivative $F_2C(SF_3)_2$ has been determined by electron diffraction[5]. However, our attempts to determine the structure of the ethane derivative **2** have been fruitless to date due to the extreme moisture sensitivity of this species. Figure 1 shows the RHF/6-311+G*-calculated[15] structure for $F_2C(SF_3)_2$, with the experimentally determined bond lengths and angles given for comparison. The conformation as well as the angles and distances are in good agreement. The experimentally observed interaction between the two SF_3 groups is also clearly seen in the calculated structure. The calculated distance between the axial fluoride F(2) and the neighbouring sulfur center S(1a) [or F(2a)−S(1)] of 263 pm lies well below the sum of the van der Waals radii of S and F (320 pm). The experimentally found value is 266 pm. The averaged S−F bond lengths of 163.6 pm (calculated) and 163.0(3) pm (experimental) are identical, although the individual values differ substantially.

Figure 1. Fully optimized structure of $F_3S-CF_2-SF_3$[a]



[a] Calculated [and experimental[5]] bond lengths [pm] and bond angles [°]: C(1)−S(1) 187.6 [188.8(7)], C(1)−F(4) 129.1 [131.8(5)], S(1)−F(1) 164.1 [166.4(4)], S(1)−F(2) 172.0 [166.6(4)], S(1)−F(3) 154.7 [156.2(6)], S(1)···F(2a) 263 [266]; S(1)−C(1)−S(1a) 108.6 [108.2(5)], F(4)−C(1)−F(4a) 110.1 [109.8(18)], F(4)−C(1)−S(1) 111.8 [109.7(5)], F(4a)−C(1)−S(1) 107.2, F(1)−S(1)−F(2) 167.7 [173.1(15)], F(1)−S(1)−F(3) 87.6 [88.1(13)], F(2)−S(1)−F(3) 85.8 [88.1(3)], F(1)−S(1)−C(1) 89.0 [89.1(8)], F(2)−S(1)−C(1) 82.0 [85.1(8)], F(3)−S(1)−C(1) 101.2 [97.2(11)].

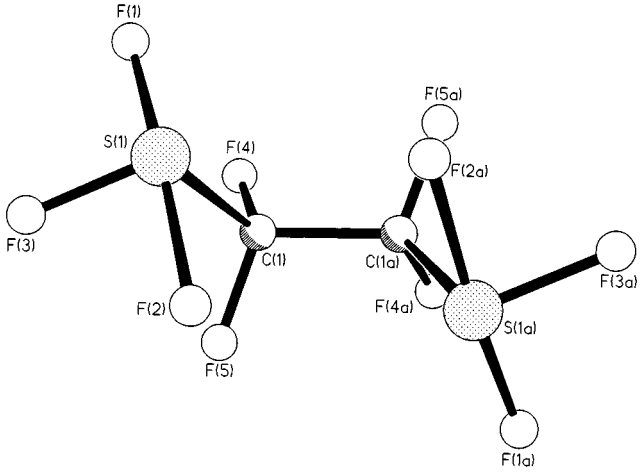
An average S−F bond length and the difference Δ = $(S-F_a) - (S-F_e)$ were obtained experimentally, equally large $S-F_a$ distances were assumed. From these data the bond lengths $S-F_a$ and $S-F_e$ were derived. However, it is expected that the interaction of the axial 3c-4e$^-$ bond system with the neighbouring centers will lead to a stretching of the bridging SF and a corresponding shortening of the non-bridging fluoride. For example, this phenomenon is observed in the structure of SF_3-SF[16]. In this case the two $S-F_a$ bonds of the pseudo-pentacoordinated sulfur center differ by approximately 10 pm, and a difference of 7.9 pm was calculated for $F_2C(SF_3)_2$ (172.0 and 164.1 pm).

The influence of the interaction between the two SF_3 groups on the geometrical configuration of the substituents at the sulfur centers is minimal. Through the lengthening of the one axial S−F bond we would expect a distortion of the pseudo-trigonal bipyramid towards a pseudo-tetrahedron and through the interaction of this bridging fluoride with the neighbouring sulfur center we would expect an increase in sulfur coordination towards a pseudo-octahedron. These interactions have little influence, as shown by a comparison with the experimentally determined structure of CF_3SF_3[17]. Deviations from ideal pseudo-trigonal bipyramidal geometry can be explained by the influence of the lone pair of electrons in accordance with VSEPR theory[18].

The RHF/6-311 + G*-calculated[15] structure of $F_3S-CF_2-CF_2-SF_3$ (**2**) with bond lengths and angles is

shown in Figure 2. Interaction of the two SF_3 groups is also clearly seen here. The distances between the non-bonded atoms S(1)F(2a) and S(1a)F(2) of 283 pm are also significantly longer than those in the methane derivative. This is in agreement with the conclusions drawn from the experimental results, i.e. that the interaction of the SF_3 groups leads to a stabilization and that the lesser interaction in **2**, compared to that in $F_2C(SF_3)_2$, is responsible for its higher reactivity towards nucleophiles.

Figure 2. Fully optimized structure of compound **2**[a]



[a] Calculated bond lengths [pm] and bond angles [°]: C(1)−C(1a) 155.8, C(1)−S(1) 188.9, C(1)−F(4) 130.2, C(1)−F(5) 130.6, S(1)−F(1) 164.3, S(1)−F(2) 170.2, S(1)−F(3) 155.0, S(1)···F(2a) 283; F(1)−S(1)−F(2) 170.9, F(1)−S(1)−F(3) 88.1, F(1)−S(1)−C(1) 89.9, F(2)−S(1)−F(3) 86.7, F(2)−S(1)−C(1) 83.6, F(3)−S(1)−C(1) 99.2, S(1)−C(1)−C(1a) 115.4, S(1)−C(1)−F(4) 110.0.

As expected, the S−C and averaged S−F bonds, as well as the bond angles in the C−SF_3 groups of **2** and $CF_2(SF_3)_2$, differ only slightly. The weaker interaction of the two SF_3 groups in **2** corresponds to the lesser stretching of the axial S−F bonds [170.2 pm compared to 172.0 pm in $CF_2(SF_3)_2$] towards bridging fluorides S(1)F(2a) and S(1a)F(2). The terminal S−F bonds are only slightly longer.

Conclusions

In α,ω-bis(trifluorosulfur)perfluoroalkanes, $F_3S(CF_2)_n$-SF_3 (n = 1, 2), the intramolecular interaction between the two SF_3 groups decreases with increasing chain length, as shown unequivocally by experimental results and ab initio calculations. In both cases fluoride-ion addition and abstraction gives intramolecular fluoride-bridged anions and cations. With excess "naked" fluoride (e.g. from TASF) only the ethane derivative forms a dianion on ring cleavage. The synthesis of dications, even with a large excess of a strong fluoro Lewis acid (e.g. AsF_5), was unsuccessful. It will be interesting to perform further investigations to assess the chain length necessary in order that the SF_3 groups have no influence on each other.

We thank the *Fonds der Chemischen Industrie* and the *Deutsche Forschungsgemeinschaft* for financial support and the *Deutsche Solvay Fluor and Derivate GmbH* for the donation of elemental fluorine. We thank Dr. *A. Waterfeld* for the preparation of $(-CF_2SCl)_2$ and Dr. *P. G. Watson* for the translation of the manuscript.

Experimental Section

All reactions were performed with rigorous exclusion of moisture in thick-walled glass reactors with Teflon valves, or in nickel vessels previously passivated with ClF_5. Work involving aggressive gases was undertaken in a metal vacuum manifold. Volatile reagents were condensed in vacuum lines and solids transferred in a glove box under argon or nitrogen. The starting materials $(-CF_2-SCl)_2$[6], TASF[19] and AsF_5[20] were prepared using literature methods. − IR: Biorad FTS-7-FT-IR. − MS: Finnigan MAT 8222, EI 70 eV. − NMR: Bruker AC 80 and WH 360. − Elemental analyses were performed by the Mikroanalytisches Labor Beller (Göttingen).

$F_3S-CF_2-CF_2-SF_3$ (**2**): In a vacuum line, 3.0 g of F_2 (79 mmol) from a reservoir was added to 5.2 g of $(-CF_2-SCl)_2$ (**1**, 22 mmol), previously condensed onto the inner surface of a 1-l nickel vessel, over a period of 10 h at −90°C. The resulting chlorine and decomposition products were removed as soon as the pressure exceeded 100 mbar. The reaction was complete when uptake of fluorine was no longer observed. Fractional condensation at 10^{-3} mbar (−78 and −196°C) led to 5.1 g of **2** as a colourless solid in the −78°C trap, yield 83%. − IR (gas, cm^{-1}): ν = 1280 m, 1261 m, 1222 vs, 1149 m, 932 s, 850 vs, 680 vs, 637 m, 583 m, 564 s, 521 m, 455 w. − ^{19}F NMR: δ = −100.5 (s, CF), 8.0 (s, br., SF). − EI MS; *m/z* (%): 259(1) [M^+], 189(5) [$M^+ - SF_3$], 119(100) [$CF_3CF_2^+$].

$FS(O)CF_2-CF_2S(O)F$ (**4**): 3.0 g of **2** (10.8 mmol), approximately 10 ml of SO_2 and 0.2 g of BF_3 (2.9 mmol) were condensed into a glass reactor fitted with a Teflon valve at −196°C. A colourless solid formed on warming the mixture to −40°C, and this solid disappeared on stirring for 3 h at ambient temperature. BF_3 was then removed by condensation onto 5 g of NaF and subsequent stirring at ambient temperature for 6 h. Fractional condensation under vacuum (−78 and −196°C) resulted in 2.3 g of **4** in the −78°C trap, yield 91%. − IR (gas, cm^{-1}): ν = 1281 sh, 1255 vs, 1234 s, 1184 s, 1129 s, 745 s, 603 w, 481 w. − ^{19}F NMR ($CDCl_3$/$CFCl_3$, 307 K): Two AA′BB′XX′ spin patterns were observed in the ratio 1:1; δ = −17.75 (m, SF), −18.1 (m, SF), −119.5 (m, CF_2, center point of the AA′BB′ part). − ^{13}C NMR: δ = 117.0 (dddddd, $^1J_{CF}$ = 309.6 Hz, $^1J_{CF}$ = 306.0 Hz, $^2J_{CCF}$ = 32.5 Hz, $^2J_{CCF}$ = 32.0 Hz, $^2J_{C\text{-}SF}$ = 16.4 Hz, $^3J_{C\text{-}SF}$ = 2.0 Hz). − EI MS; *m/z* (%): 167(24) [M^+ − SOF], 148(2) [$CF_2CF_2SO^+$], 67(100) [SOF^+]. − $C_2F_6O_2S_2$ (234.1): calcd. F 48.7, S 37.4; found F 48.7, S 37.3.

$[(-CF_2-SF_2)F]AsF_6$ (**7**): 1.9 g of **2** (6.8 mmol), 2.0 g of AsF_5 (11.8 mmol) and approximately 10 ml of SO_2 as solvent were condensed into a glass reactor fitted with a Teflon valve at −196°C. The mixture was stirred for 1 h at −40°C and the volatile materials were subsequently removed at this temperature under dynamic vacuum. 3.0 g of **7** (quantitative) remained as a colourless solid, mp. 97°C. − IR: Due to the sensitivity of the compound we have been unable to obtain satisfactory IR spectra. − ^{19}F NMR: δ = −37.2 (s, br., SF), −57.2 (s, br., AsF), −98.3 (s, CF). − $C_2AsF_{15}S_2$ (448.0): calcd. As 16.7, F 63.6; found As 17.4, F 61.8.

$Cs[(-CF_2-SF_3)_2F]$ (**8**): 1.3 g of **2** (4.7 mmol) and 10 ml of CH_3CN were condensed onto 0.6 g of CsF (4.0 mmol), previously dried at 140°C under vacuum. The mixture was stirred for 3 h at −30°C and all volatile products were subsequently removed at this temperature and for a short time at ambient temperature under dynamic vacuum. 1.7 g of **8** (quantitative) was obtained as a colourless non-volatile solid, mp. 105°C (decomp.). − IR (nujol,

cm^{-1}): $\tilde{\nu}$ = 1247 s, 1203 s, 1184 vs, 1168 sh, 1127 m, 1113 sh, 1027s, 902s, 846 m, 778 sh, 741 sh, 722 vs (br.), 655 s. − ^{19}F NMR ($CD_3CN/CFCl_3$, 307 K): δ = +12.0 (s, br., SF), −96.0 (s, br., CF).

TAS[(−CF$_2$−SF$_3$)$_2$F] (**9**): 0.80 g of **2** (2.9 mmol) was condensed on to 0.67 g of TASF (2.4 mmol) in 5 ml of CH_3CN in a glass reactor fitted with a Teflon valve at −196°C. After stirring for 15 min at −40°C, approximately 20 ml of diethyl ether was condensed onto the reaction mixture at −80°C. The resulting oily product was then washed several times with diethyl ether. 1.13 g of **9** (quantitative) remained as a colourless solid after removal of the volatile materials under vacuum, mp 96°C. − IR (nujol, cm^{-1}): ν = 1282 m (br.), 1229 s, 1200 sh, 1168 m, 1153 sh, 1112 w, 1062 w, 1027 m, 970 m, 945 m, 901 s (br.), 766 sh, 736 vs, 722 vs, 605 s (br.), 579 s (br.), 482 m. − ^{19}F NMR (CD_3CN, $CFCl_3$, 173 K): δ = 12.5 (quint, SF, $^3J_{CF-SF}$ = 15.6 Hz), −95.6 (s, br., CF). − $C_8H_{18}F_{11}N_3S_3$ (461.4): calcd. C 20.8, H 3.93, F 45.3; found C 21.3, H 4.1, F 44.0.

(TAS)$_2$(−CF$_2$SF$_4$)$_2$ (**10**): 0.45 g of **2** (1.6 mmol) was stirred with 0.93 g TASF (3.4 mmol) in approximately 5 ml of CH_3CN at −40°C for 15 min in a way similar to the synthesis of **9**. A colourless solid precipitated and was washed twice with CH_3CN at −40°C. 1.09 g of **9** (quantitative) remained after removal of the volatile materials in vacuo, mp. 132°C (decomp.). − IR (nujol, cm^{-1}); ν = 1282 m, 1197 s, 1169 m, 1152 m, 1132 s, 1113 sh, 1065 m, 1032 m, 968 s, 950 s, 899 s, 768 m, 722 vs, 689 m, 676 w, 617 s, 550 vs (br.), 426 m. − $C_{14}H_{36}F_{12}N_6S_4$ (644.7): calcd. C 26.1, H 5.63, F 35.4; found C 26.7, H 6.39, F 33.7.

SF$_5$−CF$_2$−CF$_2$−SF$_5$ (**11**): 2.2 g of **2** (7.9 mmol) and 0.3 g of F_2 (7.9 mmol) were condensed onto 5.3 g of CsF (35 mmol) in a 1-l nickel reactor. The reaction mixture was allowed to warm up to ambient temperature over 12 h and subsequently left to stand for 48 h at this temperature. Fractional condensation (−78 and −196°C) gave 0.30 g of **11** in the −78°C trap, yield 21% (based on F_2).

Keywords: Silver / Copper / Dicyanmethanidonitrite / Coordination modes

Complexes of the type $[M\{N(O)C(CN)_2\}(PPh_3)_n]$ (M = Cu^I, Ag^I, n = 2, 3) were synthesized by metathesis of $K[N(O)C(CN)_2]$ and $[M(NO_3)(PPh_3)_n]$. The complexes were characterized by ^{13}C-, ^{31}P-NMR and IR spectroscopy and elemental analyses. The crystal structures of $[M\{N(O)C(CN)_2\}(PPh_3)_2]_2$ (M = Cu^I, Ag^I) have been determined by X-ray diffraction. Depending on the metal atom in the complexes $[M\{N(O)C(CN)_2\}(PPh_3)_3]$ the ionic ligand is coordinated via the central nitrogen (copper) or the oxygen atom (silver). In addition the two copper and silver complexes $[M\{N(O)C(CN)_2\}(PPh_3)_2]_2$ are not isostructural but have quite different structures. For M = Cu the two copper atoms are doubly bridged by two NCCN sequences, forming an approximately planar $Cu(NCCN)_2Cu$ ring. On the other hand, in the homologous silver derivative the metal atoms are also doubly bridged, but by two NO groups, thus forming a planar six-membered ring.

Considering the fragment $C(CN)_2$ as an oxygen homologous functional group, the anions $[N(O)C(CN)_2]^-$ (dicyanmethanidonitrite) and $[N\{C(CN)_2\}_2]^-$ [bis(dicyanmethanido)nitrite] appear as pseudochalcogenonitrites[2]. The strength of this approach is emphasized by the fact that, like $[NO_2]^-$, $[N(O)C(CN)_2]^-$ also behaves ambidentately towards metal ions. In both species oxygen and the middle nitrogen atoms should be comparable from the electronic point of view[3]. According to the soft-soft and hard-hard orientation, exceptionally soft metal ions coordinate unidentately to these ligands via the central nitrogen (Re^I [4], Ir^I [5], Pt^{II} [6]) whilst more hard 3d-metal ions (Ni^{II} [7], Cu^{II} [8], Co^{III} [8], Fe^{III} [5]) coordinate via the oxygen atom. In contrast to this finding the ion $[N\{C(CN)_2\}_2]^-$ is preferentially linked through an end-on nitrile group (Pt^{II}). However, in solution a linkage isomerization can be assumed[6].

To our knowledge, no complexes with dicyanmethanidonitrite in bidentate function were crystallographically characterized up to now. Several bonding motifs can be expected because apart from oxygen and the central nitrogen, end-on nitrile groups can also be discussed as potential donor atoms. In the past compounds of the type $[M\{N(O)C(CN)_2\}_2L_2]$ have been synthesized; some of them have indeed proved to be addition products of the expected complex and a protic solvent such as $[Cu\{ONC(CN)C(NH)OEt\}_2(H_2O)_2]$[8]. In this context the silver salt $Ag[N(O)C(CN)_2]$[9] is also worth mentioning. Its crystal structure shows ligand-metal contacts via oxygen and both types of nitrogen atoms.

Results and Discussion

In order to study the ambidentate behaviour of dicyanmethanidonitrite, depending on the hard/soft nature of metal ions in complexes with this ligand (in a uni- and especially in a bidentate function) we prepared compounds of copper(I) and silver(I) of the types $[MX(PPh_3)_3]$ and $[MX(PPh_3)_2]_2$. The syntheses were carried out in boiling $CHCl_3$ or CH_2Cl_2.

$$\underset{\mathbf{1}}{K[N(O)C(CN)_2]} + \underset{\mathbf{2}}{[M(NO_3)(PPh_3)_3]} \longrightarrow \underset{\mathbf{3}}{[M\{N(O)C(CN)_2\}(PPh_3)_3]} + KNO_3 \quad (1)$$

$$2\,\mathbf{1} + 2\,[M(NO_3)(PPh_3)_2] \longrightarrow \underset{\mathbf{5}}{[M\{N(O)C(CN)_2\}(PPh_3)_2]_2} + 2\,KNO_3 \quad (2)$$

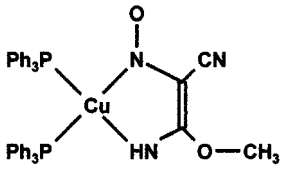
Dicyanmethanidonitrite tends to add protic agents[7] such as methanol or water. If $K[N(O)C(CN)_2]$ is treated with $[Cu(NO_3)(PPh_3)_2]$ in the presence of methanol the monomeric complex **6** is formed. In **6** $[ONC(CN)C(NH)OMe]^-$ acts as a chelating ligand which is coordinated through the nitrogen atoms of the NO and the NH groups, forming a five-membered ring (Figure 1)[10].

Figure 1. Schematic view of the molecular structure of **6**



The new compounds were characterized by ^{13}C-NMR, ^{31}P-NMR and IR spectroscopy. Surprisingly, in contrast to **1,** the vibrations $\nu_{as}(CNO)$ and $\nu(CC)$ of **3a** and **3b** are shifted in opposite directions (Table 1). The shift of $\nu_{as}(CNO)$ to higher wavenumbers characterizes $[N(O)C(CN)_2]^-$ as centrally *N*-bonded (3a)[6]. On the other hand, the decrease of the N−O bond order corresponds to coordination via the oxygen atom. The IR spectra of the species **5** are in agreement with the results of the crystal structure analyses. In contrast to **5b** the complex **5a** shows three ν(CN) bands indicating a stronger differentiation of the nitrile groups. In comparison to $K[N(O)C(CN)_2]$ the shifts of the vibrations $\nu_{as}(CNO)$, $\nu_s(CNO)$, and ν(CC) of **5a** and **5b** are opposite in direction.

Table 1. Characteristic infrared absorptions (KBr [cm^{-1}]) of potassium dicyanmethanidonitrite and corresponding complexes **3a**, **3b**, **5a**, **5b**, and **6**

Compound	ν(CN)	$\nu_{as}(CNO)$	$\nu_s(CNO)$	ν(CC)	Mode
1	2236 vs, 2225 s	1325 vs	1275 vs	1236 vs	ionic
3a	2212 m, 2193 w	1345 m	1329 m	1208 s	unidentate
3b	2204 m	1306 s	1262 s	1275 vs	unidentate
5a	2216 m, 2207 m, 2188 w	1339 s	1253 w	1214 vs	bidentate
5b	2207 s	1326 vs	1288 vs	1245 vs	bidentate
6	2212 s, 2202 m	1359 vs	1330 vs	1313 vs	

Comparing the ^{13}C-NMR spectra of **1** with those of **3** and **5** very slight shifts, with no clear trend, can be observed. The ^{31}P-NMR chemical shifts of triphenylphosphane depend on the central metal atom. So the copper complexes show one resonance at about 0 ppm; the chemical shifts of **3b** or **5b** are δ 7.93 and 11.85 respectively.

According to the structure of the anionic ligand the infrared spectrum of **6** shows bands at 1606 (vs) and 1412 (vs) cm^{-1} which can be assigned to $\nu_{as}(C{=}N)$ and $\nu_s(C{=}N)$ vibrations. The (CN) vibration indicates an uncoordinated nitrile group. As expected for *N*O coordination the bands $\nu_{as}(CNO)$ and $\nu_s(CNO)$ are shifted to higher wavenumbers. In the ^{13}C-NMR spectrum resonances at δ 61.1 and 165.1 appear, confirming the assumed structure.

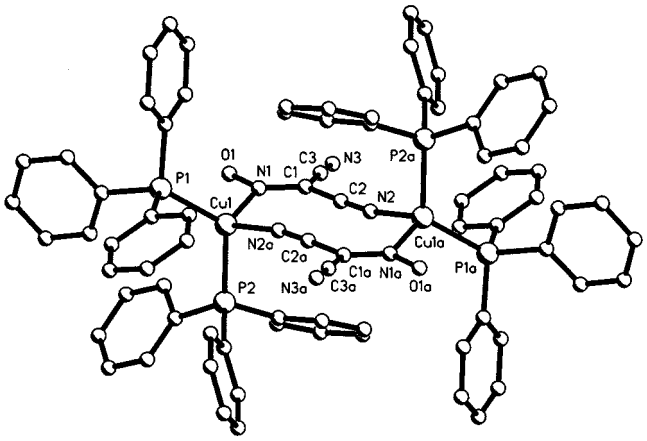
Crystal Structures of 5a and 5b

As a common feature, the homologous copper and silver complexes $[M\{N(O)C(CN)_2\}(PPh_3)_2]_2$ both exist in the crystal in form of discrete dimers in which the metal atoms are doubly bridged by two dicyanmethanidonitrite ligands $[N(O)C(CN)_2]^-$. But surprisingly, **5a** and **5b** are not isostructural and differ markedly with regard to the coordination mode of the ionic ligand. Depending on the central atom, the donor atoms are N(cyano) and N(central) in the copper complex **5a**, and O and N(central) in the silver complex **5b**.

The molecular structure of **5a** is shown in Figure 2. Two copper atoms are bridged by two ionic ligands $[N(O)C(CN)_2]^-$ coordinating the metal through the central and one cyano nitrogen atom. In this way a ten-membered ring, with a weakly pronounced chair conformation around a crystallographic inversion centre, is formed. The ligand itself is, to a good approximation, planar with significant deviations from planarity only for N1 [0.027(3) A] and O1 [0.016(3) A]. The copper atoms are at a distance of ±0.5188(4) A from the plane defined by the two NCCN fragments of the ring. The coordination geometry around Cu can be described as a distorted tetrahedron. The strongest deviation from the tetrahedral geometry is shown by the angle P1−Cu1−P2 with 122.62(3)°. The Cu−P bond lengths, being Cu1−P1 = 2.2853(8) A and Cu1−P2 = 2.2935(8) A, are in good agreement with the average value of 2.252(44) A established for Cu^I-PPh_3 complexes[11]. Surprisingly, the bond lengths between Cu and the two chemically non-equivalent N atoms are nearly the same [Cu1−N1 = 2.080(3) A, Cu1−N2a = 2.042(3) A]. In contrast to this finding, in the structurally analogous complex $[Cu(NCNNO_2)(PPh_3)_2]_2$[12], significantly different Cu−N bond lengths were found (Δ = 0.138 A). These relations are similar in the following complexes with trigonal-planar configured copper(I): $[Cu\{\mu\text{-}NCNC(NH_2)_2\}\{NCNC(NH_2)_2\}]_2A\cdot 2H_2O$ with A = SO_4 [Cu−N1 = 1.868(9) and 1.883(9) A, Cu−N2 = 2.25(1) and 2.250(9) A] and A = S_2O_6 [Cu−N1 = 1.874(4) A, Cu−N2 = 2.246(4) A][13]. On the other hand, for $[Cu(NCNC_6H_4Me\text{-}4)(PPh_3)_2]_2$ rather similar metal nitrogen bonds were found [Cu−N1 = 2.045(2) A and Cu−N2 = 2.095(2) A][14].

The molecular structure of **5b** is shown in Figure 3. The two silver atoms are doubly bridged by the NO groups of two dicyanmethanidonitrite ligands, and a centrosymmetric six-membered ring is formed in this way. A comparable bridging function is known for $[NO_2]^-$, and this is proved by X-ray analysis for $[(H_3N)_4Co(NH_2)ON(O)Co(NH_3)_4]^{4+}$[15]. The $Ag(NO)_2Ag$ ring is planar to a good approximation, the maximum deviation from the best plane shown by the O atoms [±0.083(4) A]. The coordination geometry around Ag is that of a strongly distorted tetrahedron; the greatest deviations from the ideal value shown by the bond angles P1−Ag1−P2 with 132.83(4)° and N1−Ag1−O1a with 89.7(1)°. The two Ag−P bond lengths [Ag1−P1 = 2.444(1) A, Ag1−P2 = 2.447(1) A] are equal within experimental error and agree well with experience

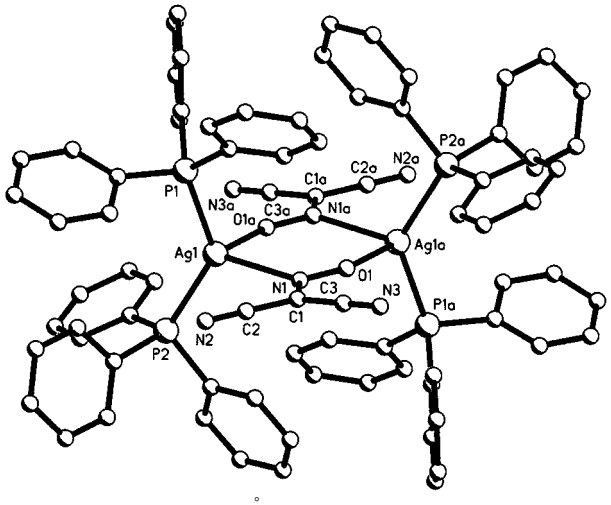
Figure 2. Molecular structure of **5a**[a]



[a] Selected bond lengths [A] and angles [°]: Cu1−N1 2.080(3), Cu1−N2a 2.042(3), Cu1−P1 2.2853(8), Cu1−P2 2.2935(8), O1−N1−Cu1 113.4(2), C1−N1−Cu1 129.1(2), C2−N2−Cu1a 169.6(3), P1−Cu1−P2 122.62(3), N1−Cu1−N2a 104.98(10).

[2.419(46) A as average of 27 $Ag^{I}-PPh_3$ complexes][11]. The Ag1−N1 distance of 2.413(3) A is quite normal compared with the values of 2.400(4) and 2.416(4) A in $[Ag(NCNNO_2)(PPh_3)_2]_2$[12] but longer than the range from 2.28(1) to 2.332(5) A observed in a series of compounds $[Ag(NCS)L_n]$ (L = py-Me-2, py-Me-3, py-Me_2−2,6, quin)[16]. The Ag1−O1a distance of 2.504(3) A is just in the middle of the wide range observed for Ag−O bond lengths, which depend on the coordination mode and are illustrated by the following examples: NO_2^- chelating in $AgNO_2$ [2.441(3) A][17], NO_3^- terminal in $[AgONO_2$(1-Me-cytosine)] [2.469(3) A][18] or chelating in $[AgNO_3$(2-pyridyleneaniline)] [2,259(3) A][19] or bridging in $[AgNO_3$(cyclosarcosylsarcosine)$_2$] [2.612(8) and 2.679(7) A][20].

Figure 3. Molecular structure of **5b**[a]



[a] Selected bond lengths [A] and angles [°]: Ag1−N1 2.413(3), Ag1−O1a 2.504(3), Ag1−P1 2.444(1), Ag1−P2 2.447(1), O1−N1−Ag1 125.4(3), C1−N1−Ag1 117.1(3), P1−Ag1−P2 132.83(4), N1−Ag1−O1a 89.7(1).

A survey of the bond lengths and angles characterizing the geometry of the ambidentate dicyanmethanidonitrite X in its ionic (**1** = KX)[21], bidentate (**5a**, **5b**) and unidentately *N*-bonded (*trans*-$[Pt(H)X(PPh_3)_2]$)[6] or *O*-bonded function ($[Co(X)Cl(en)_2]X$)[22] is given in Table 2. A comparison of the listed values reveals no significant, or only slight to moderate, differences, depending on the coordination modes. Even **5a** and **5b** agree completely within experimental error. For both compounds, within their ONC fragments, the N−O bond is slightly shortened and the N−C bond is slightly lengthened with respect to the uncoordinated anion X^- in **1**. The N−O bond lengths in **5a** and **5b** are a little bit longer than the value of 1.240(3) or 1.248(3) A found for the nitrite ion in the sodium[24] and the silver salt[17], respectively. All other bond lengths agree well with standard values[23]. The rigidity of the dicyanmethanidonitrite skeleton and its structural insensibility to variations in the coordination mode is also manifested by the small differences between the corresponding bond angles (Table 2). The maximum ranges of variation are shown by the angles C−C−C (Δ = 1.4°) and O−N−C (Δ = 3.9°).

Table 2. Geometric parameters [A, °] of $[N(O)C(CN)_2]^-$ in **1**, **5a**, **5b**, *trans*-$[Pt(H)N(O)C(CN)_2(PPh_3)_2]$ (**7a**), and $[Co(Cl)ONC(CN)_2(en)_2][ONC(CN)_2]$ (**7b**)

Experimental Section

IR (KBr): Mattson 5000 FTIR. − ^{13}C NMR (TMS as reference): WP 200. − ^{31}P NMR (85% H_3PO_4 as reference, down-field shift positive): AC 80. The compounds **2a**[25], and **4a**[25] were prepared as described previously. For the synthesis of **2b** and **4b** known procedures were modified by using triphenylphosphane and silver nitrate[26][27].

General Method for the Syntheses of **3** *and* **5**: 2 mmol of **2a**, **4a** or **4b** were dissolved in 15 ml of $CHCl_3$, or 2 mmol of **2b** in 30 ml of CH_2Cl_2. While stirring the resulting mixture was treated with a solution of 2 mmol (0.25 g) of **1** in 20 ml of methanol or ethanol (synthesis of **3a**) and heated to reflux for 6 h in a water bath with exclusion of light. Afterwards the mixture was stirred at room temp. for 3 h. After filtration and evaporation of the solvent in vacuo the resulting solid was washed with methanol and dissolved in a small amount of $CHCl_3$ (**3a** in ethanol). A quantity of *n*-pentane was added until the onset of turbidity was observed and the solution kept at about 0°C. After some hours a microcrystalline solid was formed which was filtered off and dried in vacuo.

For the preparation of single crystals 0.010 g of **5a** or **5b** were dissolved in 2 ml of $CHCl_3$ and overlayed with 6 ml of petroleum ether.

Tris(triphenylphosphane)copper(I)dicyanmethanidonitrite (**3a**): slightly brown crystals, yield 80%, m.p. 143°C (dec). − IR (KBr): ν = 2212 s cm^{-1} [ν(CN)], 2193 w [ν(CN)], 1345 s [ν_{as}(CNO)], 1329 s [ν_s(CNO)], 1209 vs [ν(CC)], 694 vs (Ph), 742 vs (Ph), 1092 vs (Ph), 1434 vs (Ph), 1479 s (Ph), 3049 s (Ph). − ^{13}C NMR ($CDCl_3$): δ = 112.9 (s, CN), 119.0 (s, CN), 107.9 (s, methanide-C), 128.4, 128.5 [t, P−C-3,5, $^1J(^{31}P,^{13}C)$ = 8 Hz), 129.6 (s, P−C-4), 132.8, 133.0 [t, P−C1, $^1J(^{31}P,^{13}C)$ = 22.9 Hz], 133.6, 133.7 [t, P−C-2,6, $^1J(^{31}P,^{13}C)$ = 15.0 Hz]. − ^{31}P NMR ($CDCl_3$): δ = −0.27 (s, PPh_3). − $C_{57}H_{45}CuN_3OP_3$ (944.47): calcd. X-ray Crystal Structure Determination: A summary of crystal data along with details of the structure determination is given in Table 3[28]. All measurements were performed with a STOE-STADI4 diffractometer using graphite-monochromatized Mo-K_α radiation (λ = 0.71069 A) in the ω-2θ scanning mode at room temp.. For structure solution and refinement programs SHELXS-86[29] and SHELXL-93[30] were used. The molecular structures in Figures 2 and 3 were plotted by use of the program XP/PC[31].

Keywords: Pentacarbonylmetal–tin bonding / Alkoxytin compounds / Inidene compounds / ^{119}Sn NMR / Bonding

Dimerized inidene complexes $[(CO)_5M{=}Sn(OR){=}M(CO)_5]_2^{2-}$ (M = Cr, W; R = Et, *i*Pr), **1**, are obtained from $[\{(CO)_5M\}_2SnCl_2]^{2-}$ by different routes. Dimerization occurs via alkoxy-donor tin-acceptor bonding by which a planar Sn_2O_2 ring is formed. The Sn–$\{M(CO)_5\}$ bonds are made in a plane vertical to this ring such that, with the R–O groups being almost coplanar with the Sn_2O_2 ring, the overall geometry of the compounds shows idealized D_{2h} symmetry. – The ^{119}Sn-NMR resonances of **1** are found at rather low fields (M = Cr: $\delta \approx 1400$; M = W: $\delta \approx 1170$) indicating a low-lying tin-centered orbital in the LUMO range. Correspondingly EHT analyses show that the 3-center-4π system, which characterizes monomeric inidene species $[L_nM{=}E(X){=}ML_n]^n$, is still prevalent in the dimeric species **1**. The low-lying π*-type LUMOs of **1** are the rationale for the observed ^{119}Sn-NMR low-field shifts of **1**. The dimeric compounds **1** react with 2,4-pentanedione to form chelate compounds of the same type as those characteristically obtained from monomeric inidene complexes: $[\{(CO)_5Cr\}_2SnOEt]_2^{2-}$ (**1a**) reacts to give $[\{(CO)_5Cr\}_2Sn(acac)]^-$ (**2**). The experimental results are verified by X-ray analyses in addition to the usual spectroscopic and analytical investigations.

Trigonal planar coordination around a tin center has so far only been achieved in a few types of compounds: stannylene complexes $[\{(CO)_5M\}SnR_2]$ (M = Cr, Mo, W)[1] which are isolobal analogues of olefins, the star-type compound $[\{(CO)_5Cr\}_3Sn]^{2-}$[2] which is isolobal to the carbonate anion, $[\{L_nM\}_2Sn{=}ML_n]$ (L_nM = $W(CO)_5$, $Cp^R(CO)_2Mn$; Cp^R = Cp, Cp′, Cp*)[3] which are analogues of the methylenecyclopropane system, and inidene compounds $[L_nM{=}Sn(X){=}ML_n]^-$ (ML_n = $MnCp'(CO)_2$, R = Cl, Br, S*t*Bu)[4] which are analogues of the allylic anion, represent the few types of compounds for which trigonal-planar coordination of tin is known. For the inidene series of compounds there is strong evidence that the species $[L_nM{=}Sn(X){=}ML_n]^-$ are only stable, as such, if the L_nM fragment is a potent d-π donor such as $[Cp^R(CO)_2Mn]$, while L_nM groups such as $[(CO)_5M]$ (M = Cr, Mo, W) with their reduced π-donor capabilities[5] will not sufficiently stabilize the allylic-type 3-center-4π system characteristic of these compounds.[6][7] Inidene compounds $[(CO)_5M{=}Sn(X){=}M(CO)_5]^-$ are obviously strongly Lewis-acidic at their unsaturated tin center, such that in any attempt to prepare them the base adducts, $[(CO)_5M{-}Sn(X)(B){-}M(CO)_5]^n$, appear to be inevitably formed. Quite a number of such base adducts have now been characterized,[8][9] while no unprotected compound $[(CO)_5M{=}Sn(X){=}M(CO)_5]^-$ has so far been obtained. In order to prepare such compounds it appears natural to try to compensate for the reduced d-π-donor capabilities of the $[(CO)_5M]$ entities by introducing a p-π donor as the substituent X at the tin center. As potentially π-donating substituents R–O or R–S entities are a straightforward choice. While an R–S substituent would be preferable due to its soft sulfur donor, hitherto uncontrollable side reactions have precluded the successful synthesis of $[(CO)_5M{=}Sn(SR){=}M(CO)_5]^-$ compounds.[8b] With the R–O substituent, which is decidedly less soft when compared to the R–S entity, the working hypothesis met with partial success: $[(CO)_5M{=}Sn(OR){=}M(CO)_5]^-$ entities are in fact formed, albeit not as monomeric species but as dimers $[\{(CO)_5M\}_2Sn(\mu_2\text{-}OR)_2Sn\{M(CO)_5\}_2]^{2-}$ (**1**) (Table 1). The Lewis acidity at the tin centers is still large enough to call for compensation by an oxygen "lone pair" of a second inidene species.

Table 1. Complexes of type **1**

	no.	M	R	cation
	$[n\text{Bu}_4\text{N}]_2\cdot$ **1a**	Cr	Et	$[n\text{Bu}_4\text{N}]$
	$[\text{Ph}_4\text{P}]_2\cdot$ **1a**	Cr	Et	$[\text{Ph}_4\text{P}]$
	$[n\text{Bu}_4\text{N}]_2\cdot$ **1b**	Cr	*i*Pr	$[n\text{Bu}_4\text{N}]$
	$[n\text{Bu}_4\text{N}]_2\cdot$ **1c**	W	Et	$[n\text{Bu}_4\text{N}]$
	$[\text{Ph}_4\text{P}]_2\cdot$ **1d**	W	Et	$[\text{Ph}_4\text{P}]$

This type of dimerization is similar to that observed for $[\{Cp(CO)_2Mn\}_2BiCl]$.[7j][10] The dimeric entities have a strong relation to the well-characterized main-group ring species $[R{-}Sn(\mu_2\text{-}OR)_2Sn{-}R]$[11] as well as to the theoretically well-understood species $[Sn_2H_4]$ and $[Sn_2H_6]^{2+}$.[12] They are also closely related to genuine inidene compounds.

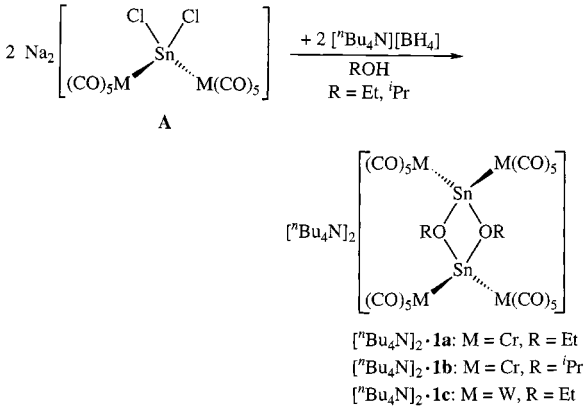
In this paper we describe the syntheses, structure, spectroscopy, and reactivity of type-**1** compounds, as well as the specific bonding situation pertaining to them.

Results and Discussion

Synthesis and Reactivity

When the dichlorostannate compounds **A**, $[\{(CO)_5M\}_2SnCl_2]^{2-}$ (M = Cr, W)[8], are treated with $[nBu_4N][BH_4]$ in an alcoholic solution the alkoxy-bridged dimers $[nBu_4N]_2 \cdot \mathbf{1}$ are obtained (Scheme 1) instead of the desired hydridotin species.

Scheme 1. Reaction of $[\{(CO)_5M\}_2SnCl_2]^{2-}$ (M = Cr, W) (**A**) with $[nBu_4N][BH_4]$ in alcoholic solution

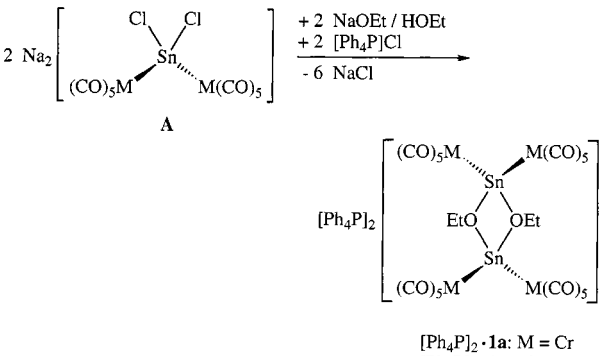


$[^nBu_4N]_2 \cdot \mathbf{1a}$: M = Cr, R = Et
$[^nBu_4N]_2 \cdot \mathbf{1b}$: M = Cr, R = ^{i}Pr
$[^nBu_4N]_2 \cdot \mathbf{1c}$: M = W, R = Et

The yellow compounds $[nBu_4N]_2 \cdot \mathbf{1}$ are obtained as microcrystalline solids, the constitution of which is documented by the usual spectroscopic and analytical techniques as well as by a series of X-ray analyses (Tables 3, 4, and 5). It is observed that under the reaction conditions described addition of $[nBu_4N][BH_4]$ to the solutions of **A** is accompanied by a rapid evolution of gas. It might therefore be assumed that the primary product, and hence intermediate in the formation of $[nBu_4N]_2 \cdot \mathbf{1}$, is a hydridotin species.

While this hypothesis can not be completely ruled out, it appears more probable that the hydridoborate is merely active as a base, deprotonating the alcohol which is used as the solvent; no hydridoborate is needed for the transformation of **A** into **1** if sodium ethoxide, NaOEt, is used as the reagent (Scheme 2).

Scheme 2. Reaction of $[\{(CO)_5M\}_2SnCl_2]^{2-}$ (M = Cr, W) (**A**) with NaOEt

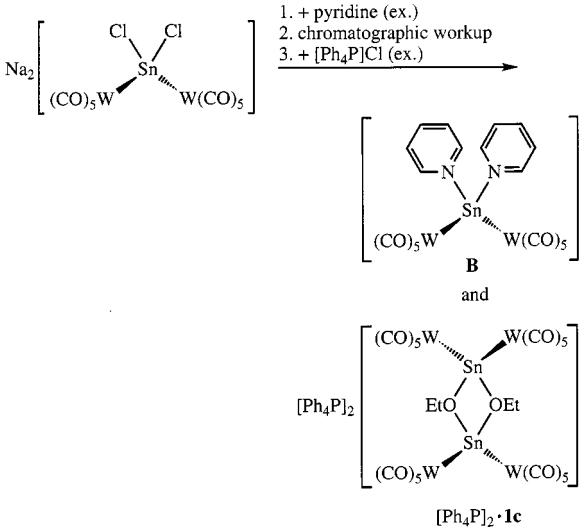


$[Ph_4P]_2 \cdot \mathbf{1a}$: M = Cr
$[Ph_4P]_2 \cdot \mathbf{1c}$: M = W

Under these conditions the dimeric dianions are immediately formed (IR control), and the salts $[Ph_4P]_2 \cdot \mathbf{1a}$ and $[Ph_4P]_2 \cdot \mathbf{1c}$ are precipitated, by the addition of $[Ph_4P]Cl$, in the form of microcrystalline yellow powders. Since solutions of **A** in alcohols are stable as such, it is evident that basic conditions are necessary to induce the transformation of **A** into **1**.

This fact is also inferred from the observation that treating THF solutions of $Na_2[\{(CO)_5W\}_2SnCl_2]$ with pyridine (py), which leads to the formation of the pyridine adduct **B**, $[\{(CO)_5W\}_2Sn(py)_2]$ as the major product[9], will also produce minor amounts of $[Ph_4P]_2 \cdot \mathbf{1c}$ when ethanol is used as the eluent during the chromatographic workup (Scheme 3). In this case pyridine obviously acts as the HCl scavenger.

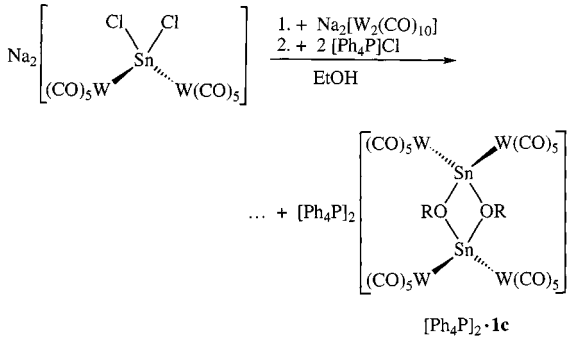
Scheme 3. Reaction of $Na_2[\{(CO)_5W\}_2SnCl_2]$ with an excess of pyridine



$[Ph_4P]_2 \cdot \mathbf{1c}$

Yet another way to produce $[Ph_4P]_2 \cdot \mathbf{1c}$ relies upon the basisity of the $[W_2(CO)_{10}]^{2-}$ anion (Scheme 4): when **A** is allowed to react with $Na_2[W_2(CO)_{10}]$ in ethanol an immediate color change from yellow to dark red is observed.

Scheme 4. Reaction of $Na_2[\{(CO)_5W\}_2SnCl_2]$ with $Na_2[W_2(CO)_{10}]$ in ethanol



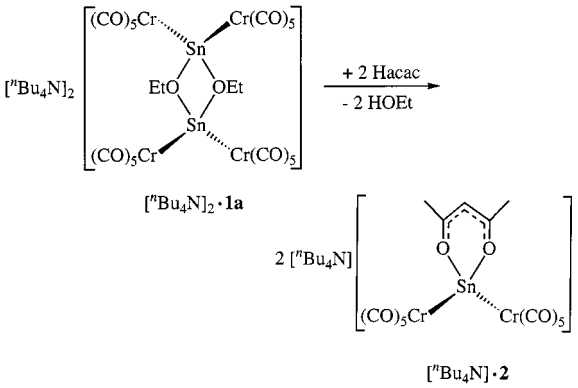
$[Ph_4P]_2 \cdot \mathbf{1c}$

^{119}Sn-NMR spectroscopy shows that a mixture of at least 5 species is formed, one of them being $[Ph_4P]_2 \cdot \mathbf{1c}$ which may be precipitated by addition of $[Ph_4P]Cl$.

As far as the reactivity of **1** is concerned the compounds behave similarly to dimerized inidene species; it is a charac-

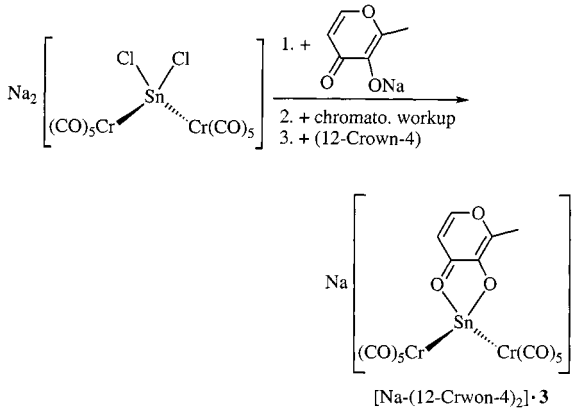
teristic of $[L_nM{=}E(X){=}ML_n]^n$ (E = group 15 element, n = 0; E = group 14 element, $n = -1$; X = leaving group: e.g. Cl, etc.) to undergo substitution and addition with monovalent chelate bases to form chelate derivatives.[13] Correspondingly, $[n\mathrm{Bu_4N}]_2 \cdot$ **1a** reacts with 2,4-pentanedione (Hacac) to give **2** as its $[n\mathrm{Bu_4N}]$ salt (Scheme 5).

Scheme 5. Reaction of $[n\mathrm{Bu_4N}]_2 \cdot$ **1a** with 2,4-pentanedione



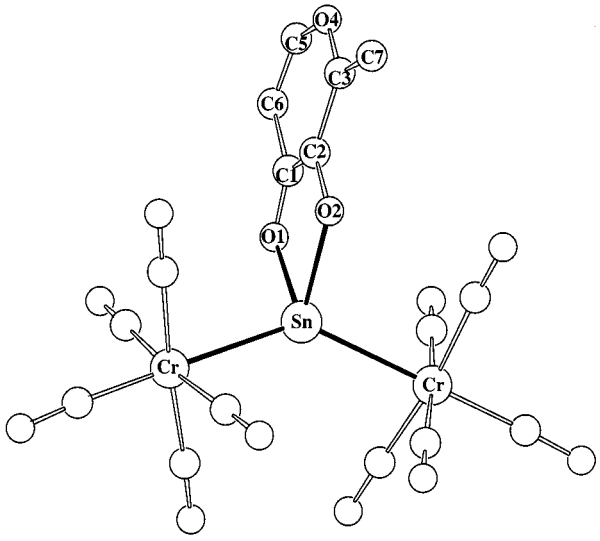
No external base is needed to promote this reaction. The reaction itself is monitored by NMR spectroscopy, either by observing the disappearance of the ^{1}H-NMR resonance of the diketo tautomer of 2,4-pentanedione in acetone solution or by observing the disappearance of the ^{119}Sn-NMR signal of $[n\mathrm{Bu_4N}]_2 \cdot$ **1a** (δ = 1445) and the appearance of the signal at δ = 1205 characterizing $[n\mathrm{Bu_4N}] \cdot$ **2** (Table 3). The spectroscopic data leave no doubt about the consitution of $[n\mathrm{Bu_4N}] \cdot$ **2**. Its solid-state structure could, however, not be analyzed since $[n\mathrm{Bu_4N}] \cdot$ **2** is (even after the chromatographic workup) an oil with no tendency to crystallize. Since the $[\mathrm{Ph_4P}]$ salt of **2** was also found to be an oil, the γ-pyronate analogue **3** of **2** was synthesized (Scheme 6) with the hope of obtaining a crystalline compound showing a bonding situation closely related to that in **2**. As an easy access to chelate compounds of this type the reaction of **A** with chelate bases had been described.[8b][9] Following this route **3** was prepared from $Na_2[\{(CO)_5Cr\}_2SnCl_2]$ and the sodium salt of 3-hydroxy-2-methyl-γ-pyrone (pyro) (Scheme 6).

Scheme 6. Reaction of $Na_2[\{(CO)_5Cr\}_2SnCl_2]$ with the sodium salt of 3-hydroxy-2-methyl-γ-pyrone



$[\mathrm{Na(12\text{-}Crown\text{-}4)_2}] \cdot$ **3** was prepared as a crystalline salt. The structure of the anion of this salt, as obtained by X-ray analysis, is shown in Figure 1. The accuracy of the structure determination is rather low due to insufficient crystal quality and the notorious disorder of the 12-Crown-4 entities.

Figure 1. Molecular strucutre of the anion of $[\mathrm{Na(12\text{-}Crown\text{-}4)_2}] \cdot$ **3**[a]



[a] The numbering system chosen does not correspond to the one adopted in the data deposited.

Even though the overall geometry of the chelate compound is established beyond doubt (Table 2), comparison of the spectrocopic properties of $[\mathrm{Na(12\text{-}Crown\text{-}4)_2}] \cdot$ **3** with those observed for $[n\mathrm{Bu_4N}] \cdot$ **2** (Table 3) shows that the general structural and electronic features of both compounds are very similar.

Table 2. Selected bond lenghts [pm], angles [°], and torsion angles [°] for the anion **3** of $[\mathrm{Na(12\text{-}Crown\text{-}4)_2}] \cdot$ **3**[a]

Structure and Bonding

X-ray analyses have been performed for the salts of $[n\mathrm{Bu_4N}]_2\cdot$**1a**, $[\mathrm{Ph_4P}]_2\cdot$**1a**, and $[\mathrm{Ph_4P}]_2\cdot$**1c**. The analysis of $[n\mathrm{Bu_4N}]_2\cdot$**1a** was hampered by the instability of the crystal, even at 173 K. Data were finally collected at 200 K (Table 5). Even when applying a rather high scan speed only the range up to $2\Theta = 28°$ could be covered . The phosphonium salts $[\mathrm{Ph_4P}]_2\cdot$**1a** and $[\mathrm{Ph_4P}]_2\cdot$**1c** did not pose these problems and data sets of good quality could be obtained up to $2\Theta \approx 50°$ for the two isotypic crystals (Table 5). The results of these three structure analyses are qualitatively similar for all three compounds (Table 4).

Only the structure of $[\mathrm{Ph_4P}]_2\cdot$**1c** is, therefore, shown in Figure 2. The structures of $[\mathrm{Ph_4P}]_2\cdot$**1a** and $[\mathrm{Ph_4P}]_2\cdot$**1c** have crystallographic inversion symmetry while the structure of $[n\mathrm{Bu_4N}]_2\cdot$**1a** has no crystallographic symmetry constraint (Table 4). The distances and angles, which by chemical reasoning should be equivalent in each case, are in fact very similar within each compound and, where appropriate, also for the whole class of compounds (Table 4).

Even the rotational position of the $[(CO)_5M]$ groups with respect to the Sn−M axes are almost identical in all three compounds; the angle α given in Table 4 (see also Table 2) refers to the pseudo torsion angle $C_{COeq}-M-M'-C_{COeq}'$ were M, C_{COeq} and M′, C_{COeq}' belong to $[(CO)_5M]$ groups bonded to one and the same tin center.[8b][9]

A characteristic feature of all three compounds $[n\mathrm{Bu_4N}]_2\cdot$**1a**, $[\mathrm{Ph_4P}]_2\cdot$**1a**, and $[\mathrm{Ph_4P}]_2\cdot$**1c** is a planar four-membered Sn_2O_2 ring (Table 4). Coordination of the $[(CO)_5M]$ groups occurs in a plane vertical to this cycle. The α-carbon atoms of the (μ_2-OEt) groups do not gener-

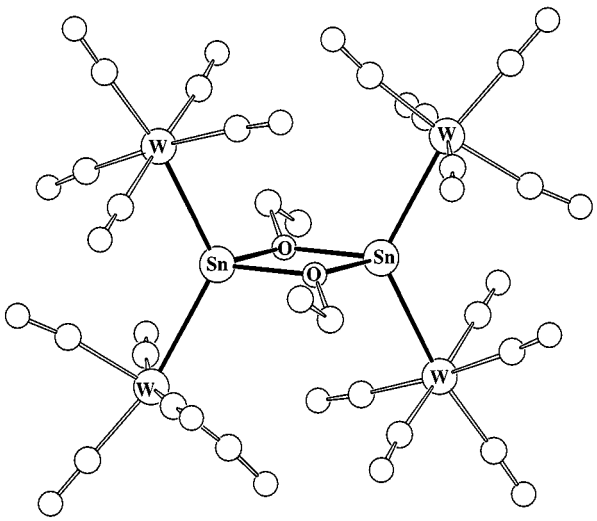
Figure 2. Molecular structure of the anion of $[\mathrm{Ph_4P}]_2 \cdot$ **1c**

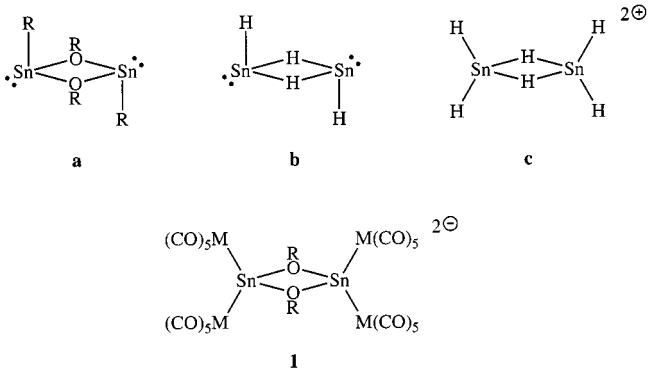


ally deviate too much from coplanarity with the heterocyclic plane (Table 4). The valence angles at the bridging oxygen atoms (Table 4) show that their coordination is more appropriately idealized as trigonal planar as compared to pseudo tetrahedral. Consequently, the torsion angles $C_\alpha-O-Sn-O$ (Table 4) are small.[11] The idealized symmetry of the core of the compounds, including the metal atoms, the tin centers and the $O-CH_2$ fragments, is close to D_{2h} (Figure 2).

As far as the bonding situation is concerned compounds **1** may be considered as composed of two $[(CO)_5M{=}Sn(OR){=}M(CO)_5]^-$ species which, due to the electron deficiency at the tin centers in these inidene-type entities, dimerize by oxygen-donor−tin-acceptor bonding (Figure 2).

On the other hand, the planar $Sn_2(OR)_2$ ring forming the central ligand entity in compounds **1** has a strong resemblance to the corresponding entities in $[RSn(OR)]_2$ (**a** in Figure 3). These species, which may be seen as dimerized stannylenes RSnOR, have been thoroughly analyzed by M. Veith and his group.[11]

Figure 3. Realtionship between **1** and some $Sn_2(OR)_2$- and Sn_2H_2-heterocycles



a **b** **c**

1

This kind of view is well born out by theoretical reasoning which makes clear that the most stable dimerized form

of H_2Sn does correspond to the cyclic structure of **b**[12] which is mutatis mutandis the same as that for the well-characterized compounds **a** (Figure 3). Protonation of the "lone pairs" in **b** leads to the dication **c** (Figure 3) which, as will be discussed later, is a close relative to the anions **1**. A structure corresponding to **c** is established as a true minimum on the potential surface for the isoelectronic $C_2H_6^{2+}$ cation and is a global minimum for B_2H_6 which is also an isoelectronic analogue.[14] The relationship of **c** to the anions **1** is the following:

1. Bridging hydrogen atoms may be replaced by bridging R−O groups without much change being caused by the three additional p-valence orbitals at the oxygen atom, as is seen by comparing **a** and **b**. The major change in bonding is the replacement of the 3-center-2-electron Sn−H−Sn bridges by 3-center-4-electron Sn−(OR)−Sn bridges, both referring to σ-bonding. The disturbance by potential π-interactions between the relevant oxygen and tin p orbitals will only be slight, due to the misfit of these two types of p orbitals in size as well as in energy. So far to the similarity of the Sn_2H_2 core in **b** and **c** and the $Sn_2(OR)_2$ core in **a** and **1**.

2. The analogy of **c** and **1** is immediately apparent by comparing the σ-bonding properties of H and $[(CO)_5Cr]^-$. Both species have just one orbital filled with one electron in each case for this type of interaction. They are "isoelectronic" in the sense that a seventeen-electron organometallic species $[(CO)_5Cr]^-$ is an analogue of a seven electron main-group species [R] or of hydrogen [H] with all three of them being short by one electron with respect to the noble-gas electronic configuration.

Many of the ideas worked out for **a**−**c** may therefore be applied to **1** as well. With compounds **a** it is observed that the O−Sn−O angles are without exception considerably smaller than 90° with the Sn−O−Sn angles being correspondingly larger.[11] This type of angle distribution has been analyzed for **b** as the model compound.[12a] It has been rationalized in terms of the charge distribution within compounds of this type with both the bridging hydrogen atoms and the terminal hydrogen atoms being rather negatively charged.[12a] A merely electrostatic model built on these grounds will reproduce structures as well as energies. Similar reasoning will apply to **1**.

The approach of looking at **1** as an analogue of **c** by replacing the terminal hydrogen atoms in **c** by negatively charged "isoelectronic" $[(CO)_5M]^-$ groups in **1** does appear somewhat less arbitrary with the ν(CO)-IR data of **1** (Table 3) in mind: these ν(CO)-IR absorptions occur at wavelengths which are characteristic for negatively charged $[(CO)_5M]$ groups.[15] The R−O groups should bear δ^- charges by simple electronegativity arguments.

When the bonding in **1** is rationalized in these terms, the structural properties of **1** are not astonishing. What is, however, astonishing at first glance is that the ^{119}Sn-NMR shift of **1** is far more on the low-field side than is usually observed for tin in pseudo-tetrahedral four-coordination (R_2SnCl_2).[16] From the observations made with inidene-type compounds there is convincing evidence that the low-field shifts observed for the central main-group elements in these compounds are intimately connected to the presence of a low-energy π* orbital of these 3-center-4π systems.[17] The theory of NMR shifts predicts that the presence of such a low-lying main-group-centered orbital will strongly contribute to the paramagnetic (low-field) term of the shift observed for this element.[18] Since the symmetry of **1** would allow for such a low-lying orbital in **1** an EHT-MO analysis of **1** was performed as well. As a simplified model of **1**, following common practice, its "isoelectronic" analogue $[\{H_5Cr\}_2Sn(\mu_2\text{-}OH)_2Sn\{CrH_5\}_2]^{22-}$ with R−O replaced by H−O and $[(CO)_5Cr]$ replaced by $[H_5Cr]^{5-}$ was chosen.[19]

3-center-4π systems, only slightly disturbed by the interaction with oxygen p orbitals localized at the Cr−Sn−Cr entities, make up an essential part of the orbital pattern.

The totally bonding combinations of the 3-center-4π-parts are found at the HOMO-10 and HOMO-12 positions (Figure 4). Due to the D_{2h} symmetry of **1** and the model compound as well, orbitals must occur in pairs, one with *gerade* (*g*) symmetry and the other one with *ungerade* (*u*) symmetry with respect to the phases characterizing the contributions of the two Cr_2Sn parts (Figure 4). Due to a modulation by minor contributions from the oxygen valence orbitals these pairs may be at slightly different energies in those cases where this interaction is allowed by symmetry (Figure 4). The energy differences calculated for these pairs are smaller than 0.1 eV for the bonding orbitals (Figure 4) but are significant for some of the unoccupied ones (Figure 4).

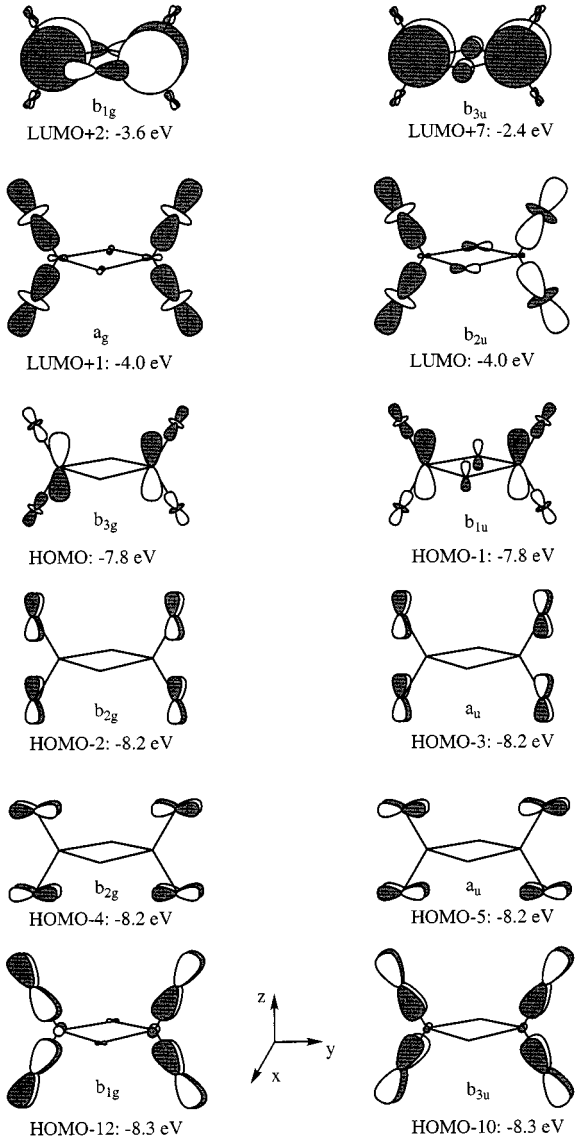
The non-bonding orbital of each 3-center-4π constituent will have a zero coefficient for the tin p_x orbital and will be composed by an anti-phase combination of the d orbitals which might by symmetry maximally interact with the tin p_x orbital as individuals. The relevant orbitals are found at the positions HOMO-2 to HOMO-5 (Figure 4). Due to the coordinate system chosen the relevant d orbitals are a combination of d_{xy} and d_{xz}. These orbitals transform in groups as a_u and b_{2g}. A linear combination of the a_u pair as well as the b_{2g} pair are the representatives of the *u* and *g* combination of the terminal orbitals of the two 3-center-4π systems characterizing the compound.

The HOMOs of the compound correspond to *g* und *u* combinations of mainly Cr−Sn σ-bonding orbitals with a significant Sn-p_z contribution (Figure 4). The LUMOs of the model compound are σ-anti-bonding with an almost negligible tin contribution (Figure 4).

The totally antibonding combinations of the 3-center-4π systems are found at the positions LUMO+2 and LUMO+7. These orbitals have large Sn-p_x contributions and comparatively small contributions from the relevant d orbitals. They are modified by contributions of the oxygen p orbitals and are thus at different energies.

The essence of this analysis is the following: the 3-center-(M−E−M)-4π system, which is characteristic for inidene compounds, is as well a characteristic ingredient to the bonding situation in **1**: non-bonding contributions of the relevant d orbitals make up MOs in the HOMO range. Anti-bonding combinations of the relevant metal d and

Figure 4. Characteristic orbitals of $[\{L_5Cr\}_2Sn(\mu_2\text{-}OR)_2Sn\{CrL_5\}_2]^{2-}$[a,b]

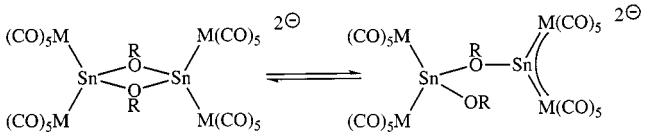


[a] The actual calculations were performed with $[CrH_5]^{5-}$ templates instead of $[L_5Cr]$. The R−O groups were replaced by H−O entities.− [b] The bottom three pairs of orbitals refer to the bonding and non-bonding sets of the (Cr−Sn−Cr) 3-center-4π-systems. The top pair corresponds to the LUMOs of these systems. The σ-type HOMO pairs and LUMO pairs of the model compound are given as well.

main-group p orbitals are found in the LUMO range. This situation is typically the one giving rise to large low-field shifts[2][8b][9][17][20] in the NMR spectra of the bridging elements as is also observed for **1**.[21]

It has been argued that real inidene-type compounds $[(CO)_5M{=}Sn(X){=}M(CO)_5]^-$ should have their ^{119}Sn-NMR shifts close to δ = 3000.[9] This argument was inferred in part from the observation that base adducts of these compounds $[(CO)_5M-Sn(X)(B)-M(CO)_5]^n$ show strong temperature dependence of their ^{119}Sn-NMR resonances. Equilibria of the type $[(CO)_5M-Sn(X)(B)-M(CO)_5]^n \rightleftarrows [(CO)_5M{=}Sn(X){=}M(CO)_5]^- + B$ have been put forward as an explanation.[9] Based on the same type of arguments the temperature dependence of the ^{119}Sn-NMR resonance of $[Ph_4P]_2\cdot$**1c** may be interpreted in terms of a ring-opening/ring-closing equilibrium (Figure 5). Upon cooling from 298 K to 198 K the ^{119}Sn-NMR signal of $[Ph_4P]_2\cdot$**1c** shifts to lower fields (from δ = 1158 to δ = 1135).

Figure 5. Ring-opening/ring-closing equilibrium



1

The shift difference observed for 10 K temperature difference is thus only 2 ppm in the case of $[Ph_4P]_2\cdot$**1c** while in other cases shifts of up to 20 ppm/10 K have been observed.[9]

Under the hypothesis that the temperature-induced shift is due to an equilibrium between three- and four-coordinated tin species the relatively small temperature dependence observed for $[Ph_4P]_2\cdot$**1c** indicates a high intrinsic stability of the four-membered Sn_2O_2 heterocycle.

Financial support by the *Fond der Chemischen Industrie* is gratefully acknowledged. The work had formerly been supported by the *Deutsche Forschungsgemeinschaft* (SFB 247).

Experimental Section

General: All manipulations were carried out under an argon atmosphere by means of standard Schlenk techniques at 25°C unless mentioned otherwise. All solvents were dried by standard methods and distilled under argon. [D$_6$]acetone and CD_2Cl_2 used for the NMR-spectroscopic measurements were degassed by three successive "freeze-pump-thaw" cycles and dried over 4-A molecular sieves. Silica gel (Kieselgel z. A., 0.06−0.2 mm, J. T. Baker Chemicals B. V.) used for chromatography and Kieselgur (Kieselgur, gereinigt, geglüht, Erg. B.6, Riedel-de Haen AG) used for filtration were degassed at 1 mbar at 180°C for 12 h and saturated with argon. − NMR: Bruker Avance DPX 200 at 200.13 MHz (^{1}H), 50.323 MHz (^{13}C{^{1}H}), 74.631 MHz (^{119}Sn{^{1}H}), 81.015 MHz (^{31}P{^{1}H}); chemical shifts (δ) in ppm with respect to [D$_6$]acetone (^{1}H: δ = 2.04, ^{13}C: δ = 29.8) and CD_2Cl_2 (^{1}H: δ = 5.32, ^{13}C: δ = 53.5) as internal standards; chemical shifts (δ) in ppm with respect to $SnMe_4$ (^{119}Sn: δ = 0, at 25°C) and to 85% H_3PO_4 (^{31}P: δ = 0) as external standard. − IR: Bruker FT-IR IFS-66; CaF_2 cells. − UV/Vis/NIR: Perkin Elmer Lambda 19; cells (0.2 cm; Hellma 110 suprasil). − MS (FAB or EI): Finnigan MAT 8400; TEA (triethanolamine) matrix. − Elemental analyses: Microanalytical laboratory of the Organisch-Chemisches Institut, Universität Heidelberg. − Melting points: Gallenkamp MFB-595 010; values not corrected. − The dinuclear sodium salts of the composition $Na_2[\{(CO)_5M\}_2SnCl_2]$ (M = Cr, W) were prepared by salt metathesis from the corresponding stable phosphonium salts $[Ph_4P]_2[\{(CO)_5M\}_2SnCl_2]$ as described[8b]. All other chemicals were commercially obtained and used without further purification.

$[nBu_4N]_2[\{(CO)_5Cr\}_2Sn(\mu_2\text{-}OEt)_2Sn\{Cr(CO)_5\}_2]$ ($[nBu_4N]_2\cdot$**1a**): $Na_2[\{(CO)_5Cr\}_2SnCl_2]$ (310 mg; 0.5 mmol) was dissolved in ethanol (50 ml). At 0°C solid $[nBu_4N][BH_4]$ (257 mg; 1 mmol) was added in portions under spontaneous evolution of gas as well as precipitation of $[nBu_4N]_2\cdot$**1a** as a yellow microcrystalline powder.

The reaction mixture was stirred until no further evolution of gas was observed. The yellow solid of $[n\mathrm{Bu_4N}]_2\cdot$ **1a** was seperated from the reaction mixture by filtration, washed with ethanol (3 × 10 ml) and diethyl ether (2 × 10 ml) and dried in vacuo. Yield: 670 mg, 85%. For growing single crystals of $[n\mathrm{Bu_4N}]_2\cdot$ **1a** the yellow powder was dissolved in dichloromethane (10 ml) and overlayered with ethanol (100 ml). Within 7 d yellow single crystals suitable for X-ray structure analysis were obtained. M.p. 65°C (dec.). − IR (CH_2Cl_2): ν_{CO} = 2032 cm^{-1} (w), 2007 (s), 1917 (vs), 1886 (s). − UV/Vis (THF): λ (lg ε) = 430 nm (3.41). − ^{1}H NMR (CD_2Cl_2, 25°C): δ = 4.30 (q, 4 H, OCH_2), 3.14 (m, 16 H, 1-H_N), 1.64 (m, 16 H, 2-H_N), 1.48 (m, 16 H, 3-H_N), 1.44 (t, 6 H, OCH_2CH_3), 1.09 (t, 24 H, 4-H_N). − ^{13}C NMR (CD_2Cl_2, 25°C): δ = 230.5 (s, C_{COax}), 222.9 (s, C_{COeq}), 61.6 (s, OCH_2), 59.2 (s, C_N-1), 24.1 (s, C_N-2), 20.0 (s, C_N-3), 19.5 (s, OCH_2CH_3), 13.6 (s, C_N-4). − ^{119}Sn NMR (CD_2Cl_2, 25°C): δ = 1445. − MS (neg.-FAB, TEA); *m/z* (%): 547 (30) $[\{(CO)_5Cr\}_2SnOEt]^-$.

[nBu4N]2[{(CO)5Cr}2Sn(μ2-iOPr)2Sn{Cr(CO)5}2] ($[n\mathrm{Bu_4N}]_2\cdot$ **1b**): In an analogous procedure to that for $[n\mathrm{Bu_4N}]_2\cdot$ **1a**, $Na_2[\{(CO)_5Cr\}_2SnCl_2]$ (310 mg; 0.5 mmol) was dissolved in 2-propanol (50 ml) and treated with $[n\mathrm{Bu_4N}][BH_4]$ (257 mg; 1 mmol) at 0°C. The workup and crystal growth followed the methods described above. Even at 200 K, the obtained yellow single crystals of $[n\mathrm{Bu_4N}]_2\cdot$ **1b**, were not stable enough to allow for the collection of high-quality X-ray diffraction data set. Yield: 280 mg, 35%. − M.p. 65°C (dec.). − IR (THF): ν_{CO} = 2032 cm^{-1} (w), 2005 (s), 1918 (vs), 1884 (s). − ^{1}H NMR (CD_2Cl_2, 25°C): δ = 5.00 (sept, 2 H, OC*H*), 3.16 (m, 16 H, 1-H_N), 1.66 (m, 16 H, 2-H_N), 1.51 (d+m, 12+16 H, $OCH(CH_3)_2$ + 3-H_N), 1.09 (t, 24 H, 4-H_N). − ^{13}C NMR (CD_2Cl_2, 25°C): δ = 230.1 (s, C_{COax}), 223.2 (s, C_{COeq}), 68.9 (s, O*C*H), 59.1 (s, C_N-1), 26.5 [s, $OCH(CH_3)_2$], 24.0 (s, C_N-2), 19.9 (s, C_N-3), 13.6 (s, C_N-4). − ^{119}Sn NMR (CD_2Cl_2, 25°C): δ = 1379.

[nBu4N]2[{(CO)5W}2Sn(μ2-OEt)2Sn{W(CO)5}2] ($[n\mathrm{Bu_4N}]_2\cdot$ **1c**): At 0°C $Na_2[\{(CO)_5W\}_2SnCl_2]$ (442 mg; 0.5 mmol) in ethanol (50 ml) was treated with $[n\mathrm{Bu_4N}][BH_4]$ (257 mg; 1 mmol) in an analogous procedure. The further workup and single-crystal growth followed the methods described for $[n\mathrm{Bu_4N}]_2\cdot$ **1a**. Yield: 830 mg, 72%. − IR (CH_2Cl_2): ν_{CO} = 2045 cm^{-1} (w), 2026 (s), 1925 (vs), 1881 (s). − ^{1}H NMR ([D$_6$]acetone, 25°C): δ = 4.24 (q, 4 H, OCH_2), 3.45 (m, 16 H, 1-H_N), 1.85 (m, 16 H, 2-H_N), 1.49 (m, 16 H, 3-H_N), 1.44 (t, 6 H, OCH_2CH_3), 1.02 (t, 24 H, 4-H_N). − ^{13}C NMR ([D$_6$]acetone, 25°C): δ = 209.2 (s, C_{COax}), 204.7 (s, C_{COeq}), 62.7 (s, OCH_2), 59.4 (s, C_N-1), 24.4 (s, C_N-2), 20.4 (s, C_N-3), 19.5 (s, OCH_2CH_3), 13.9 (s, C_N-4). − ^{119}Sn NMR ([D$_6$]acetone, 25°C): δ = 1169 ($^1J_{W,Sn}$ = 540 Hz).

[Ph4P]2[{(CO)5Cr}2Sn(μ2-OEt)2Sn{Cr(CO)5}2] ($[Ph_4P]_2\cdot$ **1a**): A yellow solution of $Na_2[\{(CO)_5Cr\}_2SnCl_2]$ (310 mg; 0.5 mmol) in ethanol (50 ml) was added to a solution of NaH (25 mg; 1 mmol) in ethanol (20 ml), with no color change observed. After stirring for 30 min, the yellow solution was filtered through Kieselgur (3 cm). By addition of solid [Ph$_4$P]Cl (375 mg; 1 mmol) in one portion the phosphonium salt $[Ph_4P]_2\cdot$ **1a** precipitated immediatly as a yellow solid. After stirring for another 1 h, the yellow microcrystalline powder was separated from the mother liquor by filtration, washed with ethanol (3 × 10 ml) and diethyl ether (2 × 10 ml) and dried in vacuo. Yield: 660 mg, 75%. For growing single crystals of $[Ph_4P]_2\cdot$ **1a** suitable for X-ray structure analysis the same procedure as described for $[n\mathrm{Bu_4N}]_2\cdot$ **1a** was performed. M.p. 182°C (slow dec.). − IR (CH_2Cl_2): ν_{CO} = 2033 cm^{-1} (w), 2007 (s), 1918 (vs), 1880 (s). − UV/Vis (THF): λ (lg ε) = 340 nm (4.32, sh), 392 (3.93, sh). − ^{1}H NMR ([D$_6$]acetone, 25°C): δ = 8.02−7.87 (m, 40 H, aromatic H), 4.35 (q, 4 H, OCH_2), 1.45 (t, 6 H, OCH_2CH_3). − ^{13}C NMR ([D$_6$]acetone, 25°C): δ = 230.6 (s, C_{COax}), 223.2 (s, C_{COeq}), 136.4 (s, C_{para}), 135.6 (d, $^2J_{P,C}$ = 11 Hz, C_{ortho}), 131.3 (d, $^3J_{P,C}$ = 13 Hz, C_{meta}), 118.9 (d, $^1J_{P,C}$ = 90 Hz, C_{ipso}), 61.9 (OCH_2), 19.8 (OCH_2CH_3). − ^{119}Sn NMR ([D$_6$]acetone, 25°C): δ = 1460. − ^{31}P NMR ([D$_6$]acetone, 25°C): δ = 24.3 ($^1J_{C,P}$ = 89 Hz). − $C_{72}H_{50}Cr_4O_{22}P_2Sn_2$ (1774.4): calcd. C 48.74, H 2.96; found C 47.90, H 2.84.

[Ph4P]2[{(CO)5W}2Sn(μ2-OEt)2Sn{W(CO)5}2] ($[Ph_4P]_2\cdot$ **1c**): In an analogous procedure $Na_2[\{(CO)_5W\}_2SnCl_2]$ (442 mg; 0.5 mmol) in ethanol (50 ml) was treated with a solution of NaH (25 mg; 1 mmol) in ethanol (20 ml). The workup and crystal growth followed the methods described above. Yield: 780 mg, 68%. − M.p. 203°C (dec.). − IR (CH_2Cl_2): ν_{CO} = 2044 cm^{-1} (w), 2025 (s), 1923 (vs), 1878 (s). − UV/Vis (THF): λ (lg ε) = 318 nm (4.21), 369 (3.86, sh), 417 (3.62). − ^{1}H NMR ([D$_6$]acetone, 25°C): δ = 8.04−7.86 (m, 40 H, aromatic H), 4.24 (q, *J* = 6.8 Hz, 4 H, OCH_2), 1.41 (t, *J* = 6.8 Hz, 6 H, OCH_2CH_3). − ^{13}C NMR ([D$_6$]acetone, 25°C): δ = 209.1 (s, C_{COax}), 204.7 (s, C_{COeq}), 136.4 (d, $^4J_{P,C}$ = 3 Hz, C_{para}), 135.7 (d, $^2J_{P,C}$ = 11 Hz, C_{ortho}), 131.5 (d, $^3J_{P,C}$ = 13 Hz, C_{meta}), 119.1 (d, $^1J_{P,C}$ = 90 Hz, C_{ipso}), 62.7 (OCH_2), 19.5 (OCH_2CH_3). − ^{119}Sn NMR ([D$_6$]acetone, 25°C): δ = 1169 ($^1J_{W,Sn}$ = 523 Hz). − ^{31}P NMR ([D$_6$]acetone, 25°C): δ = 24.3. − $C_{72}H_{50}O_{22}P_2Sn_2W_4$ (2301.9): calcd. C 37.57, H 2.19; found C 37.18, H 2.60.

[nBu4N][{(CO)5Cr}2Sn(acac)] ($[n\mathrm{Bu_4N}]_2\cdot$ **2**): 2,4-Pentandione (50 mg; 0.5 mmol) was added in one portion to a solution of $[n\mathrm{Bu_4N}]_2[\{(CO)_5Cr\}_2Sn(\mu_2\text{-}OEt)_2Sn\{Cr(CO)_5\}_2]$ ($[n\mathrm{Bu_4N}]_2\cdot$ **1a**) (790 mg; 0.5 mmol) in THF (30 ml). The reaction mixture was stirred for 2 h, filtered through Kieselgur (3 cm) and dried. The oily yellow residue was dissolved in THF (3 ml) and chromatographed on silica gel (10 cm; Ø = 3cm; diethyl ether). Elution with diethyl ether gave a yellow band which was found, by IR-spectroscopic comparison, to consist mainly of $[Cr(CO)_6]$.[22] An orange band which contained $[n\mathrm{Bu_4N}]_2\cdot$ **2** was eluted with THF. This THF solution was dried in vacuo leaving a yellow orange oil which could not be crystallized. Yield: 350 mg; 42%. − IR (THF): ν_{CO} = 2039 (w), 2004 (s), 1919 (vs), 1891 (s) cm^{-1}. − ^{1}H NMR ([D$_6$]acetone, 25°C): δ = 5.58 (s, 1 H, C*H*), 3.42 (m, 16 H, 1-H_N), 2.05 (s, 6 H, CH_3), 1.82 (m, 16 H, 2-H_N), 1.47 (m, 16 H, 3-H_N), 1.04 (t, 24 H, 4-H_N). − ^{13}C NMR ([D$_6$]acetone, 25°C): δ = 229.7 (s, C_{COax}), 222.7 (s, C_{COeq}), 192.8 (C_{C-O}), 101.4 ($C_{C=C}$), 59.5 (s, C_N-1), 27.7 (C_{Me}), 24.4 (s, C_N-2), 20.4 (s, C_N-3), 13.9 (s, C_N-4). − ^{119}Sn NMR ([D$_6$]acetone, 25°C): δ = 1205.

[Na(12-Crown-4)2][{(CO)5Cr}2Sn(pyro)] ([Na(12-Crown-4)$_2$]$\cdot$ **3**): 3-Hydroxy-2-methyl-γ-pyrone (63 mg; 0.5 mmol) was deprotonated with NaH (12 mg; 0.5 mmol) at −70°C in THF (20 ml). The solution was allowed to warm up slowly to 25°C and was poured into a yellow solution of the disodium salt $Na_2[\{(CO)_5Cr\}_2SnCl_2]$ (310 mg; 0.5 mmol) in THF (30 ml). The reaction mixture was stirred for 2 h, filtered through Kieselgur (3 cm) and dried. The oily orange residue was dissolved in diethyl ether (3 ml) and chromatographed on silica gel (15 cm; Ø = 3 cm; diethyl ether). Elution with diethyl ether gave a yellow band which contained $[Cr(CO)_6]$ and another unidentified product (by IR-spectroscopic comparison with $[\{(CO)_5Cr\}Sn(oxinato)_2]$ (oxinato = 8-oxoquinolato)[8b] it appears probable that the product is $[\{(CO)_5Cr\}Sn(pyro)_2]$). An orange band which contains $[Na(THF)_x]\cdot$ **3** could be eluted with THF. This THF fraction was concentrated to 5 ml and 12-Crown-4 (36 mg; 0.2 mmol) was added.

For growing single crystals of [Na(12-Crown-4)$_2$]$\cdot$ **3** the following procedure was carried out: A concentrated THF solution (5 ml) of [Na(12-Crown-4)$_2$]$\cdot$ **3** was shared out between three test-tubes (Ø =

1 cm) which were brought into a Schlenk tube (250 ml). Diethyl ether (30 ml), within the tube, was allowed to diffuse through the gas phase into the THF solution (3 h). After this period of time the diethyl ether was replaced by petroleum ether (boiling range 40−60°C) (50 ml). Vapor diffusion of the petroleum ether (10 d) yielded yellow single crystals suitable for X-ray structure analysis. Crystalline yield: 110 mg; 11%. M.p. 166°C (dec.). − IR (THF): ν_{CO} = 2037 (w), 2001 (s), 1917 (vs), 1889 (s) cm^{-1}. − UV/Vis (THF): λ (lg ε) = 309 (4.45), 357 (3.98). − ^1H NMR for $[Na(solv)_x]\cdot$**3** ([D$_6$]acetone, 25°C): δ = 8.04 (d, 1 H, H5), 6.73 (d, 1 H, H6), 2.44 (s, 3 H, H7) (numbers refer to Figure 1). − ^{13}C NMR for $[Na(solv)_x]\cdot$**3** ([D$_6$]acetone, 25°C): δ = 229.8 (s, C_{COax}), 222.6 (s, C_{COeq}), 177.6 (C1), 156.0 (C_5), 155.3 (C2), 153.7 (C3), 111.5 (C6), 15.3 (C7) (numbers as given in Figure 1). − ^{119}Sn NMR for $[Na(solv)_x]\cdot$**3** ([D$_6$]acetone, 25°C): δ = 1361. − [Na(12-Crown-4)$_2$]·**3**, $C_{32}H_{37}Cr_2NaO_{21}Sn$ (1003.3): calcd. C 38.31, H 3.72; found C 38.37, H 3.85.

X-ray Structure Determinations: The measurements for $[n\mathrm{Bu_4N}]_2\cdot$**1a**, $[Ph_4P]_2\cdot$**1a**, $[Ph_4P]_2\cdot$**1c**, and [Na(12-Crown-4)$_2$]·**3** were carried out with a Siemens P4 four-circle diffractometer with graphite-monochromated Mo-K_α radiation. The intensities of three check reflections (measured every 100 reflections) remained constant (except for $[n\mathrm{Bu_4N}]\cdot$**1a**) throughout the data collection, thus indicating crystal and electronic stability. All calculations were performed using the SHELXT PLUS software package. Structures were solved by direct methods with the SHELXS-86 program and refined with the SHELX93 program.[23] The program XPMA[24] was used for graphical handling of the data. Absorption corrections (ψ scan, Δψ = 10°) were applied to the data. The structures were refined in fully or partially anisotropic models by full-matrix least-squares calculations. Hydrogen atoms were introduced at calculated positions. Table 5 compiles the data for the structure determinations. Peculiarities about the structure of [Na(12-Crown-4)$_2$]·**3** are the following: One of the crown ether molecules shows disorder and could only be refined isotropically.

Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository numbers CSD-408368 ($[n\mathrm{Bu_4N}]_2\cdot$**1a**), -408369 ($[Ph_4P]_2\cdot$**1a**), -408367 ($[Ph_4P]_2\cdot$**1c**), -408370 ([Na(12-Crown-4)$_2$]·**3**).

[21] With compounds **1** as well as with compounds **a** (Figure 3) it is generally observed that the bonds to the substituents R at the bridging oxygen atoms are made in the directions approximately coplanar with the four-membered cycle with a resulting

trigonal-planar coordination around the oxygen atom (see ref.[11]). While Sn−O π-bonding might be a reason for this this π contribution is found to be small. In an EHT analysis the model as used above was compared with a model in which the hydrogen atoms of the H−O groups were deliberately set at positions 40° away from the *x* direction in the *xz* plane (Figure 4) in a mutually anti-sense. Only a minor change in the total energy was observed; the "in-plane" model being about 0.1 eV more stable than the "out-of-plane" model. Bonding and antibonding effects of this bending must therefore almost compensate each other within the set of occupied orbitals. An analogous model calculation was done for $[HSnOH]_2$ as a prototype of the species **a**. Here as well bending did not cause dramatic change in the total energy (the "in-plane" model is about 0.01 eV more stable). It appears therefore that the potential describing this bending motion is quite soft and that neither the coplanarity nor the distortion from coplanarity of the R−O-bonds has any specific and easy to interpret meaning. It is observed that the compounds $[RGe(\mu_2\text{-}SR)_2GeR]$, isoelectronic to **a**, show distinctively pyramidal coordination around sulfur (see ref.[11]).

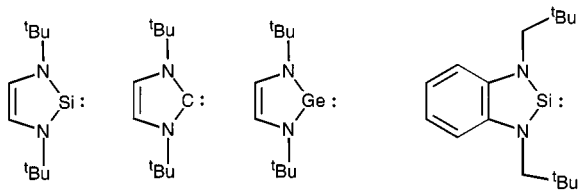
Keywords: Silylene / N Heterocycles / Carbene analogs / Tin / Subvalent compounds

The reaction of the stable silylene **1** (L′Si:) with CO, $SnCl_2$, $PbCl_2$, the stable carbene L′C: (**2**) and the stable germylene L′Ge: (**3**) was investigated as a possible approach for the synthesis of *hetero*-polysilanes (*poly*-carbosilanes, *poly*-germasilanes, *poly*-stannasilanes). The silylene **1** was found to be inert towards all substrates except $SnCl_2$ and $PbCl_2$. Reaction with $SnCl_2$ led to the formation of the yellow, tris(silyl)stannane [(L′SiCl)$_3$SnCl] (**5**) and elemental tin. The photolabile (**5**) was characterized by multinuclear NMR (^{1}H, ^{13}C, ^{29}Si, ^{119}Sn) and single crystal X-ray diffraction: $C_{30}H_{60}Cl_4N_6Si_3Sn$, M = 849.60, orthorhombic, space group $Pca2_1$. The bond angles of 115.89 ° (ave. Si–Sn–Si) and 101.87 ° (ave. Cl–Sn–Si) show a slightly flattened tetrahedral geometry around the tin atom. – Thermolysis of **5** at 100 °C led to the deposition of thin films of tin; photolysis resulted in the formation of tin powder. All thermolysis products could be isolated and were characterized as $SnCl_2$, elemental tin, L′Si: (**1**), L′$SiCl_2$ (**6**) and the new disilane L′Si(Cl)-(Cl)SiL′ (**7**). Photolysis led to a reduced product spectrum (formation of Sn + $SnCl_2$ + **7**). Reaction of **1** with $PbCl_2$ gave elemental lead and L′$SiCl_2$ as the only products.

The heavy analogs of carbenes R_2E: (E = Si, Ge, Sn, Pb) are attractive building blocks for the synthesis of inorganic polymers $[R_2E]_n$. *Homo*-polymers of silicon, germanium, and tin are typically obtained by the reduction of the dihalides R_2SiCl_2,[1] R_2GeCl_2,[2] or R_2SnCl_2.[3] These reactions may proceed through the intermediacy of free silylenes, germylenes or stannylenes as reactive intermediates. The unique electronic structure of *poly*-silanes[1], *poly*-germanes[2], and *poly*-stannanes[3] has prompted detailed investigations of their physical properties. The partial replacement of silicon in *poly*-silanes by germanium or tin is of special interest as a 1-dimensional model for Si−Ge and Si−Sn alloys. The dehalogenation of mixtures of dichlorides R_2ECl_2 has been used to obtain copolymers of type $[R_2Si]_n[R'_2Si]_k$[4] and $[R_2Si]_n[R_2Ge]_k$,[4] but the very different susceptibility of the SiCl, GeCl, and SnCl bonds towards reduction limits the scope of the dehalogenation approach.

The recent synthesis of a number of stable carbenes[5][6] and silylenes[7][8] presents a new possible strategy to obtain group 14 polymers by copolymerization of these reactive molecules. We now report preliminary results on the reaction of the stable silylene L′Si (**1**)[7] with the stable divalent group 14 compounds: CO, $SnCl_2$, $PbCl_2$, L′C: (**2**)[9] and L′Ge: (**3**)[10] (Scheme 1).

Scheme 1



1 **2** **3** **4**

The reaction of the stable silylene **4** with the germylenes, stannylenes, and plumbylenes M[N(SiMe$_3$)$_2$]$_2$ (M = Ge, Sn and Pb) was investigated by Gehrhus, Hitchcock, and Lappert and was shown to proceed by insertion of the silylene **4** into the MN bond rather than formation of Si,Ge-, Si,Sn- or Si,Pb copolymers.[8a][8b] Similar MN insertion products were obtained by Weidenbruch et al. from the reaction of a stable diaminogermylene with a stable diaminosilylene.[8c]

No reaction was observed between the silylene **1** (L′Si:) and CO, L′C: or L′Ge: or any other combination of these compounds even after prolonged heating to 150 °C in sealed NMR tubes. Rapid reaction occurred between **1** and tin(II) chloride, however, to give the tris(silyl)stannane **5**.[11]

Compound **5** was characterized by multinuclear NMR (^{1}H, ^{13}C, ^{29}Si, and ^{119}Sn)[11], CI-MS[11] and single crystal X-ray diffraction[12][19] as a tris(silyl)stannane with Sn^{IV} and Si^{IV} centers. The oxidation of both divalent silicon and

[◇] Part 6: Ref.[6].

tin in the course of the reaction is balanced by the formation of a stoichiometric amount of metallic tin. Compound **5** can be stored at −10°C in the dark for months, but slowly decompose to give deposits of metallic tin at r. t. especially if exposed to light.

The decomposition of **5** under thermolytic[13] or photolytic[14] conditions follows different pathways. Both reactions lead to a fragmentation of the Si_3Sn framework and the formation of the disilane **7**.[15] Elemental tin is deposited as film (thermolysis) or powder (photolysis). Under thermolytic conditions, the silylene **1**,[7a] and the silane **6**[7a] are formed as additional products. The thermolytic decomposition pathway of **5** matches the CI-MS fragmentation pattern[11] (high abundance of the fragments $[L'Si:]^{+\bullet}$ and $[L'SiCl_2]^{+\bullet}$).

The crystal structure of **5**[12][19] (Figure 1) shows the tin atom in a distorted tetrahedral environment. The Si−Sn−Si bond angles (114.60−116.70°) and Si−Sn−Cl bond angles (100.07−102.96°) deviate from the ideal tetrahedral geometry. Few structural data are available on silyl-stannanes, but the Si-Sn bond distances in **5** (263.0−264.2 pm) closely

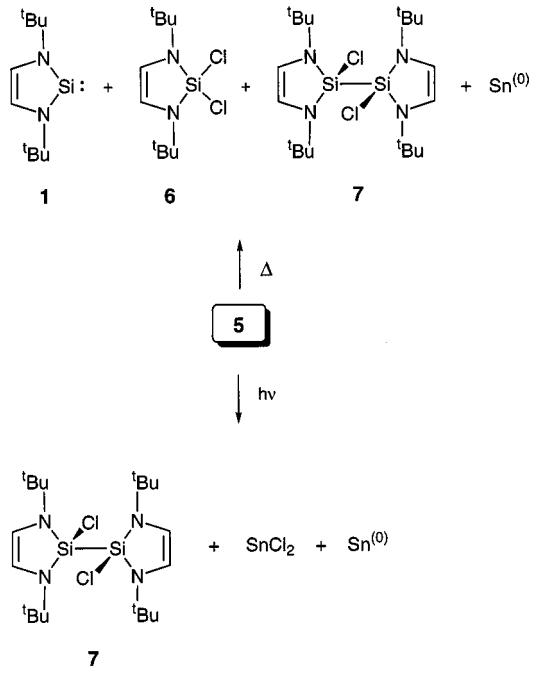

Figure 1. Molecular structure of **5** (ORTEP plot, 50% probability level, hydrogen atoms have been omitted for clarity)[a]

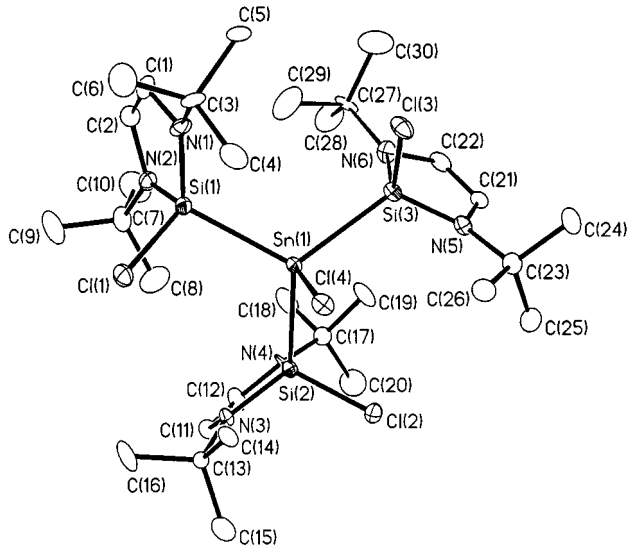

[a] Selected bond lengths [pm] and angles [°]: Sn(1)−Cl(4) 238.8(3), Sn(1)−Si(1) 263.0(4), Sn(1)−Si(2) 264.2(4), Sn(1)−Si(3) 264.0(3), Cl(1)−Si(1) 211.2(5), Cl(2)−Si(2) 209.3(5), Cl(3)−Si(3) 211.6(4); Cl(4)−Sn(1)−Si(1) 102.96(11), Cl(4)−Sn(1)−Si(2) 102.57(13), Cl(4)−Sn(1)−Si(3) 100.07(12), Si(1)−Sn(1)−Si(2) 116.38(11), Si(1)−Sn(1)−Si(3) 116.7(2), Si(2)−Sn(1)−Si(3) 114.60(12); Torsional angles: Cl(4)−Sn(1)−Si(1)−Cl(1) −50.15(0.18), Cl(4)−Sn(1)−Si(3)−Cl(3) −50.50(0.23), Cl(4)−Sn(1)−Si(2)−Cl(2) −47.95(0.17)

match those reported for the recently characterized silyl-stannanes $[(Me_3Si)_3Si]_2SnCl_2$ (259.7−260.4 pm)[16] and $[(Me_3Si)_3Sn]_2$ (260.9−261.1 pm).[17]

The normal Si−Sn bond distances, and especially the fact that the Si−Sn bonds of **5** are freely rotating in solution (equivalence of 6 *t*Bu groups and 6 ring protons in the ^1H NMR at r.t.), show that **5** is free of strong steric congestion. By contrast, the disilane L′Si(Cl)−(Cl)SiL′ (**7**, vide infra) shows hindered rotation of the *t*Bu-groups at r.t, as evidenced by the broad signals found for the methyl groups in the ^1H- and ^{13}C-spectrum. The $(SiCl)_3Sn-Cl$ framework has the idealized symmetry C_3, with Cl−Sn−Si−Cl torsional angles ranging from −47.95 to −50.15.

The reaction of **1** with $PbCl_2$ leads to the clean formation of elemental lead (powder) and $L'SiCl_2$ (**6**) as the only products.

Stable silylenes of type **1** can at present only be obtained by reduction of the corresponding dihalosilanes R_2SiCl_2 with potassium at elevated temperatures[7a]. The thermolytic generation of **1** from a stannylsilane such as **5** presents a potential alternative synthetic approach. The stannylsilanes $L'Si(SnR_3)(Cl)$ and $L'Si(SnR_3)_2$ are now under investigation as new precursors for stable silylenes.

The authors thank the *Natural Sciences and Engineering Research Council of Canada* (*NSERC*) and the *Connaught Fund of the University of Toronto* for support of this research, Dr. *Juris Strautmanis* (Toronto) for many helpful discussions and *Avinash Thadani* for preliminary experiments.

Experimental Section

General: All reactions were carried out under argon (99.994% purity) with usual Schlenk equipment or inside an inert-gas glovebox (O_2 and H_2O < 1 ppm). Solvents were purified by distillation over benzophenone/potassium (THF, hexanes, benzene) or by 30 minute sonication with CaH_2. – IR: Nicolet. – NMR: Varian Gemini 200, Unity 400 and 500. – The starting materials L′Si (**1**)[7a] L′C: (**2**)[9] and L′Ge: (**3**)[10] were obtained according to published procedures. The compounds **1**–**3** were purified by sublimation under exclusion of air and moisture. Anhydrous $SnCl_2$ was used as received (Aldrich). Reactions of **1** with CO, L′C: and L′Ge: were studied in ca. 5 wt.-% solutions in C_6D_6. Flame sealed samples were heated to 150°C for 4 weeks in 5-mm NMR tubes. For the synthesis and characterization of **6** see reference[7a].

Synthesis of **5**: $SnCl_2$ (10.0 mmol, 1.896 g) is added to a solution of the silylene **1** (20.0 mmol, 3.927 g) in 15 ml of THF at −10°C. The reaction mixture turns red and the starting material is completely consumed after 60 min. The crude reaction mixture contains **5** (> 85%) and small amounts (ca. 5%) of **6** and **7**. Analytically pure $(L'SiCl)_3SnCl$ (**5**) is isolated from the crude reaction mixture by chromatography on Celite (hexane as eluent), followed by recrystallization from toluene as orange crystals (46%) that decompose at 172°C without melting.

[12] *X-ray Crystallographic* Study[19]: $C_{30}H_{60}Cl_4N_6Si_3Sn$, **5**, ◦*M* = 849.60, orthorhombic, space group $Pca2_1$, *a* = 11.365(3) A, *b* = 18.999(4) A, *c* = 19.808(5) A, *V* = 4277(2) A^3, *Z* = 4, *D(calc.)* = 1.319 g/cm^3, μ = 0.959 mm^{-1}. Data were collected on an Siemens P4 diffractometer using graphite monochromator, λ (Mo-K_α) = 0.71073 A. The intensities of standard reflections measured every 97 reflections showed no decay. The data were corrected for Lorentz and polarization effects and semi-empirical absorption correction was applied using ψ-scans. Minimum and maximum absorption corrections were 0.5712 and 0.5276. The structure were solved and refined using the SHELXTL\PC[18] package. Refinement was by full-matrix least-squares on F^2 using all data (negative intensities included). The weighting scheme was $w = 1/[\sigma^2(F_o^2) + (0.00295P)^2 + 4.7P]$ where $P = (F_o^2 + F_c^2)/3$. Hydrogen atoms were included in fixed positions and treated as riding atoms. Maximum residual electron densities were +0.875 and −0.557 e/A^3.

[13] Sealed NMR samples of **5** in C_6D_6 were monitored by ^1H, ^{13}C, and ^{29}Si NMR. After 3 h at 100°C, the decomposition was complete and L′Si: (**1**), $L'SiCl_2$ (**6**) and L′Si(Cl)−(Cl)SiL′ (**7**) were formed in the molar ratio 2:6:3 (^1H NMR). The NMR tubes were stored "upside down" during the thermolysis to prevent the formation of a tin film in the bottom part of the NMR tube.

[14] Irradiation of **5** (5% in hexanes) in a quartz tube for 6 days resulted in 60% conversion of **5** to L′Si(Cl)−(Cl)SiL′ (**7**), $SnCl_2$ and tin powder as sole products.

[15] The disilane **7** has been obtained earlier in our group from reactions of **1** with different chlorinating agents. L′Si(Cl)−(Cl)SiL′ (**7**): ^1H NMR (200 MHz, C_6D_6): δ 1.25−1.50 (br, 36 H, CH_3), 5.8 (s, 4 H, =C*H*). – ^{13}C NMR (100 MHz, C_6D_6): δ 30.25−31.50 (br, CH_3), 52.88 [s, $C(CH_3)_3$], 114.08 (=*C*H). – ^{29}Si NMR (79.0 MHz, C_6D_6): δ −33.18. Keywords: Dinuclear complexes / Nickel / Palladium / Amine-thiolate ligands/ Amine-selenolate ligands

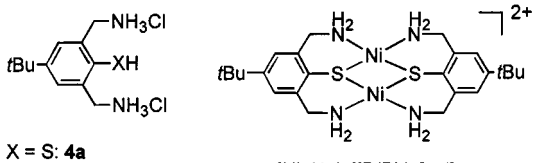
The preparation and characterization of dinuclear Ni^{II} and Pd^{II} complexes of the tridentate amine-chalcogenolate ligands 4-*tert*-butyl-2,6-di(aminomethyl)thiophenol (**4a**) and 4-*tert*-butyl-2,6-di(aminomethyl)selenophenol (**4b**) are reported. Reaction of **4a**,**b** with $Ni(ClO_4)_2 \cdot 6\,H_2O$ or $(COD)PdCl_2$ in a 1:1 molar ratio yields 1:1 complexes of composition $[M_2(L)_2][BPh_4]_2 \cdot CH_3CN \cdot CH_3OH$ [M = Ni, L = **4a**,**b** (**5a**,**b**); M = Pd, L = **4a,b** (**6a**,**b**)]. The palladium complex **6a** is isomorphous with **5a** as shown by X-ray crystal structure analysis. NMR studies reveal that both complexes retain their solid-state structure in solution and that the selenolate complexes are isostructural with the thiolate complexes. All complexes undergo electrochemically reversible one-electron transfer processes in the potential range –1.0 to –0.8 V vs. SCE ascribed to metal-centered reductions with formation of mixed-valent $M^{I,II}$ species $[M_2(L)_2]^+$. Further reduction at more negative potentials then leads to the neutral $[M_2(L)_2]$ species, which are not stable on the time scale of the CV experiment. The spectroscopic properties of the thiolate and selenolate complexes are very similar indicating electronically similar properties of the tridentate amine-chalcogenolate ligands.

Introduction

The coordination chemistry of transition-metal thiolate, selenolate, and tellurolate complexes has been actively pursued in the past several years, motivated primarily by the bonding diversity[1][2], potential use as precursors to new solid-state materials[3], and the relevance of such complexes to biomimetic chemistry[4][5]. Monodentate chalcogenolate ligands, which have been studied most, form complexes with most of the elements, however, their inherent tendency to form bridges between transition-metal ions limits their use in the preparation of complexes of well-defined nuclearity[6]. Furthermore, an investigation of chemical reactivities is often hampered by ligand-centered redox reactions and the fact that such species can be notoriously labile[7].

More recently, multidentate nitrogen/sulfur-based ligands have been employed as spectator ligands in various mononuclear[8][9][10] and dinuclear transition-metal complexes[11][12] and have been shown to offer some unique properties in coordination chemistry. The notable feature of such complexes is their enormous stability that has enabled the preparation of complexes with metal ions in unusual high formal oxidation states[13][14] and has allowed for studies on their chemical reactivity[15]. However, while mononuclear complexes have been extensively studied, dinuclear complexes have been considered less often, and very little information is available on their reactivity[16][17]. This is true in particular for complexes with polydentate nitrogen/selenium-based ligands[18].

Scheme 1. Structures of amine-chalcogenolate ligands **4a**,**b** and the binding mode of **4a** in the dinuclear $[Ni_2(\mathbf{4a})_2]^{2+}$ dication in $[Ni_2(\mathbf{4a})_2][BPh_4]_2$ (**5a**)[20]



Our work on thiolate-bridged dimetal complexes[19] has shown that the dinickel complex **5a** of the tridentate N_2S ligand **4a** is quite robust, tolerating binding of exogenous ligands without affecting the dinuclear structure[20]. Complex **5a** also serves as a versatile starting agent in the preparation of novel face-sharing bioctahedral nickel complexes. This prompted us to investigate the possibility of synthesizing related complexes with the amine-selenolate ligand **4b**.

This article describes the syntheses and characterization of dinuclear nickel and palladium complexes of the analogous ligands 2,6-bis(aminomethyl)-4-*tert*-butylthiophenol (**4a**) and 2,6-bis(aminomethyl)-4-*tert*-butylselenophenol (**4b**).

Results and Discussion

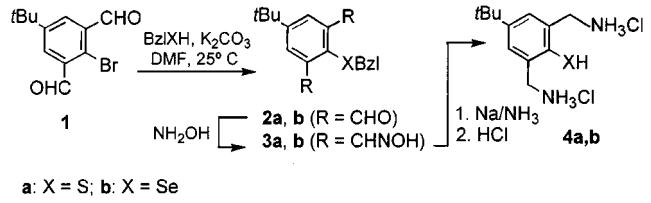
Syntheses

Compounds **4a**,**b** were prepared in 3 steps starting from **1**, as is shown in Scheme 2. In the first step, compound **1** was treated with potassium benzylthiolate in dimethylformamide to afford benzyl [4-*tert*-butyl-2,6-diformylphe-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434–1948/98/0808–1071 $ 17.50+.50/0

nyl]sulfide in nearly quantitative yield. The dialdehyde **2a** was subsequently converted to the corresponding dioxime **3a** by reaction with hydroxylamine. In the last step, reduction of compound **3a** was accomplished with sodium in liquid ammonia. The amine-thiolate compound **4a** was isolated as the hydrochloride salt **4a**·$(HCl)_2$ in 55% overall yield. A similar reaction sequence was employed to prepare the selenium analogue **4b**.

Scheme 2. Preparation of amine-chalcogenolate ligands **4a**,**b**



a: X = S; **b**: X = Se

Metal Complex Syntheses

The hydrochloride salts of the chalcogenolate ligands **4a**,**b** react with equimolar quantities of $Ni(ClO_4)_2 \cdot 6H_2O$ in the presence of base to give the air-stable dications $[Ni_2(\mathbf{4a})_2]^{2+}$ and $[Ni_2(\mathbf{4b})_2]^{2+}$, respectively (eq. 1). These cationic species were isolated as the tetraphenyl borate salts $[Ni_2(\mathbf{4a})_2][BPh_4]_2$ (**5a**) and $[Ni_2(\mathbf{4a})_2][BPh_4]_2$ (**5b**). Complexes **5a**,**b** are dark-red crystalline solids, soluble in polar aprotic solvents like acetonitrile, dichloromethane, dimethyl sulfoxide, and dimethylformamide. Similarly, reaction of **4a**,**b** with $(COD)PdCl_2$ and NaOMe in methanol produced, upon addition of $NaBPh_4$, yellow crystals of the palladium analogs of **5a**,**b** in good yields {$[Pd_2(\mathbf{4a})_2][BPh_4]_2$ (**6a**), 82%; $[Pd_2(\mathbf{4b})_2][BPh_4]_2$ (**6b**), 63%}.

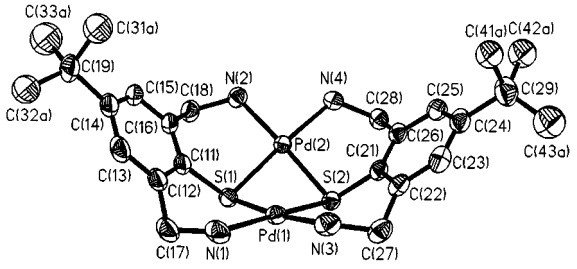
(1)

When recrystallized from acetonitrile/methanol solution, the complexes crystallize with a solvent molecule of acetonitrile and a solvent molecule of methanol per dication. The dinuclear nature of the complexes was confirmed by X-ray crystal structure determination of the palladium complex **6a** · CH_3CN · CH_3OH. The structure of **5a** · CH_3CN · CH_3OH has been determined previously[20].

Crystal Structure of 6a·CH_3CN·CH_3OH

The X-ray crystal structure determination of **6a** ·CH_3CN·CH_3OH revealed the structure to consist of well-separated molecules of the dipalladium complex and two tetraphenylborate anions. The two solvent molecules of crystallization form hydrogen bonds with nitrogen atoms [N(1), N(3)] of the dication [N(1)−H(1B)···O(1) 2.892 A, N(3)−H(3A)···N(5) 3.307 A], but feature no bonding interactions with the palladium ions. **6a**·CH_3CN·CH_3OH is isomorphous and isostructural with **5a**·CH_3CN·CH_3OH. Although the dication does not possess crystallographically imposed symmetry, its idealized symmetry is C_{2v}. A perspective view of the molecular structure of the dipalladium complex with the atomic numbering scheme is shown in Figure 1.

Figure 1. Molecular structure of the $[Pd_2(\mathbf{4a})_2]^{2+}$ cation in **6a** (50% probability thermal ellipsoids)[a]



[a] Selected bond lengths [A] and angles [°]: Pd(1)−S(1) 2.3057(9), Pd(1)−S(2) 2.3020(11), Pd(1)−N(1) 2.076(3), Pd(1)−N(3) 2.076(3), Pd(2)−S(1) 2.3009(8), Pd(2)−S(2) 2.2951(9), Pd(2)−N(2) 2.069(2), Pd(2)−N(4) 2.084(2), Pd(1)···Pd(2) 3.0847(6); S(1)−Pd(1)−S(2) 81.79(3), S(1)−Pd(1)−N(1) 94.24(9), S(1)−Pd(1)−N(3) 173.56(8), S(2)−Pd(1)−N(1) 174.98(8), S(2)−Pd(1)−N(3) 94.34(8), N(1)−Pd(1)−N(3) 89.88(11), S(1)−Pd(2)−S(2) 82.05(3), S(1)−Pd(2)−N(2) 94.70(7), S(1)−Pd(2)−N(4) 175.48(7), S(2)−Pd(2)−N(2) 176.27(7), S(2)−Pd(2)−N(4) 93.78(7), N(2)−Pd(2)−N(4) 89.40(10).

As in the dinickel complex **5a**, the coordination of each Pd atom by two nitrogen and two bridging thiolate sulfur atoms is approximately planar. Maximum deviations from the least-squares planes defined by the atoms Pd(1), S(1), S(2), N(1), N(3) and Pd(2), S(1), S(2), N(2), N(4) are 0.078 and 0.028 A, respectively. The two planar PdN_2S_2 units are joined via two bridging thiolate atoms with a folding angle of 123.3° between the two planes. While this angle is only marginally smaller than the corresponding value in **5a** (124.6°), a larger difference is found for the angle between the two least-squares planes defined by the atoms of the phenyl rings of the two ligands (91.9° in **6a**, 96.1° in **5a**). The average Pd−N and Pd−S bond lengths are 2.076 and 2.301 A. In **5a**, the corresponding values were found to be 1.936 and 2.182 A, respectively. It is noted that the difference between Ni−N and Pd−N bond lengths (0.140 A) is larger than the difference in Ni−S and Pd−S bond lengths (0.119 A). Due to the longer Pd−S bonds in **6a**, the M···M distance within the dinuclear cations has increased from 2.973 A in **5a** to 3.085 A in **6a**.

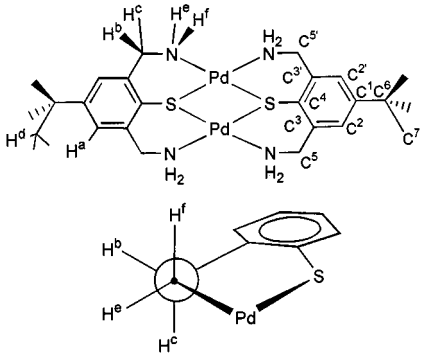
In essence, the molecular structures of **6a** and **5a** show only slight differences. The most important information, however, is that both complexes are isomorphous and isostructural. The similar analytical and spectroscopic data of the complexes **5b** and **6b** (below) suggest that the selenolate complexes are also isomorphous and isostructural with the thiolate complexes.

NMR Spectroscopy

Complexes **5a**−**6b** have been examined by ^{1}H-NMR, $^{13}C\{^1H\}$-NMR, and, where appropriate, by ^{77}Se-NMR

spectroscopy. ^{1}H- and ^{13}C-chemical shifts and assignments according to Chart 1 are collected in Table 1.

Chart 1. ^{1}H-NMR labeling scheme



The ^{1}H-NMR spectrum of a solution of **6a** in CD_2Cl_2 is representative for all homodinuclear complexes **5a**−**6b**. Characteristic features are a singlet for the hydrogen atoms of the *tert*-butyl groups (H^d) at δ = 1.32 and a singlet for the hydrogen atoms bonded to the *meta*-carbon atoms of the phenyl ring (H^a) at δ = 7.24 (for **5a**,**b** this singlet is obscured by resonances of the anion). The signals of the methylene (H^b, H^c) and amine hydrogen atoms (H^e, H^f) of the aminomethyl groups appear as four multiplets centered at δ = 3.49, 3.11, 1.88, and 1.02. These form an ABCD spin system as evidenced by H,H-COSY spectroscopy, and this ABCD spin system in the alkane region is characteristic for all compounds (see Figure 2 for the spectrum of **5b**).

The vicinal coupling constants $|^3J_{b,f}|$, $|^3J_{b,e}|$, and $|^3J_{c,e}|$ were estimated (by graphical evaluation) to be less than 2 Hz, while $|^3J_{c,f}|$ was estimated to be ca. 12 Hz. Assignment of the amine hydrogen atoms was unambiguously achieved by an NH/ND-exchange experiment. Thus, addition of a few drops of a CD_3OD/D_2O (95:5) solution caused the two multiplets observed for H_e and H_f to disappear. Under these conditions the two multiplets observed for H_b and H_c now form an AB spin system (doublet of doublets). This allowed the geminal coupling constant of the methylene hydrogen atoms $^2J_{b,c}$ to be determined ($|^2J_{b,c}| \approx 12$ Hz). The two sets of vicinal coupling constants indicate a staggered conformation of the methylene and amine hydrogen atoms within the six-membered chelate ring similar to that observed in the solid state.

In the $^{13}C\{^1H\}$-NMR spectrum of **6a**, the $[Pd_2(\mathbf{4a})]^{2+}$ dication gives rise to four signals in the aromatic region and three signals in the aliphatic region again consistent with local C_{2v} symmetry of the dication in solution. The four signals in the aromatic region correspond to the *para*- (C^1), the *ipso*- (C^4), the *ortho*- (C^3, $C^{3\prime}$), and the *meta*-carbon atoms (C^2, $C^{2\prime}$) of the phenyl ring, whereas the singlets in the aliphatic region correspond to the quaternary carbon atom of the *tert*-butyl group (C^6), the three equivalent methyl carbon atoms of the *tert*-butyl group (C^7), and the methylene carbon atoms (C^5, $C^{5\prime}$).

Although the chemical shifts of the protons of the aminomethyl groups of the nickel complex **5a** are upfield from the corresponding resonances in the palladium complex **6a**, the otherwise identical ^1H-NMR and $^{13}C\{^1H\}$-NMR data clearly reveal that **6a** and **5a** retain their solid-state structure in solution. Furthermore, the similar ^1H-NMR and ^{13}C-NMR data of the selenolate complexes suggest that these are isostructural with the thiolate complexes. The singlet ^{77}Se resonance observed for **6b** at $\delta = 24.5$ also supports this assumption, however, for reasons unclear no ^{77}Se resonance was observed for **5b**.

It should also be noted that no exchange occurs between these dinuclear complexes in solution. When pure compounds were mixed in a ca. 1:1 ratio and investigated by ^1H-NMR spectroscopy, the spectra of such solutions resemble just superpositions of the spectra of the pure compounds. These spectra remained unchanged even after one week at room temperature. If exchange had occurred under these conditions, one would expect new signals due to mixed species such as $[Ni_2(\mathbf{4a})(\mathbf{4b})]^{2+}$ or $[NiPd(\mathbf{4a})_2]^{2+}$. These results demonstrate the stability of complexes **5a**−**6b**. The same conclusions can be drawn from the electrochemical studies presented below.

Infrared and UV/Vis Spectroscopy

Complexes **5a**−**6a** exhibit very similar IR spectra which are all dominated by two strong absorptions in the region 3350−3200 cm^{-1} (Table 2). These latter absorptions were assigned to $\nu_s(NH_2)$ and $\nu_{as}(NH_2)$ stretching vibrations of the CH_2NH_2 groups[21]. As is expected, the replacement of sulfur in **5a** or **6a** by selenium in **5b** or **6b** produces no shifts in $\nu(NH_2)$ stretching frequencies. However, the $\nu(NH_2)$ stretching modes in palladium complexes **6a**,**b** appear at higher frequencies than in nickel complexes **5a**,**b**. The increase in N−H stretching frequencies in Pd complexes **6a**,**b** reflects a stronger N−H bond consistent with longer Pd−N bonds and, therefore, less polarized N−H bonds in **6a**,**b**.

The UV/Vis spectra are also very similar. In each case two features appear in the region 320−380 nm, which are assigned to π-π* transitions of the ligands. The red color of the nickel complexes is due to the absorption maxima at 499 nm in **5a** and 509 nm in **5b**, which are assigned to chalcogenolate-to-Ni charge-transfer transitions. These bands are shifted to 426 nm in **6a** and 430 nm in **6b**. Relative to the positions of the charge-transfer transitions of the thiolate complexes, those of the selenolate complexes are slightly shifted to lower energy. This is in agreement with the principle of hard and soft acids and bases that classifies selenolate selenium atoms easier to polarize than thiolate sulfur atoms[22].

Table 2. Electrochemical, IR-spectroscopic, and UV/Vis data of complexes **5a**−**6b**

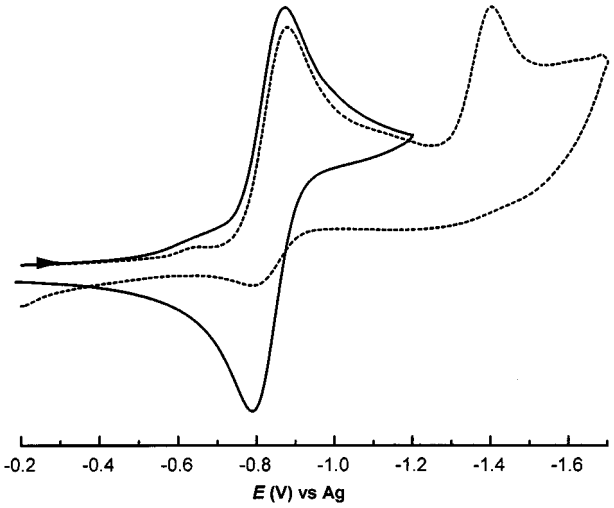
[a] Experiments were carried out using DMF as the solvent with 0.1 M n-Bu_4NPF_6 as the supporting electrolyte, Pt disc working electrode and Pt wire auxiliary electrodes. All half-cell potentials were calibrated against an internal ferrocenium/ferrocene (Fc^+/Fc) standard; $E^x_{1/2} = (E^{ox}_p + E^{red}_p)/2$ for reversible one-electron transfer processes; oxidation (E^{ox}_p) or reduction peak potentials (E^{red}_p) are given for irreversible (irr.) processes. Reported values are referenced vs. SCE. − [b] As KBr pellets. − [c] Data recorded for solutions of **5a**,**b** in CH_2Cl_2 and **6a**,**b** in CH_3CN.

Electrochemistry

Cyclic voltammograms (CVs) of complexes **5a**−**6b** have been recorded in dimethylformamide solution containing 0.10 M tetra-*n*-butylammonium hexafluorophosphate as supporting electrolyte. All potentials are referenced to the SCE. The CV of **5b** is representative for all homodinuclear complexes **5a**−**6a** (Figure 3). The complex undergoes two irreversible reduction processes with cathodic peak potentials at −0.87 and −1.38 V vs. SCE (Table 2). However, when the scan is reversed at −1.2 V vs. SCE, the first reduction process becomes quasi-reversible with the appear-

Figure 3. Cyclic voltammogram of **5b** in DMF with 0.1 M n-Bu_4NPF_6 as supporting electrolyte, Pt disc working electrode, Pt wire auxiliary electrode, and Ag wire pseudo reference electrode; scan rate 200 $mV\cdot s^{-1}$



ance of an anodic peak at −0.76 V (ΔE^1 = 84 mV). Reduction of **5b** at a constant potential of −1.2 V vs. SCE consumed 0.94 e^-/complex indicative of a one-electron transfer process. A similar electrochemical behaviour is observed for the other dinuclear complexes (Table 2).

Since the ligands in complexes **5a**−**6b** are unlikely to undergo ligand-centered redox reactions, it is concluded that all complexes undergo metal-centered redox reactions with the initial formation of mixed-valent $M^{II,I}$ monocations $[M_2(L)_2]^+$ (eq. 2). This is also supported by the electrochemical behaviour of related Ni and Pd complexes with planar $N_2(\mu_2\text{-}SR)_2$ coordination environments. The thiolate-bridged Ni^{II} complex $[Ni(pdmt)]_2$ (H_2pdmt = pyridine-2,6-dimethanethiol), for example, undergoes a one-electron reduction at $E_{1/2}$ = −1.21 V vs. SCE ascribed to the formation of the mixed-valence $Ni^{II,I}$ complex $[Ni(pdmt)]_2^-$[23], while the trimetallic compounds $[(NiL')_2Ni]^{2+}$ and $[(NiL')_2Pd]^{2+}$ [L′ = 1,5-bis(mercaptoethyl)-1,5-diazacyclooctane] are reduced at −0.77 and −0.88 V vs. SCE, respectively[24]. It is noted that complexes **5a**−**6b** are readily reduced by $NaBH_4$ in THF to afford dark-brown solutions. These solutions are assumed to contain the respective mixed-valent $M^{I,II}$ monocations $[M_2(L)_2]^+$. However, any attempts to isolate the $M^{I,II}$ species have not yet been successful.

$$[M_2(L)_2]^{2+} + e^- \rightleftharpoons [M_2(L)_2]^+ \quad (2)$$
(L = **4a**,**b**; M = Ni, Pd) $E^1_{1/2}$

Figure 4. Top: cyclic voltammogram of a solution containing **5a** and **6a** in a 1:1 molar ratio (solid line); bottom: square-wave voltammograms of a solution containing **5a** and **6a** in a 1:1 molar ratio (solid line) and of the same solution containing a slight excess of **6a** (dashed line)

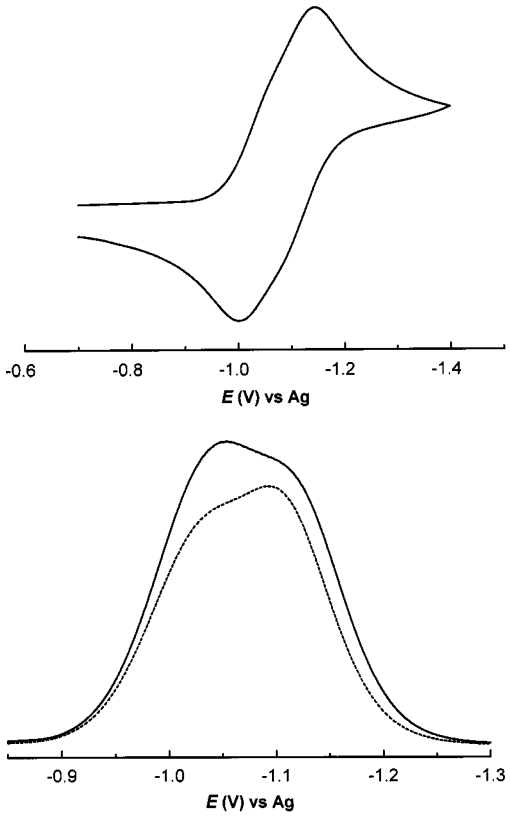


Table 2 shows that the redox potentials of the palladium complexes **6a**,**b** are only slightly shifted to more negative potentials when compared with those of the nickel complexes **5a**,**b**. Replacement of sulfur by selenium also does not dramatically shift the redox potentials, albeit both selenolate complexes are reduced at slightly less negative potentials than the thiolate complexes. It follows that the reduced species are equally well stabilized irrespective of the choice of N_2S_2 or N_2Se_2 coordination.

As previously established by NMR spectroscopy, the dinuclear complexes are quite stable in solution. These results are further confirmed by cyclic voltammetry. In Figure 4 (top), for example, is displayed the cyclic voltammogram of a mixture of complexes **5a** and **6a** in a 1:1 molar ratio in DMF solution. The CV reveals two overlapping reduction waves which correspond to independent reductions of **5a** and **6a**. Both reduction waves are clearly discernible in the corresponding square-wave voltammogram shown in Figure 4 (bottom).

In the present study it was shown that the tridentate amine-chalcogenolate ligands **4a**,**b** form dinuclear complexes with nickel and palladium. In contrast to many monodentate thiolate (or selenolate) ligands, the formation of complexes of higher or lower nuclearity was not observed. All complexes retain their solid-state structure in solution, where they do not undergo any exchange reactions. Furthermore, the existence as chalcogenolate-bridged dinuclear species in solution has allowed for reactivity studies. For example, all complexes undergo metal-centered electron-transfer reactions at potentials (−1.0 to −0.8 V vs. SCE) which are far more positive than those of mononuclear nickel or palladium complexes with N_2S_2 coordination environments ($E \approx -2.0$ V)[24]. Further studies will focus on the isolation, characterization, and an investigation of the chemical reactivity of these reduced species.

Experimental Section

General: Dichloro(1,5-cyclooctadiene)palladium(II)[25], benzylselenol[26], and compound **5a**[20] were prepared according to literature procedures. Compound **1** was prepared by oxidation of 2-bromo-1,3-dimethyl-5-(1,1-dimethylethyl)benzene with CrO_3 in acetic anhydride[27]. All other chemicals were commercially available. The solvents were predried with molecular sieves and freshly distilled from appropriate drying agents. All reactions were carried out under dry nitrogen with standard Schlenk techniques. − CHN analyses: Perkin Elmer Elemental Analyzer 240. − IR: Bruker IFS25 spectrophotometer (KBr pellets). − ^{1}H NMR, $^{13}C\{^1H\}$ NMR: Bruker AC 200 spectrometer. − ^{77}Se NMR: Varian Unity 300 spectrometer. Dibenzyl diselenide was used as external standard. ^{77}Se NMR chemical shifts are referenced to Me_2Se_2[28]. − Absorption spectra: Jasco V-750 UV/VIS/NIR spectrometer. − Cyclic voltammetry: EG&G Princeton Applied Research Potentiostat/Galvanostat Model 263 A. The cell contained a Pt working electrode, a Pt wire auxiliary electrode, and an Ag wire pseudo reference electrode. Concentration of solutions were 0.1 M in supporting

electrolyte (nBu$_4$NPF$_6$) and ca 1×10^{-3} M in sample. All potentials were scaled to ferrocenium/ferrocene as internal standard and converted to the SCE reference[29].

Benzyl (4-tert-Butyl-2,6-diformylphenyl)sulfide (**2a**): To a suspension of phenylmethanethiol (6.58 g, 53.0 mmol) and K_2CO_3 (8.29 g, 60.0 mmol) in DMF (80 ml) was added solid 1-bromo-4-*tert*-butyl-2,6-diformylbenzene (14.3 g, 53.0 mmol). After stirring the reaction mixture for 12 h, the crude product solidified upon dropwise addition of water (200 ml). The solid was isolated by filtration, washed with 100 ml of water, and dried in vacuum. The crude product was used without further purification, yield 15.4 g (93%), m.p. 78−80°C. − IR (KBr pellet): ν = 1720 cm^{-1} (CO). − ^{1}H NMR ($CDCl_3$): δ = 10.57 (s, 2 H, C*H*O), 8.13 (s, 2 H, aromatic H), 7.20-7.16 (m, 3 H, aromatic H), 6.86 (m, 2 H, aromatic *H*), 3.91 (s, 2 H, SCH_2), 1.35 (s, 9 H, CH_3). − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 191.3 (*C*HO), 153.5, 138.8, 137.4, 135.8, 130.4, 128.7, 128.6, 127.7, 43.7, 35.1, 30.8.

Benzyl (4-tert-Butyl-2,6-diformylphenyl)selenide (**2b**): Analogously to the preparation of **2a**, compound **2b** was prepared from phenylmethaneselenol (9.07 g, 53.0 mmol), K_2CO_3 (8.29 g, 60.0 mmol), and 1-bromo-4-*tert*-butyl-2,6-diformylbenzene (14.3 g, 53.0 mmol). The crude product was used without further purification, yield 16.6 g (87%), m.p. 79−81°C. − ^{1}H NMR ($CDCl_3$): δ = 10.51 (s, 2 H, C*H*O), 8.13 (s, 2 H, aromatic H), 7.16 (m, 3 H, aromatic H), 6.87 (m, 2 H, aromatic H), 3.93 (s, $^2J_{Se,H}$ = 16 Hz, 2 H, SeCH_2), 1.36 (s, 9 H, CH_3). − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 193.0 (*C*HO), 153.3, 138.4, 136.6, 133.1, 130.3, 128.4, 128.3, 127.2, 35.2, 34.9, 30.7.

Benzyl [4-tert-Butyl-2,6-di(hydroximinoformyl)phenyl]sulfide (**3a**): To a suspension of $NH_2OH \cdot HCl$ (2.78 g, 40.0 mmol) in $CHCl_3$ (100 ml) was added a solution of NEt_3 (4.05 g, 40.0 mmol) in $CHCl_3$ (50 ml). A solution of compound **2a** (6.25 g, 20.0 mmol) in $CHCl_3$ (100 ml) was added, and stirring was continued for 12 h. The organic phase was washed with 200 ml of water, separated, and dried with $MgSO_4$. The solvent was removed in vacuum to afford a pale yellow crystalline residue. This material was recrystallized from benzene, colorless crystals, 5.96 g (87%). − ^{1}H NMR ([D$_6$]DMSO): δ = 11.41 (s, 2 H, O*H*), 8.55 (s, 2 H, C*H*), 7.82 (s, 2 H, aromatic H), 7.20 (m, 3 H, aromatic H), 7.02 (m, 2 H, aromatic H), 3.85 (s, 2 H, SCH_2), 1.29 (s, 9 H, CH_3). − ^{13}C{^{1}H} NMR ([D$_6$]DMSO): δ = 151.6, 146.9, 137.1, 136.9, 128.9, 128.7, 128.3, 127.2, 123.6, 41.3, 34.5, 30.8.

Benzyl [4-tert-Butyl-2,6-di(hydroximinoformyl)phenyl]selenide (**3b**): Analogously to the preparation of **3a**, compound **3b** was prepared from **2b** (7.19 g, 20.0 mmol), $NH_2OH \cdot HCl$ (2.78 g, 40.0 mmol), and NEt_3 (4.05 g, 40.0 mmol) in $CHCl_3$, colorless crystals, 6.62 g (85%). − ^{1}H NMR ([D$_6$]DMSO): δ = 11.37 (s, 2 H, O*H*), 8.52 (s, 2 H, C*H*), 7.79 (s, 2 H, aromatic H), 7.16 (m, 3 H, aromatic H), 7.00 (m, 2 H, aromatic H), 3.89 (s, $^2J_{Se,H}$ = 16 Hz, 2 H, SeCH_2), 1.30 (s, 9 H, CH_3). − ^{13}C{^{1}H} NMR ([D$_6$]DMSO): δ = 151.5, 149.0, 138.0, 137.3, 128.4, 128.2, 126.8, 126.4, 123.6, 34.4, 33.4, 30.8.

2,6-Bis(aminomethyl)-4-tert-butylthiophenol (**4a**): A solution of **3a** (6.85 g, 20.0 mmol) in THF (50 ml) was added dropwise to a solution of sodium (6.05 g, 28.3 mmol) in liquid ammonia (100 ml). During addition the temp. was kept below −60°C by cooling with a dry ice/2-propanol bath. After the deep blue reaction mixture was stirred for further 3 h at −50°C, solid ammonium chloride was added to destroy excess reducing equivalents. After the ammonia was allowed to evaporate at atmospheric pressure, the remaining THF was evaporated in vacuum. The pale yellow solid was dissolved in 30 ml of water and the pH of the solution adjusted to 1 by addition of 1 M HCl. After stirring for 30 min, the precipitate was collected by filtration, and recrystallized from 1 M HCl to give 4.04 g (68%) of **4a**·2HCl as pale yellow needles. − ^{1}H NMR (CD_3OD): δ = 7.65 (s, 2 H, aromatic H), 4.44 (s, 4 H, CH_2), 1.37 (s, 9 H, CH_3). − ^{13}C{^{1}H} NMR (CD_3OD): δ = 153.6, 138.1, 129.6, 127.6, 43.7, 36.1, 31.6.

2,6-Bis(aminomethyl)-4-tert-butylselenophenol (**4b**): Analogously to the preparation of **4a**, compound **4b** was prepared by reduction of **3b** (7.79 g, 20.0 mmol) with sodium in liquid ammonia. Recrystallization from 1 M HCl afforded 3.98 g (58%) of **4b**·2HCl as yellow needles. − ^{1}H NMR (CD_3OD): δ = 7.68 (s, 2 H, aromatic H), 3.92 (s, 4 H, CH_2), 1.42 (s, 9 H, CH_3). − ^{13}C{^{1}H} NMR (CD_3OD): δ = 156.8, 139.6, 130.9, 129.9, 45.3, 36.2, 31.6.

Bis[2,6-bis(aminomethyl)-4-tert-butylselenophenolato]-dinickel(II) Tetraphenylborate·Acetonitrile·Methanol (**5b**): A solution of $Ni(ClO_4)_2 \cdot 6H_2O$ (731 mg, 2.00 mmol) in methanol (10 ml) was added to a solution of **4b**·$(HCl)_2$ (688 mg, 2.00 mmol) in methanol (10 ml). After the pale yellow solution was stirred for 10 min, 12.0 ml of a 0.5 M solution of NaOMe in methanol (6.00 mmol) was added. To the dark red solution was added a solution of $NaBPh_4$ (856 mg, 2.50 mmol) in methanol (2 ml). After the mixture was allowed to stand overnight, the microcrystalline residue was collected by filtration, washed with methanol (3 × 5 ml), and dried in air. The crude product was recrystallized from CH_3CN/MeOH (1:1), dark-red crystals, 1.07 g (78%), m.p. 206−209°C (decomp.). − $C_{72}H_{78}B_2N_4Ni_2Se_2 \cdot CH_3CN \cdot CH_3OH$ (1369.45): calcd. C 65.78, H 6.26, N 5.11; found C 65.46, H 6.30, N 4.84.

Bis[2,6-bis(aminomethyl)-4-tert-butylthiophenolato]-dipalladium(II) Tetraphenylborate·Acetonitrile·Methanol (**6a**): A solution of (COD)$PdCl_2$ (571 mg, 2.00 mmol) in methanol (10 ml) was added to a solution of **4a**·$(HCl)_2$ (595 mg, 2.00 mmol) in methanol (10 ml). After the pale yellow solution was stirred for 10 min, 12.0 ml of a 0.5 M solution of NaOMe in methanol (6.00 mmol) was added. To the dark-yellow solution was added a solution of $NaBPh_4$ (856 mg, 2.50 mmol) in methanol (2 ml). After the mixture was allowed to stand overnight, the microcrystalline residue was collected by filtration, washed with methanol (3 × 5 ml), and dried in air. The crude product was recrystallized from CH_3CN/MeOH (1:1), yellow crystals, 1.12 g (82%), m.p. 207−209°C (decomp.). − $C_{72}H_{78}B_2N_4Pd_2S_2 \cdot CH_3CN \cdot CH_3OH$ (1371.11): calcd. C 65.70, H 6.25, N 5.11; found C 65.39, H 6.27, N 5.02.

Bis[2,6-bis(aminomethyl)-4-tert-butylselenophenolato]-dipalladium(II) Tetraphenylborate·Acetonitrile·Methanol (**6b**): Analogously to the preparation of **6a**, compound **6b** was prepared from **4b** (688 mg, 2.00 mmol), (COD)$PdCl_2$ (571 mg, 2.00 mmol), 0.5 M NaOMe (12.0 ml, 6.00 mmol), and $NaBPh_4$ (855 mg, 2.50 mmol) in MeOH. The crude product was recrystallized from CH_3CN/MeOH (1:1), yellow crystals, 0.93 g (63%), m.p. 208−210°C (decomp.). − ^{77}Se NMR ([D$_6$]DMSO, 200 MHz): δ = 24.5. − $C_{72}H_{78}B_2N_4Pd_2Se_2 \cdot CH_3CN \cdot CH_3OH$ (1464.91): calcd. C 61.49, H 5.85, N 4.78; found C 61.43, H 6.03, N 4.72.

Crystal-Structure Determination: Crystals of **6a** suitable for X-ray structure analysis were obtained by recrystallization from an acetonitrile/methanol (1:1) solution. A yellow crystal of approximate dimensions 0.30 × 0.30 × 0.40 mm was selected and mounted on a glass fibre with a small amount of perfluoroether oil. After optical alignment at 193 K on an Enraf Nonius CAD4 diffractometer, the unit cell was determined from a least-squares fit of the setting angles of 25 carefully centered high-angle reflections. Crystal data and refinement details: $C_{75}H_{85}B_2N_5Pd_2OS_2$, M_r = 1371.11, monoclinic, space group $P2_1/n$, a = 22.130(4), b = 13.806(3), c = 23.672(5) A, β = 109.81(3)°, V = 6804.4 A^3, Z =

4, $\rho_{calcd.} = 1.34\ g\cdot cm^{-3}$, $\mu(Mo\text{-}K_\alpha) = 0.64\ mm^{-1}$, empirical absorption correction, transmission factors 0.89−0.98, 14383 reflections collected, 13297 unique reflections ($R_{int} = 0.0233$), 11448 observed reflections [$I > 2\sigma(I)$]. The structure was solved by direct methods (SHELXS-86)[30] and refined by full-matrix least-squares techniques against F^2 (SHELX-93). All non-hydrogen atoms were refined anisotropically except for the methyl carbon atoms of the disordered *tert*-butyl groups, which were refined isotropically. Hydrogen atoms were placed at calculated positions and were refined using a riding model with isotropic thermal parameters fixed at 1.2 times the equivalent isotropic U of the atom to which they were bonded. An isotropic split-atom model was applied for the disordered methyl carbon atoms. The multiplicities of the respective orientations C(31A)−C(33A), C(31B)−C(33B), C(41A)−C(43A), C(41B)−C(43B) were refined as follows: 0.58, 0.42, 0.51, 0.49. Final residuals: $R1$, $wR2$ [$F_o > 4\sigma(F_o)$]: 0.0369, 0.0955, $R1$, $wR2$ (all data): 0.0473, 0.1047, goodness-of-fit on F^2: 1.07, residual electron density: 0.771/−0.836 eA^{-3}. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101312. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax: int. code + 44(1223)336-033; E-mail: deposit@cam.ac.uk].

Keywords: Phosphorus heterocycles / P ligands / Transition metals / Carbonyl complexes

The complex chemical behaviour of 2-phosphaindolizines **1** (1,3-azaphospholo[1,5-*a*]pyridines) towards metal carbonyl compounds was studied. (η^1-2-Phosphaindolizine)$M(CO)_5$ complexes **2–4** (M = Cr, Mo, W) were formed from **1** and [(THF)$M(CO)_5$], the *cis*-$L_2Cr(CO)_4$ complex **5f** from **1f** and tetracarbonyl(norbornadiene) chromium(0). The reaction of 2-phosphaindolizines **1e**, **1f**, or **1g** with tricarbonyl(cycloheptatriene)molybdenum(0) or tricarbonyl(mesitylene)-tungsten(0) yielded σ-complexes of the types $L_2M(CO)_4$ or $L_3M(CO)_3$ rather than isolable π-complexes. In one case a strong upfield signal ($\delta^{31}P$ = 6.1) was observed with a coordination shift of $\Delta\delta$ = –161.7, which is typical for π-coordination. Prolonged reaction or work-up led, however, to dismutation yielding **1g** and the *fac*-$L_3Mo(CO)_3$ complex **6g**. X-ray structure analysis of **2a** indicates an increased 10π-delocalization compared with **1a** and a changed conformation of the acyl substituent. The influence of substituents and metals on the ^{31}P and ^{13}C complexation chemical shifts and coupling constants is discussed.

Introduction

The coordination behaviour of five-membered π-excess heterocycles has found considerable interest[1][2][3][4][5]. Mono-, di-, and triphosphole anions exhibit different coordination modes but, like cyclopentadienyl anions, they preferably form η^5-complexes[1][2][6] emphasizing the similarities of P=C and C=C structural units[7]. Pyrroles and pyrrole anions also form various types of complexes with π- and σ-coordination. Simple sandwich or η^5-coordinate (tricarbonyl)transition metal(0) complexes of pyrroles or pyrrole anions, however, need sterical stabilization by suitable substituents[4]. Thus, tricarbonyl(η^5-pyrrole)chromium(0) complexes belong to the most labile π-complexes with benzene-like ligands, reacting even with THF or benzene by ligand substitution[8], in sharp contrast to the η^5-phosphole or η^5-arsole complexes. 1*H*-1,3-azaphospholes and their anions, contain both two-coordinate phosphorus and three-coordinate nitrogen; they are aromatic 6π-systems even in the neutral state and, according to the P=C/C=C-similarity principle, should resemble the pyrroles[9][10]. There are several studies on azaphospholes and annelated azaphospholes[10][11][12] but very little is known about their behaviour in complex formation. Only two η^1-$LCr(CO)_5$ complexes with the ligands 2-phenyl-1,3-benzazaphosphole[13] and 2-phosphaindolizine[14] have been reported, which exhibit even lower ^{31}P-coordination shifts than related η^1-di- and -triazaphosphole[11][15] and η^1-phosphabenzene complexes[16] with $sp^2(p_\pi)$ hybridized phosphorus. This may be viewed in association with the reduced σ- and the increased π-charge density at phosphorus[10][14] in these π-excess heterocycles. These various aspects prompted us to investigate complexation reactions of neutral and anionic 1,3-azaphospholes or more easily accessible annelated representatives thereof and to study the preferred coordination mode and possible alternatives. We report here on reactions of 2-phosphaindolizines[14][17][18] with group VI metal carbonyl complexes and the characterization of the complexes by NMR and, for **2a**, by X-ray structural analysis.

Results and Discussion

Synthesis of Phosphaindolizine Carbonyl Complexes

Various substituted 2-phosphaindolizines **1** bearing an electron-withdrawing substituent R^2 such as acyl, carbalk-

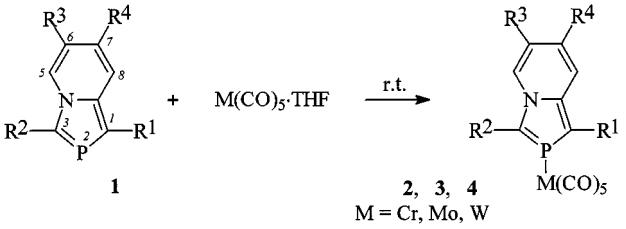
oxy or *p*-nitrophenyl in 3-position and a further substituent (Me, *n*Bu or Ph) in position 1, 6, or 7 were treated at room temperature with [(THF)M(CO)$_5$] (M = Cr, Mo, W). This led to selective formation of (η^1-2-phosphaindolizine)M(CO)$_5$ complexes **2**–**4**. The carbonyl or nitro groups did not interfere. Extractive purification or recrystallization of the crude products with hexane afforded powdery or crystalline, analytically pure, pale to dark yellow complexes. They were characterized by ^{31}P (Table 1), ^{1}H (Table 2), and ^{13}C NMR (Table 3) as well as by infrared spectroscopy (Table 4) and (for **2a**) by X-ray structural analysis (Figure 1). The spectroscopic data and structure are discussed below.

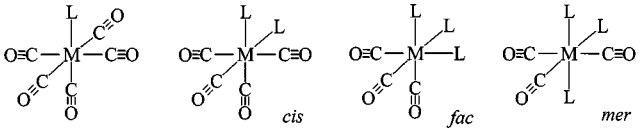
The reaction of **1e** with [(THF)Cr(CO)$_5$] to **2e** (δ^{31}P = 190.6) was accompanied by formation of a smaller amount of the tetracarbonyl bis(phosphaindolizine) complex **5e** (δ^{31}P = 201.5). Recrystallization of the crude product afforded, however, only pure **2e**. The synthesis of tetracarbonyl bis(phosphaindolizine) complexes can be achieved by refluxing **1** with tetracarbonyl(norbornadiene)chromium(0) in petroleum ether. In this way, **1f** gave an orange-yellow mixture of two complexes, **2f** (δ^{31}P = 190.8) and **5f** (δ^{31}P = 202.3). Recrystallization from hexane gave **5f**. Structure elucidation is based on ^{13}C and ^{1}H NMR investigations. The appearance of two triplets of equal intensity in the ^{13}C-NMR spectrum at δ = 217.0 [$^2J(^{31}P\text{-}^{13}C)$ = 17.2 Hz, *cis* CO] and δ = 224.0 ($J_{AX} + J_{A'X}$ = 20.2 Hz, *trans* CO) besides the signals for the ligand indicates the presence of two equally populated types of carbonyl groups and thus proves **5f** to be the tetracarbonyl-*cis*-bis(η^1-2-phosphaindolizine)chromium(0) complex. It should be mentioned that the *cis*-L$_2$M(CO)$_4$ isomers were also formed preferentially in the reaction of triphenylphosphabenzene with tetracarbonyl(norbornadiene) complexes of group VI[16a] whereas thermal reactions of phosphanes and the metal hexacarbonyls provide mixtures of *cis* and *trans* complexes[19].

Scheme 1



1 **2, 3, 4** M = Cr, Mo, W

In view of the existence of σ- and π-coordination modes in carbonyl complexes of phosphabenzene[16][20][21], phosphole anions[1][2], and π-excess heterocycles such as pyrrole[3][4][5], we tried to obtain η^5-2-phosphaindolizine π-complexes. However, isolable π-complexes were obtained neither on prolonged irradiation by a high-pressure mercury lamp, e.g. of **4b** in hexane, nor on heating, nor from the reactions of 2-phosphaindolizines **1e**, **1f**, or **1g** with tricarbonyl(cycloheptatriene)molybdenum(0) or tricarbonyl(mesitylene)tungsten(0). Instead, a variety of σ-complexes of the types L$_2$M(CO)$_4$ or L$_3$M(CO)$_3$ were formed.

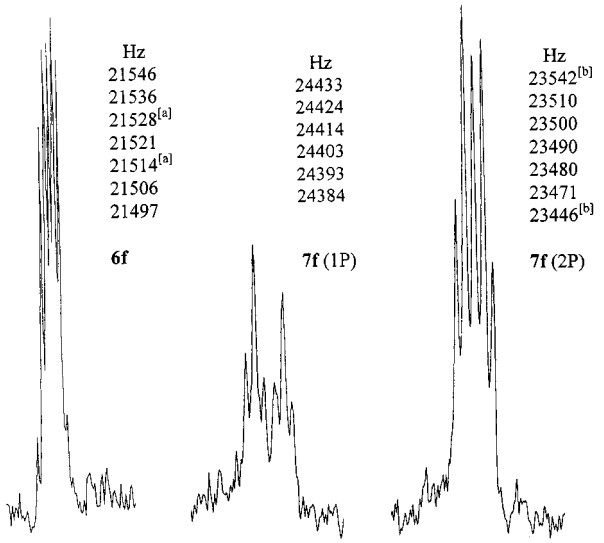


2, 3, 4 **5e, f** (M = Cr) **6e** (M = W) **6f, g** (M = Mo) **7g** (M = Mo)

Solely during the reaction of excess **1g** with tricarbonyl(cycloheptatriene)molybdenum(0) in tetrahydrofuran at room temperature could a strong upfield signal at δ^{31}P = 6.1 with a coordination shift of $\Delta\delta$ = −161.7 be observed, which is close to the phosphorus resonance δ^{31}P = 4.3 and $\Delta\delta$ = −173.9 of tricarbonyl-η^3-(2,4,6-triphenylphosphabenzene)chromium(0)[20]. On prolonged reaction or attempted isolation this signal disappeared, however, and only **1g** and the *fac*-L$_3$Mo(CO)$_3$ complex **6g** (δ^{31}P = 181.2) were detected. This suggests formation of a little stable π-complex that underwent dismutation. Curiously, if the reaction was performed in a 1:1 ratio using the same solvent and reaction conditions, the isomeric *mer*-L$_3$Mo(CO)$_3$ complex **7g** [δ^{31}P = 196.3, d, 2 P$_{trans}$; 203.8, t, 1 P$_{cis}$; $^2J(^{31}P\text{-}^{31}P_{cis})$ = 9.3 Hz] was obtained. Formation of **7g** was also observed if CDCl$_3$ was used as solvent. Attempts at extractive purification or reaction in refluxing ether/hexane furnished a mixture of **6g** and **7g**. The structure assignment is supported by proton-coupled phosphorus spectra. In **6g** the proton coupling with the initial phosphorus singlet led to a symmetric multiplet with seven resolved lines, lines 1 and 7 being weak, lines 3 and 5 broad. A calculated spectrum[22] with δ^{31}P = 173.13, $^2J(^{31}P\text{-}^{31}P)$ = 30 Hz and ^2J(PH1) = 30.8 Hz is in good accordance with the experimental coupling pattern. It consists of 9 inner lines, two pairs of which lie close together to form the experimental lines 3 and 5. Weak outer lines are hinted at in the spectrum by a raised base line. In **7g** the P$_c$ triplet becomes a double triplet by coupling with the H-1 proton within the ligand, while the doublet corresponding to the P$_{trans}$ ligands is split into a multiplet with five strong lines. A simulation using $\delta^{31}P(C_6D_6)$ = 193.34, 200.90, $^2J(^{31}P\text{-}^{31}P_{cis})$ = 9.3 Hz, $^2J(^{31}P\text{-}^{31}P_{trans})$ = 41 Hz and ^2J(PH1) = 30.8 Hz (δ_{H1} = 6.38) fits with the experimental spectrum (Figure 1). Since ^2J(PH1) is similar to the respective coupling in **3g** (31.5 Hz) and $^2J(^{31}P\text{-}^{31}P)$ generally larger in *trans* than in *cis* complexes these values seem reasonable.

In the reaction of **1f** with tricarbonyl(cycloheptatriene)-molybdenum(0), initial formation of probably **6f** was observed by a singlet at δ^{31}P = 178.9 and a line form of the proton-coupled phosphorus multiplet resembling rather a *fac*-L$_3$Mo(CO)$_3$ than a *trans*-L$_2$Mo(CO)$_4$ coupling pattern. However, this complex proved to be unstable in extractive work-up and subsequently underwent dismutation yielding the LMo(CO)$_5$ complex **3f** (δ^{31}P = 169.3), which could be isolated in spectroscopically and analytically pure form (Tables 1–4). Prolonged heating of **1e** with tricarbonyl(mesitylene)tungsten(0) in THF afforded a mixture of **6e** [δ^{31}P = 149.6, $^1J(^{31}P\text{-}^{183}W)$ = 265 Hz, multiplet with five

Figure 1. Proton-coupled phosphorus spectra of **6f** (left) and **7f** (middle and right)



[a]Each two unresolved lines (calculated 21528, 21530; 21514, 21512), of which only the stronger one is seen. – [b] Small lines (calculated 23541, 23532; 23440, 23449) are superimposed by noise.

broad lines by ^{31}P-^{1}H coupling] and **4e** (δ = 140.2, quartet by ^{31}P-^{1}H coupling).

The phosphaindolizine carbonyl complexes are less stable than phosphane carbonyl complexes and are attacked by water and by air, slowly in the solid state and more rapidly in solution. In a moist $CDCl_3$ solution of **4a** we observed the phosphorus resonance of **1a**. After four days, signals of **1a** and an addition product ($\delta^{31}P$ = 128.5) are exhibited (intensity 1:2) and after a further day all of **1a** and a part of the addition product was decomposed to give a hydrolysis product with $\delta^{31}P$ = 21.8. The volatility is low but sufficient to record EI mass spectra of the complexes $LM(CO)_5$. For **2f**, **3f**, **4e** and **4h** the molecular ion peaks M^+ were observed. The appearance of $[M - CO]^{+\cdot}$, $[M - 2\ CO]^{+\cdot}$, $[M - 3\ CO]^{+\cdot}$, $[M - 4\ CO]^{+\cdot}$ and $[M - 5\ CO]^{+\cdot}$ peaks indicates primary decomposition by the successive loss of carbon monoxide molecules from the $LM(CO)_5$ moieties. Further fragmentation follows similar pathways as for the free ligand[18].

Spectra of Phosphaindolizine $M(CO)_5$ Complexes and Structural Aspects

Phosphorus NMR: Preliminary reports of two $Cr(CO)_5$ complexes of annelated 1,3-azaphospholes, 2-phenyl-1,3-benzazaphosphole[13], and a 2-phosphaindolizine[14], had indicated small ^{31}P-coordination shifts of $\Delta\delta$ = 4.4 and 7.5, respectively. The larger body of data for **2–4** (Table 1) now reveals a much broader range of $\Delta\delta^{31}P$ and allows a comparison with $LM^{VI}(CO)_5$ complexes of phosphane and heterocyclic σ^2-phosphorus ligands. The coordination shift in complexes $R_3PM^{VI}(CO)_5$ becomes smaller with increasing group electronegativity of R, for $Hal_3PM^{VI}(CO)_5$ even negative[23][24][25][26]. η^1-Complexes of σ^2-phosphorus compounds possessing a higher s-character at phosphorus (sp^2 hybridization) may be compared with complexes of electron-poor phosphanes, which are weak σ-donor but more efficient π-acceptor ligands. In fact, $\Delta\delta^{31}P$ of the 2-phosphaindolizine complexes **2–4** is somewhat lower than $\Delta\delta^{31}P$ of $(MeO)_3PM^{VI}(CO)_5$[26][27] and similar to the η^1-phosphabenzene complexes 2,4,6-$Ph_3C_5H_2PM^{VI}(CO)_5$[16]. The electron-withdrawing effect of nitrogen and -M groups in α-position to phosphorus is partly compensated by the π-excess character of the 1,3-azaphosphole ring. The stronger upfield coordination shifts of the pivaloyl and phenacyl derivatives **a**-**d** may be attributed to the changed conformations with increased anisotropy and reduced –M effects on phosphorus as compared to the free ligand. The one-bond ^{31}P-^{183}W couplings of **4** (253–268 Hz) are larger than those in (triorganophosphane)$W(CO)_5$ complexes which, however, increase with the group electronegativity of R in $R_3PW(CO)_5$[23][24][25][26].

Proton NMR: The chemical shifts and almost all coupling constants of free ligands **1a–h**[14][17][18] and their complexes (Table 2) in $CDCl_3$ are very similar. Thus the differences of respective δ values of the complex **2e** and the ligand **1e** in $CDCl_3$ are less than 0.13. However, a strong influence on the proton resonance is exerted by deuterobenzene. Almost all signals of phosphaindolizine protons in **2–4** are upfield shifted by $\Delta\delta$ = 0.6 to 1.1 in C_6D_6 as compared to the ligands in $CDCl_3$. Methyl groups in position 7 and 1 are also affected, but to a lower extent. Phenyl groups are at most slightly influenced, indicating stacking interactions between C_6D_6 and the phosphaindolizine ring. The lack of an upfield shift of H-5 in the 3-carbalkoxy derivatives **3e**, **4e**, **2f**, and **3f** can be attributed to a superimposed deshielding anisotropy effect of the carbonyl group of COOR (R = Me, Et). Another exception, the extreme increase of δ(H-5) in **2**a ($\Delta\delta$ = 2.75), **4a** ($\Delta\delta$ = 2.34), and **5a** ($\Delta\delta$ = 2.58) compared to **1a** in $CDCl_3$, is associated with a change in conformation of the 3-pivaloyl substituent which is also found for the solid state. In crystalline **1a**, the acyl group is arranged nearly coplanar to the ring system (torsion angle P–C1–C=O 178°) with the *tert*-butyl group at the P-side, whereas in the chromium complex **2a** the latter is oriented to the N-side of the azaphosphole ring, adopting a staggered conformation (see below). This arrangement shields the proton in position 5. Concerning proton couplings, the only marked changes between **1** and **2–4** are the solvent-independent increase of the magnitude of ^3J(PH) involving the 1-methyl protons by ΔJ = 3.7 to 5.3 Hz, slightly increasing from chromium to tungsten and from the 3-pivaloyl to the 3-carbalkoxy derivatives, and the decrease of the magnitude of $^2J(^{31}P$-$^{1}H)$ of the protons in 1-position of **2b**, **4b**, **4d**, and **3g** relative to the respective ligands by 7–8 Hz.

Carbon NMR: In contrast to organometallic compounds, phosphane complexes have not been extensively investigated with respect to the impact of coordination on carbon chemical shifts and couplings in the ligands[23][24][25]. In the ^{13}C NMR spectra of **2–4** (Table 3) we observed *trans* ^{13}CO (δ = 197-225) at lower field than *cis* carbonyls (δ = 194–215) and for both an increasing shielding in the series

Cr, Mo, W. This can be seen e.g. for the series **2e**, **3e**, **4e** where each Δδ is about 10. The magnitude of the two-bond coupling with the phosphorus decreases for *cis* carbonyls in the order Cr, Mo, W pentacarbonyl (ca. 17, 12, 9 Hz, respectively) and increases with the metal radii for the respective *trans* carbonyls (ca. 4 << 32 , 32 Hz), causing small *trans* couplings in chromium carbonyl P-complexes. Marked differences in some carbon chemical shifts and coupling constants occur also between free and coordinate phosphaindolizines and can be attributed to steric and electronic effects. The solvent influence, in contrast to proton NMR data, is essentially negligible as can be seen, e.g., by the very small differences of $\delta^{13}C$ (< 0.6) and $J(^{31}P\text{-}^{13}C)$ (≤1) of **4b** in $CDCl_3$ and C_6D_6. The upfield coordination shift for C-5 and the opposite change for C-3 and the 3-carbonyl groups in **2a** and **4a**, not observed in other derivatives, are attributed to the distortion of the 3-pivaloyl group, causing enhanced shielding of C-5 by the *tert*-butyl group and reduced π-charge density at C-CO by loss of delocalization compared to the coplanar free ligand. Marked coordination shifts for C-5 are found in the phenacyl derivatives, nearly no effect for **3c**, shielding for **4b** and deshielding for **4d**, whereas δ(3-CO) is slightly influenced by the coordination, suggesting a torsion of the phenyl ring around the C−C(O) axis to give the minimum energy arrangement. A general upfield shift on coordination for C-1 and, except for **2a** and **4a**, also for C-3, with a slight increase from chromium to tungsten, may be assigned to electronic as well as steric influences, viz. the change in hybridization of phosphorus, back-bonding and steric shielding by the $M(CO)_5$ group. The same holds to an reduced extent for the α-C atoms of the substituents at C1 and C3, reflecting inductive effects. The lack of noticeable shift differences for C6 to C9 in free and coordinated ligands suggests that back donation, ascribed to $(d_M\text{-}\pi^*)\pi$ bonding[25], has a rather localized effect. Indeed, according to PM3 cal-

culations[28] phosphorus has the highest coefficient in the LUMO (π*-orbital) of 2-phosphaindolizine (ε = −0.77 eV, c^2 = 0.50) and is separated by nodal planes from C1 and C3.

A strong decrease in $^1J(^{31}P\text{-}^{13}C)$ coupling constants is observed by complexation. For C1 and C3 one-bond $^{31}P\text{-}^{13}C$ coupling constants are in the range 18−30 Hz and 10−37 Hz as compared to 38−44 and 45−59 Hz, respectively, in the free ligands[14][17][18]. The absolute magnitude of $^1J(^{31}P\text{-}^{13}C3)$ increases with the electron-withdrawing effect of the 3-substituent R^2 in the order C_6H_4-4-NO_2 << COOEt < COOMe ≈ or < COPh ≈ CO*t*Bu. The much lower one-bond couplings in the complexes may be attributed to the participation of the s-orbital in the hydridization of phosphorus. The smaller differences between $^1J(^{31}P\text{-}^{13}C1)$ and $^1J(^{31}P\text{-}^{13}C3)$ in the complexes reflect a higher degree of delocalization and aromaticity than in the ligands themselves. This is consistent with nearly equal P−C bond lengths in **2a**, whereas they differ in **1a**. In rounding off this section it should be mentioned that two-bond couplings are also reduced on complexation, $^2J(^{31}P\text{-}1\text{-}^{13}CH_3)$ larger than $^2J(^{31}P\text{-}^{13}C9)$ and $^2J(^{31}P\text{-}3\text{-}^{13}CO)$, whereas $^3J(^{31}P\text{-}^{13}C8)$ are usually increased.

X-ray Analysis of 2a

X-ray structure analysis of the $Cr(CO)_5$ complex **2a** (Figure 2) shows a planar ring system (mean deviation 3 pm) with trigonal planar coordination at phosphorus; the metal lies only slightly outside the plane (12 pm). The endocyclic angle at phosphorus in the rigid five-membered ring is not greatly affected by the steric requirements and thus only slightly opened, from 91.9(2)° in **1a**[18] to 93.5(1)° in **2a**. The P−C bond lengths become more equal [172.4, 171.7(2) pm] on complexation than in the free ligand [174.7(3), 170.8(4) pm] and on average shorter (172.1 versus 172.8 pm) indicating more effective delocalization. The rotation of the pivaloyl group from a coplanar arrangement (dihedral angle P−C1−C=O 178°) in **1a** to a staggered conformation with ϑ(P−C1−C9−O1) = 45.5° in **2a** prevents the strong -M interactions possible in **1a** and is certainly an important factor in the increase in aromaticity. Another factor may be the change in hybridization from p^2 to sp^2

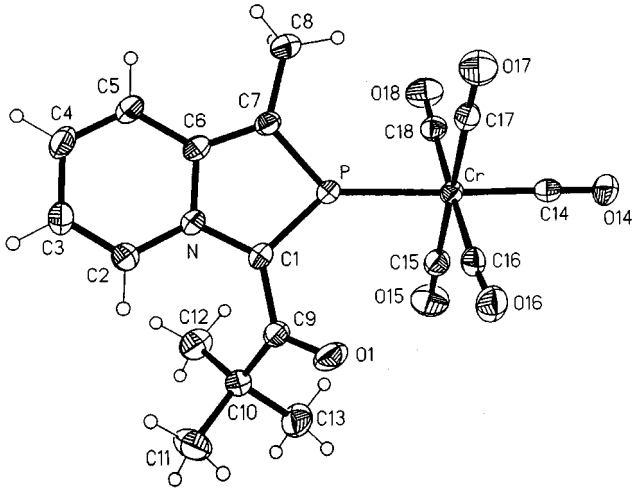
Figure 2. Structure of **2a** in the crystal. Ellipsoids represent 50% probability levels. H atom radii are arbitrary[a]



[a] Selected bond lengths [pm] and angles: Cr−C(14) 187.0(3), Cr−C(16) 189.8(3), Cr−C(15) 190.0(3), Cr−C(18) 190.3(3), Cr−C(17) 190.6(3), Cr−P 232.50(14), P−C(7) 171.7(2), P−C(1) 172.4 (2), C(1)−N 138.2(3), N−C(6) 140.4(3), C(6)−C(7) 138.7(3); C(1)−P−Cr 135.95(8), C(7)−P−Cr 130.47(8), C(7)−P−C(1) 93.51(11), N−C(1)−P 109.6(2), C(1)−N−C(6) 113.7(2), C(7)−C(6)−N 113.2(2), C(6)−C(7)−P 109.9(2).

which makes the phosphorus more similar to carbon. In **2a** the Cr−P bond [232.50(14) pm] is slightly shortened compared to a variety of $R_3PCr(CO)_5$ and phosphaalkene $Cr(CO)_5$ complexes (235-245 pm)[29] and also the Cr−C bond of *trans*-CO [187.0(3) pm] is shorter (*trans* effect) by 3 pm than those of *cis*-CO (average 190.2 pm). Finally, it should be mentioned that the averaged P−Cr−C angles of *cis*-and *trans*-carbonyls are 90.2° and 178.4°, respectively, corresponding closely to ideal octahedral geometry around chromium.

Funding by the *Deutsche Forschungsgemeinschaft* and financial support by the *Fonds der Chemischen Industrie*, Germany, is gratefully acknowledged. Furthermore, we appreciate the help by Dr. *M. K. Kindermann* and *B. Witt* for numerous NMR measurements, I. *Stoldt* for IR and Dr. *A. Müller* for mass spectra.

Experimental Section

General Comments: All reactions were carried out under a dry argon atmosphere using the Schlenk technique. − NMR spectra were recorded on Bruker ARX 300 (^{31}P-NMR at 121.5 MHz, ^{1}H-NMR at 300.1 MHz and ^{13}C-NMR at 75.5 MHz). The chemical shifts refer to 85% H_3PO_4 (external) or TMS (internal). − Mass spectra were recorded on AMD 40(intectra), IR spectra on System 2000 of Perkin-Elmer. − The synthesis of the 2-phosphaindolizines **1a-h** was recently reported[14][17][18]. [(THF)M(CO)$_5$] were freshly prepared before use[30], tetracarbonyl(norbornadiene)chromium(0) was synthesized by refluxing chromium hexacarbonyl with norbornadiene in light petroleum[31]. Tricarbonyl(cycloheptatriene)molybdenum(0) and tricarbonyl(mesitylene)tungsten(0) were commercially available and used without further treatment. Melting points of complexes are uncorrected and were determined in a capillary under argon.

Reaction of 2-Phosphaindolizines **1** *with THF·M(CO)$_5$* (**2**, **3**, **4**) − *General Procedure:* A solution of 2.0 mmol of metal hexacarbonyl [440 mg of $Cr(CO)_6$; 704 mg of $W(CO)_6$ or 528 mg of $Mo(CO)_6$] in 200 ml of oxygen-free THF was irradiated using a high-pressure mercury photo lamp with continuous stirring and monitoring of the volume of CO evolved. [If with $Mo(CO)_6$ the reaction became slower, the irradiation was interrupted and argon was bubbled through the solution to diminish the CO concentration, using a separate outlet.] After evolution of 2 mmol (44.8 ml) of CO the irradiation was stopped. The [(THF)M(CO)$_5$] solution was added to a solution of the respective 2-phosphaindolizine **1** (2.0 mmol) in THF and stirred overnight at room temperature. The solvent was removed in vacuo and the residue extracted with hexane (2 × 50 ml). Shining crystals were obtained on leaving the concentrated hexane extract (10−15 ml) in a refrigerator (−20°C). If no crystals separated, the solvent was removed completely to obtain yellow to orange powdery complexes. **2a**, **b**, **e**, **3a**, **c**, **e**, **g**, **4a**, **b**, **d**, **e** and **h** were synthesized in this manner. In case of the reaction of **1e** with [(THF)Cr(CO)$_5$], formation of some **5e** was observed in addition to **2e**. On recrystallization from hexane pure **2e** was obtained. NMR-spectroscopic data are given in Tables 1-3, substance and IR data in Table 4.

Reaction of **1f** *with Tetracarbonyl(norbornadiene)chromium(0)* (**2f** *and* **5f**): 207 mg (1.0 mmol) of **1f** was refluxed with 256 mg (1.0 mmol) of tetracarbonyl(norbornadiene)chromium(0) in petroleum ether (50 ml, b.p. 100−120°C) for three hours. The colour of the solution changed from yellow to orange. The reaction mixture was filtered, and the filtrate placed in a refrigerator (ca. −20°C). Yellow-orange crystals consisting of **2f** (δ^{31}P = 190.8) and **5f** (δ^{31}P = 202.3) precipitated. For ^{1}H- and ^{13}C-NMR data see Tables 2 and 3. Extraction of the mixture with hexane afforded spectroscopically pure **5f**, yield 18%, m.p. 135−137°C.

Reactions of **1g** *with Tricarbonyl(cycloheptatriene)molybdenum(0)* (**6g** *and* **7g**) − *A*: 236 mg of **1g** (1.35 mmol) and 123 mg (0.45 mmol) of (cycloheptatriene)Mo(CO)$_3$ were dissolved in THF. ^{31}P NMR (THF/[D$_8$]THF) spectra were recorded (i) after 18 hours and (ii) after 2 days at room temperature. In the first case we observed signals at δ (rel.int.) = 6.1 (65), 11.4 (12), 167.8 (85) **1g** and 181 (8) **6g**, in the second case only at δ (rel.int.) = 167.8 (110) and 181.2 (20).

B: 130 mg (0.75 mmol) of **1g** was stirred for 2 days with 203 mg (0.75 mmol) of (cycloheptatriene)Mo(CO)$_3$ in THF (40 ml) at room temperature. ^{31}P NMR (THF/[D$_8$]THF) control showed only signals of **7g**, δ = 196.3, d; 203.8, t; $^{2}J(^{31}P\text{-}^{31}P)$ = 9 Hz, intensity ratio 2:1. Similarly, **7g** is formed preferentially in $CDCl_3$.

C: 120 mg (0.69 mmol) of **1g** was refluxed for 2 days with 188 mg (0.69 mmol) of (cycloheptatriene)Mo(CO)$_3$ in ether/hexane (1:2). The precipitate was separated and washed with little hexane. The ^{31}P-NMR spectra of the solid, dissolved in C_6D_6, showed it to be a mixture of **7g** (δ = 193.3, d; δ = 200.9, t; $^{2}J(^{31}P\text{-}^{31}P)$ = 9.3 Hz) and **6g** (δ = 177.1, s); proton-coupled ^{31}P-NMR: **7g** δ = 193.3, dt, $^{2}J(^{31}P\text{-}^{1}H)$ = 30.5 Hz, δ = 200.8, multiplet; **6g** δ = 177.1, multiplet.

Reaction of **3f** *with Tricarbonyl(cycloheptatriene)molybdenum(0)* (**3f** *and* **6f**): 207 mg (1.0 mmol) of **1f** and 272 mg of (cycloheptatriene)Mo(CO)$_3$ was stirred in THF (50 ml) for two days. ^{31}P-NMR of the reaction mixture indicated **6f** (δ = 178.9) as major product, along with **3f** (δ = 169.3). THF was removed and the residue extracted with hexane. On concentrating the filtrate, analytically and spectroscopically pure **3f** was obtained as a yellow solid. For ^{1}H- and ^{13}C-NMR see Table 2 and 3, for substance data see Table 4.

Reaction of **1e** *with Tricarbonyl(mesitylene)tungsten(0)* (**4e** *and* **6e**): 111 mg (0.5 mmol) of **1e** was heated with 194 mg (0.5 mmol)

of tricarbonyl(mesitylene)tungsten(0) in THF (40 ml) for 20 hours at 45–50°C. ^{31}P NMR presents signals of **1e**, **4e**, and **6e** in an intensity ratio of 14:8:78. After removal of THF, the residue was extracted with hexane and filtered. Removal of the solvent in vacuo afforded a yellow solid that proved to be a mixture (m.p. 110–118°C) of **6e** as major product with some **4e**. Proton-coupled ^{31}P NMR: **6e** δ = 149.6, multiplet, $^1J(^{31}P\text{-}^{183}W)$ = 263 Hz; **4e** δ = 140.2, q, $^3J(^{31}P\text{-}^1H)$ = 17 Hz.

Keywords: Phosphenium cations / Cation stabilities / Electrophilicity / Carbene homologues / Computer Chemistry

The stabilities of low coordinated phosphorus cations can be expressed in the frame of the HSAB concept by the transferred charge density Δq(N) which a cation receives upon formation of a donor-acceptor adduct with a Lewis base N. This concept allows to differentiate between relative stabilities towards different reaction partners, and to compare the electrophilicities of phosphenium ions to those of isoelectronic carbenes and silylenes. An analysis of substituent influences on Δq(H) in cations $[P(R)_2]^+$ suggests an increasing stabilizing power of substituents in the series R = Cl < CH_3 < OH, SH < NH_2. The same ordering was derived from isodesmic hydride transfer reactions. Interpretation of population analyses suggests that the individual substituent contributions to cation stabilities result from a balance between π-donation into the empty p(P) orbital and electrostatic stabilization by polar P–R σ-bonds. A further stabilizing effect, which is of similar magnitude as in isoelectronic carbenes or silylenes, may arise from cyclic π-conjugation between a diaminophosphenium fragment and an adjacent double bond. Substituent effects influence further the nature of the frontier orbitals of phosphenium ions, resulting in orbital sequences which resemble those of carbenes, allyl anions, or phospholides, respectively. The absence of frontier orbital related changes in reactivity patterns suggests that in all reactions, including metal complex formation, phosphenium ions behave as purely *electrophilic* rather than *ambiphilic* species.

Introduction

Belonging to the first isolable compounds with (p-p)π bonding to phosphorus, amino-phosphenium ions, $[P(NR_2)(R')]^+$, and phosphanetriyl-ammonium ions, $[P{\equiv}N{-}R]^+$, have received continuous attention during the last 25 years and are still objects of current interest.[1] The results of extensive studies of chemical reactivities have coined the opinion that the cations are ambiphiles which have both nucleophilic and electrophilic properties. The electrophilic character comes to the fore in C−H- and C−C bond insertion reactions, cycloadditions, and complex formation with Lewis bases, while the nucleophilic properties are considered responsible for the formation of transition metal complexes.[1]

In contrast to the wealth of experimental studies, theoretical investigations of these cations are rare. Earlier ab-initio calculations on simple model systems ($[P(H)_2]^+$, $[P(H)(NH_2)]^+$, $[P(NH_2)_2]^+$) confirmed singlet ground states and revealed the stabilizing effect of conjugation between nitrogen lone-pairs and the empty p-orbital at phosphorus which resulted in a heteroallylic frontier orbital sequence for $[P(NH_2)_2]^+$.[1a][2] For selected cyclic cations, the issue of conjugation between amino(thioxo)phosphenium fragments and adjacent double bond systems to form "aromatic" π-systems was discussed.[3] Only recently, Schoeller et al. reported a first attempt to establish a relative scale of gas phase stabilities for selected cations from a comparison of hydride transfer reaction energies.[4] In addition, a discussion of molecular structures and frontier orbitals was presented which substantiated the isolobal relationship between phosphenium ions and carbenes, and between phosphanetriyl-ammonium ions (and the isolelectronic PO^+ and PS^+ cations) and (iso)cyanides.

Regarding that low coordinate phosphorus cations engage frequently in donor-acceptor interactions with nucleophilic counter ions or solvents,[1c] it becomes clear that in condensed phases their stability and electrophilicity are closely connected. It is the primary objective of this work to attempt an analysis of cation stabilities which not only covers a wider range of molecular structures, but also takes this effect explicitly into consideration. For this purpose, a concept is proposed which is based on a discussion of stability and electrophilicity in the frame of the extended HSAB concept.[5][6] The pivotal idea is to use the amount of charge transfer which a cation receives in the formation of a donor-acceptor adduct as a measure of its stability. In order to elucidate the origin of the stability differences, a discussion of population analyses is presented which suggests an interplay between mesomeric effects and electrostatic contributions associated with high P−R bond polarities. To highlight further the connection between electronic structure and reactivity, some comments on frontier orbital sequences and the "carbenic" nature of phosphenium ions will be made.

Results and Discussion

Stability and Electrophilicity of Low Coordinate Phosphorus Cations

Relative gas phase stabilities of phosphenium ions $[P(R^1)(R^2)]^+$ can be determined according to Schoeller et al. by comparing the energies ΔE_{GT} of the hydride transfer reaction of Eq. (1) (Scheme 1).[4] Formally, this reaction can be separated into two steps as described by Eq. (2a) and (2b). Since Eq. (2a) and ΔE_1 remain the same for different cations, ΔE_{GT} essentially quantifies the variation in hydride affinities, ΔE_2. In view of the fact that the stability of phosphenium ions in condensed phases is often limited by their tendency to form Lewis acid-base adducts with solvent molecules or counter ions [Eq. (3)],[1] of which the reaction with a hydride is just a special case, Schoeller's definition may easily be put in a more general form: relative stabilities of cations ***E*** (in condensed phases) are reflected in different energies ΔE_{Add} associated with the formation of covalent donor-acceptor adducts ***E*–*N*** with a given nucleophile ***N*** (counter ion or solvent).

Scheme 1

$$[P(R^1)(R^2)]^+ + PH_3 \longrightarrow HP(R^1)(R^2) + [P(H)_2]^+ + \Delta E_{GT} \quad \text{(Eq. (1))}$$

$$PH_3 \longrightarrow [P(H)_2]^+ + H^- + \Delta E_1 \quad \text{(Eq. (2a))}$$

$$[P(R^1)(R^2)]^+ + H^- \longrightarrow HP(R^1)(R^2) + \Delta E_2 \quad \text{(Eq. (2b))}$$

$$[P(R^1)(R^2)]^+ + |Nu \longrightarrow [Nu{\rightarrow}P(R^1)(R^2)]^+ + \Delta E_{Add}$$

E ***N*** ***E-N*** (Eq. (3))

On a first glance, this approach seems to offer no obvious advantage, since a concise evaluation of hydride or nucleophile affinities imposes more severe computational problems than calculation of the energies of isodesmic hydride transfer reactions.[7] However, as an estimation of *relative* stabilities requires only the correct evaluation of trends in adduct formation energies ΔE_{Add} rather than their true values, an approximate solution to the problem can be obtained on a much simpler level.

Thus, the formation of a donor–acceptor bond in the adduct ***E*–*N*** [Eq. (3)] induces a charge transfer Δq(N) from ***N*** to the phosphorus cation. Using the principle of electronegativity equalization,[5][8] Δq(N) can be approximated as $\Delta q(N) = (\chi^e - \chi^n)/(\eta^e + \eta^n)$. Here, $\chi^{e(n)}$ and $\eta^{e(n)}$ denote the absolute electronegativity and absolute hardness of the cation (nucleophile), whose operational definitions are $\chi = -(I + E)/2$ and $\eta = (E - I)/2$ (I = ionization potential, E = electron affinity) in the frame of the extended HSAB concept.[5] Within Hartree-Fock theory, χ and η may be approximated as $\chi = -(\varepsilon_{HOMO} + \varepsilon_{LUMO})/2$ and $\eta = (\varepsilon_{LUMO} - \varepsilon_{HOMO})/2$ by using Koopman's theorem.[6] It may be noted that, despite the severe deficiencies of this approximation,[9][10] qualitative trends in χ and η between related molecules are reproduced at this level with sufficient accuracy.[10][11]

If we compare the interactions of two cations with an arbitrary nucleophile (e.g. ***N*** = H^-), the less stable cation will receive a larger charge transfer and form a stronger bond. Presuming a monotonous relation between the transferred charge density Δq(N) and the donor–acceptor bond strength ΔE_{Add},[12] an increase in Δq(N) corresponds to an increase in ΔE_{Add} and thus a lower cation stability, and vice versa, so that Δq(N) values can in principle be used directly as indicators of relative stabilities.

In order to apply this concept we computed transferred charge densities Δq(H) for some 30 model cations with low coordinate phosphorus atoms, using hydride as an archetypal nucleophile. The studied systems (Scheme 2) include cyclic and acyclic phosphenium ions $[P(R^1)(R^2)]^+$ (R^1, R^2 = H, Ph, Cl, alkyl, alkoxy, thioxo, amino), the 1.3-bisphosphanyl-phosphapropenides and -phospholides **12**, **25** which are isolobal and isoelectronic to the diaminophosphenium ions **11**, **24**,[13] and the phosphanetriyl-ammonium ions **30–32**. Details on the calculations are given in the experimental section; the resulting values of Δq(H) are listed in Table 1, together with frontier orbital energies and the values of χ and η.

cation $[P(R^1)(R^2)]^+$ in the series R^1, R^2 = H < Cl < Me < SH, OH < Ph < NH_2 < C(H)PH_3. A general increase in stability is further observed upon replacement of hydrogens at an adjacent element E in EH_n-fragments by alkyl groups, and of $-CH_2CH_2-$ moieties in the five membered rings of cyclic cations by ethylene or phenylene units. On the whole, the order of relative stabilities of the model systems is in accord with interpretations of physical and chemical properties of experimentally known cations.[1]

Transferred charge densities for the interaction of phosphenium ions with a variety of anionic (e.g. halides) and neutral nucleophiles (NMe_3, PMe_3) can be computed straightforwardly. The results, which are not included here for the sake of shortness, give on the whole a similar account of relative cation stabilities as Δq(H) values. A detailed inspection reveals, however, some characteristic deviations which mirror a preference for "hard-hard" or "soft-soft" over "hard-soft" interactions in the sense of the HSAB concept.[5] Some examples involving the interaction of selected phosphenium ions with a hard (F^-) and soft nucleophile (I^-) are illustrated in Scheme 3. Thus, the similarity of Δq(F) for **14**−**16**, **19**, **22**, **28** suggests nearly identical stabilities towards F^-, whereas towards I^-, the softer cations with sulfur substituents receive a larger charge transfer Δq(I) (and are hence considered less stable) than cations with oxygen or nitrogen substituents. Still more pronounced variations are noted for **10**, **13** and **11**, **17′**, which display a reversed order of relative stabilities depending on whether the interaction of the cations with F^- or I^- is considered.

Extension of the concept to other species than phosphenium ions should further allow to compare the Lewis acid/base behavior of different types of electrophiles. As an example, the interaction of trimethylamine and -phosphane with cyclic diaminophosphenium ions and isoelectronic carbenes and silylenes was considered, (Scheme 4). The magnitude of Δq for the cations **22**, **24** reflects their electrophilicity and is in accord with the known tendency of phosphenium ions to form stable donor adducts.[1] In contrast, Δq values for the carbenes and silylenes **33**−**36** are close to zero, or even negative,[14] indicating that the electrophilic character is negligible. This is in line with experimental evidence for low π-acceptor capabilities and classification of these systems as *nucleophilic* carbenes (silylenes).[1c][15]

In order to compare relative stabilities derived from transferred charge densities with hydride transfer energies, we have also computed stabilization energies ΔE_{GT} for **1**−**32** at the MP2/6-31+g(d) level. The results are included in Table 1. According to a regression analysis, ΔE_{GT} and Δq(H) are connected by a linear relation (correlation coef-

Scheme 3. Comparison of transferred charge densities for the interaction of selected phosphenium ions with fluoride [$\Delta q(F^-)$] and iodide [$\Delta q(I^-)$] anions. Values of χ and η employed in the calculation of Δq were taken from table 1 for the cations; for the halide anions, the corresponding data of the neutral atoms given in ref.[5] were used

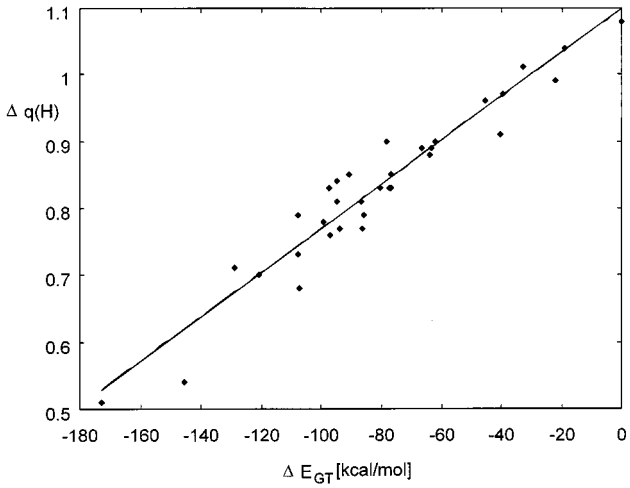
ficient $r = 0.96$, Figure 1). This suggests that despite some discrepancies in the assessment of the stability of individual cations, which are reflected in the scatter of the data, both scales give a similar account of the general trends which govern the stability of low coordinate phosphorus cations.

Electronic Origin of the Stability of Phosphenium Cations

Appealing features of the application of $\Delta q(N)$ to predict relative stabilities (and reactivities) are the use of a minimum number of parameters, and the possibility to distinguish between stabilities towards different reaction partners according to the HSAB concept. However, since the pivotally important quantities χ and η are molecular and not orbital properties, the origin of the stability differences remains obscure. In order to obtain further insight in the bonding situation of low coordinate phosphorus cations, we have attempted a more detailed analysis of the electronic structure based on the results of natural population analyses (NPA).[16]

Figure 1. Plot of $\Delta q(H)$ vs. ΔE_{GT} for **1**−**32** (solid circles) and result of a linear regression analysis [solid line, $\Delta q(H)_{regr} = 3.30 \cdot 10^{-3}$ $\Delta E_{GT} + 1.10$, correlation coefficient $r = 0.96$]



π-Interactions vs. σ-Bond Polarization: Most discussions on the origin of the stabilization of phosphenium ions focus on mesomeric interactions of the formally empty p-orbital at phosphorus with adjacent π-donors.[2][3][4] The varying extent of this π-donation in different cations may be estimated in a straightforward manner by comparing either the electron populations in the phosphorus p-orbital, $n_\pi(P)$, or the bond orders in the P−X bonds. A listing of the values of $n_\pi(P)$ as well as Wiberg bond indexes[16] for the phosphenium ions **1**−**29** is given in Table 2. For the simplest case, $[P(H)_2]^+$, $n_\pi(P)$ is nearly zero, indicating vanishing π-stabilization. Introduction of ER_n-groups at phosphorus induces partial population of the p-orbital via dative (E−P)-π-interactions (ER_n = Cl, OR, SR, NR_2), or hyperconjugation ($ER_n = CR_3$), and $n_\pi(P)$ increases in the order $ER_n = CR_3 < OR < Cl < NR_2 < SR$. The same order of increasing π-stabilizing capabilities emerges also from the comparison of Wiberg bond indexes.

Interestingly, the above mentioned ordering according to increasing degree of E−P π-stabilization differs markedly from the order of overall cation stabilities. Here, regardless if one refers to a comparison of $\Delta q(N)$ or ΔE_{GT} values, cations with NR_2- and OR groups should be more stable than analogous derivatives with SR- or Cl substituents, respectively. This discrepancy suggests that further influences beside mesomeric stabilization have a significant effect on cation stability. In order to understand the underlying mechanisms, a comparison of the bonding situation in phosphenium ions and carbenium ions of the type $[C(EH)_3]^+$ (E = chalcogen) appears useful. For the latter it

was shown recently,[17] that beside (E−C) π-donation also the polarity of the C−E bonds may add substantially to the stabilization energy. The effect is most pronounced for E = O, where the high σ bond polarity [$C^{(+)}-O^{(-)}$] overcompensates the O→C-π-electron shift. This leads to a net increase of charge separation in the C−O bond and results in a marked contribution of the Coulomb-term to the bond energy.

The assessment of a similar contribution to the stability of phosphenium ions $[P(E^1R_n)(E^2R_n)]^+$ becomes feasible from a comparison of the "electrostatic factors"

$$\varepsilon = 1/2 \sum_{i=1}^{2} \frac{q(P)\ q(E^i)}{r(PE^i)}$$

which characterize the average Coulomb stabilization associated with the presence of polar P−E bonds based on a simple point-charge model. A comparison of the listed values of ε in Table 2 reveals an increasing Coulomb stabilization in the order X = S ≈ Cl << N < O. If we assume that the overall cation stability is influenced by both Coulomb and π-donor contributions (which increase with n_π(P) in the order OH < Cl < NH_2 < SH), the higher stabilizing power of NH_2- with respect to OH- (which exert stronger Coulomb stabilization) or SH-groups (which are better π-donors) is consistently explained as the consequence of a balance of both effects. Likewise, the slightly higher stabilizing effect of a CH_3- as compared to a Cl-substituent is attributable to overcompensation of the lower π-donor capability of the former by a larger Coulomb stabilization.

A heuristic confirmation of this concept can be derived from a correlation analysis involving n_π(P), ε, and ΔE_{GT} as an indicator of overall cation stabilities. While a regression analysis between n_π(P) and ΔE_{GT} for the phosphenium ions **1−11**, **13−24**, **26−29** yielded a linear relation with a correlation coefficient $r = 0.77$, a nonlinear fit using both n_π(P) and ε as independent variables furnished the equation $E_{GT,regr} = -3(10) + 92(15)\ n_\pi(P) - 89(15)\ \varepsilon - 49(16)\ \varepsilon^2$, with a correlation coefficient $r = 0.88$. Despite the still substantial scatter of the data, it is apparent that the two parameter model gives a more concise account on phosphenium ion stabilities than the consideration of mesomeric effects alone.

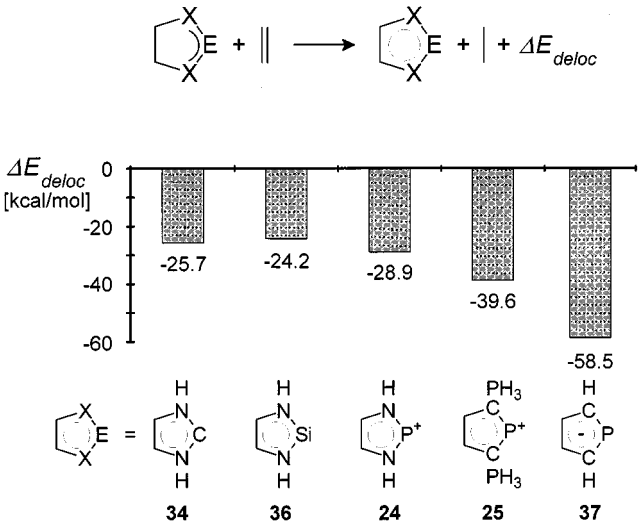
Cyclic π-Conjugation: An issue which attracted considerable interest and was debated rather controversially is the formation of delocalized 6(10)π-systems in cyclic cations such as **22−29**.[3][18][19][20] Positive evidence for the presence of conjugation of this type is provided both by the increase of n_π(P) and the decrease of Δq(H) (or increase of ΔE_{GT}, respectively) for **22 - 29** relative to their CC-saturated analogues **19−21** (cf. Table 1). The net energetic gain [e.g. $\Delta(\Delta E_{GT})$ 21.1 and 13.9 kcal/mol for **20/24** and **19/22**, respectively] is, however, much lower than the inherent mesomeric stabilization in the PE_2 fragment {E = N, S; $\Delta(\Delta E_{GT})$ 93.8 and 62.3 kcal/mol between $[P(H)_2]^+$ and $[P(NH_2)_2]^+$ or $[P(SH)_2]^+$}; it may rather be compared to the inductive stabilization which results from replacement of H in EH_n-moieties by alkyl groups {e.g. $\Delta(\Delta E_{GT})$ 13.7 kcal/mol for $[P(NH_2)_2]^+$ and $[P(NMe_2)_2]^+$}.

As we have demonstrated earlier for **25**, the energetic effects of cyclic π-conjugation may also be analyzed in terms of the reaction energy of the homodesmotic reaction of Scheme 5.[13] This approach is easily extended to a comparison of the π-electron structures in the isoelectronic carbene analogues **24**, **33**, and **35**. The value of ΔE_{deloc} in the cation **24** is higher (4−5 kcal/mol) than in **33** or **35**, but still notably lower than in **25** or the isolobal[13] phospholide anion **37** (Scheme 5). Without attempting to establish a quantitative scale, these results indicate that all three carbene analogues exhibit only weak aromatic character, even if cyclic conjugation in the cation **24** is somewhat more effective than in the neutral species **33, 35**.[21] Natural population analyses indicate further that the increase in n_π(P) in **24** relative to **20** results from a shift of π-electron density within the N_2P-unit, and not from a net transfer from the C_2 to the N_2P fragment. In a simple orbital picture, this corresponds to mixing of occupied and empty N_2P-π orbitals under perturbation by the additional double bond.

Frontier Orbital Considerations

Phosphenium ions are with regard to their reactivity generally considered as carbene analogues.[1][2] The justification for this hypothesis was derived from the similarity of the HOMO (phosphorus lone pair) and LUMO (empty p-orbital) in $[P(H)_2]^+$ (Figure 2a) and the parent carbene,

Scheme 5. Isodesmic reactions describing the interaction of heteroallylic $N_2E(C_2E)$-fragments in cyclic phosphenium ions, carbenes, silylenes, and phospholide anions with an adjacent double bond. Reaction energies ΔE_{deloc} were calculated at the MP2/6-31+g(d) + ZPE level. The value for **25** was taken from ref.[13]



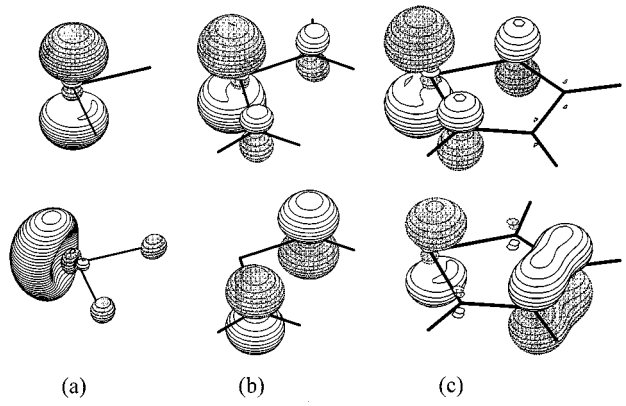
CH_2, which makes the two systems both isolobal and isoelectronic.[1][2]

Inspection of the frontier orbitals of cations **1**−**29** (Table 1) reveals that this analogy is not preserved in all cases. A true carbene analogue frontier orbital sequence is confined to cations with small to moderate E→P-π stabilization such as $[P(H)(X)]^+$ (X = any substituent) or $[P(NH_2)(Y)]^+$ (Y = Cl, CH_3, OH). The frontier orbitals of cations $[P(ER_n)_2]^+$ with two strong π-donor groups (ER_n = NH_2, NMe_2, SH) resemble in accord with earlier studies[2][4] those of an allyl anion (Figure 2b): the HOMO is an antisymmetric combination of p_π(E)-orbitals with a node at phosphorus, and the LUMO an antibonding π_3*-orbital. The "lone pair" at phosphorus corresponds to the HOMO-1 and lies 0.5−2.4 eV below the HOMO. The LUMO of the cyclic conjugated cations **22**−**29** is similar to the previous case, but the HOMO resembles now the highest occupied π-orbital of a phospholide anion[13] and has a large coefficient at phosphorus (Figure 2c). The highest σ-orbital with significant "lone-pair"-character lies 1.8−4.9 eV below the HOMO.

In the frame of frontier orbital theory, one can expect that such significant variations in the type of frontier orbitals imply concomitant changes in reactivity patterns. That this is actually not observed may be explained on the basis of a closer inspection of frontier orbital interactions for individual reactions. In the majority of known reactions which comprise oxidative additions and cycloadditions, phosphenium ions act as electrophiles,[1] and the dominant frontier orbital interaction involves the LUMO of the cation and the HOMO of the reaction partner. Since the largest lobe in the LUMO is always centered at the phosphorus-p-orbital, no changes in frontier orbital interactions or reactivity patterns are expected.

The most prominent reaction which supposedly reflects the nucleophilic character of phosphenium ions is the formation of transition metal complexes. The phosphorus-metal bonding can in this case be described as superposition of a dative P→M σ- and a retrodative P←M π-bond.[1c][22] An analysis of frontier orbital interactions must therefore consider both the HOMO(cation)-LUMO(metal) and LUMO(cation)-HOMO(metal) interactions, and the reactivity of the cation will be directed by the electron densities in *both* of its frontier orbitals.

Figure 2. MOLDEN[29] plot of the LUMO (top row) and HOMO (bottom row) of (a) $[P(H)_2]^+$ (**1**), (b) $[P(NH_2)_2]^+$ (**11**), and (c) [cyclo-$P(NH)_2(CH)_2]^+$ (**24**). The shown surfaces correspond to electron densities of (a) 0.14, (b) 0.10, and (c) 0.09, respectively



For "carbene analogue" cations such as **1** where the maximum electron density in both HOMO and LUMO occurs at phosphorus, the formation of dative P→M-σ- and P←M-π-bonds is straightforward. For "heteroallylic" cations such as **11**, the shapes of the frontier orbitals imply that a nucleophilic attack of the ligand at a transition metal should occur via the nitrogen,[23] and an electrophilic attack via the phosphorus. The observed formation of P-coordinated complexes[1] suggests therefore that the metal-ligand interaction is dominated by the LUMO(cation)-HOMO-(metal) contribution. Since the HOMO of the cation has a node at phosphorus, secondary interactions between LUMO(metal) and HOMO-1 (phosphorus lone pair) become important, leading to the same bonding description as before. It should be noted that, even if the results of this analysis agree with the generally acknowledged picture of phosphorus-metal bonding in phosphenium complexes[1], they suggest a different weighting of the two contributions: the dominant interaction is here the P←M π- rather than the P→M σ-contribution, and the electrophilic character of phosphenium cations commands even the reaction with transition metal substrates.[24][25]

In the cyclic cations **22**−**29**, the shapes of HOMO and HOMO-1 (which likewise resembles the HOMO-1 of a phospholide[13] and is very close in energy) suggest that a nucleophilic attack at a metal should favor side-on coordination via the π-electron system, while for an electrophilic attack a similar situation as in the previous examples prevails. So far, stable complexes of diazaphospholenium ions of either type are unknown, but the preference of bis-phosphonio-benzophospholides to form σ-complexes[1c] suggests

that the coordination properties may still reflect the electrophilic character of these cations.[26]

Conclusions

The results of the presented studies may be summarized as follows:

(1) Transferred charge densities Δq(N), which describe the shift of electron density upon formation of a dative bond between a low coordinate phosphorus cation and a nucleophile N, are an alternative to hydride transfer energies for the classification of relative cation stabilities. The evaluation of Δq(N) requires less computational effort, since an energy optimization of neutral reaction products in each single case is avoided. Further appealing prospects are the possibilities to discriminate between stabilities towards different nucleophiles which should allow to develop a more distinguished view on stabilities/reactivities in condensed phases, and to compare the electrophilicity of phosphenium ions with isoelectronic carbenes or silylenes.

(2) In addition to mesomeric E→P π-interactions, also the polarity of P−E σ-bonds exerts a relevant influence on the stabilities of phosphenium ions. In particular, the higher stabilizing effect of R_2N- as compared to RS-groups may be related to a balance of both contributions. The stabilities of heterocyclic cations with formal 6π-electron systems are further enhanced by cyclic conjugation. The energetic effect of this interaction is slightly higher than in the carbene or silylene system, but still significantly lower than the effect of N→P-π-interaction, or the electron delocalization energy in aromatic phospholide anions. As in aminocarbenes,[21] cyclic π-conjugation in aminophosphenium ions therefore amplifies the energetic stabilization by N→P-π-interaction, but is not the primary stabilizing factor.

(3) Depending on the substituent pattern at phosphorus, phosphenium ions exhibit different frontier orbital sequences which resemble those of carbenes, heteroallyl anions, or phospholide anions. The failure to observe any changes in reaction patterns suggests that the reactivity is in all cases determined by the LUMO of the cation. In other words: phosphenium ions that are isolobal to heteroallyl or phospholide anions exhibit carbene analogue reactivity patterns because they always react as electrophiles rather than as nucleophiles (or ambiphiles), even in the complexation of transition metals. This implies that despite the isoelectronic and isolobal relationship between diaminophosphenium ions and *nucleophilic* diaminocarbenes, the observed reactivity patterns are better comparable to those of *electrophilic* carbenes

Experimental Section

All calculations were made with the Gaussian 94 package of programs.[27] Molecular geometries of cations **1−32**, the corresponding hydrogen substituted neutral compounds, carbenes and silylenes **33−36**, and the nucleophiles Me_3P and Me_3N were first energy optimized at the HF/6-31+g* level. Frequency analyses at this stage of optimization revealed that all structures except **17′** represent local minima on the energy hypersurface. Starting from these geometries, further energy optimizations were then carried out at the MP2/6-31+g(d) level. The resulting final geometries were used for all subsequent calculations. The absolute electronegativity χ and absolute hardness η of **1−32**, Me_3P, and Me_3N were computed from orbital energies obtained with 6-31+g(d) basis sets. Because of the conceptual difficulties associated with the determination of electron affinities for anions,[5][28] the values of χ and η for the neutral atoms from ref.[5] were used for H^-, F^-, and I^-. Transferred charge densities Δq(N) were then computed as described in the text. Values of ΔE_{GT} and ΔE_{deloc} were computed according to Eq. (1) and (3) at the MP2/6-31+g(d) and MP2/6-31+g(d)+ZPE level, respectively (zero point corrections were derived from additional frequency analyses at the MP2/6-31+g(d) level). The values of orbital populations and Wiberg indexes for **1−29**, and the atomic charges required for the calculation of ε were obtained from natural population analyses[16] of MP2 electron densities. Electrostatic factors ε were calculated as described. Representations of frontier orbitals were generated with the program MOLDEN.[29]

[14] Negative values of Δq for **36** indicate the formation of adducts in which the silylene acts as a donor rather than an acceptor. The formation of such species is in accord with studies on the interaction of **36** with NH_3. Energy optimization at MP2/6-31+g(d) level revealed that a structure with a dative H_3N→Si interaction does not correspond to a minimum on the electronic hypersurface; the result of the optimization can be described as an adduct with a weak interaction between one NH moiety and the silylene π-system.

[23] A nucleophilic attack of this type is represented by the dimerization of homologous diaminoarsenium cations where the observed formation of intermolecular As···N contacts may be rationalized in terms of interaction of the HOMO of one with the LUMO of a second cation; see: N. Burford, T. M. Parks, B. W. Royan, B. Borecka, T. S. Cameron, J. F. Richardson, E. J. Gabe, R. Hynes, *J. Am. Chem. Soc.* **1992**, *114*, 8147.
[24] A similar dominance of L←M π-back donation over L→M σ-bonding had also been suggested for metal carbonyl complexes, see ref.[12].
[25] The dominance of the P←M π- over the P→M σ-contribution is supported by the results of a preliminary study of the complex $[(H_2N)_2P\text{-}Fe(CO)_4]^+$. According to a natural population analysis of the MP2 electron density (LANL2dz basis set, molecular geometry optimized at the MP2/LAN2dz-level), the coordination is accompanied by a reduction of the positive charge on the $(H_2N)_2P$-moiety from a value of +1.00 for the free ligand to +0.88 in the complex, thus implying a net transfer of electron density from the metal to the ligand. Further studies of the metal-phosphorus bonding in phosphenium complexes are in progress.
[26] It should be noted that for reactions of soft acids the influence of electron correlation becomes important and these reactions are in some cases described incorrectly at the SCF-level (see ref.[10]). One should therefore bear in mind that different predictions of the reactivities of phosphenium ions may result when correlation effects are included.

Keywords: Aminoalanes / Alanes / Ab initio calculations / ^{27}Al-NMR spectroscopy / Structure elucidation / Substituent effects

Reactions of metallated nucleophiles M^IY [Y = OR, SR, NR_2, PR_2, AsR_2, CR_3, $Si(SiMe_3)_3$, R = organyl, H] with bis(2,2,6,6-tetramethylpiperidino)aluminum halides [tmp_2AlX, (X = Cl, Br, I)] offer facile access to a variety of bis(amino)alanes of the type tmp_2AlY. As indicated by ^{27}Al-NMR spectroscopy, mass spectrometry and X-ray crystal structure determinations, all of these compounds are monomeric in the solid state, in solution, and in the gas phase. Even Al–E single bonds (E = Si, P, As etc.) that are not commonly encountered are stabilized by the supporting tmp fragments. The results of a systematic analysis of the bonding parameters determined for the tmp_2AlY compounds, combined with a quantum mechanical study on model compounds $(H_2N)_2AlY$, not only reveal the presence of a highly polar Al–N bond, but at the same time rule out AlN-pp(π) bonding, in contrast to the situation in the analogous tmp_2BY compounds. It is shown that the Al–N bond length depends on the acidic character of the protic species HY: the shorter *d*(Al–N), the less basic is Y.

Introduction

Homo- and heteroatomic multiple bonding, especially involving heavier main-group elements, has been a major field of interest in the last decade. Thus, many compounds with element−element double bonds, kinetically stabilized by using bulky substituents attached to the element atom in question, have been produced. Application of this principle has led to the synthesis and characterization of Si=Si, Ge=Ge, Sn=Sn[3][4][5] and III−V (B=N, B=P, B=As)[6][7][8] doubly bonded systems. In the latter species, bond shortening and small twist angles between the planes at boron and the group-V elements are reported, indicative of pp(π) interactions. By means of variable-temperature ^{1}H-NMR spectroscopy[9] and quantum mechanical calculations[10], activation barriers for rotation about the B−E bond (E = N, P, As) as high as 33 kcal/mol have been determined.

Considering the heavier homologues of boron, i.e. aluminum and gallium, these might also be capable of adopting such bonding arrangements. However, no compounds containing Al=P or Al=As double bonds have yet been characterized. Thus, the gallyl phosphide $tBu_2GaP(Mes)(SiPh_3)$ exhibits a barrier to rotation about the Ga−P bond of only 12.7 kcal/mol[11]. Taking this result, together with an almost planar (sum of bond angles 346.2°) geometry at the phosphorus atom and a short Ga−P bond length, the authors concluded that a small pp(π) contribution might be present[11]. In the case of aluminum amides, pp(π) interaction, well established for the homologous aminoboranes[6][9], has been used to explain short bond lengths in monomeric aminoalanes {e.g. 1.78(2) Å in $Al[N(SiMe_3)_2]_3$ and 1.782(2) Å in $(MeAlNdipp)_3$ (dipp = 2,6-$iPr_2C_6H_3$)}[12][13]. Moreover, a barrier to rotation about the Al−N bond in $tBu_2AlN(dipp)(SiPh_3)$ of 9.9 kcal/mol has been determined, indicative of weak pp(π) interactions[14]. However, Al−N bond lengths in tricoordinated aluminum amides vary considerably from 1.78 to 1.88 Å. An analysis of structural data and rotational barriers in tricoordinated Al−N compounds lead to the conclusion that the bonding is primarily determined by Al−N bond polarity[15]. However, no systematic analysis on the variation of Al−N bonding parameters in a family of compounds has so far been performed. We found that bis(tetramethylpiperidino)alanes represent such a family.

Recently, we published the synthesis and structures of the monomeric bis(2,2,6,6-tetramethylpiperidino)aluminum halides {tmp_2AlX [X = Cl (**1a**), Br (**1b**), I (**1c**)]}[16], which allow even the synthesis of transition-metal compounds such as $[tmp_2Al-Fe(cp)(CO)_2,]$ (**2**)[17]. Here, we report on a variety of additional derivatives of bis(tmp)alanes. The compounds **1a−c**, **2**, and of the type tmp_2AlY **3−6** {Y = OR, SR, NR_2, PPh_2, $AsPh_2$, CR_3, $Si[Si(Me)_3]_3$, R = organyl, H} possess tricoordinated aluminum and nitrogen centers. To allow a distinction to be made between possible pp(π) interactions, N(p)AlX(σ*) interactions and a highly polar bonding situation at the aluminum center [χ(N) = 3.1; χ(Al) = 1.6; Pauling electronegativity], the structures of these compounds were determined in the solid state. Systematic variation of the group Y not only changes the electronic situation at the aluminum atom, but − since the am-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434−1948/98/0808−1095 $ 17.50+.50/0

ino ligands remain constant − this allows quantification of the effect of various substituents at the Al−N unit.

Although most of the tmp_2AlY compounds are sterically severely crowded, we expected to obtain supporting evidence from ab initio calculations (MP2/6-31+G*) on systematically varied model compounds $(H_2N)_2Al-Y$ (**7a−h**) [Y = Cl, OH, SH, NH_2, PH_2, CH_3, SiH_3, $Al(NH_2)_2$], including NBO analysis for interpretation of their bonding situation in the LMBO picture (= Lewis picture)[18].

Synthesis and Reactions

In order to delineate the effects of a systematic change of the group Y in tmp_2AlY, the following results describe tmp_2AlY compounds in which the substituent Y is varied across the main-group elements from right to left. All bis(tmp)alanes were obtained by the metathesis of tmp_2AlX (X = Cl, Br, I) with nucleophiles Y^-. The reactions proceeded well in aliphatic organic solvents. Monitoring of the reactions by ^{1}H-NMR spectroscopy indicated the exclusive formation of compounds tmp_2AlY (**3−6**). Competing reactions, which commonly hamper aluminum chemistry (e.g. dismutation leading to mixtures), were not observed.

(i) Main Group VI Nucleophiles

When mixtures of tmp_2AlX **1a−c** with the freshly prepared lithium compounds PhOLi, dippOLi, PhSLi, and *t*BuSLi were refluxed in *n*-hexane solution for about three hours, the monomeric bis(tmp)aluminum phenolates and thiolates $tmp_2Al-OPh$ **3a**, $tmp_2Al-Odipp$ **3b**, $tmp_2Al-SPh$ **3c**, and $tmp_2Al-StBu$ **3d** were obtained in 54−87% yield. The relatively weak nucleophilic character of the lithium aryloxides and thiolates necessitates heating in this case to make reaction times suitably short.

$$tmp_2AlX + LiY \xrightarrow[-LiX]{\text{n-hexane}} tmp_2AlY \quad (1)$$

X = Cl, Br, I Y = OPh **3a**, Odipp **3b**

Y = SPh **3c**, StBu **3d**

(ii) Main Group V Nucleophiles

Powdered LiN(H)R (R = *t*Bu, Ph) and $LiEPh_2$ (E = P, As) react with tmp_2AlX (**1a−c**) in *n*-hexane solution at ambient temperature to give $tmp_2Al-N(H)tBu$ (**4a**), $tmp_2Al-N(H)Ph$ (**4b**), $tmp_2Al-PPh_2$ (**4c**), and $tmp_2Al-AsPh_2$ (**4d**) in 42−65% yield. To verify the donor properties of the phosphorus atom in **4c**, one equivalent of AlI_3 was added to a solution of the compound in benzene. From the resulting solution, crystals separated on cooling, which proved to be the trimeric I_2AlPPh_2 (**4e**). The supernatant solution was found to contain tmp_2AlI (**1c**), which was characterized by its NMR spectra[15].

(iii) Main Group IV Nucleophiles

PhLi (Bu_2O solution), *n*BuLi (*n*-hexane solution), freshly prepared *p*-$MeOC_6H_4MgBr$ (THF), $H_{10}B_{10}C_2Li_2$ (= 1,2-dilithio-1,2-dicarba-*closo*-dodecaborane) and the tmeda adduct of $FecLi_2$ (Fec = ferrocene) each reacted smoothly with tmp_2AlX (**1a−c**) (within minutes to one hour) to give the organylalanes tmp_2Al-Ph (**5a**), tmp_2Al-Bu (**5b**), $tmp_2Al-C_6H_4OMe$ (**5c**), $(tmp_2Al)_2C_2B_{10}H_{10}$ (**5d**), and $(tmp_2Al)_2Fec$ (**5e**) in 48−79% yield. Reaction with $(Me_3Si)_3Si-Li(thf)_3$ afforded the silylalane $tmp_2Al-Si(SiMe_3)_3$ (**5f**) in 65% yield, whereas addition of freshly prepared $Me_3SnLi(thf)_x$ ($x \approx 3$) led only to the transient formation of $tmp_2Al-SnMe_3$ (**5g**), which quickly decomposed by stannylene elimination $(SnMe_2)_n$ to give tmp_2Al-Me (**5h**) as the sole isolated species. On leaving the latter compound to stand for several weeks in CO_2 at −78°C, quantitative insertion of CO_2 into the Al−N bonds occurred, resulting in the methylaluminum bis(carbaminate) $[MeAl(O_2Ctmp)_2]_2$ (**5i**).

The silylalane **5f** was subjected to a series of solvolysis reactions. Treatment with stoichiometric amounts of EtOH, PhOH, and HCl led exclusively to the products of Al−N cleavage $[(Me_3Si)_3SiAl(OEt)_2]_2$ (**5j**) and $[(Me_3Si)_3SiAlZ_3]tmpH_2$ [Z = OPh (**5k**), Cl (**5l**)] in 65−85% yield. Use of bulkier alcohols such as *t*BuOH, MesOH and dippOH led to inseparable mixtures, whereas 2,4,6-$tBu_3C_6H_2OH$ did not react.

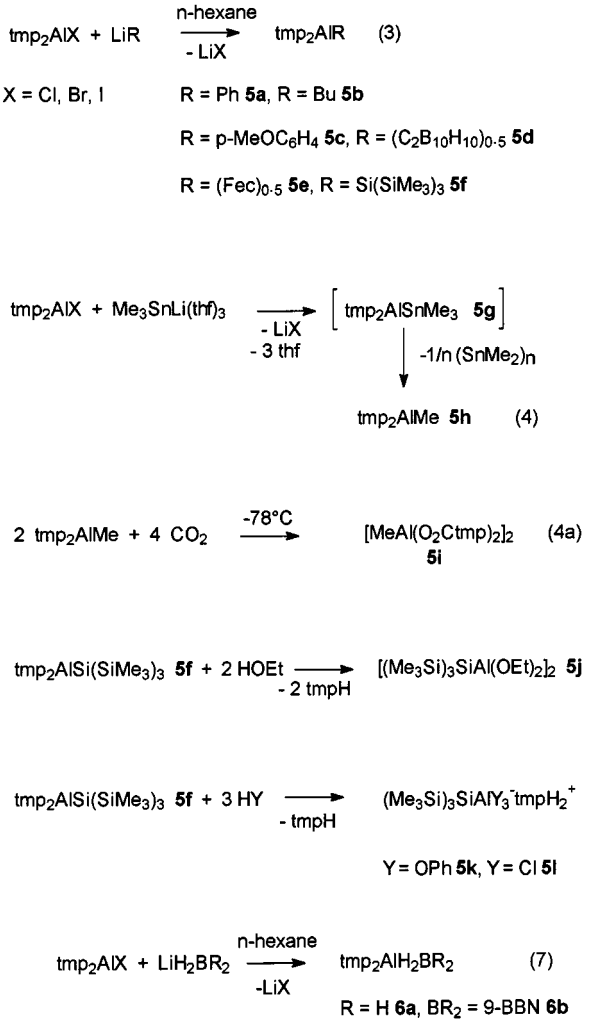
(iv) Main Group III Nucleophiles

Suspensions of $LiBH_4$ or $Li(H_29\text{-BBN})$ (9-BBN = 9-borabicyclononane) in *n*-hexane reacted with tmp_2AlX compounds (X = Cl, Br, I) to afford the highly soluble compounds $tmp_2AlH_2BH_2$ (**6a**) (42%) and tmp_2AlH_2(9-BBN) (**6b**) (74%).

Characterization

Monomeric Bis(tmp)alanes

The chemical shift of the ^{27}Al-NMR signals of **1−6** is a function of the electron density at the aluminum nucleus (see Table 1). Strong σ- and possible π-donors such as the aryloxides, phosphanides, and arsanides **3a−b** and **4c−d** induce an upfield shift of the ^{27}Al signal up to δ = 65 [compared to tmp_2AlX (X = Cl, Br, I), $\delta^{27}Al = 130$][15]. Organyl or silyl substituents cause a deshielding, which reaches its maximum for $tmp_2Al-Si(SiMe_3)_3$ (**5f**) ($\delta^{27}Al = 186$). How-



ever, there is one exception: δ^{27}Al of $(tmp_2Al)_2Fec$ (**5e**), possibly as a result of an anisotropic effect of the iron atom, exhibits a remarkable high-field shift (δ^{27}Al = 59). Due to the low local symmetry at the aluminum center, signals with half-widths as broad as 19400 Hz are a characteristic feature of the tricoordinated aminoalanes **2**−**6**[18][19]. The halides **1a**−**c** were shown to be monomeric by cryoscopic molar-mass determinations and, therefore, the signals in the ^{27}Al-NMR spectrum exhibit very broad half-widths of 9100−13700 Hz[15]. Since all other tmp_2AlY compounds possess the same local symmetry at the aluminum atom and exhibit signal half-widths similar to those observed in **1a**−**c**, it can be assumed that **2**−**6** do not form associates in solution.

In agreement with this assumption is the observation that in the ^{1}H- and ^{13}C-NMR spectra, only one set of resonances is observed for the tmp ligand, indicating free rotation about the Al−N bond and rapid inversion of the piperidinyl ring. In the case of the phosphanide **4c**, a long-range coupling [$^4J(^{31}P,^{13}C)$ = 4.1 Hz] of the tmp methyl carbon atoms and the phosphorus atom is characteristic. At ambient temperature, **5f**, probably the sterically most crowded molecule of this series, shows a set of broad ^{1}H-NMR and ^{13}C-NMR signals for the tmp methyl groups. Upon cooling to −70°C, these separate into two distinct lines (depicted in Figure 1). As the free activation enthalpy for this process has been determined to be about 54 kJ/mol (using the Eyring equation)[21], we take this as evidence for hindered inversion of the piperidinyl ring (cf. for example, the inversion barrier of cyclohexane: 46 kJ/mol)[22], while we assume free rotation about the Al−N bond even at a temperature of −70°C (if there was hindered rotation about the Al−N bond, one should observe four signals for the then magnetically inequivalent tmp methyl groups).

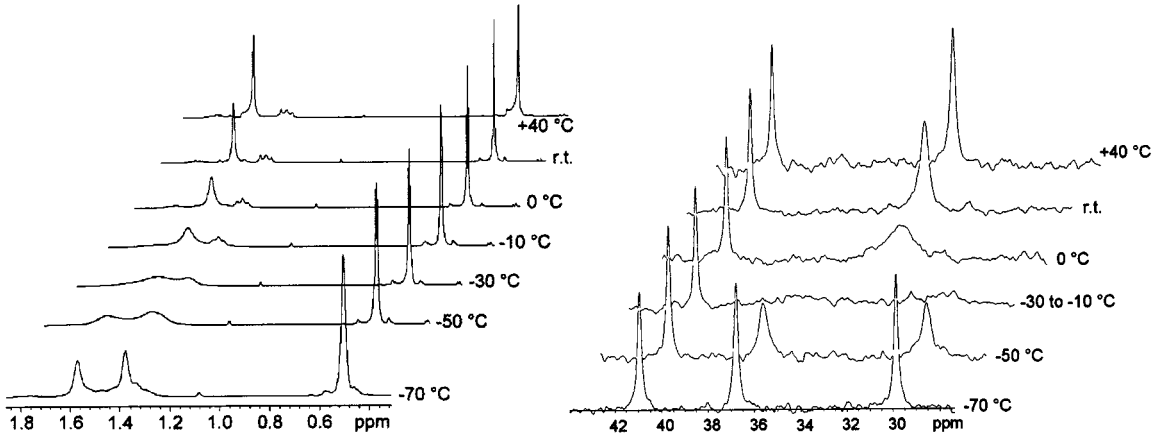
In the ^{11}B-NMR spectrum of the tetrahydroborate **6a** ($\delta^{11}B$ = −24.4), a $^1J(^{11}B,^1H)$ coupling constant of 85 Hz is found. This lies well within the range found for other aminoaluminum tetrahydroborates [e.g. $H_2B(\mu\text{-}NMe_2)\text{-}Al(BH_4)_2$, $^1J(^{11}B,^1H)$ = 89 Hz][23]. In contrast, the proton-coupled ^{11}B-NMR spectrum of **6b** exhibits only a broad, unresolved signal, which narrows on proton decoupling from 247 Hz to 207 Hz. From the IR spectra, a bidentate coordination of the BH_4 group to the aluminum atom can be deduced.

To investigate their gas-phase behavior, **3d**, **5a**−**b**, **h**, and **6a** were subjected to mass spectrometry (70 eV). No fragments of higher *m*/*z* ratios than the molecular ions of the monomers (15−20% relative intensity) were observed, confirming the unassociated nature of these species in the vapour phase. Due to the low Al−C and Al−H bond strengths[24], the bis(tmp)aluminum cation tmp_2Al^+, *m*/*z* = 307, is formed as the major fragment with 18−100% relative intensity. Since these compounds contain eight methyl groups, the (M − 15) fragment is formed very readily (31−100% relative intensity). It is noteworthy that the phosphanide **4c**, the arsanide **4d**, and the silylalane **5f** decomposed upon vaporization; only fragments of low *m*/*z* ratio were detected.

^{1}H- and ^{13}C-NMR spectroscopic analysis of the crystals and the supernatant solution obtained according to equation 2a revealed Al−P bond cleavage of the presumably formed adduct $tmp_2AlPPh_2{*}AlI_3$. The crystals only gave rise to signals in the aromatic region, while the solution

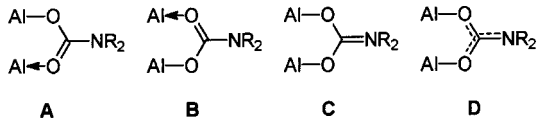
Figure 1. ^{1}H-NMR and ^{13}C-NMR spectra of **5f** in [D_8]toluene recorded at various temperatures



exhibited signals attributable to tmp_2AlI (**1c**)[15]. The ^{31}P-NMR signal of **4e** is shifted downfield compared to **4c**, appearing at $\delta^{31}P = -42.9$, thus indicating a tetracoordinated phosphorus atom. Since **4e** is trimeric in the solid state, as ascertained by X-ray crystal structure determination, it is most likely that the phosphanide retains this degree of oligomerization in solution. This would correspond to the behavior of $(Me_2AlPMe_2)_3$[25].

The ^{27}Al-NMR spectrum of the aluminum carbaminate **5i** shows two sharp signals in the region typical of pentacoordinated species [$d^{27}Al = 21$ ($\Delta_{1/2} = 1.120$ Hz); $d^{27}Al = 9$ ($\Delta_{1/2} = 980$ Hz)] {cf. $[(Me_2NCS_2)_2AlCl]_2$: $d^{27}Al = 14$}[26], indicating that the dimeric compound found in the solid state (vide infra) dissociates in solution partly into monomers . This is confirmed by ^{1}H- and ^{13}C-NMR spectroscopy. Two sets of signals are observed for the tmp ligands, those assigned to the dimer having twice the intensity (see Figure 2).

Figure 2. Possible bonding patterns of the carbaminate **5i**



Considering the IR spectrum, formula **D** is consistent with the strong absorption at 1582 cm^{-1}. Thus, the partial C−N double bond, as indicated by the rather short C−N bond length (vide infra), results in hindered rotation about this bond and makes inversion of the ring more difficult, rendering pairs of atoms in the tmp ligand magnetically inequivalent.

The presence of tetracoordinated aluminum centers in the silylalane **5j** and the silylaluminates **5k−l** is evident from the dramatically decreased line widths in the ^{27}Al-NMR spectra ($\Delta_{1/2} = 1000-3000$ Hz vs. 12400 Hz in **5f**)[18]. A double set of lines for the ethoxy groups in **5j** indicates its dimeric nature (terminal and bridging EtO resonances) and rules out the possibility that a mixture of *cis* and *trans* isomers is present, since only one signal for the bridging ethoxy group is found. Most probably, the terminal EtO groups are oriented *trans* to one another, as this isomer crystallizes from the solution (the *trans* isomer is favoured by about 6 kcal/mol according to a semiempirical AM1 calculation). Aluminate formation in the case of **5k−l** is deduced from the ^{13}C-NMR signals of the $tmpH_2^+$ cation, which differ markedly compared to those observed when a tricoordinated nitrogen atom is present in the piperidino ligand [e.g. $\delta^{13}C$ (N−*C*) = 57−58 vs. 51−53 in tmp_2AlY], and from the presence of an NH_2 stretching band in the IR spectrum. The ^{29}Si-NMR signals of the $Me_3{}^{29}Si$ groups of **5j−l** fall in the small range of $\delta = -8$ to -10, well within the range of reported values for the homologous gallium compounds prepared by Linti et al.[27]. Compared to **5f**, the ^{1}H-NMR signals for the Me_3Si groups are shifted by 0.3−0.4 ppm to higher field. We attribute this to the reduced steric crowding that results from the replacement of the tmp ligands with less bulky substituents.

Crystal Structures

Monomeric Bis(tmp)alanes tmp_2AlY (3−6)

Structural parameters are presented in Table 2, additional values are given in the caption of each ORTEP representation. Hydrogen atoms are omitted for clarity in the figures except in the plots of **4b** and **6b** where selected hydrogen atoms are depicted. All molecules **3−6** possess tricoordinated aluminium atoms residing in a planar envirnonment [sum of bond angles $\Sigma(Al) = 360.0°$]. The nitrogen atoms of the tmp ligands, which exhibit the chair conformation, seem to have sp^2 character, as their sum of bond angles range from 359.4 to 360.0°.

$tmp_2AlOdipp$ (3b)

The structure of **3b** is depicted in Figure 3. The molecule shows a rather long Al−O distance of 1.696(2) A, compared to that in the electronically similar tris(aryloxides) [e.g. $Al(OAr)_3$, OAr = 2,6-tBu$_2$-4-Me-C_6H_2, d(Al−O) = 1.647 A (av.)][28] investigated by Barron et al. Due to the steric requirements of the bulky substituents, the Al−O−C angle, 158.4(2)°, is rather large a feature commonly observed for monomeric aluminum aryloxides. This can be

taken as an indication of a strong polar Al−O bond, which should lead to a short Al−O bond[15].

tmp_2AlSPh (3c) (Figure 4) and $tmp_2AlStBu$ (3d) (Figure 5)

The asymmetric unit of **3c** contains two independent, slightly different molecules. Compared to the published structure of monomeric aluminum thiolates $(mes^*S)_3Al$ [mes* = 2,4,6-tBu$_3$C$_6$H$_2$, d(Al−S) = 2.185(2) Å][29], Bu-Al(Smes*)$_2$ [d(Al−S) = 2.188(9) Å] and tBuAl(Smes*)$_2$ [d(Al−S) = 2.196(3) Å][30], the Al−S distances found in **3c−d** are elongated [**3c**: 2.225(1), 2.233(1) Å; **3d**: 2.200(1) Å]. This is consistent with the lower basicity of PhS^- (compared to tBuS$^-$), since d(Al−S) in **3c** is longer, and d(Al−N) is shorter than in **3d**, and vice versa. The C−S−Al angles are 105.7(1)° and 106.5(1)° for **3c**, and 118.9(1)° for **3d** and, as expected, are smaller than the C−O−Al angles observed in **3b** [158.4(2)°] or $R_xAl(OAr)_{3-x}$ (R = organo, up to 171°)[27].

$tmp_2AlN(H)Ph$ (4b)

As the anilide **4b** (depicted in Figure 6) is the derivative of the primary amine $PhNH_2$, it belongs to the rare class of kinetically stabilized, hydrogen-bearing aluminum amides[15]. These are normally unstable with respect to intramolecular amine elimination and formation of oligomeric iminoalanes $(RAl-NR)_n$ (n = 2−8)[31][32]. The anilide

Al−N bond [1.790(2) Å] is shorter than the Al−N bonds to the piperidino ligand [1.813(2) and 1.822(2) Å], presumably due to the reduced steric requirement of the ligand. However, in the monomeric tris(amides) $Al[N(SiMe_3)]_3$[12] and $Al(NiPr_2)_3$[33] similar or even shorter Al−N bond

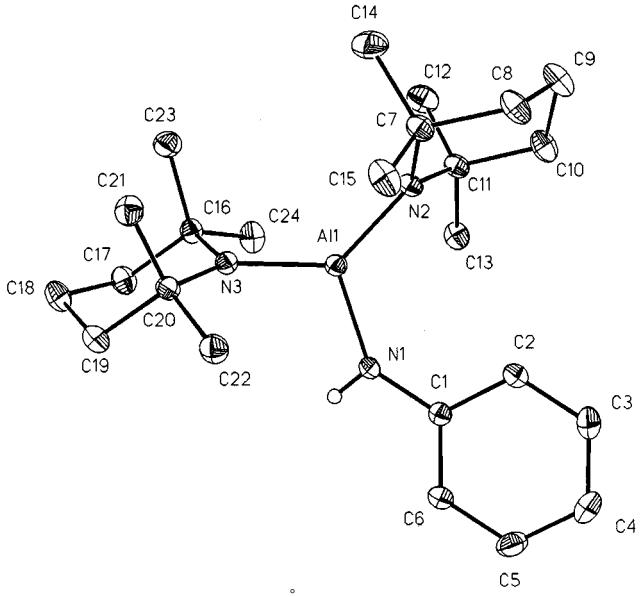
[a] Additional bond lengths [A] and bond angles [°]: Al(1)−S(1) 2.220(1); C(19)−S(1)−Al(1) 118.9(1), N(1)−Al(1)−S(1) 107.0(1), N(2)−Al(1)−S(1) 124.4(1).

lengths are reported [1.78(2) A for the silylamide and 1.791(4)−1.801(4) A for the isopropylamide]. The anilide N atom resides in a distorted trigonal-planar environment (sum of bond angles at the anilide nitrogen atom: 359.9°), with a large Al−N−C angle [138.9(2)°] and small Al−N−H and C−N−H angles [110.9(2) and 110.1(2)°].

tmp_2AlPPh_2 (4c) (Figure 7) and $tmp_2AlAsPh_2$ (4d) (Figure 8)

4c−d are isotypic. The most important structural parameter of these compounds is the Al−E bond length [E = P: 2.377(1) A; E = As: 2.485(2) A]. Only a few bonding parameters of this kind are known at the present time.[15] Compared to the recently published tricoordinated aluminum phosphanide $trip_2Al-P(Ada)(SiPh_3)$ [d(Al−P) = 2.342(2) A; trip = 2,4,6-iPr$_3$C$_6$H$_2$; Ada = adamantyl][34] and to the sum of the relevant covalent radii [1.25 A (Al) + 1.10 A (P) = 2.35 A][35], the Al−P bond in **4c** is elongated. The arsanide **4d** represents a acyclic compound featuring an aluminum−arsenic σ-bond, although two molecules, the trimeric (mes*Al−AsPh)$_3$ [d(Al−As) = 2.43 A][36] and the cp*$_3$Al$_3$As$_2$ cluster [d(Al−As) = 2.48 A][37], have previously been subjected to crystal structure analyses. The latter compound may be viewed as a subvalent species, and thus it is inappropriate to compare its Al−As bond length with that in **4d**. Considering the sum of the covalent radii [1.25 A (Al) + 1.21 A (As) = 2.46 A][33], the Al−As single bond in **4d** seems to be slightly lengthened. The phosphorus and arsenic atoms in **4c−d** reside in pyramidal environments [sum of bond angles: 316.2° (P) and 308.1° (As)]. Due to its position in the main-group V, the geometry at the arsenic atom is more pyramidalized than that at the phosphorus atom [cf. for example, the sum of bond angles in PCl_3 (300.9°) and $AsCl_3$ (296.1°)]. The pyramidal P and As atoms, as well as the geometric orientations of the EPh_2 fragments relative to the N_2Al planes, prevent the formation of Al−E pp(π) bonds.

Figure 6. Molecular structure of $tmp_2AlN(H)Ph$ (**4b**) in the solid state; thermal ellipsoids are shown at a 25% probability level[a]



[a] Additional bond lengths [A] and bond angles [°]: Al(1)−N(1) 1.790(2); Al(1)−N(1)−C(1) 138.9(2), N(2)−Al(1)−N(1) 118.57(9), N(3)−Al(1)−N(1) 109.7(1), Al(1)−N(1)−H(1) 110.9(2), C(1)−N(1)−H(1) 110.1(2).

tmp_2AlPh (5a) (Figure 9) and $(tmp_2Al)_2Fec$ (5e) (Figure 10)

Colorless needles of **5a** are monoclinic, space group $C2/c$. There are four molecules in the unit cell, which suggests crystallographically imposed C_2 symmetry. The Al−C distances of 1.971(3) A (**5a**) and 1.952(3) A (**5e**) fall well within the range of published Al−C bond lengths for organylbis(amino)alanes [e.g. 1.970(3) A for Mes−Al[N(SiMe$_3$)$_2$]$_2$][15][38]. Due to the higher electronegativity of the ferrocenyl ligand, which is associated with more contracted orbitals, the Al−C bond in this compound is slightly shorter. The C−Al−N−C torsion angles are very

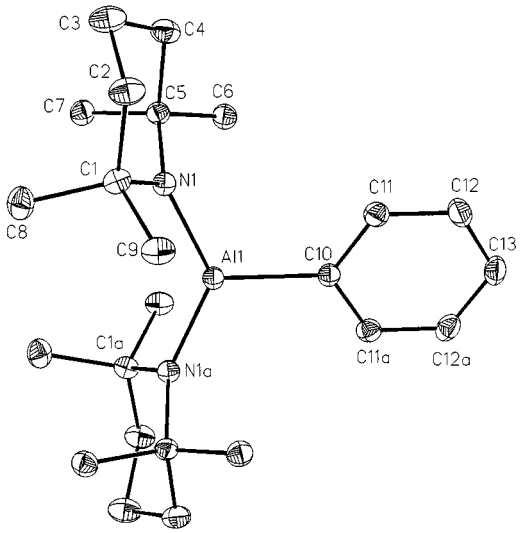
[a] Additional bond angles [°]: Al(1)−As(1) 2.485(2); Al(1)−As(1)−C(19) 108.3(1), Al(1)−As(1)−C(25) 97.6(1), N(1)−Al(1)−As(1) 108.8(1), N(2)−Al(1)−As(1) 122.1(1).

small (**5a**: 18.0°; **5e**: 7.2−15.8°), facilitating Al−C double bonding. However, closer examination of the reported Al−C distances in tetracoordinated alanes, which are not capable of bond shortening due to pp(π) interactions, is indicative of σ-bonding. Values of *d*(Al−C) similar to those in **5a** and **5e** are found in the tetracoordinated aminoalanes $(Me_2AlNC_6H_{12})_2$ [*d*(Al−C) = 1.963(6) and 1.986(7) A] and $(i\text{Bu}_2AlNMe_2)_2$ [*d*(Al−C) = 1.956(8) and 1.982(8) A][15][39]. In contrast to the crystal structures of the borylated ferrocenes $(Hal_2B)_nFec$ (Hal = Br, I; $n = 1-4$)[40], no Al−Fe interaction is apparent, which might have resulted from an interaction of the electron-deficient aluminum atom (with respect to an eight-electron system) and the electron-rich iron atom. The C−C−C−Al torsion angles of 12.5−12.9° reveal a bending of the $Altmp_2$ fragment away from the iron atom.

Figure 9. Molecular structure of tmp_2AlPh (**5a**) in the solid state; thermal ellipsoids are shown at a 25% probability level[a]



[a] Additional bond angles [°] and torsion angles [°]: Al(1)−C(10) 1.971(3); N(1)−Al(1)−C(10) 115.5(1); N(1)−Al(1)−C(10)−C(11) 18.0.

$tmp_2AlSi(SiMe_3)_3$ (5f)

The molecular structure of **5f** is depicted in Figure 11. Compared to a series of tetracoordinated silylalanes, which exhibit Al−Si distances of around 2.47 A[41], the bond length of 2.514(1) A found in **5f** is rather long, but is nevertheless in accordance with the steric demand of the ligands attached to the aluminum atom. Moreover, Linti et al. have prepared the homologous compound $tmp_2GaSi(SiMe_3)_3$, which, according to its crystal structure, exhibits the same structural features (e.g. long Ga−Si and Ga−N distances)[26] as **5f**. The decreased Si−Si−Si bond angles (av. 103.5°) may be attributable to steric factors, but could also be taken as an indication of a polar Al−Si bond (strong repulsion between the Al−Si σ-electrons and the Me_3Si groups due to the negative charge), since comparable angles have been found in the lithium silanides $(Me_3Si)_3SiLi^*(thf)_3$ and $(Me_3Si)_3SiLi(DME)_{1.5}$ (av. 102.4 and 104.0°)[42]. In the more relaxed $(Me_3Si)_3SiAlCl_3^-$, prepared by Stalke et al.[43], the Si−Si−Si bond angles are on average 110.0°.

$tmp_2AlH_2(9\text{-BBN})$ (6b)

6b forms colorless monoclinic crystals, space group *C*2/*c*, $Z = 4$ and possesses crystallographically imposed C_2 point group symmetry. The core of the structure consists of a four-membered AlH_2B ring. Since a twofold axis runs through Al1 and B1, this ring must be planar. The Al−H (1.738 A) and B−H (1.208 A) bond lengths are shorter than those found in aluminum tris(tetrahydroborate) $Al(BH_4)_3$ (1.80 A and 1.28 A). Moreover, *d*(Al−B) [2.223(7) A] is only 9 pm longer than the sum of their covalent radii (1.25 + 0.88 = 2.13 A)[33]. Assuming a bonding pattern as illustrated in Figure 13, the aluminum and boron atoms can be described as sp^2-hybridized, in accord with the large N−Al−N and C−B−C angles.

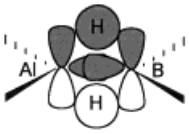
[a] Additional bond lengths [A] and bond angles [°]: Al(1)−B(1) 2.223(7), Al(1)−H(1) 1.738, B(1)−H(1) 1.208; N(1)−Al(1)−B(1) 113.8(1), H(1)−Al(1)−H(1A) 65.4, Al(1)−H(1)−B(1) 96.3, H(1)−B(1)−H(1A) 112.4.

Figure 13. Possible bonding pattern in **6b**

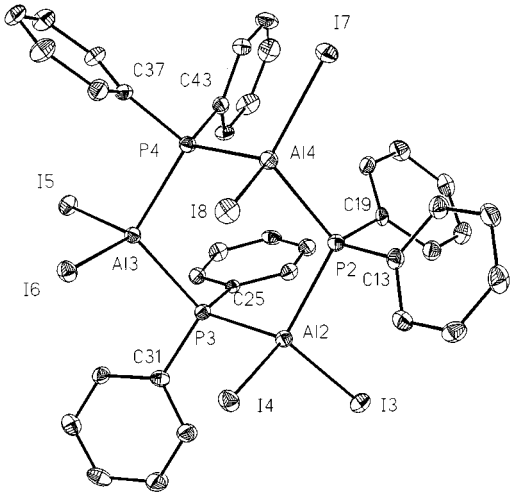


Whereas the N−Al−N angle in **6b** is as wide as 132.4°, and thus exceeds the 120° ideal by 12.4°, the C−B−C angle is only 110.2(6)°. Thus, the description of the bonding in **6b** is reminiscent of that of diborane[42]. A large exocyclic H−B−H angle of 121.8° and a short B−B distance of 1.71 A have been reported for this compound[42].

$(Ph_2PAlI_2)_3$ (4e)

Colorless prisms of **4e** crystallize in the trigonal space group $R\bar{3}$ with $Z = 24$ monomeric units. The six-membered ring is present in a chair conformation, (see Figure 14). The environment around each of the tetracoordinated Al and P atoms can be described as distorted tetrahedral, with maximum deviations of −8.2°/+4.6° from 109.5°. Values of d(Al−P) vary only slightly within the range from 2.435(2) to 2.461(3) A, and thus are very similar to the structural data of the trimeric phosphanylalane $(Me_2PAlMe_2)_3$ [d(Al−P) = 2.434(3) A], as determined by an electron diffraction study[24]. In contrast, the Al−P−Al [131.7(8)°] and P−Al−P [96.4(7)°] angles in $(Me_2PAlMe_2)_3$ differ considerably from those found in **4e** [114.8(1)−115.6(1)° and 108.2(1)−110.3(1)°]. Due to steric effects and bond polarity ($Al^{\delta+}-P^{\delta-}$), the Al−P−Al angles are widened compared to those in the cyclohexane ring. A siimilar behavior is observed in the homologous aminoalane trimers: Whereas in $(H_2Al-NMe_2)_3$ the Al−N−Al and N−Al−N angles are 114.9 and 108.8°, in $[Me_2Al-N(H)Me]_3$ these angles are 122.3 and 102.1°, respectively[24]. There is only a slight variation in the distance d(Al−I), the average being 2.532(2) A, which is in good agreement with the Schomaker-Stevenson corrected sum of the relevant sum of covalent radii (2.51 A)[33]. Moreover, for the compound $I_4Al_4(\mu\text{-}S)_2(\mu\text{-}SMe)_4$, which crystallizes in an adamantane-like Al_4S_6 framework bearing terminal iodine atoms, a similar bond length of 2.50 A has been reported[46].

Figure 14. Molecular structure of **4e** in the solid state; thermal ellipsoids are shown at a 25% probability level[a]



[a] Selected bond lengths [A] and bond angles [°]: Al(2)−P(2) 2.470(3), Al(2)−P(3) 2.461(3), Al(2)−I(3) 2.538(2), Al(2)−I(4) 2.541(2), Al(3)−P(3) 2.452(3), Al(3)−P(4) 2.438(3), Al(3)−I(5) 2.544(2), Al(3)−I(6) 2.525(2), Al(4)−P(4) 2.461(3), Al(4)−P(2) 2.444(3), Al(4)−I(7) 2.536(2), Al(4)−I(8) 2.521(2); Al(2)−P(3)−Al(3) 115.1(1), P(3)−Al(3)−P(4) 110.3(1), Al(3)−P(4)−Al(4) 114.8(1), P(4)−Al(4)−P(2) 108.2(1), Al(4)−P(2)−Al(2) 115.5(1), P(2)−Al(2)−P(3) 109.1(1), I(3)−Al(2)−I(4) 111.15(8), I(5)−Al(3)−I(6) 111.00(8), I(7)−Al(4)−I(8) 112.81(9).

$[MeAl(O_2Ctmp)_2]_2$ (5i)

Crystals of **5i** are very sensitive to warming and disintegrate when exposed to temperatures above −10°C (possibly due to a change of the modification?). The low-temperature phase is found to be monoclinic, space group $P2_1/c$, and contains two molecules in the unit cell (see Figure 15). The skeleton of **5i** is formed by two orthogonally linked, planar, eight-membered $C_2Al_2O_4$ rings, which meet at the pentacoordinated aluminum atoms. A C_4 axis (neglecting the Al−Me hydrogen atoms) passes through the Me−Al−Al−Me vector. The aluminum atoms reside in the center of a tetragonal pyramid, of which the four oxygen atoms form the base. The Al−Me groups are coordinated in an *exo* fashion, with short Al−C distances of 1.952(4) A to the pentacoordinated aluminum center. Longer Al−C bond lengths, up to 1.974(5) and 1.981(5) A, have been found for $\{AlMe_2[N(H)CH_2\text{-}2\text{-}Py]\}_2$[47]. The short Al−C bond in **5i** is due to the coordination of the Al center to four strongly electronegative oxygen atoms, which induce a positive charge at the Al atoms center, thereby reducing its effective radius due to coulombic interactions. The C30/31−N distances are consistent with a partial pp(π) double bond [d(C30/31−N) = 1.355(5) and 1.358(5) A]; the planes

through C_3N stand almost coplanar with those formed by the eight-membered rings. As indicated by the C−N−C−O torsion angles of 6.2 to 12.8°, C30 and C31 reside in planar environments, the O−C−O and N−C−O angles showing only very slight deviation from the 120° ideal (+/−0.5°). Coordination of the oxygen atoms to the aluminum nuclei is electrostatic, since the C−O−Al angles are found to be 133.4(3) to 136.4(3)°, and not of 115°, as would be expected for the appropriate hybridization of the oxygen atoms (intermediate between sp^2 and sp^3). In accordance with this description are quite long Al−O bonds, found in the range of 1.863(3) to 1.880(3) A, which adhere to the steric requirements of the carbaminate ligands.

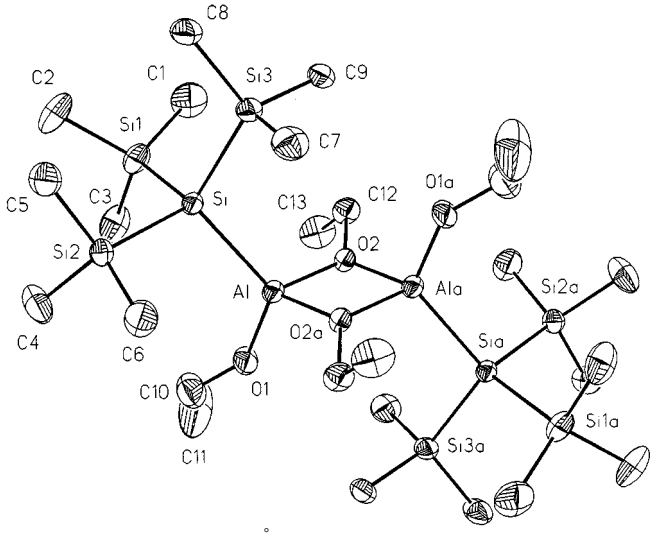
$[(Me_3Si)_3SiAl(OEt)_2]_2$ (5j)

The silylalane **5j** crystallizes in the monoclinic space group $P2_1/c$, with $Z = 2$ (see Figure 16). The central structural feature is, therefore, a four-membered, planar and crystallographically centrosymmetric Al_2O_2 ring [*d*(Al−O) = 1.833(4) A, O−Al−O = 80.7(2)°] with $(Me_3Si)_3Si$ and OEt ligands in *trans* positions. This is reminiscent of the recently published structure of $[tmp(Br)AlOEt]_2$, where these parameters are 1.827(6) A and 81.3(2)°, respectively[15]. The terminal Al−O distance [1.676(6) A] in **5j**, about 16 pm shorter than that of the Al−O bridge, is very similar to that found in $[H(OtBu)AlOtBu]_2$ [1.675(3) A][47]. The distance *d*(Al−Si) [2.444(2) A] is about 6 pm shorter than that in the starting material **5f** and other tetracoordinated silylalanes which show an average Al−Si distance of 2.47 A[39]. This lies at the lower end of the range of known Al−Si bond lengths, and indicates a relaxation in the steric strain on going from the tmp ligands to the EtO groups. Moreover, short Si−Si distances (2 pm shorter than that in **5f**) and acute Al−Si−Si angles are observed, which deviate up to 4.0° from the ideal angle of 109.5° (7.5° in **5f**).

Figure 16. Molecular structure of **5j** in the solid state; thermal ellipsoids are shown at a 25% probability level[a]



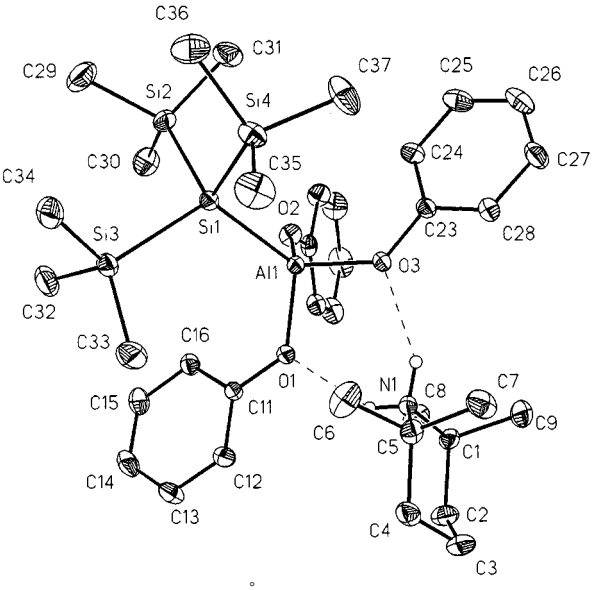
[a] Selected bond lengths [A] and bond angles [°]: Al−Si 2.444(2), Al−O(2A) 1.833(4), Al−O(1) 1.676(6), Al−O(2) 1.836(4), O(2)−Al(A) 1.833(4), Al−Al(A) 2.797(3), Si−Si(1) 2.350(2), Si−Si(2) 2.353(2), Si−Si(3) 2.353(2); O(1)−Al−O(2A) 106.0(2), O(1)−Al−O(2) 110.2(2), O(2A)−Al−O(2) 80.7 (2), O(1)−Al−Si 120.1(2), O(2)−Al−Si 115.3(1), Al(A)−O(2)−Al 99.3(2), Si(1)−Si−Si(3) 109.08(9), Si(3)−Si−Si(2) 107.94(9), Si(1)−Si−Si(2) 106.01(9), Si(3)−Si−Al 110.62 (8), Si(2)−Si−Al 109.86(8), Si(1)−Si−Al 113.11(9).

$[(Me_3Si)_3SiAl(OPh)_3]tmpH_2$ (5k) and $[(Me_3Si)_3SiAlCl_3]tmpH_2$ (5l)

Crystals of the triphenoxyaluminate **5h** are found to be monoclinic, space group $P2_1/n$. However, **5l** forms mixed crystals with $[tmpH_2]Cl$, a by-product of the reaction, without intermolecular contacts between the two species. Thus, the composition of compound **5l** corresponds to $[(Me_3Si)_3SiAlCl_3]tmpH_2*[tmpH_2]Cl$. The crystals are of the monoclinic space group $P2_1/c$, $Z = 4$. The aluminum atoms in **5k**, **l** reside in the centers of "tetrahedra" formed by three oxygen or chlorine atoms and one silicon atom (see Figures 17 and 18). Due to the steric demand of the phenoxy group, the angles in **5k** show larger deviation from the ideal value of 109.5° [97.4(1) to 117.1(1)°] than those in the trichloro derivative **5l** [104.7(1) to 113.0(1)°]. Both aluminate anions are linked to the $tmpH_2^+$ cations by hydrogen bonds. Whereas the triphenoxyaluminate **5k** forms two hydrogen

bonds to oxygen atoms incorporated in a six-membered, almost planar AlO_2H_2N ring, only one chlorine atom is coordinated by a hydrogen bond in **5l**. These atoms exhibit longer bond lengths to the aluminum center than their non-coordinated counterparts [**5k**: *d*(Al−O) = 1.775(3), 1.784(3) A vs. 1.736(3) A; **5l**: *d*(Al−Cl) = 2.187(3) A vs. 2.160(3), 2.166(3) A]. While the Al−Si distance in **5k** [2.468(3) A] corresponds to the average value[39] of 2.47 A, in the trichloro derivative **5l** it is only 2.420(3) A, which is even shorter than the Al−Si bond length found in the very similar compound $[(Me_3Si)_3SiAlCl_3]Li(thf)_4$ [2.446(1) A][41].

Figure 17. Molecular structure of **5k** in the solid state; thermal ellipsoids are shown at a 25% probability level[a]



[a] Selected bond lengths [A] and bond angles [°]: Al(1)−O(1) 1.775(3), Al(1)−O(2) 1.736(3), Al(1)−O(3) 1.784(3), Al(1)−Si(1) 2.468(3), Si(1)−Si(2) 2.344(3), Si(1)−Si(3) 2.359(3), Si(1)−Si(4) 2.346(4); O(2)−Al(1)−O(1) 112.2(1), O(2)−Al(1)−O(3) 109.4(1), O(1)−Al(1)−O(3) 97.4(1), O(2)−Al(1)−Si(1) 107.2(1), O(1)−Al(1)−Si(1) 113.6(1), O(3)−Al(1)−Si(1) 117.1(1), Si(2)−Si(1)−Si(4) 106.6(1), Si(2)−Si(1)−Si(3) 104.24(9), Si(4)−Si(1)−Si(3) 105.41(9), Si(2)−Si(1)−Al(1) 107.0(1), Si(4)−Si(1)−Al(1) 115.2(1), Si(3)−Si(1)−Al(1) 117.4(1).

Al−N Bond Lengths and Related Structural Parameters

Although in the tricoordinated tmp_2AlY species **1−6** the tmp ligand is not changed, and thus little influence on *d*(Al−N) can therefore be expected, the observed Al−N bond lengths nevertheless vary from 1.782(6) to 1.862(4) A (see Table 2). These values are close to the shortest and longest Al−N distances reported for tricoordinated aminoalanes [e.g. 1.78(2) A for $Al[N(SiMe_3)_2]_3$, 1.782(4) A for $(MeAlNdipp)_3$, (dipp = 2,6-*i*Pr_2-C_6H_3) and 1.880(4) A for $tBu_2AlN(SiPh_3)_2$][12][13][14]. Moreover, an elongation of the Al−N bonds is observed when the ligand Y is varied from main-group VII (strongly electronegative ligands) to main-group III (electropositive ligands), reaching maximum values in the dialane(4)[48] [1.851(2) A] and the ferrioalane[16] [1.862(4) A]. An analysis of the structural parameters reveal a relationship between the N−Al−N bond angle and the Al−N bond lengths. For short Al−N bonds, a wide angle (> 130°) is noted, whereas compounds with long Al−N bonds exhibit smaller angles [down to 121.8(1)°]. This relationship cannot be associated with the steric effect of the attached ligands, since the sterically crowded aryloxide $tmp_2AlOdipp$ (**3b**) shows a large angle of 128.9(1)°, while the undemanding substituted ferrioalane **2** has a value of only 121.9(2)°. The orientation of perpendiculars through the nitrogen atoms in relation to the respective aluminum atoms indicates a strongly twisted orientation of the tmp ligands, with the relevant C−N−Al−E torsion angles (E = element) in **2−6** lying in the range of 57.4−82.9°.

Ab Initio Calculations of Model Compounds $(H_2N)_2AlY$

To gain an insight into the relationship between *d*(Al−N) and the N−Al−N bond angle, a series of ab initio calculations (MP2/6-31+G*)[17] has been performed on model compounds $(H_2N)_2AlY$, in which Y is systematically varied [Y = Cl (**7a**), OH (**7b**), SH (**7c**), NH_2 (**7d**), PH_2 (**7e**), CH_3 (**7f**), SiH_3 (**7g**), $Al(NH_2)_2$ (**7h**)]. The 6-31+G* basis set was chosen in order to provide a better approximation for the nitrogen lone pair and of the potentially highly polar Al−N bond. In this basis set, diffuse functions are implemented, which adequately describe electron density even far away from the nuclei. The structural parameters of the minimum structures are given in Table 3.

To understand the bonding situation in **7a−h**, natural bonding orbital analyses (NBO analyses) have been performed on the minimum energy structures. The results are listed in Table 3, and will be discussed later. It is apparent that the results of the calculations for the model compounds **7a−h** show the same trends as those observed in the crystal structures of **1−6**. The shortest Al−N bonds (1.782 A), are

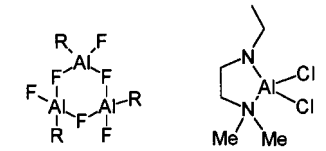
observed for the chloride **7a** and the longest for the dialane(4) **7h** (1.804 A); there is an inverse proportionality of d(Al−N) and the bond angle N−Al−N (large angles associated with short bond lengths). Moreover, the calculated Al−E bond lengths are in good agreement with the experimental values. Comparison with the crystal structures reveals that the observed correlation is not due to the steric requirements of the substituents, but is a consequence of the electronic situation (see Tables 2 and 3).

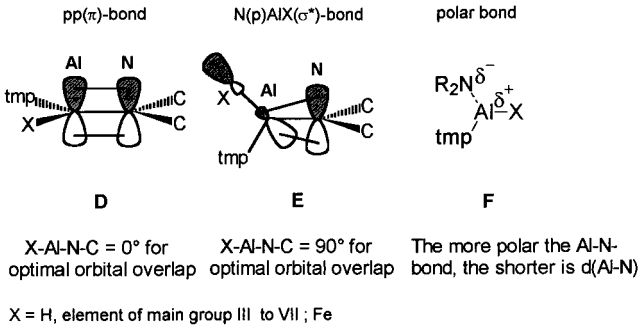
Discussion of Al−N Bonding

First of all, there is the paradox of the Al−N bonds: the shortest distances d(Al−N) ever found have been reported for compounds with tetracoordinated aluminum atoms [e.g. 1.767(3)−1.771(3) A in **9a**, 1.770(1) A in **9b**][49][50]. Therefore, the reason for the short bonds cannot be due to Al−N pp(π) interaction.



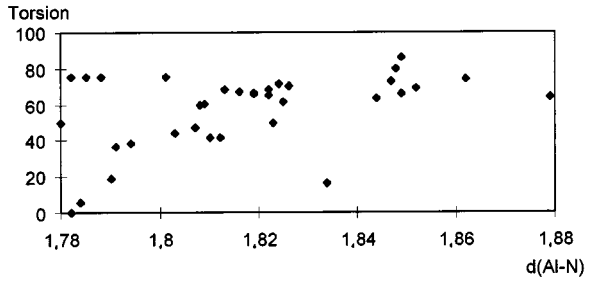
As all monomeric aminoalanes tmp_2AlX (**1**−**6**) contain planar tricoordinated nitrogen atoms in the tmp ligands, three Al−N bonding patterns (depicted in Figure 19) are possible to explain the trends in the Al−N bond lengths, namely pp(π) interaction (**D**), N(p)AlX(σ*) interaction (**E**), or a highly polar bonding situation (**F**).

Figure 19. Possible Al−N bonding patterns for the monomeric tmp_2AlY species **1**−**6**



If pp(π) or N(p)AlX(σ*) interactions are responsible for the short Al−N distances, the tmp ligands should show a preference for a parallel orientation of the nitrogen lone pairs with respect to the free p_z orbital of the aluminum atom. Optimal orbital overlap for a pp(π) bond would be achieved with a C−N−Al−X torsion angle of 0°. For an N(p)AlX(σ*) bond, however, the corresponding C−N−Al−X torsion angle should be close to 90° (see Figure 19). If the Al−N bond is to be described as highly polar, these torsion angles should be a compromise between coulombic attraction ($Al^{\delta+}-N^{\delta-}$) and the steric requirements of the ligands. These three possibilities may be distinguished from a plot of d(Al−N) versus the C−N−Al−X torsion angle. Such a plot of 35 bond lengths versus the corresponding torsion angles for monomeric aminoalanes, (see Table 5) is depicted in Figure 20.

Figure 20. Plot of 35 Al−N bond lengths against the C−N−Al−X torsion angles



The C−N−Al−X torsion angles of short Al−N bonds reveal *no* preferential orientation of the attached ligands. Values between 0 and 80° are found for short d(Al−N) (< 1.80 A) values, indicating an absence of double bond contributions. Thus, a highly polar bonding situation for the Al−N bond is clearly the best description. Taking the geometry of the bis(tmp)borinium cation (**10a**) (linear; N−B−N angle: 180°) as the limiting case of an ideal bis(tmp)aluminum cation (**10b**), (a semiempirical AM1 calculation led to an N−Al−N angle of 171° for the tmp_2Al^+ cation)[51], for the present tmp_2AlY species **1**−**6**, the N−Al−N angle can be taken as an indicator of the extent of polarity of the Al−N bond (see Figure 21). Compounds tmp_2AlY with short, highly polar Al−N bonds, associated with loosely bound ligands R of low basicity, exhibit large N−Al−N angles, and vice versa. Figure 22 gives a graphical representation of the data collected for **1**−**6**. It can be

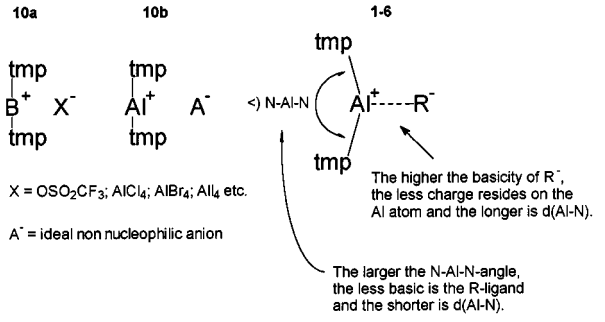
seen that d(Al−N) depends on the basicity of the substituent Y. Stabilized, weakly basic anions (like the halides) lead to strongly polar, short Al−N bonds, and vice versa. To obtain some appraisal of the influence of the basicity of the conjugate acid YH, the pK_a values of the Brønsted acids YH are plotted against d(Al−N) (Figure 23).

Figure 21. The N−Al−N angle as an indicator for a polar Al−N bonding situation



This representation reveals a good agreement with the experimental data. The insertion reaction of CO_2 with **5h** also supports the presence of a highly polar Al−N bond, as tmp_2AlMe (**5h**) possesses two reactive sites (Al−N and Al−C), of which the Al−Me site is undoubtedly also very polar. Even in the presence of excess CO_2, only the Al−N bond reacted to produce the carbaminate **5i**, leaving the Al−C bond intact. Moreover, solvolysis reactions of $tmp_2AlSi(SiMe_3)_3$ (**5f**) also support this assumption. Both the Al−N and Al−Si bonds are labile[23], but stoichiometric solvolysis reactions gave only the products of deamination, even though the Al−N bond is sterically more shielded than the Al−Si bond [cf. e.g. d(Al−N) = 1.846 Å vs. d(Al−Si) = 2.514 Å; d(C−N) = 1.50 Å vs. d(Si−Si) = 2.37 Å]. Thus, we conclude that the Al−N bonds in the present series of sterically encumbered, monomeric tmp_2AlY compounds **1**−**6** are best described as being highly polar. The degree of polarity, and thus d(Al−N), is governed by the third ligand Y.

Figure 22. Graphical representation of the dependence of d(Al−N) on the N−Al−N angles

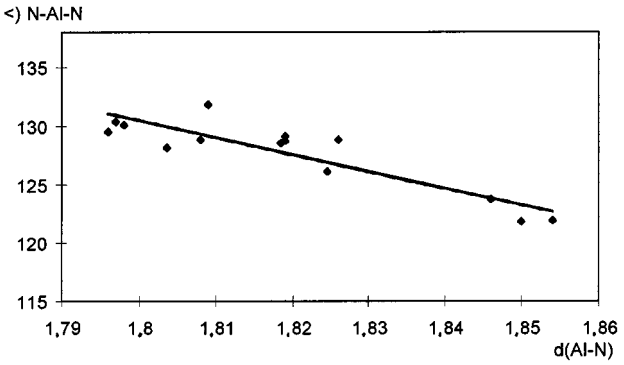


Figure 23. Plot of d(Al−N) of compounds tmp_2AlY versus the pK_a value of the corresponding Brønsted acid YH as a measure of its basicity

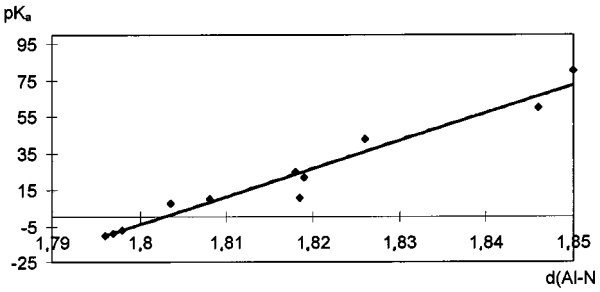
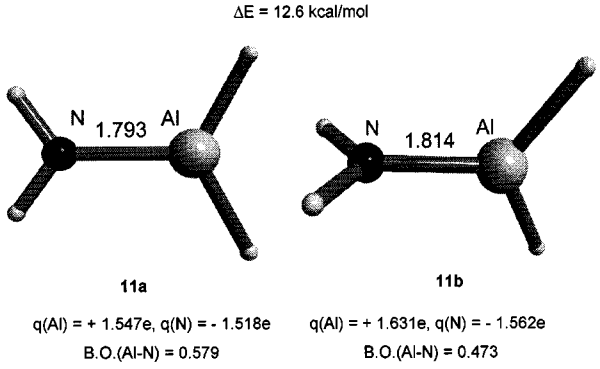


To evaluate the contributions from pp(π), N(p)AlX(σ*) and electrostatic interactions in small aminoalanes, ab initio calculations of some model compounds have been performed[17]. To understand their behavior, some results pertaining to the homologous aminoboranes are cited[10]. In the latter species, pp(π) interactions provide an additional stabilization enthalpy of up to 33 kcal/mol per B−N bond (cf. 65 kcal/mol found for the homoatomic and isoelectronic C=C double bond in ethylene)[10]. The planes around the boron and the nitrogen atoms of aminoboranes R_2NBX_2 are coplanar. In the coplanar ground state of $H_2B=NH_2$ (C_{2v}), d(B−N) is as short as 1.378 Å (calcd.). However, in the orthogonal transition state (C_s), the B−N distance is

elongated considerably (by about 9 pm) to 1.469 Å (calcd.). Due to saturation of the electron-deficient boron center, pp(π) contributions decrease with the attachment of an increasing number of π-donors. Applying this principle to aminoalanes, we will first discuss the results of ab initio calculations on H_2AlNH_2 (Figure 24: planar: **11a**; orthogonal: **11b**) and $Al(NH_2)_3$ (Figure 25: planar: **7d**; orthogonal: **12a**).

Figure 24. Structural parameters and results of the NBO analysis of **11a−b**

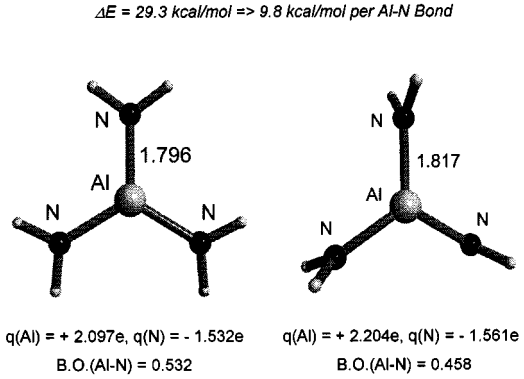


In contrast to the calculated structures for H_2BNH_2, the calculated C_{2v} structures of the planar ground state **11a** and the orthogonal transition state **11b** do not show marked differences in the values of *d*(Al−N) (1.793 vs. 1.814 Å), *d*(Al−H) (1.586 vs. 1.591 Å), Wiberg Al−N bond order (0.579 vs. 0.473) and NBO charges [*q*(Al): 1.547 vs. 1.631 e; *q*(N): −1.518 vs. −1.562 e]. Moreover, the NBO analysis reveals that in **11a** only 0.096 electrons are transferred from the N(p_z) orbital (populated with 1.905 electrons) to the 3p_z orbital of the aluminum atom. Thus, no effective pp(π) bond is formed, as is evident from the small energy difference on going to the orthogonal transition state **11b**. The pp(π) contribution amounts at most to 12.6 kcal/mol. In the transition state **11b**, which exhibits the requisite geometry for N(p)AlH(σ*) bonding, only 0.035 electrons are transferred from the N(p_z) orbital (containing 1.959 electrons) to the AlH(σ*) orbitals. Moreover, the Al−H bond is only very slightly lengthened (by 0.5 pm). These results are wholly consistent with a highly polar bonding situation, but not with effective pp(π) or N(p)AlH(σ*) bonding.

The tris(amide) $Al(NH_2)_3$ (D_{3h}) has been subjected to the same analysis in order to evaluate saturation effects, i.e. when more potential π-donors are bonded to the aluminum center (see Figure 25).

Here, the energy differences between the planar ground state **7d** and the orthogonal transition state **12a** are even smaller than those between **11a** and **11b**, even though three electronegative nitrogen atoms are present in the tris(amide), further supporting the argument for a polar bonding situation. Thus, the differences between the data for **7d** and **12a** amount to only 2.1 pm [*d*(Al−N)], 0.107 e [*q*(Al)], 0.029 e [*q*(N)] and 0.076 (Wiberg Al−N bond order). In **7d**, 0.189 electrons are transferred into the 3p_z(Al) orbital, while in **12a** only 0.043 electrons are transferred into the Al−N σ* orbital. Moreover, the pp(π) contribution per Al−N bond,

Figure 25. Structural parameters and results of the NBO analysis of **12a** and **7d**



calculated by dividing the energy difference between **7d** and **12a** by three, decreases to 9.8 kcal/mol.

In the minimum energy structures of the bis(amino)alanes $(H_2N)_2AlY$ (**7a−h**) short Al−N bond lengths are associated with highly charged aluminum centers (see Table 3), and vice versa. Since only 0.15 to 0.21 electrons are transferred to the aluminum 3p_z orbitals [which negates the presence of strong pp(π) bonding] and the NBO charge on the nitrogen atoms remains essentially constant (−1.52 e to −1.54 e), the differences in the Al−N distances must be attributed to the influence of the third substituent Y. So Y has a significant effect on the charge at the aluminum atom (varying from +1.40 to +2.15 e), and, therefore, influences the coulombic interaction between Al and N, and consequently determines the Al−N bond lengths.

Conclusion

Bis(tmp)aluminum halides **1a−c** have been subjected to a series of nucleophilic substitution reactions in order to generate a systematically varied series of compounds tmp_2AlY (**2−6**). The tmp_2Al fragment not only prevents dimerization, but is also effective in stabilizing even and as yet "unusual" Al−E σ bonds (E = P, As, Si, Al, Fe). The distances *d*(Al−N) in these compounds vary from 1.782(6) to 1.862(4) Å. There is an inverse proportionality between the Al−N bond lengths and the N−Al−N bond angles. Ab initio calculations revealed the presence of very weak dative pp(π) bonding in hypothetical sterically non-demanding aminoalanes, which becomes weaker as the number of π-donors attached to the aluminum center increases. However, these pp(π) contributions (about 10 kcal/mol) are too weak to enforce on tmp_2AlY compounds geometric restrictions required to achieve optimal π-orbital overlap. Experimental and quantum mechanical results best describe the Al−N bond as being highly polar. The orientation of the tmp ligands is a compromise between the electrostatic attraction of the charged aluminum and nitrogen centers and the steric requirements of the tmp ligand. Moreover, in the tmp_2AlY system, *d*(Al−N) is a function of the pK_a value of the conjugate Brønsted acid Y−H: the stronger the acid Y−H, the higher the Al−N bond polarity and the shorter the Al−N bond lengths. Ab initio calculations reveal that

this effect can be attributed to the considerable influence that the ligand Y exerts on the charge at the aluminum atoms (variation from +1.40 to +2.15 e). Since the charge on the nitrogen atoms remains almost constant (−1.52 to −1.54 e), the differing Al−N distances can be rationalized in terms of the changing electrostatic attraction between the nitrogen and aluminum atoms, as influenced by the inductive effect of the third substitutent Y. These results not only reinforce the qualitative analysis of Al−N and Al−X bond lengths as summarized by P. J. Brothers and P. P. Power[15] but provide a much more systematic approach supported by ab initio calculations.

Investigations into the Lewis acidity of compounds tmp_2AlX (**1a−c**) and their potential to form adducts of the type tmp_2AlX*Do have been performed also. For example, the abstraction of the halide ion by strong halide abstractors with formation of ionic species $[tmp_2AlDo^+]Y^-$ (Y^- = non-nucleophilic anion) has been studied. These results will be part of forthcoming publications.

We thank the *Fonds der Chemischen Industrie* and the *Chemetall mbH* for support of our research. Moreover, we thank Mrs. *Käser* and Mrs. *Ullmann* for carrying out the C/H/N analyses, Mr. *P. Mayr*, Mr. *R. Waldhör* and Mr. *C. Miller* for recording many NMR spectra, Mrs. *D. Ewald* for mass spectra and Mrs. *E. Kiesewetter* for IR spectra.

Experimental Section

All manipulations were performed using Schlenk techniques under dinitrogen or argon. All solvents were rigorously dried prior to use and stored under N_2 or Ar. Due to insufficient protection against oxidation and hydrolysis of the air- and moisture-sensitive compounds while weighing for microanalysis, the C/H/N data are often not very accurate; Al^{3+} was determined by EDTA titration. NMR: Bruker ACP 200, Jeol GSX400 and Jeol GSX270. − IR: Nicolet FT-IR spectrometer model 6000; CsI plates, Nujol. − MS: Varian Atlas CH7 spectrometer.

tmp_2AlOPh (**3a**): Lithiation of PhOH (0.80 g, 8.5 mmol) was performed at ambient temperature in 20 ml of *n*-hexane by the addition of a solution of *n*BuLi (5.3 ml, 1.6 M, 8.5 mmol). Then, a solution of tmp_2AlBr in *n*-hexane (47.8 ml, 0.178 M, 8.5 mmol) was added at 25°C. The mixture was heated to reflux for 3−4 h. After removal of the insoluble material by filtration (0.86 g, calcd. LiBr 0.74 g), the yellowish filtrate was reduced to one-third of its original volume in vacuo and stored overnight at −20°C. 2.96 g (87%) of yellowish crystals was recovered, m.p. 80−85°C. − ^{1}H NMR (C_6D_6) (270 MHz): δ = 1.31 (t, 8 H, tmp-β-CH_2), 1.40 (s, 24 H, tmp-CH_3), 1.55 (m, 4 H, tmp-γ-CH_2), 6.8−7.4 (m, Ph-*H*, 5 H). − ^{13}C NMR (C_6D_6) (100 MHz): δ = 18.5 (tmp-γ-*C*H_2), 34.1 (tmp-*C*H_3), 39.7 (tmp-β-*C*H_2), 51.9 (N−*C*), 119.7 (Ph-*C*), 120.5 (Ph-*C*), 129.7 (Ph-*C*), 157.4 (Ph-*C*). − ^{27}Al NMR (C_6D_6) (70 MHz): δ = 75 ($\Delta_{1/2}$ = 8800 Hz). − $C_{24}H_{41}AlN_2O$ (400.59): calcd. C 71.96, H 10.00, Al 6.7, N 6.99; found C 67.99, H 10.12, Al 6.6, N 6.11.

$tmp_2AlOdipp$ (**3b**): dippOH (0.93 ml, 5.0 mmol), dissolved in 20 ml of *n*-hexane, was lithiated at ambient temperature by addition of *n*BuLi (3.2 ml, 1.6 M, 5.0 mmol) in *n*-hexane. To this solution, tmp_2AlCl in *n*-hexane (25 ml, 0.20 M, 5.0 mmol) was added and the mixture was heated for 3 h under reflux. Removal of the insoluble material by filtration yielded a yellowish solution. After reducing its volume to one-third and cooling to −78°C, yellowish crystals of **3b** (1.30 g, 54%) were formed and isolated, m.p. 97−99°C. − ^{1}H NMR (C_6D_6) (270 MHz): δ = 1.26 (t, 8 H, tmp-β-CH_2), 1.34 (s, 24 H, tmp-CH_3), 1.57 (m, 4 H, tmp-γ-CH_2), 1.27 (d, 12 H, *i*Pr-CH_3), 3.65 (sept, 2 H, Me_2C-*H*), 6.95 (dd, 1 H, Ar-*H*), 7.12 (d, Ar-*H*). − ^{13}C NMR (C_6D_6) (100 MHz): δ = 18.6 (tmp-γ-*C*H_2), 33.9, (tmp-*C*H_3), 40.2 (tmp-β-*C*H_2), 51.8 (N−*C*), 23.9 [(H)C(*C*H_3)$_2$], 26.9 [(H)*C*(CH_3)$_2$], 120.1 (Ar-*C*), 123.7 (Ar-*C*), 137.4 (Ar-*C*). − ^{27}Al NMR (C_6D_6) (70 MHz): δ = 85 ($\Delta_{1/2}$ = 9400 Hz). − $C_{30}H_{53}AlN_2O$ (484.75): calcd. C 74.33, H 11.02, Al 5.6, N 5.78; found C 71.56, H 11.27, Al 5.8, N 5.63.

tmp_2AlSPh (**3c**): Thiophenol (0.54 g, 4.9 mmol) was metallated with BuLi (4.9 mmol, 3.1 ml, 1.6 M) by stirring in hexane at −30°C. Then, tmp_2 AlBr (4.9 mmol, 25 ml of a 0.196 M solution in hexane) was added at 20°C. Stirring was continued for 14 h, and the solid material was removed by filtration. The yellow solution was then reduced in vacuo to one-third of its original volume. Cooling the solution to −78°C furnished crystals of **3c**, yield 1.0 g (49%). − ^{1}H NMR (C_6D_6) (270 MHz): δ = 1.30 (t, 8 H, tmp-β-CH_2), 1.45 (s, 24 H, tmp-CH_3), 7.00 (m, 3 H, *m*-*H*, *p*-*H*), 7.41 (m, 2 H, *o*-*H*), the tmp-γ-CH_2 protons are represented by an unresolved, very broad signal. − ^{13}C NMR (C_6D_6) (67.9 MHz): δ = 18.0 (tmp-γ-*C*H_2), 34.1 (tmp-*C*H_3), 39.2 (tmp-β-*C*H_2), 52.0 (N−*C*), 125.4 (*p*-*C*), 128.3 (*m*-*C*), 135.0 (*o*-*C*), 135.9 (1-*C*). − ^{27}Al: δ = 153 ($\Delta_{1/2}$ = 14000 Hz).

$tmp_2AlS(tBu)$ (**3d**): Prepared analogously to **3c** from *t*BuSH (0.41 g, 4.4 mmol), BuLi (2.8 ml, 1.6 M), tmp_2AlCl (4.4 mmol, 19.5 ml of a 0.228 M hexane solution). Yield 1.0 g of **3d** (58%), m.p. 87°C. − ^{1}H NMR (C_6D_6) (270 MHz): δ = 1.32 (t, 8 H, tmp-β-CH_2), 1.52 (s, 24 H, tmp-CH_3), 1.61 (s, 9 H, *t*Bu-CH_3). − ^{13}C NMR (C_6D_6) (100 MHz): δ = 18.5 (tmp-γ-*C*H_2), 34.3 (tmp-*C*H_3), 36.9 (C*Me*$_3$), 40.3 (tmp-β-*C*H_2), 44.4 (*C*Me$_3$), 52.3 (N−*C*). − ^{27}Al (C_6D_6) (70.4 MHz): δ = 152 ($\Delta_{1/2}$ = 8000 Hz). − $C_{22}H_{45}AlN_2S$ (396.65): calcd. C 66.62, H 11.43, N 7.06; found C 62.78, H 11.33, N 6.59.

$tmp_2AlNHtBu$ (**4a**): *t*BuN(H)Li (0.62 g, 7.8 mmol) was suspended in 20 ml of *n*-hexane. A solution of tmp_2AlBr (3.0 g, 7.8 mmol) in 45 ml of *n*-hexane was then added at ambient temperature. After heating the sample for 3 h under reflux, the insoluble material (0.86 g, calcd. LiBr 0.68 g) was filtered off and the filtrate reduced to one-third of its original volume and the solution stored overnight at −20°C. 1.46 g of **4a** (3.8 mmol, 49%) was recovered as a yellowish precipitate, m.p. 148−152°C. − ^{1}H NMR (C_6D_6) (400 MHz): δ = 1.45 (s, 24 H, tmp-CH_3), 1.32 (s, 9 H, *t*Bu-CH_3), 1.31 (t, 8 H, tmp-β-CH_2), 1.65 (m, 4 H, tmp-γ-CH_2). − ^{13}C NMR (C_6D_6) (100 MHz): δ = 18.7 (C2,C6), 34.3 (tmp-Me), 35.2 [C(*C*H_3)$_3$], 40.6 (C3,C5), 50.0 [*C*(CH_3)$_3$], 51.8 (C4). − ^{27}Al NMR (C_6D_6) (70 MHz): δ = 129 ($\Delta_{1/2}$ = 8900 Hz). − $C_{22}H_{46}AlN_3$ (379.61): calcd. Al 7.1; found 7.4.

$tmp_2AlNHPh$ (**4b**): Prepared as described for **4a**. PhNHLi (0.53 g, 5.3 mmol), tmp_2AlBr (48.2 ml, 0.11 M solution in *n*-hexane, 5.3 mmol). − Yield 1.32 g of **4b** (62%); m.p. 134−137°C. − ^{1}H NMR (C_6D_6) (400 MHz): δ = 1.38 (s, 24 H, tmp-CH_3), 1.31 (t, 8 H, tmp-β-CH_2), 1.65 (m, 4 H, tmp-γ-CH_2), 6.75 (t, 1 H, *p*-Ph-*H*), 7.00 (d, 2 H, *o*-Ph-*H*), 7.17 (t, 2 H, *m*-Ph-*H*). − ^{13}C NMR (C_6D_6) (100 MHz): δ = 18.8 (C2,C6), 33.9 (tmp-Me), 40.2 (C3,C5), 52.0 (C4), 117.5 (Ph-*C*), 118.7 (Ph-*C*), 129.2 (Ph-*C*), 150.3 (Ph-*C*-N). − ^{27}Al NMR (C_6D_6) (70 MHz): δ = 124 ($\Delta_{1/2}$ = 9600 Hz). − $C_{24}H_{42}AlN_3$ (399.60): calcd. Al 6.8; found 6.7.

tmp_2AlPPh_2 (**4c**): To a suspension of $LiPPh_2$ (1.19 g, 7.4 mmol) in 15 ml of *n*-hexane, a solution of tmp_2AlBr in *n*-hexane (50 ml, 0.11 M, 5.5 mmol) was added at ambient temperature and the mixture was kept for 4 h under reflux. A clear, yellow solution was removed from insoluble material by means of a syringe and reduced

in vacuo to one-third of its original volume. Storing the solution overnight at −20°C afforded 1.14 g (42%) of colorless crystals of **4c** [m.p. > 278°C (decomp.)]. − ^{1}H NMR ($CDCl_3$) (400 MHz): δ = 1.10 (t, 8 H, tmp-β-CH_2), 1.31 (s, 24 H, tmp-CH_3), 1.54 (m, 4 H, tmp-γ-CH_2), 7.10 (d, 4 H, Ar-*H*), 7.18 (t, 4 H, Ar-*H*), 7.52 (t, 2 H, Ar-*H*). − ^{13}C NMR ($CDCl_3$) (100 MHz): δ = 18.8 (tmp-γ-*C*H$_2$), 33.5 [d, ^4J(P,C) = 4.1 Hz, tmp-*C*H$_3$], 39.5 (tmp-β-*C*H$_2$), 52.0 (N-*C*), 126.2 (s, C_6H_5), 128.1 [d, ^3J(P,C) = 6.8 Hz, C_6H_5], 133.7 [d, ^2J(P,C) = 15.5 Hz, C_6H_5], 137.8 [d, ^1J(P,C) = 15.0 Hz, C_6H_5]. − ^{27}Al NMR ($CDCl_3$) (70 MHz): δ = 110 ($\Delta_{1/2}$ = 13400 Hz). − $C_{30}H_{46}AlN_2P$ (492.66): calcd. C 73.14, H 9.41, Al 5.5, N 5.69; found C 69.30, H 8.59, Al 5.5, N 4.85 (C/H/N: calcd. 15:23:1; found 16.7:24.6:1).

tmp$_2$AlAsPh$_2$ (**4d**): $LiAsPh_2$ (0.75 g, 3.2 mmol) was suspended in 20 ml of *n*-hexane and tmp$_2$AlBr (27.3 ml, 0.11 M, 3.0 mmol) in *n*-hexane was added at ambient temperature. Stirring overnight produced a yellow suspension (insoluble material as mentioned above), which was filtered off. The filtrate was reduced to one-third of its original volume and left for 4 d at −20°C. Colorless crystals of **4d** (0.93 g, 58%) separated; m.p. > 254°C (decomp.). − ^{1}H NMR ($CDCl_3$) (400 MHz): δ = 1.13 (t, 8 H, tmp-β-CH_2), 1.30 (s, 24 H, tmp-CH_3), 1.55 (m, 4 H, tmp-γ-CH_2), 7.14 (t, 4 H, Ar-*H*), 7.19 (t, 4 H, Ar-*H*), 7.54 (d, 2 H, Ar-*H*). − ^{27}Al NMR ($CDCl_3$) (70 MHz): δ = 74 ($\Delta_{1/2}$ = 18300 Hz). − $C_{30}H_{46}AlAsN_2$ (536.61): calcd. C 67.15, H 8.84, Al 5.0, N 5.22; found C 63.22, H 6.79, Al 4.9, N 5.25.

(Ph$_2$PAlI$_2$)$_3$ (**4e**): To a solution of tmp$_2$AlPPh$_2$ (0.52 g, 1.05 mmol) in 20 ml of benzene, AlI_3 (12.2 ml, 0.086 M, 1.05 mmol) in benzene was added at ambient temperature. Addition of 20 ml of *n*-pentane and cooling to 5°C led to the precipitation of 0.40 g (27%) of colorless crystals of **4e**, m.p. > 314°C (decomp.). − ^{1}H NMR (C_6D_6) (400 MHz): δ = 6.95 (m, C_6H_5, 12 H), 7.42 (t, C_6H_5, 6 H), 7.55 (t, C_6H_5, 12 H). − ^{13}C NMR (C_6D_6) (100 MHz): δ = 129.35 [d, ^3J(P,C) = 9.6 Hz], 131.35 [d, ^4J(P,C) = 11.1 Hz], 134.30 [d, ^2J(P,C) = 12.3 Hz, C_6H_5], 134.89 [d, ^1J(P,C) = 12.3 Hz, C_6H_5], 135.01 [d, ^1J(P,C) = 12.2 Hz, C_6H_5]. − ^{31}P NMR (C_6D_6) (81 MHz): δ = −42.9. − $C_{36}H_{30}Al_3I_6P_3$ (1397.89): calcd. Al 5.8, I 54.5; found Al 6.0, I 54.1.

tmp$_2$AlPh (**5a**): To a solution of tmp$_2$AlBr in *n*-hexane (50 ml, 0.11 M, 5.5 mmol), PhLi (2.42 ml, 2.27 M, 5.5 mmol) in *n*Bu$_2$O was added at ambient temperature, resulting in the immediate formation of a colorless precipitate. After stirring for 1/2 h, the suspension was allowed to settle. The clear, yellow supernatant solution was removed by means of a syringe reduced to one-third of its original volume and stored overnight at 8°C, resulting in the deposition of 1.54 g (73%) of colorless crystals of **5a**; m.p. 85−88°C. − ^{1}H NMR ($CDCl_3$) (400 MHz): δ = 1.32 (t, 8 H, tmp-β-CH_2), 1.29 (s, 24 H, tmp-CH_3), 1.66 (m, 4 H, tmp-γ-CH_2), 7.20 (d, 2 H, Ar-*H*), 7.23 (m, 1 H, Ar-*H*), 7.72 (dd, 2 H, Ar-*H*). − ^{13}C NMR ($CDCl_3$) (100 MHz): δ = 18.5 (tmp-γ-*C*H$_2$), 34.0 (tmp-*C*H$_3$), 40.6 (tmp-β-*C*H$_2$), 51.8 (N-*C*), 127.2 (s, C_6H_5), 127.8 (C_6H_5), 137.4 (C_6H_5), Al−C signal not observed. − ^{27}Al NMR ($CDCl_3$) (70 MHz): δ = 153 ($\Delta_{1/2}$ = 12300 Hz). − $C_{23}H_{41}AlN_2$ (384.43): calcd. C 74.98, H 10.75, Al 7.0, N 7.29; found C 73.19, H 9.88, Al 7.3, N 6.39.

tmp$_2$Al(nBu) (**5b**): To a solution of tmp$_2$AlBr (5.73 g, 14.8 mmol) in 80 ml of *n*-hexane, *n*BuLi (9.25 ml, 1.6 M, 14.8 mmol) in *n*-hexane was added dropwise at ambient temperature. To complete the reaction, the mixture was stirred for 1 h at ambient temperature. After removal of the insoluble material, the solvent of the yellow filtrate was removed in vacuo providing **5b** as a viscous oil, which could not be crystallized from various solvents. Yield 5.23 g (97%). − ^{1}H NMR ($CDCl_3$) (270 MHz): δ = 1.31 (t, 8 H, tmp-β-CH_2), 1.36 [s, 24 H, tmp-C(CH_3)$_2$], 1.65 (m, 4 H, tmp-γ-CH_2), 0.39 (t, 2 H, Bu-α-CH_2), 1.10 (t, 3 H, Bu-CH_3), 1.23 and 1.47 (2 m, each 2 H, β- and γ-CH_2). − ^{13}C NMR (C_6D_6) (100 MHz): δ = 18.7 (tmp-*C*4), 34.1 (tmp-*C*7−10), 40.5 (tmp-*C*3/5), 51.9 (tmp-*C*2/6), 14.1 (Bu-*C*4), 28.4 (Bu-*C*3), 29.1 (Bu-*C*2), Al−C signal not observed. − ^{27}Al NMR ($CDCl_3$) (70 MHz): δ = 164 ($\Delta_{1/2}$ = 13400 Hz). − MS: *m*/*z* = 364 [tmp$_2$AlnBu$^+$].

tmp$_2$AlC$_6$H$_4$OCH$_3$ (**5c**): A solution of *p*-bromoanisole (0.63 ml, 5.0 mmol) in 20 ml of THF was refluxed for 1 h with 0.13 g of Mg and then cooled to ambient temperature. To this Grignard solution (assuming 100% conversion), tmp$_2$AlBr (18.7 ml, 0.268 M, 5.0 mmol) in *n*-hexane was added and the mixture was refluxed overnight. After filtration, the collected precipitate (1.67 g) was extracted with 20 ml of CH_2Cl_2 (the insoluble material subsequently weighed 0.93 g). The combined filtrates were reduced to one-third of the original volume and then stored overnight at −20°C to yield 1.61 g (79%) of **5c** as a microcrystalline precipitate, m.p. > 100°C (decomp.). − ^{1}H NMR ($CDCl_3$) (400 MHz): δ = 1.36 (t, 8 H, tmp-β-CH_2), 1.34 [s, 24 H, tmp-C(CH_3)$_2$], 1.70 (m, 4 H, tmp-γ-CH_2), 3.79 (s, 3 H, O-CH_3), 6.85 (d, 2 H, Ar-*H*), 7.70 (d, 2 H, Ar-*H*). − ^{13}C NMR ($CDCl_3$) (100 MHz): δ = 18.6 (tmp-*C*4), 33.8 (tmp-*C*7−10), 40.6 (tmp-*C*3/5), 51.6 (tmp-*C*2/6), 54.6 (O-*C*H$_3$), 113.0, 139.1, 159.9 (Ar-*C*), Al−C signal not observed. − ^{27}Al NMR ($CDCl_3$) (70 MHz): δ = 160 ($\Delta_{1/2}$ = 19400 Hz). − $C_{25}H_{43}AlN_2O$ (414.61): calcd. Al 6.5; found Al 6.7.

(tmp$_2$Al)$_2$C$_2$B$_{10}$H$_{10}$ (**5d**): To a solution of 1,2-dicarba-*closo*-dodecaborane(12) (1.0 g, 6.9 mmol) in 20 ml of toluene, *n*BuLi in *n*-hexane (40.6 ml, 1.6 M, 64.9 mmol) (cooled to 0°C) was added dropwise over a period of 20 min. After 5 min, a colorless precipitate of 1,2-dilithio-1,2-dicarba-*closo*-dodecaborane started to separate. The mixture was then stirred for a further 1.5 h to ensure completion of the reaction. The precipitate was isolated by filtration, washed with two 20-ml portions of *n*-pentane, and dried in vacuo. The resulting colorless, pyrophoric powder was suspended in 40 ml of *n*-pentane and treated at −78°C with a solution of tmp$_2$AlI (6.1 g, 14 mmol, in 50 ml of *n*-hexane). The mixture was allowed to warm to room temperature, and stirring was continued for 2 d. Removal of the insoluble material by filtration left a yellow solution, from which the solvent was removed in vacuo. The nonvolatile, yellow-brownish oil was rigorously dried in vacuo and then subjected to analysis. Yield 2.57 g of **5d** (3.4 mmol, 49%). − ^{1}H NMR ($CDCl_3$) (270 MHz): δ = 1.29 (t, 8 H, tmp-β-CH_2), 1.32 [s, 24 H, tmp-C(CH_3)$_2$], 1.64 (m, 4 H, γ-CH_2). − ^{13}C NMR ($CDCl_3$) (100 MHz): δ = 18.3 (tmp-*C*4), 33.9 (tmp-*C*7−10), 40.2 (tmp-*C*3/5), 51.7 (tmp-*C*2/6), Al−C signal not observed. − ^{27}Al NMR ($CDCl_3$) (70 MHz): δ = 164 ($\Delta_{1/2}$ = 12300 Hz). − ^{11}B NMR ($CDCl_3$) (86.4 MHz): δ = −15.0 [(^1J(B,H) = 173.3 Hz], −13.8 [^1J(B,H) = 169.2 Hz], −11.7 [^1J(B,H) not resolved], −9.4 [^1J(B,H) = 161.8 Hz], −7.1 [^1J(B,H) = 187.3 Hz], −2.6 [^1J(B,H) = 145.0 Hz]. − $C_{38}H_{82}Al_2B_{10}N_4$ (757.16): calcd. C 60.28, H 10.92, N 7.40; found C 59.35, H 10.87, N 7.64.

(tmp$_2$Al)$_2$Fec (**5e**): $FecLi_2$ (1.1 g, 5.5 mmol) was suspended in 20 ml of *n*-hexane and tmp$_2$AlCl in *n*-hexane (50 ml, 0.20 M, 5.0 mmol) was added at ambient temperature. After stirring overnight, the insoluble material was removed by filtration and the resulting red filtrate was reduced to one-third of its original volume. Storage of the solution overnight at −20°C led to the deposition of red crystals of **5e** (2.10 g, 48%), m.p. 176−179°C. − ^{1}H NMR (C_6D_6) (400 MHz): δ = 1.45 (t, 8 H, tmp-β-CH_2), 1.57 (s, 24 H, tmp-CH_3), 1.73 (m, 4 H, tmp-γ-CH_2), 4.47 (t, 4 H, cp-*H*), 4.55 (t, 4 H, cp-*H*). − ^{13}C NMR (C_6D_6) (100 MHz): δ = 18.6 (tmp-γ-*C*H$_2$), 34.3 (tmp-*C*H$_3$), 40.6 (tmp-β-*C*H$_2$), 52.0 (N-*C*), 71.9 (C_5H_4Al), 79.1

(C_5H_4Al), Al−C signal not observed. − ^{27}Al NMR (C_6D_6) (70 MHz): δ = 59 ($\Delta_{1/2}$ = 7400 Hz). − $C_{46}H_{80}Al_2FeN_4$ (798.98): calcd. C 69.15, H 10.09, Al 6.8, N 7.01; found C 63.59, H 9.04, Al 6.5, N 6.27 (C/H/N: calcd. 11.50:20:1; found 11.77:19.93:1).

$tmp_2AlSi(SiMe_3)_3$ (**5f**): To a stirred solution of $(Me_3Si)_3SiLi{\cdot}3$ thf[52] (1.01 g, 2.14 mmol) in 30 ml of *n*-hexane, was added a solution of tmp_2AlBr (0.83 g, 2.14 mmol) in 12 ml of *n*-hexane. After stirring overnight, the solvent was evaporated in vacuo. The residue was extracted with 20 ml of *n*-pentane, filtered, and the filtrate reduced to one-third of its original volume. Cooling of the yellow solution overnight at −20°C led to the deposition of 0.76 g (65%) of colorless crystals of **5f**, m.p. 203−206°C. (^{1}H-NMR and ^{13}C-NMR spectra at various temperatures are depicted in the text). − ^{1}H NMR (C_6D_6) (270 MHz): δ = 0.44 [s, 27 H, $Si(CH_3)_3$], 1.36 (t, 8 H, tmp-β-CH_2), 1.49 [s, 24 H, tmp-$C(CH_3)_2$], 1.63 (m, 4 H, tmp-γ-CH_2). − ^{13}C NMR (C_6D_6) (100 MHz): δ = 5.3 [$Si(CH_3)_3$], 18.6 (tmp-*C*4), 33.8 (tmp-*C*7−10), 41.4 (tmp-*C*3/5), 53.1 (tmp-*C*2/6). − ^{27}Al NMR (C_6D_6) (70 MHz): δ = 186 ($\Delta_{1/2}$ = 12400 Hz). − ^{29}Si NMR (C_6D_6) (55 MHz): δ = −7.9. − $C_{27}H_{63}AlN_2Si_4$ (555.13): calcd. C 58.42, H 11.44, Al 4.9, N 5.05; found C 55.99, H 11.52, Al 5.0, N 4.92 (C/H/N: calcd. 13.50:31.50:1; found 13.27:32.54:1).

tmp_2AlMe (**5h**) *and $[(tmpCO_2)_2AlMe]_2$* (**5i**): To a solution of tmp_2AlCl (40 ml, 0.20 M, 8.0 mmol) in *n*-hexane, 10 ml of a freshly prepared solution of $LiSnMe_3$ (1.0 M, 10.0 mmol) in THF was added over a period of 30 min. After stirring the mixture overnight, all volatile materials were removed in vacuo and the residue was extracted with 30 ml of *n*-pentane. From a portion of this solution all volatiles were removed in vacuo and the maining oil was subjected to analysis by NMR and mass spectrometry and proved to be **5h**. − ^{1}H NMR (C_6D_6) (60 MHz): δ = −0.24 (s, 3 H, Al-CH_3), 1.45 (s, 24 H, tmp-CH_3), 1.40 (t, 8 H, tmp-β-CH_2), 1.70 (m, 4 H, tmp-γ-CH_2). − ^{13}C NMR (C_6D_6) (100 MHz): δ = −1.0 [Al(*C*H_3)], 18.5 (tmp-*C*4), 34.3 (tmp-*C*7−10), 40.4 (tmp-*C*3/5), 52.0 (tmp-*C*2/6). − ^{27}Al NMR (C_6D_6) (70 MHz): δ = 173. − MS (70 eV, 30°C): *m*/*z* (%) = 322 (41) [$tmp_2AlMe^{+\cdot}$].

Since crystals of **5h** could not be obtained from the *n*-pentane solution, 5 ml of diethyl ether was added. The solution was then cooled to −78°C (dry-ice). During the course of several weeks, CO_2 slowly diffused into the vessel and underwent insertion into the Al−N bonds, resulting in the deposition of colorless crystals of **5i** (1.93 g, 29%), m.p. 140−142°C. − ^{1}H NMR (C_6D_6) (400 MHz): (monomer): δ = −0.24 (br. s, Al-CH_3), 1.30 (t, 8 H, tmp-β-CH_2), 1.56 (s, 24 H, tmp-CH_3); (dimer): δ = −0.24 (br. s, Al-CH_3), 1.41, 1.44 (2 t, each 8 H, tmp-β-CH_2), 1.61, 1.64 (2 s, each 24 H, tmp-CH_3). − ^{13}C NMR (C_6D_6) (100 MHz): (monomer): δ = 16.2 (tmp-γ-*C*H_2), 29.3 (tmp-*C*H_3), 42.0 (tmp-β-*C*H_2), 57.3 (N-*C*), 170.1 (N-*C*O_2), Al−C signal not observed; (dimer): δ = 15.3, 16.5 (tmp-γ-*C*H_2), 29.7, 29.9 (tmp-*C*H_3), 39.4, 42.7 (tmp-β-*C*H_2), 57.0, 57.2 (N−*C*), 160.9 (N−*C*O_2), Al−C signal not observed. − ^{27}Al NMR (C_6D_6) (70 MHz): (monomer): δ = 21 ($\Delta_{1/2}$ = 1120 Hz); (dimer): δ = 9 ($\Delta_{1/2}$ = 980 Hz). − IR (Nujol): ν = 1582 cm^{-1}, ν(C=N)].

− $C_{42}H_{78}Al_2N_4O_8$ (821.07): calcd. C 61.44, H 9.58, Al 5.1, N 6.82; found C 60.60, H 9.36, Al 5.0, N 6.72.

[(Me$_3$Si)$_3$Si(OEt)Al(μ-OEt)]$_2$ (**5j**): To a stirred solution of $tmp_2AlSi(SiMe_3)_3$ (0.78 g, 1.8 mmol) in 25 ml of *n*-hexane, was added 10 ml (3.5 mmol) of a 2% EtOH solution in *n*-hexane. The turbid mixture was exposed to ultrasound for 24 h and then filtered. The yellow filtrate thus obtained was reduced in vacuo to a volume of 5 ml and stored at −20°C, resulting in the deposition of 0.56 g (85%) of colorless crystals of **5j**. − ^{1}H NMR (C_6D_6) (270 MHz): δ = 0.17 [s, 54 H, Si(C*H*$_3$)$_3$], 1.20 (t, 6 H, OCH$_2$C*H*$_3$), 1.28 (t, 6 H, μ-OCH$_2$C*H*$_3$), 4.13 (q, 4 H, μ-OC*H*$_2$), 3.86 (q, 4 H, OC*H*$_2$). − ^{27}Al NMR (C_6D_6) (70 MHz): δ = 42.2 ($\Delta_{1/2}$ = 1660 Hz). − $C_{26}H_{74}Al_2O_4Si_8$ (729.53): calcd. Al 7.4; found 7.1.

[(PhO)$_3$AlSi(SiMe$_3$)$_3$]tmpH$_2$ (**5k**): To a stirred solution of $tmp_2AlSi(SiMe_3)_3$ (0.87 g, 2.0 mmol) in 25 ml of diethyl ether and 25 ml of *n*-hexane powdered phenol (0.37 g, 4.0 mmol) was added. The resulting suspension was stirred overnight, insoluble material filtered off, and the filtrate reduced in vacuo to a volume of 20 ml. Crystals of **5k** separated: yield 1.05 g (76%), m.p. 145−147°C. − ^{1}H NMR ($CDCl_3$) (400 MHz): δ = −0.04 [s, 27 H, Si(C*H*$_3$)$_3$], 1.36 (s, 12 H, tmp-C*H*$_3$), 1.45 [t, 4 H, ^{3}*J*(H,H) = 5.5 Hz, tmp-β-C*H*$_2$], 1.57 (m, 2 H, tmp-γ-C*H*$_2$), 6.78 [t, 3 H, ^{3}*J*(H,H) = 7.4 Hz, OPh-δ-C*H*], 6.97 [d, 6 H, ^{3}*J*(H,H) = 7.1 Hz, OPh-γ-C*H*], 7.17 [t, 6 H, ^{3}*J*(H,H) = 7.7 Hz, OPh-β-C*H*]. − ^{13}C NMR ($CDCl_3$) (100 MHz): δ = 3.4 [Si(*C*H$_3$)$_3$], 16.2 (tmp-*C*4), 28.3 (tmp-*C*H$_3$), 36.2 (tmp-*C*3/5), 57.4 (tmp-*C*2/6), 118.4 (OPh-β-*C*H), 120.5 (OPh-γ-*C*H), 129.5 (OPh-δ-*C*H), 158.7 (OPh-α-*C*H). − ^{27}Al NMR ($CDCl_3$) (70 MHz): δ = 91 ($\Delta_{1/2}$ = 1000 Hz). − ^{29}Si NMR ($CDCl_3$) (55 MHz): δ = −8.7. − IR (Nujol): ν = 3076 cm^{-1} [ν(N−H)]. − $C_{36}H_{62}AlNO_3Si_4$ (694.20): calcd. C 62.11, H 8.98, N 2.01; found C 60.57, H 8.80, N 2.1 (C/H: calcd. 1:1.72; found 1:1.73).

[(Me$_3$Si)$_3$SiAlCl$_3$][tmpH$_2$] (**5l**): To a stirred solution of $tmp_2AlSi(SiMe_3)_3$ (0.55 g, 1.25 mmol) in 40 ml of *n*-hexane at −70°C, was added HCl (21.9 ml of a 0.225 M solution of HCl in diethyl ether, 5.0 mmol). The mixture was then allowed to warm to ambient temperature and stirring was continued overnight. The insoluble material was filtered off, all volatiles from the solution were removed in vacuo, and the residue was dissolved in 15 ml of CH_2Cl_2. Cooling of this solution overnight at −20°C afforded colorless crystals of **5l**. Yield 0.41 g (65%), m.p. 154−155°C. − ^{1}H NMR ($CDCl_3$) (400 MHz): δ = 0.16 [s, 27 H, Si(C*H*$_3$)$_3$], 1.25 (m, 4 H, tmp-γ-C*H*$_2$), 1.52 (s, 24 H, tmp-C*H*$_3$), 1.67 (m, 8 H, tmp-β-C*H*$_2$). − ^{13}C NMR ($CDCl_3$) (100 MHz): δ = 0.9 [Si(*C*H$_3$)$_3$], 22.9 (tmp-*C*4), 35.0 (tmp-*C*7−10), 38.6 (tmp-*C*3/5), 58.0 (tmp-*C*2/6). − ^{27}Al NMR ($CDCl_3$) (70 MHz): δ = 133 ($\Delta_{1/2}$ = 3000 Hz). − ^{29}Si NMR ($CDCl_3$) (55 MHz): δ = −8.5. − $C_{18}H_{47}AlCl_3NSi_4$ (523.26): calcd. C 46.27, H 9.63, N 4.00; found C 45.79, H 9.50, N 3.64. − Crystal structure analysis was carried out with a crystal of the composition $[(Me_3Si)_3SiAlCl_3][tmpH_2][tmpH_2]Cl \cdot 0.25\ OEt_2$.

tmp$_2$AlH$_2$BH$_2$ (**6a**): A suspension of $LiBH_4$ (0.070 g, 3.3 mmol) in 20 ml of *n*-hexane was cooled to −78° C, and a solution of tmp_2AlBr (0.64 g, 1.7 mmol) in 5 ml of *n*-hexane was added dropwise. The mixture was then allowed to warm to ambient temperature and stirred overnight. Removal of the insoluble material by filtration yielded a yellow solution, which was reduced to a volume of 15 ml and stored overnight at −20°C. The resulting precipitate of **6a** (0.23 g, 42%) melted with decomposition at $T > 316$°C. − ^{1}H NMR (C_6D_6) (270 MHz): δ = 1.37 (s, 24 H, tmp-C*H*$_3$), 1.25 (t, 8 H, tmp-β-C*H*$_2$), 1.57 (m, 4 H, tmp-γ-C*H*$_2$). − ^{13}C NMR (C_6D_6) (100 MHz): δ = 52.5 (tmp-*C*2,6), 40.5 (tmp-β-*C*H$_2$), 34.0 (tmp-*C*H$_3$), 18.5 (tmp-γ-*C*H$_2$). − ^{11}B NMR (C_6D_6) (64 MHz): δ = −24.4 (quint) [^{1}*J*(B−H) = 85 Hz]. − ^{27}Al NMR (C_6D_6) (70 MHz):

[a] $w^{-1} = \sigma^2F_o^2 + (xP)^2 + yP$; $P = (F_o^2 + 2F_c^2)/3$.

δ = 125 ($\Delta_{1/2}$ = 7040 Hz). − IR (Nujol): $\tilde{\nu}$ [ν(B−H) region] = 2289 cm^{-1} vs, 2317 vs, 2341 vs, 2403 vs, 2455 m. − MS: m/z = 322 [$tmp_2AlH_2BH_2^+$]. − $C_{18}H_{40}AlBN_2$ (322.32): calcd. Al 8.4; found Al 8.9.

tmp_2AlH_2(9-BBN) (**6b**): LiH_2(9-BBN) (1.52 g, 6.25 mmol) was suspended in 20 ml of *n*-hexane. At ambient temperature, 25 ml of a 0.20 M *n*-hexane solution of tmp_2AlCl (5.0 mmol) was added and the mixture was stirred overnight. The clear, yellow solution was then reduced to one-third of its original volume. Cooling of the solution overnight at −20°C afforded 1.59 g (74%) of colorless crystals of **6b**, m.p. > 288°C (decomp.). − ^1H NMR (C_6D_6) (400 MHz): δ = 1.39 (s, 24 H, tmp-CH_3), 1.23 (t, 8 H, tmp-β-CH_2), 1.58 (m, 4 H, tmp-γ-CH_2), 1.60−2.20 (m, 14 H, 9-BBN-CH_2). − ^{13}C NMR (C_6D_6) (100 MHz): δ = 52.2 (tmp-*C*2,6), 41.1 (tmp-β-*C*H_2), 33.6 (tmp-*C*H_3), 18.4 (tmp-γ-*C*H_2), 24.6 (9-BBN-*C*H_2), 34.6 (9-BBN-*C*H_2), B−C signal not observed. − ^{11}B NMR (C_6D_6) (64 MHz): δ = −3.0 (s, $\Delta_{1/2}$ = 207.4 Hz ^1H-decoupled; $\Delta_{1/2}$ = 246.7 Hz ^1H-coupled). − ^{27}Al NMR (C_6D_6) (70 MHz): δ = 115 ($\Delta_{1/2}$ = 10700 Hz). − IR (Nujol): ν [ν(B−H) region] = 1706 cm^{-1} w, 1753 w, 1788 w, 1824 m, 1859 m, 1895 s, 1911 vs, 1955 vs, 1997 vs, 2057 s, 2200 w. − $C_{26}H_{52}AlBN_2$ (430.51): calcd. C 72.54, H 12.18, Al 6.3, N 6.51; found C 67.86, H 11.55, Al 6.4, N 5.54 (C/H/N: calcd. 13:26:1; found 14.28:28.97:1; C/H: calcd. 1:2; found 1:2.02).

X-ray Crystal Structure Determinations: Data collection for X-ray structure determinations was performed with a Syntex P4 or a Syntex R3 four-circle diffractometer, using graphite-monochromated Mo-K_α (0.71073 A) radiation. Single crystals were mounted in Lindemann capillaries and sealed under argon. Other data collections for X-ray structure determinations were performed with a Syntex P4 four-circle diffractometer equipped with a CCD area detector[53]. Single crystals were mounted in polyfluoroether oil and fixed on top of a glass fibre. Data collections were carried out at −80 to −100°C. All calculations were performed on PCs and workstations using the Siemens SHELXTL-Plus[54] or SHELX-93[55] software packages. The structures were solved by direct or heavy-atom methods and successive interpretation of the difference Fourier maps, followed by least-squares refinement. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in the final refinement in calculated positions by a riding model using fixed isotropic parameters. Relevant data relating to the crystallography, data collection and refinement are compiled in Table 4. Further details on the crystal structure determinations have been deposited with the Cambridge Crystallographic Data Centre and may requested by quoting the depository number CCDC-101483, the names of the authors, and the full journal citation.

Keywords: Sol-gel process / Polymers, inorganic / Transition metal alkoxides / ^{17}O-NMR spectroscopy

The behavior of titanium and zirconium alkoxides towards complexation and water addition is analyzed through water titration and calorimetric experiments. A simple model is presented, which allows evaluation of the mean hydrolysis and condensation constants, K_h and K_c, of both pure and complexed transition metal alkoxides in the sol state, through the analysis of consumed water versus initial hydrolysis ratio curves. These constants allow comparison of the extents of the hydrolysis and condensation reactions for sols obtained from several alkoxide precursors. The complexation ratio only affects the condensation constant K_c, whereas the hydrolysis constant K_h remains unchanged. Analysis of the K_h/K_c ratios has shown that in the sol state, silanol Si–OH groups are more stable than the Ti–OH or Zr–OH groups. Moreover, this study has shown that the proton concentration not only affects the kinetics, but also the final composition of the system. Calorimetric studies of the complexation and hydrolysis/condensation reactions have highlighted the role of coordination unsaturation of the transition metal alkoxides in the exothermicity of these reactions, clearly demonstrating that coordination unsaturation is the driving force behind the reactivity of these alkoxides towards nucleophilic species (e.g. water, complexing ligands, polar solvents).

Introduction

Sol-gel processes are a means of preparing dispersed materials through the growth of metal oxo-polymers in a solvent[1][2][3]. Indeed, sol-gel chemistry is based on inorganic polymerization reactions. Metal oxo-polymers can be obtained through hydrolysis and condensation of molecular precursors such as metal alkoxides $M(OR)_n$ (where M = Si, Ti, Zr, Al, Sn, Ce; OR is an alkoxy group, and n is the valence or the oxidation state of the metal). In the case of silicon alkoxides, these reactions are known to be equilibrium processes[4]. The present work demonstrates, through the use of ^{17}O-NMR spectroscopy, that, in the sol state, the hydrolysis and condensation reactions of titanium alkoxides also exhibit reversible behavior. These reactions start with the nucleophilic addition of hydroxylated groups to the electrophilic metal atom M, which leads to an increase of the coordination number of the metal atom in the transition state[3]. Consequently, the chemical reactivity of metal alkoxides toward nucleophilic reactions largely depends on the electrophilic character of the metal and its ability to increase its coordination number.

Silicon has a low electrophilicity and it remains tetracoordinated in the $Si(OR)_4$ alkoxide precursors, as well as in its oxide. Thus, silicon alkoxides are not very reactive and gelation times range from hours to several days. On the other hand, many non-silicate metal alkoxides including transition metal alkoxides, lanthanides, aluminum, tin alkoxides, etc. are coordinatively unsaturated and in most cases the metallic center exhibits a higher electrophilicity than silicon[5]. These alkoxides are consequently very reactive towards nucleophilic reagents. Both the higher electrophilicity and the coordination unsaturation of the metallic center can be invoked in explaining this higher reactivity of non-silicate alkoxides. However, coordination unsaturation seems to be the key parameter: titanium (χ = 1.32), zirconium (χ = 1.29), and cerium (χ = 1.17) have electronegativities χ lower than that of silicon (χ = 1.74), whereas the value for tin (χ = 1.89) is higher. Thus, the difference in electrophilicities of the metal atoms does not seem to be the key parameter to account fully for the much higher reactivity of these non-silicate tetravalent alkoxides. In the work described herein, we confirm experimentally that coordination unsaturation is the main driving force behind the reactivity of transition metal alkoxides.

Hydrolysis/condensation reactions of silicon alkoxides are rather slow, and consequently they can be monitored using many analytical techniques (e.g. chromatography, infrared spectroscopy[6]). Moreover, silicon has an isotope with a nuclear spin I = 1/2, so that ^{29}Si-NMR experiments offer the possibility of accurately characterizing the different species (monomers, oligomers, etc.) generated by hydrolysis and condensation[1][7][8][9][10]. This accurate NMR speciation allows the determination of kinetic and thermodynamic constants for the different reactions occurring during the formation of silica-based sol-gel materials (hydrolysis, condensation, transalcoholysis, esterification).

Hydrolysis and condensation reactions of non-silicate metal alkoxides must, on the other hand, be controlled by using inhibitors such as high proton concentration[8] or complexing ligands[9]. However, even in the presence of inhibitors, the kinetics are too fast to be monitored by the usual techniques employed for the characterization of silicon-based systems. Moreover, many of the most interesting systems, as far as the field of material science is concerned[1][2][3][4][5][6][7][8][9][10][11][12], are not amenable to study by NMR because they are paramagnetic (Fe^{III}, $Mn^{II,III}$, Co^{II}, etc.) or because they possess a strong quadrupolar moment ($^{47}Ti^{IV}$, $^{49}Ti^{IV}$, $^{91}Zr^{IV}$, $^{93}Nb^{V}$, etc.). Since it is extremely difficult to get detailed and specific information on the hydrolysis/condensation reactions of transition metal alkoxides, an alternative approach is to collect macroscopic information and to rely upon a model to estimate the chemical composition of the polycondensates. This approach has been very successful with regard to organic polymers. Preferentially, the analysis of the polycondensates should be done in the wet state, before any drying process that can result in further condensation reactions and therefore modify the chemical composition of the system. The development of new tools could be especially helpful in classifying the behavior of metal alkoxides towards complexation, hydrolysis, and condensation reactions. A better knowledge of the extent of these reactions is of paramount importance because the structures and morphologies of the resulting networks are strongly dependent on their relative contributions. Control of the growth of transition metal oxo-polymers can be achieved through changes in the chemical reactivity of each component. The hydrolysis ratio ($H = H_2O/M$), the use of a catalyst[8], of complexing ligands[11], or of a templating medium[12][13] are the main factors that must be mastered by the sol-gel chemist in order to achieve this control.

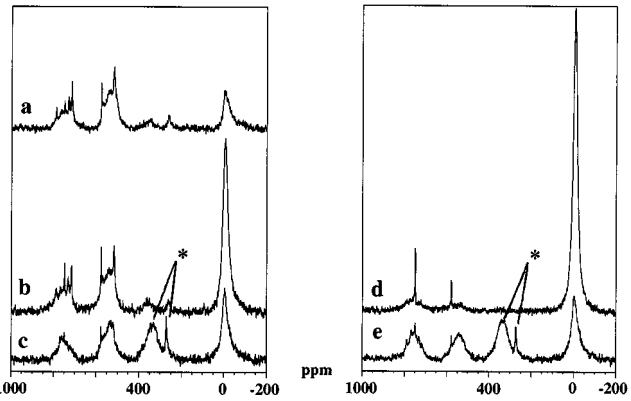
Taking titanium and zirconium alkoxides as examples, two main points will be discussed in this article: (i) the calorimetric behavior of transition metal alkoxides towards complexation and hydrolysis, and (ii) a model leading to an evaluation of mean hydrolysis and condensation pseudo-equilibrium (metastable equilibrium) constants of transition metal alkoxides through the analysis of water titration curves. This simple model, based on constants evaluated from a mean polymer formula, leads to a pertinent classification of the alkoxides, and allows determination of the extents of the hydrolysis and condensation reactions. However, because this model is simple, it necessarily involves certain approximations, which, of course, imply limitations. These limitations will be discussed in the context of the evolution of silica-based systems, for which hydrolysis and condensation constants have been evaluated using both the model and the speciation provided by ^{29}Si-NMR experiments.

Results and Discussion

Evidence of the Reversibility of Hydrolysis/Condensation Reactions

The ^{17}O-NMR spectrum of sample ① was recorded just before the second hydrolysis (a), 5 min. after the second hydrolysis (b), and after 24 h of ageing (c); the ^{17}O-NMR spectrum of sample ② was recorded 5 min. after the second hydrolysis (d), and after 24 h of ageing (e). The spectra obtained are presented in Figure 1.

Figure 1. (Left:) ^{17}O-NMR spectra of sample ①, just before the second hydrolysis (a), 5 min. after the second hydrolysis (b), and 24 h after (c). (Right:) ^{17}O-NMR spectra of sample ②, 5 min. after the second hydrolysis (d), and 24 h after (e).[a]



[a] For sample ①, the water used for the first and second hydrolyses was 5%-enriched in oxygen-17. – For sample ②, the first hydrolysis was performed with unenriched water and the second hydrolysis with 10%-enriched water. The total hydrolysis ratio of the sample was equal to 2. – The two peaks (see *) at $\delta = 273$ (enol form of free acetylacetone) and at about $\delta = 340$ (acetylacetone bonded to titanium) result from the isotopic ^{17}O exchange between H_2O and acacH (ketolization).

Spectrum (a) has already been described in a previous report[28]. Five signals are observed, which can be assigned as follows:

$\delta = 800-650$	μ_2O oxo-bridges
$\delta = 600-450$	μ_3O oxo-bridges
$\delta = 400-300$	μ_4O oxo-bridges
$\delta = 300-200$	μ_5O oxo-bridges
$\delta \approx 0$	H_2O

A second addition of water to sample ① resulted, after a short time spectrum (b)], in a significant increase in the intensity of the H_2O signal ($\delta = -50$ to 50), and in a slight increase in the intensity of the signals of the μ_2O and μ_3O oxo bridges (see Table 1); the intensities of the μ_4O and μ_5O oxo bridge signals remained the same, within an experimental error of ±10%. The ratio of residual water to oxo bridges, H_2O/Σ_{oxo}, was around 1:1. After 24 h of ageing, the intensities of the μ_2O and μ_3O oxo-bridge signals decreased slightly. The main evolution of the spectrum was seen in the $\delta = 200-400$ region, where a significant increase of the intensities was observed. In this chemical shift region, two kinds of signals can be observed:

- the signals of the μ_4O and μ_5O oxo bridges, which have been previously observed in the spectra (a) and (b);
- the signals of free and titanium-bound acac ($\delta = 273$ and 300–400, respectively).

The chemical shift and the width of the narrow peak ($\delta = 272$, $w = 370$ Hz) correspond exactly to those of free acac, and make the assignment of this peak to the free ligand unambiguous. The signal in the range $\delta = 300-400$ can be

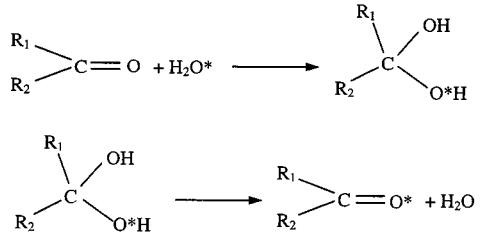
Table 1. Intensities of the peaks of the spectra of Figure 1. For sample ①, the water used for the first and second hydrolyses was 5%-enriched in oxygen-17. For sample ②, the first hydrolysis was performed with unenriched water and the second hydrolysis with 10%-enriched water. The total hydrolysis ratio of the sample was equal to 2

		μ_2O (δ = 800−650)	μ_3O (δ = 600−400)	μ_4O or bonded acac (δ = 400−300)	μ_5O or free acac (δ = 300−200)	water (δ ca. 0)	sum of the intensities[a]
	before the 2nd hydrolysis (a)	4	7	1	<1	4	16
sample ①	5 min. after (b)	5	8	1	<1	14	28
	24 hours ageing (c)	4	7	5	1	9	26
sample ②	5 min. after (d)	2	3	–	–	25	30
	24 hours ageing (e)	7	6	5	1	10	29

[a] The sum of the intensities of the spectra of samples ① and ② after the second addition of water and after 24 hours of ageing are equal within an experimental error of ±10% and the sum of the intensities of sample ① before the second hydrolysis is about half of that of sample ② after the second hydrolysis, within an experimental error of ±15%.

assigned to both μ_4O oxo bridges (which are also observed in the spectrum recorded 5 min after the second hydrolysis) and to acac bonded to titanium. However, previous studies performed on acac-complexed and uncomplexed titanium butoxide have all shown a decrease in the intensity of the signal of the μ_4O bridges with time[28]. The significant increase of intensity observed in this chemical shift region after 24 h of ageing can therefore be mainly assigned to the enrichment of acac in oxygen-17, according to the reaction described in Scheme 1.

Scheme 1. Reaction leading to ^{17}O enrichment of the ketones



Just after the second addition of water, the spectrum of sample ② was very different to that of sample ①. In spectrum (d), the signals due to the μ_2O and μ_3O oxo-bridges are weak, and the ratio of residual water to oxo bridges, H_2O/Σ_{oxo}, is around 6:1. The evolution of the spectrum of sample ② over a period of 24 h was drastic spectrum 2, (e)]. In fact, after 24 h of ageing, it became very similar to that of sample ① (see Table 1 for the intensities of the oxo bridge signals and the water signal). One could also observe the appearance of two signals in the 200−400 region, which can be assigned to free and titanium-bonded acac, respectively.

For these two samples, when the second hydrolysis takes place, many oxo-bridges are already present following the addition of the first mole of water. The difference between these two samples is the as follows: in the case of sample ①, these pre-formed oxo-polymers are 5%-enriched in oxygen-17, whereas in the case of sample ②, these oxo-polymers are initially unenriched. The second addition of water leads to a further hydrolysis of the pre-formed oxo-polymers, which results in the formation of new oxo-bridges. This second mole of water is only partially consumed by the hydrolysis reaction and some water remains in solution. In the case of sample ①, the enrichment of the pre-formed polymers, of the new oxo bridges, and of the residual water is the same (5% in oxygen-17), whereas in sample ②, the unenriched pre-formed polymers are, after the second hydrolysis, in the presence of 10%-enriched water. The slight increase in the intensities of the μ_2O and μ_3O signals in spectrum (b) of sample ①, as well as the two weak μ_2O and μ_3O signals observed in spectrum (d) of sample ②, can be assigned to this further hydrolysis. On the other hand, the oxo-bridges that appear in the spectrum of sample ② after 24 h of ageing cannot be assigned to such a reaction because the intensities of these two peaks are only weakly modified after 24 h of ageing in the case of sample ①. This further modification of the spectrum of sample ② can therefore be attributed to ^{17}O exchange between the enriched water and the unenriched oxo-polymers. The pre-formed oxo-core is consequently accessible to nucleophilic species, and depolymerization/repolymerization reactions can occur. The depolymerization reactions imply the nucleophilic attack of a water molecule at the metallic center, and, therefore, an increase of its coordination. A mechanism can be proposed, in which the first step is the change of coordination of the acetylacetonate group from bidentate to monodentate; the water molecule can then occupy the empty coordination site and subsequently be incorporated into the network by intramolecular rearrangements[14].

This experiment highlights the equilibrium behavior of the hydrolysis and condensation processes. It was performed at a low hydrolysis ratio (H = 2) in order to avoid any quantitativity problems: at a higher initial hydrolysis ratio, part of the oxo signal is lost due to the formation of large titanium oxo-polymers that cannot be detected using solution ^{17}O-NMR[28]. However SAXS experiments[15][16] have shown that the titanium oxo-polymer sols and gels synthesized under these conditions are tenuous (the fractal dimension of the titanium oxo-polymers varies between 1.5 and 2.5, depending on the hydrolysis, complexation, or proton ratio). The fact that the structure of the oxo-polymers is non-dense indicates a high surface-to-volume ratio, which will favor the equilibria between the polymers and the water and alcohol molecules present in the solution. In the sol state, the swollen titanium oxo-polymers are not kinetically "locked-in".

Evaluation of Hydrolysis/Condensation Constants Through Water Titration Data

Curves showing the consumed water h as a function of the initial hydrolysis ratio H of the various alkoxides are shown in Figures 2−4. These curves have been fitted using Equation 5 and the values of K_h and K_c obtained are reported in Table 2 (See Experimental Section).

Figure 2. Hydrolysis of Ti(O*n*Bu)$_4$: variation of the consumed water h with the initial hydrolysis ratio H at different complexation ratios r

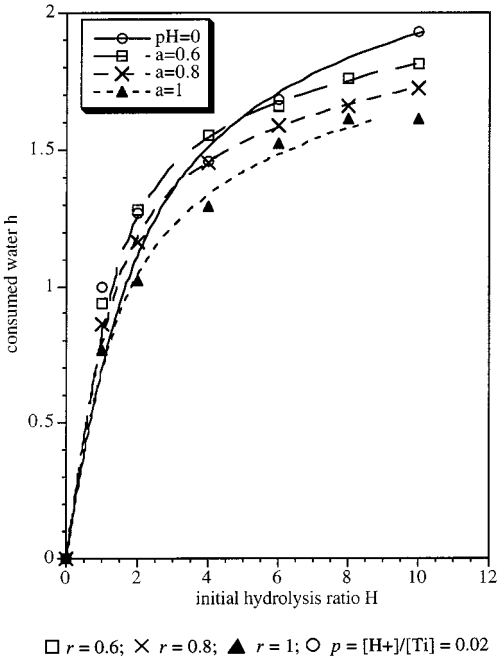


Figure 3. Hydrolysis of Zr(O*n*Pr)$_4$: variation of the consumed water h with the initial hydrolysis ratio H at different complexation ratios r

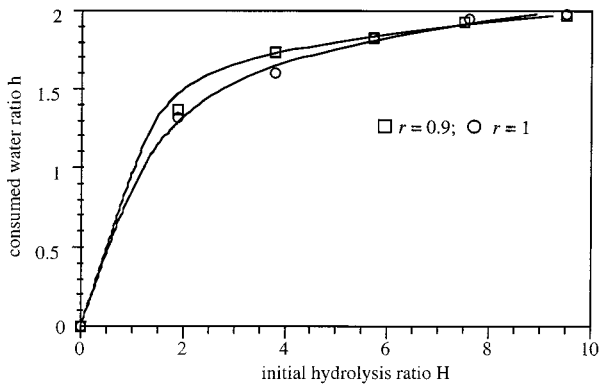

Titanium Oxide Based Sols

The curves $h = f(H)$ of Ti(O*n*Bu)$_4$ are presented in Figure 2. At low initial hydrolysis ratios ($H \leq 1$), the consumption of water is almost complete. At higher initial hydrolysis ratios, the water is only partially consumed and its consumption tends toward a limiting value that depends on the complexation ratio. The values of K_h and K_c calculated for this

Figure 4. Hydrolysis of Si(OEt)$_4$: variation of the consumed water h with the initial hydrolysis ratio H at different pH values of the hydrolysis solution

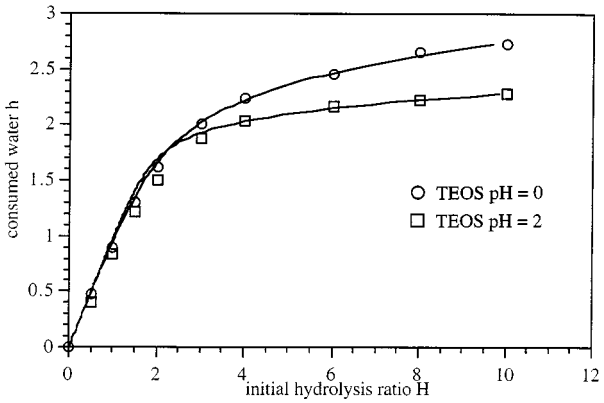

Table 2. Hydrolysis constants K_h and condensation constants K_c for reactions of Ti(O*n*Bu)$_4$, Zr(O*n*Pr)$_4$, Si(OEt)$_4$, calculated using Equation 5

Sample	Hydrolysis constant K_h	Condensation constant K_c
Ti(O*n*Bu)$_4$ $r = 0.6$	0.51 ± 0.01	16 ± 2
Ti(O*n*Bu)$_4$ $r = 0.8$	0.52 ± 0.01	15 ± 1
Ti(O*n*Bu)$_4$ $r = 1$	0.52 ± 0.1	8 ± 4
Ti(O*n*Bu)$_4$ $p = [H^+]/[Ti] = 0.02$	0.55 ± 0.04	16 ± 5
Zr(O*n*Pr)$_4$ $r = 0.9$	3 ± 1	30 ± 10
Zr(O*n*Pr)$_4$ $r = 1$	1.8 ± 0.5	7 ± 3
Si(OEt)$_4$ pH = 0	2.1 ± 0.2	6 ± 1
Si(OEt)$_4$ pH = 2	1.2 ± 0.1	26 ± 6

alkoxide do not depend strongly on the experimental conditions: K_h is equal to 0.5 in all cases (hydrolysis of acac-modified precursors or acidic hydrolysis). However, the value of K_c seems to depend slightly on the complexation ratio, increasing marginally as the complexation ratio decreases. The ratio $K_o = K_c/K_h$ is always very high (between 16 and 32), indicating that the majority of Ti−OH groups are engaged in forming oxo bridges. It is possible to calculate the theoretical values of $k = [M-O-M]/[M(OR)_4]$, h, $(h - k) = [M-OH]/[M(OR)_4]$, and $(4 - r - h - k) = [M-OR]/[M(OR)_4]$ from the values of K_h and K_c using Equations 5 and 6. Figure 5 shows the calculated consumed water ratio h, the condensation ratio k, the titanium hydroxyl ratio $(h - k)$ and the alkoxy ratio $(4 - r - h - k)$ as functions of the initial hydrolysis ratio H for $K_h = 0.51$ and $K_c = 16$ (i.e., for the complexation ratio $r = 0.6$). This simulation shows that the alkoxy ratio decreases very quickly: for an initial hydrolysis ratio $H = 10$, 90% of the alkoxy groups have been hydrolyzed. This simulation also shows that the Ti−OH ratio is very small at a low initial hydrolysis ratio; at higher initial hydrolysis ratios, however, the Ti−OH/Ti ratio becomes rather significant: at $H = 10$ it has a value of 0.5. This simulation is therefore an indirect proof of the presence in solution of such groups, the number of which increases with increasing initial hydrolysis ratio. The mean formula for the titanium oxo-polymers can be calculated from the fitted values of h, k, and r. As an

example, the mean formulae of the polymers obtained through hydrolysis ($0.5 < H < 10$) of one of the acac-modified samples ($r = 0.6$) are reported in Table 3. The self-consistency of this simple model can be checked by comparing the calculated Ti−OH/Ti ratio to that estimated from Karl-Fischer titrations. This estimation can be performed by carrying out the titration in two different solvents. The first one, 2-chloroethanol, is quite inert to the presence of M−OH groups, while the second one, methanol, reacts with M−OH groups to form M−O−Me groups with elimination of water. As a matter of fact, as shown in Figure 6 for the same sample (for example $r = 0.6$, $H = 2$), the measured consumption of water versus time in methanol solution is less than that measured in 2-chloroethanol. The difference between the two curves permits an evaluation of the M−OH/M ratio. This ratio was found to be 0.15, which is quite close to that calculated from the fitted K_h and K_c constants, and which leads to the following mean formula $[TiO_{1.09}acac_{0.6}(OH)_{0.16}(OR)_{1.06}]$.

Figure 5. Simulation of the curves h, k, $(h - k)$, $(4 - r - h - k) = f(H)$ for $K_h = 0.51$ and $K = 16$

Zirconium Oxide Based Sols

The measured values of h as a function of H for $Zr(OnPr)_4$ complexed by acetylacetone ($r = 0.9$; $r = 1$) are plotted in Figure 3. The curves $h = f(H)$ have a shape similar to those for $Ti(OnBu)_4$: the consumption of water increases as H increases. At a low initial hydrolysis, ratio most of the water is consumed. At higher initial hydrolysis ratios, the $h = f(H)$ curves show marked deviations from linearity; the h values are invariably below 2, even at $H = 10$. These results underline the fact that the hydrolysis/condensation reactions are incomplete. The curves have been fitted using Equation 5 and the values of K_h and K_c obtained for these systems are reported in Table 2. The hydrolysis constants of the two systems are rather similar, but the condensation constant seems, as in the case of $Ti(OnBu)_4$, to increase as the complexation ratio decreases. These results allow quantification of the inhibitory effect towards condensation of complexing ligands such as acac.

Silicon Oxide Based Sols

Karl-Fischer titrations were performed for the two series of samples. The values of K_h and K_c are reported in Table 2 and the curves $h = f(H)$ are plotted in Figure 4. They are

Table 3. Mean formula of titanium oxo-polymers calculated from K_h and K_c values at different hydrolysis ratios and $r = [acac]/[Ti(OnBu)_4] = 0.6$. H is the $[H_2O]/[Ti]$ ratio, h is the consumed water ratio, Ti−O−Ti is the ratio of oxo bridges per titanium, Ti−OH is the ratio of hydroxo groups per titanium, and H_2O is the ratio of unconsumed water molecules per titanium

H	h	Ti−O−Ti	Ti−OH	Ti−OR	H_2O	structural unit
0	0	0	0	3.4	0	$Ti\ (acac)_{0.6}(OR)_{3.4}$
0.5	0.45	0.42	0.02	2.52	0.05	$TiO_{0.42}(acac)_{0.6}(OH)_{0.02}(OR)_{2.52}$
1	0.85	0.78	0.07	1.77	0.19	$TiO_{0.78}(acac)_{0.6}(OH)_{0.07}(OR)_{1.77}$
2	1.25	1.09	0.16	1.06	0.73	$TiO_{1.09}(acac)_{0.6}(OH)_{0.16}(OR)_{1.06}$

6	1.67	1.26	0.41	0.47	4.29	$TiO_{1.26}(acac)_{0.6}(OH)_{0.41}(OR)_{0.47}$
8	1.75	1.26	0.49	0.39	6.19	$TiO_{1.26}(acac)_{0.6}(OH)_{0.49}(OR)_{0.39}$
10	1.81	1.25	0.56	0.33	8.31	$TiO_{1.25}(acac)_{0.6}(OH)_{0.56}(OR)_{0.33}$

similar to those of the titanium and zirconium alkoxides. At low hydrolysis ratios, most of the water is consumed; at higher initial hydrolysis ratios, the consumed water ratio h remains below 3.

The curves $h = f(H)$ of $Si(OEt)_4$ hydrolyzed at pH 0 and pH 2 are quite different. The two curves are in fact similar up to $H = 2$, but at higher initial hydrolysis ratios, the pH 2 curve stays below the pH 0 curve. The hydrolysis constants of these two systems are close, but the condensation constant at pH 2 is 4 times as high as that at pH 0. This result is consistent with the fact that the condensation is more complete at pH 2 than at pH 0[1]. Protons are usually considered as catalysts for hydrolysis/condensation reactions[8][15]. The above result shows that the proton concentration will also change the final composition of the system, and thus the effect of the protons is not merely kinetic. Protonation of the oxo- or hydroxo-bridges is likely to assist the redissolution-polymerization processes occurring during the formation of the transition metal oxo-polymers[17].

For titanium and zirconium alkoxides, the only experimental value that can be measured is the consumed water h. The measurement of the condensation ratio k should however give relevant information for the determination of the hydrolysis and condensation constants. With the values of h and k, it is indeed possible to calculate K_h and K_c, for each value of H, directly from Equations 3 and 4. The condensation ratio k can be measured for silicon alkoxides by means of ^{29}Si-NMR spectroscopy, which distinguishes the silicon atoms according to their chemical environments. The chemical shifts of the species $SiO_n(OR,OH)_{4-2n}$ ($0 < n < 4$) are reported in Table 4. We have used the commonly accepted notation to describe these species: a silicon Q^n is a silicon having n −OSi neighbors and $(4 - n)$ −OR (−OH) neighbors.

The NMR spectra of the systems {$Si(OEt)_4 + H\ H_2O$, pH = 0; $0.5 < h < 10$ } are presented in Figure 7; they have been fitted in order to derive the percentages of the atoms Q^n, as given in Table 4. The condensation ratios were calculated by using the formula:

$k = (\%Q^1 + 2 \times \%Q^2 + 3 \times \%Q^3 + 4 \times \%Q^4)/(2 \times 100)$,

where $\%Q^n$ is the percentage of the silicon atoms Q^n.

The k values are reported in Table 5, together with the consumed water ratio measured by a Karl-Fischer titration, and the values of K_h and K_c. K_h and K_c were calculated only between $H = 1.5$ and $H = 4$; at higher values of H, the Si−OR/Si ratio is too small to obtain relevant values of K_h and K_c; on the other hand, at lower values of H, the Si−OH/Si ratio is too small.

K_h and K_c values calculated for these samples using Equation 5 are reported in Table 2. The values of K_h obtained by the two methods are quite similar; however, the K_c values are different (from NMR the mean K_c is 10−12, while the mean K_c is 6−7 from water titration). These differences are especially noticeable at higher hydrolysis ratios. This discrepancy between the values of K_c obtained from ^{29}Si-NMR data and from the modelling of water titration curves, gives an indication of the limitations of the model. Such differences can have several sources:

Figure 7. ^{29}Si-NMR spectra of the systems [$Si(OEt)_4 + H\ H_2O$, pH = 0; $0.5 < H < 10$]

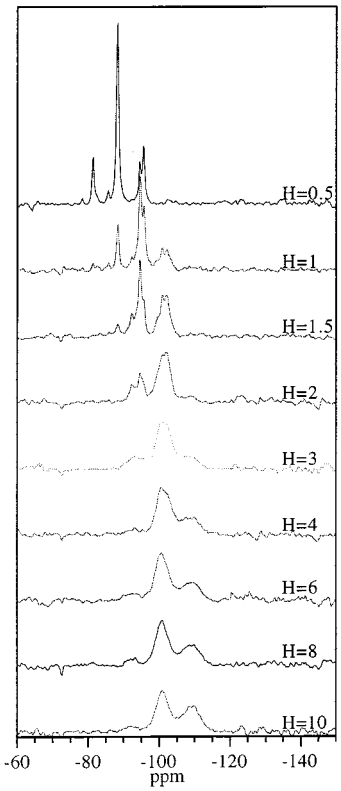

Table 4. Silicon-29 NMR chemical shifts [ppm] and percentage of Q^n species

6	2.40	1.6		
8	2.64	1.6		
10	2.99	1.7		

(i) The ^{29}Si resonances in the highly hydrolyzed samples ($H \geq 3$) are broad, indicating that some polymers have become so large that their mobility is restricted. This broadening of the NMR resonances is expected to reduce the precision of the NMR data. An accuracy of about ±15% in the integration of the NMR data would be sufficient to account for the differences observed between the two approaches.

(ii) some M−OH groups might have been partially titrated during Karl-Fischer titration, thus decreasing the accuracy of the estimation of the consumed water h.

Comparison of the Hydrolysis and Condensation Constants of Titanium, Zirconium, and Silicon Alkoxides

The curves $h = f(H)$ of these three alkoxides are similar: at low hydrolysis ratios, the hydrolysis reaction is almost complete, whereas at higher initial hydrolysis ratios, the consumed water tends towards a plateau. The titanium alkoxide has the lowest hydrolysis constant. The condensation constants of the titanium and zirconium species are similar. For these two alkoxides, the condensation constants are about 10 times higher than their respective hydrolysis constants. These results indicate that the condensation of M−OH groups is important and that the M−OH/M ratio is low. The influence of the complexation ratio on these two alkoxides is also the same: an increase of r results in a decrease of K_c, whereas K_h remains unchanged. The pH of the hydrolyzing solution does not seem to change K_h and K_c: their values are very close to those of the modified precursors. For silicon alkoxides, however, the condensation constant is strongly dependent on the pH of the hydrolyzing solution: at pH = 2, K_c is high, indicating that the condensation is almost complete. At pH = 0, K_c is low, the condensation reaction is in equilibrium, and the ratio [Si−OH]/[Si] is high. The silanol Si−OH groups seem to be more stable than the Ti−OH or Zr−OH groups. This result is consistent with previous ^{17}O-NMR studies: Ti−OH and Zr−OH have never been observed by liquid-state ^{17}O-NMR, whereas Si−OH groups give rise to readily detectable signals[16][18].

Calorimetric Study of the Complexation Reaction

The enthalpy of complexation of tetravalent transition metal alkoxides by acetylacetone provides a relevant insight into this reaction. Four alkoxides have been studied: three titanium alkoxides (ethoxide, butoxide, isopropoxide) and one zirconium alkoxide (*n*-propoxide). The curves of the enthalpy of complexation versus the complexation ratio r = [acac]/[M] are shown in Figure 8. These curves show that the complexation reaction is always exothermic ($\Delta H < 0$), but that it reaches a plateau at $r \geq 2$ for titanium alkoxides or at $r \geq 4$ for zirconium propoxide. The complexation enthalpies of these four alkoxides are reported in Table 6.

Moreover, the entropy change associated with complexation by chelating ligands is always positive[19], so that the free enthalpy $\Delta G = \Delta H - T\Delta S$ should be negative. Consequently, the equilibrium of complexation should be strongly shifted toward the formation of the chelated precursor up to $r = 2$ for titanium alkoxides or up to $r = 4$ for zirconium propoxide.

Figure 8. Variation of the enthalpies of complexation of several metal alkoxides by acetylacetone

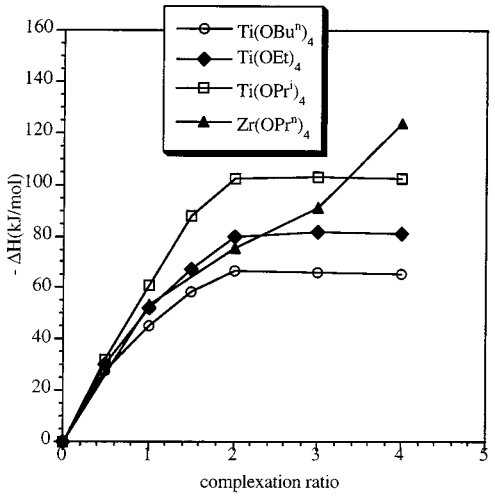

Table 6. Enthalpies (kJ·mol^{-1}) of the complexation reactions of Ti(O*n*Bu)$_4$, Ti(OEt)$_4$, Ti(O*i*Pr)$_4$, and Zr(O*n*Pr)$_4$. Gap [kJ·mol^{-1}] is the gap of enthalpy of complexation, taking Ti(O*i*Pr)$_4$ as reference

	Ti(O*n*Bu)$_4$	Ti(OEt)$_4$	Ti(O*i*Pr)$_4$	Zr(O*n*Pr)$_4$
Enthalpy of complexation	−67	−82	−102	−75 (2 acacH) −125 (4 acacH)
Energy of Ti−OR bond	−439	−422	−430	−
Gap (exp. value)	35	20	0	−
Gap (theoretical value)	18	−16	0	−

These results are in good agreement with previous observations, which have shown that, in the case of titanium alkoxides, substitution of the two first alkoxy groups by acetylacetone ligands occurs readily, but that the further replacement of a third alkoxy substituent by acetylacetone requires a large excess of the ligand[5]. Zirconium alkoxides, on the other hand, react readily with four acetylacetone ligands, thus forming the Zr(acac)$_4$ complex.

The complexation of the metallic center by acetylacetone results in an increase of its coordination number. For titanium, the most stable coordination number is 6; this is its usual coordination number in metallic oxides (rutile and anatase). The coordination number for titanium in the alkoxide precursor depends on the nature of the alkoxy group and on the solvent. For neat alkoxides, or in non-polar solvents such as benzene, the coordination number of titanium is 4 when the alkoxy is secondary or tertiary, or 5 with primary alkoxy groups. Primary alkoxides show a general tendency to form solvated dimers in alcoholic solution[5]. In the bis-complexed precursor Ti(OR)$_2$acac$_2$, however, the coordination number of the metallic center is 6. This increase in coordination number is the main reason for the exothermicity of the complexation reaction.

On the other hand, the most stable coordination numbers of zirconium are 7 and 8. Hence, zirconium propoxide can react with up to four acac ligands, forming the complex $Zr(acac)_4$, in which eightfold zirconium coordination is attained[20].

The complexation enthalpies of the various alkoxides are reported in Table 6. The enthalpies of the reactions involving $Ti(OnBu)_4$ and $Ti(OEt)_4$ are smaller than that with $Ti(OiPr)_4$. These enthalpies can be calculated from the bond energies:

$$\Delta H[Ti(OR)_4] = 2E(Ti-acac) + 2\,E(ROH) - 2E(Ti-OR) - 2E(acacH) \quad (1)$$

The bond energy values for the three titanium alkoxides are reported in Table 6. The energy of the RO−H bond depends only slightly on the nature of the R group[21].

Using Equation 1, we are able to calculate the gap between the enthalpies of two alkoxides. The calculated and experimental values of these gaps are also reported in Table 6. The reference point ($E = 0$) was taken as the value for $Ti(OiPr)_4$. The experimental and calculated values are at variance, both for $Ti(OnBu)_4$ and $Ti(OEt)_4$. In order to explain these differences, we have to take into account the structure of the alkoxides in solution in their parent alcohols. $Ti(OiPr)_4$ is monomeric, but $Ti(OEt)_4$ and $Ti(OnBu)_4$ are partially oligomerized via μ_2-OR bridges. The energies of these bridges have been previously calculated to be about 40 kJ·mol^{-1}, both for the ethoxy bridge[22] and for the butoxy bridge[23]. The enthalpy of the complexation reaction is therefore:

$$\Delta H[Ti(OR)_4] = 2E(Ti-acac) + 2E(RO-H) - 2E(Ti-OR) - 2E(acacH) - x\cdot E(alkoxo) \quad (2)$$

where x is the ratio bridges/titanium [$x = 0$ in the case of $Ti(OiPr)_4$].

Using Equation 2, we were are able to estimate the values of x for each alkoxide: $x_{Ti(OBu)4} = 0.9$ and $x_{Ti(OEt)4} = 1.8$. Of course, these values are only approximate, but they provide an interesting way of calculating the degree of oligomerization of the primary alkoxides in solution in their parent alcohols.

Calorimetric Study of Hydrolysis/Condensation Reactions

The enthalpies of hydrolysis were determined as described in the Experimental Section. The variations of the heats of hydrolysis of $Ti(OiPr)_4$, $Ti(OnBu)_4$, $Ti(OEt)_4$, and $Zr(OnPr)_4$ with the initial hydrolysis ratio, $H = H_2O$/metal, are plotted in Figure 9. The enthalpies of hydrolysis of these four alkoxides are reported in Table 7. The hydrolysis reaction is, in all cases, exothermic, which is in line with previous observations[5]. The curves $\Delta H = f(H)$ of the three titanium alkoxides show similar behavior: the hydrolysis reaction is exothermic up to $H = 1$ and reaches a plateau for $H > 1$. These results can be compared with those of the Karl-Fischer titrations, which show that at low initial hydrolysis ratios, the consumption of water is complete, while at higher initial hydrolysis ratios, the hydrolysis and condensation reactions are incomplete. These results can also be compared with those of XANES experiments, which have indicated that at low initial hydrolysis ratios, most of the titanium atoms become hexacoordinated[24]. We conclude from these results that the hydrolysis and condensation reactions are governed by the coordination unsaturation of the metallic center, which results in rapid reactions with any nucleophiles, and especially with water. However, the hydrolysis, oxolation, and alkoxolation reactions do not lead to an increase of coordination, since they correspond to nucleophilic substitution reactions. As a consequence, these results suggest that for transition metal alkoxides, the early stages of hydrolysis and condensation are driven by nucleophilic addition reactions. Among the two possible addition reactions, olation (creation of hydroxy bridges) or alkoxy bridging, olation is probably the driving force responsible for the high reactivity towards water of the transition metal alkoxides.

Figure 9. Variation of the enthalpy of hydrolysis/condensation of non-complexed alkoxides with the initial hydrolysis ratio; influence of the complexation ratio

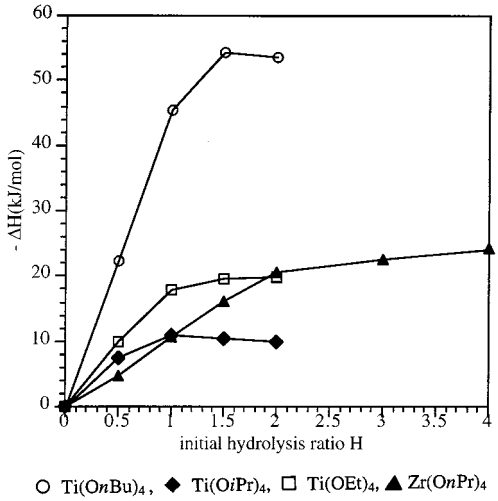

Table 7. Enthalpies of the hydrolysis reactions of: $Ti(OnBu)_4$, $Ti(OEt)_4$, $Ti(OiPr)_4$, and $Zr(OnPr)_4$

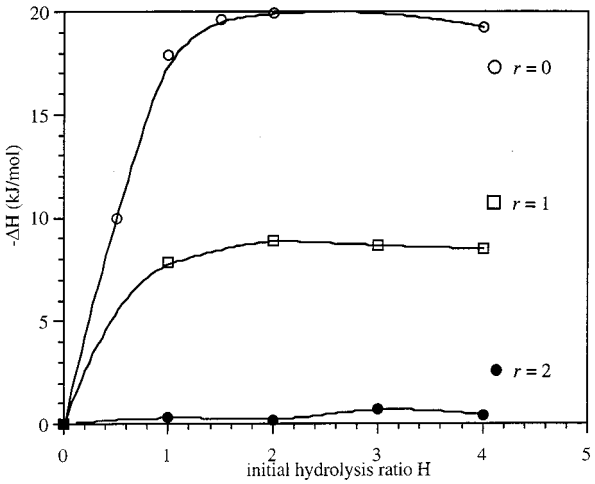
substrate	ratio	enthalpy [kJ·mol^{-1}]
$Ti(OnBu)_4$	r = [acac]/[Ti] = 0	−19.6
	r = [acac]/[Ti] = 1	−8.4
	r = [acac]/[Ti] = 2	−0.8
$Ti(OiPr)_4$	$r = 0$	−54.3
	$r = 1$	−32.6
	$r = 2$	−0.2
$Ti(OEt)_4$		−10.7
$Zr(OnPr)_4$		−20.5

The hydrolysis reaction of $Zr(OnPr)_4$ is exothermic until higher values of the initial hydrolysis ratio are reached ($H = 2$ and even $H = 4$). This result can be attributed to the previously mentioned fact[2][3][9] that the coordination unsaturation (the coordination number of the metal in the oxide minus the metal valency) is higher for zirconium alkoxides (8 − 4 = 4) than for titanium alkoxides (6 − 4 =

2). Again, the enthalpies of reactions between nucleophilic species (e.g., organic ligands, water, hydroxy groups) and transition metal alkoxide precursors are mainly due to the increase in the coordination of the metallic center. As a consequence, the enthalpies of hydrolysis/condensation should strongly depend on the complexation ratio. Indeed, the hydrolysis reaction of the precursor solution obtained from $Ti(OnBu)_4$ and acacH with a complexation ratio $r = 2$ is barely exothermic, while at lower complexation ratios, it is decidedly exothermic. Moreover, at a complexation ratio $r = 1$, the enthalpy of hydrolysis is about half of that of the non-complexed precursor (see Figure 10 and Table 7). These results confirm the importance of the coordination unsaturation in the hydrolysis/condensation reactions, since at a complexation ratio $r = 2$, the coordination of all the titanium atoms is 6. At $r = 1$, the system reacts as an equimolar mixture of non-complexed and bis-complexed precursors. The hydrolysis of acac-modified ($r = 1$; $r = 2$) $Ti(OiPr)_4$ leads to similar results (see Table 7).

Figure 10. Variation of the enthalpy of hydrolysis/condensation of pure or complexed titanium butoxide with the initial hydrolysis ratio: influence of the complexation ratio



Conclusions

This work has shown that mean hydrolysis and condensation constants calculated from water titration curves offer a useful means of quantifying the influence of parameters such as the complexation or proton ratio on the behavior of titanium alkoxides towards hydrolysis. In addition, this approach allows comparisons to be made between metal alkoxides of different metals, particularly those of transition metals, for which NMR speciation and quantitative spectroscopic analysis cannot as yet be realized.

This work has also given an indication of the limitations of the proposed model. The assumptions that were invoked to determine mean constants will benefit from further refinement. These include:

− the postulate that the polymers can all be represented by a mean structural unit;

− the assumption that the system reaches, after ageing, a metastable equilibrium state, which results in residual OR groups. We have shown using ^{17}O-NMR spectroscopy that hydrolysis and condensation reactions are equilibrium processes. It is important to point out that another interpretation can be proposed for incomplete hydrolysis of OR groups, namely the lower reactivity of OR groups of large clusters compared to those of monomers[17]. It is probable that both these phenomena (reversibility of hydrolysis/condensation reactions and decrease of the reactivity of OR groups with increasing cluster size) contribute to the presence of residual OR groups.

− for the acac-modified precursor, it was considered that acac was a non-hydrolyzable ligand. At high initial hydrolysis ratios and/or high acac ratios, however, some acac ligands can be partially hydrolyzed[28][28]. The stability of the metal−acac bond toward hydrolysis/condensation reactions strongly depends on the nature of the metallic center. From the literature, it is known that for tetravalent metals, this stability can be classified according to the sequence Ce, Zr > Ti >> Sn[3][11][25].

This work has also incorporated key thermodynamic data, which are consistent with the conclusions obtained. Estimates of the enthalpies for the complexation and hydrolysis/condensation reactions indicate that the increase of coordination number of the transition metal alkoxide is of paramount importance. The tendency of the metallic center to attain the coordination that it usually has in naturally-occurring crystalline oxide networks is the driving force of all the reactions of transition metal alkoxides that take place in sol-gel processes. Hydrolysis and oxolation are nucleophilic substitutions and, therefore, do not modify the coordination of the metallic center. As a consequence, it is addition reactions (e.g. olation and alkoxy bridging) that are responsible for the high reactivity of titanium and zirconium alkoxides. These should correspond to the consumption of the first molecules of water ($H_2O/Ti \leq 1$), for which the reaction is complete and highly exothermic. However, only a small number of M−OH groups is observed when the metastable equilibrium state is reached. This phenomenon can be explained by the high acidity of the protons of the μ_2-OH and μ_3-OH groups bonded to titanium atoms, which leads to deprotonation of these groups[26].

Experimental Section

Synthesis

Titanium Oxide Based sols and gels were prepared using two different methods:

(i) Hydrolysis of acac-Modified Precursors: $Ti(OnBu)_4$ was diluted with *n*-butanol and acetylacetone (acacH) was added dropwise under magnetic stirring, resulting in a yellow solution. Hydrolysis was performed by the dropwise addition of a solution of water in *n*-butanol. The complexation ratio [acac]/[Ti] was varied from 0.6 to 1. The hydrolysis ratio $[H_2O]/[Ti]$ was varied from 1 to 10. The titanium concentration of the resulting sols was 0.4 $mol \cdot l^{-1}$.

(ii) Hydrolysis with Water Acidified with 35% (w/w) HCl: $Ti(OnBu)_4$ was diluted with *n*-butanol as above. Hydrolysis was performed by the dropwise addition of a solution of acidified water

in *n*-butanol. The ratio $[H^+]/[Ti]$ was kept at 0.02, while the hydrolysis ratio was varied from 1 to 10. The concentration of the resulting sol was 0.18 mol·l^{-1}.

The samples used for recording ^{17}O-NMR spectra were prepared as follows:

Sample ① was prepared following procedure (i) with both the [acac]/[Ti] and $[H_2O]/[Ti]$ ratios equal to 1. The water used for this first hydrolysis was 5%-enriched with oxygen-17. After 1 h at room temperature, the sample was further hydrolyzed with a solution of 5% enriched water in *n*-butanol. The total hydrolysis ratio of the sample was thus equal to 2.

Sample ② was prepared according to the same procedure as sample ①, but the first hydrolysis was performed with unenriched water and the second hydrolysis with 10%-enriched water. Thus, after the second hydrolysis, the two systems have the same chemical composition and the same enrichment in oxygen-17.

Zirconium Oxide Based sols and gels were prepared according to a procedure analogous to (i) above: $Zr(OnPr)_4$ was first diluted with *n*-propanol, and then acetylacetone was added. The [acac]/[Zr] ratio was either 0.9 or 1. Hydrolysis was performed by the dropwise addition of a solution of water in *n*-propanol. The $[H_2O]/[Zr]$ ratio was varied from 1 to 10. The concentration of the resulting sols was 0.44 mol·l^{-1}.

Silicon Oxide Based sols and gels were prepared following procedure (ii): $Si(OEt)_4$ was first diluted with ethanol. A solution of water acidified with HCl (pH 0 or pH 2) in ethanol was then added dropwise. The hydrolysis ratio was varied from 0.5 to 10 and the concentration of the resulting sol was 0.54 mol·l^{-1}.

Characterizations

Water Titrations were performed by the Karl-Fischer method using a 701 KF Titrino apparatus. The solvent used for the titrations was Hydranal Solvent K, rather than methanol, in order to prevent side reactions of ketones and metal hydroxyls[27]. The reagent was Hydranal-composite 5K (Riedel-de-Haen).

The ^{29}Si-NMR spectra were recorded on a Bruker MSL 400 spectrometer operating at 79.48 MHz. The sample solution was placed in an 8 mm tube, which was placed inside a 10 mm tube containing C_6D_6 as a lock solvent. Tetramethylsilane was used as reference ($\delta = 0$).

Silicon-29 is a spin 1/2 nucleus with a natural abundance of 4.7%. A disadvantage of this nucleus is its high spin lattice relaxation time T_1, which results in a long recycle delay. Thus, the relaxation agent chromium acetylacetonate $Cr(acac)_3$ was added in order to reduce this delay. $Cr(acac)_3$ has previously been used in similar systems, where it was shown that it does not interfere with the polymerization process[7].

A second disadvantage of this nucleus is the presence of background Q^4 silicon units present in the silica tube, which result in a large peak at about $\delta = 110$. In order to suppress this peak, we used a $\pi.2-\tau-\pi$ echo sequence.The experimental NMR conditions were as follows: first pulse 12.8 μs; $\tau = 40$ ms; second pulse 25.6 μs; recycle delay 30 s.

The ^{17}O-NMR spectra were recorded on a Bruker MSL 400 spectrometer operating at 54.2 MHz. Again, the sample solutions were placed in an 8 mm tube, which was immersed in C_6D_6, as a lock solvent, in a 10 mm tube. H_2O was used as reference ($\delta = 0$). The experimental NMR conditions were as follows: pulse 19.6 μs; pre-acquisition delay (time between the end of the RF pulse and the beginning of the acquisition) 24 μs; recycle delay 0.2 s, number of scans 1000.

The ^{17}O spectra of ^{17}O-enriched titanium oxo-polymers have been reported previously[28]. They are characterized by four broad bands, which can be assigned, on the basis of the published literature[29][30], as follows:

- $\delta = 650-850$: μ_2O oxo-bridges
- $\delta = 450-600$: μ_3O oxo-bridges
- $\delta = 300-400$: μ_4O oxo-bridges
- $\delta = 200-300$: μ_5O oxo-bridges

- the signal appearing at around $\delta = 0$ corresponds to the residual water.

Two additional peaks can be observed in the presence of acetylacetone[28]:

- one broad peak at $\delta = 300-400$, attributable to acac bonded to titanium

- one narrow peak at $\delta = 273$, attributable to the enol form of free acetylacetone.

These two peaks appear a few hours after hydrolysis, and are only observed at complexation ratios higher than 1 and with a hydrolysis ratio higher than 2[16]. They result from the isotopic ^{17}O-exchange between enriched H_2O and the free acetylacetone released by the hydrolysis of the acac ligands[28].

$$Ti-acac + H_2O \rightarrow Ti-OH + acacH$$
$$acacH + H_2O^* \rightarrow acac^*H + H_2O$$
$$Ti-OH + acac^*H \rightarrow Ti-acac^* + H_2O$$

(the reaction leading to enrichment of the acetylacetone in oxygen-17 is described in Scheme 1).

The recording of oxygen-17 NMR spectra necessitates a pre-acquisition delay in order to eliminate the trailing edge of the high-power pulse. This delay gives rise to a rolling baseline of sin *x*/*x* shape. A baseline correction is then performed, using a cubic splines baseline function (WinNMR 1D). The total intensity of the NMR signal has been measured for all the spectra reported herein, in order to check that this area does not vary with the ageing and the preparation of the sample solution. The areas of the spectra of all the samples after the second hydrolysis are equal, within an experimental error of ±10%. A calibration has also been performed using a solution of 10%-enriched water in *n*-butanol, at the same concentration as in the samples of oxo-polymers. The total intensities of the spectra of the oxo-polymer samples before the second hydrolysis, after the second hydrolysis, and after 24 hours of ageing are all consistent with the intensity of the water peak of the calibration solution, within an experimental error of ±10%. This result indicates that the formation of large polymers, which would result in the partial loss of the signal of the oxo-polymers and, therefore, in quantitativity problems, is negligible.

Calorimetric Study of the Complexation and Hydrolysis Reactions: Four alkoxides were studied: $Ti(OnBu)_4$, $Ti(OEt)_4$, $Ti(OiPr)_4$, $Zr(OnPr)_4$.

First, m_1 g of the alkoxide (or acac-modified alkoxide) was diluted with m'_1 g of its parent alcohol. This solution was placed in a Dewar vessel and its temperature T was measured. A solution of m_2 g of acetylacetone in m'_2 g of the parent alcohol (or the hydrolysis solution of water in parent alcohol) at temperature T_2 was then added. The final temperature T_f was measured about 1 min. after the addition of acetylacetone (or water). The [acac]/[M] ratio of the resulting solution was varied from 0.5 to 2 [or to 4 for $Zr(OnPr)_4$]. The hydrolysis ratio was varied from 0.5 to 4. The molar enthalpy ΔH of the reaction was calculated using the equation:

$$(m_1\Delta H)/M + Cp(M_a + m_1 + m'_1)(T_f - T_1) + Cp(m_2 + m'_2)(T_f - T_2) = 0$$

(adiabatic reaction), where M is the molar mass of the alkoxide (or of the acac-modified alkoxide), $Cp_{alcohol}$ is the heat capacity of the alcohol, M_a is defined as $M_d \times Cp_d = M_a \times Cp_{alcohol}$, where Cp_d is the heat capacity of the Dewar vessel and M_d the mass of the Dewar vessel.

This measurement of the enthalpy is very simple, but it is only intended to give approximate data. Two assumptions are made to estimate the enthalpy of the reaction: first, we assume that the complexation occurs during the first minute after the addition of acetylacetone. This hypothesis is supported by infra-red experiments, which have shown that no free acac can be detected 1 min. after addition of the ligand[18][31]. Secondly, we have assumed that all the reactants and products have the same heat capacity of the solvent, i.e. the parent alcohol. In order to minimize the error introduced by this approximation, the concentrations of reactants were kept below 5% (*w*/*w*).

Modelling of the h = f(H) Water Titration Curves

Evaluation of Hydrolysis/Condensation Mean Equilibrium Constants: Hydrolysis and condensation reactions of metal alkoxides do not generally reach completion, showing reversible character in the sol state, as demonstrated by the ^{17}O-NMR experiments. Complete hydrolysis and condensation of a metal alkoxide $M(OR)_n$ would result in the consumption of all the added water, up to a hydrolysis ratio $H = [H_2O]/[Ti] = n/2$, and, for hydrolysis ratios H higher than $n/2$, a plateau at $h = n/2$ (h being the consumed water ratio), according to the equation:

$$M(OR)_n + H\ H_2O \rightleftharpoons MO_{n/2} + n\ ROH + (H - n/2)\ H_2O$$

For a tetravalent metal alkoxide [$Ti(OR)_4$, $Si(OR)_4$, etc.)] this equation becomes:

$$M(OR)_4 + H\ H_2O \rightleftharpoons MO_2 + 4\ ROH + (H - 2)\ H_2O$$

This behavior is only rarely observed. For all the alkoxides studied in the present paper, we have observed that the consumption of water does not follow this law. Two hypotheses can be made to explain this difference: the first one is that hydrolysis and condensation reactions are kinetically controlled, so that the system never reaches an equilibrium state. This hypothesis effectively rules out any possibility of evaluating the extent of reaction. The second hypothesis that can be made is that the system reaches a metastable equilibrium state, which represents a steady state where the reactants are no longer being consumed, but because of their high surface/volume ratio, the solvent-swollen oxo-polymers are still in equilibrium with free water and alcohol molecules. This steady state is not the lower minimum of the system (i.e. the crystalline oxide), but it is well known that chemical pathways can possess several minima of different depth. This second assumption is confirmed by ^{17}O-NMR experiments presented in the Results and Discussion section (vide infra). These experiments show that the hydrolysis and condensation reactions are equilibrium processes. Moreover, this hypothesis has the advantage that it allows one to study the extent of the hydrolysis and condensation reactions through to the determination of a mean chemical formula for the oxo-polymers.

The transition metal oxo-polymers that are formed by the sol-gel process are generally polydisperse in size and composition and it is therefore impossible to perform a straightforward calculation of the pseudo-equilibrium constants of each of these polymers. In order to circumvent this problem, we have defined a mean structural unit that has the mean composition of the polymers. This mean structural unit has the following approximate formula: $MO_k(OH)_{h-k}(OR)_{4-r-h-k}(acac)_r$, where h is the consumed water ratio, k is the ratio of oxo bridges, and r is the initial complexation ratio. Details of the calculation of the chemical composition of the mean structural unit are presented in Appendix 1.

It is possible to define two constants K_h and K_c in order to describe the hydrolysis and condensation pseudo-equilibrium:

hydrolysis:

$$\cdots M\text{–}OR + H_2O \rightleftharpoons \cdots M\text{–}OH + ROH$$

$$K_h = \frac{[\cdots M\text{–}OH]}{[\cdots M\text{–}OR][H_2O]}$$

condensation (alkoxolation):

$$\cdots M\text{–}OH + \cdots M\text{–}OR \rightleftharpoons \cdots M\text{–}O\text{–}M\cdots + ROH$$

$$K_c = \frac{[\cdots M\text{–}O\text{–}M\cdots]}{[\cdots M\text{–}OH][\cdots M\text{–}OR]}$$

condensation (oxolation):

$$\cdots M\text{–}OH + \cdots M\text{–}OH \rightleftharpoons \cdots M\text{–}O\text{–}M\cdots + H_2O$$

$$K_o = \frac{[\cdots M\text{–}O\text{–}M\cdots][H_2O]}{[\cdots M\text{–}OH][\cdots M\text{–}OR]}$$

where M is a metal and R an alkyl group

The pseudo-equilibrium oxolation constant K_o can be directly deduced from K_h and K_c, as follows: $K_o = K_c/K_h$. The formula of the mean structural unit does not depend on the kind of condensation reaction (oxolation or alkoxolation) that occurs (see Appendix 1).

It is possible to express K_h and K_c as a function of k, the mean number of oxo groups, h the water effectively consumed (expressed as the ratio water/metal), r the complexation ratio, and H the initial hydrolysis ratio $H = [H_2O]/[M(OR)_4]$:

An expression for the initial hydrolysis ratio H as a function of the water/metal ratio corresponding to the water effectively consumed can be obtained using Equations 3 and 4:

$$K_h = \frac{(h-k)}{(4-r-h-k)\cdot(H-h)\cdot[M(OR)_4]} \quad (3)$$

$$K_c = \frac{k}{(4-r-h-k)\cdot(H-h)\cdot[M(OR)_4]} \quad (4)$$

$$H = h + \frac{4-r+K'_c(4-r-2h)^2-(4-r-2h)\sqrt{K'^2_c(4-r-2h)^2+2K''_c(4-r)+1}}{2K'_h(4-r-h)} \quad (5)$$

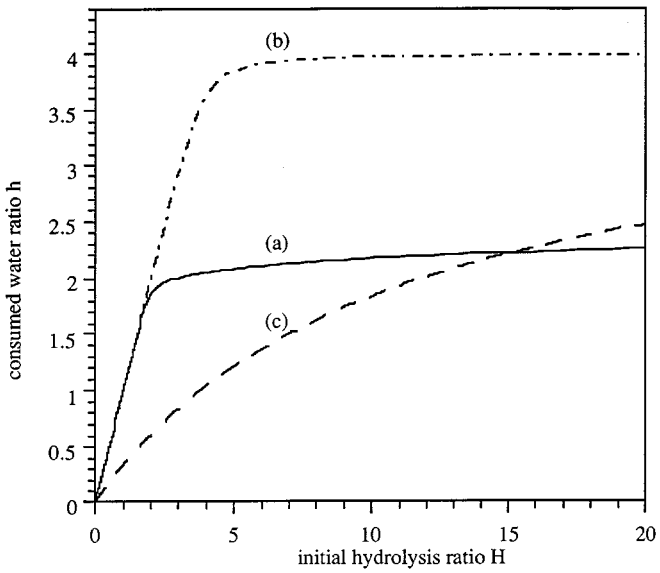
The details of the determination of this equation are presented in Appendix 2.

where $K'_c = K_c*[M(OR)_n]$; $K'_h = K_h*[M(OR)_n]$.

It is also possible to express k, the mean degree of oxo condensation, as a function of h and H:

$$k = \frac{K'_h(4-r-h)(H-h)}{K'_h(H-h)-1} \quad (6)$$

Figure 11. Examples of simulation of water titration curves: (a) $K_h = 1$, $K_c = 100$; (b) $K_h = 100$, $K_c = 1$; (c) $K_h = 0.1$; $K_c = 0.1$; K_h is the hydrolysis constant and K_c the condensation constant



The water consumed during the hydrolysis/condensation reactions was measured once the metastable equilibrium state had been reached. These measurements were performed after ageing of the sols of the various metal alkoxides for several weeks or months. The time of ageing was fixed once the consumption of water was negligible. The initial hydrolysis ratio was varied between 0.5 and 10, while the other parameters (acac/metal ratio, H^+/metal ratio and concentration) were kept constant.

Examples of Simulation

Figure 11 depicts "extreme" behavior of the $h = f(H)$ curves:

• when the condensation constant is higher than the hydrolysis constant ($K_h = 1$; $K_c = 100$; Figure 11-a), the consumption of water is complete up to $H = 2$, and for H higher than 2 it reaches a plateau. All the M−OH groups that are formed in the hydrolysis reaction are consumed in the condensation reaction, and the final composition of the system corresponds to the oxide MO_2. The shift of the equilibria toward the formation of the oxide is due to the high value of K_c.

• When the hydrolysis constant is higher than the condensation constant ($K_h = 100$; $K_c = 1$; Figure 11-b), the consumption of water is almost complete up to $H = 4$, and then reaches a plateau at higher values of H. This limiting case corresponds to the formation of $M(OH)_4$ units, which do not polymerize.

• If the hydrolysis and condensation constants are both low ($K_h = 0.1$; $K_c = 0.1$; Figure 11-c), i.e. when both hydrolysis and condensation are incomplete, the consumption of water is not complete, even at low values of H, and the number of residual alkoxy groups is high.

Appendix 1: Determination of the formula of the mean structural unit

The parameters that determine the formula of the mean structural unit are:

- H the initial hydrolysis ratio
- h the consumed water ratio
- k the ratio of oxo bridges
- r the initial complexation ratio.

Hydrolysis:

$$M(OR)_{4-r}acac_r + H\,H_2O \rightleftharpoons M(OR)_{4-r-a}acac_r(OH)_a + (H-a)\,H_2O + a\,ROH$$

considering that *oxolation* is the only condensation reaction

$$2\,M(OR)_{4-r-a}acac_r(OH)_a \rightleftharpoons 2\,M(OR)_{4-r-a}acac_r(OH)_{a-b}O_{b/2} + b/2\,H_2O$$

where b is the proportion of M–OH groups that have reacted with an M–OH group to form oxo bridges

$$\frac{n(H_2O)}{n(M)} = H - a + b/2 = H - h$$
$$\frac{n(M\text{–}O\text{–}M)}{n(M)} = b/2 = k$$
$$\frac{n(M\text{–}OR)}{n(M)} = 4 - r - a = 4 - r - h - k$$
$$\frac{n(M\text{–}OH)}{n(M)} = a - b = h - k$$

mean structural unit $M(OR)_{4-r-h-k}acac_r(OH)_{h-k}O_k$

considering that *alkoxolation* is the only condensation reaction

$$2\,M(OR)_{4-r-a}acac_r(OH)_a \rightleftharpoons 2\,M(OR)_{4-r-a-c}acac_r(OH)_{a-c}O_c + 2c\,ROH$$

where c is the proportion of M–OH groups that have reacted with an M–OR group to form oxo bridges

$$\frac{n(H_2O)}{n(M)} = H - a = H - h$$
$$\frac{n(M\text{–}O\text{–}M)}{n(M)} = c = k$$
$$\frac{n(M\text{–}OR)}{n(M)} = 4 - r - a - c = 4 - r - h - k$$
$$\frac{n(M\text{–}OH)}{n(M)} = a - c = h - k$$

mean structural unit $M(OR)_{4-r-h-k}acac_rOH)_{h-k}O_k$

The mean structural units calculated by assuming that condensation occurs via alkoxolation or oxolation are the same.

Appendix 2: Determination of the equation of H as a function of h

from Equation 3: $k = \dfrac{K'_h(4-r-h)(H-h)}{K'_h(H-h)-1}$ (3')

from Eq. 4 and Eq. 3':

$$[K'_h(4-r-h)(H-h)-h][K'_h(H-h)-1] = K'_c\,K'_h(H-h)\,(2h-4+r)^2$$

this equation can be expressed as a polynomial of degree 2 in $(H-h)$:

$$(4-r-h)K'^2_h(H-h)^2 - K'_h[4-r+K'_c(2h-4+r)^2](H-h) + h = 0$$

the discriminant of the polynomial is:

$$\Delta = K'^2_h(4-r-2h)[K'^2_h(4-r-2h)^2 + 2(4-r)K'_c + 1]$$

the root of this equation is:

$$H = h + \frac{4-r+K'_c(4-r-2h)^2-(4-r-2h)\sqrt{K'^2_c(4-r-2h)^2+2K''_c(4-r)+1}}{2K'_h(4-r-h)} \quad (5)$$

Keywords: Insertion / N ligands / Terdentate ligands / Rigid ligands / Palladium

Novel methyl complexes [Pd(Me)(N-N-N)]X (N-N-N = flexible or rigid terdentate nitrogen ligand, X = Cl, SO_3CF_3, BAr'_4) have been synthesized and fully characterized. All complexes readily underwent insertion of carbon monoxide resulting in the quantitative formation of complexes [Pd{C(O)Me}(N-N-N)]X [X = Cl (**1d–6d**), BAr'_4 (**1e–6e**)]. Subsequently, complexes **2e–6e** underwent quantitative insertion of norbornadiene, resulting in complexes [Pd{C_7H_8C(O)Me}(N-N-N)]BAr'_4 (**2f–6f**). Unexpectedly, these complexes, including even those containing rigid terdentate nitrogen ligands, possess a structure in which the nitrogen ligand is coordinated in a bidentate fashion. A kinetic study of the reaction of norbornadiene with complexes **1e–6e** revealed that the reactivity of complexes **1e–6e** toward norbornadiene increases with increasing rigidity of the terdentate ligand, i.e. with increasing strain in the PdN_3 moiety, which indicates that insertion very likely occurs via a mechanism involving nitrogen dissociation. This is fully supported by ab initio MO calculations on CO and ethylene insertion into carbon–palladium bonds of cationic model systems containing a rigid terdentate nitrogen ligand, which showed that the lowest-energy pathway for both insertion reactions consists of substitution of one of the distal nitrogen atoms of the rigid terdentate nitrogen ligand by the substrate, followed by a rate-determining migratory insertion of the substrate into the carbon–palladium bond.

In many transition-metal-catalyzed reactions the insertion of an unsaturated molecule into a carbon−metal bond is a key step.[1][2] A recent example is the palladium-catalyzed copolymerization of carbon monoxide and alkenes, leading to the formation of polyketones, which process involves the perfectly alternating insertion of CO and alkenes into carbon−palladium bonds.[3][4][5][6][7] We[8][9][10][11][12][13][14][15] and others[16][17][18][19][20][21][22][23][24] have extensively studied CO and alkene insertion reactions in model complexes of the type Pd(R)X(L-L) {R = Me, C(O)Me; X = Cl, Br, I, SO_3CF_3, BF_4, [3,5-$(CF_3)_2C_6H_3)_4$B]; L-L = P-P, P-N, N-N} mimicking the intimate steps of the catalytic cycle of polyketone formation.[25] From these studies it is clear that the mechanism of CO and alkene insertion reactions is highly dependent on the nature of the ligands. In the case of ionic complexes [Pd(R)(solv)(L-L)]X {R = Me, C(O)Me; solv = Et_2O, MeCN; L-L = P-P, P-N, N-N; X = SO_3CF_3, BF_4, [3,5-$(CF_3)_2C_6H_3)_4$B} it has been shown that precoordination of CO and alkenes occurs via dissociation of the weakly coordinated solvent molecule. Both CO and alkene precoordinated complexes of the type [Pd(Me)(CO)(L-L)]X[10][19][23] and [Pd{C(O)Me}(η^2-alkene)(N-N)]X[23], respectively, have been characterized as intermediates. Studies of the insertion reactions of CO into the methyl−palladium bond of complexes Pd(Me)X(P-P) (X = Cl, PPh_3, MeCN; P-P = bidentate phosphorus ligand) showed that the reactions were enhanced by flexible bidentate phosphorus ligands, which are able to coordinate with a large bite angle, thereby lowering the energy of the transition state.[8] Furthermore, the reactions were strongly dependent on the coordinating capability of the X ligand, which indicates that insertion occurs mainly by X dissociation. Unexpectedly, insertion reactions in complexes containing flexible and rigid bidentate nitrogen ligands with a small bite angle were much faster than those in complexes containing

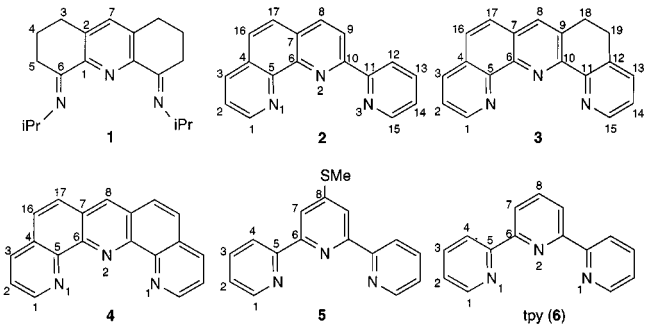
bidentate phosphorus ligands.[11][12][26] Mechanistic studies provided strong evidence that insertion reactions in neutral complexes containing bidentate nitrogen ligands occur via intermediates in which these ligands are coordinated in a unidentate fashion.[12][13][14][15]

Although most experimental studies indicate that insertion by a mechanism involving four-coordinate intermediates is more favorable than insertion by a mechanism involving five-coordinate intermediates, for a few insertion reactions a mechanism involving five-coordinate species has been suggested. For example, both intra-[27] and intermolecular[28] alkene insertions into hydride−platinum bonds and also CO insertions into aryl−[29] and alkyl−palladium[30] bonds have been proposed to occur from five-coordinate intermediates. Recently, we reported the high reactivity toward CO of the ionic complex [Pd(Me)(tpy)]Cl, containing a terdentate 2,2′:6′,2′′-terpyridine ligand.[31][32] At first, insertion was proposed to occur via five-coordinate species, as creation of a free coordination site was assumed to be rather difficult due to the favorable terdentate coordination of the tpy ligand.[31] However, Orrell et al.[33][34][35][36][37] and also others[38][39][40][41][42][43] have reported on the ability of tpy to coordinate in a bidentate fashion, which suggests that the CO insertion reaction in [Pd(Me)(tpy)]Cl may occur by a mechanism involving four-coordinate intermediates, which contain a bidentate coordinated tpy ligand. Therefore, we turned our attention to complexes containing rigid terdentate nitrogen ligands, in which dissociation of one of the distal nitrogen atoms was expected to be unlikely. We have used the novel rigid ligand **1** and the known ligands **2**[44], **3**[45], **4**[45], **5**[46], and **6** (Figure 1). In this series ligands **3** and **4** can be considered as rigid analogs of **5** and tpy (**6**).

Figure 1. Terdentate nitrogen ligands **1**−**6** with the adopted numbering schemes

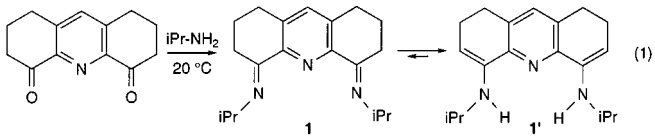


We report here the results of our study of the palladium coordination chemistry of ligands **1**−**6**. Furthermore, we present the results of an extensive kinetic study of the norbornadiene insertion in acetylpalladium complexes containing the ligands **1**−**6** and the results of ab initio MO calculations of CO and ethylene insertion reactions into carbon−palladium bonds of model complexes containing a rigid terdentate nitrogen ligand, which lead to a novel view of the role and behavior of rigid terdentate ligands in CO and alkene insertion reactions.

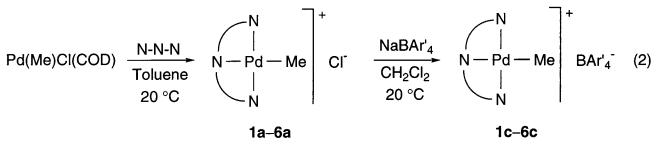
Results and Discussion

Synthesis and Characterization of Compound 1 and Methylpalladium Complexes 1a−5a, 1b, and 1c−6c

The novel compound 4,5-bis(isopropylimino)-1,2,3,4,5,6,7,8-octahydroacridine (**1**) was synthesized by a condensation reaction of 1,2,3,4,5,6,7,8-octahydroacridine-4,5-dione with isopropylamine in the presence of an excess $MgSO_4$ and a catalytic amount of formic acid (Equation 1). Compound **1** was obtained as a yellow oil. In this form or in solution at 20°C, compound **1** is rather unstable and decomposes into several uncharacterized products within a few hours. At −80°C compound **1** can be stored for several days without decomposition. As reported for 1,2-bis(isopropylimino)cyclohexane[47], (5,6-dihydro[1]pyrindin-7-ylidene)isopropylamine[15], and isopropyl-(5*H*-[1]pyrindin-7-yl)amine[15], compound **1** exists predominantly in the tautomeric form **1′**. Formation of this tautomer was revealed by NMR where a two-proton resonance at δ = 4.85 in the ^{1}H-NMR spectrum and a resonance at δ = 74.7 in the ^{13}C-NMR spectrum were observed, both characteristic of a = CH fragment. Furthermore, the IR spectrum of **1** revealed an NH stretching frequency at 3390 cm^{-1}. The instantaneous disappearance of the 5-H NMR resonance upon addition of a drop of D_2O to a solution of **1** in $CDCl_3$ indicates the presence of a rapid equilibrium between enamine and imine forms.



The chloro(methyl)palladium complexes **1a**−**5a** were synthesized by substitution of COD (= 1,5-cyclooctadiene) in Pd(Me)Cl(COD) by ligands **1**−**5** (Equation 2), similar to what is reported for methylpalladium complexes containing bidentate N-N,[11][12] N-S[48][49], P-N[10], P-P[8], and terdentate N-N-N[31][32], P-N-N[50], P-N-S[51], and N-N-S[51] ligands. Analogously to [Pd(Me)(**6**)]Cl (**6a**)[32], complexes **2a**−**5a** were obtained as yellow, air-stable solids, which are only moderately soluble in polar solvents such as methanol, ethanol, and water. In contrast, complex **1a** readily dissolves in dichloromethane and chloroform.



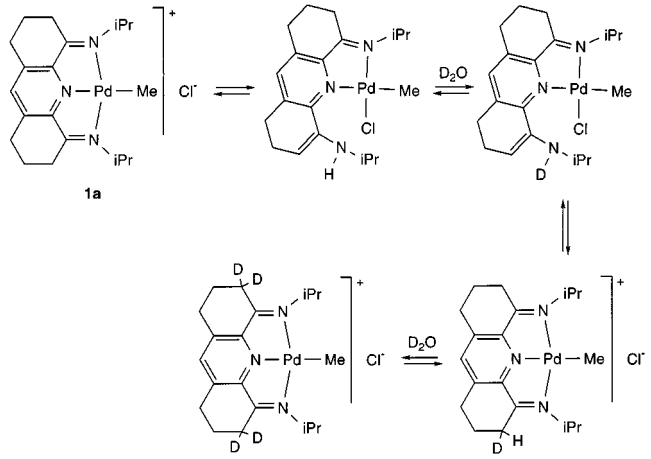
The complexes of the type [Pd(N-N-N)(Me)]X [N-N-N = terdentate nitrogen ligands **1**−**6**; X = SO_3CF_3 (**b**), BAr'_4 (**c**)] were obtained by the reaction the complexes **1a**−**6a** with silver trifluoromethanesulfonate and sodium tetrakis[3,5-bis(trifluoromethyl)phenyl]borate (Equation 2). Complexes **1b**−**6b**, however, except for **1b**, are insoluble in

common solvents and could not be characterized. In contrast, complexes **1c**−**6c** are soluble in dichloromethane, chloroform, and even in diethyl ether. Complexes **1a**,**c**−**6a**,**c** and **1b** were isolated and fully characterized. Crystals of **1b** and **4c**, suitable for X-ray analyses, were obtained by recrystallization from dichloromethane/hexane at 4°C (vide infra).

All methylpalladium complexes show a characteristic *Me*−Pd resonance at $\delta \approx 1$ in the ^{1}H-NMR spectra and at $\delta \approx 0$ in the ^{13}C-NMR spectra.[11][12][15][32][52][53][54] At 20°C, as well as at −60°C, the ^{1}H-NMR spectra of complexes **1a**, **4a**, and **5a**, show a symmetrically bonded nitrogen ligand, indicating that these ligands are coordinated in the expected terdentate fashion to the palladium center and that the chloride is present as a counter anion. The observed high equivalent conductivities for **1a**−**5a** in methanol at 20°C of 51−70 Ω^{-1} cm^2 mol^{-1} are also in agreement with an ionic complex, whereas that of the neutral precursor Pd(Me)Cl(COD) is 2.3 Ω^{-1} cm^2 mol^{-1}.

Interestingly, addition of a drop of D_2O to a solution of **1a** in $CDCl_3$ led to a complete disappearance of the 5-H NMR resonance due to H/D exchange. This result can be explained by dissociation of one of the distal nitrogen atoms of the ligand, caused by coordination of the chloride (Scheme 1). This mechanism is supported by the absence of H/D exchange for **1a** in CD_3OD, which efficiently solvates the chloride ion, hereby preventing chloride-initiated dissociation of one of the distal nitrogen atoms. Furthermore, it is in agreement with the absence of H/D exchange for **1b** and **1c**, which contain weakly coordinating anions.

Scheme 1



1a

In order to investigate the relative coordinating capabilities of the terdentate nitrogen ligands **2**−**6**, competition experiments were carried out. Addition of an equimolar amount of free **6** to a solution of complex **5c** in $CDCl_3$ at 20°C resulted in a mixture of complexes **5c** and **6c** and the free ligands **5** and **6** in a ratio **5c**/**6c** (= **6**/**5**) = 1:2. A mixture with the same **5c**/**6c** ratio was obtained upon addition of an equimolar amount of free **6** to a solution of complex **5**. These experiments and similar competition experiments with the other nitrogen ligands show that the coordinating capabilities of **2**, **3**, **4**, and **6** are comparable, but higher than that of **5**.

Molecular Structures of [Pd(Me)(1)]SO_3CF_3 (1b) and [Pd(Me)(4)]BAr'_4 (4c)

The molecular structures of **1b** and **4c** are shown in Figures 2 and 3. Selected bond lengths and bond angles of the non-hydrogen atoms are listed in Tables 1 and 2. The molecular structures of **1b** and **4c** both show a square-planar geometry with the three nitrogen atoms of the terdentate nitrogen ligand and a methyl ligand coordinated to the palladium(II) center. The relatively short Pd−N(2) bond lengths of 1.959(5) A for **1b** and 1.993(3) A for **4c** and the small *trans*-N(1)−Pd−N(3) bond angles of 155.50(19)° for **1b** and 156.95(11)° for **4c** have been observed also for **6a**[32] and for other palladium complexes containing comparable symmetric terdentate nitrogen ligands.[43][55][56][57][58][59][60][61] Interestingly, the Pd−N(1) and Pd−N(3) bond lengths in **4c** [2.103(4) and 2.116(4) A, respectively] are longer than those in [Pd(Me)(**6**)]Cl (**6a**) [Pd−N(1) = 2.048(9) A; Pd−N(3) = 2.057(8) A][32] and the angles Pd−N(1)−C(1) and Pd−N(3)−C(19) in **4c** [132.4(3) and 132.1(3)°] show a larger deviation from the ideal 120° than to those in **6a** [Pd−N(1)−C(1) = 128.8(7)°; Pd−N(3)−C(19) = 128.4(7)°].[32] These data indicate that the more rigid terdentate ligand **4** coordinates less strongly to the palladium center than the more flexible tpy ligand **6**. Whereas the four donor atoms and the palladium atom are confined to one plane in **4c** [maximum deviation from the least-squares plane is 0.005(3) A], the methyl ligand in complex **1b** is bent out of the coordination plane with an angle of 12.4(3)° between the methyl−palladium bond and the plane defined by N(1), N(2), and N(3). As a result, the methyl−palladium bond length of 2.189(4) A is large as compared to those of other palladium complexes containing a methyl ligand *trans*-positioned to a nitrogen atom (2.00−2.09 A).[10][11][12][32][47][48][50][52][53][54][58][61][62][63][65][66] The distances between C20 and the nearest hydrogen atoms on C15 and C18 of 2.67 A and 2.59 A, which are 0.23 A and 0.31 A shorter than the sum of the Van der Waals radii, clearly show that the distortion from planarity in **1b** is caused by steric interaction between the methyl ligand and the isopropyl groups. Recently, a similar observation has been made for a series of chlororhodium(I) complexes containing a terdentate nitrogen ligand. In these complexes, substituents on the side arms of the terdentate nitrogen ligand were found to force the chloride ligand out of the coordination plane.[61]

Carbon Monoxide Insertion

The methylpalladium complexes **1a**−**5a** and **1c**−**6c** reacted within 1 minute with carbon monoxide to give the corresponding acetylpalladium complexes **1d**−**5d** and **1e**−**6e**, respectively (Equation 3).

The acetylpalladium complexes **1e**−**6e** were isolated and characterized by ^{1}H NMR, ^{13}C NMR, and IR spectroscopy. In contrast, complexes **1d**−**5d** could not be iso-

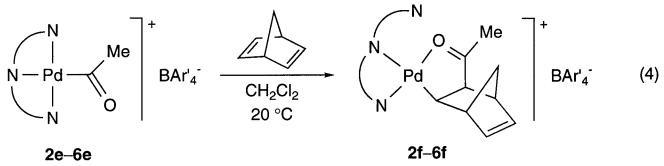
[D_6]ethanol respectively, indicating that the instability of complexes **1d**−**5d** in alcohols is caused by alcoholysis of the acetyl−palladium bond. A mechanism of this degradation process might involve dissociation of one of the distal nitrogen atoms of the terdentate ligand caused by coordination of the chloride counter anion,[67][68] followed by methanol coordination and reductive elimination of methyl acetate. This mechanism is supported by the observation that decomposition in alcohols proceeds much more slowly for complexes **2e**−**6e**, which contain the weakly coordinating tetrakis[3,5-bis(trifluoromethyl)phenyl]borate anion.[69]

The insertion of CO into the methyl−palladium bond of **1c**−**6c** is a reversible reaction. In solution decarbonylation of **1e**−**6e** occurs, resulting in reformation of the methylpalladium complexes **1c**−**6c**, without formation of any palladium black. For example, after 1 h of bubbling N_2 through a solution of **4e** in dichloromethane, 80% of decarbonylated [Pd(Me)(**4**)]BAr'_4 (**4c**) and 20% unreacted **4e** were present, whereas complete decarbonylation took place within 1 h in refluxing dichloromethane. Interestingly, complexes **1e**−**6e** also undergo decarbonylation in the solid state. Drying in vacuo for several hours or storage at 20°C for several days resulted in formation of the methylpalladium complexes **1c**−**6c**, without any other decomposition.

Alkene Insertion

(a) *Synthesis and Characterization of Alkylpalladium Complexes* **1f**−**6f**: Whereas insertion of ethylene, styrene, maleic anhydride, and cyclopentene does not occur, the acetylpalladium complexes **2e**−**6e**, but not **1e**, do react with the strained alkenes norbornene, norbornadiene, and dicyclopentadiene. Because of their complex NMR spectra, the products obtained after insertion of norbornene and dicyclopentadiene were difficult to characterize. However, the insertion of norbornadiene into the acetyl−palladium bond

of complexes **2e**−**6e** yielded the novel characterizable alkylpalladium complexes [Pd{$C_7H_8C(O)Me$}(N-N-N)]BAr'_4 (**2f**−**6f**) (Equation 4).



2e–6e **2f–6f** (4)

The reactions were completed within 30 minutes for **2e**−**6e** showing rates comparable to those found for the neutral complexes Pd{C(O)Me}Cl(Ar-BIAN) containing the rigid bidentate nitrogen ligands bis(arylimino)acenaphthene,[11][13] but the rates were slower than those observed for the ionic complexes [Pd{C(O)Me}(solv)(N-N)]SO_3CF_3 (solv = solvent; N-N = Ar-BIAN, bpy).[11][22] Complexes **2f**−**6f** were isolated and characterized by spectroscopic techniques. The ^{1}H-NMR spectra of **2f**−**6f** show the typical pattern of an inserted norbornadiene moiety and a coupling constant between the former olefinic protons of about 6 Hz, which indicates the expected *cis* addition of the carbon−palladium bond to the *exo* face of the norbornadiene.[9][11][13][16][22][32][70] Furthermore, the spectral data of **2f**−**6f** show the following interesting features: (i) In the IR spectra a low CO stretching frequency at ca. 1600 cm^{-1} is observed; (ii) In the ^{13}C-NMR spectra a low-field CO resonance appears at $\delta \approx 235$; (iii) In the ^{1}H-NMR spectra of **4f**−**6f** at −70°C separate signals for the two arms of the nitrogen ligands are observed; (iv) In the ^{15}N-NMR spectra of **2f**, **4f**, and **6f**, which will be discussed in detail separately,[71] a signal representing one distal nitrogen atom appears at $\delta \approx -150$, which is characteristic of a coordinated pyridine nitrogen atom.[72] In the case of **2f**, the signal of the other distal nitrogen atom is observed at $\delta = -68$, which is characteristic of a noncoordinated pyridine moiety[72] and can be compared to the distal nitrogen resonances of $\delta \approx -75$ for the free ligands **2**, **4**, and **6**.[71] Unfortunately, in the case of **4f** and **6f**, the signal of the noncoordinated nitrogen atom could not be observed, most probably due to the absence of a sufficiently large N-H coupling constant.

From these spectroscopic data, we conclude that the acyl oxygen atom is coordinated to the palladium center forming a C,O chelate and that, unexpectedly, the nitrogen ligand is coordinated in a bidentate fashion. In the case of flexible terdentate ligands such as **5** and **6**, the noncoordinated pyridyl moiety is most probably in a position perpendicular with regard to the palladium coordination plane, as observed in molecular structures of $Pd(C_6F_5)_2$(tpy)[36] and [Pd(η^3-C_3H_5)(tpy)]ClO_4[43], which contain a bidentate tpy ligand. In the case of rigid terdentate nitrogen ligands such as **4**, an asymmetrically bidentate coordination mode of the nitrogen ligand, i.e. with a relatively long Pd−N(central) bond and a relatively short Pd−N(distal) bond, may result in a long distance between palladium and the dissociated nitrogen atom (ca. 3.5 A, vide infra), which enables C,O chelate formation.

Complexes **4f**−**6f** show fluxional behavior on the ^{1}H-NMR time scale, as both sides of the terdentate ligand become magnetically equivalent in the temperature range of −50 to 20°C. The mechanism probably proceeds by site exchange of the distal nitrogen atoms involving a species in which the nitrogen ligand is coordinated in a terdentate fashion.

(b) *Kinetic Study of Norbornadiene Insertion:* To study the kinetics of the norbornadiene insertion into the carbon−palladium bond of complexes **1e**−**6e**, the reactions were carried out under pseudo-first-order conditions and were recorded by means of UV/Vis spectroscopy. In all cases, plotting the observed rate constants k_{obsd} versus time led to straight lines with a zero intercept, within experimental error, indicating that the rate law $k_{obsd} = k_2$[nbd] is obeyed. The experimental values of k_2 are independent of the presence of free terdentate nitrogen ligand and are listed with the respective activation parameters in Table 3.

Table 3. Rate constants k_2 and the enthalpy and entropy of activation of the reaction of complexes **1e**, **2e**, **4e**−**6e**, and **5d** with norbornadiene (standard deviations in parentheses)[a]

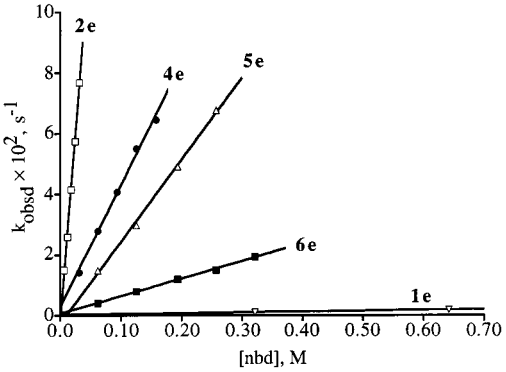
Compound	T [°C]	$10^2 k_2$ [s^{-1} м$^{-1}$]	$\Delta H^{\neq}$ [kJ mol^{-1}]	$\Delta S^{\neq}$ [J mol^{-1} K^{-1}]
1e	10.0(5)	0.11(1)	58(4)	−96(13)
	20.5(5)	0.24(1)		
	31.0(5)	0.65(1)		
2e	6.0(5)	120(5)	31(1)	−132(5)
	11.0(5)	150(6)		
	20.5(5)	251(12)		
	29.0(5)	350(9)		
4e	6.0(5)	17.7(3)	39(2)	−119(7)
	13.0(5)	25.1(4)		
	20.5(5)	40(2)		
	30.0(5)	72(3)		
5d	7.5(5)	655(28)		
5e	7.5(5)	16(1)	32(2)	−144(8)
	13.5(5)	25(1)		
	20.5(5)	33(2)		
	30.5(5)	52(2)		
6e	6.0(5)	1.86(3)	51(1)	−95(1)
	13.0(5)	3.22(3)		
	20.5(5)	5.8(1)		
	30.0(5)	11.5(3)		

[a] Conditions: dichloromethane as solvent, [Pd] = 0.19 мм.

The activation enthalpy (31−58 kJ mol^{-1}) and the large negative activation entropy (−144 to −95 J mol^{-1} K^{-1}) are comparable with those of the k_2 pathway of reaction of norbornadiene with Pd{C(O)Me}Cl(*p*-An-BIAN) containing the rigid bidentate nitrogen ligand bis(*p*-anisylimino)acenaphthene ($\Delta H^{\neq}$ = 48.4(18) kJ mol^{-1}; $\Delta S^{\neq}$ = −126(6) J mol^{-1} K^{-1}).[13] The rate constant k_2 is highly dependent on the terdentate nitrogen ligand in [Pd{C(O)Me}(N-N-N)]BAr'_4 (**1e**−**6e**) and increases in the order N-N-N = **1** << **6** << **5** < **4** << **2** (Figure 4). The reaction of norbornadiene with **1e** proceeded very slowly and an extremely large excess of norbornadiene (800−4000 equiv.) was required in order to ensure relatively fast norbornadiene insertion as compared to decarbonylation. Due to the absence of isosbestic points for the reaction of **3e**

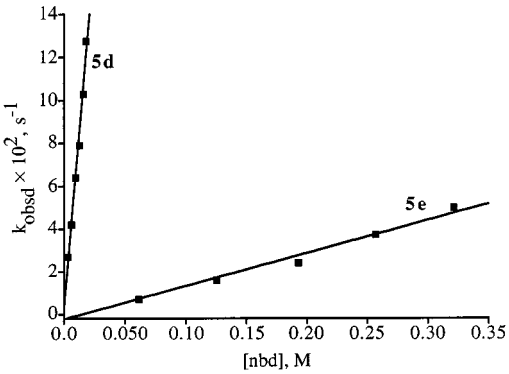
with norbornadiene, no rate constants were determined for this reaction.

Figure 4. Pseudo-first-order rate constants (k_{obsd}) of the reaction of [Pd{C(O)Me}(N-N-N)]BAr'_4 (**1e**, **2e**, and **4e**−**6e**) with nbd as a function of the concentration of nbd; conditions: dichloromethane as solvent, 20.5°C, [Pd] = 0.19 mM



The influence of the counter anion X of [Pd{C(O)Me}(N-N-N)]X on the reaction with nbd was studied for the rigid ligand **4** and the flexible ligands **5** and **6**. In order to prevent decomposition of the unstable acetylchloropalladium complexes **4d**−**6d**, the reactions were carried out at 7.5°C. Unfortunately, a rate constant could be determined only in the case of **5d**, as isosbestic points were not obtained for **4d** or **6d**. From Figure 5 it is clear that the k_2 value of the reaction of [Pd{C(O)Me}(**5**)]X [X = Cl (**5d**), BAr'_4 (**5e**)] with nbd is highly dependent on the nature of the counter anion X; the k_2 rate constant increases from 0.16(1) s^{-1} M^{-1} for **5e** to 6.55(28) s^{-1} M^{-1} for **5d**.

Figure 5. Pseudo-first-order rate constants (k_{obsd}) of the reaction of [Pd{C(O)Me}(**5**)]X [X = Cl (**5d**), BAr'_4 (**5e**)] with nbd as a function of the concentration of nbd; conditions: dichloromethane as solvent, 7.5°C, [Pd] = 0.19 mM



Ab Initio MO Calculations

To obtain more insight into the mechanism of insertion reactions of CO and alkenes into the carbon−palladium bond of complexes containing rigid terdentate nitrogen ligands, we have carried out for the first time ab initio MO calculations of the cationic model systems [Pd(Me)(N-N-N)]$^+$ (**I**) + CO and [Pd{C(O)Me}(N-N-N)]$^+$ + ethylene.

(a) *Carbon Monoxide Insertion:* The optimized geometries and selected bond lengths and bond angles of the starting methylpalladium complex **I**, the intermediate **III**, the transition states **II** and **IV**, and the acetylpalladium product **V** are shown in Scheme 2. The relative RHF and MP2 energies have been collected in Table 4 and the potential energy profile at the MP2 level is shown in Figure 6. The calculated bond angles N(1)−Pd−N(2) and N(2)−Pd−N(3) and nitrogen−palladium bond lengths for starting complex **I** and product **V** are in good agreement with those observed experimentally for the terdentate nitrogen ligand containing methylpalladium complexes **1b** (vide supra), **4c** (vide supra), and **6a**.[32] The calculated carbon−palladium distances in structures **I** (2.05 A) and **V** (1.97 A) are as expected for methyl-[12][32][47][50][52][53][62][73][74] and acetylpalladium[12][15][23][50][52][53][75] complexes, respectively. The Pd−CO bond lengths in CO-coordination transition state **II** (2.10 A) and CO-containing complex **III** (2.10 A) are very close to that calculated for *cis*-[Pd(Me)$(NH_3)_2$(CO)]$^+$ (2.106 A)[59], but somewhat longer than that calculated for [Pd(Me)$(NH_2CH_2CH_2NH_2)$(CO)]$^+$ (1.922 A)[76] and that experimentally observed for [Pd{C(O)Me}(phen)(CO)]BAr'_4 [1.922(11) A].[23] The geometry of the CO-containing species **III** can be considered to be square-planar, in which the four coordination sites are occupied by two nitrogen atoms of the terdentate nitrogen ligand, a CO and a methyl group. At the RHF level there is a small barrier (E_a = +13 kJ mol^{-1}) for formation of species **III**, but at the MP2 level formation of species **III** appears to be barrierless (E_a = −3 kJ mol^{-1}). The formation of species **III** is much less exothermic (−64 kJ mol^{-1}, MP2 value), however, than in the case of [Pd(Me)(**8**)]$^+$ containing the rigid bidentate model ligand HN=$CHCH_2$N=CH_2 (**8**) (−170 kJ mol^{-1}, MP2 value), as expected. The CO insertion is found to proceed via a three-centered insertion transition state **IV**, which is rather close to those reported for CO insertion into the carbon−palladium bond of the complexes Pd(Me)H(PH_3)(CO)[77], *cis*-[Pd(Me)$(NH_3)_2$(CO)]$^+$[59], and [Pd(Me)$(NH_2CH_2CH_2NH_2)$(CO)]$^+$[76]. The geometry of the acetyl species **V** suggests that the reaction occurs by CO insertion into the carbon−palladium bond. The geometry of species **IV**, however, clearly shows that it is the methyl group, not the carbonyl group, that migrates during the reaction, as experimentally demonstrated for platinum and palladium complexes with bidentate phosphorus ligands by van Leeuwen et al.[20][21] The formation of the transition state for CO insertion, **IV**, appears to be the rate-determining step for acetyl formation. The transition state **IV** lies 48 kJ mol^{-1} (MP2 value) above **III**. This activation barrier is slightly lower than those found for systems containing the bidentate ligands **8** (+59 kJ mol^{-1}, MP2 value) and $NH_2CH_2CH_2NH_2$ (+62 kJ mol^{-1}, B3LYP/I value)[76], presumably because of the stronger steric repulsion in the case of species **III**. The energy of the acetyl species **V** lies only 10 kJ mol^{-1} below that of **III**, which is completely in agreement with the experimentally observed reversibility of the CO insertion in complexes **1c**−**6c** (vide supra).

Scheme 2

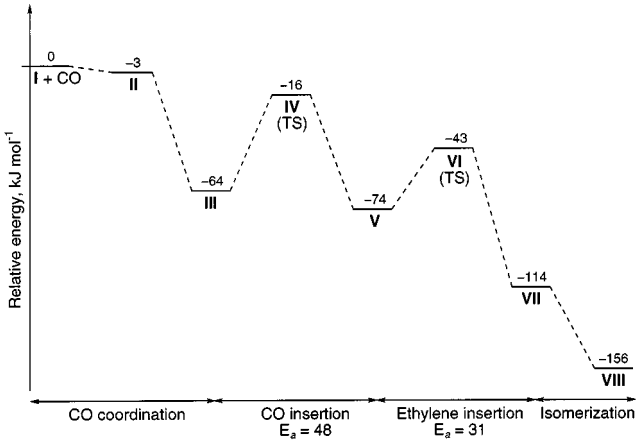
$[Pd\{\kappa^2\text{-}CH_2CH_2C(O)Me\}(L)]^+$ (**IX**)	−149	−150	–	–

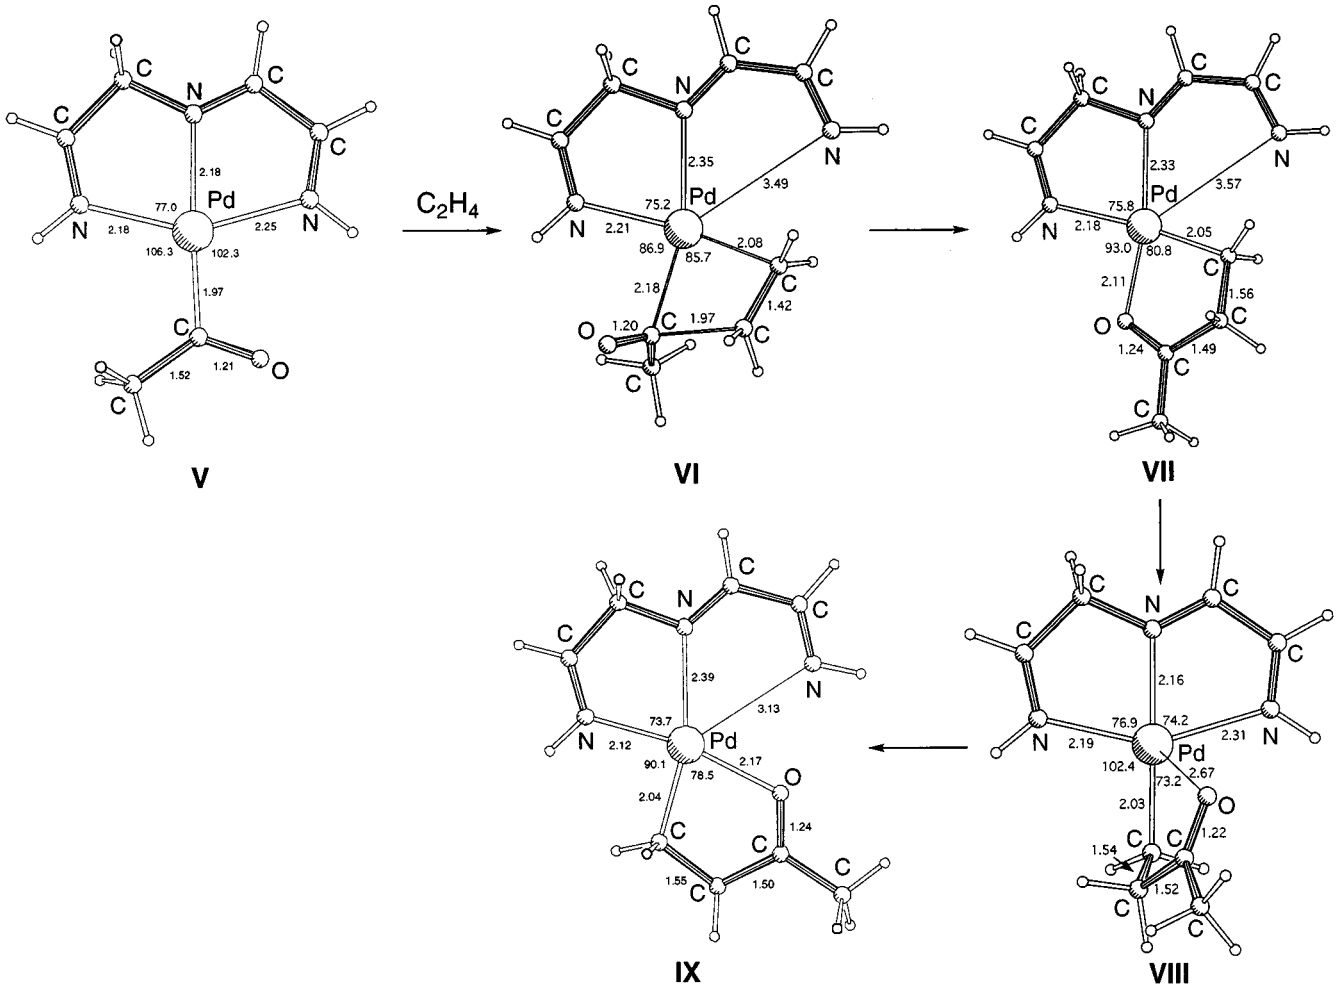
[a] Numbers of species with L = **7** are given in parentheses. – [b] Formation of $[Pd(Me)(CO)(\mathbf{8})]^+$ from $[Pd(Me)(\mathbf{8})]^+$ and CO appears to be barrierless. – [c] No minimum was found for this structure.

Figure 6. Potential-energy profile of CO and subsequent ethylene insertion in $[Pd(Me)(\mathbf{7})]^+$ (**I**), in kJ mol^{-1} at the MP2 level, relative to **I** + CO



(b) *Ethylene Insertion:* The optimized geometries and selected bond lengths and bond angles of the starting complex, the transition state, and the initial and final product are shown in Scheme 3. The relative RHF and MP2 energies have been collected in Table 4 and the potential energy profile at the MP2 level is shown in Figure 6. Analogously to the CO insertion reaction in $[Pd(Me)(\mathbf{7})]^+$, the ethylene insertion into the acetyl−palladium bond of $[Pd\{C(O)Me\}(\mathbf{7})]^+$ is found to proceed via a four-coordinate transition state (species **VI**), in which two nitrogen atoms, the inserting ethylene molecule and the acetyl ligand occupy the four coordination sites. The ethylene insertion is found to pass through a four-centered transition state, similar to those found by others in systems which contain

Scheme 3



a bidentate ligand.[76][78][79][80] At the RHF level, we did not find a minimum for a structure containing a coordinated alkene and a nitrogen ligand coordinated in a bidentate fashion; therefore, the activation energy has been calculated relative to the acetyl species and free ethylene. Since complexation energies are much higher at the MP2 level, there might be a shallow local minimum at this level, which would result in a slightly higher activation energy. In any case, the calculated activation energy of 31 kJ mol^{-1} (MP2 value) is fairly low and comparable to that of the system, which contains the bidentate ligand **8** (E_a = 37 kJ mol^{-1} at MP2 level), despite the obvious crowding in structure **VI**. In the structure of the initial product **VII**, the acyl oxygen atom interacts strongly with the palladium center, which results in a relatively long C−O bond of 1.24 A and a short Pd−O distance of 2.11 A. These values agree well with that theoretically observed in [Pd{$C_2H_4C(O)Me$}($NH_2CH_2CH_2NH_2$)]$^+$ (C−O = 1.28 A; Pd−O = 2.07 A)[76] and those experimentally observed for [Pd{$C_7H_{10}C(O)Me$}(PPh_3)$_2$]BF_4[16] (C−O = 1.240(10) A; Pd−O = 2.114(6) A) and [Pd{$C_{10}H_{12}C(O)Me$}(bpy)]SO_3CF_3[22] (C−O = 1.249(6) A; Pd−O = 2.026(3) A). In the calculations, the chelate structure **VII** isomerizes to species **VIII**, in which the nitrogen ligand is coordinated in a terdentate fashion. The carbonyl group now occupies an apical position, as theoretically observed in [Pd($C_2H_4C(O)Et$)(PH_2CH=$CHPH_2$)(CO)]$^+$[79]. Our experiments show that for complexes **2f**−**6f**, obtained after norbornadiene insertion, species **IX** is more stable than structure **VIII**. On both the RHF and MP2 level, the energies of species **IX** and **VIII** are similar. This is completely in agreement with the experimentally observed fluxional behavior on the ^{1}H-NMR time scale for complexes **4f**−**6f**, which process is proposed to proceed via species of type **VIII**.

Comparison Between Theoretical and Experimental Results

The results of the ab initio MO calculations are fully in agreement with our experimental results. The observed H/D exchange in **1a** in the presence of D_2O, the fast alcoholysis of the acetylchloropalladium complexes **1d**−**6d**, and the structure of complexes **1f**−**6f** show the ability of ligands **1**−**6** to coordinate in a bidentate fashion. Furthermore, a mechanism by substitution of one of the distal nitrogen donor atoms by the substrate followed by rate-determining migratory insertion explains the following observations.

(i) Strained alkenes undergo facile insertion in complexes **2e**−**6e**, whereas simple unstrained alkenes failed to react. Strained alkenes are known to coordinate more strongly to palladium than unstrained alkenes[9][32], so it seems reasonable to assume that unstrained alkenes are unable to compete with the distal nitrogen atoms of the nitrogen ligand for coordination to the palladium.

(ii) Complex **1e** reacts very slowly with nbd, as the two bulky isopropyl groups in **1e** will hinder alkene association significantly.

(iii) The nbd insertion rate increases in the order **6e** < **5e**, with decreasing coordinating capability of the nitrogen ligand (vide supra).[81] Consequently, the distal nitrogen atoms will dissociate more easily, resulting in a more facile substitution by the alkene.

(iv) The nbd insertion rate increases in the order **5e** << **5d**. The chloride counter anion in **5d** may initiate nitrogen dissociation by coordination to the palladium.[32][67][68]

Interestingly, the nbd insertion rate increases in the order **6e** < **4e** < **2e**, whereas on the basis of the rigidity of nitrogen ligands **2**, **4**, and **6** an insertion rate for **2e** in between those of **4e** and **6e** would be expected. Both from calculations and from the molecular structures of **1b**, **4c**, and **6a**[32], it appears that considerable deformations of the ligand skeleton are needed to achieve terdentate coordination with acceptable nitrogen−palladium distances.[82] Even so, the coordination environment is distorted, with *trans* N−Pd−N angles deviating significantly from the ideal value of 180°. In that sense, these complexes can be considered to be strained. Dissociation of one of the arms of the nitrogen ligand, relieving the strain, can be expected to be a low-energy process, which indeed is observed in the experimental and theoretical studies. The strain in the ligand backbone in the terdentate coordinated situations obviously increases in the order **6** < **2** < **4**, reflecting the tendency of the ligand to coordinate in a bidentate fashion. However, ligands **6** and **2** can both create space with the same ease by rotating the dangling pyridyl group, whereas creation of space is much more difficult in the case of ligand **4**. Thus, we believe that the higher insertion rate for **2e** and **4e** relative to **6e** reflects the higher strain in **2e** and **4e**. Furthermore, the higher insertion rate for **2e** relative to **4e** is most probably caused by more facile creation of a free coordination site.

Complexes **2f**−**6f** showed further reactivity toward CO and nbd, but the complexity of the ^{1}H-NMR spectra made assignment difficult. Furthermore, further insertions are expected to proceed alike, and our results have demonstrated that not only complexes containing flexible terdentate nitrogen ligands, but also complexes containing rigid terdentate nitrogen ligands are useful in studying the intimate steps of the catalytic cycle of polyketone formation.

Conclusion

We have shown that ionic methyl- and acetylpalladium complexes containing flexible and rigid terdentate nitrogen ligands undergo sequential insertion of carbon monoxide and strained alkenes. Although nitrogen dissociation was expected to be difficult for complexes containing rigid terdentate nitrogen ligands, ab initio MO calculations show that the mechanism of both insertion reactions unexpectedly proceeds by substitution of one of the distal nitrogen atoms of the terdentate nitrogen ligand, followed by a rate-determining migratory insertion reaction. These theoretical results, which indicate that even rigid terdentate nitrogen ligands may coordinate in a bidentate fashion, are fully supported by the experimentally observed bidentate coordination mode of both flexible and rigid terdentate nitrogen ligands in alkylpalladium complexes, obtained after norbornadiene insertion and the kinetic study of this insertion reaction. In our attempt to prevent nitrogen dissociation by employing rigid terdentate nitrogen ligands, the opposite effect has been observed, as the increasing rigidity of this particular set of terdentate nitrogen ligands leads to increasing strain, *facilitating* nitrogen dissociation.

B. thanks Dr. *J.H. van Lenthe* (Utrecht University) for generous amounts of computer time. Q. X. and R. P. T. thank the *Robert A. Welch Foundation* and the *National Science Foundation* (Grant CHE-9224686) for the financial support. We thank Dr. *R. E. Rülke* for helpful discussions and for the GC-MS measurements, and *J. W. H. Peeters* for the mass-spectrometry measurements.

Experimental Section

General: All manipulations were carried out in purified dry nitrogen by using standard Schlenk techniques. Solvents were dried and stored under nitrogen. Carbon monoxide 99.5% was purchased from HoekLoos and was used without further purification. The compounds 1,2,3,4,5,6,7,8-octahydroacridine-4,5-dione[83], 2-(2′-pyridyl)-1,10-phenanthroline (**2**)[44], 1,2-dihydrodipyrido[4,3-*b*;5,6-*b*]-acridine (**3**)[45], dipyrido[4,3-*b*;5,6-*b*]acridine (**4**)[45], 4′-methylthio-2,2′:6′,2′′-terpyridine (**5**)[46], Pd(Me)Cl(COD)[72] (COD = 1,5-cyclooctadiene), [Pd(Me)(**6**)]Cl (**6a**)[32], [Pd{C(O)Me}(**6**)]Cl (**6d**)[32], and sodium tetrakis[3,5-bis(trifluoromethyl)phenyl]borate (NaBAr′$_4$)[84] were prepared according to the literature. All other starting chemicals were used as commercially obtained. Silver trifluoromethanesulfonate was stored under nitrogen in the dark. − ^{1}H- and ^{13}C-NMR spectra (300.13 and 75.48 MHz, respectively) were recorded with a Bruker AMX 300 spectrometer at 20°C, unless noted otherwise. Chemical shifts are in ppm relative to TMS as external standard (s = singlet, d = doublet, dd = doublet of doublets, t = triplet, q = quadruplet, qq = quadruplet of quadruplet, sept = septuplet, m = multiplet, br. = broad). ^{15}N chemical shifts, which are in ppm relative to nitromethane as external standard, were extracted from gradient-selected (^{1}H,^{15}N)-HMQC experiments[85][86][87] with a Bruker DRX 300 spectrometer. For adopted numbering schemes see Figure 1. − IR spectra were obtained with a Bio-Rad FTS-7 spectrophotometer and mass spectra were obtained with a JEOL JMS SX/SX102A four-sector mass spectrometer, coupled to a JEOL MS-MP7000 data system. GC-MS spectra were obtained with a Hewlett-Packard 5890 series II gas chromatograph with a Gerstel CIS III temperature-controllable injector, an HP 5971A mass-selective detector with electron-impact ionization at 70 eV, and an HP Ultra-2 column (25 m, 0.20 mm inner diameter, 0.33 μm film thickness).

4,5-Bis(isopropylimino)-1,2,3,4,5,6,7,8-octahydroacridine (**1**): A solution of 1,2,3,4,5,6,7,8-octahydroacridine-4,5-dione (1.04 g, 4.84

mmol) in 20 ml of isopropylamine, to which formic acid (2 drops) and $MgSO_4$ (2 g) were added, was stirred at 20°C. After 5 h, the solution was filtered and the isopropylamine was evaporated in vacuo, which resulted in a red oil. Purification by chromatography on neutral alumina with hexane/diethyl ether (4:1) as eluent, resulted in **1** as a yellow oil (704 mg, 49%). – ^{1}H NMR ($CDCl_3$): δ = 7.16 (s, 7-H), 4.85 (d, *J* = 4.8 Hz, 5-H), 4.80 (br., NH), 3.48 (sept, *J* = 6.3 Hz, C*H*Me$_2$), 2.76 (t, *J* = 7.6 Hz, 3-H), 2.35 (m, 4 H, 4-H), 1.24 (d, *J* = 6.3 Hz, CH*Me*$_2$). – ^{13}C NMR ($CDCl_3$): δ = 146.1 (C-1), 139.0 (C-2), 133.8 (C-7), 130.5 (C-6), 94.7 (C-5), 43.5 (*C*HMe$_2$), 27.5, 21.5 (C-3 and C-4), 22.6 (CH*Me*$_2$). – IR (KBr): ν = 3390 cm^{-1} (NH). – MS (EI): calcd. for $C_{19}H_{27}N_3$ 297.2205; found 297.2202.

Chloro(methyl)palladium Complexes **1a–5a**: 4,5-Bis(isopropylimino)-1,2,3,4,5,6,7,8-octahydroacridine (**1**) (714 mg, 2.38 mmol) was added to a solution of Pd(Me)Cl(COD) (431 mg, 1.63 mmol) in 20 ml of toluene. The yellow precipitate, which was formed instantaneously, was separated from the toluene and was washed with diethyl ether (2 × 20 ml). This resulted in **1a** as a yellow solid (577 mg, 78%).

By following the procedure for **1a**, complexes **2a–5a** were synthesized in yields varying from 83 to 95%.

*[Pd(Me)(**1**)]Cl* (**1a**): ^{1}H NMR ($CDCl_3$): δ = 8.03 (s, 7-H), 4.28 (sept, *J* = 6.5 Hz, C*H*Me$_2$), 3.14 (t, *J* = 5.9 Hz, 3-H), 3.09 (t, *J* = 6.4 Hz, 5-H), 2.14 (m, 4 H, 4-H), 1.33 (d, *J* = 6.5 Hz, CH*Me*$_2$), 0.86 (s, Pd–Me). – ^{13}C NMR ($CDCl_3$): δ = 175.6 (C-6), 146.3 (C-1), 142.9 (C-2), 138.9 (C-7), 55.1 (*C*HMe$_2$), 29.9 (C-5), 26.9 (C-3), 22.2 (C-4), 21.5 (CH*Me*$_2$), –6.0 (Pd–Me). – MS (FAB): calcd. for $[C_{20}H_{30}N_3Pd]^+$ 418; found 418. – $C_{20}H_{30}ClN_3Pd \cdot H_2O$: calcd. Alkylpalladium Tetrakis[3,5-bis(trifluoromethyl)phenyl]borate Complexes **2f**−**6f**: Norbornadiene (30 µl, 0.28 mmol) was added to a solution of [Pd{C(O)Me}(**2**)]BAr'_4 (**2e**) (98.0 mg, 0.077 mmol) in 20 ml of dichloromethane. The solution was stirred at 20°C and after 30 min concentrated to dryness. The product was washed with hexane (2 × 20 ml) and dried in vacuo, yielding **2f** as a yellow oil (91.3 mg, 86%).

By following the procedure for **2f**, complexes **3f**−**6f** were synthesized from complexes **3e**−**6e** in yields of 88−91%. Since the complexes **2f**−**6f** were isolated as oils, correct analytical data could not be obtained.

Kinetics: The rates of the reactions of norbornadiene with complexes **1e**−**6e**, resulting in complexes **1f**−**6f**, were followed spectrophotometrically by repetitive scanning of the spectrum at suitable time intervals at a fixed wavelength, at which the difference between absorbance of educt and product was largest. The reactions were started by addition of norbornadiene to a $1.9\cdot10^{-4}$ M solution of the acetylpalladium complex in a quartz cell, which was placed in the thermostated cell compartment of a Perkin-Elmer Lambda 5 spectrophotometer, with a temperature accuracy of ± 0.5°C. The use of at least a 10-fold excess of norbornadiene over acetylpalladium complex ensured pseudo-first-order kinetics in all runs. All reactions, except for the reaction of **3e** with nbd, were clean and quantitative, and in all cases isosbestic points were obtained. Furthermore, the reactions obeyed a first-order rate law for at least four half-lives of the reaction. The rate constants k_{obsd} were calculated from the slopes of plots of $\ln\{(A_t - A_\infty)/(A_0 - A_\infty)\}$ vs time (A_0 = absorbance after mixing of the reagents, A_∞ = absorbance at completion of the reaction). The activation parameters $\Delta S^{\neq}$ and $\Delta H^{\neq}$ were obtained from an Eyring plot.

X-ray Structure Determinations of **1b** *and* **4c**[88]: Crystals suitable for X-ray structure determination were mounted on a Lindemann-glass capillary and transferred to an Enraf-Nonius CAD4-Turbo diffractometer on rotating anode. Accurate unit-cell parameters and an orientation matrix were determined by least-squares fitting of the setting angles of a set of well-centered reflections (SET4).[89] Reduced-cell calculations did not indicate higher lattice symmetry.[90] Crystal data and some details on data collection are given in Table 5. Reflection data were collected at 150 K in ω-scan mode, using graphite-monochromated Mo-K_α radiation (λ = 0.71073A). Data were corrected for Lp effects and for the linear instability of the reference reflections, but not for absorption. The structure of **1b** was solved by automated direct methods (SHELXS96)[91]; the structure of **4c** was solved by automated Patterson methods (SHELXS86)[92]. Refinement on F^2 was carried out by full-matrix least-squares techniques (SHELXL-96);[93] no observance criterion was applied during refinement. Hydrogen atoms were included in the refinement on calculated positions riding on their carrier atoms. In complex **4c** two CF_3 groups of the counterion displayed conformational disorder. A two-site model was introduced to describe this disorder. Severely disordered solvent molecules occupy two of the crystallographic inversion centers of structure **4c**. Since no discrete solvent model could be refined, this electron density was taken into account using the SQUEEZE/BYPASS procedure[94], as implemented in PLATON[95]. The two solvent areas were found to have a volume of 100.5 and 80.5 A^3, containing 38.9 and 24.7 e, respectively. Non-hydrogen atoms were refined with anisotropic thermal parameters, with exception of the minor component of the disordered atoms. The hydrogen atoms were refined with a fixed isotropic displacement parameter related to the value of the equivalent isotropic displacement parameter of their carrier atoms. Neutral atom scattering factors and anomalous dispersion corrections were taken from the International Tables for Crystallography[96]. Geometrical calculations and illustrations were performed with PLATON[95].

Ab initio MO Calculations on the Insertion Reactions: The split-valence 3-21G basis was used for C, N, O, and H atoms.[97] The Pd basis was based on the (18s,11p,9d)→[6s,5p,3d] basis of Godbout[98], but the (9d)→[3d] contraction was replaced by a (9d)→[4d] contraction by releasing the most diffuse d primitive of the middle d shell. In order to save computational time, ligand HN=CHCH$_2$N=CHCH=NH (**7**) was used as a model and solvation and counter anions were left out. To simulate the enforced planarity of the rigid ligands used in the experimental study, the structure of **7** was forced to keep a horizontal mirror plane (local C_s symmetry). Apart from this restriction, all structures were fully optimized (in particular, the metal atom and remaining fragments were allowed to move out of the ligand plane). All structures were optimized at the restricted Hartree-Fock (RHF) level; improved single-point energies were then obtained from second-order Møller-Plesset perturbation (MP2) calculations at the RHF optimized geometries. To enable comparison with bidentate systems, a similar set of calculations was performed on ligand HN=CHCH$_2$N=CH$_2$ (**8**), which was again forced to have local C_s symmetry. All calculations were carried out using the GAMESS[99] and Gaussian[100] packages.

Table 5. Crystallographic data for **1b** and **4c**

Complex	**1b**	**4c**
Formula	$[C_{20}H_{30}N_3Pd]^+$ $[CF_3SO_3]^-$	$[C_{20}H_{14}N_3Pd]^+$ $[C_{32}H_{12}BF_{24}]^-$[a]

[81] It should be noted that the higher rate constant for **5e** than that for **6e** is not caused by inter- or intramolecular coordination of the sulfur donor atom in the nitrogen ligand of **5e**, as addition of 1−100 equiv. of free C_6H_5SMe did not influence the rate constant for **6e**.
[82] One may think that trinitrogen ligands containing three instead

of two carbon atoms between the nitrogen atoms exhibit a more favorable terdentate coordination fashion. However, it is known that this type of terdentate ligands coordinate less strongly to a palladium center.[50]

Keywords: Boron / Diazaboroles / Halogens / Isocyanides / Heterocycles

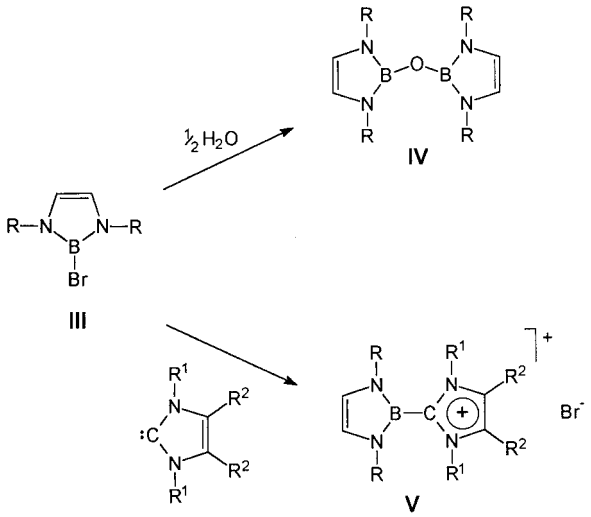
A series of differently substituted 2-chloro-, 2-fluoro- and 2-iodo-2,3-dihydro-1*H*-1,3,2-diazaboroles have been prepared by various methods. 1,3-Di-*tert*-butyl-2-fluoro-2,3-dihydro-1*H*-1,3,2-diazaborole (**3a**), 1,3-di-*tert*-butyl-2-chloro-2,3-dihydro-1*H*-1,3,2-diazaborole (**5a**), 1,3-bis(2,6-dimethylphenyl)-2-chloro-2,3-dihydro-1*H*-1,3,2-diazaborole (**5b**), 2-chloro-4,5-dimethyl-1,3-dineopentyl-2,3-dihydro-1*H*-1,3,2-diazaborole (**5c**), and 1,3-di-*tert*-butyl-2-iodo-2,3-dihydro-1*H*-1,3,2-diazaborole (**6a**) were formed from the corresponding lithiated Z-1,2-diaminoethenes, by treatment with $BF_3{\cdot}OEt_2$, BCl_3, or BI_3 in *n*-hexane. Compounds **3a**, **5a**, and **5b** are also available by sodium amalgam reduction of the adduct (*t*Bu)(BF_3)N=CH–CH=N(BF_3)(*t*Bu) (**2a**), and the borolium salts [RN^a=CH–CH=N^b(R)BCl_2]X (N^a–B) (**4a**: R = *t*Bu, X = BCl_4 and **4b**: R = 2,6-$Me_2C_6H_2$, X = Cl) respectively. The iodo derivative (2,6-$Me_2C_6H_2$)–N^a–CH=CH–N^b(2,6-$Me_2C_6H_2$)BI (N^a–B) (**6b**) was synthesized in a redox reaction between the 1,4-diazabutadiene **1b** and BI_3. The novel compounds were characterized by ^{1}H-, ^{11}B- and ^{13}C-NMR spectroscopy, as well as by an X-ray structure analysis of **6b**.

The formal replacement of a C=C fragment in pyrrole **I** by a B−N unit affords 2,3-dihydro-1*H*-1,3,2-diazaboroles **II**.

I **II**

The first reports on heterocycles of the type **II** date back to the early 1970s[1][2]. Meanwhile, a series of papers concerned with the synthesis, structure, and bonding of such molecules has been published.[3][4] Apart from the synthesis of [$Cr(CO)_3$] complexes with η^5-1,3,2-diazaborole ligands[5][6] and the cleavage of the N−Si bond in *N*-silylated derivatives by metal amides or alcoholates to yield the corresponding alkali metal 1,3,2-diazaborolides,[7] the chemistry of heterocycles **II** has remained largely unexplored. The lack of functional groups in the 2,3-dihydro-1*H*-1,3,2-diazaboroles examined to date may account for this situation.

Recently we launched a program for the synthesis of 2-halo-2,3-dihydro-1*H*-1,3,2-diazaboroles as precursors for a variety of chemical transformations. In a first account we described the preparation of 2-bromo-2,3-dihydro-1*H*-1,3,2-diazaboroles **III** and their reactions with water and imidazol-2-ylidenes. The resulting salts such as **V** contain the first borylated carbenium ions.[8]



III **IV** **V**

The intention of the work described herein is to provide efficient syntheses for 2-fluoro-, 2-chloro- and 2-iodo-2,3-dihydro-1*H*-1,3,2-diazaboroles.

Results and Discussion

For the preparation of 2-bromo-2,3-dihydro-1*H*-1,3,2-diazaboroles, as well as the corresponding fluoro, chloro and iodo derivatives, two synthetic approaches are generally available. The first pathway [Scheme 1 (a)], involves the gen-

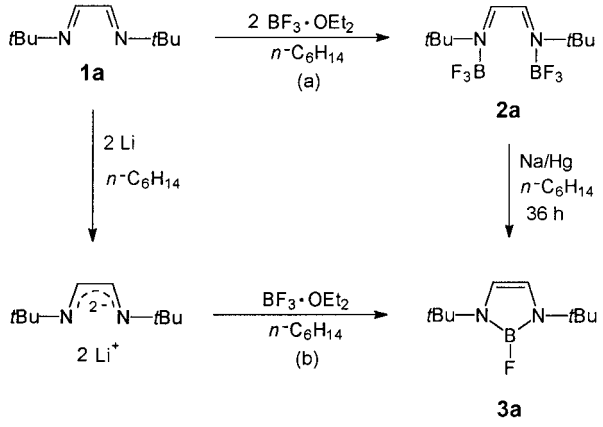
eration of the bis(trifluoroborane) adduct **2a**, by the combination of 1,4-diazabutadiene **1a** with two molar equivalents of $BF_3{\cdot}Et_2O$ in *n*-hexane.

Scheme 1

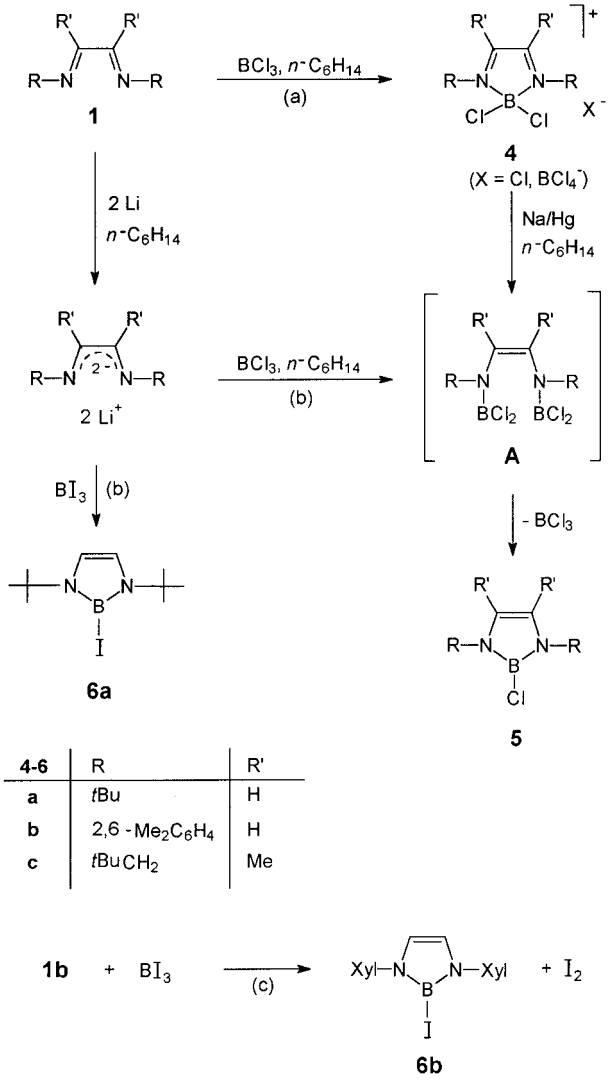


The adduct was obtained as a yellow amorphous solid in 74% yield. Its $^{11}B\{^1H\}$-NMR spectrum in CD_3CN shows only one singlet (at $\delta = 0.4$) for the two chemically and magnetically equivalent boron atoms. Similarly, only one resonance was observed in the $^{19}F\{^1H\}$-NMR spectrum of **2a** (at $\delta = 73.0$) for the six fluorine atoms. The synthesis of 2-fluoro-1,3,2-diazaborole (**3a**) was accomplished by the reduction of **2a** with an excess of sodium amalgam in an *n*-hexane slurry (Scheme 1). After 36 h, the ^{11}B-NMR spectrum only showed the resonance for **3a** at $\delta^{11}B = 20.8$. The crude yellow **3a** was purified by fractional condensation at 40°C and 0.01 Torr to give colorless crystals. At temperatures above 40°C the 2-fluoro-1,3,2-diazaborole decomposed with liberation of **1a**. Compound **3a** is soluble in common aprotic organic solvents. In solution complete decomposition of the heterocycle occurred within 2 days.

A second approach to **3a** [Scheme 1 (b)] made use of the reduction of **1a** by two equivalents of lithium in hexane, prior to the condensation with $BF_3{\cdot}Et_2O$.

In contrast to the symmetrical adduct **2a**, the treatment of **1a** with two molar equivalents of BCl_3 in *n*-hexane at −30°C afforded the colorless amorphous borolium tetrachloroborate **4a** in 71% yield. Accordingly, the ^{11}B-NMR spectrum of the salt gave rise to two singlets for the BCl_4^- ion[9] and the boron atom of the ring at $\delta = 1.6$ and 7.7 respectively. The analogous borolium chloride, described in the literature, gave a boron resonance at $\delta = 7.2$ (in $CDCl_3$).[3] The reduction of **4a** with sodium amalgam in *n*-hexane led to the formation of 2-chloro-1,3,2-diazaborole (**5a**) as a colorless solid after sublimation (40−60°C, 0.01 Torr, 91%). The course of the reduction was followed by ^{11}B-NMR spectroscopy. After 5 h, the spectrum of the supernatant solution showed signals at $\delta = 32.3$ and 21.0 in a ratio of 2:1. A small resonance at $\delta = 47.0$ was assigned to BCl_3. After 14 h, the spectrum was dominated by two intense singlets at $\delta = 21.1$ and 47.0, in addition to a weak singlet at $\delta = 31.8$. This observation may be rationalized by the initial formation of the intermediate acyclic aminoborane $(tBu)N(BCl_2)-CH=CH-N(BCl_2)(tBu)$ (**A**)[10] which subsequently disproportionated into **5a** and BCl_3 (Scheme 2). The synthesis of **5a** can also be effected by the reaction of the lithiated diazabutadiene with BCl_3 [Scheme 2 (b)].

Scheme 2



The reaction of 1,4-diazabutadiene **1b** with an equimolar amount of BCl_3 in a hexane/dichloromethane mixture, led to the violet borolium chloride **4b** (38%) and the corresponding black tetrachloroborate **4b′** (7%). The ^{11}B-NMR spectra of the salts displayed signals at $\delta = 7.2$ for **4b**, and at $\delta = 7.7$ and 1.5 for **4b′**.

Reduction of **4b** by an excess of sodium amalgam in *n*-hexane afforded the 2-chloro-1,3,2-diazaborole **5b** (55% yield). Treatment of 1,4-diazabutadiene **1b** with lithium sand and condensation of the lithium derivative with BCl_3 gave 1,3,2-diazaborole **5b** (53%) as the final product after 3 d. After 1 h, the ^{11}B-NMR spectrum of the yellow solution showed a resonance at $\delta = 32.5$ for an intermediate. Minor resonances at $\delta = 22.0$ and 47.0 were attributed to **5b** and BCl_3, respectively. After 14 h, a spectrum of the same sample displayed only the singlets of **5b** and BCl_3. In an

additional experiment, the reaction mixture was filtered after 1 h of stirring at ambient temperature and the concentrated hexane solution was stored overnight at −80°C to give a tan precipitate. The ^{11}B-NMR spectrum of the tan precipitate in $CDCl_3$ showed a major resonance at δ = 32.6 and an impurity of **5b** at δ = 21.8. The ^{1}H-NMR spectrum of the tan solid in C_6D_6 was dominated by singlets at δ = 1.99 (s, 12 H, CH_3), 6.40 (s, 2 H, N=CH), and 6.93 (m, 6 H, aryl-H), in addition to the resonances of **5b**. A 2:1 ratio of the intermediate to **5b** was determined. Based on the spectroscopic data and its good solubility in non-polar solvents, we attributed the formula (Xyl)(Cl_2B)N−CH=CH−N(BCl_2)(Xyl) to this intermediate (Scheme 2).

Lithium reduction of 1,4-diazabutadiene **1c** for 10 d in *n*-hexane, and the subsequent quenching of the lithium derivative with BCl_3 furnished 1,3,2-diazaborole **5c** as a dark brown oil, which slowly solidified to a tan wax (60%).

The synthesis of the 2-iodo-1,3,2-diazaborole (*t*Bu)-N^a−CH=CH−N^b(*t*Bu)BI(*N*^{a}−B) (**6a**) was achieved by allowing Li_2[(*t*Bu)NCH=CHN(*t*Bu)] to react with an equimolar amount of BI_3 to give a colorless, light-sensitive oil (83%), which completely decomposed within 5 h at room temperature. In contrast, 2-iodo-1,3,2-diazaborole **6b**, accessible by the redox reaction between **1b** and BI_3, was sublimed at 380°C/0.01 Torr without significant decomposition.

As previously shown, 2-bromo-2,3-dihydro-1*H*-1,3,2-diazaborole (**7a**) can be brought to reaction with imidazolylidenes to give borylated imidazolium salts (eq. 1). In the light of these data, an analogous synthesis of borylated nitrilium salts seemed possible, by reaction of compounds **5**−**7** with organic isocyanides.

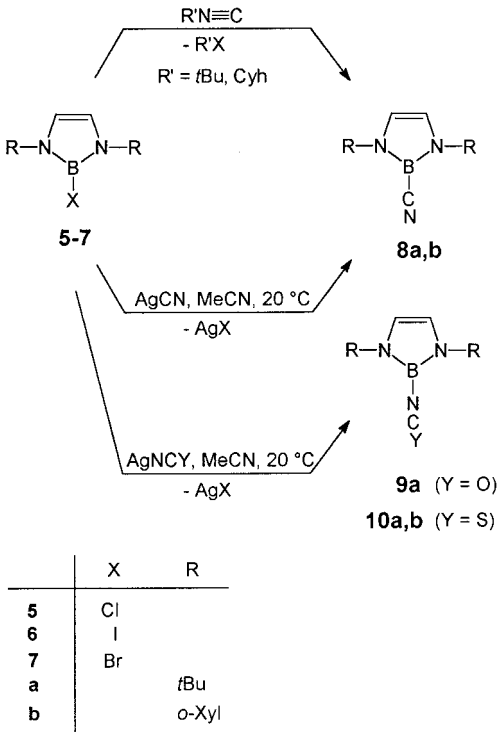
Treatment of **5a**, **6a**, and **7a** with an equimolar amount of *tert*-butyl isocyanide in *n*-hexane, led to the formation of the 2-cyano-1,3,2-diazaborole (**8a**). The expected nitrilium salt could not be detected spectroscopically. The formation of *tert*-butylbromide as a byproduct was proven by ^{1}H-NMR spectroscopy (δ = 1.78) and by comparison with an authentic sample.

The corresponding reaction of **7a** with cyclohexyl isocyanide afforded **8a** in 38% yield after 5 days. No intermediates were observed spectroscopically. Similarly, **5b** and **6b** were converted into **8b** by *tert*-butyl isocyanide in 70% and 55% yield, respectively (Scheme 3).

No reaction was observed between 2-halo-1,3,2-diazaboroles **5**−**7** and 2,6-$Me_2C_6H_3$N≡C. The cyano compound **8a** was also synthesized in high yield by treatment of the diazaboroles **5a** or **7a** with a slight excess of silver cyanide in acetonitrile at room temperature. The 2-bromo compound was found to be more reactive than the 2-chloro analogue. Similarly, compound **8b** was obtained by treatment of **6b** with AgCN over a period of 2 days (79%).

In line with the synthetic approach to isocyanatoboranes and isothiocyanatoboranes devised by Lappert et al.,[11] diazaborole **5a** was converted by silver cyanate in acetonitrile into the isocyanato diazaborole **9a**, which was isolated after 30 min as a colorless thermolabile oil in 78% yield. The analogous reaction between **7a** and AgOCN to afford **9a**

Scheme 3



was complete after 5 min (83%). The corresponding isothiocyanato diazaborole **10a**, resulted from the reaction of **5a** or **7a** with AgSCN under similar conditions. Again, the reactivity of **7a** exceeded that of **5a**. Derivative **10b** was synthesized from **6b**, **5b**, or (2,6-$Me_2C_6H_3$)N^a−CH=CH−N^b(2,6-$Me_2C_6H_3$)BBr(*N*^{a}−B) (**7b**) (78−93% yield). The reactivity of the 2-halo-1,3,2-diazaboroles was found to be: **7b** > **5b** > **6b**.

It was not possible to unambiguously identify the B−X stretching frequencies in the IR-spectra of the 2-halo-1,3,2-diazaboroles **3**, **5**, **6**, and **7**. In the IR spectra (KBr) of **8a** and **8b**, weak bands at ν = 2207 and 2218 cm^{-1} are attributed to the stretching frequency of the C≡N group. In the IR spectra of MeN^a−CH_2−CH_2−N^b(Me)BCN(*N*^{a}−B)[12] and MeN^a−N^b=N^c−N^d(Me)BCN(*N*^{a}−B)[13] the ν(CN) mode was observed as weak bands at 2225 and 2239 cm^{-1}, respectively. A very intense band in the IR spectrum of **9a** at ν = 2317 cm^{-1} was assigned to the asymmetric stretching frequency of the isocyanato group, which is consistent with the data for compounds (R_2N)$_2$B−N=C=O [ν_{as}(NCO) = 2290 ± 15 cm^{-1}],[11c] and the IR spectrum of Me_2B−N=C=O [ν_{as}(NCO) = 2285 cm^{-1} vs].[14] These frequencies also underline the presence of an isocyanatoborane R_2BN=C=O, and disfavor the isomeric cyanatoborane structure R_2BOC≡N. Similar arguments support an isothiocyanatoborane structure in the 1,3,2-diazaboroles **10a** and **10b**, where very strong bands at 2121 and 2114 cm^{-1}, respectively, are assigned to the ν_{as}(NCS) mode. Intense bands at 871 and 856 cm^{-1} are due to the symmetric stretching frequency of the NCS group. The ν_{as}(NCS) of a series of isothiocyanatoboranes occurs in the range 2089 ± 31 cm^{-1}.[11]

The $^{11}B\{^1H\}$-NMR spectra of the halo- and pseudohalodiazaboroles display an increased shielding as follows: **3a** ≈ **5a** (δ = 20.2) > **7a** (16.2) > **9a** ≈ **10a** (14.7) > **8a** (12.0) > **6a** (6.5). Similarly, the ^{11}B-NMR signals of **5b**, **7b**, **10b**, **8b**, and **6b** range from δ = 21.1 to 11.8. The significant high-field shift of **8a** relative to the saturated analogue Me-$N^a-CH_2CH_2-N^b$(Me)BCN(*N*^{a}−B) (δ = 21.0)[12] sustains the heteroaromatic nature of the rings under discussion. The ring protons in **3a** and **5a**−**10a** are observed at δ = 5.99−6.40, whereas in the dixylyl-substituted derivatives **5b**−**8b** and **10b**, singlets at δ = 5.71−5.99 are assigned to these protons. In the $^{13}C\{^1H\}$-NMR spectra of **3a** and **5a**−**10a**, singlets at δ = 109.9−114.6 were assigned to the C=C group of the rings. The respective ^{13}C-nuclei of **5b**−**8b**, and **10b** gave rise to resonances at δ = 117.2−120.0.

X-ray Structural Analysis of 6b

The molecular structure of **6b** (Figure 1) features a planar 1,3,2-diazaborole ring with two nearly orthogonally oriented *ortho*-xylyl substituents at the nitrogen atoms (interplanar angle between the heterocycle and an arene ring ψ = 85.6°). A C_2 axis bisects the molecule along the B(1)−I(1) vector. The bond length B(1)−I(1) [2.119(5) A] is close to the sum of the covalent radii of boron (0.81 A) and iodine (1.33 A)[15] and compares well with the atomic distance between the tricoordinate boron and an iodine atom in the dimer of $IB^a-C(Et)=C(Et)-B^b(I)S$(*B*^{a}−S) [2.13(2) A][16]. B−I bond lengths involving sp^2-hybridized boron atoms range from 2.10(4) A in BI_3[17] to 2.237(6) A in the triborane $[(Me_2N)(I)B]_2BNMe_2$[18]. Atomic distances and valence angles within the diazaborole ring are in good agreement with the respective data for $EtN^a-CH=CH-N^b$(Et)BMe(*N*^{a}−B).[4] In **6b**, the B−N bond length [1.418(4) A] indicates multiple-bond character. In a series of diazaboroles the B−N bond lengths range from 1.407(3) to 1.450(2) A. The atomic distance C(1)−C(1′) [1.362(8) A], and the N−C(sp^2) bond length [1.401(4) A] also indicate multiple bonding. For the N(sp^2)−C(sp^2) single bond, N(1)−C(2) bond lenghths of 1.438(4) A were measured. The endocyclic angles in **6b**: N(1)−B(1)−N(1)′ [106.9(4)°], B(1)−N(1)−C(1) [107.5(3)°], and N(1)−C(1)−C(1)′ [109.1(2)°] resemble those in the borylimidazolium cation **V** [107.1(6), 105.9(4), and 110.5(3)°, respectively].[1] This also applies to the exocyclic angle N(1)−B(1)−I(1) [126.6(2)°] in **6b**, and the corresponding angle N(1)−B(1)−C(6) in **V** [126.5(3)°].

The packing of **6b** shows some interesting features. The molecules are arranged in a pattern with the iodine atoms pointing to the centers of the carbon−carbon double bonds (distance from the iodine atom to the center of the bond 3.17 A), such that each iodine atom is in contact with two hydrogen atoms (distance from iodine to hydrogen 3.093 A, with a normalized 1.08 A distance for C−H). This linkage produces chains of molecules with adjacent chains running in opposite directions, and with the phenyl groups interlocked (Figure 2).

In the layer depicted in Figure 2, one of the methyl groups is oriented so that a hydrogen atom points towards

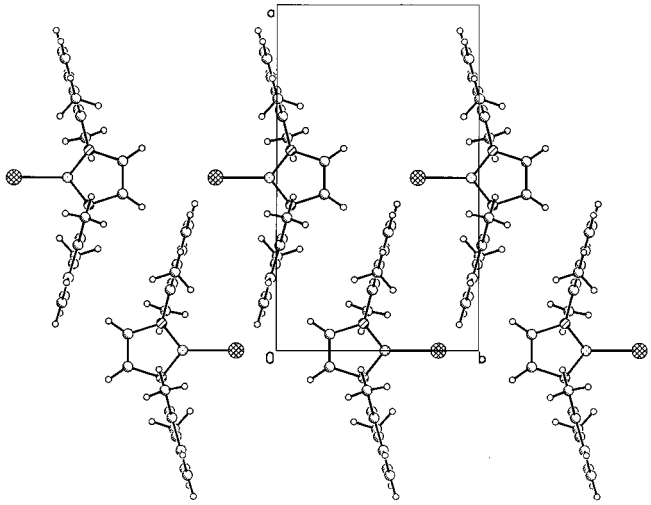
Figure 2. View of the crystal structure of **6b** along the *c* axis; depicted are two adjacent chains with three molecules each



the aromatic ring system of the adjacent chain. A cheletropic intermolecular interaction of iodine with two hydrogen atoms bonded to sp^2-carbon atoms is expected to be mostly electrostatic in nature, and seems to dominate the molecular packing of **6b**. An analysis of specific packing motifs is possible with the help of a statistical approach which involves plots of intermolecular distances and angles for groups of crystals structures that contain the motif under investigation (scatter-plots). The more frequent certain short contacts with reasonable angles occur, the more likely it is that this represents a "supramolecular synthon".[19] Therefore we performed a search in the CSD,[20] which revealed 5703 structures that possess: (1) a *cis*-1,2-dihydro group, attached to a double or aromatic bond of two carbon atoms, and (2) an uncharged halogen (not fluorine) atom with a single bond. Amongst these, 426 structures and 1079 fragments have an intermolecular distance from the halogen atom to the hydrogen atoms of less than the sum of van der Waals radii plus 1 A (H···Cl 3.95 A; H···Br 4.05 A; H···I 4.18 A). A characteristic cheletropic interaction is evident from the polar scatter diagrams, given in Figures 3

and 4. Figure 3 represents the positions of the halogen atoms relative to the aromatic carbon−carbon double bond, with this bond at the equator, and the *cis*-oriented hydrogen atoms situated in the northern hemisphere. An accumulation of structures at a distance of 4 A from the center of the aromatic C=C bond and perpendicular to this bond axis demonstrates that the halogen atoms prefer to be located in the same manner as we found for **6b**. In our case, the intermolecular distance with iodine, and even with bromine, is amongst the smallest found for all the given fragments.

Figure 3. Polar scatter plot of the distance from the halogen to the center of the carbon−carbon double bond, the angle between the carbon−carbon double bond, and the projection of the intermolecular vector to the plane for 1079 fragments in the Cambridge Data Base that contain the halogen···HC=CH motif as defined

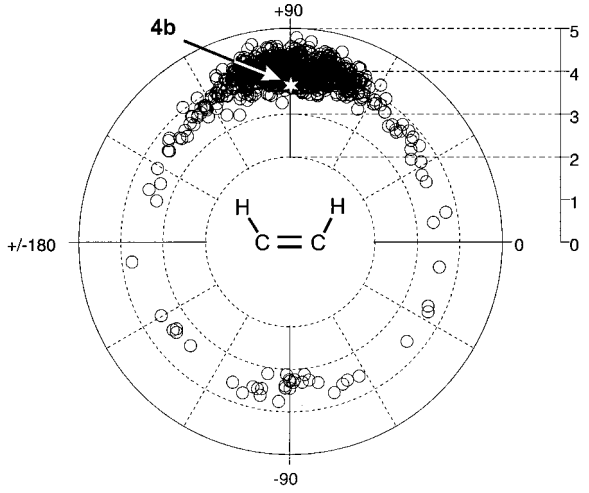


Figure 4. Polar scatter plot of the distance from the halogen to the center of the carbon−carbon double bond and the angle between the molecular plane and the intermolecular vector (section perpendicular to Figure 3)

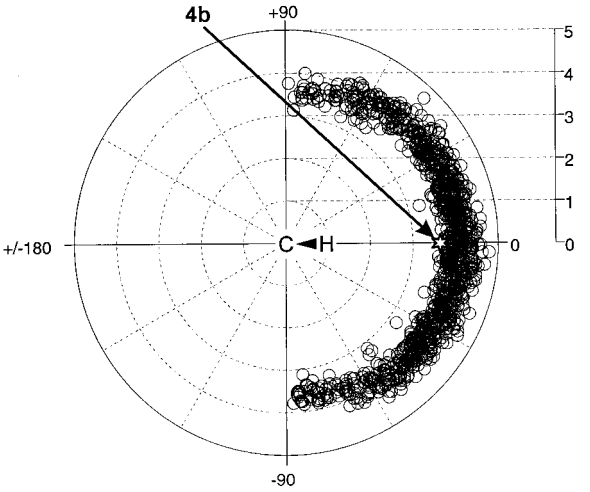

The distribution of halogen positions below and above the one in Figure 3 is shown in Figure 4. Here the equator of the pole scatter diagram intercepts the center of the double (aromatic) C=C bond, with the hydrogen atoms below and above the plane of the diagram. An accumulation, albeit not so pronounced, of halogen atoms in the plane of the carbon and hydrogen atoms (at 0°) again demonstrates the cheletropic character of the interaction in **6b**. The angles used in Figures 3 and 4 were obtained from the *LP2 method in Quest3D[21], where the positions of one hydrogen atom, the nearest carbon atom, the center of the carbon−carbon bond, and the halogen atom were used as the parameters. The scatter plot was produced by the distance between the halogen atom and the center of the carbon−carbon double bond. Equivalent scatter plots produced for iodine, bromine, and chlorine are available as supporting information on the WWW or from the author.

Experimental Section

General: All manipulations were performed under dry argon. Solvents were rigorously dried with an appropriate drying agent and distilled before use. − The following compounds were prepared as described in the literature: *t*BuN=CH−CH=N*t*Bu (**1a**),[22] 2,6-$Me_2C_6H_3N$=CH−CH=$NC_6H_3Me_2$-2,6 (**1b**),[23] *t*$BuCH_2N$=C(Me)−C(Me)=NCH_2*t*Bu (**1c**),[24] and BI_3.[25] Boron trichloride, boron trifluoride−diethyl ether, *t*BuNC, cyclohexyl isocyanide, AgCN, AgOCN, and AgSCN were purchased. − IR spectra: Bruker FTIR IFS66. − ^{1}H-, ^{11}B-, ^{13}C-, and ^{19}F-NMR spectra: Bruker AC 100 (^{1}H, 100.13 MHz; ^{13}C, 25.18 MHz), and Bruker AM Avance DRX 500 (^{1}H, 500.13 MHz; ^{11}B, 160.46 MHz; ^{13}C, 125.75 MHz; ^{19}F, 470.60 MHz). References: $SiMe_4$ (^{1}H, ^{13}C), $BF_3{\cdot}OEt_2$ (^{11}B), $CFCl_3$ (^{19}F). − Mass spectra (EI): VG Autospec sector-field mass spectrometer (Micromass) 70 eV.

(tBu)(BF_3*)N=CH−CH=N(tBu)(*BF_3*)* (**2a**): A solution of *t*BuN=CH−CH=N*t*Bu (**1a**) (10.0 g, 59.0 mmol) in 200 ml of *n*-hexane, and an emulsion of $BF_3{\cdot}OEt_2$ (18.6 g, 118.0 mmol) in 200 ml of *n*-hexane were added separately, dropwise, into a flask filled with chilled *n*-hexane (1000 ml, −10°C). After 24 h of stirring at room temp., a yellow solid was filtered off and washed with *n*-hexane (4 × 30 ml). Drying at 0.01 Torr for 2 h gave **2a** as a bright yellow powder (13.2 g, 74%). − IR (KBr): ν = 3206cm^{-1} w, 3102 w, 2984 vs, 2892 s, 2796 m, 2695 m, 2585 m, 2486 m, 2034 m, 1950 w, 1608 w, 1509 m, 1476 w, 1404 m, 1378 m, 1299 m, 1214 m, 1055 vs, br. [ν(BF)], 534 m, 522 m, 444 m, 419 w. − ^{1}H NMR (CD_3CN): δ = 1.48 (s, 18 H, *t*Bu), 8.90 (s, 2 H, CH). − ^{13}C{^{1}H} NMR (CD_3CN): δ = 28.5 [s, C(CH_3)$_3$], 66.3 [s, C(CH_3)$_3$], 163.2 (s, CH). − ^{11}B{^{1}H} NMR (CD_3CN): δ = 0.4 (s). − ^{19}F{^{1}H} NMR (CD_3CN): δ = 73.0 (s). − $C_{10}H_{20}B_2F_6N_2$ (303.86): calcd. C 39.52, H 6.65, N 9.21; found C 39.40, H 6.83, N 9.23.

(tBu)N^a*−CH=CH−*N^b*(tBu)BF(*N^a*−B)* (**3a**). − *Path (a):* A slurry of adduct **2a** (5.0 g, 16.5 mmol) in *n*-hexane (100 ml) was treated at 20°C with sodium amalgam prepared from 3.8 g (165.2 mmol) of sodium and 500 g of mercury. After 36 h of stirring, the yellow hexane phase was decanted. Solvent and volatile components were removed in vacuo (0.1 Torr, 10°C) to give a yellow solid residue. Purification of crude **3a** was achieved by fractional condensation at 40°C and 0.01 Torr (yield 2.38 g, 73%).

Path (b): 1.4-Diazabutadiene **1a** (1.67 g, 10.0 mmol) was reduced with lithium sand (0.139 g, 20.0 mmol) in 70 ml of *n*-hexane for 7 d at 20°C. The yellow slurry obtained was treated with 1.58 g (10.0 mmol) of $BF_3{\cdot}Et_2O$, and the mixture was stirred for 10 min. The red solution was filtered, concentrated to ca. 10 ml, and stored

overnight at −78°C to afford 1.1 g (56%) of colorless crystalline **3a**. − IR (nujol): ν = 1631cm^{-1} w, 1489 sh, 1428 s, 1395 sh, 1366 s, 1293 m, 1273 w, 1244 s, 1224 m, 1211 m, 1136 s, 1062 w, 1028 w, 951 w, 933 w, 879 w, 822 w, 746 w, 658 w, 623 s. − ^{1}H NMR (C_6D_6): δ = 1.26 (d, $^5J_{FH}$ = 1.1 Hz, 18 H, *t*Bu), 5.99 (d, $^4J_{FH}$ = 2.3 Hz, 2 H, CH). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 30.9 [s, C(*C*H$_3$)$_3$], 51.6 [s, *C*(CH$_3$)$_3$], 109.9 (s, CH). − ^{11}B{^{1}H} NMR (C_6D_6): δ = 20.3 (s). − ^{19}F{^{1}H} NMR (C_6D_6): δ = 57.9 (s). − MS/EI (70 eV); *m*/*z*: 199 [M$^+$]. − $C_{10}H_{20}BFN_2$ (198.09): calcd. C 60.63, H 10.18, N 14.14; found C 60.44, H 10.59, N 14.17.

[tBuN^a=CH−CH=N^b(tBu)BCl$_2$]$^+$BCl$_4^-$(N^a−B) (**4a**): A three-necked 2-l flask was filled with 900 ml of *n*-hexane and cooled to −30°C. Solutions of **1a** (8.10 g, 48.0 mmol) in 200 ml of *n*-hexane and BCl_3 (11.30 g, 96.0 mmol) in 200 ml of *n*-hexane were added dropwise at a similar rate into the well-stirred *n*-hexane. The resulting mixture was stirred overnight. The colorless precipitate was filtered off and washed with *n*-hexane (2 × 50 ml) and *n*-pentane (2 × 50 ml) before drying in vacuo to give 13.7 g (71%) of **4a**. − IR (KBr): ν = 2985 cm^{-1} m, 2360 w, 1580 m, 1465 s, br., 1405 s, 1385 s, 1232 m, 1191 s, 1119 w, 1071 m, 1036 w, 920 w, 898 m, 821 s, 804 s, 711 m, 657 m, 547 w, 481 w. − ^{1}H NMR (CD_3CN): δ = 1.70 (s, 18 H, *t*Bu), 8.90 (s, br., 2 H, CH). − ^{13}C{^{1}H} NMR (CD_3CN): δ = 30.0 [s, C(*C*H$_3$)$_3$], 67.3 [s, *C*(CH$_3$)$_3$], 162.7 (s, CH). − ^{11}B{^{1}H} NMR (CH_3CN): δ = 1.6 (s, BCl_4^-), 7.7 (s, N_2BCl_2). − $C_{10}H_{20}B_2Cl_6N_2$ (402.62): calcd. C 29.83, H 5.01, N 6.96; found C 29.91, H 5.00, N 6.80.

[2,6-Me$_2$C$_6$H$_3$N^a=CH−CH=N^b(2,6-Me$_2$C$_6$H$_3$)BCl$_2$]$^+$Cl$^-$(N^a−B) (**4b**) *and [2,6-Me$_2$C$_6$H$_3$N^a=CH−CH=N^b(2,6-Me$_2$C$_6$H$_3$)BCl$_2$]$^+$BCl$_4^-$(N^a−B)* (**4b′**): A three-necked 2-l flask was charged with 1200 ml of *n*-hexane and chilled to −20°C. As described before the solutions of BCl_3 (5.90 g, 50.0 mmol) in 200 ml of *n*-hexane and **1b** (13.2 g, 50.0 mmol) in a mixture of *n*-hexane (150 ml) and CH_2Cl_2 (50 ml) were added dropwise into the flask. After warming up to ambient temp., a violet precipitate was filtered off, washed with *n*-hexane (3 × 30 ml) and dried in vacuo to give 7.2 g (38%) of **4b**. The mother liquor was concentrated to ca 500 ml and stored at 5°C overnight to yield 1.7 g (7%) of black crystalline **4b′**.

4b: IR (KBr): $\tilde{\nu}$ = 2567 cm^{-1} w, 1585 w, 1473 s, br., 1197 m, 1095 w, 884 w, 821 m, 775 m, 656 w, 548 w. − Due to the poor solubility and due to decomposition no reliable ^{1}H- and ^{13}C-NMR spectra were available. − ^{11}B{^{1}H} NMR ($CDCl_3$): δ = 7.2 (s). − $C_{18}H_{20}BCl_3N_2$ (381.54): calcd. C 56.66, H 5.28, N 7.34; found C 57.87, H 5.20, N 6.95.

4b′: IR (KBr): $\tilde{\nu}$ = 2963 cm^{-1} w, 2922 w, 1608 sh, 1535 sh, 1473 s, 1444 s, 1374 s, 1252 sh, 1227 m, 1094 s, 1000 s, 933 m, 908 w, 771 s, 722 w, 668w, 542 w. − ^{11}B{^{1}H} NMR (CD_3CN): δ 7.7 (s, BN_2), 1.5 (s, BCl_4^-). − $C_{18}H_{20}B_2Cl_6N_2$ (498.71): calcd. C 43.35, H 4.04, N 5.62; found C 38.6, H 4.31, N 4.77. − Repeated attempts to purify the crude product by recrystallization failed.

(tBu)N^a−CH=CH−N^b(tBu)BCl(N^a−B) (**5a**). − *Path (a):* A sample of 4.46 g (11.0 mmol) of borolium salt **4a** was stirred overnight with 305.2 g of sodium amalgam (96.0 mmol sodium) in 120 ml of hexane. The reaction mixture was protected from light. The slightly yellow solution was decanted from a yellow precipitate. Filtration and removal of volatile components in vacuo afforded an orange-yellow oil, which slowly solidified to give orange crystalline **5a**. The crude material was sublimed at 40−60°C (0.01 Torr) to yield 2.18 g (91%) of colorless product.

Path (b): A sample of 1,4-diazabutadiene **1a** (2.50 g, 14.8 mmol) was stirred with lithium sand (0.21 g, 29.6 mmol) in 70 ml of *n*-hexane for 7 d at 20°C. A solution of 1.75 g (14.8 mmol) of BCl_3 in 30 ml of *n*-hexane was added dropwise to the chilled yellow slurry (−50°C). The mixture was allowed to warm up to room temp., and stirring was continued overnight. Filtration and removal of solvent from the filtrate in vacuo gave 1.74 g (55%) of **5a**. − IR (CsI, film): ν = 1515 cm^{-1} w, 1464 m, 1399 s, 1367 s, 1347 sh, 1327 s, 1285 m, 1237 s, 1209 m, 1136 m, 1030 w, 987 m, 943 w, 893 w, 822 w, 696 w, 662 m. − ^{1}H NMR (C_6D_6): δ = 1.35 (s, 18 H, *t*Bu), 6.19 (s, 2 H, CH). − ^{13}C{^{1}H} NMR (C_6D_6: δ = 30.9 [s, C(*C*H$_3$)$_3$], 53.2 [s, *C*(CH$_3$)$_3$], 112.0 (s, CH). − ^{11}B{^{1}H} NMR (C_6D_6): δ = 20.2 (s). − MS/EI; *m*/*z* (%): 214 (20) [M$^+$], 158 (8.5) [M$^+$ − C$_4$H$_8$], 143 (13) [M$^+$ − C$_4$H$_8$ − CH$_3$], 102 (100) [M$^+$ − 2 C$_4$H$_8$]. − $C_{10}H_{20}BClN_2$ (214.55): calcd. C 55.99, H 9.39, N 13.05; found C 55.11, H 9.42, N 12.85.

2,6-Me$_2$C$_6$H$_3$N^a−CH=CH−N^b(2,6-Me$_2$C$_6$H$_3$)BCl(N^a−B) (**5b**). − *Path (a):* A slurry of 4.00 g of **4b** (10.5 mmol) in 150 ml of *n*-hexane was treated with sodium amalgam obtained from 1.38 g of Na (60.0 mmol) and 200 g of mercury. Stirring at ambient temp. was maintained for 5 d. The solution was decanted from the metal, and volatile components were removed in vacuo to yield 1.80 g (55%) of **5b** as a colorless solid.

Path (b): A solution of the 1,4-diazabutadiene **1b** (4.00 g, 15.0 mmol) in 80 ml of *n*-hexane was reduced by 0.21 g (30.0 mmol) of lithium sand during 7 d at 20°C. The resulting brown slurry was chilled to −30°C and a solution of 1.76 g (15.0 mmol) of BCl_3 in 50 ml of *n*-hexane was added dropwise. Stirring at room temp. was continued for 3 d. Filtration was followed by removing volatile components in vacuo to afford a colorless solid. Recrystallization from *n*-hexane gave 2.48 g (53%) of pure **5b**. − ^{1}H NMR (C_6D_6): δ = 2.17 (s, 12 H, CH_3), 5.86 (s, 2 H, HC=N), 6.99 (m, 6 H, aryl-H). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 18.1 (s, CH_3), 117.7 (s, HC=N), 127.3 (s, *p*-C aryl), 135.8 (s, *o*-C aryl), 139.9 (*i*-C aryl). − ^{11}B{^{1}H} NMR (C_6D_6): δ = 21.1 (s). − MS/EI; *m*/*z*: 310 [M$^+$]. − $C_{18}H_{20}BClN_2$ (310.63): calcd. C 69.60, H 6.49, N 9.02; found C 68.78, H 6.45 N 8.87.

(tBuCH$_2$)N^a−C(Me)=C(Me)−N^b(CH$_2$tBu)BCl(N^a−B) (**5c**): Lithium sand (0.32 g, 46.8 mmol) was added to a solution of 3.50 g (15.0 mmol) of 1,4-diazabutadiene (**1c**) in 100 ml of *n*-hexane. After stirring the mixture for 10 d at room temp., the resulting green slurry was chilled to −30°C, and a solution of 1.76 g (15.0 mmol) of BCl_3 in 50 ml of *n*-hexane was added dropwise. After 2 h of stirring, the slurry was filtered, and the solvent was removed in vacuo to afford 2.53 g (60%) of **5c** as a dark brown oil, which solidified to a tan wax. − Due to the lability of the product no reliable IR spectrum was available. − ^{1}H NMR (C_6D_6): δ = 0.89 (s, 18 H, *t*Bu), 1.77 (s, 6 H, CH_3), 3.21 (s, 4 H, CH_2). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 10.9 (s, =C−*C*H$_3$), 28.4 [s, C(*C*H$_3$)$_3$], 34.3 (s, CH_2), 53.7 [s, *C*(CH$_3$)$_3$], 118.9 (s, C=C). − ^{11}B{^{1}H} NMR (C_6D_6): δ = 22.7 (s). − MS/EI; *m*/*z*: 270 [M$^+$ in relation to ^{11}B and ^{35}Cl]. − $C_{14}H_{28}BClN_2$ (270.65): calcd. C 62.13, H 10.43, N 10.35; found C 62.02, H 10.56, N 10.31.

(tBu)N^a−CH=CH−N^b(tBu)BI(N^a−B) (**6a**): A slurry of 2.50 g (14.8 mmol) of 1,4-diazabutadiene **1a** in 100 ml of *n*-hexane was allowed to react with lithium sand (0.21 g, 29.6 mmol) for 7 d at 20°C. A solution of 5.83 g (14.9 mmol) of BI_3 in 50 ml of *n*-hexane was added dropwise to the chilled slurry (−20°C). Stirring for 2 h was followed by filtration. The filtrate was liberated from volatile components in vacuo to afford 3.78 g (83%) of **6a** as a colorless oil. At room temp. the pure compound decomposed completely within 5 d, whereas in the dark at −30°C a *n*-hexane solution of **6a** remained unaffected. − Due to decomposition a reliable IR spectrum was not available. − ^{1}H NMR (C_6D_6): δ = 1.45 (s, 18 H, *t*Bu), 6.40 (s, 2 H, CH). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 31.7 [s,

C(CH_3)$_3$], 54.2 [s, C(CH$_3$)$_3$], 114.6 (s, C=C). − ^{11}B{^{1}H} NMR (C_6D_6): δ = 6.5 (s). − MS /EI; *m/z*: 306 (27) [M$^+$], 250 (11) [M$^+$ − C_4H_8], 194 (100) [M$^+$ − 2 C_4H_8], 178 (3) [M$^+$ − I]. − $C_{10}H_{20}BIN_2$ (305.99): calcd. C 39.21, H 6.59, N 9.15; found C 39.35, H 6.48, N 8.99.

(2,6-Me$_2$C$_6$H$_3$)N^a−CH=CH−N^b(2,6-Me$_2$C$_6$H$_3$)BI(N^a−B) (**6b**): A mixture of CH_2Cl_2 (600 ml) and *n*-hexane (400 ml) was cooled to −10°C and two separate solutions of 6.00 g (22.7 mmol) of 1,4-diazabutadiene **1b** in CH_2Cl_2 (250 ml) and 8.89 g (22.7 mmol) of BI_3 in *n*-hexane (200 ml) were added dropwise. The reaction was filtered after warming up to room temp. and stirring for 5d. The filtrate was concentrated to dryness. The brown-black residue was extracted with 150 ml of *n*-hexane, and the red *n*-hexane solution was decanted from insoluble components. Storing the concentrated filtrate (ca 20 ml) at −4°C for 3 d afforded 2.43 g (26%) of colorless crystalline **6b**. The compound was purified by sublimation at 0.01 Torr and 380°C. − IR (KBr): ν = 1554 cm^{-1} w, 1551 w, 1475 vs, 1439 m, 1397 s, 1340 m, 1279 s, 1263 s, 1244 m, 1197 m, 1162 w, 1105 s, 1032 w, 908 s, 772 vs, 688 s, 621 s, 569 w, 530 w. − ^{1}H NMR (C_6D_6): δ = 2.16 (s, 6 H, CH_3), 5.99 (s, 2 H, HC=N), 6.98 (m, 6 H, arylH). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 18.3 (s, CH_3), 120.0 (s, HC=N), 126.2 (s, *p*-C-aryl), 135.7 (s, *o*-C-aryl), 140.7(s, *i*-C-aryl), − ^{11}B{^{1}H} NMR (C_6D_6): δ = 11.8 (s). − MS/EI; *m/z*: 402 (96) [M$^+$], 275 (100) [M$^+$ − I]. − $C_{18}H_{20}BIN_2$(402.08): calcd. C 53.72, H 5.01, I 31.56, N 6.97; found C 53.56, H 5.16, I 31.44, N 6.99.

(tBu)N^a−CH=CH−N^b(tBu)BCN(N^a−B) (**8a**). − *From Isocyanides:* A solution of **5a** (1.07 g, 5.00 mmol) in 50 ml of *n*-hexane was treated at room temp. with 0.43 g (5.0 mmol) of *tert*-butyl isocyanide. After 4 h of stirring it was filtered, and the volatile components removed from the filtrate in vacuo (0.01 Torr) to give crude **8a** as a colorless solid. Purification was achieved either by recrystallization from *n*-hexane or by sublimation at 0.03 Torr and 55°C, yield 0.61 g (60%). Similarly, 1.30 g (5.00 mmol) of (*t*Bu)N^a−CH=CH−N^b(*t*Bu)BBr(N^a−B) (**7a**) was converted into 0.66 g (64%) of **8a**. Starting from **6a** (1.53 g, 5.0 mmol) 0.41 g of **8a** (41%) was obtained analogously. The reaction of 0.78 g (3.0 mmol) of **7a** with 0.33 g (3.0 mmol) of cyclohexyl isocyanide in 50 ml of *n*-hexane at 20°C for 5 d also afforded **8a** (0.23 g, 38%).

From AgCN: A mixture of **5a** (0.43 g, 2.0 mmol) and silver cyanide (0.32 g, 2.4 mmol) was stirred in acetonitrile (50 ml) for 1 h at room temp. After concentration to dryness, the residue was extracted with *n*-hexane (3 × 50 ml) and the combined extracts were filtered. Repeated concentration to dryness gave analytically pure **8a** (0.35 g, 84%). The analogous reaction of **7a** (0.52 g, 2.0 mmol) with AgCN (0.32 g, 2.4 mmol) in 50 ml of CH_3CN for 20 min afforded 0.46 (89%) of **8a**. − IR (KBr): ν = 2207 cm^{-1} w [ν(C≡N)], 1501 w, 1467 m, 1405 s, 1368 s, 1344 m, 1295 m, 1261 m, 1234 s, 1207 m, 1147 s, 1100 w, 1032 w, 953 w, 824 s, 804 s, 694 s, 660 sh, 649 s, 500 m. − ^{1}H NMR (C_6D_6): δ = 1.29 (s, 18 H, *t*Bu), 6.14 (s, 2 H, CH). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 31.5 [s, C(CH_3)$_3$], 53.7 [s, C(CH$_3$)$_3$], 114.6 (s, C=C). − ^{11}B{^{1}H} NMR (C_6D_6): δ = 12.0 (s). − MS/EI; *m/z* (%): 205 (27) [M$^+$], 149 (10) [M$^+$ − C_4H_8], 93 (100) [M$^+$ − 2 C_4H_8]. − $C_{11}H_{20}BN_3$ (205.12): calcd. C 64.40, H 9.85, N 20.48; found C 63.72, H 9.45, N 19.45.

(2,6-Me$_2$C$_6$H$_3$)N^a−CH=CH−N^b(2,6-Me$_2$C$_6$H$_3$)BCN(N^a−B) (**8b**). − *From Isocyanides:* Equimolar amounts of **5b** (0.62 g, 2.0 mmol) and *tert*-butyl isocyanide (0.17 g, 2.0 mmol) were allowed to react in 40 ml of *n*-hexane for 8 h at room temp. The solution was filtered and the colorless filtrate was concentrated to dryness. The remaining yellow solid was sublimed at 0.001 Torr and ca. 400°C to give 0.42 g (70%) of **8b**. Similarly, a sample of 0.80 g (2.0 mmol) of **6b** was converted into 0.33 g of **8b** by treatment with 0.17 g (2.0 mmol) of *tert*-butyl isocyanide.

From AgCN: A mixture of **6b** (0.80 g, 2.0 mmol) and AgCN (0.32 g, 2.4 mmol) was stirred in 50 ml of CH_3CN for 2 d at room temp. Concentration to dryness, extraction with *n*-hexane, filtration and removal of volatile components from the filtrate yielded 0.47 g (79%) of **8b**. − IR (KBr): ν = 2218 cm^{-1} w [ν(C≡N)], 1949 w, 1868 w, 1791 w, 1647 w, 1594 w, 1541 w, 1479 s, 1441 m, 1399 m, 1368 w, 1282 m, 1207 m, 1109 m, 915 m, 775 s, 717 m, 658 m, 421 w. − ^{1}H NMR (C_6D_6): δ = 2.06 (s, 12 H, CH_3), 5.75 (s, 2 H, CH), 6.95 (m, 6 H, H-aryl). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 17.8 (s, CH_3), 119.4 (s, C=C), 128.6 (s, *p*C-aryl). − ^{11}B{^{1}H} NMR (C_6D_6): δ = 13.5 (s). − MS/EI; *m/z* (%): 301 (100) [M$^+$]. − $C_{19}H_{20}BN_3$ (301.18): calcd. C 75.70 , H 6.69, N 13.95; found C 75.30, H 7.25, N 13.61.

(tBu)N^a−CH=CH−N^b(tBu)BNCO(N^a−B) (**9a**): Analogously, the treatment of **5a** (0.43 g, 2.0 mmol) with AgOCN (0.53 g, 2.4 mmol) in 50 ml of CH_3CN for 30 min at 20°C afforded 0.35 g (78%) of **9a** as a colorless viscous oil. Complete decomposition of **9a** occurred within 2 d. Heterocycle **9a** was also prepared from **7a** and AgOCN in CH_3CN (50 ml) for 5 min (83% yield). − IR (CsI): ν = 2972 cm^{-1} s, 2317 vs [ν_{as}(NCO)], 1699 m, 1684 m, 1527 w, 1474 m, 1458 m, 1404 s, 1367 s, 1322 s, 1288 w, 1240 s, 1138 m, 1033 w, 1001 w, 822 w, 807 w, 632 m [ν_{sym}(NCO)], 596 w. − ^{1}H NMR (C_6D_6): δ = 1.21 (s, 18 H. *t*Bu), 6.04 (s, 2 H, =CH). − ^{11}B{^{1}H} NMR (C_6D_6): δ = 14.7 (s). − ^{13}C{^{1}H} NMR (C_6D_6): δ = 31.0 [s, C(CH_3)$_3$], 52.5 [s, C(CH$_3$)$_3$], 111.6 (s, =CH), 123.9 (s, br., N=C=O). − MS/EI (70 eV); *m/z* (%): 221 (20) [M$^+$]. − $C_{11}H_{20}BN_3O$ (221.12): calcd. C 59.74, H 9.13, N 18.99; found C 59.30, H 9.33, N 18.63.

(tBu)N^a−CH=CH−N^b(tBu)BNCS(N^a−B) (**10a**): Compound **10a** was prepared analogously from **5a** (0.43 g, 2.0 mmol) and AgSCN (0.40 g, 2.4 mmol) in CH_3CN (50 ml, 20°C, 1 h), yield: 0.42 g (74%). The corresponding reaction of **7a** and AgSCN took place within 10 min to give a 76% yield of **10a**. − IR (CsI): ν = 3133 cm^{-1} w, 2975 s, 2936 sh, 2910 sh, 2875 sh, 2122 vs, br. [ν_{as}(NCS)], 1475 m, 1406 s, 1375 s, 1291 m, 1241 s, 1205 m, 1141 s, 1029 w, 948 w, 871 s [ν_{sym}(NCS)], 822 w, 802 m, 683 w, 632 s. − ^{1}H NMR (C_6D_6): δ = 1.20 (s, 18 H, *t*Bu), 5.99 (s, 2 H, =CH); ($CDCl_3$): δ = 1.42 (s, 18 H, *t*Bu), 6.16 (s, 2 H, =CH). − ^{11}B{^{1}H} NMR (C_6D_6): δ 14.7 (s). − ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 31.1 [s, C(CH_3)$_3$], 53.0 [s, C(CH$_3$)$_3$], 111.8 (s, =CH), 140.5 (s, NCS), (C_6D_6): δ = 31.0 [s, C(CH$_3$)$_3$], 52.9 [s, C(CH$_3$)$_3$], 112.1 (s, =CH). − MS/EI (70 eV); *m/z* (%): 237 (70) [M$^+$], 125 (100) [M$^+$ − 2 *t*Bu]. − $C_{11}H_{20}BN_3S$ (237.17): calcd. C 55.71, H 8.50, N 17.72; found C 54.89, H 8.78, N 17.24.

(2,6-Me$_2$C$_6$H$_3$)N^a−CH=CH−N^b(2,6-Me$_2$C$_6$H$_3$)BNCS-(N^a−B) (**10b**): A sample of solid AgSCN (0.41 g, 3.0 mmol) was added to a slurry of **6b** (1.00 g, 2.5 mmol) in CH_3CN (40 ml) and stirred for 5 h at 20°C. The slurry was filtered, and the filtrate concentrated to dryness. The residue was extracted with *n*-hexane (3 × 50 ml) and the combined extracts were filtered. The volatile components were removed from the filtrate to give pure **10b** (0.77 g, 93%) as a waxy solid. Analogously, **5b** was converted into **10b** within 3 h in 78% yield. The corresponding bromide gave **10b** after 1 h in 87% yield. − IR (KBr): ν = 2918 cm^{-1} w, 2177 sh, 2114 vs [ν_{as}(NCS)], 2038 sh, 1516 w, 1479 s, 1441 s, 1402 s, 1390 s, 1303 w, 1285 m, 1201 w, 1111 s, 1032 w, 992 w, 909 m, 856 s [ν_{sym}(NCS)], 768 s, 702 w, 656 w, 643 s. − ^{1}H NMR (C_6D_6): δ = 2.10 (s, 12 H, CH_3), 5.71 (s, 2 H, =CHN), 6.97 (m, 6 H, aryl-H). − ^{11}B{^{1}H} NMR (C_6D_6): δ = 14.5 (s). −^{13}C{^{1}H} NMR (C_6D_6): δ = 17.9 (s, CH_3), 117.2 (s, =CHN), 127.3 (s, *p*-aryl-C), 128.6 (s, *m*-aryl-C), 135.2 (s, *o*-aryl-C), 139.2 (s, *i*-aryl-C). − MS/EI (70 eV); *m/z* (%):

333 (100) [M^+]. – $C_{19}H_{20}BN_3S$ (333.15): calcd. C 68.44, H 6.05, N 12.61; found C 68.38, H 6.30, N 12.38.

X-ray Structural Analysis of **6b**: Colorless single crystals from *n*-hexane; 0.42 × 0.37 × 0.32 mm; T = 293 K; Siemens P4 four-circle diffractometer; Mo-K_α (graphite monochromator, λ = 0.71073 A), empirical formula $C_{18}H_{20}BIN_2$, monoclinic space group $C2/c$; unit cell dimensions: a = 14.911(2), b = 7.9706(8), c = 16.9105(12) A; β = 114.360(6)°; V = 1830.9(3) A^3, $d_{calcd.}$ = 1.459 g cm^{-3}, Z = 4; μ(Mo-K_α) = 1.747 mm^{-1}; range for data collection: 5.3° ≤ 2Θ ≤ 60.1°; ω-scan, index ranges: $-20 \le h \le 0$, $-11 \le k \le 0$, $-21 \le l \le 23$; reflections collected 2769 (R_{int} = 0.017); independent reflections 2675; parameters 102; absorption correction: empirical φ-scans, min/max transmission 0.94/0.79 [R_{merg}(before/after) = 0.0333/0.0136]. Program used: Siemens SHELXTL Ver. 5.03. Structure solution: Direct Methods; structure refinement: Full-matrix least-squares on F^2, $R1$ = 0.042, $wR2$ = 0.1043 based on 1884 reflections with $I > 2\sigma(I)$, $wR2$ (all data) = 0.1189 with $w = 1/[\sigma^2(F_o^2) + (0.0484P)^2 + 3.11P]$, where $P = (F_o^2 + 2F_c^2)/3$; GOOF (F^2) = 1.029, maximum residual electron density 0.922 eA^{-3}, hydrogen atoms treated as riding groups with the 1.2-fold isotropic U value of the corresponding C atom and 1.5-fold for methyl groups.[26]

Keywords: "Constrained-geometry" Ziegler catalysts / Cp/amido zirconium complex / 6-Aminofulvene deprotonation / Ethene polymerization

6-Amino-6-methylfulvene (**4**) is cleanly *N*-acylated by treatment with pivaloylchloride/triethylamine to give the fulvene (C_5H_4)=C(CH_3)NHCOCMe_3 (**5c**). Treatment of **4** with trimethylchlorosilane similarly yields the mono-*N*-silylated fulvene (C_5H_4)=C(CH_3)NHSiMe_3 (**7**). Both **5c** and **7** are cleanly doubly deprotonated e.g. by treatment with LDA to give ligand systems $[(C_5H_4)C(=CH_2)NR]Li_2$ [**8a** (R = COCMe_3) and **8b** (R = SiMe_3), respectively]. Their treatment with $MCl_4 \cdot 2$ THF (M = Ti, Zr) yield the *spiro*-metallocenes $[(C_5H_4)C(=CH_2)NR]_2M$ (**9**, **10**). Complex **10a** (M = Zr, R = COCMe_3) was characterized by X-ray diffraction. The reaction of **8a** with $(Et_2N)_2ZrCl_2$ in THF gives rise to the formation of $[(C_5H_4)C(=CH_2)NCOCMe_3]Zr(NEt_2)_2$ (**11**) (70 % isolated), and the reaction of **8b** with $(Et_2N)_2ZrCl_2$ yields $[(C_5H_4)C(=CH_2)NSiMe_3]Zr(NEt_2)_2$ (**12**) (76 % isolated). Treatment of complex **12** with an excess of methylalumoxane (MAO) in toluene solution results in the generation of an active homogeneous Ziegler catalyst for the polymerization of ethene. A comparison with the usually employed $[(Me_5C_4)SiMe_2NCMe_3]ZrCl_2$/MAO "constrained-geometry" Ziegler catalyst system reveals a similar catalyst activity and performance of this novel type of a C_1-bridged "constrained-geometry" catalyst as it is exemplified by the $[(C_5H_4)C(=CH_2)NSiMe_3]ZrX_2$ (**12**)/MAO combination.

Introduction

Homogeneous Ziegler catalysts on the basis of group-4 bent metallocenes have become of enormous importance in metal-catalyzed α-olefin polymerization and related processes.[1] Variation of the ligand systems and the development of novel types of catalyst precursors have been of great interest recently in order to expand the scope of the application of this general type of very active and at the same time often extremely selective catalyst systems.[2] In this context the "constrained-geometry catalysts" have recently found a special attention. They are catalyst systems that are formally derived from the dimethylsilylene-bridged ansa-metallocenes in which one of the Cp units is replaced by an amido-nitrogen atom. The most frequently employed ligand system was introduced by J. E. Bercaw et al. at a group-3 metal complex.[3] It is comprized by a tetramethylcyclopentadienyl moiety that is connected with a *tert*-butylamido building block by means of a bridging Me_2Si group. The scandium complex **1a** (ML_n = Sc−Cl) is a typical early example. The corresponding titanium and zirconium complexes (**2b**, **c**) were prepared consecutively and used as Ziegler catalyst precursors. These systems have achieved a great interest with regard to the practical application of ligand-controlled Ziegler catalysts in α-olefin polymerization processes.[4]

The use of the silylene bridge for connecting the Cp and amido subunits has appeared to be essential for these organometallic systems for quite some time. The presence of the silylene group prevents the elimination reaction to the corresponding fulvene system and additional fragmentation reactions to occur at some intermediate stages of the synthesis, reaction alternatives that are very favourable and have been observed in previous attempts to prepare the corresponding C_1-bridged constrained-geometry Ziegler systems.[5] These facile alternative reactions have probably favoured the design of hydrocarbyl-bridged $Cp(CR_2)_n-NR'$ systems with longer bridging chains ($n > 1$).[6] Practically feasible synthetic pathways to C_1-bridged constrained Ziegler catalyst systems to the best of our knowledge appear not to have been reported on so far with one potential exception.[7] We have now developed a simple synthetic entry to such organometallic complexes of the group-4 metals and shown that homogeneous Ziegler catalysts can be derived from examples of such $[Cp-C_1(R)-NR']ML_n$ systems that

Scheme 1

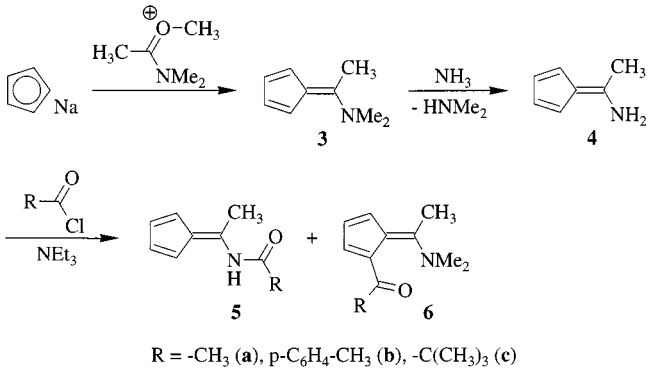
are of at least equal catalyst quality as compared to the commonly employed [Cp*−SiR_2−NR′]MCl_2 derived systems.

Results and Discussion

Starting material for our synthesis is 6-dimethylamino-6-methylfulvene (**3**), which is readily available by treatment of cyclopentadienide with *O*-methylated *N,N*-dimethylacetamide. As also described by K. Hafner et al.[8] **3** was treated with excess NH_3 to give 6-amino-6-methylfulvene (**4**). We have then acylated the aminofulvene system. Here the general problem arises that in **4** two positions are amenable to electrophilic attack, namely the amino group and the α-carbon center (C-2) at the five-membered carbocyclic ring.[9]

Scheme 2



Treatment of the aminofulvene **4** with acetyl chloride indeed furnished a mixture of the regioisomers **5a**, resulting from *N*-acylation, and **6a**, resulting from *C*-acylation at the fulvene α-carbon center C-2, respectively. The isomers **5a** (major) and **6a** (minor) were separated by column chromatography and isolated in ca. 70 and 5% yield, respectively. The spectral appearance of the two regioisomeric acetylation products is quite different. The four fulvene CH groups in the major product **5a** are just marginally differentiated [^{1}H NMR ($CDCl_3$): δ = 6.58−6.35 (m, 4 H); ^{13}C NMR: δ = 129.2, 128.3, 122.2, 116.8], whereas a clearly separated AMX system is characterized for the ^{1}H NMR fulvene section of **6a** (δ = 7.56, 7.27, 6.42; coupling constants: J_{HH} = 1.9, 3.2, 4.8 Hz). The situation is even less favourable for the aroylation of **4** with *p*-methylbenzoyl chloride. In this case a mixture of products was obtained from which the required *N*-aroylated product **5b** was isolated only in ca. 20% yield after chromatographic workup. In contrast, the acylation reaction with the bulky pivaloyl chloride reagent was very clean and selectively resulted in the formation of the *N*-pivaloylfulvene system **5c**, which was obtained in 80% yield as a yellow crystalline material after recrystallization from ether.

Single crystals were obtained from the three *N*-acylated fulvenes **5a−c** that allowed their characterization by X-ray crystal structure analyses. As a typical example, a view of the molecular structure of the *N*-acetylated fulvene **5a** is depicted in Figure 1. It can be seen from Table 1 that all three fulvenes exhibit the typical carbon−carbon bond length alternation in their frameworks and a transoidal connection of fulvene and carboxamide structural subunits with conformer **B** being favoured over **A** (see Scheme 3).

[a] Averaged absolute values of the three independent molecules in the unit cell of **5c**.

The fulvenes **5** are not monomeric in the crystal but connected by intermolecular hydrogen bonds, that link the carbonyl and NH functionalities of the amide groups,[10] to form oligomeric chain-type structures. In the resulting supra-structure the core atoms of the individual amide groups of **5a** and **5b** are oriented in a single plane, giving rise to elongated narrow sheet-like structures. The two-dimensional arrangement of the self-assembled associate of **5a** is depicted in Figure 1. It is probably due to the steric bulk of the *tert*-butyl substituent that a related but spatially different supra-structure is found for **5c**. Again a linear arrangement of fulv−NHCO−R units is found, with the individual carboxamide functionalities being connected via intermolecular N−H···O=C−NHR hydrogen bonds, only in this case are the individual −NH−CO− planes rotated substantially [angle between the planes O1−C8−N1/O2−C18−N2: 8.8(2)°; O1−C8−N1/O3−C28−N3: 54.5(2)°; O2−C18−N2/O3−C28−N3: 58.8(2)°]. A projection of the resulting three-dimensional arrangement is given in Figure 2.

Treatment of **4** with chlorotrimethylsilane in the presence of excess triethylamine results in the selective *N*-silylation

Figure 1. A view of the hydrogen-bonded associated structure of **5a** (**5b** exhibits a similar two-dimensional supramolecular core structure in the crystal)

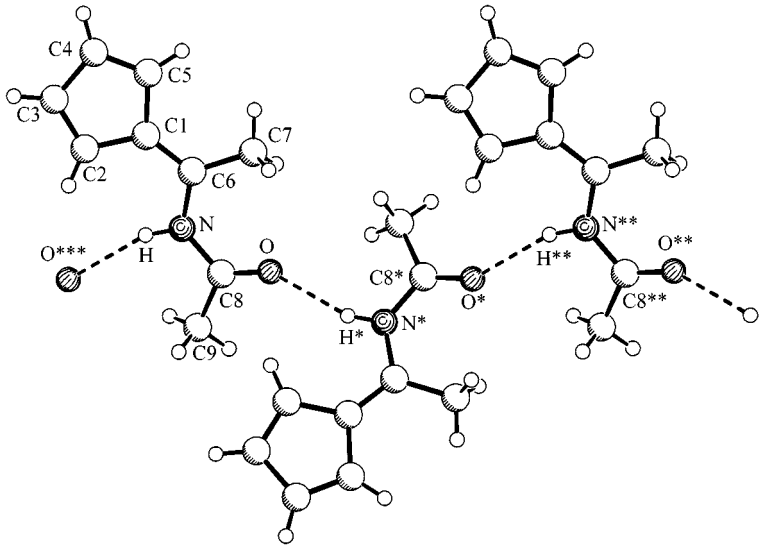

Figure 2. The three-dimensional assembled supramolecular solid-state structure of the *N*-pivaloylfulvene **5c**

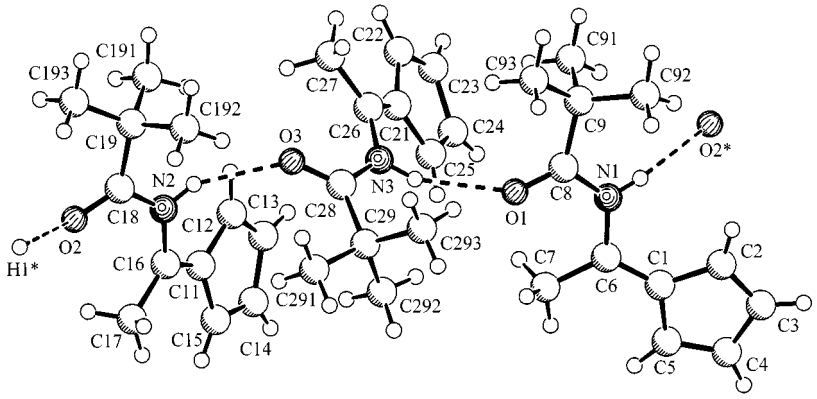

of the aminofulvene. Only mono-silylation is achieved under these conditions to give the product **7** which was isolated in near-to-quantitative yield. Compound **7** shows a very characteristic ^{13}C-NMR spectrum with the electrophilic fulvene carbon center C-6 (δ = 154.7) being spectroscopically clearly differentiated from the remaining sp^2-carbon atoms of the ring system (C-1: δ = 117.9; C2−C5: δ = 124.6, 122.1, 119.7, 112.3).

4 **7**

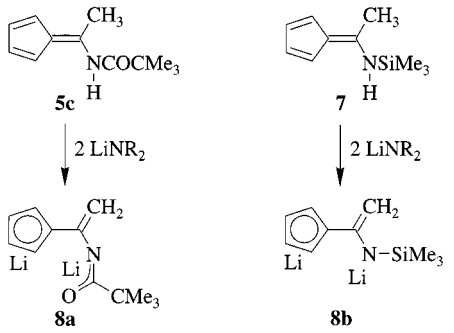
Our experiments had thus shown that 6-methyl-6-(pivaloylamino)fulvene (**5c**) and 6-methyl-6-(trimethylsilylamino)fulvene (**7**) among the investigated series of compounds were the easiest and most selective to be synthesized on a preparative scale,[11] and we consequently have decided to use these two compounds as the starting materials for the preparation of the anticipated Cp−C(R)$_n$−NR′ dianion-type ligands and the corresponding C$_1$-bridged constrained-geometry group-4 metal complex systems.

Principally, fulvene systems can be converted to cyclopentadienides by either the addition of a suitable nucleophile to the electrophilic C-6 carbon center[12] or by a deprotonation reaction at the alkyl carbon atom directly adjacent to the C-6 fulvene center.[13] For this study we have briefly tested the former procedure. We found out that a sufficiently soft nucleophile can be added to the C-6 carbon atom of the systems **5**. Thus the reaction of **5c** with two molar equivalents of lithium dimethylcuprate[14] eventually leads to the formation of the $[Cp-CMe_2-N(COCMe_3)]^{2-}$ ligand system that can be transmetallated with $Cl_2Zr(NEt_2)_2$. However, the resulting ansa-metallocene-like system was never obtained free of sizable amounts of as yet unidentified contaminants. For practical purposes it has thus turned out to be advantageous to rely on the second alternative methode and deprotonate the fulvenes at the C^6-CH_3 group (in addition to the kinetically rapid NH deprotonation) to generate the required C$_1$-bridged ligand system. This route has turned out to be very convenient and

successful. It can easily be applied to all the *N*-monosubstituted fulvene systems described above. The outcome of the reactions starting from **5c** and **7** will be described in the following as very typical examples.

Treatment of 6-methyl-6-(pivaloylamino)fulvene (**5c**) with two molar equivalents of methyllithium or even better with the less nucleophilic bases lithium hexamethyldisilazide or lithium diisopropylamide cleanly furnished the corresponding ligand system $[Cp-C(=CH_2)-N(COCMe_3)]^{2-}$ as the dilithio compound **8a** [$^1H/^{13}C$ NMR ([D_8]THF, 200.1 MHz): δ = 5.82, 5.89/118.2 (*ipso*-C), 106.3, 103.2 (C_5H_4); 4.47, 3.66 (^2J = 2.4 Hz)/155.4, 87.5 ($C=CH_2$), 1.08/179.3, 39.0, 29.5 ($COCMe_3$)]. Analogously, treatment of 6-methyl-6-(trimethylsilylamino)fulvene (**7**) with these bases gave the corresponding ligand system $[Cp-C(=CH_2)-NSiMe_3]^{2-}$ (obtained and isolated as the dilithio compound **8b**).

Scheme 5



The reaction of **8b** with zirconium tetrachloride results, under all reaction conditions tested by us, in a rapid substitution of all four halogen atoms[7b][15] to yield the organometallic *spiro*-metallocene complex **10b**. The product **10b** was isolated in close to 80% yield. It shows typical $^1H/^{13}C$-NMR spectra {in [D_6]benzene: C_5H_4 resonances at δ = 6.36, 6.00, 5.41, 5.36/118.4 (*ipso*-C), 116.3, 114.4, 112.6, 109.1; ($C=CH_2$): δ = 4.22, 4.18/144.7, 88.7; $SiMe_3$: δ = 0.24/1.75}. The analogous reaction of the dilithio ligand system **8b** with $TiCl_4$ gives the corresponding *spiro*-titanocenebisamido complex **9b** (isolated in 81% yield). Treatment of the *N*-acylated ligand system employed as the dilithiated reagent **8a** with $TiCl_4$ or $ZrCl_4$ proceeds quite analogously. In these cases the corresponding chiral *spiro*-metallocene complexes **9a** (M = Ti, 58% yield) and **10a** (M = Zr, isolated in 74% yield) were obtained (see Scheme 6).

The *spiro*-metallocene complex **10a** was characterized by an X-ray crystal structure analysis. Single crystals of **10a** suitable for X-ray diffraction were obtained by crystallization from pentane/toluene. The central zirconium atom in complex **10a** is coordinated to two cyclopentadienyl units and the acylamido groups of the pair of near-to-symmetry-equivalent $[Cp-C(=CH_2)-NC(CMe_3)O]$ ligand systems in an overall pseudotetrahedral coordination geometry [D1−Zr1−D2 = 131.0° (D1 and D2 denote the centroids of the Cp ring systems), O14−Zr1−O34 = 99.95(13)°]. Complex **10a** is chiral; in the crystal it is chemically, but not strictly crystallographically, to be regarded as C_2-symmetric (see Figure 3).

The C6=C7 double bond of **10a** [1.332(6) Å; accordingly C26−C27: 1.341(6) Å] is oriented approximately coplanar with the adjacent cyclopentadienyl ring system. The dihedral angle θ C4−C5−C6−C7 amounts to −31.9(7)°; the corresponding value of θ C21−C25−C26−C27 is −29.4(7)°. The adjacent nitrogen atom N8 is also oriented in this substituent plane [dihedral angles θ C1−C5−C6−N8 −19.2(6)°, and correspondingly C24−C25−C26−N28 −15.6(6)°]. The N8−C9 bond is short [1.278(5) Å; N28−C29 1.289(5) Å] and must be regarded as an N=C double bond. Consequently, the C9−O14 linkage is elongated [1.338(5) Å; C29−O34 1.334(5) Å]. Apparently the ambidentate *N*-acylamido functional group is present as the imino tautomer in complex **10a**. Coordination of this group to the group-4 metal takes place exclusively by means of the oxygen atom [O14−Zr1 2.026(2) Å; O34−Zr1 2.038(3) Å] and not through the nitrogen center [the N8···Zr1 separation is 3.682(4) Å; N28···Zr1 3.666(4) Å]. Consequently, the individual ligand systems in **10a** are not planar but the two sections used for coordinating to the transition-metal center are segregated by a strong rotation about the C6−N8 vector [dihedral angles θ C5−C6−N8−C9 −52.1(5)°, C25−C26−N28−C29 −52.9(5)°, C7−C6−N8−C9 130.5(5)°, C27−C26−N28−C29 129.6(4)°, C6−N8−C9−O14 −5.4(6)°, C26−N28−C29−O34 −6.6(6)°] to allow for the thermodynamically favourable coordination of the ligand system to the zirconium center through the carboxamido oxygen atom. The bond angles at these oxygen atoms are substantially enlarged at 136.5(3)° (C9−O14−Zr1) and 136.0(2)° (C29−O34−Zr1), respectively. This probably indicates a tendency to form a stabilizing Zr−O π interaction, similar as it has been observed in a variety of Zr−O linkages in metallacyclic systems of ring sizes of 6 and larger.[16] The remaining angles inside the metallacyclic framework of **10a** are in a normal and expected range [C6−N8−C9 117.9(4)°, C26−N28−C29 118.3(3)°, N8−C9−O14 125.2(4)°, N28−C29−O34 124.8(4)°].

We have then treated the dilithio compound **8a** with the dichlorobis(diethylamido)zirconium reagent, employed as its bis(tetrahydrofuran) adduct.[17] This results in a clean reaction that takes place by a selective displacement of the two chloride ligands by the $[Cp-C(=CH_2)-N(CMe_3)O]^{2-}$ ligand system. The $Zr(NEt_2)_2$ moiety is retained during this transformation.[18] The resulting zirconium complex **11** was obtained in 70% yield. The spectroscopic data of the newly introduced $[Cp-C=CH_2)-N(CMe_3)O]$ ligand in **11** are quite similar as previously observed for the *spiro* complexes **9a** and **10a** {**11**: $^1H/^{13}C$ NMR in [D_8]THF: δ = 6.60, 5.95/111.3, 110.5 (C_5H_4), 4.77, 4.72 ($^2J_{HH}$ = 1.8 Hz)/147.6, 102.4 ($C=CH_2$), 171.4 (NCO)}. Therefore, we assume that the $[Cp-C(=CH_2)N(CMe_3)O]$ ligand system in **11** is coordinated by means of the Cp ring and the carboxamido oxygen, and not the nitrogen center, just analogously as it was previously observed for the *spiro*-metal complexes **9a** and **10a** (see above).

Scheme 6

[a] Selected bond lengths [A] and angles [°]: Zr1−O14 2.026(2), Zr1−O34 2.038(3), Zr1−N8 3.682(4), Zr1−N28 3.666(4), Zr1−C_{Cp} 2.511(5), C5−C6 1.474(6), C25−C26 1.466(6), C6−C7 1.332(6), C26−C27 1.341(6), C6−N8 1.418(5), C26−N28 1.414(5), N8−C9 1.278(5), N28−C29 1.289(5), C9−O14 1.338(5), C29−O34 1.334(5), C9−C10 1.523(6), C29−C30 1.524(6); O14−Zr1−O34 99.95(13), Zr1−O14−C9 136.5(3), Zr1−O34−C29 136.0(2), C5−C6−C7 122.2(4), C25−C26−C27 123.5(4), C5−C6−N8 116.5(4), C25−C26−N28 116.0(3), C7−C6−N8 121.3(4), C27−C26−N28 120.5(4), N8−C9−O14 125.2(4), N28−C29−O34 124.8(4), N8−C9−C10 120.8(4), N28−C29−C30 120.0(4), O14−C9−C10 113.9(4), O34−C29−C30 115.2(3); see text for additional values.

As expected, the $[Cp-C(=CH_2)-NSiMe_3]^{2-}$ ligand, employed as the respective dilithio reagent **8b**, reacts analogously with the $(Et_2N)_2ZrCl_2(THF)_2$ reagent very cleanly and in good yield to give the C_1-bridged constrained-geometry metal-complex system $[Cp-C(=CH_2)-NSiMe_3]Zr(NEt_2)_2$ (**12**). Exclusive metathetical exchange of the chloride ligands takes place, and the C_1-bridged Cp/amido-zirconium complex **12** was isolated in 76% yield. It shows very typical $^1H/^{13}C$-NMR spectra {in [D_6]benzene: δ = 6.03, 5.92/112.2 (*ipso*-C), 115.4, 111.3 (C_5H_4), 4.36, 4.34/150.9, 87.9 ($C=CH_2$), 0.39/0.8 ($SiMe_3$), 3.13, 0.90/43.2, 15.6 (NEt_2)}.

We have employed the $[Cp-C(=CH_2)-NSiMe_3]Zr(NEt_2)_2$ complex **12** as a starting material for generating a homogeneous Ziegler catalyst system and used it for carrying out a small series of preliminary ethene polymerization experiments. These few and as yet unoptimized polymerization reactions have revealed that the Ziegler catalysts, based on the C_1-bridged constrained-geometry framework, are at least comparable in activity and performance to the commonly used and studied Si_1-bridged "parent" system. This lets us hope that future variations of our here described $[Cp-C(R^*)NR']MX_2$ complexes will indeed lead to an even better catalyst performance and open ways to novel and advanced catalytic applications.

For the series of catalytic experiments carried out in the course of this study we have activated the zirconium complex **12** by treatment with a large excess of methylalumoxane (employed as a standard toluene solution).[19] In a typical experiment a solution of 19.4 mg (47.0 μmol) of **12** was activated by treatment with 10 ml of a 10% solution of methylalumoxane in toluene (Al/Zr = 340) at ambient temperature under an initial ethene pressure of 37 bar. After a short induction period a rapid temperature increase took place (up to 87°C) and the pressure dropped due to rapid consumption of the monomer. Ethene pressure was reestablished and the monomer constantly fed into the reactor for a time period of ca. 10 min. The reaction was stopped by ceasing the monomer fed. Opening of the reactor revealed that the interior of the reaction vessel was almost filled with an amorphous lump of polymer. Workup, as described in the Experimental Section, gave 16.6 g of polyethylene (mp 129°C, DSC), which corresponds to an overall catalyst activity of ca. 57 g polymer/mmol [Zr]·bar·h under these unoptimized non-isothermal conditions. A number of similar experiments, which gave comparable results, are listed in the Experimental Section.

For a direct comparison we have carried out a few ethene polymerization experiments under analogous reaction conditions using the Si_1-bridged "Bercaw/Exxon/Dow" system $[Me_4C_5-SiMe_2-NCMe_3]ZrCl_2$ (**1c**, see Scheme 1)[4] as the Ziegler catalyst precursor. In a typical experiment under very similar conditions as described above a sample of **1c**

(8.6 mg, 20.9 μmol) was activated by treatment with methylalumoxane (Al/Zr = 1530) in toluene under ethene (40 bar) in an autoclave. Rapid polymerization set in at once; the contents of the autoclave increased its temperature up to 103°C. A yield of 14.4 g of polyethylene was obtained under these conditions (mp 135°C, by DSC), corresponding to an overall catalyst activity of ca. 52 g polymer/mmol [Zr]·h·bar under these non-isothermal conditions.

We have also carried out the ethene polymerization reaction in a thermostated glass autoclave employing the **12**/methylalumoxane system in toluene (Al/Zr = 700) at 25°C and a constant pressure of 2.2 bar and obtained polyethylene (mp 137°C) with a slightly lower activity of a = 23 g polymer/mmol [Zr]·h·bar.

Conclusions

We had recently shown that the C_1-bridged fluorenyl/amido system $[Flu-CH_2-NCMe_3]^{2-}$ (generated and studied as the corresponding lithiated compound) is kinetically and thermodynamically rather stable, but, of course, difficult to handle because of its high basicity.[5] Much more problematic seems to be a prediction of the chemistry of related systems on the mono-anionic stage. For the examples $[Flu(H)-CH_2-NCMe_3]^-$/$[Flu-CH_2-NHCMe_3]^-$ (Flu = fluorenylidene) we had in a detailed study been able to characterize a number of readily available competing reaction pathways, involving e.g. fulvene formation and fragmentation pathways.[5] It appears, that similar multiple reaction pathways are getting involved when such dianions are treated with early transition-metal reagents that, due to the highly covalent character of e.g. the N−Zr or C−Zr bonds, can lead to very reactive intermediates, that then are prone to enter into the manifold of the competing pathways that are so typical for the respective $[Cp-CR_2-NR']^-$ mono-anion systems. This effect does not generally preclude the successful synthesis of such $[Cp-CR_2-NR']MX_2$-type systems,[7] but will in very many cases lead to complicated organometallic mixtures of products and will make the handling of such systems probably rather difficult. This is very likely to be the reason why reports on such C_1-bridged constrained-geometry systems are extremely sparse, in contrast to their Si_1- or their elongated C_n-bridged analogues.[3][4][6][7] The system developed by us and described with some first examples in this article seems to provide a useful and generally easily accessible alternative. Introduction of the sp^2-carbon center in the system adjacent to the Cp-ring as a bridging atom between the C_5H_4 and N−R′ moieties appears very effectively to make all the usually encountered reactive alternatives and diversions on the intermediate stages of the overall reaction sequence to the final group-4 metal complexes sufficiently unfavourable to allow for a straightforward and easily performed synthesis of the respective $[Cp-C(=CH_2)-NR]ML_n$-type systems. Our preliminary ethene polymerization experiments have shown that the first examples of the thus derived C_1-bridged constrained-geometry Ziegler catalysts are at least equally effective, very active polymerization catalysts as the commonly employed $[Cp^*-SiMe_2-NCMe_3]ZrCl_2$ system.

Our entry into the novel class of the $[Cp-C(=CH_2)-NR']ZrX_2$-type catalyst precursors should allow for the synthesis of a large number of easily accessible variations of such systems. We are confident that this will lead to a significant extension and further development of the scope of application of such interesting catalyst types in polymerization reactions and in organic synthesis.[20] The further development of the C_1-bridged "constrained-geometry catalysts" is, therefore, actively pursued in our laboratory.

Financial support from the *Fonds der Chemischen Industrie*, the *Bundesminister für Bildung, Wissenschaft, Forschung und Technologie (BMBF),* and the *Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen* is gratefully acknowledged.

Experimental Section

General Information: All reactions with organometallic reagents or substrates were carried out under argon using Schlenk-type glassware or in a glove-box. Solvents (including deuterated solvents used for NMR spectroscopy) were dried and distilled under argon prior to use. − The following instruments were used for spectroscopic and physical characterization of the compounds: Bruker AC 200P (^{1}H: 200.13, ^{13}C: 50.3 MHz), Bruker ARX 300, and Varian Unity Plus (^{1}H: 599.2, ^{13}C: 150.8 MHz) NMR spectrometers (spectral assignments were usually secured by GCOSY, GHSQC and GHMBC experiments[21]); Nicolet 5 DXC FT-IR spectrometer; melting points: DSC 2910 (Thermo Analysis/DuPont); elemental analyses: Foss-Heraeus CHN-Rapid; X-ray crystal structure analyses: Enraf-Nonius CAD4 and MACH3 diffractometers (programs used: data reduction MolEN, structure solution SHELXS-86, structure refinement SHELXL-93, graphics SCHAKAL-92). − The reagent $(Et_2N)_2ZrCl_2(THF)_2$ was prepared according to a literature procedure.[17] The aminofulvenes were synthesized by variations of the procedures previously described by K. Hafner et al.[8]

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101213. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [fax: int. code + 44(1223)336-033, e-mail: deposit@ccdc.cam.ac.uk].

6-Dimethylamino-6-methylfulvene (**3**): Dimethyl sulfate (49 ml, 62 g, 0.49 mol) was added dropwise with gentle heating in such a way to 49 ml (43 g, 0.49 mol) of freshly distilled *N,N*-dimethylacetamide that the temperature was maintained at 50−60°C. Then the solution was kept at 70−80°C for 2 h. The viscous oil was added with stirring to a solution of 44 g (0.50 mol) of sodium cyclopentadienide in 300 ml of tetrahydrofuran with external cooling at a rate that the reaction temperature was kept between −5 and −10°C. The precipitated sodium methyl sulfate was filtered off and the solvent removed from the filtrate in vacuo. The dark brown oil was treated with 2 g of active charcoal in 400 ml of hot cyclohexane and filtered. The product **3** crystallizes upon cooling. The mother liquor was concentrated and treated again with charcoal to give a combined yield of 59.5 g (88%) of **3**, mp 90°C. − $C_9H_{13}N$ (135.2): calcd. C 79.95, H 9.69, N 10.36; found C 79.81, H 9.90, N 10.18. − ^{1}H NMR (200.1 MHz, [D$_1$]chloroform): δ = 6.83−6.44 (m, 4 H, C_5H_4), 3.48 (s, 6 H, NCH_3), 2.62 (s, 3 H, 6-CH_3). − ^{13}C NMR (50.3 MHz, [D$_1$]chloroform): δ = 158.5 (C-6), 121.4, 120.1, 118.5, 116.5 (Cp, C-2−5), 117.3 (C-1), 43.4 (NCH_3), 20.5 (6-CH_3).

6-Amino-6-methylfulvene (**4**): A 300-ml autoclave, containing an internal glass vessel, was charged with 59.7 g (400 mmol) of **3** and ca. 150 ml condensed NH_3 at −78°C. The closed system was left for 7 d at 40°C (at 10 bar pressure). The system was then cooled (< −33°C) and the autoclave opened. NH_3 was allowed to evaporate and the yellow product dried in vacuo to give 41.6 g (97%) of **4**, mp. 85°C. − C_7H_9N (107.1): calcd. C 78.46, H 8.47, N 13.07; found C 78.33, H 8.72, N 12.68. − ^{1}H NMR (200.1 MHz, [D$_1$]chloroform): δ = 6.56−6.27 (m, 4 H, C_5H_4), 5.13 (br., 2 H, NH_2), 2.31 (s, 3 H, 6-CH_3). − ^{13}C NMR (50.3 MHz, [D$_1$]chloroform): δ = 154.7 (C-6), 117.9 (C-1), 124.6, 122.1, 119.7, 112.3 (Cp, C-2−5), 19.5 (6-CH_3).

6-Acetylamino-6-methylfulvene (**5a**) *and 2-Acetyl-6-amino-6-methylfulvene* (**6a**): A solution of acetyl chloride (314 mg, 4.03 mmol) in 15 ml of ether was added dropwise to a solution of 599 mg (4.00 mmol) of the fulvene **4** in 30 ml of ether containing 3 ml of triethylamine at 0°C. The mixture was stirred overnight and was then concentrated to one half of its volume in vacuo. Triethylammonium chloride was removed by filtration. The product was precipitated by cooling to −20°C. The resulting crude product was purified by column chromatography (silica gel, 60 mesh, diethyl ether/triethylamine, 50:1). Compound **6a** (30 mg, 5% yield) was recovered from the first eluate, compound **5a** (406 mg, 68%) was collected from the third fraction. **5a**: mp 119°C (DSC). − $C_9H_{11}NO$ (149.2): calcd. C 72.46, H 7.43, N 9.39; found C 70.98, H 7.38, N 8.75. − ^{1}H NMR (200.1 MHz, [D$_1$]chloroform): δ = 7.78 (br., NH), 6.58−6.35 (m, 4 H, C_5H_4), 2.68 (s, 3H), 2.17 (s, 3 H, COCH_3). − ^{13}C NMR (50.3 MHz, [D$_8$]tetrahydrofuran): δ = 169.5 (C=O), 146.8 (C-6), 129.4 (C-1), 129.0, 128.3, 122.2, 116.8 (Cp, C-2−5), 24.3 (COCH_3), 19.2 (C-7).

X-ray Crystal Structure Analysis of **5a**: Formula $C_9H_{11}NO$, M = 149.19, 0.25 × 0.20 × 0.10 mm, a = 7.265(2), b = 11.576(3), c = 9.729(1) A, β = 104.84(2)°, V = 790.9(3) A^3, $\rho_{calcd.}$ = 1.253 g cm^{-3}, μ = 0.82 cm^{-1}, no absorption correction, Z = 4, monoclinic, space group $P2_1/c$ (No. 14), λ = 0.71073 A, T = 223 K, ω/2θ scans, 1721 reflections collected (−h, +k, ±l), [(sinθ)/λ] = 0.62 A^{-1}, 1596 independent and 733 observed reflections [$I \geq 2\ \sigma(I)$], 105 refined parameters, R = 0.063, wR^2 = 0.158, max. residual electron density 0.28 (−0.33) e A^{-3}, hydrogen atom at N from difference Fourier, others calculated and all refined as riding atoms.

6a: ^{1}H NMR (200.1 MHz, [D$_1$]chloroform): δ = 14.6 (br., 2 H, NH), 7.56 (1 H), 7.27 (1 H), and 6.42 (1 H, ABX, C_5H_3, J_{HH} = 1.9, 3.2, and 4.8 Hz), 2.87, 2.56 (s, each 3 H, CH_3).

6-Methyl-6-[(p-methylbenzoyl)amino]fulvene (**5b**): Triethylamine (7 ml) was added to a solution of 4.14 g (38.7 mmol) of the aminofulvene **4** in 150 ml of ether. *p*-Methylbenzoyl chloride (5.40 ml, 41.0 mmol) was very slowly added by syringe to the vigorously stirred solution at 0°C. After 24 h, the mixture was concentrated to half its volume in vacuo and the precipitated triethylammonium chloride removed by filtration. The remaining solvent was then removed in vacuo. The resulting crude product (5.6 g, ca. 60%) was purified by column chromatography at a deactivated (by treatment with 5% triethylamine in pentane/ether, 8:1) silica gel column (60 mesh). Elution with pentane/ether (8:1) gave the product **5b** as the third fraction, yield 1.8 g (21%). Single crystals suited for the X-ray crystal structure analysis were obtained from ether at 0°C; mp 104°C (DSC). − $C_{15}H_{15}NO$ (225.3): calcd. C 79.97, H 6.71, N 6.22; found C 78.62, H 7.05, N 6.10. − ^{1}H NMR (200.1 MHz, [D$_8$]tetrahydrofuran): δ = 9.32 (br., 1 H, NH), 7.83 (m, 2 H), 7.29 (m, 2 H, *o*,*m*-Ph), 6.66−6.54 (m, 2 H), 6.32−6.28 (m, 2 H, C_5H_4), 2.73 (s, 3 H, 6-CH_3), 2.40 (s, 3 H, Ph-CH_3). − ^{13}C NMR (150.8 MHz, [D$_1$]chloroform): δ = 165.1 (C=O), 145.9 (C-6), 143.4 (*p*-C, Ph), 131.3 (*ipso*-C, Ph), 130.2 (C-5), 129.7 (*m*-C, Ph), 128.9 (C-1), 128.7 (C-3), 127.1 (*o*-C, Ph), 121.8 (C-2), 113.9 (C-4), 21.5 (Ph-CH_3), 18.6 (6-CH_3). − IR (KBr): ν = 3335, 1662, 1622 cm^{-1}.

X-ray Crystal Structure Analysis of **5b**: Formula $C_{15}H_{15}NO$, M = 225.28, 0.50 × 0.30 × 0.10 mm, a = 7.169(1), b = 24.276(2), c = 7.289(1) A, β = 97.99(1)°, V = 1256.2(3) A^3, $\rho_{calcd.}$ = 1.191 g cm^{-3}, μ = 5.84 cm^{-1}, no absorption correction, Z = 4, monoclinic, space group $P2_1/n$ (No. 14), λ = 1.54178 A, T = 223 K, ω/2θ scans, 2743 reflections collected (±h, −k, +l), [(sinθ)/λ] = 0.62 A^{-1}, 2547 independent and 1673 observed reflections [$I \geq 2\ \sigma(I)$], 160 refined parameters, R = 0.056, wR^2 = 0.146, max. residual electron density 0.20 (−0.20) e A^{-3}, hydrogen atom at N from difference Fourier, others calculated and all refined as riding atoms.

6-Methyl-6-(pivaloylamino)fulvene (**5c**): Pivaloyl chloride (5.60 g, 46.7 mmol) was added at 0°C to a solution of 5.00 g (46.7 mmol) of **4** and 3 ml of triethylamine in 30 ml of tetrahydrofuran. After warming and stirring overnight at room temperature, the emulsion was filtered. The solvent was removed in vacuo. The residue was taken up in ether, filtered and the product crystallized from the clear ethereal solution at −30°C. Some of the thus obtained crystals were suitable for X-ray diffraction. Yield of **5c**: 7.14 g (80%), mp 82°C (DSC). − $C_{12}H_{17}NO$ (191.3): calcd. C 75.35, H 8.96, N 7.32; found C 75.14, H 9.08, N 7.25. − ^{1}H NMR (200.1 MHz, [D$_1$]chloroform): δ = 8.17 (br., 1 H, NH), 6.60−6.34 (m, 4 H, C_5H_4), 2.70 (s, 3 H, 6-CH_3), 1.29 [s, 9 H, C(CH_3)$_3$]. − ^{13}C NMR (50.3 MHz, [D$_1$]chloroform): δ = 176.5 (C=O), 146.3 (C-6), 128.3 (C-1), 130.1, 128.5, 121.8, 113.6 (Cp, C-2−5), 40.4 [C(CH$_3$)$_3$], 27.4 [C(CH_3)$_3$], 18.6 (6-CH_3). − IR (KBr): ν = 3342, 1683, 1620 cm^{-1}. − HRMS (70eV); $C_{12}H_{17}NO$: calcd. 191.13101; found 191.13054; *m*/*z* (%): 191 [M$^+$] (38), 134 [M$^+$ − C_4H_9] (10), 107 [M$^+$ − COC_4H_8] (9), 57 [$C_4H_9^+$] (100).

X-ray Crystal Structure Analysis of **5c**: Formula $C_{12}H_{17}NO$, M = 191.27, 0.60 × 0.30 × 0.10 mm, a = 14.076(1), b = 8.474(1), c = 28.982(3) A, β = 91.16(1)°, V = 3456.3(6) A^3, $\rho_{calcd.}$ = 1.103 g cm^{-3}, μ = 5.44 cm^{-1}, empirical absorption correction with ψ scan data (0.945 ≤ C ≤ 0.999), Z = 12, monoclinic, space group $P2_1/c$ (No. 14), λ = 1.54178 A, T = 223 K, ω/2θ scans, 7207 reflections collected (±h, +k, −l), [(sinθ)/λ] = 0.62 A^{-1}, 7057 independent and 5847 observed reflections [$I \geq 2\ \sigma(I)$], 401 refined parameters, R = 0.040, wR^2 = 0.116, max. residual electron density 0.21 (−0.15) e A^{-3}, hydrogen atom at N from difference Fourier, others calculated and all refined as riding atoms.

6-Methyl-6-[(trimethylsilyl)amino]fulvene (**7**): To a cold solution (0°C) of 702 mg (6.55 mmol) of the aminofulvene **4** in 100 ml of ether, containing three molar equivalents of triethylamine (2.0 g) was slowly added with stirring 1.5 molar equivalents (1.25 ml, 1.07 g, 9.83 mmol) of chlorotrimethylsilane. After 8 h at ambient temperature, the mixture was filtered and the solvent removed in vacuo to give the product **7** as a viscous oil. Yield of **7**: 1.15 g (98%), mp 12°C (DSC). − $C_{10}H_{17}NSi$ (179.3): calcd. C 66.97, H 9.55, N 7.81; found C 66.83, H 9.50, N 8.03. − ^{1}H NMR (200.1 MHz, [D$_1$]chloroform): δ = 6.57−6.28 (m, 4 H, C_5H_4), 5.4 (br., 1 H, NH), 2.39 (s, 3 H, 6-CH_3), 0.35 (s, 9 H, SiCH_3). − ^{13}C NMR (50.3 MHz, [D$_1$]chloroform): δ = 158.8 (C-6), 125.0, 122.4, 119.5, 111.9 (C-2−5), 122.1 (C-1), 19.3 (6-CH_3), 0.8 [Si(CH$_3$)$_3$]. − IR (NaCl): ν = 3353, 1616 cm^{-1}. − MS (70eV); *m*/*z* (%): 179 [M$^+$] (84), 164 [M$^+$ − CH_3] (100), 73 [$SiMe_3^+$] (71).

Lithium [1-(Lithio-N-pivaloylamido)ethenyl]cyclopentadienide (**8a**): A solution of the fulvene **5c** (380 mg, 1.99 mmol) in 30 ml of ether was treated at −20°C with two molar equivalents of lithium hexamethyldisilazide (675 mg, 4.04 mmol), dissolved in 20 ml of ether. The mixture was warmed to room temperature and stirred

for 4 h. The resulting precipitate of **8a** was collected by filtration, washed with ether (10 ml), then with pentane (20 ml), and dried in vacuo to give 363 mg (81%) of **8a** (· 0.3 Et_2O). – ^1H NMR (200.1 MHz, [D_8]tetrahydrofuran): δ = 5.82 (m, 2 H), 5.69 (m, 2 H, Cp), 4.47 (1 H), and 3.66 (1 H, AB system, $^2J_{HH}$ = 2.3 Hz, C=CH_2), 1.08 [s, 9 H, C(CH_3)$_3$]. – ^{13}C NMR (50.3 MHz, [D_8]tetrahydrofuran): δ = 179.3 (C=O), 155.4 (*C*=CH_2), 118.2 (*ipso*-C, Cp), 106.3, 103.2 (Cp), 87.5 (C=*C*H_2), 39.0 [*C*(CH_3)$_3$], 29.5 [C(*C*H_3)$_3$].

Lithium [1-(Lithio-N-trimethylsilylamido)ethenyl]cyclopentadienide (**8b**): A solution of lithium diisopropylamide (LDA, 2.1 g, 20 mmol) in 5 ml of tetrahydrofuran was added to a solution of 1.81 g (10 mmol) of the fulvene **7** in 30 ml of ether at 0°C. The mixture was stirred for 20 h at ambient temperature, then the solvent was removed in vacuo. The residue was suspended in pentane and the solid product collected by filtration, washed with pentane and dried in vacuo to yield 3.10 g (89%) of **8b** (· 1.5 THF). – ^1H NMR (200.1 MHz, [D_8]tetrahydrofuran): δ = 5.81 (m, 2 H) and 5.66 (m, 2 H, Cp), 3.61 (1 H) and 3.17 (1 H, AB system, $^2J_{HH}$ = 2.6 Hz, C=CH_2), −0.01 [s, 9 H, Si-CH_3)$_3$]. – ^{13}C NMR (50.3 MHz, [D_8]tetrahydrofuran): δ = 130.0 (*C*=CH_2), 119.1 (*ipso*-C of Cp), 104.5, 101.3 (Cp), 73.3 (C=*C*H_2), 2.4 [Si(*C*H_3)$_3$].

Reaction of **8a** *with Titanium Tetrachloride, Preparation of Bis{η⁵:κ-O-[1-(pivaloylamido)ethenyl]cyclopentadienyl}titanium* (**9a**): A suspension of the dilithium compound **8a**, generated by treatment of 191 mg (1.00 mmol) of the fulvene **5c** with 220 mg (2.06 mmol) of LDA in 50 ml of THF at −20°C (24 h), was slowly added at −20°C to a solution of 167 mg (502 μmol) $TiCl_4$ · 2 THF in 50 ml of THF. The dark red mixture was warmed to room temperature and then stirred for 3 h. The solvent was removed in vacuo and the residue extracted with 80 ml of pentane. Removal of the solvent in vacuo gave the product **9a** as a red, microcrystalline solid, yield 124 mg (58%), mp 123°C (DSC, decomp.), that was characterized spectroscopically. – ^1H NMR ([D_2]dichloromethane): δ = 6.21, 6.12, 6.07, 5.82 (m, each 2 H, Cp), 5.32, 4.89 (d, ^2J = 0.96 Hz, each 1 H, C=CH_2), 1.13 [s, 18 H, C(CH_3)$_3$]. – ^{13}C NMR (CD_2Cl_2): δ = 176.9 (N*C*O), 146.0 (*C*=CH_2), 124.5 (*ipso*-C, Cp), 126.3, 117.3, 109.9, 107.3 (Cp), 105.3 (C=*C*H_2), 39.1, 28.6 [C(CH_3)$_3$]. – IR (KBr): ν = 1619, 1566, 1557 cm^{-1}.

Preparation of Bis(η⁵:κ-N-{1-[(trimethylsilyl)amido]ethenyl}-cyclopentadienyl)titanium (**9b**): Analogously as described above, treatment of 688 mg (3.84 mmol) of the fulvene **7** with 822 mg (7.68 mmol) of LDA followed by reaction with 641 mg (1.92 mmol) of $TiCl_4$ · 2 THF gave **9b**, yield 626 mg (81%), mp 135°C (DSC, decomp.). – ^1H NMR ([D_6]benzene): δ = 6.55, 6.91, 5.28, 5.11 (m, each 2 H, Cp), 4.07, 3.95 (d, each 1 H, =CH_2), 0.27 [s, 18 H, Si(CH_3)$_3$]. – ^{13}C NMR ([D_8]tetrahydrofuran): δ = 151.3 (*C*=CH_2), 122.3 (*ipso*-C, Cp), 117.7, 116.6, 115.4, 114.0 (Cp), 84.3 (C=*C*H_2), 2.65 ($SiMe_3$). – IR (KBr): ν = 1623 cm^{-1}.

Synthesis of Bis{η⁵:κ-O-[1-(pivaloylamido)ethenyl]cyclopentadienyl}zirconium (**10a**): 546 mg (2.86 mmol) of the fulvene **5c** was doubly deprotonated by treatment with 614 mg (5.74 mmol) of LDA in 50 ml of THF, analogously as described above. A solution of $ZrCl_4$ · 2 THF (539 mg, 1.43 mmol) in 50 ml of THF was added at ambient temperature. After stirring for 20 h at room temperature, the solvent was removed in vacuo. Extraction with pentane yielded 739 mg (74%) of the product **10a**, mp 111°C (DSC, decomp.). – $C_{24}H_{30}N_2O_2Zr$ (469.8): calcd. C 61.37, H 6.44, N 5.96; found C 59.84, H 6.63, N 5.96. – ^1H NMR ([D_8]tetrahydrofuran, 600 MHz): δ = 6.40, 6.35, 6.17, 5.82 (m, each 2 H, Cp), 4.80, 4.73 (d, ^2J = 1.4 Hz, each 2 H, =CH_2), 1.12 [s, 18 H, C(CH_3)$_3$]. – ^{13}C NMR ([D_2]dichloromethane, 50 MHz): δ = 174.1 (N*C*O), 145.9 (*C*=CH_2), 125.8 (*ipso*-C, Cp), 120.9, 113.0, 108.3, 106.0 (Cp), 103.9 (C=*C*H_2), 38.7, 28.4 (CMe_3). – IR (KBr): $\tilde{\nu}$ = 1621, 1589, 1502 cm^{-1}.

X-ray Crystal Structure Analysis of **10a**: Formula $C_{24}H_{30}N_2O_2Zr$, *M* = 469.72, 0.40 × 0.40 × 0.10 mm, *a* = 13.301(1), *b* = 14.968(1), *c* = 11.099(1) A, *V* = 2209.7(3) A^3, $\rho_{calcd.}$ = 1.412 g cm^{-3}, μ = 5.19 cm^{-1}, no absorption correction, *Z* = 4, orthorhombic, space group $Pna2_1$ (No. 33), λ = 0.71073 A, *T* = 223 K, ω/2θ scans, 2364 reflections collected (−*h*, +*k*, −*l*), [(sinθ)/λ] = 0.62 A^{-1}, 2364 independent and 1960 observed reflections [$I \geq 2\sigma(I)$], 268 refined parameters, R = 0.025, wR^2 = 0.061, Flack parameter 0.00(6), max. residual electron density 0.27 (−0.34) e A^{-3}, hydrogen atoms calculated and refined as riding atoms.

Synthesis of Bis(η⁵:κ-N-{1-[(trimethylsilyl)amido]ethenyl}cyclopentadienyl)zirconium (**10b**): 362 mg (2.62 mmol) of the fulvene **7** was doubly deprotonated by treatment with 566 mg (5.28 mmol) of LDA in 50 ml of THF. This solution was then added dropwise at −20°C to a solution of 489 mg (1.30 mmol) of $ZrCl_4$ · 2 THF in 40 ml of THF. The reaction mixture was warmed to room temperature and stirred for 2 h. The solvent was then removed in vacuo and the product extracted from the residue with 100 ml of pentane to yield 446 mg (77%) of **10b**, mp 117°C (DSC, decomp.). – $C_{20}H_{30}N_2Si_2Zr$ (445.9): calcd. C 53.88, H 6.78, N 6.28, found C 53.42, H 7.35, N 6.18. – ^1H NMR ([D_2]dichloromethane): δ = 6.36 (m, 4 H), 6.20, 5.80 (m, each 2 H, Cp), 3.95, 3.90 (AB, each 2 H, =CH_2), 0.16 [s, 18 H, Si(CH_3)$_3$]. – ^{13}C NMR ([D_2]dichloromethane): δ = 150.1 (*C*=CH_2), 118.2 (*ipso*-C, Cp), 116.3, 114.7, 122.9, 109.6 (Cp), 87.6 (=*C*H_2), 1.6 ($SiMe_3$). – IR (KBr): ν = 1591 cm^{-1}.

Synthesis of Bis(diethylamido){η⁵:κ-O-[1-(pivaloylamido)ethenyl]cyclopentadienyl}zirconium (**11**): A suspension of the dilithium reagent **8a**, generated by treatment of the fulvene **5c** (339 mg, 1.78 mmol) with 381 mg (3.56 mmol) of LDA in 50 ml of THF, was combined with a suspension of 794 mg (1.77 mmol) of $(Et_2N)_2ZrCl_2$ · 2 THF in 50 ml of THF at 0°C. After stirring for 2 h at room temperature, the solvent was removed in vacuo and the product isolated from the residue by extraction with 50 ml of pentane. Yield of **11**: 528 mg (70%) as a red viscous oil. – $C_{20}H_{35}N_3OZr$ (424.7): calcd. C 56.56, H 8.31, N 9.89, found C 55.66, H 8.54, N 9.71. – ^1H NMR ([D_6]benzene): δ = 5.97, 5.90 (m, each 2 H, Cp), 5.25, 5.00 (d, ^2J = 1.6 Hz, each 1 H, C=CH_2), 3.12 (q, ^3J = 7.4 Hz, 8 H, NCH_2), 1.38 [s, 9 H, C(CH_3)$_3$], 0.88 (t, ^3J = 7.4 Hz, 12 H, NCH_2CH_3). – ^{13}C NMR ([D_8]THF): δ = 171.4 (N*C*O), 147.6 (*C*=CH_2), 125.3 (*ipso*-C, Cp), 111.3, 110.5 (Cp), 102.4 (C=*C*H_2), 44.3 (N*C*H_2), 38.8, 28.6 (CMe_3), 15.6 (NCH_2*C*H_3). – IR (NaCl): ν = 1590 cm^{-1}.

Synthesis of Bis(diethylamido)(η⁵:κ-N-{1-[(trimethylsilyl)amido]ethenyl}cyclopentadienyl)zirconium (**12**): Analogously as described above, the fulvene **7** (100 mg, 55.9 mmol) was doubly deprotonated by treatment with 120 mg (112 mmol) of LDA in 50 ml of THF. The resulting solution of **8b** was then allowed to react with a solution of 253 mg (561 μmol) of $(Et_2N)_2ZrCl_2$ · 2 THF in 50 ml of THF. After workup of the mixture as described above and extraction with pentane, complex **12** was obtained as a dark colored viscous oil, yield 176 mg (76%). – $C_{18}H_{35}N_3SiZr$ (412.8): calcd. C 52.37, H 8.55, N 10.18; found C 52.39, H 7.98, N 9.85. – ^1H NMR ([D_6]benzene): δ = 6.03, 5.92 (m, each 2 H, Cp), 4.36, 4.34 (AB, each 1 H, =CH_2), 3.13 (q, ^3J = 6.9 Hz, 8 H, NCH_2), 0.90 (t, ^3J = 6.9 Hz, 12 H, NCH_2CH_3), 0.39 [s, 9 H, Si(CH_3)$_3$]. – ^{13}C NMR ([D_6]benzene): δ = 150.9 (*C*=CH_2), 112.2 (*ipso*-C, Cp), 115.4, 111.3 (Cp), 87.9 (=*C*H_2), 43.3 (N*C*H_2), 15.6 (NCH_2*C*H_3), 0.8 [Si(CH_3)$_3$]. – IR (NaCl): ν = 1626 cm^{-1}.

Ethene Polymerization Reactions: For the high-pressure polymerization reactions [p(ethene) ≈ 40 bar] a steel autoclave was used that was equipped with a connected steel dropping funnel that could be kept under the same pressure. This 100-ml autoclave was charged through the dropping funnel under argon with 20 ml of a 10% methylalumoxane solution in toluene. The dropping funnel was rinsed with 20 ml of toluene which was added to the contents of the autoclave. Ethene pressure (ca. 40 bar) was applied to the reaction vessel, and the system was allowed to equilibrate for 0.5 h with stirring. 10 ml of a toluene solution of the organometallic catalyst precursor (**12** or **1c**, respectively) was added under pressure. The temperature of the reaction mixture raised rapidly, in a specific case (see Table 2, entry 2) to 141°C. After a typical reaction time of e.g. 20 min the monomer feed was stopped which resulted in a rapid termination of the polymerization reaction. The autoclave was vented and its contents hydrolyzed by treatment with 20 ml of a 1:1 volume mixture of methanol and 2 N aqueous hydrochloric acid. The polymer was collected by filtration, extracted with toluene and then washed 3 × consecutively with half conc. HCl, H_2O, and then with acetone. The resulting polyethylene samples were then dried for 24 h at 70°C. Details of the respective polymerization experiments carried out according to this general procedure are compiled in Table 2. In a number of experiments (Table 2, entries 4, 5, and 7) the starting materials **12** and **1c** were pretreated with trimethylaluminum in toluene before they were given into the reactor.

Table 2. Details of the ethene polymerization reactions employing the C_1-(**12**-) and Si_1-(**1c**-)bridged constrained-geometry Ziegler catalyst systems

Entry	Precursor (mg/μmol)	ml MAO[a]	Al/Zr	p[b]	t[c]	T[d]	PE[e]	mp [°C]	act[f]
1	**12** (19.4/47.0)	10	340	37	10	87	16.6	129	57.7
2	**12** (11.0/26.7)	20	1200	42	25	141	15.2	145	32.5
3	**12** (9.8/23.8)	20	1340	42	20	78	10.1	137	30.3
4	**12** (5.9/14.3)	20[g]	2590	40	25	53	3.8	132	15.9
5	**12** (5.6/13.6)	20[g]	2730	40	25	70	7.0	138	30.9
6	**1c** (8.6/20.9)	20	1530	40	20	103	14.4	135	51.7
7	**1c** (7.1/17.2)	20[g]	2150	40	20	81	11.5	137	50.1

[a] Ca. 1.6 M methylalumoxane solution in toluene. – [b] Ethene pressure [bar]. – [c] Reaction time [min]. – [d] Final temperature [°C] reached under the employed non-isothermal conditions. – [e] Polyethylene isolated [g]. – [f] Catalyst activity in g polymer/mmol [Zr]·bar·h. – [g] 5 ml of ca. 1 M $AlMe_3$ solution in toluene added for in situ methylation.

Ethene Polymerization at Low Pressure: A thermostated Büchi glass autoclave (25°C) was charged with 200 ml of toluene and 20 ml of a 10% MAO solution in toluene. Ethene was introduced at a pressure of 2.2 bar. After 0.5 h, a solution of 18.9 mg of **12** in 10 ml of toluene was added and the polymerization reaction allowed to proceed for 1.5 h. The system was then vented and its contents quenched by treatment with aqueous HCl/CH_3OH. Workup analogously as described above gave 3.6 g polyethylene [mp 137°C, DSC (after premelting)].

Received March 24, 1998

Keywords: Chelates / P,N ligands / Phosphaferrocene / Catalysis / Heterocycles

The new pyridyl-substituted phosphaferrocene ligands **3** and **6** are prepared by addition of lithiated pyridine or α-picoline to 2-formyl-3,4-dimethylphosphaferrocene (**1**). The ligands **3** and **6** react with $[Cp^*RuCl]_4$ in THF to give the *P,N*-chelate complexes $[Cp^*RuCl\cdot\mathbf{3}]$ (**9**) and $[Cp^*RuCl\cdot\mathbf{6}]$ (**10**) with high diastereoselectivity. Addition of monodentate ligands like CO or PPh_3 to the complexes leads by displacement of the Ru-bound pyridyl group to the respective carbonyl or phosphane complexes with monodentate *P*-coordinated phospha-ferrocene ligands. Reaction of the ligand **6** with $[(C_3H_5)PdCl]_2$ and NH_4PF_6 gives the seven-membered chelate complex $[(C_3H_5)Pd\cdot\mathbf{6}]PF_6$ (**13**) which was characterized by X-ray diffraction. The ligands **3** and **6** were tested in the palladium-catalyzed asymmetric alkylation of 1,3-diphenylallyl acetate.

Chiral chelate ligands continue to be of interest in coordination chemistry and asymmetric catalysis. Recently, we reported a new concept for chelate ligands with planar chirality based on substituted phosphaferrocenes. Meanwhile, we have prepared a variety of *P,P* and *P,N* compounds comprising, inter alia, those with aminoalkyl, phosphanylalkyl and phosphinite donor substituents attached to the phosphaferrocene nucleus.[1][2] In this contribution we wish to report the syntheses of pyridyl-substituted phosphaferrocenes as well as the coordination behaviour of the new ligands toward transition-metal fragments. Furthermore, preliminary results obtained with the new ligands in the Pd-catalyzed asymmetric alkylation of 1,3-diphenylallyl acetate are reported.

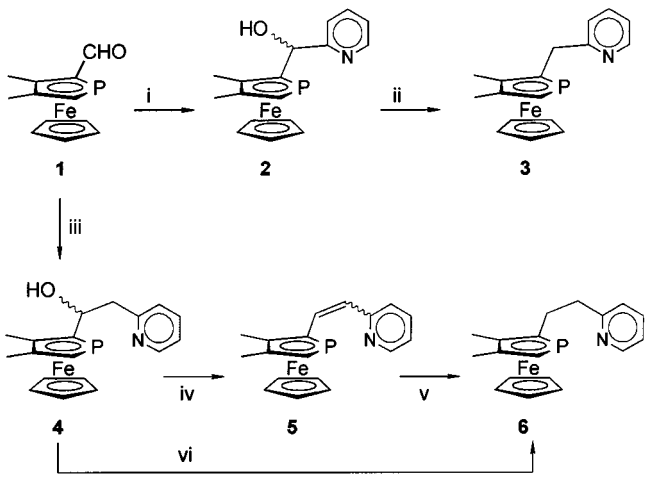
Results

Ligand Synthesis

As depicted in Scheme 1, the synthesis of the pyridyl ligands **3** and **6** can be carried out in one-pot procedures starting from 2-formyl-3,4-dimethylphosphaferrocene (**1**) which has already proven to be a versatile building block for the synthesis of phosphaferrocene ligands before.[1][2] Treatment of the aldehyde **1** with 2-lithiopyridine − prepared in situ from 2-bromopyridine and *n*BuLi − leads to the alcohol **2** (de 83%) which can be deoxygenated with $NaBH_4$ and trifluoroacetic acid to yield the pyridylmethyl ligand **3** as a brown oil which crystallizes on standing. The homologous pyridylethyl ligand **6** with a backbone extended by one CH_2 unit is obtained in an analogous reaction sequence when 2-(lithiomethyl)pyridine − prepared from 2-methylpyridine by deprotonation with *n*BuLi − is employed as the nucleophilic reagent.

If the work-up procedure of the preliminarily formed alcohol **4** (de 60%) is carried out under slightly acidic conditions, the formation of the olefin **5** (as a mixture of *E* and *Z* isomers) is observed by elimination of water. However, the olefin can successfully be transformed into the desired saturated ligand **6** by treatment with $NaBH_4$ and trifluoroacetic acid. The ligands **3** and **6** are obtained in good yield in analytically pure form after chromatography on deactivated alumina and exhibit resonances in the ^{31}P-NMR spectra in the expected range [δ = −77.1 (**3**) and −80.2 (**6**)]. Recently, Mathey and coworkers reported the synthesis of the 2-(2′-pyridyl)phosphaferrocene ligand **8** by combining the [1,5]-sigmatropic rearrangement of the *P*-pyridyl-substituted phosphole **7** with the complexation reaction with $[CpFe(CO)_2]_2$ in a one-pot procedure.[3]

Scheme 1. Preparation of ligands **3** and **6**[a]



[a] Reagents: i: 2-Lithiopyridine, Et_2O, 55%. − ii: $NaBH_4$, CF_3CO_2H, CH_2Cl_2, 64%. − iii: 2-(lithiomethyl)pyridine, THF, 77%. − iv: Aqueous acidic conditions. − v, vi: $NaBH_4$, CF_3CO_2H, CH_2Cl_2, 80%.

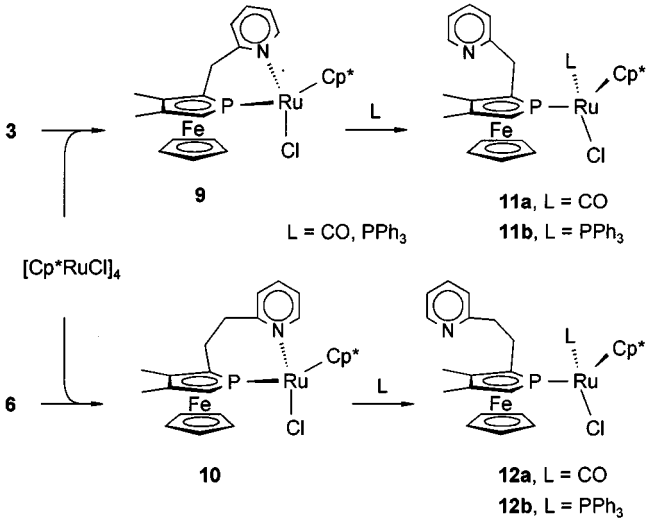
However, since Mathey's synthesis is carried out under non-stereoselective conditions the racemate of ligand **8** was obtained, whereas our approach allows the synthesis of the enantiomerically pure ligands **3** and **6**, starting from the enantiomerically pure aldehyde **1** which is readily available on a preparative scale.[4]

Complexation Experiments

*Cp*Ru Complexes:* Reaction of the ligands **3** and **6** with appropriate metal fragments should lead to six- and seven-membered chelate complexes, respectively. First, experiments were carried out with $[Cp^*RuCl]_4$ as a source of Cp*RuCl fragments with two vacant coordination sites.[1][5] If the reactants are mixed in a metal-to-ligand ratio of 1:1 in THF the quantitative formation of the anticipated chelate complexes [Cp*RuCl·**3**] (**9**) and [Cp*RuCl·**6**] (**10**) is observed within a few moments by NMR spectroscopy. The complexes **9** and **10** are isolated in analytically pure form as yellow and orange microcrystalline solids in 95 and 93% yield, respectively. In the ^{31}P-NMR spectra a characteristic downfield shift of ca. 95 ppm is observed for the phospholyl P atom on going from the free ligands to the complexes. Whereas the typical reduction of the ^2J(HP) coupling constant for the α-phospholyl proton from 36 Hz to 33 Hz is observed for the complexation of ligand **3**, an unprecedented increase of that coupling constant to 40 Hz was observed for the transformation of the ligand **6** to the complex **10**. The *N*-coordination of the pyridyl group to the Ru centre in that complex leads to a downfield shift for the pyridine 6-H from δ = 8.47 to 9.70. As a result of the chelate formation reaction with the Cp*Ru fragment the Ru atom becomes a stereogenic centre in the complexes. Only one set of signals is observed in the NMR spectra of the six-membered chelate complex **9** indicating the stereoselective formation of only one diastereomer (dr > 99:1). The more flexible seven-membered chelate complex **10** is also formed with high, but significantly decreased selectivity (dr = 95:5). The high diastereoselectivity observed in the reaction of the ligands **3** and **6** with $[Cp^*RuCl]_4$ is in contrast to the findings of Consiglio et al. who observed the formation of almost 1:1 mixtures of diastereomers in the reaction of chiral bidentate *P,P*-chelate ligands with the tetrameric ruthenium complex.[6]

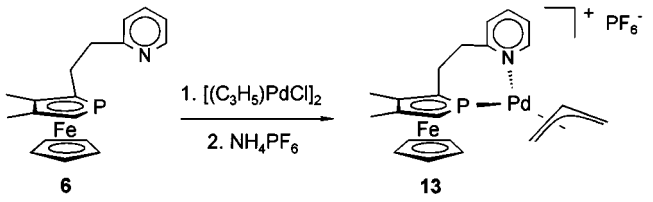
Addition of monodentate ligands such as CO or PPh_3 to THF solutions of the chelate complexes **9** and **10** leads under selective rupture of the Ru−N bond to the formation of the respective carbonyl or PPh_3 complexes **11** and **12** in which the ligands **3** and **6** behave as monodentate *P* ligands (Scheme 2). The reactions were monitored by IR and multinuclear NMR spectroscopy. The diastereomeric ratios of

Scheme 2. Synthesis of complexes



the reaction products are easily obtained from the integrated ^{31}P-NMR spectra. Interestingly, the reactions with CO lead to almost complete epimerization at the Ru centre (dr < 60:40), whereas the additions of PPh_3 proceed with diastereoselectivities of dr = 92:8 and 86:14; thus, the stereochemical integrity is at least partially preserved in the latter case. The carbonyl complex [Cp*RuCl(CO)·**3**] (**11a**) now exhibits a coupling constant of ^2J(HP) = 31 Hz in the expected range and the resonance for the pyridyl 6-H at δ = 8.50 is characteristic for an uncoordinated pyridyl group. The carbonyl C signal appears as a doublet with ^2J(CP) = 36 Hz, comparable to the value reported by Kirchner et al. for the complex $[Cp^*RuCl(CO)(Ph_2PCH_2CH_2NMe_2)]$.[7] In the PPh_3 complexes **11b** and **12b** the resonances of the P nuclei appear as doublets with ^2J(PP) coupling constants in the range of 55 to 68 Hz (see Experimental Section).

(Allyl)palladium Complexes: (Allyl)palladium complexes with *P,N*-chelate ligands have been intensively studied in view of their superior performance in catalytic asymmetric allylic substitutions.[8] The reaction of the ligands **3** and **6** with $[(C_3H_5)PdCl]_2$ in ethanol proceeds smoothely and is accompanied by a color change from orange to deep red. The complexes were precipitated by addition of NH_4PF_6 and isolated by filtration. The complex formed with ligand **3** turned out to be insoluble in common organic solvents which precluded further characterization. We anticipate the formation of a polymeric structure with the ligand **3** acting in a bridging rather than a chelating manner. In contrast, the complex $[(C_3H_5)Pd\cdot\mathbf{6}]PF_6$ (**13**) is soluble in polar solvents and can be recrystallized from ethanol to give orange needles which were suited for X-ray diffraction analysis.



6 13

A PLATON plot of the molecular structure of the cation of complex **13** is depicted in Figure 1, selected bond lenghts and angles are compiled in Table 1. The structure features the typical parameters for a Pd centre in a distorted square-planar coordination geometry with a bite angle P1−Pd−N of 93.6(3)°.

Figure 1. Molecular structure (PLATON) of the cation of complex **13**; hydrogen atoms have been omitted for clarity

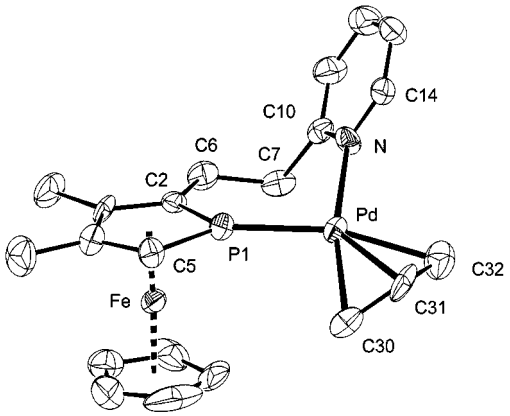


Table 1. Selected bond lengths [A] and angles [°] of complex **13**

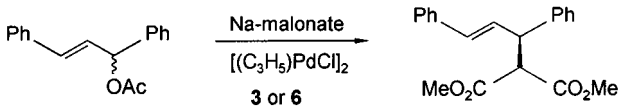
Pd−P1	2.274(3)	P1−Pd−N	93.6(3)
Pd−N	2.13(1)	P1−Pd−C30	99.0(5)
Pd−C30	2.12(1)	P1−Pd−C31	134.2(7)
Pd−C31	2.09(1)	N−Pd−C31	130.6(7)
Pd−C32	2.18(2)	N−Pd−C32	99.1(6)
P1−C2	1.75(1)	Pd−P1−C2	126.7(5)
P1−C5	1.71(1)	Pd−P1−C5	141.2(5)
C30−C31	1.39(2)	C2−P1−C5	91.4(7)
C31−C32	1.34(2)	C10−N−C14	120(1)
N−C10	1.33(2)	Pd−C30−C31	69.5(8)
N−C14	1.34(2)	Pd−C32−C31	68(1)
C2−C3	1.41(2)	C30−C31−C32	123(2)
C4−C5	1.39(2)		

As is usually observed for palladium complexes with *P,N* ligands the distance Pd−P1 [2.274(3) A] is significantly longer than the corresponding bond to the nitrogen donor [Pd−N: 2.13(1) A], although the differences tend to be more pronounced for *P,N* ligands with phosphane donor groups.[9][10] The high π-acceptor character of the phospholyl P atom leads to the rather short Pd−P distance. This π acidity has another consequence involving the Pd−C bond lenghts: the distances Pd−C30 [2.12(1) A] and Pd−C32 [2.18(2) A] are not very different if compared to (allyl)Pd complexes with softer *P* donors, where the Pd−C bond *trans* to the phosphorus atom is often found to be roughly 10 pm longer than the Pd−C bond *trans* to the sp^2 nitrogen donor atom.[9][10] The allyl ligand adopts an almost symmetrical orientation with respect to the coordination plane of the palladium centre as is evident from the virtually identical angles between the plane (P1,Pd,N) and the planes (Pd,C30,C31) (27.8°) and (Pd,C31,C32) (28.4°), respectively. In contrast, a pronounced rotation of the 1,3-diphenylallyl moiety about the (allyl)Pd axis by ca. 15−20° was observed in complexes with ferrocene-derived *P,N* ligands.[9] This rotation seems to be the consequence of the sterically more demanding 1,3-diphenyl substitution on the allyl ligand. In complex **13** the Pd−P1 vector is only slightly tilted out of the phospholyl mean plane away from the CpFe fragment [tilt angle: 3.7(4)°]. The coordination plane about the Pd atom forms an angle with the allyl plane of 112.3(9)°.

The ^{31}P-NMR spectrum of complex **13** shows one broad signal (δ = −42.6) at room temperature. On cooling to −20°C four baseline-separated signals are observed in the range from δ = −39 to −44 in the ratio of 15:16:39:30. We assume, that these signals are due to the presence of two isomers with *exo* and *endo* orientation of the allyl ligand, which both exist in two different chelate ring conformations. Such conformational isomers of seven-membered (allyl)Pd-*P,N*-chelate complexes have been observed by Togni et al.[9b]

Reaction of the pyridine ligand **6** with $[(1,3\text{-}Ph_2C_3H_3)PdCl]_2$ under the same conditions as above leads to the analogous chelate complex **14** with a (diphenylallyl)palladium fragment which was recrystallized from CH_2Cl_2/hexane. At room temperature 3 broad signals are found in the ^{31}P-NMR spectrum in CD_2Cl_2, which split into 4 resonances at −20°C. Obviously, the activation enthalpy for the dynamic interconversion of the isomers is higher in the 1,3-diphenylallyl case.

Preliminary experiments were carried out with ligands **3** and **6** to test their applicability in asymmetric allylic substitutions. 1,3-Diphenylallyl acetate was treated with sodium malonate as *C*-nucleophile in the presence of $[(C_3H_5)PdCl]_2$ and the enantiomerically pure ligands **3** or **6** (5 mol-%) in THF. The substitution reaction is complete after 3 h at room temperature and the product **15** was isolated in 65−80% yield. However, the enantiomeric purity was only 19 and 11%, respectively.



15

We are currently modifying the ligands in order to obtain higher selectivity in catalysis. Furthermore, we are looking for other catalytic reactions for which the ligand type described here might be better suited.

Support of this work by the *Deutsche Forschungsgemeinschaft* (SFB 380) is greatfully acknowledged.

Experimental Section

General: All manipulations were carried out under dry N_2 in Schlenk glassware. Solvents were dried and purified by standard methods and were stored under N_2. − NMR: Varian Unity 500 (499.843 MHz, ^{1}H, int. TMS; 125.639 MHz, ^{13}C{^{1}H}, APT, int. TMS; 202.265 MHz, ^{31}P{^{1}H}, ext. 85% H_3PO_4). − MS: Finnigan MAT 95. − Elemental analysis (C, H, N): Carlo-Erba elemental analyzer, Modell 1106. − IR: Perkin-Elmer 1720 X FTIR. − 2-Formyl-3,4-dimethylphosphaferrocene (**1**),[11] $[Cp^*RuCl]_4$,[5] $[(C_3H_5)PdCl]_2$[12] and di-μ-chlorobis(1,3-diphenyl-π-allyl)dipalladium[13] were prepared as described in the literature.

(3,4-Dimethylphosphaferrocene-2-yl)(pyridin-2-yl)methanol (**2**): 2-Bromopyridine (0.83 ml, 8.71 mmol) was dissolved in 5 ml of Et_2O, cooled to −78°C and *n*BuLi (5.4 ml of a 1.6 M solution in hexane, 8.71 mmol) was added. After stirring for 30 min at −78°C, a solution of 2-formyl-3,4-dimethylphosphaferrocene (**1**) (1.75 g, 6.3 mmol) in 10 ml Et_2O was added, the cooling bath was removed and the mixture was stirred for additional 3 h. The reaction was quenched by 10 ml of H_2O and the phases were seperated. The aqueous phase was washed twice with Et_2O, the combined organic phases were washed with H_2O and brine and dried with Na_2SO_4. Filtration and concentration gave the crude product as a brown oil which was further purified by chromatography on alumina (eluent: THF). **2** was isolated as brown crystals (1.25 g, 3.5 mmol, 55%) after removal of the solvent in vacuo, de 83%. − ^{1}H NMR ($CDCl_3$, major isomer): δ = 2.21 (s, 3 H, CH_3), 2.28 (s, 3 H, CH_3), 3.77 (d, $^2J_{PH}$ = 36 Hz, 1 H, α-C*H*), 4.17 (s, 1 H, O*H*), 4.29 (s, 5 H, Cp), 5.43 (br. s, 1 H, C*H*OH), 7.30−8.60 (4 H, pydidine H). − ^{13}C NMR ($CDCl_3$, major isomer): δ = 14.4 (s, 1 C, *C*H_3), 16.6 (s, 1 C, *C*H_3), 72.1 (s, 5 C, Cp), 73.2 (d, *J* = 12.5 Hz, 1 C, *C*HOH), 76.4 (d, *J* = 59.1 Hz, 1 C, α-*C*H), 92.6 (s, 1 C, *C*CH_3), 96.3 (s, 1 C, *C*CH_3), 104.9 (d, *J* = 57.6 Hz, 1 C, α-*C*CHOH), 120.7 (s, 1 C, *C*H), 122.2 (s, 1 C, *C*H), 136.4 (s, 1 C, *C*H), 147.8 (s, 1 C, N*C*H), 162.3 (s, 1 C, N*C*CHOH). − ^{31}P NMR ($CDCl_3$): δ = −86.1 (major isomer), −77.9 (minor isomer). − MS (70 eV); *m*/*z* (%): 339.0 (100) [M^+], 322.8 (10) [$(M - O)^+$], 274.1 (45) [$(M - Cp)^+$], 232.0 (20) [$(M - CHOHC_5H_4N)^+$]. − $C_{17}H_{18}{}^{56}$FeNOP (339.3): calcd. C 339.047539; found 339.047502 (HRMS).

2-[(3,4-Dimethylphosphaferrocene-2-yl)methyl]pyridine (**3**): 5 ml of CF_3COOH was cooled to 0°C and 1/2 of an $NaBH_4$ tablet was added. A solution of **2** (0.52 g, 1.48 mmol) in 10 ml of CH_2Cl_2 was slowly added and the reaction mixture was stirred over night at room temp. Solvents were evaporated in vacuo and 10 ml of H_2O and 10 ml of CH_2Cl_2 were added. Phases were separated, the aqueous phase was washed twice with CH_2Cl_2, the combined organic layers were washed with water and brine and dried with Na_2SO_4. Filtation and evaporation of the solvent gave the crude product. Chromatography on alumina with hexane/Et_2O (4:1) as eluent gave **3** (0.32 g, 0.95 mmol, 64%) as brown oil, which crystallized within 24 h. − ^{1}H NMR ($CDCl_3$): δ = 2.11 (s, 3 H, CH_3), 2.18 (s, 3 H, CH_3), 3.70 (m, 2 H, CH_2), 3.73 (d, *J* = 36.0 Hz, 1 H, α-C*H*), 4.14 (s, 5 H, Cp), 7.05 (m, 2 H, C*H*), 7.51(m, 1 H, C*H*), 8.47 (br. s, 1 H, NC*H*). − ^{13}C NMR ($CDCl_3$): δ = 13.7 (s, 1 C, *C*H_3), 16.9 (s, 1 C, *C*H_3), 39.9 (d, *J* = 6.0 Hz, 1 C, *C*H_2), 72.1 (s, 5 C, Cp), 76.0 (d, *J* = 57.0 Hz, 1 C, α-*C*H), 93.7 (d, *J* = 3.9 Hz, 1 C, *C*CH_3), 95.8 (d, *J* = 6.8 Hz, 1 C, *C*CH_3), 96.3 (d, *J* = 57.4 Hz, 1 C, α-*C*CH_2), 121.2 (s, 1 C, CH), 122.6 (s, 1 C, *C*H), 136.1 (s, 1 C, *C*H), 148.7 (s, 1 C, N*C*H), 161.6 (s, 1 C, N*C*CH_2). − ^{31}P NMR ($CDCl_3$): δ = −77.1 . − MS (70 eV); *m*/*z* (%): 322.9 (100) [M^+], 258.0 (60) [$(M - Cp)^+$]. − $C_{17}H_{18}$FeNP (323.2): calcd. C 63.18, H 5.61, N 4.33; found C 62.93, H 5.71, N 4.28.

1-(3,4-Dimethylphosphaferrocene-2-yl)-2-(pyridin-2-yl)ethanol (**4**): To a solution of α-picoline (0.72 ml, 7.27 mmol) in 10 ml of THF at −40°C was added a solution of *n*BuLi in hexane (4.5 ml, 1.6 M solution of *n*BuLi, 1.51 mmol). After warming up to room temp. and stirring for 15 min, the orange solution was again cooled to −40°C and 2-formyl-3,4-dimethylphosphaferrocene (**1**) (1.27 g, 4.85 mmol), dissolved in 10 ml of THF, was added. The reaction mixture was stirred at room temp. for 3 h, then 10 ml of H_2O was added and the organic solvent was evaporated in vacuo. After addition of 10 ml of CH_2Cl_2, the phases were separated, the aqueous phase was extracted twice with CH_2Cl_2, the combined organic phases were washed with water and brine and dried with Na_2SO_4. Filtration and evaporation of the solvent yielded the crude product which was further purified by chomatography on alumina. Elution with Et_2O/THF (1:1) and evaporation of solvents gave **3** (1.32 g, 3.73 mmol, 77%) as orange powder, de 60%. − ^{1}H NMR ($CDCl_3$, major isomer): δ = 2.12 (s, 3 H, CH_3), 2.19 (s, 3 H, CH_3), 2.80−3.00 (m, 2 H, CH_2), 3.70 (d, *J* = 36.6 Hz, 1 H, α-C*H*), 4.19 (s, 5 H, Cp), 4.57 (s, 1 H, O*H*), 4.68 (m, 1 H, C*H*OH), 7.10−7.60 (m, 3 H, C*H*), 8.50 (d, *J* = 4.9 Hz, 1 H, NC*H*). − ^{13}C NMR ($CDCl_3$, major isomer): δ =.13.9 (s, 1 C, *C*H_3), 16.6 (s, 1 C, *C*H_3), 47.1 (s, 1 C, *C*H_2), 71.6 (d, *J* = 12,0 Hz, 1 C, *C*HOH), 72.0 (s, 5 C, Cp), 75.5 (d, *J* = 60.0 Hz, 1 C, α-*C*H), 91.7 (s, 1 C, *C*CH_3), 96.2 (s, 1 C, *C*CH_3), 105.5 (d, *J* = 60.6 Hz,1 C, α-*C*CHOH), 121.7 (s, 1 C, *C*H), 124.2 (s, 1 C, *C*H), 136.4 (s, 1 C, *C*H), 148.4 (s, 1 C, N*C*H), 159.5 (s, 1 C, N*C*CH_2). − ^{31}P NMR ($CDCl_3$): δ = −86.5 (major isomer), −85.0 (minor isomer). − MS (70 eV); *m*/*z* (%): 353.1 (50) [M^+], 335.2 (55) [$(M - H_2O)^+$], 232 (70) [$(M - CHOHCH_2C_5H_4N)^+$]. − $C_{18}H_{20}$FeNOP (353.2): calcd. C 61.21, H 5.71, N 3.96; found C 61.53, H 6.12, N 4.14.

2-[(3,4-Dimethylphosphaferrocene-2-yl)ethyl]pyridine (**6**): **4** (1.32 g, 3.72 mmol) was treated as described above for the preparation of **3**. The product **6** (0.98 g, 2.91 mmol, 80%) was isolated as a brown oil. − ^{1}H NMR ($CDCl_3$): δ = 2.10 (s, 3 H, CH_3), 2.18 (s, 3 H, CH_3), 2.58 (m, 2 H, CH_2), 2.87 (m, 2 H, CH_2). 3.67 (d, *J* = 35.7 Hz, 1 H, α-C*H*), 4.07 (s, 5 H, Cp), 7.10 (m, 2 H, C*H*), 7.55 (m 1 H, C*H*), 8.55 (s, 1 H, NC*H*). − ^{13}C NMR ($CDCl_3$): δ = 13.4 (s, 1 C, *C*H_3), 16.8 (s, 1 C, *C*H_3), 31.0 (s, 1 C, *C*H_2), 41.2 (s, 1 C, *C*H_2), 71.8 (s, 5 C, Cp), 75.3 (d, *J* = 58.7 Hz, 1 C, α-*C*H), 93.0 (s, 1 C, *C*CH_3), 95.4 (s, 1 C, *C*CH_3), 99.1 (d, *J* = 58.6 Hz, 1 C, α-*C*CH_2), 121.0 (s, 1 C, *C*H), 123.0 (s, 1 C, *C*H), 136 (s, 1 C, *C*H), 149.1 (s, 1 C, N*C*H), 161.5 (s, 1 C, N*C*CH_2). − ^{31}P NMR ($CDCl_3$): δ = −80.2 . − MS (70 eV); *m*/*z* (%): 337.2 (100) [M^+], 272.3 (60) [$(M - Cp)^+$], 245.1 (20) [$(M - CH_2C_5H_4N)^+$]. − $C_{18}H_{20}$FeNP (337.2): calcd. C 64.12, H 5.98, N 4.15; found C 63.46, H 5.87, N 4.01.

*[Cp*RuCl·**3**]* (**9**): **3** (38,0 mg, 0.12 mmol) was dissolved in 3 ml of THF and added to a suspension of $[Cp^*RuCl]_4$ (31.9 mg, 0.029 mmol) in 2 ml of THF. The resulting clear red solution was stirred for 30 min, filtered and the solvent was evaporated. The yellow powder was washed with a small portion of hexane and dried in vacuo to give spectroscopically pure **9** (67.8 mg, 0.11 mmol, 95%), dr > 99:1. − ^{1}H NMR ([D_8]THF): δ = 1.53 (d, *J* = 2.9 Hz, 15 H, Cp*), 2.20 (s, 3 H, CH_3), 2.22 (s, 3 H, CH_3), 3.38 (m, 2 H, CH_2), 3.58 (d, *J* = 40 Hz, 1 H, α-C*H*), 3.79 (s, 5 H, Cp), 7.10 (m, 1 H, C*H*), 7.18 (m, 1 H, C*H*), 7.59 (m, 1 H, C*H*), 9.70 (d, *J* = 4.9 Hz, 1 H, NC*H*). − ^{13}C NMR ([D_8]THF): δ = 8.5 (s, 5 C, *C*H_3-Cp*), 11.5 (s, 1 C, *C*H_3), 14.9 (s, 1 C, *C*H_3), 36.3 (d, *J* = 13.8 Hz, 1 C, *C*H_2), 65.1 (d, *J* = 30 Hz, 1 C, α-*C*H), 71.0 (s, 5 C, Cp), 79.6 (s, 1 C, *C*CH_3), 81.2 (d, *J* = 3.1 Hz, 5 C, *C*CH_3-Cp*), 87.5 (d, *J* = 35 Hz, 1 C, α-*C*CH_2), 120.1 (s, 1 C, *C*H), 123.9 (s, 1 C, *C*H), 134.5 (s, 1 C, *C*H), 158.2 (s, 1 C, N*C*H), 162.1 (d, *J* = 4.9 Hz, 1 C, N*C*CH_2). − ^{31}P NMR ([D_8]THF): δ = 14.9 . − SIMS (70 eV); *m*/*z* (%): 560.3 (100) [$(M - Cl)^+$]. − $C_{27}H_{33}$ClFeNPRu (594.9): calcd. C 55.23, H 5.79, N 2.30; found C 55.21, H 5.98, N 2.18.

NMR Experiments: For the substitution reaction of the pyridine moiety with CO about 30 mg of the complex [Cp*RuCl·**3**/**6**] was prepared in situ by dissolving ligand **3** or **6** and [Cp*RuCl]$_4$ in [D$_8$]THF. Purity was proven by NMR and 10 ml of CO was bubbled through the solution by syringe. Then the NMR spectra were recorded. For the substitution with triphenylphosphane, the complexes **9** and **10** were prepared as described and the stoichiometric amount of PPh_3 was added. The resulting clear red solution was analyzed by NMR spectroscopy.

*[Cp*RuCl(CO)·**3**]* (**11a**): dr = 50:50. − ^{1}H NMR ([D$_8$]THF): δ = 1.64 (br. s, 15 H, Cp*), 2.20 (br. s, 6 H, C*H*$_3$), 3.46 (d, J = 30.5 Hz, 1 H, α-C*H*, isomer I), 3.70 (d, J = 30.8 Hz, 1 H, α-C*H*, isomer II), 3.84 (br. s, 2 H, C*H*$_2$), 4.31 (s, 5 H, Cp), 7.07 (br. s, 2 H, C*H*), 7.49 (br. s, 1 H, C*H*), 8.49 (s, 1 H, NC*H*). − ^{13}C NMR ([D$_8$]THF): δ = 9.7 (d, J = 5.8 Hz, 5 C, C*C*H$_3$-Cp*), 13.8 (s, 1 C, *C*H$_3$), 16.4 (s, 1 C, *C*H$_3$), 37.5 (s, 1 C, *C*H$_2$), 74.0 + 74.1 (s, 1 C, Cp), 85.2 (s, 1 C, *C*CH$_3$), 88.1 (s, 1 C, *C*CH$_3$), 91.5 (d, J = 47.8 Hz, 1 C, α-*C*CH$_2$), 96.1 (s, 5 C, *C*CH$_3$-Cp*), 122.0 (br. s, 2 C, *C*H), 135.7 (br. s, 1 C, *C*H), 148.5 (br. s, 1 C, N*C*H), 162.0 (br. s, 1 C, N*C*CH$_2$), 203.7 (d, J = 36 Hz, 1 C, *C*O). − ^{31}P NMR ([D$_8$]THF): δ = 10.3 (isomer I), 22.0 (isomer II). − IR ([D$_8$]THF): ν = 1940 cm^{-1}.

*[(C$_{13}$H$_{13}$)Pd·**6**][PF$_6$]* (**14**): The complex was prepared from [(C$_{13}$H$_{13}$)PdCl]$_2$ as described above for **13**. Recrystallisation from CH_2Cl_2/hexane (1:1) afforded orange-red crystals in 54% yield. − ^{1}H NMR (CD_2Cl_2, −20°C): δ = 1.93 (s, 3 H, C*H*$_3$), 2.03 (s, 3 H, C*H*$_3$), 2.35−2.44 (m, 2 H, C*H*$_2$), 2.78−2.91 (m, 2 H, C*H*$_2$), 3.34−3.53 (m, 1 H, α-C*H*), 3.50−4.25 (4 s, 5 H, Cp), 5.40 (2 d, 1 H, 2-allyl-H), 5.84−5.95 (m, 1 H, allylic H), 6.79−7.07 (m, 1 H, allylic H), 7.30−7.80 (m, 14 H, aromatic H). − ^{13}C NMR (CD_2Cl_2, +23°C): δ = 13.4 (s, 1 C, *C*H$_3$), 16.6 (s, 1 C, *C*H$_3$), 32.2 (s, 1 C, *C*H$_2$), 38.7 (s, 1 C, *C*H$_2$), 63.4 (br. m, 1 C, α-*C*H), 73.5−76.7 (4 s, 5 C, Cp), 93.8 (m, 3 C, quat. phospholyl-C), 97.0 (d, J = 26.3 Hz, 1 C, allylic C), 109.5 (d, J = 7.2 Hz, 1 C, allylic C), 110.4 (br. s, 1 C, allylic C), 124.3−130.2 (m, 13 C, aromatic C), 138.2−139.4 (m, 3 C, aromatic *ipso*-C), 150.4 (s, 1 C, N*C*H), 164.5 (s, 1 C, N*C*CH$_2$). − ^{31}P NMR (CD_2Cl_2, +24°C): δ = −19.7, −29.4, −37.1 (8:42:50), (3 br. s, 1 P, cycl. P), −144.6 (sept, J = 708 Hz, 1 P, PF_6), (CD_2Cl_2, −20°C): δ = −18.8, −28.8, −36.4, −38.0 (7:46:38:8), (4 s, 1 P, cycl. P), 144.6 (sept, J = 708 Hz, PF_6). − SIMS (70 eV); *m*/*z* (%): 636.5 (4)[(M − PF_6)$^+$], 338.3 (100) [(**5** + H)$^+$]. − $C_{33}H_{33}F_6FeNP_2Pd \cdot 0.5\ CH_2Cl_2$ (824.3): calcd. C 48.85, H 4.13, N 1.70; found C 48.80, H 4.24, N 1.77.

General Procedure for the Catalytic Allylic Alkylation: [(C$_3$H$_5$)PdCl]$_2$ (0.012 mmol, 4.6 mg), the ligand (**3** or **6**, 0.025 mmol) and 1,3-diphenyl-2-propenyl acetate (126.1 mg, 0.5 mmol) were dissolved in 5 ml of THF to give a clear orange solution. NaH (24 mg, 1.0 mmol) and dimethyl malonate (132.1 mg, 1 mmol) were dissolved in 5 ml of THF and added to the orange solution by syringe. The solution was stirred for 13−19 h, then 1 ml of acetic acid was added and the solvent was removed in vacuo. 10 ml of water was added to the mixture, followed by extraction with Et_2O. Then the organic layers were washed with water and brine, dried with Na_2SO_4 and the solvent was removed in vacuo. The resulting yellow oil was further purified by chromatography on silica gel with hexane/ethyl acetate (5:1) to yield pure product **15**. The enantiomeric excess of **15** was determined by polarimetry, the NMR data are consistent with those reported in the literature.[14]

X-ray Structural Analysis of **13**: $C_{21}H_{25}F_6FeNP_2Pd$, M = 629.63 g mol^{-1}, orthorhombic space group *Pna*2$_1$ (no. 33), a = 8.978(1), b = 29.010(4), c = 9.102(2) A, V = 2370(1) A^3, Z = 4, $d_{calcd.}$ = 1.76 g cm^{-3}, μ(Mo-K_α) = 15.49 cm^{-1}, F(000) = 1256. ENRAF-

Nonius CAD4, ω-2θ scan, Mo-K_α radiation (0.71073 Å), graphite monochromator, 7865 reflections at 298 K with $2° \leq \theta \leq 30°$, crystal size 0.04 × 0.30 × 0.60 mm. Structure solution with Patterson methods. Refinement[15] with anisotropic thermal parameters for all non-hydrogen atoms converged at $R = 0.067$, $R_w = 0.049$ for 288 parameters and 2609 independent observations with $I > 1.5\ \sigma(I)$. Hydrogen atoms were treated as riding atoms. A final difference Fourier synthesis showed a residual density of 2.31 (0.51 Å from Pd)/−0.62 eA^{-3}. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-101282. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ (Fax: int. code + 1223/336-033; E-mail: deposit@ccdc.cam.ac.uk).

Keywords: Heterobimetallic complexes / Lanthanides / Nickel / Mass spectrometry / Thermochemistry

Heterobimetallic [Ni(salen)Ln(hfa)$_3$] species [H$_2$salen and Hhfa being *N,N′*-ethylenebis(salicylideneimine) and hexafluoroacetylacetone respectively], where Ni(salen) acts as a neutral chelating ligand towards Ln^{III}, form a series of isostructural compounds for Ln = Y^{III} and any lanthanide^{III} cation from La to Yb. They are also isostructural with some of the [Cu(salen)Ln(hfa)$_3$] compounds. They sublime without decomposition under vacuum which makes them potential single-source precursors in MOCVD. Sublimation, thermal behaviour, pressure and composition of the vapour phase versus temperature have been studied for the yttrium derivative, by means of thermal analyses, and mass spectrometry using a Knudsen cell. The dissociation process [Ni(salen)Y(hfa)$_3$] = Ni(salen) + Y(hfa)$_3$ has been thermodynamically investigated. Information on the solid-state intermolecular interactions in relation with volatility was obtained through the crystal structure determination of the gadolinium derivative. A comparative structural study of [Ni(salen)Gd(hfa)$_3$] and [Cu(saloph)Y(hfa)$_3$], [H$_2$saloph is *N,N′*-*o*-phenylenebis(salicylideneimine)], allows to understand why the latter is less volatile than the former despite similar molecular and solid-state structures.

Introduction

Many materials for high technology applications are heterometallic compounds in which at least two different metal elements are associated ($BaTiO_3$, $NaNbO_3$, $YBa_2Cu_3O_7$, AsGa, NiAl, ...). Their preparation as thin films using the technique of CVD requires as much precursors as metal elements to deposit. The idea of using single-source precursors is somewhat attractive since it allows a simplification of the reactor design and processing conditions, and a good control of the gas phase composition up to the deposition zone[1]. It has initiated a quest for volatile heterometallic compounds which is by itself a chemical challenge. Pioneering works include the growth of AsGa films from compounds such as $R_3As-GaR'_3$[2]. More recently, intermetallic films associating a p^3 element (Ga, In) and a *d* element (Ni, Co, Pt) have been grown from complexes with non-bridged[3][4][5] or bridged[6][7] $d-p^3$ bond. This approach was boosted up when the technique of CVD started to be used to grow thin films of heterotrimetallic $YBa_2Cu_3O_7$ for which not only there are three metals to deposit, but also arises a difficulty inherent to the CVD of barium.

To make a volatile complex associating two elements having different chemistries, such as a *d* and a *s* or a *f* element, is somewhat challenging. Surprisingly, the first reported volatile heterobimetallic complex was ionic Cs[Y(hfa)$_4$], which Lippard sublimed without decomposition both in air and in vacuum[8]. More recently, Purdy et al. reported the synthesis of heterometallic alkoxides among which NaCu(OCMe$_3$)$_3$ and Na$_2$Cu[OCH(CF$_3$)$_2$]$_4$ start to sublime without decomposition in dynamic vacuum at temperatures as low as 70°C and 90°C respectively, and Ba[Cu(OCMe$_3$)$_3$]$_2$ sublimes at 133−160°C with partial decomposition[9].

A strategy based on the use of alkoxides as bridging ligands and β-diketonates as terminal ligands allowed Hubert-Pfalzgraf et al. to prepare $YBa_3(OtBu)_6(thd)_3$ which sublimes at 190°C/10^{-3} torr[10], BaY$_2$[OCH(CF$_3$)$_2$]$_4$(thd)$_4$, BaCu$_2$[OCH(CF$_3$)$_2$]$_4$(thd)$_2$, and YCu[OCH(CF$_3$)$_2$]$_2$(thd)$_3$ which sublime without decomposition at 150°C/10^{-3} torr, 170°C/10^{-3} torr, 160°C/10^{-3} torr respectively[11]. A $LaNb_3$ complex, [La{OC$_2$H$_4$)$_3$N}$_2${Nb(OPr^i)$_4$}$_3$], which sublimes at about 180−250°C/10^{-1} torr, was obtained using triethanolamine as a bridging ligand and isopropoxide as a terminal ligand[12].

We present here a thourough study of a new kind of volatile heterobimetallic complexes made from two complexes, Ni(salen) and $Ln(hfa)_3$, which add to form [Ni(salen)-$Ln(hfa)_3$] in which Ni(salen) acts as a bidentate ligand and coordinatively saturates $Ln(hfa)_3$ as confirmed by the crystal structure determination of the gadolinium derivative. This structure determination was part of an investigation of the magnetism of heterobimetallic compounds of general formula [M(salen)$Ln(hfa)_3$] and [M(saloph)$Ln(hfa)_3$], M being Ni or Cu[13]. We observed that [Ni(salen)$Gd(hfa)_3$] could be transported in the vapour phase at 180°C/10^{-2} torr, without decomposition as checked by infra-red and powder X-ray diffraction analyses. We have also established that yttrium and lanthanide derivatives are isostructural. As a preliminary study for qualification as a precursor for MOCVD, we decided to further investigate the thermal behaviour of the yttrium derivative, both in the solid state and in the vapour phase, through thermal analyses (TGA, DTG, DTA), and mass-spectrometry using single-cell and double-cell Knudsen chambers. Thermodynamical parameters relative to sublimation and partial dissociation have been derived. This presentation will be completed with a description of the intermolecular interactions in the solid state, and a brief comparative study with [Cu(saloph)$Gd(hfa)_3$] which proved less easy to sublime despite an alike solid-state structure.

This work is part of an INTAS program on synthesis and application of heterobimetallic complexes as precursors for the preparation of thin film materials by the technique of MOCVD.

Results and Discussion

Crystal and Molecular Structure of [Ni(salen)$Gd(hfa)_3$]

From single crystal studies run for the Gd, Yb and Y derivatives in this work, and the La derivative in a previous work[14], it may be inferred that [Ni(salen)$Y(hfa)_3$] and [Ni-(salen)$Ln(hfa)_3$] for Ln going from La to Yb are isostructural (the Lu derivative was not investigated). They crystallize in the monoclinic system, space group $P2_1/n$, with the following unit-cell constants: a = 17.2(1), b = 22.41(6) A, c = 19.7(3) A, β = 90.4(9)° for La[14]; a = 17.153(1), b = 22.296(2), c = 19.454(2) A, β = 90.36(1)° for Gd; a = 17.29(1), b = 22.349(6), c = 19.59(1) A, β = 90.12(6)° for Y; a = 17.191(3), b = 22.056(6), c = 19.563(4) A, β = 90.18(2)° for Yb. They are isostructural with [Cu(salen)$Gd(hfa)_3$] whose structure has been described in ref.[14] but was not published at the time of this study. Crystal and molecular structures of [Ni(salen)$Gd(hfa)_3$] have been determined as part of an investigation of the magnetic behaviour[13] and of the volatility (this study) of compounds of the [M(salen)$Ln(hfa)_3$] (M = Cu, Ni) series.

The asymmetric unit is made of two symmetrically independent [Ni(salen)$Gd(hfa)_3$] molecules, namely mol__1 and mol__2, paired up into a pseudo-centrosymmetrical dimeric entity in which Ni(salen) moieties overlap, as shown in Figure 1. There are four such dimers per unit-cell. The Ni__1−Ni__2 distance is equal to 3.583(1) A, and the Gd−Ni distances are equal to 3.165(1) A in mol__1 and 3.225(1) A in mol__2. Ni(salen) chelates gadolinium through its oxygen atoms. It is almost planar with atom-to-plane deviations ranging from −0.24 to 0.33 A in mol__1, and −0.40 to 0.24 A in mol__2. The folding angles of the NiO(1)O(2)Gd bridging parts about O(1)O(2) are 52.2(2)° in mol__1 and 47.4(2)° in mol__2. In both molecules, the gadolinium atom is bound to eight oxygen atoms forming a pseudo square antiprism.

A screening of van der Waals contacts gave results shown in Table 1. The shortest contacts between fluorine atoms are larger than 2.8 A, that is more than twice their van der Waals radius of 1.35 A[15]. Examination of H···H distances and C−H···H angles revealed no van der Waals contacts between −CH or $-CH_2$ groups. No π-interactions was no-

Figure 1. Pseudo-centrosymmetrical pairing of molecule__1 and molecule__2 in [Ni(salen)$Gd(hfa)_3$] (letters a, b and c number *hfa* ligands in either molecules)

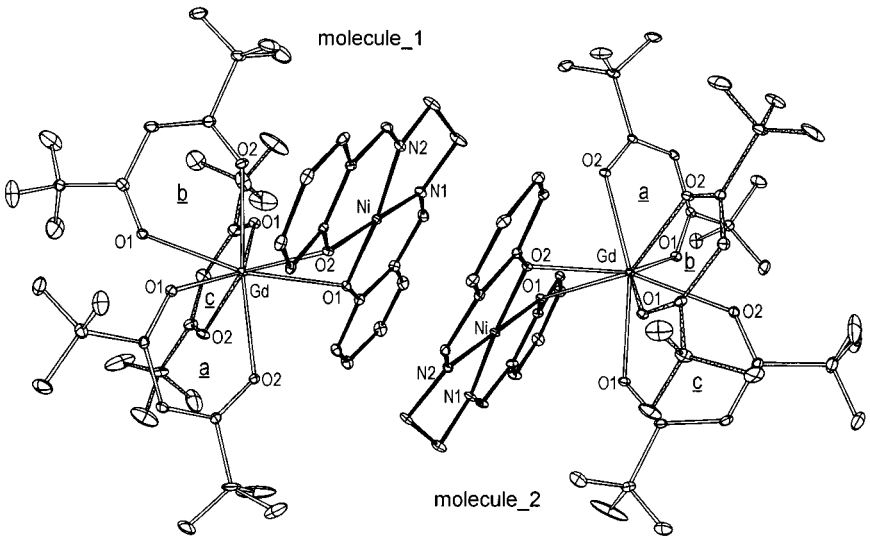

Table 1. Tentative comparison of van der Waals interactions in [Ni(salen)Gd(hfa)$_3$] and [Cu(saloph)Y(hfa)$_3$] (distances in A and angles in deg.). Van der Waals radii are those of Pauling[15]: F, 1.35 A; H, 1.20 A; half-thickness of an aromatic molecule, 1.70 A

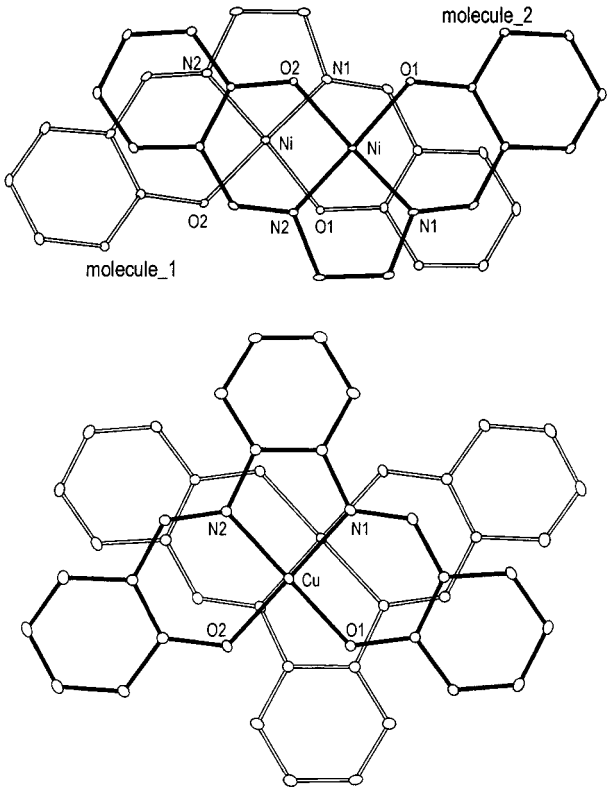
ticed between six-membered rings of ajacent molecules. The main significant interactions occur in the dimers between overlaping Ni(salen) entities. The overlaping scheme of two Ni(salen) entities in a dimer is shown in Figure 2. The mean planes make an angle of 1.1(1)° and are 3.354(8) A apart. This value is slightly less than twice the van der Waals half-thickness of a planar cycle with delocalized π-electrons (1.70 A[15]).

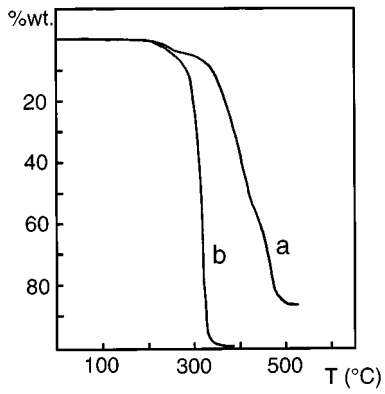
Figure 2. Overlap scheme of two pseudo-centrosymmetrically related Ni(salen) entities in [Ni(salen)Gd(hfa)$_3$] (top), and of two centrosymmetrically related Cu(saloph) entities in [Cu(saloph)Y(hfa)$_3$] (bottom)



Thermal Analyses and Vacuum Sublimation

Thermogravimetric (TGA) curve recorded at 1 atmosphere under nitrogen [Figure 3 (a)] shows that [Ni(salen)Y(hfa)$_3$] is thermally stable up to 210°C, and decomposes in the 210−510°C temperature range. The total loss of weight is about 85% which is consistent with the formation of a 1:1 mixture of YF_3 and NiO. Corresponding DTG-curve showed a six-step process with the main effect occuring at 460°C. Figure 3 (b) shows the thermogravimetric curve recorded under vacuum (0.01 torr). A single-stepped and quasi total (>99%) weight loss occurs in the 220−340°C range. The DTA curve showed a single endothermic peak at about 300°C. This corresponds to sublimation exclusively.

Figure 3. Thermal gravimetric analyses of [Ni(salen)Y(hfa)$_3$] at 1 atm; (a) and under vacuum (b)



Several samples of [Ni(salen)Y(hfa)$_3$] were submitted to isothemal vacuum sublimation (0.01 torr). Freshly prepared product could be totally sublimed at 240°C without decomposition, and an X-ray powder diffraction analysis showed that the sublimate was isostructural with the starting material. A sublimed sample could be sublimed again more than once in the 240−300°C temperature range without decomposition. Air storing over 6 months proved not to affect the sublimation process.

In order to determine whether [Ni(salen)Y(hfa)$_3$] exists in the vapour phase, or if the solid dissociates into gaseous Y(hfa)$_3$ and Ni(salen) which recombine in the cold part of the reactor, mass-spectrometry experiments were carried out, not only for the heterobimetallic complex but also for the component monometallic complexes Y(hfa)$_3$ and Ni(salen).

Table 2. Intensities of main ion currents (relative units) in mass spectra of $Y(hfa)_3$, Ni(salen), and $[Ni(salen)Y(hfa)_3]$ (U = 80 eV)

$Y(hfa)_3$ (341 K)		Ni(salen) (515 K)		$[Ni(salen)Y(hfa)_3]$ (450 K)

Mass Spectrometry Study of $[Ni(salen)Y(hfa)_3]$, $Y(hfa)_3$, and Ni(salen)

The results are displayed in Table 2.

$Y(hfa)_3$: The mass spectrum of $Y(hfa)_3$ shows that the major species are three yttrium-containing ions with m/z of 446 ($[Y(hfa)_2 - 3\ F]^+$), 265 ($[Y(hfa) - CF]^+$), and 503 amu ($[Y(hfa)_2]^+$). Therefore, the saturated vapour over anhydrous $Y(hfa)_3$ mainly consists of monomeric molecules $Y(hfa)_3$. Ions including two yttrium atoms are present as minor species, thus indicating that the vapour phase contains dimeric $[Y(hfa)_3]_2$ molecules too. At 341 K, the respective vapour pressures are $3.9\cdot10^{-3}$ torr ($5.13\cdot10^{-6}$ atm) for $Y(hfa)_3$, and $3.8\cdot10^{-4}$ torr ($5.0\cdot10^{-7}$ atm) for $[Y(hfa)_3]_2$. The enthalpy of dissociation of $[Y(hfa)_3]_2$ in the gas phase according to the equation $[Y(hfa)_3]_{2\ (g)} = 2\ [Y(hfa)_3]_{(g)}$ (*1*) was determined in the 312−365 K temperature range: $\Delta_D H°_T$ = 78.0 kJ/mol. The enthalpy of sublimation of monomeric $Y(hfa)_3$ was also calculated (Table 3).

Table 3. Temperature dependence of saturated vapour pressures of $Y(hfa)_3$, Ni(salen), and $[Ni(salen)Y(hfa)_3]$

Complex	A[a]	B[a]	T range [K]	$\Delta_s H°_T$ [kJ/mol]
$Y(hfa)_3$	4786±500	8.75±0.2	312−365	91.6±8.5
Ni(salen)	7823±350	9.74±0.15	459−545	149.8±7
$[Ni(salen)Y(hfa)_3]$	8894±1000	13.4±0.2	420−471	170.3

[a] A and B are the coefficients of the equation $\log P_{atm} = -A/T + B$.

Ni(salen): Peaks assigned to monomeric species only were detected in the mass spectrum of Ni(salen). At 501 K, the vapour pressure of Ni(salen) is equal to $7.82\cdot10^{-4}$ torr ($1.03\cdot10^{-6}$ atm). The enthalpy of sublimation was calculated (Table 3).

[Ni(salen)Y(hfa)$_3$]: The mass spectrum shows that the vapour phase over $[Ni(salen)Y(hfa)_3]$ contains the heterobimetallic ions $[Y(hfa)_3Ni(salen)]^+$, $[Y(hfa)(CO)Ni(salen)]^+$, $[Y(OH)_2Ni(salen)]^+$, thus indicating that molecules $[Ni(salen)Y(hfa)_3]$ are present in the saturated vapour. However, ion currents corresponding to monometallic species were also detected. A *LAMMA* analysis of the solid residue after sublimation of 50% of the starting material showed the Y/Ni ratio to be still 1:1, from what it may be deduced that $[Ni(salen)Y(hfa)_3]$ sublimes congruously. It may be inferred that monomeric species originate by dissociation of gaseous $[Ni(salen)Y(hfa)_3]$.

$$[Ni(salen)Y(hfa)_3]_{(s)} \rightleftharpoons [Ni(salen)Y(hfa)_3]_{(g)} \quad (2)$$

$$[Ni(salen)Y(hfa)_3]_{(g)} \rightleftharpoons Y(hfa)_{3\ (g)} + Ni(salen)]_{(g)} \quad (3)$$

One notices that the intensities for monometallic Ni species are higher (relative intensity of 19.9 in Table 2) than the ones for bimetallic species. In our opinion, such an unbalanced distribution of relative intensities might result from a dissociative mechanism during the ionization process of $[Ni(salen)Y(hfa)_3]$ (under electron impact) with predominant formation of Ni-containing cationic species. Similar distributions of ion current intensities were observed for volatile $M[Ln(hfa)_4]$ (M = alkaline element)[8] and for complex halogenides of alkaline elements[16].

The temperature dependencies of ion current intensities were studied for heterobimetallic and monometallic species in the mass spectra of $[Ni(salen)Y(hfa)_3]$ in the 420−471 K range. A two-temperature Knudsen chamber was used to study the composition of the unsaturated overheated vapour. It was found that the dissociation process *3* took place in the top part of the chamber. Using these results and assuming a congruent sublimation for $[Ni(salen)Y(hfa)_3]$ − $(P_{[Ni(salen)Y(hfa)3]} + P_{Ni(salen)})/(P_{[Ni(salen)Y(hfa)3]} + P_{Y(hfa)3}) = 1$ and $P_{Ni(salen)} = P_{Y(hfa)3}$ − we calculated the enthalpies for processes *2* and *3*: $\Delta_s H°_T$ = 170.3 ± 21.0 kJ/mole for *2*; $\Delta_D H°_T$ = 127.2 ± 9.0 kJ/mol for *3* (Table 3). A comparison of the latter value with the enthalpy of process *1* shows that $[Ni(salen)Y(hfa)_3]$ is more stable than $[Y(hfa)_3]_2$.

The variation of the equilibrium constant versus temperature for process *3* was determined in the 487−581 K range:

$$\log K_{patm} = -(6643\pm500)/T + (6.33\pm0.3)$$

Table 4 shows partial pressures and vapour phase compositions calculated at 420 and 520 K. In the working tem-

Table 4. Partial pressures [torr] and composition [%] of the vapour phase of $[Ni(salen)Y(hfa)_3]$ at 420 and 520 K

T [K]	$[Ni(salen)Y(hfa)_3]$		Ni(salen)		$Y(hfa)_3$	
420	78%	$1.2\cdot10^{-5}$	11%	$1.7\cdot10^{-6}$	11%	$1.7\cdot10^{-6}$
520	54%	$1.4\cdot10^{-1}$	23%	$6.0\cdot10^{-2}$	23%	$6.0\cdot10^{-2}$

perature range of the present study (420−471 K), the vapour phase over solid [Ni(salen)Y(hfa)$_3$] contains [Ni(salen)-Y(hfa)$_3$] molecules as its main species. However, the partial pressures of the dissociation products, Y(hfa)$_3$ and Ni-(salen), increase rapidly with temperature.

Comparison with [Cu(saloph)Y(hfa)$_3$]: The solid-state structure of [Ni(salen)Ln(hfa)$_3$] shows that part of intermolecular forces to be overcome for vaporization originates with non bonded contacts between Ni(salen) moieties in the pseudo dimers (Figure 1). To discuss this point, it is interesting to make a comparison with [Cu(saloph)Y(hfa)$_3$]. This compound has a structure[13] closely related to the one of [Ni(salen)Gd(hfa)$_3$], but proved less volatile[17]. The *saloph* ligand possesses one more peripheral phenyl ring than *salen*. Like [Ni(salen)Gd(hfa)$_3$], [Cu(saloph)Y(hfa)$_3$] molecules form dimers in which the Cu(saloph) entities overlap. The presence of an extra phenyl ring results in a different overlapping scheme as shown in Figure 2. The molecules are centrosymmetrically related so that the overlapping entities have their mean planes strictly parallel, which is not the case for [Ni(salen)Gd(hfa)$_3$]. The interplanar distance is equal to 3.149(1) A, that is 0.20 A shorter than for the Ni(salen). However, to be more correct it should be noticed that in [Ni(salen)Gd(hfa)$_3$], the phenyl rings are involved in the overlapping scheme, which is not the case for [Cu(saloph)Y(hfa)$_3$]. In this compound, only the three cycles comprising the metal atom overlap while the peripheral phenyl cycles do not. The plane-to-plane distance for the overlapping parts is equal to 3.291(1) A. This is still shorter (by 0.06 A) than for [Ni(salen)Gd(hfa)$_3$]. This shortening most likely results from slightly stronger intermolecular interactions in the *saloph* derivative with respect to the *salen* one. These interactions are all the more efficient that the planes are strictly parallel. They mainly account for the lesser volatility of [Cu(saloph)Y(hfa)$_3$]. Van der Waals contacts between fluorine atoms are very similar in both compounds (Table 1).

Conclusion

[Ni(salen)Ln(hfa)$_3$], which results from the coordination of Ni(salen) to Ln(hfa)$_3$, has proved to sublime congruently. In the working temperature range of this study (420−471 K), the vapour phase contains [Ni(salen)Y(hfa)$_3$] molecules as its main species. At higher temperature, dissociation of gaseous [Ni(salen)Y(hfa)$_3$] into Y(hfa)$_3$ and Ni(salen) increases rapidly with temperature. Therefore, dissociation might play a more or less important role in a MOCVD experiment depending on substrate temperature. It could influence the process of deposition, and it has to be taken into account for a practical use of [Ni(salen)Y(hfa)$_3$] and related complexes in a MOCVD process.

MOCVD experiments are in progress. Since substitution of copper for nickel and/or of one lanthanide for an other one does not change the crystal structure, this kind of complex is expected to be precursors of materials containing both Ni or Cu and Y or a lanthanide element.

Examination of the crystal structure clearly suggests to modify the ligand around Ni in order to prevent dimerization hence increase volatility. This is under current investigation. Complexes of formula [(Ni$_{1-y}$Cu$_y$)(salen)-(Ln$_{1-x}$Ln′$_x$)(hfa)$_3$], which would allow transportation of more than two metal elements in the vapour phase, are being studied too.

Experimental Section

Preparation and Characterization of the Complexes [Ni(salen)Ln(hfa)$_3$], [M = Y (1) and Gd (2)]: Ni(salen) was prepared according to a literature method[18]. For Ln(hfa)$_3$(H$_2$O)$_2$ (Ln = Y, Gd), a procedure adapted from the one described in ref.[19] was used. Elemental analyses (C, H, N) were carried out by the Microanalytical Service of the Universidad Autonoma de Madrid (Spain). IR spectra were taken on a Perkin-Elmer 1750 FTIR spectrophotometer for KBr disks in the 4000−300 cm^{-1} region. Magnetic susceptibility measurements of polycrystalline samples at room temperature were performed with a pendulum-type susceptometer.

Compounds **1** and **2** were synthesized by reaction of Ni(salen) with Ln(hfa)$_3$(H$_2$O)$_2$ in chloroform. A typical preparation is as follows: 0.5 mmol of Ln(hfa)$_3$(H$_2$O)$_2$ dissolved in a minimum amount of chloroform was slowly added under continuous stirring to a hot chloroform solution (50 ml) containing 0.5 mmol of Ni(salen). The orange solution was heated under reflux for 1 hr. Slow evaporation of the resulting solution in a refrigerator yields orange single crystals. − $C_{31}H_{17}F_{18}N_2NiO_8Y$ (**1**) (1035.1): calcd. C 35.93, H 1.65, N 2.70; found C 36.10, H 1.51, N 2.69. − $C_{31}H_{17}F_{18}GdN_2NiO_8$ (**2**) (1103.4): calcd. C 33.59, H 1.54, N 2.53; found C 33.60, H 1.47, N 2.87.

Compound **1** was found diamagnetic whereas a C_MT value (X_M = molar magnetic susceptibility) of 7.90 cm^{3}mol^{-1}K was measured for compound **2** at room temperature. This is consistent with the occurrence of diamagnetic Ni(salen) with a diamagnetic Y^{III} containing unit in **1** and a paramagnetic Gd^{III} containing unit in **2**. IR data for **1** and **2** clearly support the coordination of Ni-(salen) to Ln(hfa)$_3$: shifting towards higher wavenumbers of the C=N stretching vibration and out-of-plane aromatic C−H bend of the *salen* ligand (1622 and 736 cm^{-1} for Ni(salen) to be compared with 1630 and 760 cm^{-1} for **1** and **2**) as well as a splitting of the C=O stretching vibration of the *hfa* ligand (a strong sharp peak at 1647 cm^{-1} for Ln(hfa)$_3$(H$_2$O)$_2$, but two strong sharp peaks at 1663 and 1645 cm^{-1} for **1** and **2**).

X-ray Structure Studies: Gadolinium, ytterbium, and yttrium derivatives of the series [Ni(salen)Ln(hfa)$_3$] were shown to be isomorphous by measuring unit-cell constants from single crystals mounted on an Enraf-Nonius CAD4 diffractometer using Mo-*K*α radiation. The structure of [Ni(salen)Gd(hfa)$_3$] was determined from a single crystal mounted on a Stoe Imaging Plate Diffraction System (IPDS). The structure of [Cu(saloph)Y(hfa)$_3$] was determined from a single crystal mounted on an Enraf-Nonius CAD4 diffractometer. Experimental conditions and structure determinations are reported elsewhere[13].

Thermal Analyses: Samples of [Ni(salen)Y(hfa)$_3$] were submitted to thermal analyses. Thermogravimetric and differential thermogravimetric analyses at the atmospheric pressure were performed in a nitrogen stream, at a heating rate of 5°/min, on a 1500-Q MOM derivatograph. Thermogravimetric and differential thermal analyses under vacuum (0.01 torr) were carried out on a Sinuki-Riko TGD-700 thermal analyzer, at a heating rate of 10°/min. Iso-

thermal dynamic sublimation experiments were run with samples (100 mg) placed in glass test tubes for periods of 30 min. at a pressure of 0.01 torr. Weight losses were determined by gravimetric and complexometric analyses.

Mass Spectrometry and Study of the Vapour Phase: The mass spectra of [Ni(salen)Y(hfa)$_3$], Y(hfa)$_3$, and Ni(salen) were recorded on a MS 1301 spectrometer having a 50−1500 amu mass range, and using 80 eV ionizing electrons. The complexes were vaporized from a Knudsen effusion cell. The ratio of surface of evaporation to surface of the effusion hole was about 600. The cell temperature was measured with a Pt/Pt(Rh) thermocouple (±0.1 K). The experiments were carried out in ranges 312−365 K for Y(hfa)$_3$, 459−545 K for Ni(salen) and 420−471 K for [Ni(salen)Y(hfa)$_3$]. The main molecular ion peaks in mass spectra of Y(hfa)$_3$, Ni(salen), and [Ni(salen)Y(hfa)$_3$] are given in Table 2.

Vapour pressures versus temperature were determined by means of isothermal vaporization experiments and use of the Herz-Knudsen equation. Enthalpies of sublimation were calculated from the temperature dependences of ion current intensities by using Clausius-Clapeyron equation and a least-squares method.

A two-temperature Knudsen cell was used to determine the composition of overheated unsaturated vapour of [Ni(salen)Y(hfa)$_3$]. The saturated vapour was passed from the lower part of a double Knudsen cell to the top part. The temperature of the top part was varied from 487 to 581 K.

Crystallographic data (excluding the structure factor tables) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication CCDC-101159. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [Fax (internat): +44(0)1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Keywords: Hydrogen bonds / Indium / Lithium / Nitrogen heterocycles / Zinc

The lithiation of 2,5-di(*tert*-butyl)pyrrole (**1**) yields bis(tetrahydrofuran)lithium 2,5-di(*tert*-butyl)pyrrolide (**2**), which is monomeric in solution as well as in the solid state. Due to the coordination number of three for the lithium atom, short Li–O and Li–N bond lengths of 193 pm are observed. The metathesis reaction of **2** with tris(trimethylsilyl)-methylzinc chloride (**3**) gives colorless bis[tris(trimethylsilyl)methylzinc] chloride 2,5-di(*tert*-butyl)pyrrolide (**4**). The pyrrolide ligand and the chlorine atom bridge the zinc atoms. One of the zinc atoms is bonded to the nitrogen atom of the pyrrolide substituent, while the other bonds to the opposite C–C bond. At 215 pm, the Zn–N bond is very long compared to those in alkylzinc amides, whereas the Zn–C distances lie in the range of Zn–C bond lengths found between zinc and η^5-bonded cyclopentadienide ligands. The molecular structures of **1** and of the low-melting THF adduct **1**·thf show a similar 2,5-di(*tert*-butyl)pyrrole molecule, but in the latter case a weak N–H···O bond is observed (N–H 97 pm, O···H 199 pm).

The pyrrolide substituent $[NC_4H_4]^-$ is isoelectronic with the cyclopentadienide anion, and since it possesses 6π electrons can be regarded as a Hückel aromatic system. In contrast to this (formal) analogy of these ligands, the substitution of a cyclopentadienide ligand of the well-known ferrocene by a pyrrolide substituent to yield an azaferrocene was first reported in 1963.[1] The significantly lower tendency of the $NC_4H_4^-$ anion to coordinate as a π ligand and the enhanced tendency to form M−N σ bonds is a consequence of the high electronegativity of the heteroatom. On the other hand, the bonding properties depend on the substitution pattern on the pyrrolide ring. In 2,2′,5,5′-tetramethyl-1,1′-diazaplumbocene, η^1 bonding to the 2,5-dimethylpyrrolide is observed,[2] whereas the corresponding 2,5-di-*tert*-butyl-substituted pyrrolide crystallizes with an η^5-bonded ring.[3] In contrast to these findings, the group-13 metals (boron group, triels) form derivatives of the type $Me_2M^{III}NC_4H_{4-x}R_x$ with σ(M−N) bonds (η^1 coordination), although in the solid state the M^{III} metal centers are also bonded to the π-system of a pyrrolide ligand of a neighboring molecule, thus forming π associates.[4]

Here, we describe three different coordination modes of the 2,5-di(*tert*-butyl)pyrrolide anion Pyr*$^-$. This ligand forms Li−N σ bonds, but the reaction of LiPyr* with InCl[5] yields the indium(I) derivative with a η^5-bonded Pyr* anion. The unusual bridging mode is found to be adopted in bis[tris(trimethylsilyl)methylzinc] chloride 2,5-di(*tert*-butyl)pyrrolide. For the sake of comparison, the molecular structures of 2,5-di(*tert*-butyl)pyrrole and of its tetrahydrofuran complex are also included.

Results

Preparation

The starting material 2,5-di(*tert*-butyl)pyrrole[6] (H−Pyr*, **1**), which crystallizes from a concentrated tetrahydrofuran solution as a THF solvate (**1**·thf), has been well known for more than 30 years. With *n*-butyllithium, **1** is lithiated according to eq. 1 to give quantitatively bis(tetrahydrofuran-*O*)lithium 2,5-di(*tert*-butyl)pyrrolide (**2**).

$$\underset{\mathbf{1}}{\text{HPyr*}} + n\text{BuLi} \rightarrow \underset{\mathbf{2}}{\text{Li–Pyr*}} + n\text{BuH} \quad (1)$$

Meanwhile, the reaction of lithium tris(trimethylsilyl)-methanide with anhydrous $ZnCl_2$ yields $[(thf)_4Li][(Me_3Si)_3$-

[+] X-ray structure analysis.

$CZn]_2(\mu\text{-}Cl)_3$. In order to obtain a product free from lithium halide and THF, tris(trimethylsilyl)methylzinc chloride (**3**) was purified by sublimation. Reactions of **3** with alkyl- and phenyllithium compounds yield the heteroleptic compounds $(Me_3Si)_3C-Zn-R$, which have in part been characterized by X-ray crystallography.[7] All these derivatives are monomeric and contain solely σ(Zn−C) bonds. The metathesis reaction of **3** with $(thf)_2$LiPyr* (**2**) (eq. 2) yields bis[tris(trimethylsilyl)methylzinc] chloride 2,5-di(*tert*-butyl)pyrrolide (**4**) as a colorless and moisture-sensitive solid with a melting point of 74−75°C.

$$\underset{\mathbf{3}}{2\,(Me_3Si)_3C\text{–}ZnCl} + \underset{\mathbf{2}}{Li\text{–}Pyr^*} \rightarrow \underset{\mathbf{4}}{[(Me_3Si)_3C\text{–}Zn]_2(\mu\text{-}Cl)(\mu\text{-}Pyr^*)} + LiCl \qquad (2)$$

The stoichiometry of this metathesis reaction obeys a 2:1 ratio, irrespective of the molar ratio of the reactants. Stirring or refluxing of a 1:1 mixture of the starting materials does not lead to the formation of a halogen-free derivative, as is known for the metathesis reactions with lithium alkanides.[7] The cryoscopically determined molecular mass of **4** is consistent with the proposed structure shown in eq. 2. Dissociation into **3** and mononuclear, heteroleptic tris(trimethylsilyl)methylzinc 2,5-di(*tert*-butyl)pyrrolide does not occur under these conditions.

Indium(I) chloride reacts with lithiated 2,5-dimethyl-, 2,3,4,5-tetramethyl- as well as 2,5-di-*tert*-butylpyrrole in toluene, hexane, or tetrahydrofuran at low temperatures. However, the expected products of the methyl-substituted species are not isolable, since decomposition occurs even at temperatures of −90°C and −30°C, respectively, and precipitation of indium metal is observed. In contrast to this instability, indium(I) 2,5-di(*tert*-butyl)pyrrolide $In^I[Pyr^*]$ (**5**), which forms in tetrahydrofuran at low temperatures according to eq. 3, can be isolated and purified by distillation or sublimation in vacuo. During the melting of **5** at 77−78°C, the compound turns grey. The volatility of In[Pyr*] (**5**) is comparable to that of hexameric (pentamethylcyclopentadienyl)indium [pentamethylindocene(I)].[8] The sensitivities of these compounds towards oxygen are also similar, since In[Pyr*] (**5**) decomposes immediately with precipitation of metallic indium.

$$\underset{\mathbf{2}}{InCl} + \underset{}{Li\text{–}Pyr^*} \rightarrow \underset{\mathbf{5}}{In[Pyr^*]} + LiCl \qquad (3)$$

Molecular Structures

For comparison purposes, the molecular structure of HPyr* (**1**) is briefly described. Suitable single crystals form during the sublimation of **1** at 35°C in vacuo. The molecular structure is shown in Figure 1. The asymmetric unit contains three crystallographically independent molecules, which are distinguished by the first digit n = 1, 2 and 3 following the element symbol. The delocalization within the five-membered ring is disturbed, as is evident from the bond lengths of 137 pm for C(n1)−C(n2) and C(n3)−C(n4), and the value of 142 pm for C(n2)−C(n3). The bond lengths N(n)−H(n) fall in the narrow range from 83 to 91 pm.

The molecular structure of the tetrahydrofuran complex **1**·thf is depicted in Figure 2. This adduct shows a crystallographically imposed C_{2v} symmetry. The bond lengths in the pyrrole ring are not affected by coordination of a tetrahydrofuran molecule to the N1−H1 group. Even the N1−H1 distance of 97 pm differs only by 3 times the esd. On the other hand, the O2···H1 contact of 199 pm is quite long (cf. the O−H distances in ice, which vary between 99 and 176 pm). This weak interaction explains the low melting point of **1**·thf (below 0°C).

The molecular structure of lithium 2,5-di(*tert*-butyl)pyrrolide (**2**) is shown in Figure 3. To date, only one related molecule has been described in the literature, namely an *N*-lithiocarbazole dimer. Compound **2** crystallizes as a monomer due to the steric shielding of the lithium atom by the *tert*-butyl groups. The lithium atom is in a trigonal-planar coordination sphere, with a short Li−N bond length of 193 pm. The low coordination number of the alkali metal is also the reason for the short Li−O distances of 193 pm. In comparison to **1**, the endocyclic C−C bond lengths in the pyrrolide ligand of **2** are 138 and 140 pm for C1−C2 and C2−C2′, respectively, and are therefore very similar.

The molecular structure of **4** is depicted in Figure 4. The molecule contains a crystallographic mirror plane, although this symmetry element does not indicate the molecular symmetry, but rather leads to a two-site disorder of the 2,5-di(*tert*-butyl)pyrrolide ligand. However, only one orientation is shown in Figure 4. The atoms generated by the crystallographic mirror plane are marked with apostrophes. The two zinc atoms of the isomer shown in Figure 4 are in different environments; Zn has a coordination number of four, whereas Zn′ is threefold coordinated by the atoms C1′, Cl and N2.

The chlorine atom bridges the two zinc atoms with Zn−Cl bond lengths of 241 pm and a Zn−Cl−Zn′ bond angle of 110.3°. Terminal Zn−Cl bond lengths, as for example in $(bpy)ZnCl_2$[10] or (tmeda)Zn(Cl)R[11] are typically around 225 pm, and similar values are observed for various zinc(II) chloride modifications.[12] The Zn−Cl distances in dimeric $(Me_2PhSi)_3C-Zn-Cl$[13] as well as in dimeric $F_3C-CCl_2-Zn(OEt_2)Cl$[14] are distinctly shorter (average 233 pm) than those in **4**. Moreover, the endocyclic Zn−Cl−Zn angle is approximately 18° smaller than the corresponding angle in **4**. This distortion of the $(RZn)_2Cl$ moiety is due to the 2,5-di-*tert*-butylpyrrolide ligand, which also bridges the two zinc atoms. The planes Cl/Zn/Zn′ and N2/C21/C22/C23/C24 are oriented almost perpendicular to one another, with an angle between their normals of 93.5°.

Sterically uncrowded cyclopentadienyl complexes of zinc tend to form polymers. Whereas methyl(cyclopentadienyl)zinc is monomeric in the gaseous phase, it polymerizes in the solid state to form a structure with bridging $C_5H_5^-$ ligands and the metal atoms on opposite sides of the aromatic rings.[15] Analogous behavior is observed for bis(cyclopentadienyl)zinc with a bridging and a terminal η^1-bonded ligand.[16] In the gas phase, monomeric decamethyl-

zincocene [bis(pentamethylcyclopentadienyl)zinc] has a structure of the type $(\eta^1\text{-}C_5Me_5)(\eta^5\text{-}C_5Me_5)Zn$.[17] The pyrrolide substituent in **3** is planar and shows a different coordination behavior. Both the zinc atoms coordinate at the same side of the ligand, but one zinc atom bonds via a σ(Zn−N2) bond whereas the other metal center shows an η^2 coordination to the C22−C23 bond. The Zn−N2 bond length of 215 pm is very long compared to the values in [tris(trimethylsilyl)methyl]zinc bis(trimethylsilyl)amide[11] (185 pm), in monomeric zinc bis(amides)[18] (characteristic value 182 pm), or even in bridging μ-bonded bis(trimethylsilyl)amide substituents, where Zn−N distances of approximately 200 pm are found.[19] The Zn−N2 vector shows a deviation of 40.6° from an imaginary in-plane vector; the

A

N2-bonded zinc atom lies 143 pm above the calculated plane containing the atoms N2, C21, C22, C23, and C24.

The Zn−C22 and Zn−C23 distances of 219.0 and 219.4 pm fall within the broad range of values found for multihapto-bonded cyclopentadienide ligands. The chain-like zincocene[16] has Zn−C bond lengths between 204 and 241 pm, whereas in the zig-zag chain of methylzinc cyclopentadienide[15] Zn−C distances of 222 to 241 pm are observed. In both these molecules, the cyclopentadienide substituents bridge zinc atoms on opposite sides of the aromatic ring. Monomeric zincocenes such as decamethyl-, 1,1′-diphenyl- and 1,1′-bis(trimethylsilyl)zincocene[17] display one η^1-bonded (Zn−C 204−209 pm) and one η^5-coordinated cyclopentadienide ligand (217−230 pm). A similar bonding situation as in **4** is observed for dizinc tris(cyclopentadienide) bis(trimethylsilyl)amide (**A**)[19b] (Scheme 1), although the bridging ligand in this case is doubly η^1-coordinated; the third Zn−C distance of 250 pm is clearly too long to be considered as a bond.

The bridging mode of the ligand Pyr* is not very common, however, there are some other examples.[20] To the σ-bonded nitrogen heterocycles of tricarbonyl(diphenylacetato)manganese dipyrrolide a tricarbonylmanganese fragment is bonded side-on.[20a] Dicarbonylrhodium 2,5-dimethylpyrrolide dimerizes via an unsymmetric heterocycle bridge.[20b] The bridging mode of the pyrrolide anion in this molecule is quite similar to the geometry observed for **4** since the rhodium atoms do not lie above the center of the NC_5 cycle. Solvent-free sodium tetramethylpyrrolide crystallizes as a polymer with a similar bridging pattern of the pyrrolide substituent.[20d] Kuhn et al.[20c] linked two octamethyl-1,1′-diazaferrocene molecules via silver cations σ-bonded to the nitrogen atoms.

The Zn−C1 bond length in **4** exceeds the Zn−C bond lengths in [tris(trimethylsilyl)methyl]zinc derivatives $(Me_3Si)_3C-Zn-R$ with R as phenyl[7] (196 pm), bis(trimethylsilyl)methyl[7] (197 pm), and tris(trimethylsilyl)methyl[7][21] (198 pm); Zn−C bond lengths of sterically unstrained molecules are even shorter. All these findings are indicative of the steric strain within the molecule. The shielding of the $ClZn_2$ moiety by the bulky substituents, which is illustrated in Figure 5, accounts for the fact that this molecule cannot react with a further equivalent of lithium 2,5-di(*tert*-butyl)-pyrrolide (**2**).

Figure 5. Space-filling model of **4** viewed from the chlorine atom, showing the steric shielding of the Zn_2Cl fragment

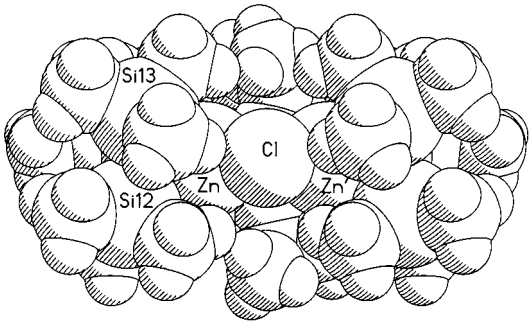

Figure 6 gives a stereoscopic view of the arrangement of **4**, together with the incorporated pentane. There are no significant intermolecular contacts; the pentane molecules lead to an additional separation of the molecules of **4**.

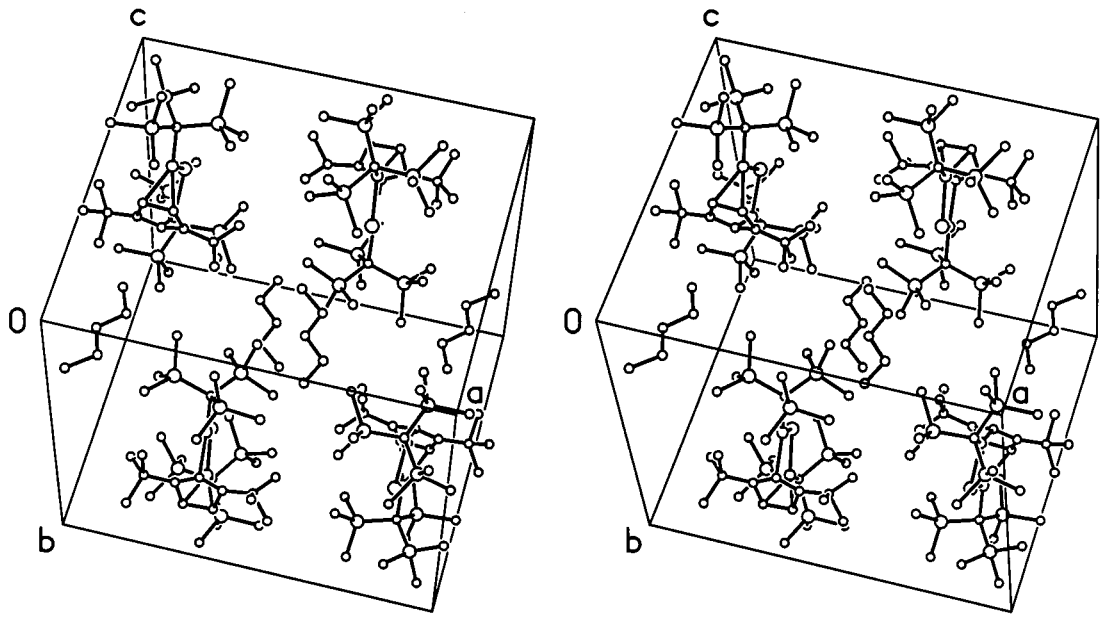
$Me_3Sn-Pyr^*$, the resonances of these nuclei are shifted to higher field by approximately 20 ppm.

Considering the molecular structure of the zinc derivative **2**, the magnetic equivalence of the tris(trimethylsilyl)methyl groups was not expected. However, the long distances between the zinc atoms and the pyrrolide substituent and the shape of the coordination gap allow a tilting motion, leading to a dynamic equilibrium through a Zn−N−Zn-bonded intermediate, in which the pyrrolide is rotated through approximately 90°. This situation is depicted in eq. 4.

The mass spectrum of **4** shows the dissociation products **3** and [tris(trimethylsilyl)methyl]zinc 2,5-di(*tert*-butyl)pyrrolide if the sample is heated above the melting point. At 425 K, the mass peaks of these compounds are the signals of highest intensity, besides that at *m/z* 179 for H−Pyr*. At 460 K, even fragments containing two zinc atoms and one chlorine atom are detected. Products of a dismutation reaction such as $Zn[C(SiMe_3)_3]_2$ or Cl−Zn−Pyr* were not observed.

Figure 6. Stereoscopic representation of the molecular packing of **4** in the unit cell; the atoms are drawn with arbitrary radii and H atoms are omitted for clarity; the *n*-pentane molecules were refined with a fixed population factor of 0.67; the disordering of the 2,5-di(*tert*-butyl)pyrrolide ligand is not shown



Spectroscopic Characterization

The NMR parameters of the 2,5-di-*tert*-butylpyrrolide ligands of **1**−**5** are compared in Table 1, along with data for $Me_2Ga-Pyr^*$,[2] $Me_3Sn-Pyr^*$,[2] $Sn^{II}[Pyr^*]_2$,[22] and $Pb^{II}[Pyr^*]_2$.[3] The coordination mode of Pyr* does not affect the NMR parameters of the *tert*-butyl groups. The influence of the hapticity of the pyrrolide ligand on the chemical shifts of the carbon atoms in the 2- and 5-positions is small, although η^5 coordination leads to a low-field shift of the ^{13}C resonances. The δ values of the carbon atoms in the 3- and 4-positions show no dependency on the coordination mode, except that in the case of the Sn^{IV} derivative

Due to the insensitivity of the NMR parameters to the hapticity of the Pyr* ligand, the characterization of the In^I derivative **5** is limited. In this case, the most significant results were obtained from Raman spectroscopy, although the In^I derivative **5** decomposes during laser irradiation. For σ(M−N)- and σ(H−N)-bonded derivatives such as H−Pyr*, $Me_2Ga-Pyr^*$, and $Me_3Sn-Pyr^*$, a characteristic polarized high-intensity band at approximately 1560 cm^{-1} is observed. For the compounds $In^I[Pyr^*]$ (**5**) and $Sn^{II}[Pyr^*]_2$, this band is shifted to lower energies, appearing in the region 1500−1510 cm^{-1}. On the other hand, other vibrations of the ring at lower frequencies are shifted to higher values [for example, 1124 (η^1) → 1165 (η^5) cm^{-1}],

Table 1. NMR parameters of the 2,5-di(*tert*-butyl)pyrrolide ligand in HPyr* (**1**), $(thf)_2LiPyr^*$ (**2**), $[(Me_3Si)_3CZn]_2(\mu\text{-}Cl)(\mu\text{-}Pyr^*)$ (**4**), and $In^I\{Pyr\}^*$ (**5**) compared with data for $Sn\{Pyr^*\}_2$[22], $Pb\{Pyr^*\}_2$[3], $Me_2Ga-Pyr^*$[2] and $Me_3Sn-Pyr^*$[2] (M{Pyr*} symbolizes an η^5-bonded, M−Pyr* a σ_N-bonded azacyclopentadienide moiety)

(4)

which has to be interpreted in terms of a change of the π-system of the nitrogen heterocycle. Characteristic for the In^I derivative **5** is the vibration In Pyr* at 170 cm^{-1}, which is lower in energy by 60 cm^{-1} compared to the In C_5 mode of the simple, unsubstituted indocene.[23]

Finally, it should be mentioned that theoretical investigations on a monomeric (hypothetical) 2,5-dimethylazaindocene $In^I(NC_4H_2Me_2\text{-}2,5)$ predict a very short distance of 238 pm between the indium atom and the heterocycle.[24] Such a bond length is only comparable with the values determined for the permethylated indocenes $In^I(C_5R_5)$.[8][25]

Conclusion

The diverse coordination modes adopted by the 2,5-di(*tert*-butyl)pyrrolide ligand have been illustrated by an η^5 coordination to an indium(I) atom as well as bridging between two zinc atoms. Whereas the properties of 2,5-di(*tert*-butyl)azaindocene (**5**) are approximately as one would expect by analogy with pentamethylindocene, the zinc derivative **4** shows a unique structure as well as surprisingly low reactivity. Not even treatment with excess lithium 2,5-di(*tert*-butyl)pyrrolide (**2**) leads to substitution of the chloride ligand by a pyrrolide anion. The reason for this lack of reactivity is the steric shielding of the central $ClZn_2$ moiety by two tris(trimethylsilyl)methyl and two *tert*-butyl groups. These demanding substituents also lead to an extension of the Zn−Cl, Zn−N and Zn−C distances.

This work has been generously supported by the *Deutsche Forschungsgemeinschaft* (DFG) and the *Fonds der Chemischen Industrie*.

Experimental Section

General: All experiments and manipulations were carried out under argon purified by passage through BTS catalyst and P_4O_{10}. Reactions were performed in dried, thoroughly deoxygenated solvents using standard Schlenk techniques. The starting materials 2,5-di(*tert*-butyl)pyrrole (**1**),[6] indium(I) chloride,[5] and [tris(trimethylsilyl)methyl]lithium[26] were prepared by literature procedures. The extreme sensitivity of **5** has thwarted all attempts to prove its purity by elemental analysis.

Bis(tetrahydrofuran-O)lithium 2,5-Di(tert-butyl)pyrrolide (**2**): At −78°C, a solution of *n*-butyllithium (15% in hexane, 9.4 ml) was added dropwise to a solution of 2,5-di(*tert*-butyl)pyrrole (2.70 g, 15.1 mmol) in 50 ml of *n*-hexane. On warming to room temp., a colorless solid precipitated, which was collected. Washing with two portions of *n*-hexane and subsequent drying in vacuo gave lithium 2,5-di(*tert*-butyl)pyrrolide (2.65 g, 14.3 mmol, 95%, dec. at 197°C; lithium analysis for $C_{12}H_{20}NLi$: calcd. 3.75; found 3.7). Carrying

out this reaction in a solvent mixture of diethyl ether and tetrahydrofuran yielded colorless **2** after recrystallization from tetrahydrofuran at −30°C (4.71 g, 14.3 mmol, 95%). Loss of THF at 60°C, m.p. of the residue 348°C. − ^{1}H NMR ([D$_8$]THF): δ = 5.59 [CH(Pyr*)], 1.22 [CMe$_3$(Pyr*)]. − ^{13}C NMR ([D$_8$]THF): δ = 146.72 [C-2,5(Pyr*)], 100.13 [dd, C-3,4(Pyr*), ^1J(C^{3,4}H) = 157.03 Hz, ^2J(C^{3,4}H^{4,3}) = 5.5 Hz], 33.47 (*C*Me$_3$), 32.77 (C*Me*$_3$). − ^{7}Li NMR ([D$_8$]THF): δ = 3.60. − IR (Nujol, CsBr): ν = 1584 cm^{-1} w, 1560 w, 1487 m, 1459 m, 1450 sh, 1392 w, 1388 m, 1381 w, 1348 s, 1299 m, 1265 w, 1248 s, 1200 s, 1139 w, 1051 sh, 1040 vs, 983 m, 954 sh, 949 w, 910 m, 886 s, 848 w, 822 w, 764 w, 732 vs, 713 vs, 674 w, 622 w, 574 m, 519 s, 515 sh, 429 m, 405 w, 337 w. − MS (70 eV, sample temp. 293 K); *m*/*z* (%): 185 (4) [LiPyr*$^+$], 179 (15) [HPyr*$^+$], 164 (83) [HPyr*$^+$ − Me], 149 (18) [HPyr*$^+$ − 2Me], 115 (73), 72 (100) [thf$^+$], 57 (21) [*t*Bu$^+$].

[Tris(trimethylsilyl)methyl]zinc Chloride (**3**): Tris(trimethylsilyl)-methane (8.47 g, 36.4 mmol) was dissolved in a mixture of tetrahydrofuran (45 ml) and diethyl ether (8.5 ml). At 0°C, a solution of methyllithium in diethyl ether (27.7 ml, 1.6 M, 44.3 mmol) was added. After stirring for 8 h at room temp., the solution was heated under reflux for an additional 6 h to destroy the remaining methyllithium. At room temp., anhydrous ZnCl$_2$ (4.96 g) was added in small portions and the mixture was stirred for 8 h. All volatile materials were then removed in vacuo and the residue was redissolved in diethyl ether. The insoluble part of the residue (LiCl) was filtered off, and the ethereal solution was dried and concentrated. The solid material was sublimed at 110°C in vacuo to afford LiCl-free **3** (3.1 g, 9.3 mmol, 26%), m.p. 211°C. − ^{1}H NMR ([D$_8$]THF): δ = 0.19. − ^{13}C NMR ([D$_8$]THF): δ = 6.38 [SiMe$_3$, ^1J(SiC) = 49.8 Hz]. − ^{29}Si NMR ([D$_8$]THF): δ = −2.75. − IR: ν = 1462 cm^{-1} m, 1377 m, 1262 s, 1250 s, 861 vs, 842 vs, 784 w, 725 w, 673 m, 661 m, 630 w, 614 w. − MS (70 eV, sample temp. 360 K, source temp. 470 K); *m*/*z* (%): 315 (12.8) [M$^+$ − Me], 201 (100) [C(SiMe$_3$)$_3^+$ − 2Me], 73 (27) [SiMe$_3^+$]. − C$_{10}$H$_{27}$ClSi$_3$Zn: calcd. C 36.13, H 8.19; found C 34.57, H 8.19.

Bis[tris(trimethylsilyl)methyl]zinc Chloride 2,5-Di(tert-butyl)-pyrrolide (**4**): At 0°C, a solution of *n*-butyllithium (2.5 M in hexane) was added dropwise to a solution of **1** (0.65 g, 3.62 mmol) in 20 ml diethyl ether, so as to give a colorless suspension of **2**. Sublimed **3** (2.4 g, 7.2 mmol), dissolved in 20 ml of diethyl ether, was then slowly added to this suspension. Once a clear solution had been obtained, all volatile materials were removed in vacuo. The residue was redissolved in *n*-pentane and insoluble LiCl was filtered off. At −20°C, colorless **4** co-crystallized with a stoichiometric amount of *n*-pentane (1.85 g, 2.1 mmol, 58%); dec. at 75°C. − ^{1}H NMR (C$_6$D$_6$): δ = 6.22 [CH(Pyr*)], 1.40 [CMe$_3$(Pyr*)], 0.32 [SiMe$_3$]. − ^{13}C NMR (C$_6$D$_6$): δ = 148.57 [C-2,5(Pyr*)], 104.60 [C-3,4(Pyr*)], 34.63 [C*Me*$_3$], 7.13 [SiMe$_3$]. − IR (Nujol, CsBr): ν = 1364 cm^{-1} m, 1349 m, 1283 m, 1259 vs, 1248 vs, 1207 m, 1154 w, 1148 sh, 1077 w, 1047 m, 1021 m, 982 w, 860 vs, 850 sh, 797 s, 782 s, 749 m, 723 m, 673 s, 660 s, 621 m, 550 w, 529 w, 471 m, 442 w, 362 w. − MS (70 eV, sample temp. 425 K, source temp. 460 K); *m*/*z* (%): 611 (4.5) {[(Me$_3$Si)$_3$CZn]$_2$Cl − CH$_2^+$}, 473 (49.5) [(Me$_3$Si)$_3$-CZnPyr*$^+$], 458 (7.9) [(Me$_3$Si)$_3$CZnPyr*$^+$ − Me], 315 (54.9) [(Me$_3$Si)$_3$CZnCl$^+$ − Me], 295 (17.3) [(Me$_3$Si)$_3$CZn$^+$], 216 (7.4) [(Me$_3$Si)$_3$C$^+$ − Me], 201 (30.5) [(Me$_3$Si)$_3$C$^+$ − 2Me], 179 (100) [HPyr*$^+$]. − MS (70 eV, sample temp. 460 K, source temp. 460 K); *m*/*z* (%): 626 (1.3) [M$^+$ − 2SiMe$_3$ − 2MeH], 611 (15.3) {[(Me$_3$Si)$_3$CZn]$_2$Cl − CH$_2^+$}, 593 (100) [M$^+$ − Me − 2SiMe$_3$ − CH$_2$], 315 (20.6) [(Me$_3$Si)$_3$CZnCl$^+$ − Me], 295 (98.1) [(Me$_3$Si)$_3$CZn$^+$], 216 (8.7) [(Me$_3$Si)$_3$C$^+$ − Me], 201 (23.3) [(Me$_3$Si)$_3$C$^+$ − 2Me]. − C$_{32}$H$_{74}$ClNSi$_6$Zn$_2$: calcd. C 47.58, H 9.24, N 1.73; found C 47.65, H 9.23, N 1.44.

Indium(I) 2,5-Di(tert-butyl)pyrrolide (**5**): As described above, a suspension of LiPyr* was prepared from HPyr* (2.7 g, 15 mmol) and a stoichiometric amount of *n*BuLi in 50 ml of THF. At −110°C, In$^{\mathrm{I}}$Cl powder (2.2 g, 14.6 mmol) was added. During warming to room temp., the orange color of InCl disappeared. Thereafter, the reaction mixture was stirred for an additional 10 h. The solution was then concentrated to a volume of approximately

[a] Definition of the *R* values: $R_1 = (\Sigma||F_o| - |F_c||)/\Sigma|F_o|$; $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$ with $w^{-1} = \sigma^2(F_o^2) + (aP)^2$. − [b] $s = \{\Sigma[w(F_o^2 - F_c^2)^2]/(N_o - N_p)\}^{1/2}$.

20 ml and the precipitated LiCl was filtered off. All volatiles were then removed in vacuo. Subsequent sublimation at 80°C and 5×10^{-3} Torr yielded a fraction of InPyr* still contaminated with traces of THF. A second sublimation gave colorless cuboids of InPyr* (4.5 mmol, 31%). These crystals were found to be composed of very thin plates and proved unsuitable for an X-ray structure determination. For NMR data, see Table 1; for discussion of relevant IR/Raman data, see text. – $C_{12}H_{20}NIn$ (293.12): calcd. In 39.17; found In 38.3 (complexometric titration), 38.9 (ICP).

X-ray Crystallographic Studies:[27] Suitable single crystals of **1**, **1**·thf, and **4** were covered with Nujol, mounted on a Siemens P4 diffractometer, and examined with graphite-monochromated Mo-K_α radiation (λ = 71.073 pm). For the collection of data sets for **1** and **1**·thf, the diffractometer was equipped with a Siemens SMART-CCD area detector. Due to its low melting point, compound **1**·thf was kept at temperatures below −30°C during handling and mounting on the diffractometer. For the data collection of **2**, a STOE-IPDS diffractometer was used. Crystallographic parameters and details of the data collection are summarized in Table 2.

All structures were solved by direct methods with the software package SHELXTL-Plus[29] and refined with the program SHELXL-93.[30] Neutral atom scattering factors were taken from Cromer and Mann[31] and for the hydrogen atoms from Stewart et al.[32] The non-hydrogen atoms were refined anisotropically. The H atoms of **1** and **1**·thf were refined as a riding model with restriction of ideal geometry at the corresponding carbon atoms, whereas the nitrogen-bonded hydrogen atoms were refined isotropically. The H atoms of **2** were refined group by group to a common C–H bond length while maintaining ideal geometry at the corresponding C atoms, whereas the azacyclopentadienide-bonded hydrogen atoms were refined isotropically. The hydrogen atoms of **4** were refined isotropically, with the exception of those of the *tert*-butyl groups and of the *n*-pentane molecule, which were calculated in ideal positions with a C–H distance of 96 pm. The *n*-pentane molecules located between the molecules of **4** (Figure 6) were considered to have an occupancy factor of 0.67.

Keywords: Fullerides / Crystal structure analysis / Jahn-Teller effect

The fullerides $[M(NH_3)_6]C_{60}$ ($M = Mn^{2+}$, Cd^{2+}) have been synthesized by ion exchange in liquid ammonia and analyzed by X-ray single-crystal diffraction. With both complex cations the C_{60}^{2-} units are in fixed orientations, and their geometries have been determined with good accuracy. An inspection of the fulleride dianions with respect to geometric deformations in the title compounds and three further independent determinations has led to the conclusion that no significant static Jahn-Teller distortion is present.

Introduction

Due to the high symmetry of icosahedral C_{60} its LUMO is triply degenerate (t_{1u}). In accordance with the Jahn-Teller theorem[1] partial filling of the LUMO with one to five electrons should remove this degeneracy and possibly cause a structural distortion in the carbon cage. The nature and the degree of this distortion, however, are difficult to determine experimentally since in most cases structure determinations suffer from orientational disorder of the almost spheric fullerides. Jahn-Teller distortion could reduce the symmetry to D_{5d}, D_{3d}, D_{2h}, C_{2h}, or C_i, all of which are subgroups of I_h. From linear approximation D_{5d} and D_{3d} structures have been derived as possible minima, and the D_{2h} structure as a saddle point of the associated potential energy surface[2]. For the monoanion C_{60}^- the relative energies of these configurations have been calculated as roughly equal[3]. Thus, rearrangement among different Jahn-Teller distorted structures on the potential energy surface would be an easy process. Density functional calculations[4] have yielded D_{2h} symmetry for the singlet and D_{3d} symmetry for the triplet ground state of the dianion C_{60}^{2-}. All theoretical approaches end up with the result that structural changes due to a Jahn-Teller splitting of the formerly degenerate t_{1u} LUMO should be very small. Only modest static Jahn-Teller energy gains of approximately 0.1 eV are predicted which fall in the range of typical vibrational frequencies. Thus, C_{60}^{2-} anions could well be subject to a dynamic exchange between several Jahn-Teller distorted structures[5][6][7]. In the superposition of, e.g., the six degenerate D_{5d} configurations the higher symmetry I_h would be restored. In order to be able to investigate the degree of distortion and to decide, whether those distortions are static or dynamic in nature, precise X-ray crystal structure data are desirable.

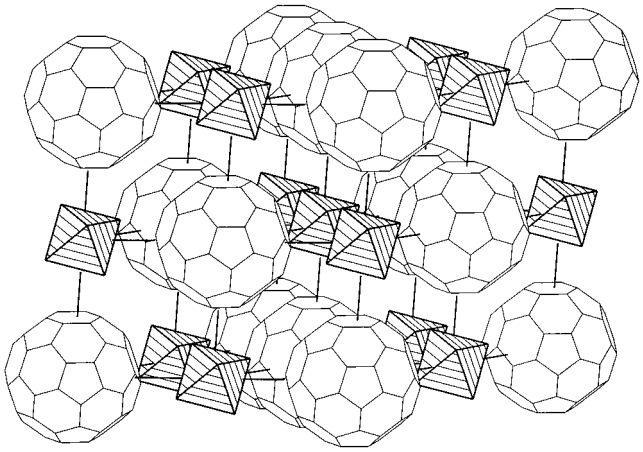
In our earlier work we have introduced bulky organic cations into the structure to stabilize fulleride anions in a fixed orientation[8][9]. Other groups have used different organic or organometallic cations, or cryptates of alkali metals[10][11][12][13][14]. Nevertheless, many of the structures still exhibit disorder in the anionic or cationic parts of the structure, thereby reducing the accuracy of the information gained from structure determinations. By the synthesis of $[Ba(NH_3)_7]C_{60} \cdot NH_3$[15] we have demonstrated that complex ammines are well suited to fix the orientation of the fulleride cages. More recently we have exemplified with the preparation of $[Ni(NH_3)_6]C_{60} \cdot 6\ NH_3$ that a broad variety of fulleride salts with different counterions is accessible by ion exchange in liquid ammonia[16]. Here we present the synthesis and characterization of two new fullerides, $[M(NH_3)_6]C_{60} \cdot 6\ NH_3$ ($M = Mn^{2+}$, Cd^{2+}). Both compounds are sufficiently well determined to allow for an inspection of geometrical distortions in the C_{60}^{2-} cage. The results are discussed with respect to the Jahn-Teller effect and compared to those obtained in the crystal-structure investigations of $[Ba(NH_3)_7]C_{60} \cdot NH_3$, $[Ni(NH_3)_6]C_{60} \cdot 6\ NH_3$ and $(PPN)_2C_{60}$ [PPN^+ = bis(triphenylphosphanyl)iminium cation][12].

Results and Discussion

Like isostructural $[Ni(NH_3)_6]C_{60} \cdot 6\ NH_3$ the title compounds crystallize in a distorted rock salt type of structure (Figure 1). The fulleride dianions form a distorted *fcc* sublattice where hexaammine complexes of the metal ions occupy the octahedral sites.

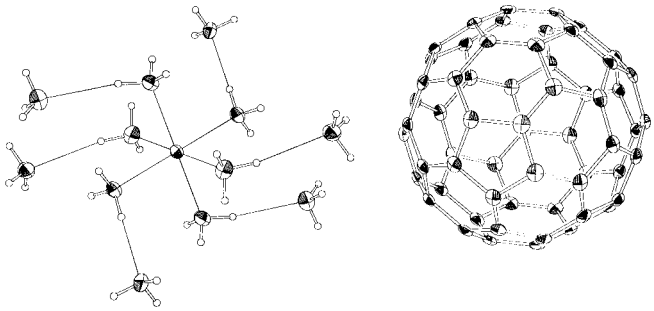
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434–1948/98/0808–1183 $ 17.50+.50/0

Figure 1. Rock salt type arrangement of fulleride anions and transition metal ammine complexes



Each molecule of ammonia of solvation is coordinated via a hydrogen bond to one of the ammonia molecules in the ligand sphere of the ammine complex. This extended coordination sphere (Figure 2) can change its shape flexibly to meet the needs of the octahedral site of the C_{60}^{2-} sublattice, at the same time absorbing differences in the size of the cations [$r(Ni^{2+})$ = 69 pm, $r(Mn^{2+})$ = 83 pm (high spin), $r(Cd^{2+})$ = 95 pm[17]] and fixing the orientation of the fulleride anion.

Figure 2. ORTEP plot[24] of the fulleride dianion in $[Mn(NH_3)_6]C_{60}\cdot 6\ NH_3$ (50% probability ellipsoids)



The obvious relationship between the structures presented here and the NaCl-type structure implies Coulomb interactions mainly to determine the crystal structure. However, the deviation from cubic symmetry indicates the presence of other forces which affect the structure at the same time. Short distances of hydrogen atoms to the fulleride carbon atoms suggest interactions between the $N^{\delta-}-H^{\delta+}$ dipoles and electron density on the surface of the dianion. The hydrogen atoms are located above the centres of the 6:6 and 6:5 ring junctures where the majority of π-electron density is located. Similar interactions between $C^{\delta-}-H^{\delta+}$ dipoles and fullerides have been reported previously and are assumed to be responsible for the stabilization of the dianion in a fixed orientation[12].

In all fullerides of complex ammoniates thermal displacement parameters of the carbon atoms are physically reasonable and do not indicate any static or rotational disorder. Thus, the structures seem to be of sufficient accuracy to allow for an inspection of geometric distortions of C_{60}^{2-}, e.g. of Jahn-Teller type. In an earlier investigation of $(PPN)_2C_{60}$ [PPN^+ = bis(triphenylphosphanyl)iminium cation][12] such distortions have been reported to be present. The authors have observed a change in point symmetry of the fullerene moiety from I_h to C_i and have interpreted this distortion as due principally to the Jahn-Teller effect.

For an evaluation of the degree of ellipsoidal distortion from the ideal sphere we have considered the longest and shortest carbon-to-carbon diameters. In Table 1 such diameters of the title compounds, of $[Ni(NH_3)_6]C_{60}\cdot 6\ NH_3$, $[Ba(NH_3)_7]C_{60}\cdot NH_3$, $(PPN)_2C_{60}$, and of neutral C_{60} as determined in two different investigations[18][19] are given. The variation in diameters is largest for $(PPN)_2C_{60}$ and very small for $[Ba(NH_3)_7]C_{60}\cdot NH_3$, while all other compounds fall in between. Remarkably, even in the most reliable determinations neutral C_{60} exhibits a small deviation from the ideal shape of a sphere.

In order to reveal any particular pattern in the arrangement of atoms with an elongated or shortened radial distance to the centre of the fullerene cage, the distances between the carbon atoms and the centre of the fulleride dianion have been calculated with the program package PARST97[20]. The calculations were based on the lattice parameters, the atom coordinates and their respective standard deviations as determined in the different crystal-structure analyses.

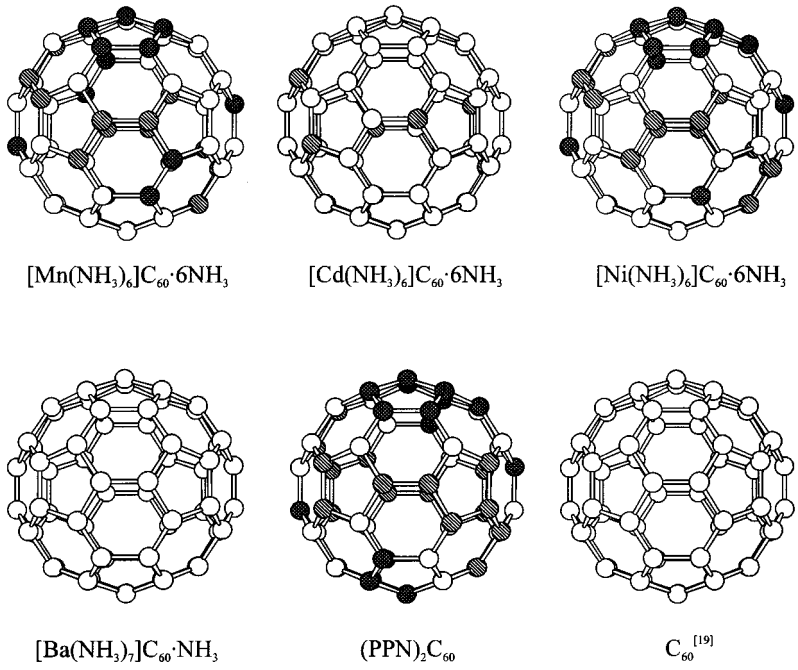
For each fulleride the individual distances (d_i) of the carbon atoms from the centre have been compared to the mean radius r. All differences $d_i - r$ that are larger than three times the standard deviation of the individual radial distances have been treated as significant.

The results of the calculations are visualized in Figure 3. For the fulleride moieties in the different crystal structure analyses those atoms with a significantly elongated radial distance to the centre are plotted with a crossed hatching, those with a shortened radial distance are plotted with a simple hatching.

Three of the triclinic structures {$[Mn(NH_3)_6]C_{60}\cdot 6\ NH_3$, $[Ni(NH_3)_6]C_{60}\cdot 6\ NH_3$, and $(PPN)_2C_{60}$} seem to exhibit similarities in the pattern. Elongated atoms form a closed pentagon, suggesting a symmetry reduction to D_{5d} which has been discussed previously[7] as the most probable distortion caused by the Jahn-Teller effect. However, the elongations discussed here are as small as 0.01 A and in addition to experimental error might be caused by crystal packing effects. As some of the dianions, e.g. in $[Ba(NH_3)_7]C_{60}\cdot NH_3$, are not significantly distorted at all, the present experimental data give no conclusive evidence for an intrinsic distortion of C_{60}^{2-} due to a static Jahn Teller effect.

In order to check our approach, the deviation from ideal I_h symmetry was determined using a procedure which has been described previously[4]: First, the dianion was oriented in a fixed Cartesian frame, with x, y, and z directions coinciding with C_2 symmetry axes. For each atom, the Cartesian displacements from the icosahedral position (i.e., from the position of that atom in a C_{60} cage of I_h symmetry

Figure 3. Geometry of fulleride anions as determined in different crystal structure analyses; atoms with an elongated distance to the centre are plotted with a cross-hatched pattern, those with a shortened distance relative to the mean radius are plotted as hatched spheres



with the same average single and double bond lengths as found for the anion) were calculated and the root mean squares (r.m.s.) value for the distances between corresponding atoms was determined. To put these values into an appropriate context we have applied the same formalism to neutral C_{60} and have included the results in Table 1.

as a result of experimental error, even at very favourable experimental conditions.

The considerations presented here have led us to the conclusion that at the present state of knowledge there is no experimental evidence for a static deviation from icosahedral symmetry of the dianion C_{60}^{2-}. As an alternative a dynamic Jahn-Teller effect could be discussed. The related "breathing" movement of the fullerene cage should lead to enlarged thermal parameters of the carbon atoms in radial direction with respect to the centre of the fulleride. However, the thermal displacement parameters as determined reflect the rigid body librational motion of the fulleride rather well and do not show any significant enlargement in radial direction (Figure 2). Thus, the amplitudes of vibrations caused by a dynamic Jahn-Teller effect must be smaller than or equal to the thermal displacement parameters in radial direction, as determined by X-ray crystal-

Table 1. Geometry of the fullerides: largest and shortest carbon-to-carbon distances ($Ø_{max.}$, $Ø_{min.}$) and their difference ΔØ are given; r.m.s values were calculated as described in the text

Compound	$Ø_{max.}$ [A]	$Ø_{min.}$ [A]	ΔØ [A]	r.m.s. value [A]
$[Ni(NH_3)_6]C_{60}\cdot 6\ NH_3$ (triclinic)	7.1106 (C13−C13′)	7.0408 (C16−C16′)	0.0698	0.0118
$[Mn(NH_3)_6]C_{60}\cdot 6\ NH_3$ (triclinic)	7.1132 (C4−C4′)	7.0484 (C9−C9′)	0.0648	0.0110
$[Cd(NH_3)_6]C_{60}\cdot 6\ NH_3$ (triclinic)	7.1034 (C14−C14′)	7.0286 (C13−C13′)	0.0748	0.0144
$[Ba(NH_3)_7]C_{60}\cdot NH_3$ (trigonal)	7.0923 (C5−C10)	7.0781 (C3−C11)	0.0142	0.0075
$[PPN]_2C_{60}$ (triclinic)	7.1264 (C15−C15′)	7.0394 (C9−C9′)	0.087	0.0155
C_{60} (cubic)[19]	7.0926 (C8−C8′)	7.0678 (C2−C2′)	0.0248	0.031
C_{60} (cubic)[18]	7.112 (C8−C8′)	7.0824 (C4−C4′)	0.0296	0.0171

Again the dianion in $[Ba(NH_3)_7]C_{60}\cdot NH_3$ shows the smallest variation from ideal atom positions, while this time the deviation from I_h is strongest for neutral C_{60}. Even for $(PPN)_2C_{60}$, which has shown the greatest ellipsoidal distortion, the deviation from icosahedral atom positions is modest. Neutral C_{60} clearly can not be subject to a Jahn-Teller distortion. Thus, the observed deviations can only reflect experimental error and perhaps effects of crystal packing. Since in a crystalline environment not all symmetry elements of point group I_h can agree with a given site symmetry, small deviations from the ideal have to be expected

lography. Based on theoretical calculations only very small deviations from an ideal icosahedron have been predicted upon filling the formerly degenerate LUMO of neutral C_{60}. In this paper we present experimental evidence that in a crystalline environment I_h symmetry of anionic C_{60}^{2-} units can be retained. Any deviation found is in the range of or smaller than the experimental error.

We are grateful to *Hoechst AG*, Frankfurt, for providing C_{60}.

Experimental Section

$[M(NH_3)_6]C_{60}\cdot 6\ NH_3$ (M = Mn^{2+}, Cd^{2+}) has been synthesized by ion exchange in liquid ammonia. All reactions were carried out under dry argon, either in all-glass reaction and handling vessels that were dried in vacuo, or in a glove box. Liquid ammonia (Bayer AG, purity 2.8) was first distilled from sodium, then from potassium, and was stored as a potassium/ammonia solution at 195 K. Buckminsterfullerene C_{60} (Hoechst AG, gold grade) was dried before use for 12 h at 300°C in vacuo. A thoroughly dried exchange resin (Amberlyst 15, Fluka) was loaded with M^{2+} (M = Mn^{2+}, Cd^{2+}) and placed on one side of an H-type glass vessel equipped with a glass sieve (porosity 3). K_2C_{60} was placed on the other side of the sieve. After cooling (ethanol/dry-ice slush) ammonia was condensed into the vessel until the glass sieve was completely covered. The reaction mixture was stored at 230 K for about 3 weeks. During this period K_2C_{60} slowly diffused onto the ion-exchange resin where $[M(NH_3)_6]C_{60}\cdot 6\ NH_3$ precipitated as shiny black platelets that are sensitive to air, moisture and elevated temperatures. Crystals were transferred from liquid ammonia into a mixture of inert oils (1:1 Perfluorpolyether 216, Riedel-de Haen/Perfluorpolyether Fomblin Y HVAC 40/11, Aldrich) which was cooled with a nitrogen stream to 230 K, and picked up on the tip of a glass capillary mounted on a goniometer head[21].

Structure Determination: Diffraction data were collected with an Enraf-Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation (λ = 71.069 pm) at 113(2) K. The structures were solved by the Patterson method[22] and refined on F^2 using all independent reflections[23]. Hydrogen atoms of the ammonia molecules were located by difference Fourier synthesis. Details of the crystal structure determinations for $[M(NH_3)_6]C_{60}\cdot 6\ NH_3$ (M = Mn, Cd) are given in Table 2.

Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen, on quoting the depository numbers CSD-408601 (Mn) and -408602 (Cd).

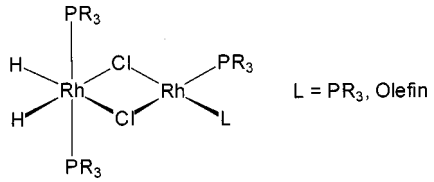
Keywords: Iridium / Rhodium / Chloro-bridged complexes / Heterobimetallic complexes

The synthesis and characterization of heterobimetallic and mixed-valence complexes in which orthometalated $[(ppy)_2MCl]$ (M = Rh, Ir; ppy = 2-phenylpyridine anion) and $[(bzq)_2RhCl]$ (bzq = benzo[*h*]quinoline anion) fragments are linked via chloro-bridges with rhodium(I), iridium(I), palladium(II), and platinum(II) fragments is reported. These complexes are formed in nearly quantitative yields by metathesis reactions from the respective homodimeric compounds. The structures of $[(ppy)_2Rh(\mu\text{-}Cl)_2Rh(cod)]$ (cod = η^4-1,5-cyclooctadiene) and $[(ppy)_2Rh(\mu\text{-}Cl)_2Pt(PBu_3)\text{-}Cl]$ were determined by X-ray structure analyses.

Introduction

Dichloro-bridged complexes of rhodium and iridium play an important role as starting materials in organometallic chemistry and catalysis. Subsequent functionalization of these complexes is easily possible through bridge-splitting reactions with various donor ligands.[1] Generally, the two metal fragments are symmetrically linked by halide ligands. Dinuclear complexes in which rhodium or iridium complexes are *asymmetrically joined* with a different transition metal fragment, on the other hand, are rare.[2][3][4][5][6][7] Among the more prominent examples are the mixed-valence hydrido complexes shown below. They are produced in catalytic hydrogenation[3] and dehydrogenation[4] reactions with rhodium(I) phosphine complexes. At present there is no general methodology available for the synthesis of such heterodimeric or mixed-valence complexes. Furthermore the reactivity of these compounds is virtually unexplored.



L = PR_3, Olefin

Here we describe the synthesis and characterization of new dinuclear, chloro-bridged complexes containing Rh^{III} or Ir^{III} fragments together with Rh^{I}, Ir^{I}, Pd^{II}, and Pt^{II} fragments. They are obtained by metathesis reactions of $[(cod)MCl]_2$ (M = Rh, Ir) or $[(R_3P)MCl_2]_2$ (M = Pd, Pt; R = Et, *n*-Bu) with the orthometalated Rh^{III} and Ir^{III} complexes $[(bzq)_2RhCl]_2$ or $[(ppy)_2MCl]_2$ (M = Rh, Ir). The latter compounds have found considerable attention since they are powerful photoreducing agents.[8][9]

Dinuclear Rh^{III}-Rh^{I}, Rh^{III}-Ir^{I}, and Ir^{III}-Ir^{I} Complexes

The dinuclear complexes **1**–**3** were obtained in nearly quatitative yield when a suspension of $[(ppy)_2MCl]_2$ (M = Rh, Ir) in dichloromethane was stirred with equivalent amounts of $[(cod)MCl]_2$ (M = Rh, Ir) (Scheme 1). Upon completion of the reactions clear yellow solutions were formed indicating a strongly enhanced solubility of the heterodimeric products with respect to the homodimeric Rh^{III} and Ir^{III} complexes. Yellow powders were obtained after removal of the solvent. Other Rh^{III}-Rh^{I} complexes containing Rh^{III} fragments with orthometalated ligands (e.g. the tridentate *o*,*o*′-$(Me_2NCH_2)C_6H_3$) were described by van Koten[5], Bruce[6], and Mills.[7]

Scheme 1

	M^1	M^2
1	Rh	Rh
2	Rh	Ir
3	Ir	Ir

1–**3**

The ^1H and ^{13}C NMR spectra ($CDCl_3$) of racemic **1**–**3** are in accordance with the structures shown in Scheme 1. For the two phenylpyridyl ligands one set of signals is observed. The ^1H NMR spectra of the cyclooctadiene ligand reflect the reduced symmetry of **1**–**3** as compared to $[(cod)MCl]_2$: the vinylic proton signals appear as two well separated groups at δ 3.8 and 4.0.

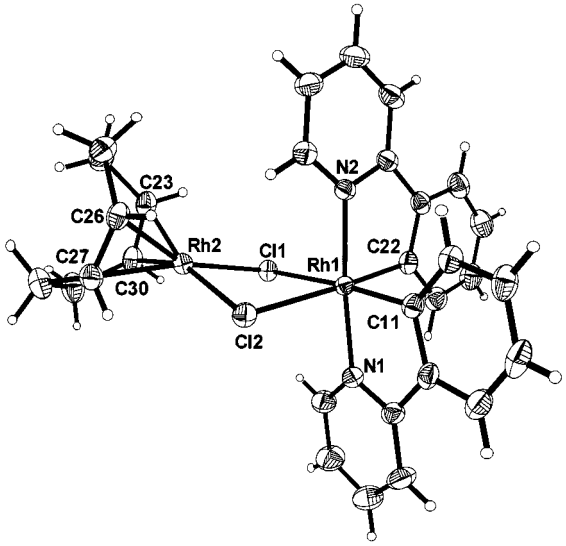
Minor amounts of starting material can be detected in the ^1H NMR spectra of **1**–**3** indicating a dynamic equilib-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1434–1948/98/0808–1187 $ 17.50+.50/0

rium between homo- and heterodimeric complexes (K_{eq} > 100). Similar equilibria were observed in solutions of $[(R_3P)PtCl_2]_2$ together with $[(R_3P)PdCl_2]_2$.[10] In these cases, however, the amount of heterodinuclear Pd-Pt complexes present in solution were close to what is expected for a statistical distribution. Quantitative formation of heterodimeric complexes, on the other hand, was also observed in reactions of $[(\eta^3{:}\eta^3\text{-}C_{10}H_{16})RuCl_2]_2$ with various chloro-bridged complexes.[11]

The molecular structure of **1** was confirmed by single crystal X-ray analysis (Figure 1). The Rh^{III} center is coordinated in a slightly distorted octahedral fashion with the two N-donor groups adopting a *trans* configuration. The Rh(μ-Cl)$_2$Rh unit is markedly non-planar with a dihedral angle between the normals to the planes defined by Rh1, Cl1, Cl2 and Rh2, Cl1, Cl2, of 24.14°. Folded Rh(μ-Cl)$_2$Rh units are also found for $[(CO)_2RhCl]_2$,[12] $[(PMe_2Ph)(CO)RhCl]_2$,[13] $[(C_6H_{10})_2RhCl]_2$,[14] $[(PhN{=}NC_6H_4)_2(CO)_2Rh_2]$,[7] $[(CO)_2(cod)Rh_2]$,[2a] and for **5** (Figure 2). According to a recent theoretical and structural analysis of square-planar complexes of the general formula $[L_2M(\mu\text{-}Cl)_2ML_2]$ the main driving force for bending are attractive metal−metal interactions[15] but for **1** direct Rh−Rh interactions are unlikely due to a Rh−Rh bond length of 3.60 A. The Rh2−Cl bond lengths are very close to that in the homodimeric complex $[(cod)RhCl]_2$.[16] Significantly longer are the Rh1−Cl bond lengths (2.55 and 2.57 A), presumably due to the strong σ-donor character of the coordinating carbons in *trans* position.

Figure 1. Molecular structure of complex **1**. Selected bond lengths [A] and angles [°]: Rh2−C26 2.104(4), Rh2−C27 2.120(4), Rh2−Cl2 2.407(1), Rh2−Cl1 2.410(2), Rh1−C11 1.980(4), Rh1−C22 1.982(4), Rh1−N2 2.046(3), Rh1−N1 2.043(4), Rh1−Cl1 2.553(1), Rh1−Cl2 2.569(2), N1−Rh1−Cl1 95.56(11), N1−Rh1−Cl2 86.42(11), Cl1−Rh1−Cl2 81.36(5), N1−Rh1−N2 174.66(14), Cl2−Rh2−Cl1 87.74(5)



Dinuclear Rh^{III}-Pd^{II}, Rh^{III}-Pt^{II}, and Ir^{III}-Pt^{II} Complexes

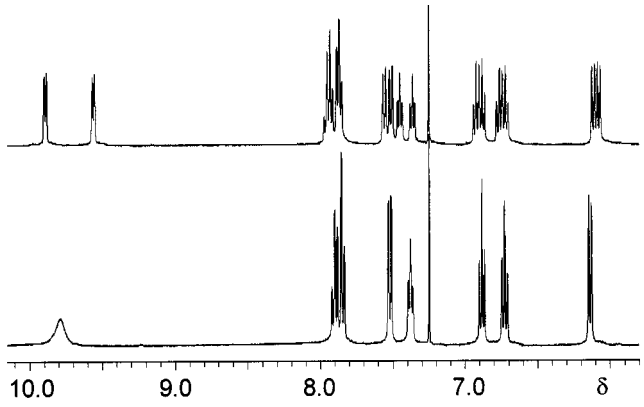
Similar as for **1**−**3** the heterobimetallic complexes **4**−**8** are obtained by metathesis reactions of $[(ppy)_2MCl]_2$ (M = Rh, Ir) with the respective chloro-bridged palladium or platinum phosphine complex (Scheme 2). The yields are quantitative for the platinum complexes **5**, **7**, and **8**. ^{1}H NMR spectra ($CDCl_3$) of the palladium complexes **4** and **6** show very small amounts of homodimeric starting material (K_{eq} > 100). The dynamic nature of these metathesis reactions as well as the higher stability of Rh^{III}-Pt^{II} complexes in comparison to the corresponding Rh^{III}-Pd^{II} complexes was confirmed by a direct competition experiment: if one equivalent of $[(ppy)_2Rh(\mu\text{-}Cl)_2Pd(PBu_3)Cl]_2$ (**4**) was mixed with 0.5 equivalents of $[(Bu_3P)PtCl_2]_2$ in dichloromethane the immediate formation of $[(ppy)_2Rh(\mu\text{-}Cl)_2Pt(PBu_3)Cl]_2$ (**5**) together with $[(Bu_3P)PdCl_2]_2$ was observed by ^{31}P NMR spectroscopy. The ratio between **5** and **4**, which was estimated by integration of the respective ^{31}P NMR signals, was 3:1.

Scheme 2

	M^1	R	M^2
4	Rh	Bu	Pd
5	Rh	Bu	Pt
6	Rh	Et	Pd
7	Ir	Bu	Pt
8	Ir	Et	Pt

The ^{1}H- and ^{13}C-NMR spectra ($CDCl_3$) of **4**−**6** are strongly temperature dependent. At temperatures below 250 K the phenylpyridyl ligands show two distinct sets of signals in accordance with the structure depicted in Scheme 2. At room temperature, however, only one set of signals can be observed (Figure 2).

Figure 2. Aromatic region of the ^{1}H NMR spectra of complex **5** at 233 K (top) and at 328 K (bottom) in $CDCl_3$

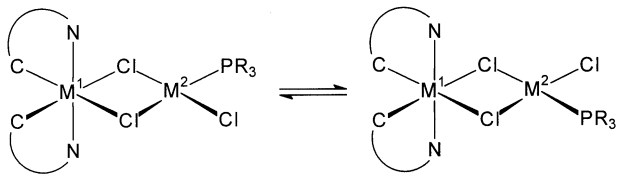


The fluctional process most probably consists of a "*cis-trans*" isomerisation as shown in Scheme 3. Plausible intermediates are solvent stabilized complexes with only one chloride bridge. From the coalescence temperature T_c and the difference in chemical shift Δν of selected signals a $\Delta G^{\#}$ value of 59 (±1) kJ mol^{-1} was calculated for **5**.[17] A similar

dynamic behaviour was previously observed for mixtures of *cis*- and *trans*-$[(Ph_3P)(CO)RhCl]_2$.[18] In contrast to the rhodium complexes **4**−**6** the iridium complexes **7** and **8** exhibit no fluxional behavior at room temperature. Coalescence effects are observed at temperatures above 325 K. For **7** a $\Delta G^{\#}$ value of 69 (±1) kJ mol^{-1} was calculated.

When the ^{1}H NMR spectra of **5** and **7** are recorded in $CDCl_3$ containing 20% CD_3OD only minor changes in the coalescence temperature can be observed. Interestingly this more polar solvent mixture disfavors the formation of the heterobimetallic complexes: significant amounts ($K_{eq} \approx 10$) of the homodimeric starting materials are present in solution as judged by integration of selected ^{1}H NMR signals. NMR experiments in neat CD_3OD were not performed due to the very low solubility of the complexes in this solvent. Other polar solvents like dimethyl sulfoxide or acetonitrile were likewise omitted because they are known to react with chloro-bridged complexes to yield the respective monomeric species.

Scheme 3

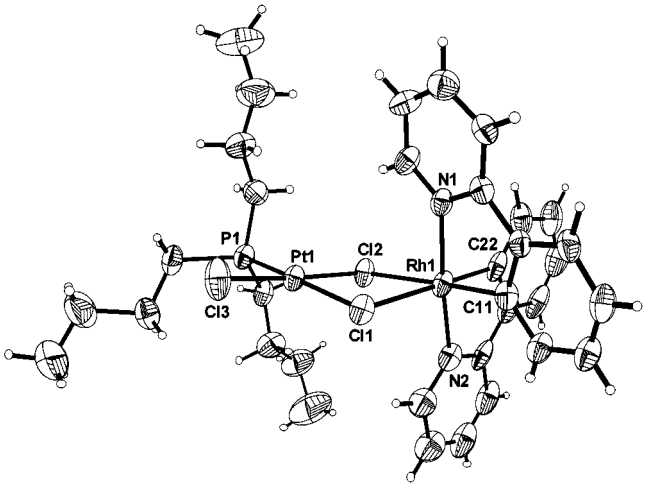


In analogy to **4**−**8** the Rh^{III}-Pd^{II} complex **9** and the Rh^{III}-Pt^{II} complex **10** containing two metalated benzoquinoline ligands were synthesized. Again, the NMR spectra ($CDCl_3$) exhibit dynamic behavior with a coalescence temperature close to what was observed for the rhodium complexes **4**−**6**.

	M
9	Pd
10	Pt

The structural assignments for **4**−**10** are supported by a single crystal X-ray analysis of **5** (Figure 3). There are two independent molecules in the unit cell, the metric parameters of which are very similar. As in **1**, the two metal centers are bridged by a slightly bent dichloro-bridge with the dihedral angle of the folded Rh(μ-Cl)$_2$Pt unit beeing 13.2°. Furthermore, the dichloro bridge is highly asymmetric with four distinct M−Cl bond lengths between 2.31 (Pt1−Cl2) and 2.54 A (Rh1−Cl2). Metal-metal interactions are unlikely due to a Rh−Pt bond length of 3.61 A. The configuration and the bond lengths of the octahedral Rh^{III} fragment are similar to that observed for **1**.

Figure 3. Molecular structure of complex **5**. Selected bond lengths [A] and angles [°]: Pt1−P1 2.216(3), Pt1−Cl1 2.407(2), Pt1−Cl2 2.313(2), Pt1−Cl3 2.270(3), Rh1−C11 1.975(9), Rh1−C22 1.995(11), Rh1−N2 2.036(8), Rh1−N1 2.038(8), Rh1−Cl1 2.528(3), Rh1−Cl2 2.540(2); N1−Rh1−Cl1 85.8(2), N1−Rh1−Cl2 96.8(2), Cl1−Rh1−Cl2 80.52(8), N1−Rh1−N2 175.2(3), Cl1−Pt1−Cl2 87.85(8), Cl3−Pt1−Cl2 174.70(10)



Conclusions

The present study establishes that heterobimetallic and mixed-valence complexes containing orthometalated Rh^{III} and Ir^{III} fragments can be obtained in nearly quantitative yields by metathesis reactions of $[(N-C)_2MCl]_2$ (M = Rh, Ir) with various dichloro-bridged complexes of the late transition metals. It is conceivable that this synthetic scheme is not restricted to the cyclooctadiene and phosphine complexes described here. Indeed, preliminary experiments have shown that chloro-bridged, orthometalated Pd^{II} and Pt^{II} complexes undergo similar disproportion reactions. It remains to be seen, how general the concept of chloro-bridge metathesis is appliciable for the synthesis of new, heterometallic complexes. Studies along these lines will be reported shortly.

We thank Prof. Dr. *W. Beck* (LMU München) for his generous support. Financial funding from the *Bayerischer Habilitations-Förderpreis* is gratefully acknowledged.

Experimental Section

General: All solvents were of analytical grade quality, obtained commercially and used without further purification. Reactions with $[(cod)IrCl]_2$ were performed with degassed solvents under an inert atmosphere. The complexes $[(R_3P)MCl_2]_2$ (M = Pd, Pt; R = Et, *n*-Bu),[18] $[(ppy)_2MCl]_2$ (M = Rh, Ir),[8b] $[(bzq)_2RhCl]_2$,[8b] $[(cod)RhCl]_2$,[20] and $[(cod)IrCl]_2$[21] were prepared as described in the literature. − IR: Perkin-Elmer 841, Nicolet 520. − NMR: JEOL EX 400,GSX 270. The NMR spectra were recorded at room temperature − exceptions are indicated. Due to the low solubility of **6** and **8** ^{13}C NMR spectra were not recorded.

General Procedure for the Synthesis of **1**−**10**: 10 ml of dichloromethane were added to 0.1 mmol of $[(ppy)_2MCl]_2$ (M = Rh, Ir) or

$[(bzq)_2RhCl]_2$ and 0.1 mmol of the respective chloro-bridged complex $[(cod)RhCl]_2$ (M = Rh, Ir) or $[(R_3P)MCl_2]_2$ (M = Pd, Pt). After 1 h clear yellow or orange solutions were observed. The products were isolated after evaporation of the solvent under reduced pressure and dried in vacuo at 50°C.

X-ray Crystallographic Investigations: An Enraf Nonius CAD 4 diffractometer was employed for data collection using Mo-K_α radiation (T = 295 K). The structures were solved by direct methods (SHELXS86) and were refined by means of the full-matrix least squares procedures using SHELXL93 (Table 1). All non-hydrogen atoms were refined anisotropically. For the hydrogen atoms a riding model was employed. **1** crystallizes with 1.5 molecules of chloroform and 0.5 molecules of diethyl ether, all of which are disordered (restraints were used for $CHCl_3$). **5** crystallizes with 0.5 molecules of dichloromethane. The *n*-butyl groups as well as the solvent molecule are disordered (restraints were used for CH_2Cl_2).[21]

Electrospray Ionization Mass Spectrometry (ESI-MS) measurements and *ab initio* calculations on $[OV(O_2)(H_2O)_m(CH_3OH)_n]^+$ (*m*,*n*: 0–4) peroxo cations have been carried out. This experimental technique allowed the direct observation of the above mentioned species for the first time. The results obtained clearly indicate that the exchange reactions between water and methanol molecules, within the coordination sphere of monoperoxo-vanadium complexes, is a conceivable and fast process.

Introduction

The peroxo species formed in aqueous acid solutions by interaction of vanadates with hydrogen peroxide have been studied by several techniques, including heteronuclear NMR[1][2], Raman spectroscopy[3] and ab initio calculations.[4][5] In spite of all these studies, however, a fundamental aspect of these systems, i.e. the nature of the first coordination sphere of the peroxovanadium derivatives present in solution, is still a matter of debate.[1][2] As an example recent ab initio calculations indicate that the oxo(monoperoxo)vanadium cation likely binds three H_2O molecules to form a species whose structure is a distorted octahedron,[5] whereas in the solid state peroxovanadium complexes prefer the pentagonal bipyramid geometry.[6][7]

In order to obtain direct experimental information on the solution structure of peroxovanadium species, we have undertaken an electrospray ionization mass spectrometry (ESI-MS)[8][9] analysis of water/methanol acid solutions of vanadates in the presence of hydrogen peroxide. The electrospray technique is a gentle ionization method of transferring ions from solution to the gas phase with no apparent fragmentation, and has been successfully applied to the analysis of many inorganic and organometallic systems.[10] In our case the direct observation of $[OV(O_2)(H_2O)_m(CH_3OH)_n]^+$ (m, n = 0−4) peroxo cations has been achieved for the first time. Ab initio calculations were also carried out, whose results appear to rationalize most of the experimental behaviors observed.

Results and Discussion

Preliminary data, reported in Table 1, were obtained for solutions containing weighted amounts of ammonium vanadate in CH_3OH/H_2O (1:1; pH = 1, $HClO_4$). The electrospray mass spectrum of this solution, obtained by direct infusion into the ESI source, showed the occurrence of different species[11][12][13] identified as monomeric homo ions $[OV(OH)_3H]^+$ (*m*/*z* 119) and $[OV(OCH_3)_3H]^+$ (*m*/*z* 161), and mixed ions $[OV(OH)_2(OCH_3)H]^+$ and $[OV(OH)(OCH_3)_2H]^+$ (centered at *m*/*z* 133 and 147, respectively). The base peak of the spectrum is associated with the formation of the dimeric species[14] $[OV-O-VO(OH)_4H]^+$ at *m*/*z* 219. Other significant peaks, related to dimeric complexes and formally having the composition reported in Table 1, were found at *m*/*z* 237, 247 and 279.

As expected, addition of an equimolar amount of H_2O_2 to the vanadate solutions produces significant changes in the electrospray mass spectrum. Besides the above-mentioned ions at *m*/*z* 147 and 161, new ionic monoperoxo species at *m*/*z* 117, 131, 135, 181 and 195 were detected (see Table 1). Signals corresponding to the tetraaquo complex $[OV(O_2)(H_2O)_4]^+$ at *m*/*z* 171 and to the mixed $[OV(O_2)(H_2O)_m(CH_3OH)_n]^+$ ($m + n = 4$) cations at *m*/*z* 199 and 213 are also observed, although in low relative intensity.

Acid catalysis appears to play a fundamental role in the chemistry of peroxovanadium species, particularly when they are involved in the catalytic cycle of bromoperoxidase

enzymes.[15] In that respect the knowledge of the protonation site of peroxovanadium complexes is an important piece of information. In the present work, where cationic peroxovanadium species are studied in acid solutions, we have addressed such a problem by carrying out ab initio calculations on the oxoperoxo complexes $[OV(O_2)(H_2O)]^+$ and $[OV(O_2)(CH_3OH)]^+$. The calculations have been made by using two different levels of theory, i.e. Hartree-Fock with a small all-electron basis set (HF/3-21G(*))[16] and density functional theory (DFT) with effective core potentials (B3LYP/LANL2DZ),[17][18] and are shown in a pictorial way in Figure 1. As it can be seen, the differences in energies of the three possible protonation sites, i.e. the oxo oxygen atom , the peroxo oxygen atom and solvent molecule, for both peroxo complexes are rather small, thus suggesting the occurrence of equilibria among them. Details on the calculations are reported in the experimental section.[19]

Although in the case of vanadium derivatives a comparison between the theoretically calculated and experimentally found isotopic cluster in ESI-MS spectra is hampered by the lack of vanadium isotopes, further support to the identification of the ions reported in Table 1 was obtained with tandem (MS^2) analysis and deuteration experiments.

The preferential decomposition patterns of the peroxidic species, as obtained by MS^2 experiments, are the loss of

Figure 1. Relative-energy diagrams for the gas-phase proton-migration reactions of species $[OV(O_2)(H_2O)]^+$ (**A**) and $[OV(O_2)(CH_3OH)]^+$ (**B**); energy values are given in kcal/mol

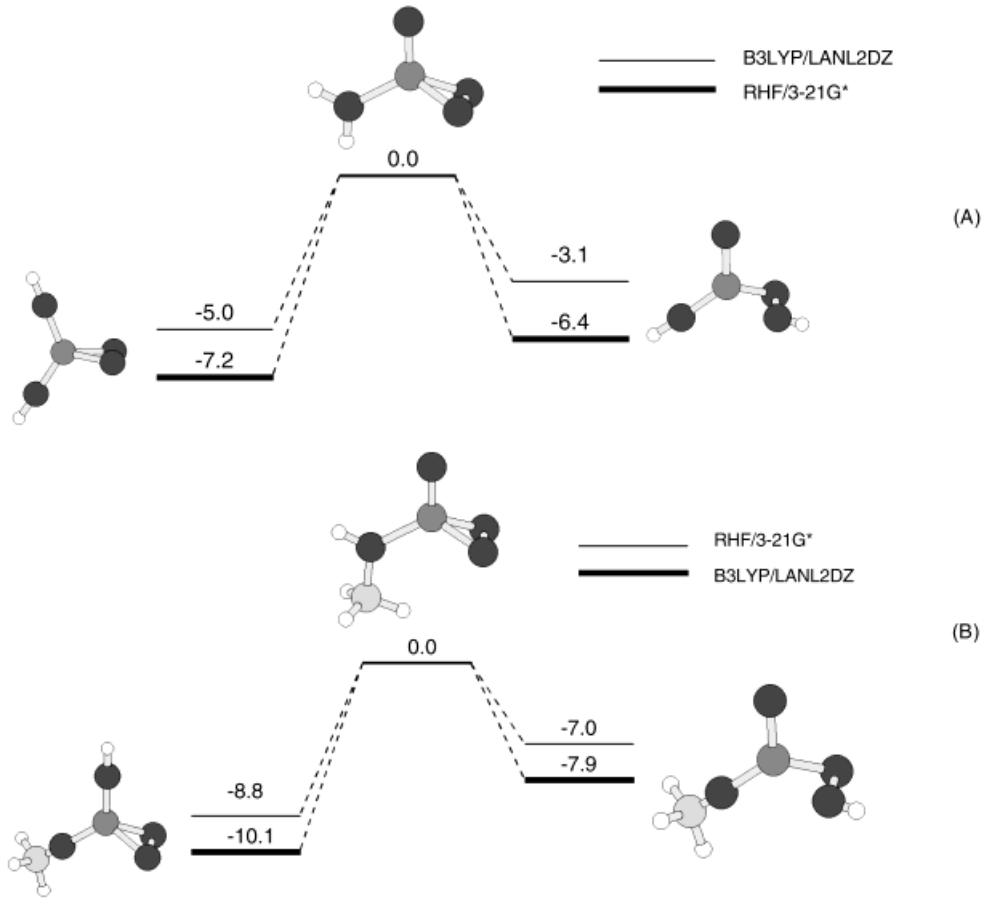

Figure 2. MS/MS mass spectrum of $[OV(O_2)(H_2O)(CH_3OH)_2]^+$ (*m*/*z* 181) using 2 V tickling voltage

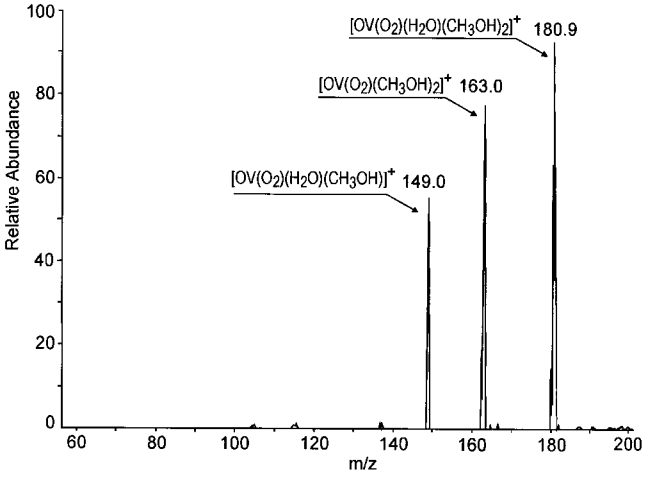

Figure 3. MS/MS mass spectra of $[OV(O_2)(H_2O)]^+$ using tickling voltages of: 3 V (**A**), 1 V (**B**) and 15 mV (**C**), respectively

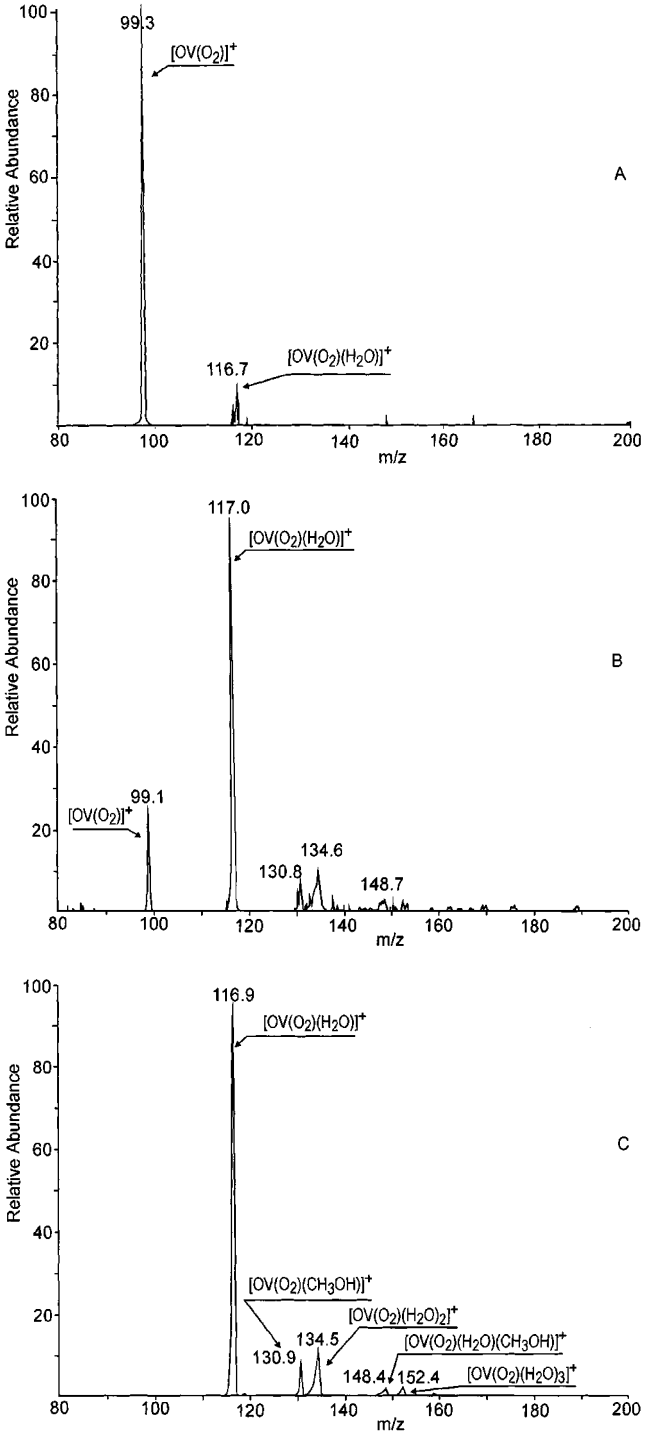
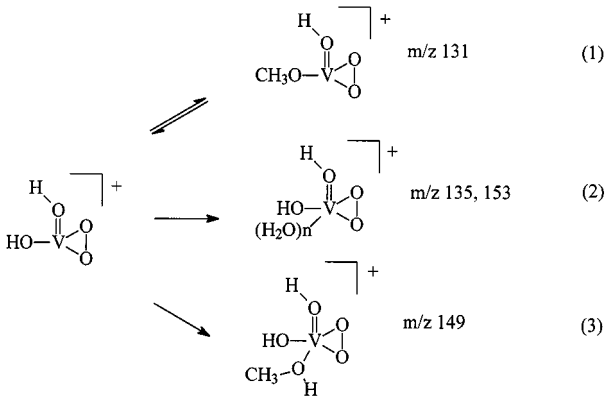


H_2O and/or CH_3OH molecules. As an example, at 2 V tickling voltage, the mixed species $[OV(O_2)(H_2O)(CH_3OH)_2]^+$ (*m*/*z* 181) fragments through expulsion of H_2O and CH_3OH, affording the ions at *m*/*z* 163 and 149, respectively (see Figure 2). On the other hand, the aquo(oxo)peroxovanadium cation $[OV(O_2)(H_2O)]^+$ (*m*/*z* 117) decomposes to the "naked" ion $[OV(O_2)]^+$ (*m*/*z* 99) by using 3 V tickling voltage (Figure 3A). Most noteworthy however, ionic species at higher mass-over-charge values are detected upon isolation of the ion under analysis. This is shown for ion $[OV(O_2)(H_2O)]^+$ (*m*/*z* 117), which has been isolated and trapped within the ion-trap analyzer in the presence of relatively small tickling voltages (10−15 mV), for times of about 0.1 ms. Under these conditions (Figure 3C) no fragmentation products, but formation of ions at *m*/*z* 131, 135, 149, 153 is observed. A likely explanation for such a result is the reaction of the ion $[OV(O_2)(H_2O)]^+$ with solvent molecules present in the ion trap (see Scheme 1), i.e. exchange between H_2O and CH_3OH (eq. 1), coordination of water [eq. 2 (n = 1, 2)] or coordination of methanol (eq. 3). At intermediate tickling voltage (1 V) formation of these ions is reduced and collision-induced decomposition product ions prevail (Figure 3B). An analogous behavior has been recently reported for (allyl)Pt^{II} compounds.[20]

The same ion-molecule reactions have been observed with the corresponding deuterated ion $[OV(O_2)(D_2O)]^+$ (*m*/*z* 119) and with other oxoperoxo species with different coordination-sphere composition. Thus, after the isolation of the ion $[OV(O_2)(H_2O)_2]^+$ (*m*/*z* 135), the ionic species at *m*/*z* 167 (addition of methanol) and 185 (addition of water and methanol) are formed, whereas the complex $[OV(O_2)(H_2O)(CH_3OH)]^+$ (*m*/*z* 149) gives rise to ions at *m*/*z* 163 (exchange water/methanol), 167 (addition of water) and 181 (addition of methanol). Furthermore, the occurrence of these ion-molecule reactions upon trapping the selected ions in the ion trap and the high tickling voltages that must be used (up to 3 V, see Figures 2 and 3C) to have complete collision-induced decomposition of peroxovanadium compounds $[OV(O_2)(H_2O)_m(CH_3OH)_n]^+$ (m, n = 0−4), likely suggest[20] the binding of water and/or methanol to the vanadium center.

^{51}V-NMR studies in mixed H_2O/CH_3OH solvents, revealed for oxo(monoperoxo)vanadium species the presence of a single broad peak ($\delta \approx -540$, ca. 1200 Hz at half width),[1b] thus suggesting the occurrence of fast equilibria, on the ^{51}V-NMR time scale, between water and methanol molecules for complexation to the metal center. A direct observation of the rapidly exchanging species by lowering

Scheme 1



the temperature is hampered by the simultaneous increase of the line width due to the increase of the correlation time. The ESI-MS results here reported, however, show that the substitution of water molecules with methanol, and vice versa, in the coordination sphere of monoperoxovanadium complexes, is a conceivable and detectable process which leads to several peroxo complexes. The tandem use of ESI-MS and low-temperature NMR spectroscopy in the investigation of rapidly exchanging organometallic systems has been recently reported.[21]

In order to obtain further support to the occurrence of exchange process between water and methanol molecules in the coordination sphere of oxo(monoperoxo)vanadium complexes, ab initio calculations were also carried out. The reactions taken into consideration are the addition to the "naked" ion $[OV(O_2)]^+$ of either H_2O or CH_3OH molecule. As in the calculations reported above, two different levels of theory were used[16][17][18] and the relevant results are collected in Table 2.

The binding of a methanol molecule to the "naked" oxo(peroxo) ion involves a larger degree of stabilization as compared with that observed in the binding of a water molecule [99.6 kcal/mol against 86.4 kcal/mol with RHF/3-21G(*) calculation]. Such a result, supported also by the good agreement with that obtained with the DFT level of theory (see Table 2), may indeed substantiate the evidence that exchange between water and methanol molecules in the coordination sphere of oxo(monoperoxo)vanadium complexes is a likely process. If this were not the case, the exchange reaction between water and methanol detected upon isolation in the ion trap of the previously reported cations, could not be observed (see eq. 1, Scheme 1).

The higher affinity of methanol molecules for peroxovanadium center as compared with that of water is also confirmed by various experiments such as that shown in Figure 2. In particular, the relative abundance of ion $[OV(O_2)(CH_3OH)_2]^+$ at *m/z* 163, corresponding to the expulsion of a water molecule from $[OV(O_2)(H_2O)(CH_3OH)_2]^+$ (*m/z* 181), is higher than that of the ion at *m/z* 149, $[OV(O_2)(H_2O)(CH_3OH)]^+$, corresponding to the loss of methanol, despite of the statistical factor of 2 which would favor the latter process. The use of closely related
